CHAPTER 20: Gestational Trophoblastic Disease

> *… the terminal extremities of the chorionic villi are converted into transparent vesicles with clear, viscid contents. These vary in size from minute bodies a few millimetres in diameter to cystic structures the size of hazel-nuts, and hang in clusters from the villous stems, to which they are connected by thin pedicles, giving to the external surface of the chorion a grape-like appearance.*
>
> —J. Whitridge Williams (1903)

INTRODUCTION

Gestational trophoblastic disease (GTD) is the term used to encompass a group of tumors typified by abnormal trophoblast proliferation. Trophoblast produces human chorionic gonadotropin (hCG), thus the measurement of this peptide hormone in serum is essential for GTD diagnosis, management, and surveillance. GTD histologically is divided into *hydatidiform moles,* which are characterized by the presence of villi, and into nonmolar trophoblastic malignant neoplasms, which lack villi.

Hydatidiform moles are excessively edematous immature placentas (Benirschke, 2012). These include the benign *complete hydatidiform mole* and *partial hydatidiform mole* and the malignant *invasive mole.* Invasive mole is deemed malignant due to its marked penetration into and destruction of the myometrium and its ability to metastasize.

Nonmolar trophoblastic neoplasms include choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These three are differentiated by the type of trophoblast they contain.

The malignant forms of gestational trophoblastic disease are termed *gestational trophoblastic neoplasia (GTN).* These include invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. Other terms applied to GTN are *malignant gestational trophoblastic disease* and *persistent gestational trophoblastic disease.* These malignancies develop weeks or years following any type of pregnancy, but frequently follow a hydatidiform mole.

Each of the GTN malignancy types is histologically distinct and varies in its propensity to invade and metastasize. However, histological confirmation is typically not available. Instead, measurement of serum hCG levels combined with clinical findings— rather than a histological specimen—is used to diagnose and treat this malignancy. Accordingly, GTN is often identified and effectively treated as a group.

In the past, these metastatic tumors had a prohibitively high mortality rate. However, with chemotherapy, most tumors currently are highly curable. Early-stage GTN is typically cured with single-agent chemotherapy, whereas later-stage disease usually responds to combination chemotherapy (Ngan, 2015).

HYDATIDIFORM MOLE

The classic histological findings of molar pregnancy include trophoblast proliferation and villi with stromal edema (Fig. 20-1). The degree of histological changes, karyotypic differences, and the absence or presence of embryonic elements are used to classify them as either *complete* or *partial moles.* These two also vary in their associated risks for developing medical comorbidities and postevacuation GTN. Of the two, GTN more frequently follows complete hydatidiform mole.

FIGURE 20-1
Complete hydatidiform mole. **A.** Gross specimen with characteristic vesicles of variable size. (Used with permission from Dr. Brian Levenson.) **B.** Low-magnification photomicrograph shows generalized edema and cistern formation (*black asterisks*) within avascular villi. Haphazard trophoblastic hyperplasia is marked by a yellow asterisk on the right. (Used with permission from Dr. Erika Fong.)

A complete mole has abnormal chorionic villi that grossly appear as a mass of clear vesicles. These vary in size and often hang in clusters from thin pedicles. In contrast, a partial molar pregnancy has focal and less advanced hydatidiform changes and contains some fetal tissue. Both forms of moles usually fill the uterine cavity, but they rarely may be tubal or other forms of ectopic pregnancy (Hassadia, 2012; Sebire, 2005).

Epidemiology and Risk Factors

An ethnic predisposition is seen with hydatidiform mole, which has increased prevalence in Asians, Hispanics, and American Indians (Drake, 2006; Lee, 2011; Smith, 2006). The incidence in the United States and Europe has been relatively constant at 1 to 2 per 1000 deliveries (Eysbouts, 2016; Lee, 2011).

The strongest risk factors are age and a prior hydatidiform mole. Women at both extremes of reproductive age are most vulnerable. Specifically, adolescents and women aged 36 to 40 years have a twofold risk, but those older than 40 have an almost tenfold risk (Altman, 2008; Sebire, 2002a). With a prior complete mole, the risk of another mole is 0.9 percent, and with a previous partial mole, the rate is 0.3 percent. After two prior complete moles, approximately 20 percent of women have a third mole (Eagles, 2015).

Pathogenesis

Molar pregnancies typically arise from chromosomally abnormal fertilizations Figure 20-2. Complete moles most often have a diploid chromosomal composition (Table 20-1). These usually are 46,XX and result from *androgenesis,* meaning both sets of chromosomes are paternal in origin. The chromosomes of the ovum are either absent or inactivated. The ovum is fertilized by a haploid sperm, which then duplicates its own chromosomes after meiosis. Less commonly, the chromosomal pattern may be 46,XY or 46,XX and due to fertilization by two sperm, that is, *dispermic fertilization* or *dispermy* (Lawler, 1991; Lipata, 2010).

TABLE 20-1

Features of Partial and Complete Hydatidiform Moles

Feature	Partial Mole	Complete Mole
Karyotype[a]	69,XXX or 69,XXY	46,XX
Clinical Presentation		
Preliminary diagnosis	Missed abortion	Molar gestation
Uterine size	Small for dates	Large for dates
Theca-lutein cysts	Rare	25–30% of cases
Initial hCG levels	<100,000 mIU/mL	>100,000 mIU/mL
Medical complications[b]	Rare	Uncommon
Rate of subsequent GTN	1–5% of cases	15–20% of cases
Pathology		
Pathology		
Embryo-fetus	Often present	Absent
Amnion, fetal erythrocytes	Often present	Absent
Villous edema	Focal	Widespread
Trophoblastic proliferation	Focal, slight to moderate	Slight to severe
Trophoblast atypia	Mild	Marked
$p57^{KIP2}$ immunostaining	Positive	Negative

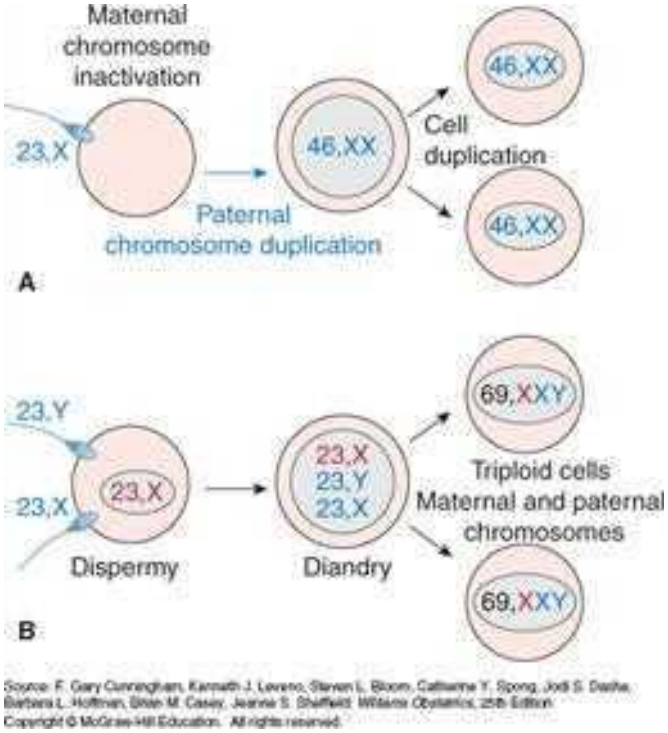
[a]Typical karyotypes.

[b]These include anemia, hyperthyroidism, hyperemesis gravidarum, preeclampsia, and infection.

GTN = gestational trophoblastic neoplasia; hCG = human chorionic gonadotropin.

FIGURE 20-2

Typical pathogenesis of complete and partial moles. **A.** A 46,XX complete mole may be formed if a 23,X-bearing haploid sperm penetrates a 23,X-containing haploid egg whose genes have been "inactivated." Paternal chromosomes then duplicate to create a 46,XX diploid complement solely of paternal origin. **B.** A partial mole may be formed if two sperm—either 23,X- or 23,Y-bearing—both fertilize (dispermy) a 23,X-containing haploid egg whose genes have not been inactivated. The resulting fertilized egg is triploid with two chromosome sets being donated by the father. This paternal contribution is termed diandry..



Partial moles usually have a triploid karyotype—69,XXX, 69,XXY—or much less commonly, 69,XYY. These are each composed of two paternal haploid sets of chromosomes contributed by dispermy and one maternal haploid set (see Fig. 20-2B). Less frequently, a similar haploid egg may be fertilized by an unreduced diploid 46,XY sperm. These triploid zygotes result in some embryonic development, however, it ultimately is a lethal fetal condition (Joergensen, 2014; Lakovschek, 2011). Fetuses that reach advanced ages have severe growth restriction, multiple congenital anomalies, or both.

Twin Pregnancy

Rarely, in some twin pregnancies, one chromosomally normal fetus is paired with a complete diploid molar pregnancy. Importantly, these cases must be distinguished from a single partial molar pregnancy with its associated abnormal fetus. Amniocentesis and fetal karyotyping aid confirmation.

Several unique pregnancy problems complicate such twin pregnancies. And, many women may choose to terminate the gestation, if diagnosed early. In those with continuing pregnancy, survival of the normal fetus varies and depends on associated comorbidity from the molar component. The most worrisome are preeclampsia or hemorrhage, which frequently necessitate preterm delivery. Wee and Jauniaux (2005) reviewed outcomes in 174 women, of whom 82 chose termination. Of the remaining 92 pregnancies, 42 percent either miscarried or had a perinatal death; approximately 60 percent delivered preterm; and only 40 percent delivered at term.

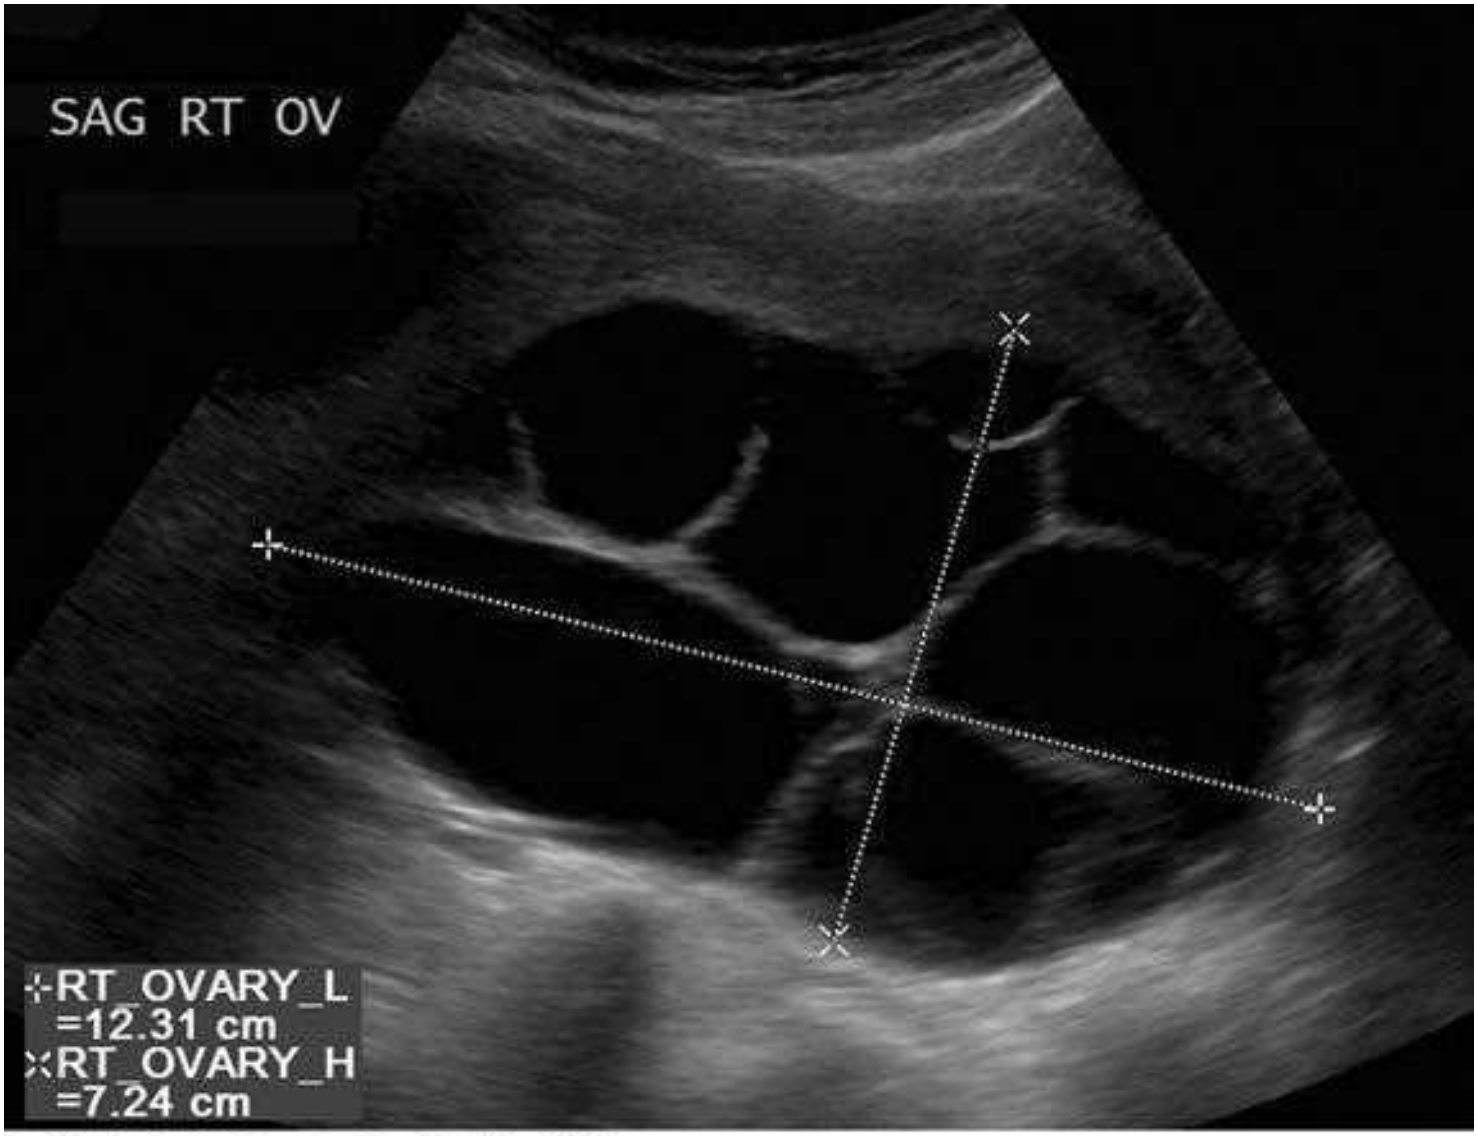
Another concern for those continuing their pregnancy is the risk for developing subsequent GTN. However, most data indicate no significant difference between women who continue or terminate their pregnancy (Massardier, 2009; Sebire, 2002b). Postdelivery surveillance is conducted as for any molar pregnancy (Gestational Trophoblastic Neoplasia).

Clinical Findings

The presentation of women with a molar pregnancy has changed remarkably over the past several decades because prenatal care is sought much earlier and because sonography is virtually universal. Typically, 1 to 2 months of amenorrhea precede the diagnosis. For example, in 194 women with a complete mole, evacuation was completed at a median gestational age of 9 weeks and at 12 weeks for 172 patients with a partial mole (Sun, 2015b). As a result, most molar pregnancies are detected before complications ensue (Kerkmeijer, 2009; Mangili, 2008).

As gestation advances, symptoms tend to be more pronounced with complete compared with partial moles (Niemann, 2007). Untreated molar pregnancies will almost always cause uterine bleeding that varies from spotting to profuse hemorrhage. Bleeding may presage spontaneous molar abortion, but more often, it follows an intermittent course for weeks to months. In more advanced moles with considerable concealed uterine hemorrhage, moderate iron-deficiency anemia develops. Nausea and vomiting may be significant. Of physical findings, many women have uterine growth that is more rapid than expected, and the enlarged uterus is comparatively softer. Fetal heart motion is absent with complete moles. The ovaries can be fuller and cystic from multiple theca-lutein cysts (Fig. 20-3). These are more common with a complete mole and likely result from ovarian overstimulation by excessive hCG levels. Because theca-lutein cysts regress following pregnancy evacuation, expectant management is preferred. Occasionally a larger cyst may undergo torsion, infarction, and hemorrhage. However, oophorectomy is not performed unless extensive infarction persists after untwisting.

FIGURE 20-3
Sonographic image of an ovary with theca-lutein cysts in a woman with a hydatidiform mole.



The thyrotropin-like effects of hCG frequently cause serum free thyroxine (fT_4) levels to be elevated and thyroid-stimulating hormone (TSH) levels to be decreased. Despite this, clinically apparent thyrotoxicosis is unusual and in our experience can be mimicked by bleeding and sepsis from infected products. Moreover, the serum free T_4 levels rapidly normalize after uterine evacuation. Despite this, cases of presumed "thyroid storm" have been reported (Kofinas, 2015).

Severe preeclampsia and eclampsia are relatively common with advanced molar pregnancies. However, these are seldom seen today because of early diagnosis and evacuation. An exception is the case of a normal fetus coexisting with a complete mole, described earlier. In continuing twin gestations, severe preeclampsia frequently mandates preterm delivery.

Diagnosis

Serum β-HCG Measurements

Most women initially have irregular bleeding that almost always prompts pregnancy testing and sonography. Some women will present with spontaneous passage of molar tissue.

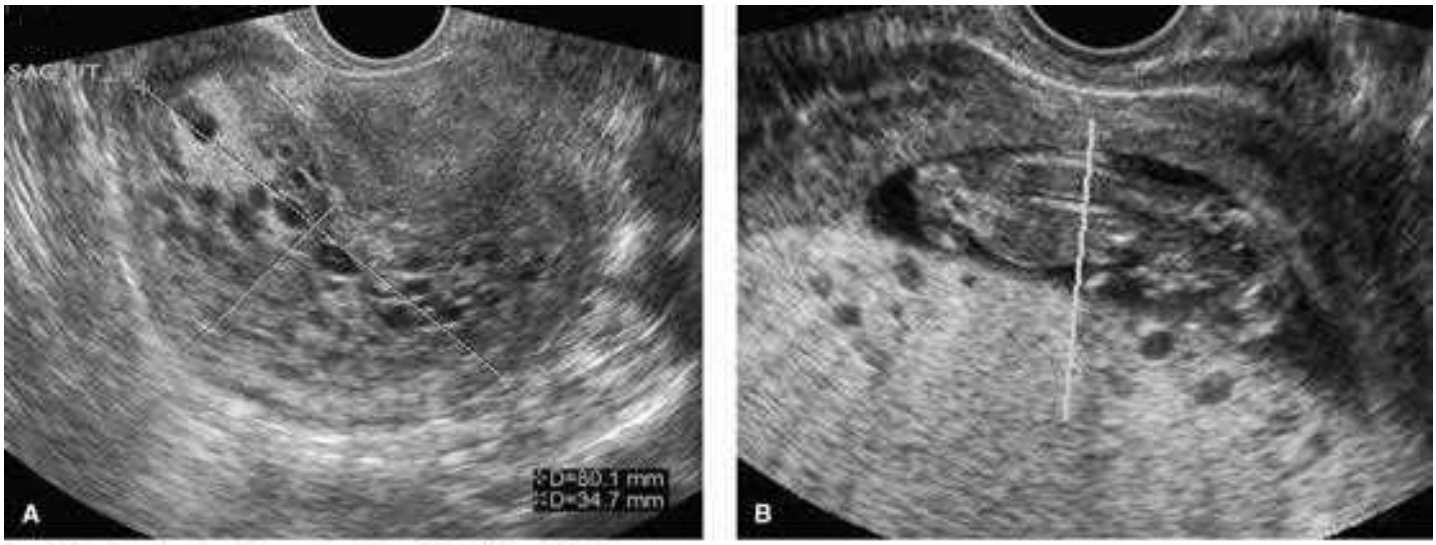
With a complete molar pregnancy, serum β-hCG levels are commonly elevated above those expected for gestational age. With more advanced moles, values in the millions are not unusual. Importantly, these high values can lead to erroneous false-negative *urine* pregnancy test results. Termed a "hook effect," excessive β-hCG hormone levels oversaturate the assay's targeting antibody and create a falsely low reading (Cormano, 2016). In these cases, *serum* β-hCG determinations with or without sample dilution will clarify the conundrum. With a partial mole, β-hCG levels may also be significantly elevated, but more commonly concentrations fall into ranges expected for gestational age.

Sonography

Although this is the mainstay of trophoblastic disease diagnosis, not all cases are confirmed initially. Sonographically, a complete mole appears as an echogenic uterine mass with numerous anechoic cystic spaces but without a fetus or amnionic sac. The appearance is often described as a “snowstorm” (Fig. 20-4). A partial mole has features that include a thickened, multicystic placenta along with a fetus or at least fetal tissue. However, in early pregnancy, these sonographic characteristics are seen in fewer than half of hydatidiform moles. In the largest series of more than 1000 patients with molar pregnancy, the reported sensitivity and specificity of sonography were 44 and 74 percent, respectively (Fowler, 2006). The most common mimics are incomplete or missed abortion. Occasionally, molar pregnancy may be confused for a multifetal pregnancy or a uterine leiomyoma with cystic degeneration.

FIGURE 20-4

Sonograms of hydatidiform moles. **A.** Sagittal view of a uterus with a complete hydatidiform mole. The characteristic “snowstorm” appearance is due to an echogenic uterine mass, marked by calipers, that has numerous anechoic cystic spaces. Notably, a fetus and amnionic sac are absent. **B.** In this image of a partial hydatidiform mole, the fetus is seen above a multicystic placenta. (Used with permission from Dr. Elysia Moschos.)



Pathology

Surveillance for subsequent neoplasia following molar pregnancy is crucial. Thus, moles must be distinguished from other types of pregnancy failure that have hydropic placental degeneration, which can mimic molar villous changes. Some distinguishing histological characteristics are shown in Table 20-1.

In pregnancies before 10 weeks, classic molar changes may not be apparent because villi may not be enlarged and molar stroma may not yet be edematous and avascular. Histopathologic evaluation can be enhanced by immunohistochemical staining for p57 expression and by molecular genotyping (Banet, 2014). $p57^{KIP2}$ is a nuclear protein whose gene is paternally imprinted and maternally expressed. This means that the gene product is produced only in tissues containing a maternal allele. Because complete moles contain only paternal genes, the $p57^{KIP2}$ protein is absent in complete moles, and tissues do not pick up this stain (Merchant, 2005). In contrast, this nuclear protein is strongly expressed in normal placentas, in spontaneous pregnancy losses with hydropic degeneration, and in partial hydatidiform moles (Castrillon, 2001). Accordingly, immunostaining for $p57^{KIP2}$ is an effective means to isolate complete mole from the diagnostic list. For distinction of a partial mole from a nonmolar hydropic abortus, both of which express p57, molecular genotyping can be used. Molecular genotyping determines the parental source of alleles. Thereby, it can distinguish among a diploid diandric genome (complete mole), a triploid diandric-monogynic genome (partial mole), or biparental diploidy (nonmolar abortus).

Management

Maternal deaths from molar pregnancies are rare because of early diagnosis, timely evacuation, and vigilant postevacuation surveillance for GTN. Preoperative evaluation attempts to identify known potential complications such as preeclampsia, hyperthyroidism, anemia, electrolyte depletions from hyperemesis, and metastatic disease (Table 20-2) (Lurain, 2010). Most recommend chest radiography, whereas computed tomography (CT) and magnetic resonance (MR) imaging are not routinely done unless a chest radiograph shows lung lesions or unless other extrauterine disease is suspected.

TABLE 20-2

Some Considerations for Management of Hydatidiform Mole

Preoperative
Laboratory
Hemogram; serum β-hCG, creatinine, electrolyte, and hepatic aminotransferase levels
TSH, free T_4 levels
Type and Rh; group and screen or crossmatch
Chest radiograph
Consider hygroscopic dilators
Intraoperative
Large-bore intravenous catheter(s)
Regional or general anesthesia
Oxytocin (Pitocin): 20 units in 1000 mL Ringer lactate for continuous infusion
One or more other uterotonic agents may be added as needed:
Methylergonovine (Methergine): 0.2 mg = 1 mL = 1 ampule IM every 2 hr prn
Carboprost tromethamine ($PGF_{2\alpha}$) (Hemabate): 250 µg = 1 mL = 1 ampule IM every 15–90 min prn
Misoprostol (PGE_1) (Cytotec): 200 mg tablets for rectal administration, 800–1000 mg once
Karman cannula—size 10 or 14 mm
Consider sonography machine
Postevacuation
Anti-D immune globulin (Rhogam) if Rh D-negative
Initiate effective contraception[a]
Review pathology report
Serum hCG levels: within 48 hours of evacuation, weekly until undetectable, then monthly for 6 months

[a]Intrauterine devices are not suitable during surveillance.

hCG = human chorionic gonadotropin; IM = intramuscular; PG = prostaglandin; T_4 = thyroxine; TSH = thyroid-stimulating hormone.

Molar Pregnancy Termination

Regardless of uterine size, molar evacuation by suction curettage is usually the preferred treatment. Preoperative cervical dilatation with an osmotic dilator is recommended if the cervix is minimally dilated. Intraoperative bleeding can be greater with molar pregnancy than with a comparably sized uterus containing nonmolar products. Thus with large moles, adequate anesthesia, sufficient intravenous access, and blood-banking support is imperative. The cervix is mechanically dilated to preferably allow insertion of a larger suction curette. Depending on uterine size, a 10- to 14-mm diameter is typical. As evacuation is begun, oxytocin is infused to limit bleeding. Intraoperative sonography is often recommended to help ensure complete uterine cavity emptying. When the myometrium has contracted, a thorough but gentle curettage with a sharp large-loop Sims curette is performed. If bleeding continues despite uterine evacuation

and oxytocin infusion, other uterotonic agents are given (see Table 20-2). In rare cases, pelvic arterial embolization or hysterectomy may be necessary (Tse, 2007). Profuse hemorrhage and surgical methods that may be useful for its management are discussed in Chapter 41 (General Considerations).

Some volume of trophoblast is deported into the pelvic venous system during molar evacuation (Hankins, 1987). With large moles, the amount of tissue may be sufficient to produce clinically apparent respiratory insufficiency, pulmonary edema, or even embolism. In our earlier experiences with substantial moles, these and their chest radiographic manifestations clear rapidly without specific treatment. However, fatalities have been described (Delmis, 2000). Because of deportation, there is concern that trophoblastic tissue will thrive within the lung parenchyma to cause persistent disease or even overt malignancy. Fortunately, no evidence suggests that this is a major problem.

Following curettage, anti-D immunoglobulin (Rhogam) is given to Rh D-negative women because fetal tissues with a partial mole may include red cells with D-antigen (Chap. 15, Prevention of Anti-D Alloimmunization). Those with suspected complete mole are similarly treated because a definitive diagnosis of complete versus partial mole may not be confirmed until histological evaluation of the evacuated products.

Following evacuation, the long-term prognosis for women with a hydatidiform mole is not improved with prophylactic chemotherapy. Moreover, chemotherapy toxicity—including death—may be significant, and thus it is not recommended routinely (Gueye, 2014; Wang, 2017).

Methods other than suction curettage can be considered for select cases. Hysterectomy with ovarian preservation may be preferable for women with complete moles who have finished childbearing. Of women aged 40 to 49 years, 30 to 50 percent will subsequently develop GTN, and hysterectomy markedly reduces this likelihood (Bandy, 1984; Elias, 2010, 2012). Theca-lutein cysts seen at the time of hysterectomy do not require removal, and they spontaneously regress following molar termination. Labor induction or hysterotomy is seldom used for molar evacuation in the United States. Both will likely increase blood loss and theoretically may increase the incidence of persistent trophoblastic disease (American College of Obstetricians and Gynecologists, 2016; Tidy, 2000).

Postevacuation Surveillance

Close biochemical surveillance for persistent gestational neoplasia follows each hydatidiform mole evacuation. This monitoring is by serial measurement of serum β-hCG to detect persistent or renewed trophoblastic proliferation. As a glycoprotein, hCG shows structural heterogeneity and exists in different isoforms. Thus for surveillance, an hCG assay that can detect all forms of hCG should be used (Harvey, 2010; Ngan, 2015). These are different from those used for routine pregnancy testing (de Medeiros, 2009). The initial β-hCG level is obtained within 48 hours after evacuation. This serves as the baseline, which is compared with β-hCG quantification done thereafter every 1 to 2 weeks until levels progressively decline to become undetectable.

The median time for such resolution is 7 weeks for partial moles and 9 weeks for complete moles. Once β-hCG is undetectable, this is confirmed with monthly determinations for another 6 months (Lurain, 2010; Sebire, 2007). Concurrently, reliable contraception is imperative to avoid confusion caused by rising β-hCG levels from a new pregnancy. Most recommend combination hormonal contraception, injectable depot medroxyprogesterone acetate, or progestin implant (Dantas, 2017). The latter two are particularly useful if poor patient compliance is anticipated. Intrauterine devices are not used until β-hCG levels are undetectable because of the risk of uterine perforation if there is an invasive mole. Although not recommended, if a woman conceives during surveillance, live-birth rates and risk for congenital anomalies appear to mirror the general population (Tuncer, 1999a,b). After these 6 months, monitoring is discontinued and pregnancy allowed.

Importantly, during β-hCG level surveillance, either increasing or persistently plateaued levels mandate evaluation for trophoblastic neoplasia. If the woman has not become pregnant, then these levels signify increasing trophoblastic proliferation that is most likely malignant. Several factors predispose a patient to trophoblastic neoplasia following molar evacuation. Most important, complete moles have a 15 to 20 percent incidence of malignant sequelae, compared with 1 to 5 percent following partial moles. Surprisingly, with much earlier recognition and evacuation of molar pregnancies, the risk for neoplasia has not been lowered (Schorge, 2000; Sun, 2015a). Other risk factors are older maternal age, β-hCG levels >100,000 mIU/mL, uterine size that is large for gestational age, theca-lutein cysts >6 cm, and slow decline in β-hCG levels (Berkowitz, 2009; Kang, 2012; Wolfberg, 2005).

GESTATIONAL TROPHOBLASTIC NEOPLASIA

This group includes invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These tumors almost always develop with or after some form of recognized pregnancy. Half follow hydatidiform mole, a fourth follow miscarriage or tubal pregnancy, and another fourth develop after a preterm or term pregnancy (Goldstein, 2012). Although these four tumor types are histologically distinct, they are usually diagnosed solely by persistently elevated serum β-hCG levels because tissue is infrequently available for study. Criteria to diagnose postmolar GTN are shown in Table 20-3.

TABLE 20-3

Criteria for Diagnosis of Gestational Trophoblastic Neoplasia

1. Plateau of serum β-hCG level (± 10 percent) for four measurements during a period of 3 weeks or longer—days 1, 7, 14, 21
2. Rise of serum β-hCG level >10 percent during three weekly consecutive measurements or longer, during a period of 2 weeks or more—days 1, 7, 14
3. Serum β-hCG level remains detectable for 6 months or more
4. Histological criteria for choriocarcinoma

Clinical Findings

These placental tumors are characterized clinically by their aggressive invasion into the myometrium and propensity to metastasize. The most common finding with GTN is irregular bleeding associated with uterine subinvolution. The bleeding may be continuous or intermittent, with sudden and sometimes massive hemorrhage. Myometrial perforation from trophoblastic growth may cause intraperitoneal hemorrhage. In some women, lower genital tract metastases are evident, whereas in others only distant metastases are found with no trace of uterine tumor.

Diagnosis, Staging, and Prognostic Scoring

Consideration for the possibility of GTN is the most important factor in its recognition. Unusually persistent bleeding after any type of pregnancy should prompt measurement of serum β-hCG levels and consideration for diagnostic curettage if levels are elevated. Uterine size is assessed along with careful examination for lower genital tract metastases, which usually appear as bluish vascular masses (Cagayan, 2010). Tissue diagnosis is unnecessary, thus biopsy is not required and may cause significant bleeding.

Once the diagnosis is verified, in addition to a baseline serum β-hCG level and hemogram, a search for local disease and metastases includes tests of liver and renal function, transvaginal sonography, chest CT scan or radiograph, and brain and abdominopelvic CT scan or MR imaging. Less commonly, positron-emission tomographic (PET) scanning and cerebrospinal fluid β-hCG level determination are used to identify metastases (Lurain, 2011).

GTN is staged clinically using the system of the International Federation of Gynecology and Obstetrics (FIGO) (2009). This includes a modification of the World Health Organization (WHO) (1983) prognostic index score, with which scores of 0 to 4 are given for each of the categories shown in Table 20-4. Women with WHO scores of 0 to 6 are considered to have low-risk disease, whereas those with a score ≥7 are considered in the high-risk group.

TABLE 20-4

International Federation of Gynecology and Obstetrics (FIGO) Staging and Diagnostic Scoring System for Gestational Trophoblastic Neoplasia

Anatomical Staging					
Stage I	Disease confined to the uterus				
Stage II	GTN extends outside of the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)				
Stage III	GTN extends to the lungs, with or without known genital tract involvement				
Stage IV	All other metastatic sites				
Modified World Health Organization (WHO) Prognostic Scoring System[a]					
Scores[b]		**0**	**1**	**2**	**4**
Age (years)		<40	≥40	—	—
Antecedent pregnancy		Mole	Abortion	Term	—
Interval after index pregnancy (mo)		<4	4–6	7–12	>12
Pretreatment serum β-hCG (mIU/mL)		$<10^3$	10^3 to 10^4	10^4 to 10^5	≥10^5
Largest tumor size (including uterus)		<3 cm	3–4 cm	≥5 cm	—
Site of metastases		—	Spleen, kidney	GI	Liver, brain
Number of metastases		—	1–4	5–8	>8
Previous failed chemotherapy drugs			—	1	≥2

[a]Adapted by FIGO.

[b]Low risk = WHO score of 0 to 6; high risk = WHO score of ≥7.

β-hCG = beta human chorionic gonadotropin; GI = gastrointestinal; GTN = gestational trophoblastic neoplasia.

Adapted with permission from FIGO Committee on Gynecologic Oncology: Current FIGO staging for cancer of the vagina, fallopian tube, ovary, and gestational trophoblastic neoplasia, Int J Gynaecol Obstet 2009 Apr;105(1):3–4.

Histological Classification

Again, it is stressed that the diagnosis of trophoblastic neoplasias is usually made by persistently elevated serum β-hCG levels without confirmation by tissue study. Clinical staging is assigned without regard to histological findings, even if available. Still, there are distinct histological types, described next.

Invasive Mole

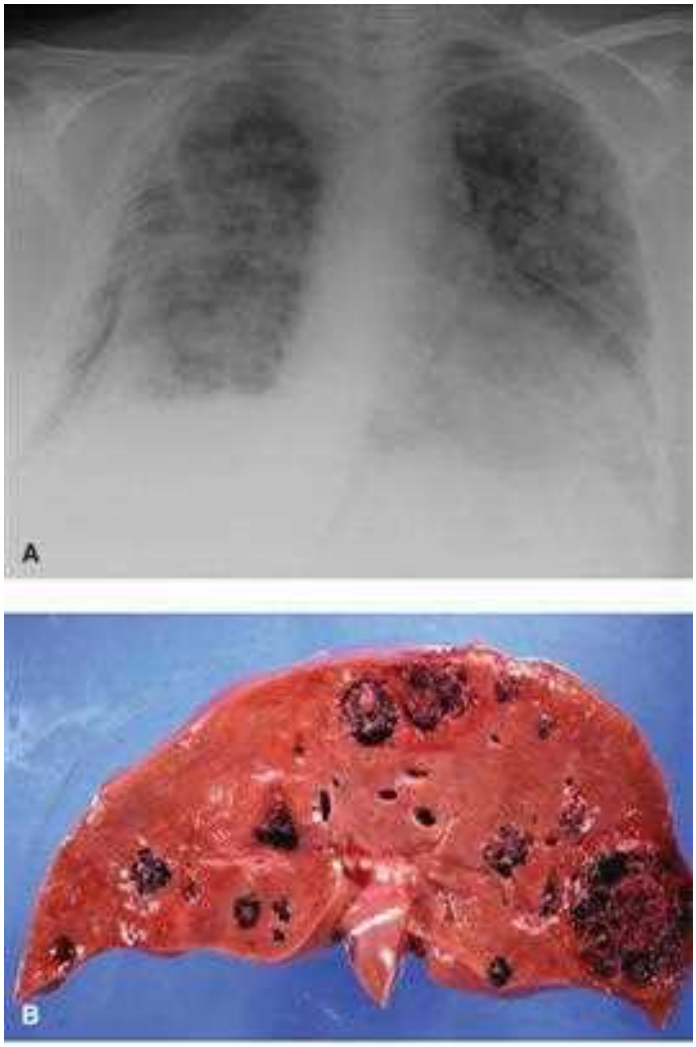
These are the most common trophoblastic neoplasms that follow hydatidiform moles, and almost all invasive moles arise from partial or complete moles. Previously known as *chorioadenoma destruens*, invasive mole is characterized by extensive tissue invasion by trophoblast and whole villi. There is penetration deep into the myometrium, sometimes with involvement of the peritoneum, adjacent parametrium, or vaginal vault. Although locally aggressive, invasive moles are less prone to metastasize.

Gestational Choriocarcinoma

This is the most common type of trophoblastic neoplasm to follow a term pregnancy or a miscarriage, and only a third of cases follow a molar gestation (Soper, 2006). Choriocarcinoma is composed of cells reminiscent of early cytotrophoblast and syncytiotrophoblast, however, it contains no villi. This rapidly growing tumor invades both myometrium and blood vessels to create hemorrhage and necrosis. Myometrial tumor may spread outward and become visible on the uterine surface as dark, irregular nodules. Metastases often develop early and are generally blood-borne (Fig. 20-5). The most common sites are the lungs and vagina, but tumor may travel to the vulva, kidneys, liver, brain, ovaries, and bowel. Bleeding can complicated these metastases (Fatema, 2016; Wei, 2016; Zhang, 2017). Choriocarcinomas are commonly accompanied by ovarian theca-lutein cysts.

FIGURE 20-5

Metastatic choriocarcinoma. **A.** Chest radiograph demonstrates widespread metastatic lesions. **B.** Autopsy specimen with multiple hemorrhagic hepatic metastases. (Used with permission from Dr. Michael Conner.)



Placental Site Trophoblastic Tumor

This rare tumor arises from *intermediate trophoblasts* at the placental site. These tumors have associated serum β-hCG levels that may be only modestly elevated. However, they produce variant forms of hCG, and identification of a high proportion of free β-hCG is considered diagnostic. Treatment of placental site trophoblastic tumor by hysterectomy is preferred because these locally invasive tumors are usually resistant to chemotherapy (Baergen, 2006). For higher-risk stage I and for later stages, adjuvant multidrug chemotherapy is also given (Schmid, 2009).

Epithelioid Trophoblastic Tumor

This rare tumor develops from chorionic-type intermediate trophoblast. The uterus is the main site of involvement, and bleeding and low hCG levels are typical findings (Scott, 2012). Primary treatment is hysterectomy because this tumor is relatively resistant to chemotherapy. Metastatic disease is common, and combination chemotherapy is employed (Davis, 2015).

Treatment

Women with GTN are best managed by oncologists, and some evidence supports treatment in centers specializing in GTN (Kohorn, 2014). The prognosis is excellent with rare exceptions, and patients are routinely cured even in the presence of widespread disease. Chemotherapy alone is usually the primary treatment. Although controversial, some also consider a second uterine evacuation to be an adjuvant therapeutic option in some GTN cases to avoid or minimize chemotherapy (Pezeshki, 2004; van Trommel, 2005). In other cases, suction curettage may infrequently be needed to resolve bleeding or remove a substantial amount of retained molar tissue. In specific cases, hysterectomy may be primary or adjuvant treatment (Clark, 2010).

Single-agent chemotherapy protocols are usually sufficient for nonmetastatic or low-risk metastatic neoplasia (Lawrie, 2016). In their review of 108 women with low-risk disease, Abrão and colleagues (2008) reported that monotherapy protocols with either methotrexate or actinomycin D were equally effective compared with a regimen containing both. In general, methotrexate is less toxic than actinomycin D (Chan, 2006; Seckl, 2010). Regimens are repeated until serum β-hCG levels are undetectable.

Combination chemotherapy is given for high-risk disease, and reported cure rates approximate 90 percent (Lurain, 2010). Several regimens have been used with success. One is EMA-CO, which includes etoposide, methotrexate, actinomycin D, cyclophosphamide, and Oncovin (vincristine). In selected cases, adjuvant surgical and radiotherapy may also be employed (Hanna, 2010). Frequent causes of death include hemorrhage from metastatic sites, respiratory failure, sepsis, and multiorgan failure due to widespread chemoresistant disease (Lybol, 2012; Neubauer, 2015).

With either low- or high-risk disease, once serum β-hCG levels are undetectable, serosurveillance is continued for 1 year. During this time, effective contraception is crucial to avoid any teratogenic effects of chemotherapy to the fetus and to mitigate confusion from rising β-hCG levels caused by superimposed pregnancy (Seckl, 2010; Williams, 2014). For those who conceive despite this within the surveillance year following treatment, pregnancy may continue since most will have a favorable outcome (Tse, 2012; Woolas, 1998). Importantly, this group is advised of the low but important risk of delayed diagnosis if tumor recurs during the pregnancy (Blagden, 2002; Tuncer, 1999b).

A small number of women during surveillance, despite no evidence of metastases, will be found to have very low β-hCG levels that plateau. This phenomenon is called *quiescent hCG* and presumably is caused by dormant trophoblast. Close observation without therapy is recommended, but 20 percent will eventually have recurrent active and progressive trophoblastic neoplasia (Ngu, 2014).

SUBSEQUENT PREGNANCY

Women with prior hydatidiform mole generally do not have impaired fertility, and their pregnancy outcomes are usually normal (Joneborg, 2014; Matsui, 2011; Sebire, 2003). One concern is the 2-percent risk for developing trophoblastic disease in a subsequent pregnancy, which was described earlier. Sonographic evaluation is recommended in early pregnancy, and subsequently if indicated.

Women who have successfully completed GTN chemotherapy are advised to delay pregnancy for 12 months. Fertility and pregnancy outcomes are typically normal, and congenital anomaly rates are not increased (Berkowitz, 2000; Tse, 2012). One exception is an unexplained higher stillbirth rate of 1.5 percent compared with a background rate of 0.8 percent (Vargas, 2014).

After hydatidiform mole or GTN treatment, in subsequent pregnancy, the placenta or products of conception are sent for pathological evaluation at delivery. A serum β-hCG level is measured 6 weeks postpartum (Lurain, 2010).

CHAPTER 21: Physiology of Labor

From time immemorial inquiring minds have sought an explanation for the fact that labour usually ensues about 280 days after the appearance of the last menstrual period, but thus far no satisfactory universal cause has been discovered.

—J. Whitridge Williams (1903)

INTRODUCTION

The importance of labor physiology was highlighted in the first edition of *Williams Obstetrics*, in which an entire section was devoted to the topic. Given the science at that time, those nine chapters were concerned with the mechanics of labor and delivery. However, the current understanding of labor includes a wide spectrum of preparedness even before the first regular contractions.

Labor is the last few hours of human pregnancy. It is characterized by forceful and painful uterine contractions that effect cervical dilation and cause the fetus to descend through the birth canal. Extensive preparations take place in both the uterus and cervix long before this. During the first 36 to 38 weeks of normal gestation, the myometrium is in a preparatory yet unresponsive state. Concurrently, the cervix begins an early stage of remodeling yet maintains structural integrity. Following this prolonged uterine quiescence, a transitional phase follows during which myometrial unresponsiveness is suspended and the cervix undergoes ripening, effacement, and loss of structural cohesion.

The physiological processes that regulate *parturition*—the bringing forth of young—and the onset of labor continue to be defined. Three general contemporaneous theories describe labor initiation. Viewed simplistically, the first is the *functional loss of pregnancy maintenance factors.* The second focuses on *synthesis of factors that induce parturition*. The third suggests that the mature fetus is the source of the initial *signal for parturition commencement*. Current research supports a model that draws from all three themes. However, labor onset clearly represents the culmination of a series of biochemical changes in the uterus and cervix. These result from endocrine and paracrine signals emanating from both mother and fetus. Their relative contributions vary between species, and it is these differences that complicate elucidation of the exact factors that regulate human parturition. When parturition is abnormal, then preterm labor, dystocia, or postterm pregnancy may result. Of these, preterm labor remains the major contributor to neonatal mortality and morbidity.

MATERNAL AND FETAL COMPARTMENTS

Uterus

The myometrial layer of the uterus is composed of bundles of smooth muscle cells surrounded by connective tissue. In contrast to skeletal or cardiac muscle, the smooth muscle cell is not terminally differentiated and therefore is readily adaptable to environmental changes. Varied stimuli such as mechanical stretch, inflammation, and endocrine and paracrine signals can modulate the transition of the smooth muscle cell among phenotypes that provide cell growth, proliferation, secretion, and contractility.

In addition to this phenotypic plasticity, several smooth muscle qualities confer advantages for uterine contraction efficiency and fetal delivery. First, the degree of smooth muscle cell shortening with contractions may be one order of magnitude greater than that attained in striated muscle cells. Second, forces can be exerted in smooth muscle cells in multiple directions. This differs from the contraction force generated by skeletal muscle, which is always aligned with the axis of the muscle fibers. Third, smooth muscle is not organized in the same manner as skeletal muscle. In myometrium, the thick and thin filaments are found in long, random bundles throughout the cells. This plexiform arrangement aids greater shortening and force-generating capacity. Last, greater multidirectional force generation in the uterine fundus compared with that of the lower uterine segment permits versatility in expulsive force directionality.

Lining the thick muscular uterine walls, the endometrium is transformed by pregnancy hormones and is then termed *decidua*. Composed of stromal cells and maternal immune cells, the decidua serves to maintain the pregnancy via unique immunoregulatory functions that suppress inflammatory signals during gestation. However, at the end of pregnancy, decidual activation ensues. With this, the decidua transitions to induce inflammatory signals and withdraw active immunosuppression, which contribute to parturition initiation.

During pregnancy, the cervix has multiple functions that include: (1) maintenance of barrier function to protect the reproductive tract from infection, (2) maintenance of cervical competence despite greater gravitational forces as the fetus grows, and (3) orchestration of extracellular matrix changes that allow progressively greater tissue compliance.

In nonpregnant women, the cervix is closed and firm, and its consistency is similar to nasal cartilage. By the end of pregnancy, the cervix is easily distensible, and its consistency is similar to the lips of the oral cavity. Observations in three-dimensional sonography and magnetic resonance imaging show increases in

the cross-sectional area of the cervical canal and in the cervical stroma from early to late pregnancy (House, 2009; Lang, 2010). Concurrent with expansion of the stroma, the cervical epithelia proliferate and exert a pregnancy-specific immunoprotection.

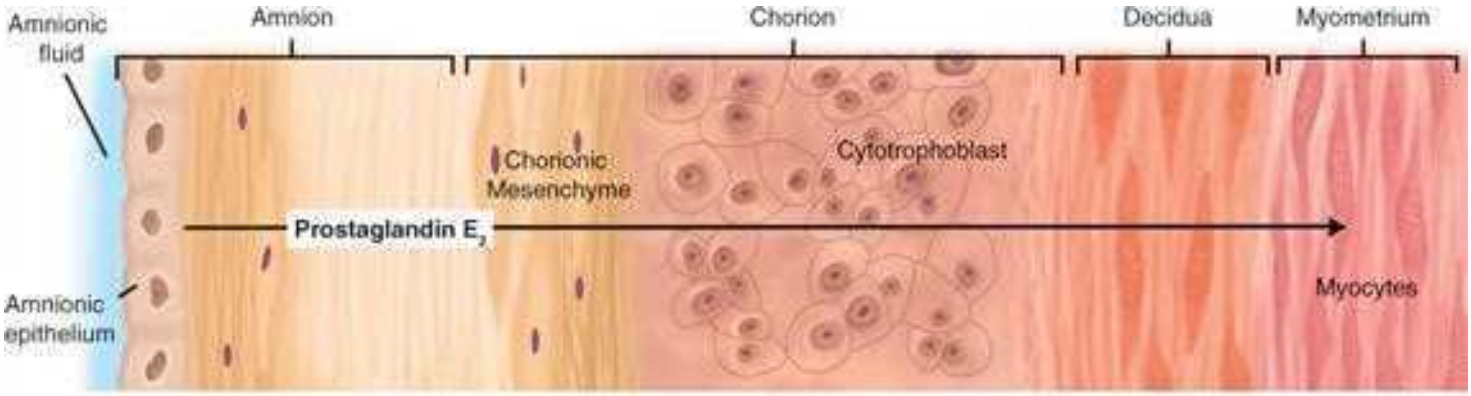
Placenta

In addition to providing the exchange of nutrients and waste between mother and fetus, the placenta is a key source of steroid hormones, growth factors, and other mediators that maintain pregnancy and potentially aid the transition to parturition. The fetal membranes—amnion and chorion and adjacent decidua—make up an important tissue shell around the fetus that serves as a physiological, immunological, and metabolic shield to protect against untimely parturition initiation.

The amnion provides virtually all of the fetal membranes' tensile strength to resist membrane tearing and rupture (Chap. 5, Amnion). This avascular tissue is highly resistant to penetration by leukocytes, microorganisms, and neoplastic cells (Fig. 21-1). It also constitutes a selective filter to prevent fetal particulate-bound lung and skin secretions from reaching the maternal compartment. In this manner, maternal tissues are protected from amnionic fluid constituents that could prematurely accelerate decidual or myometrial activation or could promote adverse events such as amnionic fluid embolism.

FIGURE 21-1

The amnion synthesizes prostaglandins, and late in pregnancy, synthesis is augmented by increased phospholipase A_2 and prostaglandin H synthase, type 2 (PGHS-2) activity. During pregnancy, the transport of prostaglandins from the amnion to maternal tissues is limited by expression of the inactivating enzymes, prostaglandin dehydrogenase (PGDH), in the chorion. During labor, PGDH levels decline, and amnion-derived prostaglandins can influence membrane rupture and uterine contractility. The role of decidual activation in parturition is unclear but may involve local progesterone metabolism and higher prostaglandin receptor concentrations, thus enhancing uterine prostaglandin actions and cytokine production. (Redrawn from Smith R: Parturition. N Engl J Med. 2007 Jan 18;356(3):271–283.)



The chorion is a primarily protective tissue layer and provides immunological acceptance. It is also enriched with enzymes that inactivate *uterotonins,* which are agents that stimulate contractions. Inactivating enzymes include prostaglandin dehydrogenase, oxytocinase, and enkephalinase (Cheung, 1990; Germain, 1994).

SEX STEROID HORMONE ROLE

In many species, the role of sex steroid hormones is clear— estrogen promotes and progesterone inhibits the events leading to parturition. And, the removal of progesterone, that is, *progesterone withdrawal,* directly precedes progression of parturition. In addition, providing progesterone to some species will delay parturition via a decline in myometrial activity and continued cervical competency (Challis, 1994). In humans, however, it seems most likely that both estrogen and progesterone are components of a broader molecular system that maintains uterine quiescence.

Plasma levels of estrogen and progesterone in normal pregnancy are enormous and in great excess of the affinity constants for their receptors. For this reason, it is difficult to comprehend how relatively subtle changes in the ratio of their concentrations could modulate physiological processes during pregnancy. The teleological evidence, however, for an increased progesterone-to-estrogen ratio in the maintenance of pregnancy and a decline in this ratio for parturition is overwhelming. In all species studied, including humans, administration of the progesterone-receptor antagonists *mifepristone (RU-486)* or *onapristone* will promote some or all key features of parturition. These include cervical ripening, greater cervical distensibility, and augmented uterine sensitivity to uterotonins (Bygdeman, 1994; Chwalisz, 1994b; Wolf, 1993).

The exact role of estrogen in regulation of human uterine quiescence and cervical competency is less well understood. That said, estrogen can advance progesterone responsiveness and, in doing so, promote uterine quiescence. At the end of pregnancy, estrogen aids processes that mediate uterine activation and cervical ripening.

Both progesterone and estrogen bind to nuclear receptors that regulate gene transcription in a cell- and context-specific pattern. Two nuclear receptors for estrogen are estrogen receptor α (ERα) and estrogen receptor β (ERβ). Nuclear receptor isoforms of the progesterone receptor (PR-A and PR-B) are encoded

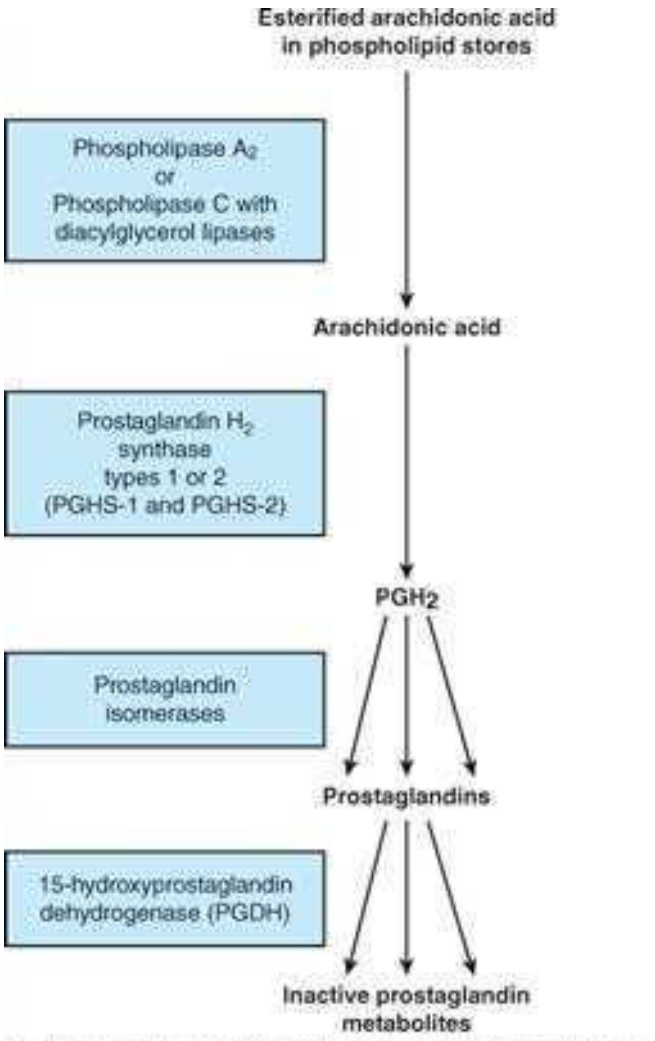
by differing transcripts from a single gene (Patel, 2015).

PROSTAGLANDINS ROLE

Prostaglandins are lipid molecules with varied hormone-like actions. In parturition, they play a prominent role in myometrial contractility, relaxation, and inflammation. Prostaglandins interact with a family of eight different G-protein–coupled receptors (G-Protein–Coupled Receptors), several of which are expressed in myometrium and cervix (Konopka, 2015; Myatt, 2004).

The major synthetic pathways involved in prostaglandin biosynthesis are shown in Figure 21-2. Prostaglandins are produced using plasma membrane-derived arachidonic acid, which usually is released by the action of phospholipase A_2 or C. Arachidonic acid can then act as substrate for both type 1 and 2 prostaglandin H synthase (PGHS-1 and -2), which are also called cyclooxygenase-1 and -2 (COX-1 and -2). Both PGHS isoforms convert arachidonic acid to the unstable prostaglandin G_2 and then to prostaglandin H_2. These enzymes are the target of many nonsteroidal antiinflammatory drugs (NSAIDs). Indeed, the tocolytic actions of specific NSAIDs, as discussed in Chapter 42 (β-Adrenergic Receptor Agonists), were considered promising until they were shown to have adverse fetal effects (Loudon, 2003; Olson, 2003, 2007).

FIGURE 21-2
Overview of the prostaglandin biosynthetic pathway.



Through prostaglandin isomerases, prostaglandin H_2 is converted to active prostaglandins. These include prostaglandins E_2 (PGE_2), $F_{2\alpha}$ ($PGF_{2\alpha}$), and I_2 (PGI_2). Isomerase expression is tissue-specific and thereby controls the relative production of various prostaglandins. Another important control point for prostaglandin activity is its metabolism, which most often is through the action of 15-hydroxyprostaglandin dehydrogenase (PGDH). Expression of this enzyme is upregulated during pregnancy in the uterus and cervix, which provides the important ability to rapidly inactivate prostaglandins (Giannoulias, 2002; Kishore, 2014). Thus, myometrial responses to prostaglandins stem from a balance between prostaglandin synthesis versus metabolism, from the relative expression of various prostaglandin receptors, or from a switch in receptor-signaling pathways (Kandola, 2014; Lyall, 2002; Olson, 2007; Smith, 2001). It is entirely possible that prostanoids contribute to myometrial relaxation at one stage of pregnancy and to myometrial contractions after parturition initiation (Myatt, 2004).

In addition to the myometrium, the amnion synthesizes several bioactive peptides and prostaglandins that cause myometrial relaxation or contraction (see Fig. 21-1). Late in pregnancy, amnionic prostaglandin biosynthesis is increased, and phospholipase A_2 and PGHS-2 show greater activity (Johnson, 2002).

Accordingly, many hypothesize that prostaglandins regulate events leading to parturition. The amnion is likely the major source for amnionic fluid prostaglandins, and their role in the activation of cascades that promote membrane rupture is clear. The influence of amnion-derived prostaglandins on uterine quiescence and activation, however, is less delineated. This is because prostaglandin transport from the amnion through the chorion to access maternal tissues is limited by expression of PGDH.

PHASE 1: UTERINE QUIESCENCE AND CERVICAL SOFTENING

As shown in Figure 21-3, parturition can be arbitrarily divided into four overlapping phases that correspond to the major physiological transitions of the myometrium and cervix during pregnancy (Casey, 1993, 1997; Challis, 2000; Word, 2007). These phases of parturition include: (1) a prelude to it, (2) the preparation for it, (3) the process itself, and (4) recovery. Importantly, the *phases of parturition* should not be confused with the *clinical stages of labor,* that is, the first, second, and third stages—which make up phase 3 of parturition (Fig. 21-4).

FIGURE 21-3
The phases of parturition.

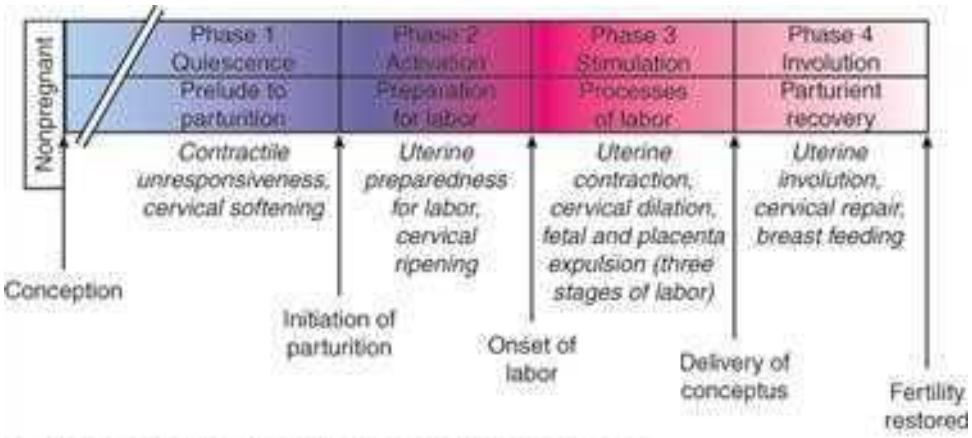


FIGURE 21-4
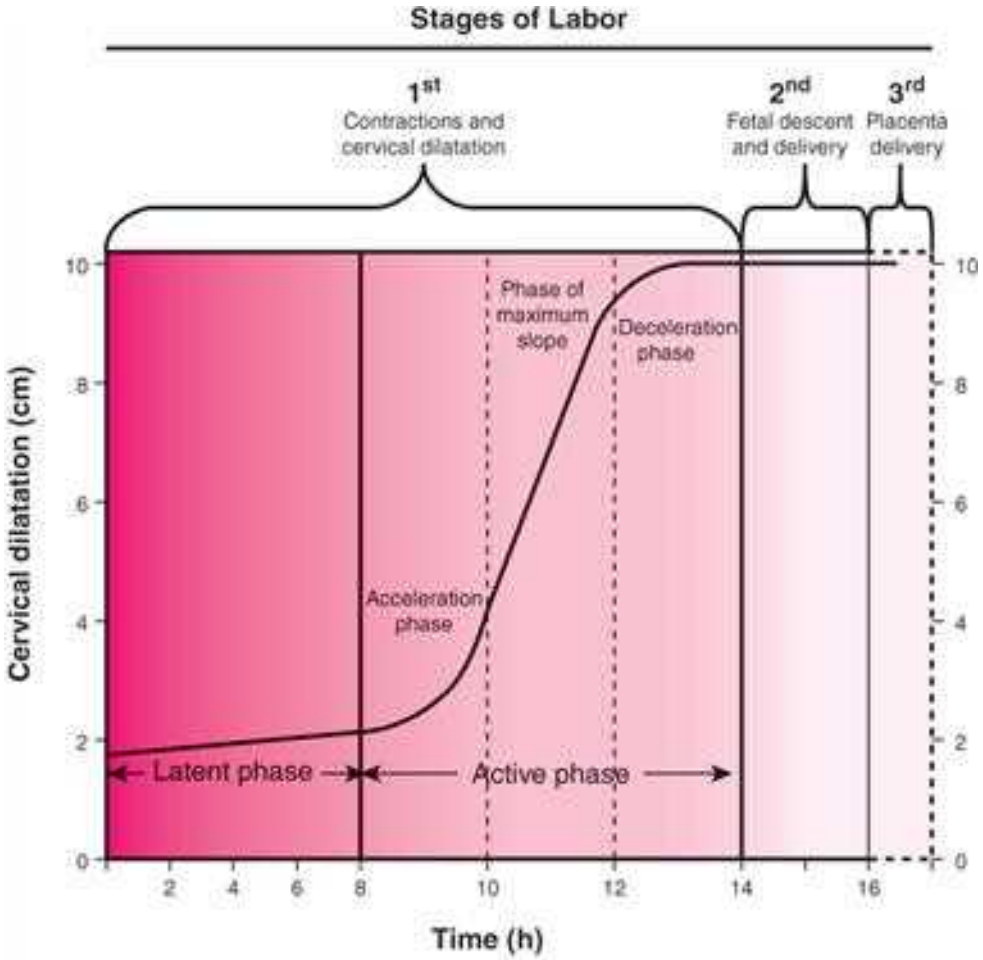
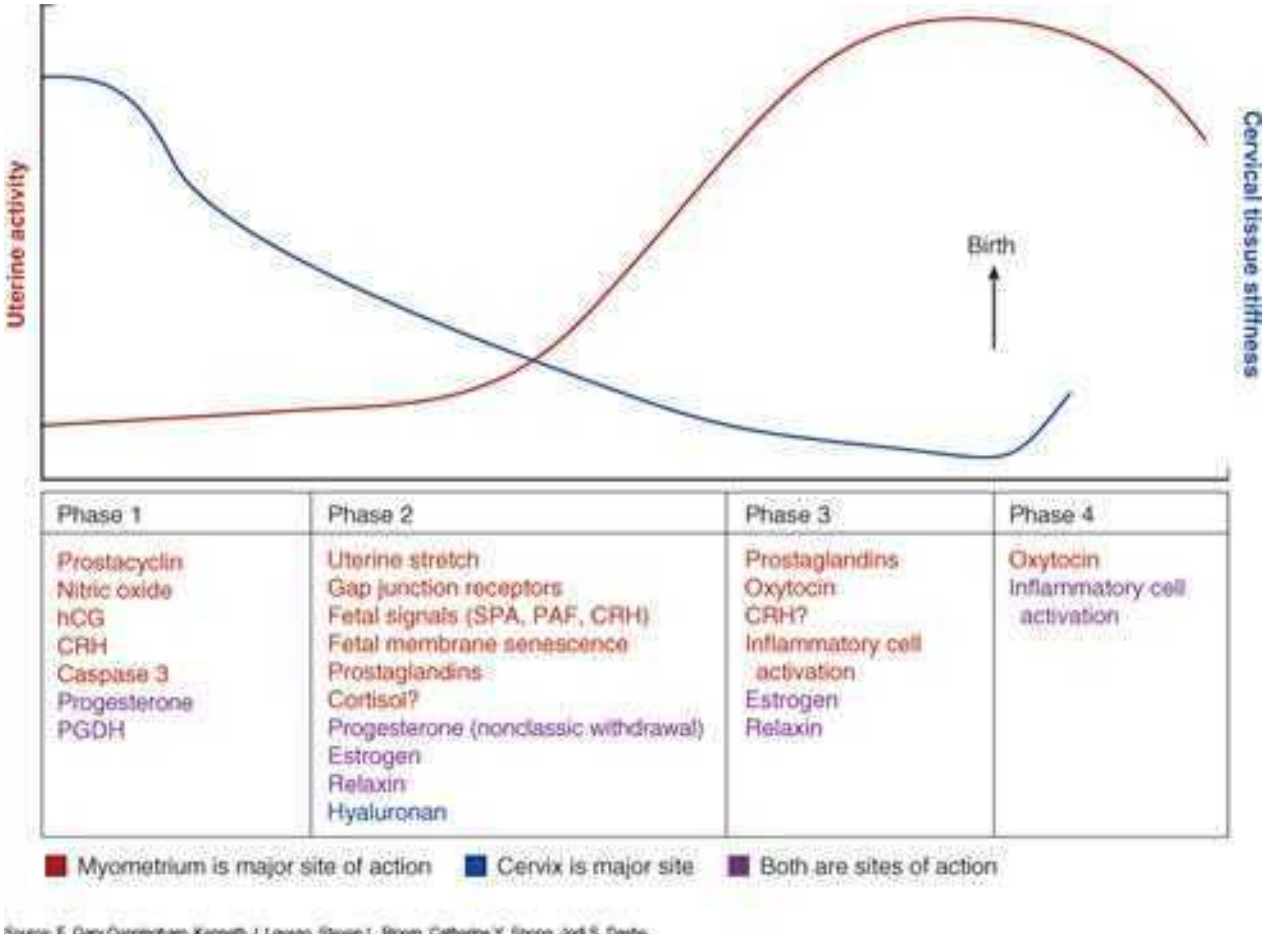
Composite of the average dilation curve for labor in nulliparous women. The curve is based on analysis of data derived from a large, nearly consecutive series of women. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable parts: an acceleration phase, a linear phase of maximum slope, and a deceleration phase. (Redrawn from Friedman EA: Labor: Clinical Evaluation and Management, 2nd ed. New York, Appleton-Century-Crofts, 1978.)



Beginning even before implantation, a remarkably effective period of myometrial quiescence is imposed. This phase 1 normally comprises 95 percent of pregnancy and is characterized by uterine smooth muscle tranquility with maintenance of cervical structural integrity (Fig. 21-5). All manner of molecular systems—neural, endocrine, paracrine, and autocrine—are likely called to implement and coordinate a state of relative uterine unresponsiveness. Moreover, a complementary "fail-safe" system that protects the uterus against agents that could perturb the tranquility of phase 1 also must be in place.

FIGURE 21-5

The key factors thought to regulate the phases of human parturition. CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotropin; PAF = platelet-activating factor; PGDH = prostaglandin dehydrogenase; SPA = surfactant protein A.



During phase 1, the myometrial cells undergo a phenotypic modification to a noncontractile state, and uterine muscle is rendered unresponsive to natural stimuli. Concurrently, the uterus must initiate extensive changes in its size and vascularity to accommodate fetal growth and prepare for uterine contractions. The myometrial unresponsiveness of phase 1 continues until near the end of pregnancy. That said, some low-intensity myometrial contractions are felt during the quiescent phase, but they do not normally cause cervical dilation. These contractions are common toward the end of pregnancy, especially in multiparas, and are referred to as *Braxton Hicks contractions* or *false labor* (Chap. 4, Uterine Contractility).

The quiescence of phase 1 likely stems from: (1) actions of estrogen and progesterone via intracellular receptors, (2) myometrial-cell plasma membrane receptor-mediated increases in cyclic adenosine monophosphate (cAMP), (3) generation of cyclic guanosine monophosphate (cGMP), and (4) other systems, including modification of myometrial-cell ion channels.

Myometrial Relaxation and Contraction

The balance between myometrial relaxation and contraction is controlled by steroid- and peptide-hormone transcriptional regulation of key genes and their protein products. Quiescence is achieved in part by: (1) diminished intracellular crosstalk and reduced intracellular Ca^{2+} ($[Ca^{2+}]_i$) levels; (2) ion- channel regulation of cell membrane potential; (3) activation of the uterine endoplasmic reticulum stress–unfolded protein response; and (4) uterotonin degradation. In contrast, contractility results from: (1) enhanced interactions between the actin and myosin proteins; (2) heightened excitability of individual myometrial cells; and (3) promotion of intracellular crosstalk that allows synchronous contractions to develop.

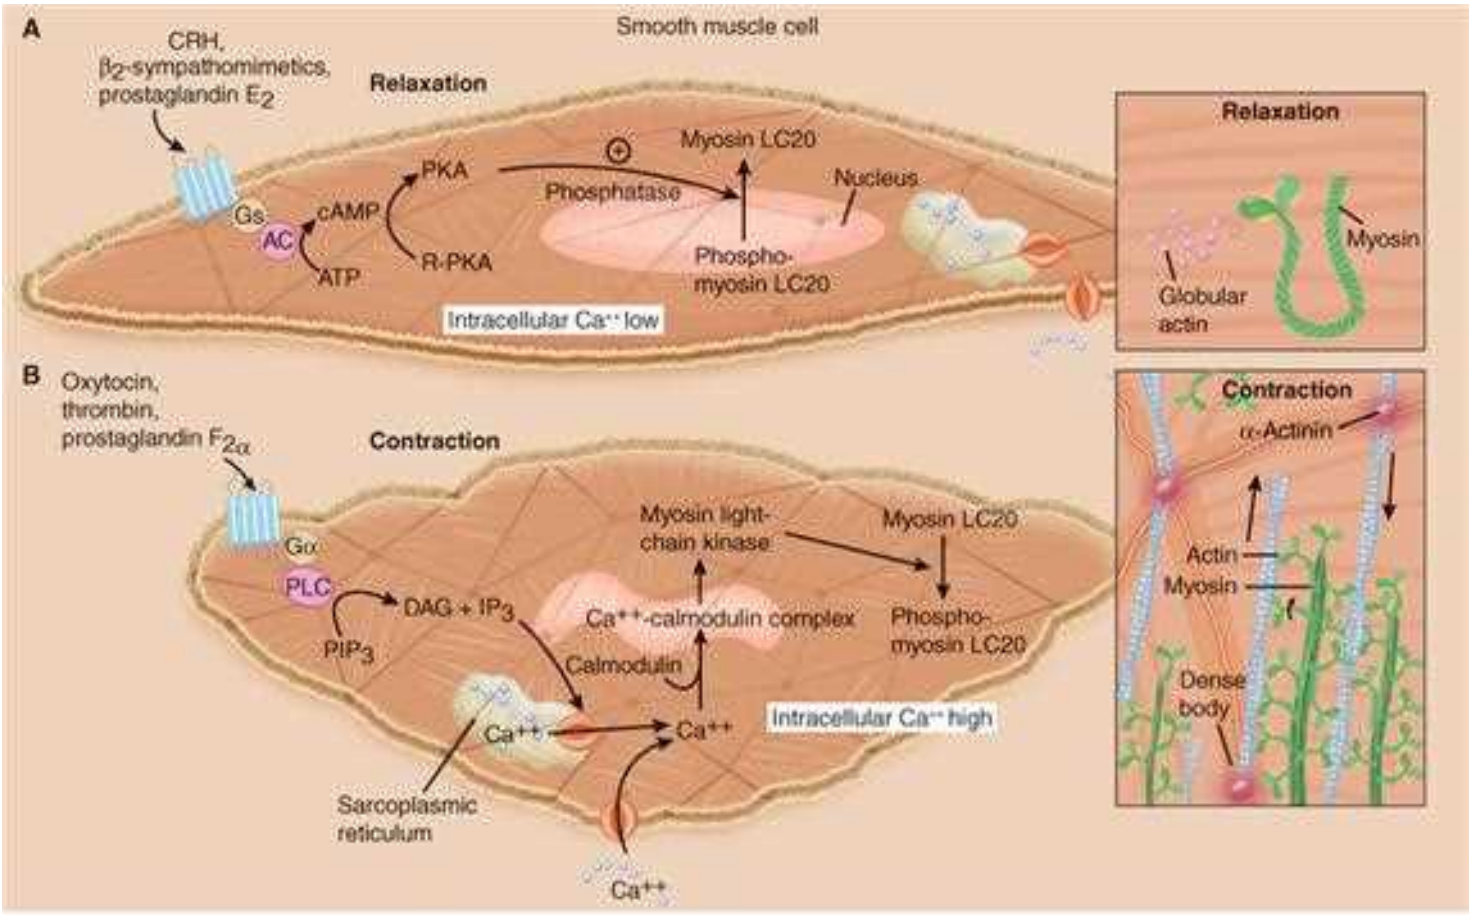
Actin-Myosin Interactions

Actin and myosin proteins are essential to muscle contraction. For this, actin must be converted from a globular to a filamentous form. Indeed, a potential mechanism for maintenance of relaxation is the promotion of actin into a globular form rather than into fibrils, which are required for contraction (Fig. 21-6). Moreover, actin must be attached to the cytoskeleton at focal points in the cell membrane to allow tension to develop.

FIGURE 21-6

Uterine myocyte relaxation and contraction. **A.** Uterine relaxation is maintained by factors that increase myocyte cyclic adenosine monophosphate (cAMP) levels. This activates protein kinase A (PKA) to promote phosphodiesterase activity with dephosphorylation of myosin light-chain kinase (MLCK). Other processes serve to maintain actin in a globular form and thus to prevent the fibril formation necessary for contractions. **B.** Uterine contractions result from reversal of these sequences. Actin now assumes a fibrillar form, and calcium enters the cell to combine with calmodulin to form complexes. These complexes activate MLCK to bring about phosphorylation of the myosin light chains. This generates ATPase activity to cause sliding of myosin over the actin fibrils, which is a uterine contraction. AC = adenylyl cyclase; Ca^{2+} = calcium; DAG = diacylglycerol; Gs and Gα = G-receptor proteins; IP_3 = inositol triphosphate; LC20

= light chain 20; PIP_3 = phosphatidylinositol 3,4,5–triphosphate; PLC = phospholipase C; R-PKA = inactive protein kinase. (Redrawn from Smith R: Parturition. N Engl J Med. 2007 Jan 18;356(3):271–283.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Actin must partner with myosin, which is composed of multiple light and heavy chains. The coupling of myosin and actin activates adenosine triphosphatase (ATPase), hydrolyzes adenosine triphosphate, and generates force. This interaction is brought about by enzymatic phosphorylation of the 20-kDa light chain of myosin (Stull, 1998). This is catalyzed by the enzyme *myosin light-chain kinase*, which is activated by calcium. Calcium binds to *calmodulin*, a calcium-binding regulatory protein, which in turn binds to and activates myosin light-chain kinase.

Thus, logically, uterine relaxation ordinarily is promoted by conditions that lower concentrations of $(Ca^{2+})_i$. In contrast, agents that prompt contraction act on myometrial cells to augment $(Ca^{2+})_i$ levels. Or, they allow an influx of extracellular calcium through ligand- or voltage-regulated calcium channels (see Fig. 21-6). Voltage-gated ion channels open, additional calcium ions move into the cell, and cellular depolarization follows. For example, prostaglandin $F_{2\alpha}$ and oxytocin bind their respective receptors during labor to open ligand-activated calcium channels. Activation of these receptors also releases calcium from the sarcoplasmic reticulum to lower electronegativity within the cell. Additionally, greater localization of nonselective cation channels on the cell membrane promotes Ca^{2+} entry (Ying, 2015). The rise in $(Ca^{2+})_i$ levels is often transient. But, contractions can be prolonged by inhibition of myosin phosphatase, an enzyme which dephosphorylates myosin (Woodcock, 2004).

Regulation of Membrane Potentials

As just noted, myocyte excitability is regulated in part by changes in the electrochemical potential gradient across the plasma membrane. Before labor, myocytes maintain a relatively high interior electronegativity. Maintenance of a hyperpolarized membrane potential attenuates smooth muscle cell excitation and is regulated by ion channels.

Consistent with the importance of myometrial quiescence, numerous potassium channels control membrane potential. One key regulator is the large-conductance voltage- and Ca^{2+}-activated K channel (BK_{Ca}) (Pérez, 1993). In normal physiology, the myometrial BK_{Ca} channel plays dual and opposing roles to maintain a balance between uterine quiescence and contractility. The BK_{Ca} channel is abundantly expressed in the myometrium. For most of pregnancy, opening the BK_{Ca} channel allows potassium to leave the cell to maintain interior electronegativity, thus preventing voltage-gated Ca^{2+} influx and contraction. Enhancing BK_{Ca} channel opening results in myometrial relaxation, whereas inhibition of the BK_{Ca} channel augments myometrial contractility.

The ability of BK_{Ca} channel to regulate calcium dynamics and ultimately uterine contractility from early to late gestation may result from temporal changes in expression of the BK_{Ca} channel and/or BK_{Ca} interacting partners (Wakle-Prabagaran, 2016).

Myometrial Gap Junctions

Cellular signals that control myometrial contraction and relaxation can be effectively transferred between cells through intercellular junctional channels. Communication is established between myocytes by gap junctions, which aid the passage of electrical or ionic coupling currents as well as metabolite coupling. The transmembrane channels that make up the gap junctions consist of two protein "hemi-channels" (Saez, 2005). These *connexons* are each composed of six *connexin* subunit proteins (Fig. 21-7). Of these, connexin-43 is expressed in myometrium, and concentrations rise near labor onset. Pairs of connexons establish a conduit between coupled cells for the exchange of small molecules that can be nutrients, waste, metabolites, second messengers, or ions. Optimal numbers and types of gap junctions are believed to be important for electrical myometrial synchrony.

FIGURE 21-7

The protein subunits of gap junction channels are called connexins. Six connexins form a hemichannel (connexon), and two connexons (one from each cell) form a gap junction channel. Connexons and gap junction channels can be formed from one or more connexin proteins. The composition of the gap junction channel is important for these channels' selectivity with regard to passage of molecules and communication between cells.

Progesterone maintains uterine quiescence in part by mechanisms that lower expression of various key proteins needed for contractility. These *contraction-associated proteins (CAPs)* include the oxytocin receptor, prostaglandin F receptor, and connexin-43. At the end of pregnancy, increased stretch along with greater estrogen dominance raises CAP levels. Integration of diverse regulatory pathways culminates in released inhibition of connexin-43 and oxytocin receptor levels to promote greater uterine contractility (Nadeem, 2016; Renthal, 2010; Williams, 2012b).

Endoplasmic Reticulum Stress Response

As another potential mechanism, progesterone maintains uterine quiescence through support of myometrial *caspase 3,* which is an anticontractile agent (Jeyasuria, 2009). This protein degrades both actin and the specific gap junction protein, connexin-43 (Kyathanahalli, 2015).

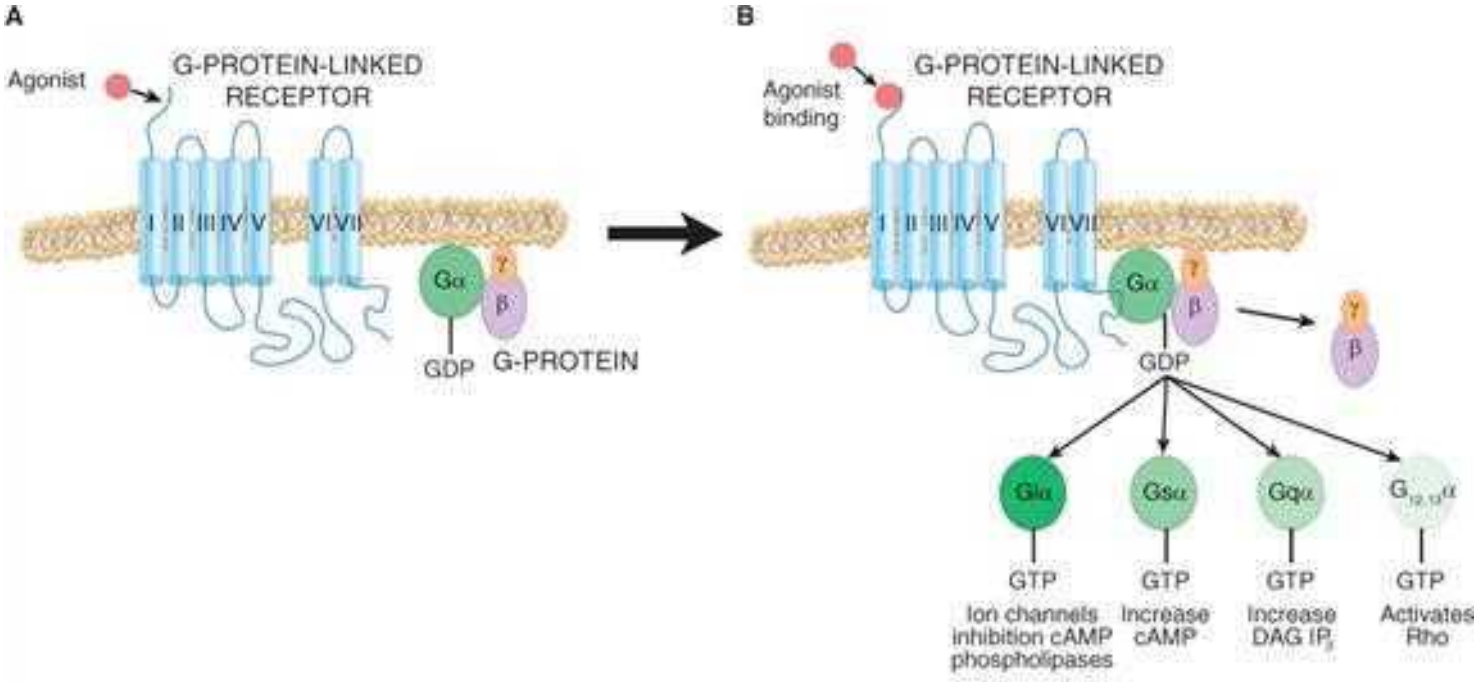
In mice, myometrial caspase 3 activation is regulated by a pregnancy-induced *endoplasmic reticulum stress response (ERSR).* As background, the endoplasmic reticulum aids protein folding and transport. Functional irregularities cause misfolded proteins to accumulate and trigger the ERSR. The ERSR and its *unfolded-protein response (UPR)* are cellular mechanisms that work to maintain homeostasis in the face of stimuli, such as stretch and inflammation. Prolonged ERSR promotes caspase 3 activation to preserve quiescence despite these stimuli.

G-Protein–Coupled Receptors

Various cell surface receptors directly regulate myocyte contractility. Discussions thus far have described ion channel-linked receptors that regulate intracellular Ca^{2+} and membrane potential. In addition, numerous G-protein–coupled receptors appear to be modified during the phases of parturition. Several of these are present in myometrium and associated with $G_{\alpha s}$-mediated activation of adenylyl cyclase to yield higher cAMP levels. These receptors together with appropriate ligands may act with sex steroid hormones to maintain uterine quiescence (Price, 2000; Sanborn, 1998). Examples are the LH receptor and corticotropin-releasing hormone receptor 1 (CRHR1), both described in this section (Fig. 21-8). Other G-protein–coupled myometrial receptors, instead, are associated with G-protein–mediated activation of phospholipase C, which remember releases arachidonic acid. Ligands for the G-protein–coupled receptors include numerous neuropeptides, hormones, and autacoids. Many of these are available to the myometrium during pregnancy in high concentration via *endocrine* or *autocrine* mechanisms.

FIGURE 21-8

G-protein–coupled receptor signal transduction pathways. **A.** Receptors coupled to heterotrimeric guanosine-triphosphate (GTP)-binding proteins (G proteins) are integral transmembrane proteins that transduce extracellular signals to the cell interior. G-protein–coupled receptors exhibit a common structural motif consisting of seven membrane-spanning regions. **B.** Receptor occupation promotes interaction between the receptor and the G protein on the interior surface of the membrane. This induces an exchange of guanosine diphosphate (GDP) for GTP on the G protein α subunit and dissociation of the α subunit from the βγ heterodimer. Depending on its isoform, the GTP-α subunit complex mediates intracellular signaling either indirectly by acting on effector molecules such as adenylyl cyclase (AC) or phospholipase C (PLC), or directly by regulating ion channel or kinase function. cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; IP_3 = inositol triphosphate.



β-Adrenoreceptors are prototypical examples of cAMP signaling causing myometrium relaxation. β-Adrenergic receptors mediate $G_{\alpha s}$-stimulated increases in adenylyl cyclase, elevated levels of cAMP, and myometrial cell relaxation. The rate-limiting factor is likely the number of receptors expressed and the level of adenylyl cyclase expression. Agents binding to these receptors have been used for tocolysis of preterm labor and include ritodrine and terbutaline (Chap. 42, β-Adrenergic Receptor Agonists).

LH and hCG hormones share the same receptor, and this G-protein–coupled receptor has been found in myometrial smooth muscle and blood vessels (Ziecik, 1992). Levels of myometrial LH-hCG receptors during pregnancy are greater before than during labor. Chorionic gonadotropin acts to activate adenylyl cyclase by way of a plasma membrane receptor $G_{\alpha s}$-linked system. This lessens contraction frequency and force and lowers the number of tissue-specific myometrial cell gap junctions (Ambrus, 1994; Eta, 1994). Thus, high circulating levels of hCG may be one mechanism of uterine quiescence. In the mouse, variations in FSH-receptor density also regulate myometrial contractile activity (Stilley, 2016).

Prostaglandin E_2 mediates its diverse cellular effects through four G-protein–coupled receptors. Specifically, prostaglandin E receptors 1 through 4 (EP_1-EP_4) are expressed in the myometrium during pregnancy and with labor onset (Astle, 2005; Leonhardt, 2003). EP_2 and EP_4 act through $G_{\alpha}s$ to raise cAMP levels and maintain myometrial cell quiescence but switch to a $G_{\alpha}q$/11 calcium-activating pathway during labor (Kandola, 2014). EP_1 and EP_3 receptors act through $G_{\alpha}q$ and $G_{\alpha}i$ to augment intracellular Ca^{2+} and contractility.

The peptide hormone relaxin binds to the G-protein–coupled receptor named *relaxin family peptide receptor 1 (RXFP1). Binding* activates adenylyl cyclase in uterine smooth muscle cells. Adenylyl cyclase in turn prevents increased intracellular Ca^{2+} and thus promotes uterine quiescence (Downing, 1993; Meera, 1995). There are two separate human relaxin genes, designated *H1* and *H2*. Of these, *H1* is primarily expressed in the decidua, trophoblast, and prostate, whereas *H2* is primarily expressed in the corpus luteum. Relaxin in plasma of pregnant women is believed to originate exclusively from corpus luteum secretion. Plasma levels peak at approximately 1 ng/mL between 8 and 12 weeks' gestation. Thereafter, they decline to lower levels that persist until term.

Corticotropin-releasing hormone (CRH) is synthesized in the placenta and hypothalamus. Discussed in Fetal Contributions to Parturition, CRH plasma levels rise dramatically during the final 6 to 8 weeks of normal pregnancy and are implicated in mechanisms that control the timing of human parturition (Smith, 2007; Wadhwa, 1998). CRH appears to promote myometrial quiescence during most of pregnancy but then aids myometrial contractions with parturition onset. Studies suggest that these opposing actions are achieved by differential actions of CRH via its receptor CRHR1. In nonlaboring myometrium at term, the interaction of CRH with its CRHR1 receptor activates the Gs-adenylate cyclase-cAMP signaling pathway. This results in inhibition of inositol triphosphate (IP_3) and stabilization of $(Ca^{2+})_i$ levels (You, 2012). However, in term laboring myometrium, $(Ca^{2+})_i$ concentrations are augmented by CRH activation of G proteins Gq and Gi and prompts stimulation of IP_3 production and greater contractility.

Cyclic Guanosine Monophosphate

As just described, cAMP is an important mediator of myometrial relaxation. However, activation of guanylyl cyclase raises intracellular cyclic guanosine monophosphate (cGMP) levels. This also promotes smooth muscle relaxation (Word, 1993). Intracellular cGMP levels are increased in the pregnant myometrium and can be stimulated by atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP) receptors, and nitric oxide (Telfer, 2001). All of these factors and their receptors are expressed in the pregnant uterus.

Accelerated Uterotonin Degradation

In addition to pregnancy-induced compounds that promote myometrial cell refractoriness, the activity of enzymes that degrade or inactivate endogenously produced uterotonins are strikingly increased in phase 1. Some of these degrading enzymes and their respective targets include PGDH and prostaglandins; enkephalinase and endothelins; oxytocinase and oxytocin; diamine oxidase and histamine; catechol *O*-methyltransferase and catecholamines; angiotensinases and angiotensin-II; and platelet-activating factor (PAF) and PAF acetylhydrolase. Levels of several of these enzymes decrease late in gestation (Germain, 1994).

Decidua

To ensure uterine quiescence, the synthesis in the decidua of prostaglandins, in particular $PGF_{2\alpha,}$ is markedly suppressed. Suppression of prostaglandin production here persists throughout most of pregnancy, and suppression withdrawal is a prerequisite for parturition (Norwitz, 2015).

Phase 1 of parturition also promotes an environment of immune tolerance to protect the fetus. Namely, decidual stromal cells proactively ensure that fetal antigens do not elicit a maternal immune response. This stems from a reduced capacity to attract T cells. This limited ability derives in part from epigenetic silencing of T cell–attracting inflammatory chemokine genes (Erlebacher, 2013; Nancy, 2012; PrabhuDas, 2015).

Cervical Softening

The initial stage of cervical remodeling—termed *softening*—begins in phase 1 of parturition. It is characterized by greater tissue compliance, yet the cervix remains firm and unyielding. Hegar (1895) first described palpable softening of the lower uterine segment at 4 to 6 weeks' gestation, and this sign was once used to diagnose pregnancy. Clinically, the maintenance of cervical anatomical and structural integrity is essential for pregnancy to continue to term. Preterm cervical dilation, structural insufficiency, or both may forecast delivery.

Cervical softening results from increased vascularity, cellular hypertrophy and hyperplasia, and slow, progressive compositional and structural changes in the extracellular matrix (Mahendroo, 2012; Myers, 2015; Word, 2007). Key to matrix changes, collagen, which is the main structural protein in the cervix, undergoes conformational changes that alter tissue stiffness and flexibility (Zhang, 2012). Specifically, collagen processing and the number or type of stable covalent cross-links between collagen triple helices is altered. Mature cross-links between newly synthesized collagen monomers are reduced due to diminished expression and activity of the cross-link-forming enzymes beginning in early pregnancy (Akins, 2011; Drewes, 2007; Yoshida, 2014). These enzymes are lysyl hydroxylase and lysyl oxidase. Together, these early pregnancy changes contribute to greater tissue compliance.

Clinical evidence for the importance of matrix changes to cervical softening is supported by in vivo mechanical evaluation of the cervix (Badir, 2013; Parra-Saavedra, 2011). The prevalence of cervical insufficiency is also higher in those with inherited defects in the synthesis or assembly of collagen or elastic fibers (Anum, 2009; Hermanns-Le, 2005; Rahman, 2003; Wang, 2006). Examples are Ehlers-Danlos and Marfan syndromes, discussed in Chapter 59 (Hereditary Connective Tissue Disorders). Concurrent with matrix remodeling in the softening period, genes involved in cervical dilation and parturition are actively repressed (Hari Kishore, 2012).

PHASE 2: PREPARATION FOR LABOR

To prepare for labor, the myometrial tranquility of phase 1 of parturition must be suspended—so-called *uterine awakening* or *activation.* This phase 2 of parturition is a progression of uterine changes during the last few weeks of pregnancy. Importantly, shifting events associated with phase 2 can cause either

preterm or delayed labor.

Progesterone Withdrawal

Key factors in uterine activation are depicted in Figure 21-5. In species that exhibit progesterone withdrawal, parturition progression to labor can be blocked by administering progesterone to the mother. Whether progesterone administration in the absence of classic progesterone withdrawal in pregnant women can delay the timely onset of parturition or prevent preterm labor continues to be investigated. The possibility that progesterone-containing injections or vaginal suppositories may prevent preterm labor has been studied in several randomized trials conducted during the past 15 years. These are discussed in Chapter 42 (Prophylaxis with Progestogen Compounds), and their use in preventing recurrent preterm birth continues to be debated (Norman, 2016).

Classic progesterone withdrawal resulting from decreased secretion does not occur in human parturition. However, a mechanism for progesterone inactivation, whereby the myometrium and cervix become refractory to progesterone's inhibitory actions, is supported by studies using progesterone-receptor antagonists. Mifepristone is a classic steroid antagonist, acting at the level of the progesterone receptor. Although less effective in inducing abortion or labor in women later in pregnancy, mifepristone appears to have some effect on cervical ripening and on increasing myometrial sensitivity to uterotonins (Berkane, 2005; Chwalisz, 1994a).

The diverse mechanisms by which functional progesterone withdrawal or antagonism is achieved is an active area of research. These include: (1) changes in the relative expression of the nuclear progesterone-receptor isoforms, PR-A, PR-B, and PR-C; (2) differential interaction of PR-A and PB-B with enhancers and inhibitors of gene expression; (3) alterations in PR activity through changes in the expression of coactivators or corepressors that directly influence receptor function; (4) local inactivation of progesterone by steroid-metabolizing enzymes or synthesis of a natural antagonist; and (5) microRNA regulation of progesterone-metabolizing enzymes and transcription factors that modulate uterine quiescence (Condon, 2003; Mahendroo, 1999; Mesiano, 2002; Nadeem, 2016; Renthal, 2010; Williams, 2012a). Taken together, these observations support the concept that multiple pathways exist for a functional progesterone withdrawal.

Myometrial Changes

Phase 2 myometrial changes prepare it for labor contractions. This results from a shift in the expression of key proteins that control uterine quiescence to an expression of contraction-associated proteins, described earlier (Myometrial Gap Junctions) (Renthal, 2015). Of these CAPs, myometrial oxytocin receptors and gap junction proteins, such as connexin-43, markedly rise in number. These CAPs increase uterine irritability and responsiveness to *uterotonins.*

Another critical change in phase 2 is formation of the lower uterine segment from the isthmus. With this development, the fetal head often descends to or even through the pelvic inlet—so-called *lightening.* The abdomen commonly undergoes a shape change, sometimes described by women as "the baby dropped." It is also likely that the lower segment myometrium is unique from that in the upper uterine segment, resulting in distinct roles for each near term and during labor. This is supported by human studies that demonstrate differential expression of prostaglandin receptors and CAPs within the upper- and lower-segment myometrial regions (Astle, 2005; Blanks, 2003; Sparey, 1999). Near term, elevated expression of the *HoxA13* gene in the lower myometrial segment compared with the upper segment also induces CAP expression and regionalized contractility of the lower segment (Li, 2016).

Oxytocin Receptors

Because of its long-standing application for labor induction, it seemed logical that oxytocin must play a central role in spontaneous human labor. Myometrial oxytocin receptor levels do rise during phase 2 of parturition, and the level of oxytocin receptor mRNA in human myometrium at term is greater than that found in preterm myometrium (Wathes, 1999). However, it is unclear whether oxytocin plays a role in the early phases of uterine activation or whether its sole function is in the expulsive phase of labor. Most studies of regulation of myometrial oxytocin receptor synthesis have been performed in rodents. Disruption of the oxytocin receptor gene in the mouse does not affect parturition. This suggests that, at least in this species, multiple systems likely ensure that parturition occurs.

Progesterone and estradiol appear to be the primary regulators of oxytocin receptor expression. Estradiol treatment in vivo or in myometrial explants raises myometrial oxytocin receptor concentrations. This action, however, is prevented by simultaneous treatment with progesterone (Fuchs, 1983). Progesterone also may act within the myometrial cell to enhance oxytocin receptor degradation and inhibit oxytocin activation of its receptor at the cell surface (Bogacki, 2002). These data indicate that one of the mechanisms whereby progesterone maintains uterine quiescence is through inhibition of a myometrial oxytocin response.

Cervical Ripening

Before contractions begin, the cervix must undergo extensive remodeling. This eventually leads to the cervix yielding and dilating from forceful uterine contractions. Cervical modifications during phase 2 principally involve connective tissue changes—termed *cervical ripening.* The transition from the softening to the ripening phase begins weeks or days before labor. During this transformation, the cervical matrix changes its total amounts of *glycosaminoglycans*, which are large linear polysaccharides, and *proteoglycans,* which are proteins bound to these glycosaminoglycans.

Many of the processes that aid cervical remodeling are controlled by the same hormones regulating uterine function. That said, the molecular events of each are varied because of differences in cellular composition and physiological requirements. For example, the hormone relaxin regulates myometrial quiescence. It also regulates cervical ripening, but through cell proliferation and modulation of extracellular matrix components (Park, 2005; Soh, 2012). The uterine corpus is predominantly smooth muscle. In contrast, the cervix has a high ratio of fibroblasts to smooth muscle cells, and extracellular matrix

contributes significantly to overall tissue mass. Recent studies in the nonpregnant human cervix report a spatial gradient of smooth muscle cells. Specifically, smooth muscle cells make up approximately 50 percent of stromal cells at the internal os but only 10 percent at the external os (Vink, 2016).

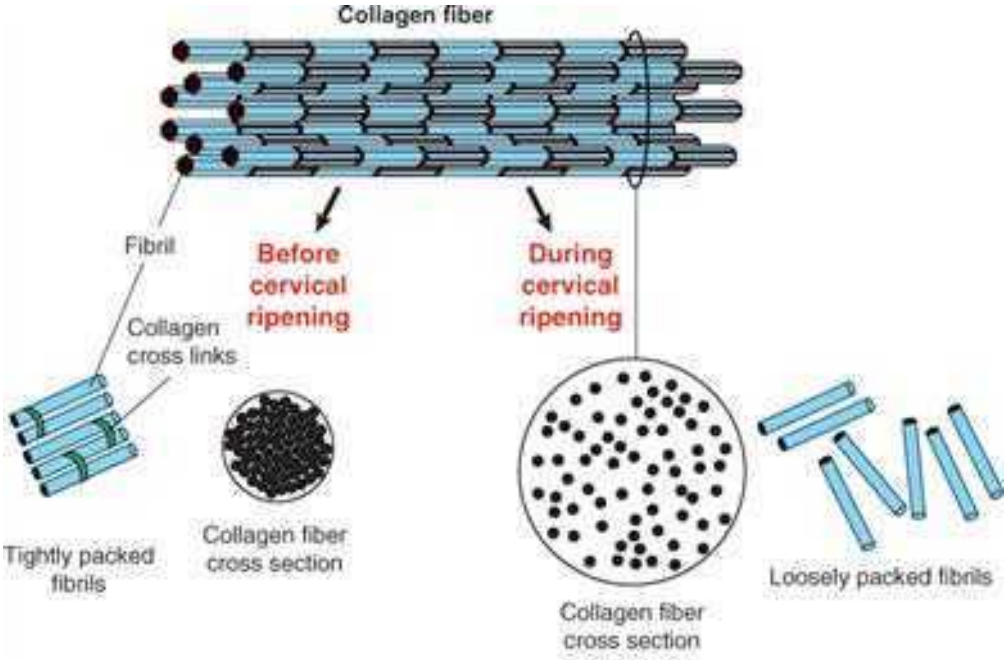
Cervical Connective Tissue

Collagen

The cervix is an extracellular-matrix-rich tissue. Constituents of the matrix include type I, III, and IV collagen, matricellular proteins, glycosaminoglycans, proteoglycans, and elastic fibers. Of these, collagen is largely responsible for the structural disposition of the cervix. During collagen assembly, multiple collagen triple-helical molecules are cross-linked to one another by the actions of lysyl oxidase to form fibrils. In addition, fibril size, packing, and organization determine the strength and mechanical properties of the cervix. These properties are regulated in part by collagen-binding proteoglycans such as decorin or biglycan, as well as matricellular proteins such as thrombospondin 2 (Fig. 21-9).

FIGURE 21-9

The collagen fiber architecture is reorganized in phases 1 and 2 of parturition to allow a gradual increase in mechanical compliance of the cervix. A collagen fiber is made up of many fibrils. Fibril size and packing are regulated in part by small proteoglycans such as decorin and by the density of collagen cross-links. In phase 1, fibril size is uniform and fibrils are well organized, although a decline in cross-link density aids softening. During cervical ripening in phase 2, fibril size is less uniform, and spacing between collagen fibrils and fibers is greater and disorganized.



Higher turnover of collagen during pregnancy likely allows the gradual replacement of mature cross-linked collagen fibrils with poorly cross-linked fibrils, which yield greater collagen disorganization. This increased turnover, rather than loss of collagen to achieve cervical remodeling, is supported by mouse and human studies that document no changes in collagen content between nonpregnant states and term pregnancy (Akins, 2011; Myers, 2008; Read, 2007; Yoshida, 2014). In further support, polymorphisms or mutations in genes required for collagen assembly are associated with an elevated incidence of cervical insufficiency (Anum, 2009; Rahman, 2003; Warren, 2007).

Glycosaminoglycans and Proteoglycans

Hyaluronan is a high-molecular-weight polysaccharide that functions alone, whereas most other glycosaminoglycans (GAGs) complex with proteins to form proteoglycans. Hyaluronan is a hydrophilic, space-filling molecule, and thus greater hyaluronan production during cervical ripening is thought to increase viscoelasticity, hydration, and matrix disorganization. Hyaluronan synthesis is carried out by hyaluronan synthase isoenzymes, and expression of these enzymes is elevated in the cervix during ripening (Akgul, 2012; Straach, 2005).

Although not well defined, changes in proteoglycan composition are also suggested to accompany cervical ripening. At least three small leucine-rich proteoglycans are expressed in the cervix—decorin, biglycan, and fibromodulin (Westergren-Thorsson, 1998). In other connective tissues, decorin interacts with collagen to regulate the packing, order, and strength of collagen fibrils (see Fig. 21-9) (Ameye, 2002). In addition to the cervix, these proteoglycans are expressed in the fetal membranes and uterus.

Inflammatory Changes

In phase 2, resident immune cells are localized to the cervical stroma, although a functional role for these cells in this phase of remodeling has been challenged. Microarray studies comparing gene expression patterns at term both before and after cervical ripening show little rise in proinflammatory gene expression. In contrast, proinflammatory and immunosuppressive gene expression in the cervix after delivery increases markedly compared with that during cervical ripening (Bollapragada, 2009; Hassan, 2006, 2009). Further, detailed studies in mice provide evidence that leukocyte migration but not activation

takes place before labor. Once labor is underway, activation of neutrophils, proinflammatory M1 macrophages, and tissue repair M2 macrophages in the cervix is augmented. This suggests a role for inflammatory cells in postpartum cervical remodeling and repair (Mahendroo, 2012).

Induction of Cervical Ripening

No therapies prevent premature cervical ripening. In contrast, treatment to promote cervical ripening for labor induction includes direct application of prostaglandins PGE_2 and $PGF_{2\alpha}$. Prostaglandins likely modify extracellular matrix structure to aid ripening. Although the role of prostaglandins in the normal physiology of cervical ripening remains unclear, this property is useful clinically to assist labor induction (Chap. 26, Preinduction Cervical Ripening).

In some nonhuman species, the cascades of events that allow cervical ripening are induced by dropping serum progesterone concentrations. And in humans, administration of progesterone antagonists causes cervical ripening.

Endocervical Epithelia

In addition to matrix changes, during pregnancy, endocervical epithelial cells proliferate such that endocervical glands account for a significant percentage of cervical mass. The endocervical canal is lined with mucus-secreting columnar and stratified squamous epithelia. These cells form both a mucosal barrier and a tight junctional barrier that protect against microbial invasion (Akgul, 2014; Blaskewicz, 2011; Timmons, 2007). The mucosal epithelium recognizes and deters pathogen invasion via expression of toll-like receptors that identify pathogens and via antimicrobial peptides and protease inhibitors. In addition, these epithelia express signals to underlying immune cells when a pathogenic challenge exceeds their protective capacity (Wira, 2005).

Fetal Contributions to Parturition

It is intriguing to envision that the mature human fetus provides the signal to initiate parturition, and evidence for fetal signaling is mounting (Mendelson, 2017). The fetus may give signals through blood-borne agents that act on the placenta or through secretion into the amnionic fluid.

Uterine Stretch

Fetal growth is an important component in uterine activation in phase 2 of parturition. With uterine activation, stretch is required for induction of specific CAPs. Namely, stretch increases expression of connexin-43 and oxytocin receptors. Levels of gastrin-releasing peptide, a stimulatory agonist for smooth muscle, are also augmented by stretch in the myometrium (Tattersall, 2012).

Clinical clues for a role of stretch come from the observation that multifetal pregnancies carry a much greater risk for preterm labor than singleton ones. And, preterm labor is also significantly more common in pregnancies complicated by hydramnios. Although the mechanisms causing preterm birth in these two examples are debated, a role for uterine stretch must be considered.

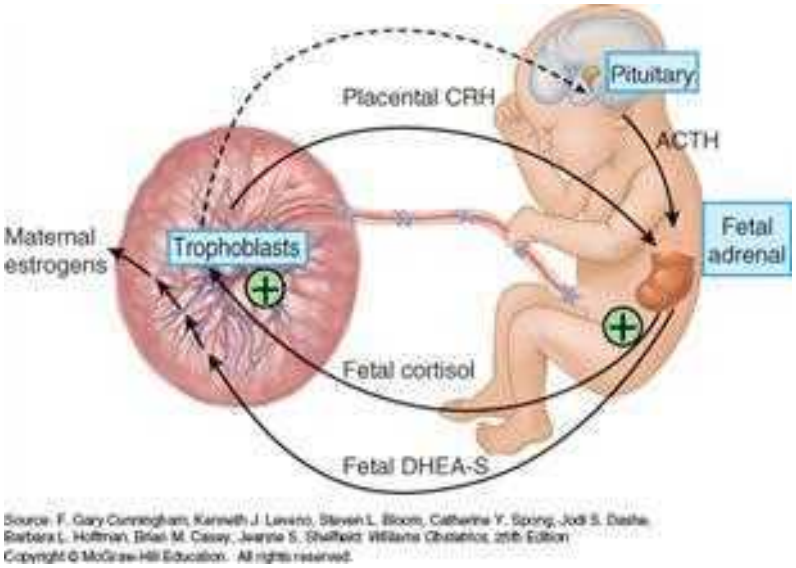
Cell signaling systems that are influenced by stretch to regulate the myometrial cell continue to be defined. This process—*mechanotransduction*—may include activation of cell-surface receptors or ion channels, transmission of signals through extracellular matrix, or release of autocrine molecules that act directly on myometrium (Shynlova, 2007; Young, 2011).

Fetal Endocrine Cascades

The ability of the fetus to provide endocrine signals that initiate parturition has been demonstrated in several species. However, evidence suggests that it is not regulated in the same manner in humans. That said, the human fetal hypothalamic-pituitary-adrenal-placental axis is considered a critical component of normal parturition. Moreover, premature activation of this axis is considered to prompt many cases of preterm labor (Challis, 2000, 2001). As in the sheep, steroid products of the human fetal adrenal gland are believed to have effects on the placenta and membranes that eventually transform the myometrium from a quiescent to a contractile state. A key component in the human may be the unique ability of the placenta to produce large amounts of CRH (Fig. 21-10).

FIGURE 21-10

The placental–fetal adrenal endocrine cascade. In late gestation, placental corticotropin-releasing hormone (CRH) stimulates fetal adrenal production of dehydroepiandrosterone sulfate (DHEA-S) and cortisol. The latter stimulates production of placental CRH, which leads to a feed-forward cascade that enhances adrenal steroid hormone production. ACTH = adrenocorticotropic hormone.



A CRH hormone that is identical to maternal and fetal hypothalamic CRH is synthesized by the placenta in relatively large amounts (Grino, 1987; Saijonmaa, 1988). However, unlike hypothalamic CRH, which is under glucocorticoid negative feedback, cortisol instead *stimulates* placental CRH production. This ability makes it possible to create a feed-forward endocrine cascade that does not end until delivery.

Maternal plasma CRH levels are low in the first trimester and rise from midgestation to term. In the last 12 weeks, CRH plasma levels rise exponentially, peak during labor, and then fall precipitously after delivery (Frim, 1988; Sasaki, 1987). Amnionic fluid CRH concentrations similarly increase in late gestation. CRH is the only trophic hormone-releasing factor to have a specific serum binding protein. During most of pregnancy, CRH-binding protein (CRH-BP) binds most maternal circulating CRH, and this inactivates it (Lowry, 1993). During later pregnancy, however, CRH-BP levels in both maternal plasma and amnionic fluid decline, leading to markedly greater levels of bioavailable CRH (Perkins, 1995; Petraglia, 1997).

In pregnancies in which the fetus can be considered "stressed" from various complications, concentrations of CRH in fetal plasma, amnionic fluid, and maternal plasma are greater than those seen in normal gestation (Berkowitz, 1996; McGrath, 2002). The placenta is the likely source of this elevated CRH concentration. For example, placental CRH content is fourfold higher in placentas from women with preeclampsia than in those from normal pregnancies (Perkins, 1995).

Placental CRH is thought to play several roles in parturition regulation. It may enhance fetal cortisol production to provide positive feedback so that the placenta produces more CRH. Late in pregnancy—phase 2 or 3 of parturition—modification in the CRH receptor favors a switch from cAMP formation to increased myometrial cell calcium levels via protein kinase C activation (You, 2012). Oxytocin acts to attenuate CRH-stimulated accumulation of cAMP in myometrial tissue. CRH acts to augment myometrial contractile force in response to $PGF_{2\alpha}$ (Benedetto, 1994). Finally, CRH stimulates fetal adrenal C_{19}-steroid synthesis, thereby increasing substrate for placental aromatization.

Some have proposed that the rising CRH level at the end of gestation reflects a *fetal-placental clock* (McLean, 1995). CRH concentrations vary greatly among women, and the rate of rise in maternal CRH levels is a more accurate predictor of pregnancy outcome than is a single measurement (Leung, 2001; McGrath, 2002). In this regard, the placenta and fetus, through endocrinological events, influence the timing of parturition at the end of normal gestation.

Fetal Lung Surfactant and Platelet-Activating Factor

Surfactant protein A (SP-A) produced by the fetal lung is required for lung maturation. SP-A is expressed by the human amnion and decidua, is present in the amnionic fluid, and prompts signaling pathways in human myometrial cells (Garcia-Verdugo, 2008; Lee, 2010; Snegovskikh, 2011). The exact mechanisms by which SP-A activates myometrial contractility in women, however, remain to be clarified. One mode may be its effects on prostaglandins. Namely, SP-A selectively inhibits prostaglandin $F_{2\alpha}$ in the term decidua, but SP-A levels drop in the amnionic fluid at term (Chaiworapongsa, 2008). In addition to SP-A, the fetal lung makes the uterotonic agent platelet-activating factor (Frenkel, 1996; Toyoshima, 1995). This factor and SP-A play a role in fetal–maternal signaling for parturition (Gao, 2015).

Fetal-Membrane Senescence

Toward the end of pregnancy, fetal membranes undergo physiological aging termed cellular senescence (Menon, 2016). In human fetal membranes and animal models, stretch and oxidative stress induce senescent fetal membrane to manifest a form of sterile inflammation termed senescent-associated secretory phenotype (SASP). This in turn propagates inflammatory signals that further weaken the fetal membrane and activate signals in the decidua and myometrium to initiate parturition. Thus, as the functional necessity of fetal membranes declines at term, they are able to promote signals that contribute to parturition initiation.

Fetal Anomalies and Delayed Parturition

Some evidence shows that pregnancies with markedly diminished estrogen production may be associated with prolonged gestation. These "natural experiments" include women with inherited placental sulfatase deficiency and fetal anencephaly with adrenal hypoplasia. The broad range of gestational length seen with these disorders, however, calls into question the exact role of estrogen in human parturition initiation.

Other fetal abnormalities that prevent or severely reduce the entry of fetal urine or lung secretions into amnionic fluid do not prolong human pregnancy. Examples are renal agenesis and pulmonary hypoplasia, respectively. Thus, a fetal signal through the paracrine arm of the fetal–maternal communication system does not appear to be mandated for parturition initiation.

Some brain anomalies of the fetal calf, fetal lamb, and sometimes the human fetus delay the normal timing of parturition. More than a century ago, Rea (1898) observed an association between fetal anencephaly and prolonged human gestation. Malpas (1933) extended these observations and described a pregnancy with an anencephalic fetus that was prolonged to 374 days—53 weeks. He concluded that the association between anencephaly and prolonged gestation was attributable to anomalous fetal brain-pituitary-adrenal function. Indeed, the adrenal glands of the anencephalic fetus are very small and, at term, may be only 5 to 10 percent as large as those of a normal fetus. This is caused by developmental failure of the fetal zone that normally accounts for most of fetal adrenal mass and production of C_{19}-steroid hormones (Chap. 5, Fetal Adrenal Gland–Placental Interactions). Such pregnancies are associated with delayed labor and suggest that the fetal adrenal glands are important for the timely onset of parturition.

PHASE 3: LABOR

This phase is synonymous with active labor, which is customarily divided into three stages. These compose the commonly used labor graph shown in Figure 21-4. The first stage begins when spaced uterine contractions of sufficient frequency, intensity, and duration are attained to bring about cervical thinning, termed *effacement*. Several uterotonins may be important to the success of this stage of active labor (see Fig. 21-5). These have been shown to stimulate smooth muscle contraction through G-protein coupling. This labor stage ends when the cervix is fully dilated—about 10 cm—to allow passage of the term-sized fetus. The first stage of labor, therefore, is the *stage of cervical effacement and dilation.* The second stage begins when cervical dilation is complete and ends with delivery. Thus, the second stage of labor is the *stage of fetal expulsion.* Last, the third stage begins immediately after delivery of the fetus and ends with the delivery of the placenta. Thus, the third stage of labor is the *stage of placental separation and expulsion*.

First Stage: Clinical Onset of Labor

Uterine Labor Contractions

In some women, forceful uterine contractions that effect delivery begin suddenly. In others, labor initiation is heralded by spontaneous release of a small amount of blood-tinged mucus from the vagina. This extrusion of the mucus plug that had previously filled the cervical canal during pregnancy is referred to as “show” or “bloody show.” Its passage indicates that labor is already in progress or likely will ensue in hours to days.

Unique among physiological muscular contractions, those of uterine smooth muscle during labor are painful. Several possible causes have been suggested: (1) hypoxia of the contracted myometrium—such as that with angina pectoris; (2) compression of nerve ganglia in the cervix and lower uterus by contracted interlocking muscle bundles; (3) cervical stretching during dilation; and (4) stretching of the peritoneum overlying the fundus.

Of these, compression of nerve ganglia in the cervix and lower uterine segment by the contracting myometrium is an especially attractive hypothesis. Paracervical infiltration with local anesthetic usually produces appreciable pain relief with contractions (Chap. 25, Neuraxial Analgesia). Uterine contractions are involuntary and, for the most part, independent of extrauterine control. Neural blockade from epidural analgesia does not diminish their frequency or intensity. In other examples, myometrial contractions in paraplegic women and in women after bilateral lumbar sympathectomy are normal but painless.

Mechanical stretching of the cervix enhances uterine activity in several species, including humans. This phenomenon is the *Ferguson reflex* (Ferguson, 1941). Its exact mechanism is unclear, and release of oxytocin has been suggested but not proven. Manipulation of the cervix and “stripping” the fetal membranes is associated with a rise in blood levels of prostaglandin $F_{2\alpha}$ metabolites.

The interval between contractions narrows gradually from approximately 10 minutes at the onset of first-stage labor to as little as 1 minute or less in the second stage. Periods of relaxation between contractions, however, are essential for fetal welfare. Unremitting contractions compromise uteroplacental blood flow sufficiently to cause fetal hypoxemia. In active-phase labor, the duration of each contraction ranges from 30 to 90 seconds and averages 1 minute. Contraction intensity varies appreciably during normal labor. Specifically, amnionic fluid pressures generated by contractions during spontaneous labor average 40 mm Hg, but vary from 20 to 60 mm Hg (Chap. 24, Patterns of Uterine Activity).

Distinct Lower and Upper Uterine Segments

During active labor, the anatomical uterine divisions that were initiated in phase 2 of parturition become increasingly evident (Figs. 21-11 and 21-12). By abdominal palpation, even before membrane rupture, the two segments can sometimes be differentiated. The upper segment is firm during contractions, whereas the lower segment is softer, distended, and more passive. This mechanism is imperative because if the entire myometrium, including the lower uterine segment and cervix, were to contract simultaneously and with equal intensity, the net expulsive force would markedly decline. Thus, the upper segment contracts, retracts, and expels the fetus. In response to these contractions, the softened lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out tube through which the fetus can pass.

FIGURE 21-11

Sequence of development of the segments and rings in the uterus at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower uterine segment is derived from the isthmus, and the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. Anat. I.O. = anatomical internal os; E.O. = external os; Hist. I.O. = histological internal os; Ph.R.R. = physiological retraction ring.

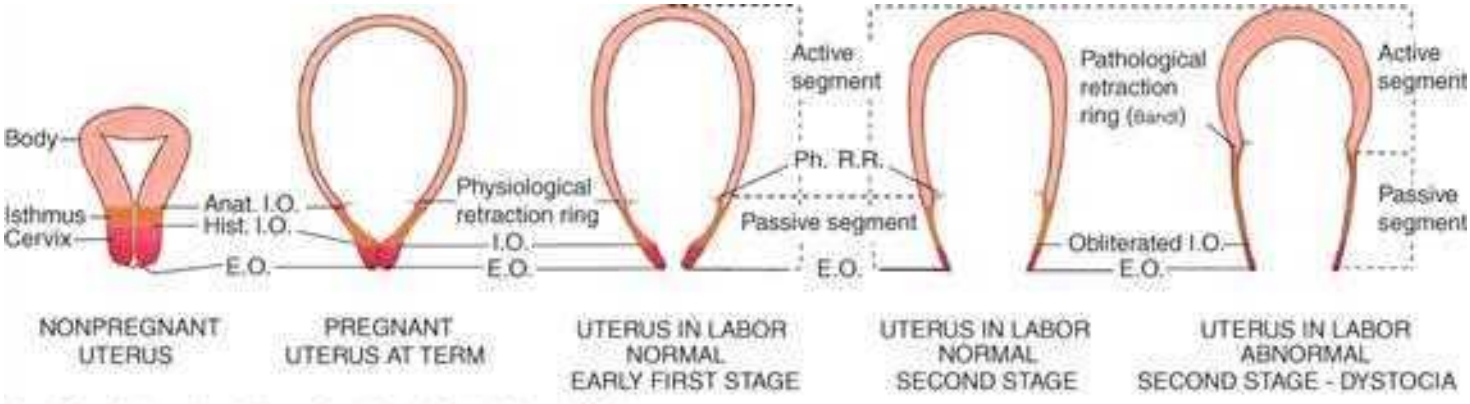


FIGURE 21-12

The uterus at the time of vaginal delivery. The active upper segment retracts around the presenting part as the fetus descends through the birth canal. In the passive lower segment, there is considerably less myometrial tone.

The myometrium of the upper segment does not relax to its original length after contractions. Instead, it becomes relatively fixed at a shorter length. The upper active uterine segment contracts down on its diminishing contents, but myometrial tension remains constant. The net effect is to take up slack, thus maintaining the advantage gained in expulsion of the fetus. Concurrently, the uterine musculature is kept in firm contact with the uterine contents. As the consequence of retraction, each successive contraction commences where its predecessor left off. Thus, the upper part of the uterine cavity becomes slightly smaller with each successive contraction. Because of the successive shortening of the muscular fibers, the upper active segment becomes progressively thickened throughout first- and second-stage labor (see Fig. 21-11). This process continues and results in a tremendously thickened upper uterine segment immediately after delivery.

Clinically, it is important to understand that the phenomenon of upper segment retraction is contingent on a decrease in the volume of its contents. For this to happen, particularly early in labor when the entire uterus is virtually a closed sac with only minimal cervical dilation, the musculature of the lower segment must stretch. This permits a greater portion of the uterine contents to occupy the lower segment. The upper segment retracts only to the extent that the lower segment distends and the cervix dilates.

Relaxation of the lower uterine segment mirrors the same gradual progression of retraction. Recall that after each contraction of the upper segment, the muscles do not return to their previous length, but tension remains essentially the same. By comparison, in the lower segment, successive lengthening of the fibers with labor is accompanied by thinning, normally to only a few millimeters in the thinnest part. As a result of the lower segment thinning and concomitant upper segment thickening, a boundary between the two is marked by a ridge on the inner uterine surface—the *physiological retraction ring.* When the thinning of the lower uterine segment is extreme, as in obstructed labor, the ring is prominent and forms a *pathological retraction ring*. This abnormal condition is also known as the *Bandl ring,* which is discussed further in Chapter 23 (Perinatal Complications).

Changes in Uterine Shape

Each contraction gradually elongates the ovoid uterine shape and thereby narrows the horizontal diameter. This change in shape has important effects on the labor process. First, there is greater *fetal axis pressure,* that is, the smaller horizontal diameter serves to straighten the fetal vertebral column. This presses the upper pole of the fetus firmly against the fundus, whereas the lower pole is thrust farther downward. The lengthening of the ovoid shape has been estimated at 5 to 10 cm. Second, with lengthening of the uterus, the longitudinal muscle fibers are drawn taut. As a result, the lower segment and cervix are the only parts of the uterus that are flexible, and these are pulled upward and around the lower pole of the fetus.

Ancillary Forces

After the cervix is dilated fully, the most important force in fetal expulsion is produced by maternal intraabdominal pressure. Contraction of the abdominal muscles simultaneously with forced respiratory efforts with the glottis closed is referred to as *pushing*. The force is similar to that with defecation, but the intensity usually is much greater. The importance of intraabdominal pressure is shown by the prolonged descent during labor in paraplegic women and in those with a dense epidural block. And, although increased intraabdominal pressure is necessary to complete second-stage labor, pushing accomplishes little in the first stage. It exhausts the mother, and its associated elevated intrauterine pressures may be harmful to the fetus.

Cervical Changes

As the result of contraction forces, two fundamental changes—effacement and dilation—occur in the ripened cervix. For an average-sized fetal head to pass through the cervix, its canal must dilate to a diameter of approximately 10 cm. At this time, the cervix is said to be completely or fully dilated. Although there may be no fetal descent during cervical effacement, most commonly the presenting fetal part descends somewhat as the cervix dilates.

Cervical effacement is “obliteration” or “taking up” of the cervix. It is manifest clinically by shortening of the cervical canal from a length of approximately 3 cm to a mere circular orifice with almost paper-thin edges. The muscular fibers at the level of the internal cervical os are pulled upward, or “taken up,” into the lower uterine segment. The condition of the external os remains temporarily unchanged (Fig. 21-13).

FIGURE 21-13

Schematic showing effacement and dilation. **A.** Before labor, the primigravid cervix is long and undilated in contrast to that of the multipara, which has dilation of the internal and external os. **B.** As effacement begins, the multiparous cervix shows dilation and funneling of the internal os. This is less apparent in the primigravid cervix. **C.** As complete effacement is achieved in the primigravid cervix, dilation is minimal. The reverse is true in the multipara.

Effacement may be compared to a funneling process in which the whole length of a narrow cylinder is converted into a very obtuse, flaring funnel with a small distal circular opening. Because of growing myometrial activity during uterine preparedness for labor, appreciable effacement of a softened cervix sometimes is accomplished before active labor begins. Effacement causes expulsion of the mucous plug as the cervical canal is shortened.

Because the lower segment and cervix have less resistance during a contraction, a centrifugal pull is exerted on the cervix and creates *cervical dilation* (Fig. 21-14). As uterine contractions cause pressure on the membranes, the hydrostatic action of the amnionic sac in turn dilates the cervical canal like a wedge. The process of cervical effacement and dilation causes formation of the *forebag* of amnionic fluid. This is the leading portion of fluid and amnionic sac located in front of the presenting part. In the absence of intact membranes, the pressure of the presenting fetal part against the cervix and lower uterine segment is similarly effective. Early rupture of the membranes does not retard cervical dilation so long as the presenting fetal part is positioned to exert pressure against the cervix and lower segment.

FIGURE 21-14
Hydrostatic action of membranes in effecting cervical effacement and dilation. With labor progression, note the changing relations of the internal and external os in **(A)**, **(B)**, and **(C)**. Although not shown in this diagram, with membrane rupture, the presenting part, applied to the cervix and the forming lower uterine segment, acts similarly.

Referring back to Figure 21-4, recall that cervical dilation is divided into latent and active phases. The active phase is subdivided further into the acceleration phase, the phase of maximum slope, and the deceleration phase (Friedman, 1978). The duration of the latent phase is more variable and sensitive to extraneous factors. For example, sedation may prolong the latent phase, and myometrial stimulation shortens it. The latent phase duration has little bearing on the subsequent course of labor, whereas the characteristics of the accelerated phase are usually predictive of labor outcome. The first stage ends when cervical dilation is complete.

Second Stage: Fetal Descent

In many nulliparas, engagement of the head is accomplished before labor begins. That said, the head may not descend further until late in labor. In the descent pattern of normal labor, a typical hyperbolic curve is formed when the station of the fetal head is plotted as a function of labor duration. *Station* describes descent of the fetal biparietal diameter in relation to a line drawn between maternal ischial spines (Chap. 22, Management of First-Stage Labor). Active descent usually takes place after dilation has progressed for some time (Fig. 21-15). During second-stage labor, the speed of descent is maximal and is maintained until the presenting part reaches the perineal floor (Friedman, 1978). In nulliparas, the presenting part typically descends slowly and steadily. In multiparas, however, particularly those of high parity, descent may be rapid.

FIGURE 21-15
Labor course divided on the basis of expected evolution of the dilatation and descent curves into three functional divisions. The preparatory division includes the latent and acceleration phases. The dilatational division is the phase of maximum slope of dilatation. The pelvic division encompasses both the deceleration phase and the second stage, which is concurrent with the phase of maximum slope of fetal descent. (Redrawm from Friedman EA: Labor: Clinical Evaluation and Management, 2nd ed. New York, Appleton-Century-Crofts, 1978.)

Pelvic Floor Changes

The birth canal is supported and functionally closed by the pelvic floor (Chap. 2, Pelvic Diaphragm). The most important component of the floor is the levator ani muscle and the fibromuscular connective tissue that covers its upper and lower surfaces. The biomechanical properties of these structures and of the vaginal wall change markedly during parturition. These result from altered extracellular matrix structure or composition (Alperin, 2015; Rahn, 2008; Lowder, 2007).

The levator ani muscle closes the lower end of the pelvic cavity as a diaphragm. Thereby, a concave upper and a convex lower surface are presented. The posterior and lateral portions of the pelvic floor, which are not spanned by the levator ani muscle, are occupied bilaterally by the piriformis and coccygeus muscles.

The levator ani muscle varies in thickness from 3 to 5 mm, although its margins encircling the rectum and vagina are somewhat thicker. During pregnancy, the levator ani usually undergoes hypertrophy, forming a thick band that extends backward from the pubis and encircles the vagina about 2 cm above the plane of the hymen. On contraction, the levator ani draws both the rectum and the vagina forward and upward in the direction of the symphysis pubis and thereby acts to close the vagina.

In the first stage of labor, the membranes, when intact, and the fetal presenting part serve to dilate the upper vagina. The most marked change consists of stretching levator ani muscle fibers. This is accompanied by thinning of the central portion of the perineum, which becomes transformed from a wedge-shaped, 5-cm-thick tissue mass to a thin, almost transparent membranous structure less than 1 cm thick. When the perineum is distended maximally, the anus becomes markedly dilated and presents an opening that varies from 2 to 3 cm in diameter and through which the anterior wall of the rectum bulges.

Third Stage: Delivery of Placenta and Membranes

This stage begins immediately after fetal delivery and involves separation and expulsion of the placenta and membranes. As the neonate is born, the uterus spontaneously contracts around its diminishing contents. Normally, by the time the newborn is completely delivered, the uterine cavity is nearly obliterated. The organ consists of an almost solid mass of muscle, several centimeters thick, above the thinner lower segment. The uterine fundus now lies just below the level of the umbilicus.

This sudden diminution in uterine size is inevitably accompanied by a decrease in the area of the placental implantation site (Fig. 21-16). For the placenta to accommodate itself to this reduced area, it thickens, but because of limited placental elasticity, it is forced to buckle. The resulting tension pulls the weakest layer—decidua spongiosa—from that site. Thus, placental separation follows the disproportion created between the relatively unchanged placental size and the reduced implantation site size.

FIGURE 21-16
Diminution in size of the placental site after birth of the newborn. **A.** Spatial relations before birth. **B.** Placental spatial relations after birth.

Cleavage of the placenta is aided greatly by the loose structure of the spongy decidua. As detachment proceeds, a hematoma forms between the separating placenta and the adjacent decidua, which remains attached to the myometrium. The hematoma is usually the result rather than the cause of the separation, because in some cases bleeding is negligible.

The great decline in uterine cavity surface area simultaneously throws the fetal membranes—the amniochorion and the parietal decidua—into innumerable folds (Fig. 21-17). Membranes usually remain in situ until placental separation is nearly completed. These are then peeled off the uterine wall, partly by further contraction of the myometrium and partly by traction that is exerted by the separated placenta as it descends during expulsion.

FIGURE 21-17
Postpartum, membranes are thrown up into folds as the uterine cavity decreases in size. (Used with permission from Dr. Kelley S. Carrick.)

After the placenta has detached, it can be expelled by increased abdominal pressure. Completion of the third stage is also accomplished by alternately compressing and elevating the fundus, while exerting minimal traction on the umbilical cord. The retroplacental hematoma either follows the placenta or is found within the inverted sac formed by the membranes. In this process, known as the *Schultze mechanism* of placental expulsion, blood from the placental site pours into the membrane sac and does not escape externally until after extrusion of the placenta. In the other form of placental extrusion, known as the *Duncan mechanism,* the placenta separates first at the periphery and blood collects between the membranes and the uterine wall and escapes from the vagina. In this circumstance, the placenta descends sideways, and its maternal surface appears first.

UTEROTONINS IN PARTURITION PHASE 3

Oxytocin

Late in pregnancy, during phase 2 of parturition, the number of myometrial oxytocin receptors grows appreciably (Fuchs, 1982; Kimura, 1996). This increase coincides with a greater uterine contractile responsiveness to oxytocin. Prolonged gestation is associated with a delay in the rise of these receptor levels (Fuchs, 1984).

Oxytocin—literally, *quick birth*—was the first uterotonin to be implicated in parturition initiation. This nanopeptide is synthesized in the magnocellular neurons of the supraoptic and paraventricular neurons. The prohormone is transported with its carrier protein, *neurophysin*, along the axons to the neural lobe of the posterior pituitary gland in membrane-bound vesicles for storage and later release. The prohormone is converted enzymatically to oxytocin during transport (Gainer, 1988; Leake, 1990).

In addition to its effectiveness in pharmacologically inducing labor at term, oxytocin is a potent uterotonin and occurs naturally in humans. Subsequent observations provide additional support for this theory: (1) the number of oxytocin receptors strikingly rises in myometrial and decidual tissues near the end of gestation; (2) oxytocin acts on decidual tissue to promote prostaglandin release; and (3) oxytocin is synthesized directly in decidual and extraembryonic fetal tissues and in the placenta (Chibbar, 1993; Zingg, 1995).

Although little evidence suggests a role for oxytocin in phase 2 of parturition, abundant data support its important role during second-stage labor and in the puerperium—phase 4 of parturition. Specifically, maternal serum oxytocin levels are elevated: (1) during second-stage labor, which is the end of phase 3 of parturition; (2) in the early puerperium; and (3) during breastfeeding (Nissen, 1995). Immediately after delivery of the fetus, placenta, and membranes, which completes parturition phase 3, firm and persistent uterine contractions are essential to prevent postpartum hemorrhage. Oxytocin likely causes persistent contractions.

Prostaglandins

Although their role in phase 2 of parturition in uncomplicated pregnancies is less well defined, a critical role for prostaglandins in phase 3 of parturition is clear (MacDonald, 1993). First, levels of prostaglandins—or their metabolites—in amnionic fluid, maternal plasma, and maternal urine are increased during labor. Second, receptors for PGE_2 and $PGF_{2\alpha}$ are expressed in the uterus and cervix. Thus, if these tissues are exposed to prostaglandins, they will respond.

Third, treatment of pregnant women with prostaglandins, by any of several administration routes, causes abortion or labor at all gestational ages. Moreover,

administration of prostaglandin H synthase type 2 (PGHS-2) inhibitors to pregnant women will delay spontaneous labor onset and sometimes arrest preterm labor (Loudon, 2003). Last, prostaglandin treatment of myometrial tissue in vitro sometimes causes contraction, dependent on the prostanoid tested and the physiological status of the tissue treated.

During labor, prostaglandin production within the myometrium and decidua is an efficient mechanism of activating contractions. For example, prostaglandin synthesis is high and unchanging in the decidua during phase 2 and 3 of parturition. Moreover, the receptor level for $PGF_{2\alpha}$ is augmented in the decidua at term, and this increase most likely is the regulatory step in prostaglandin action in the uterus.

The fetal membranes and placenta also produce prostaglandins. Primarily $PGE_{2,}$ but also $PGF_{2\alpha}$, are detected in amnionic fluid at all gestational ages. As the fetus grows, prostaglandin levels in the amnionic fluid rise gradually. Their greatest elevation in concentration within amnionic fluid, however, is demonstrable after labor begins. These higher levels likely result as the cervix dilates and exposes decidual tissue (Fig. 21-18). These higher levels in the forebag, compared with those in the upper compartment, are believed to follow an inflammatory response that signals the events leading to active labor. Together, the rise in cytokine and prostaglandin concentrations further degrade the extracellular matrix, thus weakening fetal membranes.

FIGURE 21-18
Sagittal view of the exposed forebag and attached decidual fragments after cervical dilation during labor. (Redrawn from MacDonald PC, Casey ML: Preterm birth. Sci Am 3:42, 1996.)

Endothelin-1

The endothelins are a family of 21-amino-acid peptides that powerfully induce myometrial contraction (Word, 1990). The endothelin A receptor is preferentially expressed in smooth muscle, and when activated, it effects a rise in intracellular calcium. Endothelin-1 is produced in myometrium of term gestations and is able to induce synthesis of other contractile mediators such as prostaglandins and inflammatory mediators (Momohara, 2004; Sutcliffe, 2009). The requirement of endothelin-1 in normal parturition physiology remains to be established.

Angiotensin II

Two G-protein-linked angiotensin II receptors are expressed in the uterus—AT1 and AT2. In nonpregnant women, the AT2 receptor predominates, but the AT1 receptor is preferentially expressed in gravidas (Cox, 1993). Angiotensin II binding to the plasma-membrane receptor evokes contraction. During pregnancy, the vascular smooth muscle that expresses the AT2 receptor is refractory to the pressor effects of infused angiotensin II (Chap. 4, Renin, Angiotensin II, and Plasma Volume).

PHASE 4: THE PUERPERIUM

Immediately and for about an hour after delivery, the myometrium remains persistently contracted. This directly compresses large uterine vessels and allows thrombosis of their lumens to prevent hemorrhage. This is typically augmented by endogenous and pharmacological uterotonic agents (Chap. 27, Management of the Third Stage).

Uterine involution and cervical repair are prompt remodeling processes that restore these organs to the nonpregnant state. These protect the reproductive tract from invasion by commensal microorganisms and restore endometrial responsiveness to normal hormonal cyclicity.

During the early puerperium, lactogenesis and milk let-down begin in mammary glands (Chap. 36, Lactation and Breastfeeding). Reinstitution of ovulation signals preparation for the next pregnancy. Ovulation generally occurs within 4 to 6 weeks after birth. However, it is dependent on the duration of breastfeeding and lactation-induced, prolactin-mediated anovulation and amenorrhea.

CHAPTER 22: Normal Labor

It follows that some process of adaptation or accommodation of suitable portions for the head to the various pelvic planes is necessary to insure the completion of childbirth. This is brought about by certain movement of the presenting part, which belong to what is termed the mechanism of labour.

—J. Whitridge Williams (1903)

INTRODUCTION

Labor is the process that leads to childbirth. It begins with the onset of regular uterine contractions and ends with delivery of the newborn and expulsion of the placenta. Pregnancy and birth are physiological processes, and thus, labor and delivery should be considered normal for most women.

MECHANISMS OF LABOR

Pelvic Floor Changes

Many adaptive changes are required for pregnancy and for labor and delivery. According to Nygaard (2015), vaginal delivery is a traumatic event. To assess this in part, Staer-Jensen and colleagues (2015) obtained transperineal sonographic measurements of the pelvic floor muscles at 21 weeks' and 37 weeks' gestation, and again at 6 weeks, 6 months, and 12 months postpartum. In 300 nulliparas, they measured bladder neck mobility and the area within the urogenital hiatus during Valsalva. This hiatus is the U-shaped opening in the pelvic floor muscles through which the urethra, vagina, and rectum pass (Chap. 2, Perineum). In this study, the levator hiatus area was significantly larger at 37 weeks' gestation and at 6 weeks postpartum compared with earlier pregnancy. Then, by 6 months postpartum, the hiatus had improved and narrowed to return to an area comparable to that at 21 weeks' gestation. However, no further improvement was noted by 12 months postpartum. Of note, hiatal area enlargement was only seen in those who delivered vaginally.

These findings demonstrate antepartum changes in pelvic floor structure that may reflect adaptations needed to permit vaginal delivery (Nygaard, 2015). Additional pelvic floor changes are discussed in Chapter 4 (Fallopian Tubes), and the contributions of pregnancy and delivery to later pelvic organ prolapse and incontinence are described in Chapter 30 (Cesarean Delivery Risks).

Fetal Lie

At the onset of labor, the position of the fetus with respect to the birth canal is critical to the route of delivery and thus should be determined in early labor. Important relationships include fetal lie, presentation, attitude, and position.

Fetal lie describes the relationship of the fetal long axis to that of the mother. In more than 99 percent of labors at term, the fetal lie is *longitudinal*. A *transverse lie* is less frequent, and predisposing factors include multiparity, placenta previa, hydramnios, and uterine anomalies (Chap. 23, Brow Presentation). Occasionally, the fetal and maternal axes may cross at a 45-degree angle, forming an *oblique lie.* This is unstable and becomes longitudinal or transverse during labor.

Fetal Presentation

The presenting part is the portion of the fetal body that is either foremost within the birth canal or in closest proximity to it. It typically can be felt through the cervix during vaginal examination. Accordingly, in longitudinal lies, the presenting part is either the fetal head or the breech, creating *cephalic* and *breech presentations*, respectively. When the fetus lies with the long axis transversely, the *shoulder* is the presenting part. Table 22-1 describes the incidences of these various presentations.

TABLE 22-1

Fetal Presentation in 68,097 Singleton Pregnancies at Parkland Hospital

Presentation	Percent	Incidence
Cephalic	96.8	—
Breech	2.7	1:36
Transverse lie	0.3	1:335
Compound	0.1	1:1000
Face	0.05	1:2000
Brow	0.01	1:10,000

Cephalic Presentation

These presentations are classified according to the relationship between the head and body of the fetus (Fig. 22-1). Ordinarily, the head is flexed sharply so that the chin contacts the thorax. The occipital fontanel is the presenting part, and this presentation is referred to as a *vertex* or *occiput presentation.* Much less often, the fetal neck may be sharply extended so that the occiput and back come into contact, and the face is foremost in the birth canal—*face presentation.* The fetal head may assume a position between these extremes. When the neck is only partly flexed, the anterior (large) fontanel may present—*sinciput presentation.* When the neck is only partially extended, the brow may emerge—*brow presentation.* These latter two are usually transient. As labor progresses, sinciput and brow presentations almost always convert into vertex or face presentations by neck flexion or extension, respectively. Failure to do so can lead to dystocia, discussed in Chapter 23 (Brow Presentation).

FIGURE 22-1

Longitudinal lie. Cephalic presentation. Differences in attitude of the fetal body in **(A)** vertex, **(B)** sinciput, **(C)** brow, and **(D)** face presentations. Note changes in fetal attitude in relation to fetal vertex as the fetal head becomes less flexed.

The term fetus usually presents with the vertex, most logically because the uterus is piriform or pear shaped. Although the fetal head at term is slightly larger than the breech, the entire *podalic pole* of the fetus—that is, the breech and extremities—is bulkier and more mobile than the cephalic pole. The *cephalic pole* is composed of the fetal head only. Until approximately 32 weeks, the amnionic cavity is large compared with the fetal mass, and the fetus is not crowded by the uterine walls. Subsequently, however, the ratio of amnionic fluid volume declines relative to the growing fetal mass. As a result, the uterine walls are apposed more closely to the fetal parts. The fetus orients its polarity to make use of the roomier fundus for its bulkier and more mobile podalic pole. The high incidence of breech presentation in hydrocephalic fetuses is in accord with this theory, as the larger fetal cephalic pole requires more room than its podalic pole.

Breech Presentation

The incidence of breech presentation drops with gestational age and approximates 3 percent at term.

When the fetus presents breech, the three general configurations are *frank, complete,* and *footling presentations,* described in Chapter 28 (Classification of Breech Presentations). Breech presentation may result from circumstances that prevent normal version from taking place. One example is a septum that protrudes into the uterine cavity (Chap. 3, Diethylstilbestrol Reproductive Tract Abnormalities (Class VII)). Variances of fetal attitude, particularly extension of the vertebral column as

seen in frank breeches, also may prevent the fetus from turning. If the placenta is implanted in the lower uterine segment, it may distort normal intrauterine anatomy and result in a breech presentation.

Fetal Attitude

In the later months of pregnancy, the fetus assumes a characteristic posture described as attitude or habitus (see Fig. 22-1). As a rule, the fetus forms an ovoid mass that corresponds roughly to the shape of the uterine cavity. The fetus becomes folded upon itself to create a convex back. The head is sharply flexed; the chin is almost in contact with the chest; the thighs are flexed over the abdomen; and the legs are bent at the knees. In all cephalic presentations, the arms usually lie across the thorax or parallel to the sides. The umbilical cord fills the space between the extremities. This characteristic posture results from the mode of fetal growth and its accommodation to the uterine cavity.

Abnormal exceptions to this attitude occur as the fetal head becomes progressively more extended from the vertex to the face presentation. This results in a progressive change in fetal attitude from a convex (flexed) to a concave (extended) contour of the vertebral column.

Fetal Position

Position refers to the relationship of an arbitrarily chosen portion of the fetal presenting part to the right or left side of the birth canal. Accordingly, with each presentation, there may be two positions—right or left. The fetal occiput, chin (mentum), and sacrum are the determining points in vertex, face, and breech presentations, respectively (Figs. 22-2 to 22-6). Because the presenting part may be in either the left or right position, there are left and right occipital (LO and RO), left and right mental (LM and RM), and left and right sacral (LS and RS) designations.

FIGURE 22-2

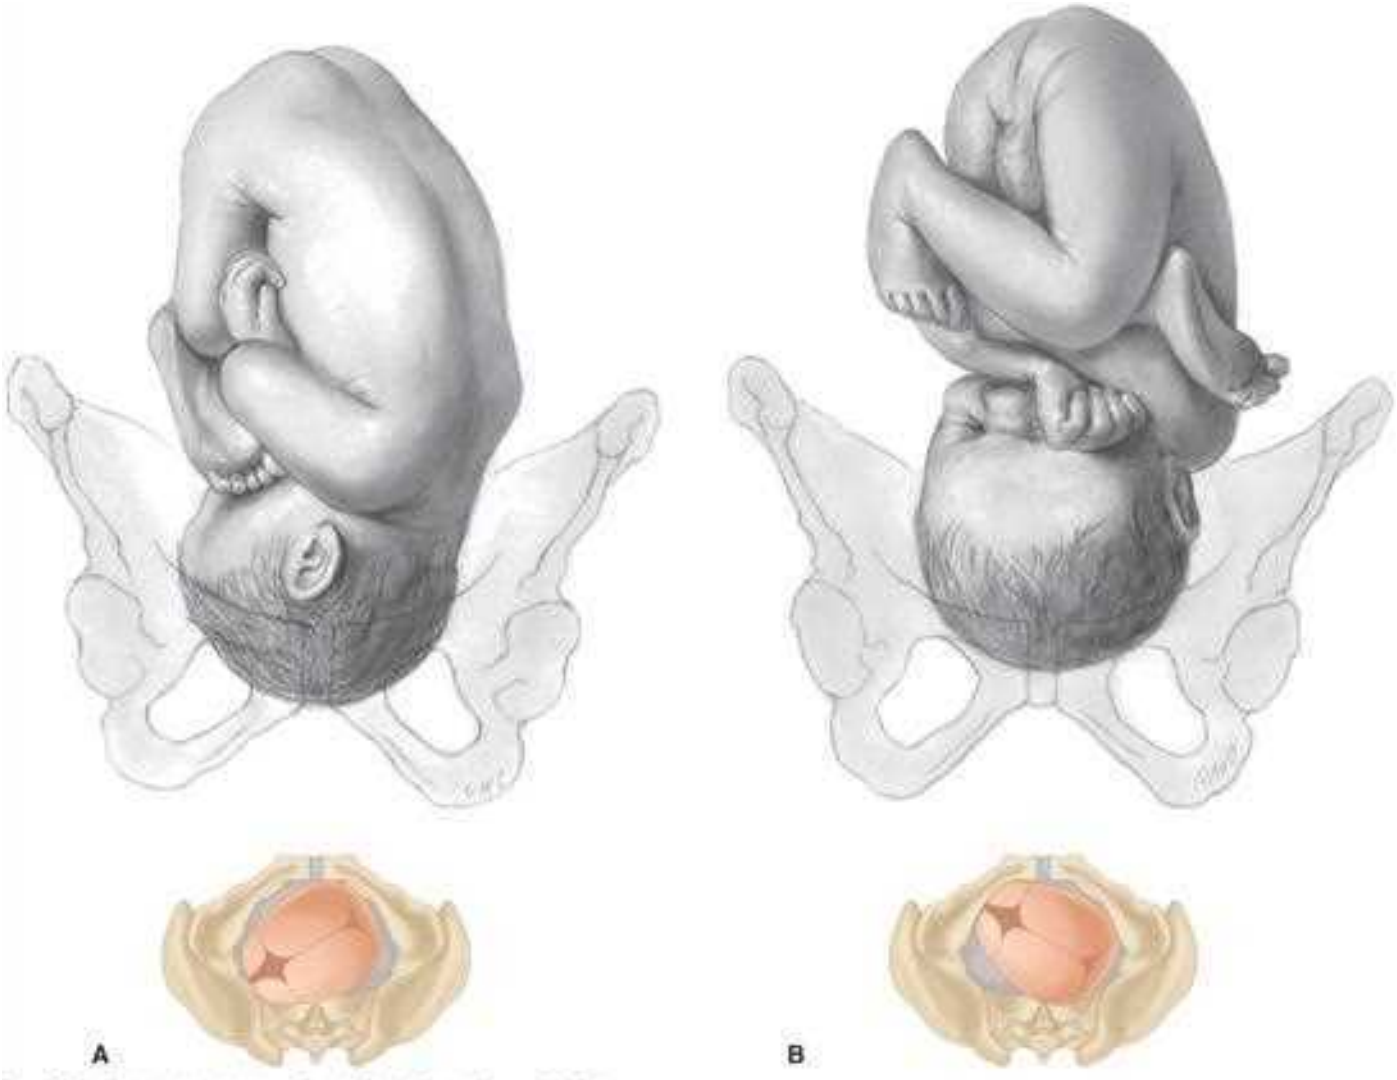

FIGURE 22-3
Longitudinal lie. Vertex presentation. **A.** Right occiput posterior (ROP). **B.** Right occiput transverse (ROT).

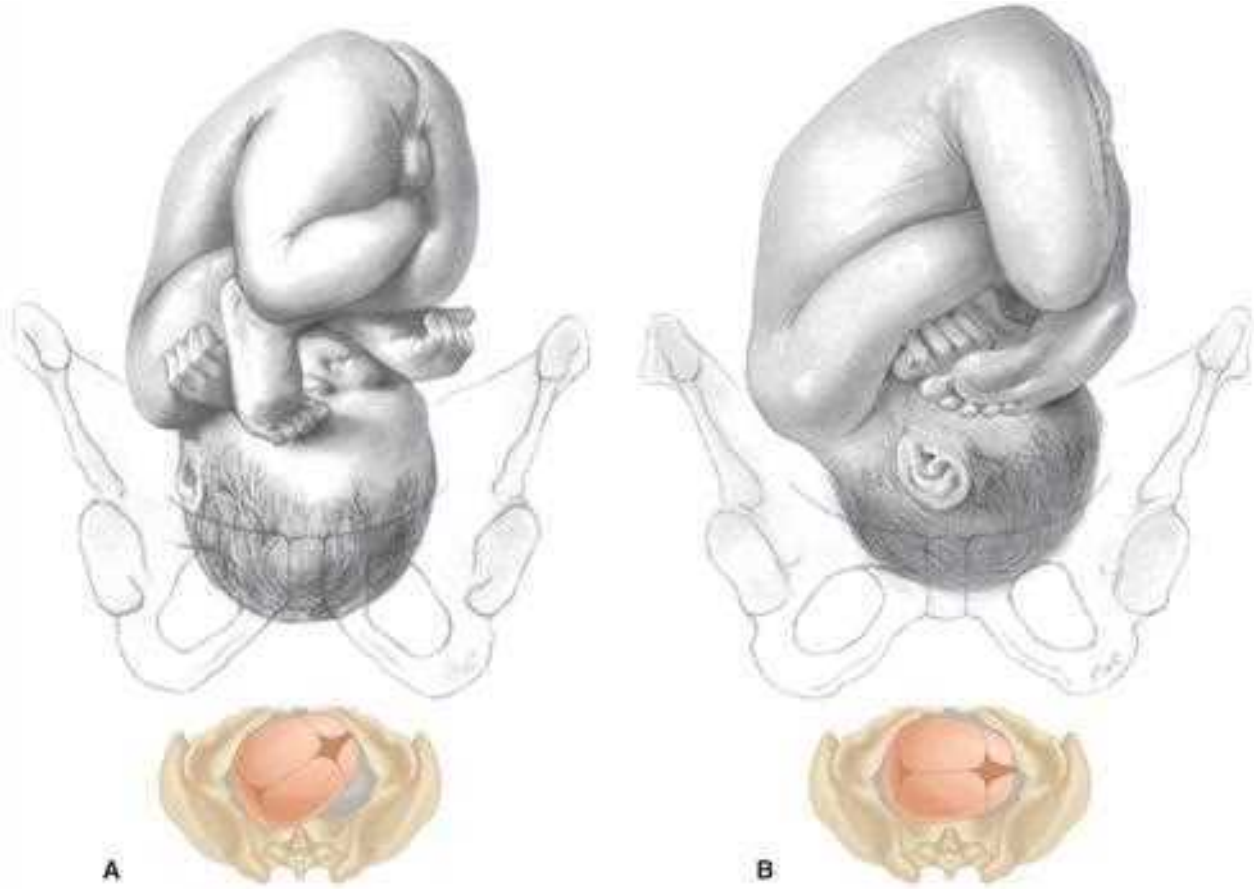

FIGURE 22-4

Longitudinal lie. Vertex presentation. Right occiput anterior (ROA).

FIGURE 22-5

Longitudinal lie. Face presentation. Left and right mentum anterior and right mentum posterior positions.

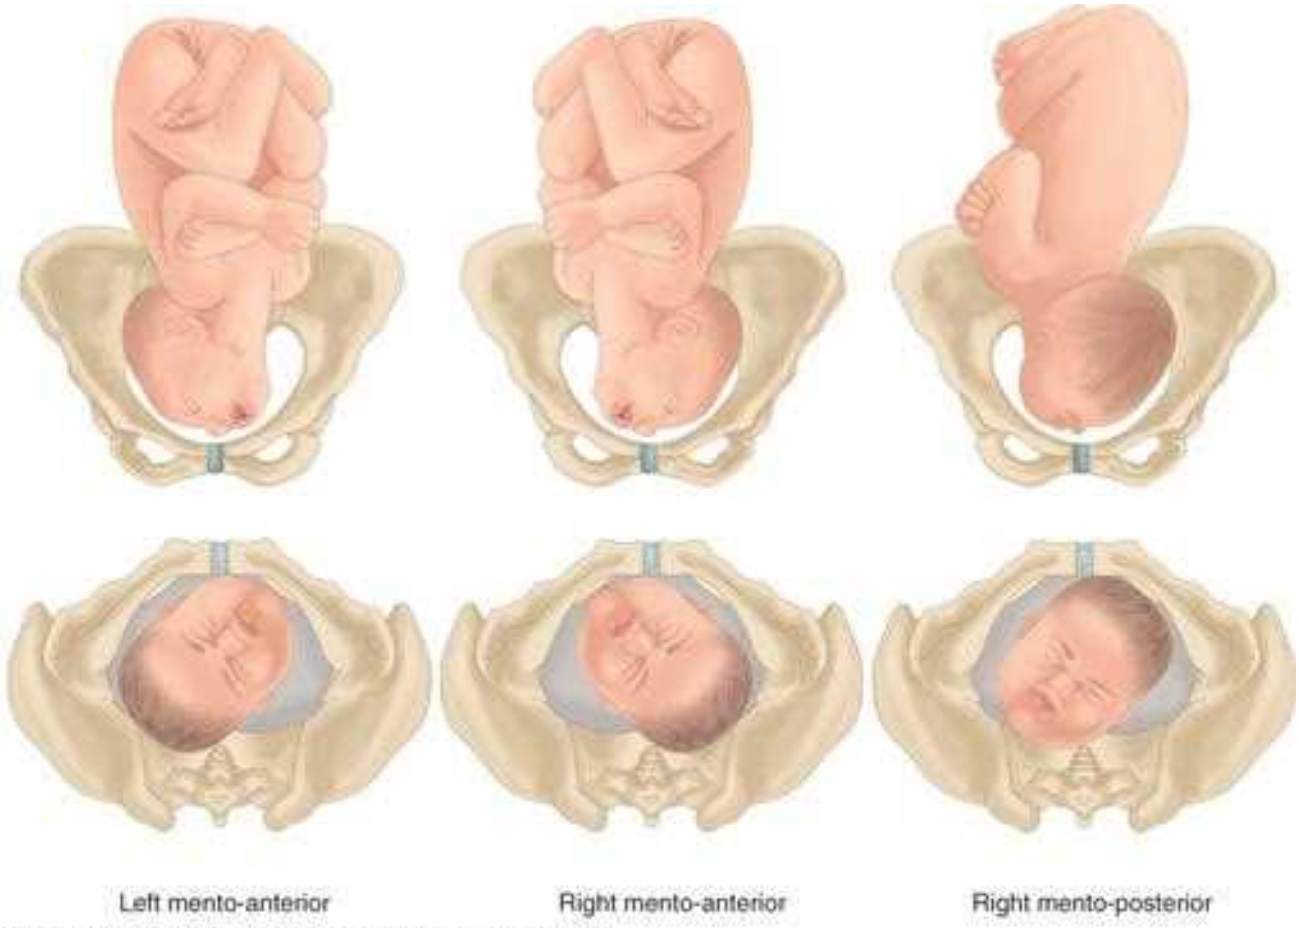

FIGURE 22-6

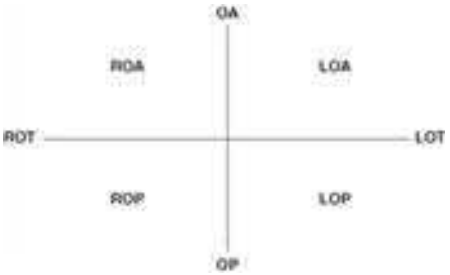
Longitudinal lie. Breech presentation. Left sacrum posterior (LSP).

Further, the relationship of a given portion of the presenting part to the anterior (A), transverse (T), or posterior (P) portion of the maternal pelvis is considered. As shown in Figures 22-2 to 22-6, there are six varieties of each of the three presentations. Thus, in an occiput presentation, the presentation, position, and variety may

be abbreviated in clockwise fashion as:



Approximately two thirds of all vertex presentations are in the left occiput position, and one third in the right.

In shoulder presentations, the acromion (scapula) is the portion of the fetus arbitrarily chosen for orientation with the maternal pelvis. One example of the terminology sometimes employed for this purpose is illustrated in Figure 22-7. The acromion or back of the fetus may be directed either posteriorly or anteriorly and superiorly or inferiorly. Because it is impossible to differentiate exactly the several varieties of shoulder presentation by clinical examination and because such specific differentiation serves no practical purpose, it is customary to refer to all transverse lies simply as *shoulder presentations.* Another term used is *transverse lie,* with *back up* or *back down*, which is clinically important when deciding incision type for cesarean delivery (Chap. 23, Etiology).

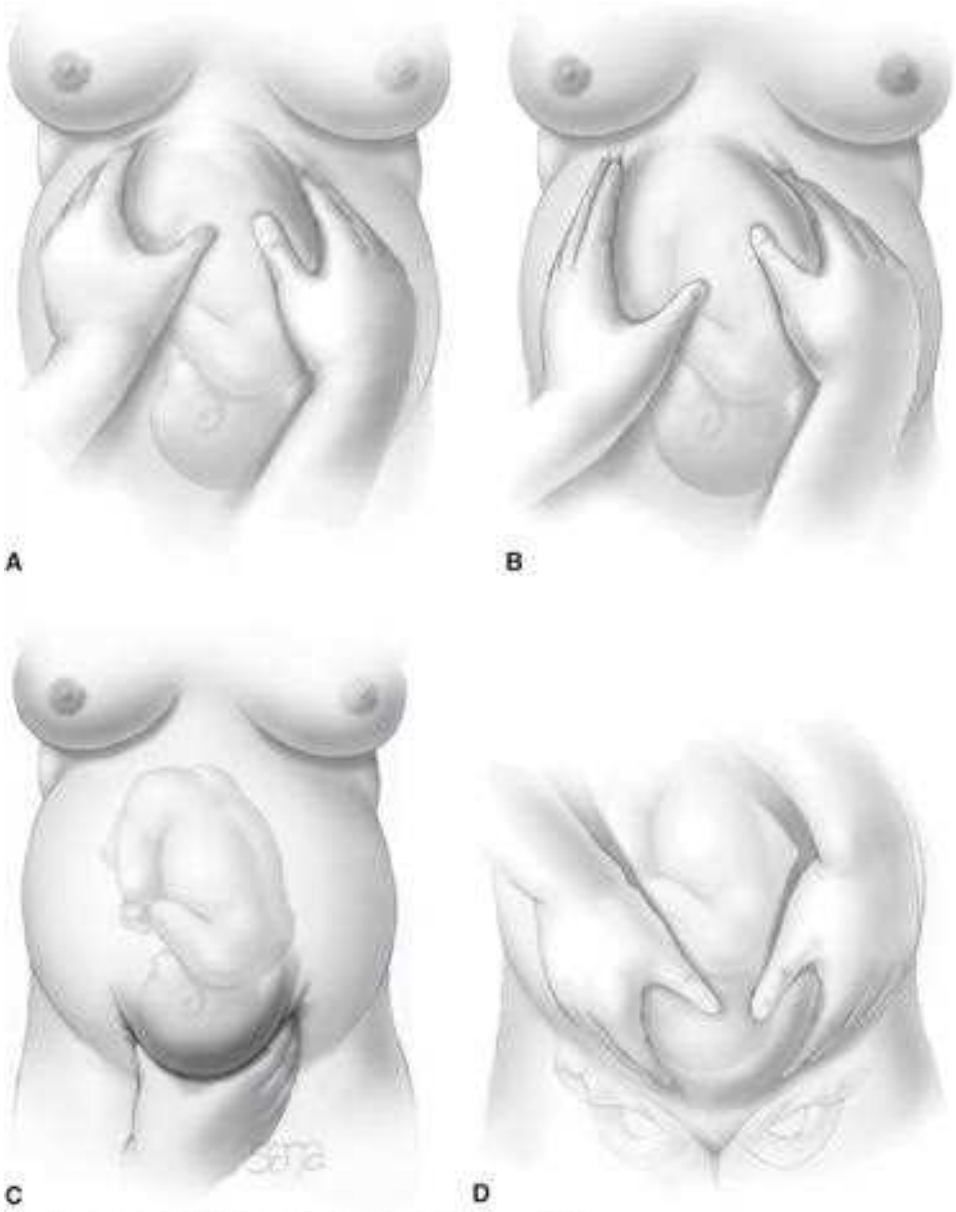
FIGURE 22-7
Transverse lie. Right acromiodorsoposterior (RADP). The shoulder of the fetus is to the mother's right, and the back is posterior.

Diagnosis

Leopold Maneuvers

Several methods can be used to diagnose fetal presentation and position. Abdominal examination can be conducted systematically employing the four maneuvers described by Leopold in 1894 and shown in Figure 22-8. The mother lies supine and comfortably positioned with her abdomen bared. These maneuvers may be difficult if not impossible to perform and interpret if the patient is obese, if amnionic fluid volume is excessive, or if the placenta is anteriorly implanted.

FIGURE 22-8
Leopold maneuvers **(A–D)** performed in fetus with a longitudinal lie in the left occiput anterior position (LOA).



The first maneuver assesses the uterine fundus. It permits identification of fetal lie and determination of which fetal pole—that is, cephalic or podalic—occupies the fundus. The breech gives the sensation of a large, nodular mass, whereas the head feels hard and round and is more mobile.

The second maneuver is accomplished as the palms are placed on either side of the maternal abdomen, and gentle but deep pressure is exerted. On one side, a hard, resistant structure is felt—the back. On the other, numerous small, irregular, mobile parts are felt—the fetal extremities. By noting whether the back is directed anteriorly, transversely, or posteriorly, fetal orientation can be determined.

The third maneuver aids confirmation of fetal presentation. The thumb and fingers of one hand grasp the lower portion of the maternal abdomen just above the symphysis pubis. If the presenting part is not engaged, a movable mass will be felt, usually the head. The differentiation between head and breech is made as in the first maneuver.

The fourth maneuver helps determine the degree of descent. The examiner faces the mother's feet, and the fingertips of both hands are positioned on either side of the presenting part. They exert inward pressure and then slide caudad along the axis of the pelvic inlet. In many instances, when the head has descended into the pelvis, the anterior shoulder or the space created by the neck may be differentiated readily from the hard head.

Abdominal palpation can be performed throughout the latter months of pregnancy and during and between the contractions of labor. At least in the past, according to Lydon-Rochelle and colleagues (1993), experienced clinicians have accurately identified fetal malpresentation using Leopold maneuvers with a high sensitivity—88 percent, specificity—94 percent, positive-predictive value—74 percent, and negative-predictive value—97 percent. With experience, it is possible to estimate the size of the fetus with these maneuvers (Field, 1995). However, and especially with an obese woman, estimates by palpation and actual birth weights often correlate poorly (Fox, 2009; Goetzinger, 2014; Noumi, 2005).

Vaginal Examination

Before labor, the diagnosis of fetal presentation and position by vaginal examination is often inconclusive because the presenting part must be palpated through a closed cervix and lower uterine segment. With the onset of labor and after cervical dilation, vertex presentations and their positions are recognized by palpation of the various fetal sutures and fontanels. Face and breech presentations are identified by palpation of facial features or the fetal sacrum and perineum, respectively. During this vaginal examination, it is advisable to pursue a definite routine, comprising four movements. First, the examiner inserts two fingers into the vagina and the presenting part is found. Differentiation of vertex, face, and breech is then accomplished readily. Second, if the vertex is presenting, the fingers are directed posteriorly and then swept forward over the fetal head toward the maternal symphysis (Fig. 22-9). During this movement, the fingers necessarily cross the sagittal suture, and its linear course is delineated. Next, the positions of the two fontanels, found at either end of the sagittal suture, are ascertained. For this, fingers are passed to the most anterior extension of the sagittal suture, and the fontanel encountered there is examined and identified. Then, the fingers pass along the suture to the other end of the head until the other fontanel is felt and differentiated (Fig. 22-10). Last, the station, or extent to which the presenting part has descended into the pelvis, can also be established at this time (Management of First-Stage Labor). Using these maneuvers, the various sutures and fontanels are determined (Fig. 29-1).

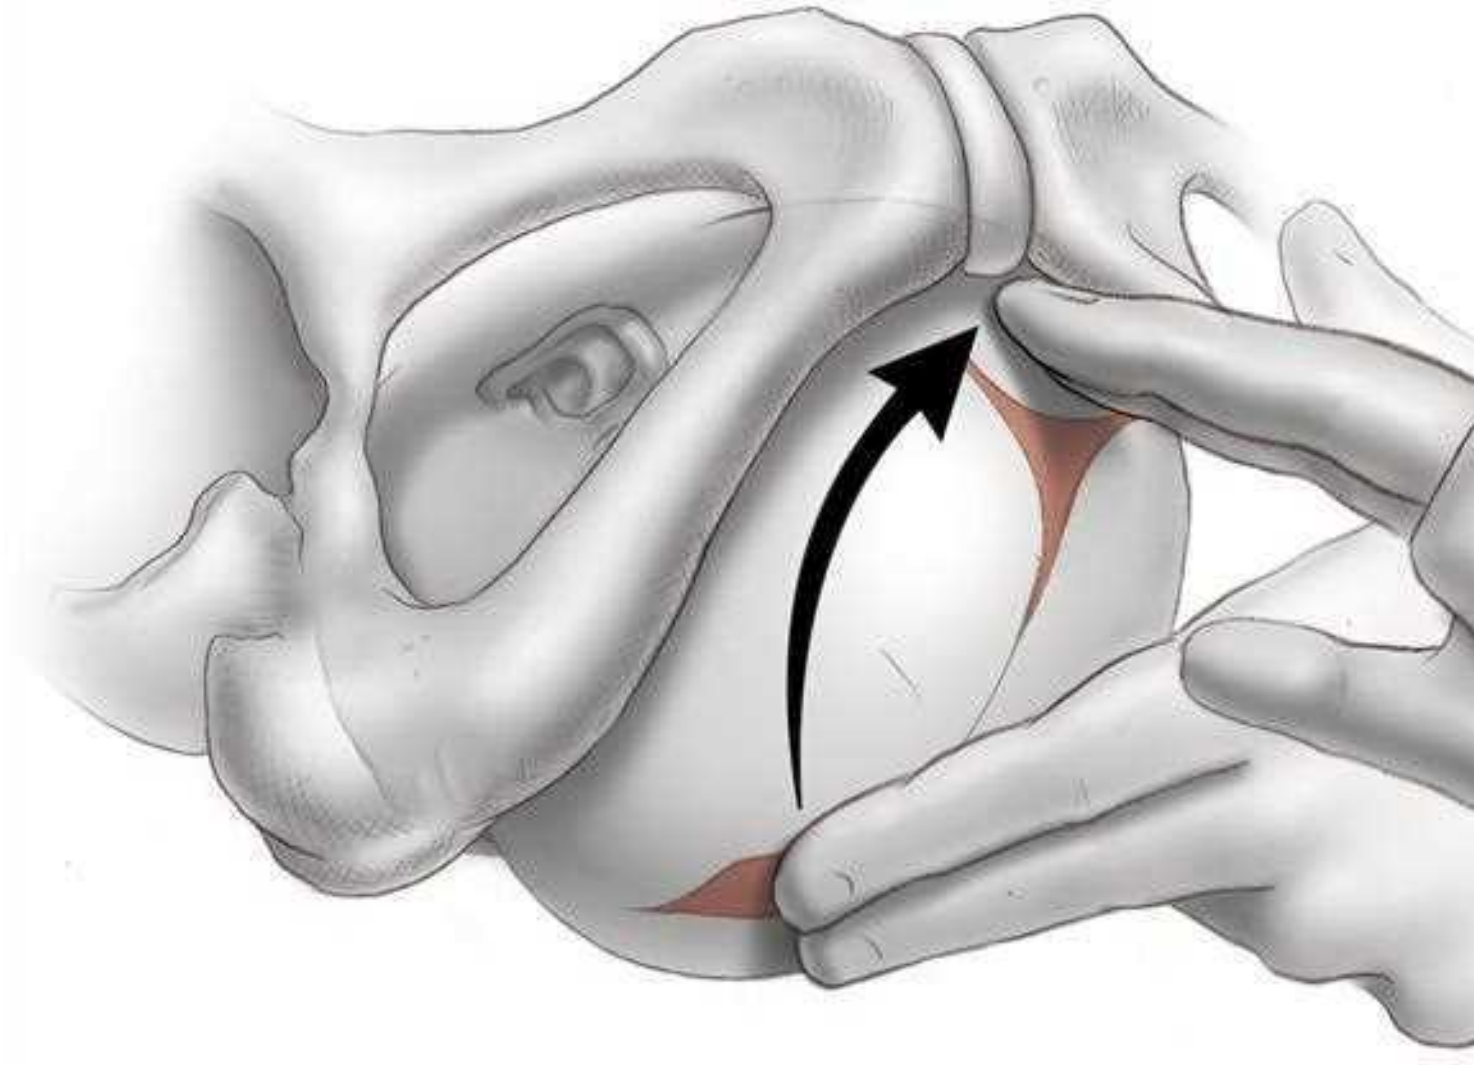
Differentiating the fontanels by vaginal examination.



Sonography and Radiography

Sonographic techniques can aid fetal position identification, especially in obese women or in women with muscular abdominal walls. Compared with digital examinations, sonography for fetal head position determination during second-stage labor is more accurate (Ramphul, 2014; Wiafe, 2016).

Occiput Anterior Presentation

In most cases, the vertex enters the pelvis with the sagittal suture lying in the transverse pelvic diameter. The fetus enters the pelvis in the *left occiput transverse (LOT)* position more commonly than *right occiput transverse (ROT)* position (Caldwell, 1934). In *occiput anterior positions—LOA* or *ROA*—either the head enters the pelvis with the occiput rotated 45 degrees anteriorly from the transverse position, or this rotation occurs subsequently. The mechanism of labor in all these presentations is usually similar.

The positional changes of the presenting part required to navigate the pelvic canal constitute the *mechanisms of labor.* The *cardinal movements of labor* are engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion (Fig. 22-11). During labor, these movements not only are sequential but also show great temporal overlap. For example, as part of engagement, there is both flexion and descent of the head. It is impossible for the movements to be completed unless the presenting part descends simultaneously. Concomitantly, uterine contractions effect important modifications in fetal attitude, or habitus, especially after the head has descended into the pelvis. These changes consist principally of fetal straightening, with loss of dorsal convexity and closer application of the extremities to the body. As a result, the fetal ovoid is transformed into a cylinder, with the smallest possible cross section typically passing through the birth canal.

FIGURE 22-11
Cardinal movements of labor and delivery from a left occiput anterior position.

Engagement

The mechanism by which the biparietal diameter—the greatest transverse diameter in an occiput presentation—passes through the pelvic inlet is designated *engagement.* The fetal head may engage during the last few weeks of pregnancy or not until after labor commencement. In many multiparas and some nulliparas, the fetal head is freely movable above the pelvic inlet at labor onset. In this circumstance, the head is sometimes referred to as "floating." A normal-sized head usually does not engage with its sagittal suture directed anteroposteriorly. Instead, as discussed, the fetal head usually enters the pelvic inlet either transversely or obliquely. Segel and coworkers (2012) analyzed labor in 5341 nulliparous women and found that fetal head engagement before labor onset did not affect vaginal delivery rates in either spontaneous or induced labor.

The fetal head tends to accommodate to the transverse axis of the pelvic inlet, whereas the sagittal suture, while remaining parallel to that axis, may not lie exactly midway between the symphysis and the sacral promontory. The sagittal suture frequently is deflected either posteriorly toward the promontory or anteriorly toward the symphysis (Fig. 22-12). Such lateral deflection to a more anterior or posterior position in the pelvis is called *asynclitism.* If the sagittal suture approaches the sacral promontory, more of the anterior parietal bone presents itself to the examining fingers, and the condition is called *anterior asynclitism.* If, however, the sagittal suture lies close to the symphysis, more of the posterior parietal bone will present, and the condition is called *posterior asynclitism.* With extreme posterior asynclitism, the posterior ear may be easily palpated.

FIGURE 22-12
Synclitism and asynclitism.

Moderate degrees of asynclitism are the rule in normal labor. However, if severe, the condition is a common reason for cephalopelvic disproportion even with an otherwise normal-sized pelvis. Successive fetal head shifting from posterior to anterior asynclitism aids descent.

Descent

This movement is the first requisite for birth of the newborn. In nulliparas, engagement may take place before the onset of labor, and further descent may not follow until the onset of the second stage. In multiparas, descent usually begins with engagement. Descent is brought about by one or more of four forces: (1) pressure of the amnionic fluid, (2) direct pressure of the fundus upon the breech with contractions, (3) bearing-down efforts of maternal abdominal muscles, and (4) extension and straightening of the fetal body.

Flexion

As soon as the descending head meets resistance, whether from the cervix, pelvic walls, or pelvic floor, it normally flexes. With this movement, the chin is brought into more intimate contact with the fetal thorax, and the appreciably shorter suboccipitobregmatic diameter is substituted for the longer occipitofrontal diameter (Fig. 22-13).

FIGURE 22-13
Lever action produces flexion of the head. Conversion from occipitofrontal (*left*) to suboccipitobregmatic (*right*) diameter typically reduces the anteroposterior diameter from nearly 12 to 9.5 cm.

Internal Rotation

This movement turns the occiput gradually away from the transverse axis. Usually the occiput rotates anteriorly toward the symphysis pubis, but less commonly, it may rotate posteriorly toward the hollow of the sacrum (Figs. 22-14 and 22-15). Internal rotation is essential for completion of labor, except when the fetus is unusually small.

FIGURE 22-14
Mechanism of labor for the left occiput transverse position, lateral view. **A.** Engagement with posterior asynclitism at the pelvic brim. During descent, the sagittal suture is then deflected toward the sacrum. **B.** This leads to anterior asynclitism. **C.** Internal rotation and descent. **D.** Further internal rotation and descent with extension of the neck.

FIGURE 22-15
Mechanism of labor for right occiput posterior position showing anterior rotation.

Calkins (1939) studied more than 5000 women in labor to ascertain the time of internal rotation. He concluded that in approximately two thirds, internal rotation is completed by the time the head reaches the pelvic floor; in about another fourth, internal rotation is completed shortly after the head reaches the pelvic floor; and in the remaining 5 percent, rotation does not take place. When the head fails to turn until reaching the pelvic floor, it typically rotates during the next one or two contractions in multiparas. In nulliparas, rotation usually occurs during the next three to five contractions.

Extension

After internal rotation, the sharply flexed head reaches the vulva and undergoes extension. If the sharply flexed head, on reaching the pelvic floor, did not extend but was driven farther downward, it would impinge on the posterior portion of the perineum and would eventually be forced through the perineal tissues. When the head presses on the pelvic floor, however, two forces come into play. The first force, exerted by the uterus, acts more posteriorly, and the second, supplied by the resistant pelvic floor and the symphysis, acts more anteriorly. The resultant vector is in the direction of the vulvar opening, thereby causing head extension. This brings the base of the occiput into direct contact with the inferior margin of the symphysis pubis (see Fig. 22-14).

With progressive distention of the perineum and vaginal opening, an increasingly large portion of the occiput gradually appears. The head is born as the occiput, bregma, forehead, nose, mouth, and finally the chin pass successively over the anterior margin of the perineum. Immediately after its delivery, the head drops

downward so that the chin lies over the maternal anus.

External Rotation

The delivered head next undergoes *restitution* (see Fig. 22-11). If the occiput was originally directed toward the left, it rotates toward the left ischial tuberosity. If it was originally directed toward the right, the occiput rotates to the right. Restitution of the head to the oblique position is followed by external rotation completion to again reach a transverse position. This movement corresponds to rotation of the fetal body and serves to bring its bisacromial diameter into relation with the anteroposterior diameter of the pelvic outlet. Thus, one shoulder is anterior behind the symphysis and the other is posterior. This movement apparently is brought about by the same pelvic factors that produced internal rotation of the head.

Expulsion

Almost immediately after external rotation, the anterior shoulder appears under the symphysis pubis, and the perineum soon becomes distended by the posterior shoulder. After delivery of the shoulders, the rest of the body quickly passes. When the anterior shoulder is tightly wedged beneath the symphysis, then *shoulder dystocia* is diagnosed, which is described in Chapter 27 (Shoulder Dystocia).

Occiput Posterior Presentation

In approximately 20 percent of labors, the fetus enters the pelvis in an *occiput posterior (OP)* position (Caldwell, 1934). The right occiput posterior (ROP) is slightly more common than the left (LOP). It appears likely from radiographic evidence that posterior positions are more often associated with a narrow forepelvis. They also are more commonly seen in association with anterior placentation (Gardberg, 1994a).

In most occiput posterior presentations, the mechanism of labor is identical to that observed in the transverse and anterior varieties, except that the occiput has to internally rotate to the symphysis pubis through 135 degrees, instead of 90 and 45 degrees, respectively (see Fig. 22-15).

Effective contractions, adequate head flexion, and average fetal size together permit most posteriorly positioned occiputs to rotate promptly as soon as they reach the pelvic floor, and labor is not lengthened appreciably. In perhaps 5 to 10 percent of cases, however, rotation may be incomplete or may not take place at all, especially if the fetus is large (Gardberg, 1994b). Poor contractions, faulty head flexion, or epidural analgesia, which diminishes abdominal muscular pushing and relaxes pelvic floor muscles, may predispose to incomplete rotation. If rotation is incomplete, *transverse arrest* may result. If no rotation toward the symphysis takes place, the occiput may remain in the direct occiput posterior position, a condition known as *persistent occiput posterior.* Both can lead to dystocia and cesarean delivery. Techniques to manually rotate from OP to OA positions are illustrated in Chapter 29 (Occiput Posterior Positions).

Fetal Head Shape Changes

In vertex presentations, labor forces alter fetal head shape. In prolonged labors before complete cervical dilation, the portion of the fetal scalp immediately over the cervical os becomes edematous. This swelling is known as the *caput succedaneum* (Fig. 22-16). It usually attains a thickness of only a few millimeters, but in prolonged labors it may be sufficiently extensive to prevent differentiation of the various sutures and fontanels. More commonly, the caput is formed when the head is in the lower portion of the birth canal and frequently only after the resistance of a rigid vaginal outlet is encountered. Because it develops over the most dependent area of the head, one may deduce the original fetal head position by noting the location of the caput succedaneum.

FIGURE 22-16
Considerable molding of the head and caput succedaneum formation in a recently delivered newborn.

Molding refers to changes in the bony fetal head shape as a result of external compressive forces (see Fig. 22-16). Possibly related to Braxton Hicks contractions, some molding develops before labor. Most studies indicate that there is seldom overlapping of the parietal bones. A “locking” mechanism at the coronal and lambdoidal sutures actually prevents such overlapping (Carlan, 1991). Molding results in a shortened suboccipitobregmatic diameter and a lengthened mentovertical diameter. These changes are of greatest importance in women with contracted pelves or asynclitic presentations. In these circumstances, the degree to which the head is capable of molding may make the difference between spontaneous vaginal delivery and an operative delivery. Some older literature cited severe head molding as a cause for possible cerebral trauma. Because of the multitude of associated factors, for example, prolonged labor with fetal sepsis and acidosis, it is impossible to link molding to any alleged fetal or neonatal neurological sequelae. Most cases of molding resolve within the week following delivery, although persistent cases have been described (Graham, 2006). Differentiation of molding, caput succedaneum, and *cephalohematoma* is discussed in Chapter 33 (Intracranial Hemorrhage).

NORMAL LABOR CHARACTERISTICS

The greatest impediment to understanding normal labor is recognizing its start. The strict definition of labor is: *uterine contractions that bring about demonstrable effacement and dilation of the cervix.* This does not easily aid the clinician in determining when labor has actually begun, because this diagnosis is confirmed only retrospectively. Several methods may be used to mark its start. One defines onset as the clock time when painful contractions become regular. Unfortunately, uterine activity that causes discomfort, but that does not represent true labor, may develop at any time during pregnancy. False labor often stops spontaneously, or it may proceed rapidly into effective contractions.

A second method defines the onset of labor as beginning at the time of admission to the labor unit. In the United States, admission for labor is frequently based on the extent of cervical dilation accompanied by painful contractions. If a woman has intact membranes, then a cervical dilation of 3 to 4 cm or greater is presumed to be a reasonably reliable threshold for the diagnosis of labor. In this case, labor onset commences with the time of admission. This presumptive method obviates many of the uncertainties in diagnosing labor during earlier stages of cervical dilation. Laughon and associates (2012) compared the duration of spontaneous labor

at term in nulliparas delivered in the United States between 1959 and 1966 to that of those delivered from 2002 to 2008. As shown in Figure 22-17, during those 50 years, the length of labor increased by approximately 2 hours.

FIGURE 22-17
Average labor curves for women with singleton term pregnancies presenting in spontaneous labor with vaginal delivery for nulliparas from 1959–1966 compared with those from 2002–2008. (Redrawn from Laughon SK, Branch W, Beaver J, et al: Changes in labor patterns over 50 years. Am J Obstet Gynecol 206:419.e1.9, 2012.)

First Stage of Labor

For labor, Friedman (1954) described a characteristic sigmoid pattern by graphing cervical dilation against time. This graphical approach, which was based on statistical observations, changed labor management. Friedman developed the concept of three functional labor divisions to describe the physiological objectives of each division (Fig. 22-18). First, during the *preparatory division,* although the cervix dilates little, its connective tissue components change considerably (Chap. 21, Ancillary Forces). Sedation and conduction analgesia are capable of arresting this labor division. The *dilational division,* during which dilation proceeds at its most rapid rate, is unaffected by sedation. Last, the *pelvic division* commences with the deceleration phase of cervical dilation. The classic labor mechanisms that involve the cardinal fetal movements of the cephalic presentation take place principally during this pelvic division. In actual practice, however, the onset of the pelvic division is seldom clearly identifiable.

FIGURE 22-18
Labor course divided functionally on the basis of dilatation and descent curves into: (1) a preparatory division, including latent and acceleration phases; (2) a dilatational division, occupying the phase of maximum slope; and (3) a pelvic division, encompassing both deceleration phase and second stage concurrent with the phase of maximum slope of descent. (Redrawn from Friedman EA: Labor: Clinical Evaluation and Management, 2nd ed. New York, Appleton-Century-Crofts, 1978.)

As shown in Figure 22-18, the pattern of cervical dilation during the preparatory and dilational divisions of normal labor is a sigmoid curve. Two phases of cervical dilation are defined. The *latent phase* corresponds to the preparatory division, and the *active phase* to the dilational division. Friedman further subdivided the active phase into the *acceleration phase,* the *phase of maximum slope,* and the *deceleration phase* (Fig. 22-19).

FIGURE 22-19
Composite of the average dilatation curve for nulliparous labor. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts that include an acceleration phase, a phase of maximum slope, and a deceleration phase. (Redrawn from Friedman EA: Labor: Clinical Evaluation and Management, 2nd ed. New York, Appleton-Century-Crofts, 1978.)

Latent Phase

The onset of latent labor, as defined by Friedman (1972), is the point at which the mother perceives regular contractions. The latent phase for most women ends once dilation of 3 to 5 cm is achieved. This threshold may be clinically useful, for it defines dilation limits beyond which active labor can be expected. More recently, a Consensus Committee of the American College of Obstetricians and Gynecologists and Society for Maternal-Fetal Medicine (2016c) has redefined active labor to begin at 6 cm. A fuller discussion of these labor changes is found in Chapter 23 (Background for the 6-cm Rule).

This concept of a latent phase has great significance in understanding normal human labor, because labor is considerably longer when a latent phase is included. To better illustrate this, Figure 22-20 shows eight labor curves from nulliparas in whom labor was diagnosed beginning with their admission, rather than with the onset of regular contractions. When labor is defined similarly, individual labor curves are remarkably comparable.

FIGURE 22-20
Progress of labor in primigravid women from the time of admission. When the starting point on the abscissa begins with admission to the hospital, a latent phase is not observed.

A *prolonged latent phase* was defined by Friedman and Sachtleben (1963) as one exceeding 20 hours in the nullipara and 14 hours in the multipara. These times corresponded to the 95th percentiles. Factors that affected latent phase duration include excessive sedation or epidural analgesia; unfavorable cervical condition, that is, thick, uneffaced, or undilated; and false labor. Of women who had been administered heavy sedation, 85 percent eventually entered active labor. In another 10 percent, uterine contractions ceased, suggesting that they had false labor. The remaining 5 percent experienced persistence of an abnormal latent phase and required oxytocin stimulation. Amniotomy was discouraged because of the 10-percent incidence of false labor. Sokol and associates (1977) reported a 3- to 4-percent incidence of prolonged latent phase, regardless of parity. Friedman (1972) reported that latent phase prolongation did not adversely influence fetal or maternal morbidity or mortality rates. However, Chelmow and coworkers (1993) disputed the long-held belief that prolongation of the latent phase is benign.

Active Phase

The progress of labor in nulliparas has particular significance because these curves all reveal a rapid change in the slope of cervical dilation rates between 3 and 5 cm (see Fig. 22-20). *Thus, cervical dilation of 3 to 6 cm or more, in the presence of uterine contractions, can be taken to reliably represent the threshold for active labor.* Similarly, these curves provide useful guideposts for labor management.

Turning again to Friedman (1955), the mean duration of active-phase labor in nulliparas was 4.9 hours. But, the standard deviation of 3.4 hours is large, hence, the active phase was reported to have a statistical maximum of 11.7 hours. Indeed, rates of cervical dilation ranged from a minimum of 1.2 up to 6.8 cm/hr. Friedman (1972) also found that multiparas progress somewhat faster in active-phase labor, with a *minimum* normal rate of 1.5 cm/hr. His analysis of active-phase labor concomitantly describes rates of fetal descent and cervical dilation (see Fig. 22-18). Descent begins in the later stage of active dilation, commencing at 7 to 8 cm in nulliparas and becoming most rapid after 8 cm.

Hendricks and coworkers (1970) challenged Friedman's conclusions about the course of normal human labor. Their principal differences included: (1) absence of a latent phase, (2) no deceleration phase, (3) brevity of labor, and (4) dilation at similar rates for nulliparas and multiparas after 4 cm. They disputed the concept of a latent phase because they observed that the cervix dilated and effaced slowly during the 4 weeks preceding labor. They contended that the *latent phase* actually progressed over several weeks. They also reported that labor was relatively rapid. Specifically, the average time from admission to complete dilation was 4.8 hours for nulliparas and 3.2 hours for multiparas.

Others have reassessed the Friedman labor curves. Zhang and associates (2010) studied electronic labor records from 62,415 parturients with spontaneous labor at term and vaginal birth. For nulliparas, the median time to progress from 4 to 5 cm was 1.3 hours, from 5 to 6 cm 0.8 hours, and thereafter, additional centimeters were gained approximately each 0.5 hours. They found that normal labor may take more than 6 hours to progress from 4 to 5 cm and more than 3 hours to progress from 5 to 6 cm dilation. Rates for multiparas were similar from 4 to 6 cm. Then, labor accelerated much faster in multiparas. Data from this study form the foundation for new guidelines regarding cesarean delivery indications for labor arrest put forth in the Obstetric Care Consensus document by the American College of Obstetrics and Gynecology and Society for Maternal-Fetal Medicine (2016c) and described in Chapter 23 (Obstetric Care Consensus Committee).

In a study performed at Parkland Hospital, epidural analgesia was found to lengthen the active phase of the Friedman labor curve by 1 hour (Alexander, 2002). This increase was the result of a slight but significant decline in the rate of cervical dilation—1.4 cm/hr in women given epidural analgesia compared with 1.6 cm/hr in those without such analgesia. Several other reports also note that maternal obesity lengthens the first stages of labor by 30 to 60 minutes (Chin, 2012; Kominiarek, 2011). Finally, Adams and coworkers (2012) found that maternal fear prolonged labor by approximately 45 minutes.

Active-phase abnormalities have been reported to occur in 25 percent of nulliparous and 15 percent of multiparous labors (Sokol, 1977). Friedman (1972) subdivided active-phase problems into *protraction* and *arrest disorders*. Abnormal labor patterns, diagnostic criteria, and treatment methods are summarized in Chapter 23 (Abnormalities of the Expulsive Forces).

Second Stage of Labor

This stage begins with complete cervical dilation and ends with fetal delivery. The median duration is approximately 50 minutes for nulliparas and about 20 minutes for multiparas, but it is highly variable (Kilpatrick, 1989). In a woman of higher parity with a previously dilated vagina and perineum, two or three expulsive efforts after full cervical dilation may suffice to complete delivery. Conversely, in a woman with a contracted pelvis, with a large fetus, or with impaired expulsive efforts from conduction analgesia or sedation, the second stage may be longer. Higher maternal body mass index does not interfere with second-stage labor length (Carlhäll, 2013; Robinson, 2011). Abnormalities of this labor stage are described in Chapter 23 (Second-Stage Descent Disorders).

Labor Duration

The normal duration of labor may be clouded by the many clinical variables that affect the conduct of labor in modern obstetrical units. Kilpatrick and Laros (1989) reported that the mean length of first- and second-stage labor was approximately 9 hours in nulliparas without regional analgesia, and that the 95th percentile upper limit was 18.5 hours. Corresponding times for multiparas were a mean of 6 hours and a 95th percentile maximum of 13.5 hours. These authors defined labor onset as the time when a woman recalled regular, painful contractions every 3 to 5 minutes that led to cervical change.

Spontaneous labor was analyzed in nearly 25,000 women delivered at term at Parkland Hospital in the early 1990s. Almost 80 percent of women were admitted with a cervical dilation of 5 cm or less. Parity—nulliparous versus multiparous—and cervical dilation at admission were significant determinants of the length of spontaneous labor. The median time from admission to spontaneous delivery for all parturients was 3.5 hours, and 95 percent of all women delivered within 10.1 hours. These results suggest that normal human labor is relatively short.

Summary of Normal Labor

Labor is characterized by brevity and considerable biological variation. Active labor can be reliably diagnosed when cervical dilation is ≥3 cm in the presence of uterine contractions. Once this cervical dilation threshold is reached, normal progression to delivery can be expected, depending on parity, in the ensuing 4 to 6 hours. Anticipated progress during a 1- to 3-hour second stage is monitored to ensure fetal safety. Finally, most women in spontaneous labor, regardless of parity, if left unaided, will deliver within approximately 10 hours after admission for spontaneous labor. Insufficient uterine activity is a common and correctable cause of abnormal labor progress. *Therefore, when the length of otherwise normal labor exceeds the expected norm, interventions other than cesarean delivery—for example, oxytocin administration—must be first considered.*

MANAGEMENT OF NORMAL LABOR

The ideal management of labor and delivery requires two potentially opposing viewpoints on the part of clinicians. First, birthing should be recognized as a normal physiological process that most women experience without complications. Second, intrapartum complications, often arising quickly and unexpectedly, should be anticipated. Thus, clinicians must simultaneously make every woman and her supporters feel comfortable, yet ensure safety for the mother and newborn if complications suddenly develop. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) have collaborated in the development of *Guidelines for Perinatal Care*. These provide detailed information on the appropriate content of intrapartum care, including both personnel and facility requirements (Table 22-2).

TABLE 22-2

Recommended Nurse/Patient Ratios for Labor and Delivery

Ratio	Clinical Setting
2:1	Birth
1:2	Patients in labor without complications
1:1	Patients in second-stage labor
1:1	Patients with medical/obstetrical complications
1:1	Oxytocin induction/augmentation
1:1	During epidural analgesia initiation
1:1	Circulation for cesarean delivery

Labor and delivery outside the hospital is elected by some parturients. This option and its risks and benefits are discussed in Chapter 27 (Special Populations).

Emergency Medical Treatment and Labor Act—EMTALA

Congress enacted EMTALA in 1986 to ensure public access to emergency services regardless of the ability to pay. All Medicare-participating hospitals with emergency services must provide an appropriate screening examination for any pregnant woman experiencing contractions and presenting to the emergency department for evaluation.

The definition of an emergency condition makes specific reference to a pregnant woman who is having contractions. Labor is defined as "the process of childbirth beginning with the latent phase of labor continuing through delivery of the placenta. A woman experiencing contractions is in true labor unless a physician certifies that after a reasonable time of observation the woman is in false labor." A woman in true labor is considered "unstable" for interhospital transfer purposes until the newborn and placenta are delivered. A stable woman may, however, be transferred at the direction of the patient or by a physician who certifies that the benefits of treatment at another facility outweigh the transfer risks. Physicians and hospitals violating these federal requirements are subject to civil penalties and termination from participation in the Medicare program.

Identification of Labor

Pregnant women are urged to report early in labor rather than to procrastinate until delivery is imminent for fear that they might be experiencing false labor. Early admittance is especially important if during antepartum care the woman, her fetus, or both are found to have risk factors for intrapartum complications.

Although the differentiation between false and true labor is difficult at times, the diagnosis usually can be clarified by contraction frequency and intensity and by cervical dilation. Pates and associates (2007) studied one commonly used recommendation given to pregnant women. Namely, in the absence of ruptured membranes or bleeding, uterine contractions 5 minutes apart for 1 hour—that is, ≥12 contractions in 1 hour—may signify labor onset. Among 768 women in this study at Parkland Hospital, active labor defined as cervical dilation ≥4 cm was diagnosed within 24 hours in three fourths of women with ≥12 contractions per hour. Bailit and coworkers (2005) compared labor outcomes of 6121 women who presented in active labor defined as uterine contractions plus cervical dilation ≥4 cm with those of 2697 women who presented in the latent phase. Women admitted during latent-phase labor had more active-phase arrest, more frequent need for oxytocin labor stimulation, and higher rates of chorioamnionitis. It was concluded that physician interventions in women presenting in the latent phase may have been the cause of subsequent labor abnormalities.

In those instances when a diagnosis of labor cannot be established with certainty, observation for a longer period is often wise. Women who present to Parkland Hospital for labor symptoms at $24^{0/7}$ weeks' gestation or greater are routinely evaluated in a labor triage unit contiguous to our labor and delivery unit. All women in the triage area are evaluated by nurse practitioners and certified nurse midwives using written protocols. Women with uncomplicated pregnancies with intact membranes and cervical dilation <4 cm receive continuous external fetal monitoring for up to 2 hours. Women diagnosed with labor by either cervical change or persistent uterine contractions are admitted. After review by a physician, women without cervical change or with abatement of contractions return home with a diagnosis of false labor. In a recent study, a total of 3949 women with uncomplicated pregnancies between $37^{0/7}$ and $41^{6/7}$ weeks' gestation were diagnosed with false labor. The mean interval from hospital discharge to when they again presented was 4.9 days (Nelson, 2017). Within this protocol, hospital discharge with false labor at term was not associated with higher rates of adverse neonatal outcomes or cesarean delivery. The American College of Obstetricians and Gynecologists (2016a) has endorsed hospital-based obstetrical triage units.

Initial Evaluation

Maternal blood pressure, temperature, pulse, and respiratory rate are recorded. Fetal heart rate is evaluated using a portable Doppler device, sonography, or fetoscope. The pregnancy record is promptly reviewed to identify complications. Problems identified or anticipated during prenatal care should be displayed

prominently in the pregnancy record. Most often, *unless there has been bleeding in excess of bloody show,* a cervical examination is performed. The gloved index and second fingers are introduced into the vagina while avoiding the anal region.

Ruptured Membranes

During prenatal care, the woman is instructed to be aware of fluid leakage from the vagina and to report such an event promptly. Rupture of the membranes is significant for three reasons. First, if the presenting part is not fixed in the pelvis, the umbilical cord can prolapse and be compressed. Second, labor is likely to begin soon if the pregnancy is at or near term. Third, if delivery is delayed after membrane rupture, intrauterine and neonatal infection is more likely as the time interval increases (Herbst, 2007).

During sterile speculum examination, ruptured membranes are diagnosed if amnionic fluid pools in the posterior fornix or clear fluid flows from the cervical canal. Although several diagnostic tests for the detection of ruptured membranes have been recommended, none is completely reliable. If the diagnosis remains uncertain, another method involves pH determination of vaginal fluid. The pH of vaginal secretions normally ranges from 4.5 to 5.5, whereas that of amnionic fluid is usually >7.0. The use of the indicator *nitrazine* to identify ruptured membranes is a simple and fairly reliable method. Test papers are impregnated with the dye, and the color of the reaction between these paper strips and vaginal fluids is interpreted by comparison with a standard color chart. A pH above 6.5 is consistent with ruptured membranes. False-positive test results may occur with coexistent blood, semen, or bacterial vaginosis, whereas false-negative tests may result with scant fluid.

Other tests to identify amnionic fluid include arborization or ferning of vaginal fluid, which suggests amnionic rather than cervical fluid. Amnionic fluid crystallizes to form a fernlike pattern due to its relative concentrations of sodium chloride, proteins, and carbohydrates. Detection of alpha-fetoprotein in the vaginal vault has been used to identify amnionic fluid (Yamada, 1998). Although rarely required, identification may also follow injection of indigo carmine into the amnionic sac via abdominal amniocentesis. Last, specific amnionic fluid proteins can be sought using point-of-care assays. These include AmniSure, which binds placental alpha microglobulin-1, and ROM Plus, which detects insulin growth factor binding protein-1 plus alpha-fetoprotein (Doret, 2013; Igbinosa, 2017).

Cervical Assessment

The degree of *cervical effacement* reflects the length of the cervical canal compared with that of an uneffaced cervix. When the length of the cervix is reduced by one half, it is 50-percent effaced. When the cervix becomes as thin as the adjacent lower uterine segment, it is completely, or 100-percent, effaced.

Cervical dilation is determined by estimating the average diameter of the cervical opening by sweeping the examining finger from the margin of the cervical opening on one side to that on the opposite side. The diameter traversed is estimated in centimeters. The cervix is said to be fully dilated when the diameter measures 10 cm, because the presenting part of a term-size newborn usually can pass through a cervix this widely dilated.

The *position* of the cervix is determined by the relationship of the cervical os to the fetal head and is categorized as posterior, midposition, or anterior. Along with position, the *consistency* of the cervix is determined to be soft, firm, or intermediate between these two.

The *fetal station*, that is, the level of the presenting fetal part in the birth canal, is described in relationship to the ischial spines. These spines lie halfway between the pelvic inlet and the pelvic outlet. When the lowermost portion of the presenting fetal part is at the level of the spines, it is designated as being at zero (0) station.

In the past, the long axis of the birth canal above and below the ischial spines was arbitrarily divided into thirds by some and into fifths (approximately 1 cm) by other groups. In 1989, the American College of Obstetricians and Gynecologists adopted the classification of station that divides the pelvis above and below the spines into fifths. Each fifth represents 1 cm above or below the spines. Thus, as the presenting fetal part descends from the inlet *toward* the ischial spines, the designation is –5, –4, –3, –2, –1, then 0 station. Below the spines, as the presenting fetal part descends, it passes +1, +2, +3, +4, and +5 stations to delivery. Station +5 cm corresponds to the fetal head being visible at the introitus.

If the leading part of the fetal head is at 0 station or below, most often the fetal head has engaged—thus, the biparietal plane has passed through the pelvic inlet. *If the head is unusually molded or if caput succedaneum formation is extensive, or both, engagement might not have taken place although the head appears to be at 0 station.*

In a study done at five teaching centers in Denver, residents, nurses, and faculty were surveyed to determine what definitions were being used to describe fetal station (Carollo, 2004). Four different definitions were in use. Disturbingly, these investigators found that few caregivers were aware that others were using different definitions of station! Dupuis and associates (2005) tested the reliability of clinical estimations of station using the position of the leading part in centimeters above or below the spines. A birth simulator was used in which station could be precisely measured and compared with the vaginal examination done by clinicians. They reported that the clinical examiners were incorrect a third of the time.

These five characteristics—cervical dilation, effacement, consistency, position, and fetal station—are assessed when tabulating the Bishop score. This score is commonly used to predict labor induction outcome and is discussed in Chapter 26 (Preinduction Cervical Ripening). Taken together, these factors suggest the subjective “favorability” of the cervix for induction success.

Laboratory Studies

When a woman is admitted in labor, most often the hematocrit or hemoglobin concentration is checked. The hematocrit can be measured easily and quickly. At Parkland Hospital, blood is collected in a standard collection tube with anticoagulant. From this, a heparinized capillary tube is filled to spin in a microhematocrit centrifuge in the labor and delivery unit. This provides a hematocrit value within 3 minutes. The initial collection tube is also sent to the hematology laboratory for evaluation if the point-of-care hematocrit is <30 volume percent. Another labeled tube of blood is allowed to clot and sent to the blood bank for blood type and

antibody screen, if needed. A final sample is collected for syphilis and human immunodeficiency virus (HIV) serology. In some labor units, a clean-catch voided specimen is examined in all women for protein and glucose. At Parkland Hospital, however, we obtain a urine specimen for protein determination in hypertensive women only (Table 40-1).

Women with no prenatal care are considered to be at risk for syphilis, hepatitis B, and HIV, and laboratory screening studies for these, as well as a blood type and antibody screen, are performed (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017). Some states, for example, Texas, require routine testing for syphilis, hepatitis B, and HIV in all women admitted to labor and delivery units, even if these were done during prenatal care.

Management of First-Stage Labor

As soon as possible after admittance, the remainder of a general examination is completed. Whether a pregnancy is normal can best be determined when all examinations, including record and laboratory review, are completed. A rational plan for monitoring labor can then be established based on the needs of the fetus and the mother. Because labor lengths vary markedly among individuals, precise statements regarding anticipated labor duration are unwise.

In general, pain relief should depend on the needs and desires of the woman. The American College of Obstetricians and Gynecologists (2017) has specified optimal goals for anesthesia care in obstetrics. This is discussed in detail in Chapter 25. In some units, women can choose to spend part of first-stage labor in a large water tub. Risks and benefits are described in Chapter 27 (Special Populations).

Intrapartum Fetal Monitoring

This is discussed in detail in Chapter 24. Briefly, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2017) recommend that during first-stage labor, in the absence of any abnormalities, the fetal heart rate should be checked immediately after a contraction at least every 30 minutes and then every 15 minutes during the second stage. If continuous electronic monitoring is used, the tracing is evaluated at least every 30 minutes during the first stage and at least every 15 minutes during second-stage labor. For women with pregnancies at risk, fetal heart auscultation is performed at least every 15 minutes during first-stage labor and every 5 minutes during the second stage. Continuous electronic monitoring may be used with evaluation of the tracing every 15 minutes during the first stage of labor, and every 5 minutes during the second stage.

Maternal Monitoring

Temperature, pulse, and blood pressure are evaluated at least every 4 hours. If membranes have been ruptured for many hours before labor onset or if there is a borderline temperature elevation, the temperature is checked hourly.

Although uterine contractions are usually assessed with electronic monitoring, they can be quantitatively and qualitatively evaluated manually (Chap. 24, Intrapartum Surveillance of Uterine Activity). With the palm of the hand resting lightly on the uterus, the time of contraction onset is determined. Its intensity is gauged from the degree of firmness the uterus achieves. At the acme of effective contractions, the finger or thumb cannot readily indent the uterus during a “firm” contraction. The time at which the contraction disappears is noted next. This sequence is repeated to evaluate the frequency, duration, and intensity of contractions.

During the first stage of labor, the need for subsequent vaginal examinations to monitor cervical change and presenting part position will vary considerably. When the membranes rupture, an examination to exclude cord prolapse is performed expeditiously if the fetal head was not definitely engaged at the previous examination. The fetal heart rate is also checked immediately and during the next uterine contraction to help detect occult umbilical cord compression. At Parkland Hospital, periodic pelvic examinations are typically performed at 2- to 3-hour intervals to evaluate labor progress. Evidence implicating the number of vaginal examinations in infection-related morbidity is conflicting (Cahill, 2012; Soper, 1989).

Oral Intake

Food and liquids with particulate matter should be withheld during active labor and delivery. Gastric emptying time is remarkably prolonged once labor is established and analgesics are administered. As a consequence, ingested food and most medications remain in the stomach and are not absorbed. Instead, they may be vomited and aspirated (Chap. 25, Inhalational Anesthetics). According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017), oral intake of moderate amounts of clear liquids is reasonable for women with uncomplicated labor. Modest amounts of clear liquids such as water, clear tea, black coffee, carbonated beverages, Popsicles, and pulp-free fruit juices are allowed in uncomplicated laboring women. In those with appreciable risks for aspiration or those with significant risks for cesarean delivery, further restriction may be instituted. For example, for those with planned cesarean delivery, liquids are halted 2 hours before and solids are stopped 6 to 8 hours prior to surgery (American College of Obstetricians and Gynecologists, 2016b).

Intravenous Fluids

Although an intravenous (IV) infusion system is often routinely established early in labor, real need for this in the normal pregnant woman is limited, at least until analgesia is administered. However, venous access is advantageous during the immediate puerperium to administer oxytocin prophylactically and at times therapeutically when uterine atony persists. Moreover, with longer labors, the administration of glucose, sodium, and water to the otherwise fasting woman at the rate of 60 to 120 mL/hr prevents dehydration and acidosis. Shrivastava and associates (2009) noted shorter labors in nulliparas delivering vaginally who were provided an intravenous normal saline with dextrose solution compared with those given saline solution only. In another study, 195 women in labor received lactated Ringer or isotonic sodium chloride solution at a rate of either 125 or 250 mL/hr. The mean volume of total IV fluid was 2008 mL in the 125 mL/hr group and 2487 mL in the 250 mL/hr group (Garite, 2000). Labor lasted more than 12 hours in significantly more of the women given a 125 mL/hr infusion compared with those given 250 mL/hr—26 versus 13 percent, respectively. In yet another study, 311 nulliparas with uncomplicated pregnancies in spontaneous labor at term received one of three IV infusions (Edwards, 2014). Group 1 was given 125 mL/hr of lactated Ringer solution with 5 percent dextrose (D5LR), Group 2 received 250 mL/hour of the

same solution (D5LR), and Group 3 was administered 25 mL/hr of D5LR. Groups 1 and 2 were allowed ice chips, Popsicles, and hard candy, and Group 3 also received Gatorade. Oral intake was limited in Groups 1 and 2 but was ad libitum in Group 3. The authors concluded that any of the regimens studied was safe but none was superior for labor performance.

Maternal Position

In bed, the laboring woman may assume the position she finds most comfortable, and often this will be lateral recumbency. Lying supine is typically avoided to avert aortocaval compression and its potential to lower uterine perfusion (Chap. 4, Hemodynamic Function in Late Pregnancy). However, the normal laboring woman need not be confined to bed early in labor. A comfortable chair may be beneficial psychologically and perhaps physiologically. Others encourage ambulation.

Proponents of walking report that it shortens labor, lowers rates of oxytocin augmentation, diminishes the need for analgesia, and decreases the frequency of operative vaginal delivery (Flynn, 1978; Read, 1981). In their Cochrane review, Lawrence and associates (2013) found that labor in ambulant or upright positions shortened first-stage labor by about 1 hour and lowered cesarean delivery and epidural analgesia rates. Lupe and Gross (1986) concluded, however, that no conclusive evidence supports assertions that upright maternal posture or ambulation improves labor. They reported that women preferred to lie on their side or sit in bed. Few chose to walk, fewer to squat, and none wanted the knee-chest position. Parturients tended to assume fetal positions in later labor. Most women enthusiastic about ambulation returned to bed when active labor began (Carlson, 1986; Williams, 1980).

Bloom and colleagues (1998) conducted a randomized trial to study the effects of walking during first-stage labor. In 1067 women with uncomplicated term pregnancies delivered at Parkland Hospital, these investigators reported that ambulation did not affect labor duration. Ambulation did not reduce the need for analgesia, nor was it harmful to the newborn. Because of these observations, we give women without complications the option to select either recumbency or supervised ambulation during labor.

Rupture of Membranes

If the membranes are intact, temptation is great, even during normal labor, to perform amniotomy. The presumed benefits are more rapid labor, earlier detection of meconium-stained amnionic fluid, and the opportunity to apply an electrode to the fetus or insert a pressure catheter into the uterine cavity for monitoring. The advantages and disadvantages of amniotomy are discussed in Chapter 26 (Amniotomy for Induction and Augmentation). Importantly, the fetal head must be well applied to the cervix and not be dislodged from the pelvis during the procedure to avoid umbilical cord prolapse.

In cases with prolonged membrane rupture, defined as greater than 18 hours, antimicrobial administration for prevention of group B streptococcal infections is recommended. This is discussed in Chapter 64 (GBS Vaccine). This practice similarly lowers rates of chorioamnionitis and endometritis (Saccone, 2015).

Urinary Bladder Function

Distention of the bladder can hinder descent of the fetal presenting part and lead to subsequent bladder hypotonia and infection. Periodically during labor, the suprapubic region is inspected and palpated to detect distention. If the bladder is readily seen or palpated above the symphysis, the woman should be encouraged to void. At times, those who may be unable to void on a bedpan may be able to ambulate with assistance to a toilet and successfully void. If the bladder is distended and voiding is not possible, catheterization is indicated. Carley and coworkers (2002) found that 51 of 11,332 vaginal deliveries (1 in 200) were complicated by postpartum urinary retention. Most women resumed normal voiding before discharge from the hospital. Musselwhite and associates (2007) reported retention in 4.7 percent of women who had labor epidural analgesia. Risk factors for retention were primiparity, oxytocin-induced or augmented labor, perineal lacerations, operative vaginal delivery, catheterization during labor, and labor duration >10 hours.

Management of Second-Stage Labor

With full cervical dilation, which signifies the onset of the second stage, a woman typically begins to bear down. With descent of the presenting part, she develops the urge to defecate. Uterine contractions and the accompanying expulsive forces may now last 1 minute and recur at an interval no longer than 90 seconds. As discussed earlier, the median duration of the second stage is 50 minutes in nulliparas and 20 minutes in multiparas, although the interval can vary. Monitoring intervals of the fetal heart rate were discussed in Management of First-Stage Labor, and interpretation of second-stage electronic fetal heart rate patterns is discussed in Chapter 24 (Fetal Heart Rate Patterns During Second-Stage Labor).

In most cases, bearing down is reflexive and spontaneous during second-stage labor. Occasionally, a woman may not employ her expulsive forces to good advantage and coaching is desirable. Her legs should be half-flexed so that she can push with them against the mattress. When the next uterine contraction begins, she is instructed to exert downward pressure as though she were straining at stool. A woman is not encouraged to push beyond the completion of each contraction. Instead, she and her fetus are allowed to rest and recover. During this period of actively bearing down, the fetal heart rate auscultated during the contraction is likely to be slow but should recover to normal range before the next expulsive effort. Fetal and obstetrical outcomes appear to be unaffected whether pushing is coached or uncoached during second-stage labor (Bloom, 2006; Tuuli, 2012). Bloom and colleagues (2006) studied effects of actively coaching expulsive efforts in women without epidural analgesia. They reported that although the second stage was slightly shorter in coached women, no other maternal advantages were gained.

Several positions during the second stage have been recommended to augment pushing efforts. Eason and colleagues (2000) reviewed various positions and their effect on the incidence of perineal trauma. They found that the supported upright position had no advantages over the recumbent one. Upright positions include sitting, kneeling, squatting, or resting with the back at a 30-degree elevation. In women with regional analgesia, one recent randomized trial found higher vaginal delivery rates in those in a recumbent position compared with an upright one—41 versus 35 percent (The Epidural and Position Trial Collaborative Group, 2017). In women without epidural analgesia, Gupta (2017) in their review compared upright positions with supine or lithotomy positions and their effect on labor. Upright positions offered a slightly shorter interval to delivery as well as fewer episiotomies and operative vaginal deliveries. However, rates of blood loss >500 mL and

perhaps of second-degree lacerations were increased. Berghella and coworkers (2008) hypothesized that parity, less intense aortocaval compression, improved fetal alignment, and larger pelvic outlet diameters might explain these findings. In an earlier study, a 20- to 30-percent increase in the area of the pelvic outlet was noted with squatting compared with the supine position (Russell, 1969). Finally, Babayer and associates (1998) cautioned that prolonged sitting or squatting during the second stage may cause neuropathy of the common fibular (formerly common peroneal) nerve.

As the head descends through the pelvis, the perineum begins to bulge and the overlying skin becomes stretched. Now the scalp of the fetus may be visible through the vulvar opening. At this time, the woman and her fetus are prepared for delivery, which is described in Chapter 27 (Preparation for Delivery).

LABOR MANAGEMENT PROTOCOLS

An orderly and systematic approach to labor management results in reproducible beneficial maternal and perinatal outcomes (Althabe, 2008). Several labor management protocols are subsequently presented. These include those from the National Maternity Hospital in Dublin, from the World Health Organization, and from Parkland Hospital.

In Dublin more than 30 years ago, O'Driscoll and associates (1984) pioneered the concept that a disciplined, standardized labor management protocol reduced the number of cesarean deliveries for dystocia. Their overall cesarean delivery rate was 5 percent in the 1970s and 1980s with such management. The approach is now referred to as *active management of labor.* Two of its components—amniotomy and oxytocin—have been widely used, especially in English-speaking countries outside the United States. With this protocol, labor is diagnosed when painful contractions are accompanied by complete cervical effacement, bloody "show," or ruptured membranes. Women with such findings are committed to delivery within 12 hours. Pelvic examination is performed each hour for the next 3 hours, and thereafter at 2-hour intervals. When dilation has not increased by at least 1 cm/hr, amniotomy is performed. Progress is again assessed at 2 hours, and high-dose oxytocin infusion, described in Chapter 26 (Oxytocin), is started unless dilation of at least 1 cm/hr is attained. Women are constantly attended by midwives. If membranes rupture before admission, oxytocin is begun for no progress at the 1-hour mark.

López-Zeno and colleagues (1992) prospectively compared such active management with their "traditional" approach to labor management at Northwestern Memorial Hospital in Chicago. They randomly assigned 705 nulliparas with uncomplicated pregnancies in spontaneous labor at term. The cesarean delivery rate was significantly lower with active versus traditional management—10.5 versus 14.1 percent, respectively. Subsequent studies did not show this. Wei and associates (2013) in a Cochrane database review found a modest reduction in cesarean delivery rates when active management of labor was compared with standard care. Frigoletto and coworkers (1995) reported another randomized trial with 1934 nulliparous women at Brigham and Women's Hospital in Boston. Although they found that such management somewhat shortened labor, it did not affect the cesarean delivery rate. These observations have since been reported by others (Brown, 2013).

A *partograph* was designed by the World Health Organization (WHO) for use in developing countries (Dujardin, 1992). According to Orji (2008), the partograph is similar for nulliparas and multiparas. Labor is divided into a latent phase, which should last no longer than 8 hours, and an active phase. The active phase starts at 3 cm dilation, and progress should be no slower than 1 cm/hr. A 4-hour wait is recommended before intervention when the active phase is slow. Labor is graphed, and analysis includes use of alert and action lines. Lavender and colleagues (2006) randomized 3000 nulliparous women to labor interventions at 2 hours versus 4 hours as recommended by WHO. Their cesarean delivery rate was unaffected, and they concluded that interventions such as amniotomy and oxytocin were needlessly increased using the 2-hour time interval. From their Cochrane Database review, Lavender and associates (2013) do not recommend use of the partograph for standard labor management.

At Parkland Hospital, women are admitted if active labor is diagnosed or if ruptured membranes are confirmed. Labor is defined as cervical dilation of 3 to 4 cm or more in the presence of uterine contractions. Management guidelines direct that a pelvic examination be performed approximately every 2 hours. Ineffective labor is suspected when the cervix does not dilate within approximately 2 hours of admission. Amniotomy is then performed, and labor progress determined at the next 2-hour evaluation. In women whose labors do not progress, an intrauterine pressure catheter is placed to assess uterine function. Hypotonic contractions and no cervical dilation after an additional 2 to 3 hours result in stimulation of labor using the high-dose oxytocin regimen described in Chapter 26 (Oxytocin). The goal is uterine activity of 200 to 250 Montevideo units for 2 to 4 hours before dystocia can be diagnosed. If hypotonic contractions are strongly suspected, internal monitors may be placed with amniotomy and again cervical change and contraction pattern are assessed in 2 hours. Confirmation of deficient Montevideo units at that time may prompt oxytocin augmentation for maternal or fetal indications.

Dilation rates of 1 to 2 cm/hr are accepted as evidence of progress after satisfactory uterine activity has been established with oxytocin. This can require up to 8 hours or more before cesarean delivery is performed for dystocia. The cumulative time required to effect this stepwise management approach permits many women to establish effective labor. This management protocol has been evaluated in more than 20,000 women with uncomplicated pregnancies. Importantly, these labor interventions and the relatively infrequent use of cesarean delivery did not jeopardize the fetus–newborn.

CHAPTER 23: Abnormal Labor

… pains become less frequent and less intense, although giving rise to quite as much or even more suffering than previously. At the same time, the cervix, which was becoming obliterated and dilated in a satisfactory manner, ceases to make further progress and labour apparently comes to a standstill.

—J. Whitridge Williams (1903)

INTRODUCTION

The term *dystocia* as described by Williams in the first edition of this text still applies today. It literally means *difficult labor* and is characterized by abnormally slow labor progress. Similar to the factors described by Williams, dystocia arises from three distinct abnormality categories. First, uterine contractions may be insufficiently strong or inappropriately coordinated to efface and dilate the cervix—*uterine dysfunction*. Also, voluntary maternal muscle effort during second-stage labor may be inadequate. Second, fetal abnormalities of presentation, position, or anatomy may slow progress. Last, structural changes can contract the maternal bony pelvis. Or, soft tissue abnormalities of the reproductive tract may form an obstacle to fetal descent. More simply, these alterations can be mechanistically simplified into three categories that include abnormalities of the *powers*—uterine contractility and maternal expulsive effort; of the *passenger*—the fetus; and of the *passage*—the pelvis and lower reproductive tract.

DYSTOCIA

Descriptors

Abnormalities shown in Table 23-1 often interact singly or in combination to produce dysfunctional labor. Commonly used expressions today such as *cephalopelvic disproportion* and *failure to progress* are used to describe ineffective labors. Of these, *cephalopelvic disproportion* is a term that came into use before the 20th century to describe obstructed labor resulting from disparity between the fetal head size and maternal pelvis. But, the term originated at a time when the main indication for cesarean delivery was overt pelvic contracture due to rickets (Olah, 1994). Such absolute disproportion is now rare, and most cases result from malposition of the fetal head within the pelvis (asynclitism) or from ineffective uterine contractions. True disproportion is a tenuous diagnosis because many women who undergo cesarean delivery for this reason subsequently deliver even larger newborns vaginally in subsequent pregnancies. A second phrase, *failure to progress* in either spontaneous or stimulated labor, has become an increasingly popular description of ineffectual labor. This term reflects lack of progressive cervical dilation or lack of fetal descent. Neither of these two terms is specific.

TABLE 23-1

Common Clinical Findings in Women with Ineffective Labor

Inadequate cervical dilation or fetal descent:
Protracted labor—slow progress
Arrested labor—no progress
Inadequate expulsive effort—ineffective pushing
Fetopelvic disproportion:
Excessive fetal size
Inadequate pelvic capacity
Malpresentation or position of the fetus
Abnormal fetal anatomy
Ruptured membranes without labor

Mechanisms of Dystocia

At the end of pregnancy, the fetal head encounters a relatively thick lower uterine segment and undilated cervix. With the onset of labor, the factors influencing progress are uterine contractions, cervical resistance, and the forward pressure exerted by the leading fetal part.

After complete cervical dilation, the mechanical relationship between the fetal head size and position and the pelvic capacity, namely *fetopelvic proportion*, becomes clearer as the fetus attempts to descend. Because of this, abnormalities in fetopelvic proportions become more apparent once the second stage is reached.

Uterine muscle malfunction can result from uterine overdistention, obstructed labor, or both. *Thus, ineffective labor is generally accepted as a possible warning sign of fetopelvic disproportion.* Although artificial separation of labor abnormalities into pure *uterine dysfunction* and *fetopelvic disproportion* simplifies classification, it is an incomplete characterization because these two abnormalities are closely interlinked. Indeed, the bony pelvis rarely limits vaginal delivery. In the absence of objective means of precisely distinguishing these two causes of labor failure, clinicians must rely on a *trial of labor* to determine if labor can be successful in effecting vaginal delivery.

ABNORMALITIES OF THE EXPULSIVE FORCES

Cervical dilation as well as propulsion and expulsion of the fetus are brought about by uterine contractions. During second-stage labor, these contractions are then reinforced by voluntary or involuntary muscular action of the abdominal wall—"pushing." The diagnosis of uterine dysfunction in the latent phase is difficult and sometimes can be made only in retrospect. Women who are not yet in active labor commonly are erroneously treated for this dysfunction.

Beginning in the 1960s, at least three significant advances have aided treatment of uterine dysfunction. First is the realization that undue labor prolongation may contribute to maternal and perinatal morbidity and mortality rates. Second, dilute intravenous infusion of oxytocin is administered to treat certain types of uterine dysfunction. Last, cesarean delivery is selected rather than difficult midforceps delivery when oxytocin fails or its use is inappropriate.

Types of Uterine Dysfunction

Reynolds and coworkers (1948) emphasized that uterine contractions of normal labor are characterized by a gradient of myometrial activity. These forces are greatest and last longest at the fundus—considered *fundal dominance*—and they diminish toward the cervix. Caldeyro-Barcia and colleagues (1950) from Montevideo, Uruguay, inserted small balloons into the myometrium at various levels (Chap. 24, Intrapartum Surveillance of Uterine Activity). They reported that in addition to a gradient of activity, the onset of the contractions differed in the fundus, midzone, and lower uterine segments. Larks (1960) described the stimulus as starting in one cornu and then several milliseconds later in the other. The excitation waves then join and sweep over the fundus and down the uterus. Normal spontaneous contractions often exert pressures approximating 60 mm Hg (Hendricks, 1959). Even so, the Montevideo group ascertained that the lower limit of contraction pressure required to dilate the cervix is 15 mm Hg.

From these observations, two physiological types of uterine dysfunction are defined. In the more common *hypotonic uterine dysfunction,* there is no basal hypertonus, and uterine contractions have a normal gradient pattern (synchronous). However, pressure during a contraction is insufficient to dilate the cervix.

In the second type, *hypertonic uterine dysfunction* or *incoordinate uterine dysfunction,* either basal tone is elevated appreciably or the pressure gradient is distorted. Gradient distortion may result from more forceful contraction of the uterine midsegment than the fundus, from complete asynchrony of the impulses originating in each cornu, or from a combination of these two.

Labor Disorders

Latent-Phase Prolongation

These just-described types of uterine dysfunction can in turn lead to labor abnormalities (Table 23-2). First, the latent phase may be prolonged, which is defined as exceeding 20 hours in the nullipara and 14 hours in the multipara. In some, uterine contractions cease, suggesting false labor. In the remainder, an abnormally long latent phase persists and is often treated with oxytocin stimulation.

TABLE 23-2

Abnormal Labor Patterns, Diagnostic Criteria, and Methods of Treatment

	Diagnostic Criteria			
Labor Pattern	**Nulliparas**	**Multiparas**	**Preferred Treatment**	**Exceptional Treatment**
Prolongation Disorder				
Prolonged latent phase	>20 hr	>14 hr	Bed rest	Oxytocin or cesarean delivery for urgent problems
Protraction Disorders				
Protracted active-phase dilation Protracted descent	<1.2 cm/hr <1 cm/hr	1.5 cm/hr <2 cm/hr	Expectant and support	Cesarean delivery for CPD
Arrest Disorders				
Prolonged deceleration phase Secondary arrest of dilation Arrest of descent Failure of descent	>3 hr >2 hr >1 hr	>1 hr >2 hr >1 hr	Evaluate for CPD: CPD: cesarean No CPD: oxytocin	Rest if exhausted Cesarean delivery
	No descent in deceleration phase or second stage			

CPD = cephalopelvic disproportion.

Modified from Cohen, 1983.

Active-Phase Disorders

In active labor, disorders are divided into slower-than-normal progress—a *protraction disorder*—or complete cessation of progress—an *arrest disorder*. Terms presented in Table 23-2 and their diagnostic criteria more precisely describe abnormal labor. To be diagnosed with either of these, a woman must be in the active phase of labor, which is defined by cervical change.

These criteria and management of abnormal labor have recently undergone a sea change. In 2014, the American College of Obstetricians and Gynecologists and the Society for Maternal–Fetal Medicine issued their first Obstetric Care Consensus titled *Safe Prevention of the Primary Cesarean Delivery*. It was reaffirmed in 2016. This consensus statement was a response to concerns that cesarean delivery was overused in the United States. Namely, approximately one in three women who give birth each year undergoes this surgery (Fig. 31-1). New recommendations from the Consensus Committee are based on "more recent data used to revise the definition of contemporary normal labor progress" and reflect a significant revision of the preexisting understanding of abnormal labor.

Active-Phase Protraction

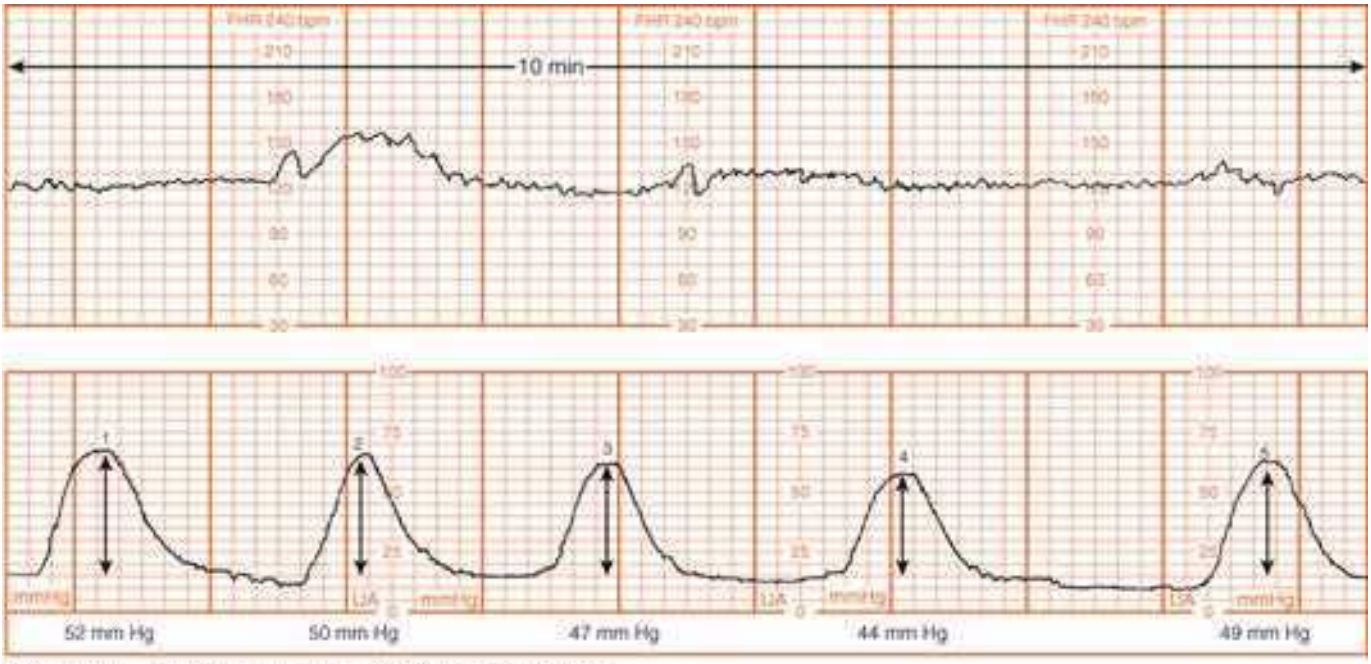
Of active-phase disorders, protraction disorders are less well described, and the time necessary before diagnosing slow progress is undefined. The World Health Organization (1994) has proposed a labor management *partograph* in which protraction is defined as <1 cm/hr cervical dilation for a minimum of 4 hours. These criteria were adapted from those of Cohen and Friedman (1983) and shown in Table 23-2. For this disorder, observation for further progress is appropriate treatment. If insufficient Montevideo units are noted, oxytocin augmentation is initiated. According to the Consensus Committee (2016), slow but progressive first-stage labor should not be an indication for cesarean delivery.

Active-Phase Arrest

Handa and Laros (1993) diagnosed active-phase arrest, defined as no dilation for 2 hours or more, in 5 percent of term nulliparas. This incidence has not changed since the 1950s (Friedman, 1978). Inadequate uterine contractions, defined as less than 180 Montevideo units, calculated as shown in Figure 23-1, were diagnosed in 80 percent of women with active-phase arrest. Hauth and coworkers (1986, 1991) reported that when labor is effectively induced or augmented with oxytocin, 90 percent of women achieve 200 to 225 Montevideo units, and 40 percent achieve at least 300 Montevideo units. These results suggest that certain minimums of uterine activity should be achieved before performing cesarean delivery for dystocia.

FIGURE 23-1

Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. In the example shown, there were five contractions, producing pressure changes of 52, 50, 47, 44, and 49 mm Hg, respectively. The sum of these five contractions is 242 Montevideo units.



Other criteria should also be met. First, the latent phase should be completed, and the cervix is dilated ≥4 cm. Also, a uterine contraction pattern of 200 Montevideo units or more in a 10-minute period has been present for 2 or more hours without cervical change. Rouse and associates (1999) challenged the "2-hour rule" on the grounds that a longer time, that is, at least 4 hours, is necessary before concluding that the active phase of labor has failed. We agree. The Consensus Committee (2016) has expanded the criteria, as described next.

Obstetric Care Consensus Committee

There are four recommendations by the Consensus Committee (2016) applicable to management of the first-stage labor. The first admonishes against cesarean delivery in the latent phase of labor. Specifically, a prolonged latent phase is not an indication for cesarean delivery. This guideline is not new and is traceable to the work of Friedman (1954), on which traditional tenets are based.

The second directive, too, is conventional practice. It recommends against cesarean delivery if labor is progressive but slow—a *protraction disorder*. This instance is typically managed with observation, assessment of uterine activity, and stimulation of contractions as needed.

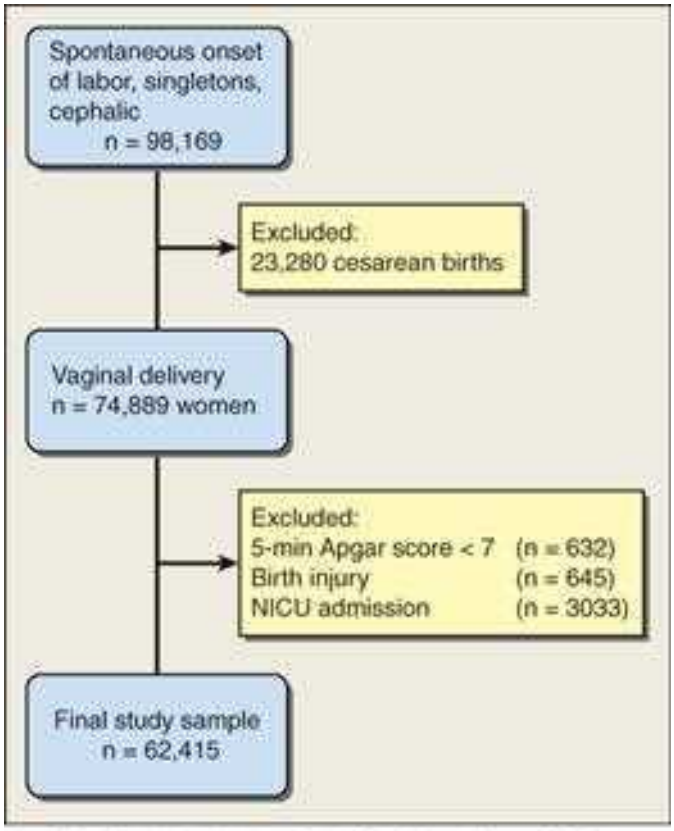
A third instruction addresses the cervical dilation threshold that serves to herald active labor. Namely, a cervical dilation of 6 cm—not 4 cm—is now the recommended threshold. Thus, before this threshold, standards for active-phase progress should not be applied.

A fourth stipulation notes that cesarean delivery for active-phase arrest "should be reserved for women at or beyond 6 cm of dilation with ruptured membranes who fail to progress despite 4 hours of adequate uterine activity, or at least 6 hours of oxytocin administration with inadequate contractions and no cervical change."

According to the Consensus Committee (2016), the "6-cm rule" stems from labor data from the Consortium on Safe Labor study (Zhang, 2010). This study derived its numbers from a retrospective observational dataset built from abstracted labor and delivery information from 19 hospitals across the United States. Various statistical methods and heavy manipulations of these numbers were used (Cohen, 2015b). As shown in Figure 23-2, a total of 62,415 women were analyzed after excluding all women with cesarean deliveries or asphyxiated newborns. The Consensus Committee (2016) was explicit that "the Consortium on Safe Labor data, rather than the standards proposed by Friedman should inform evidence-based labor management." Described in Chapter 21 (First Stage of Labor), the latter are labor curves that have been used since first proposed by Friedman (1955).

FIGURE 23-2

Study cohort for the analysis of spontaneous labor in the Consortium on Safe Labor study. NICU = neonatal intensive care unit. (Data from Zhang, 2010.)



Critics of the Consensus Committee (2016) recommendations note that the Consortium on Safe Labor data were derived from clinical settings with a net cesarean rate of 30 percent. Thus, adherence to the new recommendations may fail to achieve desired cesarean rate reductions. Also, the study lacked a focus on neonatal safety, given that all the asphyxiated neonates were excluded. Supporters note that the study of prolonged first-stage labors by Cheng and coworkers (2010) found higher rates of cesarean delivery and chorioamnionitis but not higher rates of neonatal morbidity. However, Harper and associates (2014) analyzed maternal and neonatal adverse outcomes related to first-stage labor lengths. In 5030 women, first-stage labor durations were divided into those <90th percentile or those ≥90th percentile, with incremental increases thereafter. These authors concluded that a longer first-stage labor was associated with maternal and neonatal complications and that these should be balanced against the risks of cesarean delivery. This concern for adverse fetal and maternal effects resulting from the new Consensus Committee guidelines was echoed by Cohen and Friedman (2015a,b).

Another caveat notes that the efficacy of these recommendations to achieve their primary goal is limited. In support, one retrospective cohort study of 200 women undergoing induction or augmentation before and 200 after guideline changes found a cesarean delivery rate drop from 35 to 25 percent (Wilson-Leedy, 2016). However, although the study was not powered to assess adverse neonatal outcomes, nonsignificant but higher rates of umbilical artery gases with pH <7 and base deficit >12 mmol/L were noted in the postguideline group (Marte, 2016). In another evaluation of outcomes before and after guideline implementation, cesarean delivery rates were unchanged. Overall, there were no associations between length of arrest and maternal or neonatal morbidity, but neonatal respiratory morbidity rates rose in newborns of women with longer periods of arrested dilation (Rosenbloom, 2017). Thus, additional studies are needed to define risks and benefits of the new guidelines.

Background for the 6-cm Rule

Review of selected publications helps explain the Consensus Committee (2016) evolution to a 6-cm rule. First, Zhang and coworkers (2002) compared study populations from one report by Friedman (1955) with one from 1992 to 1996 at Tripler Army Hospital, Hawaii (Table 23-3). The Friedman labor curves reflected women in spontaneous labor with infrequent use of neuraxial labor analgesia or oxytocin augmentation. In contrast, in the Tripler cohort, approximately 50 percent of women had neuraxial analgesia or augmentation. The rate of cervical change for the ensuing hour at each cervical dilation between 2 and 9 cm in the Tripler group is shown in Table 23-4. Progress is slow between 4 and 6 cm but accelerates thereafter. This could reasonably be interpreted as the active phase beginning at 6 cm. Shown in Figure 23-3 are the labor curves for Friedman (1955) compared to the Tripler cohort. These differ in a flattening of the active phase beginning at 3 to 4 cm in the Tripler group. This is consistent with the labor results obtained in the Safe Labor Consortium study (Zhang, 2010). Namely, the 6-cm rule for active labor derives from a slowing of the rate or flattening of the slope of cervical change in first-stage labor.

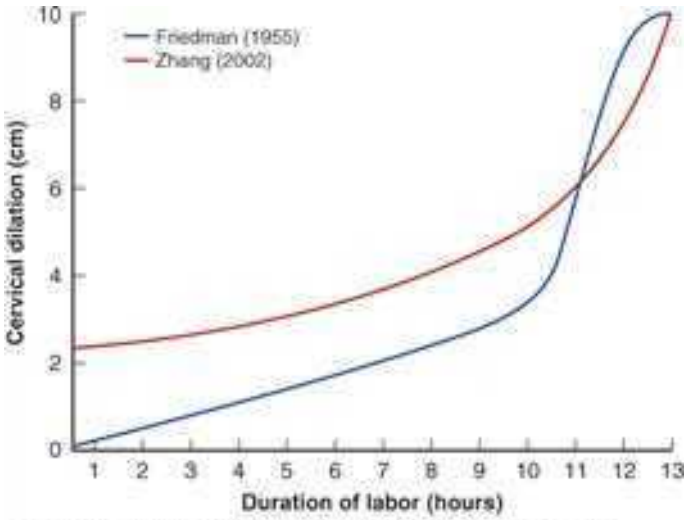
FIGURE 23-3

Cervical dilation curves. (From Friedman (1955) and Zhang (2002).)



Neuraxial analgesia delays the active phase of spontaneous labor and flattens the slope. For example, Gambling and associates (1998) compared combined spinal epidural (CSE) labor analgesia against intermittent intravenous (IV) boluses of 50 mg meperidine in 1223 nulliparas in spontaneous labor at term. The active phase of labor was diagnosed when cervical dilation was 4 cm in the presence of regular uterine contractions. As shown in Table 23-5, mean cervical dilation at first pain relief was 5 cm in both study groups. Oxytocin augmentation rates were significantly greater in the CSE group. Also, the first analgesia-to-delivery interval was lengthened (5 versus 4 hours). However, cesarean delivery rates did not differ significantly.

TABLE 23-5

Combined Spinal Epidural (CSE) Analgesia Compared with Meperidine for Nulliparas in Spontaneous Labor at Term

Labor Progress	CSE (n = 616)	Meperidine[a] (n = 607)	*p* value
Cervical dilation at first analgesia[b]	5	5	NS
Postanalgesia oxytocin augmentation[c]	132 (22%)	97 (16%)	.01
First analgesia to delivery (hr)[d]	5.0 ± 3.3	4.0 ± 3.1	.0001
Cesarean delivery[c]	39 (6%)	34 (6%)	NS

Data from Gambling, 1998.

Importantly, the effect of neuraxial analgesia to slow active-phase labor should not negatively affect use of neuraxial pain relief. As described in Chapter 25 (Effects on Labor), investigators at Parkland Hospital completed five randomized trials involving a total of 2703 nulliparas in spontaneous labor at term (Sharma, 2004). Various neuraxial techniques were compared with meperidine for pain relief. First-stage labor was significantly lengthened with neuraxial analgesia (8.1 versus 6.6 hours) but cesarean delivery rates for dystocia were unaffected (9.1 versus 8.1 percent).

In sum, neuraxial analgesia slows the active phase of first-stage labor. This currently is empirically corrected by augmentation of uterine contractions. Thus, recommendations of the Consensus Committee regarding protraction disorders are correct. Second, the Consensus Committee (2016) suggests that cesarean deliveries for dystocia are being done before 6 cm cervical dilation. However, there is good reason to believe that all of the Committee's first-stage recommendations are actually already empirically in use but are concurrent with an overall cesarean delivery rate in excess of 30 percent. For example, Table 23-6 lists labor characteristics in 9000 women with primary cesarean deliveries for dystocia at 13 university hospitals between 1999 and 2000 (Alexander, 2003). Notably, the median cervical dilation at the time of cesarean for dystocia was 6 cm. Moreover, Figure 23-4 depicts primary cesarean delivery rates for dystocia at Parkland Hospital between 1988 and 2017. The rate has not changed significantly in 28 years. Thus, Consensus Committee (2016) guidelines may fail to prevent additional cesareans for dystocia. Again, additional studies are needed.

TABLE 23-6

9000 Women Undergoing Primary Cesarean Delivery for Dystocia

Labor Characteristic	Percentage of Women with Noted Characteristic	Median (1st, 3rd quartiles)
Nulliparous	83%	—
Ruptured membranes	99%	—
Oxytocin stimulation	99%	—
Intrauterine pressure catheter	85%	—
≥200 Montevideo units	62%	—
Active phase labor (>4 cm dilation)	92%	—
Cervical dilation	—	6 cm (5, 8)
Augmentation to delivery time	—	9.3 hr (6, 13)

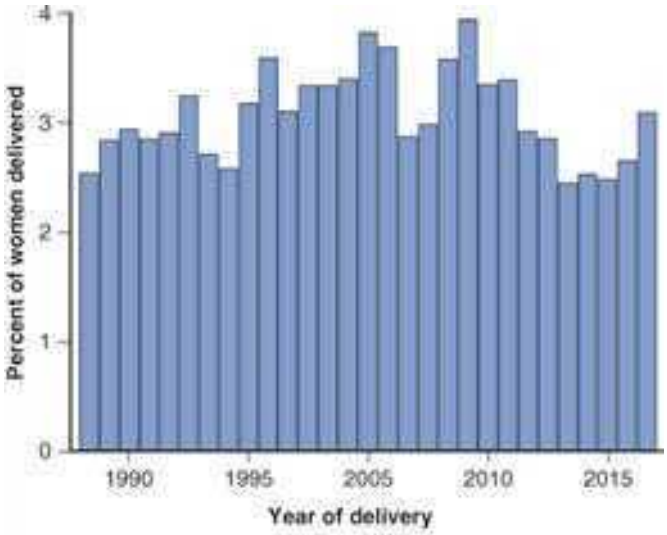
Primary caesarean delivery rates for dystocia in low-risk women at term at Parkland Hospital from 1988 to 2017.



Second-Stage Descent Disorders

Fetal descent largely follows complete dilation. Moreover, the second stage incorporates many of the cardinal movements necessary for the fetus to negotiate the birth canal (Chap. 22, Descent). Accordingly, disproportion of the fetus and pelvis frequently becomes apparent during second-stage labor.

Similar to first-stage labor, time boundaries have been supported to limit second-stage duration to minimize adverse maternal and fetal outcomes. The second stage in nulliparas is limited to 2 hours and extended to 3 hours when regional analgesia is used. For multiparas, 1 hour is the limit, extended to 2 hours with regional analgesia.

Cohen (1977) investigated the fetal effects of second-stage labor length at Beth Israel Hospital. He included 4403 term nulliparas in whom electronic fetal heart rate monitoring was performed. The neonatal mortality rate was not increased in women whose second-stage labor exceeded 2 hours. Epidural analgesia was used commonly, and this likely accounted for the large number of pregnancies with a prolonged second stage. These data influenced decisions to permit an additional hour for the second stage when regional analgesia is used.

Menticoglou and coworkers (1995a,b) also challenged the prevailing dicta on second-stage duration. Their concern stemmed from grave neonatal injuries associated with forceps rotations to shorten second-stage labor. As a result, they allowed a longer second stage to decrease the operative vaginal delivery rate. Between 1988 and 1992, second-stage labor exceeded 2 hours in a fourth of 6041 nulliparas at term. Labor epidural analgesia was used in 55 percent. The length of the second stage, even in those lasting up to 6 hours or more, was not related to neonatal outcome. These results were attributed to careful use of electronic monitoring and

scalp pH measurements. These investigators concluded that there is no compelling reason to intervene with a possibly difficult forceps or vacuum extraction because a certain number of hours have elapsed. They observed, however, that after 3 hours in the second stage, delivery by cesarean or other operative method increased progressively. By 5 hours, the prospects for spontaneous delivery in the subsequent hour were only 10 to 15 percent.

Newer guidelines have been promoted by the Consensus Committee (2016) for second-stage labor. These recommend allowing a nullipara to push for at least 3 hours and a multipara to push for at least 2 hours before second-stage labor arrest is diagnosed. One caveat is that maternal and fetal status should be reassuring. These authors provide options to these times before cesarean delivery is performed. Namely, longer durations may be appropriate as long as progress is documented. Also, a specific maximal length of time spent in second-stage labor beyond which all women should undergo operative delivery has not been identified.

Intuitively, the goal to lower cesarean delivery rates is best balanced with one to ensure neonatal safety. And, it is problematic that no robust data on neonatal outcomes support the safety of allowing prolonged second-stage labor. Data from many evaluations reveal that serious newborn consequences attend second-stage labors longer than 3 hours (Allen, 2009; Bleich, 2012; Laughon, 2014; Leveno, 2016; Rosenbloom, 2017). Other data, when adjusted for labor variables, show no difference in neonatal complications for these longer second stages (Cheng, 2004; Le Ray, 2009; Rouse, 2009). Grobman and colleagues (2016) have argued that the absolute number of such adverse outcomes is small and "overall outcomes remain good." That said, some of the complications are severe. Thus, to fully ascertain specific effect of these guidelines on morbidity rates, randomized controlled trials are needed.

It is possible that prolonged first-stage labor presages that with the second stage. Nelson and associates (2013) studied the relationships between the lengths of the first and second stages of labor in 12,523 nulliparas at term delivered at Parkland Hospital. The second stage significantly lengthened concomitantly with increasing first-stage duration. The 95th percentile was 15.6 and 2.9 hours for the first and second stages, respectively. Women with first stages lasting longer than 15.6 hours (>95th percentile) had a 16-percent rate of second-stage labor lasting 3 hours (95th percentile). This compared with a 4.5-percent rate of prolonged second stages in women with first-stage labors lasting <95th percentile.

Maternal Pushing Efforts

With full cervical dilation, most women cannot resist the urge to "bear down" or "push" each time the uterus contracts (Chap. 22, Labor Management Protocols). The combined force created by contractions of the uterus and abdominal musculature propels the fetus downward. At times, force created by abdominal musculature is compromised sufficiently to slow or even prevent spontaneous vaginal delivery. Heavy sedation or regional analgesia may reduce the reflex urge to push and may impair the ability to contract abdominal muscles effectively. In other instances, the inherent urge to push is overridden by the intense pain created by bearing down. Two approaches to second-stage pushing in women with epidural analgesia have yielded contradictory results. The first advocates pushing forcefully with contractions after complete dilation, regardless of the urge to push. With the second, analgesia infusion is stopped and pushing begins only after the woman regains the sensory urge to bear down. Fraser and coworkers (2000) found that delayed pushing reduced difficult operative deliveries, whereas Manyonda and associates (1990) reported the opposite. Hansen and colleagues (2002) randomly assigned 252 women with epidural analgesia to one of the two approaches. No adverse maternal or neonatal outcomes were linked to delayed pushing despite significantly prolonging second-stage labor. Plunkett and coworkers (2003), in a similar study, confirmed these findings.

Fetal Station at Labor Onset

Descent of the leading edge of the presenting part to the level of the ischial spines (0 station) is defined as engagement. A higher station at the onset of labor is significantly linked with subsequent dystocia (Friedman, 1965, 1976; Handa, 1993). Roshanfekr and associates (1999) analyzed fetal station in 803 nulliparas at term in active labor. At admission, the third with the fetal head at or below 0 station had a 5-percent cesarean delivery rate. This compared with a 14-percent rate for those with higher stations. The prognosis for dystocia, however, was not related to incrementally higher fetal head stations above the pelvic midplane (0 station). Importantly, 86 percent of nulliparous women without fetal head engagement at diagnosis of active labor delivered vaginally. These observations apply especially for parous women because the head typically descends later in labor.

Risks for Uterine Dysfunction

Various labor factors have been implicated as causes of uterine dysfunction. As described, neuraxial analgesia can slow labor and has been associated with lengthening both first and second stages of labor and slowing the rate of fetal descent.

Chorioamnionitis is associated with prolonged labor, and some clinicians have suggested that this maternal intrapartum infection itself contributes to abnormal uterine activity. Satin and coworkers (1992) studied the effects of chorioamnionitis on oxytocin stimulation in 266 pregnancies. Infection diagnosed late in labor was found to be a marker of cesarean delivery performed for dystocia. Specifically, 40 percent of women developing chorioamnionitis after requiring oxytocin for dysfunctional labor later required cesarean delivery for dystocia. However, this was not a marker in women diagnosed as having chorioamnionitis early in labor. It is likely that uterine infection in this clinical setting is a consequence of dysfunctional, prolonged labor rather than a cause of dystocia.

PREMATURELY RUPTURED MEMBRANES AT TERM

Membrane rupture at term without spontaneous uterine contractions complicates approximately 8 percent of pregnancies. In the past, labor stimulation was initiated if contractions did not begin after 6 to 12 hours. Practice-changing research included that of Hannah (1996) and Peleg (1999) and their associates, who enrolled a total of 5042 pregnancies with ruptured membranes in a randomized investigation. They measured the effects of induction versus expectant management and also compared induction using intravenous oxytocin with that using prostaglandin E_2 gel. There were approximately 1200 pregnancies in each of the four study arms. They concluded that labor induction with intravenous oxytocin was preferred management. This was based on significantly fewer intrapartum and

postpartum infections in women whose labor was induced. There were no significant differences in cesarean delivery rates. Subsequent analysis by Hannah and coworkers (2000) indicated higher rates of adverse outcomes when expectant management at home was compared with in-hospital observation. Mozurkewich and associates (2009) reported lower rates of chorioamnionitis, metritis, and neonatal intensive care unit admissions for women with term ruptured membranes whose labors were induced compared with those managed expectantly. At Parkland Hospital, labor is induced soon after admission when ruptured membranes are confirmed at term. In those with hypotonic contractions or with advanced cervical dilation, oxytocin is selected to lower potential hyperstimulation risk. In those with an unfavorable cervix and no or few contraction, prostaglandin E_1 (misoprostol) is chosen to promote cervical ripening and contractions. The benefit of prophylactic antibiotics in women with ruptured membranes before labor at term is unclear (Passos, 2012). However, in those with membranes ruptured longer than 18 hours, antibiotics are instituted for group B streptococcal infection prophylaxis (Chap. 64, GBS Vaccine).

PRECIPITOUS LABOR AND DELIVERY

Labor can be too slow, but it also can be abnormally rapid. *Precipitous labor and delivery* is extremely rapid labor and delivery. It may result from an abnormally low resistance of the soft parts of the birth canal, from abnormally strong uterine and abdominal contractions, or rarely from the absence of painful sensations and thus a lack of awareness of vigorous labor.

Precipitous labor terminates in expulsion of the fetus in less than 3 hours. Using this definition, 25,260 live births—3 percent—were complicated by precipitous labor in the United States in 2013 (Martin, 2015). Despite this incidence, little published information describes maternal and perinatal outcomes.

For the mother, precipitous labor and delivery seldom are accompanied by serious maternal complications if the cervix is effaced appreciably and compliant, if the vagina has been stretched previously, and if the perineum is relaxed. Conversely, vigorous uterine contractions combined with a long, firm cervix and a noncompliant birth canal may lead to uterine rupture or extensive lacerations of the cervix, vagina, vulva, or perineum (Sheiner, 2004). It is in these latter circumstances that *amnionic-fluid embolism* most likely develops (Chap. 41, General Management). Precipitous labor is frequently followed by uterine atony. *The uterus that contracts with unusual vigor before delivery is likely to be hypotonic after delivery.* In one report of 99 term pregnancies, short labors were more common in multiparas who typically had contractions at intervals less than 2 minutes. Precipitous labors have been linked to cocaine abuse and associated with placental abruption, meconium, postpartum hemorrhage, and low Apgar scores (Mahon, 1994).

For the neonate, adverse perinatal outcomes from rapid labor may be increased considerably for several reasons. The tumultuous uterine contractions, often with negligible intervals of relaxation, prevent appropriate uterine blood flow and fetal oxygenation. Resistance of the birth canal may rarely cause intracranial trauma. Acker and coworkers (1988) reported that Erb or Duchenne brachial palsy was associated with such labors in a third of cases. Finally, during an unattended birth, the newborn may fall to the floor and be injured, or it may need resuscitation that is not immediately available.

As treatment, analgesia is unlikely to modify these unusually forceful contractions to a significant degree. The use of tocolytic agents such as magnesium sulfate or terbutaline is unproven in these circumstances. Use of general anesthesia with agents that impair uterine contractibility such as isoflurane is often excessively heroic. Certainly, any oxytocin being administered should be stopped immediately.

FETOPELVIC DISPROPORTION

Pelvic Capacity

Fetopelvic disproportion arises from diminished pelvic capacity, from abnormal fetal size or presentation, or more usually from both. The pelvic inlet, midpelvis, or pelvic outlet may be contracted solely or in combination. Any contraction of the pelvic diameters that diminishes pelvic capacity can create dystocia during labor. Normal pelvic dimensions are additionally discussed and illustrated in Chapter 2 (Planes and Diameters of the Pelvis).

Contracted Inlet

Using clinical measures, it is important to identify the shortest anteroposterior diameter through which the fetal head must pass. Before labor, the fetal biparietal diameter averages from 9.5 to as much as 9.8 cm. Therefore, it might prove difficult or even impossible for some fetuses to pass through a pelvic inlet that has an anteroposterior diameter <10 cm. Mengert (1948) and Kaltreider (1952), employing x-ray pelvimetry, demonstrated that the incidence of difficult deliveries rises when either the anteroposterior diameter of the inlet is <10 cm or the transverse diameter is <12 cm. As expected, when both diameters are contracted, dystocia rates are much greater than when only one is contracted. Either of these measures is used to consider a pelvis contracted.

The anteroposterior diameter of the inlet, which is the obstetrical conjugate, is commonly approximated by manually measuring the diagonal conjugate, which is approximately 1.5 cm greater. Ascertainment of these measures is described in Chapter 2 (Planes and Diameters of the Pelvis). Therefore, inlet contraction usually is defined as a diagonal conjugate <11.5 cm.

A small woman is likely to have a small pelvis, but she is also likely to have a small neonate. Thoms (1937) studied 362 nulliparas and found that the mean birthweight of their offspring was significantly lower—280 g—in women with a small pelvis than in those with a medium or large pelvis.

Normally, cervical dilation is aided by hydrostatic action of the unruptured membranes or after their rupture, by direct application of the presenting part against the cervix. In contracted pelves, however, because the head is arrested in the pelvic inlet, the entire force exerted by the uterus acts directly on the portion of membranes that contact the dilating cervix. Consequently, early spontaneous rupture of the membranes is more likely.

After membrane rupture, absent pressure by the head against the cervix and lower uterine segment predisposes to less effective contractions. Hence, further dilation may proceed very slowly or not at all. Cibils and Hendricks (1965) reported that the mechanical adaptation of the fetal passenger to the bony passage plays an

important part in determining the efficiency of contractions. The better the adaptation, the more efficient the contractions. Thus, cervical response to labor provides a prognostic view of labor outcome in women with inlet contraction.

A contracted inlet also plays an important part in the production of abnormal presentations. In nulliparas with normal pelvic capacity, the presenting part at term commonly descends into the pelvic cavity before labor onset. When the inlet is contracted considerably or there is marked asynclitism, descent usually does not take place until after labor onset, if at all. Cephalic presentations still predominate, but the head floats freely over the pelvic inlet or rests more laterally in one of the iliac fossae. Accordingly, very slight influences may cause the fetus to assume other presentations. In women with contracted pelves, face and shoulder presentations are encountered three times more frequently, and the cord prolapses four to six times more often.

Contracted Midpelvis

This finding is more common than inlet contraction. It frequently causes transverse arrest of the fetal head, which potentially can lead to a difficult midforceps operation or to cesarean delivery.

The obstetrical plane of the midpelvis extends from the inferior margin of the symphysis pubis through the ischial spines and touches the sacrum near the junction of the fourth and fifth vertebrae. A transverse line theoretically connecting the ischial spines divides the midpelvis into anterior and posterior portions (Fig. 2-16). The former is bounded anteriorly by the lower border of the symphysis pubis and laterally by the ischiopubic rami. The posterior portion is bounded dorsally by the sacrum and laterally by the sacrospinous ligaments, forming the lower limits of the sacrosciatic notch.

Average midpelvis measurements are as follows: *transverse,* or interischial spinous, 10.5 cm; *anteroposterior,* from the lower border of the symphysis pubis to the junction of S_{4-5}, 11.5 cm; and *posterior sagittal*, from the midpoint of the interspinous line to the same point on the sacrum, 5 cm. The definition of midpelvic contractions has not been established with the same precision possible for inlet contractions. Even so, the midpelvis is likely contracted when the sum of the interspinous and posterior sagittal diameters of the midpelvis—normally, 10.5 plus 5 cm, or 15.5 cm—falls to 13.5 cm or less. This concept was emphasized by Chen and Huang (1982) in evaluating possible midpelvic contraction. Midpelvic contraction is suspected whenever the interspinous diameter is <10 cm. When it measures <8 cm, the midpelvis is contracted.

Although no precise manual method permits measure of midpelvic dimensions, a suggestion of contraction sometimes can be inferred if the spines are prominent, the pelvic sidewalls converge, or the sacrosciatic notch is narrow. Moreover, Eller and Mengert (1947) noted that the relationship between the intertuberous and interspinous diameters of the ischium is sufficiently constant that narrowing of the interspinous diameter can be anticipated when the intertuberous diameter is narrow. A normal intertuberous diameter, however, does not always exclude a narrow interspinous diameter.

Contracted Outlet

This finding usually is defined as an interischial tuberous diameter of 8 cm or less. The pelvic outlet may be roughly likened to two triangles, with the interischial tuberous diameter constituting the base of both. The sides of the anterior triangle are the pubic rami, and its apex is the inferoposterior surface of the symphysis pubis. The posterior triangle has no bony sides but is limited at its apex by the tip of the last sacral vertebra—not the tip of the coccyx. Diminution of the intertuberous diameter with consequent narrowing of the anterior triangle must inevitably force the fetal head posteriorly. Floberg and associates (1987) reported that outlet contractions were found in almost 1 percent of more than 1400 unselected nulliparas with term pregnancies. A contracted outlet may cause dystocia not so much by itself but by an often-associated midpelvic contraction. *Outlet contraction without concomitant midplane contraction is rare.*

Although the disproportion between the fetal head and the pelvic outlet is not sufficiently great to give rise to severe dystocia, it may play an important part in perineal tears. With increased narrowing of the pubic arch, the occiput cannot emerge directly beneath the symphysis pubis but is forced farther down upon the ischiopubic rami. The perineum, consequently, becomes increasingly distended and thus exposed to risk of laceration.

Pelvic Fractures

Vallier (2012) reviewed experiences with pelvic fractures and pregnancy. Trauma from automobile collisions was the most common cause. Moreover, they note that fracture pattern, minor malalignment, and retained hardware are not absolute indications for cesarean delivery. In determining suitability for vaginal delivery, fracture healing requires 8 to 12 weeks and thus recent fracture merits cesarean delivery (Amorosa, 2013). A history of pelvic fracture warrants careful review of previous radiographs and possible imaging pelvimetry later in pregnancy.

Pelvic Capacity Estimation

The techniques for clinical evaluation using digital examination of the bony pelvis during labor are described in detail in Chapter 2 (Planes and Diameters of the Pelvis). The value of radiological imaging to assess pelvic capacity has also been examined. First, with x-ray pelvimetry alone, the prognosis for successful vaginal delivery in any given pregnancy with cephalic presentation cannot be established (Mengert, 1948). Similarly, one systematic review found insufficient evidence to support the use of x-ray pelvimetry with cephalic presentations (Pattinson, 2017).

Advantages of pelvimetry with computed tomography (CT) compared with those of conventional x-ray pelvimetry include greater accuracy and easier performance. With either method, costs are comparable, and x-ray exposure is small (Chap. 46, X-Ray Dosimetry). Depending on the machine and technique employed, fetal doses with CT pelvimetry may range from 250 to 1500 mrad (Moore, 1989).

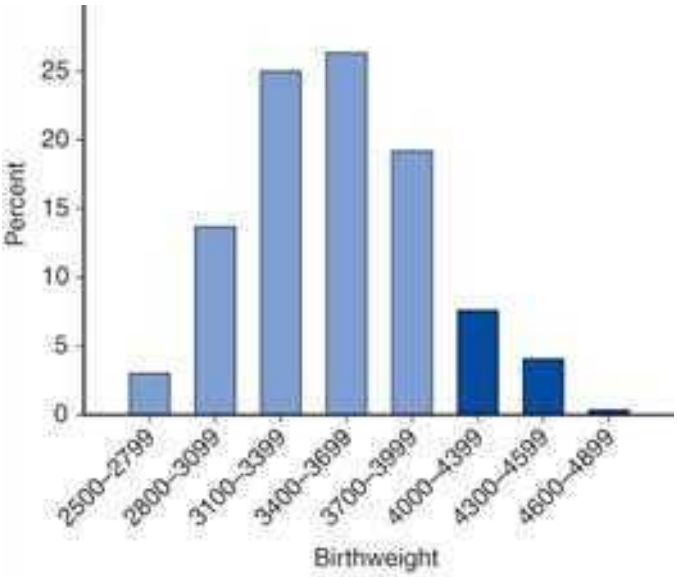
Advantages of magnetic resonance (MR) pelvimetry include lack of ionizing radiation, accurate measurements, complete fetal imaging, and the potential for evaluating soft tissue dystocia (McCarthy, 1986; Stark, 1985). Zaretsky and colleagues (2005) used MR imaging to measure pelvic and fetal head volume to identify those women at greatest risk of undergoing cesarean delivery for dystocia. Significant associations were found between some of the measures and cesarean delivery

for dystocia. However, these researchers could not with accuracy predict which individual woman would require cesarean delivery. Others have reported similar findings (Sporri, 1997).

Fetal Body and Head Size

Fetal size alone is seldom a suitable explanation for failed labor. Even with current technology, a fetal size threshold to predict fetopelvic disproportion is still elusive. Most cases of disproportion arise in fetuses whose weight is well within the range of the general obstetrical population. As shown in Figure 23-5, two thirds of neonates who required cesarean delivery after failed forceps delivery weighed <3700 g. Thus, other factors—for example, malposition of the head—obstruct fetal passage through the birth canal. These include asynclitism, occiput posterior position, and face or brow presentation.

FIGURE 23-5
Birthweight distribution of 362 newborns born by cesarean delivery after a failed forceps attempt at Parkland Hospital from 1989–1999. Only 12 percent (n = 44) of the newborns weighed >4000 g (*dark bars*).



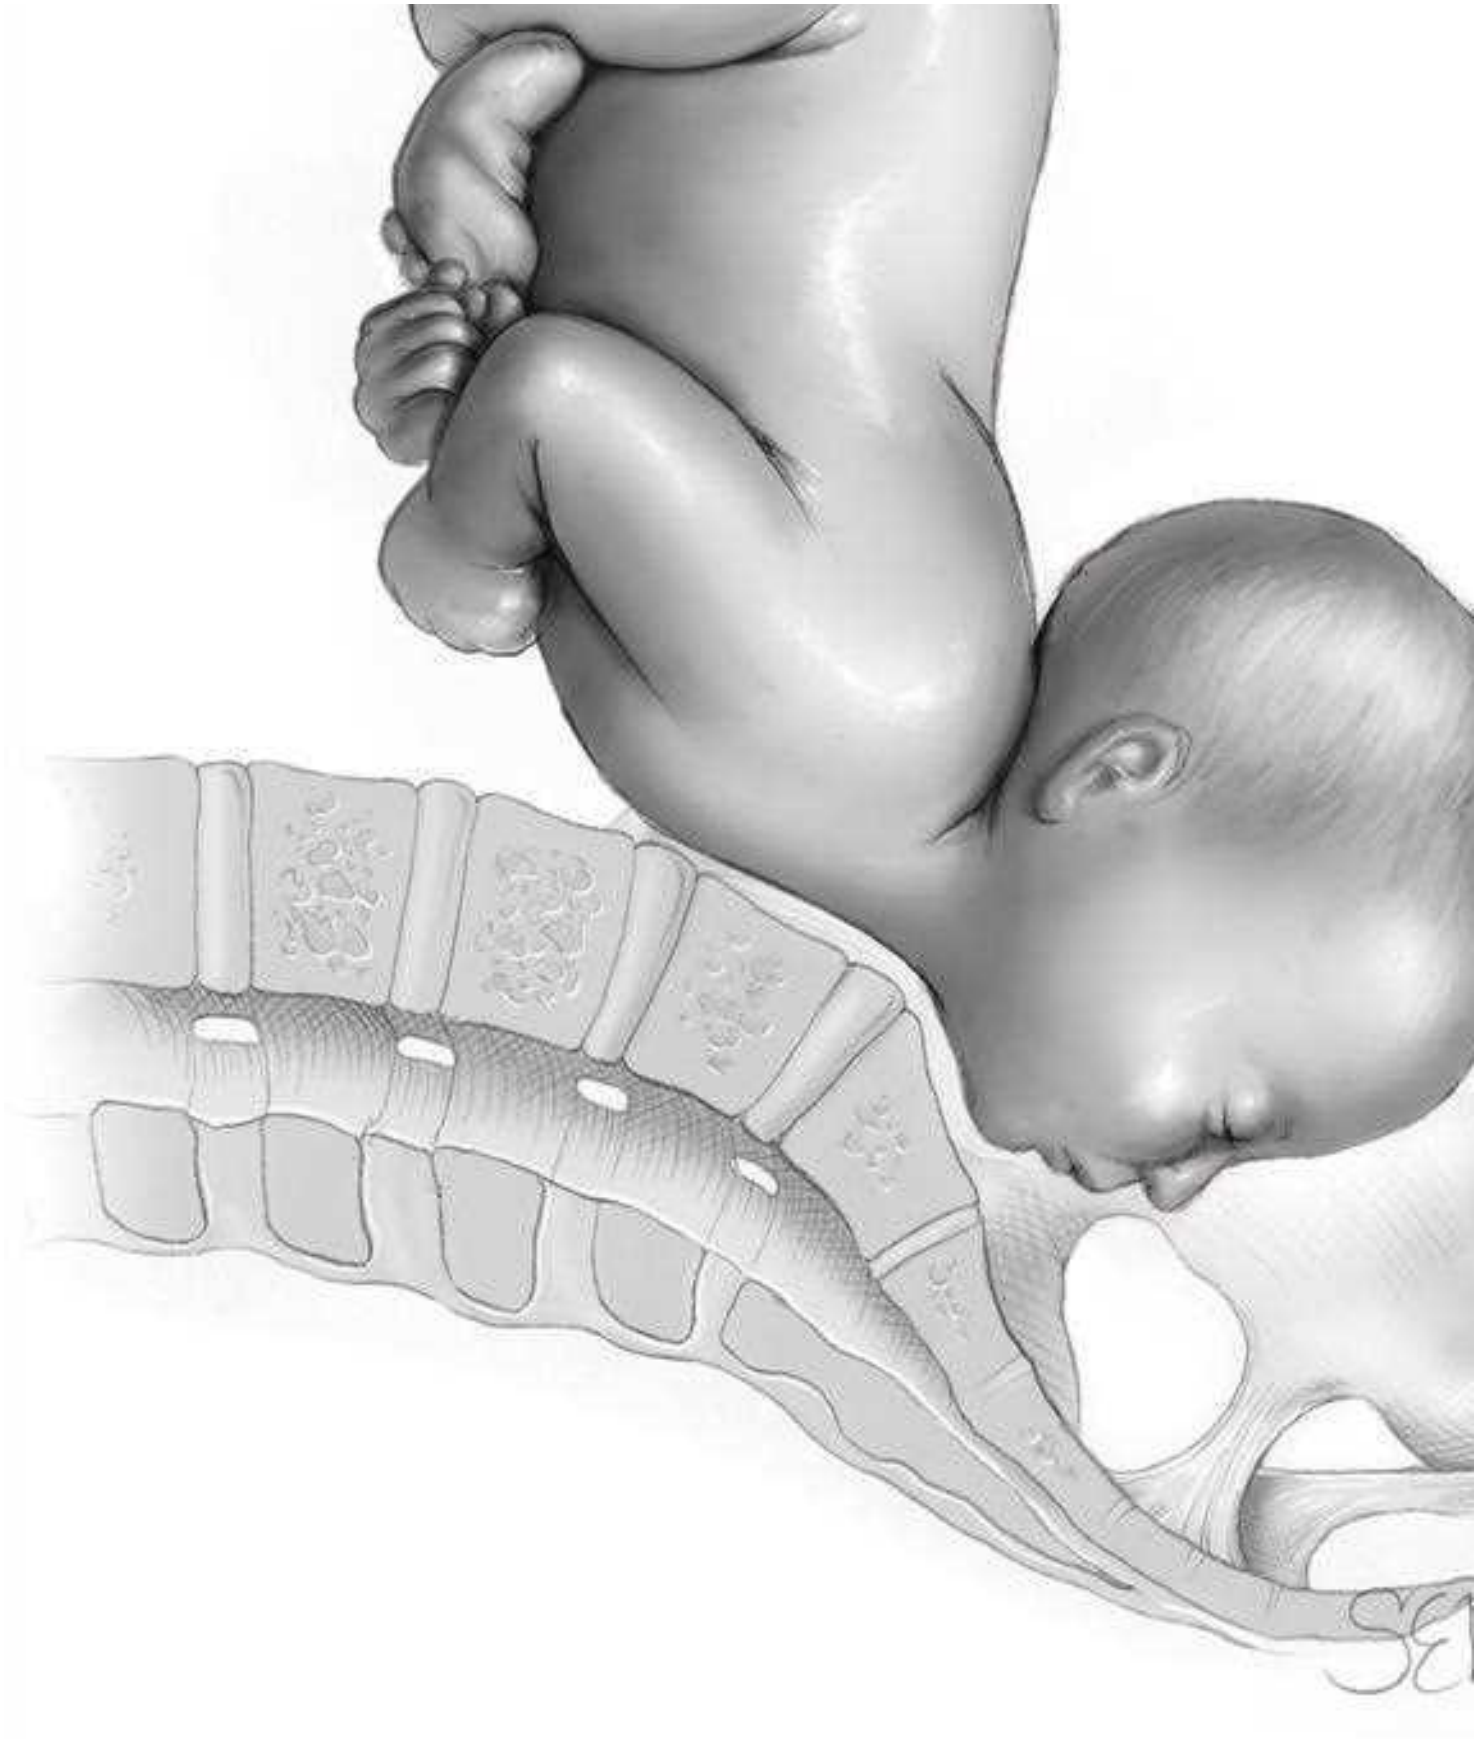
For fetal head size estimation, clinical and radiographical methods to predict fetopelvic disproportion have proved disappointing. Mueller (1885) and Hillis (1930) described a clinical maneuver to predict disproportion. The fetal brow and the suboccipital region are grasped through the abdominal wall with the fingers, and firm pressure is directed downward in the axis of the inlet. If no disproportion exists, the head readily enters the pelvis, and vaginal delivery can be predicted. Thorp and coworkers (1993) performed a prospective evaluation of this *Mueller-Hillis maneuver.* They found no relationship between failed descent during the maneuver and subsequent labor dystocia.

Measurements of fetal head diameters using plain radiographical techniques are not used because of parallax distortions. The biparietal diameter and head circumference can be measured sonographically, and investigators have attempted to use this information in the management of dystocia. Thurnau and colleagues (1991) used the *fetal-pelvic index* to identify labor complications. Unfortunately, the sensitivity of such measurements to predict cephalopelvic disproportion is poor (Ferguson, 1998; Korhonen, 2015). We believe that no current method of measurement satisfactorily predicts fetopelvic disproportion based on head size.

Face Presentation

With this presentation, the neck is hyperextended so that the occiput is in contact with the fetal back, and the chin (mentum) is presenting (Fig. 23-6). The fetal face may present with the chin (mentum) anteriorly or posteriorly, relative to the maternal symphysis pubis (Chap. 22, Diagnosis). Although some mentum posterior presentations persist, most convert spontaneously to anterior even in late labor (Duff, 1981). If not, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion of the fetal head necessary to negotiate the birth canal. Thus, a mentum posterior presentation is undeliverable except with a very preterm fetus.

FIGURE 23-6
Face presentation. The occiput is the longer end of the head lever. The chin is directly posterior. Vaginal delivery is impossible unless the chin rotates anteriorly.



Face presentation is diagnosed by vaginal examination and palpation of facial features. A breech may be mistaken for a face presentation. Namely, the anus may be mistaken for the mouth, and the ischial tuberosities for the malar prominences. Digital differentiation is described in Chapter 28 (Diagnosis). Radiographically, demonstration of the hyperextended head with the facial bones at or below the pelvic inlet is characteristic.

Cruikshank and White (1973) reported an incidence of 1 in 600, or 0.17 percent. As shown in Table 22-1, among more than 70,000 singleton newborns delivered at Parkland Hospital, approximately 1 in 2000 had a face presentation at delivery.

Etiology

Causes of face presentations are numerous and include conditions that favor extension or prevent head flexion. Preterm fetuses, with their smaller head dimensions, can engage before conversion to vertex position (Shaffer, 2006). In exceptional instances, marked enlargement of the neck or coils of cord around the neck may cause extension. Bashiri and associates (2008) reported that fetal malformations and hydramnios were risk factors for face or brow presentations. Anencephalic fetuses naturally present by the face.

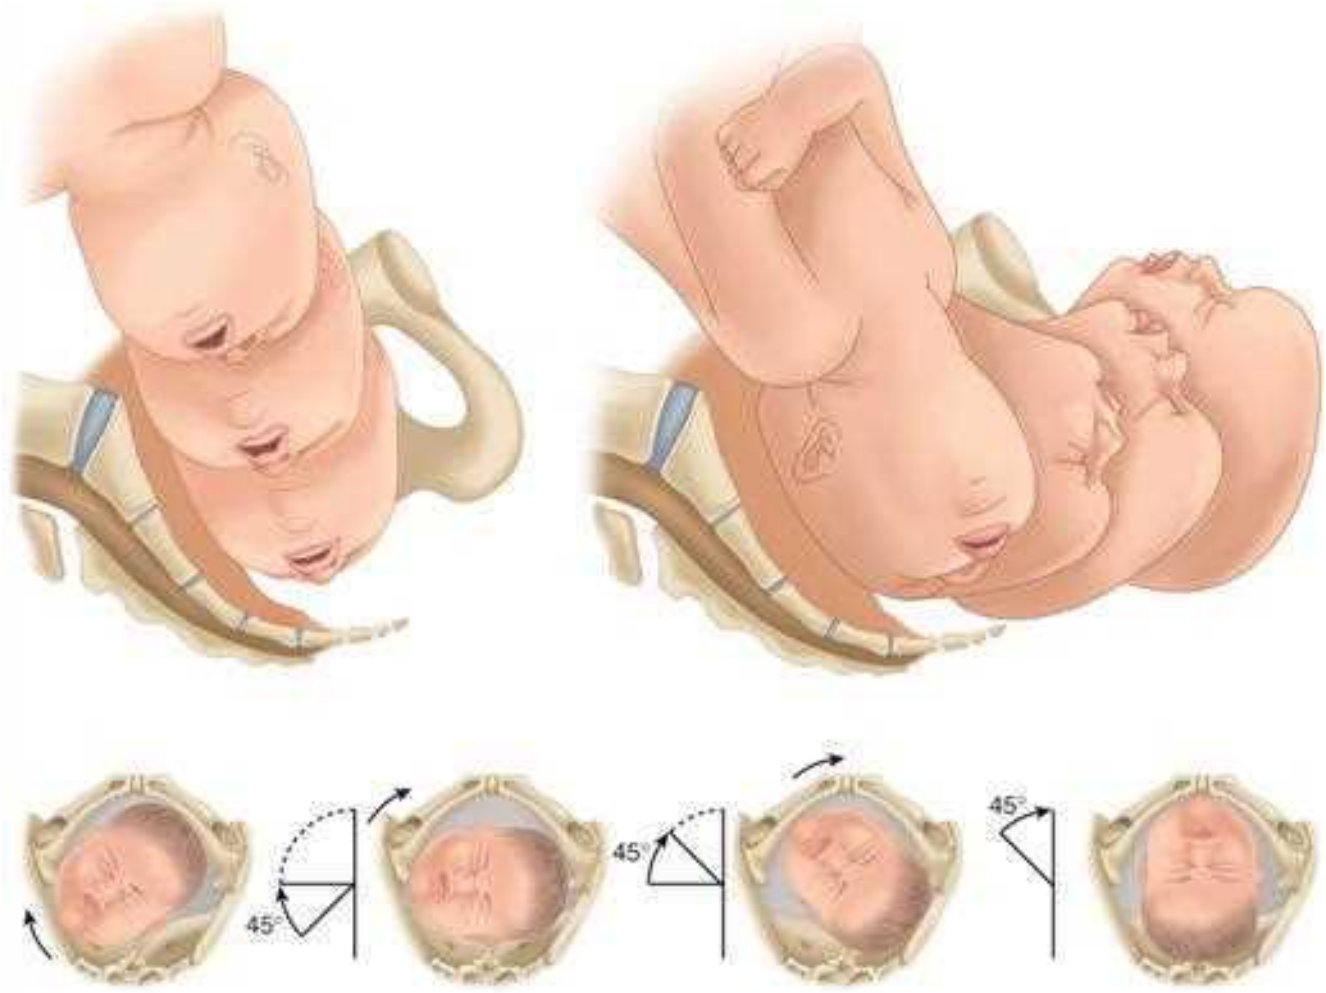
Extended neck positions develop more frequently when the pelvis is contracted or the fetus is very large. In a series of 141 face presentations studied by Hellman and coworkers (1950), the incidence of inlet contraction was 40 percent. This high incidence of pelvic contraction should be kept in mind when considering management.

High parity is a predisposing factor for face presentation (Fuchs, 1985). In these cases, a pendulous abdomen permits the back of the fetus to sag forward or laterally, often in the same direction in which the occiput points. This promotes extension of the cervical and thoracic spine.

Mechanism of Labor

Face presentations rarely are observed above the pelvic inlet. Instead, the brow generally presents early and is usually converted to present the face after further extension of the neck during descent. The mechanism of labor in these cases consists of the cardinal movements of descent, internal rotation, and flexion, and the accessory movements of extension and external rotation (Fig. 23-7). Descent is brought about by the same factors as in cephalic presentations. Extension results from the relation of the fetal body to the deflected head, which is converted into a two-armed lever, the longer arm of which extends from the occipital condyles to the occiput. When resistance is encountered, the occiput must be pushed toward the back of the fetus while the chin descends.

FIGURE 23-7
Mechanism of labor for right mentoposterior position with subsequent rotation of the mentum anteriorly and delivery.



The objective of internal rotation of the face is to bring the chin under the symphysis pubis. Only in this way can the neck traverse the posterior surface of the symphysis pubis. If the chin rotates directly posteriorly, the relatively short neck cannot span the anterior surface of the sacrum, which measures about 12 cm in length. Moreover, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion necessary to negotiate the birth canal.

Hence, as discussed earlier, birth of the head from a mentum posterior position is impossible unless the shoulders enter the pelvis at the same time, an event that is impossible except when the fetus is extremely small or macerated. Internal rotation results from the same factors as in vertex presentations.

After anterior rotation and descent, the chin and mouth appear at the vulva, the undersurface of the chin presses against the symphysis, and the head is delivered by flexion. The nose, eyes, brow (bregma), and occiput then appear in succession over the anterior margin of the perineum. After birth of the head, the occiput sags backward toward the anus. Next, the chin rotates externally to the side toward which it was originally directed, and the shoulders are born as in cephalic presentations.

Edema may sometimes significantly distort the face. At the same time, the skull undergoes considerable molding, manifested by an increase in length of the occipitomental diameter of the head.

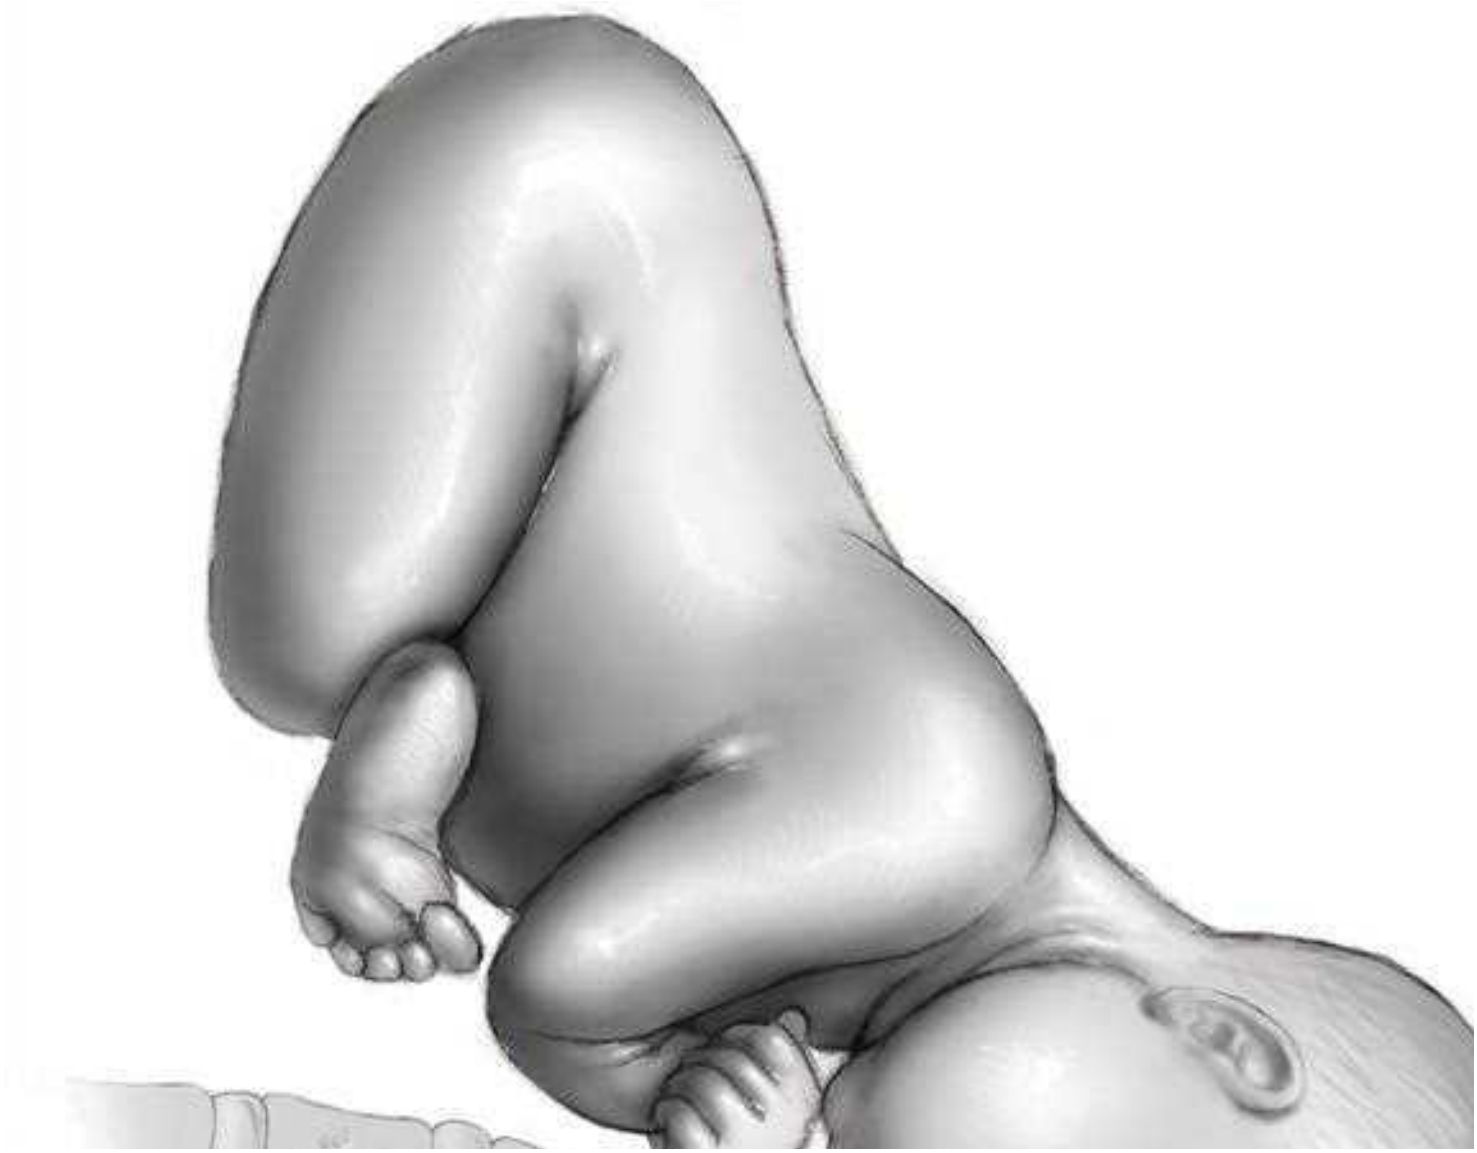
Management

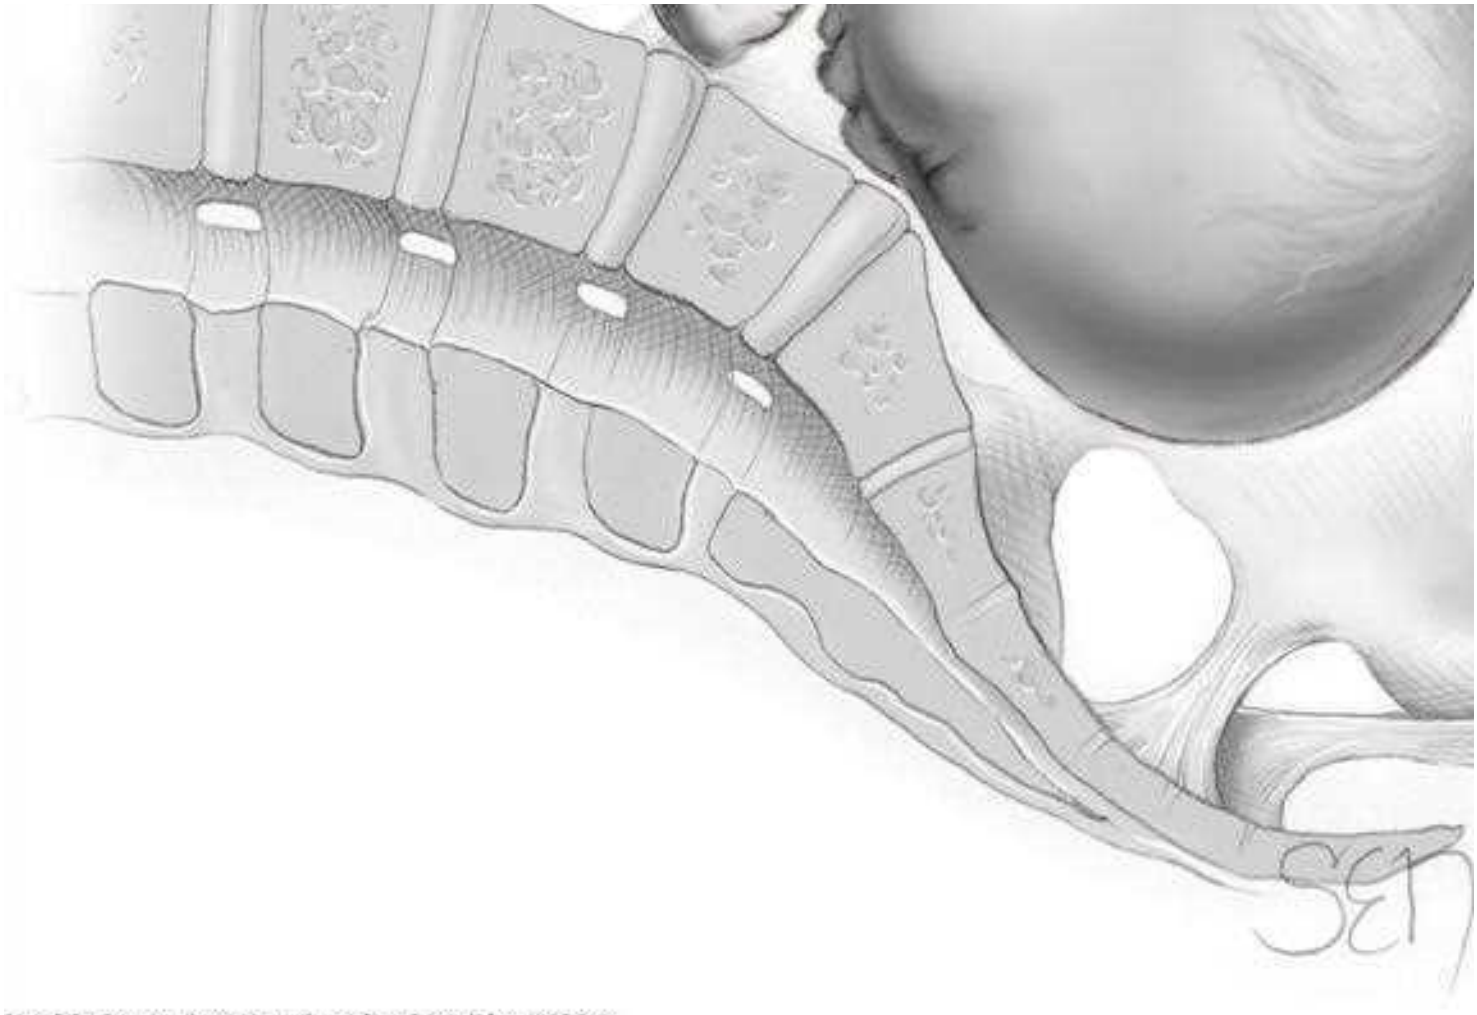
In the absence of a contracted pelvis and with effective labor, successful vaginal delivery usually will follow. Fetal heart rate monitoring is probably better done with external devices to avoid damage to the face and eyes. Because face presentations among term-size fetuses are more common when there is some degree of pelvic inlet contraction, cesarean delivery frequently is indicated. Attempts to convert a face presentation manually into a vertex presentation, manual or forceps rotation of a persistently posterior chin to a mentum anterior position, and internal podalic version and extraction are dangerous and should not be attempted. Low or outlet forceps delivery of a mentum anterior face presentation can be completed and is described in Chapter 29 (Vacuum Extraction).

Brow Presentation

This rare presentation is diagnosed when that portion of the fetal head between the orbital ridge and the anterior fontanel presents at the pelvic inlet. As shown in Figure 23-8, the fetal head thus occupies a position midway between full flexion (occiput) and extension (face). Except when the fetal head is small or the pelvis is unusually large, engagement of the fetal head and subsequent delivery cannot take place as long as the brow presentation persists.

FIGURE 23-8
Brow posterior presentation.





The causes of persistent brow presentation are the same as those for face presentation. A brow presentation is commonly unstable and often converts to a face or an occiput presentation (Cruikshank, 1973). The presentation may be recognized by abdominal palpation when both the occiput and chin can be palpated easily, but vaginal examination is usually necessary. The frontal sutures, large anterior fontanel, orbital ridges, eyes, and root of the nose are felt on vaginal examination, but neither the mouth nor the chin is palpable.

With a very small fetus and a large pelvis, labor is generally easy. With a larger fetus, it is usually difficult. This is because engagement is impossible until there is marked molding that shortens the occipitomental diameter or more commonly, until the neck either flexes to an occiput presentation or extends to a face presentation. The considerable molding essential for vaginal delivery of a persistent brow characteristically deforms the head. The caput succedaneum is over the forehead, and it may be so extensive that identification of the brow by palpation is impossible. In these instances, the forehead is prominent and squared, and the occipitomental diameter is diminished.

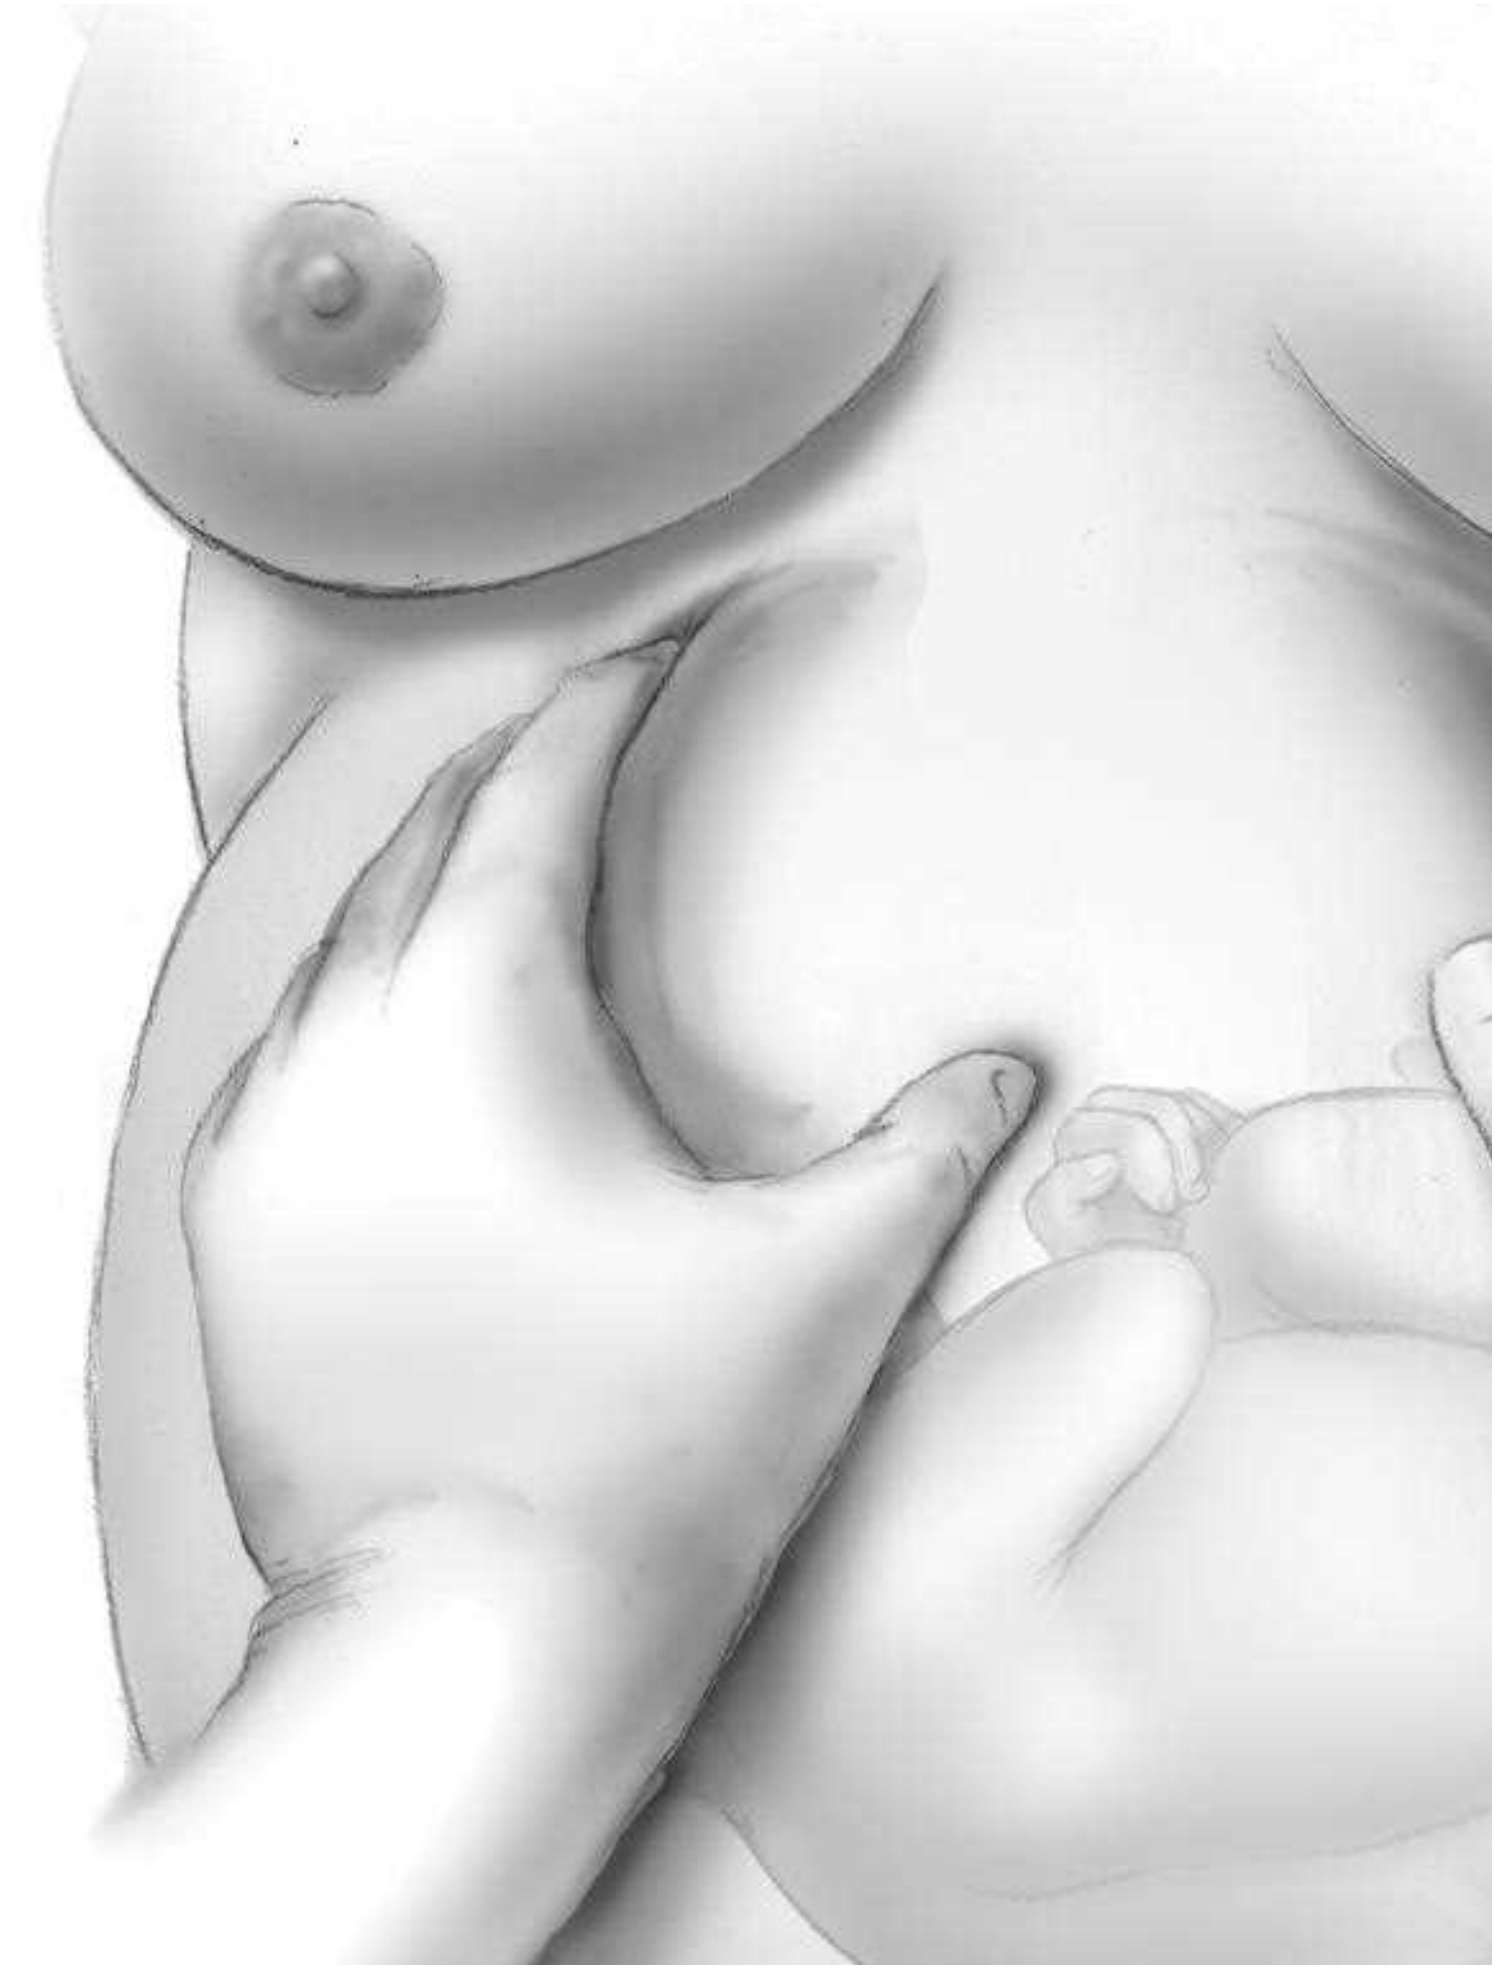
In transient brow presentations, the prognosis depends on the ultimate presentation. If the brow persists, prognosis is poor for vaginal delivery unless the fetus is small or the birth canal is large. Principles of management are the same as those for a face presentation.

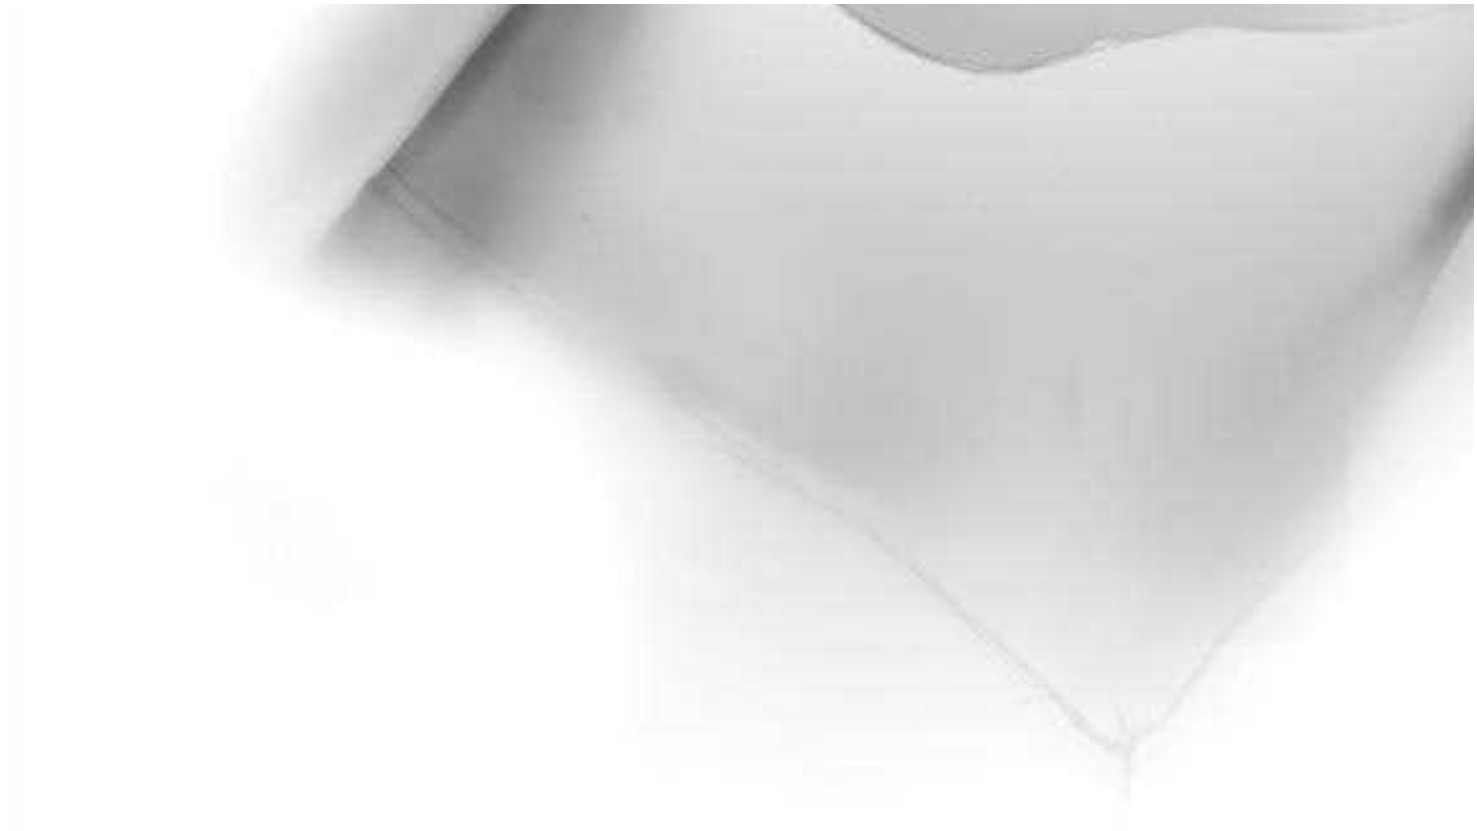
Transverse Lie

In this position, the long axis of the fetus is approximately perpendicular to that of the mother. When the long axis forms an acute angle, an *oblique lie* results. The latter is usually only transitory, because either a longitudinal or transverse lie commonly results when labor supervenes. For this reason, the oblique lie is called an *unstable lie* in Great Britain.

In a transverse lie, the shoulder is usually positioned over the pelvic inlet. The head occupies one iliac fossa, and the breech the other. This creates a *shoulder presentation* in which the side of the mother on which the acromion rests determines the designation of the lie as right or left acromial. And because in either position the back may be directed anteriorly or posteriorly, superiorly or inferiorly, it is customary to distinguish varieties as dorsoanterior and dorsoposterior (Fig. 23-9).

FIGURE 23-9
Leopold maneuver performed on a woman with a fetal transverse lie, right acromiodorsoanterior position.





A transverse lie is usually recognized easily, often by inspection alone. The abdomen is unusually wide, whereas the uterine fundus extends to only slightly above the umbilicus. No fetal pole is detected in the fundus, and the ballottable head is found in one iliac fossa and the breech in the other. The position of the back is readily identifiable. When the back is anterior, a hard resistance plane extends across the front of the abdomen. When it is posterior, irregular nodulations representing fetal small parts are felt through the abdominal wall.

On vaginal examination, in the early stages of labor, if the side of the thorax can be reached, it may be recognized by the "gridiron" feel of the ribs. With further dilation, the scapula and the clavicle are distinguished on opposite sides of the thorax. The position of the axilla indicates the side of the mother toward which the shoulder is directed.

Transverse lie was found once in 322 singleton deliveries (0.3 percent) at both the Mayo Clinic and the University of Iowa Hospital (Cruikshank, 1973; Johnson, 1964). This is remarkably similar to the incidence at Parkland Hospital of approximately 1 in 335 singleton fetuses.

Etiology

Some of the more common causes of transverse lie include: (1) abdominal wall relaxation from high parity, (2) preterm fetus, (3) placenta previa, (4) abnormal uterine anatomy, (5) hydramnios, and (6) contracted pelvis.

Women with four or more deliveries have a tenfold incidence of transverse lie compared with nulliparas. A relaxed and pendulous abdomen allows the uterus to fall forward, deflecting the long axis of the fetus away from the axis of the birth canal and into an oblique or transverse position. Placenta previa and pelvic contraction act similarly. A transverse or oblique lie occasionally develops in labor from an initial longitudinal position.

Mechanism of Labor

Spontaneous delivery of a fully developed newborn is impossible with a persistent transverse lie. After rupture of the membranes, if labor continues, the fetal shoulder is forced into the pelvis, and the corresponding arm frequently prolapses (Fig. 23-10). After some descent, the shoulder is arrested by the margins of the pelvic inlet. As labor continues, the shoulder is impacted firmly in the upper part of the pelvis. The uterus then contracts vigorously in an unsuccessful attempt to overcome the obstacle. With time, a retraction ring rises increasingly higher and becomes more marked. With this *neglected transverse lie,* the uterus will eventually rupture. Even without this complication, morbidity is increased because of the frequent association with placenta previa, the increased likelihood of cord prolapse, and the necessity for major operative efforts.

FIGURE 23-10
Neglected shoulder presentation. A thick muscular band forming a pathological retraction ring has developed just above the thin lower uterine segment. The force generated during a uterine contraction is directed centripetally at and above the level of the pathological retraction ring. This serves to stretch further and possibly to rupture the thin lower segment below the retraction ring.

If the fetus is small—usually <800 g—and the pelvis is large, spontaneous delivery is possible despite persistence of the abnormal lie. The fetus is compressed with the head forced against its abdomen. A portion of the thoracic wall below the shoulder thus becomes the most dependent part, appearing at the vulva. The head and thorax then pass through the pelvic cavity at the same time. The fetus, which is doubled upon itself and thus sometimes referred to as *conduplicato corpore*, is expelled.

Management

Active labor in a woman with a transverse lie is usually an indication for cesarean delivery. Before labor or early in labor, with the membranes intact, attempts at external version are worthwhile in the absence of other complications. If the fetal head can be maneuvered by abdominal manipulation into the pelvis, it should be held there during the next several contractions in an attempt to fix the head in the pelvis.

With cesarean delivery, because neither the feet nor the head of the fetus occupies the lower uterine segment, a low transverse incision into the uterus may lead to difficult fetal extraction. This is especially true of dorsoanterior presentations. Therefore, a vertical hysterotomy incision is often indicated.

Compound Presentation

With this, an extremity prolapses alongside the presenting part, and both present simultaneously in the pelvis (Fig. 23-11). Goplerud and Eastman (1953) identified a hand or arm prolapsed alongside the head once in every 700 deliveries. Much less common was prolapse of one or both lower extremities alongside a cephalic presentation or a hand alongside a breech. At Parkland Hospital, compound presentations were identified in only 68 of more than 70,000 singleton fetuses—an incidence of approximately 1 in 1000. Causes of compound presentations are conditions that prevent complete occlusion of the pelvic inlet by the fetal head, including preterm labor.

FIGURE 23-11
Compound presentation. **A.** The left hand is lying in front of the vertex. With further labor, the hand and arm may retract from the birth canal, and the head may then descend normally. **B.** Photograph of a small 34-week fetus with a compound presentation that delivered uneventfully with the hand presenting first. (Used with permission from Dr. Elizabeth Mosier.)

In most cases, the prolapsed part should be left alone, because most often it will not interfere with labor. If the arm is prolapsed alongside the head, the condition should be observed closely to ascertain whether the arm retracts out of the way with descent of the presenting part. If it fails to retract and if it appears to prevent descent of the head, the prolapsed arm should be pushed gently upward and the head simultaneously downward by fundal pressure.

In general, rates of perinatal mortality and morbidity are increased as a result of concomitant preterm delivery, prolapsed cord, and traumatic obstetrical procedures. Serious injury to the forearm is rare (Kwok, 2015; Tebes, 1999).

COMPLICATIONS WITH DYSTOCIA

Maternal Complications

Dystocia, especially if labor is prolonged, is associated with a higher incidence of several common obstetrical and neonatal complications. *Infection*, either intrapartum chorioamnionitis or postpartum pelvic infection, is more common with desultory and prolonged labors. *Postpartum hemorrhage* rates from atony are increased with prolonged and augmented labors. *Uterine tears with hysterotomy* also occur at greater incidence if the fetal head is impacted in the pelvis.

Uterine rupture is another risk. Abnormal thinning of the lower uterine segment creates a serious danger during prolonged labor, particularly in women of high parity and in those with a prior cesarean delivery. When disproportion is so pronounced that there is no engagement or descent, the lower uterine segment becomes increasingly stretched, and rupture may follow. In such cases, the normal *contraction ring* is usually exaggerated, like that shown in Figure 23-10.

Such pathological retraction rings are localized constrictions of the uterus that develop in association with prolonged obstructed labors. Seldom encountered today, the *pathological retraction ring of Bandl* is associated with marked stretching and thinning of the lower uterine segment. In contemporary practice, after birth of a

first twin, a pathological ring may still develop occasionally as an hourglass constriction of the uterus. The band may be seen clearly as a uterine indentation and signifies impending rupture of the lower uterine segment. The ring can sometimes be relaxed and delivery effected with appropriate general anesthesia, but occasionally prompt cesarean delivery offers a better prognosis for the second twin (Chap. 45, Vaginal Birth after Cesarean Delivery).

Fistula formation may result from dystocia, as the presenting part is firmly wedged into the pelvic inlet. Tissues of the birth canal lying between the leading part and the pelvic wall may be subjected to excessive pressure. Because of impaired circulation, necrosis can result and become evident several days after delivery as vesicovaginal, vesicocervical, or rectovaginal fistulas. Most often, pressure necrosis follows a very prolonged second stage. Such fistulas are rarely seen today except in undeveloped countries.

Pelvic floor injury during pregnancy and childbirth has gained recent attention. The pelvic floor is exposed to direct compression from the fetal head and to downward pressure from maternal expulsive efforts. These forces stretch and distend the pelvic floor, resulting in functional and anatomical alterations in the muscles, nerves, and connective tissues. Accumulating evidence suggests that such effects on the pelvic floor during childbirth can affect urinary or anal continence and pelvic support. These relationships are discussed in Chapter 30 (Cesarean Delivery Risks).

Lower extremity nerve injury in the mother can follow prolonged second-stage labor. Wong and colleagues (2003) reviewed neurological injury involving the lower extremities in association with labor and delivery. The most common mechanism is external compression of the common fibular (formerly common peroneal) nerve. This is usually caused by inappropriate leg positioning in stirrups, especially during prolonged second-stage labor. These and other injuries are discussed in Chapter 36 (Pain, Mood, and Cognition). Fortunately, symptoms resolve within 6 months of delivery in most women.

Perinatal Complications

Similar to the mother, the incidence of peripartum fetal sepsis rises with longer labors. *Caput succedaneum* and *molding* develop commonly and may be impressive (Fig. 22-16) (Buchmann, 2008). Mechanical trauma such as nerve injury, fractures, and cephalohematoma are also more frequent and are discussed further in Chapter 33 (Injuries of the Newborn).

CHAPTER 24: Intrapartum Assessment

To study the forces exerted by labour, a rubber bag was inserted into the uterus which was connected with a manometer. In this way it was found that the intra-uterine pressure, in the intervals between the contractions, was represented by a column of mercury 20 millimeters high, 5 of which were due to the tonicity of the walls and 15 to its contents. During the pains, however, the mercury rose considerably, reaching a height of from 80 to 250 millimeters.

—J. Whitridge Williams (1903)

INTRODUCTION

Little is written in the first edition of this textbook concerning monitoring of the fetus during labor. Much later, periodic auscultation of the fetal heartbeat with a fetoscope was adopted. These practices were eclipsed in the late 1960s and early 1970s by the development of electronic fetal monitoring (Hon, 1958). It was hoped that the continuous graph-paper portrayal of the fetal heart rate was potentially diagnostic in assessing pathophysiological events affecting the fetus.

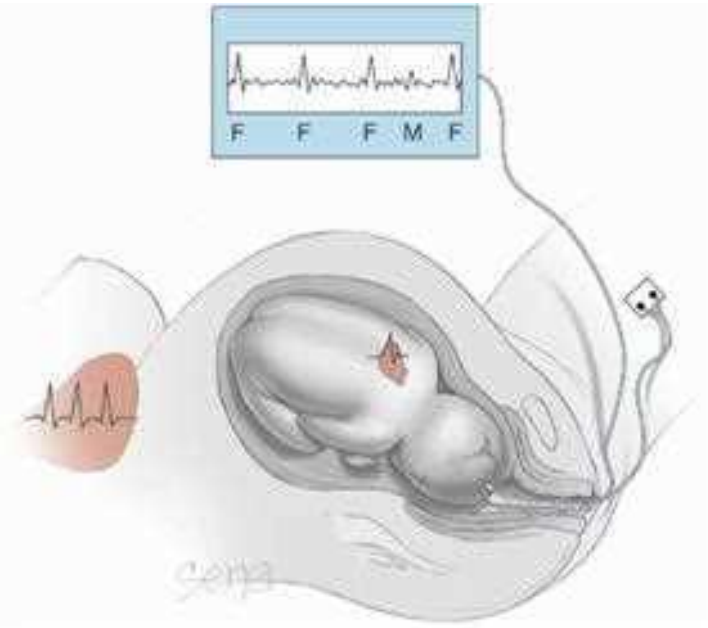
When first introduced, electronic fetal heart rate monitoring was used primarily in complicated pregnancies but gradually became used in most pregnancies. Now, more than 85 percent of all live births in the United States undergo electronic fetal monitoring (Ananth, 2013).

ELECTRONIC FETAL MONITORING

Internal (Direct) Electronic Monitoring

Direct fetal heart measurement is accomplished by attaching a bipolar spiral electrode directly to the fetus (Fig. 24-1). The wire electrode penetrates the fetal scalp, and the second pole is a metal wing on the electrode. The electrical fetal cardiac signal—P wave, QRS complex, and T wave—is amplified and fed into a cardiotachometer for heart rate calculation. The peak R-wave voltage is the portion of the fetal electrocardiogram (ECG) most reliably detected.

FIGURE 24-1
Internal electronic fetal monitoring. Schematic representation of a bipolar electrode attached to the fetal scalp for detection of fetal QRS complexes (F). Also shown is the maternal heart and corresponding electrical complex (M) that is detected.

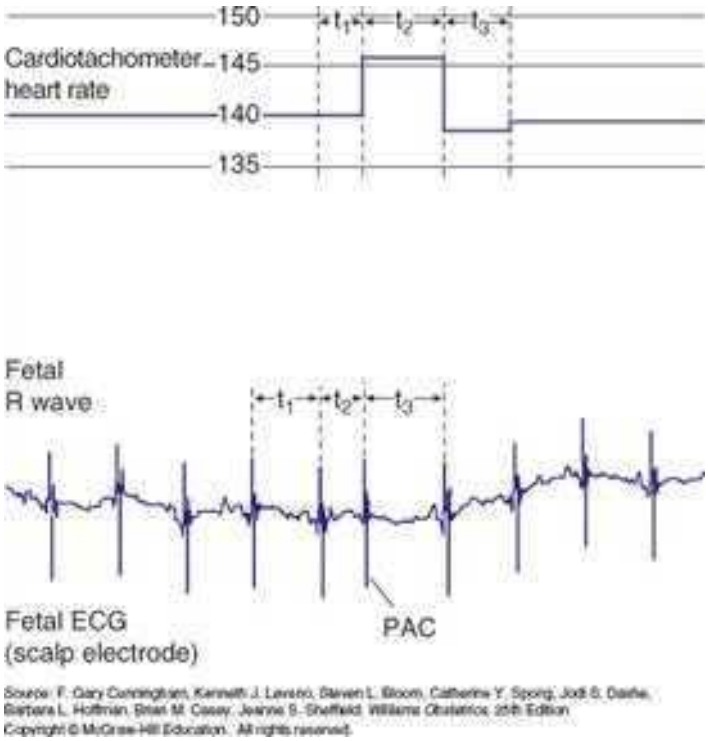


Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

An example of the method of fetal heart rate processing employed when a scalp electrode is used is shown in Figure 24-2. Time (t) in milliseconds between fetal R waves is fed into a cardiotachometer, where a new fetal heart rate is set with the arrival of each new R wave. As also shown in Figure 24-2, a premature atrial contraction is computed as a heart rate acceleration because the interval (t_2) is shorter than the preceding one (t_1). The phenomenon of continuous R-to-R wave fetal heart rate computation is known as *beat-to-beat variability.*

FIGURE 24-2

Schematic representation of fetal electrocardiographic signals used to compute continuing beat-to-beat heart rate with scalp electrodes. Time intervals (t_1, t_2, t_3) in milliseconds between successive fetal R waves are used by a cardiotachometer to compute instantaneous fetal heart rate. ECG = electrocardiogram; PAC = premature atrial contraction.



Electrical cardiac complexes detected by the electrode include those generated by the mother. However, the amplitude of the maternal ECG signal is diminished when recorded through the fetal scalp electrode and is masked by the fetal ECG. Shown in Figure 24-3 are simultaneous recordings of maternal chest wall ECG signals and fetal scalp electrode ECG signals. This fetus is experiencing premature atrial contractions, which cause the cardiotachometer to rapidly and erratically seek new heart rates, resulting in the "spiking" shown in the standard fetal monitor tracing. Importantly, when the fetus is dead, the maternal R waves are still detected by the scalp electrode as the next best signal and are counted by the cardiotachometer (Fig. 24-4).

FIGURE 24-3

The top tracing shows standard fetal monitor tracing of heart rate using a fetal scalp electrode. Spiking of the fetal rate in the monitor tracing is due to premature atrial contractions. The second panel displays accompanying contractions. The bottom two tracings represent cardiac electrical complexes detected from fetal scalp and maternal chest wall electrodes. ECG = electrocardiogram; F = fetus; M = mother; PAC = fetal premature atrial contraction.

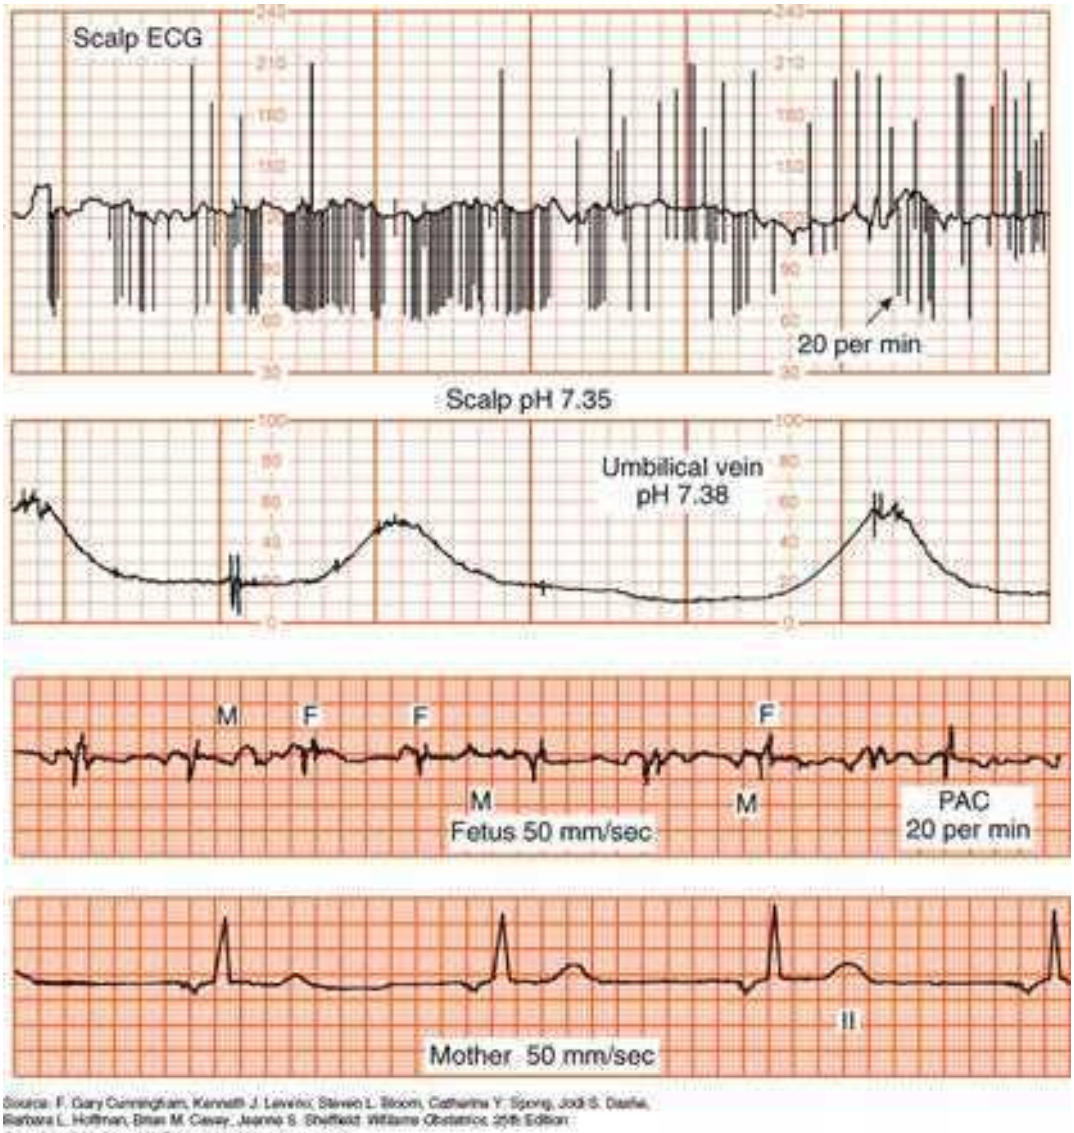


FIGURE 24-4

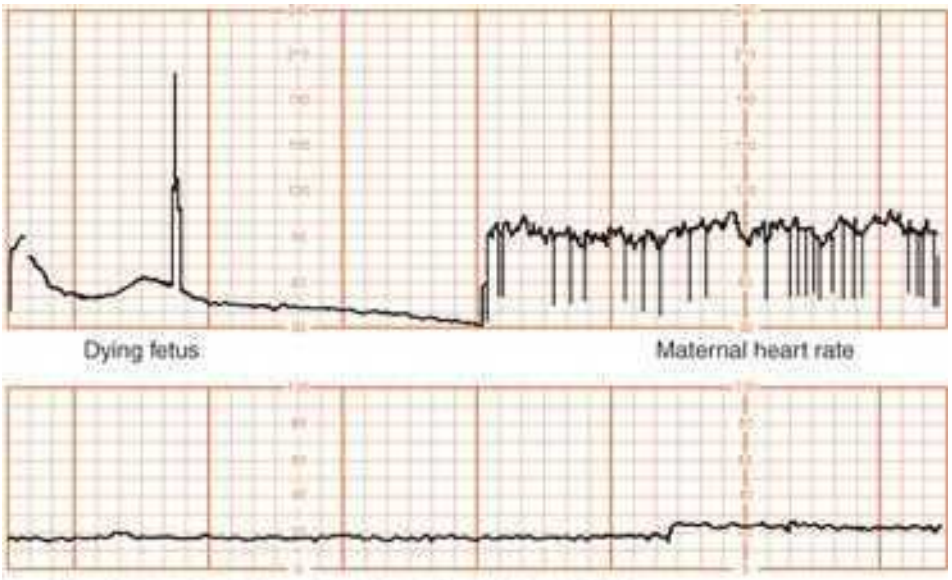
Placental abruption. In the upper panel, the fetal scalp electrode first detected the heart rate of the dying fetus. After fetal death, the maternal electrocardiogram complex is detected and recorded. The second panel displays an absence of uterine contractions.



External (Indirect) Electronic Monitoring

Although membrane rupture may be avoided, external monitoring does not provide the precision of fetal heart rate measurement afforded by internal monitoring (Nunes, 2014). In some women—for example, those who are obese—external monitoring may be difficult (Brocato, 2017).

With external monitoring, the fetal heart rate is detected through the maternal abdominal wall using the *ultrasound Doppler principle*. Ultrasound waves undergo a shift in frequency as they are reflected from moving fetal heart valves and from pulsatile blood ejected during systole (Chap. 10, Doppler). The unit consists of a transducer that emits ultrasound and a sensor to detect a shift in frequency of the reflected sound. The transducer is placed on the maternal abdomen at a site where fetal heart action is best detected. A coupling gel must be applied because air conducts ultrasound waves poorly. The device is held in position by an elastic belt. Correct positioning enhances differentiation of fetal cardiac motion from maternal arterial pulsations (Neilson, 2008).

Ultrasound Doppler signals are edited electronically before fetal heart rate data are printed onto monitor paper. Reflected ultrasound signals from moving fetal heart valves are analyzed through a microprocessor that compares incoming signals with the most recent previous signal. This process, called *autocorrelation*, is based on the premise that the fetal heart rate has regularity, whereas "noise" is random and without regularity. Several fetal heart motions must be deemed electronically acceptable by the microprocessor before the fetal heart rate is printed. Such electronic editing has greatly improved the tracing quality of the externally recorded fetal heart rate. Other features of current fetal monitors include the capability to monitor twin fetuses, monitor concurrent maternal heart rate, display the fetal ECG, and record maternal pulse oximetry values. Many fetal monitors are capable of interfacing with archival storage systems, which obviates maintaining actual paper tracings.

Technological advances now allow fetal heart rate monitoring from a remote, centralized location. Theoretically, the ability to monitor several patients simultaneously was hoped to improve neonatal outcomes. That said, only one study on centralized fetal monitoring has been reported. Anderson and colleagues (2011) measured the ability of 12 individuals to detect critical signals in fetal heart rate tracings on one, two, or four monitors. The results showed that detection accuracy declined as the number of displays increased.

Fetal Heart Rate Patterns

The interpretation of fetal heart rate patterns can be problematic without definitions and nomenclature. In one example, Blackwell and colleagues (2011) asked three Maternal-Fetal Medicine specialists to independently interpret 154 fetal heart rate tracings. Interobserver agreement was poor for the most ominous tracings and moderate for less severe patterns. The National Institute of Child Health and Human Development (NICHD) Research Planning Workshop (1997) brought together investigators with expertise in the field to propose standardized, unambiguous definitions for interpretation of fetal heart rate patterns during labor. This workshop reconvened in 2008. The definitions proposed as a result of this second workshop are used in this chapter and have been adopted by the American College of Obstetricians and Gynecologists (2017a) (Table 24-1). Importantly, interpretation of electronic fetal heart rate data is based on the visual pattern of the heart rate as portrayed on chart recorder graph paper. Thus, the choice of vertical and horizontal scaling greatly affects the appearance of the fetal heart rate. Scaling factors recommended by the NICHD Workshop are 30 beats per minute (beats/min or bpm) per vertical cm (range, 30 to 240 bpm) and 3 cm/min chart recorder paper speed. Fetal heart rate variation is falsely displayed at the slower 1 cm/min paper speed compared with that of the smoother baseline recorded at 3 cm/min. Thus, pattern recognition can be considerably distorted depending on the scaling factors used.

TABLE 24-1

Electronic Fetal Monitoring Definitions

Pattern	Definition
Baseline	• The mean FHR rounded to increments of 5 bpm during a 10-min segment, excluding: —Periodic or episodic changes —Periods of marked FHR variability —Segments of baseline that differ by more than 25 bpm • The baseline must be for a minimum of 2 min in any 10-min segment or the baseline for that time period is indeterminate. In this case, one may refer to the prior 10-min window for determination of baseline. • Normal FHR baseline: 110–160 bpm • Tachycardia: FHR baselines is greater than 160 beats per minute • Bradycardia: FHR baseline is less than 110 beats per minute
Baseline variability	• Fluctuations in the baseline FHR that are irregular in amplitude and frequency • Variability is visually quantified as the amplitude of peak-to-trough in beats per minute —Absent: amplitude range undetectable —Minimal: amplitude range detectable but 5 beats per minutes or fewer —Moderate (normal): amplitude range 6–25 beats per minute —Marked: amplitude range greater than 25 beats per minute
Acceleration	• A visually apparent abrupt increase (onset to peak in less than 30 seconds) in the FHR • At 32 weeks of gestation and beyond, an acceleration has a peak of 15 bpm or more above baseline, with a duration of 15 sec or more but less than 2 minutes from onset to return • Before 32 weeks, an acceleration has a peak of 10 bpm or more above baseline, with a duration of 10 seconds or more but less than 2 minutes from onset to return • Prolonged acceleration lasts 2 minutes or more but less than 10 minutes in duration • If an acceleration lasts 10 minutes or longer, it is a baseline change
Early deceleration	• Visually apparent usually symmetrical gradual decrease and return of the FHR associated with a uterine contraction • A gradual FHR decrease is defined as from the onset to the FHR nadir of 30 seconds or more • The decrease in FHR is calculated from the onset to the nadir of the deceleration • The nadir of the deceleration occurs at the same time as the peak of the contraction • In most cases the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively
Late deceleration	• Visually apparent usually symmetrical gradual decrease and return of the FHR associated with a uterine contraction • A gradual FHR decrease is defined as from the onset to the FHR nadir of 30 seconds or more • The decrease in FHR is calculated from the onset to the nadir of the deceleration • The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction • In most cases the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively
Variable deceleration	• Visually apparent abrupt decrease in FHR • An abrupt FHR decrease is defined as from the onset of the deceleration to the beginning of the FHR nadir of less than 30 seconds • The decrease in FHR is calculated from the onset to the nadir of the deceleration • The decrease in FHR is 15 beats per minute or greater, lasting 15 seconds or greater, and less than 2 minutes in duration • When variable decelerations are associated with uterine contraction, their onset, depth, and duration commonly vary with successive uterine contractions
Prolonged deceleration	• Visually apparent decrease in the FHR below the baseline • Decrease in FHR from the baseline that is 15 beats per minute or more, and less than 2 minutes in duration • If a deceleration last 10 minutes or longer, it is a baseline change

Pattern	Definition
Sinusoidal pattern	• Visually apparent, smooth, sine wave-line undulating pattern in FHR baseline with a cycle frequency of 3–5 per minute which persists for 20 minutes or more

FHR = fetal heart rate.

Data from Macones, 2008.

Baseline Fetal Heart Activity

This refers to the modal characteristics that prevail apart from periodic accelerations or decelerations associated with uterine contractions. Descriptive characteristics of baseline fetal heart activity include *rate, beat-to-beat variability, fetal arrhythmia*, and distinct patterns such as *sinusoidal* or *saltatory* fetal heart rates.

Rate

With increasing fetal maturation, the heart rate decreases. This continues postnatally such that the average rate is 85 bpm by age 8 years (Tintinalli, 2016). Pillai and James (1990) reported that the baseline fetal heart rate declined an average of 24 bpm between 16 weeks' gestation and term, or approximately 1 bpm per week. This normal gradual slowing of the fetal heart rate is thought to correspond to maturation of parasympathetic (vagal) heart control (Renou, 1969).

The baseline fetal heart rate is the approximate mean rate rounded to increments of 5 bpm during a 10-minute tracing segment. In any 10-minute window, the minimum interpretable baseline duration must be at least 2 minutes. If the baseline fetal heart rate is less than 110 bpm, it is termed *bradycardia.* If the baseline rate is greater than 160 bpm, it is called *tachycardia.* The average fetal heart rate is considered the result of tonic balance between *accelerator* and *decelerator* influences on pacemaker cells. In this concept, the sympathetic system is the accelerator influence, and the parasympathetic system is the decelerator factor mediated by vagal slowing of heart rate (Dawes, 1985). Heart rate also is under the control of arterial chemoreceptors such that both hypoxia and hypercapnia can modulate rate. More severe and prolonged hypoxia, with a rising blood lactate level and severe metabolic acidemia, induces a prolonged fall in heart rate (Thakor, 2009).

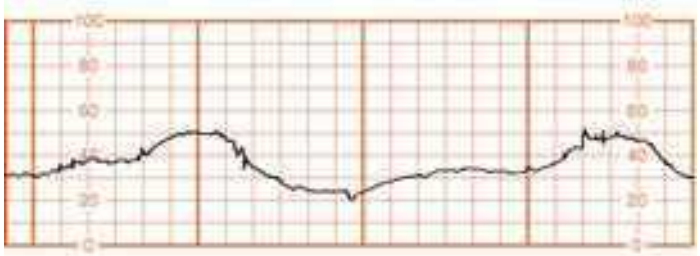
Bradycardia

In the third trimester, the normal mean baseline fetal heart rate has generally been accepted to range between 120 and 160 bpm. But, pragmatically, a rate between 100 and 119 bpm, in the absence of other changes, usually is not considered to represent fetal compromise. Such low but potentially normal baseline heart rates also have been attributed to head compression from occiput posterior or transverse positions, particularly during second-stage labor (Young, 1976). Such mild bradycardias were observed in 2 percent of monitored pregnancies and averaged approximately 50 minutes in duration. Freeman and associates (2003) have concluded that bradycardia within the range of 80 to 120 bpm and with good variability is reassuring. Interpretation of rates less than 80 bpm is problematic, and such rates generally are considered nonreassuring.

Some causes of fetal bradycardia include congenital heart block and serious fetal compromise (Jaeggi, 2008; Larma, 2007). Figure 24-5 shows bradycardia in a fetus dying from placental abruption. Maternal hypothermia under general anesthesia for repair of a cerebral aneurysm or during maternal cardiopulmonary bypass for open-heart surgery can also cause fetal bradycardia. Sustained fetal bradycardia in the setting of severe pyelonephritis and maternal hypothermia also has been reported (Hankins, 1997). Involved fetuses apparently are not harmed by several hours of such bradycardia.

FIGURE 24-5

Fetal bradycardia measured with a scalp electrode (*upper panel*) in a pregnancy complicated by placental abruption and subsequent fetal death. Concurrent uterine contractions are shown in the lower panel.



Tachycardia

Fetal tachycardia is defined as a baseline heart rate greater than 160 bpm. The most common explanation for fetal tachycardia is maternal fever from chorioamnionitis, although fever from any source can produce this. In some cases, fetal tachycardia may precede overt maternal fever (Gilstrap, 1987). Fetal tachycardia caused by maternal infection typically is not associated with fetal compromise unless there are associated periodic heart rate changes or fetal sepsis.

Other causes of fetal tachycardia include fetal compromise, cardiac arrhythmias, and maternal administration of parasympathetic inhibiting (atropine) or sympathomimetic (terbutaline) drugs. Prompt relief of the compromising event, such as correction of maternal hypotension caused by epidural analgesia, can result in fetal recovery. The key feature to distinguish fetal compromise in association with tachycardia seems to be concomitant heart rate decelerations.

Wandering Baseline

This baseline rate is unsteady and “wanders” between 120 and 160 bpm (Freeman, 2003). This rare finding is suggestive of a neurologically abnormal fetus and may occur as a preterminal event. In contrast, changes of the normal baseline are common in labor and do not predict morbidity (Yang, 2017).

Beat-to-Beat Variability

Baseline variability is an important index of cardiovascular function and appears to be regulated largely by the autonomic nervous system (Kozuma, 1997). That is, a sympathetic and parasympathetic “push and pull” mediated via the sinoatrial node produces moment-to-moment or beat-to-beat oscillation of the baseline heart rate. Such heart rate change is defined as baseline variability. Variability can be further analyzed over the short term and long term, although these terms have fallen out of use. *Short-term variability* reflects the instantaneous change in fetal heart rate from one beat—or R wave—to the next. This variability is a measure of the time interval between cardiac systoles (Fig. 24-6). Short-term variability can most reliably be determined to be normally present only when electrocardiac cycles are measured directly with a scalp electrode. *Long-term variability* is used to describe the oscillatory changes during 1 minute and result in the waviness of the baseline (Fig. 24-7). The normal frequency of such waves is three to five cycles per minute (Freeman, 2003).

FIGURE 24-6

Schematic representation of short-term beat-to-beat variability measured by a fetal scalp electrode. t = time interval between successive fetal R waves. (Adapted with permission from Klavan M, Laver AT, Boscola MA: Clinical concepts of fetal heart rate monitoring. Waltham, Hewlett-Packard, 1977.)

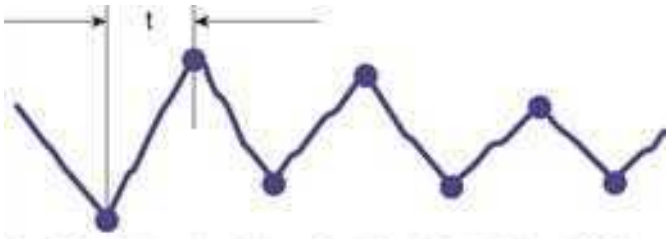


FIGURE 24-7

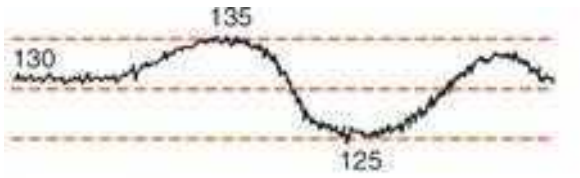
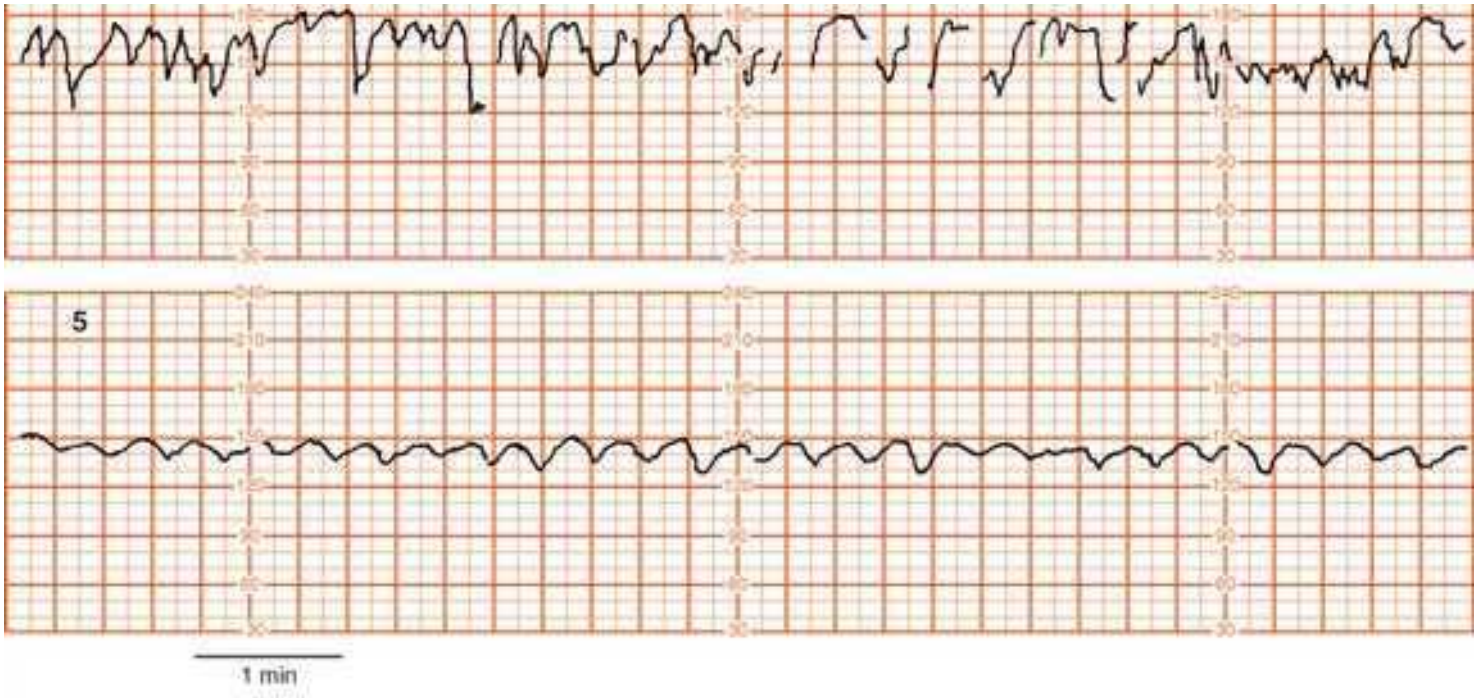
Schematic representation of long-term beat-to-beat variability of the fetal heart rate ranging between 125 and 135 bpm. (Adapted with permission from Klavan M, Laver AT, Boscola MA: Clinical concepts of fetal heart rate monitoring. Waltham, Hewlett-Packard, 1977.)



It should be recognized that precise quantitative analysis of both short- and long-term variability presents several frustrating problems due to technical and scaling factors (Parer, 1985). Thus, most clinical interpretation is based on visual analysis with subjective judgment of the smoothness or flatness of the baseline. According to Freeman and associates (2003), no evidence suggests that the distinction between short- and long-term variability has clinical relevance. Similarly, the NICHD Workshop (1997) did not recommend differentiating short- and long-term variability because in actual practice they are visually determined as a unit. The workshop panel defined baseline variability as those baseline fluctuations of two cycles per minute or greater. They recommended the criteria shown in Figure 24-8 for quantification of variability. Normal beat-to-beat variability was accepted to be 6 to 25 bpm.

FIGURE 24-8

Grades of baseline fetal heart rate variability shown in the following five panels. **1.** Undetectable, absent variability. **2.** Minimal variability, ≤5 bpm. **3.** Moderate (normal) variability, 6 to 25 bpm. **4.** Marked variability, >25 bpm. **5.** Sinusoidal pattern. This differs from variability in that it has a smooth, sinelike pattern of regular fluctuation and is excluded in the definition of fetal heart rate variability. (Adapted with permission from National Institute of Child Health and Human Development Research Planning Workshop, 1997.)



Increased Variability

Several physiological and pathological processes can affect beat-to-beat variability. Greater variability accompanies fetal breathing and body movements (Dawes, 1981; Van Geijn, 1980). Pillai and James (1990) reported increased baseline variability with advancing gestation. Up to 30 weeks, baseline characteristics were similar during both fetal rest and activity. After 30 weeks, fetal inactivity was associated with diminished baseline variability, but fetal activity enhanced it. Last, the baseline fetal heart rate becomes more physiologically fixed (less variable) as the rate rises. This phenomenon presumably reflects less cardiovascular physiological wandering as beat-to-beat intervals shorten with a higher heart rate.

Decreased Variability

A common cause of diminished beat-to-beat variability is administration of analgesic drugs during labor (Chap. 25, Analgesia and Sedation During Labor). Various central nervous system depressant drugs can cause transient diminished beat-to-beat variability. Included are narcotics, barbiturates, phenothiazines, tranquilizers, and general anesthetics. Corticosteroids also dampen variability (Knaven, 2017). As one specific example, variability regularly diminishes within 5 to 10 minutes following intravenous meperidine administration, and the effects may last up to 60 minutes or longer (Hill, 2003; Petrie, 1993). Butorphanol given intravenously has similar effects (Schucker, 1996). And, chronically administered buprenorphine suppresses fetal heart rate and movement (Jansson, 2017).

Magnesium sulfate, widely used in the United States for tocolysis or management of hypertensive gravidas, is associated with diminished beat-to-beat variability. In a study of nearly 250 term gestations, magnesium sulfate administration led to decreased variability but without evidence of adverse neonatal effects (Duffy, 2012). Others have echoed these findings (Hallak, 1999; Lin, 1988). With magnesium sulfate tocolysis of preterm labor, variability was also diminished in most reviewed studies (Nensi, 2014; Verdurmen, 2017).

Of greatest concern, diminished beat-to-beat variability can be an ominous sign indicating a seriously compromised fetus. Paul and coworkers (1975) reported that loss of variability in combination with decelerations was associated with *fetal acidemia*. Decreased variability was defined as an excursion of the baseline of ≤5 bpm (see Fig. 24-8). Severe *maternal acidemia* can also lower fetal beat-to-beat variability, for example, in a mother with diabetic ketoacidosis.

According to Dawes (1985), metabolic acidemia that causes depression of the fetal brainstem or the heart itself creates the loss of variability. Thus, diminished beat-to-beat variability, when it reflects fetal compromise, likely reflects acidemia rather than hypoxia. Indeed, mild degrees of fetal hypoxemia have been reported actually to *enhance* variability, at least initially (Murotsuki, 1997).

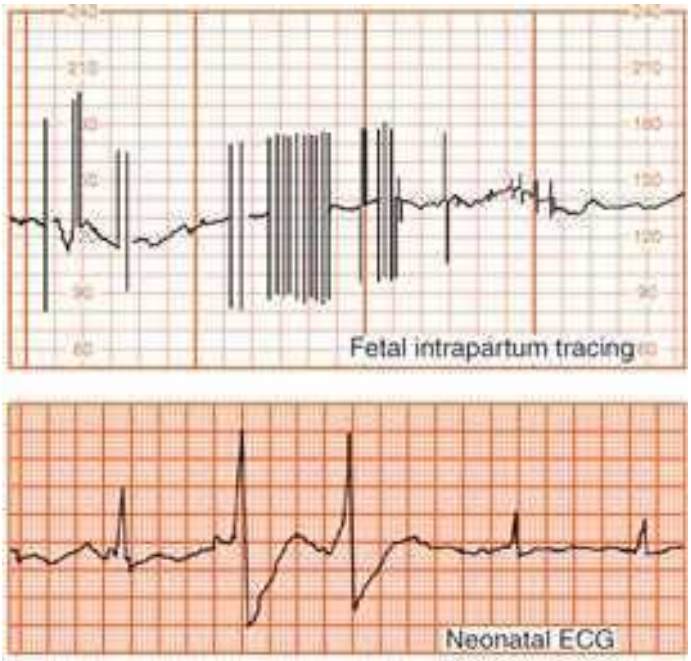
Reduced baseline heart rate variability is the single most reliable sign of fetal compromise. Smith and coworkers (1988) performed a computerized analysis of beat-to-beat variability in growth-restricted fetuses before labor. Diminished variability (≤4.2 bpm) maintained for 1 hour was diagnostic of developing acidemia and imminent fetal death. In contrast, Samueloff and associates (1994) evaluated variability in 2200 consecutive deliveries and concluded that variability by itself could not be used as the only indicator of fetal well-being. They also warned that good variability should not be interpreted as necessarily reassuring. Blackwell and associates (2011) found that even experts often disagreed as to whether variability was absent or minimal (≤5 bpm).

In sum, beat-to-beat variability is affected by fetal physiology, and its meaning differs depending on the clinical setting. Decreased variability in the absence of decelerations is unlikely to reflect fetal hypoxia (Davidson, 1992). A persistently flat fetal heart rate baseline—absent variability—within the normal baseline rate range and without decelerations may reflect a previous fetal insult that has resulted in neurological damage (Freeman, 2003).

Cardiac Arrhythmia

When fetal cardiac arrhythmias are first suspected using electronic monitoring, findings can include baseline bradycardia, tachycardia, or most commonly in our experience, *abrupt baseline spiking* (Fig. 24-9). An arrhythmia can only be documented, practically speaking, when scalp electrodes are used. Some fetal monitors can be adapted to output the scalp electrode signals into an ECG recorder. Because only a single lead is obtained, analysis and interpretation of rhythm and rate disturbances are severely limited.

FIGURE 24-9
Internal fetal monitoring at term demonstrated occasional abrupt beat-to-beat fetal heart rate spiking due to erratic extrasystoles shown in the corresponding fetal electrocardiogram. The normal newborn was delivered spontaneously and had normal cardiac rhythm in the nursery.



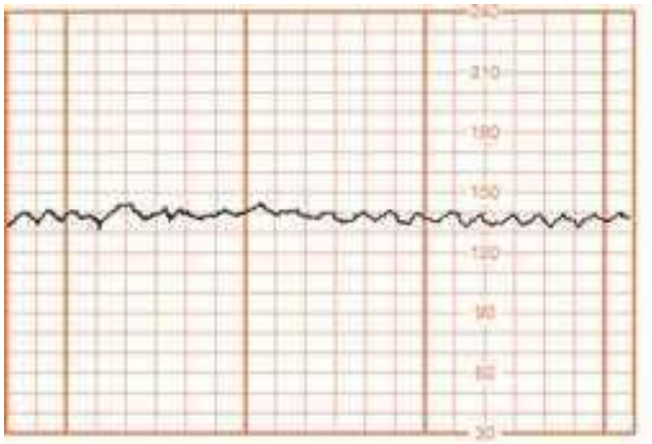
Southall and associates (1980) studied fetal cardiac rate and rhythm disturbances in 934 normal pregnancies between 30 and 40 weeks. Arrhythmias, episodes of bradycardia <100 bpm, or tachycardia >180 bpm were encountered in 3 percent. Most supraventricular arrhythmias are of little significance during labor unless there is coexistent fetal heart failure as evidenced by hydrops. Many supraventricular arrhythmias disappear in the immediate neonatal period, although some are associated with structural cardiac defects (Api, 2008). Intermittent baseline bradycardia is frequently due to congenital heart block. Conduction defects, most often complete atrioventricular (AV) block, usually are found in association with maternal connective tissue diseases (Chap. 59, Perinatal Mortality and Morbidity). Antepartum evaluation of the fetus with an identified arrhythmia and potential treatment options are discussed in Chapter 16 (Tachyarrhythmias).

Most fetal arrhythmias without comorbid fetal hydrops are inconsequential during labor, but they may hinder interpretation of fetal heart rate tracings. Sonographic evaluation of fetal anatomy and echocardiography can be useful. Generally, in the absence of fetal hydrops, neonatal outcome is not measurably improved by pregnancy intervention. At Parkland Hospital, intrapartum fetal cardiac arrhythmias, especially those associated with clear amnionic fluid, are typically managed conservatively.

Sinusoidal Heart Rate

A true sinusoidal pattern such as that shown in panel 5 of Figure 24-8 can be observed with fetal intracranial hemorrhage, with severe fetal asphyxia, and with severe fetal anemia. The last may stem from anti-D alloimmunization, fetomaternal hemorrhage, twin-twin transfusion syndrome, fetal parvoviral infection, or vasa previa with bleeding. Insignificant sinusoidal patterns have been reported following administration of meperidine, morphine, alphaprodine, and butorphanol (Angel, 1984; Egley, 1991; Epstein, 1982). Shown in Figure 24-10 is a sinusoidal pattern seen with maternal meperidine administration. An important characteristic of this pattern when due to narcotics is the sine frequency of 6 cycles per minute. A sinusoidal pattern also has been described with chorioamnionitis, fetal distress, and umbilical cord occlusion (Murphy, 1991). Young (1980a) and Johnson (1981) with their coworkers concluded that intrapartum sinusoidal fetal heart patterns were not generally associated with fetal compromise. Thus, management is usually dictated by the clinical setting. Modanlou and Freeman (1982), based on their extensive review, proposed adoption of a strict definition:

FIGURE 24-10
Sinusoidal fetal heart rate pattern associated with maternal intravenous meperidine administration. Sine waves are occurring at a rate of 6 cycles per minute.



1. Stable baseline heart rate of 120 to 160 bpm with regular oscillations
2. Amplitude of 5 to 15 bpm (rarely greater)
3. Long-term variability frequency of 2 to 5 cycles per minute
4. Fixed or flat short-term variability
5. Oscillation of the sinusoidal waveform above or below a baseline
6. Absent accelerations.

Although these criteria were selected to define a sinusoidal pattern that is most likely ominous, they observed that the pattern associated with alphaprodine is indistinguishable. Other investigators have proposed a classification of sinusoidal heart rate patterns into mild—amplitude 5 to 15 bpm, intermediate—16 to 24 bpm, and major—≥25 bpm to quantify fetal risk (Murphy, 1991; Neesham, 1993).

Some have defined intrapartum sine wavelike baseline variation with periods of acceleration as *pseudosinusoidal.* Murphy and colleagues (1991) reported that pseudosinusoidal patterns were seen in 15 percent of monitored labors. Mild pseudosinusoidal patterns were associated with use of meperidine and epidural analgesia. Intermediate pseudosinusoidal patterns were linked to fetal sucking or transient episodes of fetal hypoxia caused by umbilical cord compression. Egley and associates (1991) reported that 4 percent of fetuses demonstrated sinusoidal patterns transiently during normal labor. These authors observed patterns persisting for up to 90 minutes in some cases.

The pathophysiology of sinusoidal patterns is unclear, in part due to various definitions. There seems to be general agreement that *antepartum* sine wave baseline undulations portend severe fetal anemia. Still, few anti-D alloimmunized fetuses develop this pattern (Nicolaides, 1989). The sinusoidal pattern has been reported to develop or disappear after fetal transfusion (Del Valle, 1992; Lowe, 1984). Ikeda and associates (1999) proposed that the pattern is related to waves of arterial blood pressure, reflecting oscillations in the baroreceptor-chemoreceptor feedback mechanism.

Periodic Fetal Heart Rate Changes

These refer to deviations from baseline that are temporally related to uterine contractions. *Acceleration* refers to a rise in fetal heart rate above baseline, and *deceleration* is a drop below the baseline rate. The nomenclature most commonly used in the United States is based on the *timing* of the deceleration in relation to contractions—thus, *early, late,* or *variable*. The waveform of these decelerations is also significant for pattern recognition. In early and late decelerations, the slope of fetal heart rate change is gradual, resulting in a curvilinear and uniform or symmetrical waveform. With variable decelerations, the slope of fetal heart rate change is abrupt and erratic, giving the waveform a jagged appearance. The NICHD Workshop (1997) proposed that decelerations be defined as *recurrent* if they accompanied ≥50 percent of contractions in any 20-minute period.

Another system now used less often to describe decelerations is based on the pathophysiological events considered most likely to underlie the pattern. In this system, early decelerations are termed *head compression,* late decelerations are termed *uteroplacental insufficiency,* and variable decelerations are *cord compression patterns.*

Accelerations

These are abrupt heart rate increases above the fetal heart rate baseline and defined by an onset-to-peak rise within 30 seconds (American College of Obstetricians and Gynecologists, 2017a). At 32 weeks' gestation and beyond, an acceleration has a peak ≥15 bpm above baseline. Its duration is ≥15 sec but <2 minutes from onset to baseline return (see Table 24-1). Before 32 weeks, a peak ≥10 bpm for 10 seconds to 2 minutes is considered normal. Prolonged acceleration is defined as ≥2 minutes but <10 minutes.

According to Freeman and coworkers (2003), accelerations most often occur antepartum, in early labor, and in association with variable decelerations. Proposed mechanisms for intrapartum accelerations include fetal movement, stimulation by uterine contractions, umbilical cord occlusion, fetal stimulation during pelvic examination, scalp blood sampling, and acoustic stimulation. Accelerations are common during labor. These are virtually always reassuring and almost always confirm that the fetus is not acidemic at that time.

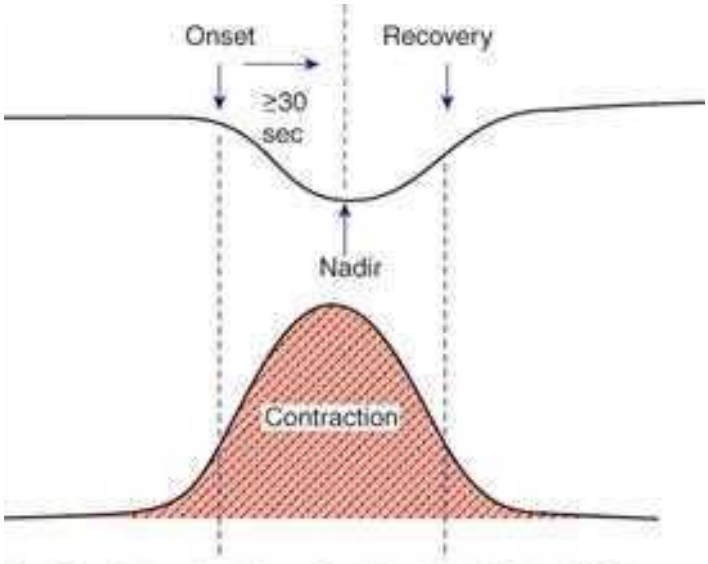
As with beat-to-beat variability, accelerations represent intact neurohormonal cardiovascular control mechanisms linked to fetal behavioral states. Krebs and colleagues (1982) analyzed electronic heart rate tracings in nearly 2000 fetuses and found sporadic accelerations during labor in 99.8 percent. Fetal heart rate accelerations during the first or last 30 minutes during labor, or both, were a favorable sign for fetal well-being. The absence of such accelerations during labor, however, is not necessarily an unfavorable sign unless coincidental with other nonreassuring changes. The chance of acidemia in the fetus that fails to respond to stimulation in the presence of an otherwise nonreassuring pattern approximates 50 percent (Clark, 1984; Smith, 1986).

Early Deceleration

This physiological response shows a gradual fetal heart rate decline and then return to baseline associated with a contraction (Fig. 24-11). Freeman and associates (2003) defined early decelerations as those generally seen in active labor between 4 and 7 cm cervical dilation. In their definition, the degree of deceleration is generally proportional to the contraction strength and rarely falls below 100 to 110 bpm or 20 to 30 bpm below baseline. Such decelerations are common during active labor and not associated with tachycardia, loss of variability, or other fetal heart rate changes. Importantly, early decelerations are not associated with fetal hypoxia, acidemia, or low Apgar scores.

FIGURE 24-11

Features of early fetal heart rate deceleration. Characteristics include a gradual decline in the heart rate with both onset and recovery coincident with the onset and recovery of the contraction. The nadir of the deceleration is 30 seconds or more after the deceleration onset.

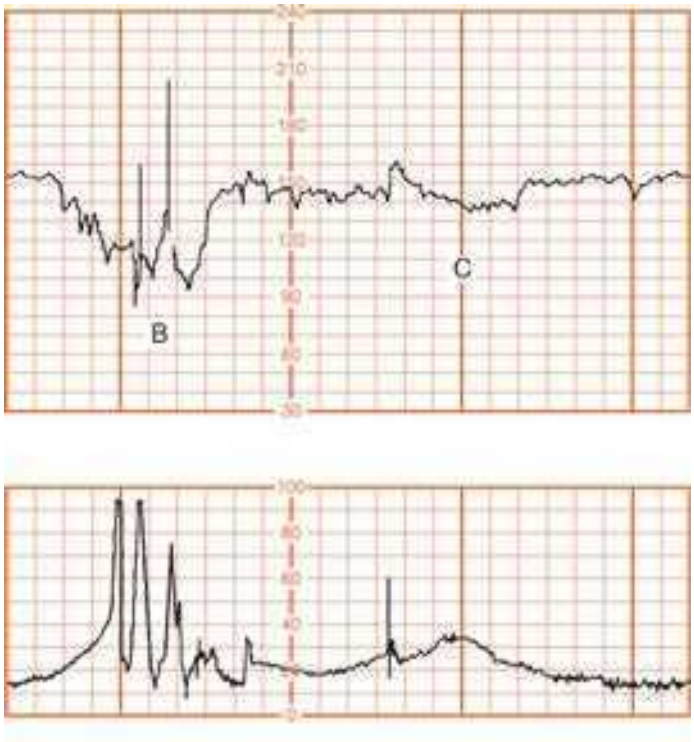


Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Head compression probably causes vagal nerve activation as a result of dural stimulation, and this mediates the heart rate deceleration (Paul, 1964). Ball and Parer (1992) concluded that fetal head compression is a likely cause not only of the deceleration shown in Figure 24-11 but also of those shown in Figure 24-12, which typically occur during second-stage labor. Indeed, they observed that head compression is the likely cause of many variable decelerations classically attributed to cord compression.

FIGURE 24-12

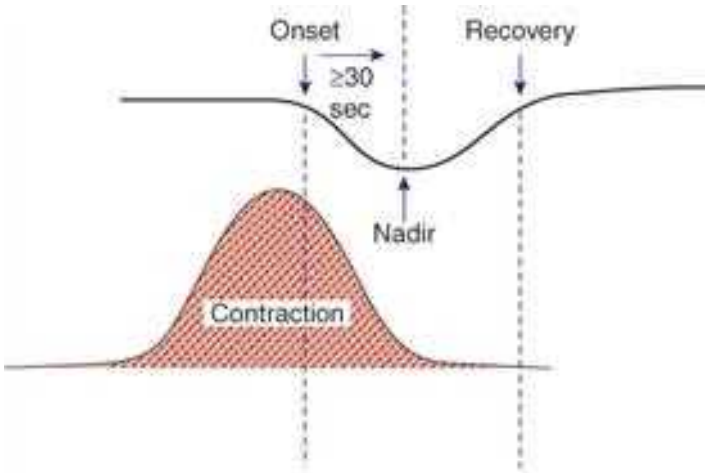
Two different fetal heart rate patterns during second-stage labor that are likely both due to head compression (*upper panel*). Maternal pushing efforts (*lower panel*) correspond to the spikes with uterine contractions. Fetal heart rate deceleration (*C*) is consistent with the pattern of head compression shown in Figure 24-11. Deceleration (*B*), however, is “variable” in appearance because of its jagged configuration and may alternatively represent cord occlusion.



Late Deceleration

The fetal heart rate response to uterine contractions can reflect uterine perfusion or placental function. A late deceleration is a smooth, gradual, symmetrical decline in fetal heart rate beginning at or after the contraction peak and returning to baseline only after the contraction has ended. This deceleration reaches its nadir within 30 seconds of its onset. In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively (Fig. 24-13). The magnitude of late decelerations is seldom more than 30 to 40 bpm below baseline and typically not more than 10 to 20 bpm. Late decelerations usually are not accompanied by accelerations. Myers and associates (1973) studied monkeys in which they compromised uteroplacental perfusion by lowering maternal aortic blood pressure. The interval or lag from the contraction onset until the late deceleration onset was directly related to basal fetal oxygenation. They demonstrated that the length of the lag was predictive of the fetal Po_2 but not fetal pH. The lower the fetal Po_2 before contractions, the shorter the lag to the onset of late decelerations. This lag reflected the time necessary for the fetal Po_2 to fall below a critical level necessary to stimulate arterial chemoreceptors, which mediated the decelerations.

FIGURE 24-13
Features of late fetal heart rate deceleration. Characteristics include gradual decline in the heart rate with the contraction nadir, and recovery occurring after the end of the contraction. The nadir of the deceleration occurs 30 seconds or more after the onset of the deceleration.



Murata and coworkers (1982) also showed that a late deceleration was the first fetal heart rate consequence of uteroplacental-induced hypoxia. During the course of progressive hypoxia that led to death over 2 to 13 days, monkey fetuses invariably exhibited late decelerations before development of acidemia.

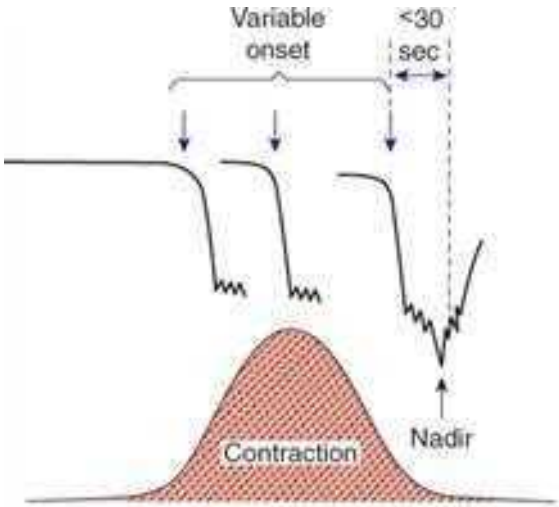
Variability of the baseline heart rate disappeared as acidemia developed.

Generally, any process that produces maternal hypotension, excessive uterine activity, or placental dysfunction can induce late decelerations. The two most common sources are hypotension from epidural analgesia and uterine hyperactivity from oxytocin stimulation. Maternal diseases such as hypertension, diabetes, and collagen vascular disorders can cause chronic placental dysfunction. Placental abruption can produce acute late decelerations.

Variable Deceleration

The most frequent deceleration patterns encountered during labor are variable decelerations attributed to umbilical cord occlusion. In a study of more than 7000 monitor tracings, variable decelerations were identified in 40 percent when labor had progressed to 5 cm dilation and in 83 percent by the end of first-stage labor (Melchior, 1985). A variable deceleration is defined as an abrupt drop in the fetal heart rate beginning with the onset of the contraction and reaching a nadir in less than 30 seconds. The decrease must last between 15 seconds and 2 minutes and must be ≥15 bpm in amplitude. The onset of deceleration typically varies with successive contractions (Fig. 24-14).

FIGURE 24-14
Features of variable fetal heart rate decelerations. Characteristics include an abrupt decline in the heart rate, and onset that commonly varies with successive contractions. The deceleration measures ≥15 bpm for ≥15 seconds and has an onset-to-nadir phase of <30 seconds. Total duration is <2 minutes.



Hon (1959) tested the effects of umbilical cord compression on fetal heart rate (Fig. 24-15). In experimental animals, complete occlusion of the umbilical cord produces abrupt, jagged-appearing deceleration of the fetal heart rate (Fig. 24-16). Concomitantly, fetal aortic pressure rises. Itskovitz and colleagues (1983) observed that variable decelerations in fetal lambs occurred only after umbilical blood flow was reduced by at least 50 percent.

FIGURE 24-15
A. The effects of 25-second cord compression compared with those of 40 seconds in panel **(B)**. (Redrawn with permission from Hon EH: The fetal heart rate patterns preceding death in utero, Am J Obstet Gynecol. 1959 Jul;78(1):47–56.)

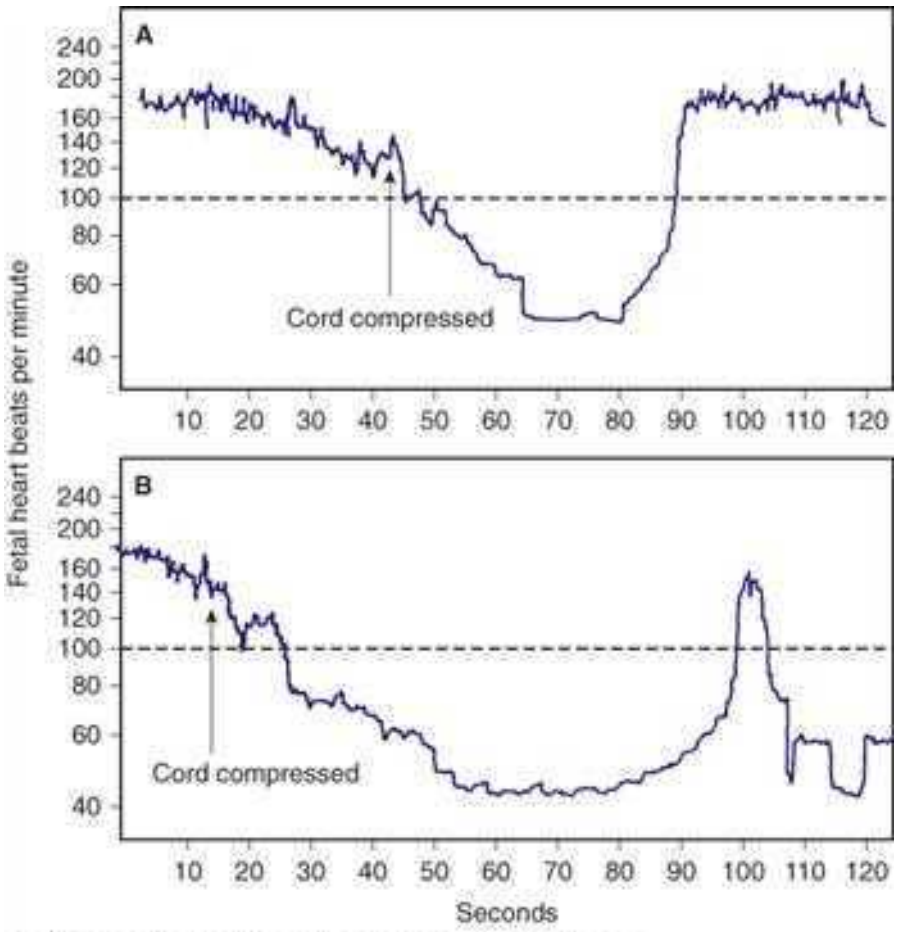


FIGURE 24-16

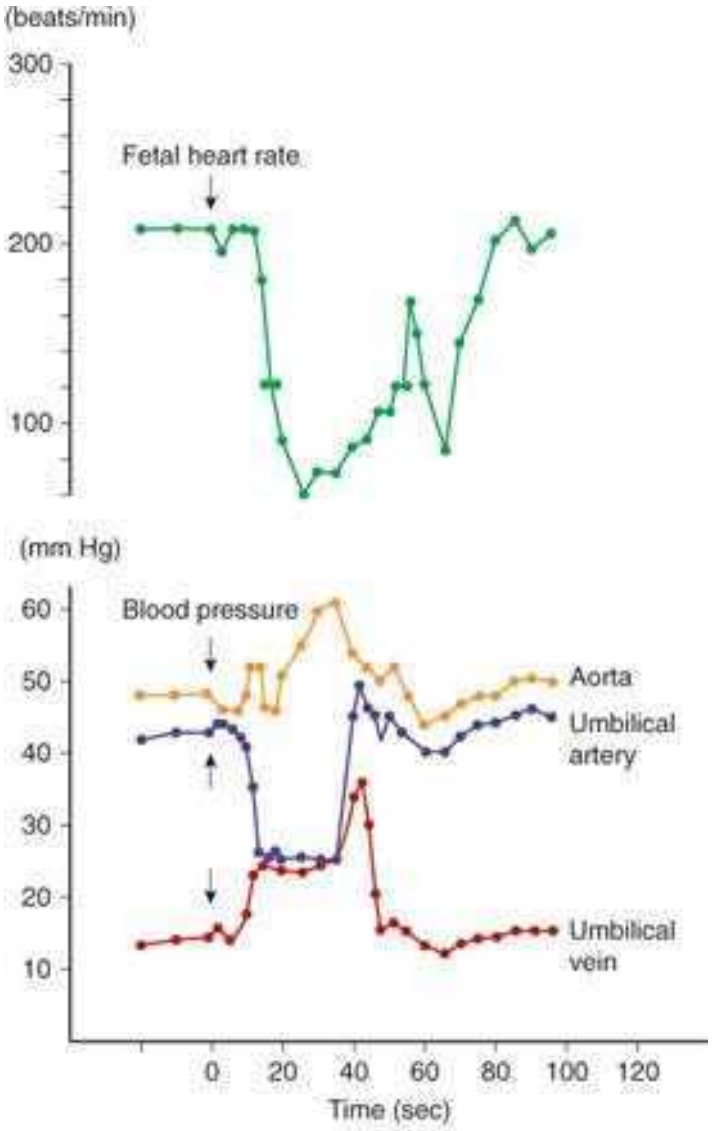
Total umbilical cord occlusion (*arrow*) in the sheep fetus is accompanied by an increase in fetal aortic blood pressure. Blood pressure changes in the umbilical vessels are also shown. (Redrawn with permission from Künzel W: Fetal heart rate alterations in partial and total cord occlusion. In Künzel W (ed): Fetal Heart Rate Monitoring: Clinical Practice and Pathophysiology. Berlin, Springer, 1985.)



Two types of variable decelerations are shown in Figure 24-17. The deceleration denoted by “A” is very much like that seen with complete umbilical cord occlusion in experimental animals (see Fig. 24-16). Deceleration “B,” however, has a different configuration because of the “shoulders” of acceleration before and after the deceleration component. Lee and coworkers (1975) proposed that this form of variable deceleration was caused by differing degrees of partial cord occlusion. In this physiological scheme, occlusion of only the vein reduces fetal blood return, thereby triggering a baroreceptor-mediated acceleration. With increasing intrauterine pressure and subsequent complete cord occlusion, fetal systemic hypertension develops due to obstruction of umbilical artery flow. This stimulates a baroreceptor-mediated deceleration. Presumably, the aftercoming shoulder of the acceleration represents the same events occurring in reverse (Fig. 24-18).

FIGURE 24-17
Varying (variable) fetal heart rate decelerations. Deceleration (*B*) exhibits “shoulders” of acceleration compared with deceleration (*A*).

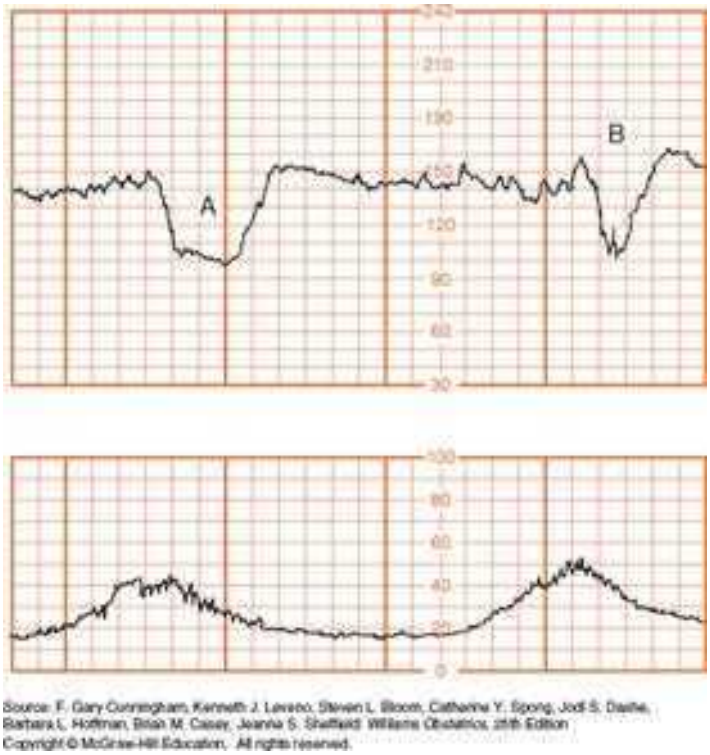


FIGURE 24-18

Schematic representation of the fetal heart rate effects with partial and complete umbilical cord occlusion. Uterine pressures generated early in a contraction cause cord compression predominantly of the thin-walled umbilical vein. The resulting decrease in fetal cardiac output leads to an initial compensatory rise in fetal heart rate. As cord compression intensifies, umbilical arteries are then also compressed. The resulting rise in fetal systolic blood pressure leads to a vagal-mediated fetal heart rate deceleration. As the contraction abates and compression is relieved first on the umbilical arteries, elevated fetal systolic blood pressures drop and the deceleration resolves. A final increase in fetal heart rate is seen as a result of persistent umbilical vein occlusion. With completion of the uterine contraction and cord compression, the fetal heart rate returns to baseline. BP = blood pressure. (Adapted with permission from Lee CV, DiLaretto PC, Lane JM: A study of fetal heart rate acceleration patterns, Obstet Gynecol. 1975 Feb;45(2):142–146.)

Ball and Parer (1992) concluded that variable decelerations are mediated vagally and that the vagal response may be due to chemoreceptor or baroreceptor activity or both. Partial or complete cord occlusion produces an increase in afterload (baroreceptor) and a drop in fetal arterial oxygen content (chemoreceptor). These both result in vagal activity leading to deceleration. In fetal monkeys, the baroreceptor reflexes appear to operate during the first 15 to 20 seconds of umbilical cord occlusion followed by decline in Po_2 at approximately 30 seconds, which then serves as a chemoreceptor stimulus (Mueller-Heubach, 1982).

Thus, variable decelerations represent fetal heart rate reflexes that reflect either blood pressure changes due to interruption of umbilical flow or changes in oxygenation. It is likely that most fetuses have experienced brief but recurrent periods of hypoxia due to umbilical cord compression during gestation. The frequency and inevitability of cord occlusions undoubtedly have provided the fetus with these physiological mechanisms as a means of coping. The great dilemma for the obstetrician in managing variable fetal heart rate decelerations is determining when variable decelerations are pathological. According to the American College of Obstetricians and Gynecologists (2017a), recurrent variable decelerations with minimal-to-moderate beat-to-beat variability are *indeterminate,* whereas those with absent variability are *abnormal*.

Other fetal heart rate patterns have been associated with umbilical cord compression. *Saltatory* baseline heart rate (Fig. 24-19) was first linked to umbilical cord complications during labor (Hammacher, 1968). The pattern consists of rapidly recurring couplets of acceleration and deceleration causing relatively large oscillations of the baseline fetal heart rate. We also observed a relationship between cord occlusion and the saltatory pattern in postterm pregnancies (Leveno, 1984). In the absence of other fetal heart rate findings, these do not signal fetal compromise. *Lambda* is a pattern involving an acceleration followed by a variable deceleration with no acceleration at the end of the deceleration. This pattern typically is seen in early labor and is not ominous (Freeman, 2003). This lambda pattern may result from mild cord compression or stretch. *Overshoot* is a variable deceleration followed by acceleration. The clinical significance of this pattern is controversial (Westgate, 2001).

FIGURE 24-19

Saltatory baseline fetal heart rate showing rapidly recurring couplets of acceleration combined with deceleration.

Prolonged Deceleration

This pattern, which is shown in Figure 24-20, is defined as an isolated deceleration ≥15 bpm that lasts ≥2 minutes but <10 minutes from onset to return to baseline. Prolonged decelerations are difficult to interpret because they are seen in many different clinical situations. Some of the more frequent causes are

cervical examination, uterine hyperactivity, cord entanglement, and maternal supine hypotension.

FIGURE 24-20
Prolonged fetal heart rate deceleration due to uterine hyperactivity. Approximately 3 minutes of the tracing are shown, but the fetal heart rate returned to normal after uterine hypertonus resolved. Vaginal delivery later ensued.

Epidural, spinal, or paracervical analgesia may induce a prolonged deceleration (Eberle, 1998). Hill and associates (2003) observed prolonged deceleration in 1 percent of women given epidural analgesia during labor at Parkland Hospital. Other causes of prolonged deceleration include maternal hypoperfusion or hypoxia from any cause, placental abruption, umbilical cord knots or prolapse, maternal seizures including eclampsia and epilepsy, application of a fetal scalp electrode, impending birth, or maternal Valsalva maneuver. In one example, Ambia and colleagues (2017) described prolonged decelerations lasting 2 to 10 minutes following an eclamptic seizure.

The placenta is effective in resuscitating the fetus if the original insult does not recur immediately. Occasionally, such self-limited prolonged decelerations are followed by loss of beat-to-beat variability, baseline tachycardia, and even a period of late decelerations, all of which resolve as the fetus recovers. Freeman and colleagues (2003) emphasize that the fetus may die during prolonged decelerations. Thus, management of prolonged decelerations can be extremely tenuous. Management of isolated prolonged decelerations is based on bedside clinical judgment, which inevitably will sometimes be imperfect given the unpredictability of these decelerations.

Fetal Heart Rate Patterns During Second-Stage Labor

Decelerations are virtually ubiquitous during the second stage of labor. In one study, only 1.4 percent of more than 7000 deliveries lacked decelerations during second-stage labor (Melchior, 1985). Both cord and fetal head compressions have been implicated as causes of decelerations and baseline bradycardia in this stage. Profound, prolonged fetal heart rate deceleration in the 10 minutes preceding vaginal delivery has been described (Boehm, 1975). And, similar prolonged second-stage decelerations were associated with a stillbirth and neonatal death (Herbert, 1981). These experiences attest to the unpredictability of the fetal heart rate during second-stage labor.

Spong and associates (1998) analyzed the characteristics of second-stage variable fetal heart rate decelerations in 250 deliveries. They found that as the total number of decelerations <70 bpm increased, the 5-minute Apgar score decreased. Of other patterns in second-stage labor, Picquard and coworkers (1988) reported that loss of beat-to-beat variability and baseline fetal heart rate <90 bpm predicted fetal acidemia. Krebs and associates (1981) also found that persistent or progressive baseline bradycardia or baseline tachycardia was associated with lower Apgar scores. Gull and colleagues (1996) observed that abrupt fetal heart rate deceleration to <100 bpm associated with loss of beat-to-beat variability for 4 minutes or longer was predictive of fetal acidemia. Thus, abnormal baseline heart rate—either bradycardia or tachycardia, absent beat-to-beat variability, or both—in the presence of deep second-stage decelerations is associated with a greater risk for fetal compromise (Fig. 24-21).

FIGURE 24-21
Cord-compression fetal heart rate decelerations in second-stage labor associated with tachycardia and loss of variability. The umbilical cord arterial pH was 6.9.

Admission Fetal Monitoring in Low-Risk Pregnancies

With this approach, women with low-risk pregnancies are monitored for a short time on admission for labor. In one study, 3752 low-risk women in spontaneous labor at admission were randomly assigned either to auscultation of the fetal heart or to 20 minutes of electronic fetal monitoring (Mires, 2001). Use of admission electronic fetal monitoring did not improve neonatal outcome. Moreover, its use resulted in a greater number of interventions, including operative delivery. A similar study echoed these neonatal outcomes (Impey, 2003). More than half of the women enrolled in these studies eventually required continuous monitoring. A review by Devane and associates (2017) found that admission fetal monitoring programs for low-risk pregnancy are associated with a higher risk for cesarean delivery. Somewhat related, with the increasing rate of scheduled cesarean deliveries in the United States, clinicians and hospitals must decide whether fetal monitoring is required before the procedure in low-risk women.

Computerized Interpretation

Fetal heart rate pattern interpretations are subjective. Thus, the potential for computer assistance to enhance the precision of identifying abnormal patterns appeared promising. The INFANT Collaborative Group (2017) studied whether the addition of computer-based decision-support software for interpretation of fetal heart rate patterns lowered the number of poor neonatal outcomes. In this trial, 23,515 women were randomized to computer-assisted interpretation compared with 23,055 women in a conventional clinical interpretation arm. Perinatal outcomes such as intrapartum stillbirth, early neonatal death, and neonatal encephalopathy were not improved by computer assistance. Cesarean delivery rates were similar in both groups. Moreover, a 2-year follow-up of a subset of the surviving children showed no differences in their neurological development.

OTHER INTRAPARTUM ASSESSMENT TECHNIQUES

Fetal Scalp Blood Sampling

According to the American College of Obstetricians and Gynecologists (2017a), measurements of the pH in capillary scalp blood may help identify the fetus in serious distress. However, this group also emphasizes that neither normal nor abnormal scalp pH results are predictive of neonatal outcome. Notably, the procedure is now used uncommonly and is not available at most hospitals in the United States.

With sampling, an illuminated endoscope is inserted through the dilated cervix after membrane rupture and is pressed firmly against the fetal scalp (Fig. 24-22). The skin is wiped clean with a cotton swab and coated with a silicone gel, which allows fetal blood to accumulate as discrete globules. An incision is made through the fetal scalp to a depth of 2 mm with a special blade on a long handle. As a drop of blood forms on the surface, it is immediately collected into a heparinized glass capillary tube. The pH of the blood is measured promptly.

FIGURE 24-22
The technique of fetal scalp sampling using an amnioscope. The end of the endoscope is displaced from the fetal vertex approximately 2 cm to show the disposable blade against the fetal scalp before incision.

The pH of fetal capillary scalp blood is usually lower than that of umbilical venous blood and approaches that of umbilical arterial blood. In one algorithm, if the pH is ≥7.25, labor is observed, and if between 7.20 and 7.25, the pH measurement is repeated within 30 minutes (Zalar, 1979). If the pH is <7.20, another scalp blood sample is collected immediately, and the mother is taken to an operating room and prepared for surgery. Delivery is performed promptly if the low pH is confirmed. Otherwise, labor is allowed to continue, and scalp blood samples are repeated periodically.

The only benefits reported for scalp blood pH testing are fewer cesarean deliveries for fetal distress (Young, 1980b). However, Goodwin and coworkers (1994) showed a decrease in the scalp pH sampling rate from approximately 1.8 percent in the mid-1980s to 0.03 percent by 1992. This drop in sampling rate was not associated with a higher cesarean delivery rate for fetal distress. They concluded that scalp blood pH sampling was unnecessary.

Kruger and colleagues (1999) have advocated the use of fetal scalp blood lactate concentration as an adjunct to pH. Wiberg-Itzel and associates (2008) randomly assigned 1496 fetuses to scalp blood pH analysis and 1496 to scalp blood lactate analysis. They found either to be equivalent in predicting fetal acidemia. The advantage of lactate measurement was that a smaller amount of blood was needed, which led to a lower procedural failure rate compared with scalp blood sampling for pH.

Scalp Stimulation

Clark and coworkers (1984) have suggested that fetal scalp stimulation is an alternative to scalp blood sampling. This proposal was based on the observation that heart rate acceleration in response to pinching the fetal scalp with an Allis clamp just before obtaining blood was invariably associated with a normal pH. Conversely, failure to provoke acceleration was not uniformly predictive of fetal acidemia. Later, Elimian and associates (1997) reported that of 58 cases in which the fetal heart rate accelerated >10 bpm after 15 seconds of gentle digital stroking of the scalp, 100 percent had a scalp blood pH of >7.20. Without an acceleration, however, only 30 percent had a scalp blood pH >7.20. Following a prospective cohort study, Tahir Mahmood and coworkers (2017) concluded that fetal scalp stimulation was a reliable alternative to scalp blood pH determination.

Vibroacoustic Stimulation

Fetal heart rate acceleration in response to vibroacoustic stimulation has been recommended as a substitute for fetal scalp blood sampling (Edersheim, 1987). The technique uses an electronic artificial larynx placed approximately 1 cm from or directly onto the maternal abdomen (Chap. 17, Acoustic Stimulation Tests). Response to vibroacoustic stimulation is considered normal if a fetal heart rate acceleration of at least 15 bpm for at least 15 seconds occurs within 15 seconds after the stimulation and with prolonged fetal movements (Sherer, 1994).

Lin and colleagues (2001) prospectively studied vibroacoustic stimulation in 113 women in labor with either moderate-to-severe variable or late fetal heart rate decelerations. They concluded that this technique is an effective predictor of fetal acidosis in the setting of variable decelerations. The predictability for fetal acidosis, however, is limited in the setting of late decelerations. Other investigators have reported that vibroacoustic stimulation in second-stage labor did not predict neonatal outcome or enhance labor management (Anyaegbunam, 1994).

Skupski and coworkers (2002) performed a metaanalysis of reports on intrapartum fetal stimulation tests published between 1966 and 2000. Four types of fetal stimulation were analyzed and included fetal scalp puncture for blood pH testing, Allis clamp pinching of the fetal scalp, vibroacoustic stimulation, and digital stroking of the fetal scalp. Results were similar for all four methods. These investigators concluded that intrapartum stimulation tests were useful to exclude fetal acidemia. They cautioned, however, that these tests are “less than perfect.”

Fetal Pulse Oximetry

Using technology similar to that of adult pulse oximetry, this instrumentation allows assessment of fetal oxyhemoglobin saturation once membranes are ruptured. A unique padlike sensor is inserted through the cervix and positioned against the fetal face. The transcervical device reliably registers fetal oxygen saturation in 70 to 95 percent of women throughout 50 to 88 percent of their labors (Yam, 2000). Using fetal pulse oximetry, the lower limit for normal fetal oxygen saturation is generally considered to be 30 percent (Gorenberg, 2003; Stiller, 2002). However, when measured in umbilical arterial blood, fetal oxygen saturation normally varies greatly, as shown in Figure 24-23. Bloom and associates (1999) reported that brief, transient fetal oxygen saturations <30 percent were common during labor because such values were observed in 53 percent of fetuses with normal outcomes. When persistent for 2 minutes or longer, however, saturation values <30 percent were associated with a greater risk of potential fetal compromise.

FIGURE 24-23
Frequency distribution of umbilical artery oxygen saturation values in 1281 vigorous newborn infants. Dotted line indicates normal distribution. (Redrawn with permission from Arikan GM, Scholz HS, Petru E, et al: Cord blood oxygen saturation in vigorous infants at birth: what is normal? BJOG. 2000 Aug;107(8):987–994.)

Garite and colleagues (2000) randomly assigned 1010 women with term pregnancies and in whom predefined abnormal fetal heart rate patterns developed. Patients received either conventional fetal monitoring alone or fetal monitoring plus continuous fetal pulse oximetry. The use of fetal pulse oximetry significantly reduced the cesarean delivery rate for nonreassuring fetal status from 10.2 to 4.5 percent. Alternatively, the cesarean delivery rate for dystocia rose significantly from 9 to 19 percent when pulse oximetry was used. No neonatal benefits or adverse effects were associated with fetal pulse oximetry. Based on these observations, the Food and Drug Administration approved marketing of the Nellcor N-400 Fetal Oxygen Monitoring System.

Since then, three other randomized trials have compared fetal pulse oximetry with standard care. In all three trials, neonatal outcomes were similar between the two study arms. East and coworkers (2006) reported that the addition of oximetry significantly reduced cesarean delivery rates for a nonreassuring fetal heart rate pattern. However, Bloom (2006) and Klauser (2005), each with their colleagues, found no difference in cesarean delivery rates between the two study groups. Because of these findings, in 2005, the manufacturer discontinued sale of the fetal oximeter system in the United States.

Fetal Electrocardiography

As fetal hypoxia worsens, the fetal ECG changes. Namely, the mature fetus exposed to hypoxemia develops an elevated ST segment and a progressive rise in the T-wave height that can be expressed as a T:QRS ratio (Fig. 24-24). Increasing T:QRS ratios are thought to reflect the fetal cardiac ability to adapt to hypoxia and appear before neurological damage. Further worsening of hypoxia then leads to progressively negative ST-segment deflection that takes on a biphasic form (Fig. 24-25). It is reasonable to consider that ST-segment abnormalities might occur late in the course of fetal compromise. Indeed, it has been hypothesized that ST-segment changes reflect myocardial tissue hypoxia.

FIGURE 24-24
A. ST segment changes in normal and hypoxic conditions. **B.** Generation of T:QRS ratios. (Redrawn with permission from Devoe L: ECG analysis: the next generation in electronic fetal monitoring? Contemporary Ob/Gyn, September 15, 2006.)

FIGURE 24-25
Biphasic ST-segment waveform with progressive fetal hypoxia. (Adapted with permission from Devoe L: ECG analysis: the next generation in electronic fetal monitoring? Contemporary Ob/Gyn, September 15, 2006.)

Because of these findings, several investigators have assessed the value of analyzing these parameters as an adjunct to conventional fetal monitoring. The technique requires internal fetal heart monitoring and special equipment to process the fetal ECG. In 2005, the manufacturer—Neoventa Medical—received Food and Drug Administration approval for their ST analysis program named the STAN system.

Several studies have evaluated ST-segment changes with fetal monitoring. In one randomized trial of 2400 pregnancies, neonatal outcomes were not improved compared with those in which conventional fetal monitoring alone was used (Westgate, 1993). However, the cesarean delivery rate for fetal distress declined in those with ST-segment analysis. Amer-Wåhlin and colleagues (2001, 2007) found that the addition of ST-segment analysis to conventional fetal monitoring significantly lowered cesarean delivery rates for fetal distress and reduced metabolic acidemia in umbilical artery blood.

Subsequently, Doria and associates (2007) introduced STAN as a clinical practice and reported no changes in the incidence of operative delivery or neonatal encephalopathy. And, one metaanalysis of five randomized trials comprising 15,352 patients found that ST-segment analysis did not lower rates of cesarean delivery or fetal metabolic acidemia at birth (Becker, 2012).

Last, in a trial by the NICHD, 5532 women were randomly assigned to an ST-segment analysis arm (the open group) and 5576 to standard intrapartum management (the masked group). The primary outcome was a composite of one or more of seven events associated with fetal compromise (Belfort, 2015). In the open group, clinical practice was directed to some degree by predetermined ST-segment analysis guidelines. These stipulated that intervention should be withheld, that is, expectant management adopted, for at least 60 minutes despite the presence of minimal variability; variable decelerations lasting ≥60 seconds or dropping to ≥60 bpm; recurrent late decelerations; or prolonged decelerations lasting >2 minutes, so long as no ST-event was present. These guidelines did not pertain to the standard usual management group. Notably, in the open group, 55 women were delivered when STAN guidelines indicated that labor should continue. This composed 20 percent of the total 287 cesarean deliveries performed for fetal distress in this group. Clearly, the attending physicians abandoned the open group protocol that stipulated nonintervention. They likely perceived the fetal heart rate patterns to reflect those formerly accepted in their usual practice as nonreassuring.

The results of this trial showed that STAN had no effect on neonatal outcome or cesarean delivery rates (Belfort, 2015). In their review, Neilson and colleagues (2015) reached similar conclusions. These results have essentially eliminated use of ST-segment analysis in the United States, but this technology is still used in Europe.

Intrapartum Doppler Velocimetry

Doppler interrogation of the umbilical artery has been studied as another potential adjunct to conventional fetal monitoring. Further described in Chapter 10 (Doppler), abnormal Doppler waveforms may signify pathological umbilical-placental vessel resistance. From their review, Farrell and associates (1999)

concluded that this technique, used intrapartum, was a poor predictor of adverse perinatal outcomes.

NONREASSURING FETAL STATUS

The term *fetal distress* is too broad and vague to be applied with any precision to clinical situations (American College of Obstetricians and Gynecologists, 2014). Uncertainty regarding the diagnosis based on interpretation of fetal heart rate patterns has given rise to descriptions such as *reassuring* or *nonreassuring.* The term "reassuring" suggests a restoration of confidence in the health of the fetus by a particular pattern. In contrast, a "nonreassuring" designation suggests inability to remove doubt. These patterns during labor are dynamic, and they can rapidly change from reassuring to nonreassuring and vice versa. *These assessments are subjective clinical judgments that are inevitably subject to imperfection and must be recognized as such.*

The difficulty in assigning a nonreassuring label to fetal heart rate patterns stems in part from the fact that these patterns are more a reflection of fetal physiology than of pathology. Physiological control of heart rate includes various interconnected mechanisms that depend on blood flow and oxygenation. Moreover, the activity of these control mechanisms is influenced by the preexisting state of fetal oxygenation, for example, as seen with chronic placental insufficiency. Importantly, the fetus is tethered by an umbilical cord, whereby blood flow is constantly in jeopardy. Moreover, normal labor is a process of increasing acidemia (Rogers, 1998). Thus, normal labor is a process of repeated fetal hypoxic events that can infrequently lead to significant acidemia.

Diagnosis

Identification of "fetal distress" based on fetal heart rate patterns is imprecise and controversial. Experts in interpretation of these patterns often disagree with each other. Ayres-de-Campos and colleagues (1999) investigated interobserver agreement of fetal heart rate pattern interpretation and found that agreement—or conversely, disagreement—was related to whether the pattern was normal, suspicious, or pathological. Specifically, experts agreed on 62 percent of normal patterns, 42 percent of suspicious patterns, and only 25 percent of pathological patterns. Keith and coworkers (1995) asked each of 17 experts to review 50 tracings on two occasions, at least 1 month apart. Approximately 20 percent changed their own interpretations, and approximately 25 percent did not agree with the interpretations of their colleagues.

To develop standardized and unambiguous definitions of fetal heart rate (FHR) tracings, the NICHD (1997) held a succession of workshops in 1995 and 1996 and published recommendations for interpreting these patterns. As previously shown in Table 24-1, a second workshop was convened to reevaluate these recommendations and clarify terminology (Macones, 2008). A major result was the recommendation of a three-tier system for classification of FHR patterns (Table 24-2). The American College of Obstetricians and Gynecologists (2017b) has recommended use of this tiered system.

TABLE 24-2

Three-Tier Fetal Heart Rate Interpretation System

Category I—Normal

Include all of the following:

- Baseline rate: 110–160 bpm
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

Category II—Indeterminate

Include all FHR tracings not categorized as Category I or III.

Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples include any of the following:

Baseline rate

- Bradycardia not accompanied by absent baseline variability
- Tachycardia

Baseline FHR variability

- Minimal baseline variability
- Absent baseline variability not accompanied by recurrent decelerations
- Marked baseline variability

Accelerations

- Absence of induced accelerations after fetal stimulation

Periodic or episodic decelerations

- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration ≥2 min but <10 min
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” or “shoulders”

Category III—Abnormal

Include either:

- Absent baseline FHR variability and any of the following:

Recurrent late decelerations

Recurrent variable decelerations

Bradycardia

- Sinusoidal pattern

bpm = beats per minute; FHR = fetal heart rate.

Reproduced with permission from Macones GA, Hankins GD, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, Obstet Gynecol. 2008 Sep;112(3):661–666.

A few studies have assessed this three-tiered system. Jackson and coworkers (2011) studied 48,444 women in labor and found that category I (normal FHR) patterns were observed during labor in 99.5 percent of tracings. Category II (indeterminate FHR) patterns were found in 84.1 percent of tracings, and category III (abnormal FHR) patterns were seen in 0.1 percent (54 women). Most—84 percent of women—had a mix of categories during labor. Cahill and colleagues (2012) retrospectively correlated the incidence of umbilical cord acidemia (pH ≤7.10) with fetal heart rate characteristics during the 30 minutes preceding delivery. None of the three categories demonstrated a significant association with cord blood acidemia. The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2014) concluded that a category I or II tracing with a 5-minute Apgar score >7 or with normal arterial blood acid–base values was not consistent with an acute hypoxic-ischemic event.

Sholapurkar (2012) challenged the validity of the three-tier system because most abnormal fetal heart rate patterns fall into the indeterminate category II. It was further suggested that this resulted from most fetal heart rate decelerations being inappropriately classified as *variable* decelerations due to cord compression. A group of 19 experts led by Clark (2013) observed that more than 80 percent of fetuses have FHR patterns in tier II. They proposed a management algorithm for these fetuses, however, their hypothetical algorithm was not clinically tested.

Parer and King (2010) compared this situation in the United States with that of other countries in which a consensus on classification and management has been reached by several professional societies. Some of these include the Royal College of Obstetricians and Gynaecologists, the Society of Obstetricians and Gynaecologists of Canada, the Royal Australian and New Zealand College of Obstetricians and Gynaecologists, and the Japan Society of Obstetrics and Gynecology. These authors further comment that the NICHD three-tier system is inadequate because category II—an indeterminate FHR pattern—contains a vast heterogenous mixture of patterns that prevents development of a management strategy.

Parer and Ikeda (2007) had previously proposed a color-coded five-tier system for both FHR interpretation *and* management. Two subsequent reports have compared the five- and three-tier systems. Bannerman and associates (2011) found that the two systems were similar in fetal heart rate interpretations for tracings that were either very normal or very abnormal. Coletta and coworkers (2012) found that the five-tier system had better sensitivity than the three-tier system. Elliott and colleagues (2010) used computerization to measure the performance of a five-tier classification system but failed to successfully analyze and categorize 2472 fetal heart recordings.

It is apparent that, after 50 years of continuous electronic fetal heart rate monitoring use, there is not a consensus on interpretation and management recommendations for FHR patterns (Parer, 2011).

Meconium in the Amnionic Fluid

Obstetricians have long realized that meconium during labor is problematic in the prediction of fetal distress or asphyxia. Indeed, although 12 to 22 percent of labors are complicated by meconium, only a few are linked to neonatal mortality. In an investigation from Parkland Hospital, meconium was found to be a "low-risk" obstetrical hazard because the perinatal mortality rate attributable to meconium was only 1 death per 1000 live births (Nathan, 1994).

Three theories regarding fetal passage of meconium may explain, in part, the tenuous connection between its detection and neonatal mortality. First, fetuses may pass meconium in response to hypoxia, and meconium therefore signals fetal compromise (Walker, 1953). Second, in utero passage of meconium may represent normal gastrointestinal tract maturation under neural control (Mathews, 1979). A final theory posits that meconium passage follows vagal stimulation from common but transient umbilical cord entrapment with resultant increased bowel peristalsis (Hon, 1961).

Ramin and associates (1996) studied almost 8000 pregnancies with meconium-stained amnionic fluid delivered at Parkland Hospital. Meconium aspiration syndrome was significantly associated with fetal acidemia at birth. Other significant correlates of aspiration included cesarean delivery, forceps to expedite delivery, intrapartum heart rate abnormalities, depressed Apgar scores, and need for assisted ventilation at delivery. Analysis of the type of fetal acidemia based on umbilical blood gases suggested that the fetal compromise associated with meconium aspiration syndrome was an acute event. This is because most acidemic fetuses had abnormally increased P_{CO_2} values rather than a pure metabolic acidemia.

Dawes and coworkers (1972) observed that such hypercarbia in fetal lambs induces gasping and resultant increased amnionic fluid inhalation. Jovanovic and Nguyen (1989) observed that meconium gasped into the fetal lungs caused aspiration syndrome only in asphyxiated animals.

Ramin and colleagues (1996) hypothesized that the pathophysiology of meconium aspiration syndrome includes, but is not limited to, fetal hypercarbia, which stimulates fetal respiration leading to aspiration of meconium into the alveoli. Lung parenchymal injury is secondary to acidemia-induced alveolar cell damage. In this pathophysiological scenario, meconium in amnionic fluid is a fetal environmental hazard rather than a marker of preexistent compromise. This proposed pathophysiological sequence is not all-inclusive, because it does not account for approximately half of the cases of meconium aspiration syndrome in which the fetus is not acidemic at birth.

Thus, it was concluded that the high incidence of meconium observed in the amnionic fluid during labor often represents fetal passage of gastrointestinal contents in conjunction with normal physiological processes. Although normal, such meconium becomes an environmental hazard when fetal acidemia supervenes. Importantly, such acidemia occurs acutely, and therefore meconium aspiration is unpredictable and likely unpreventable. Moreover, Greenwood and colleagues (2003) showed that clear amnionic fluid was also a poor predictor. In a prospective study of 8394 women with clear amnionic fluid, they found that clear fluid was an unreliable sign of fetal well-being.

Growing evidence indicates that many newborns with meconium aspiration syndrome have suffered chronic hypoxia before birth (Ghidini, 2001). Blackwell and associates (2001) found that 60 percent of neonates diagnosed with meconium aspiration syndrome had umbilical artery blood pH ≥7.20, implying that the syndrome was unrelated to the neonatal condition at delivery. Similarly, markers of chronic hypoxia, such as elevated fetal erythropoietin levels and increased nucleated red blood cell counts in newborns, suggest that chronic hypoxia is involved in many meconium aspiration syndrome cases (Dollberg, 2001; Jazayeri, 2000).

In the recent past, routine obstetrical management of a newborn with meconium-stained amnionic fluid included intrapartum suctioning of the oropharynx and nasopharynx. In 2005, management guidelines were significantly modified. Now, the American College of Obstetricians and Gynecologists (2017c) recommends that newborns with meconium-stained amnionic fluid, regardless of their vigor, should no longer routinely receive intrapartum suctioning. Suctioning is reserved for those with airway obstruction. They also recommend that an appropriately credentialed team with full resuscitation skills be available (Chap. 32, Care in the Delivery Room).

Management Options

Principal management options for variant fetal heart rate patterns consist of correcting any fetal insult, if possible. Suggestions are listed in Table 24-3. The woman is moved to a lateral position, and supplemental oxygen is provided by mask. Correcting maternal hypotension caused by regional analgesia and discontinuing oxytocin both serve to improve uteroplacental perfusion. Vaginal examination excludes a prolapsed cord or impending delivery. Simpson and James (2005) assessed the benefits of three maneuvers in 52 women with fetal oxygen saturation sensors already in place. They used intravenous hydration —500 to 1000 mL of lactated Ringer solution given over 20 minutes; lateral versus supine positioning; and administration of supplemental oxygen at 10 L/min using a nonrebreathing mask. Each of these maneuvers significantly raised fetal oxygen saturation levels.

TABLE 24-3

Some Resuscitative Measures for Category II or Category III Tracings

Fetal Heart Rate Abnormality[a]	Interventions[b]
Recurrent late decelerations Prolonged decelerations or bradycardia Minimal or absent FHR variability	Lateral decubitus positioning; administer maternal oxygen; intravenous fluid bolus; reduce uterine contraction frequency
Tachysystole with category II or III tracing	Discontinue oxytocin or prostaglandins; Give tocolytics: terbutaline, magnesium sulfate
Recurrent variable decelerations Prolonged decelerations or bradycardia	Reposition mother; amnioinfusion; with cord prolapse, manually elevate the presenting part while preparing for immediate delivery

[a]Simultaneous evaluation of the suspected cause(s) is also an important step in management of abnormal FHR tracings.

[b]The combination of multiple interventions simultaneously may be appropriate and potentially more effective than doing them individually or serially.

FHR = fetal heart rate.

Tocolysis

Terbutaline sulfate given to relax the uterus can be a temporizing maneuver in the management of nonreassuring fetal heart rate patterns during labor. A single 250-µg intravenous or subcutaneous injection is used to inhibit uterine contractions and thereby improve fetal oxygenation. Cook and Spinnato (1994) described their 10-year experiences with terbutaline tocolysis in 368 pregnancies. Such resuscitation improved fetal scalp blood pH values, although all fetuses underwent cesarean delivery. These investigators concluded that although the studies were small and rarely randomized, most reported favorable results with terbutaline tocolysis for nonreassuring patterns. Small intravenous doses of nitroglycerin—60 to 180 µg—also have been reported to be beneficial (Mercier, 1997). Bullens and associates (2015) concluded in their review that tocolysis was beneficial. Still, the American College of Obstetricians and Gynecologists (2017b) cites that evidence is insufficient to recommend tocolysis for nonreassuring fetal heart rate patterns.

Amnioinfusion

Miyazaki and Taylor (1983) infused saline through an intrauterine pressure catheter in laboring women who had either variable or prolonged decelerations attributed to cord entrapment. Such therapy improved the heart rate pattern in half of the women studied. Later, Miyazaki and Nevarez (1985) randomly assigned 96 nulliparas in labor with cord compression patterns and found that those who were treated with amnioinfusion required cesarean delivery for fetal distress less often. Based on many of these early reports, transvaginal amnioinfusion has been extended into three clinical areas (Dad, 2016). These include: (1) treatment of variable or prolonged decelerations; (2) prophylaxis for women with oligohydramnios, as with prolonged ruptured membranes; and (3) attempts to dilute or wash out thick meconium (Chap. 33, Neonatal Encephalopathy and Cerebral Palsy).

Many different amnioinfusion protocols have been reported, but most provide a 500- to 800-mL bolus of warmed normal saline followed by a continuous infusion of approximately 3 mL/min (Owen, 1990; Pressman, 1996). In another study, Rinehart and colleagues (2000) gave either a 500-mL bolus of normal saline at room temperature alone or a similar bolus plus a continuous infusion at 3 mL/min. Their study included 65 women with variable decelerations, and the investigators found neither method to be superior. Wenstrom and associates (1995) surveyed use of amnioinfusion in teaching hospitals in the United States. The procedure was used in 96 percent of the 186 centers surveyed, and it was estimated that 3 to 4 percent of all women delivered at these centers received such infusion. Potential complications of amnioinfusion are summarized in Table 24-4.

TABLE 24-4

Complications Associated with Amnioinfusion from a Survey of 186 Obstetrical Units

Complication	No. of Centers (%)
Uterine hypertonus	27 (14)
Abnormal fetal heart rate tracing	17 (9)
Chorioamnionitis	7 (4)
Cord prolapse	5 (2)
Uterine rupture	4 (2)
Maternal cardiac or respiratory compromise	3 (2)
Placental abruption	2 (1)
Maternal death	2 (1)

Data from Wenstrom, 1995.

For variable decelerations, Hofmeyr and Lawrie (2012) reviewed the effects of amnioinfusion in the management of fetal heart rate patterns associated with umbilical cord compression. They concluded that amnioinfusion appeared to be useful in reducing the occurrence of variable decelerations, improving neonatal outcome, and lowering cesarean delivery rates. The American College of Obstetricians and Gynecologists (2016) has concluded that amnioinfusion is a reasonable approach in the treatment of repetitive variable decelerations regardless of meconium status.

For oligohydramnios, amnioinfusion has been used prophylactically to avoid intrapartum fetal heart rate patterns from cord occlusion. Nageotte and coworkers (1991) found that this resulted in significantly fewer and less severe variable decelerations in labor. However, the cesarean delivery rate or condition of term newborn was not improved. In a randomized investigation, Macri and colleagues (1992) studied prophylactic amnioinfusion in 170 term and postterm pregnancies complicated by both thick meconium and oligohydramnios. Amnioinfusion significantly reduced meconium aspiration syndrome rates and cesarean delivery rates for fetal distress. In contrast, Ogundipe and associates (1994) randomly assigned 116 term pregnancies with an amnionic fluid index <5 cm to receive prophylactic amnioinfusion or standard obstetrical care. Overall cesarean delivery rates, delivery rates for fetal distress, or umbilical cord acid–base studies did not differ significantly between groups.

For meconium-stained amnionic fluid, Pierce and associates (2000) reviewed 13 prospective trials of intrapartum amnioinfusion for 1924 women with meconium-stained fluid. In the amnioinfusion group, newborns were significantly less likely to have meconium below the vocal cords, and meconium aspiration syndrome rates were lower. The cesarean delivery rate was also reduced in the amnioinfusion group. Similar results were reported by Rathore and coworkers (2002).

In contrast, several investigators were not supportive of amnioinfusion for meconium staining. For example, Usta and associates (1995) reported that amnioinfusion was not feasible in half of women with moderate or thick meconium who were randomized to this treatment. These investigators were unable to demonstrate improved neonatal outcomes with this treatment. Spong and coworkers (1994) also concluded that although prophylactic amnioinfusion did dilute meconium, it did not improve perinatal outcome. Last, Fraser and colleagues (2005) randomized amnioinfusion in 1998 women with thick meconium-stained amnionic fluid in labor and found no benefits. Hofmeyr and associates (2014) reported mixed results from their review. Because of these findings, the American College of Obstetricians and Gynecologists (2016) does not recommend amnioinfusion to dilute meconium-stained amnionic fluid.

Fetal Heart Rate Patterns and Brain Injury

Studies that have attempted to correlate fetal heart rate patterns with brain injury primarily have examined infants identified in medicolegal actions. Phelan and Ahn (1994) reported that among 48 fetuses later found to be neurologically impaired, a persistent nonreactive fetal heart rate tracing was already present at the time of admission in 70 percent. They concluded that fetal neurological injury occurred predominately before arrival to the hospital. When they looked retrospectively at heart rate patterns in 209 brain-injured newborns, they concluded that there was not a single unique pattern associated with fetal neurological injury (Ahn, 1996). Graham and associates (2006) reviewed the world literature published between 1966 and 2006 on the effect of fetal heart rate monitoring to prevent perinatal brain injury and found no benefit.

Fetal heart rate patterns necessary for perinatal brain damage have been studied in experimental animals. Myers (1972) described the effects of complete and partial asphyxia in rhesus monkeys. Complete asphyxia was produced by total occlusion of umbilical blood flow that led to prolonged deceleration (Fig.

24-26). Fetal arterial pH did not drop to 7.0 until approximately 8 minutes after complete cessation of oxygenation and umbilical flow. At least 10 minutes of such prolonged deceleration was required before there was evidence of brain damage in surviving fetuses.

FIGURE 24-26
Prolonged deceleration in a rhesus monkey shown with blood pressure and biochemical changes during total occlusion of umbilical cord blood flow. (Data from Myers, 1972.)

Myers (1972) also produced partial asphyxia in rhesus monkeys by impeding maternal aortic blood flow. This resulted in late decelerations due to uterine and placental hypoperfusion. He observed that several hours of these late decelerations did not damage the fetal brain unless the pH fell below 7.0. Indeed, Adamsons and Myers (1977) reported subsequently that late decelerations were a marker of partial asphyxia long before brain damage occurred.

The most common fetal heart rate pattern during labor—due to umbilical cord occlusion—requires considerable time to significantly affect the fetus in experimental animals. Clapp and colleagues (1988) partially occluded the umbilical cord for 1 minute every 3 minutes in fetal sheep. Rocha and associates (2004) totally occluded the umbilical cord for 90 seconds every 30 minutes for 3 to 5 hours a day for 4 days without producing necrotic brain cell injury. Results from such studies suggest that the effects of umbilical cord entrapment depend on the degree of occlusion—partial versus total, the duration of individual occlusions, and the frequency of such occlusions.

The contribution of intrapartum events to subsequent neurological handicaps has been greatly overestimated, as discussed in further detail in Chapter 33 (Neonatal Encephalopathy). It is clear that for brain damage to occur, the fetus must be exposed to much more than a brief period of hypoxia. Moreover, the hypoxia must cause profound, just barely sublethal metabolic acidemia. Because of this, the American College of Obstetricians and Gynecologists (2014) has recommended umbilical cord blood gases be obtained whenever cesarean delivery is performed for fetal compromise, a low 5-minute Apgar score, severe fetal-growth restriction, an abnormal fetal heart rate tracing, maternal thyroid disease, or multifetal gestation (Chap. 32, Umbilical Cord Blood Acid–Base Studies).

Until recently, the prognosis for moderately affected newborns with hypoxic-ischemic encephalopathy (HIE) was poor. This has stimulated research aimed at mitigating these consequences. Animal experiments beginning in the late 1990s suggested that reducing brain temperature after an inciting event could reduce the incidence of cerebral damage (Gunn, 1997, 2000; Nedelcu, 2000; Tooley, 2003; Wagner, 2002). These findings led to several studies worldwide that showed brain cooling administered to newborns suffering neonatal HIE could ameliorate the development of subsequent cerebral palsy. These studies are further described in Chapter 33 (Cerebral Palsy).

Benefits of Electronic Fetal Heart Rate Monitoring

Several false assumptions underlie the expectation of improved perinatal outcome with electronic monitoring. One is that fetal distress is a slowly developing phenomenon and that electronic monitoring permits early detection of the compromised fetus. Another presumption is that all fetal injury develops in the hospital. Within the past 20 years, attention has focused on the reality that most neurologically damaged fetuses suffered insults before arrival at labor units. The very term *fetal monitor* implies that this inanimate technology in some fashion "monitors." The assumption is made that if a dead or damaged fetus is delivered, the tracing strip must provide some clue, because this device was monitoring fetal condition. All of these assumptions led to great expectations and fostered the belief that all neonatal deaths or injuries were preventable.

By the end of the 1970s, questions regarding the efficacy, safety, and costs of electronic monitoring were being voiced from the Office of Technology Assessment, the United States Congress, and the Centers for Disease Control and Prevention. Banta and Thacker (2002) reviewed 25 years of the controversy on the benefits, or lack thereof, of electronic fetal monitoring. More recently, Alfirevic and colleagues (2017) reviewed 13 randomized trials involving more than 37,000 women. They concluded that electronic fetal monitoring was associated with fewer neonatal seizures but a higher rate of cesarean and operative vaginal deliveries. Importantly, rates of perinatal mortality or cerebral palsy did not decline. Grimes and Peipert (2010) wrote a *Current Commentary* on electronic fetal monitoring in *Obstetrics & Gynecology.* They summarized that such monitoring, although it has been used in 85 percent of the almost 4 million annual births in the United States, has failed as a public health screening program. They noted that the positive-predictive value of electronic fetal monitoring for fetal death in labor or cerebral palsy is near zero—meaning that "almost every positive test result is wrong."

There have been at least two attempts to study the epidemiological effects of electronic fetal monitoring in the United States. Chen and coworkers (2011) used 2004 data on more than 1.7 million singleton live births, 89 percent of which underwent electronic fetal monitoring. They reported that monitoring raised operative delivery rates but lowered early neonatal mortality rates. This benefit was gestational-age dependent, however, and the highest effect was seen in preterm fetuses. Later, Ananth and colleagues (2013) reported a similar but larger epidemiological study in the United States. They studied nearly 58 million nonanomalous singleton liveborn neonates delivered between 1990 and 2004. The temporal increase in fetal monitoring use was associated with a decline in neonatal mortality rates, especially in preterm gestations. In an accompanying editorial, Resnik (2013) cautioned that an epidemiological association between fetal monitoring and reduced neonatal death does not establish causation. He suggested that the limitations of the study by Ananth should make the reader skeptical of the findings.

At Parkland Hospital in July 1982, an investigation began to ascertain whether all women in labor should undergo electronic monitoring (Leveno, 1986). In alternating months, universal electronic monitoring was rotated with selective heart rate monitoring, which was the prevailing practice. During the 3-year investigation, more than 17,000 labors were managed using universal electronic monitoring, and these outcomes were compared with a similar-sized cohort of women selectively monitored electronically. No significant differences were found in any perinatal outcome. With universal monitoring, a small but

significant increase in the cesarean delivery rate for fetal distress was noted. Thus, greater application of electronic monitoring at Parkland Hospital did not improve perinatal results but did slightly raise the frequency of cesarean delivery for fetal distress. More recently, a Cochrane Database review found that intermittent auscultation had a higher cesarean delivery rate compared with continuous monitoring (Martis, 2017).

Current Recommendations

Methods most commonly used for intrapartum fetal heart rate monitoring include auscultation with a fetal stethoscope or a Doppler ultrasound device, or continuous electronic monitoring of the fetal heart rate and uterine contractions. No scientific evidence has identified the most effective method, including the frequency or duration of fetal surveillance that ensures optimum results. Summarized in Table 24-5 are the recommendations of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017). Intermittent auscultation or continuous electronic monitoring is considered an acceptable method of intrapartum surveillance in both low- and high-risk pregnancies. The recommended interval between checking the heart rate, however, is longer in the uncomplicated pregnancy. When auscultation is used, it is recommended that it be performed after a contraction and for 60 seconds. It also is recommended that a 1-to-1 nurse–patient ratio be used if auscultation is employed. The position taken by the American College of Obstetricians and Gynecologists (2017b) acknowledges that available data do not show a clear benefit to the use of electronic monitoring over intermittent auscultation. At Parkland Hospital, all high-risk labors are continuously monitored electronically. In low-risk pregnancies, both intermittent auscultation and continuous electronic monitoring are used depending on clinical circumstances, including the woman's desire to ambulate.

TABLE 24-5

Guidelines for Methods of Intrapartum Fetal Heart Rate Monitoring

Surveillance	Low-Risk Pregnancies	High-Risk Pregnancies
Acceptable methods		
Intermittent auscultation	Yes	Yes[a]
Continuous electronic monitoring (internal or external)	Yes	Yes[b]
Evaluation intervals		
First-stage labor (active)	30 min	15 min[a,b]
Second-stage labor	15 min	5 min[a,c]

[a]Preferably before, during, and after a uterine contraction.

[b]Includes tracing evaluation and charting at least every 15 min.

[c]Tracing should be evaluated at least every 5 min.

Data from the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2017.

INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY

Analysis of electronically measured uterine activity permits some generalities concerning the relationship of certain contraction patterns and labor outcome. However, uterine muscle efficiency to bring about delivery varies greatly. Thus, caution should be exercised before diagnosing true labor or its absence solely from a monitor tracing.

With *internal monitoring* of contractions, amnionic fluid pressure is measured between and during contractions. In the past, a fluid-filled plastic catheter with its distal tip located above the presenting part was used (Fig. 24-27). The catheter was connected to a strain-gauge pressure sensor adjusted to the same level as the catheter tip in the uterus. The amplified electrical signal produced in the strain gauge by variation in pressure within the fluid system was recorded on a calibrated moving paper strip simultaneously with the fetal heart rate recording. Today, intrauterine pressure catheters are used that have the pressure sensor in the catheter tip, which obviates the need for the fluid column.

FIGURE 24-27

Placement of an intrauterine pressure catheter to monitor contractions and their pressures. The catheter, contained within the introducer, is inserted into the birth canal and placed along one side of the fetal head. The catheter is then gently advanced into the uterus, and the introducer is withdrawn.

With *external monitoring*, uterine contractions can be measured by a displacement transducer in which the transducer button, or "plunger," is held against the maternal abdominal wall. As the uterus contracts, the button moves in proportion to the strength of the contraction. This movement is converted into a measurable electrical signal that indicates the *relative* intensity of the contraction. It has generally been accepted that internal monitoring provided a more accurate measure of intensity. That said, Bakker and associates (2010) performed a randomized trial comparing internal versus external monitoring of uterine contractions in 1456 women. The two methods were equivalent in terms of operative delivery rates and neonatal outcomes.

Patterns of Uterine Activity

Caldeyro-Barcia and Poseiro (1960), from Montevideo, Uruguay, were pioneers in elucidating the patterns of spontaneous uterine activity throughout pregnancy. Contractile waves of uterine activity were usually measured using intraamnionic pressure catheters. But early in their studies, as many as four simultaneous intramyometrial microballoons were also used to record uterine pressure. Contraction intensity was defined as the rise in this pressure above a resting pressure baseline. These investigators also introduced the concept of *Montevideo units* to define uterine activity (Chap. 23, Active-Phase Protraction). With this definition, uterine performance is the product of contraction intensity in mm Hg multiplied by the number of contractions in a 10-minute span. For example, three contractions in 10 minutes, each of 50 mm Hg intensity, would equal 150 Montevideo units.

During the first 30 weeks of pregnancy, uterine activity is comparatively quiescent. Contractions are seldom greater than 20 mm Hg, and these have been equated with those first described by John Braxton Hicks. Uterine activity increases gradually after 30 weeks, and it is noteworthy that these *Braxton Hicks contractions* also increase in intensity and frequency. Uterine activity is further enhanced during the last weeks of pregnancy. During this phase, the cervix ripens (Chap. 21, Cervical Ripening).

According to Caldeyro-Barcia and Poseiro (1960), clinical labor usually commences when uterine activity reaches values between 80 and 120 Montevideo units. This translates into approximately three contractions of 40 mm Hg every 10 minutes. Importantly, no clear-cut division marks labor onset, which is a gradual and progressive transition.

In first-stage labor, uterine contractions progressively grow in intensity from approximately 25 mm Hg at labor commencement to 50 mm Hg at its end. At the same time, the frequency advances from three to five contractions per 10 minutes, and uterine baseline tone rises from 8 to 12 mm Hg. Uterine activity is further enhanced during second-stage labor, aided by maternal pushing. Indeed, contraction intensity of 80 to 100 mm Hg is typical, and the uterus contracts as frequently as five to six times each 10 minutes. Hauth and coworkers (1986) quantified uterine contraction pressures in 109 women at term who received oxytocin for labor induction or augmentation. Most of these women achieved 200 to 225 Montevideo units, and 40 percent had up to 300 units to effect delivery. The authors suggested that these levels of uterine activity should be sought before consideration of cesarean delivery for presumed dystocia (Chap. 23, Active-Phase Protraction).

Interestingly, the duration of uterine contractions—60 to 80 seconds—does not lengthen appreciably from early active labor through the second stage (Bakker, 2007; Pontonnier, 1975). Presumably, this duration constancy serves fetal respiratory gas exchange. During a uterine contraction, as the intrauterine pressure exceeds that of the intervillous space, respiratory gas exchange is halted. This leads to functional fetal "breath holding," which has a 60- to 80-second limit that remains relatively constant.

Caldeyro-Barcia and Poseiro (1960) also observed empirically that uterine contractions are clinically palpable only after their intensity exceeds 10 mm Hg. Moreover, until the intensity of contractions reaches 40 mm Hg, the uterine wall can readily be depressed by the finger. At greater intensities, the uterine wall then becomes so hard that it resists easy depression. Uterine contractions usually are not associated with pain until their strength exceeds 15 mm Hg. Presumably, this is the minimum pressure required to distend the lower uterine segment and cervix. It follows that Braxton Hicks contractions exceeding 15 mm Hg may be perceived as uncomfortable because distention of the uterus, cervix, and birth canal is generally thought to produce discomfort.

Hendricks (1968) observed that "the clinician makes great demands upon the uterus." The uterus is expected to remain well relaxed during pregnancy, to contract effectively but intermittently during labor, and then to remain in a state of almost constant contraction for several hours postpartum. Figure 24-28 demonstrates an example of normal uterine activity during labor. Uterine activity progressively and gradually rises from early through late labor. Interestingly, uterine contractions after birth are identical to those resulting in delivery of the newborn. Logically, the uterus that performs poorly before delivery is also prone to atony and puerperal hemorrhage.

FIGURE 24-28
Intrauterine pressure recorded through a single catheter. **A.** Prelabor. **B.** Early labor. **C.** Active labor. **D.** Late labor. **E.** Spontaneous activity ½ hour postpartum. **F.** Spontaneous activity 2½ hours postpartum. (Redrawn from Hendricks CH: Uterine contractility changes in the early puerperium, Clin Obstet Gynecol. 1968 Mar;11(1):125–144.)

Origin and Propagation of Contractions

The normal contractile wave of labor originates near the uterine end of one of the fallopian tubes. Thus, these areas act as "pacemakers" (Fig. 24-29). The right pacemaker usually predominates over the left and starts most contractile waves. Contractions spread from the pacemaker area throughout the uterus at 2 cm/sec, and the whole organ is depolarized within 15 seconds. This depolarization wave propagates downward toward the cervix. Intensity is greatest in the fundus, and it diminishes in the lower uterus. This phenomenon is thought to reflect the reduced myometrial thickness from the fundus to the cervix. Presumably, this descending pressure gradient serves to direct fetal descent toward the cervix and to efface the cervix. Importantly, all parts of the uterus are

synchronized and reach their peak pressure almost simultaneously, giving rise to the curvilinear waveform shown in Figure 24-29. Young and Zhang (2004) have shown that the initiation of each contraction is triggered by a tissue-level bioelectrical event.

FIGURE 24-29
Schematic representation of the normal contractile wave of labor. Large uterus on the left shows the four points at which intramyometrial pressure was recorded with microballoons. Four corresponding pressure tracings are shown in relation to each other by shading on the small uteri at top. (Adapted with permission from Caldeyro-Barcia R, Poseiro JJ: Physiology of the uterine contraction. Clin Obstet Gynecol 1960 3:386.)

The pacemaker theory also serves to explain the varying intensity of adjacent coupled contractions shown in panels A and B of Figure 24-28. Such coupling was termed *incoordination* by Caldeyro-Barcia and Poseiro (1960). A contractile wave begins in one cornual-region pacemaker but does not synchronously depolarize the entire uterus. As a result, another contraction begins in the contralateral pacemaker and produces the second contractile wave of the couplet. These small contractions alternating with larger ones appear to be typical of early labor. Indeed, labor may progress with such uterine activity, albeit at a slower pace. These authors also observed that labor would progress slowly if regular contractions were hypotonic—that is, contractions with intensity <25 mm Hg or frequency <2 per 10 minutes.

Uterine Contraction Terminology

Terms for the description and quantification of uterine contractions have been recommended by the American College of Obstetricians and Gynecologists (2017b). *Normal uterine activity* is defined as five or fewer contractions in 10 minutes, averaged during a 30-minute span. *Tachysystole* is more than five contractions in 10 minutes, averaged over 30 minutes. Tachysystole can be applied to spontaneous or induced labor. The term *hyperstimulation* was abandoned.

Stewart and associates (2012) prospectively studied uterine tachysystole in 584 women undergoing labor induction with misoprostol at Parkland Hospital. A higher rate of adverse neonatal outcomes was not associated with an increasing number of contractions per 10 minutes or per 30 minutes. Counts of six or more contractions in 10 minutes, however, were significantly associated with fetal heart rate decelerations.

Electronic Fetal Monitoring Complications

Electrodes for fetal heart rate evaluation and catheters for uterine contraction measurement are both associated with infrequent but potentially serious complications. Rarely, an intrauterine pressure catheter during placement may lacerate a fetal vessel in the placenta. Also with insertion, placental and possibly uterine perforation can cause hemorrhage, abruption, serious morbidity, and spurious recordings that have resulted in inappropriate management. Severe cord compression has been described from entanglement with the pressure catheter. Injury to the fetal scalp or breech by a heart rate electrode is rarely severe. However, application at some other site—such as the eye in face presentations—can be serious.

Both the fetus and the mother may be at greater risk of infection from internal monitoring (Faro, 1990). Scalp wounds from the electrode may become infected, and subsequent cranial osteomyelitis has been reported (Brook, 2005; Eggink, 2004; McGregor, 1989). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) have recommended that certain maternal infections, including human immunodeficiency virus (HIV), herpes simplex virus, and hepatitis B and C virus, are relative contraindications to internal fetal monitoring.

CHAPTER 25: Obstetrical Analgesia and Anesthesia

We are indebted to Sir James Y. Simpson, the discoverer of chloroform, for the introduction of anaesthesia into obstetrical practice. He employed ether for this purpose in 1847, and replaced it by chloroform. Every one agrees as to the marked benefits derived from anaesthesia when operative procedures are to be undertaken, but there is still considerable difference of opinion as to the advisability of its routine employment in normal labour.

—J. Whitridge Williams (1903)

INTRODUCTION

As cited by Williams, anesthetic techniques were a most welcome addition to obstetrics. That said, obstetrical anesthesia presents unique challenges. Labor begins without warning, and anesthesia may be required within minutes of a full meal. Vomiting with potential aspiration of the gastric contents is a constant threat due to delayed gastric emptying during pregnancy. Disorders of pregnancy such as preeclampsia, placental abruption, or sepsis further compound provision of obstetrical anesthesia.

Of all anesthesia-related deaths in the United States from 1995 to 2005, 3.6 percent were in pregnant women (Li, 2009). Creanga and colleagues (2017) analyzed deaths of women during or within 1 year of pregnancy in the United States from 2011 through 2013. Of these deaths, they found that 3 of 2009 (0.2 percent) were attributable to anesthesia complications. As shown in Table 25-1, between 1979 and 2002, anesthesia-related maternal mortality rates decreased nearly 60 percent, and currently approximately five deaths per million live births are attributed to anesthesia complications.

TABLE 25-1

Case-Fatality Rates and Rate Ratios of Anesthesia-Related Deaths During Cesarean Delivery by Type of Anesthesia in the United States, 1979–2002

	Case-Fatality Rates[a]		
Year	**General**	**Regional**	**Rate Ratios**
1979–1984	20.0	8.6	2.3 (95% CI 1.9–2.9)
1985–1990	32.3	1.9	16.7 (95% CI 12.9–21.8)
1991–1996	16.8	2.5	6.7 (95% CI 3.0–14.9)
1997–2002	6.5	3.8	1.7 (95% CI 0–4.6)

[a]Deaths per million general or regional anesthetics.

CI = confidence interval.

Data from Hawkins, 2011.

About two thirds of deaths associated with general anesthesia are caused by intubation failure or induction problems during cesarean delivery. Deaths associated with regional analgesia are caused by high spinal or epidural blocks—26 percent; respiratory failure—19 percent; and drug reaction—19 percent. The improved case-fatality rate for general anesthesia is especially notable considering that such anesthesia is now used for the highest-risk patients and the most hurried emergencies, that is, decision-to-incision intervals <15 minutes (Bloom, 2005).

The most significant factor linked to lower maternal mortality rates is the greater use of regional analgesia (Hawkins, 2011). In-house anesthesia coverage that is available around the clock is certainly another contributing factor. Logically, with increased use of regional analgesia, there are now reports of complications with these techniques. Indeed, compared to pre-1990 data, post-1990 obstetrical anesthesia was associated with more legal claims involving regional analgesia (Davies, 2009). In a recent analysis of 466,442 obstetrical hospital discharges, complications associated with regional analgesia accounted for 81 percent of anesthesia-related adverse events (Guglielminotti, 2015).

For the fetus, recent human studies suggest that single, relatively short exposure to general anesthetic and sedation is unlikely to have negative effects on subsequent behavior or learning. This evidence is presented in Chapter 46 (Medications and Surgeries). That said, in 2016, the Food and Drug Administration (FDA) warned that repeated or lengthy use of general anesthetic and sedation drugs in pregnant women during their third trimester may affect fetal brain development. Listed drugs include inhalation agents used in general anesthesia as well as lorazepam, ketamine, propofol, and midazolam. Notably, the American College of

Obstetricians and Gynecologists (2016a) and the Society for Obstetric Anesthesia and Perinatology (2017) have voiced concerns with this statement and cited the lack of significant human data, especially in pregnant women, to underpin this warning.

GENERAL PRINCIPLES

Obstetrical Anesthesia Services

The American College of Obstetricians and Gynecologists (2017a) recognizes that a woman's request for labor pain relief is sufficient medical indication for its provision. Identification of any of the risk factors shown in Table 25-2 should prompt consultation with anesthesia personnel to permit a joint management plan. This plan should include strategies to minimize the need for emergency anesthesia.

TABLE 25-2

Maternal Factors That May Prompt Anesthetic Consultation

Body mass index >30 kg/m^2
Short or thick neck or skeletal neck abnormality
Obstructive lesions: edema, anatomical abnormalities, trauma
Decreased range of motion in opening the mouth or small mandible
Thyromegaly or other neck tumor
Severe preeclampsia syndrome
Bleeding disorders
Obstetrical complications with a high risk of operative delivery
Maternal medical complications such as cardiopulmonary disease
Previous anesthetic complications

Goals for optimizing obstetrical anesthesia services have been established by the American College of Obstetricians and Gynecologists (2017a) and the American Society of Anesthesiologists (2016) and include:

1. Availability of a licensed practitioner who is credentialed to administer an appropriate anesthetic whenever necessary and to maintain support of vital functions in an obstetrical emergency.
2. Availability of anesthesia personnel to permit the start of a cesarean delivery within 30 minutes of the decision to perform the procedure.
3. Anesthesia personnel immediately available to perform an emergency cesarean delivery during the active labor of a woman attempting vaginal birth after cesarean (Chap. 31, Labor and Delivery Considerations).
4. Appointment of a qualified anesthesiologist to be responsible for all anesthetics administered.
5. Availability of a qualified physician with obstetrical privileges to perform operative vaginal or cesarean delivery during administration of anesthesia.
6. Availability of equipment, facilities, and support personnel equal to that provided in any surgical suite.
7. Immediate availability of personnel, other than the surgical team, to assume responsibility for resuscitation of a depressed newborn (Chap. 32, Transition to Air Breathing).

To meet these goals, 24-hour, in-house anesthesia coverage is usually necessary. Providing such service in smaller facilities is more challenging—a problem underscored by the fact that approximately a third of all hospitals providing obstetrical care perform fewer than 500 deliveries per year. The financial burden incurred to provide 24/7 obstetrical anesthesia coverage may result in cost deficits (Bell, 2000). Compounding this burden, some third-party payers have denied reimbursement for epidural analgesia in the absence of a specific medical indication—an approach repudiated by the American College of Obstetricians and Gynecologists (2017a).

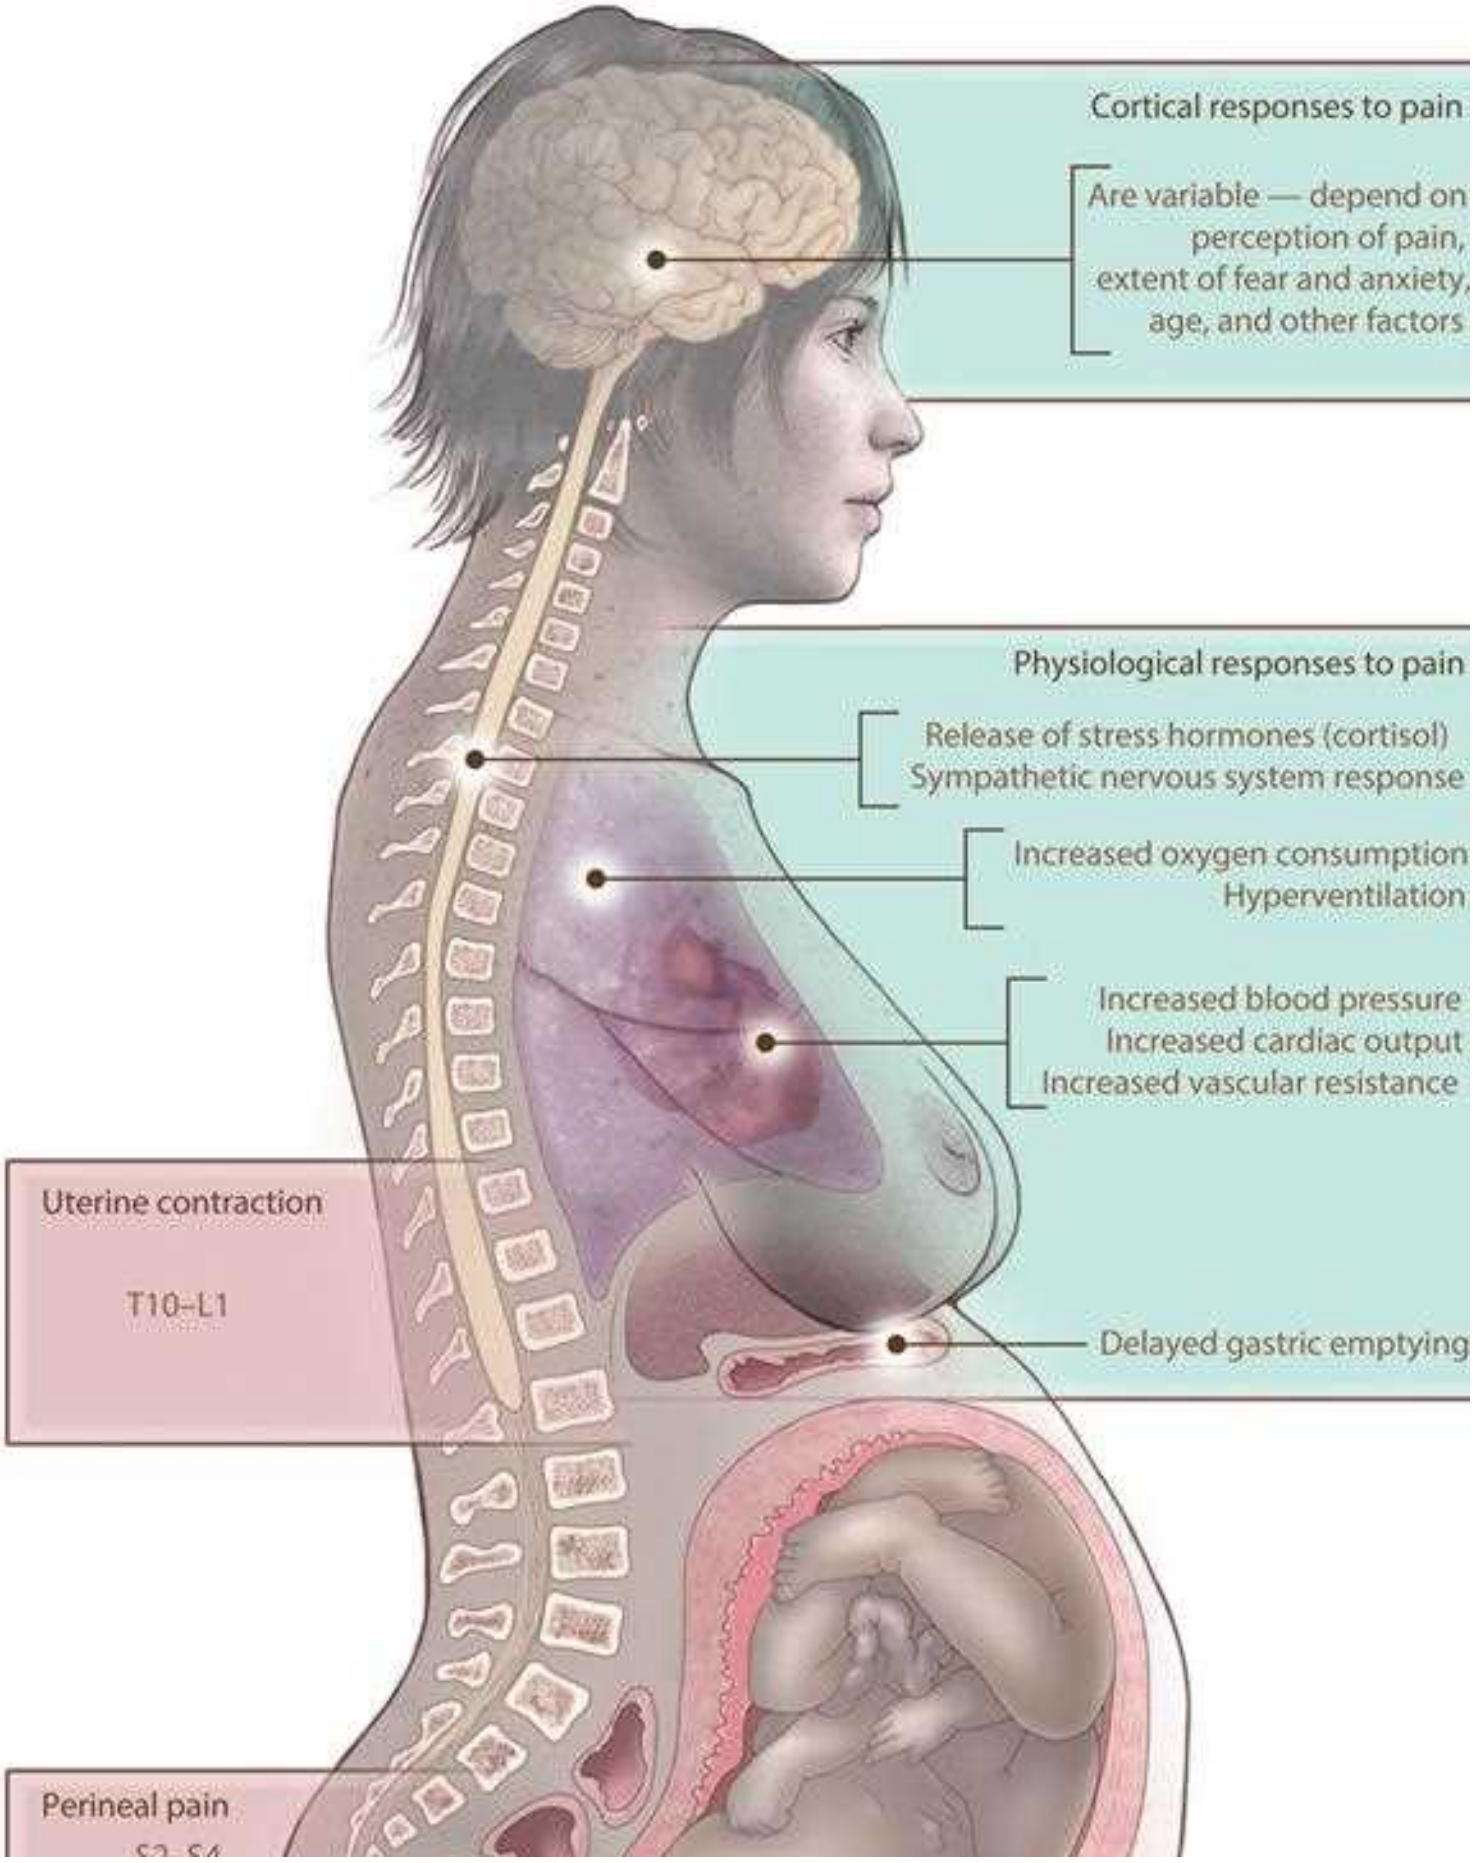
Regarding obstetricians, they should be proficient in local and pudendal analgesia. These may be administered in appropriately selected circumstances described in Central Nervous System Toxicity.

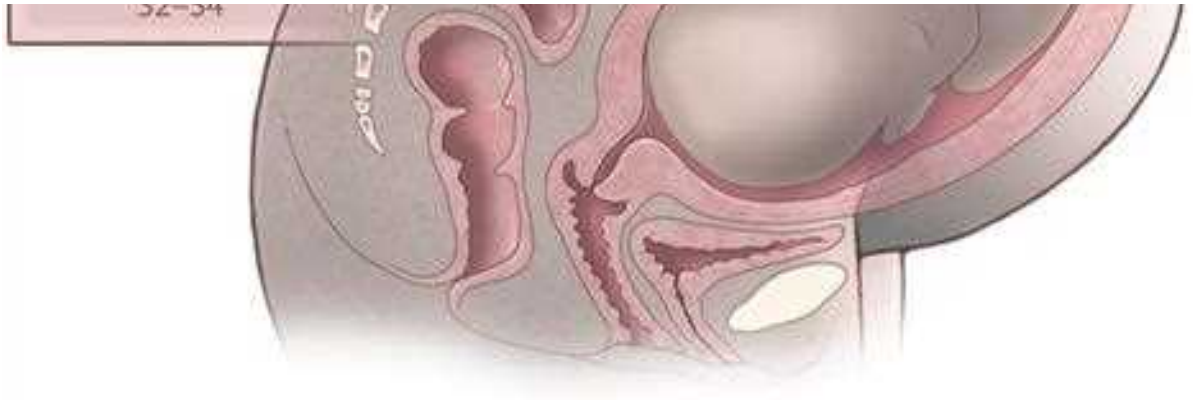
Pain Relief Principles

Hawkins (2010) emphasized that labor pain is a highly individual response to variable stimuli that are uniquely received and interpreted (Fig. 25-1). These stimuli are modified by emotional, motivational, cognitive, social, and cultural circumstances. Labor pain caused by uterine contractions and cervical dilation is transmitted through visceral afferent sympathetic nerves entering the spinal cord from T_{10} through L_1. Later in labor, perineal stretching transmits painful stimuli through the pudendal nerve and sacral nerves S_2 through S_4. Cortical responses to pain and anxiety during labor are complex and may be influenced by maternal expectations for childbirth, her age, preparation through education, emotional support, and other factors. Pain perception is heightened by fear and the need to move into various positions. A woman may be motivated to have a certain type of birthing experience, and these opinions will influence her judgment regarding pain management.

FIGURE 25-1

Sources of pain during labor and maternal physiological responses. (Reproduced with permission from Hawkins JL: Epidural analgesia for labor and delivery, N Engl J Med. 2010 Apr 22;362(16):1503–1510.)





Maternal physiological responses to labor pain can influence maternal and fetal well-being and labor progress. For example, hyperventilation may induce hypocarbia. A greater metabolic rate augments oxygen consumption. Increases in cardiac output and vascular resistance may raise maternal blood pressure. Pain, stress, and anxiety trigger release of stress hormones such as cortisol and β-endorphins. The sympathetic nervous system response to pain leads to a marked elevation in circulating catecholamines that can adversely affect uterine activity and uteroplacental blood flow. Effective analgesia attenuates or eliminates these responses.

ANALGESIA AND SEDATION DURING LABOR

If uterine contractions and cervical dilatation cause discomfort, pain relief is offered. If neuraxial analgesia is contraindicated or unavailable or is declined, a narcotic from Table 25-3 plus one of the tranquilizer-antiemetic drugs such as promethazine (Phenergan) is usually appropriate. With a successful program of analgesia and sedation, the mother ideally rests quietly between contractions. In this circumstance, discomfort usually is felt at the acme of an effective uterine contraction.

TABLE 25-3

Some Parenteral Analgesic Agents for Labor Pain

Agent	Usual Dose	Frequency	Onset	Neonatal Half-Life
Meperidine	25–50 mg (IV)	Q 1–2 hr	5 min (IV)	~18–20 hr
	50–100 mg (IM)	Q 2–4 hr	30–45 min (IM)	~60 hr
Fentanyl	50–100 µg (IV)	Q 1 hr	1 min	~5 hr
Morphine	2–5 mg (IV)	Q 4 hr	5 min (IV)	~7 hr
	10 mg (IM)		30–40 min (IM)	

IV = intravenously; IM = intramuscularly; Q = every.

Parenteral Agents

Meperidine and Promethazine

Meperidine, 50 to 100 mg, with promethazine, 25 mg, may be administered intramuscularly at intervals of 2 to 4 hours. A more rapid effect is achieved by giving meperidine intravenously in doses of 25 to 50 mg every 1 to 2 hours. Whereas analgesia is maximal 30 to 45 minutes after an intramuscular injection, it develops almost immediately following intravenous administration. Meperidine readily crosses the placenta and can have a prolonged half-life in the newborn (American College of Obstetricians and Gynecologists, 2017a). Its depressant effect in the fetus follows closely behind the peak maternal analgesic effect.

According to Bricker and Lavender (2002), meperidine is the most common opioid used worldwide for pain relief during labor. In one randomized study at Parkland Hospital, patient-controlled intravenous analgesia with meperidine was found to be an inexpensive and reasonably effective method for labor analgesia (Sharma, 1997). Women randomized to self-administered analgesia were given a 50-mg meperidine plus 25-mg promethazine dose intravenously as an initial bolus. Thereafter, an infusion pump was set to deliver 15 mg of meperidine every 10 minutes as needed until delivery. Neonatal sedation, as measured by the need for naloxone treatment in the delivery room, was identified in 3 percent of newborns. Both meperidine and its metabolite, normeperidine, are lipophilic and readily cross the placenta. Analgesia with meperidine was associated with lower Apgar scores in comparison to epidural analgesia (Sharma, 2004). Normeperidine is a strong respiratory depressant that has a significantly longer half-life than meperidine and is likely responsible for the fetal side effects of meperidine.

Butorphanol

This synthetic opioid receptor agonist–antagonist analgesic, given in 1- to 2-mg intravenous doses, compares favorably with 40 to 60 mg of meperidine. Its major side effects are somnolence, dizziness, and dysphoria. Neonatal respiratory depression is reported to be less than with meperidine. Importantly, the two drugs are not given contiguously because butorphanol antagonizes the narcotic effects of meperidine. Butorphanol has been associated with transient sinusoidal fetal heart rate patterns (Hatjis, 1986).

Nalbuphine

This is another mixed opioid receptor agonist–antagonist analgesic. It can be given intramuscularly, intravenously, or subcutaneously. The usual dose is 10 to 20 mg, administered every 4 to 6 hours irrespective of the route of administration. Small doses of nalbuphine may also be used to treat pruritus associated with neuraxial opioids.

Fentanyl

This short-acting and potent synthetic opioid may be given in doses of 50 to 100 µg intravenously every hour. Its main disadvantage is its short duration of action, which requires frequent dosing or use of a patient-controlled intravenous infusion pump.

Remifentanil

This is a synthetic opioid with an extremely rapid onset of action. It is hydrolyzed rapidly, resulting in a half-life of 3.5 minutes (Ohashi, 2016). Although it readily crosses the placenta, it is quickly metabolized or redistributed within the fetus (Kan, 1998). Various dosing regimens have been studied, and single boluses appear to mirror the periodic uterine contraction pattern. Infusions, on the other hand, have been reported to cause maternal apnea (Waring, 2007). Due to the aforementioned risks, only trained personnel should administer it, and only under strictly controlled circumstances.

Efficacy and Safety of Parenteral Agents

Hawkins and colleagues (1997) reported that four of 129 maternal anesthetic-related deaths were from parenteral sedation—one from aspiration, two from inadequate ventilation, and one from overdosage. Opioids used during labor may cause newborn respiratory depression. Naloxone is a narcotic antagonist capable of reversing this respiratory depression. It acts by displacing the narcotic from specific receptors in the central nervous system. Withdrawal symptoms may be precipitated in recipients who are physically dependent on narcotics. For this reason, naloxone is contraindicated in a newborn of a narcotic-addicted mother.

Nitrous Oxide

Inhaled nitrous oxide has a rapid onset and offset that provides analgesia during episodic contractions. It can be self-administered as a mixture of 50-percent nitrous oxide and 50-percent oxygen premixed in a single cylinder (Entonox) or using a blender that mixes the two gases from separate tanks (Nitronox). The gases are connected to a breathing circuit through a one-way valve that opens only during inspiration. The use of intermittent nitrous oxide for labor pain is generally regarded as safe for the mother and newborn, but pain control is less effective than epidural analgesia (Barbieri, 2014; Likis, 2014). In many cases, nitrous oxide simply serves to delay more definitive neuraxial analgesia. For maximal efficacy, nitrous oxide is inhaled 30 seconds prior to the start of a contraction, although this prevents adequate rest for the mother. Nitrous oxide is also associated with nausea and vomiting. The environmental and health risk of its use without proper scavenging remains to be carefully evaluated (King, 2014).

REGIONAL ANALGESIA

Various nerve blocks have been developed over the years to provide pain relief during labor and/or delivery. These include pudendal, paracervical, and neuraxial blocks such as spinal, epidural, and combined spinal-epidural techniques.

Anesthetic Agents

Some of the more commonly used nerve block anesthetics, along with their usual concentrations, doses, and durations of action, are summarized in Table 25-4. The dose of each agent varies widely and is dependent on the particular nerve block and physical status of the woman. The onset, duration, and quality of analgesia can be enhanced by raising the volume and/or concentration. This can be done safely only by incrementally administering small-volume boluses of the agent and by carefully monitoring early warning signs of toxicity. Administration of these agents must be followed by appropriate monitoring for adverse reactions. Equipment and personnel to manage these reactions must be immediately available.

TABLE 25-4

Local Anesthetic Agents Commonly Used in Obstetrics

Anesthetic Agent[a]	Usual Concentration (%)	Usual Volume (mL)	Onset	Average Duration (min)	Maximum Dose (mg)	Clinical Use
Aminoesters[b]						
2-Chloroprocaine	2 3	10–20 10–20	Rapid	30–60 30–60	800	Local infiltration or pudendal block Epidural *only* for cesarean
Aminoamides[b]						
Bupivacaine	0.0625–0.125 0.75	10–15 1.5–2	Slow	60–90 60–120	175	Epidural for labor Spinal for cesarean
Lidocaine	1–1.5 1.5–2 5	10–20 5–20 1.5–2	Rapid	30–60 60–90 45–60	300	Local infiltration or pudendal block Epidural for labor or cesarean Spinal for D&C or puerperal tubal
Ropivacaine	0.08–0.2 0.5–1	5–10 10–30	Slow	60–90 90–150	200 250	Epidural for labor Epidural for cesarean

[a]Without epinephrine.

[b]Esters are hydrolyzed by plasma cholinesterases and amides by hepatic clearance.

D&C = dilatation and curettage.

Data from Liu SS, Lin Y: Local anesthetics. In Barash P, Cullen B, Stoeling R, et al (eds): Clinical Anesthesia, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2009.

Most often, serious toxicity follows inadvertent intravenous injection. Systemic toxicity from local anesthetics typically manifests in the central nervous and cardiovascular systems. For this reason, when epidural analgesia is initiated, dilute epinephrine is sometimes added and given as a test dose. A sudden significant rise in the maternal heart rate or blood pressure immediately after administration suggests intravenous catheter placement. This should halt further injection and should prompt catheter repositioning. Local anesthetic agents are manufactured in more than one concentration and ampule size, which raises the potential for dosing errors.

Central Nervous System Toxicity

Early symptoms are those of *stimulation,* but as serum levels rise, *depression* follows. Symptoms may include light-headedness, dizziness, tinnitus, metallic taste, and numbness of the tongue and mouth. Patients may show bizarre behavior, slurred speech, muscle fasciculation and excitation, and ultimately, generalized convulsions, followed by loss of consciousness.

Cardiovascular Toxicity

These manifestations generally develop later than those of cerebral toxicity. Moreover, no symptoms may develop because signs are usually induced by higher serum drug levels. The notable exception is bupivacaine, which is associated with neurotoxicity and cardiotoxicity at virtually identical levels (Mulroy, 2002). Because of its toxicity risk, use of a 0.75-percent solution of bupivacaine for epidural injection has been proscribed by the FDA. Similar to neurotoxicity, cardiovascular toxicity is characterized first by stimulation and then by depression. Accordingly, hypertension and tachycardia are soon followed by hypotension, cardiac arrhythmias, and impaired uteroplacental perfusion.

Management of Local Anesthetic Systemic Toxicity

Seizures and severe ventricular arrhythmias can follow large doses of local anesthetics that are given inadvertently. Labor and delivery units should be stocked with a 20-percent lipid emulsion solution (Intralipid). It is administered as a rapid intravenous bolus followed by an infusion upon the first sign of local anesthetic systemic toxicity (Neal, 2012). Controlling seizures and securing the airway are essential to prevent aspiration and hypoxemia. Benzodiazepines, such as midazolam or lorazepam, may be used to help control seizures, particularly if lipid emulsions are not available. Magnesium sulfate also controls convulsions (Chap 40, Management of Eclampsia). Abnormal fetal heart rate patterns that include late decelerations or bradycardia can follow and stem from maternal hypoxia. With proper management, including supportive measures, the fetus usually recovers. Therefore, it is best for the fetus and mother to delay delivery until the mother is stabilized.

With proper treatment of local anesthetic systemic toxicity (LAST) with lipid emulsions, vital signs usually return to normal. The woman, however, should be monitored, placed in the lateral decubitus position to avoid aortocaval compression, and provided continued supportive care. Vasopressors can be used to support

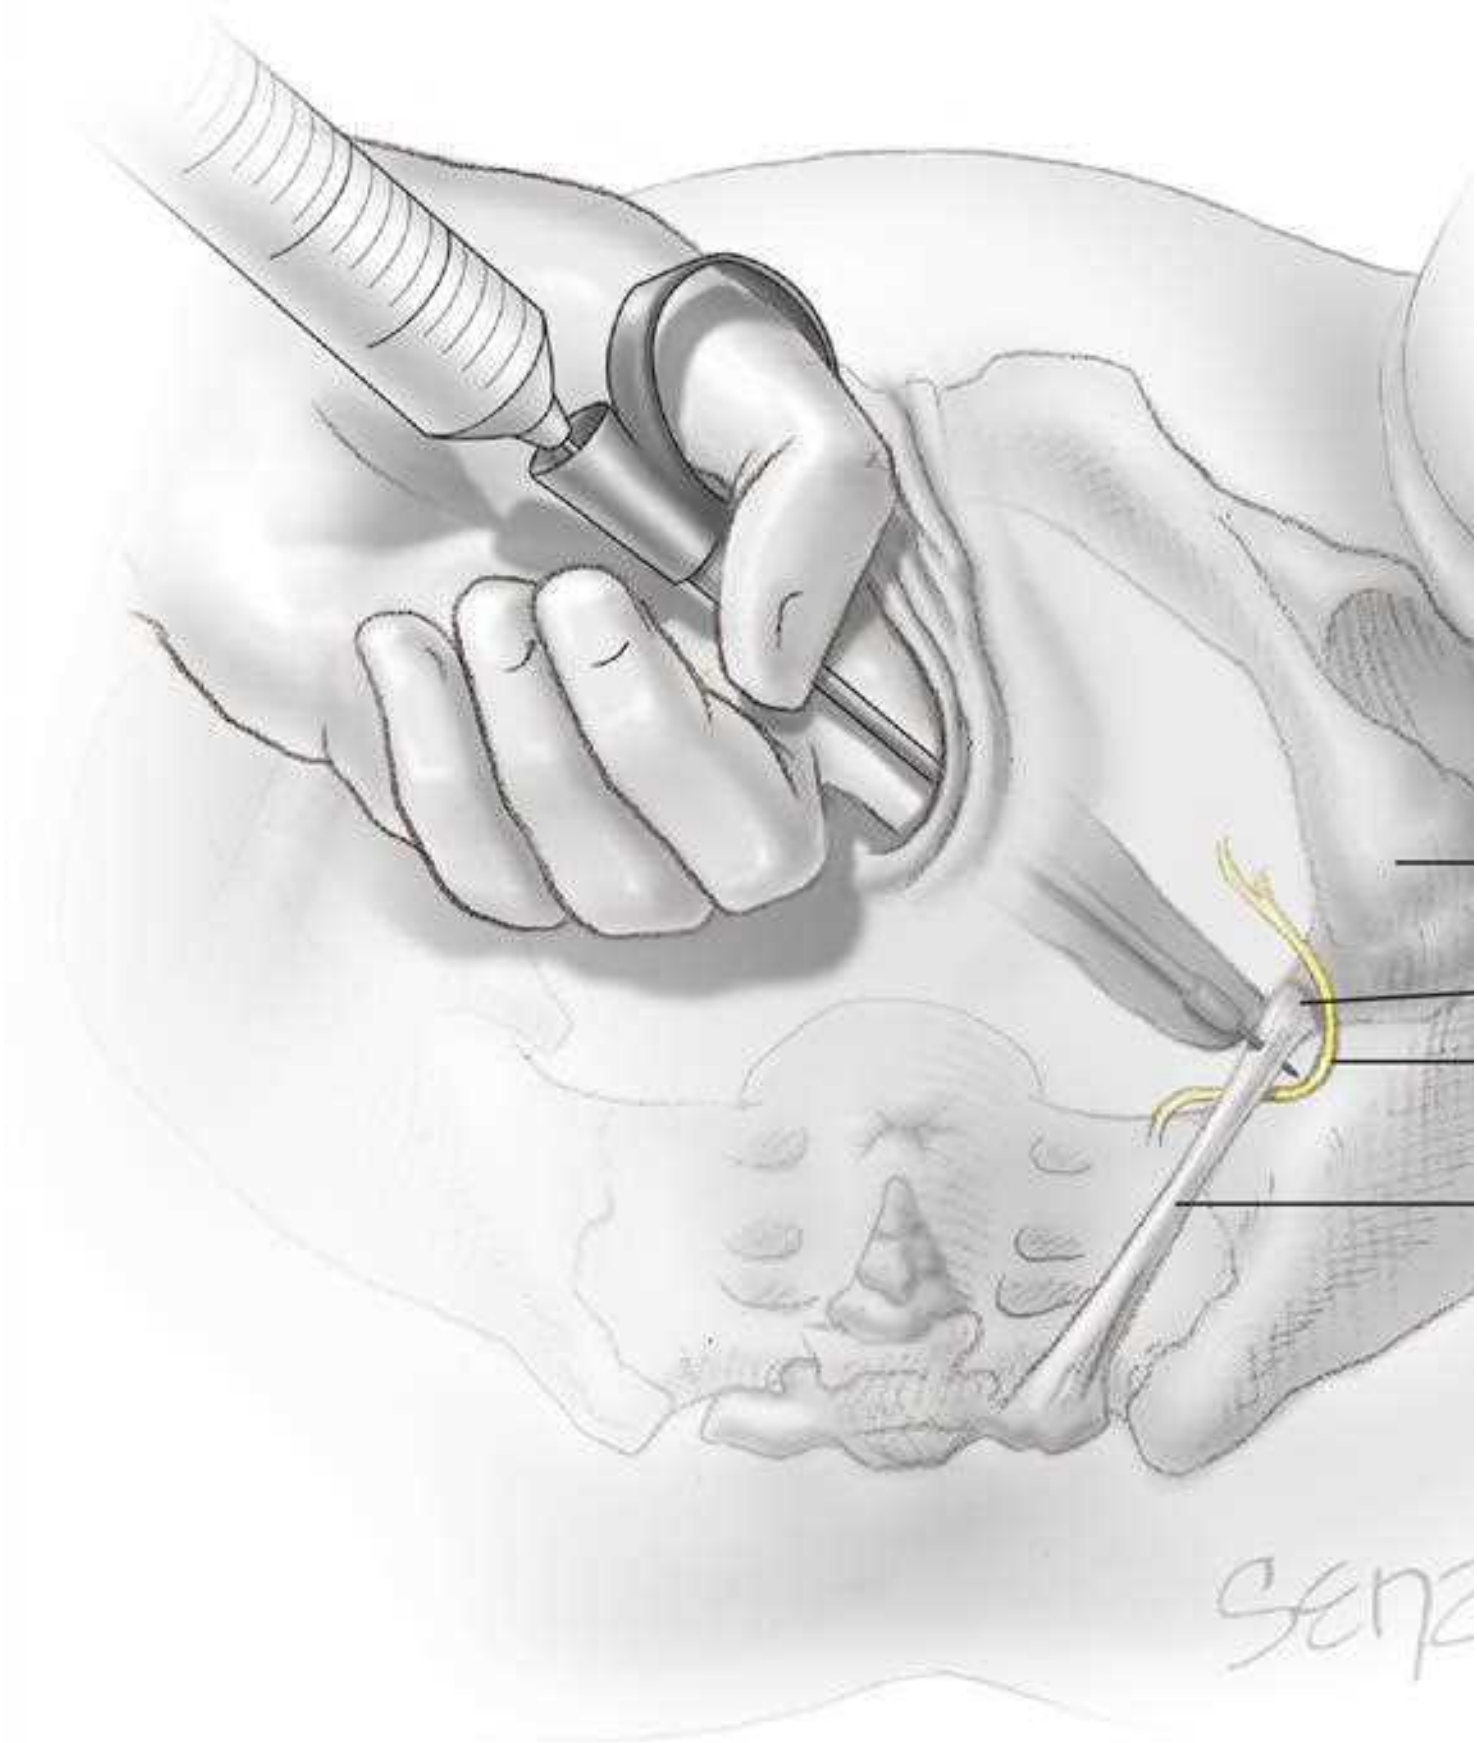
blood pressure. With cardiac arrest, emergency cesarean delivery is considered if maternal vital signs have not been restored within 5 minutes (Chap, 47, Cardiopulmonary Resuscitation). As with convulsions, however, the fetus is likely to recover more quickly in utero once maternal cardiac output is reestablished.

Pudendal Block

Pain with vaginal delivery arises from stimuli from the lower genital tract. These are transmitted primarily through the pudendal nerve, the peripheral branches of which provide sensory innervation to the perineum, anus, vulva, and clitoris. The pudendal nerve passes beneath the sacrospinous ligament just as the ligament attaches to the ischial spine. Sensory nerve fibers of the pudendal nerve are derived from ventral branches of the S_2 through S_4 nerves.

The pudendal nerve block is a relatively safe and simple method of providing analgesia for spontaneous delivery. As shown in Figure 25-2, a tubular introducer is used to sheathe and guide a 15-cm-long 22-gauge needle into position near the pudendal nerve. The end of the introducer is placed against the vaginal mucosa just beneath the tip of the ischial spine. The introducer allows 1.0 to 1.5 cm of needle to protrude beyond its tip, and the needle is pushed beyond the introducer tip into the mucosa. A mucosal wheal is made with 1 mL of 1-percent lidocaine solution or an equivalent dose of another local anesthetic (see Table 25-4). To guard against intravascular infusion, aspiration is attempted before this and all subsequent injections. The needle is then advanced until it touches the sacrospinous ligament, which is infiltrated with 3 mL of lidocaine. The needle is advanced farther through the ligament. As the needle pierces the loose areolar tissue behind the ligament, resistance against the plunger drops. Another 3 mL of solution is injected in this region. Next, the needle is withdrawn into the introducer, which is moved to a point just above the ischial spine. The needle is inserted through the mucosa and a final 3 mL is deposited. The procedure is then repeated on the other side.

FIGURE 25-2
Local infiltration of the pudendal nerve. Transvaginal technique showing the needle extended beyond the needle guard and passing through the sacrospinous ligament to reach the pudendal nerve.



Within 3 to 4 minutes of injection, a successful pudendal block will allow pinching of the lower vagina and posterior vulva bilaterally without pain. If delivery occurs before the pudendal block becomes effective and an episiotomy is indicated, then the fourchette, perineum, and adjacent vagina can be infiltrated with 5 to 10 mL of 1-percent lidocaine solution directly at the planned episiotomy site. By the time of repair, the pudendal block usually has become effective.

Pudendal block usually does not provide adequate analgesia when delivery requires extensive obstetrical manipulation. Moreover, such analgesia is usually inadequate for women in whom complete visualization of the cervix and upper vagina or manual exploration of the uterine cavity is indicated.

Infrequently, complications may follow this block. As previously described, intravascular injection of a local anesthetic agent may cause serious systemic toxicity. Hematoma formation from perforation of a blood vessel is most likely when there is a coagulopathy (Lee, 2004). Rarely, severe infection may originate at the injection site. The infection may spread posteriorly to the hip joint, into the gluteal musculature, or into the retropsoas space (Svancarek, 1977).

Paracervical Block

This block usually provides satisfactory pain relief during first-stage labor. However, because the pudendal nerves are not blocked during paracervical blockade, additional analgesia is required for delivery. For paracervical blockade, usually 5 to 10 mL of lidocaine (1 to 2 percent) or chloroprocaine (3 percent) is injected into the cervix laterally at 3 and 9 o'clock. Because these anesthetics are relatively short acting, this block may have to be repeated during labor.

Fetal bradycardia is a worrisome complication that occurs with approximately 15 percent of paracervical blocks (Rosen, 2002). Bradycardia usually develops within 10 minutes and may last up to 30 minutes. Doppler studies have shown a rise in the pulsatility index of the uterine arteries following paracervical blockade. These observations support the hypothesis of drug-induced arterial vasospasm as a cause of fetal bradycardia (Manninen, 2000). For these reasons, paracervical block is not used in situations of potential fetal compromise.

NEURAXIAL ANALGESIA

Epidural, spinal, or combined spinal-epidural techniques are the most common methods used for pain relief during labor and delivery. In the United States in 2008, epidural analgesia was used in nearly 70 percent of mothers during labor and had a success rate of 98.8 percent. Neuraxial analgesia was used even more often in operative vaginal deliveries and supported 84 percent of forceps deliveries and 77 percent of vacuum extractions (Osterman, 2011).

Spinal (Subarachnoid) Block

Anesthetic in this block can be given as a single dose, can be partnered with an epidural catheter as combined spinal-epidural analgesia, or can be administered as a continuous infusion. Injection of a local anesthetic into the subarachnoid space to effect analgesia has long been used for delivery. Advantages include rapid analgesia onset, short duration of action, and high success rate. The subarachnoid space during pregnancy is smaller, which likely results from internal vertebral venous plexus engorgement. Thus, in parturients, the same amount of anesthetic agent in the same volume of solution produces a much higher blockade than in nonpregnant women.

Vaginal Delivery

The first stage of labor requires a sensory block to the level of the umbilicus (T_{10}). During the second stage of labor and for operative vaginal delivery, a sensory block of S_2 through S_4 is usually adequate to cover pain from perineal stretching and/or instrumentation. Analgesic options include continuous lumbar epidural analgesia, combined spinal-epidural, continuous spinal analgesia, and other blocks such as pudendal and paracervical blocks.

Local anesthetic agents are usually given to establish a sensory block to the desired dermatome level. They are almost exclusively used in conjunction with neuraxial opioids. The mechanism of action is a function of the administration route and lipid solubility. Analgesia is induced by absorption into the vascular system (supraspinal), actions on the dorsal horns, and direct spread in the cerebrospinal fluid to the brainstem. Highly-soluble lipid opioids such as fentanyl and sufentanil have a rapid onset of action. But, because they are absorbed into lipid membranes and the epidural vasculature, their duration of action is short. Hydrophilic solutions such as morphine, on the other hand, provide extended analgesia (Lavoie, 2013). The major advantages of using such a combination are the rapid onset of pain relief, a decrease in shivering, and less dense motor blockade. Side effects are common and include pruritus and urinary retention. Nalbuphine, 2.5 to 5 mg intravenously, can be used to treat pruritis without diminishing the analgesic effect.

Cesarean Delivery

A level of sensory blockade extending to the T_4 dermatome is desired for cesarean delivery. Depending on maternal size, 10 to 12 mg of bupivacaine in a hyperbaric solution or 50 to 75 mg of lidocaine hyperbaric solution is administered. The addition of opioid increases the rapidity of blockade onset, reduces shivering, and minimizes referred pain and other symptoms such as nausea and vomiting. The addition of a preservative-free morphine (Duramorph or Astramorph), 0.1 to 0.3 mg intrathecal or 2 to 4 mg epidural, provides pain control up to 24 hours postoperatively.

Complications

Hypotension

Shown in Table 25-5 are some of the more common adverse events associated with neuraxial analgesia. Importantly, obese women have significantly impaired ventilation, and thus close clinical monitoring is imperative (Vricella, 2011).

TABLE 25-5

Complications of Regional Analgesia

Complication
Not infrequent
Hypotension
Fever Postdural puncture headache
Breakthrough pain
Uncommon
Inadvertant intrathecal, subdural, or intravascular injection of local anesthetic drugs
Neurologic injury

Hypotension is a common complication that may develop soon after injection of the local anesthetic agent. It is the consequence of vasodilatation from sympathetic blockade and is compounded by obstructed venous return due to uterine compression of the great vessels. In the supine position, even in the absence of maternal hypotension measured in the brachial artery, placental blood flow may still be significantly reduced. Treatment includes uterine displacement by left lateral patient positioning, intravenous crystalloid hydration, and intravenous bolus injections of ephedrine or phenylephrine.

Ephedrine is a sympathomimetic drug that binds to α- and β-receptors but also indirectly enhances norepinephrine release. It raises blood pressure by raising heart rate and cardiac output and by variably elevating peripheral vascular resistance. In early animal studies, ephedrine preserved uteroplacental blood flow during pregnancy compared with α_1-receptor agonists. Accordingly, it had been the preferred vasopressor for obstetrical use. Phenylephrine is a pure α-agonist and elevates blood pressure solely through vasoconstriction. A metaanalysis of seven randomized trials by Lee (2002a) suggests that the safety profiles of ephedrine and phenylephrine are comparable. Following their systematic review of 14 reports, Lee (2002b) questioned whether routine prophylactic ephedrine is needed for elective cesarean delivery. Although fetal acidemia has been reported with prophylactic ephedrine use, this was not observed with prophylactic phenylephrine use (Ngan Kee, 2004).

High or Total Spinal Blockade

Most often, high or total spinal blockade follows administration of an excessive dose of local anesthetic or inadvertent injection into the subdural or subarachnoid space. Subdural injection manifests as a high but patchy block even with a small dose of local anesthetic agent, whereas subarachnoid injection typically leads to complete spinal blockade with hypotension and apnea. These conditions must be immediately treated to prevent cardiac arrest. In the undelivered woman: (1) the uterus is immediately displaced laterally to minimize aortocaval compression; (2) effective ventilation is established, preferably with tracheal intubation; and (3) intravenous fluids and vasopressors are given to correct hypotension. If chest compressions are to be performed, the woman is placed in the left-lateral position to allow left uterine displacement.

Postdural Puncture Headache

Leakage of cerebrospinal fluid (CSF) from the dura mater puncture site can lead to postdural puncture or “spinal headache.” Presumably, when the woman sits or stands, the diminished CSF volume creates traction on pain-sensitive central nervous system structures. Another mechanism may be the compensatory cerebral vasodilation in response to the loss of CSF—the Monro-Kellie doctrine (Mokri, 2001).

Rates of this complication can be reduced by using a small-gauge spinal needle and avoiding multiple punctures. In a prospective, randomized study of five different spinal needles, Vallejo and associates (2000) concluded that Sprotte and Whitacre needles had the lowest risks of postdural puncture headaches. Sprigge and Harper (2008) reported that the incidence of postdural puncture headache was 1 percent in more than 5000 women undergoing spinal analgesia. Postdural puncture headaches are much less frequent with epidural blockade because the dura mater is not intentionally punctured. The incidence of inadvertent dural puncture with epidural analgesia approximates 0.2 percent (Introna, 2012; Katircioglu, 2008). There is no good evidence that placing a woman absolutely flat on her back for several hours is effective in preventing this headache.

Once headache develops, it is managed aggressively, as expectant management increases hospital-stay lengths and subsequent emergency-room visits (Angle, 2005). Conservative management, such as fluid administration and bed rest, is largely ineffective. If not effectively treated, postdural puncture headache can persist as a chronic headache (Webb, 2012).

Epidural blood patch is considered the gold standard for treatment. Typically, 10 to 20 mL of autologous blood obtained aseptically by venipuncture is injected into the epidural space. Further CSF leakage is halted by either mass effect or coagulation. Relief is almost always immediate, and complications are uncommon. The initial success rate of an epidural blood patch ranges from 61 to 73 percent (Paech, 2011). Performing a “prophylactic” blood patch is debatable and is thought not to be as effective as if performed after the headache develops (Scavone, 2004, 2015).

If a headache does not have the pathognomonic postural characteristics or persists despite treatment with a blood patch, other diagnoses are considered. Chisholm and Campbell (2001) described a case of superior sagittal sinus thrombosis that manifested as a postdural headache. Smarkusky and colleagues (2006) described pneumocephalus, which caused immediate cephalgia. Finally, intracranial and intraspinal subarachnoid hematomas have developed after spinal analgesia (Dawley, 2009; Liu, 2008).

Convulsions

In rare instances, postdural puncture cephalgia is associated with temporary blindness and convulsions. Shearer and associates (1995) described eight such cases associated with 19,000 regional analgesic procedures done at Parkland Hospital. It is presumed that these too are caused by CSF hypotension. Immediate treatment of seizures and a blood patch were usually effective in these cases.

Bladder Dysfunction

With neuraxial analgesia, bladder sensation is likely to be obtunded and bladder emptying impaired for several hours after delivery. As a consequence, bladder distention is a frequent postpartum complication, especially if appreciable volumes of intravenous fluid are given. Millet and colleagues (2012) randomized 146 women with neuraxial analgesia to either intermittent or continuous bladder catheterizations and found that the intermittent method was associated with significantly higher rates of bacteriuria. That said, we do not recommend routine postpartum use of indwelling catheters following uncomplicated vaginal delivery.

Arachnoiditis and Meningitis

Local anesthetics are no longer preserved in alcohol, formalin, or other toxic solutes, and disposable equipment is usually used. These practices, coupled with aseptic technique, have made meningitis and arachnoiditis rare (Centers for Disease Control and Prevention, 2010).

Contraindications to Neuraxial Analgesia

Shown in Table 25-6 are absolute contraindications. Obstetrical complications that are associated with maternal hypovolemia and hypotension—for example, severe hemorrhage—are contraindications (Kennedy, 1968).

TABLE 25-6

Absolute Contraindications to Neuraxial Analgesia

Refractory maternal hypotension
Maternal coagulopathy
Thrombocytopenia (variously defined)
Low-molecular-weight heparin within 12 hours
Untreated maternal bacteremia
Skin infection over site of needle placement
Increased intracranial pressure caused by a mass lesion

Disorders of coagulation and defective hemostasis also preclude neuraxial analgesia use. Although no randomized studies guide the management of anticoagulation at the time of delivery, consensus opinion suggests that women given subcutaneous unfractionated heparin or low-molecular-weight heparin should be instructed to stop therapy when labor begins (Krivak, 2007). Subarachnoid puncture is also contraindicated if cellulitis involves the planned needle entry site. Many consider neurological disorders to be a contraindication, if for no other reason than that exacerbation of the neurological disease might be erroneously attributed to the anesthetic agent. Other maternal conditions, such as aortic stenosis or pulmonary hypertension, are also relative contraindications (Chap. 49, Physiological Considerations in Pregnancy).

Severe preeclampsia is another comorbid condition in which markedly decreased blood pressure can be predicted when neuraxial analgesia is used. Wallace and associates (1995) randomly assigned 80 women with severe preeclampsia undergoing cesarean delivery at Parkland Hospital to receive general anesthesia or either epidural or combined spinal-epidural analgesia. Maternal and neonatal outcomes did not differ. Still, 30 percent of women given epidural analgesia and 22 percent of those given spinal-epidural blockade developed hypotension. The average reduction in mean arterial pressure ranges between 15 and 25 percent.

Epidural Analgesia

Relief of labor and childbirth pain, including cesarean delivery, can be accomplished by injection of a local anesthetic agent into the epidural or peridural space (Fig. 25-3). This potential space contains areolar tissue, fat, lymphatics, and the internal vertebral venous plexus. This plexus becomes engorged during pregnancy such that the volume of the epidural space is appreciably reduced. Entry for obstetrical analgesia is usually through a lumbar intervertebral space. Although only one injection may be elected, usually an indwelling catheter is placed for subsequent agent boluses or infusion via a volumetric pump. The American College of Obstetricians and Gynecologists (2017a) concludes that under appropriate physician supervision, labor and delivery nursing personnel who have been specifically trained in the management of epidural infusions should be able to adjust dosage and also discontinue infusions.

Continuous Lumbar Epidural Block

Complete analgesia for the pain of labor and vaginal delivery necessitates a block from the T_{10} to the S_5 dermatomes (see Fig. 25-1). For cesarean delivery, a block extending from the T_4 to the S_1 dermatomes is desired. The effective spread of anesthetic depends on the catheter tip location; the dose, concentration, and volume of anesthetic agent used; and whether the mother is head-down, horizontal, or head-up (Setayesh, 2001). Individual variations in anatomy or presence of synechiae may preclude a completely satisfactory block. Finally, the catheter tip may migrate from its original location during labor.

Technique

One example of the sequential steps and techniques for performance of epidural analgesia is detailed in Table 25-7. Before injection of the local anesthetic therapeutic dose, a test dose is given. The woman is observed for features of toxicity from intravascular injection and for signs of high or total blockade from subdural or subarachnoid injection. If these are absent, only then is a full dose given. Analgesia is maintained by intermittent boluses of similar volume or by small volumes delivered continuously by infusion pump (Halpern, 2009). Current pumps used for epidural analgesia offer a programmed intermittent epidural bolus (PIEB) mode, which reduces the required concentration of local anesthetics, the degree of lower extremity motor blockade, and rates of operative vaginal delivery (Capogna, 2011). The addition of small doses of a short-acting narcotic—fentanyl or sufentanil—has been shown to improve analgesic efficacy while avoiding motor blockade (Chestnut, 1988). As with spinal blockade, close monitoring, including the level of analgesia, is imperative and must be performed by trained personnel. Appropriate resuscitation equipment and drugs must be available during administration of epidural analgesia.

TABLE 25-7

Technique for Labor Epidural Analgesia

Informed consent is obtained, and the obstetrician consulted
Monitoring includes the following:
Blood pressure every 1 to 2 minutes for 15 minutes after giving a bolus of local anesthetic
Continuous maternal heart rate monitoring during analgesia induction
Continuous maternal pulse oximetry
Continuous fetal heart rate monitoring
Continual verbal communication
Hydration with 500 to 1000 mL of lactated Ringer solution
The woman assumes a lateral decubitus or sitting position
The epidural space is identified with a loss-of-resistance technique
The epidural catheter is threaded 3 to 5 cm into the epidural space
A test dose of 3 mL of 1.5% lidocaine with 1:200,000 epinephrine or 3 mL of 0.25% bupivacaine with 1:200,000 epinephrine is injected after careful aspiration to avert intravascular injection and after a uterine contraction. This minimizes the chance of confusing tachycardia that results from labor pain with tachycardia from intravenous injection of the test dose.
If the test dose is negative, 10–15 mL of 0.0625–0.125% bupivacaine are injected to achieve a sensory T_{10} level.
After 15 to 20 minutes, the block is assessed using loss of sensation to cold or pinprick. If no block is evident, the catheter is replaced. If the block is asymmetrical, the epidural catheter is withdrawn 0.5 to 1.0 cm and an additional 5 to 10 mL of 0.0625–0.125% bupivacaine is injected. If the block remains inadequate, the catheter is replaced.
The woman is positioned in the lateral or semilateral position to avoid aortocaval compression.
Subsequently, maternal blood pressure is recorded every 5 to 15 minutes. The fetal heart rate is monitored continuously.
The level of analgesia and intensity of motor blockade are assessed at least hourly.

Complications

Higher or Total Spinal Blockade

In general, complications with epidural analgesia are similar to those with spinal analgesia (see Table 25-5). Dural puncture with inadvertent subarachnoid injection may cause total spinal blockade. Sprigge and Harper (2008) cited an incidence of 0.91 percent recognized accidental dural punctures at the time of epidural analgesia in more than 18,000 women. Personnel and facilities must be immediately available to manage this complication as described earlier (Cesarean Delivery). In other aspects, however, complications are unique and inherent to epidural analgesia use.

Ineffective Analgesia

Using currently popular continuous epidural infusion regimens such as 0.125-percent bupivacaine with 2-µg/mL fentanyl, 90 percent of women rate their pain relief as good to excellent (Sharma, 1997). Alternatively, a few women find epidural analgesia to be inadequate for labor. In a study of almost 2000 parturients, Hess and associates (2001) found that approximately 12 percent complained of three or more episodes of pain or pressure. Risk factors for such breakthrough pain included nulliparity and heavier fetal weights. Dresner and colleagues (2006) also reported that epidural analgesia was more likely to fail as body mass index increased. If epidural analgesia is allowed to dissipate before another injection of anesthetic drug, subsequent pain relief may be delayed, incomplete, or both.

In some women, epidural analgesia is insufficient for cesarean delivery. For example, in a Maternal Fetal Medicine Units (MFMU) Network study, 4 percent of women initially given epidural analgesia required a general anesthetic for cesarean delivery (Bloom, 2005). Also at times, perineal analgesia for delivery is difficult to obtain, especially with the lumbar epidural technique. When this situation is encountered, pudendal block or systemic analgesia or rarely general anesthesia may be added.

Hypotension

Sympathetic blockade from epidurally injected analgesic agents can cause hypotension and decreased cardiac output. Despite precautions, hypotension is the most frequent side effect and is severe enough to require treatment in a third of women (Sharma, 1997). According to Miller and coworkers (2013), hypotension is more common—20 percent—in women with an admission pulse pressure <45 mm Hg, compared with 6 percent in those whose pulse pressure is >45 mm Hg. In normal gravidas, hypotension induced by epidural analgesia usually can be prevented by rapid infusion of 500 to 1000 mL of crystalloid solution as described for spinal analgesia. Maintaining a lateral position also minimizes hypotension.

Maternal Fever

Fusi and colleagues (1989) observed that the mean temperature rose in laboring women given epidural analgesia. Subsequently, several randomized and retrospective cohort studies have confirmed that some women develop intrapartum fever following this procedure. Many studies are limited by inability to control for other risk factors such as labor length, duration of ruptured membranes, and number of vaginal examinations. With this in mind, the frequency of intrapartum fever associated with epidural analgesia was found by Lieberman and O'Donoghue (2002) to be 10 to 15 percent above the baseline rate.

The two general theories concerning the etiology of maternal hyperthermia are *maternal-fetal infection* or *dysregulation of body temperature*. Dashe and coworkers (1999) studied placental histopathology in laboring women given epidural analgesia and identified intrapartum fever only when there was placental inflammation. This suggests that fever is due to infection. The other proposed mechanisms include alteration of the hypothalamic thermoregulatory set point; impairment of peripheral thermoreceptor input to the central nervous system, with selective blockage of warm stimuli; or imbalance between heat production and heat loss. Sharma (2014) randomized 400 nulliparas with labor epidural analgesia to receive cefoxitin 2 g prophylactically versus placebo. It was hypothesized that epidural-related fever was due to infection and that prophylactic antimicrobial use should significantly reduce the rate of fever. Approximately equal proportions—about 40 percent—of women developed fever >38°C during labor. This suggests that infection is unlikely to be the cause of fever.

Back Pain

An association between epidural analgesia and subsequent back pain has been reported by some but not all. In a prospective cohort study, Butler and Fuller (1998) reported that back pain after delivery was common with epidural analgesia, however, persistent pain was uncommon. Based on their systematic review, Lieberman and O'Donoghue (2002) concluded that available data do not support an association between epidural analgesia and development of de novo, long-term backache.

Miscellaneous Complications

A spinal or epidural hematoma is a rare complication of an epidural catheter (Grant, 2007). Epidural abscesses are equally infrequent (Darouiche, 2006). And uncommonly, the plastic epidural catheter can be sheared off (Noblett, 2007).

Effects on Labor

Most studies, including the five from Parkland Hospital, report that epidural analgesia prolongs labor and increases the use of oxytocin stimulation (Table 25-8). Alexander and associates (2002) examined the effects of epidural analgesia on the Friedman (1955) labor curve described in Chapter 22 (First Stage of Labor). Compared with original Friedman criteria, epidural analgesia prolonged the active phase of labor by 1 hour. As further shown in Table 25-8, epidural analgesia also increased the need for operative vaginal delivery because of prolonged second-stage labor. But importantly, this led to no greater rates of adverse neonatal effects.

TABLE 25-8

Selected Labor Events in 2703 Nulliparous Women Randomized to Epidural Analgesia or Intravenous Meperidine Analgesia

Event[a]	Epidural Analgesia *n* = 1339	Intravenous Meperidine *n* = 1364	*p* value
Labor outcomes

SVD = spontaneous vaginal delivery.

Adapted with permission from Sharma SK, McIntire DD, Wiley J, et al: Labor analgesia and cesarean delivery. An individual patient meta-analysis of nulliparous women, Anesthesiology. 2004 Jan;100(1):142–148.

This association among epidural analgesia and prolonged second-stage labor and operative vaginal delivery has been attributed to anesthesia-induced motor blockade and resultant impaired maternal expulsive efforts. Craig and colleagues (2015) randomized 310 nulliparous women with labor epidural analgesia to bupivacaine plus fentanyl or fentanyl alone during second-stage labor. Epidural bupivacaine analgesia did cause motor blockade during the second stage, however, the duration of the second stage was not increased.

Fetal Heart Rate

Hill and associates (2003) examined the effects of epidural analgesia with 0.25-percent bupivacaine on fetal heart rate patterns. Compared with intravenous meperidine, no deleterious effects were identified. Reduced beat-to-beat variability and fewer accelerations were more frequent sequelae in fetuses whose mothers received meperidine (Chap. 24, Cardiac Arrhythmia). Based on their systematic review, Reynolds and coworkers (2002) reported that epidural analgesia was associated with improved neonatal acid-base status compared with meperidine.

Cesarean Delivery Rates

A contentious issue in the past was whether epidural analgesia increased the risk for cesarean delivery. Supporting evidence for this view came from the era when dense blocks of local anesthetic agents were used that impaired motor function and therefore likely did contribute to higher cesarean delivery rates. As techniques were refined, however, many investigators came to believe that epidural administration of *dilute* anesthetic solutions did not increase cesarean delivery rates.

Several studies conducted at Parkland Hospital were designed to answer this and related questions. From 1995 to 2002, a total of 2703 nulliparas at term and in spontaneous labor were enrolled in five trials to evaluate epidural analgesia techniques compared with methods of intravenous meperidine administration. The results from these are summarized in Figure 25-4 and show that epidural analgesia does not significantly raise cesarean delivery rates.

FIGURE 25-4

Results of five studies comparing the incidence of cesarean delivery in women given either epidural analgesia or intravenous meperidine. The individual odds ratios (ORs) with 95-percent confidence intervals (CIs) for each randomized study, as well as overall crude and adjusted ORs with 95-percent CIs, are shown. An OR <1.0 favored epidural over meperidine analgesia. (Reproduced with permission from Sharma SK, McIntire DD, Wiley J, et al: Labor analgesia and cesarean delivery. An individual patient meta-analysis of nulliparous women, Anesthesiology. 2004 Jan;100(1):142–148.)

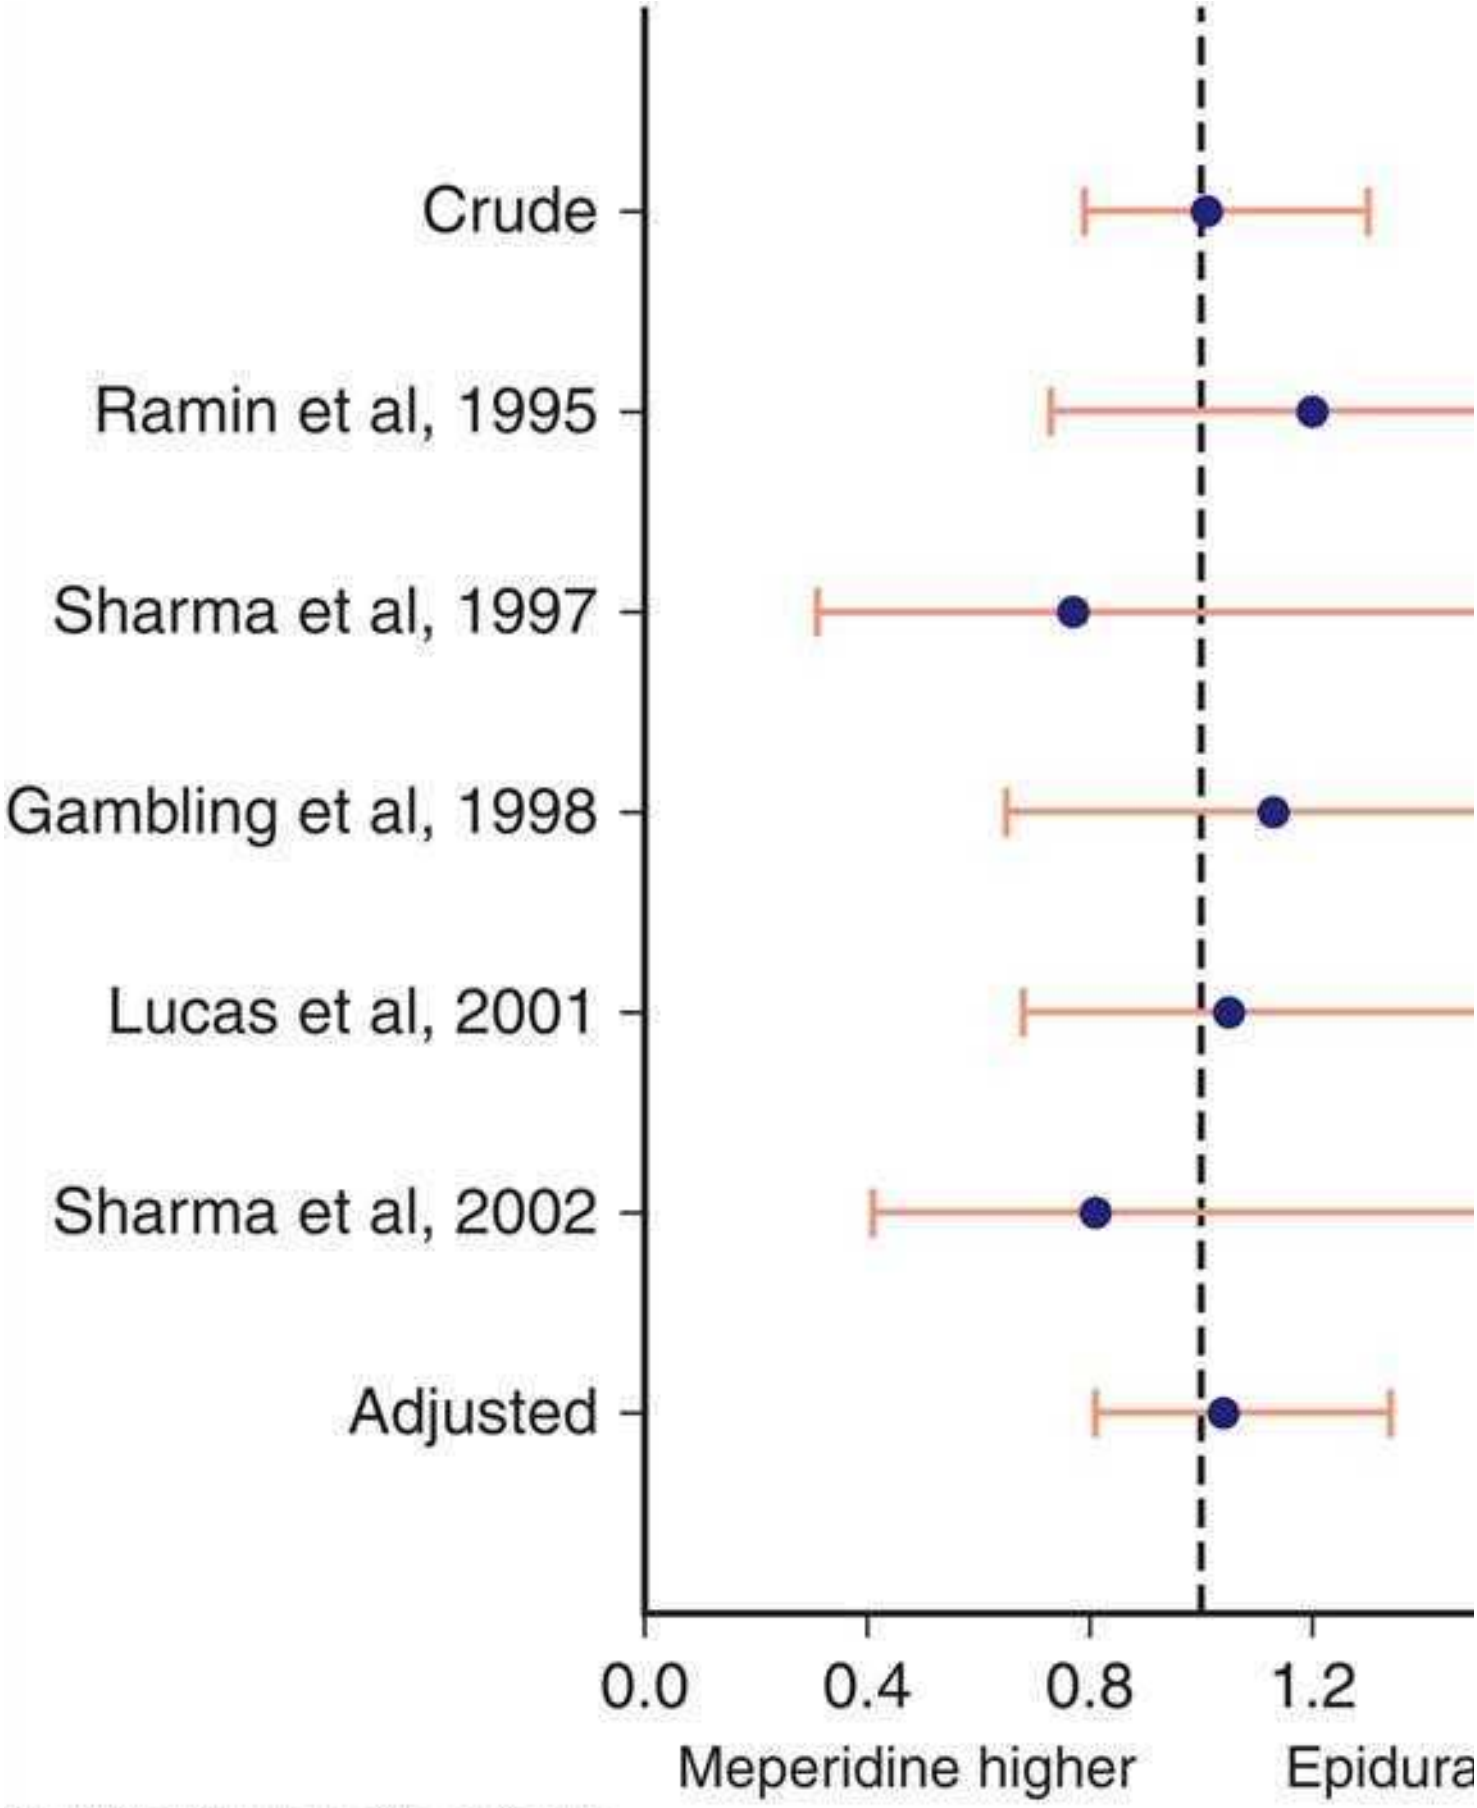

FIGURE 25-5

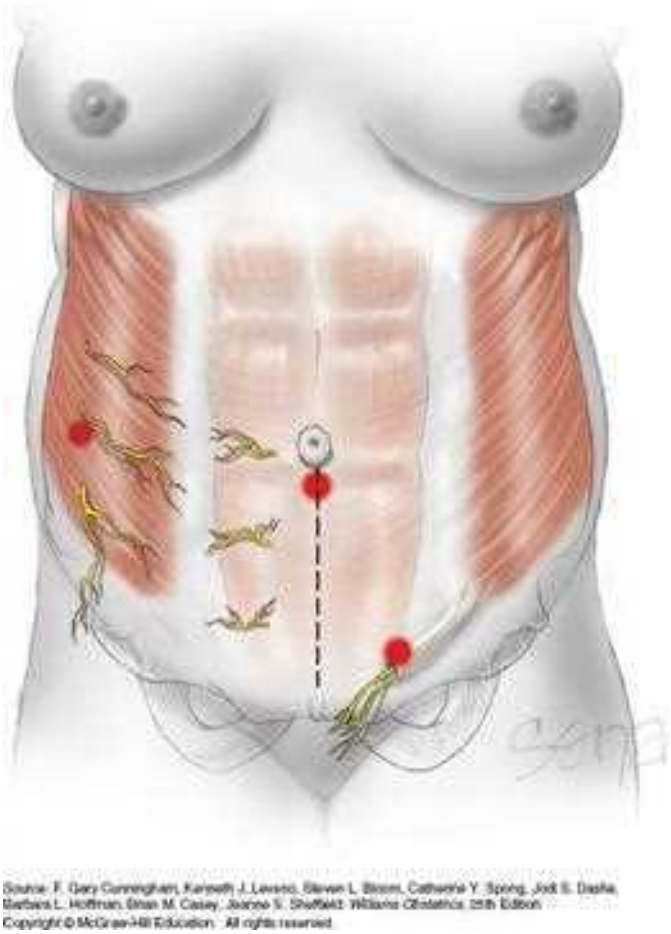
Local anesthetic block for cesarean delivery. The first injection site is halfway between the costal margin and iliac crest in the midaxillary line to block the 10th, 11th, and 12th intercostal nerves. A second injection at the external inguinal ring blocks branches of the genitofemoral and ilioinguinal nerves. These two sites are

infiltrated bilaterally. The fifth and final site is along the line of proposed skin incision.



Timing of Epidural Placement

In several retrospective studies, epidural placement in early labor was linked to an increased risk of cesarean delivery (Lieberman, 1996; Rogers, 1999; Seyb, 1999). These observations prompted at least five randomized trials, which showed that timing of epidural placement has no effect on the risk of cesarean birth, forceps delivery, or fetal malposition (Chestnut, 1994a,b; Ohel, 2006; Wong, 2005, 2009). Thus, withholding epidural placement until some arbitrary cervical dilation has been attained is unsupportable and serves only to deny women maximal labor pain relief.

Safety

The relative safety of epidural analgesia is reflected by the extraordinary earlier experiences reported by Crawford (1985) from the Birmingham Maternity Hospital in England. Similarly, there were no anesthesia-related maternal deaths among nearly 20,000 women who received epidural analgesia in the MFMU Network study cited earlier (Bloom, 2005). And, Ruppen and associates (2006) reviewed data from 27 studies involving 1.4 million pregnant women who received epidural analgesia. They calculated risks of 1:145,000 for deep epidural infection, 1:168,000 for epidural hematoma, and 1:240,000 for persistent neurological injury.

Contraindications

Thrombocytopenia

For epidural analgesia, contraindications are similar to those with spinal analgesia (see Table 25-6). Although low platelet counts are intuitively worrisome, the level at which epidural bleeding *might* develop is unknown according to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2016). Epidural hematomas are rare, and incidence of nerve damage from a hematoma is estimated to be 1 in 150,000 (Grant, 2007). The American College of Obstetricians and Gynecologists (2016b) has concluded that selected women with platelet counts of 80,000 to 100,000/μL may be candidates for regional analgesia. Caveats include a stable platelet count, no acquired or congenital coagulopathy, normal platelet function, no antiplatelet-specific drugs, and anticoagulation parameters, described next, that are met. Counts between 50,000 and 80,000 require an individualized decision on risks and benefits (van Veen, 2010). Single-shot spinal anesthesia with a 25-gauge needle is less traumatic than epidural or combined spinal-epidural anesthesia with a 17- or 18-gauge epidural needle and thus may be safer for patients with platelets in this range.

Anticoagulation

Women receiving anticoagulation therapy who are given regional analgesia are at increased risk for spinal cord hematoma and subsequent cord compression (Chap. 52, Labor and Delivery). Our practice pattern includes the following:

1. Women receiving unfractionated heparin therapy should be able to receive regional analgesia if they have a normal activated partial thromboplastin time (aPTT).

2. Women receiving prophylactic doses of unfractionated heparin or low-dose aspirin are not at increased risk and can be offered regional analgesia.
3. For women receiving once-daily, low-dose low-molecular-weight heparin, regional analgesia should not be placed until 12 hours after the last injection.
4. Low-molecular-weight heparin should be withheld for at least 2 hours after epidural catheter removal.
5. The safety of regional analgesia in women receiving twice-daily low-molecular-weight heparin has not been studied sufficiently. It is not known whether delaying regional analgesia for 24 hours after the last injection is adequate.

Severe Preeclampsia-Eclampsia

Potential concerns with epidural analgesia in women with severe preeclampsia include hypotension as well as hypertension from pressor agents given to correct hypotension. Additionally, pulmonary edema following infusion of large volumes of crystalloid is a potential risk. These are outweighed by disadvantages of general anesthesia. Tracheal intubation may be difficult because of upper airway edema. Moreover, general anesthesia can lead to severe, sudden hypertension that can cause pulmonary or cerebral edema or intracranial hemorrhage.

With improved techniques for infusion of dilute local anesthetics into the epidural space, most obstetricians and obstetrical anesthesiologists have come to favor epidural blockade for labor and delivery in women with severe preeclampsia. There seems to be no argument that epidural analgesia for women with severe preeclampsia-eclampsia can be safely used when implemented by trained anesthesiologists and obstetricians (Lucas, 2001).

Women with severe preeclampsia have remarkably diminished intravascular volumes compared with unaffected gravidas (Zeeman, 2009). Conversely, extravascular volume is increased because of the capillary leak caused by endothelial cell activation (Chap. 40, Pathophysiology). This imbalance is manifested as pathological peripheral edema, proteinuria, ascites, and total lung water. For all of these reasons, aggressive volume replacement increases the risk for pulmonary edema, especially in the first 72 hours postpartum. In one study, Hogg and associates (1999) reported that 3.5 percent of women with severe preeclampsia developed pulmonary edema when preloaded without a protocol limitation to volume. Importantly, this risk can be reduced or obviated with judicious prehydration—usually with 500 to 1000 mL of crystalloid solution. Specifically, in the study by Lucas and colleagues (2001), there were no instances of pulmonary edema among the women in whom the crystalloid preload was limited to 500 mL. Moreover, vasodilation produced by epidural blockade is less abrupt if the analgesia level is achieved slowly with dilute solutions of local anesthetic agents. This allows maintenance of blood pressure while simultaneously avoiding infusion of large crystalloid volumes.

Combined Spinal–Epidural Analgesia

The combination of spinal and epidural techniques has increased in popularity and may provide rapid and effective analgesia for labor and for cesarean delivery. An introducer needle is first placed in the epidural space. A small-gauge spinal needle is then introduced through the epidural needle into the subarachnoid space—this is called the *needle-through-needle technique* (see Fig. 25-3). A single bolus of an opioid, sometimes in combination with a local anesthetic, is injected into the subarachnoid space. The spinal needle is withdrawn, and an epidural catheter is then placed through the introducer needle. A subarachnoid opioid bolus results in the rapid onset of profound pain relief with virtually no motor blockade. The epidural catheter permits repeated analgesia dosing. Miro and associates (2008) compared epidural analgesia with combined spinal-epidural analgesia for labor in 6497 women and found the overall outcomes and complications to be similar for the two techniques. In a randomized comparison, however, Abrão and colleagues (2009) reported that combined spinal-epidural analgesia was associated with a greater incidence of fetal heart rate abnormalities related to uterine hypertonus. Beamon and coworkers (2014) reported similar results.

Continuous Spinal Analgesia During Labor

There is emerging interest in continuous spinal analgesia for relief of labor pain. Arkoosh (2008) randomized 429 laboring women to either continuous spinal or conventional epidural analgesia. Complication rates between these two neuraxial techniques did not differ. Tao and colleagues (2015) reported their experiences with 113 women. With a dilute bupivacaine solution for analgesia, they found no cases of peripheral nerve injury and a headache rate of 2.6 percent. The utility of continuous spinal analgesia in labor and delivery remains to be further studied.

LOCAL INFILTRATION FOR CESAREAN DELIVERY

A local block is occasionally useful to augment an inadequate or “patchy” regional block that was given emergently. Rarely, local infiltration may be needed to perform an emergent cesarean delivery to save the life of a fetus in the absence of anesthesia support (Young, 2012).

In one technique, the skin is infiltrated along the proposed incision, and the subcutaneous, muscle, and rectus sheath layers are injected as the abdomen is opened. Up to a total of 70 mL of 0.5-percent lidocaine with 1:200,000 epinephrine is prepared for infiltration. Injection of large volumes into the fatty layers, which are relatively devoid of nerve supply, is avoided to limit the total dose of local anesthetic needed.

A second technique involves a field block of the major branches supplying the abdominal wall, to include the 10th, 11th, and 12th intercostal nerves and the ilioinguinal and genitofemoral nerves (Nandagopal, 2001). As shown in Figure 25-5, the former group of nerves is located at a point midway between the costal margin and iliac crest in the midaxillary line. The latter group is found at the level of the external inguinal ring. Only one skin puncture is made at each of the four sites (right and left sides). At the intercostal block site, the needle is directed medially, and injection is carried down to the fascia, avoiding injection of the subcutaneous fat. Approximately 5 to 8 mL of 0.5-percent lidocaine is injected. The procedure is repeated at a 45-degree angle cephalad and caudad to this line. The other side is then injected. At the ilioinguinal and genitofemoral sites, the injection is started at a site 2 to 3 cm lateral from the pubic tubercle at a 45-degree angle. Finally, the skin overlying the planned incision is injected.

GENERAL ANESTHESIA

Trained personnel and specialized equipment including alternative airways, video laryngoscopes, and fiberoptic intubation scopes are mandatory for the safe use of general anesthesia. A common cause of death cited for general anesthesia is failed intubation. This occurs in approximately 1 of every 400 general anesthetics administered to pregnant women (Kinsella, 2015). There is a growing trend to continue surgery with a supraglottic airway device, such as a laryngeal mask airway, in the event of a failed intubation (Mushambi, 2015). Because of these relatively greater morbidity and mortality rates, neuraxial analgesia is the preferred method of pain control and should be used unless contraindicated (see Table 25-6). Indeed, in two reports from the MFMU Network, 93 percent of more than 54,000 cesarean deliveries were performed using neuraxial analgesia (Bloom, 2005; Brookfield, 2013). A higher incidence of general anesthesia use for nonwhite women has been reported (Butwick, 2014).

Patient Preparation

Before anesthesia induction, several steps are taken to help minimize complication risks:

1. Antacid administration shortly before anesthesia induction has probably lowered mortality rates from general anesthesia more than any other single practice. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2016) recommends timely administration of a nonparticulate antacid, an H_2-receptor antagonist, or metoclopramide. For many years, we have administered 30 mL of Bicitra—sodium citrate with citric acid—a few minutes before anesthesia induction by either general or major neuraxial block. If more than 1 hour has passed after the first dose was given and anesthesia has not yet been induced, then a second dose is given.

2. Lateral uterine displacement is also provided, as the uterus may compress the inferior vena cava and aorta when the mother is supine. With uterine displacement, the duration of general anesthesia has less effect on neonatal condition than if the woman remains supine.

3. Preoxygenation is done because functional reserve lung capacity is reduced and the pregnant woman becomes hypoxemic more rapidly during periods of apnea. Obesity exacerbates this tendency (McClelland, 2009). To minimize hypoxia between the time of muscle relaxant injection and intubation, oxygen is introduced into the lungs in place of nitrogen. This preoxygenation is accomplished by administering 100-percent oxygen via face mask for 2 to 3 minutes before anesthesia induction. In an emergency, four vital capacity breaths of 100-percent oxygen via a tight breathing circuit will provide similar benefit (Norris, 1985).

Induction and Intubation

Almost all parturients are considered to have a full stomach, which necessitates a rapid-sequence induction. Namely, an intravenous anesthetic and rapid-onset muscle relaxant are simultaneously administered while cricoid pressure is applied by an assistant.

Of anesthetics, intravenous propofol or etomidate is widely used and offers a smooth, rapid induction. Propofol is associated with a quick onset and recovery, and it may lower the incidence of nausea and vomiting. Since thiopental is no longer available, propofol is used as the primary agent for induction of general anesthesia with a reasonable safety record. Etomidate is the induction agent of choice for hemodynamically unstable parturients. Alternatively, ketamine can be used but is avoided in hypertensive women. For muscle relaxation, succinylcholine is an ultrafast-onset, short-acting agent commonly used in obstetrics. It offers intense muscle relaxation to aid endotracheal intubation but also allows for the rapid return of spontaneous respiration in the case of failed intubation. Rocuronium is an alternative muscle relaxant if succinylcholine is contraindicated or unavailable. Its duration is much longer than succinylcholine unless its effect is reversed by sugammadex (Bridion), a specific binding agent recently approved by the FDA. To decrease the incidence of fetal respiratory depression, an intermediate or long-acting opioid is usually avoided upon induction of general anesthesia. The intense stimulation from direct laryngoscopy may worsen hypertension and tachycardia in certain women. Remifentanil, an ultrashort-acting narcotic, has been used during induction for cesarean deliveries with favorable maternal hemodynamics and fetal outcome (Heesen, 2013).

During induction and intubation, cricoid pressure is applied by a trained assistant to occlude the esophagus and thereby minimize regurgitation of the gastric contents—the Sellick maneuver. Positive mask ventilation during rapid sequence induction is typically avoided to lower the risk of increased intragastric pressure, which raises the risk of vomiting. Surgery should begin only after an airway is secured or, depending on the status of the mother and fetus, effective ventilation has been established.

Failed Intubation

Although uncommon, failed intubation is a major cause of anesthesia-related maternal mortality. A history of prior difficult intubation and a careful anatomical assessment of the neck and maxillofacial, pharyngeal, and laryngeal structures may help predict intubation complications. Even in cases in which the initial airway assessment was unremarkable, edema may develop intrapartum and present considerable challenges. Morbid obesity is another major factor for failed or difficult intubation. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2016) stresses the importance of appropriate preoperative preparation. This includes the immediate availability of specialized equipment such as different-shaped laryngoscopes, laryngeal mask airways, a fiberoptic bronchoscope, and a transtracheal ventilation set, as well as liberal use of awake oral intubation techniques.

Management

Ideally, an operative procedure is initiated only after it has been ascertained that tracheal intubation has been successful and that adequate ventilation can be accomplished. Even with an abnormal fetal heart rate pattern, cesarean delivery initiation will only serve to complicate matters if there is difficult or failed intubation. Frequently, the woman must be allowed to awaken and a different technique used, such as an awake intubation or regional analgesia.

Following failed intubation, the woman is ventilated by mask and cricoid pressure is applied to reduce the aspiration risk. Surgery may proceed with mask ventilation, or the woman may be allowed to awaken. In those cases in which the woman has been paralyzed and ventilation cannot be reestablished by insertion of

an oral airway, by laryngeal mask airway, or by use of a fiberoptic laryngoscope to intubate the trachea, then a life-threatening emergency exists. To restore ventilation, percutaneous or even open cricothyrotomy is performed and jet ventilation begun. Failed intubation drills have been recommended to optimize the response to such an emergency.

Inhalational Anesthetics

With the endotracheal tube secured, anesthesia is maintained with a halogenated agent, typically mixed with air or nitrous oxide. The most commonly used inhalational anesthetics in the United States include desflurane and sevoflurane. Both have low solubility in blood and fat. As a result, they offer faster onset and clearance than more traditional gases such as isoflurane. In addition to providing amnesia, they produce profound uterine relaxation when given in high concentrations. This is advantageous when relaxation is a requisite, such as for internal podalic version of the second twin, for breech decomposition, or for replacement of the acutely inverted uterus. That said, unless the woman is already under general anesthesia, intravenous nitroglycerine is preferred by many in such situations.

Extubation

The endotracheal tube may be safely removed only if the woman is conscious to a degree that enables her to follow commands and is capable of maintaining oxygen saturation with spontaneous respiration. Consideration is given to emptying the stomach via a nasogastric tube before extubation. As induction has become safer, extubation may now be relatively more perilous. Of 15 anesthesia-related deaths of pregnant women from 1985 to 2003 in Michigan, none occurred during induction. Five resulted from hypoventilation or airway obstruction during emergence, extubation, or recovery (Mhyre, 2007).

Aspiration

Massive gastric acidic inhalation may cause pulmonary insufficiency from aspiration pneumonitis. In the past, this was the most common cause of anesthetic deaths in obstetrics and therefore deserves special attention. To minimize this risk, antacids are given routinely, intubation is accompanied by cricoid pressure, and regional analgesia is employed when possible.

Fasting

According to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2016) and the American College of Obstetricians and Gynecologists (2017b), data are insufficient regarding fasting times for clear liquids and the risk of pulmonary aspiration during labor. Recommendations are that modest amounts of clear liquids such as water, clear tea, black coffee, carbonated beverages, and pulp-free fruit juices be allowed in uncomplicated laboring women (Chap 22, Oral Intake). Obvious solid foods are avoided. A fasting period of 6 to 8 hours for solid food is recommended for uncomplicated parturients prior to undergoing elective cesarean delivery or puerperal tubal ligation.

O'Sullivan (2009) randomized 2426 low-risk nulliparas to consume either water and ice chips alone or small amounts of bread, biscuits, vegetables, fruits, yogurt, soup, and fruit juice. Approximately 30 percent of women in each arm of the study underwent cesarean delivery. No cases of aspiration occurred during the study, although approximately a third of women in each study arm vomited during labor or delivery. Epidural analgesia during labor was used in this study, although the authors did not report the type of anesthesia used for cesarean deliveries. Presumably, neuraxial analgesia was used, and this greatly minimized the pulmonary aspiration risk. Given the low prevalence of aspiration, this trial was not powered to measure whether feeding during labor was safe (Sperling, 2016).

Pathophysiology

In 1952, Teabeaut demonstrated experimentally that if the pH of aspirated fluid was <2.5, severe chemical pneumonitis developed. It was later demonstrated that the pH of gastric juice in nearly half of women tested intrapartum was <2.5 (Taylor, 1966). The right mainstem bronchus usually offers the simplest pathway for aspirated material to reach the lung parenchyma, and therefore, the right lower lobe is most often involved. In severe cases, there is bilateral widespread involvement.

The woman who aspirates may develop evidence of respiratory distress immediately or several hours after aspiration, depending in part on the material aspirated and the severity of the response. Aspiration of a large amount of solid material causes obvious airway obstruction. Smaller particles without acidic liquid may lead to patchy atelectasis and later to bronchopneumonia.

When highly acidic liquid is inspired, decreased oxygen saturation along with tachypnea, bronchospasm, rhonchi, rales, atelectasis, cyanosis, tachycardia, and hypotension are likely to develop. At the injury sites, there is pulmonary capillary leakage and exudation of protein-rich fluid containing numerous erythrocytes into the lung interstitium and alveoli. This causes decreased pulmonary compliance, shunting of blood, and severe hypoxemia. Radiographic changes may not appear immediately, and these may be variable, although the right lung most often is affected. Thus, chest radiographs alone should not be used to exclude aspiration.

Treatment

The methods recommended for treatment of aspiration have changed appreciably in recent years, indicating that previous therapy was not very successful. Suspicion of aspiration of gastric contents demands close monitoring for evidence of pulmonary damage. Respiratory rate and oxygen saturation as measured by pulse oximetry are the most sensitive and earliest indicators of injury.

Inhaled fluid should be immediately and thoroughly wiped from the mouth and removed from the pharynx and trachea by suction. Saline lavage may further disseminate the acid throughout the lung and is not recommended. If large particulate matter is inspired, bronchoscopy may be indicated to relieve airway obstruction. No convincing evidence supports that corticosteroid therapy or prophylactic antimicrobial administration is beneficial (Marik, 2001). If infection

develops, however, then vigorous treatment is given. If acute respiratory failure develops, mechanical ventilation with positive end-expiratory pressure may be lifesaving (Chap. 47, Clinical Course).

POSTPARTUM ANALGESIA

Goals for postoperative pain management include maximizing patient satisfaction, minimizing side effects, aiding functional capacity, and preventing prolonged hospital stays (Lavoie, 2013). In a prospective study, 96 percent of women reported pain immediately after delivery (Eisenach, 2008). The incidence of persistent pain 1 and 2 years following cesarean delivery was reported to approximate 20 percent (Hannah, 2004; Kainu, 2010).

The American Society of Anesthesiologists (2016) recommends neuraxial opioids for postoperative analgesia. Although most cesarean deliveries in the United States are performed under neuraxial anesthesia, in certain situations a peripheral nerve block such as a transversus abdominis plane (TAP) block may be considered (McDonnell, 2007). These include cases in which the parturient did not receive neuraxial opioids, underwent general anesthesia, or has persistent pain following neuraxial anesthesia. It is usually performed under ultrasound guidance and involves injection of a local anesthetic into the transversus abdominis plane between the internal oblique and transversus abdominis muscles. The nerves lying in this plane supply the anterior abdominal wall at the T_6 to L_1 dermatomes. A metaanalysis of 31 controlled trials showed that ultrasound-guided TAP block marginally reduced opioid consumption at 6 hours following abdominal surgery (Baeriswyl, 2015).

CHAPTER 26: Induction and Augmentation of Labor

In other cases, if interference becomes imperative, the introduction of a bougie into the uterus, or the employment of a small Champetier de Ribes rubber bag acts as an effective uterine irritant and brings about complete dilatation.

—J. Whitridge Williams (1903)

INTRODUCTION

No effective means of labor induction were available when Williams wrote the first edition of this book. Labor augmentation methods were largely ineffective, and manual cervical dilation was performed as a last resort. Contrast with today, when several pharmacological agents permit labor induction or augmentation, and ironically the use of a "bougie" has come back into vogue.

Induction implies stimulation of contractions before the spontaneous onset of labor, with or without ruptured membranes. When the cervix is closed and uneffaced, labor induction will often commence with *cervical ripening*, a process that generally employs prostaglandins to soften and open the cervix. *Augmentation* refers to enhancement of spontaneous contractions that are considered inadequate because of failed cervical dilation and fetal descent—*inertia uteri*—as described by Williams (1903).

In the United States, the incidence of labor induction rose 2.5-fold from 9.5 percent in 1991 to 23.8 percent in 2015 (Martin, 2017). The incidence varies between practices. At Parkland Hospital, approximately 35 percent of labors are induced or augmented. By comparison, at the University of Alabama at Birmingham Hospital, labor is induced in approximately 20 percent of women, and another 35 percent are given oxytocin for augmentation—a total of 55 percent. This chapter discusses indications for labor induction and augmentation and various techniques to effect preinduction cervical ripening.

LABOR INDUCTION

Indications

Induction is indicated when the benefits to either mother or fetus outweigh those of pregnancy continuation. The more common indications include membrane rupture without labor, gestational hypertension, oligohydramnios, nonreassuring fetal status, postterm pregnancy, and various maternal medical conditions such as chronic hypertension and diabetes (American College of Obstetricians and Gynecologists, 2016).

Methods to induce or augment labor are contraindicated by most conditions that preclude spontaneous labor or delivery. The few maternal contraindications are related to prior uterine incision type, contracted or distorted pelvic anatomy, abnormally implanted placentas, and uncommon conditions such as active genital herpes infection or cervical cancer. Fetal factors include appreciable macrosomia, severe hydrocephalus, malpresentation, or nonreassuring fetal status.

Techniques

Oxytocin has been used for decades to induce or augment labor. Other effective methods include prostaglandins, such as misoprostol and dinoprostone, and mechanical methods that encompass membrane stripping, artificial rupture of membranes, extraamnionic saline infusion, transcervical balloons, and hygroscopic cervical dilators. Importantly, and as recommended in *Guidelines for Perinatal Care*, each obstetrical department should have its own written protocols that describe administration of these methods for labor induction and augmentation (American Academy of Pediatrics, 2017).

Risks

Maternal complications associated with labor induction are cesarean delivery, chorioamnionitis, uterine rupture, and postpartum hemorrhage from uterine atony. Of these, labor induction carries a two- to threefold greater risk for cesarean delivery (Hoffman, 2003; Maslow, 2000; Smith, 2003). This risk is particularly higher among nulliparas (Luthy, 2004; Wolfe, 2014; Yeast, 1999). More recently, this association has been questioned (Macones, 2009; Melamed, 2016; Miller, 2015; Saccone, 2015). Indeed, Darney and colleagues (2012) reported the cesarean delivery risk was actually lower for women with labor induction at 39 weeks' gestation compared with that in women expectantly managed. In their review, Little and Caughey (2015) found a reduced cesarean delivery rate when women undergoing labor induction were compared with women expectantly managed, as opposed to women spontaneously laboring. Currently, this is the topic of a randomized trial by the Maternal–Fetal Medicine Units (MFMU) Network—A Randomized Trial of Induction Versus Expectant Management—ARRIVE (National Institutes of Health, 2015).

Amniotomy is often selected to augment labor (Amniotomy for Induction and Augmentation). Women whose labor is managed with amniotomy have a higher incidence of chorioamnionitis compared with those in spontaneous labor (American College of Obstetricians and Gynecologists, 2016).

Rupture of a prior uterine incision during labor in women with a history of prior uterine surgery can be catastrophic (Chap. 31, Uterine Scar Rupture). The MFMU Network reported a threefold greater risk of uterine scar rupture with oxytocin, and this was even higher with prostaglandin use (Landon, 2004). The American College of Obstetricians and Gynecologists (2017b) recommends against the use of prostaglandins for preinduction cervical ripening or labor induction in women with a prior uterine incision.

Uterine atony and associated postpartum hemorrhage are more common in women undergoing induction or augmentation (Chap. 41, Risk Factors). And, atony with intractable hemorrhage, especially during cesarean delivery, is a frequent indication for peripartum hysterectomy. In a study from Parkland Hospital, labor induction was associated with 17 percent of 553 emergency peripartum hysterectomies (Hernandez, 2013). In the United States, the postpartum hysterectomy rate rose 15 percent between 1994 and 2007 (Bateman, 2012). This was largely attributed to increased rates of atony associated with more medical labor inductions and more primary and repeat cesarean deliveries. In another analysis, elective induction was also linked with a threefold higher rate of hysterectomy (Bailit, 2010).

Elective Labor Induction

Until recently, elective induction for convenience had become increasingly prevalent. Clark and coworkers (2009) described 14,955 deliveries at ≥37 weeks' gestation. They noted that 32 percent were elective deliveries, and 19 percent were elective labor inductions.

The American College of Obstetricians and Gynecologists (2016) does not endorse this once widespread practice. Occasional exceptions might include logistical and other reasons such as a risk of rapid labor, a woman who lives a long distance from the hospital, or psychosocial indications. Because of the greater risks for adverse maternal outcomes, we are also of the opinion that routine elective induction at term is not justified. Elective delivery before 39 completed weeks is also associated with significant adverse neonatal morbidity (Chiossi, 2013; Clark, 2009; Salemi, 2016; Tita, 2009). If elective induction is considered at term, inherent risks must be discussed, informed consent obtained, and guidelines followed as promulgated by the American College of Obstetricians and Gynecologists (2016), which are detailed in Chapter 31 (Labor and Delivery Considerations).

Guidelines to discourage elective inductions have been described by Fisch (2009) and Oshiro (2013) and their associates. Both groups reported significant declines in elective delivery rates following guideline initiation. In 2011, the Texas Medicaid program began to deny payment for elective induction prior to 39 weeks' gestation. This resulted in a 14-percent drop in such early-term deliveries and a rise in birthweights (Dahlen, 2017). A program in Oregon also reduced early-term deliveries, but maternal and fetal outcomes were not improved (Snowden, 2016).

Factors Affecting Induction Success

Several factors affect the ability of labor induction to achieve vaginal delivery. Favorable factors include younger age, multiparity, body mass index (BMI) <30, favorable cervix, and birthweight <3500 g (Gibson, 2015; Roland, 2017; Sievert, 2017). In many cases, the uterus is simply poorly prepared for labor. One example is an "unripe cervix." Indeed, investigators with the *Consortium on Safe Labor* reported that elective induction resulted in vaginal delivery in 97 percent of multiparas and 76 percent of nulliparas, but that induction was more often successful with a ripe cervix (Laughon, 2012).

The greater cesarean delivery risk associated with induction is likely also strongly influenced by the induction attempt duration, especially with an unfavorable cervix (Spong, 2012). In one study, labor duration to reach the active phase and to complete dilation was adversely affected by a higher BMI (Kominiarek, 2011). Similar findings were reported for women with diabetes (Hawkins, 2017). Simon and Grobman (2005) concluded that a latent phase as long as 18 hours allowed most women undergoing labor induction to achieve a vaginal delivery without a significantly increased risk of maternal or neonatal morbidity. Rouse and associates (2000) recommend a minimum of 12 hours of uterine stimulation with oxytocin after membrane rupture, whereas Kawakita and coworkers (2016) recommend up to 15 hours for multiparas.

PREINDUCTION CERVICAL RIPENING

As discussed, the condition of the cervix—described as cervical "ripeness" or "favorability"—is important to successful labor induction. However, at least some estimates of favorability are highly subjective (Feltovich, 2017). That said, pharmacological and mechanical methods can enhance cervical favorability—also termed *preinduction cervical ripening*.

Some of the techniques described may have benefits when compared with oxytocin induction alone (Table 26-1). Some are also quite successful for initiating labor. However, few data support the premise that any of these techniques lower cesarean delivery rates or lessen maternal or neonatal morbidity compared with women in whom these methods are not used.

TABLE 26-1

Some Commonly Used Regimens for Preinduction Cervical Ripening and/or Labor Induction

Techniques	Agent	Route/Dose	Comments
Pharmacological			
Prostaglandin E_2	Dinoprostone gel, 0.5 mg (Prepidil) Dinoprostone insert, 10 mg (Cervidil)	Cervical 0.5 mg; repeat in 6 hr; permit 3 doses total Posterior fornix, 10 mg	1. Shorter I-D times with oxytocin infusion than oxytocin alone 2. Insert has shorter I-D times than gel 3. 6–12 hr interval from last insert to oxytocin infusion
Prostaglandin E_1[a]	Misoprostol tablet, 100 or 200 µg (Cytotec)[b]	Vaginal, 25 µg; repeat 3–6 hr prn Oral, 50–100 µg; repeat 3–6 hr prn	1. Contractions within 30–60 min 2. Success comparable to oxytocin for ruptured membranes at term and/or favorable cervix 3. Tachysystole common with vaginal doses >25 µg
Mechanical			
Transcervical 36F Foley catheter	30-mL balloon		1. Improves Bishop scores rapidly 2. 80-mL balloon more effective 3. Combined with oxytocin infusion is superior to PGE_1 vaginally 4. With EASI, results improved and possible decreased infection rate
Hygroscopic dilators		Laminaria, hydrogel	1. Rapidly improves Bishop score 2. May not shorten I-D times with oxytocin 3. Uncomfortable, requires speculum and placement on an examination table

[a]Off-label use.

[b]Tablets must be divided for 25- and 50-µg dose, but drug is evenly dispersed.

EASI = extraamnionic saline infusion at 30–40 mL/hr; I-D = induction-to-delivery.

Cervical "Favorability"

One quantifiable method used to predict labor induction outcomes is the score described by Bishop (1964) and presented in Table 26-2. As favorability or Bishop score declines, the rate of induction to effect vaginal delivery also decreases. A *Bishop score* of 9 conveys a high likelihood for a successful induction. For research purposes, a Bishop score of 4 or less identifies an unfavorable cervix and may be an indication for cervical ripening.

TABLE 26-2

Bishop Scoring System Used for Assessment of Inducibility

	Cervical Factor				
Score	**Dilatation (cm)**	**Effacement (%)**	**Station (–3 to +2)**	**Consistency**	**Position**
0	Closed	0–30	–3	Firm	Posterior
1	1–2	40–50	–2	Medium	Midposition
2	3–4	60–70	–1	Soft	Anterior
3	≥5	≥80	+1, +2	—	—

From Bishop, 1964.

Laughon and coworkers (2011) attempted to simplify the Bishop score by performing a regression analysis on 5610 singleton, uncomplicated deliveries between $37^{0/7}$ and $41^{6/7}$ weeks' gestation in nulliparas. Only cervical dilation, station, and effacement were significantly associated with successful vaginal delivery. Thus, a simplified Bishop score, which incorporated only these three parameters, had a similar or improved positive- or negative-predictive value compared with that of the original Bishop score. Other investigators have reported similar findings when consistency and position are omitted (Ivars, 2016; Raghuraman, 2016).

Transvaginal sonographic measurement of cervical length is the only biophysical marker that has been evaluated as a Bishop score alternative (Feltovich, 2017). In one metaanalysis of trials in which cervical length was used to predict successful induction, study criteria heterogeneity precluded the authors from reaching a summary answer (Hatfield, 2007). A subsequent metaanalysis of 31 trials found overall low sensitivity and specificity and limited predictive utility for sonographic cervical length and "wedging" to predict successful labor induction (Verhoeven, 2013).

Pharmacological Techniques

Unfortunately, women frequently have an indication for induction but also have an unfavorable cervix. Several techniques are available, and these can also stimulate contractions and thereby aid subsequent labor induction or augmentation. Methods most commonly used for preinduction cervical ripening and induction include several prostaglandin analogues.

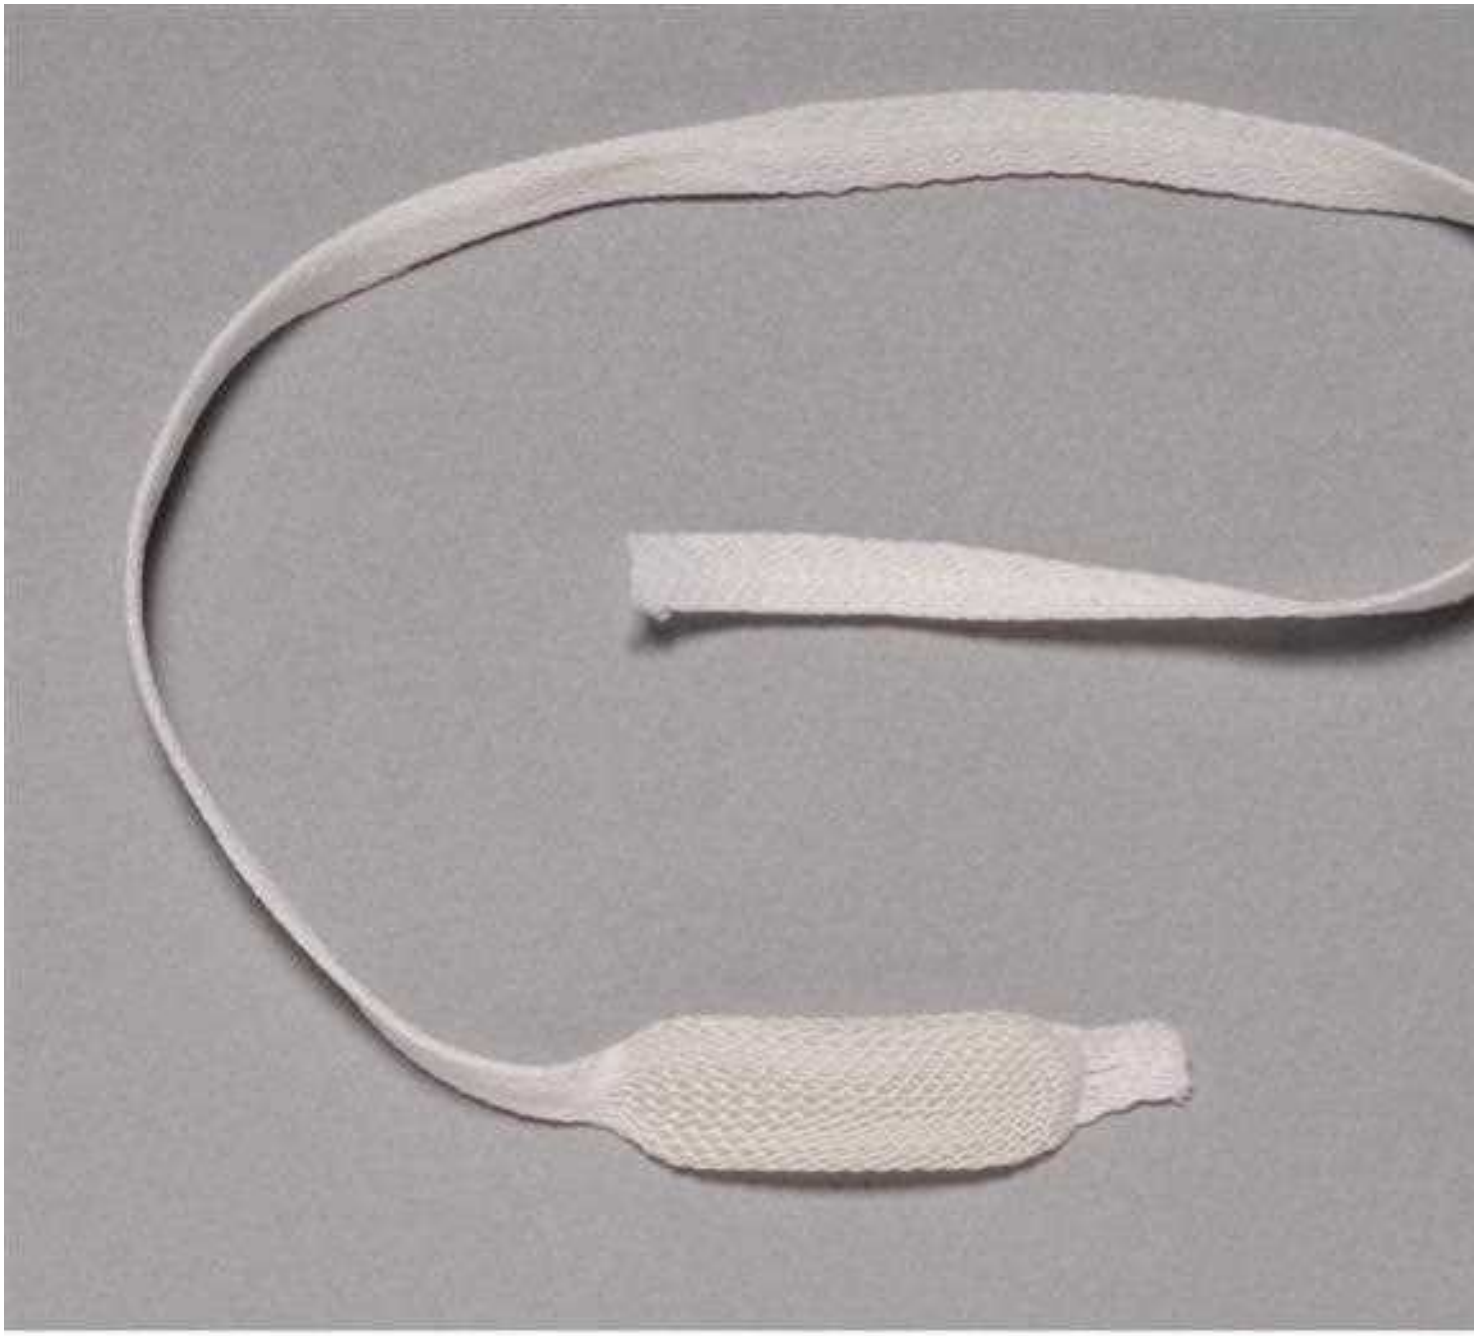
Prostaglandin E_2

Dinoprostone is a synthetic analogue of prostaglandin E_2 (PGE_2). It is commercially available in three forms: a gel, a time-release vaginal insert, and a 20-mg suppository (Table 26-1). The gel and time-release vaginal insert formulations are indicated only for cervical ripening before labor induction. However, the 20-mg suppository is not indicated for cervical ripening. It instead is used for pregnancy termination between 12 and 20 weeks' gestation and for evacuation of the uterus after fetal demise up to 28 weeks.

Local application of its gel form—*Prepidil*—is available in a 2.5-mL syringe for an intracervical application of 0.5 mg of dinoprostone. With the woman supine, the tip of a prefilled syringe is placed intracervically, and the gel is deposited just below the internal cervical os. After application, the woman remains reclined for at least 30 minutes. Doses may be repeated every 6 hours, with a maximum of three doses recommended in 24 hours.

A 10-mg dinoprostone vaginal insert—*Cervidil*—is also approved for cervical ripening. This is a thin, flat, rectangular polymeric wafer held within a small, white, mesh polyester sac (Fig. 26-1). The sac has a long attached tail to allow easy removal from the vagina. The insert provides slower release of medication—0.3 mg/hr—than the gel form. Cervidil is used as a single dose placed transversely in the posterior vaginal fornix. Lubricant is used sparingly, if at all, because it can coat the device and hinder dinoprostone release. Following insertion, the woman remains recumbent for at least 2 hours. The insert is removed after 12 hours or with labor onset and at least 30 minutes before the administration of oxytocin.

FIGURE 26-1
Cervidil vaginal insert contains 10 mg of dinoprostone designed to release approximately 0.3 mg/hr during a 10-hour period.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Most metaanalyses of dinoprostone efficacy report a reduced time-to-delivery within 24 hours, however, they do not consistently show a reduction in the cesarean delivery rate. Thomas and colleagues (2014) provided a Cochrane review of 70 trials and 11,487 women given vaginal prostaglandins or either placebo or no treatment. They noted a higher vaginal delivery rate within 24 hours when prostaglandins were used. They also reported a threefold greater risk of tachysystole accompanied by fetal heart rate changes, but cesarean delivery rates were not significantly decreased. Similar results were noted in another Cochrane review of intracervical dinoprostone gel (Boulvain, 2008). Compared with placebo or no treatment, a reduced risk of cesarean delivery was found only in a subgroup of women with an unfavorable cervix and intact membranes. Finally, the Foley catheter versus vaginal PGE_2 gel for induction of labor at term—PROBAAT-P and -M trials—were unblinded, randomized trials comparing these two options (Jozwiak, 2011, 2013, 2014). The cesarean delivery rate did not differ, a finding consistent with accompanying metaanalyses.

Side Effects

Uterine tachysystole follows vaginally administered PGE_2 in 1 to 5 percent of women (Hawkins, 2012). Although definitions of abnormal uterine activity vary among studies, most use the definition recommended by the American College of Obstetricians and Gynecologists (2017a):

1. *Uterine tachysystole* is defined as >5 contractions in a 10-minute period. It should always be qualified by the presence or absence of fetal heart rate abnormalities.
2. *Uterine hypertonus, hyperstimulation,* and *hypercontractility* are terms no longer defined, and their use is not recommended.

Because uterine tachysystole associated with fetal compromise may develop when prostaglandins are used with preexisting spontaneous labor, such use is not recommended. If tachysystole follows the 10-mg insert, its removal by pulling on the tail of the surrounding net sac will usually reverse this effect. Irrigation to remove the gel preparation has not been shown to be helpful.

The manufacturers recommend caution when these preparations are used in women with ruptured membranes. This concern is also extended to women with glaucoma or asthma. However, in a review of 189 women with asthma, dinoprostone was not associated with asthma worsening or exacerbation (Towers, 2004). Other contraindications listed by the manufacturers include a history of dinoprostone hypersensitivity, suspicion of fetal compromise or cephalopelvic disproportion, unexplained vaginal bleeding, women already receiving oxytocin, those with six or more previous term pregnancies, those with a contraindication to vaginal delivery, or women with a contraindication to oxytocin or who may be endangered by prolonged uterine contractions, for example, those with a history of cesarean delivery or uterine surgery.

Administration

PGE_2 preparations should only be administered in or near the delivery suite. Moreover, uterine activity and fetal heart rate should be monitored (American College of Obstetricians and Gynecologists, 2016). These guidelines stem from the risk of uterine tachysystole. When contractions begin, they are usually apparent in the first hour and show peak activity in the first 4 hours. According to manufacturer guidelines, oxytocin induction that follows prostaglandin use for cervical ripening should be delayed for 6 to 12 hours following PGE_2 gel administration or for at least 30 minutes after removal of the vaginal insert.

Prostaglandin E_1

Misoprostol—*Cytotec*—is a synthetic prostaglandin E_1 (PGE_1) that is approved as a 100- or 200-µg tablet for peptic ulcer prevention. It has been used "off label" for preinduction cervical ripening and may be administered orally or vaginally. The tablets are stable at room temperature. Although widespread, the off-label use of misoprostol has been controversial (Wagner, 2005; Weeks, 2005). Specifically, G. D. Searle & Company notified physicians that misoprostol is not approved for labor induction or abortion (Cullen, 2000). Still, the American College of Obstetricians and Gynecologists (2016) reaffirmed its recommendation for use of the drug because of proven safety and efficacy. It currently is the preferred prostaglandin for cervical ripening at Parkland Hospital. In one review of 234 women administered misoprostol, no instances of asthma exacerbation were associated with its use, and the risk of this was calculated to be <2 percent (Rooney Thompson, 2015).

Vaginal Administration

Compared with intracervical or intravaginal PGE_2, vaginally administered misoprostol tablets offer equivalent or superior efficacy for cervical ripening or labor induction. A metaanalysis of 121 trials also confirmed these findings (Hofmeyr, 2010). Compared with oxytocin or with intravaginal or intracervical dinoprostone, vaginal misoprostol increased the vaginal delivery rate within 24 hours. In this review, although the uterine tachysystole rate rose, this did not affect cesarean delivery rates. Moreover, compared with dinoprostone, misoprostol lowered the need for oxytocin induction, but it increased the frequency of meconium-stained amnionic fluid. Higher doses of misoprostol are associated with a decreased need for oxytocin but with more uterine tachysystole, with and without fetal heart rate changes. The American College of Obstetricians and Gynecologists (2016) recommends a 25-µg vaginal dose—a fourth of a 100-µg tablet. The drug is evenly distributed among these quartered tablets.

Wing and colleagues (2013) described use of a vaginal polymer insert containing 200 µg of PGE_1. They compared its efficacy with 10-mg dinoprostone inserts, and preliminary observations are favorable.

Oral Administration

PGE_1 tablets are also effective when given orally. One Cochrane metaanalysis of 76 trials reported that oral misoprostol compared with placebo significantly raised the rate of vaginal birth within 24 hours, while decreasing the need for oxytocin and lowering the cesarean delivery rate. Comparisons of oral misoprostol and oxytocin and of oral misoprostol and dinoprostone also found significantly reduced rates of cesarean delivery with misoprostol. Similar efficacy was noted between oral misoprostol and vaginal administration, although oral administration was associated with significantly higher Apgar scores and less postpartum hemorrhage (Alfirevic, 2014). Thorbiörnson and associates (2017) also reported lower rates of cesarean delivery for oral misoprostol compared with vaginal dinoprostone.

Nitric Oxide Donors

Several findings have prompted a search for clinical agents that stimulate nitric oxide (NO) production locally (Chanrachakul, 2000). First, NO is likely a mediator of cervical ripening. Also, cervical NO metabolite concentrations are increased at the beginning of uterine contractions. And, cervical NO production is very low in postterm pregnancy (Väisänen-Tommiska, 2003, 2004).

Bullarbo and colleagues (2007) reviewed rationale and use of two NO donors, *isosorbide mononitrate* and *glyceryl trinitrate*. Isosorbide mononitrate induces cervical cyclooxygenase 2 (COX-2), and it also initiates cervical ultrastructure rearrangement similar to that seen with spontaneous cervical ripening (Ekerhovd, 2002, 2003). Despite this, NO donors are less effective clinically than prostaglandins, either PGE_2 or misoprostol, for cervical ripening. In one large metaanalysis, the rate of cesarean delivery was not reduced in those given NO donors compared with those given placebo, intravaginal or intracervical prostaglandins, intravaginal misoprostol, or intracervical catheter (Ghosh, 2016). However, NO donors were associated with significantly more headaches, nausea, and vomiting.

Mechanical Techniques

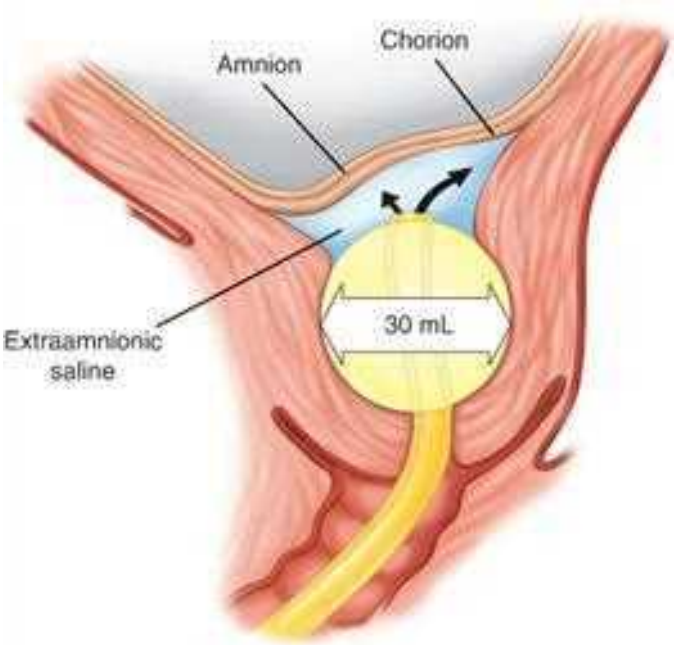
These include transcervical placement of a Foley catheter, with or without extraamnionic saline infusion; hygroscopic cervical dilators; and membrane stripping. In their metaanalysis, Jozwiak and associates (2012) reported that mechanical techniques reduced the risk of uterine tachysystole compared with prostaglandins, although cesarean delivery rates were unchanged. Trials comparing mechanical techniques with oxytocin found a lower rate of cesarean delivery with mechanical methods. Trials comparing mechanical techniques with dinoprostone found a higher rate of multiparas undelivered at 24 hours with mechanical techniques. In

another metaanalysis comparing Foley catheter placement with intravaginal dinoprostone inserts, rates of cesarean delivery were similar, but uterine tachysystole was less frequent with catheter use (Jozwiak, 2013).

Transcervical Catheter

Generally, these techniques are only used when the cervix is unfavorable because the catheter tends to come out as the cervix opens. It is suitable for women with intact or ruptured membranes. In most cases, a Foley catheter is placed through the internal cervical os, and downward tension is created by taping the catheter to the thigh (Mei-Dan, 2014). A modification of this—*extraamnionic saline infusion (EASI)*—adds a constant saline infusion through the catheter into the space between the internal os and placental membranes (Fig. 26-2). Karjane and coworkers (2006) reported that chorioamnionitis was significantly less frequent when infusion was done compared with no infusion—6 versus 16 percent. Similarly, in a large metaanalysis, transcervical catheters were not associated with higher rates of maternal or fetal infection (McMaster, 2015).

FIGURE 26-2
Extraamnionic saline infusion (EASI) through a 26F Foley catheter that is placed through the cervix. The 30-mL balloon is inflated with saline and pulled snugly against the internal os, and the catheter is taped to the thigh. Room-temperature normal saline is infused through the catheter port of the Foley at 30 or 40 mL/hour by intravenous infusion pump.



As discussed above, transcervical catheters do not reduce the cesarean delivery rate compared with prostaglandins. The PROBAAT trials (-I, -P, -M, and II), in which cervical ripening with a Foley catheter was compared with vaginal dinoprostone gel, dinoprostone vaginal inserts, and vaginal or oral misoprostol, reported similar outcomes between the mechanical technique and the prostaglandin agents. Also, fewer overall cases of cardiotocographic changes were seen in the mechanical technique group (Jozwiak, 2011, 2013, 2014; Ten Eikelder, 2016).

Similar cesarean delivery rate results are found in other comparison studies. Schoen and coworkers (2017) observed that concurrent oxytocin with a transcervical Foley catheter shortened the median time-to-delivery compared with a Foley catheter followed by oxytocin. However, rates of cesarean delivery were unchanged. Connolly and associates (2016) reported similar findings for women within intact membranes undergoing labor induction. Amorosa and colleagues (2017) found no benefit for transcervical catheter coupled with oxytocin compared against oxytocin alone for women with ruptured membranes. Other studies of concurrent misoprostol reported reduced time-to-delivery without affecting cesarean delivery rates (Carbone, 2013; Levine, 2016). Finally, the concurrent addition of tension does not appear to enhance catheter efficacy. Fruhman and coworkers (2017) randomized 140 women to transcervical Foley catheter with and without tension, and reported similar vaginal delivery rates within 24 hours or overall.

Hygroscopic Cervical Dilators

Cervical dilation can be accomplished using hygroscopic osmotic cervical dilators, as described for early pregnancy termination (Chap. 18, First-Trimester Abortion Methods). Intuitive concerns of ascending infection have not been verified, and their use appears to be safe. Placement generally requires a speculum and positioning of the woman on an examination table. Several studies performed in the 1990s compared hygroscopic cervical dilators and prostaglandins and found few benefits of this mechanical technique. And, more recent studies verified these conclusions (Maier, 2017).

METHODS OF INDUCTION AND AUGMENTATION

Labor induction has primarily been effected with the use of amniotomy, prostaglandins, and oxytocin, alone or in combination. Because preinduction cervical ripening frequently eventuates in labor, studies to determine induction efficacy for some of these agents have produced sometimes confusing results. The use of

prostaglandins for labor augmentation has generally been considered experimental due to their high rates of uterine tachysystole.

Prostaglandin E_1

Both vaginal and oral misoprostol are used for either cervical ripening or labor induction. For labor induction in women at or near term with either prematurely ruptured membranes or a favorable cervix, 100 µg of oral or 25 µg of vaginal misoprostol has similar efficacy compared with intravenous oxytocin. From these studies, evidence supports that oral misoprostol may be superior (Alfirevic, 2014; Hofmeyr, 2010; Lo, 2003). Misoprostol may be associated with a greater rate of uterine tachysystole, particularly at higher doses. Also, induction with PGE_1 may prove ineffective and require subsequent induction or augmentation with oxytocin.

Thus, although there are trade-offs regarding the risks, costs, and ease of administration of each drug, either is suitable for labor induction. At Parkland Hospital, we administer an initial oral 100-µg dose, which may be repeated after 6 hours for inadequate labor. Six hours after the second dose or in those with tachysystole, an oxytocin infusion is begun, if needed, for hypotonic labor. Döbert and colleagues (2017) have described preliminary use of a misoprostol vaginal insert.

For *labor augmentation*, results of a randomized controlled trial showed oral misoprostol, 75 µg given at 4-hour intervals for a maximum of two doses, to be safe and effective (Bleich, 2011). The 75-µg dose was based on a previous dose-finding study (Villano, 2011). Although there was more uterine tachysystole among women with labor augmented with misoprostol, the frequency of nonreassuring fetal status or cesarean delivery did not differ between oxytocin and misoprostol.

Oxytocin

In many instances, preinduction cervical ripening and labor induction are simply a continuum. Thus, “ripening” can also stimulate labor. If not, induction or augmentation may be continued with solutions of oxytocin given by infusion pump. Its use in augmentation is a key component in the *active management of labor,* described in Chapter 22 (Labor Management Protocols). With oxytocin use, the American College of Obstetricians and Gynecologists (2016) recommends fetal heart rate and uterine contraction monitoring. Contractions can be monitored either by palpation or by electronic means.

Intravenous Oxytocin Administration

The goal of induction or augmentation is to effect uterine activity sufficient to produce cervical change and fetal descent, while avoiding development of a nonreassuring fetal status. In general, oxytocin is discontinued if the number of contractions persists with a frequency of more than five in a 10-minute period or more than seven in a 15-minute period or with a persistent nonreassuring fetal heart rate pattern. Oxytocin discontinuation nearly always rapidly lowers contraction frequency. When oxytocin is stopped, its concentration in plasma rapidly falls because the half-life is approximately 3 to 5 minutes. Seitchik and associates (1984) found that the uterus contracts within 3 to 5 minutes of beginning an oxytocin infusion and that a plasma steady state is reached in 40 minutes. Response is highly variable and depends on preexisting uterine activity, cervical status, pregnancy duration, and individual biological differences. Caldeyro-Barcia and Poseiro (1960) reported that the uterine response to oxytocin increases from 20 to 30 weeks’ gestation and rises rapidly at term (Chap. 24, Intrapartum Surveillance of Uterine Activity).

Oxytocin Dosage

A 1-mL ampule containing 10 units of oxytocin usually is diluted into 1000 mL of a crystalloid solution and administered by infusion pump. A typical infusate consists of 10 or 20 units, which is 10,000 or 20,000 mU or one or two 1-mL vials, respectively, mixed into 1000 mL of lactated Ringer solution. This mixture results in an oxytocin concentration of 10 or 20 mU/mL, respectively. To avoid bolus administration, the infusion should be inserted into the main intravenous line close to the venipuncture site.

Oxytocin is generally very successful when used to stimulate labor. In one large Cochrane metaanalysis, oxytocin was compared with expectant management, and fewer women—8 versus 54 percent—failed to deliver vaginally within 24 hours with oxytocin (Alfirevic, 2009). This analysis studied different oxytocin dosing regimens.

Oxytocin Regimens

Several evidence-based regimens for labor stimulation are now recommended by the American College of Obstetricians and Gynecologists (2016). These and others are shown in Table 26-3. Initially, only variations of low-dose protocols were used in the United States. Subsequently, O’Driscoll and colleagues (1984) described their Dublin protocol for the active management of labor that called for oxytocin at a starting dosage of 6 mU/min and advanced in 6-mU/min increments. Subsequent comparative trials during the 1990s studied high-dose (4 to 6 mU/min) versus conventional low-dose (0.5 to 1.5 mU/min) regimens, both for labor induction and for augmentation.

TABLE 26-3

Various Low- and High-Dose Oxytocin Regimens Used for Labor Induction

Regimen	Starting Dose (mU/min)	Interval (min)	Incremental Increase (mU/min)
Low-dose	0.5–1.5	15–40	1
	2	15	4, 8, 12, 16, 20, 25, 30
High-dose	4	15	4
	4.5	15–30	4.5
	6	20–40[a]	6[b]

[a]Uterine tachysystole is more common with shorter intervals.

[b]With uterine tachysystole and after oxytocin infusion is discontinued, it is restarted at one half the previous dose and then increased at 3 mU/min incremental doses.

Data from Merrill, 1999; Satin, 1992, 1994; Xenakis, 1995.

From Parkland Hospital, Satin and associates (1992) evaluated an oxytocin regimen using an initial and incremental dosage of 6 mU/min compared with one using 1 mU/min. Increases at 20-minute intervals were provided as needed. Among 1112 women undergoing induction, the 6-mU/min regimen resulted in a shorter mean admission-to-delivery time, fewer failed inductions, and no cases of neonatal sepsis. Among 1676 women who had labor augmentation, those who received the 6-mU/min regimen had a shorter duration-to-delivery time, fewer forceps deliveries, fewer cesarean deliveries for dystocia, and lower rates of intrapartum chorioamnionitis or neonatal sepsis. With this protocol, uterine tachysystole was managed by oxytocin discontinuation followed by resumption when indicated and at half the stopping dosage. Thereafter, the dosage was increased at 3 mU/min when appropriate, instead of the usual 6-mU/min increase used for women without tachysystole. No adverse neonatal effects were observed.

Xenakis and coworkers (1995) reported benefits using an incremental oxytocin regimen starting at 4 mU/min. In another study, 816 women were randomly assigned for labor induction and 816 for augmentation with incremental oxytocin given at either 1.5 or 4.5 mU/min (Merrill, 1999). Women randomized to the 4.5 mU/min dosage had significantly shorter mean durations of induction-to-second-stage labor and induction-to-delivery times. Nulliparas randomized to the 4.5 mU/min dosage had a significantly lower cesarean delivery rate for dystocia compared with those given 1.5 mU/min dosage—6 versus 12 percent. Thus, benefits favor higher-dose regimens of 4.5 to 6 mU/min compared with lower dosages of 0.5 to 1.5 mU/min.

In 1990 at Parkland Hospital, routine use of the 6-mU/min oxytocin beginning and incremental dosage was incorporated and continues through today. In other labor units, a 2-mU/min beginning and incremental oxytocin regimen is preferred and administered. With either regimen, dosages are employed for either labor induction or augmentation. Although a Cochrane metaanalysis of randomized and quasi-randomized trials comparing high-dose versus low-dose regimens for labor induction at term reported no benefit of higher dosing, the metaanalysis included studies judged to have high potential bias. The authors concluded that the results might be confounded by these poor-quality studies (Budden, 2014).

Interval between Incremental Dosing

Intervals to increase oxytocin doses vary from 15 to 40 minutes (see Table 26-3). Satin and associates (1994) addressed this aspect with a 6-mU/min regimen providing increases at either 20- or 40-minute intervals. Women assigned to the 20-minute interval regimen for labor augmentation had a significantly reduced cesarean delivery rate for dystocia compared with that for the 40-minute interval regimen—8 versus 12 percent. As perhaps expected, uterine tachysystole was significantly more frequent with the 20-minute escalation regimen.

Other investigators reported even more frequent incremental increases. Frigoletto (1995) and Xenakis (1995) and their coworkers gave oxytocin at 4 mU/min with increases as needed every 15 minutes. Merrill and Zlatnik (1999) started with 4.5 mU/min doses and increased this every 30 minutes. López-Zeno and associates (1992) used 6 mU/min doses and 15-minute intervals. Thus, there are several acceptable oxytocin protocols that at least appear dissimilar. But, a comparison of protocols from two institutions indicates that this is not so:

1. The Parkland Hospital protocol uses a starting dose of oxytocin at 6 mU/min, which is increased by 6-mU/min every 40 minutes, and employs flexible dosing based on uterine tachysystole.

2. The University of Alabama at Birmingham Hospital protocol begins oxytocin at 2 mU/min and increases it as needed every 15 minutes to 4, 8, 12, 16, 20, 25, and 30 mU/min.

Thus, although the regimens at first appear disparate, if there is no uterine activity, either regimen is delivering 12 mU/min by 45 minutes into the infusion.

Maximal Oxytocin Dosage

The *maximal* effective dose of oxytocin to achieve adequate contractions in all women is different. Wen and colleagues (2001) studied 1151 consecutive nulliparas and found that the likelihood of progression to vaginal delivery decreased at and beyond an oxytocin dosage of 36 mU/min. Still, at a dosage of 72 mU/min, half of

the nulliparas were delivered vaginally. Thus, if contractions are not adequate—less than 200 Montevideo units—and if the fetal status is reassuring and labor has arrested, an oxytocin infusion dose greater than 48 mU/min has no apparent risks.

Risks versus Benefits

Unless the uterus is scarred, uterine rupture associated with oxytocin infusion is rare, even in parous women. Flannelly and associates (1993) reported no cases of uterine ruptures, with or without oxytocin, in 27,829 nulliparas. There were eight instances of overt uterine rupture during labor in 48,718 parous women. Only one of these was associated with oxytocin use. A population-based retrospective review from Denmark reported a rupture rate of 3.3 per 100,000 women without prior cesarean, with the highest risk among multiparas (Thisted, 2015). Our experiences from Parkland Hospital are that oxytocin induction and augmentation are associated with uterine rupture (Happe, 2017). During an 8-year period in which there were about 95,000 births, 15 women suffered a primary uterine rupture, and 14 of these cases were associated with oxytocin use. In half of these women, prostaglandins were also given before augmentation with oxytocin.

Oxytocin has amino-acid homology similar to arginine vasopressin and has significant antidiuretic action. When infused at doses of 20 mU/min or more, renal free water clearance drops markedly. If aqueous fluids are infused in appreciable amounts along with oxytocin, *water intoxication* can lead to convulsions, coma, and even death. In general, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than raising the flow rate of a more dilute solution. Consideration also should be given to use of crystalloids—either normal saline or lactated Ringer solution.

Uterine Contraction Pressures

Contraction forces in spontaneously laboring women range from 90 to 390 Montevideo units (Chap. 24, Intrapartum Surveillance of Uterine Activity). Caldeyro-Barcia (1950) and Seitchik (1984) with their coworkers found that the mean or median spontaneous uterine contraction pattern between 140 and 150 Montevideo units resulted in progression to vaginal delivery.

In the management of active-phase arrest, and with no contraindication to intravenous oxytocin, decisions must be made with knowledge of the safe upper range of uterine activity. Hauth and colleagues (1986) described an effective and safe protocol for oxytocin augmentation for active-phase arrest. With it, more than 90 percent of women achieved an average of at least 200 to 225 Montevideo units. They later reported that nearly all women in whom active-phase arrest persisted despite oxytocin generated more than 200 Montevideo units (Hauth, 1991). Importantly, despite no labor progression, no adverse maternal or perinatal effects were noted in those ultimately requiring cesarean delivery. There are no data regarding safety and efficacy of contraction patterns in women with a prior cesarean delivery, with twins, or with an overdistended uterus.

Active-Phase Arrest

First-stage arrest of labor is defined as a completed latent phase and contractions exceeding 200 Montevideo units for more than 2 hours without cervical change. Some have attempted to define a more accurate duration for active-phase arrest (Spong, 2012). Arulkumaran and coworkers (1987) extended the 2-hour limit to 4 hours and reported a 1.3-percent cesarean delivery rate in women who continued to have adequate contractions and progressive cervical dilation of at least 1 cm/hr. In women without progressive cervical dilation who were allowed another 4 hours of labor, half required cesarean delivery.

Rouse and colleagues (1999) prospectively managed 542 women at term with active-phase arrest and no other complications. Their protocol was to achieve a sustained pattern of at least 200 Montevideo units for a *minimum* of 4 hours. This time frame was extended to 6 hours if activity of 200 Montevideo units or greater could not be sustained. Almost 92 percent of these women were delivered vaginally. As discussed in Chapter 23 (Active-Phase Protraction), these and other studies support the practice of allowing an active-phase arrest of 4 hours (Rouse, 2001).

Zhang and coworkers (2002) analyzed labor duration from 4 cm to complete dilatation in 1329 nulliparas at term. They found that before dilation of 7 cm was reached, lack of progress for more than 2 hours was not uncommon in those who delivered vaginally. Alexander and associates (2002) reported that epidural analgesia prolonged active labor by 1 hour compared with duration of the active phase as defined by Friedman (1955). Consideration of these changes in the management of labor, especially in nulliparas, may safely reduce the cesarean delivery rate.

As data have accrued, investigators have increasingly questioned the thresholds for labor arrest disorders established by Friedman and others in the 1960s. In particular, investigators with the *Consortium on Safe Labor* reported that half of cases of dystocia after labor induction occurred before 6 cm of cervical dilation (Boyle, 2013; Zhang, 2010c). Even for women with spontaneous labor, these researchers found that active-phase labor was more likely to occur at 6 cm, and after slow progress between 4 and 6 cm (Zhang, 2010a). Additionally, they reported that a 2-hour threshold for diagnosing arrest disorders may be too brief when cervical dilation is <6 cm (Zhang, 2010b). This is discussed in detail in Chapter 23 (Obstetric Care Consensus Committee). Importantly, however, these studies of data from the Collaborative Perinatal Project included only singleton term gestation with spontaneous onset of labor, vaginal delivery, and a normal perinatal outcome. By excluding abnormal outcomes, cesarean deliveries, and those who were more than 6 cm dilated upon arrival, the above studies that sought to redefine the labor curve have been faulted for introducing biases that limit general use of these findings (Cohen, 2015a,b).

Amniotomy for Induction and Augmentation

Elective amniotomy with the intention of accelerating labor is often performed. Shown in Table 26-4, amniotomy at approximately 5-cm dilation accelerated spontaneous labor by 1 to 1½ hours. Importantly, neither the need for oxytocin stimulation nor the overall cesarean delivery rate was increased. Although the incidences of mild and moderate cord compression patterns were raised following amniotomy, cesarean delivery rates for fetal distress were not higher. Most importantly, there were no adverse perinatal effects.

TABLE 26-4

Randomized Clinical Trials of Elective Amniotomy in Early Spontaneous Labor at Term

		Effects of Amniotomy					
Study	**Number**	**Mean Dilation at Amniotomy**	**Mean Shortening of Labor**	**Need for Oxytocin**	**Cesarean Delivery Rate**	**Abnormal Tracing**	**Neonatal Effects**
Fraser (1993)	925	<5 cm	125 min	None	None[a]	None	None
Garite (1993)	459	5.5 cm	81 min	Decreased	None	Increased[b]	None
UK Amniotomy Group (1994)	1463	5.1 cm	60 min	None	None	NA	None

[a]No effect on overall rate; cesarean delivery for fetal distress significantly increased.

[b]Increased mild and moderate umbilical cord compression patterns.

NA = not assessed.

For labor induction, artificial rupture of the membranes—sometimes called *surgical induction*—can be used and always implies a commitment to delivery. The main disadvantage of amniotomy used alone for labor induction is the unpredictable and occasionally long interval until labor onset. That said, in a randomized trial, Bakos and Bäckström (1987) found that amniotomy alone or combined with oxytocin was superior to oxytocin alone. Mercer and colleagues (1995) randomly assigned 209 women undergoing oxytocin induction to either early amniotomy at 1 to 2 cm or late amniotomy at 5 cm. Early amniotomy was associated with a 4-hour reduction in labor duration. With early amniotomy, however, the incidence of chorioamnionitis was elevated.

For labor augmentation, amniotomy is commonly performed when labor is abnormally slow. Rouse and associates (1994) found that amniotomy with oxytocin augmentation for arrested active-phase labor shortened the time to delivery by 44 minutes compared with that of oxytocin alone. Although amniotomy did not alter the delivery route, one drawback was that it significantly increased the incidence of chorioamnionitis.

Regardless of the indication, amniotomy is associated with a risk of cord prolapse. To minimize this risk, disengagement of the fetal head during amniotomy is avoided. Toward this goal, fundal or suprapubic pressure or both may be helpful. Some clinicians prefer to rupture membranes during a contraction. If the vertex is not well applied to the lower uterine segment, a gradual egress of amnionic fluid can sometimes be accomplished by several membrane punctures with a 26-gauge needle held with a ring forceps and with direct visualization using a vaginal speculum. In many of these, however, membranes tear and fluid is lost rapidly. Because of the risk of cord prolapse or rarely abruption, the fetal heart rate is assessed before and immediately after amniotomy.

Membrane Stripping for Labor Induction

Labor induction by membrane "stripping" is a frequent practice. Several studies have suggested that membrane stripping is safe and lowers the incidence of postterm pregnancy without consistently raising the incidence of ruptured membranes, infection, or bleeding. Authors of one large metaanalysis found that membrane stripping reduced the number of women remaining undelivered after 41 weeks without elevating the infection risk. They concluded that eight women would need to undergo membrane stripping to avoid one labor induction. Downsides are discomfort and associated bleeding (Boulvain, 2005).

CHAPTER 27: Vaginal Delivery

As soon as the head appears at the vulva the physician should be ready to restrain its progress. He should hold his hand in such a manner as to be able to bring it immediately into action, for in many instances the resistance of the vulva is unexpectedly overcome, and a single pain may be sufficient to push the head suddenly through it with a resulting perineal tear.

—J. Whitridge Williams (1903)

INTRODUCTION

As described by Williams, the natural culmination of second-stage labor is controlled vaginal delivery of a healthy neonate with minimal trauma to the mother. Vaginal delivery is the preferred route of delivery for most fetuses, although various clinical settings may favor cesarean delivery. Of delivery routes, spontaneous vaginal vertex delivery poses the lowest risk of most maternal comorbidity, and comparisons with cesarean delivery are found in Chapter 30 (Cesarean Delivery Risks). Delivery is usually spontaneous, although some maternal or fetal complications may warrant operative vaginal delivery, described in Chapter 29 (Indications). Last, a malpresenting fetus or multifetal gestation in many cases may be delivered vaginally but requires special techniques. These are described in Chapters 28 (Labor and Delivery Management) and 45 (Evaluation of Fetal Presentation).

PREPARATION FOR DELIVERY

The end of second-stage labor is heralded as the perineum begins to distend, the overlying skin becomes stretched, and the fetal scalp is seen through the separating labia. Increased perineal pressure from the fetal head creates reflexive bearing-down efforts, which are encouraged when appropriate. At this time, preparations are made for delivery. If the bladder is distended, catheterization may be necessary. Continued attention is also given to fetal heart rate monitoring. As one example, a nuchal cord often tightens with descent and may lead to deepening variable decelerations.

During second-stage labor, pushing positions may vary. But for delivery, the dorsal lithotomy position is most common and often the most satisfactory. For better exposure, leg holders or stirrups are used. Corton and associates (2012) found no increased rates of perineal lacerations with or without their use. With positioning, legs are not separated too widely or placed one higher than the other. Within the leg holder, the popliteal region should rest comfortably in the proximal portion and the heel in the distal portion. The legs are not strapped into the stirrups, thereby allowing quick flexion of the thighs backward onto the abdomen should shoulder dystocia develop. Legs may cramp during second-stage pushing, and cramping is relieved by repositioning the affected leg or by brief massage.

Preparation for delivery includes vulvar and perineal cleansing. If desired, sterile drapes may be placed in such a way that only the immediate area around the vulva is exposed. Scrubbing, gowning, gloving, and donning protective mask and eyewear protect both the laboring woman and accoucheur from infectious agents.

OCCIPUT ANTERIOR POSITION

Delivery of the Head

By the time of perineal distention, the position of the occiput is usually known. In some cases, however, molding and caput formation may have precluded early accurate identification. At this time, careful assessment is again performed as described in Chapter 22 (Vaginal Examination). In most cases, position is directly occiput anterior (OA) or is rotated slightly oblique. But, in perhaps 5 percent, occiput posterior (OP) positioning persists.

With each contraction, the vulvovaginal opening is dilated by the fetal head to gradually form an ovoid and finally, an almost circular opening (Fig. 27-1). This encirclement of the largest head diameter by the vulvar ring is termed *crowning*. The perineum thins and may spontaneously lacerate. The anus becomes greatly stretched, and the anterior wall of the rectum can easily be seen through it.

Routine episiotomy is no longer recommended, and selective use aims to enlarge the vaginal opening for specific indications (Episiotomy). To limit spontaneous vaginal laceration, some perform antenatal massage of the perineal body to increase perineal distensibility or intrapartum perineal massage to widen the introitus for head passage. During massage with a lubricant, the perineum is grasped in the midline by both hands using the thumb and opposing fingers. Outward and lateral stretching to thin the perineum is repeatedly performed. But in randomized studies, this technique did not significantly prevent perineal laceration (Beckmann, 2013; Mei-dan, 2008; Stamp, 2001). Antepartum use of the *Epi-No* intravaginal pump balloon has a similar aim, but it also fails to prevent perineal trauma or levator injury (Brito, 2015; Kamisan Atan, 2016).

When the head distends the vulva and perineum enough to open the vaginal introitus to a diameter of 5 cm or more, a gloved hand may be used to support the perineum (Fig. 27-2). The other hand is used to guide and control the fetal head to deliver the smallest head diameter through the introitus and to avoid expulsive delivery. Slow delivery of the head may decrease lacerations (Laine, 2008). Overall, bracing the perineum lowers rates of anal sphincter injury compared with a "hands off" approach to delivery (Bulchandani, 2015; McCandlish, 1998).

FIGURE 27-1
Perineum is supported as the head crowns.

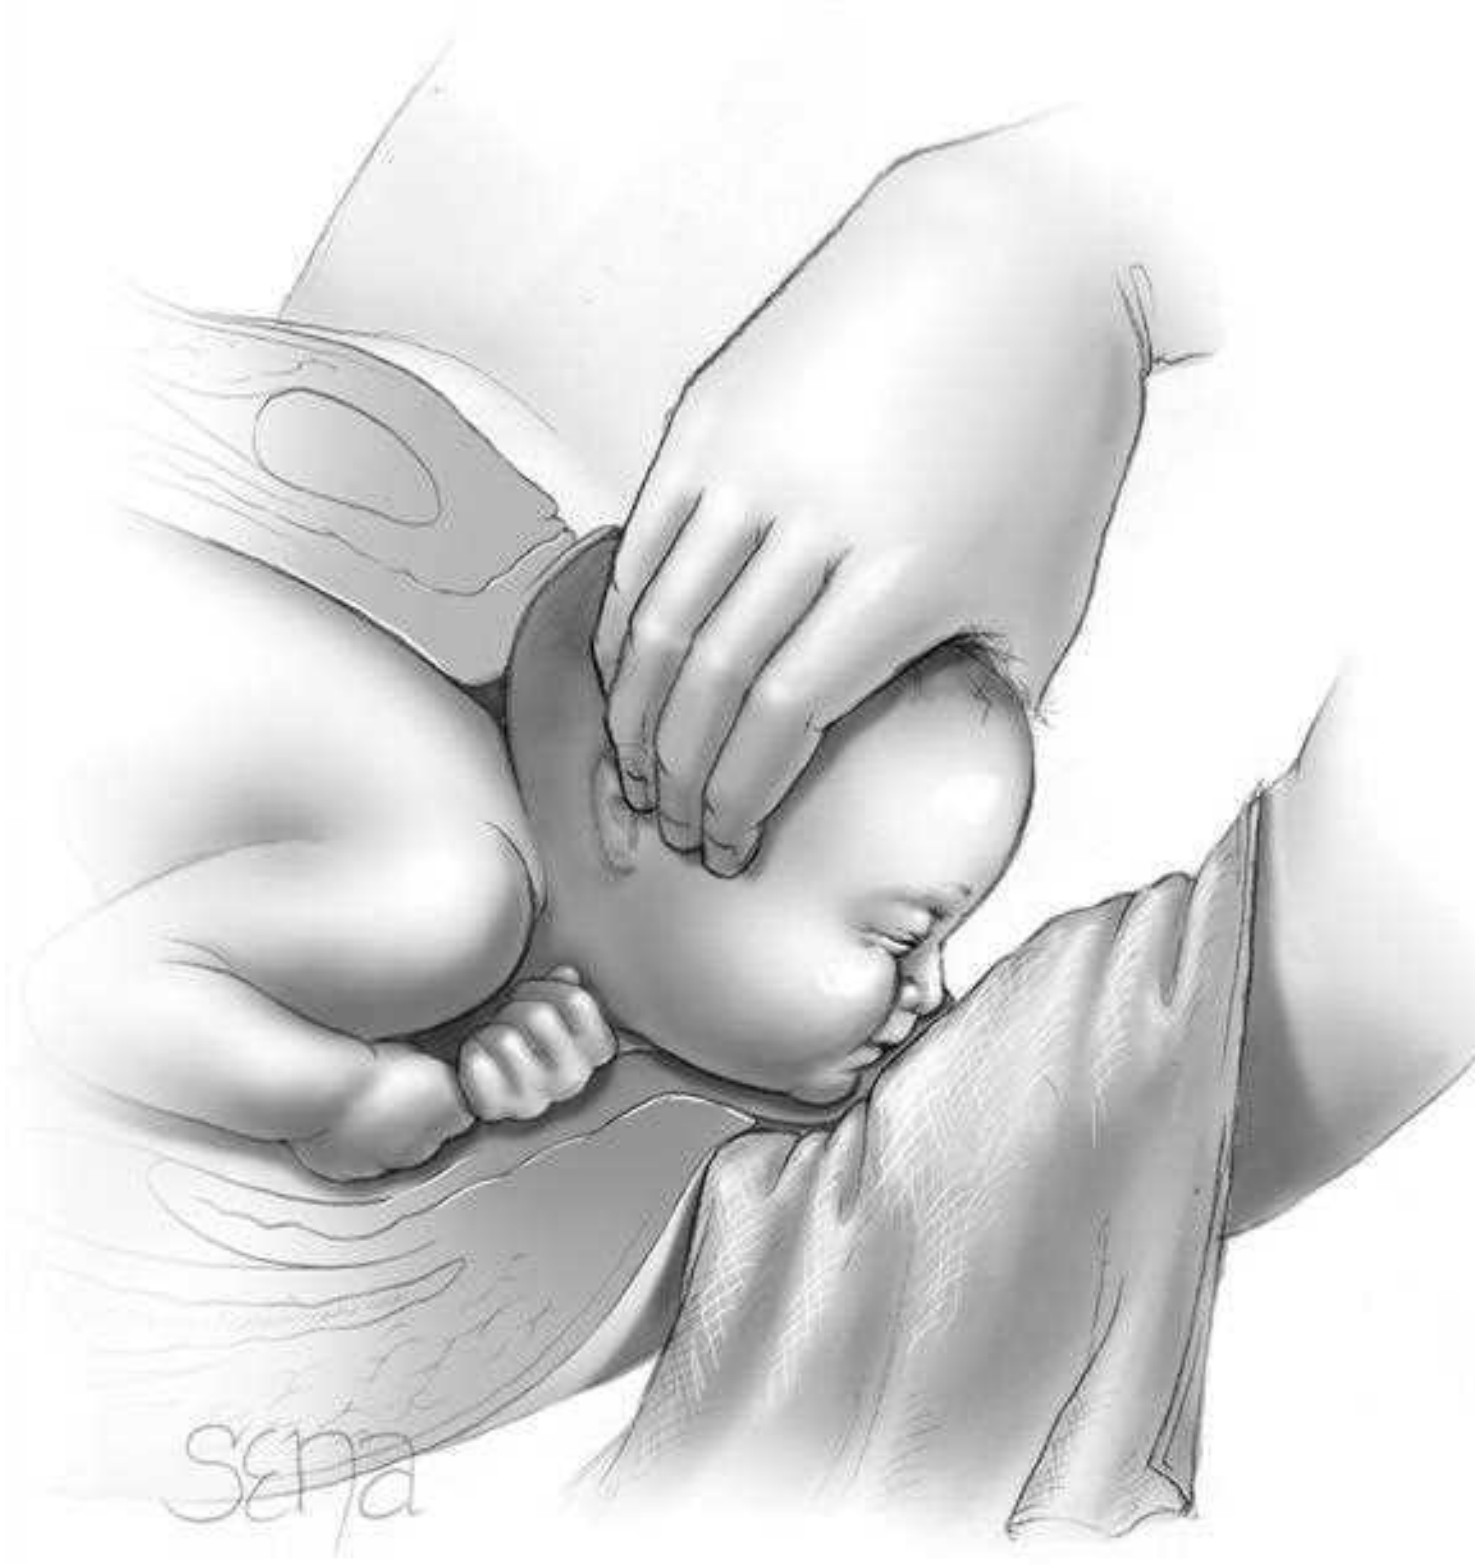
FIGURE 27-2

Delivery of the head. The mouth appears over the perineum.

Alternatively, if expulsive efforts are inadequate or expeditious delivery is needed, the *modified Ritgen maneuver* may be employed or an episiotomy cut. With the modified maneuver, gloved fingers beneath a draped towel exert forward pressure on the fetal chin through the perineum just in front of the coccyx. Concurrently, the other hand presses against the occiput (Fig. 27-3). Originally described in 1855, the maneuver allows controlled fetal head delivery (Cunningham, 2008). It also favors neck extension so that the head passes through the introitus and over the perineum with its smallest diameters. Comparing the Ritgen maneuver with simple perineal support in 1623 women, Jönsson and colleagues (2008) found a similar incidence of third- and fourth-degree tears, defined later (Immediate Postpartum Care).

FIGURE 27-3

Modified Ritgen maneuver. Moderate upward pressure is applied to the fetal chin by the posterior hand covered by a sterile towel. The other hand applies occipital pressure.



Delivery of the Shoulders

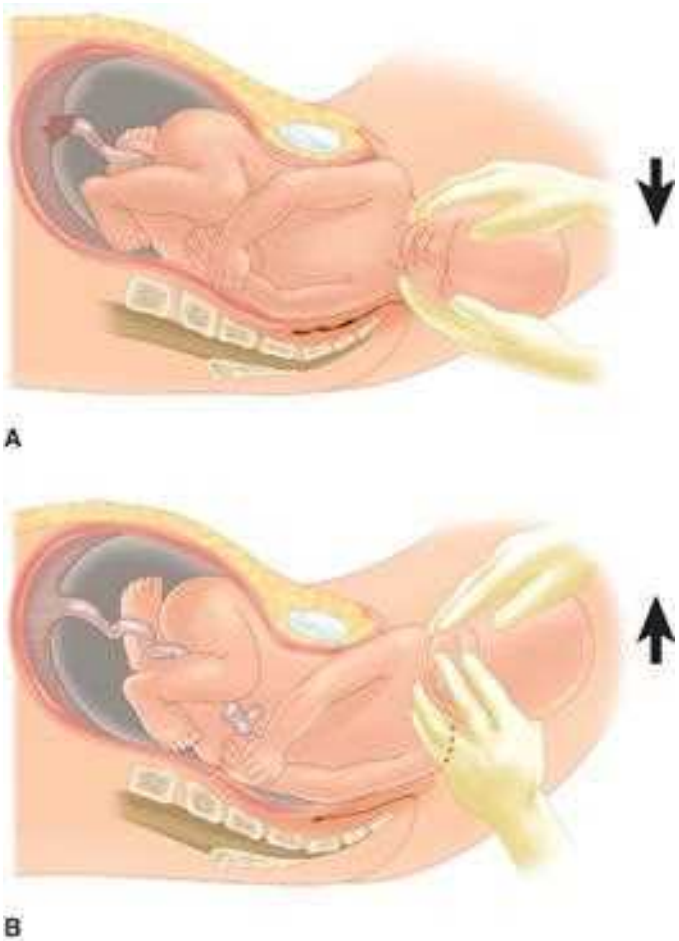
Following delivery of the fetal head, a finger is passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops. The nuchal cord incidence increases with gestational age and is found in nearly 25 percent of deliveries at term (Larson, 1997; Ogueh, 2006). If an umbilical cord coil is felt, it is slipped over the head if loose enough. If applied too tightly, the loop is cut between two clamps. Tight nuchal cords complicate approximately 6 percent of all deliveries but are not associated with worse neonatal outcome than those without a cord loop (Henry, 2013).

Following its delivery, the fetal head falls posteriorly, bringing the face almost into contact with the maternal anus. The occiput promptly turns toward one of the maternal thighs, and the head assumes a transverse position. This external rotation indicates that the bisacromial diameter, which is the distance between the shoulders, has rotated into the anteroposterior diameter of the pelvis.

Most often, the shoulders appear at the vulva just after external rotation and are born spontaneously. If delayed, extraction aids controlled delivery. The sides of the head are grasped with two hands, and *gentle* downward traction is applied until the anterior shoulder appears under the pubic arch (Fig. 27-4). Next, by an upward movement, the posterior shoulder is delivered. During delivery, abrupt or powerful force is avoided to avert fetal brachial plexus injury.

FIGURE 27-4

Delivery of the shoulders. **A.** Gentle downward traction to effect descent of the anterior shoulder. **B.** Delivery of the anterior shoulder completed. Gentle upward traction to deliver the posterior shoulder.



The rest of the body almost always follows the shoulders without difficulty. With prolonged delay, however, its birth may be hastened by moderate outward traction on the head and moderate pressure on the uterine fundus. Hooking the fingers in the axillae is avoided. This can injure upper extremity nerves and produce a transient or possibly permanent paralysis. Immediately after delivery of the newborn, a gush of amnionic fluid that is often blood-tinged but not grossly bloody usually follows.

Previously, immediate nasopharyngeal bulb suctioning of the newborn was routine to remove secretions. It was found, however, that suctioning of the nasopharynx may lead to neonatal bradycardia (Gungor, 2006). The current American Heart Association neonatal resuscitation recommendations eschew most suctioning immediately following birth—even with meconium present (Chap. 33, Neonatal Encephalopathy and Cerebral Palsy). And with meconium-stained fluid, routine intubation for tracheal suction is not recommended for vigorous or for nonvigorous neonates. Suctioning is reserved for neonates who have obvious obstruction to spontaneous breathing or who require positive-pressure ventilation (Wyckoff, 2015). For suctioning, options are bulb syringe or suction catheter aspiration and may include intubation and suctioning if the airway is obstructed.

Cord Clamping

The umbilical cord is cut between two clamps placed 6 to 8 cm from the fetal abdomen, and later an umbilical cord clamp is applied 2 to 3 cm from its insertion into the fetal abdomen.

For term neonates, the timing of umbilical cord clamping remains debatable. Delayed umbilical cord clamping transfers a greater volume of blood to the newborn. A delay for up to 60 seconds may increase total body iron stores, expand blood volume, and decrease anemia incidence in the neonate (Andersson, 2011; Yao, 1974). This practice may be particularly valuable in populations in which iron deficiency is prevalent (Kc, 2017; World Health Organization, 2014).

Conversely, a higher hemoglobin concentration increases risks for hyperbilirubinemia and extended hospitalization for neonatal phototherapy (McDonald, 2013). Delayed cord clamping may also hinder timely and needed neonatal resuscitation. That said, early pilot studies are assessing the value of resuscitating newborns at the bedside to permit delayed clamping (Katheria, 2017; Winter 2017). Fortunately, in general, delayed umbilical cord clamping compared with early clamping does

not worsen Apgar scores, umbilical cord pH, or respiratory distress caused by polycythemia. Regarding maternal outcomes, rates of postpartum hemorrhage are similar between early and delayed clamping groups (Andersson, 2013). Fewer data are available regarding cord "milking," in which the operator pushes blood through the cord toward the newborn. This maneuver appears safe and may be advantageous if rapid cord clamping is clinically indicated (Upadhyay, 2013).

For the preterm neonate, delayed cord clamping has several benefits. These include higher red cell volume, decreased need for blood transfusion, and lower rates of intraventricular hemorrhage and of necrotizing enterocolitis (Backes, 2014; Rabe, 2012). For neonates who require expedited resuscitation, cord milking may have benefits to quickly transfer volume (Al-Wassia, 2015; Katheria, 2015; Patel, 2014). Still, because of rapid blood volume changes, the American Heart Association currently suggests against the routine use of cord milking for neonates born <29 weeks' gestation (Wyckoff, 2015).

The American College of Obstetricians and Gynecologists (2017a) notes sufficient evidence to support delayed umbilical cord clamping for term and preterm neonates for at least 30 to 60 seconds after birth. This opinion is also endorsed by the American Academy of Pediatrics (2017a). The American Heart Association guidelines advise that the practice may have benefits for term or preterm neonates not needing immediate resuscitation at birth (Wyckoff, 2015).

Occiput Transverse Position

In the absence of a pelvic architecture abnormality or asynclitism, the occiput transverse (OT) position is usually transitory. Thus, unless contractions are hypotonic, the head usually spontaneously rotates to an OA position. If rotation ceases because of poor expulsive forces, vaginal delivery usually can be accomplished readily in several ways. The easiest is manual rotation of the occiput either anteriorly to OA or less commonly, posteriorly to occiput posterior. If either is successful, Le Ray and coworkers (2007) reported a 4-percent cesarean delivery rate compared with a 60-percent rate in women in whom manual rotation was not successful. Some recommend rotation with Kielland forceps for the persistent OT position as outlined in Chapter 29 (Occiput Transverse Positions). These forceps are used to rotate the occiput to the anterior position, and delivery is accomplished with the same forceps or by substitution with Simpson, Tucker–McLane, or similar forceps.

In some cases, pelvic shape leads to a persistent OT position that is not easily overcome. For example, a platypelloid pelvis is flattened anteroposteriorly and an android pelvis is heart shaped. With these, space may be inadequate for occipital rotation to either an anterior or posterior position (Fig. 2-17). Because of these concerns, undue force is avoided if forceps delivery is attempted.

PERSISTENT OCCIPUT POSTERIOR POSITION

Approximately 2 to 10 percent of singleton term cephalic fetuses deliver in an occiput posterior (OP) position (Cheng, 2010). Many fetuses delivering OP are OA in early labor and reflect malrotation during labor. Predisposing risks include epidural analgesia, nulliparity, greater fetal weight, and prior delivery with OP positioning (Cheng, 2006a; Gardberg, 2004; Lieberman, 2005). Regarding pelvic shape, an anthropoid pelvis and narrow subpubic angle can predispose (Barth, 2015; Ghi, 2016).

Morbidity

Women with a persistent OP position have higher associated rates of prolonged second-stage labor, cesarean delivery, and operative vaginal delivery. For women who deliver vaginally, rates of blood loss and of third- and fourth-degree lacerations are increased (Senécal, 2005).

Newborns delivered from an OP position have higher complication rates then those born positioned OA. Cheng and coworkers (2006b) compared outcomes of 2591 women undergoing delivery with a persistent OP position with those of 28,801 women whose newborns were delivered OA. Virtually every possible delivery complication was found more frequently with persistent OP position. Only 46 percent of these women delivered spontaneously, and the remainder accounted for 9 percent of cesarean deliveries performed. These investigators also found that an OP position at delivery was associated with more adverse short-term neonatal outcomes that included acidemic umbilical cord gases, birth trauma, Apgar scores <7, and intensive care nursery admission, among others. Similar results were reported by Ponkey (2003) and Fitzpatrick (2001) and their associates.

Methods to prevent persistent OP position and its associated morbidity have been investigated. First, digital examination for identification of fetal head position can be inaccurate, and transabdominal sonography can be used to increase accuracy (Dupuis, 2005; Zahalka, 2005). The transducer is placed transversely just cephalad to the maternal mons pubis. In the sonogram, fetal orbits and nasal bridge lie ventrally, whereas the occiput apposes the lower sacrum. Such information may provide an explanation for prolonged second-stage labor or may identify suitable candidates for rotation. Of other possible interventions, varying maternal position either antepartum or during labor does not appear to lower rates of persistent OP position (Desbriere, 2013; Kariminia, 2004; Le Ray, 2016).

Delivery

The fetus in an OP position may be delivered either spontaneously or by operative vaginal delivery. First, if the bony pelvic outlet is roomy and the perineum is somewhat relaxed from prior deliveries, rapid spontaneous OP delivery will often take place. Conversely, if the perineum is resistant to stretch, second- stage labor may be appreciably prolonged. During each expulsive effort, the head is driven against the perineum to a much greater degree than when the head position is OA. This leads to greater rates of third- and fourth-degree lacerations (Groutz, 2011; Melamed, 2013).

In some cases, spontaneous vaginal delivery from an OP position does not appear feasible or expedited delivery is needed. Here, manual rotation with spontaneous delivery from an OA position may be preferred. This technique is described fully in Chapter 29 (Occiput Posterior Positions). Successful rotation rates range from 47 to 90 percent. And, as would be expected, lower rates of cesarean delivery, vaginal laceration, and maternal blood loss follow rotation to OA position and vaginal delivery (Le Ray, 2005; Sen, 2013; Shaffer, 2006, 2011). Disadvantageously, manual rotation is linked with higher cervical laceration rates. Thus, careful inspection of the cervix following rotation is mandatory.

For exigent delivery, forceps or vacuum device can be applied to a persistent OP position. This is often performed in conjunction with an episiotomy. Also, if the head is engaged, the cervix fully dilated, and the pelvis adequate, forceps rotation may be attempted for those with suitable skills. These operative vaginal techniques are detailed in Chapter 29 (Occiput Transverse Positions).

Infrequently, protrusion of fetal scalp through the introitus is the consequence of marked elongation of the fetal head from molding combined with formation of a large caput succedaneum. In some cases, the head may not even be engaged—that is, the biparietal diameter may not have passed through the pelvic inlet. In these, labor is characteristically long and descent of the head is slow. Careful palpation above the symphysis may disclose the fetal head to be above the pelvic inlet. Prompt cesarean delivery is appropriate.

At Parkland Hospital, spontaneous delivery or manual rotation is preferred for management of persistent OP position. When needed, either manual rotation to OA position followed by forceps delivery or forceps delivery from the OP position is used. If neither can be completed with ease and safety, cesarean delivery is performed.

SHOULDER DYSTOCIA

Following complete emergence of the fetal head during vaginal delivery, the remainder of the body may not rapidly follow. The anterior fetal shoulder can become wedged behind the symphysis pubis and fail to deliver using normally exerted downward traction and maternal pushing. Because the umbilical cord is compressed within the birth canal, this dystocia is an emergency. Several maneuvers, in addition to downward traction on the fetal head and neck, may be performed to free the shoulder. This requires a team approach, in which effective communication and leadership are critical.

Consensus regarding a specific definition of shoulder dystocia is lacking. Some focus on whether maneuvers to free the shoulder are needed, whereas others use the head-to-body delivery time interval as defining (Beall, 1998). Spong and coworkers (1995) reported that the mean head-to-body delivery time in normal births was 24 seconds compared with 79 seconds in those with shoulder dystocia. These investigators proposed that a head-to-body delivery time >60 seconds be used to define shoulder dystocia. Currently, however, the diagnosis continues to rely on the clinical perception that the normal downward traction needed for fetal shoulder delivery is ineffective.

Because of these differing definitions, the incidence of shoulder dystocia varies. One recent review cites a clinically useful average of 1 percent of all deliveries (Ouzounian, 2016). The incidence has increased in recent decades, likely due to increasing fetal birthweight (MacKenzie, 2007; Øverland, 2014). Increased identification and documentation may also raise the incidence (Kim, 2016).

Maternal and Neonatal Consequences

In general, shoulder dystocia poses greater risk to the fetus than to the mother. The main maternal risks are serious perineal tears and postpartum hemorrhage, usually from uterine atony but also from lacerations (Gauthaman, 2016; Rahman, 2009). In contrast, significant neonatal neuromusculoskeletal injury and asphyxia are concerns. These specific injuries are described in Chapter 33 (Spinal Cord Injury). In one review of 1177 shoulder dystocia cases, brachial plexus injury was diagnosed in 11 percent and clavicular or humeral fracture in 2 percent (Chauhan, 2014). MacKenzie and associates (2007) reviewed 514 cases. Of the neonates, 7 percent showed evidence of acidosis at delivery, and 1.5 percent required cardiac resuscitation or developed hypoxic ischemic encephalopathy (HIE). In another review of 200 cases, rates of severe fetal acidosis and HIE were each 0.5 percent if delivery was completed within 5 minutes. These rates rose to 6 and 24 percent, respectively, with delivery delays ≥5 minutes (Leung, 2011a).

Prediction and Prevention

Fetal macrosomia, maternal obesity, prolonged second-stage labor, and a prior event raise risks for shoulder dystocia (Mehta, 2004; Overland, 2009; Schummers, 2015). Although these factors are clearly associated with this complication, identification of individual instances before the fact has proved to be impossible. The American College of Obstetricians and Gynecologists (2017c) reviewed studies and concluded that:

1. Most cases of shoulder dystocia cannot be accurately predicted or prevented.
2. Elective induction of labor or elective cesarean delivery for all women suspected of having a macrosomic fetus is not appropriate.
3. Planned cesarean delivery may be considered for the nondiabetic woman with a fetus whose estimated fetal weight is >5000 g or for the diabetic woman whose fetus is estimated to weigh >4500 g.

Birthweight

There is a corresponding rise in the incidence of shoulder dystocia with increasing birthweight (Acker, 1985; Øverland, 2012; Stotland, 2004). Commonly cited maternal characteristics associated with increased fetal birthweight are obesity, postterm pregnancy, multiparity, and diabetes (Jolly, 2003; Koyanagi, 2013). The combination of fetal macrosomia and maternal diabetes mellitus escalates the frequency of shoulder dystocia (Langer, 1991; Nesbitt, 1998). This predisposition may stem from the fact that fetuses of diabetic women have larger shoulder and extremity circumferences and greater shoulder-to-head and chest-to-head size differences relative to comparable-weight fetuses of nondiabetic mothers (McFarland, 1998; Modanlou, 1982). That said, translating these specific measurements into stand-alone sonographic clinical thresholds has shown poor predictive sensitivity (Burkhardt, 2014).

Preventively, early labor induction has yielded conflicting results. In one study, approximately 800 women with suspected macrosomic fetuses were randomized either to early induction between 37 and 39 weeks or to expectant care (Boulvain, 2015). Dystocia rates were lowered by two thirds in the intervention group, and neither group suffered brachial plexus injury. Although not measured, this practice is balanced against morbidity of early delivery. Moreover, the poor accuracy of

antepartum fetal weight prediction should be considered as well (Hoopmann, 2010; Malin, 2016; Noumi, 2005). In contrast, an earlier randomized study of 284 women showed that rates of shoulder dystocia were not lowered by early induction at 38 weeks (Gonen, 1997).

As previously discussed, cesarean delivery may be considered to prevent shoulder dystocia. That said, Rouse and Owen (1999) concluded that a prophylactic cesarean delivery policy for macrosomic fetuses would require more than 1000 cesarean deliveries with attendant morbidity to avert a single permanent brachial plexus injury.

Prior Shoulder Dystocia

The risk of recurrent shoulder dystocia ranges from 1 to 13 percent (Bingham, 2010; Moore, 2008; Ouzounian, 2013). For many women with prior shoulder dystocia, a trial of labor may be reasonable. The American College of Obstetricians and Gynecologists (2017c) recommends that estimated fetal weight, gestational age, maternal glucose intolerance, and severity of prior neonatal injury be evaluated and risks and benefits of cesarean delivery discussed with any woman with a history of shoulder dystocia. After discussion, either mode of delivery may be appropriate.

Management

Because shoulder dystocia cannot be accurately predicted, clinicians should be well versed in its management principles. Because of ongoing cord compression with this dystocia, one goal is to reduce the head-to-body delivery time. This is balanced against the second goal, which is avoiding fetal and maternal injury from aggressive manipulations. Accordingly, an initial gentle attempt at traction, assisted by maternal expulsive efforts, is recommended. Adequate analgesia is certainly ideal. Some clinicians advocate performing a large episiotomy to provide room for manipulations. Episiotomy itself does not lower brachial plexus injury rates but raises third- and fourth-degree laceration rates (Gurewitsch, 2004; Paris, 2011; Sagi-Dain, 2015). Episiotomy may be elected to complete needed maneuvers.

After gentle traction, various techniques can be used to free the anterior shoulder from its impacted position behind the symphysis pubis. A more detailed discussion of these and the topic is found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Cunningham, 2017). Of these, moderate *suprapubic pressure* can be applied by an assistant, while downward traction is applied to the fetal head. Pressure is applied with the heel of the hand to the anterior shoulder wedged above and behind the symphysis. The anterior shoulder is thus either depressed or rotated, or both, so the shoulders occupy the oblique plane of the pelvis. Here, the anterior shoulder can be freed.

The *McRoberts maneuver* is often selected next if additional steps are needed. The maneuver consists of removing the legs from the stirrups and sharply flexing them up toward the abdomen. Suprapubic pressure is often concurrently applied (Fig. 27-5). Gherman and associates (2000) analyzed the McRoberts maneuver using x-ray pelvimetry. They found that the procedure caused straightening of the sacrum relative to the lumbar vertebrae, rotation of the symphysis pubis toward the maternal head, and a decrease in the angle of pelvic inclination. Although this does not increase pelvic dimensions, pelvic rotation cephalad tends to free the impacted anterior shoulder. Gonik and coworkers (1989) tested the McRoberts position objectively with laboratory models and found that the maneuver reduced the forces needed to free the fetal shoulder. If unsuccessful, most move next either to free the posterior shoulder or to rotate the bisacromial diameter into one of the oblique diameters of the maternal pelvis.

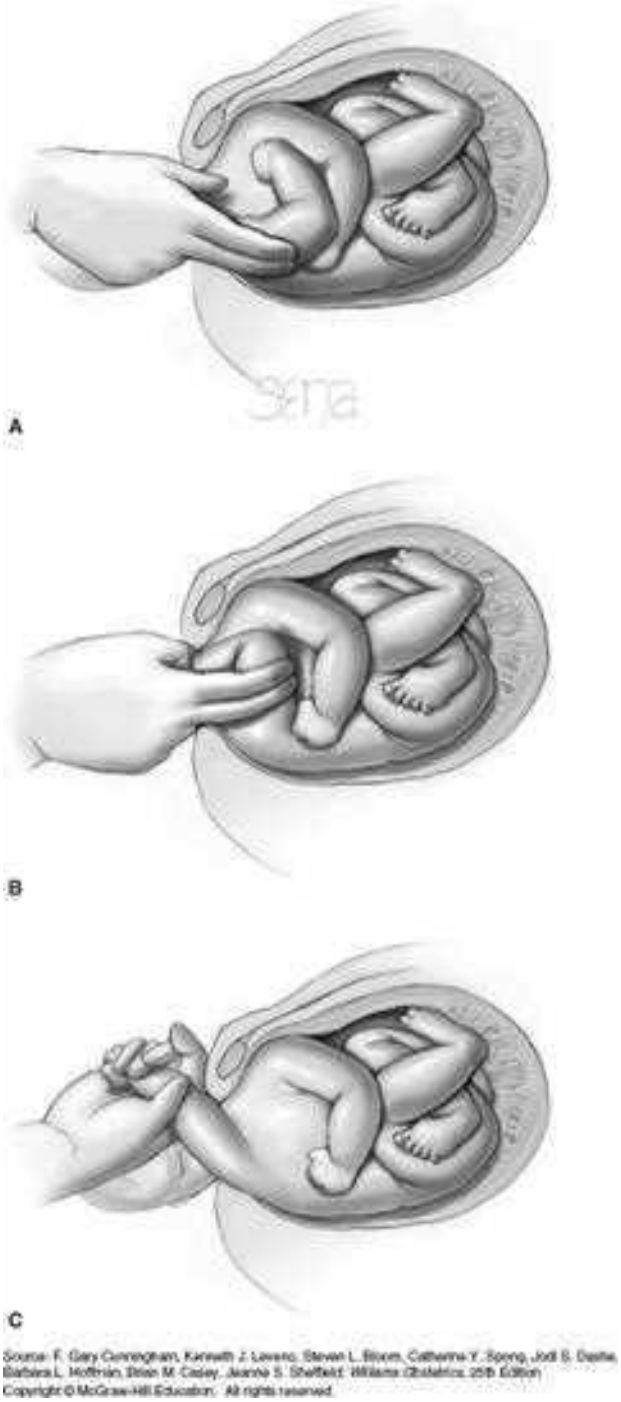
FIGURE 27-5

The McRoberts maneuver. The maneuver consists of removing the legs from the stirrups and sharply flexing the thighs up toward the abdomen. The assistant is also providing suprapubic pressure simultaneously (*arrow*).

With *delivery of the posterior shoulder,* the accoucheur carefully sweeps the posterior arm of the fetus across its chest, followed by delivery of the arm (Fig. 27-6). If possible, the operator's fingers are aligned parallel to the long axis of the fetal humerus to lower bone fracture risks. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder.

FIGURE 27-6

Delivery of the posterior shoulder for relief of shoulder dystocia. **A.** The operator's hand is introduced into the vagina along the fetal posterior humerus. **B.** The arm is splinted and swept across the chest, keeping the arm flexed at the elbow. **C.** The fetal hand is grasped and the arm extended along the side of the face. The posterior arm is delivered from the vagina.



Of rotational maneuvers, Woods (1943) reported that by progressively rotating the posterior shoulder 180 degrees in a corkscrew fashion, the impacted anterior shoulder could be released. This is frequently referred to as the *Woods corkscrew maneuver* (Fig. 27-7). Rubin (1964) recommended two maneuvers. First, the fetal shoulders are rocked from side to side by applying force to the maternal abdomen. If this is not successful, the pelvic hand reaches the most easily accessible fetal shoulder, which is then pushed toward the anterior surface of the chest. This maneuver most often abducts both shoulders, which in turn produces a smaller bisacromial diameter. This permits displacement of the anterior shoulder from behind the symphysis (Fig. 27-8).

FIGURE 27-7

Woods maneuver. The hand is placed behind the posterior shoulder of the fetus. The shoulder is then rotated in a corkscrew manner so that the impacted anterior shoulder is released.

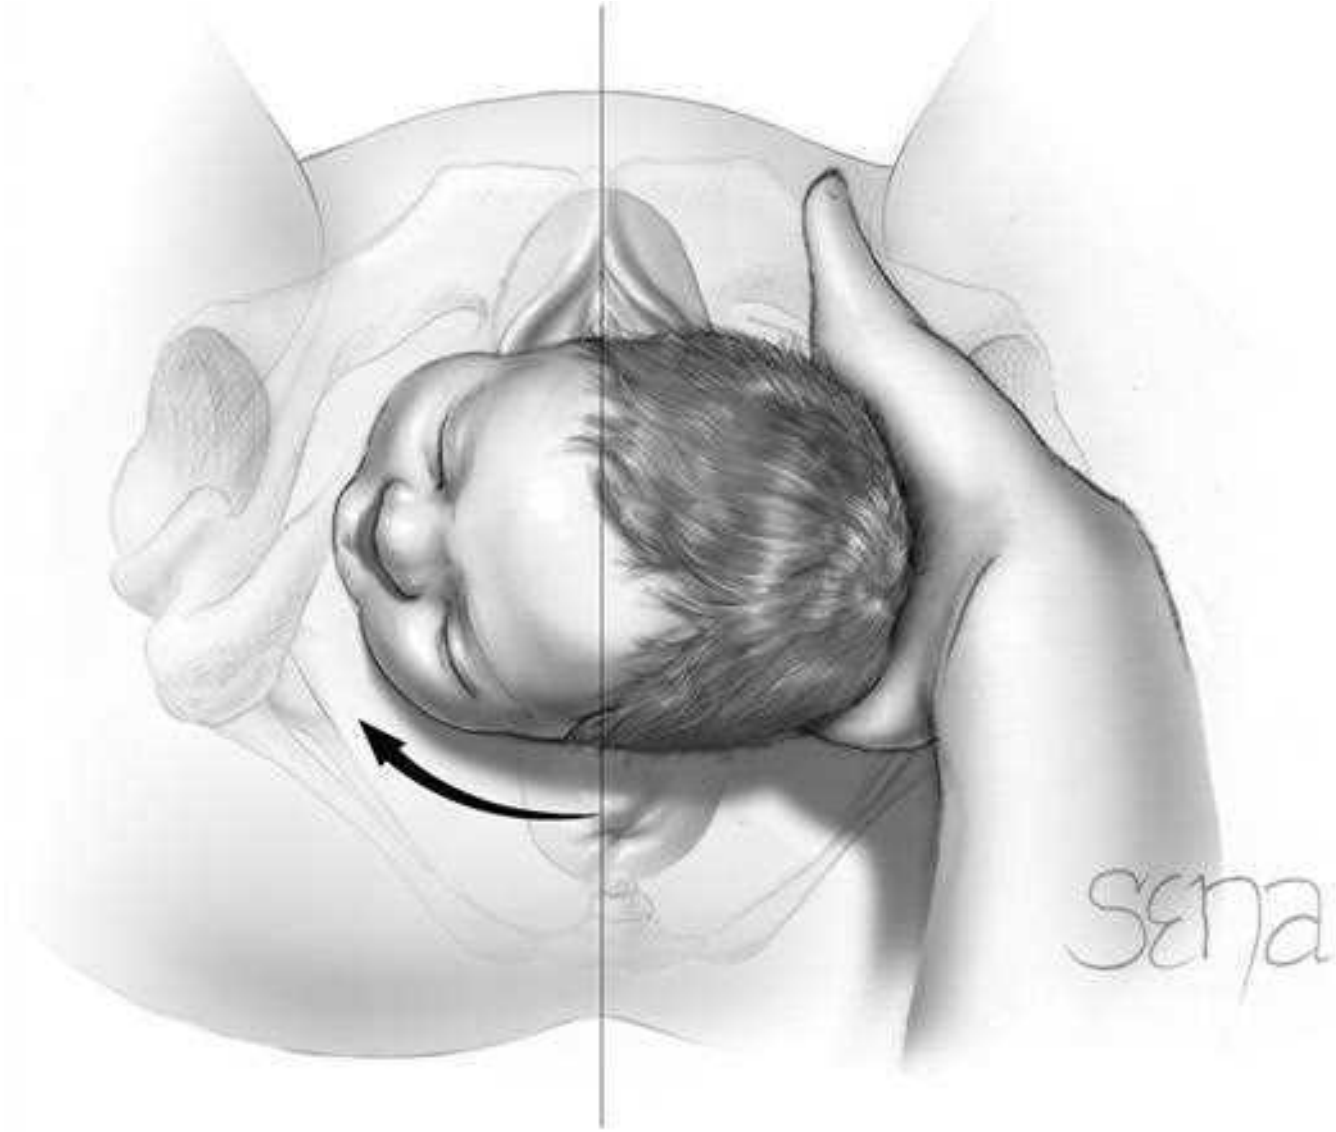


FIGURE 27-8

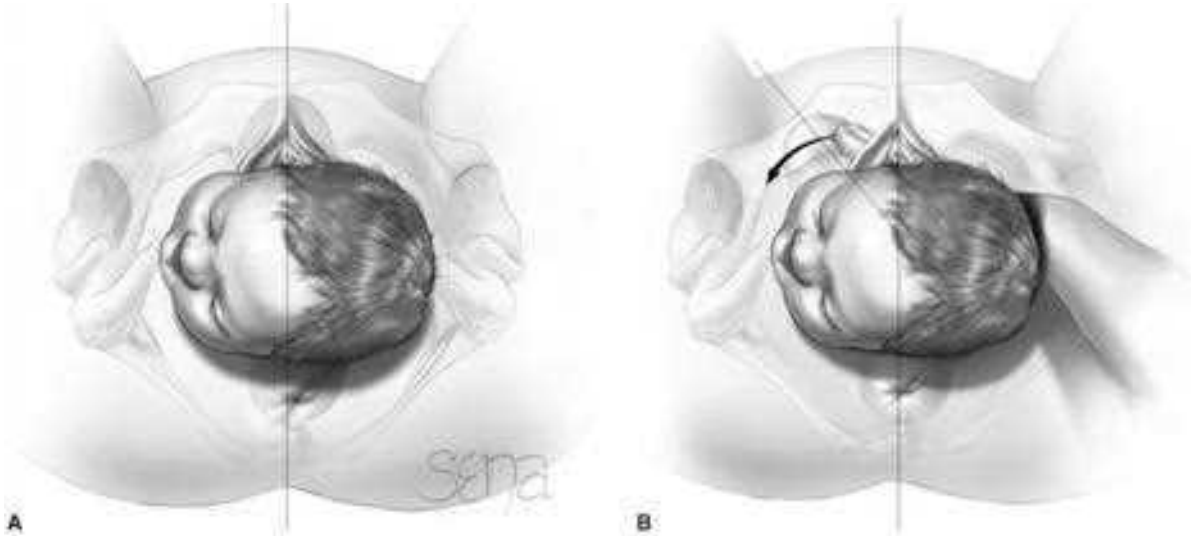
The second Rubin maneuver. **A.** The bisacromial diameter is aligned vertically. **B.** The more easily accessible fetal shoulder (the anterior is shown here) is pushed toward the anterior chest wall of the fetus (*arrow*). Most often, this results in abduction of both shoulders, which reduces the bisacromial diameter and frees the impacted anterior shoulder.



If the above are initially unsuccessful, they may be repeated, and finally other methods may be elected. With an *all-fours maneuver*, also called the Gaskin maneuver, the parturient rolls onto her knees and hands. Here, downward traction against the head and neck attempts to free the posterior shoulder (Bruner, 1998). Challenges with this include immobility from regional analgesia and time lost in patient repositioning.

In some, the posterior arm is inaccessible for delivery. Cluver and Hofmeyr (2009) described *posterior axilla sling traction* to deliver the posterior arm. With this alternative method, a suction catheter is threaded under the axilla and both ends are brought together above the shoulder. Upward and outward traction on the catheter loop delivers the shoulder. In a small series of 19 cases, this maneuver was successful in 18 cases. However, neonatal injury included three cases of humeral fracture and one permanent and four transient cases of Erb palsy (Cluver, 2015).

Deliberate *fracture of the anterior clavicle* using the thumb to press it toward and against the pubic ramus can be attempted to free the shoulder impaction. In practice, however, deliberate fracture of a large neonate's clavicle is difficult. If successful, the fracture will heal rapidly and is usually trivial compared with brachial nerve injury, asphyxia, or death.

The *Zavanelli maneuver* involves replacement of the fetal head into the pelvis followed by cesarean delivery (Sandberg, 1985). Terbutaline, 0.25 mg, is given subcutaneously to produce uterine relaxation. The first part of the maneuver consists of returning the head to an OA or OP position. The operator flexes the head and slowly pushes it back into the vagina. Cesarean delivery is then performed. Sandberg (1999) reviewed 103 reported cases. It was successful in 91 percent of cephalic cases and in all cases of breech head entrapments. Despite successful replacement, fetal injuries were common but may have resulted from the multiple manipulations used before the Zavanelli maneuver (Sandberg, 2007).

Symphysiotomy, in which the intervening symphyseal cartilage and much of its ligamentous support is cut to widen the symphysis pubis, is described in Chapter 28 (Total Breech Extraction). It has been used successfully for shoulder dystocia (Goodwin, 1997; Hartfield, 1986). Maternal morbidity can be significant due to urinary tract injury. *Cleidotomy* consists of cutting the clavicle with scissors or other sharp instruments and is usually done for a dead fetus (Schramm, 1983).

Shoulder Dystocia Drill

Hernandez and Wendel (1990) suggest use of a shoulder dystocia drill to better organize emergency management:

1. Call for help—mobilize assistants and anesthesia and pediatric personnel. Initially, a gentle attempt at traction is made. Drain the bladder if it is distended.
2. A generous episiotomy may be desired at this time to afford room posteriorly.
3. Suprapubic pressure is used initially by most practitioners because it has the advantage of simplicity. Only one assistant is needed to provide suprapubic pressure, while normal downward traction is applied to the fetal head.
4. The McRoberts maneuver requires two assistants. Each assistant grasps a leg and sharply flexes the maternal thigh toward the abdomen.

   These maneuvers will resolve most cases of shoulder dystocia.

   If the above listed steps fail, the following steps may be attempted, and any of the maneuvers may be repeated:
5. Delivery of the posterior arm is attempted. With a fully extended arm, however, this is usually difficult to accomplish.
6. Woods screw maneuver is applied.
7. Rubin maneuver is attempted.

The American College of Obstetricians and Gynecologists (2017c) has concluded that no one maneuver is superior to another in releasing an impacted shoulder or reducing the chance of injury. Performance of the McRoberts maneuver, however, is deemed a reasonable initial approach. In one review of more than 2000 cases, Hoffman and colleagues (2011) noted an 84-percent success rate with posterior shoulder delivery and comparable rates of neonatal injury compared with other standard methods. This contrasts with a review of 205 cases, in which posterior shoulder delivery yielded greater neonatal injury rates than rotational methods (Leung, 2011b). Spain and associates (2015) found that duration rather than a specific maneuver increased neonatal injury.

Importantly, progression from one maneuver to the next should be organized and methodical. As noted, the urgency to relieve the dystocia should be balanced against potentially injurious traction forces and manipulations. Lerner and coworkers (2011) in their evaluation of 127 shoulder dystocia cases reported that all neonates without sequelae from shoulder dystocia were born by 4 minutes. Conversely, most depressed neonates–57 percent–had head-to-body delivery intervals >4 minutes. The percentage of depressed neonates rose sharply after 3 minutes.

Shoulder dystocia training and protocols using simulation-based education and drills has evidence-based support. These tools improve performance and retention of drill steps (Buerkle, 2012; Crofts, 2008; Grobman, 2011). Their use has translated into improved neonatal outcome in some, but not all, investigations (Crofts, 2016; Fransen, 2017; Kim, 2016; Walsh, 2011). The American College of Obstetricians and Gynecologists (2012) also has created a Patient Safety Checklist to guide the documentation process with shoulder dystocia.

SPECIAL POPULATIONS

Home Birth

In 2014, 0.7 percent of deliveries in the United States were planned home births and 0.2 percent were unplanned (MacDorman, 2016). Of *unplanned* births in a 15-year epoch in Norway, 69 of 6027 or 1.1 percent resulted in fetal or neonatal death. This high rate was attributable to infection, prematurity, and placental abruption

(Gunnarsson, 2017). Multiparity and distance from the hospital were ascribed risks (Gunnarsson, 2014). In the United States, youth, lack of prenatal care, minority race, and lower educational attainment were associated risks for unplanned home birth (Declercq, 2010).

In contrast, the demographics of women choosing *planned* home birth in the United States favor those who are white, nonsmoking, self-pay, college-educated, and multiparous (MacDorman, 2016). As perceived benefits, planned delivery at home for those with low-risk pregnancies results in fewer medical interventions that include labor augmentation, episiotomy, operative vaginal delivery, and cesarean delivery (Bolten, 2016; Cheyney, 2014). Regarding the safety of planned home birth, data from randomized trial are lacking, and large observational studies derive from heterogeneous care systems, whose results may not be generalizable. For example, several developed countries deliver at home a large volume of carefully screened women, delivered by midwives with substantial training and in a setting closely integrated with the local health-care system (Birthplace in England Collaborative Group, 2011; de Jonge, 2015; Hutton, 2016). The level of such coordination in the United States is less uniform.

Overall, risks of home births in the United States are small but greater than those of hospital delivery. Midwife-attended home births carry a neonatal mortality risk of 1.3 per 1000 births. This is a nearly fourfold greater rate compared with midwife-attended hospital births. The most common underlying causes of death are those attributed to labor and delivery events, to congenital anomalies, and to infection. Of neonatal injuries, rates of neonatal seizure and serious neurological dysfunction are similarly elevated in home-birth groups (Grünebaum, 2013, 2014, 2017; Snowden, 2015; Wasden, 2016). Importantly, substantial risks attend home birth for those with prior cesarean delivery, with breech presentation, and with multifetal gestation (Cheyney, 2014; Cox, 2015). The American College of Obstetricians and Gynecologists (2017b) considers these to be absolute contraindications. Further, the College considers accredited hospitals and birthing centers to be the safest site for birth but recognizes the autonomy of the well-counseled patient.

Water Birth

As one option for pain relief, some women choose to spend part of first-stage labor in a large water tub. With this practice, one Cochrane review found lower rates of anesthesia block use and no greater adverse neonatal or maternal effects compared with traditional labor (Cluett, 2009).

For delivery, however, water birth carries greater concern for neonatal harm and without proven benefits. Case reports describe aspiration leading to fresh-water drowning (Pinette, 2004). The risk of cord avulsion during water birth approximates 3 per 1000 births, and stems primary from abruptly bringing the newborn out of the water (Schafer, 2014). Last, case reports also enumerate serious infections, which emphasize the need for rigorous sanitizing protocols. That said, in most large studies comparing land and water births, overall maternal or neonatal infection rates are not increased (Bovbjerg, 2016; Burns, 2012; Thoeni, 2005). In sum, several reviews comment on study shortcomings and isolated complications but do not identify definitive evidence for overall greater rates of neonatal harm from water birth in low-risk populations (Davies, 2015; Taylor, 2016). However, given the paucity of robust data and potential for serious complications, the American College of Obstetricians and Gynecologists (2016a) currently recommend that “birth occur on land, not in water.”

Female Genital Mutilation

This practice refers to medically unnecessary vulvar and perineal modification. In the United States, it is a federal crime to perform unnecessary genital surgery on a girl younger than 18 years. That said, forms of female genital mutilation are practiced in countries throughout Africa, the Middle East, and Asia. As many as 200 million women worldwide have undergone one of these procedures, and approximately 513,000 girls in the United States were at risk for this practice in 2012 (Goldberg, 2016; UNICEF, 2016). Cultural sensitivity is imperative, because many women may be offended by the suggestion that they have been assaulted or mutilated (American College of Obstetricians and Gynecologists, 2014).

The World Health Organization (2008) classifies genital mutilations into four types (Table 27-1). Long-term complications from surgery and its associated scarring include infertility, genital pain, diminished sexual quality of life, and propensity for urogenital infection (Almroth, 2005; Andersson, 2012; Nour, 2015). In general, women with significant symptoms following type III procedures are candidates for corrective surgery. Specifically, division of midline scar tissue to reopen the vulva is termed *deinfibulation*.

TABLE 27-1

World Health Organization Classification of Female Genital Mutilation

Type I	Partial or total removal of the clitoris and/or prepuce
Type II	Partial or total removal of the clitoris and the labia minora, with or without labia majora excision
Type III	Partial or total labial minora and/or majora excision, followed by fusion of the wound, termed infibulation, to cover and narrow the vagina. With or without clitoridectomy
Type IV	Pricking, piercing, incising, scraping, cautery, or other injury to female genitalia

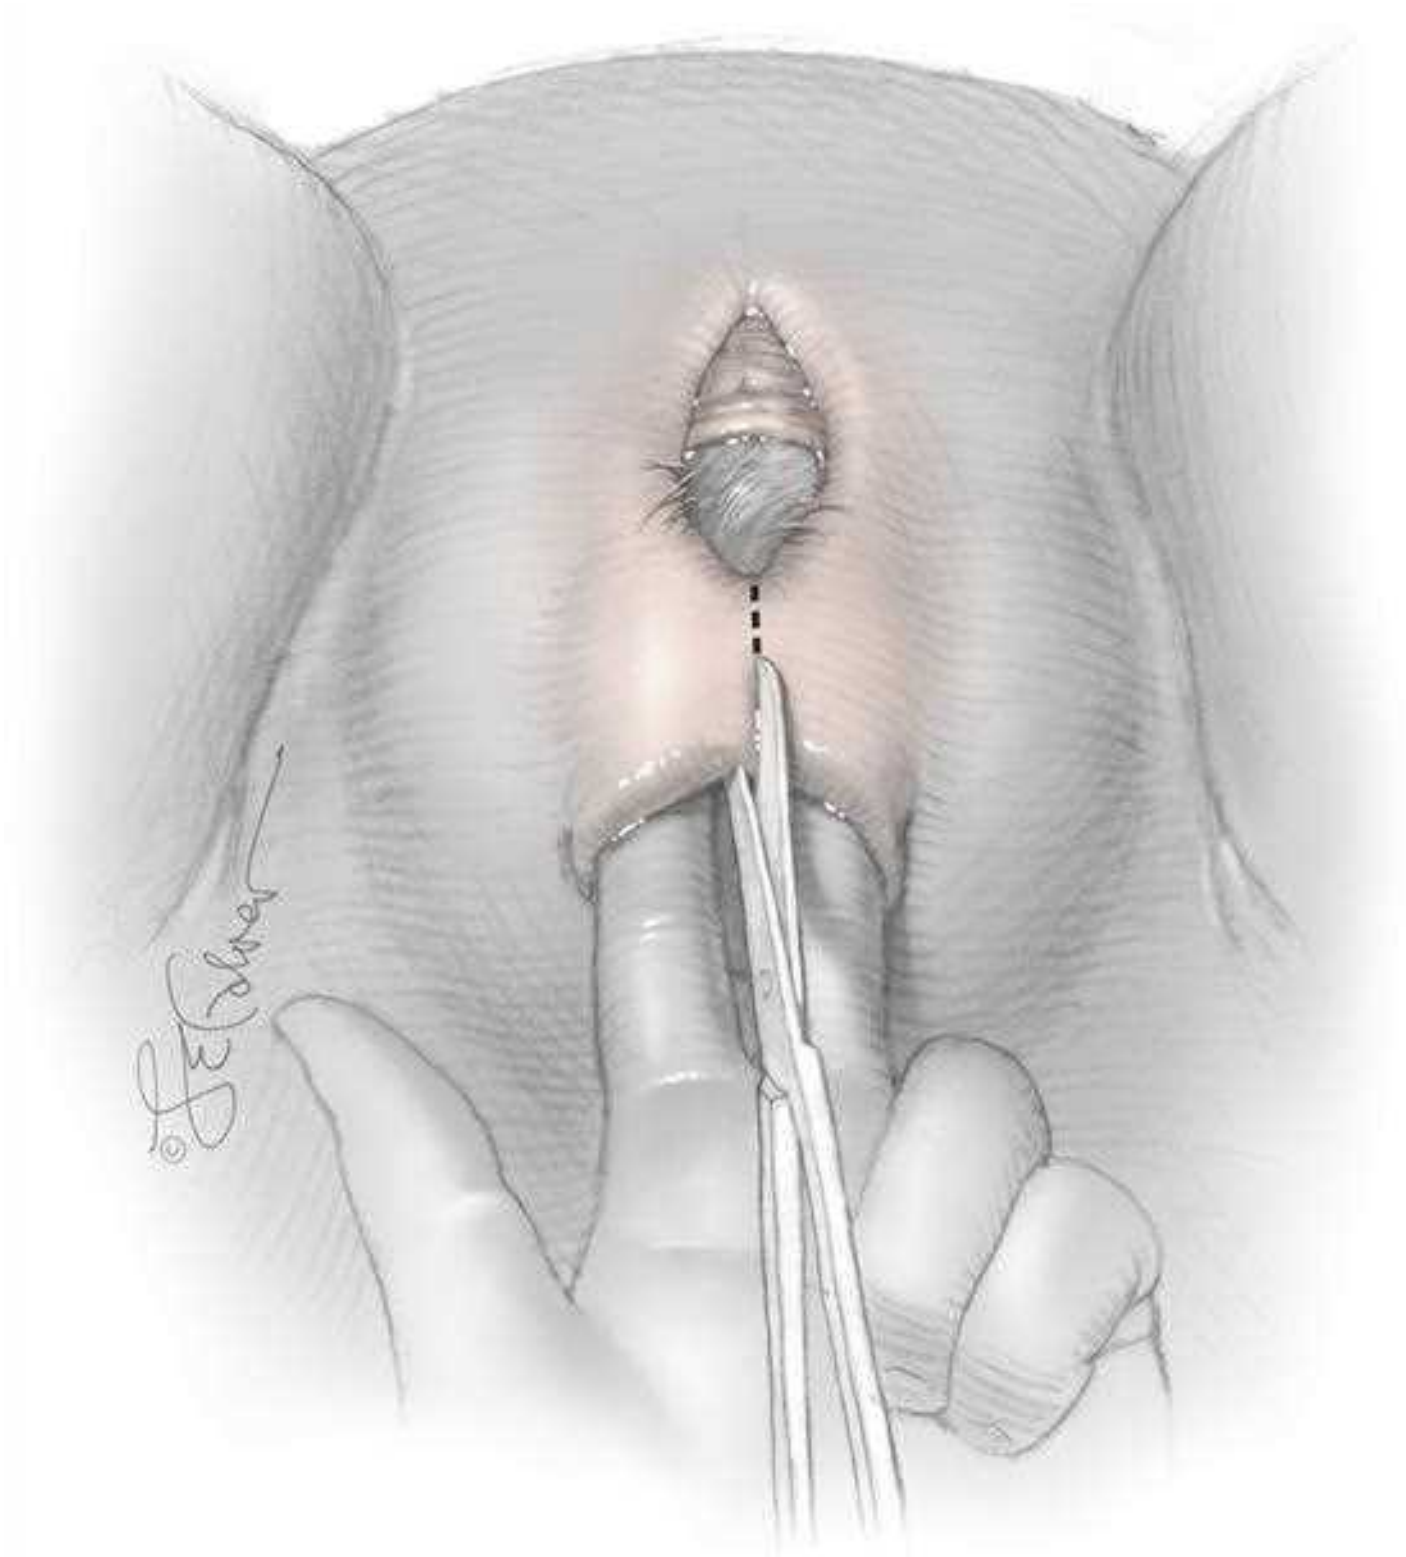
Adapted from the World Health Organization, 2008.

Female genital mutilation has been associated with some adverse maternal and neonatal complications. The World Health Organization (2006, 2008) estimated that these procedures increased perinatal morbidity rates by 10 to 20 per 1000. Small increased risks for prolonged labor, cesarean delivery, and postpartum hemorrhage are also found (Berg, 2014; Chibber, 2011; Wuest, 2009). Importantly, the psychiatric consequences can be profound.

To prevent obstetrical complications, deinfibulation can be performed either antepartum or intrapartum (Fig. 27-9) (Esu, 2017). In women not undergoing deinfibulation, anal sphincter tear rates with vaginal delivery may be increased (Berggren, 2013; Rodriguez, 2016). In our experiences, intrapartum deinfibulation in many cases allows successful vaginal delivery without major complications.

FIGURE 27-9

Deinfibulation. Although not shown here, lidocaine is first infiltrated along the planned incision if regional analgesia is not in place already. As protection, two fingers of one hand are insinuated behind the shelf created by fused labia but in front of the urethra and crowning head. The shelf is then incised in the midline. After delivery, the raw edges are sutured with rapidly absorbable material to secure hemostasis. (Reproduced with permission from Hawkins JS: Lower genital tract procedures. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



Prior Pelvic Reconstructive Surgery

These surgeries are performed with increasing frequency in reproductive-aged women, and thus pregnancy following these procedures is not uncommon. Logically, there are concerns for symptom recurrence following vaginal delivery, and high-quality data to aid evidenced-based decisions are limited. For women with prior stress urinary incontinence surgery, slightly greater protection against postpartum incontinence is gained by elective cesarean delivery (Pollard, 2012; Pradhan, 2013). Stated another way, most women with prior corrective surgery for incontinence can be delivered vaginally without symptom recurrence. Also, cesarean delivery is not always protective. Obviously, symptom recurrence and the need for additional vaginal surgery should be weighed against the surgical risk of cesarean delivery (Groenen, 2008). In those with prior surgeries for anal incontinence or pelvic organ prolapse, only scant information regarding outcomes is available. Such cases require individualization.

Anomalous Fetuses

Rarely, delivery can be obstructed by extreme hydrocephaly, by body stalk anomaly, or by massive fetal abdominal enlargement from a greatly distended bladder, ascites, or organomegaly (Costa, 2012; Sikka, 2011). With milder forms of hydrocephaly, if the biparietal diameter is <10 cm or if the head circumference is <36 cm, then vaginal delivery may be permitted (Anteby, 2003).

In rare cases in which neonatal death has occurred or is certain due to associated anomalies, vaginal delivery may be reasonable, but the head or abdomen must be reduced in size for delivery. Removal of fluid by cephalocentesis or paracentesis with sonographic guidance can be performed intrapartum. As described in Shoulder Dystocia Drill, cleidotomy can shorten the bisacromial diameter. For hydrocephalic fetuses that are breech, cephalocentesis can be accomplished suprapubically when the aftercoming head enters the pelvis. Currently, these practices are more germane in developing countries.

THIRD STAGE OF LABOR

Delivery of the Placenta

Third-stage labor begins immediately after fetal birth and ends with placental delivery. Goals include delivery of an intact placenta and avoidance of uterine inversion or postpartum hemorrhage. The latter two are grave intrapartum complications and constitute emergencies, as described in Chapter 41 (General Considerations).

Immediately after newborn birth, uterine fundal size and consistency are examined. If the uterus remains firm and there is no unusual bleeding, watchful waiting until the placenta separates is the usual practice. Neither massage nor downward fundal pressure is employed, but the fundus is frequently palpated to ensure that it does not become atonic and filled with blood from placental separation. *To prevent uterine inversion, umbilical cord traction must not be used to pull the placenta from the uterus.* Signs of separation include a sudden gush of blood into the vagina, a globular and firmer fundus, a lengthening of the umbilical cord as the placenta descends into the vagina, and elevation of the uterus into the abdomen. With the last, the placenta, having separated, passes down into the lower uterine segment and vagina. Here, its bulk pushes the uterine body upward.

These signs appear within minutes after newborn delivery, and the median time ranges from 4 to 12 minutes (Combs, 1991; Frolova, 2016; Shinar, 2016b). Once the placenta has detached from the uterine wall, the mother may be asked to bear down, and the intraabdominal pressure often expels the placenta into the vagina. These efforts may fail or may not be possible because of analgesia. After ensuring that the uterus is contracted firmly, the umbilical cord is kept slightly taut but is not pulled. Pressure is exerted by a hand wrapped around the fundus to propel the detached placenta into the vagina (Fig. 27-10). Concurrently, the heel of the hand exerts downward pressure between the symphysis pubis and the uterine fundus. This also aids inversion prevention. Once the placenta passes through the introitus, pressure on the uterus is relieved. The placenta is then gently lifted away. Care is taken to prevent placental membranes from being torn off and left behind. If the membranes begin to tear, they are grasped with a clamp and removed by gentle teasing (Fig. 27-11).

FIGURE 27-10
Expression of placenta. Note that the hand is *not* trying to push the fundus of the uterus through the birth canal! As the placenta leaves the uterus and enters the vagina, the uterus is elevated by the hand on the abdomen while the cord is held in position. The mother can aid in the delivery of the placenta by bearing down. As the placenta reaches the perineum, the cord is lifted, which in turn lifts the placenta out of the vagina.

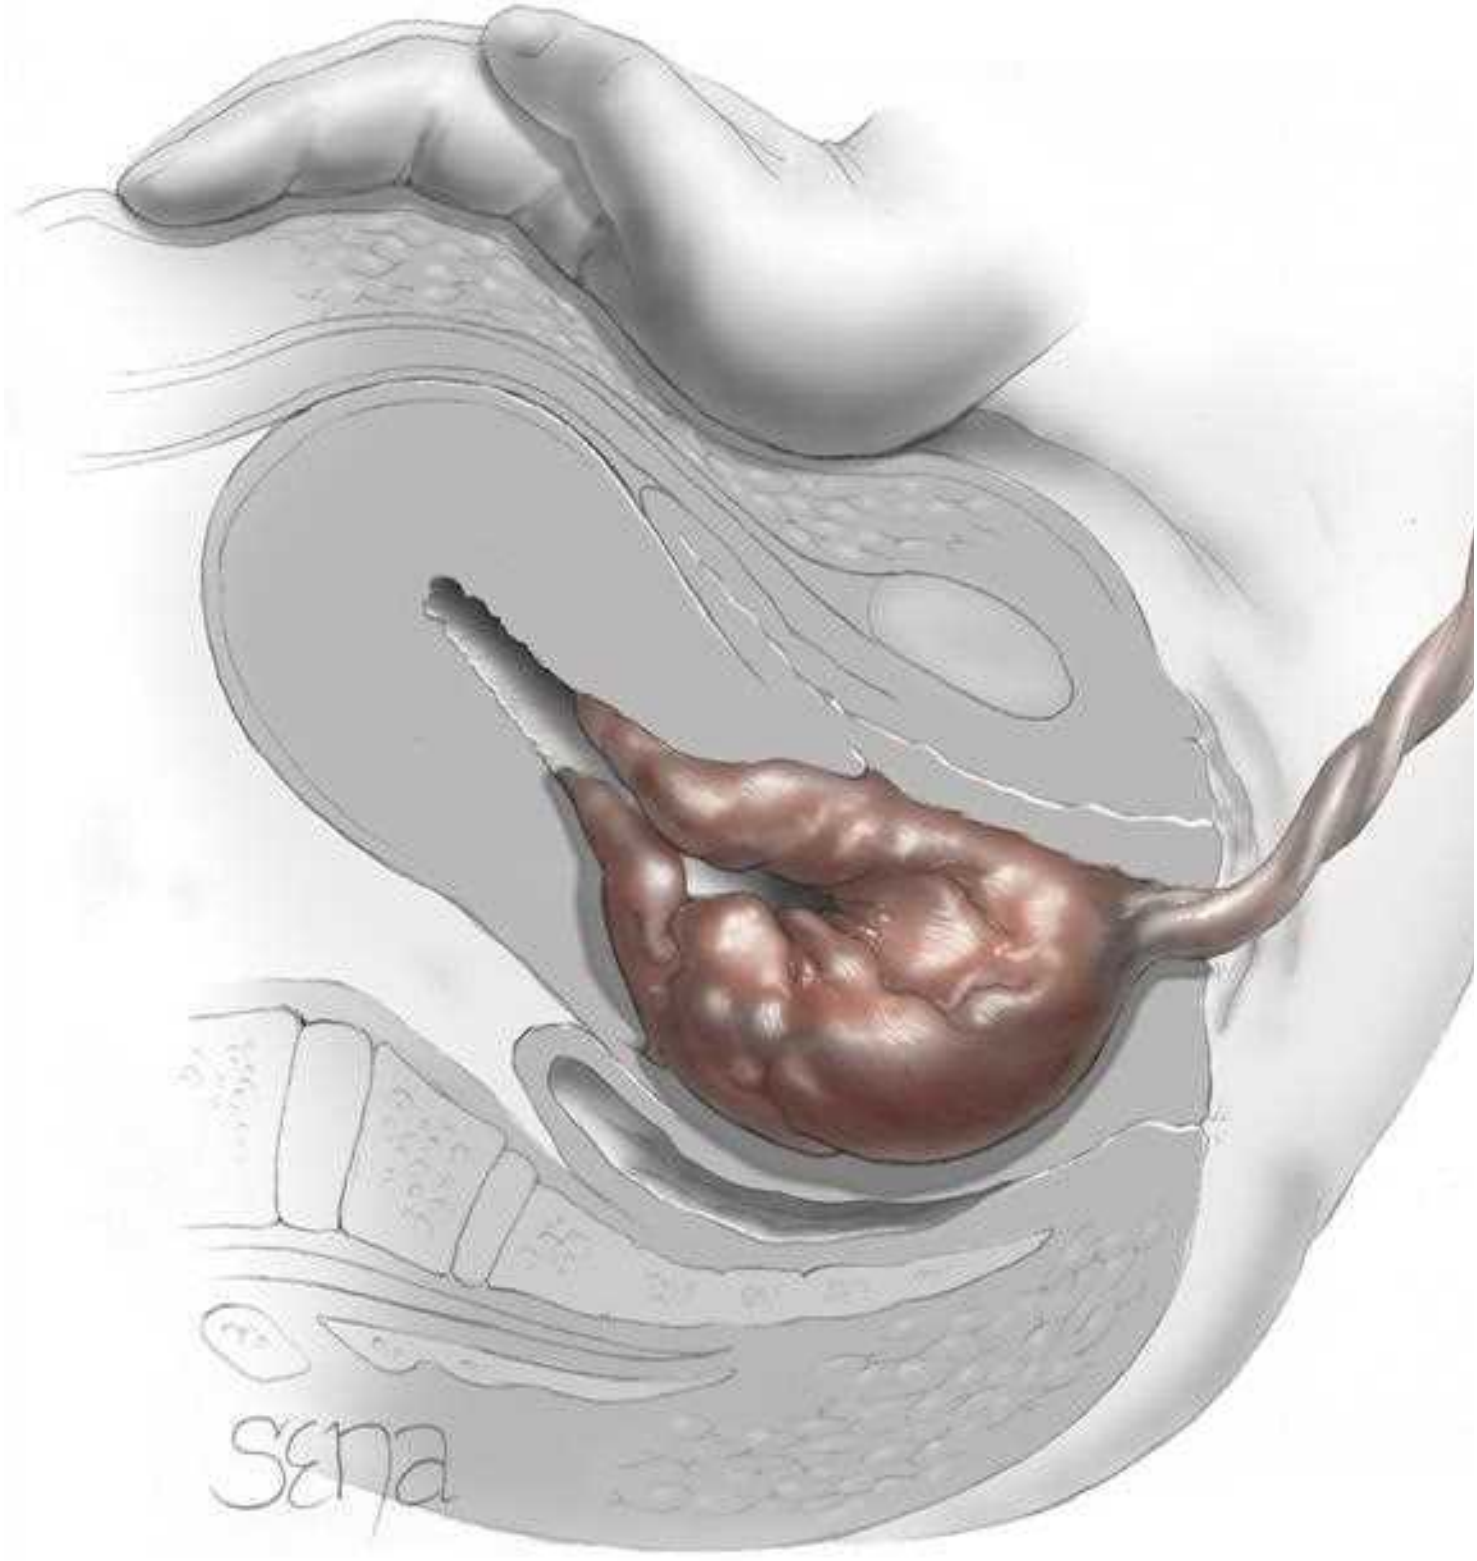


FIGURE 27-11

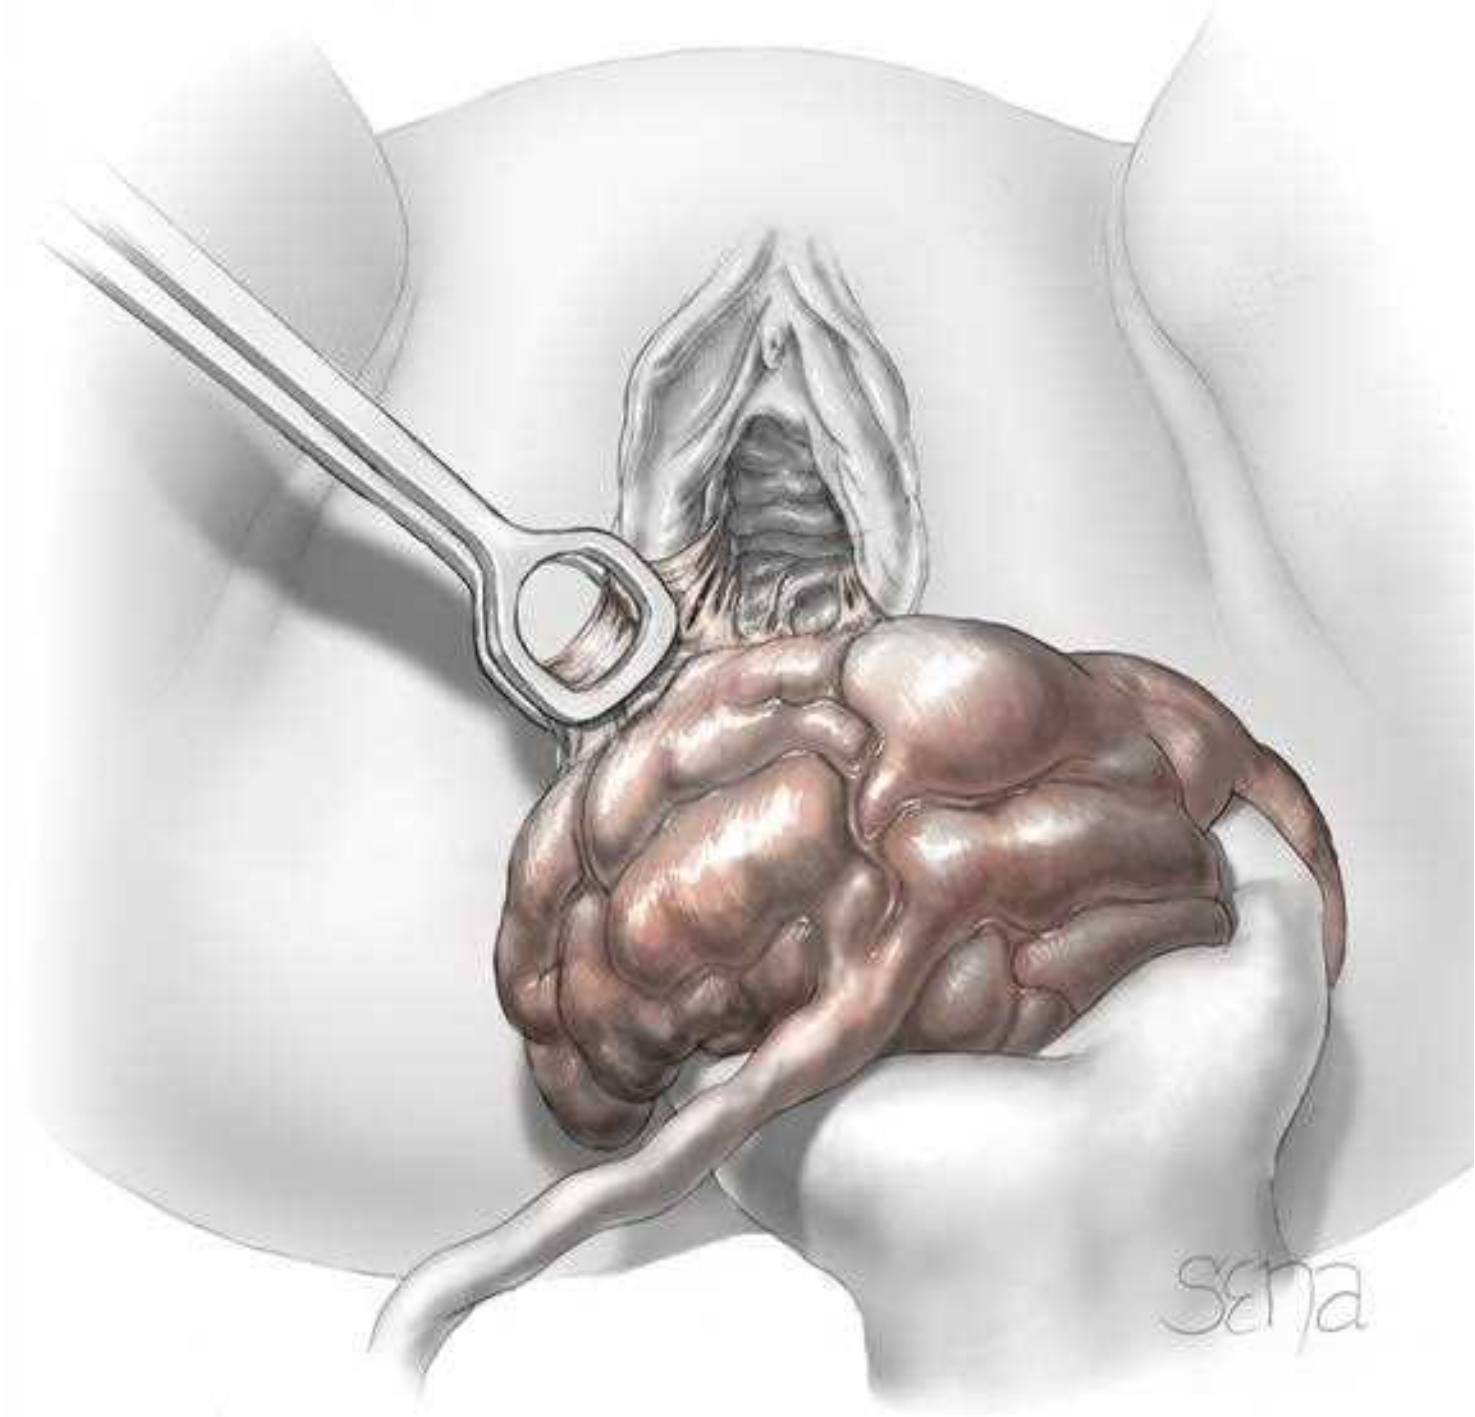
Membranes that were somewhat adhered to the uterine lining are separated by gentle traction with ring forceps.



Management of the Third Stage

Practices within the third stage of labor may be broadly considered as either expectant or active management. Expectant management involves waiting for placental separation signs and allowing the placenta to deliver either spontaneously or aided by nipple stimulation or gravity (World Health Organization, 2012). In contrast, active management of third-stage labor consists of early cord clamping, controlled cord traction during placental delivery, and immediate administration of prophylactic oxytocin. The goal of this triad is to limit postpartum hemorrhage (Begley, 2015; Jangsten, 2011; Westhoff, 2013).

As noted earlier, delayed cord clamping does not increase postpartum hemorrhage rates, and thus early clamping is a less important component of this trio. Similarly, cord traction may also be less critical (Deneux-Tharaux, 2013; Du, 2014; Gülmezoglu, 2012). Uterine massage following placental delivery is recommended by many, but not all, to prevent postpartum hemorrhage. We support this with the caveat that evidence for this practice is not strong (Abdel-Aleem, 2010).

Therefore, uterotonics play an essential role to decrease postpartum blood loss. Choices include oxytocin (Pitocin), misoprostol (Cytotec), carboprost (Hemabate), and the ergots, namely ergonovine (Ergotrate) and methylergonovine (Methergine). In addition, a combination agent of oxytocin and ergonovine (Syntometrine) is used outside the United States. Also in other countries, carbetocin (Duratocin), a long-acting oxytocin analogue, is available and effective for hemorrhage prevention

during cesarean delivery (Attilakos, 2010; Su, 2012). Of these, the World Health Organization (2012) recommends oxytocin as a first-line agent. Ergot-based drugs and misoprostol are alternatives in settings that lack oxytocin.

Uterotonics may be given before or after placental expulsion without affecting rates of postpartum hemorrhage, placental retention, or third-stage labor length (Soltani, 2010). If they are given before delivery of the placenta, however, they may entrap an undiagnosed, undelivered second twin. Thus, abdominal palpation should confirm no additional fetuses. Notably, this concern is less relevant with current widespread sonography use.

High-Dose Oxytocin

Synthetic oxytocin is identical to that produced by the posterior pituitary. Its action is noted at approximately 1 minute, and it has a mean half-life of 3 to 5 minutes. When given as a bolus, oxytocin can cause profound hypotension. Secher and coworkers (1978) reported that an intravenous bolus of 10 units of oxytocin caused a marked transient fall in blood pressure with an abrupt increase in cardiac output. Svanström and associates (2008) confirmed those findings. These hemodynamic changes could be dangerous for women hypovolemic from hemorrhage or those with certain types of cardiac disease. Thus, oxytocin should be given as a dilute solution by continuous intravenous infusion or as an intramuscular injection.

Water intoxication can result from the antidiuretic action of high-dose oxytocin if administered in a large volume of electrolyte-free dextrose solution (Whalley, 1963). Thus, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the infusion flow rate.

Despite the routine use of oxytocin, no standard prophylactic dose has been established for its use following either vaginal or cesarean delivery. Our practice is to add 20 units (2 mL) of oxytocin per liter of infusate. This solution is administered after delivery of the placenta at a rate of 10 to 20 mL/min—200 to 400 mU/min—for a few minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate then is reduced to 1 to 2 mL/min until the mother is ready for transfer from the recovery suite to the postpartum unit. The infusion is usually then discontinued. For women without intravenous access, 10 units of intramuscular oxytocin are injected.

Other Uterotonics

Ergonovine and methylergonovine have similar activity levels in myometrium, and only methylergonovine is currently manufactured in the United States. These ergot alkaloid agents do not provide superior protection against postpartum hemorrhage compared with oxytocin. Moreover, safety and tolerability are greater with oxytocin (Liabsuetrakul, 2011). For these reasons, ergot alkaloid agents are considered second-line for prevention of postpartum hemorrhage. If selected, a 0.2-mg dose of methylergonovine is slowly given intravenously in a period not less than 60 seconds to avoid sudden hypertension (Novartis, 2012). Methylergonovine is relatively contraindicated in the hypertensive woman.

Misoprostol is a prostaglandin E_1 analogue, which has proved inferior to oxytocin for postpartum hemorrhage prevention (Tunçalp, 2012). However, in resource-poor settings that lack oxytocin, misoprostol is suitable for hemorrhage prophylaxis and is given as a single oral 600-µg dose (Mobeen, 2011; World Health Organization, 2012). Notably, although oxytocin is preferred for prevention of hemorrhage, ergot alkaloids and prostaglandins play a greater role in postpartum hemorrhage treatment, discussed in Chapter 41 (Risk Factors).

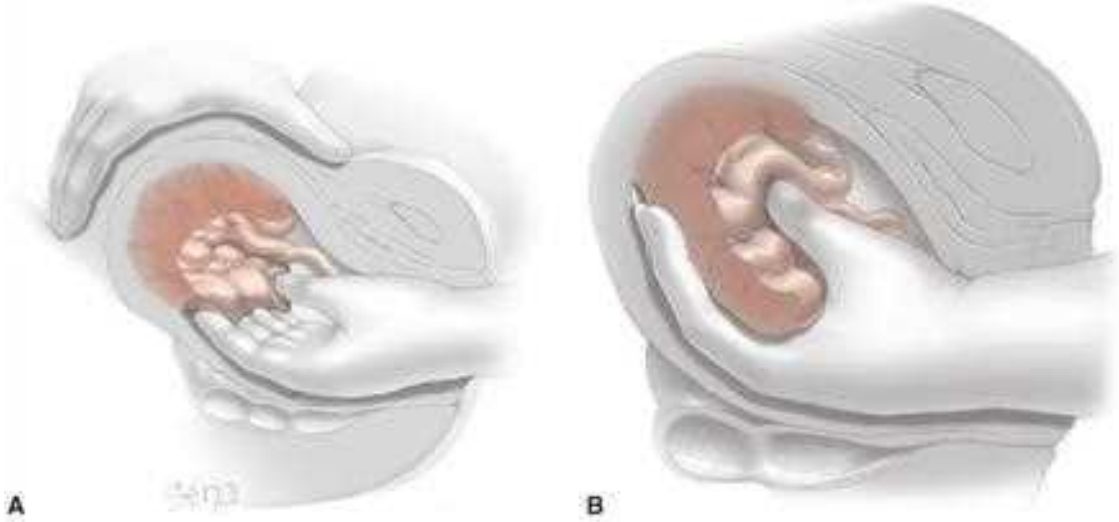
Manual Removal of Placenta

In approximately 2 percent of singleton births, the placenta may not deliver promptly (Cheung, 2011). Three possibilities include *placenta adherens*, in which uterine contractions are insufficient to detach the placenta; lower uterine segment constriction and a detached but trapped placenta; or a morbidly adherent placenta. Consistent risks for retained placenta include stillbirth, prior cesarean delivery, prior retention, and preterm delivery (Belachew, 2014; Coviello, 2015; Endler, 2014; Nikolajsen, 2013). For the last, in one study with nearly 46,000 deliveries, analysis predicted that 90 percent of placentas would spontaneously deliver by 180 minutes for gestations at 20 weeks; 21 minutes at 30 weeks; and 14 minutes at 40 weeks (Dombrowski, 1995).

Postpartum hemorrhage can complicate a retained placenta, and bleeding risk accrues with third-stage length. Thus, in the absence of bleeding, some recommend expectant management for 30 minutes, whereas others use a 15-minute threshold (Cummings, 2016; Deneux-Tharaux, 2009; Shinar, 2016a). The World Health Organization (2012) cites a 60-minute threshold. Notably, if brisk bleeding ensues and the placenta cannot be delivered by standard technique, manual removal of the placenta is indicated (Fig. 27-12). When performed, some administer a single dose of intravenous antibiotics, however, one systematic review of observational studies found no benefits (Chibueze, 2015). Although the American College of Obstetricians and Gynecologists (2016c) concludes that data neither support nor refute this practice, the World Health Organization (2012) recommends prophylaxis. At our institution, we administer a single dose to women not already receiving antibiotics.

FIGURE 27-12

Manual removal of placenta. **A.** One hand grasps the fundus and the other hand is inserted into the uterine cavity and the fingers are swept from side to side as they are advanced. **B.** When the placenta detaches, it is grasped and removed.



IMMEDIATE POSTPARTUM CARE

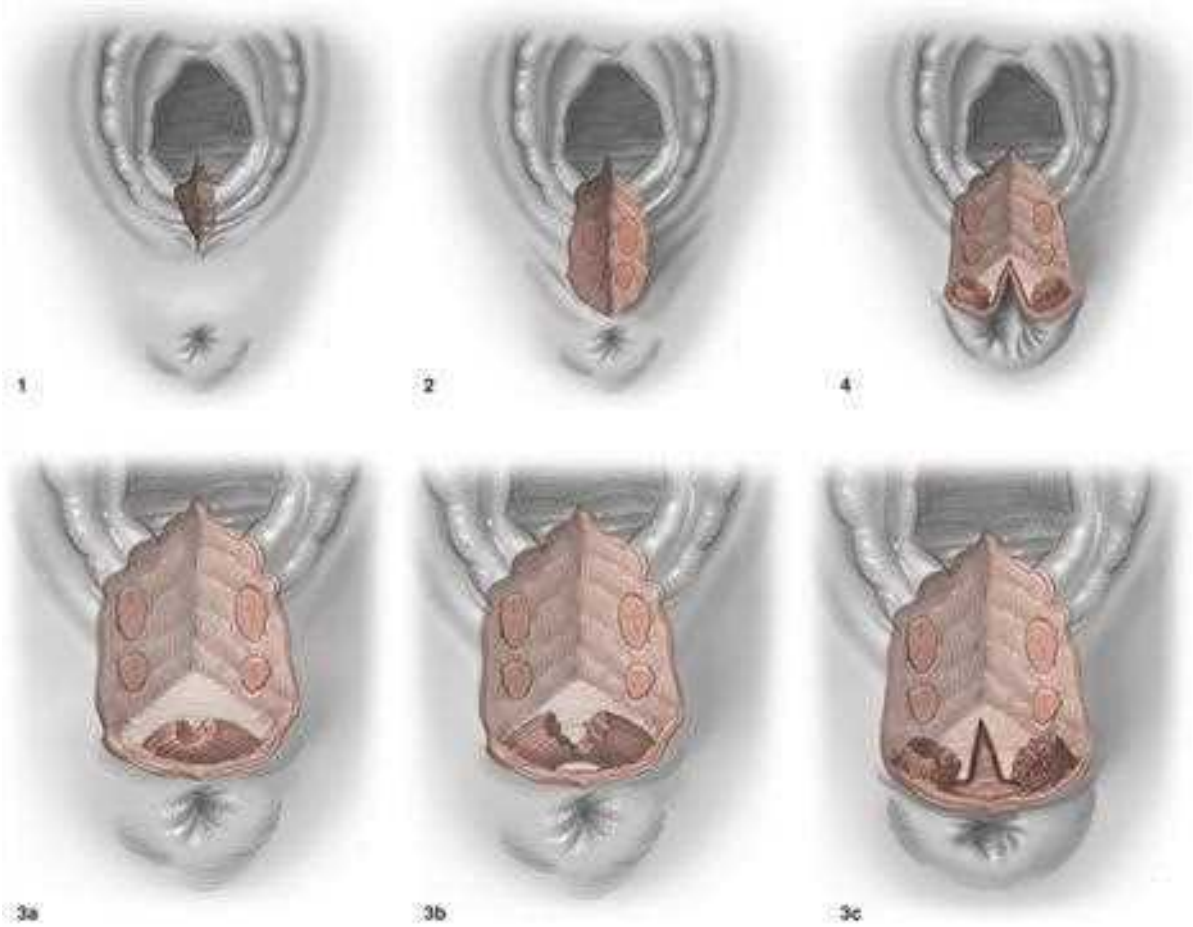
The hour immediately following delivery of the placenta is critical. During this time, lacerations are repaired. Although uterotonics are administered, postpartum hemorrhage as the result of uterine atony is most likely at this time. Hematomas may expand. Consequently, uterine tone and the perineum are frequently evaluated. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017b) recommend that maternal blood pressure and pulse be recorded immediately after delivery and every 15 minutes for the first 2 hours. The placenta, membranes, and umbilical cord are examined for completeness and for anomalies, as described in Chapter 6 (Normal Placenta).

Birth Canal Lacerations

Lower genital tract lacerations may involve the cervix, vagina, or perineum. Those of the cervix and vagina are described in Chapter 41 (Injuries to the Birth Canal). Those of the perineum often follow vaginal delivery, and most are first- and second-degree lacerations. Lacerations are classified by their depth, and complete definitions and visual examples are given in Figure 27-13. Of these, third-degree lacerations reflect anal sphincter injury and are now subcategorized as:

FIGURE 27-13

1. First-degree perineal laceration: injury to only the vaginal epithelium or perineal skin. **2.** Second-degree laceration: injury to perineum that spares the anal sphincter complex but involves the perineal muscles, which are the bulbospongiosus and superficial transverse perineal muscles. **3a.** Third-degree laceration: <50 percent of the external anal sphincter (EAS) is torn. **3b.** Third-degree laceration: >50 percent of the EAS is torn, but the internal anal sphincter (IAS) remains intact. **3c.** Third-degree laceration: EAS and IAS are torn. **4.** Fourth-degree laceration: the perineal body, entire anal sphincter complex, and anorectal mucosa are lacerated. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



(3a) <50 percent external anal sphincter (EAS) tear;

(3b) >50 percent EAS tear; and

(3c) EAS plus internal anal sphincter (IAS) tears.

Third- and fourth-degree lacerations are considered obstetrical anal sphincter injuries (OASIS), and their combined incidence varies from 0.5 to 5 percent (Blondel, 2016; Friedman, 2015). Risk factors for these more complex lacerations include nulliparity, midline episiotomy, persistent OP position, operative vaginal delivery, Asian race, short perineal length, and increasing fetal birthweight (Ampt, 2013; Dua, 2009; Gurol-Urganci, 2013; Landy, 2011). Mediolateral episiotomy is protective in most, but not all, studies (Jangö, 2014; Räisänen, 2011; Shmueli, 2016).

Morbidity rates rise as laceration severity increases. Compared with simpler lacerations, anal sphincter injuries are associated with greater blood loss and puerperal pain. Wound disruption and infection rates are other risks (Goldaber, 1993; Lewicky-Gaupp, 2015). Stock and coworkers (2013) reported that approximately 7 percent of 909 OASIS lacerations had complications. Long term, anal sphincter injuries are linked with approximately doubled rates of fecal incontinence compared with vaginal delivery without OASIS (Evers, 2012; Gyhagen, 2014). Data on long-term dyspareunia are limited, and rates are increased in some but not all studies (Mous, 2008; Otero, 2006; Salim, 2014; Sundquist, 2012).

To ensure appropriate repair, identification and correct categorization is essential. Diagnosis rates of OASIS improve with clinical experience (Andrews, 2006). Intrapartum endoanal ultrasound, performed in research studies, also boosts detection, and rates of clinically occult tears in primiparas range from 6 to 12 percent (Corton, 2013; Faltin, 2005; Ozyurt, 2015). That said, few data currently support routine intrapartum endoanal sonography, and the American College of Obstetricians and Gynecologists (2016b) does not recommended it (Walsh, 2015).

Women with a prior OASIS have a higher recurrence rate compared with multiparas without prior OASIS (Baghestan, 2012; Edozien, 2014; Elfaghi, 2004). That said, the risk mirrors that of primiparas in the general population and is low (Basham, 2013; Boggs, 2014; Priddis, 2013). Fetal macrosomia and operative vaginal delivery are notable risks in this cohort of parturients and can influence counseling in future pregnancies. Specifically, patients may choose to deliver by cesarean to avoid repeat OASIS. This consideration may be most pertinent for those with prior postpartum anal incontinence, with OASIS complications requiring corrective surgery, or with psychological trauma (American College of Obstetricians and Gynecologists, 2016b). However, planned cesarean delivery is balanced against its associated operative risks discussed in Chapter 30 (Cesarean Delivery Risks).

Episiotomy

Types

In contrast to spontaneous lacerations, *perineotomy* is intended incision of the perineum. *Episiotomy* is incision of the pudendum–the external genital organs. In common parlance, however, the term episiotomy often is used synonymously with perineotomy, a practice that we follow here. Obstetrical textbooks and organizational guidelines differ considerably in their description of episiotomy techniques. Kalis and associates (2012) have presented a classification, and we agree with the need for terminology standardization.

Midline and mediolateral episiotomies are the two main types and vary by the angle of perineal incision. Involved structures mirror those found with second-degree laceration, and their repairs are analogous. The *midline episiotomy* begins at the fourchette, incises the perineal body in the midline, and ends well before the external anal sphincter is reached. The incision length varies from 2 to 3 cm depending on perineal length and degree of tissue thinning. The *mediolateral episiotomy* begins at the midline of the fourchette and is directed to the right or left at an angle 60 degrees off the midline (Fig. 27-14). This angle accounts for perineal anatomy distortion during crowning and ultimately yields an incision 45 degrees off the midline for suturing (El-Din, 2014; Kalis, 2011). The *lateral episiotomy* begins at point 1 to 2 cm lateral from the midline. It too is angled toward either the right or the left ischial tuberosity.

FIGURE 27-14

A mediolateral episiotomy is cut as the baby's head crowns. Fingers are insinuated between the perineum and head. The incision begins in the midline and is directed toward the ipsilateral ischial tuberosity at an angle 60 degrees off the midline. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)

Before episiotomy, analgesia may be provided by existing labor regional analgesia, by bilateral pudendal nerve blockade, or by local infiltration of 1-percent lidocaine. Some instead advocate 2.5-percent lidocaine-prilocaine cream (EMLA cream), but this requires application an hour before expected delivery, which may be logistically difficult (Franchi, 2009; Kargar, 2016).

If episiotomy is performed unnecessarily early, incisional bleeding may be considerable before delivery. If it is performed too late, lacerations will not be prevented. Typically, episiotomy is completed when the head is visible during a contraction to a diameter of approximately 4 cm, that is, crowning. When used in conjunction with forceps delivery, most perform an episiotomy after application of the blades.

Few data directly compare midline and mediolateral types. As noted, midline episiotomy has a greater likelihood of associated anal sphincter lacerations (Coats, 1980; de Leeuw, 2001). Short-term rates of self-perceived pain and dyspareunia are similar or increased with mediolateral episiotomy (Fodstad, 2013, 2014; Sartore, 2004).

Even fewer studies compare lateral episiotomy to either mediolateral or midline. One randomized trial compared lateral and mediolateral types in nulliparas. Groups did not differ in pain scores, in sexual quality of life, or in vaginal or perineal trauma, including OASIS (Karbanova, 2014a,b; Necesalova, 2016). The authors also

reported that mediolateral episiotomies required less time and suture for the repair. Thus, among the three, mediolateral episiotomy may be the preferred incision to reduce OASIS rates.

Indications

In the past, routine episiotomy was practiced to avoid a ragged laceration and to limit postoperative pain and anal sphincter injury rates. But, a Cochrane review of randomized trials showed lower rates of severe perineal/vaginal trauma in women managed with a restrictive, that is, selective use of episiotomy for spontaneous delivery rather than with routine episiotomy (Jiang, 2017). Importantly, this review did not discern between midline and mediolateral episiotomies.

The American College of Obstetricians and Gynecologists (2016b) has concluded that restricted use of episiotomy is preferred to routine use. We are of the view that the procedure should be applied selectively for appropriate indications. Thus, episiotomy can be *considered* for indications such as shoulder dystocia, breech delivery, fetal macrosomia, operative vaginal deliveries, persistent OP positions, markedly short perineal length, and other instances in which failure to perform an episiotomy will result in significant perineal rupture. The final rule is that there is no substitute for surgical judgment and common sense.

With this new approach, episiotomy rates have dropped. Oliphant and coworkers (2010) used the National Hospital Discharge Survey to analyze episiotomy rates between 1979 and 2006 in the United States. They noted a 75-percent decline in the age-adjusted episiotomy rate. In the United States in 2012 episiotomy was performed in approximately 12 percent of vaginal births (Friedman, 2015).

Laceration and Episiotomy Repairs

Typically, perineal repairs are deferred until the placenta has been delivered. This policy permits undivided attention to the signs of placental separation and delivery. A further advantage is that the repair is not interrupted or disrupted by placenta delivery. This is especially true if manual removal must be performed. The major disadvantage is continuing blood loss until the repair is completed. Direct pressure from an applied gauze sponge will help to limit this volume.

For suitable repair, an understanding of perineal support and anatomy is necessary and is discussed in Chapter 2 (Perineum). Adequate analgesia is imperative, and women without regional analgesia can experience high levels of pain during perineal suturing. Again, locally injected lidocaine can be used solely or as a supplement to bilateral pudendal nerve blockade. In those with epidural analgesia, additional dosing may be necessary.

First-degree lacerations do not always require repair, and sutures are placed to control bleeding or restore anatomy. Here, few data guide suture selection, and fine-gauge absorbable or delayed-absorbable suture or adhesive glue is suitable.

Second-degree laceration correction as well as midline and mediolateral episiotomy repairs include similar steps. Namely, these close the vaginal epithelium and reapproximate the bulbospongiosus and superficial transverse perineal muscles during restoration of the perineal body (Figs. 27-15 and 27-16). For this, most studies support a continuous suturing method, which is faster than placing interrupted sutures and, with few exceptions, yields less pain (Grant, 2001; Kettle, 2012; Kindberg, 2008; Valenzuela, 2009). Blunt needles are suitable and likely decrease the incidence of needle-stick injuries (El-Refaie, 2012; Mornar, 2008). Commonly used suture materials are 2–0 polyglactin 910 (Vicryl) or chromic catgut. With the former, a decrease in postsurgical pain and lower risk of wound dehiscence are cited as major advantages (Jallad, 2016; Kettle, 2010). Closures with traditional polyglactin 910, however, occasionally require removal of residual suture from the repair site because of pain or dyspareunia. This disadvantage may be reduced by using a rapidly absorbed polyglactin 910 (Vicryl Rapide) (Bharathi, 2013; Kettle, 2002; Leroux, 2006).

FIGURE 27-15

Mediolateral episiotomy repair. **A.** The vaginal epithelium and deeper tissues are closed with a single, continuous, locking suture. The angle seems less acute now (approximately 45°) since the perineum is no longer distended. **B.** After the vaginal component of the laceration is repaired, deeper perineal tissues are reapproximated by a single, continuous, nonlocking suture. Small episiotomies may not require this deeper layer. **C.** With a similar continuous, nonlocking technique, the superficial transverse perineal and bulbospongiosus muscles are reapproximated. **D.** Last, the perineal skin is closed using a subcuticular stitch. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)

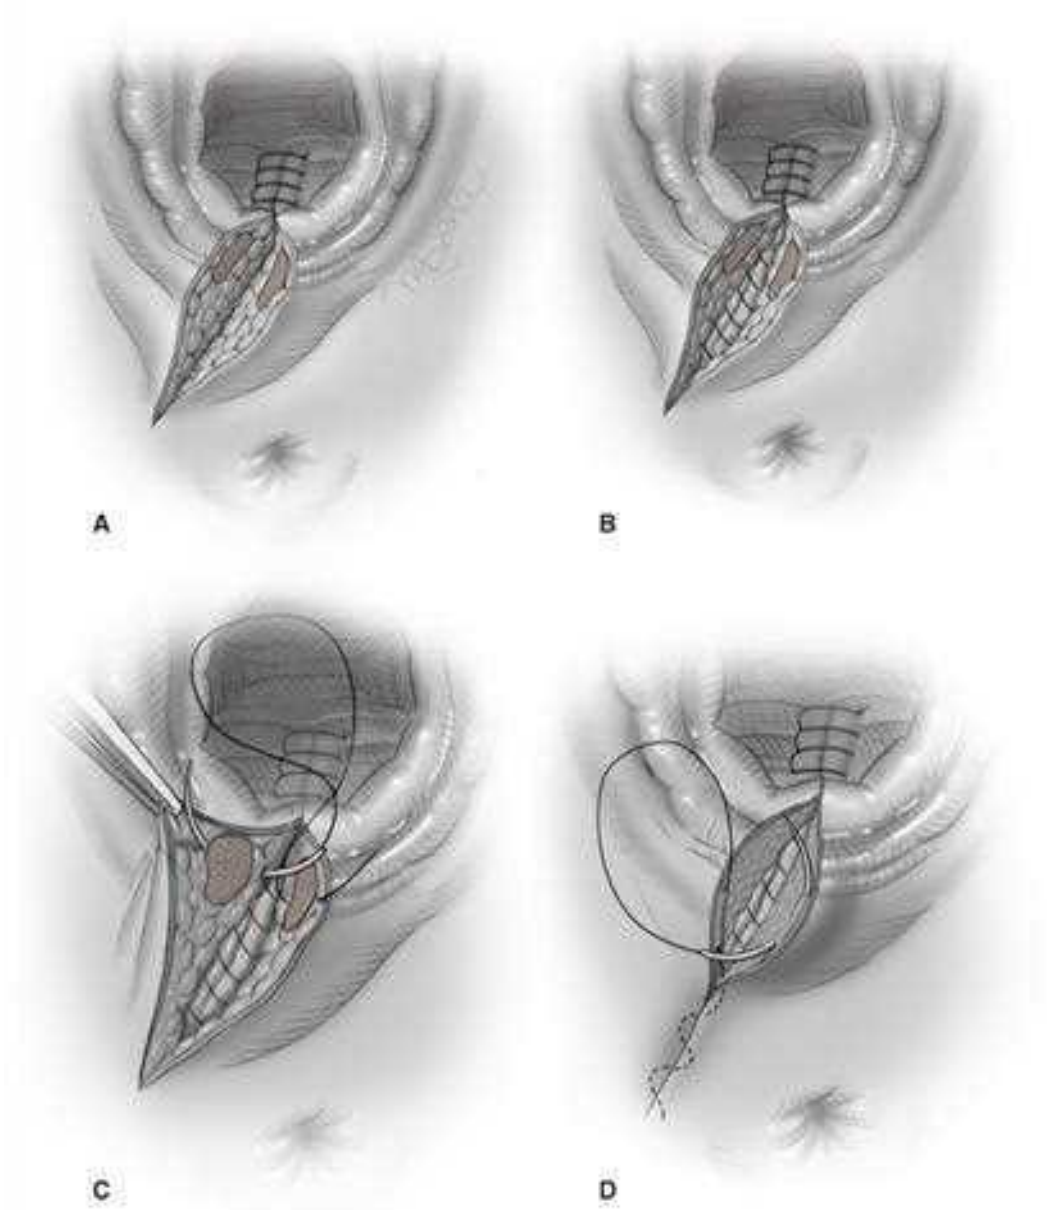


FIGURE 27-16

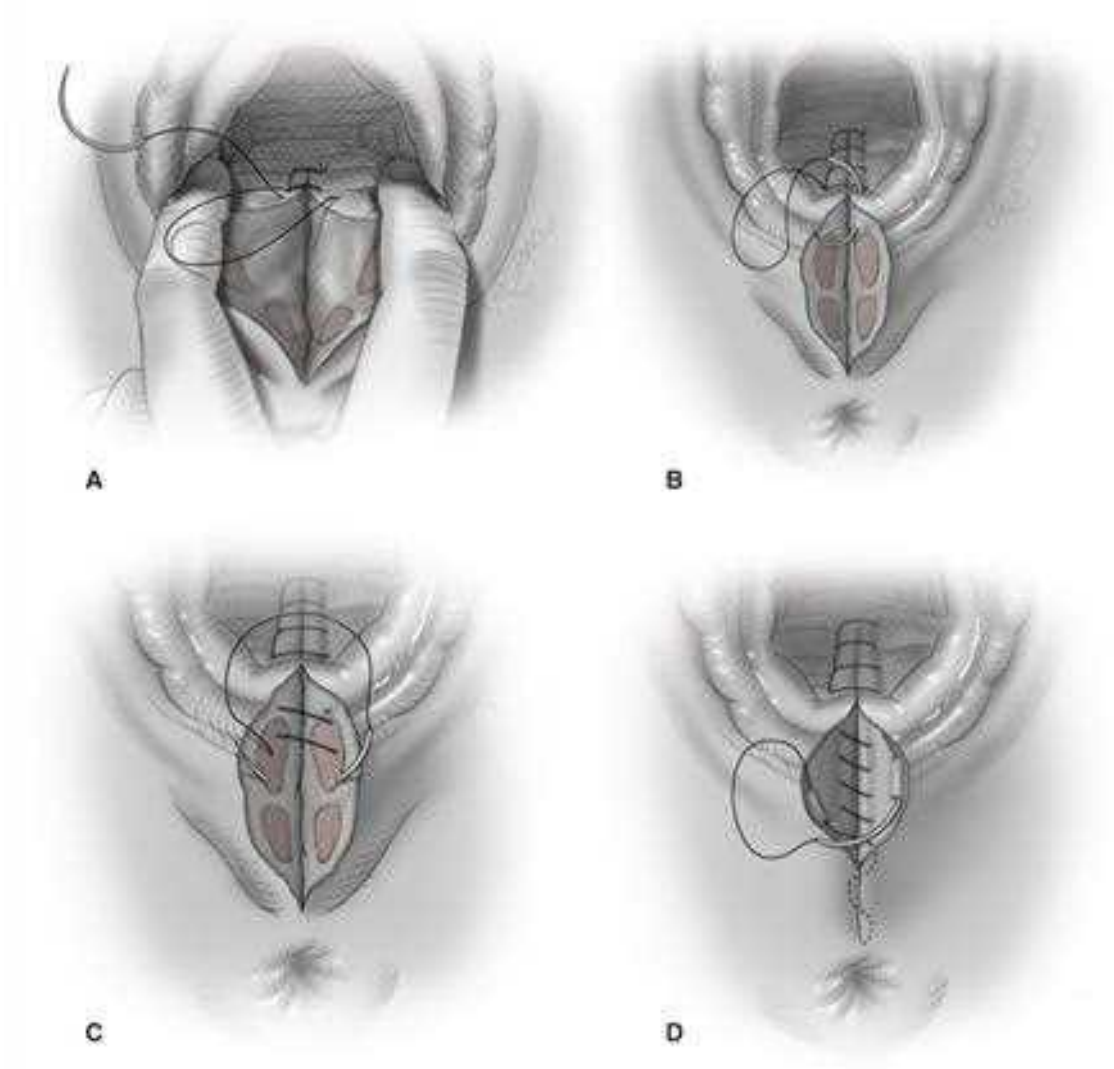
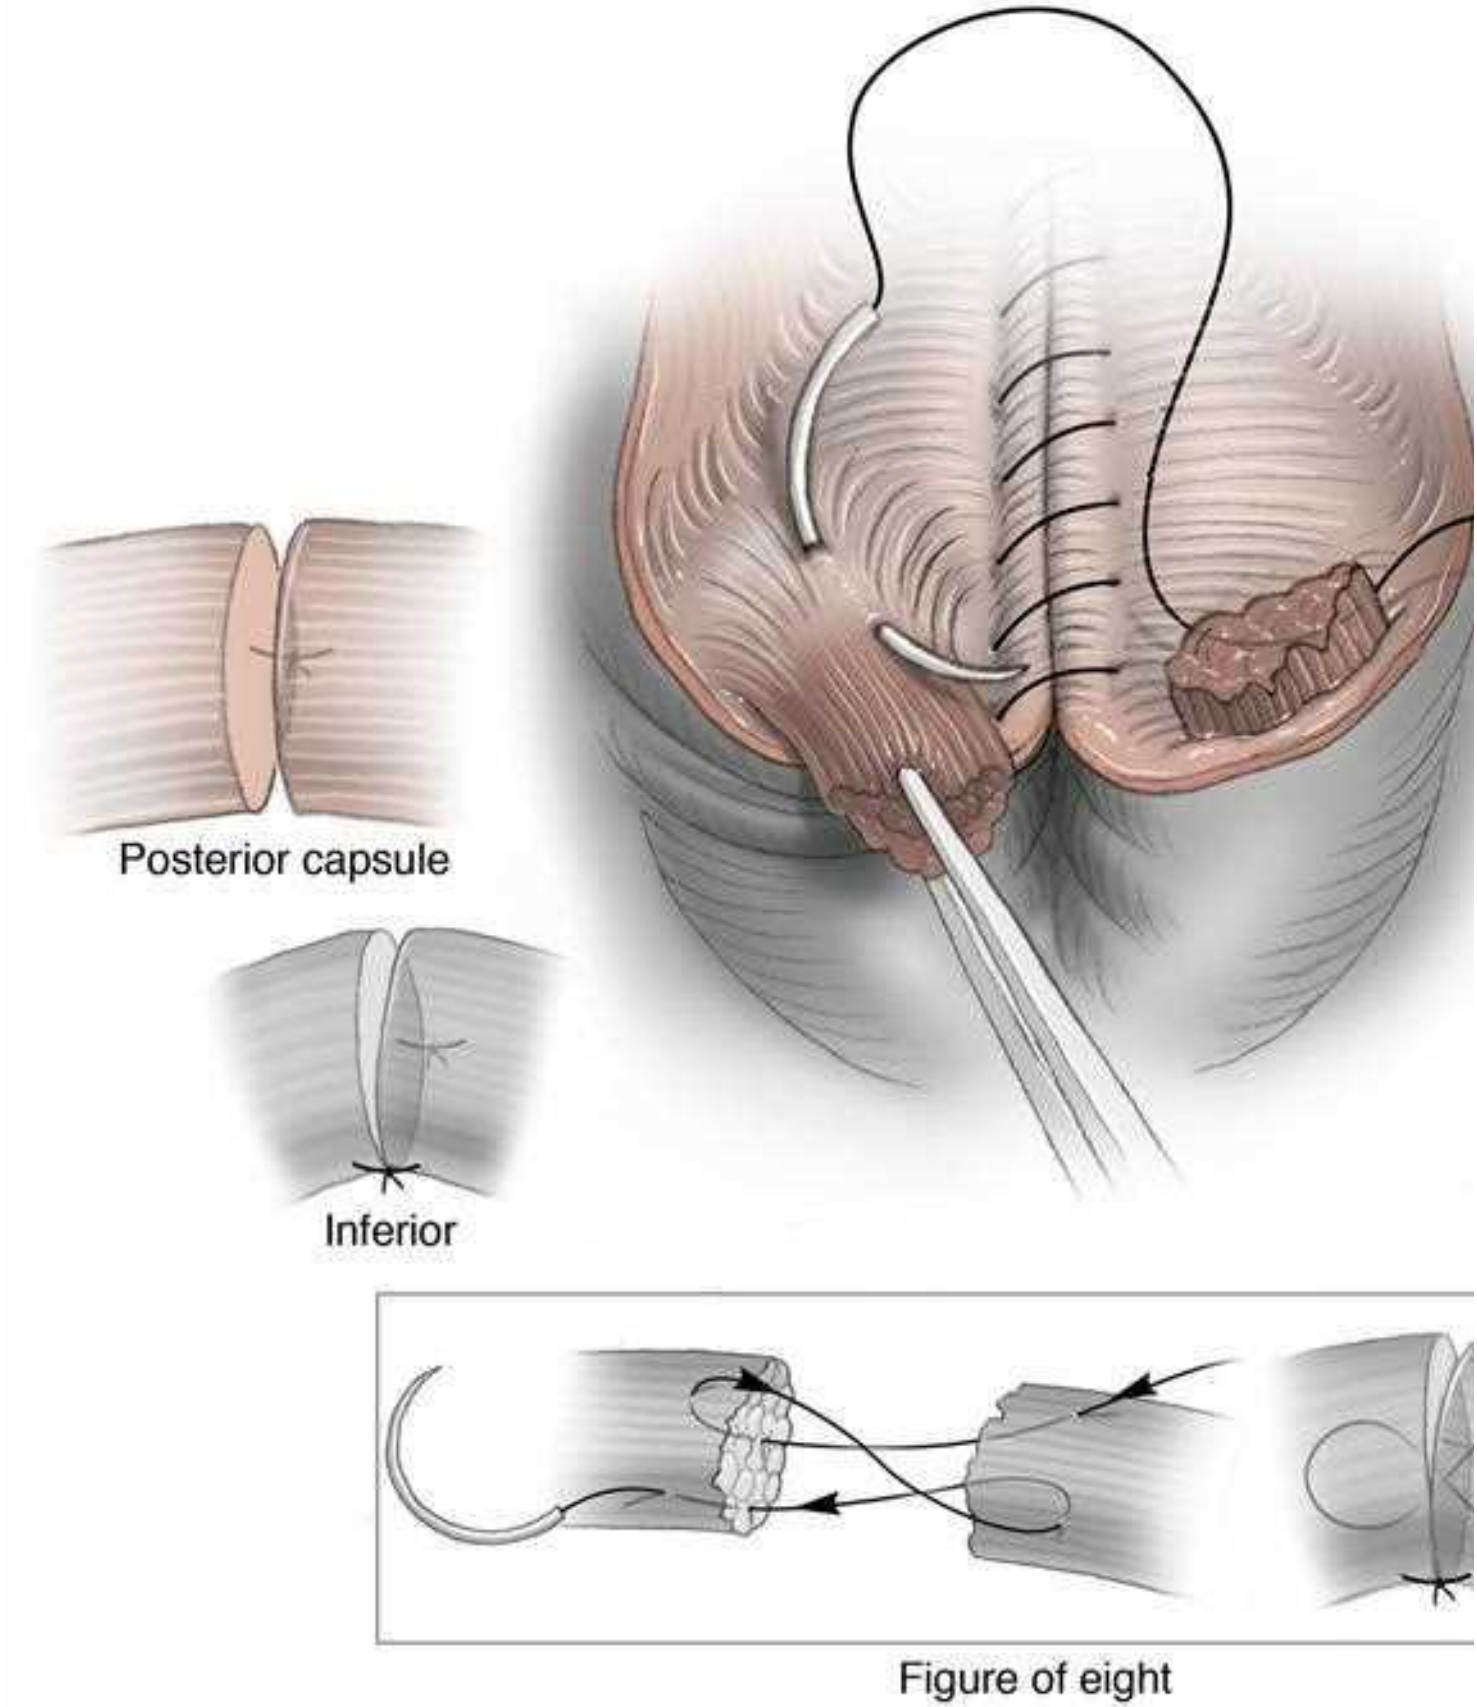
Midline episiotomy repair. **A.** An anchor stitch is placed above the wound apex to begin a running, locking closure with 2–0 suture to close the vaginal epithelium and deeper tissues and reapproximate the hymeneal ring. **B.** A transition stitch redirects suturing from the vagina to the perineum. **C.** The superficial transverse perineal and bulbospongiosus muscles are reapproximated using a continuous, nonlocking technique with the same length of suture. This aids restoration of the perineal body for long-term support. **D.** The continuous suture is then carried upward as a subcuticular stitch. The final knot is tied proximal to the hymeneal ring. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



For third-degree laceration repair, two methods are available to repair the external anal sphincter. The first is an *end-to-end technique*, which we prefer, and is shown in Figure 27-17. Initially, the cut ends of the external anal sphincter, which often retract, are isolated and brought to the midline. Importantly, the strength of this closure is derived from the connective tissue surrounding the sphincter—often called the *capsule*—and not the striated muscle. Thus, serial interrupted sutures incorporate sphincter fibers and perisphincter connective tissue, to bring sphincter ends together. There are few evidence-based data to guide suture selection for sphincter repair, but delayed-absorbable material can provide sustained tensile strength during healing. This theory is supported by the above study by Jallad and coworkers (2016), which showed higher perineal breakdown rate following OASIS repair with chromic gut.

FIGURE 27-17

In overview, with end-to-end approximation of the external anal sphincter (EAS), a suture is placed through the EAS muscle, and four to six simple interrupted 2–0 or 3–0 sutures of polyglactin 910 are placed at the 3, 6, 9, and 12 o'clock positions through the perisphincter connective tissue. To begin, disrupted ends of the striated EAS muscle and capsule are identified and grasped. The first suture is placed posteriorly to maintain clear exposure. Another suture is then placed inferiorly at the 6 o'clock position. The sphincter muscle fibers are next reapposed by a figure-of-eight stitch. Last, the remainder of the fascia is closed with a stitch placed anterior to the sphincter cylinder and again with once placed superior to it. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)

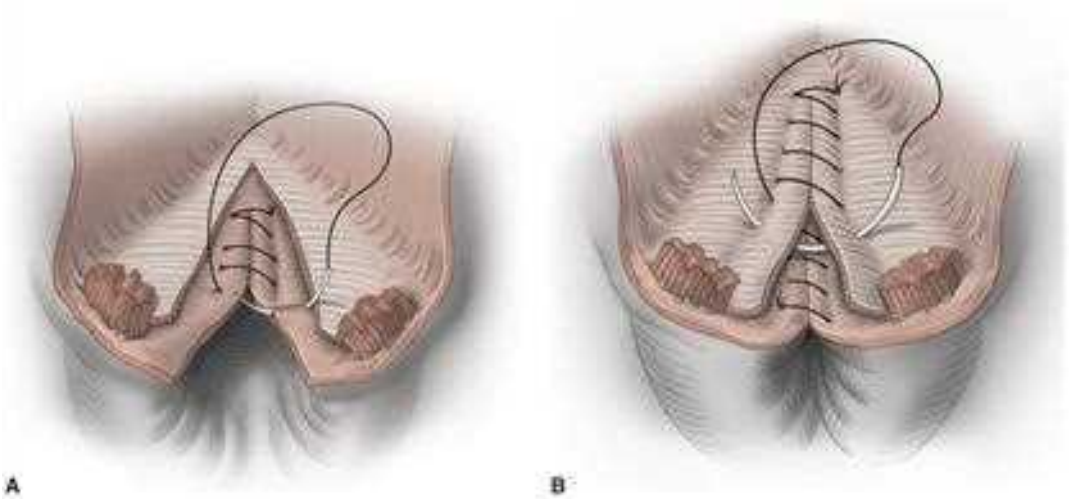


With the *overlapping technique,* the ends of the external anal sphincter are brought to the midline and lie atop one another. This method is only suitable for type 3c lacerations—those involving the external and internal anal sphincter. Two rows of mattress sutures travel through both sphincter ends to recreate the anal ring. In comparing the two methods, neither yields superior long-term anatomical or functional results (Farrell, 2012; Fernando, 2013; Fitzpatrick, 2000). Also with type 3c lacerations, the IAS is repaired before the EAS and is described next.

With fourth-degree laceration repairs, the torn edges of the rectal mucosa are reapproximated (Fig. 27-18). At a point 1 cm proximal to the wound apex, sutures are placed approximately 0.5 cm apart in the rectal muscularis and do not enter the anorectal lumen. Clinicians often use 4–0 polyglactin 910 or chromic gut for this running suture line. Some recommend a second reinforcing layer above this (Hale, 2007). If this is not done, then the next layer to cover the anorectal mucosa is formed by reapproximation of the internal anal sphincter. This running, nonlocking closure is completed with 3–0 or 4–0 suture (see Fig. 27-18B). Following any repair, needle and sponge counts are reconciled and recorded in the delivery note.

FIGURE 27-18

A. Suturing of the anorectal mucosa begins above the laceration apex using a continuous, nonlocking method with fine-gauge absorbable suture such as 3–0 or 4–0 chromic gut or polyglactin 910. Sutures are placed through the anorectal submucosa approximately 0.5 cm apart down to the anal verge. **B.** A second reinforcing layer uses 3–0 delayed-absorbable suture in a continuous, nonlocking fashion. This incorporate the torn ends of the internal anal sphincter (IAS), which can be identified as the glistening white fibrous structure lying between the anal canal submucosa and the fibers of the external anal sphincter. In many cases, the IAS retracts laterally and must be sought and retrieved for repair. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



For reduction of infectious morbidity associated with anal sphincter lacerations, a single dose of antibiotic at the time of repair is recommended by the American College of Obstetricians and Gynecologists (2016c). This practice is supported by evidence (Buppasiri, 2014; Duggal, 2008; Lewicky-Gaupp, 2015; Stock, 2013). A single dose of a second-generation cephalosporin is suitable, or clindamycin for penicillin-allergic women. With OASIS, postoperatively, stool softeners are prescribed for a week, and enemas and suppositories are avoided.

Unfortunately, normal function is not always ensured even with correct and complete surgical repair. Some women may experience continuing fecal incontinence caused by injury to the innervation of the pelvic floor musculature (Roberts, 1990).

Perineal Laceration Care

Initially, locally applied ice packs help reduce swelling and allay discomfort (de Souza Bosco Paiva, 2016). In subsequent days, warm sitz baths aid comfort and hygiene. Additionally, a small squirt bottle of warm water can cleanse the site after voiding or stooling. For pain, topical application of 5-percent lidocaine ointment was not effective in relieving episiotomy or perineal laceration discomfort in one randomized trial (Minassian, 2002). Oral analgesics containing codeine provide considerable relief. For lesser degree of discomfort, NSAID tablets can be given.

Because pain may signal a large vulvar, paravaginal, or ischiorectal fossa hematoma or perineal cellulitis, these sites should be examined carefully if pain is severe or persistent. Management of these complications is discussed in Chapters 37 and 41 (Perineal Infections and Puerperal Hematomas). In addition to pain, urinary retention may complicate episiotomy recovery (Mulder, 2012, 2016). Its management is described in Chapter 36 (Perineal Care).

For those with second-degree lacerations or anal sphincter tears, intercourse is usually proscribed until after the first puerperal visit at 6 weeks. Compared with women with intact perineum, those with perineal trauma show higher rates of delayed intercourse at 3 and 6 months, but not at 1 year (McDonald, 2015; Rådestad, 2008; Signorello, 2001).

CHAPTER 28: Breech Delivery

The essential prerequisite for the successful performance of breech extraction lies in the complete dilatation of the cervix and the absence of any serious mechanical obstacle. It is true that in a certain number of cases extraction through an imperfectly dilated cervix is possible, but this is usually effected only at the cost of deep cervical tears.

—J. Whitridge Williams (1903)

INTRODUCTION

Near term, the fetus typically has spontaneously assumed a cephalic presentation. Conversely, if the fetal buttocks or legs enter the pelvis before the head, the presentation is breech. This fetal lie is more common remote from term, as earlier in pregnancy each fetal pole has similar bulk. At term, breech presentation persists in approximately 3 to 5 percent of singleton deliveries (Cammu, 2014; Lyons, 2015; Macharey, 2017).

CLASSIFICATION OF BREECH PRESENTATIONS

The categories of frank, complete, and incomplete breech presentations differ in their varying relations between the lower extremities and buttocks. With a frank breech, lower extremities are flexed at the hips and extended at the knees, and thus the feet lie close to the head (Fig. 28-1). With a complete breech, both hips are flexed, and one or both knees are also flexed (Fig. 28-2). With an incomplete breech, one or both hips are extended. As a result, one or both feet or knees lie below the breech, such that a foot or knee is lowermost in the birth canal (Fig. 28-3). A footling breech is an incomplete breech with one or both feet below the breech.

FIGURE 28-1
Frank breech presentation.

FIGURE 28-2

Complete breech presentation.

FIGURE 28-3

Incomplete breech presentation.

Of term breech fetuses, the neck may be extremely hyperextended in perhaps 5 percent, and the term *stargazing fetus* is used (Cimmino, 1975). With these, fetal or uterine anomalies may be more prevalent and are sought if not previously identified (Phelan, 1983). With this hyperextension, vaginal delivery can result in injury to the cervical spinal cord. Thus, if identified at term, this is an indication for cesarean delivery (Westgren, 1981). That said, flexion itself may be implicated, as cases of spinal cord injury have been reported following uneventful cesarean delivery of such fetuses (Hernandez-Marti, 1984). With transverse lie and similar hyperextension of the fetal neck, the term *flying fetus* is applied.

DIAGNOSIS

Risk Factors

Understanding the clinical settings that predispose to breech presentation can aid early recognition. Other than early gestational age, risk factors include extremes of amnionic fluid volume, multifetal gestation, hydrocephaly, anencephaly, structural uterine abnormalities, placenta previa, pelvic tumors, and prior breech delivery. One study found that following one breech delivery, the recurrence rate for a second breech presentation was 10 percent, and for a subsequent third breech it was 28 percent (Ford, 2010).

Examination

Leopold maneuvers to ascertain fetal presentation are discussed in Chapter 22 (Diagnosis). With the first maneuver, the hard, round fetal head occupies the fundus. The second maneuver identifies the back to be on one side of the abdomen and the small parts on the other. With the third maneuver, if not engaged, the softer breech is movable above the pelvic inlet. After engagement, the fourth maneuver shows the breech to be beneath the symphysis. The accuracy of this palpation varies (Lydon-Rochelle, 1993; Nassar, 2006). Thus, with suspected breech presentation—or any presentation other than cephalic—sonographic evaluation is indicated.

During cervical examination with a frank breech, no feet are appreciated, but the fetal ischial tuberosities, sacrum, and anus are usually palpable. After further fetal descent, the external genitalia may also be distinguished. When labor is prolonged, the fetal buttocks may become markedly swollen, rendering digital differentiation of a face and breech difficult. In some cases, the anus may be mistaken for the mouth and the ischial tuberosities for the malar eminences. With careful examination, however, the finger encounters muscular resistance with the anus, whereas the hard, less yielding jaws are felt through the mouth. The finger, upon removal from the anus, may be stained with meconium. The mouth and malar eminences form a triangular shape, whereas the ischial tuberosities and anus lie in a straight line. With a complete breech, the feet may be felt alongside the buttocks. In footling presentations, one or both feet are inferior to the buttocks.

The fetal sacrum and its spinous processes are palpated to establish position. As with cephalic presentations, fetal position is designated to reflect the relations of the fetal sacrum to the maternal pelvis. Positions include left sacrum anterior (LSA), right sacrum anterior (RSA), left sacrum posterior (LSP), right sacrum posterior (RSP), and sacrum transverse (ST).

ROUTE OF DELIVERY

Multiple factors aid determination of the best delivery route for a given mother-fetus pair. These include fetal characteristics, maternal pelvic dimensions, coexistent pregnancy complications, provider experience, patient preference, hospital capabilities, and gestational age.

Compared with their term counterparts, preterm breech fetuses have distinct complications related to their small size and immaturity. For example, rates of head entrapment, birth trauma, and perinatal mortality can be greater. Accordingly, separate discussions of term and preterm breech fetuses are more appropriate.

Term Breech Fetus

Current obstetrical thinking regarding vaginal delivery of the term breech fetus has been tremendously influenced by results of the Term Breech Trial (Hannah, 2000). This trial included 1041 women randomly assigned to planned cesarean and 1042 to planned vaginal delivery. In the planned vaginal delivery group, 57 percent were actually delivered vaginally. Planned cesarean delivery was associated with a lower risk of perinatal mortality compared with planned vaginal delivery—3 per 1000 versus 13 per 1000. Cesarean delivery was also associated with a lower risk of “serious” neonatal morbidity—1.4 versus 3.8 percent. Short-term maternal morbidity was similar between groups.

Critics of the Term Breech Trial emphasize that fewer than 10 percent of candidates underwent radiological pelvimetry. Also, most of the outcomes included in the “serious” neonatal morbidity composite did not actually portend long-term infant disability (Whyte, 2004).

Since that trial, however, additional data favoring cesarean delivery has come from the World Health Organization (Lumbiganon, 2010). From their evaluation of more than 100,000 deliveries from nine participating Asian countries, they reported improved perinatal outcomes for the term breech fetus with planned cesarean compared with planned vaginal delivery. Other studies have evaluated neonatal outcome with cesarean delivery and also found lowered neonatal morbidity and mortality rates (Hartnack Tharin, 2011; Lyons, 2015; Rietberg, 2005; Vistad, 2015). From their metaanalysis, Berhan and Haileamlak (2016) calculate absolute risk of perinatal mortality to be 0.3 percent and of fetal birth trauma or neurological morbidity to be 0.7 percent.

In contrast, other studies support vaginal delivery as a suitable option at term (Hofmeyr, 2015a). The *Presentation et Mode d'Accouchement—PREMODA* study—which translates as presentation and mode of delivery—showed no differences in corrected neonatal mortality rates and neonatal outcomes according to delivery mode (Goffinet, 2006). This French prospective observational study involved more than 8000 women with term breech singletons. Strict criteria were used to select 2526 of these for planned vaginal delivery, and 71 percent of that group were delivered vaginally. Similarly, data from the Lille Breech Study Group in France showed

no excessive morbidity in term breech singletons delivered vaginally provided strict fetal biometric and maternal pelvimetry parameters were applied (Michel, 2011). Other smaller studies support these findings as long as guidelines are part of the selection process (Alarab, 2004; Giuliani, 2002; Toivonen, 2012).

Long-term evidence in support of vaginal breech delivery comes from Eide and associates (2005). These investigators analyzed intelligence testing scores of more than 8000 men delivered breech and found no differences in intellectual performance in those undergoing vaginal or cesarean delivery. Also, a 2-year follow up from the Term Breech trial showed similar risks for death and for neurodevelopmental delay between delivery groups (Whyte, 2004).

Despite evidence on both sides of the debate, at least in the United States, rates of planned vaginal delivery attempts continue to decline. And as predicted, the number of skilled providers able to safely select and vaginally deliver breech fetuses continues to dwindle (Chinnock, 2007). Moreover, obvious medicolegal concerns make physician training in such deliveries difficult. In response, some institutions have developed birth simulators to improve resident competence in vaginal breech delivery (Deering, 2006; Maslovitz, 2007).

Preterm Breech Fetus

In contrast to the term breech fetus, there are no randomized trials regarding delivery of the preterm breech fetus. Moreover, study comparisons are often made difficult by lumping, splitting, or overlapping of preterm gestational age groups. All that said, it would appear that for the preterm breech fetus, planned cesarean delivery confers a survival advantage compared with planned vaginal delivery. Reddy and associates (2012) reported data from deliveries between 24 and 32 weeks' gestation. For breech fetuses within these gestational ages, attempting vaginal delivery yielded a low success rate, and those completed were associated with higher neonatal mortality rates compared with planned cesarean delivery. Other investigations have reported similar findings (Bergenhenegouwen, 2014; Demirci, 2012; Muhuri, 2006).

For preterm fetuses in younger subgroups—23 to 28 weeks—the data are more conflicting, and some studies describe no improved survival rate with planned cesarean delivery (Bergenhenegouwen, 2015; Kayem, 2015; Thomas, 2016). For *periviable fetuses*, defined by them as 20 to $25^{6/7}$ weeks, a consensus workshop of perinatal organizations concluded that "available data do not consistently support routine cesarean delivery to improve perinatal mortality or neurological outcomes for early preterm infants" (Raju, 2014). A subsequent joint statement by the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2017) suggested consideration for cesarean delivery for periviable fetuses beginning at $23^{0/7}$ weeks, with a recommendation for cesarean delivery at $25^{0/7}$ weeks.

For more mature preterm breech fetuses, that is, between 32 and 37 weeks, again there are sparse data to guide delivery route selection. Bergenhenegouwen and coworkers (2015) studied more than 6800 breech deliveries in a subgroup between 32 and 37 weeks. With planned cesarean delivery, they found similar perinatal mortality rates but less composite mortality and severe morbidity. It appears in this subgroup that fetal weight rather than gestational age is likely more important. The Maternal-Fetal Medicine Committee of the Society of Obstetricians and Gynaecologists of Canada (SOGC) states that vaginal breech delivery is reasonable when the estimated fetal weight is >2500 g (Kotaska, 2009). There are especial concerns for delivery of the second noncephalic-presenting twin fetus that are discussed in Chapter 45 (Evaluation of Fetal Presentation).

In the United States, all these findings shape practice, and cesarean delivery is almost uniformly favored for the preterm breech fetus for which resuscitation is planned.

Delivery Complications

Increased rates of maternal and perinatal morbidity can be anticipated with breech presentations. For the mother, with either cesarean or vaginal delivery, genital tract laceration can be problematic. With cesarean delivery, added stretching of the lower uterine segment by forceps or by a poorly molded fetal head can extend hysterotomy incisions. With vaginal delivery, especially with a thinned lower uterine segment, delivery of the aftercoming head through an incompletely dilated cervix or application of forceps may cause vaginal wall or cervical lacerations, and even uterine rupture. Manipulations may also extend an episiotomy, create deep perineal tears, and increase infection risks. Anesthesia sufficient to induce appreciable uterine relaxation during vaginal delivery may cause uterine atony and in turn postpartum hemorrhage. Maternal death is rare, but rates appear higher in those with planned cesarean delivery for breech presentation—a case fatality rate of 0.47 maternal deaths per 1000 births (Schutte, 2007). Last, the risks associated with vaginal breech delivery are balanced against general cesarean delivery risks described in Chapter 30 (Cesarean Delivery Risks). Long-term, cesarean risks include those associated with repeated hysterotomy or with vaginal birth after cesarean —VBAC—further described in Chapter 31 (Delivery Route Risks).

For the fetus, prematurity and its complications are frequently comorbid with breech presentation. Rates of congenital anomalies are also greater (Cammu, 2014; Mostello, 2014). Compared with cephalic presentation, umbilical cord prolapse is more frequent with breech fetuses (Behbehani, 2016; Obeidat, 2010). Birth trauma can include fractures of the humerus, clavicle, and femur (Canpolat, 2010; Matsubara, 2008). In some cases, traction may separate scapular, humeral, or femoral epiphyses (Lamrani, 2011). Trauma is more common with vaginal births, but fetal trauma is also seen with cesarean deliveries.

Rare traumatic injuries may involve soft tissues. Brachial plexus injury and paralysis is one example (Foad, 2008). The spinal cord may be injured or even severed, or vertebrae fractured, especially if great force is employed (Vialle, 2007). Hematomas of the sternocleidomastoid muscles occasionally develop after delivery but usually disappear spontaneously. Last, genital injury may follow breech delivery (Saroha, 2015).

Some perinatal outcomes may be inherent to the breech position rather than delivery. For example, development of hip dysplasia is more common in breech compared with cephalic presentation and is unaffected by delivery mode (de Hundt, 2012; Fox, 2010; Ortiz-Neira, 2012).

Imaging Techniques

In many fetuses—especially those that are preterm—the breech is smaller than the aftercoming head. Moreover, unlike cephalic presentations, the head of a breech-presenting fetus does not undergo appreciable molding during labor. Thus, if vaginal delivery is considered, fetal size, type of breech, and degree of neck flexion or extension are evaluated. In addition, pelvic dimensions are assessed to avoid head entrapment from cephalopelvic disproportion. Sonography and fetal pelvimetry are options.

Sonographic fetal evaluation will have been performed in most cases as part of prenatal care. If not, gross fetal abnormalities, such as hydrocephaly or anencephaly, can be rapidly ascertained with sonography. This will identify many fetuses not suitable for vaginal delivery. It will also help to ensure that a cesarean delivery is not performed under emergency conditions for an anomalous fetus with no chance of survival.

Head flexion can usually also be determined sonographically, and for vaginal delivery, the fetal head should not be extended (Fontenot, 1997; Rojansky, 1994). If imaging is uncertain, then simple two-view radiography of the maternal abdomen is useful to define fetal head inclination. Sonographic identification of a nuchal arm may warrant cesarean delivery to avoid neonatal harm (Sherer, 1989).

The accuracy of fetal weight estimation by sonography is not altered by breech presentation (McNamara, 2012). Although variable, many protocols use fetal weights >2500 g and <3800 to 4000 g or evidence of growth restriction as exclusion criteria for planned vaginal delivery (Azria, 2012; Kotaska, 2009). Similarly, a biparietal diameter (BPD) >90 to 100 mm is often considered exclusionary (Giuliani, 2002; Roman, 2008).

Pelvimetry assesses the maternal bony pelvis before vaginal delivery, and one-view computed tomography (CT), magnetic resonance (MR) imaging, or plain film radiography is suitable. Comparative data among these modalities for pelvimetry are lacking, but CT is favored due to its accuracy, low radiation dose, and widespread availability (Thomas, 1998). At Parkland Hospital, we use CT pelvimetry when possible to assess the critical dimensions of the pelvis (Chap. 2, Planes and Diameters of the Pelvis). Although variable, some suggest specific measurements to permit a planned vaginal delivery: inlet anteroposterior diameter ≥10.5 cm; inlet transverse diameter ≥12.0 cm; and midpelvic interspinous distance ≥10.0 cm (Azria, 2012; Vendittelli, 2006). Some have recommended maternal-fetal biometry correlation. Appropriate values include: the sum of the inlet obstetrical conjugate minus the fetal BPD is ≥15 mm; the inlet transverse diameter minus the BPD is ≥25 mm; and the midpelvis interspinous distance minus the BPD is ≥0 mm (Michel, 2011). With MR imaging, Hoffmann and colleagues (2016) found vaginal delivery success rates of 79 percent in selected candidates if the interspinous distance exceeded 11 cm.

Decision-Making Summary

Currently, the American College of Obstetricians and Gynecologists (2016b) recommends that “the decision regarding the mode of delivery should depend on the experience of the health-care provider” and that “planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines.” These guidelines have been echoed by other obstetrical organizations (Kotaska, 2009; Royal College of Obstetricians and Gynaecologists, 2006). Risks versus benefits are weighed and discussed with the patient. If possible, this is preferably done before admission. A diligent search is made for other complications, actual or anticipated, that might warrant cesarean delivery. Common circumstances are listed in Table 28-1. For a favorable outcome with any breech delivery, at the very minimum, the birth canal must be sufficiently large to allow passage of the fetus without trauma. The cervix must be fully dilated, and if not, then a cesarean delivery nearly always is the more appropriate method of delivery if suspected fetal compromise develops.

TABLE 28-1

Factors Favoring Cesarean Delivery of the Breech Fetus

Lack of operator experience
Patient request for cesarean delivery
Large fetus: >3800 to 4000 g
Apparently healthy and viable preterm fetus either with active labor or with indicated delivery
Severe fetal-growth restriction
Fetal anomaly incompatible with vaginal delivery
Prior perinatal death or neonatal birth trauma
Incomplete or footling breech presentation
Hyperextended head
Pelvic contraction or unfavorable pelvic shape determined clinically or with pelvimetry
Prior cesarean delivery

LABOR AND DELIVERY MANAGEMENT

Vaginal Delivery Methods

The conduct of both labor and delivery differ between cephalic and breech presentations. First, breech labor in general proceeds more slowly, but steady cervical progress is a positive indicator of adequate pelvic proportions (Lennox, 1998). Vaginal breech delivery is accomplished by one of three methods. With *spontaneous breech delivery*, the fetus is expelled entirely without any traction or manipulation other than support of the newborn. With *partial breech extraction*, the fetus is delivered spontaneously as far as the umbilicus, but the remainder of the body is delivered by provider traction and assisted maneuvers, with or without maternal expulsive efforts. With *total breech extraction*, the entire fetal body is extracted by the provider.

Labor Induction and Augmentation

As with many other aspects of breech position, induction or augmentation of labor is controversial. Here again, data are limited and mostly retrospective. With labor induction, Burgos and coworkers (2017) reported equivalent vaginal delivery rates compared with spontaneous labor. With induction, however, they reported higher rates of neonatal intensive care unit admission. But, others have found similar perinatal outcome and cesarean delivery rates (Jarniat, 2017; Marzouk, 2011). Finally, others described greater cesarean delivery rates with induction but similar neonatal outcomes (Macharey, 2016).

In many studies, successful vaginal delivery is associated with orderly labor progression. Thus, some protocols avoid augmentation for the breech-presenting fetus, whereas others recommend it only for hypotonic contractions (Alarab, 2004; Kotaska, 2009). In women with a viable fetus, at Parkland Hospital, we attempt amniotomy induction but prefer cesarean delivery instead of pharmacological labor induction or augmentation.

Labor Management

On arrival to the labor unit, surveillance of fetal heart rate and uterine contractions begins, and immediate recruitment of necessary staff includes: (1) a provider skilled in the art of breech extraction, (2) an associate to assist with the delivery, (3) anesthesia personnel who can ensure adequate analgesia or anesthesia when needed, and (4) an individual trained in newborn resuscitation. For the mother, intravenous access is obtained. This allows, if needed, emergency induction of anesthesia or maternal resuscitation following hemorrhage from lacerations or from uterine atony.

At admission, the status of the membranes and progression of labor are assessed. Knowledge regarding cervical dilatation, cervical effacement, and presenting part station is essential for preparation. If labor is too far advanced, pelvimetry may be unsafe if fetal expulsion in the radiology department is a possibility. This alone, however, should not force the decision for cesarean delivery. As mentioned, stepwise labor progression itself is a good indicator of pelvic adequacy (Biswas, 1993). Sonographic assessment, described earlier, is completed. Ultimately, the choice of abdominal or vaginal delivery is based on factors discussed earlier and listed in Table 28-1.

During labor, one-on-one nursing is ideal because of cord prolapse risks, and physicians must be readily available for such emergencies. Guidelines for monitoring the high-risk fetus are applied (Chap. 24, Intrapartum Surveillance of Uterine Activity). For first-stage labor, while most clinicians prefer continuous electronic monitoring, the fetal heart rate is recorded at a minimum of every 15 minutes. A scalp electrode can be safely affixed to the buttock, but genitalia are avoided. If a nonreassuring fetal heart rate pattern develops, then a decision must be made regarding the necessity of cesarean delivery.

When membranes rupture, either spontaneously or artificially, the cord prolapse risk is appreciable and is increased when the fetus is small or when the breech is not frank. Therefore, vaginal examination is performed immediately following rupture, and special attention is directed to the fetal heart rate for the first 5 to 10 minutes thereafter.

For women in labor with a breech presentation, continuous epidural analgesia is advocated by some. This may increase the need for labor augmentation and prolong second-stage labor (Chadha, 1992; Confino, 1985). These potential disadvantages are weighed against the advantages of better pain relief and increased pelvic relaxation should extensive manipulation be required. Analgesia must be sufficient for episiotomy, for breech extraction, and for Piper forceps application. Nitrous oxide plus oxygen inhalation can provide further relief from pain. If general anesthesia is required, it must be induced quickly.

Spontaneous Breech Delivery

Similar to vertex delivery, spontaneous expulsion of a breech fetus entails sequential cardinal movements. First, engagement and descent of the breech usually take place with the bitrochanteric diameter in one of the oblique pelvic diameters. The anterior hip usually descends more rapidly than the posterior hip, and when the resistance of the pelvic floor is met, internal rotation of 45 degrees usually follows, bringing the anterior hip toward the pubic arch and allowing the bitrochanteric diameter to occupy the anteroposterior diameter of the pelvic outlet. If the posterior extremity is prolapsed, however, it, rather than the anterior hip, rotates to the symphysis pubis.

After rotation, descent continues until the perineum is distended by the advancing breech, and the anterior hip appears at the vulva. By lateral flexion of the fetal body, the posterior hip then is forced over the perineum, which retracts over the fetal buttocks, thus allowing the fetus to straighten out when the anterior hip is born (Fig. 28-4). The legs and feet follow the breech and may be born spontaneously or require aid.

After the birth of the breech, there is slight external rotation, with the back turning anteriorly as the shoulders are brought into relation with one of the oblique diameters of the pelvis. The shoulders then descend rapidly and undergo internal rotation, with the bisacromial diameter occupying the anteroposterior plane. Immediately following the shoulders, the head, which is normally sharply flexed on the thorax, enters the pelvis in one of the oblique diameters and then rotates to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

The breech may engage in the transverse diameter of the pelvis, with the sacrum directed anteriorly or posteriorly. The mechanism of labor in the transverse position differs only in that internal rotation is through an arc of 90 rather than 45 degrees. Infrequently, rotation renders the back of the fetus to lie posteriorly

instead of anteriorly. Such rotation is prevented if possible. Although the head can be delivered by allowing the chin and face to pass beneath the symphysis, the slightest traction on the body may cause extension of the head, which increases the diameter of the head that must pass through the pelvis.

Partial Breech Extraction

With breech delivery, successively larger and less compressible parts are born. Thus, spontaneous expulsion is the exception, and vaginal delivery typically requires skilled provider participation for the fetus to navigate the birth canal. Noteworthy clinical pearls are provided by Yeomans (2017) in the third edition of *Cunningham and Gilstrap's Operative Obstetrics*.

First, with all breech deliveries, unless the perineum is considerably lax, an episiotomy is made and is an important adjunct to delivery. As discussed in Chapter 27 (Episiotomy), mediolateral episiotomy may be preferred for its lower associated risk of anal sphincter lacerations. Ideally, the breech is allowed to deliver spontaneously to the umbilicus. Delivery of the breech draws the umbilicus and attached cord into the pelvis. Therefore, once the breech has passed beyond the vaginal introitus, the abdomen, thorax, arms, and head must be delivered promptly either spontaneously or assisted.

The posterior hip will deliver, usually from the 6 o'clock position, and often with sufficient pressure to evoke passage of thick meconium (see Fig. 28-4). The anterior hip then delivers, followed by external rotation to a sacrum anterior position. The mother is encouraged to continue to push as the fetus descends until the legs are accessible. The legs are sequentially delivered by splinting the femur with the operator's fingers positioned parallel to the long axis of the femur, and by exerting pressure upward and laterally to sweep each leg away from the midline (Fig. 28-5).

FIGURE 28-4
The hips of the frank breech are delivering over the perineum. The anterior hip usually delivers first.

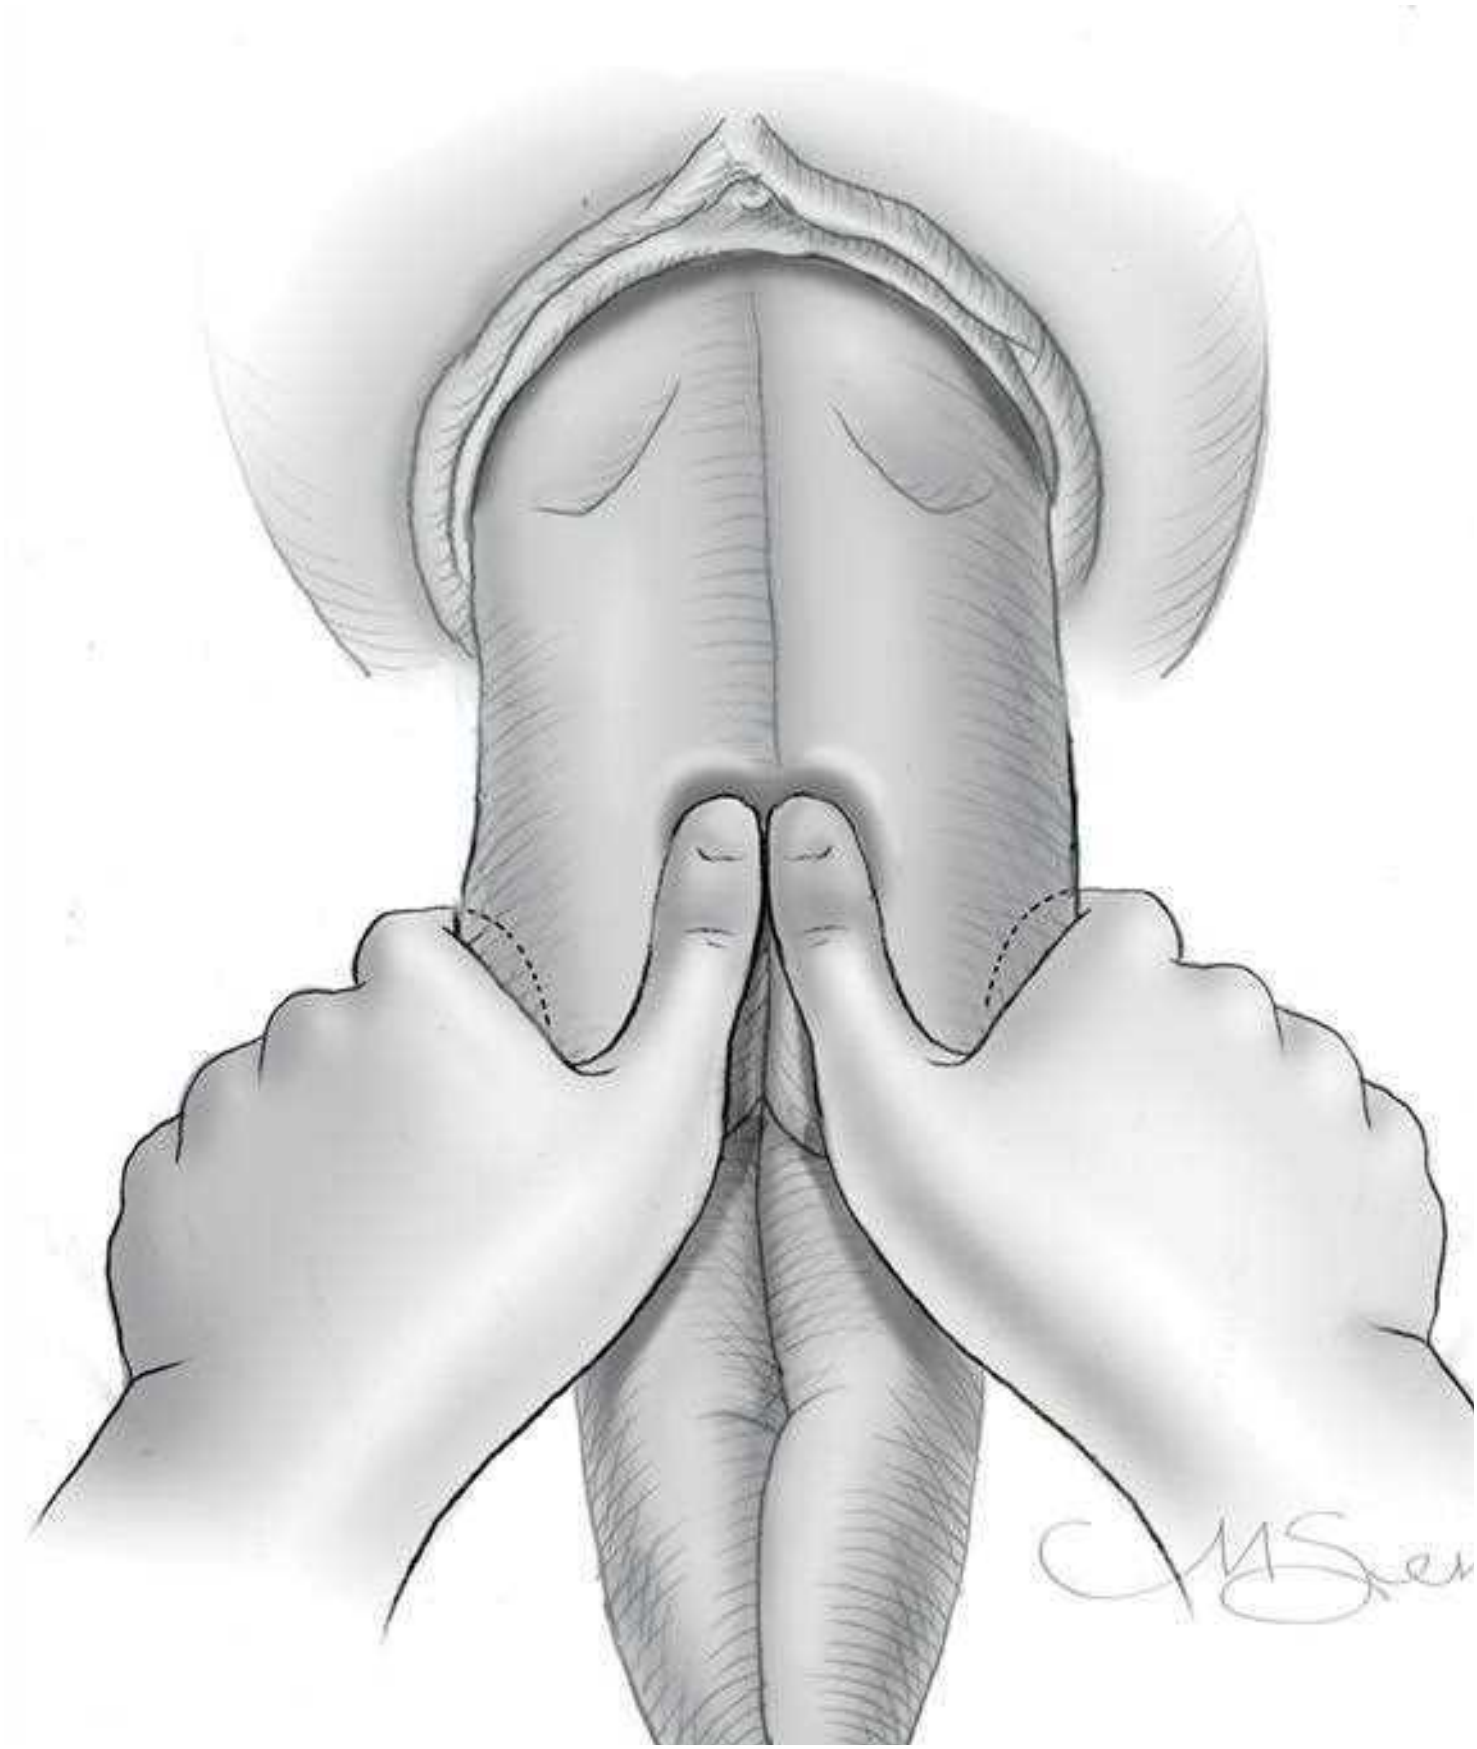
FIGURE 28-5
To deliver the left leg, two fingers of the provider's left hand are placed beneath and parallel to the femur. The thigh is then slightly abducted and pressure from the fingertips in the popliteal fossa should induce knee flexion and bring the foot within reach. The foot is then grasped to gently deliver the entire leg outside the vagina.

A similar procedure is followed on the right. (Figures 28-5 though 28-8: Reproduced with permission from Yeomans ER: Vaginal breech delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)

Following delivery of the legs, the fetal bony pelvis is grasped with both hands. The fingers should rest on the anterior superior iliac crests and the thumbs on the sacrum. This minimizes the chance of fetal abdominal soft-tissue injury (Fig. 28-6). Maternal expulsive efforts are again used in conjunction with downward traction to affect delivery.

FIGURE 28-6

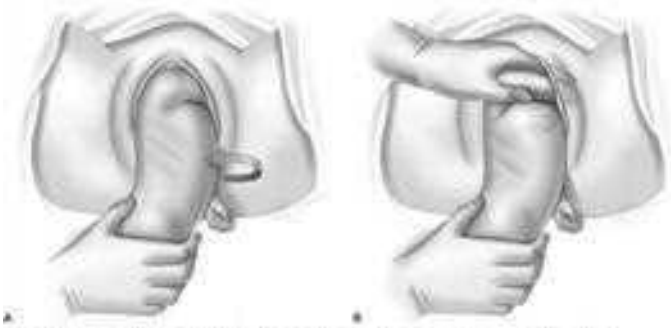
To deliver the body, thumbs are placed over the sacrum, and each index finger wraps over the top of the corresponding fetal iliac crest. Gentle downward traction is applied until the scapulas are clearly visible.



A cardinal rule in successful breech extraction is to employ steady, gentle, downward traction until the lower halves of the scapulas are delivered, making no attempt at delivery of the shoulders and arms until one axilla becomes visible. It makes little difference which shoulder is delivered first, and two methods are suitable for their delivery. In the first method, with the scapulas visible, the trunk is rotated either clockwise or counterclockwise to bring the anterior shoulder and arm into view (Fig. 28-7). During delivery of the arm, fingers and hand are aligned parallel to the humerus and act to splint and prevent humeral fracture. The body of the fetus is then rotated 180 degrees in the reverse direction to bring the other shoulder and arm into position for delivery.

FIGURE 28-7

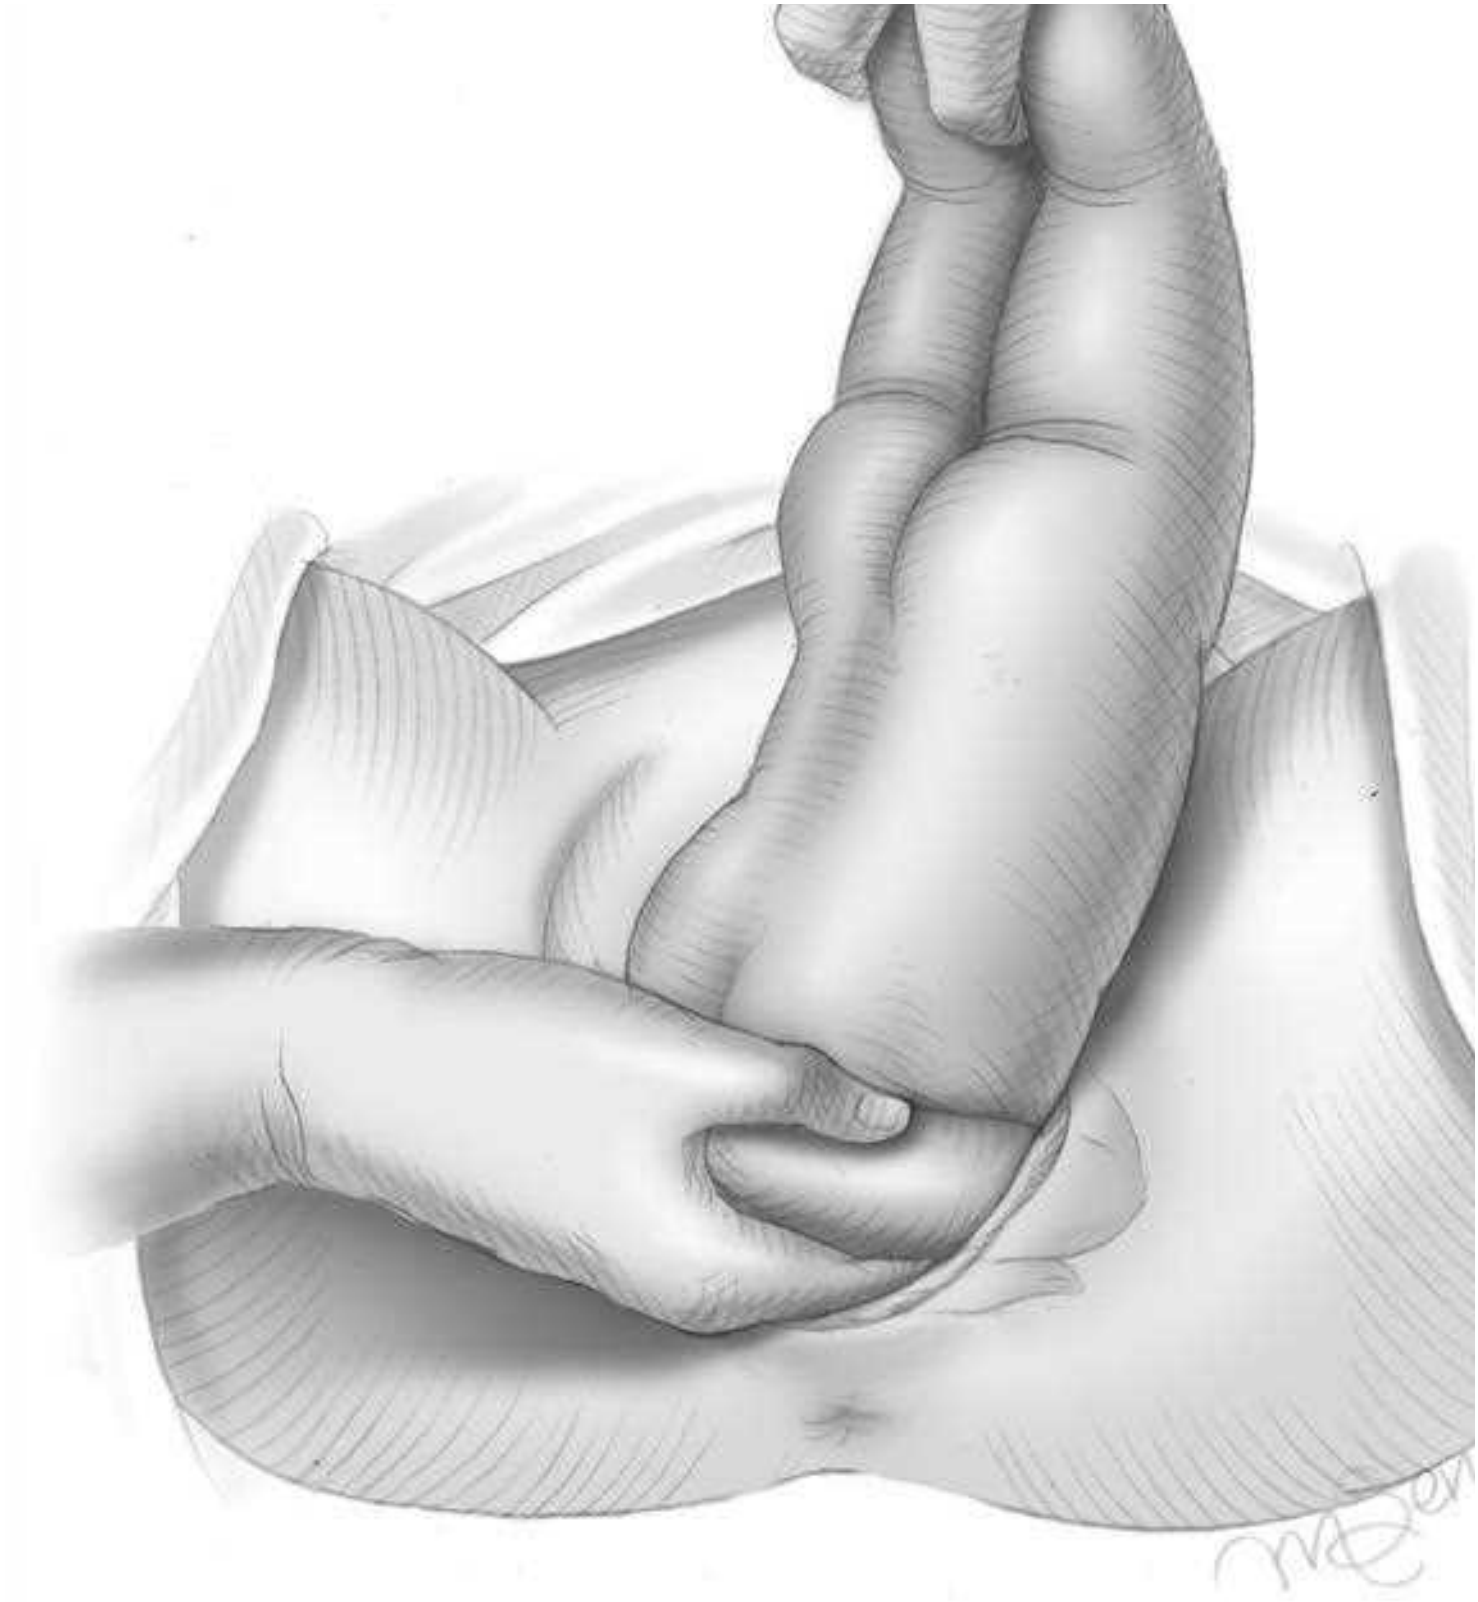
A. After delivery of the first arm, 180-degree rotation of the fetal body brings the sacrum to a right sacrum transverse (RST) position. **B.** Fingers of the provider's hand extended over the right shoulder and parallel to the humerus. These sweep the arm downward across the chest and out.



The second method is employed if trunk rotation is unsuccessful. With this maneuver, the posterior shoulder is delivered first. For this, the feet are grasped in one hand and drawn upward over the inner thigh of the mother (Fig. 28-8). The hand enters over the shoulder, fingers are aligned parallel to the long axis of the humerus, and the fetal arm is swept upward. The posterior shoulder slides out over the perineal margin and is usually followed by the arm and hand. Then, by depressing the body of the fetus, the anterior shoulder emerges beneath the pubic arch, and the arm and hand usually follow spontaneously. After both shoulders are delivered, the back of the fetus tends to rotate spontaneously to the symphysis. Delivery of the head may then be accomplished.

FIGURE 28-8

Infrequently, the posterior arm must be delivered first. For this, the lower half of the fetal body is raised up and over the maternal groin. The provider's fingers are inserted under the posterior shoulder and aligned with the humerus.

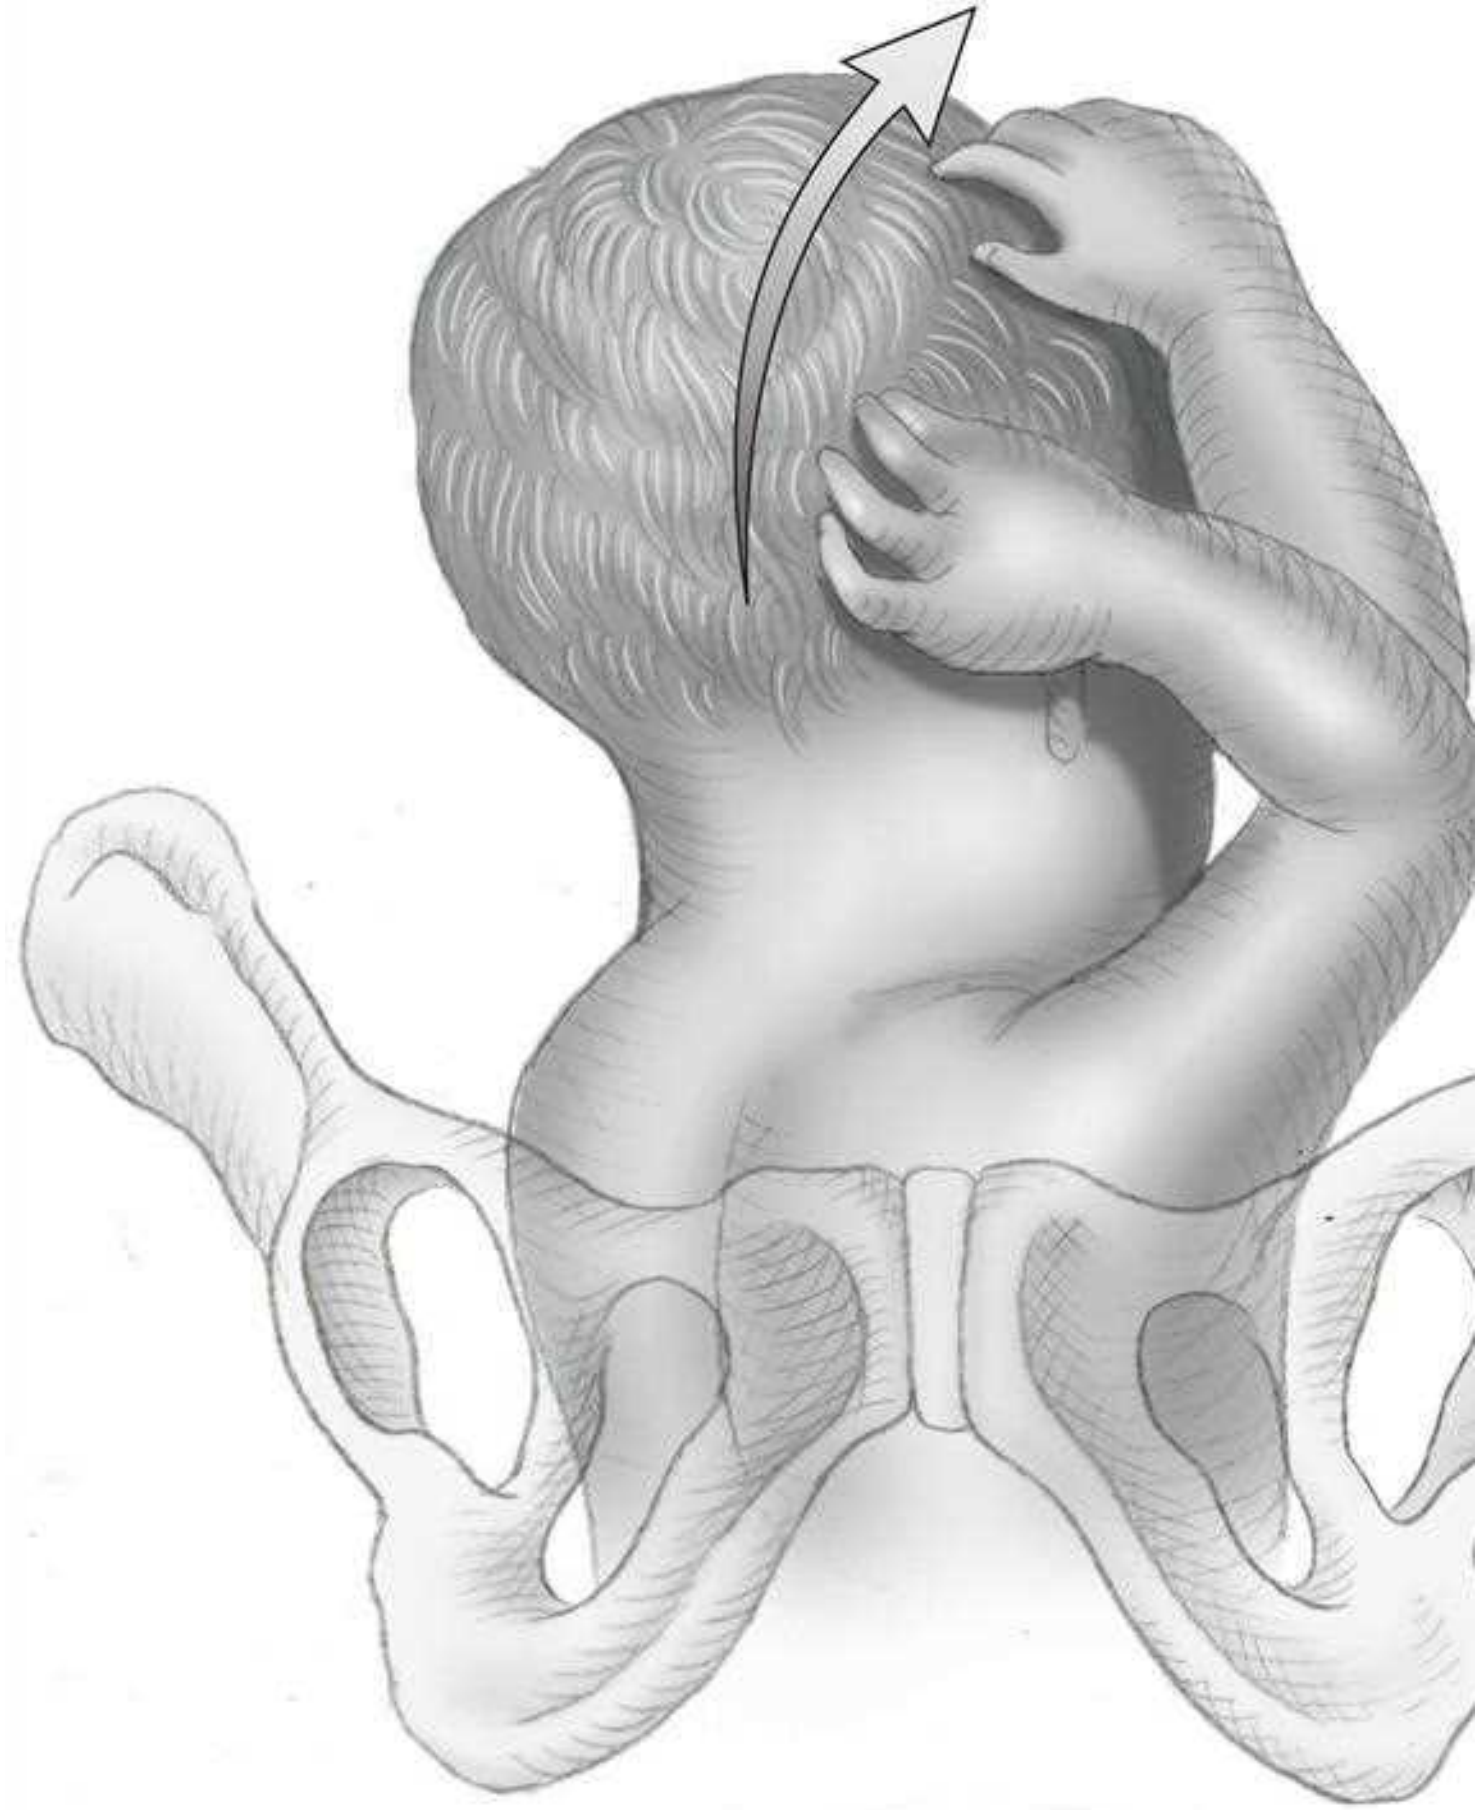


Nuchal Arm

During delivery, one or both fetal arms occasionally may lie across the back of the neck and become impacted at the pelvic inlet. With such a nuchal arm, delivery is more difficult and can be aided by rotating the fetus through a half circle in such a direction that the friction exerted by the birth canal will draw the elbow toward the face (Fig. 28-9). With a right nuchal arm, the body should be rotated counterclockwise, which rotates the fetal back toward the maternal right. With a left nuchal arm, the rotation is clockwise. If rotation fails to free the nuchal arm, it may be necessary to push the fetus upward to a roomier part of the pelvis. If the rotation is still unsuccessful, the nuchal arm often is extracted by hooking a finger(s) over it and forcing the arm over the shoulder, and down the ventral surface for delivery of the arm. In this event, fracture of the humerus or clavicle is common.

FIGURE 28-9

Reduction of a right nuchal arm is accomplished by rotating the fetal body 180 degrees counterclockwise, which directs the fetal back to the maternal right. Friction exerted by the birth canal will draw the elbow toward the face. (Reproduced with permission from Yeomans ER: Vaginal breech delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



Delivery of the Aftercoming Head

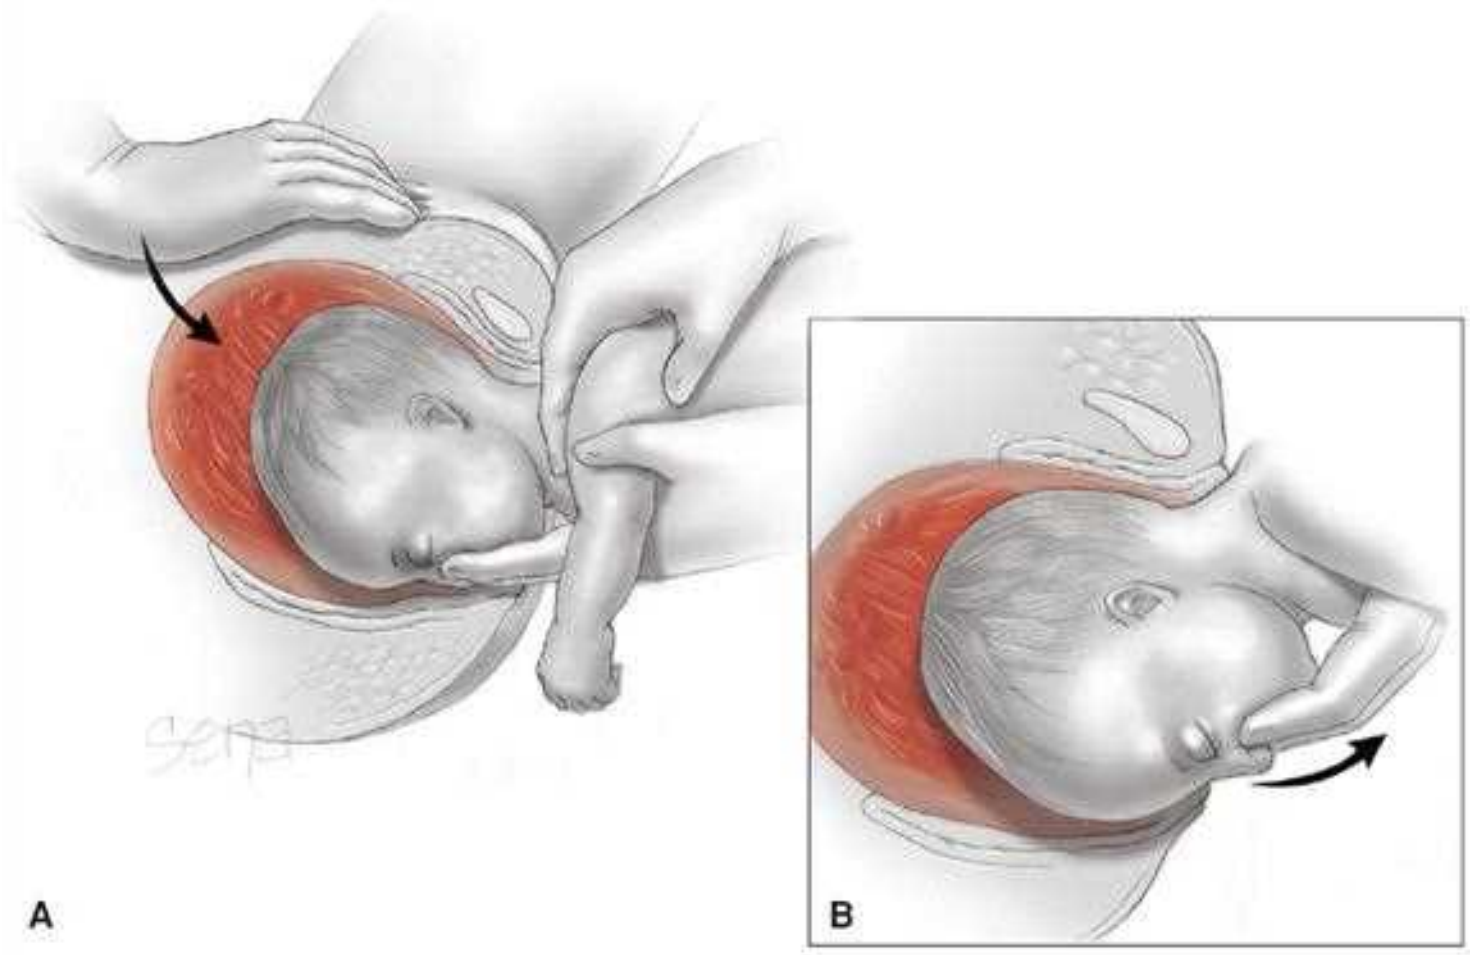
Mauriceau Maneuver

The fetal head is normally extracted with forceps or by one of several maneuvers. With any of these techniques, hyperextension of the fetal neck is avoided.

With the Mauriceau maneuver, the index and middle finger of one hand are applied over the maxilla, to flex the head, while the fetal body rests on the palm of the same hand and forearm (Fig. 28-10). Fetal legs straddle the forearm. Two fingers of the other hand then are hooked over the fetal neck and grasp the shoulders. Downward traction is concurrently applied until the suboccipital region appears under the symphysis. Gentle suprapubic pressure simultaneously applied by an assistant helps keep the head flexed. The body then is slightly elevated toward the maternal abdomen, and the mouth, nose, brow, and eventually the occiput emerge successively over the perineum. With this maneuver, the provider uses both hands simultaneously to exert continuous downward gentle traction while balancing forces between the fetal neck and maxilla to avoid neck hyperextension.

FIGURE 28-10

A. Delivery of the aftercoming head using the Mauriceau maneuver. Note that as the fetal head is being delivered, flexion of the head is maintained by suprapubic pressure provided by an assistant. **B.** Pressure on the maxilla is applied simultaneously by the operator as upward and outward traction is exerted.

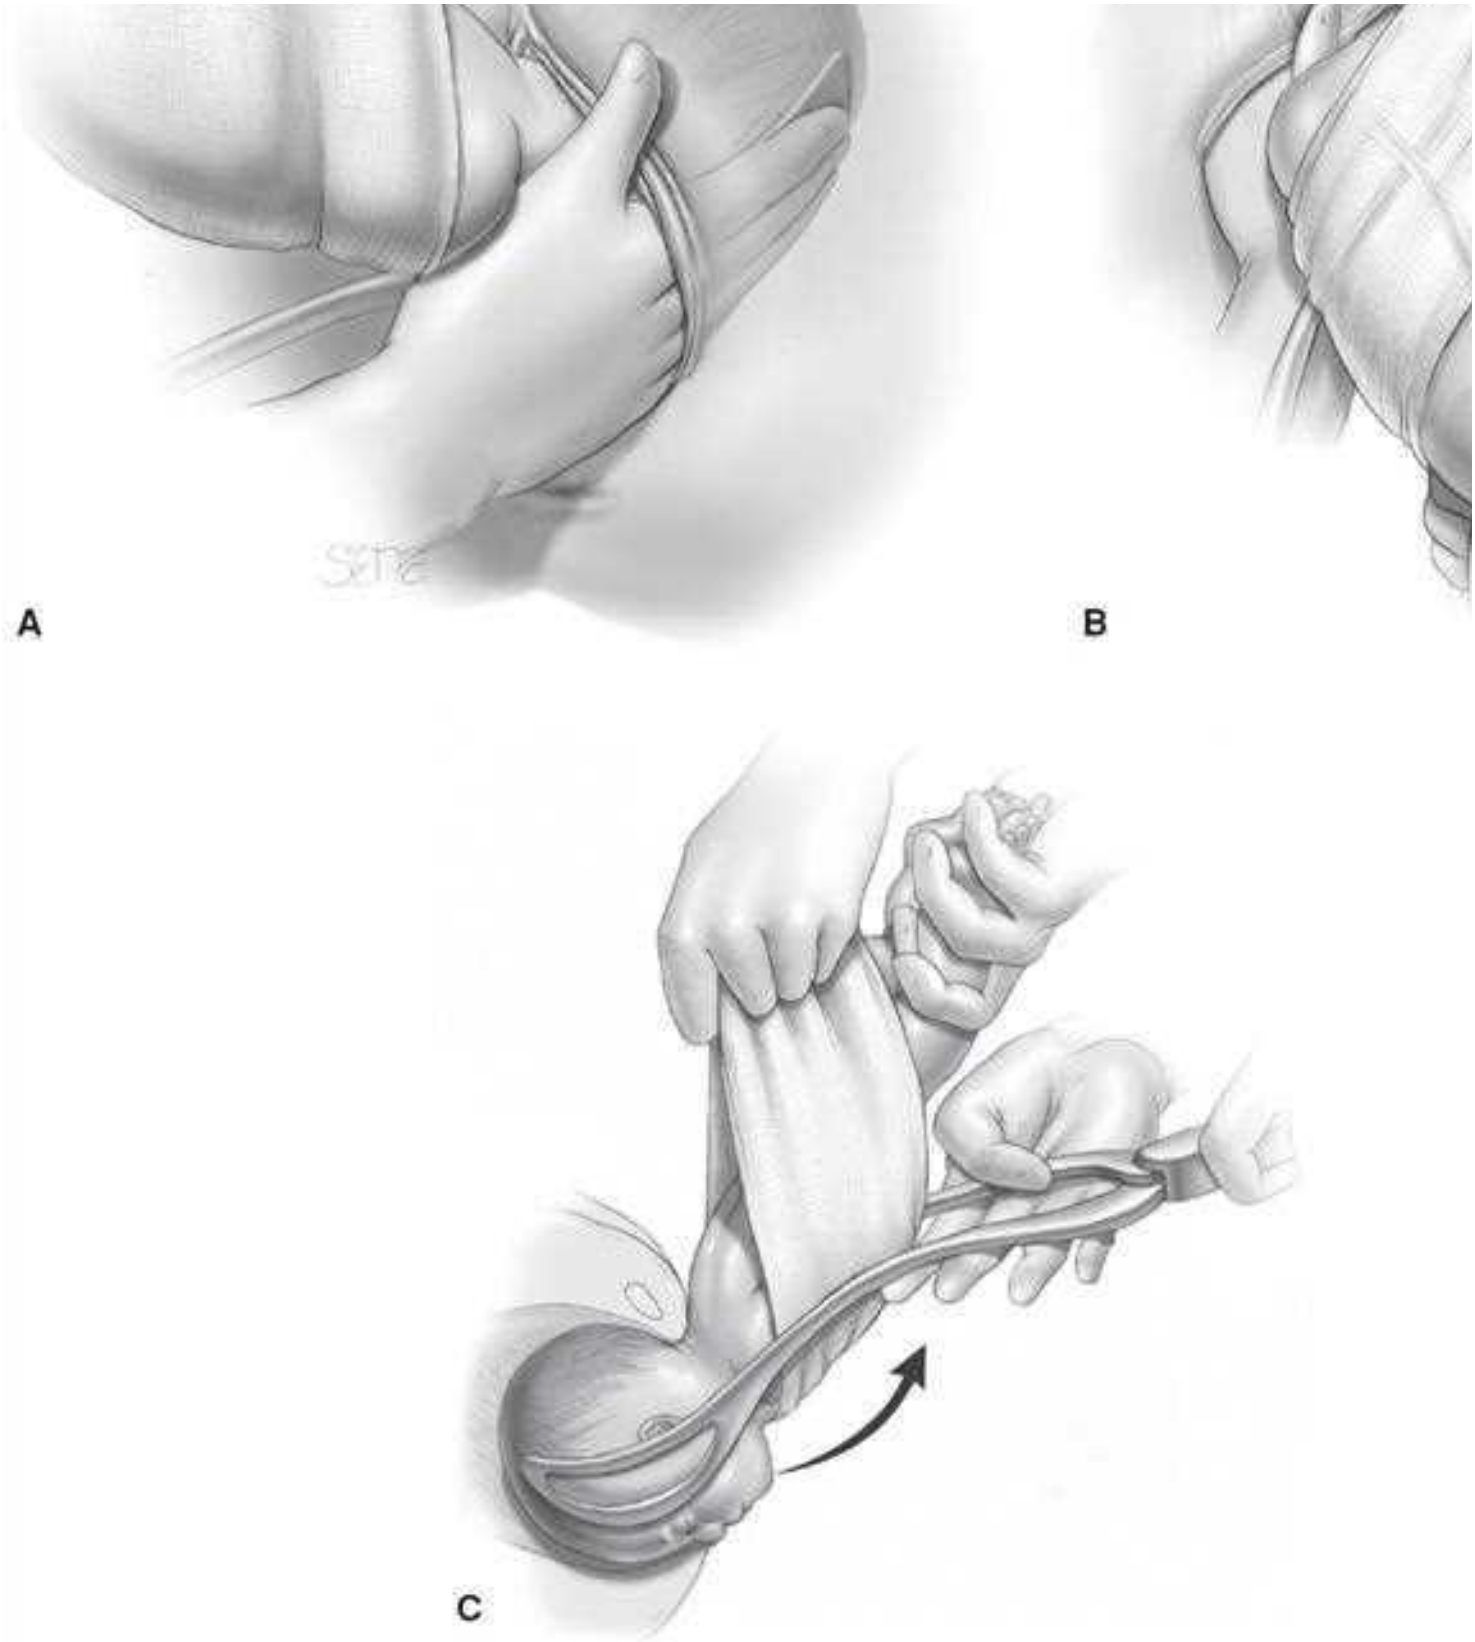


Forceps

Specialized forceps can be used to deliver the aftercoming head. Piper forceps, shown in Figure 28-11, or Laufe-Piper forceps may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps are not applied to the aftercoming head until it has been brought into the pelvis by gentle traction, combined with suprapubic pressure, and is engaged. Suspension of the body of the fetus in a towel effectively holds the fetus up and helps keep the arms and cord out of the way as the forceps blades are applied.

FIGURE 28-11

Piper forceps for delivery of the aftercoming head. **A.** The fetal body is held elevated using a warm towel and the left blade of forceps is applied to the aftercoming head. **B.** The right blade is applied with the body still elevated. **C.** Forceps delivery of the aftercoming head. Note the direction of movement shown by the arrow.



Because the forceps blades are directed upward from the level of the perineum, some choose to apply them from a one-knee kneeling position. Piper forceps have a downward arch in the shank to accommodate the fetal body and lack a pelvic curve. This shape permits direct application of the cephalic curve of the blade along the length of the maternal vagina and fetal parietal bone. The blade to be placed on the maternal left is held in the provider's left hand. The right hand slides between the fetal head and left maternal vaginal sidewall to guide the blade inward and around the parietal bone. The opposite blade mirrors this application.

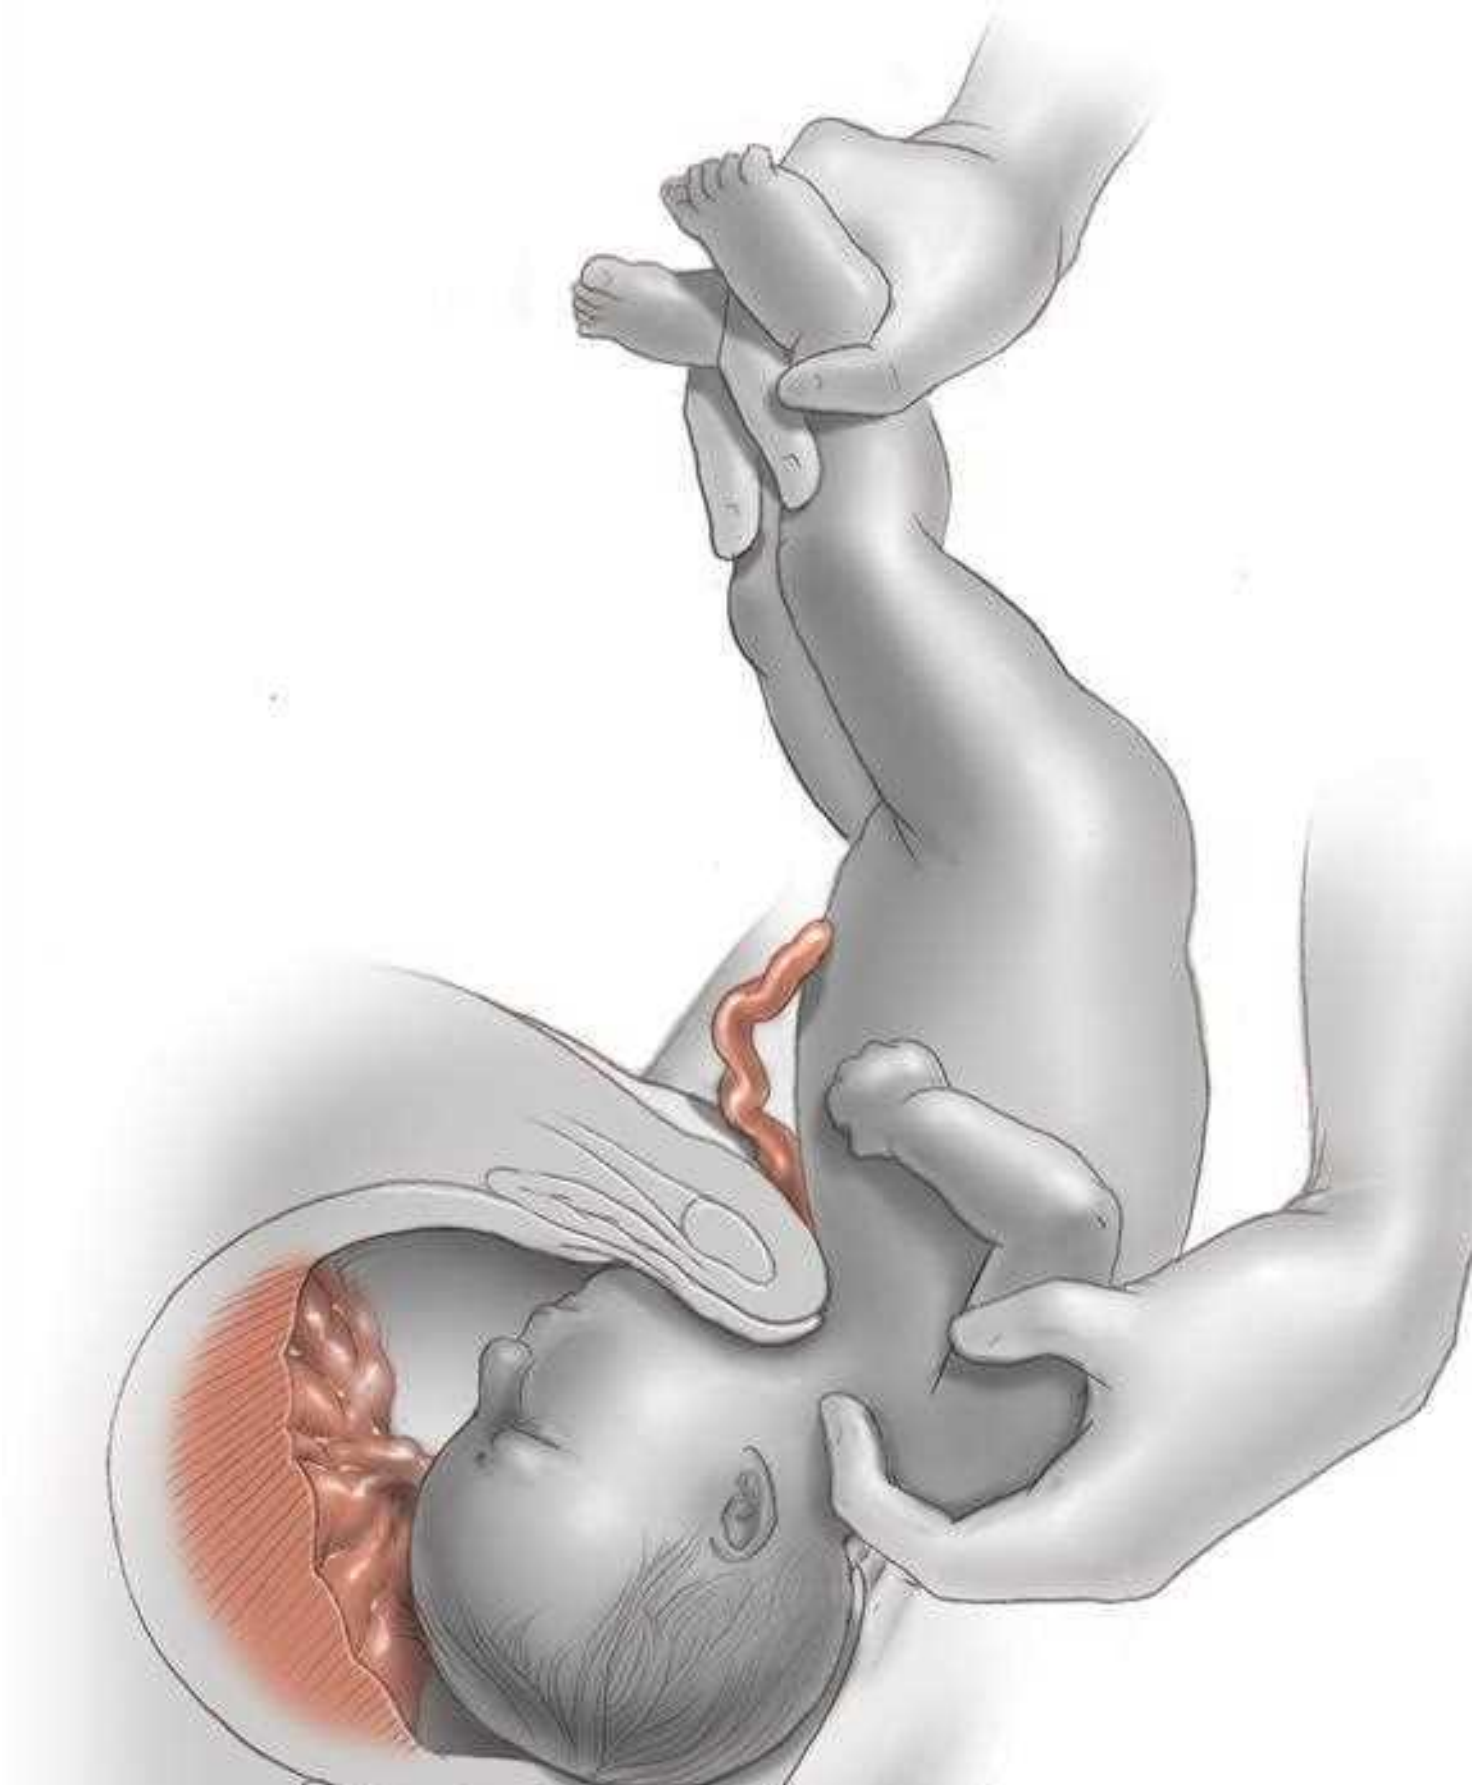
Once in place, the blades are articulated, and the fetal body rests across the shanks. The head is delivered by pulling gently outward and slightly raising the handle simultaneously. This rolls the face over the perineum, while the occiput remains beneath the symphysis until after the brow delivers. Ideally, the head and body move in unison to minimize neck hyperextension.

Modified Prague Maneuver

Rarely, the back of the fetus fails to rotate to the symphysis. The fetus still may be delivered using the modified Prague maneuver. With this, two fingers of one hand grasp the shoulders of the back-down fetus from below while the other hand draws the feet up and over the maternal abdomen (Fig. 28-12).

FIGURE 28-12

Delivery of the aftercoming head using the modified Prague maneuver necessitated by failure of the fetal trunk to rotate anteriorly.

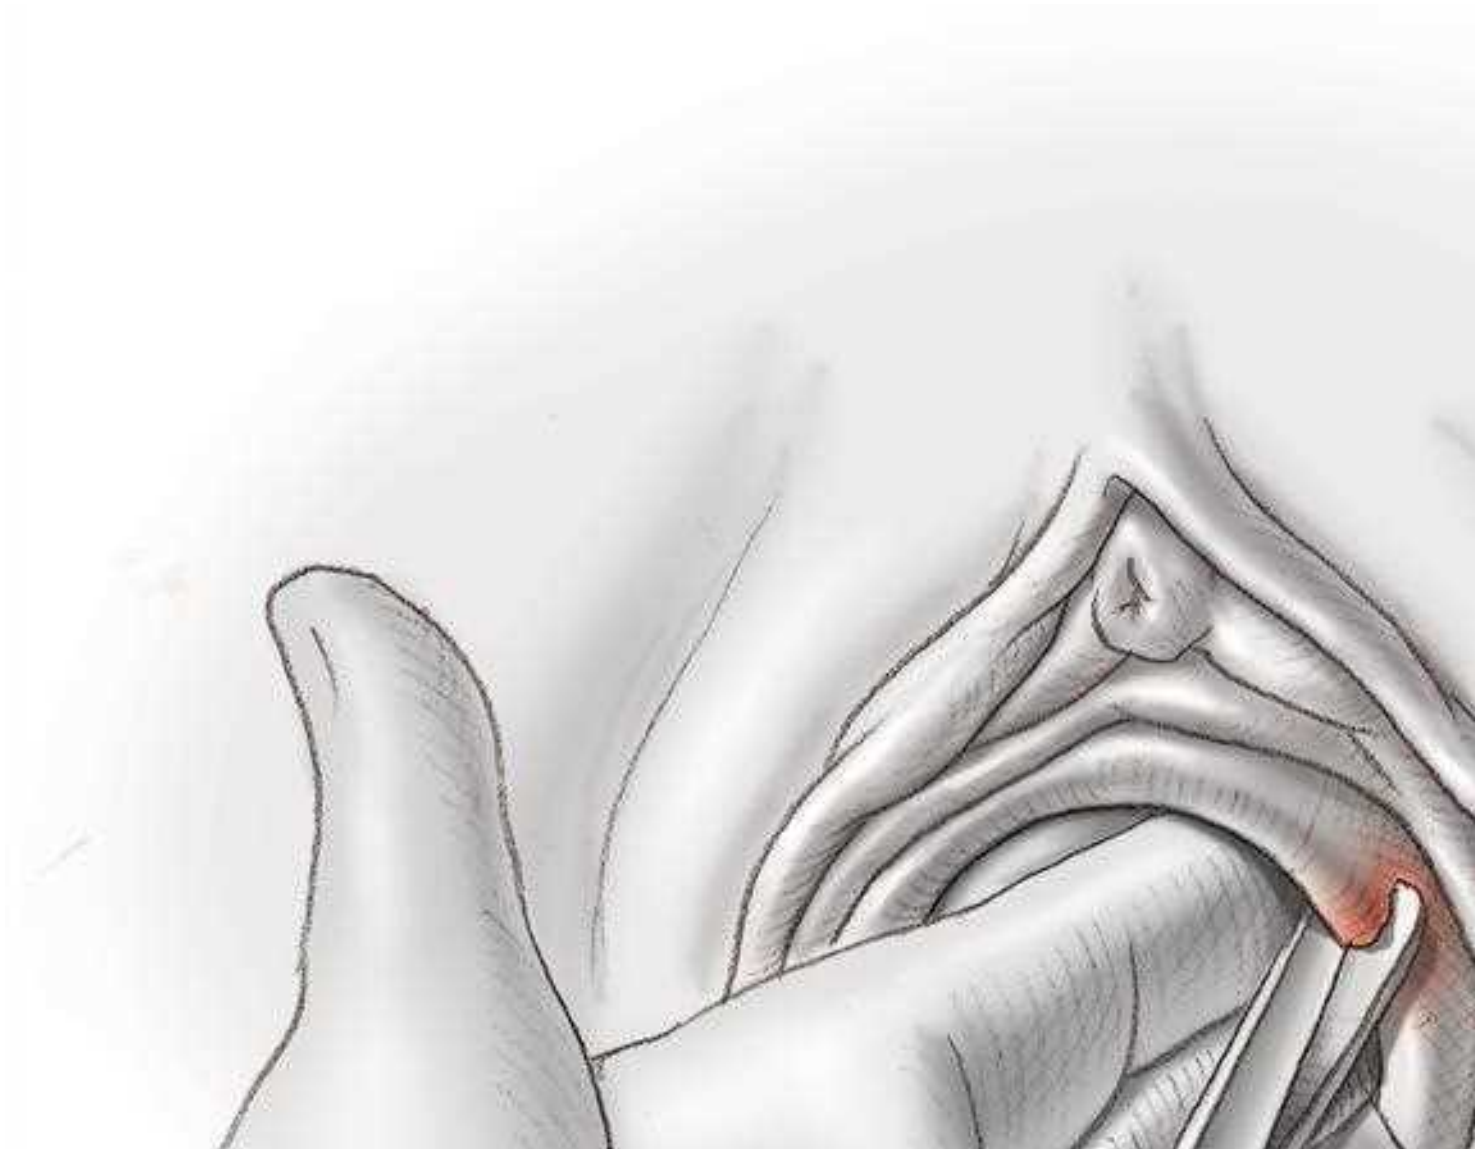


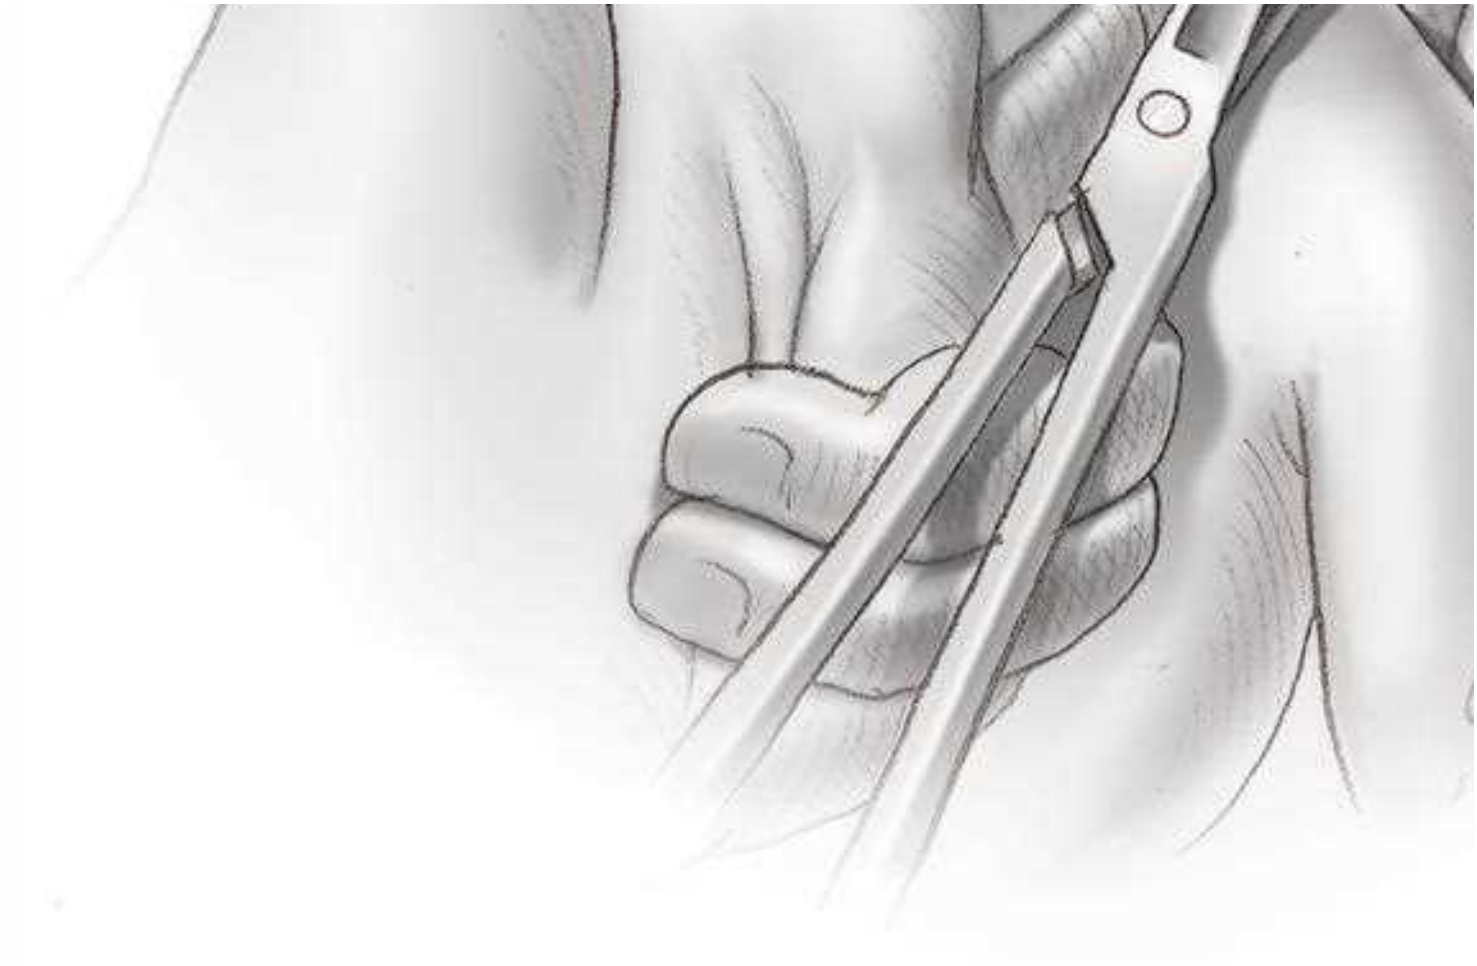
Head Entrapment

This emergency reflects either an incompletely dilated cervix or cephalopelvic disproportion. First, especially with a small preterm fetus, an incompletely dilated cervix can constrict around the neck and impede delivery of the aftercoming head. At this point, significant cord compression must be assumed, and time management is essential. With gentle traction on the fetal body, the cervix, at times, may be manually slipped over the occiput. If unsuccessful, then Dührssen incisions may be necessary (Fig. 28-13). General anesthesia with halogenated agents or intravenous nitroglycerin is another option to aid lower uterine segment relaxation. As an extreme measure, replacement of the fetus higher into the vagina and uterus, followed by cesarean delivery, can rescue an entrapped breech fetus. This *Zavanelli maneuver* is classically performed to relieve intractable shoulder dystocia (Sandberg, 1988). However, case reports also have described its use for an entrapped aftercoming head (Sandberg, 1999; Steyn, 1994).

FIGURE 28-13

Dührssen incision being cut at 2 o'clock, which is followed by a second incision at 10 o'clock. Infrequently, an additional incision is required at 6 o'clock. The incisions are so placed as to minimize bleeding from the laterally located cervical branches of the uterine artery. After delivery, the incisions are repaired as described in Chapter 41 (Injuries to the Birth Canal).





In cases with cephalopelvic disproportion and arrest of aftercoming head, the Zavanelli maneuver or symphysiotomy are options (Sunday-Adeoye, 2004; Wery, 2013). Using local analgesia, symphysiotomy surgically divides the intervening symphyseal cartilage and much of its ligamentous support to widen the symphysis pubis up to 2.5 cm (Basak, 2011). Lack of provider training and potentially serious maternal pelvic or urinary tract injury explain its rare use in the United States. That said, if cesarean delivery is not possible, symphysiotomy may be lifesaving for both mother and baby (Hofmeyr, 2012).

Total Breech Extraction

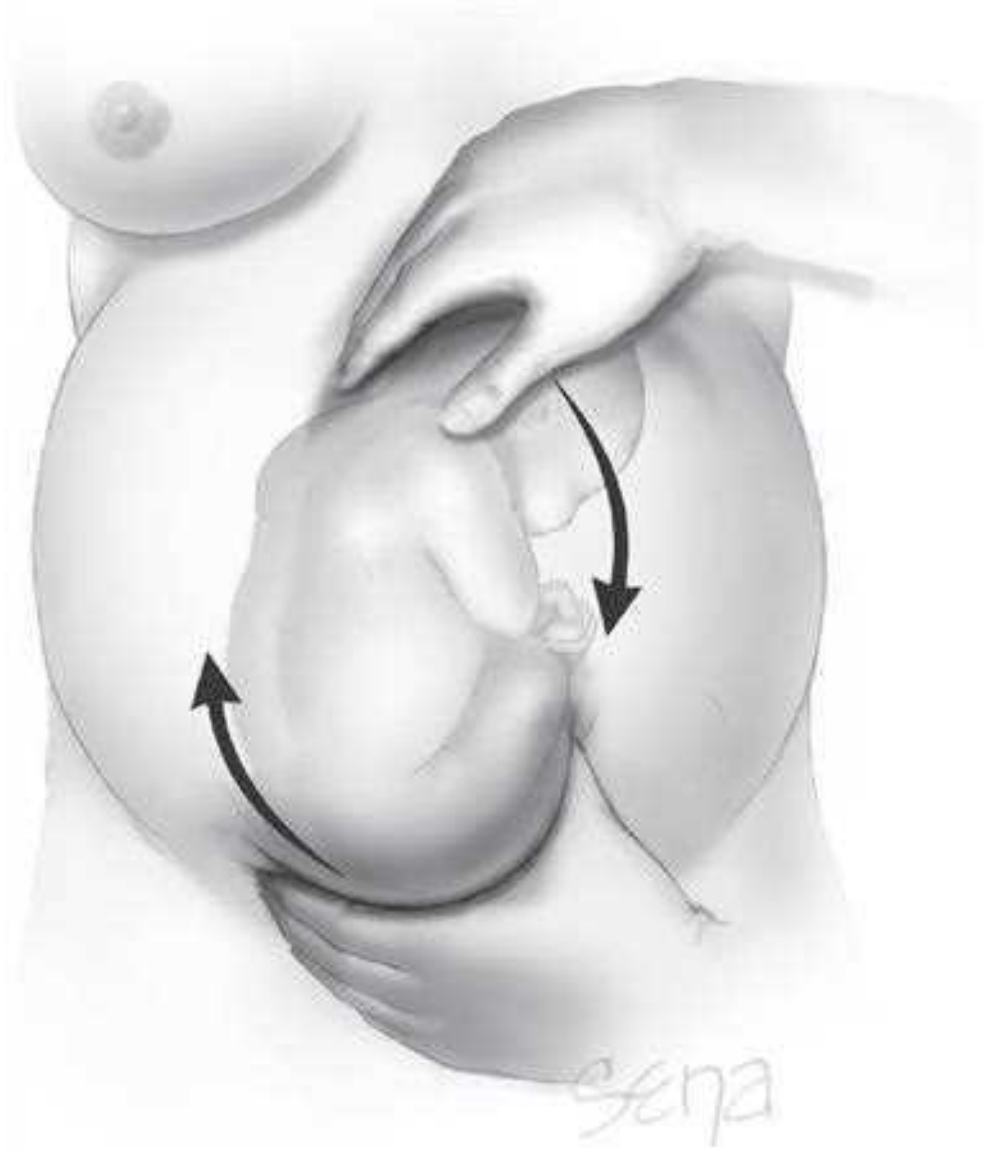
Complete or Incomplete Breech

At times, total extraction of a complete or incomplete breech may be required. A hand is introduced through the vagina, and both fetal feet are grasped. The ankles are held with the middle finger lying between them. With gentle traction, the feet are brought through the introitus (Fig. 28-14). As the legs begin to emerge through the vulva, downward gentle traction is continued. As the legs emerge, successively higher portions are grasped, first the calves and then the thighs. When the breech appears at the vaginal outlet, gentle traction is applied until the hips are delivered. The thumbs are then placed over the sacrum and the fingers over the iliac crests. Breech extraction is then completed, as described for partial breech extraction (Partial Breech Extraction).

FIGURE 28-14
Complete breech extraction begins with traction on the feet and ankles.

FIGURE 28-15

External cephalic version. With an attempted forward roll, clockwise pressure is exerted against the fetal poles.



If only one foot can be grasped, it can be brought down into the vagina and held with the appropriate hand, right hand for right foot and left hand for left foot (Yeomans, 2017). With the first foot secure, the opposite hand is introduced, passed upward along the leg, and guided to locate the other foot. If the remaining hip is extended, the second foot is usually easily grasped and brought down. If the hip is flexed and knee extended, a finger is hooked into that groin, and traction will bring the lower half of the fetus down until the leg can be reached. For cesarean delivery, these total breech extraction maneuvers can be used to deliver a complete, incomplete, or footling breech through the hysterotomy incision.

Frank Breech

During complete extraction of a frank breech, moderate traction is exerted by a finger in each groin and aided by a generous episiotomy. Once the breech is pulled through the introitus, the steps described for partial breech extraction are then completed (Partial Breech Extraction). These maneuvers are also used during cesarean delivery of a frank breech through a hysterotomy incision.

Rarely during vaginal delivery, a frank breech will require decomposition inside the uterine cavity. Attributed to Pinard (1889), this procedure converts a frank breech into a footling breech. It is accomplished more readily if the membranes have ruptured only recently. It becomes extremely difficult if amnionic fluid is scant and the uterus is tightly contracted around the fetus. Pharmacological relaxation by general anesthesia or intravenous magnesium sulfate, nitroglycerin, or a betamimetic agent may be required. To begin, two fingers are carried up along one leg to externally rotate the hip by pressing on the medial side of the thigh parallel to the femur. Simultaneously, pressure in the popliteal fossa should prompt spontaneous knee flexion, which brings the corresponding foot into contact with the back of the provider's hand. The fetal foot then may be grasped and brought down.

EXTERNAL CEPHALIC VERSION

With *version*, fetal presentation is altered by physically substituting one pole of a longitudinal presentation for the other, or converting an oblique or transverse lie into a longitudinal presentation. Manipulations performed through the abdominal wall that yield a cephalic presentation are termed *external cephalic version*.

Manipulations accomplished inside the uterine cavity that yield a breech presentation are designated *internal podalic version*. This latter procedure is reserved for delivery of a second twin and described in Chapter 45 (Vaginal Birth after Cesarean Delivery).

Indications

External cephalic version (ECV) reduces the rate of noncephalic presentation at birth (Hofmeyr, 2015b). For breech fetuses near term, the American College of Obstetricians and Gynecologists (2016a,b) recommends that version be offered and attempted whenever possible. Its success rate averages about 60 percent (de Hundt, 2014). For women with a transverse lie, the overall success rate is significantly higher.

In general, ECV is attempted before labor in a woman who has reached 37 weeks' gestation. Before this time, breech presentation still has a high likelihood of correcting spontaneously. And, if ECV is performed too early, time may allow a reversion back to breech (Bogner, 2012). Last, if attempts at version cause a need for immediate delivery, complications of iatrogenic late-preterm delivery generally are not severe.

Absolute contraindications to external version are few. It is contraindicated if vaginal delivery is not an option, such as with placenta previa. Another is multifetal gestation. Relative contraindications are early labor, oligohydramnios or rupture of membranes, known nuchal cord, structural uterine abnormalities, fetal-growth restriction, and prior abruption or its risks (Rosman, 2013). While many consider a prior cesarean delivery a contraindication, a few small studies found ECV was not associated with uterine rupture (Burgos, 2014; Keepanasseril, 2017; Weill, 2017). At Parkland Hospital, we do not attempt version in these women. More data from clinical studies are needed.

Several factors can improve the chances of a successful attempt. These include multiparity, unengaged presenting part, nonanterior placenta, nonobese patient, and abundant amnionic fluid (Kok, 2009, 2011; Velzel, 2015). To augment the last parameter, Burgos and coworkers (2014) administered a preprocedural 2-L intravenous fluid bolus. While this improved amnionic fluid volume, it did not increase version success rates.

Complications

Patient counseling includes a discussion regarding small but real risks for placental abruption, preterm labor, and fetal compromise. Rarely, uterine rupture, fetomaternal hemorrhage, alloimmunization, amnionic fluid embolism, and even death may also complicate attempts at external version. That said, fetal deaths are rare, serious complication rates are typically very low, and emergent cesarean rates are 0.5 percent or less (Grootscholten, 2008; Rodgers, 2017). And even after successful ECV, several reports suggest that the cesarean delivery rate does not completely revert to the baseline for vertex presentations. Specifically, dystocia, malpresentation, and nonreassuring fetal heart patterns may be more common in these fetuses completing successful version (Chan, 2004; de Hundt, 2014; Vézina, 2004).

Technique

ECV should be carried out in an area that has ready access to a facility equipped to perform emergency cesarean delivery (American College of Obstetricians and Gynecologists, 2016a). Because of the risk for surgical intervention, intravenous access is obtained, and patients abstain from eating for 6 or more hours. Sonographic examination is performed to confirm nonvertex presentation, document amnionic fluid volume adequacy, exclude obvious fetal anomalies if not done previously, and identify placental location and fetal spine orientation. Preprocedural external monitoring is performed to assess fetal heart rate reactivity. Anti-D immune globulin is given to Rh-D negative women. Tocolysis and regional analgesia may be elected, and rationale for these is provided in subsequent sections.

The woman is placed in left lateral tilt to aid uteroplacental perfusion, and Trendelenburg positioning helps during elevation of the breech. During the procedure, we prefer to monitor fetal heart motion sonographically. An abundant abdominal coating of ultrasound gel permits this and also minimizes painful skin friction (Vallikkannu, 2014).

A forward roll of the fetus usually is attempted first. One or two providers may participate, and one hand grasps the head. The fetal buttocks are then elevated from the maternal pelvis and displaced laterally (Fig. 28-15). The buttocks are then gently guided toward the fundus, while the head is simultaneously directed toward the pelvis. If the forward roll is unsuccessful, a backward flip is attempted. ECV attempts are discontinued for excessive discomfort, persistently abnormal fetal heart rate, or after multiple failed attempts. Failure is not always absolute. Ben-Meir and colleagues (2007) reported a spontaneous version rate of 7 percent among 226 failed versions—2 percent among nulliparas and 13 percent among multiparas.

If ECV is successful, a nonstress test is repeated until a normal test result is obtained. If version is completed before 39 weeks' gestation, then awaiting spontaneous labor and fetal maturity is preferred. In some studies, immediate labor induction is linked to higher cesarean delivery rates (Burgos, 2015; Kuppens, 2013).

Tocolysis

To relax the uterus prior to an ECV attempt, existing evidence supports the use of tocolysis (American College of Obstetricians and Gynecologists, 2016a). Most data support the use of the beta-mimetics terbutaline and ritodrine (Cluver, 2015). In one such trial, Fernandez and coworkers (1996) reported that the success rate with subcutaneous terbutaline—52 percent—was significantly higher than without—27 percent. Our policy at Parkland Hospital is to administer 250 µg of terbutaline subcutaneously to most women before attempted ECV. When maternal tachycardia—a known side effect of terbutaline—is noted, the attempt is begun. Data are limited and, in some cases nonsupportive, for alternate agents that include calcium-channel blockers, such as nifedipine; nitric oxide donors, such as nitroglycerin; the oxytocin-receptor antagonist atosiban; and another betamimetic salbutamol (Burgos, 2010; Hilton, 2009; Kok, 2008; Vani, 2009; Velzel, 2017; Wilcox, 2011).

Conduction Analgesia

Epidural analgesia coupled with tocolysis has been reported to increase version success rates compared with tocolysis alone (Goetzinger, 2011; Magro-Malosso, 2016). Moreover, rates of complications that include fetal heart rate aberrations, emergency cesarean delivery, or placental abruption were not greater with regional analgesia. Of randomized trials, spinal and epidural have both shown success (Khaw, 2015; Weiniger, 2010). Currently, the superior technique and best drugs to administer are unclear. In contrast, from limited data, intravenous sedation does not appear to improve success rates (Burgos, 2016; Khaw, 2015).

Moxibustion

This is a traditional Chinese medicine technique that burns a cigarette-shaped stick of ground *Artemisia vulgaris*—which is also known as mugwort or in Japanese as *moxa.* At the BL 67 acupuncture point, the stick is directly placed against the skin or indirectly heats an acupuncture needle at the site to increase fetal movement and promote spontaneous breech version (Ewies, 2002). It is performed usually between 33 and 36 weeks' gestation to permit a trial of ECV if not successful. Results from randomized controlled studies are conflicting (Bue, 2016; Coulon, 2014; Coyle, 2012; Sananes, 2016; Vas, 2013).

CHAPTER 29: Operative Vaginal Delivery

The most important function of forceps is traction exercised for the purpose of drawing the head through the genital tract. In not a few cases, however, particularly in occipito-posterior presentations, its employment as a rotator is attended by most happy results.

—J. Whitridge Williams (1903)

INTRODUCTION

Operative deliveries are vaginal deliveries accomplished with the use of forceps or a vacuum device. Once either is applied to the fetal head, outward traction generates forces that augment maternal pushing to deliver the fetus vaginally. The most important function of both devices is traction. In addition, forceps may also be used for rotation, particularly from occiput transverse and posterior positions.

According to the birth certificate data from the National Vital Statistics Report, forceps- or vacuum-assisted vaginal delivery was used for 3.2 percent of births in the United States in 2014. This is a decline from 9.0 percent in 1990 (Hamilton, 2015). For these deliveries, a vacuum is disproportionately selected, and the vacuum-to-forceps delivery ratio is nearly 5:1 (Merriam, 2017). In general, most of these attempts are successful. In 2006, only 0.4 percent of forceps trials in the United States and 0.8 percent of vacuum extraction attempts failed to result in vaginal delivery (Osterman, 2009).

INDICATIONS

If it is technically feasible and can be safely accomplished, termination of second-stage labor by traction instruments is indicated in any condition threatening the mother or fetus that is likely to be relieved by delivery. Some fetal indications include nonreassuring fetal heart rate pattern and premature placental separation (Schuit, 2012). In the past, forceps delivery was believed to be somewhat protective of the fragile preterm infant head. However, outcomes for neonates who weigh 500 to 1500 g do not significantly differ if delivered spontaneously or by outlet forceps (Fairweather, 1981; Schwartz, 1983).

Some maternal indications include heart disease, pulmonary compromise, intrapartum infection, and certain neurological conditions. The most common are exhaustion and prolonged second-stage labor. However, a specific maximum length beyond which all women should be considered for operative vaginal delivery has not been identified (American College of Obstetricians and Gynecologists, 2016).

Operative delivery is generally performed from either a low or outlet station. Additionally, forceps or vacuum delivery should not be used *electively* until the criteria for an outlet delivery have been met. In these circumstances, operative delivery is a simple and safe operation, although with some risk of maternal lower reproductive tract injury (Yancey, 1999).

CLASSIFICATION AND PREREQUISITES

Classification for operative vaginal delivery is summarized in Table 29-1. It emphasizes that the two most important discriminators of risk for both mother and neonate are station and rotation. Station is measured in centimeters, –5 to 0 to +5. Zero station reflects a line drawn between the ischial spines. Deliveries are categorized as outlet, low, and midpelvic procedures. *High forceps, in which instruments are applied above 0 station, have no place in contemporary obstetrics.*

TABLE 29-1

Operative Vaginal Delivery Prerequisites and Classification According to Station and Rotation[a]

Procedure	**Criteria**	
Outlet forceps	Scalp is visible at the introitus without separating the labia Fetal skull has reached pelvic floor Fetal head is at or on perineum Head is OA or OP ***or*** Head is right or left OA or OP position but rotation ≤45 degrees	
Low forceps (2 types)	Leading point of fetal skull is at station ≥+2 cm, and not on the pelvic floor, and: (a) Rotation is ≤45 degrees, ***or*** (b) Rotation is >45 degrees	
Midforceps	Station is between 0 and +2 cm	
Prerequisites		
Engaged head	Experienced operator	No fetal coagulopathy
Vertex presentation[b,c]	Ruptured membranes	No fetal demineralization disorder
Known fetal head position	Completely dilated cervix	Willingness to abandon OVD
CPD not suspected	Adequate anesthesia	Informed consent completed
Fetal weight estimated	Emptied maternal bladder	

[a]Classification for the vacuum delivery system is the same as for forceps except that vacuum is used for traction but not rotation.

[b]Forceps, but not vacuum extractor, may be used for delivery of a face presentation with mentum anterior.

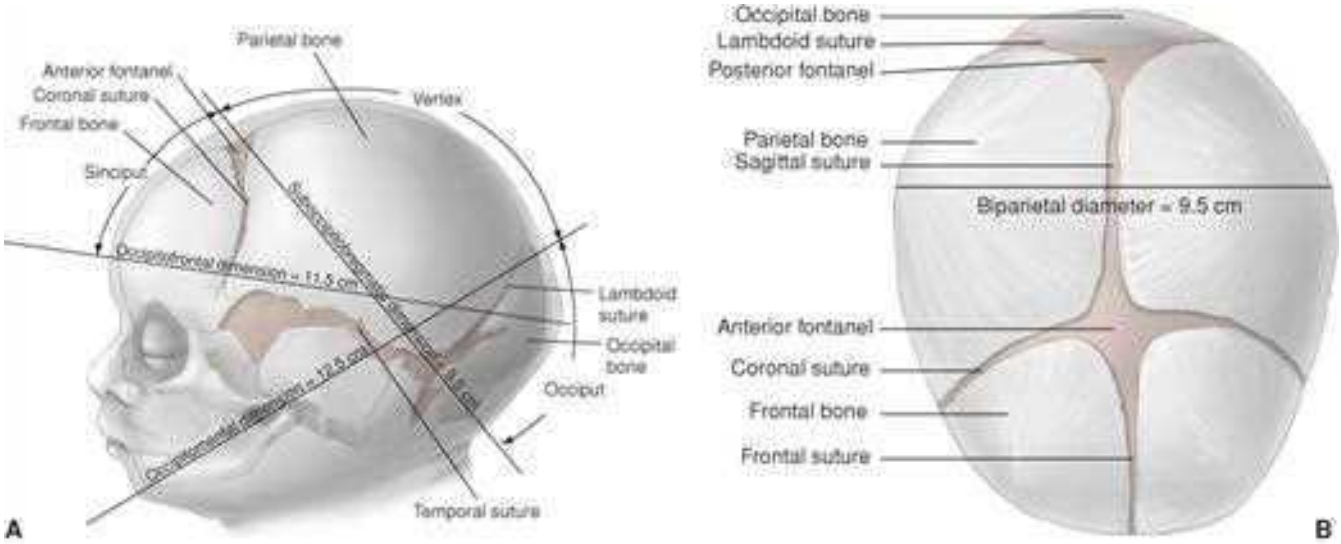
[c]Piper forceps may be used to deliver the head during breech delivery.

CPD = cephalopelvic disproportion; OA = occiput anterior; OP = occiput posterior; OVD = operative vaginal delivery.

Once station and rotation are assessed, several prerequisites are met and are listed in Table 29-1. For vacuum extraction, fetuses should also be at least 34 weeks' gestation, and although infrequently used in the United States, fetal scalp blood sampling should not have been recently performed. Of requisites, ascertaining correct head position is essential, and the anatomy of the fetal skull is described in Figure 29-1. In unclear cases, sonography is useful to identify fetal orbits and nasal bridge to aid orientation (Malvasi, 2014).

FIGURE 29-1

Fetal head (**A, B**) at term showing fontanels, sutures, and various dimensions.



Regional analgesia or general anesthesia is preferable for low forceps or midpelvic procedures, although pudendal blockade may prove adequate for outlet forceps. As discussed in Chapter 25 (Effects on Labor), regional analgesia during labor does not appear to increase the risk for operative delivery (Halpern, 2004; Marucci, 2007; Wassen, 2014).

The bladder is emptied to provide additional pelvic space and minimize bladder trauma. Urinary retention and bladder dysfunction are often short-term effects of forceps and vacuum deliveries (Mulder, 2012; Pifarotti, 2014). Notably, episiotomy and epidural analgesia, both common associates, are also identified risks for urinary retention. Symptoms are brief and typically resolve with 24 to 48 hours of passive Foley catheter bladder drainage.

MORBIDITY

There is an increased risk of certain morbidities for both mother and fetus when operative delivery is employed. In general, these are related to the ease with which the delivery is accomplished.

Maternal Morbidity

In general, a higher station and/or greater degrees of rotation increase the chance of maternal or fetal injury. Morbidity is most properly compared with morbidity from cesarean delivery, and not with that from spontaneous vaginal delivery. This is the most appropriate comparator because the alternative to indicated operative delivery is cesarean delivery. For example, postpartum wound or uterine infection is more frequent in women following cesarean compared with operative vaginal delivery (Bailit, 2016; Halscott, 2015). Moreover, in a study of more than 1 million births, Spiliopoulos and associates (2011) reported cesarean delivery, but not operative vaginal delivery, as a risk for peripartum hysterectomy.

Lacerations

The very conditions that lead to indications for operative delivery also increase the need for episiotomy and the likelihood of lacerations (de Leeuw, 2008). That said, forceps and vacuum deliveries are associated with higher rates of third- and fourth-degree lacerations as well as vaginal wall and cervical lacerations (Gurol-Urganci, 2013; Hirayama, 2012; Landy, 2011; Pergialiotis, 2014). These appear to occur more frequently with forceps compared with vacuum extraction, and especially if there is a midline episiotomy (Kudish, 2006; O'Mahony, 2010). Hagadorn-Freathy and coworkers (1991) reported a 13-percent rate of third- and fourth-degree episiotomy extensions and vaginal lacerations for outlet forceps, 22 percent for low forceps with less than 45-degree rotation, 44 percent for low forceps with more than 45-degree rotation, and 37 percent for midforceps deliveries.

In an effort to lower rates of third- and fourth-degree lacerations, and coincident with overall efforts to reduce routine episiotomy use, many advocate only indicated episiotomy with operative delivery. If episiotomy is required, a protective effect against these more extensive perineal lacerations may be afforded by mediolateral episiotomy (de Leeuw, 2008; de Vogel, 2012; Hirsch, 2008). Early disarticulation of forceps and cessation of maternal pushing during disarticulation can also be protective. Last, these injuries are more common with an occiput posterior position (Damron, 2004). Thus, manual or forceps rotation to an occiput anterior position and then subsequent traction delivery may decrease rates of lower reproductive tract injury (Bradley, 2013).

Pelvic Floor Disorders

This term encompasses urinary incontinence, anal incontinence, and pelvic organ prolapse. Operative vaginal delivery has been suggested as a possible risk for each of these. Proposed mechanisms include structural compromise and/or pelvic floor denervation secondary to forces exerted during delivery.

Parity and specifically vaginal delivery are risk factors for urinary incontinence (Gyhagen, 2013; Rortveit, 2003). But, many studies do not support an increased risk compared with vaginal delivery alone (Gartland, 2016; Leijonhufvud, 2011; MacArthur, 2016; Tähtinen, 2016).

Evidence linking anal incontinence with operative vaginal delivery is conflicting. Some studies show that anal sphincter disruption caused by higher-order episiotomy, but not delivery mode, is the main etiological factor strongly associated with anal incontinence (Bols, 2010; Evers, 2012; Nygaard, 1997). In contrast, others directly link operative delivery with this complication (Dolan, 2010; MacArthur, 2013). But, these studies may not be incongruous—recall that operative delivery is associated with increased rates of higher-order episiotomy. Importantly, several studies and reviews have not found cesarean delivery to be protective for anal incontinence (Nelson, 2010). Last, evidence linking pelvic organ prolapse with operative delivery also indicates mixed results (Gyhagen, 2013; Handa, 2012; Volløyhaug, 2015).

Perinatal Morbidity

Acute Perinatal Injury

These injuries are more frequent with operative vaginal delivery than with cesarean delivery or spontaneous vaginal delivery. Injuries may be seen with either method. They are more common with vacuum extraction, and types associated with this device include cephalohematoma, subgaleal hemorrhage, retinal hemorrhage, neonatal jaundice secondary to these hemorrhages, shoulder dystocia, clavicular fracture, and scalp lacerations. Cephalohematoma and subgaleal hemorrhage are both extracranial lesions described in Chapter 33 (Intracranial Hemorrhage). Forceps-assisted vaginal delivery has higher rates of facial nerve injury, brachial plexus injury, depressed skull fracture, and corneal abrasion (American College of Obstetricians and Gynecologists, 2015; Demissie, 2004; Dupuis, 2005). For intracranial hemorrhage, some studies have associated vacuum extraction with higher rates, whereas others show similar rates with either of the two methods (Towner, 1999; Wen, 2001; Werner, 2011).

Comparing operative vaginal with cesarean delivery, rates of extracranial hematoma, skull fracture, facial nerve or brachial plexus injury, retinal hemorrhage, and facial or scalp laceration are lower with cesarean delivery, and shoulder dystocia is eliminated. Importantly, however, fetal acidemia rates are not increased with operative delivery (Contag, 2010; Walsh, 2013). Intracranial hemorrhage rates are similar among newborns delivered by vacuum extraction, forceps, or cesarean delivery during labor (Towner, 1999). But, these rates are higher than among those delivered spontaneously or by cesarean delivery before labor. These authors suggest that the common risk factor for intracranial hemorrhage is abnormal labor. Werner and associates (2011), in their evaluation of more than 150,000 singleton deliveries, reported that forceps-assisted delivery was associated with fewer total neurological complications compared with vacuum-assisted or cesarean delivery. However, as a subset, subdural hemorrhage was significantly more frequent in both instrumental cohorts compared with neonates in the cesarean delivery group.

Comparing rotational operative delivery and second-stage cesarean delivery, maternal and neonatal morbidity rates are similar (Aiken, 2015; Bahl, 2013; Stock, 2013). For example, in their large series, Tempest and associates (2013) found similar morbidity rates among malpositioned fetuses during second-stage labor that underwent Kielland rotation, rotational vacuum extraction, or emergency cesarean delivery.

Comparing midforceps and cesarean delivery, reports of neonatal morbidity rates are from older studies and are conflicting. In the study by Towner and colleagues (1999), similar risks were reported for intracranial hemorrhage. Bashore and associates (1990) observed comparable Apgar scores, cord blood acid-base values, neonatal intensive care unit admission, and birth trauma between these two. In another study, however, Robertson and coworkers (1990) reported significantly higher rates of these adverse outcomes in the midforceps group. Hagadorn-Freathy and colleagues (1991) reported an increased risk for facial nerve palsy—9 percent—with midforceps delivery. In a recent report comparing low and midforceps procedures, Ducarme and coworkers (2015) found comparable morbidity rates.

Mechanisms of Acute Injury

The types of fetal injury with operative delivery can usually be explained by the forces exerted. In cases of cephalohematoma or subgaleal hemorrhage, suction and perhaps rotation during vacuum extraction may lead to a primary vessel laceration. Intracranial hemorrhage may result from skull fracture and vessel laceration or from vessel laceration alone due to exerted forces. With facial nerve palsy, one of the forceps blades may compress the nerve against the facial bones. The higher rates of shoulder dystocia seen with vacuum extraction may result from the angle of traction. With the vacuum, this angle creates vector forces that actually pull the anterior shoulder into the symphysis pubis (Caughey, 2005). To explain brachial plexus injury, Towner and Ciotti (2007) proposed that as the fetal head descends down the birth canal, the shoulders may stay above the pelvic inlet. Thus, similar to shoulder dystocia at the symphysis, this “shoulder dystocia at the pelvic inlet” is overcome by traction forces but with concomitant stretch on the brachial plexus.

Long-Term Infant Morbidity

Evidence regarding long-term neurodevelopmental outcomes in children born by operative delivery is reassuring. In an older study, Seidman and colleagues (1991) evaluated more than 52,000 Israeli Defense Forces draftees at age 17 years and found that regardless of delivery mode, rates of physical or cognitive impairments were similar. Wesley and associates (1992) noted similar intelligence scores among 5-year-olds following spontaneous, forceps, or vacuum deliveries. Murphy and coworkers (2004) found no association between forceps delivery and epilepsy in a cohort of more than 21,000 adults. In their epidemiological review, O’Callaghan and colleagues (2011) found no association between cerebral palsy and operative delivery. Last, Bahl and associates (2007) noted that the incidence of neurodevelopmental morbidity was similar in those undergoing successful forceps delivery, failed forceps with cesarean delivery, or cesarean delivery without forceps.

Data regarding midforceps deliveries are for the most part reassuring. Broman and coworkers (1975) reported that infants delivered by midforceps had slightly higher intelligence scores at age 4 years compared with those of children delivered spontaneously. Using the same database, however, Friedman and associates (1977, 1984) analyzed intelligence scores at or after age 7 years. They concluded that children delivered by midforceps had lower mean intelligence quotients compared with those delivered by outlet forceps. In yet another report from this database, Dierker and colleagues (1986) compared long-term outcomes of children delivered by midforceps with those delivered by cesarean after dystocia. The strength of this study is the appropriateness of the control group. These investigators reported that delivery by midforceps was not associated with neurodevelopmental disability. Last, Nilsen (1984) evaluated 18-year-old men and found that those delivered by Kielland forceps had higher intelligence scores than those delivered spontaneously, by vacuum extraction, or by cesarean.

TRIAL OF OPERATIVE VAGINAL DELIVERY

If an attempt to perform an operative delivery is expected to be difficult, then it should be considered a trial. Moving the woman to an operating room for this attempt, which could be followed by immediate cesarean delivery if operative delivery fails, has merit. If forceps cannot be satisfactorily applied, then the procedure is stopped and either vacuum extraction or cesarean delivery is performed. With the former, if the fetus does not descend with traction, the trial should be abandoned and cesarean delivery performed.

With such caveats, cesarean delivery after an attempt at operative vaginal delivery was not associated with adverse neonatal outcomes if there was a reassuring fetal heart rate tracing (Alexander, 2009). A similar study evaluated 122 women who had a trial of midcavity forceps or vacuum extraction in a setting with full preparations for cesarean delivery (Lowe, 1987). Investigators found no significant difference in immediate neonatal or maternal morbidity compared with that of 42 women delivered for similar indications by cesarean but without such a trial. Conversely, in 61 women who had "unexpected" vacuum or forceps failure in which there was no prior preparation for immediate cesarean delivery, neonatal morbidity was higher.

Some factors associated with operative delivery failure are persistent occiput posterior position and birthweight >4000 g (Ben-Haroush, 2007; Verhoeven, 2016). However, Palatnik and associates (2016) found that risk factors poorly predicted success. In general, to avert morbidity with failed forceps or vacuum delivery, the American College of Obstetricians and Gynecologists (2015) cautions that these trials should be attempted only if the clinical assessment suggests a successful outcome. We also emphasize proper training.

Sequential instrumentation most often involves an attempt at vacuum extraction followed by one with forceps. This most likely stems from the higher completion rate with forceps compared with vacuum extraction noted earlier. This practice significantly increases risks for fetal trauma (Dupuis, 2005; Gardella, 2001; Murphy, 2011). Because of these adverse outcomes, the American College of Obstetricians and Gynecologists (2015) recommends against the sequential use of instruments unless there is a "compelling and justifiable reason."

TRAINING

As the rate of operative vaginal delivery has declined, so have opportunities for training (Fitzwater, 2015; Kyser, 2014). In many programs, training in even low and outlet forceps procedures has reached critically low levels. For residents completing training in 2015, the Accreditation Council for Graduate Medical Education reported a median of only five forceps deliveries, and that for vacuum deliveries was 16.

Because traditional hands-on training has evolved, residency programs should have readily available skilled operators to teach these procedures by simulation as well as through actual cases (Skinner, 2017; Spong, 2012). And, the effectiveness of simulation training has been reported (Dupuis, 2006, 2009; Leslie, 2005). In one program, maternal and neonatal morbidity rates with operative delivery decreased after the implementation of a formal education program that included a manikin and pelvic model (Cheong, 2004). In another, a 59-percent increase in forceps deliveries over 2 years was related to a single experienced and proactive instructor assigned to teach forceps to residents in labor and delivery (Solt, 2011).

FORCEPS DELIVERY

Design

Forceps refers to the paired instrument, and each member of this pair is called a branch. Branches are designated left or right according to the side of the maternal pelvis to which they are applied (Fig. 29-2). Each branch has four components: blade, shank, lock, and handle (Fig. 29-3). Each blade has a toe, a heel, and two curves. Of these, the outward cephalic curve conforms to the round fetal head, whereas the upward pelvic curve corresponds more or less to the curve of the birth canal. Some blades have an opening within or a depression along the blade surface and are termed *fenestrated* or *pseudofenestrated*, respectively. True fenestration reduces the degree of head slippage during forceps rotation. Disadvantageously, it can increase friction between the blade and vaginal wall. With pseudofenestration, the forceps blade is smooth on the outer maternal side but indented on the inner fetal surface. The goal is to reduce head slipping yet improve the ease and safety of application and removal of forceps compared with pure fenestrated blades. In general, fenestrated blades are used for a fetus with a molded head or for rotation. In most situations, however, despite these subtle differences any are appropriate.

FIGURE 29-2
Simpson forceps have fenestrated blades, parallel shanks, and English lock. The cephalic curve accommodates the fetal head.

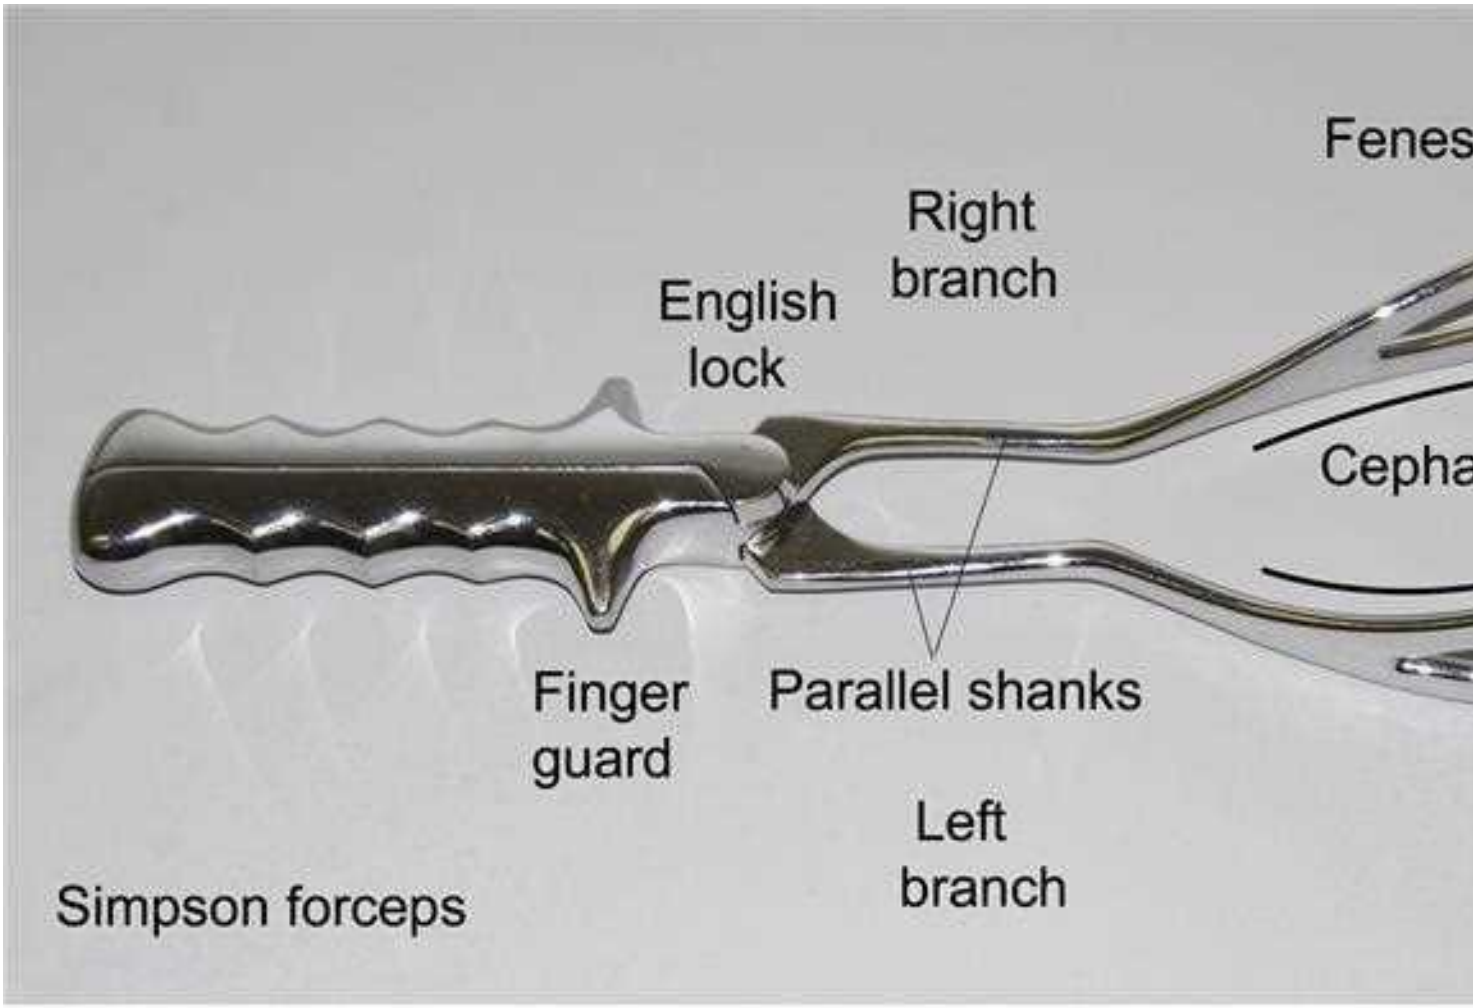


FIGURE 29-3

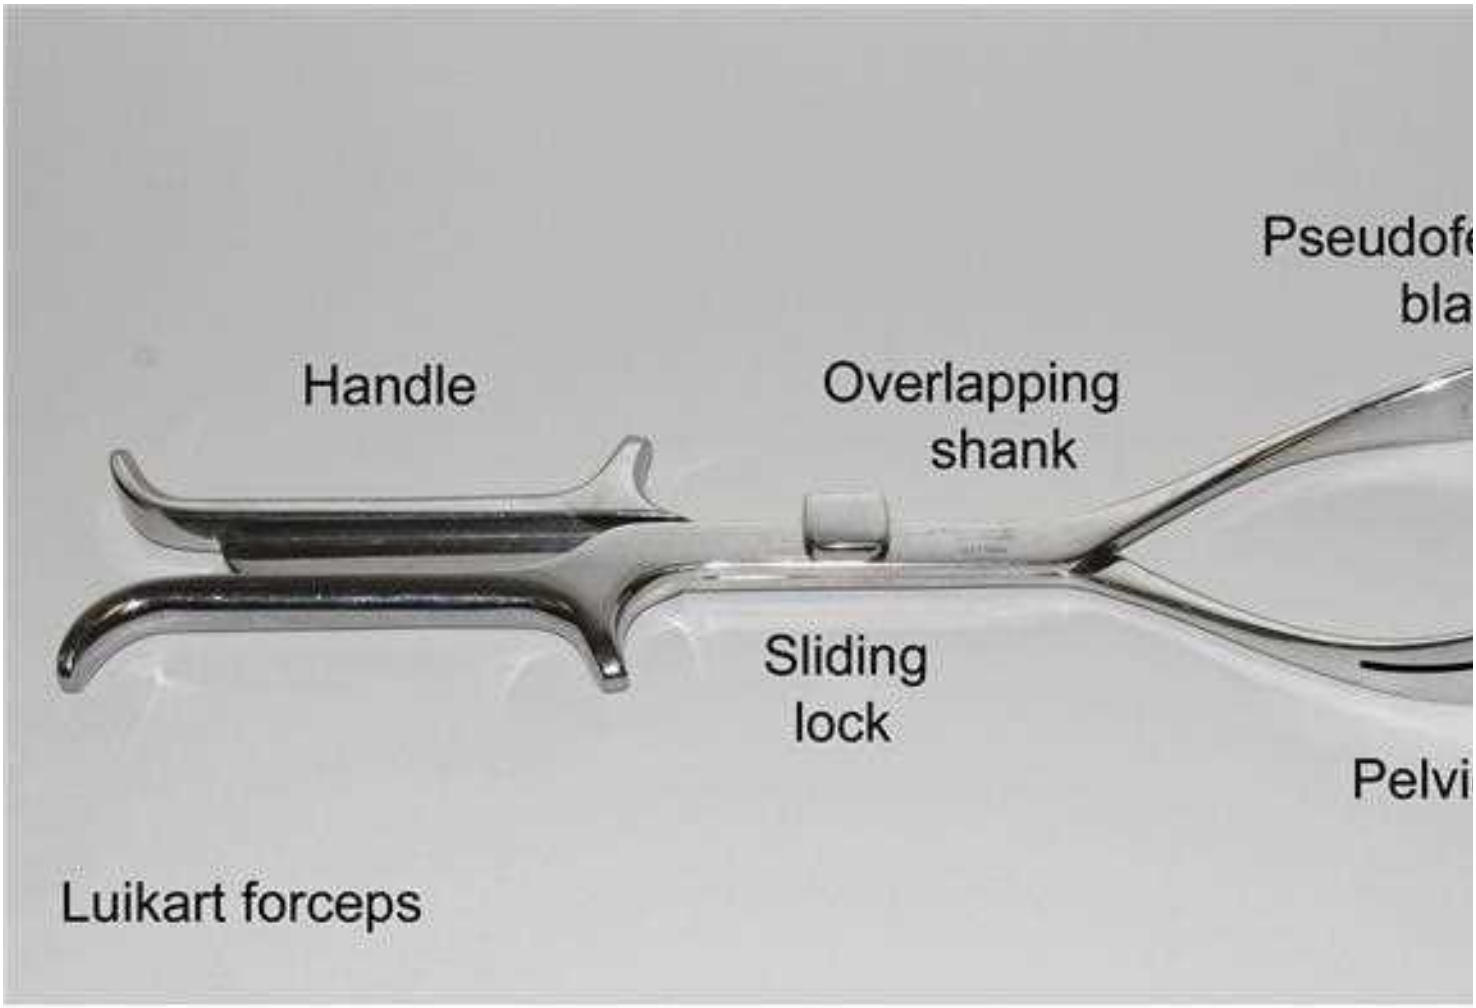
Luikart forceps have pseudofenestrated blades, overlapping shanks, sliding lock, tongue groove handles. The pelvic curve is marked in this example by the black line.



The blades are connected to shanks, which may be parallel or overlapping. Locks are found on all forceps and help to connect the right and left branches and stabilize the instrument. They can be located at the end of the shank nearest to the handles (English lock), at the ends of the handles (pivot lock), or along the shank (sliding lock). Although varied in design, handles, when squeezed, raise compression forces against the fetal head. Thus, forces to consider include traction and compression.

Blade Application and Delivery

Forceps blades grasp the head and are applied according to fetal head position. If the head is in an occiput anterior (OA) position, two or more fingers of the right hand are introduced inside the left posterior portion of the vulva and then into the vagina beside the fetal head. The handle of the left branch is grasped between the thumb and two fingers of the left hand (Fig. 29-4). The blade tip is then gently passed into the vagina between the fetal head and the palmar surface of the fingers of the right hand (Fig. 29-5). For application of the right blade, two or more fingers of the left hand are introduced into the right posterior portion of the vagina to serve as a guide for the right blade. This blade is held in the right hand and introduced into the vagina. With each blade, the thumb is positioned behind the heel, and most of the insertion force comes from this thumb (Fig. 29-6). If the head is positioned in a left OA (LOA) or right OA (ROA) position, then the lower of the two blades is typically placed first. After positioning, the branches are articulated.

FIGURE 29-4

For OA or LOA positions, the left handle of the forceps is held in the left hand. The blade is introduced into the left side of the pelvis between the fetal head and the fingers of the operator's right hand.

FIGURE 29-5

Insertion arc of the blade. Importantly, the thumb of the right hand, guides the blade during placement, as shown in Figure 29-6.

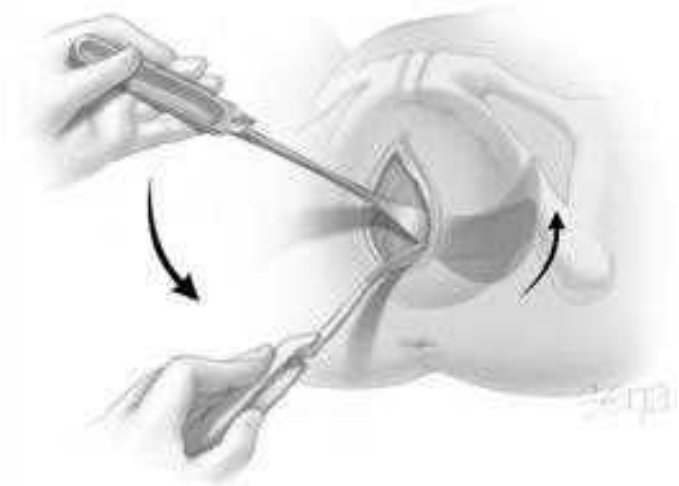


FIGURE 29-6

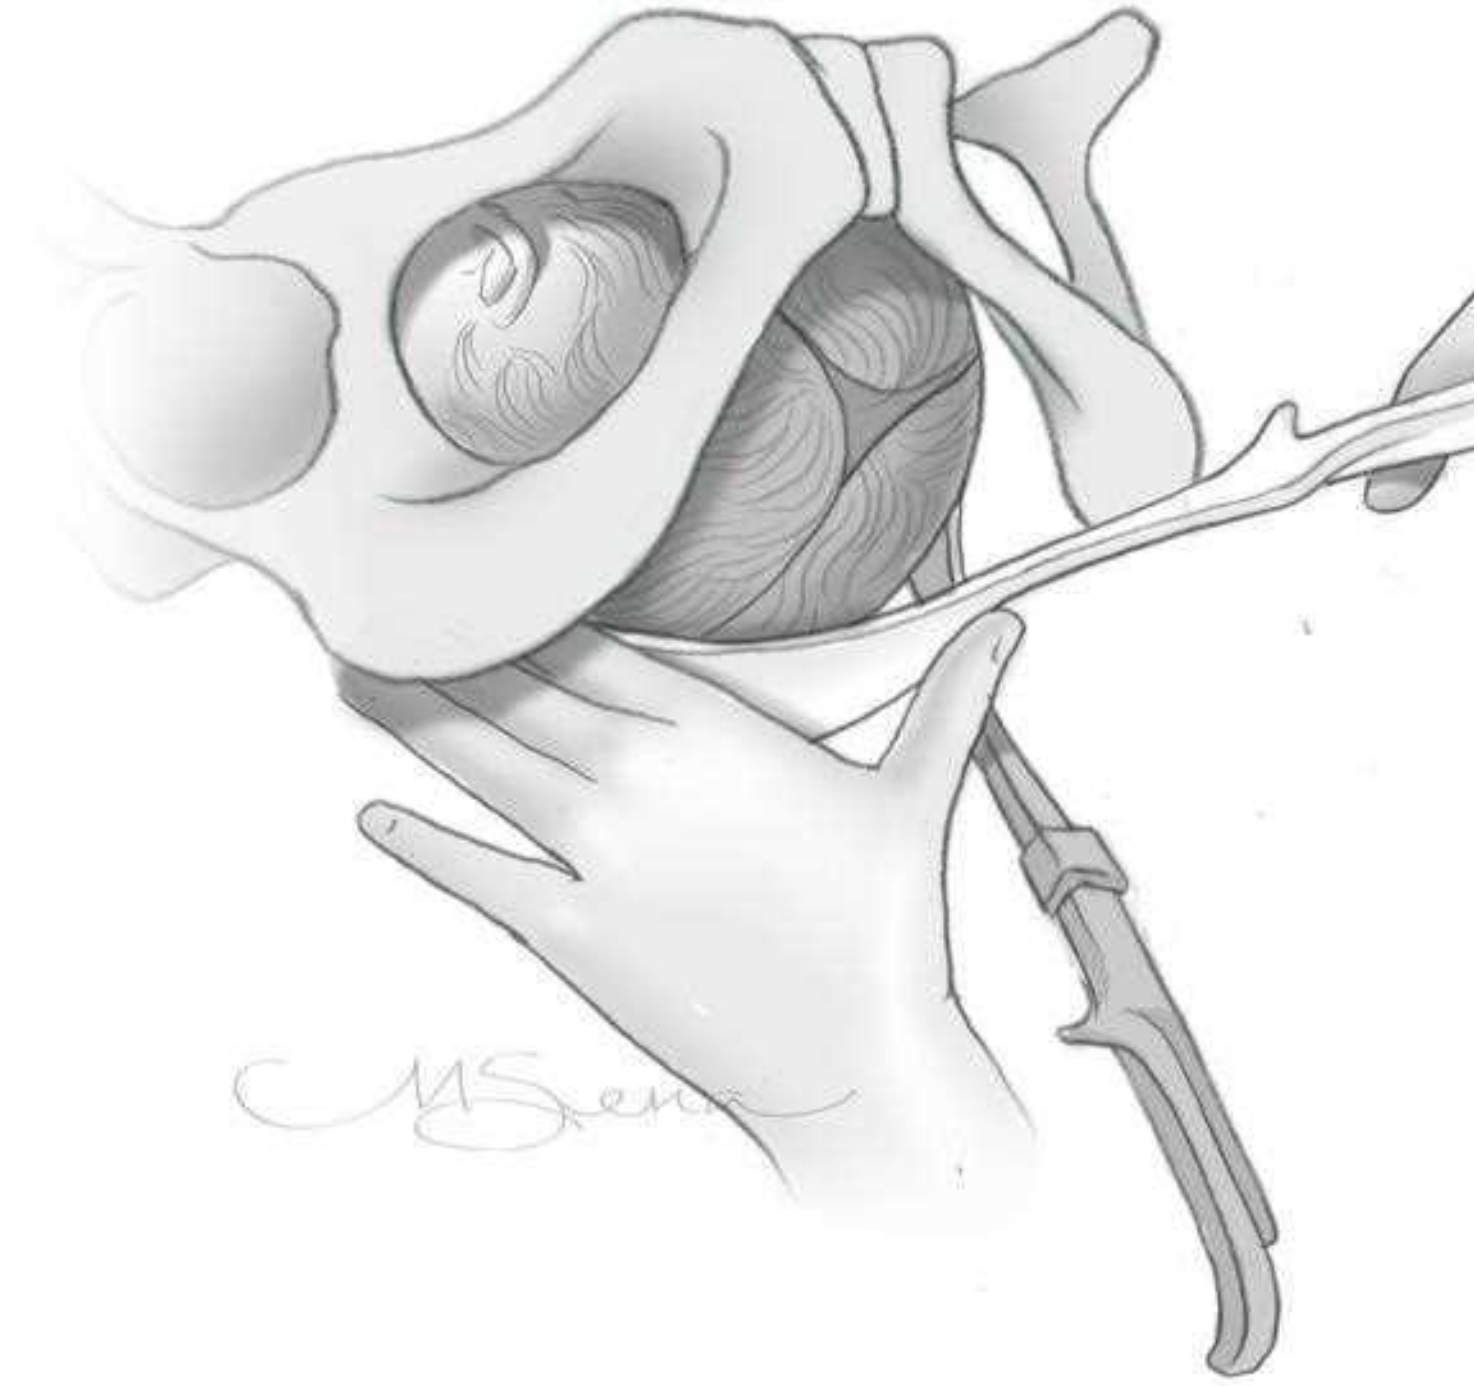
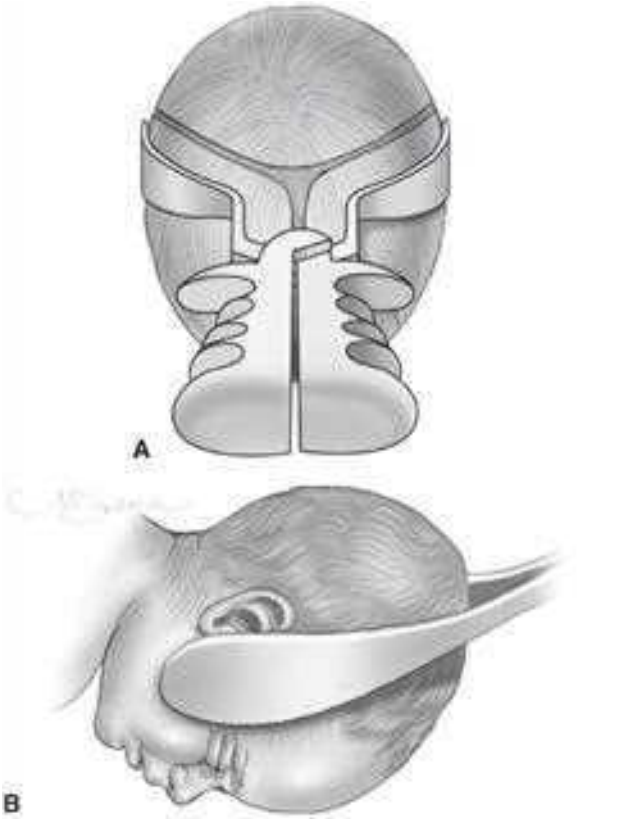
In applying the second blade, insertional force is generated mainly by the thumb. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



The blades are constructed so that their cephalic curve is closely adapted to the sides of the fetal head (Fig. 29-7). The fetal head is perfectly grasped only when the long axis of the blades corresponds to the occipitomental diameter (see Fig. 29-1). As a result, most of the blade lies over the lateral face. If the fetus is in an OA position, then the concave arch of the blades is directed toward the sagittal suture. If the fetus is in an occiput posterior (OP) position, then the concave arch is directed toward the midline face.

FIGURE 29-7

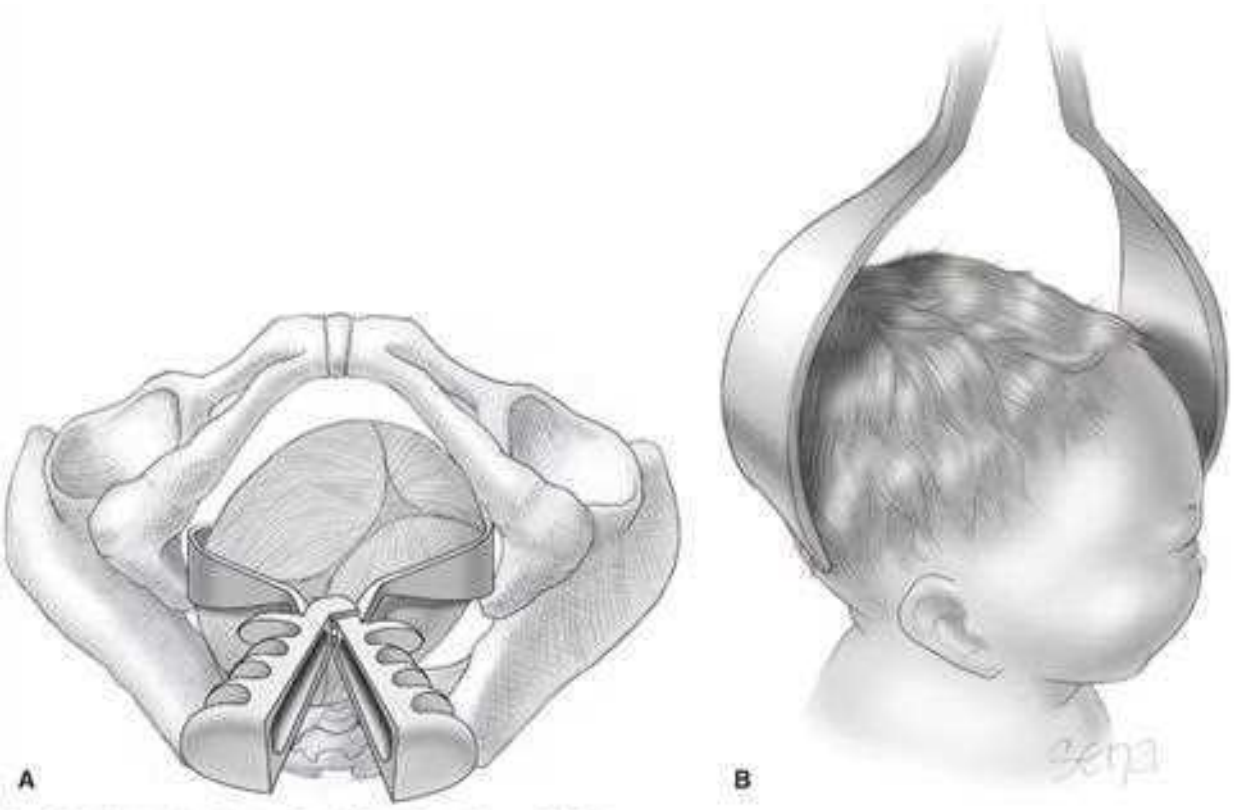
A. The forceps are symmetrically placed and articulated. **B.** The vertex is OA. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



Suboptimal blade placement can increase morbidity (Ramphul, 2015). For OA position, appropriately applied blades are equidistant from the sagittal suture, and each blade is equidistant from its adjacent lambdoidal suture. In the OP position, the blades are equidistant from the midline of the face and brow. Also for OP position, blades are symmetrically placed relative to the sagittal suture and each coronal suture. Applied in this way, the forceps should not slip, and traction may be applied most advantageously. With most forceps, if one blade is applied over the brow and the other over the occiput, the instrument cannot be locked, or if locked, the blades will slip off when traction is applied (Fig. 29-8).

FIGURE 29-8

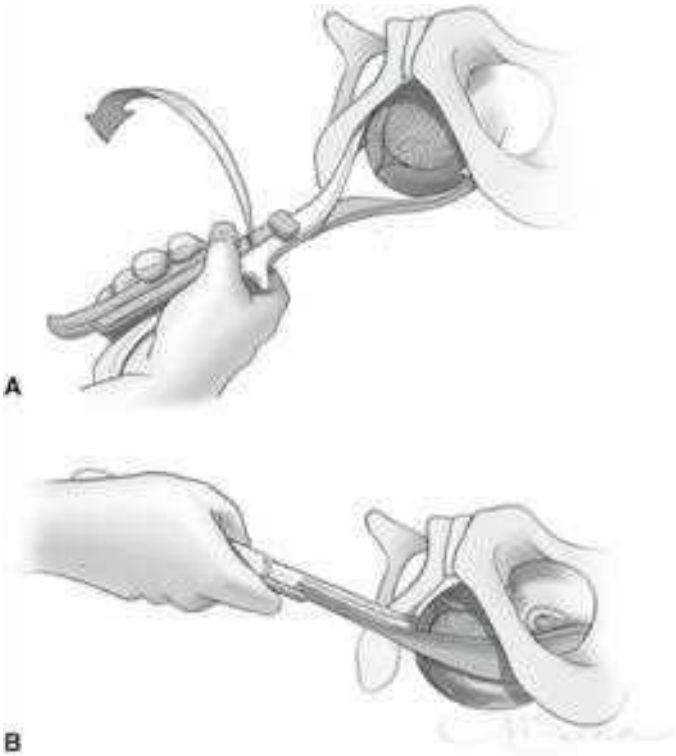
Incorrect application of forceps. **A.** One blade over the occiput and the other over the brow. Forceps cannot be locked. **B.** With incorrect placement, blades tend to slip off with traction.



With both branches in place, it should be an easy matter to articulate the handles, engage the lock, and correct asynclitism if present. Asynclitism is resolved by pulling and/or pushing each branch along the long axis of the instrument until the finger guards align. If necessary, rotation to OA position is performed before traction is applied (Fig. 29-9).

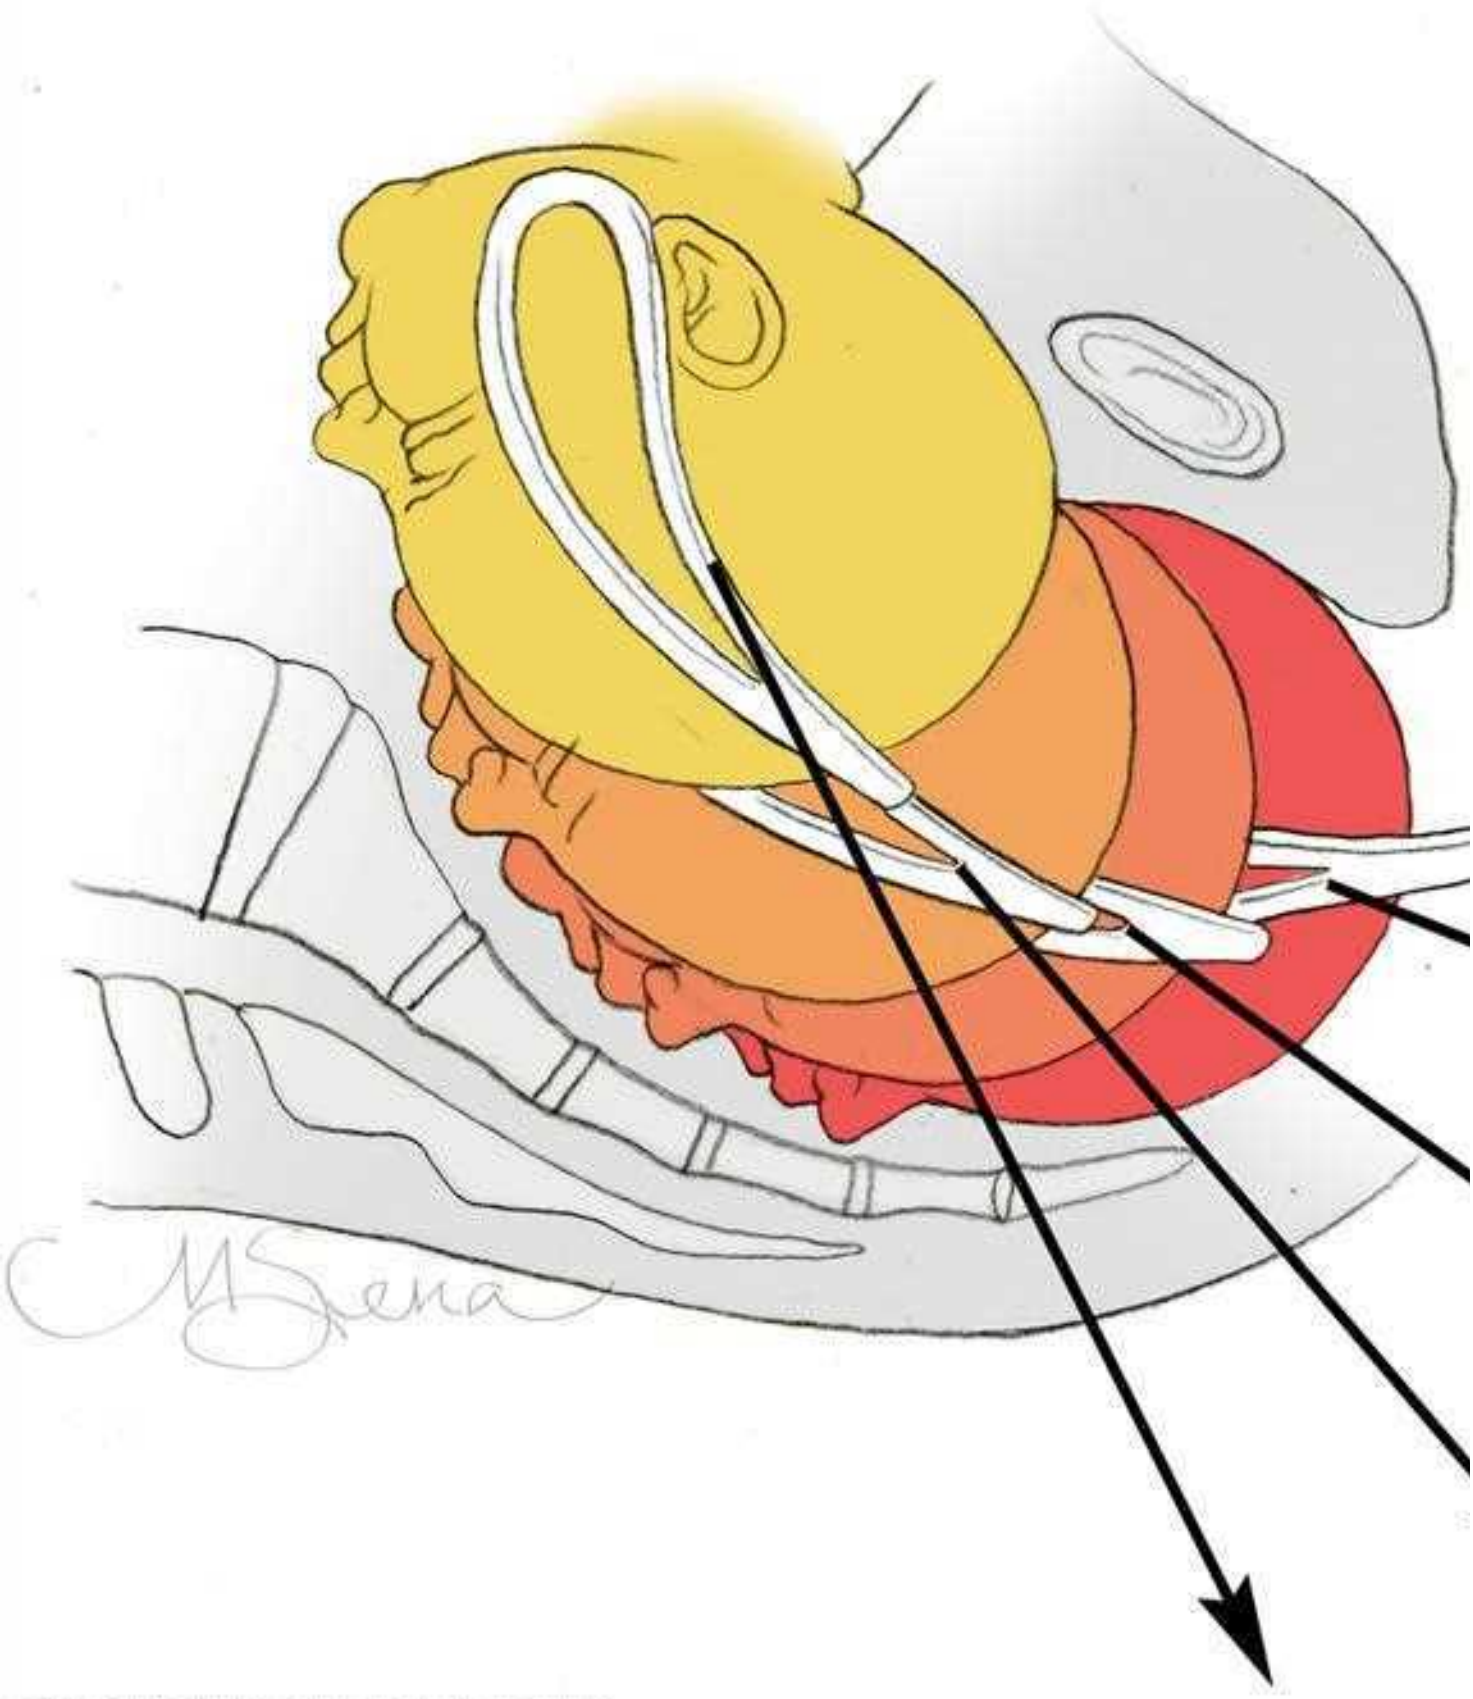
FIGURE 29-9

A. If LOA, the vertex is rotated (*arrow*) from this position to OA **(B).** (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



When it is certain that the blades are placed satisfactorily, then gentle, intermittent, downward and outward traction is exerted concurrent with maternal efforts until the perineum begins to bulge. When the head is at 0 to +2 of +5 station, the initial direction of traction is quite posterior, almost toward the floor. With head descent, the vector of forces changes continuously (Fig. 29-10). As a teaching tool for this, a *Bill axis traction device* can be attached over the finger guards of most forceps. The instrument has an arrow and indicator line. When the arrow points directly to the line, traction is along the path of least resistance. With traction, as the vulva is distended by the occiput, an episiotomy may be performed if indicated. Additional horizontal traction is applied, and the handles are then gradually elevated. As the handles are raised, the head is extended. During the birth of the head, mechanisms of spontaneous delivery should be simulated as closely as possible.

FIGURE 29-10
With low forceps, the direction of gentle traction for delivery of the head is indicated (*arrow*). The vector changes with fetal descent.



The force produced by the forceps on the fetal skull is a function of both traction and compression by the forceps, as well as friction produced by maternal tissues. It is impossible to ascertain the amount of force exerted by forceps for an individual patient. Traction should therefore be intermittent, and the head should be allowed to recede between contractions, as in spontaneous labor. Except when urgently indicated, as in severe fetal bradycardia, delivery should be sufficiently slow, deliberate, and gentle to prevent undue head compression. It is preferable to apply traction only with each uterine contraction. Maternal pushing will augment these efforts.

After the vulva has been well distended by the head, the delivery may be completed in several ways. Some clinicians keep the forceps in place to control the head. If this is done, however, the blade volume adds to vulvar distention, thus increasing the likelihood of laceration or necessitating a large episiotomy. To prevent this, the forceps may be removed, and delivery is then completed by maternal pushing (Fig. 29-11). Importantly, if blades are disarticulated and removed too early, the head may recede and lead to a prolonged delivery. Delivery in some cases may be aided by addition of the modified Ritgen maneuver.

FIGURE 29-11

Branches are removed in the opposite order from that in which they were originally placed. The fingers of the right hand, covered by a sterile towel, bolster the perineum. The thumb is placed directly on the head to prevent sudden egress. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)

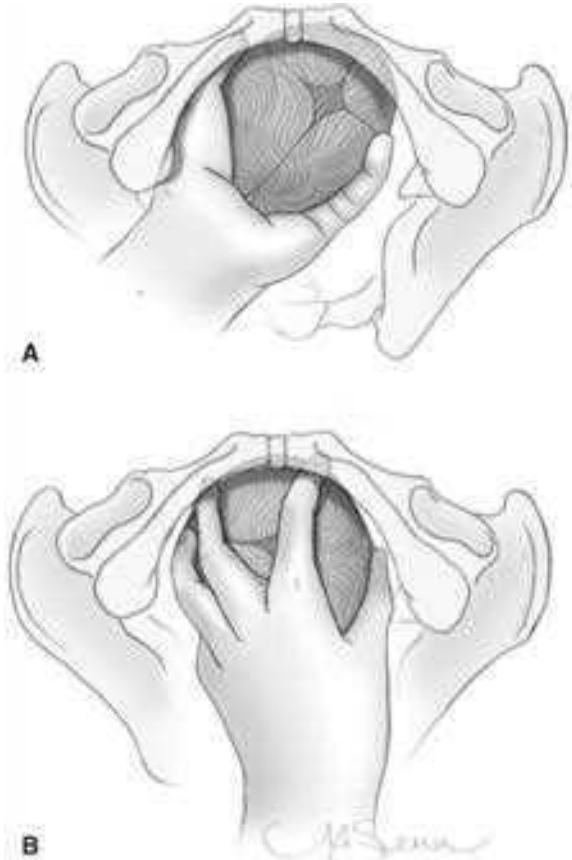
Occiput Posterior Positions

Prompt delivery may at times become necessary when the small occipital fontanel is directed toward one of the sacroiliac synchondroses. In these right OP (ROP) or left OP (LOP) positions, the fetal head is often imperfectly flexed. With OP positions, second-stage labor can be lengthened. In these cases, the head may spontaneously deliver OP, may be manually or instrumentally rotated to an OA position, or may be delivered OP by forceps or vacuum.

With manual rotation, an open hand is inserted into the vagina. The palm straddles the sagittal suture of the fetal head. The operator's fingers wrap around one side of the fetal face and thumb extends along the other side. If the occiput is ROP, rotation is clockwise to bring it to an ROA or OA position (Fig. 29-12). With LOP position, rotation is counterclockwise. Three actions are performed simultaneously between contractions. The first is fetal head flexion to provide a smaller diameter for rotation and subsequent descent. Second, slight destationing of the fetal head moves the head to a level in the maternal pelvis with sufficient room to complete the rotation. Importantly, destationing should not be confused with disengaging the fetal head, which is proscribed. Concurrently, some prefer to also place the other hand externally on the corresponding side of the maternal abdomen to pull the fetal back up toward the midline in synchrony with the internal rotation. Le Ray and colleagues (2007, 2013) reported a success rate of greater than 90 percent with manual rotation. Barth (2015) provides an excellent summary of this technique.

FIGURE 29-12

A. Manual rotation using the left hand, palm-up, to rotate from ROP. **B.** The head is flexed and destationed during clockwise rotation to reach an OA position. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)

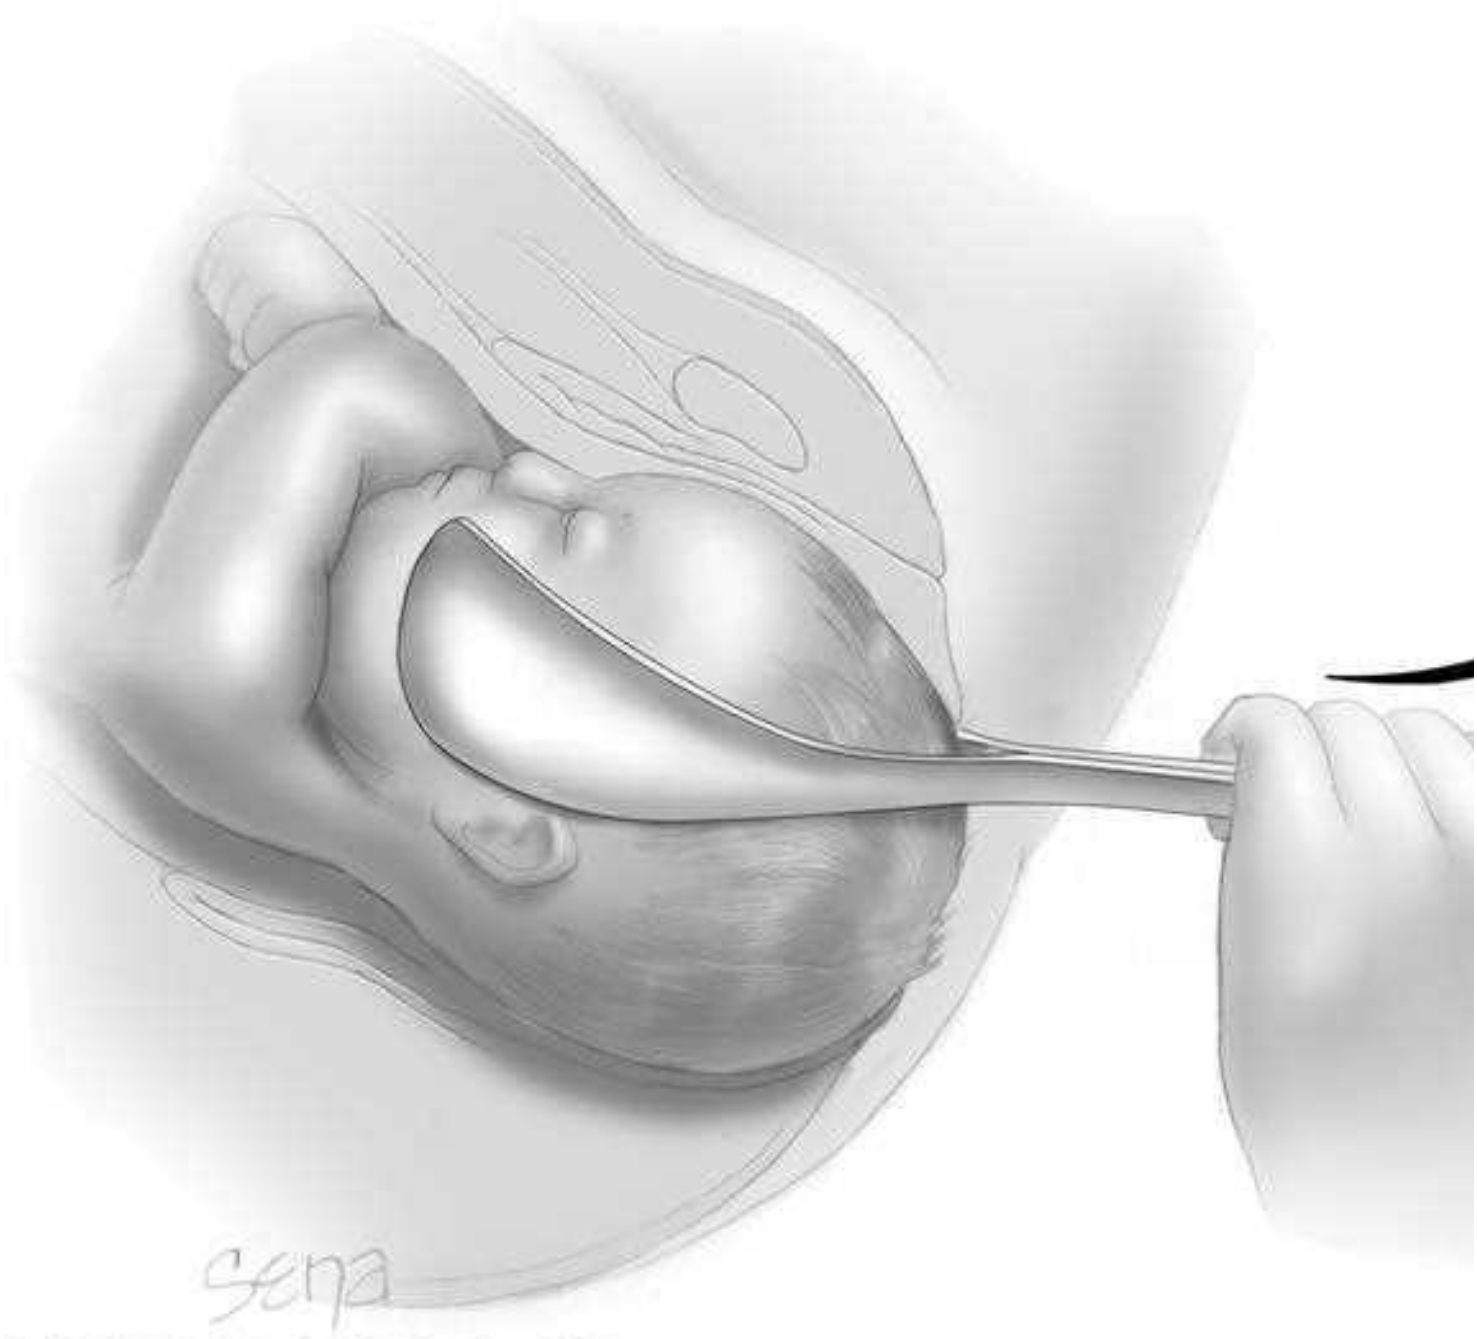


Manual rotations are most easily completed in multiparas. If manual rotation cannot be easily accomplished, application of forceps blades to the head in the posterior position and delivery from an OP position may be the safest procedure. In many cases, the cause of a persistent OP position and of the difficulty in accomplishing rotation is an anthropoid pelvis. This architecture opposes rotation and predisposes to posterior delivery (Fig. 2-17).

With forceps delivery from an OP position, downward and outward traction is applied until the base of the nose passes under the symphysis (Fig. 29-13). The handles are then slowly elevated until the occiput gradually emerges over the upper margin of the perineum. The forceps are directed downward again, and the nose, mouth, and chin successively emerge from the vulva.

FIGURE 29-13

Outlet forceps delivery from an OP position. The head should be flexed after the bregma passes under the symphysis.

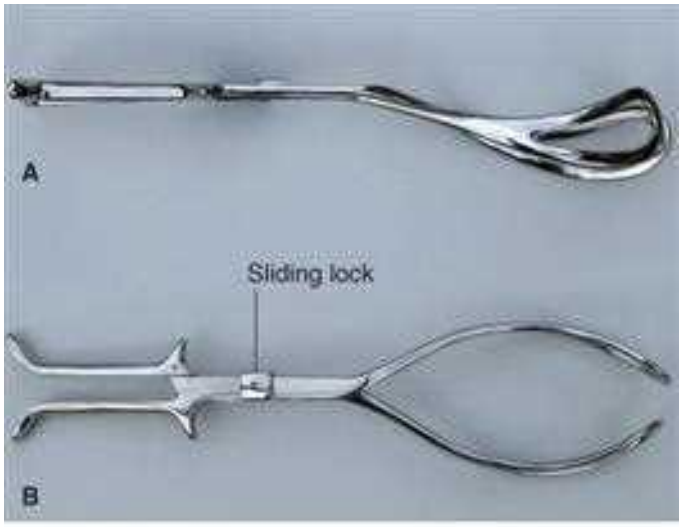


OP delivery causes greater distention of the vulva, and a large episiotomy may be needed. OP deliveries have a higher incidence of severe perineal lacerations and extensive episiotomy compared with OA positions (de Leeuw, 2008; Pearl, 1993). Also, newborns delivered from OP positions have a higher incidence of Erb and facial nerve palsies, 1 and 2 percent, respectively, than those delivered from OA positions. As expected, rotations to OA ultimately decrease perineal delivery trauma (Bradley, 2013).

Last, for forceps rotations from an OP to OA position, the Kielland instruments are preferred because they have a less pronounced pelvic curve (Fig. 29-14). *Cunningham and Gilstrap's Operative Obstetrics, 3rd edition,* offers a more detailed description of this Kielland forceps procedure (Yeomans, 2017).

FIGURE 29-14

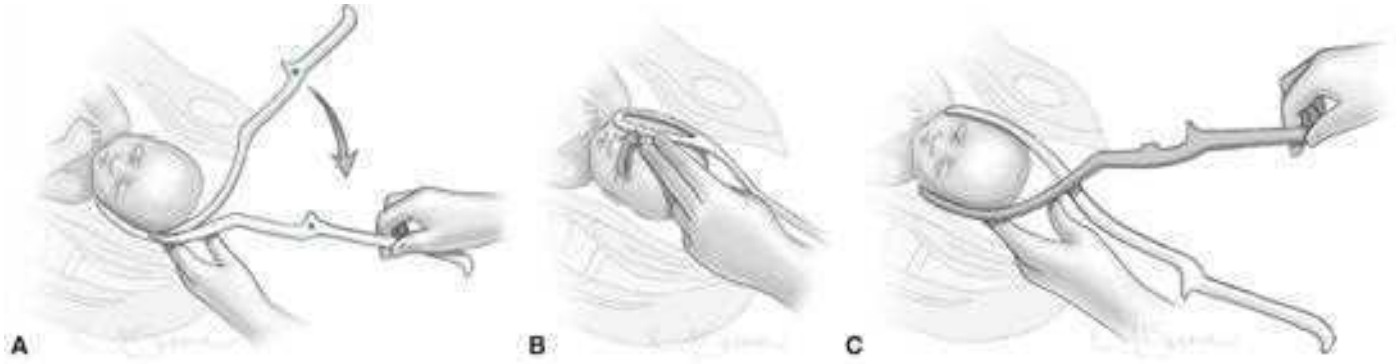
Kielland forceps. The characteristic features are minimal pelvic curvature **(A)**, sliding lock **(B)**, and light weight.



Occiput Transverse Positions

With occiput transverse (OT) positions, rotation is required for delivery. With experienced operators, high success rates with minimal maternal morbidity can be achieved (Burke, 2012; Stock, 2013). Either standard forceps, such as Simpson, or specialized forceps, such as Kielland, are employed. With Kielland forceps, each handle has a small knob, and branches are placed so that this knob faces the occiput. The station of the fetal head must be accurately determined to be at, or preferably below, the level of the ischial spines, especially in the presence of extreme molding.

FIGURE 29-15
A. Application of the right branch of the Kielland forceps to a head in LOT position. The knob on this branch (*colored blue*) will ultimately face the occiput. **B.** The right branch is wandered to its final position behind the symphysis. **C.** Insertion of the left branch of the Kielland forceps directly posterior along the hollow of the sacrum. This branch is inserted to the maternal right of the anterior branch to aid in engaging the sliding lock. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



Kielland described two methods of applying the anterior blade. In our example, placement with a left OT (LOT) position is described. With the wandering method, the anterior blade is first introduced into the posterior pelvis (Fig. 29-15). The blade is then arched around the face to an anterior position. To permit this sweep of the blade, the handle is held close to the maternal left buttock throughout the maneuver. The second blade is introduced directly posteriorly, and the branches are locked.

After checking the application, the handles of the Kielland forceps are pulled slightly to the patient's right to increase fetal head flexion and create a smaller diameter for rotation. The first and second fingers of the left hand are placed over the finger guards with the palm against the handles. This palm faces the maternal left. Concurrently, the first two fingers of the operator's right hand are placed against the anterior lambdoid suture. The fetal head is then destationed approximately 1 cm. For rotation in a counterclockwise direction, the wrist of the left hand supinates, to direct this palm upward. Simultaneously, two fingers of the right hand press on the edge of the right parietal bone that borders the lambdoid suture. This ensures that the fetal head turns with the blades and does not slip.

The second type of blade application introduces the anterior blade with its cephalic curve directed upward to curve under the symphysis. After it has been advanced far enough toward the upper vagina, it is turned on its long axis through 180 degrees to adapt the cephalic curvature to the head.

With either application, after rotation completion, the operator may choose from two acceptable methods for delivery. In one, the operator applies traction on the Kielland forceps using a bimanual grip described previously for conventional forceps (Forceps Delivery). When the posterior fontanel has passed under the subpubic arch, the handles can be elevated to the horizontal. Raising the handles above the horizontal may cause vaginal sulcus tears because of the reverse pelvic curve (Dennen, 1955). Alternatively, the Kielland forceps can be removed after rotation and replaced with conventional forceps. With this approach, moderate traction is first employed to seat the head before switching instruments.

Face Presentations

With a mentum anterior face presentation, forceps can be used to effect vaginal delivery. The blades are applied to the sides of the head along the occipitomental diameter, with the pelvic curve directed toward the neck. Downward traction is exerted until the chin appears under the symphysis. Then, by an upward movement, the face is slowly extracted, with the nose, eyes, brow, and occiput appearing in succession over the anterior margin of the perineum. *Forceps should not be applied to the mentum posterior presentation because vaginal delivery is impossible except in very small fetuses.*

VACUUM EXTRACTION

Vacuum Extractor Design

With vacuum delivery, suction is created within a cup placed on the fetal scalp such that traction on the cup aids fetal expulsion. In the United States, *vacuum extractor* is the preferred term, whereas in Europe it is commonly called a *ventouse* (Fig. 29-16). Theoretical benefits of this tool compared with forceps include simpler requirements for precise positioning on the fetal head and avoidance of space-occupying blades within the vagina, thereby mitigating maternal trauma.

FIGURE 29-16
Vacuum delivery systems. **A.** The *Kiwi OmniCup* contains a handheld vacuum-generating pump, which is attached via flexible tubing to a rigid plastic mushroom cup. **B.** The *Mityvac Mystic II MitySoft Bell Cup* has a soft bell cup attached by a semirigid shaft to a handheld pump.

Vacuum devices contain a cup, shaft, handle, and vacuum generator. Vacuum cups may be metal or hard or soft plastic, and they may also differ in their shape, size, and reusability. In the United States, nonmetal cups are generally preferred, and there are two main types. The soft cup is a pliable bell-shaped dome, whereas the rigid type has a firm flattened mushroom-shaped cup and circular ridge around the cup rim (Table 29-2). When compared, rigid mushroom cups generate significantly more traction force (Hofmeyr, 1990; Muise, 1993). With OP positions or with asynclitism, the flatter cup also permits improved placement at the flexion point, which is typically less accessible with these head positions. The trade-off is that the flatter cups have higher scalp laceration rates. Thus, many manufacturers recommend soft bell cups for more straightforward OA deliveries.

[a]Reusable cups.

[b]Suitable for occiput posterior positions or asynclitism.

[c]For extractions through a hysterotomy incision during cesarean delivery.

Several investigators have compared outcomes with various rigid and soft cups. Metal cups provide higher success rates but greater rates of scalp injuries, including cephalohematomas (O'Mahony, 2010). In another study, Kuit and coworkers (1993) found that the only advantage of the soft cups was a lower incidence of scalp injury. They reported a 14-percent episiotomy extension rate with both rigid and pliable cups. In a review, Vacca (2002) concluded that there were fewer scalp lacerations with the soft cup, but that the rate of cephalohematomas and subgaleal hemorrhage was similar between soft and rigid cups. Importantly, high-pressure vacuum generates large amounts of force regardless of the cup used (Duchon, 1998).

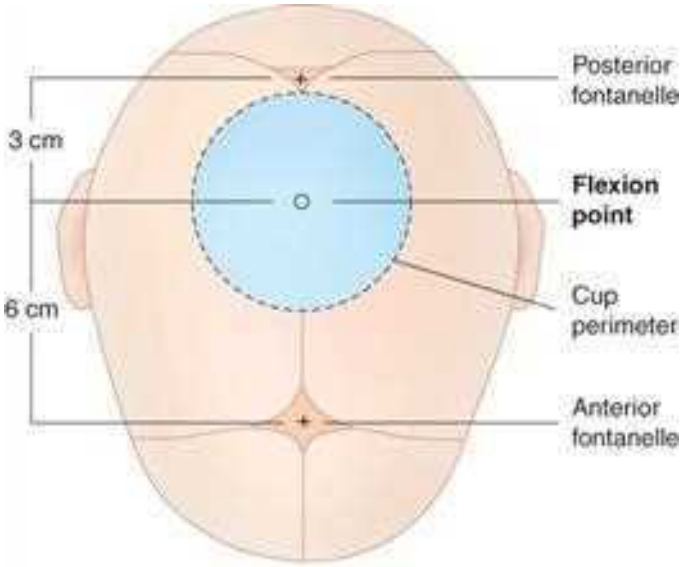
Aside from the cup, the shaft that connects the cup and handle may be flexible or semiflexible. Tubing-like flexible shafts may be preferred for OP positions or asynclitic presentation to permit better seating of the cup. Last, the vacuum generator may be handheld and actuated by the operator or may be held and operated by an assistant.

Technique

An important step in vacuum extraction is proper cup placement over the *flexion point*. This pivot point maximizes traction, minimizes cup detachment, flexes but averts twisting the fetal head, and delivers the smallest head diameter through the pelvic outlet. This improves success rates, lowers fetal scalp injury rates, and lessens perineal trauma because the smallest fetal head diameter distends the vulva (Baskett, 2008).

The flexion point is found along the sagittal suture, approximately 3 cm in front of the posterior fontanel and approximately 6 cm from the anterior fontanel. Because cup diameters range from 5 to 6 cm, when properly placed, the cup rim lies 3 cm from the anterior fontanel (Fig. 29-17). Placement of the cup more anteriorly on the fetal cranium—near the anterior fontanel—should be avoided as it leads to cervical spine extension during traction unless the fetus is small. Such placement also delivers a wider fetal head diameter through the vaginal opening. Last, asymmetrical placement relative to the sagittal suture may worsen asynclitism. For elective use, cup placement in OA positions is seldom difficult. In contrast, when the indication for delivery is failure to descend caused by occipital malposition— with or without asynclitism or deflexion—cup positioning can be difficult.

FIGURE 29-17
Drawing demonstrates correct cup placement at the flexion point. Along the sagittal suture, this spot lies 3 cm from the posterior fontanel and 6 cm from the anterior fontanel.



During cup placement, maternal soft tissue entrapment predisposes the mother to lacerations and virtually ensures cup dislodgement, colloquially called a "pop off." Thus, the entire cup circumference should be palpated both before and after the vacuum has been created and again prior to traction to exclude such entrapment. Gradual vacuum creation is advocated by some and is generated by increasing the suction in increments of 0.2 kg/cm^2 every 2 minutes until a total negative pressure of 0.8 kg/cm^2 is reached (Table 29-3). That said, other studies have shown that negative pressure can be increased to 0.8 kg/cm^2 in <2 minutes without a significant difference in efficacy or in maternal and fetal outcomes (Suwannachat, 2011, 2012).

TABLE 29-3
Vacuum Pressure Conversions

mm Hg	cm Hg	inches Hg	lb/in^2	kg/cm^2
100	10	3.9	1.9	0.13
200	20	7.9	3.9	0.27
300	30	11.8	5.8	0.41
400	40	15.7	7.7	0.54
500	50	19.7	9.7	0.68
600	60	23.6	11.6	0.82

Once suction is created, the instrument handle is grasped, and traction is initiated. Similar to forceps delivery, traction angles mirror that in Figure 29-10. Efforts are intermittent and coordinated with maternal expulsive efforts. Manual torque to the cup is avoided as it can cause cup displacement or cephalohematomas and, with metal cups, "cookie-cutter"–type scalp lacerations. Thus, OA oblique positions are corrected not by rotation, but solely by downward outward traction. During pulls, the operator should place the nondominant hand within the vagina, with the thumb on the extractor cup and one or more fingers on the fetal scalp. So positioned,

descent of the presenting part can be judged and the traction angle can be adjusted with head descent. In addition, the relationship of the cup edge to the scalp can be assessed to help detect cup separation.

Between contractions, some physicians will lower the suction levels to decrease rates of scalp injury, whereas others will maintain suction in cases with a nonreassuring fetal heart rate to aid rapid delivery. No differences in maternal or fetal outcome were noted if the level of vacuum was decreased between contractions or if an effort was made to prevent fetal loss of station (Bofill, 1997). Once the head is extracted, the vacuum pressure is relieved and the cup removed.

Vacuum extraction should be considered a trial. Without early and clear evidence of descent toward delivery, an alternative delivery approach should be considered. As a general guideline, progressive descent should accompany each traction attempt. Neither data nor consensus are available regarding the number of pulls required to effect delivery, the maximum number of cup pop-offs that can be tolerated, or optimal total duration of the procedure. Some manufacturers have recommendations regarding these in their instructional literature (Clinical Innovations, 2016; CooperSurgical, 2011).

During a vacuum extraction trial, cup dislodgement due to technical failure or less than optimal placement should not be equated with dislodgement under ideal conditions of exact cup placement and optimal vacuum maintenance. These cases may merit either additional attempts at placement or, alternatively, a trial of forceps (Ezenagu, 1999; Williams, 1991). The least desirable cases are those in which traction without progress or multiple disengagements occur following correct cup application and appropriate traction. As with forceps, clinicians should embrace a willingness to abandon attempts at vacuum extraction if satisfactory progress is not made (American College of Obstetricians and Gynecologists, 2015).

CHAPTER 30: Cesarean Delivery and Peripartum Hysterectomy

The anterior surface of the uterus is opened longitudinally along its midline. This is best accomplished by making an incision a few centimetres long with a scalpel, and then rapidly enlarging it with the scissors to 16 or 18 centimetres. The membranes are then ruptured, the child is seized by one foot and rapidly extracted.

—J. Whitridge Williams (1903)

INTRODUCTION

From the above description, cesarean technique has evolved during the past century. For example, preference for classical hysterotomy has given way to low transverse incision. Evidence-based data now guide many surgical steps and are presented throughout this chapter.

Of definitions, *cesarean delivery* defines the birth of a fetus via laparotomy and then hysterotomy. This definition is not applied to removal of the fetus from the abdominal cavity in the case of uterine rupture or with abdominal pregnancy. Rarely, hysterotomy is performed in a woman who has just died or in whom death is expected soon—*postmortem* or *perimortem cesarean delivery* (Chap. 47, Cardiopulmonary Resuscitation).

In some instances, abdominal hysterectomy is indicated following delivery. When performed at the time of cesarean delivery, the operation is termed *cesarean hysterectomy*. If done within a short time after vaginal delivery, it is termed *postpartum hysterectomy*. *Peripartum hysterectomy* is a broader term that combines these two. In most cases, hysterectomy is total, but supracervical hysterectomy is an option. The adnexa are not usually removed. In most instances, a simple or type I hysterectomy is performed. However, for women with invasive cervical cancer, *radical hysterectomy* removes the uterus, parametrium, and proximal vagina to achieve tumor excision with negative margins. Also, for cases of placenta percreta that extend toward the pelvic sidewall, similar radical excision of the parametrium may be needed.

CESAREAN DELIVERY IN THE UNITED STATES

In the United States, the cesarean delivery rate rose from 4.5 percent in 1970 to 32.9 percent in 2009. Following this peak, the rate has trended slightly downward, and it was 32.0 percent in 2015 (Martin, 2017). Some indications for performing cesarean delivery are shown in Table 30-1. More than 85 percent of these operations are performed for four reasons—prior cesarean delivery, dystocia, fetal jeopardy, or abnormal fetal presentation. The latter three compose the main indications for primary cesarean delivery (Barber, 2011; Boyle, 2013).

TABLE 30-1

Some Indications for Cesarean Delivery

Maternal
Prior cesarean delivery
Abnormal placentation
Maternal request
Prior classical hysterotomy
Unknown uterine scar type
Uterine incision dehiscence
Prior full-thickness myomectomy
Genital tract obstructive mass
Invasive cervical cancer
Prior trachelectomy
Permanent cerclage
Prior pelvic reconstructive surgery
Prior significant perineal trauma
Pelvic deformity
HSV or HIV infection
Cardiac or pulmonary disease
Cerebral aneurysm or arteriovenous malformation
Pathology requiring concurrent intraabdominal surgery
Perimortem cesarean delivery
Maternal-Fetal
Cephalopelvic disproportion
Failed operative vaginal delivery
Placenta previa or placental abruption
Fetal
Nonreassuring fetal status
Malpresentation
Macrosomia
Congenital anomaly
Abnormal umbilical cord Doppler study
Thrombocytopenia

Prior neonatal birth trauma

HIV = human immunodeficiency virus; HSV = herpes simplex virus.

The reasons for persistently significant cesarean rates are not completely understood, but some explanations include the following:

1. Women are having fewer children, thus, a greater percentage of births are among *nulliparas,* who are at increased risk for cesarean delivery.
2. The average *maternal age* is rising, and older women, especially nulliparas, have a higher risk of cesarean delivery.
3. The use of *electronic fetal monitoring* is widespread. This practice is associated with an increased cesarean delivery rate compared with intermittent fetal heart rate auscultation. Fetal distress accounts for only a minority of all cesareans. In many more cases, concern for an abnormal or "nonreassuring" fetal heart rate tracing prompts cesarean delivery.
4. Most fetuses presenting *breech* are now delivered by cesarean.
5. The frequency of *operative vaginal delivery* has declined.
6. Rates of *labor induction* continue to rise, and induced labor, especially among nulliparas, raises the cesarean delivery rate.
7. *Obesity,* which is a cesarean delivery risk, has reached epidemic proportions.
8. Rates of cesarean delivery in women with preeclampsia have increased, whereas labor induction rates for these patients have declined.
9. The rate of *vaginal birth after cesarean—VBAC*—has decreased from a high of 28 percent in 1996 and was 11 percent in 2014 (Hamilton, 2015).
10. Elective cesarean deliveries are increasingly being performed for various indications that include *maternal request,* concern for *pelvic floor injury* associated with vaginal birth, and reduction of *fetal injury* rates.
11. *Assisted reproductive technology* is more widely used than in the past and is associated with greater cesarean delivery rates (Reddy, 2007).
12. *Malpractice litigation* related to fetal injury during spontaneous or operative vaginal delivery continues to contribute to the present cesarean delivery rate.

CESAREAN DELIVERY RISKS

To provide accurate informed consent, understanding both maternal and neonatal risks and benefits with surgery is essential. In broad terms, cesarean delivery has higher maternal surgical risks for the current and subsequent pregnancies compared with spontaneous vaginal birth. This is balanced against lower rates of perineal injury and short-term pelvic floor disorders. For the neonate, cesarean delivery offers lower rates of birth trauma and stillbirth but greater rates of initial respiratory difficulties.

Maternal Mortality and Morbidity

For the mother, death attributable solely to cesarean delivery is rare in the United States. Even so, numerous studies attest to increased mortality risks. Clark and colleagues (2008), in a review of nearly 1.5 million pregnancies, found maternal mortality rates of 2.2 per 100,000 cesarean deliveries compared with 0.2 per 100,000 vaginal births. In a metaanalysis of 203 studies, Guise and coworkers (2010) reported a maternal mortality rate of 13 per 100,000 with elective repeat cesarean delivery compared with 4 per 100,000 women undergoing a trial of labor after prior cesarean.

Similar to mortality rates, the frequencies of some maternal complications are increased with all cesarean compared with vaginal deliveries. Villar and associates (2007) reported that maternal morbidity rates increased twofold with cesarean compared with vaginal delivery. Principal among these are infection, hemorrhage, and thromboembolism. In addition, anesthetic complications, which also rarely include death, have a greater incidence with cesarean compared with vaginal delivery (Cheesman, 2009; Hawkins, 2011). Adjacent organs infrequently may be injured, which is described in detail in Urinary Tract or Bowel Injury.

Women who undergo a cesarean delivery are much more likely to be delivered by a repeat operation in subsequent pregnancies. For women undergoing subsequent cesarean, the maternal risks just described are even greater (Cahill, 2006; Marshall, 2011; Silver, 2006).

As an advantage, cesarean delivery is associated with lower rates of urinary incontinence and pelvic organ prolapse than is vaginal birth (Glazener, 2013; Gyhagen, 2013a,b; Handa, 2011; Leijonhufvud, 2011). Rates of anal incontinence appear uninfluenced by delivery route (Fritel, 2007; Nelson, 2010). Protective advantages persist to some degree over time, but cesarean delivery is not totally protective. Moreover, longitudinal studies suggest that initial pelvic floor advantages gained from cesarean delivery are lost as women age (Dolan, 2010; MacArthur, 2011, 2013; Nelson, 2010). To address this, the National Institutes of Health (2006) held a conference on cesarean delivery on maternal request. It summarized that stress urinary incontinence rates after elective cesarean delivery are lower than those following vaginal delivery. However, the duration of this protection is unclear, particularly in older and multiparous populations. This same panel considered the evidence implicating vaginal delivery in other pelvic floor disorders to be weak and not favoring either delivery route.

Neonatal Morbidity

Cesarean delivery is associated with a lower rate of fetal trauma (Linder, 2013; Moczygemba, 2010). Alexander and colleagues (2006) found that fetal injury complicated 1 percent of cesarean deliveries. Skin laceration was most common, but others included cephalohematoma, clavicular fracture, brachial plexopathy, skull fracture, and facial nerve palsy. Cesarean deliveries following a failed operative vaginal delivery attempt had the highest injury rate, whereas the lowest rate—0.5 percent—occurred in the elective cesarean delivery group. That said, Worley and colleagues (2009) noted that approximately a third of women who were delivered at Parkland Hospital entered spontaneous labor at term, and 96 percent of these delivered vaginally without adverse neonatal outcomes.

Some evidence shows higher asthma and allergy rates in those delivered by cesarean. With the hope to improve neonatal microbiota, swabbing the newborn mouth with a gauze that was incubated in the maternal vagina 1 hour before surgery is described in preliminary studies. However, the American College of Obstetricians and Gynecologists (2017e) does not encourage this practice due to few data and the potential for transmission of harmful organisms.

Cesarean Delivery on Maternal Request

Some women request elective cesarean delivery. Data regarding the true incidence of *cesarean delivery on maternal request (CDMR)* are poor. Rate estimates range from 1 to 8 percent in the United States (Barber, 2011; Declercq, 2005; Gossman, 2006; Menacker, 2006).

Reasons for the request include pelvic floor protection, convenience, fear of childbirth, and reduced risk of fetal injury. Data to address these concerns are slowly accruing. One study of more than 66,000 Chinese parturients compared outcomes of those who elected planned vaginal or primary cesarean delivery (Liu, 2015). Short-term serious maternal morbidity and neonatal mortality rates were similar. For the newborns, rates of birth trauma, infection, and hypoxic ischemic encephalopathy were low in both groups but statistically lower with cesarean delivery. Respiratory distress syndrome rates were greater in the CMDR cohort. A smaller study comparing these two routes of delivery support these findings (Larsson, 2011).

The debate surrounding CDMR includes these medical points, the concept of informed free choice by the woman, and the autonomy of the physician in offering CMDR. During the National Institutes of Health panel (2006) cited above, participants noted that most of the maternal and neonatal outcomes examined had insufficient data to permit recommendations. Despite this, the panel was able to draw a few conclusions, which are echoed by the American College of Obstetricians and Gynecologists (2017a). Namely, CMDR should not be performed before 39 weeks' gestation unless fetal lung maturity is confirmed. Cesarean delivery is ideally avoided in women desiring several children because of placental implantation abnormalities and cesarean hysterectomy risks. Finally, CMDR should not be motivated by the unavailability of effective pain management.

PATIENT PREPARATION

Delivery Availability

No nationally recognized standard of care currently dictates the acceptable time interval to begin cesarean delivery. Previously, a 30-minute decision-to-incision interval was recommended. In studying this, Bloom and coworkers (2001) found that 69 percent of 7450 cesareans performed in labor commenced more than 30 minutes after the decision to operate. In a second study, Bloom and colleagues (2006) evaluated cesarean deliveries performed for emergency indications. They reported that failure to achieve a cesarean delivery decision-to-incision time of less than 30 minutes was not associated with a negative neonatal outcome. A subsequent systematic review echoed this finding (Tolcher, 2014). Despite this, when faced with an acute, catastrophic deterioration in fetal condition, cesarean delivery usually is indicated as rapidly as possible, and thus purposeful delays are inappropriate. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that facilities giving obstetrical care should have the ability to initiate cesarean delivery in a time frame that best incorporates maternal and fetal risks and benefits.

Informed Consent

Obtaining informed consent is a process and not merely a medical document (American College of Obstetricians and Gynecologists, 2015). The conversation should enhance a woman's awareness of her diagnosis and contain a discussion of medical and surgical care alternatives, procedure goals and limitations, and surgical risks. For women with a prior cesarean delivery, the option of a trial of labor should be included for suitable candidates. Also, in those desiring permanent sterilization or intrauterine device insertion, consenting for these can be completed concurrently.

An informed patient may decline a particular recommended intervention, and a woman's decision-making autonomy must be respected. In the medical record, clinicians should document her reasons for refusal and should note that the intervention's value and the health consequences of not proceeding with it have been explained.

For Jehovah's Witnesses, informed consent discussions regarding blood products ideally begin early in pregnancy. Acceptable blood products vary widely among individual women, and a preoperative checklist of approved products allows superior preparation (Hubbard, 2015; Husarova, 2016). In general, red cells, white cells, platelets, and plasma are viewed as primary blood components and are eschewed. However, certain clotting factors or cell fractions may be acceptable (Lawson, 2015). Before and after surgery, iron, folate, and, if necessary, erythropoietin are accepted agents to help maximize hemoglobin levels. Perioperatively, phlebotomy should be limited, and pediatric collection tubes are preferable. Intraoperative options include treatment of atony to limit blood loss; topical hemostatic agents, tranexamic acid, and desmopressin to promote clot formation; red blood cell salvage or acute normovolemic hemodilution to provide autologous donation; and controlled hypotensive anesthesia, uterine artery embolization, occlusive vascular balloons, and temporary aortic compression for uncontrolled bleeding (Belfort, 2011; Mason, 2015).

Timing of Scheduled Cesarean Delivery

Adverse neonatal sequelae from neonatal immaturity with elective delivery before 39 completed weeks are appreciable (Clark, 2009; Tita, 2009). To avoid these, assurance of fetal maturity before scheduled elective surgery is essential as outlined by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) and discussed in Chapter 31 (Labor and Delivery Considerations). To assist with this and other components of cesarean delivery planning, the American College of Obstetricians and Gynecologists (2011, 2014b) has created Patient Safety Checklists to be completed before the planned surgery.

Preoperative Care

If cesarean delivery is scheduled, a sedative may be given at bedtime the night before surgery. In general, no other sedatives, narcotics, or tranquilizers are administered until after the fetus is born. In one small randomized trial, no benefits were gained from a presurgical enema (Lurie, 2012). Solid food intake is stopped at least 6 to 8 hours before the procedure. Uncomplicated patients may have moderate amounts of clear liquids up to 2 hours before surgery (American Society of Anesthesiologists, 2016). This comports with Enhanced Recovery After Surgery (ERAS) protocols that strive to maintain anabolic homeostasis and advocate clear carbohydrate drinks up to 2 hours before scheduled surgery and early postoperative feeding (Ljungqvist, 2017). Although evidence supports an ERAS approach for many procedures, data specifically addressing this for cesarean delivery are scarce (Wrench, 2015).

The woman scheduled for repeat cesarean delivery typically is admitted the day of surgery and evaluated by the obstetrical and anesthesia teams. Recently performed hematocrit and indirect Coombs test are reviewed. If the latter is positive, then availability of compatible blood must be ensured.

As discussed in Chapter 25 (Neuraxial Analgesia), regional analgesia is preferred for cesarean delivery. An antacid is given shortly before regional analgesia or induction of general anesthesia. One example is Bicitra, 30 mL orally in a single dose. This minimizes the lung injury risk from gastric acid aspiration. Once the woman is supine, a wedge beneath the right hip and lower back creates a left lateral tilt to aid venous return and avoid hypotension. Data are insufficient to determine the value of fetal monitoring before scheduled cesarean delivery in women without risk factors. Our practice is to obtain a 5-minute tracing prior to elective cases. At minimum, fetal heart sounds should be documented in the operating room prior to surgery.

Of further preparations, hair removal at the surgical site does not lower surgical site infection (SSI) rates (Kowalski, 2016). However, if hair is obscuring, it is removed the day of surgery by clipping, which is associated with fewer SSIs than shaving (Tanner, 2011). Chemical depilation the night before surgery compared with clipping has similar SSI rates (Lefebvre, 2015). An electrosurgical grounding pad is placed near the surgical incision and typically on the lateral thigh. An indwelling bladder catheter is typically placed at Parkland Hospital to collapse the bladder away from the hysterotomy incision, to avert urinary retention secondary to regional analgesia, and to allow accurate postoperative urine measurement. Small studies show that catheterization may be withheld in hemodynamically stable women to minimize urinary infections (Abdel-Aleem, 2014; Li, 2011; Nasr, 2009).

The risk of venous thromboembolism is increased with pregnancy and almost doubled in those undergoing cesarean delivery (James, 2006). Accordingly, for all women not already receiving thromboprophylaxis, the American College of Obstetricians and Gynecologists (2017d) recommends initiation of pneumatic compression hose before cesarean delivery. These are usually discontinued once the woman ambulates. Recommendations between organizations vary, and the American College of Chest Physicians suggests only early ambulation for women without risk factors who are undergoing cesarean delivery (Bates, 2012). For women already receiving prophylaxis or those with increased risk factors, they support escalation of prophylaxis. Last, the Royal College of Obstetricians and Gynaecologists (2015) are the most conservative and suggest pharmacological prophylaxis for the largest proportion of patients. These various methods and recommendations are discussed in Chapter 52 and are shown in Table 52-6.

Some women scheduled for cesarean delivery have concurrent comorbidity that requires specific management in anticipation of surgery. Among others, these include insulin-requiring or gestational diabetes, coagulopathy or thrombophilia, chronic corticosteroid use, and significant reactive airway disease. Surgical preparations are discussed in the respective chapters covering these topics.

Infection Prevention

Antibiotic Prophylaxis

Cesarean delivery is considered a clean contaminated case, and postoperative febrile morbidity is common. Numerous good-quality trials show that a single dose of an antibiotic given at the time of cesarean delivery significantly decreases infectious morbidity (Smaill, 2014). Although more obvious for women undergoing unscheduled cesarean delivery, this practice also pertains to women undergoing elective surgery (American College of Obstetricians and Gynecologists, 2016). Depending on drug allergies, most recommend a single intravenous dose of a β-lactam antibiotic—either a cephalosporin or extended-spectrum penicillin. A 1-g dose of cefazolin (Ancef) is an efficacious and cost-effective choice. Additional doses are considered in cases with blood loss >1500 mL or with duration longer than 3 hours. Recommendations for the best dose in obese parturients are conflicting (Ahmadzia, 2015; Maggio, 2015; Swank, 2015; Young, 2015). One recent pharmacokinetic analysis showed sufficient tissue levels with a 2-g dose for cesarean deliveries lasting 1.5 hours. Authors recommended consideration for redosing in obese women if surgeries were longer (Grupper, 2017).

A growing body of evidence supports extending the antibiotic spectrum (Andrews, 2003; Tita, 2008). One large randomized trial added azithromycin, 500 mg intravenously, to standard prophylaxis prior to cesarean delivery for women in labor or with ruptured membranes (Tita, 2016). Rates of wound infection and endometritis were significantly lower in the extended-spectrum group compared with those in the standard prophylaxis cohort.

In pregnant women with a history of infection with methicillin-resistant *Staphylococcus aureus* (MRSA), a single dose of vancomycin added to the standard prophylaxis for cesarean deliveries can be elected. Decolonization plays a limited role but may be considered prior to a planned cesarean delivery in women with known MRSA colonization (American College of Obstetricians and Gynecologists, 2016).

Significant penicillin or cephalosporin allergy, which manifests by anaphylaxis, angioedema, respiratory distress, or urticaria, merits prophylaxis with a single 600-mg intravenous dose of clindamycin combined with a weight-based dose of an aminoglycoside as an alternative. A 900-mg clindamycin dose is used for obese patients.

Antibiotic administration before surgical incision lowers postoperative infection rates without adverse neonatal effects compared with drug administration after umbilical cord clamping (Mackeen, 2014b; Sullivan, 2007; Witt, 2011). Prophylaxis is ideally administered within the 60 minutes prior to the start of planned cesarean delivery. For emergent delivery, antibiotics are given as soon as feasible.

Preoperative preparation of the abdominal wall skin is effective to prevent wound infection. Either chlorhexidine or povidone-iodine solutions are suitable (Hadiati, 2014; Ngai, 2015; Springel, 2017). In studies that found a difference, chlorhexidine was favored, and this is our practice (Menderes, 2012; Tuuli, 2016a). In addition, preoperative vaginal cleansing with a povidone-iodine scrub has been evaluated in small randomized trials (Haas, 2014; Caissutti, 2017). Some showed lower rates of metritis, especially for those with ruptured membranes or active labor, but not lower rates of wound infection (Haas, 2010; Memon, 2011; Yildirim, 2012). Some recommend preoperative vaginal cleansing, but we do not do this at Parkland Hospital.

Antibiotic prophylaxis against infective endocarditis is not recommended for most cardiac conditions—exceptions are women with cyanotic heart disease, prosthetic valves, or both (American College of Obstetricians and Gynecologists, 2016). Regimens selected for routine cesarean infection prophylaxis will also serve as appropriate endocarditis coverage (Chap. 49, Infective Endocarditis).

Other Preventions

Glycemic control in diabetics lowers wound infection rates and is emphasized in Chapter 57 (First Trimester). Smoking is another modifiable risk, and its mitigation is especially helpful for morbidly obese women (Alanis, 2010; Avila, 2012; Shree, 2016). Intraoperative normothermia lowers wound infection rates in general surgery and is a Surgical Care Improvement Project measure (Kurz, 1996; The Joint Commission, 2016). This tenet might logically be extrapolated to cesarean delivery, although definitive studies are lacking (Carpenter, 2012). Perioperative supplementation with high-concentration inspired oxygen does not lower wound infection rates (Duggal, 2013; Klingel, 2013).

Surgical Safety

The Joint Commission (2013) established a protocol to prevent surgical errors. For cesarean delivery, all relevant documents are verified immediately before surgery, and a “time out” is completed. The “time out” requires attention of the entire team to confirm that the patient, site, and procedure are correct. Important discussions also include introduction of the patient-care team members, verification of prophylactic antibiotics, estimation of procedure length, and communication of anticipated complications. Additionally, requests for special instrumentation should be addressed preoperatively to prevent potential patient compromise and intraoperative delays.

An instrument, sponge, and needle count before and after surgery is crucial to surgical safety. If counts are not reconciled, radiographic imaging for retained foreign objects is obtained (American College of Obstetricians and Gynecologists, 2014a).

CESAREAN DELIVERY TECHNIQUE

With minor variations, surgical performance of cesarean delivery is comparable worldwide. Most steps are founded on evidence-based data, and these have been reviewed by Dahlke and associates (2013). As with all surgery, a clear understanding of relevant anatomy is essential, and this is described and illustrated in Chapter 2 (Anterior Abdominal Wall).

Laparotomy

In obstetrics, a suprapubic transverse incision or a midline vertical one is chosen for laparotomy. Transverse abdominal entry is by either Pfannenstiel or Maylard incisions. Of all these, the Pfannenstiel incision is selected most frequently for cesarean delivery.

Transverse incisions follow Langer lines of skin tension. Thus, compared with vertical ones, Pfannenstiel incisions offer superior cosmesis and lower incisional hernia rates. Use of the Pfannenstiel incision, however, is often discouraged for cases in which a large operating space is essential or in which access to the upper abdomen may be needed. With transverse incisions, because of the layers created during incision of the internal and external oblique aponeuroses, purulent fluid can collect between these. Therefore, some favor a midline vertical incision for cases with high infection risks. Emergent entry is typically faster with vertical incision during primary and repeat cesarean delivery (Wylie, 2010). Last, neurovascular structures, which include the ilioinguinal and iliohypogastric nerves and superficial and inferior epigastric vessels, are often encountered with transverse incisions. Logically, bleeding, wound hematoma, and neurological disruption may more frequently complicate these incisions compared with vertical ones. The best incision for the morbidly obese parturient is unclear (Smid, 2016). As discussed in Chapter 48 (Bariatric Surgery), our preference with very obese women is a periumbilical midline vertical incision.

The Maylard incision differs mainly from the Pfannenstiel in that the bellies of the rectus abdominis muscle are transected horizontally to widen the operating space. It is technically more difficult due to its required muscle cutting and isolation and ligation of the inferior epigastric arteries, which lie laterally to these muscle bellies.

Once access is gained, metal handheld retractors provide exposure for hysterotomy. A few small randomized studies have evaluated postcesarean wound infection rates with a disposable plastic barrier retractor (Alexis-O). Results showing benefit are contradictory (Hinkson, 2016; Scolari Childress, 2016; Theodoridis, 2011).

Transverse Incisions

With the Pfannenstiel incision, the skin and subcutaneous tissue are incised using a low, transverse, slightly curvilinear incision. This is made at the level of the pubic hairline, which is typically 3 cm above the superior border of the symphysis pubis. The incision is extended laterally sufficiently to accommodate delivery—12 to 15 cm is typical.

Sharp dissection is continued through the subcutaneous layer to the fascia. The superficial epigastric vessels can usually be identified halfway between the skin and fascia, several centimeters from the midline, and are coagulated. If lacerated, these may be suture ligated with 3–0 plain gut suture or coagulated with an electrosurgical blade.

The fascia is then incised sharply at the midline. The anterior abdominal fascia is typically composed of two visible layers, the aponeurosis from the external oblique muscle and a fused layer containing aponeuroses of the internal oblique and transverse abdominis muscles. Ideally, the two layers are individually incised during lateral extension of the fascial incision. The inferior epigastric vessels usually lie outside the lateral border of the rectus abdominis muscle and beneath the fused aponeuroses of the internal oblique and transverse abdominis muscles. Thus, although infrequently required, extension of the fascial incision further laterally may cut these vessels. With extension, these vessels are best identified and coagulated or ligated to prevent bleeding and vessel retraction.

Once the fascia is incised, the inferior fascial edge is grasped with Kocher clamps and elevated by an assistant as the operator separates the fascial sheath from the underlying rectus abdominis muscle either bluntly or sharply until the superior border of the symphysis pubis is reached. Next, the superior fascial edge is grasped and again, separation of fascia from the rectus muscle is completed. Blood vessels coursing between the sheath and muscles are clamped, cut, and ligated, or they are coagulated with an electrosurgery blade. Meticulous hemostasis is imperative to lower rates of incisional hematoma and infection. The fascial separation progresses cephalad and laterally to create a semicircular area above the transverse incision with a radius of approximately 8 cm. This will vary depending on fetal size. The rectus abdominis and pyramidalis muscles are then separated in the midline, first superiorly and then inferiorly, by sharp and blunt dissection to expose the transversalis fascia and peritoneum.

The transversalis fascia and preperitoneal fat are bluntly dissected away to reach the underlying peritoneum. The peritoneum near the upper end of the incision is opened carefully, either bluntly or by elevating it with two hemostats placed approximately 2 cm apart. This upper site lowers cystotomy risks. The tented fold of peritoneum between the clamps is examined and palpated to ensure that omentum, bowel, or bladder is not adjacent. The peritoneum is then incised. The peritoneal incision is extended superiorly to the upper pole of the fascial dissection and downward to just above the peritoneal reflection over the bladder. Importantly, in women with prior intraabdominal surgery, including cesarean delivery, omentum or bowel may be adhered to the undersurface of the peritoneum. In women with obstructed labor, the bladder may be pushed cephalad almost to the level of the umbilicus.

Midline Vertical Incision

This incision begins 2 to 3 cm above the superior margin of the symphysis. It should sufficiently long to allow fetal delivery, and 12 to 15 cm is typical. Sharp or electrosurgical blade dissection through the subcutaneous layers ultimately exposes the anterior rectus sheath. A small opening is made sharply with scalpel in the upper half of the linea alba. Placement here helps avoid potential cystotomy. Index and middle fingers are placed beneath the fascia to elevate it, and the fascial incision is extended first superiorly and then inferiorly with scissors. Midline separation of the rectus muscles and pyramidalis muscles and peritoneal entry are similar to those with the Pfannenstiel incision.

Hysterotomy

Most often, the lower uterine segment is incised transversely as described by Kerr in 1921. Occasionally, vertical incision confined solely to the lower uterine segment may be elected (Krönig, 1912). In contrast, a classical incision begins as a low-vertical incision, which is then extended cephalad into the active portion of the uterine corpus. Last, a fundal or even posterior incision may be selected for cases with placental accrete syndromes.

Low Transverse Cesarean Incision

For most cesarean deliveries, this incision is preferred. Compared with a classical incision, it is easier to repair, causes less incision-site bleeding, and promotes less bowel or omentum adherence to the myometrial incision. Located in the inactive segment, it also is less likely to rupture during a subsequent pregnancy.

Before any hysterotomy, the surgeon palpates the fundus to identify degrees of uterine rotation. The uterus may be rotated so that one round ligament is more anterior and closer to the midline. In such cases, the uterus can be manually reoriented and held to permit centering of the incision. This avoids incision extension into and laceration of the adjacent uterine artery. A moist sponge may be used to pack protruding bowel away from the operative field.

The reflection of peritoneum at the upper margin of the bladder and overlying the lower uterine segment is grasped in the midline with forceps and incised transversely with scissors (Fig. 30-1). Following this initial incision, scissors are inserted between peritoneum and lower uterine segment. Open scissors are pushed laterally from the midline on each side. This transverse peritoneal incision extends almost the full length of the lower uterine segment. As the lateral margin on each side is approached, the scissors are directed slightly cephalad (Fig. 30-2). The lower edge of peritoneum is elevated, and the bladder is gently separated from the underlying lower uterine segment with blunt or sharp dissection within this vesicouterine space (Fig. 30-3). This bladder flap creation effectively moves the bladder away from the planned hysterotomy site. It also helps prevent bladder laceration if an unintended inferior hysterotomy extension occurs during fetal delivery.

FIGURE 30-1
The loose peritoneum above the bladder reflection is grasped with forceps and incised with Metzenbaum scissors.

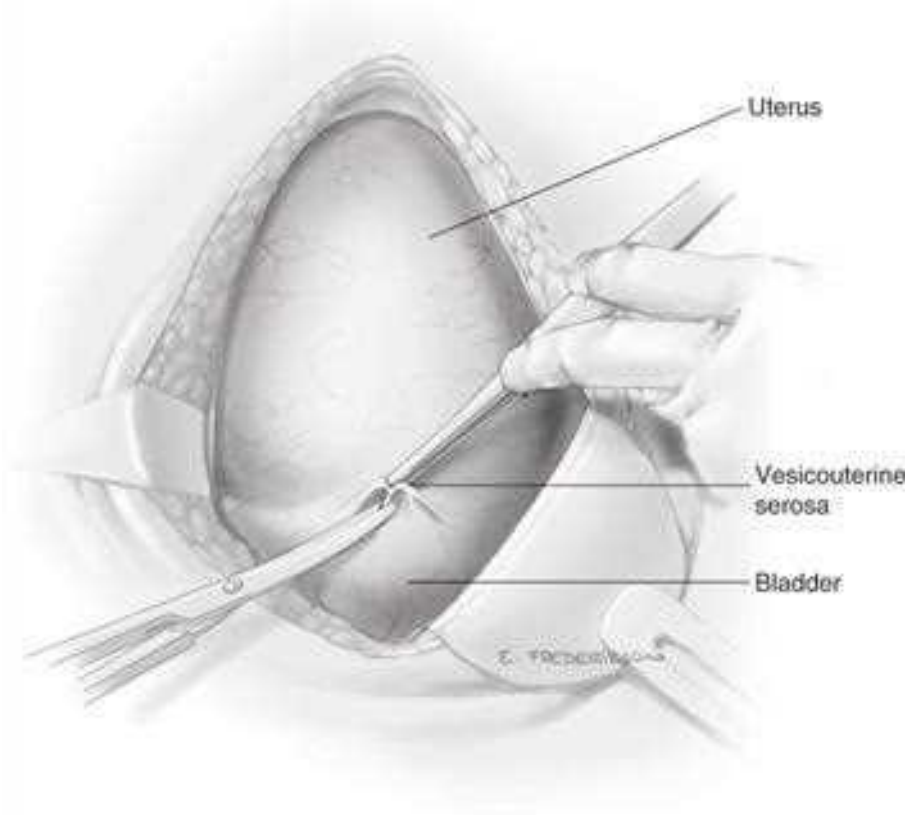

FIGURE 30-2

This peritoneal edge is elevated and incised laterally.

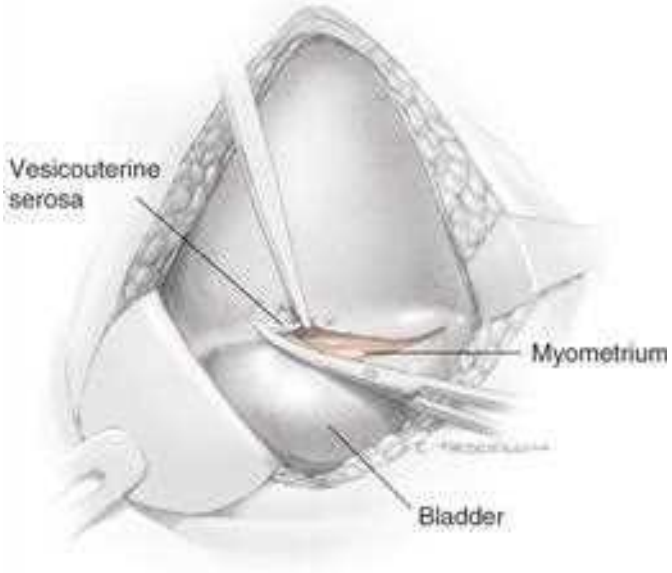

FIGURE 30-3

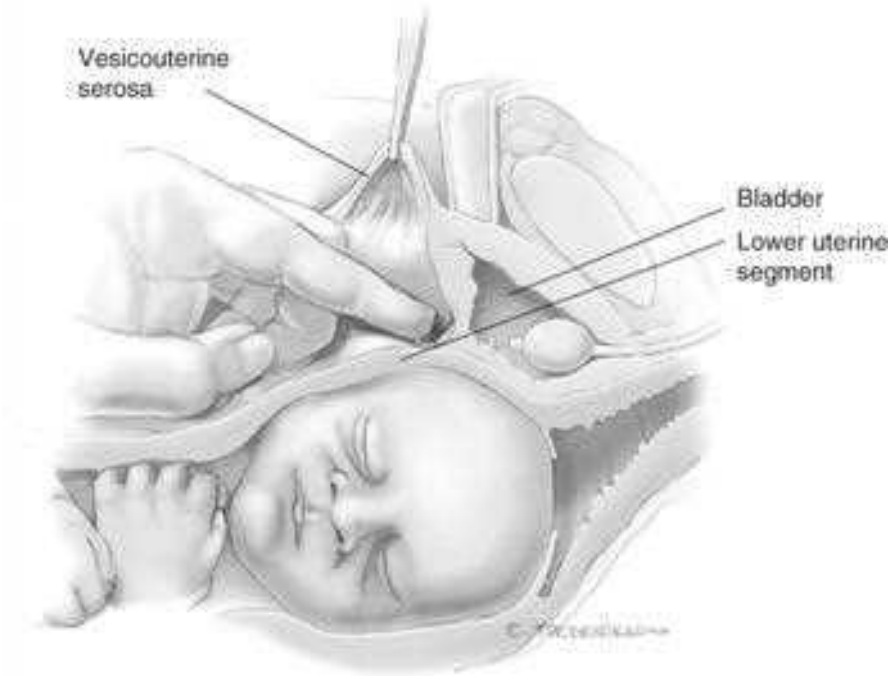
Cross section shows blunt dissection of the bladder off the uterus to expose the lower uterine segment.



In general, this caudad separation of bladder does not exceed 5 cm and usually is less. However, in instances in which cesarean hysterectomy is planned or anticipated, extended caudad dissection is recommended to aid total hysterectomy and decrease the risk of cystotomy.

Some surgeons do not create a bladder flap. The main advantage is a shorter skin incision-to-delivery time. However, data supporting this practice are limited (O'Neill, 2014; Tuuli, 2012).

Uterine Incision

The uterus is entered through the lower uterine segment. Digital palpation to find the physiological border between firmer upper segment myometrium and the more flexible lower segment can guide placement. The bladder flap incision can also serve as a guide, and a hysterotomy site near this line is often selected.

For women with advanced or complete cervical dilatation, the hysterotomy is placed relatively higher. Failure to adjust increases the risk of lateral extension of the incision into the uterine arteries. It may also lead to incision of the cervix or vagina rather than the lower uterine segment. Such incisions into the cervix can distort postoperative cervical anatomy.

The uterus can be incised by various techniques. Each is initiated by using a scalpel to transversely incise the exposed lower uterine segment for 1 to 2 cm in the midline (Fig. 30-4). Repetitive shallow strokes avoid fetal laceration. As the myometrium thins, a fingertip can then bluntly enter the uterine cavity. Once the uterus is opened, the hysterotomy is lengthened by simply spreading the incision, using lateral and slightly upward pressure applied with each index finger (Fig. 30-5). Some evidence also supports widening the lower-uterine-segment incision instead with fingers pulling in opposition in a cephalocaudad direction (Cromi, 2008; Xodo, 2016).

FIGURE 30-4

The myometrium is incised with shallow strokes to avoid cutting the fetal head.

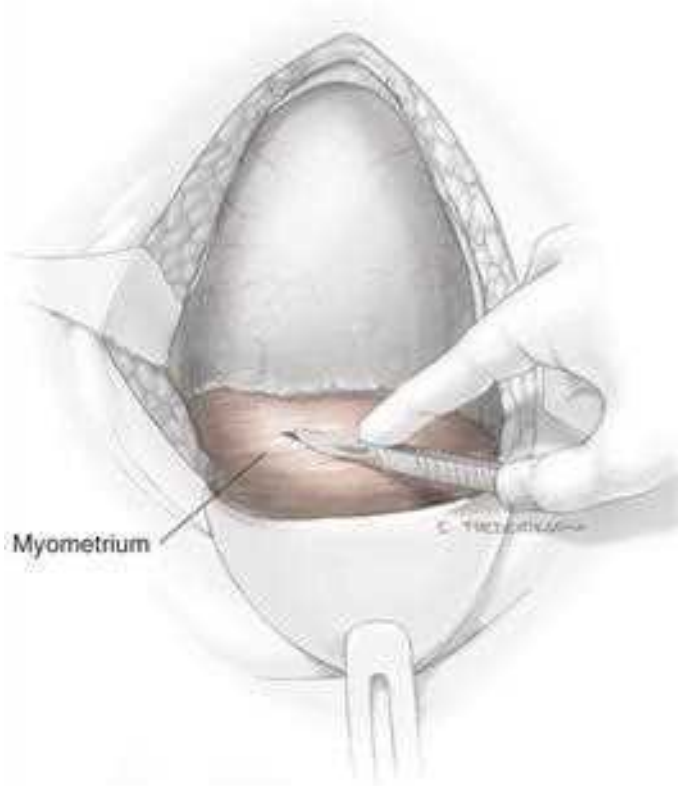


FIGURE 30-5

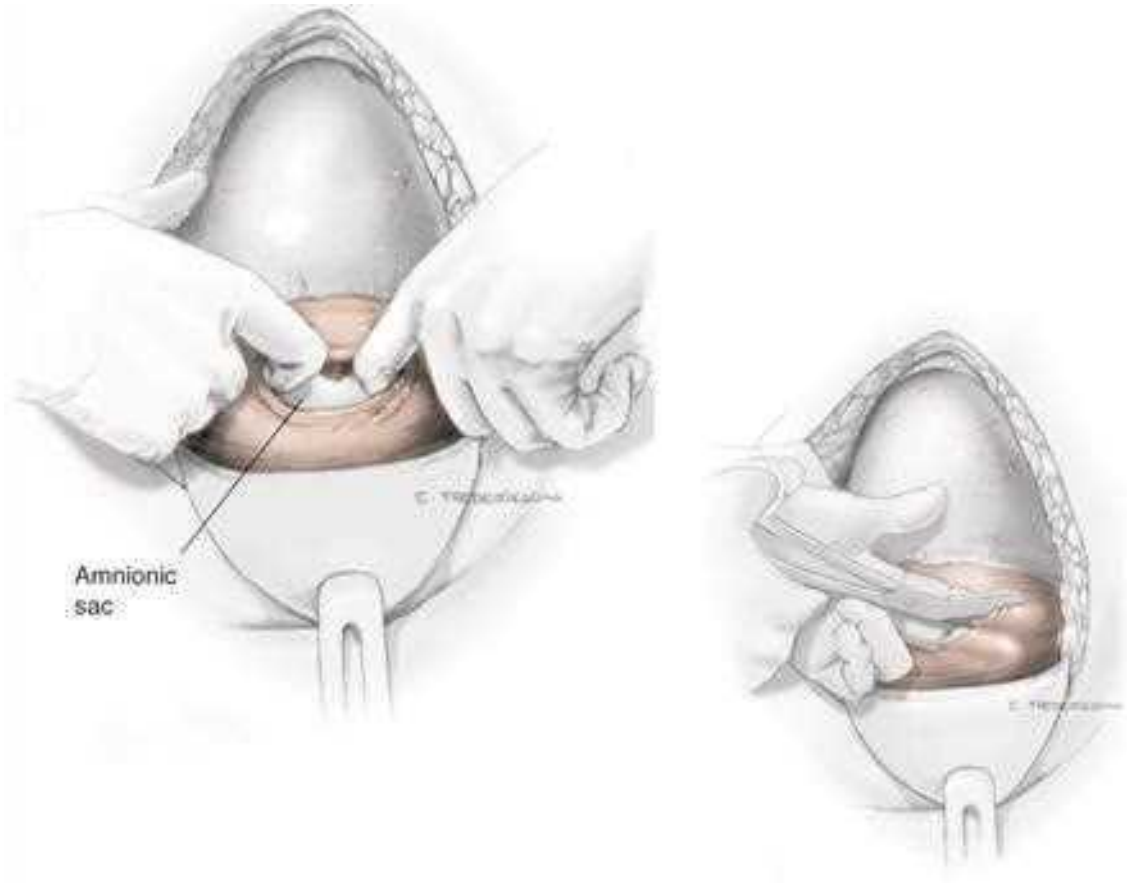
After entering the uterine cavity, the incision is extended laterally with fingers or with bandage scissors (*inset*).



Alternatively, if the lower uterine segment is thick and unyielding, cutting laterally and then slightly upward with bandage scissors will lengthen the incision. Importantly, when scissors are used, the index and midline fingers of the nondominant hand should be insinuated beneath the myometrium and above fetal parts to

prevent fetal laceration. Comparing blunt and sharp expansion of the initial uterine incision, blunt stretch is associated with fewer unintended incision extensions, shorter operative time, and less blood loss. However, the rates of infection and need for transfusion do not differ (Asıcıoglu, 2014; Saad, 2014).

The uterine incision is made large enough to allow delivery of the fetus without tearing into the uterine vessels that course along the lateral uterine margins. If the placenta is encountered in the incision line, it must be either detached or incised. Placental function is thereby compromised, and thus delivery is performed expeditiously.

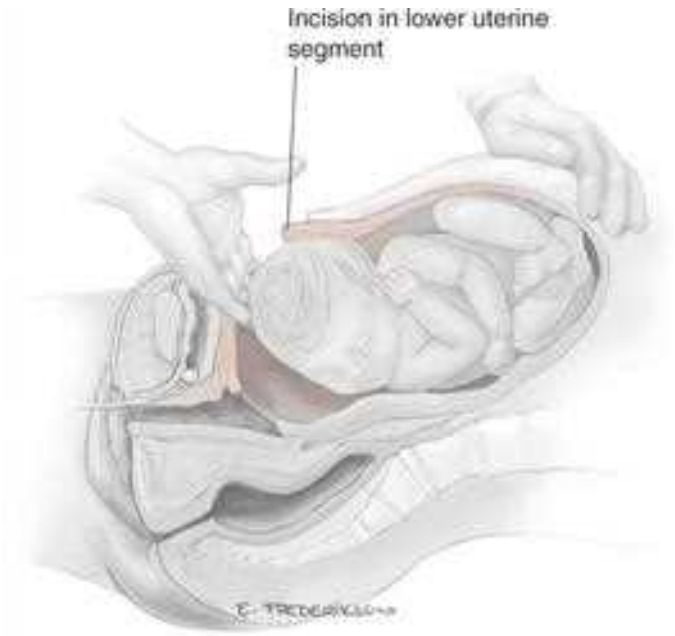
At times, a low transverse hysterotomy is selected but provides inadequate room for delivery. In such instances, one corner of the hysterotomy incision is extended cephalad into the contractile portion of the myometrium—a *J incision*. If this is completed bilaterally, a *U incision* is formed. Last, some prefer instead to extend in the midline—a *T incision*. As expected, each has higher intraoperative blood loss (Boyle, 1996; Patterson, 2002). Moreover, as these extend into the contractile portion, a trial of labor is more likely to be complicated by uterine rupture in future pregnancies.

Delivery of the Fetus

In a cephalic presentation, a hand is slipped into the uterine cavity between the symphysis and fetal head. The head is elevated gently with the fingers and palm through the incision. Once the head enters the incision, delivery may be aided by modest transabdominal fundal pressure (Fig. 30-6).

FIGURE 30-6

Delivery of the fetal head.



After a long labor with cephalopelvic disproportion, the fetal head may be tightly wedged in the birth canal. Release of an impacted fetal head raises the risk of hysterotomy extension, of associated blood loss, and of fetal skull fracture. In this situation, there are three considerations for delivery. First, a “push” method may be used. With this, upward pressure exerted by a hand in the vagina by an assistant will help to dislodge the head and allow its delivery above the symphysis. If this is anticipated, a patient in frog-leg position may allow easier vaginal access.

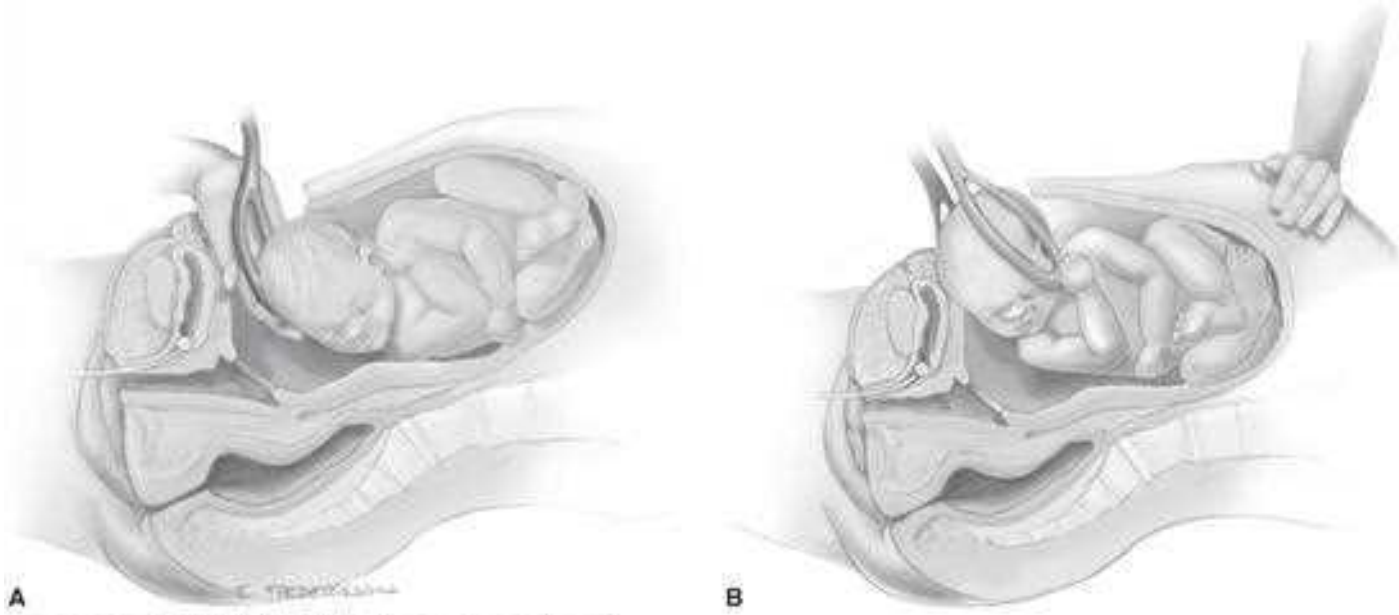
Second, as an alternative, a “pull” method grasps the fetal legs to bring them through the hysterotomy. The fetus is then delivered by traction as one would complete a breech extraction. Support for this latter approach comes only from small randomized trials and retrospective cohort studies (Berhan, 2014; Jeve, 2016; Nooh, 2017). A low vertical hysterotomy incision, which will give more room for the “pull” technique, may be selected. If a low transverse incision has already been made, then this can be extended to a J-, U-, or T-incision as previously discussed.

The third method is use of the “fetal pillow,” which is a distensible intravaginal balloon that when inflated, elevates the fetal head. The device is available outside the United States, but evidence for its efficacy is limited (Safa, 2016; Seal, 2016).

Conversely, in women without labor, the fetal head may be unmolded and without a leading cephalic point. The round head may be difficult to lift through the uterine incision in a relatively thick lower segment that is unattenuated by labor. In such instances, either forceps or a vacuum device may be used to deliver the fetal head (Fig. 30-7).

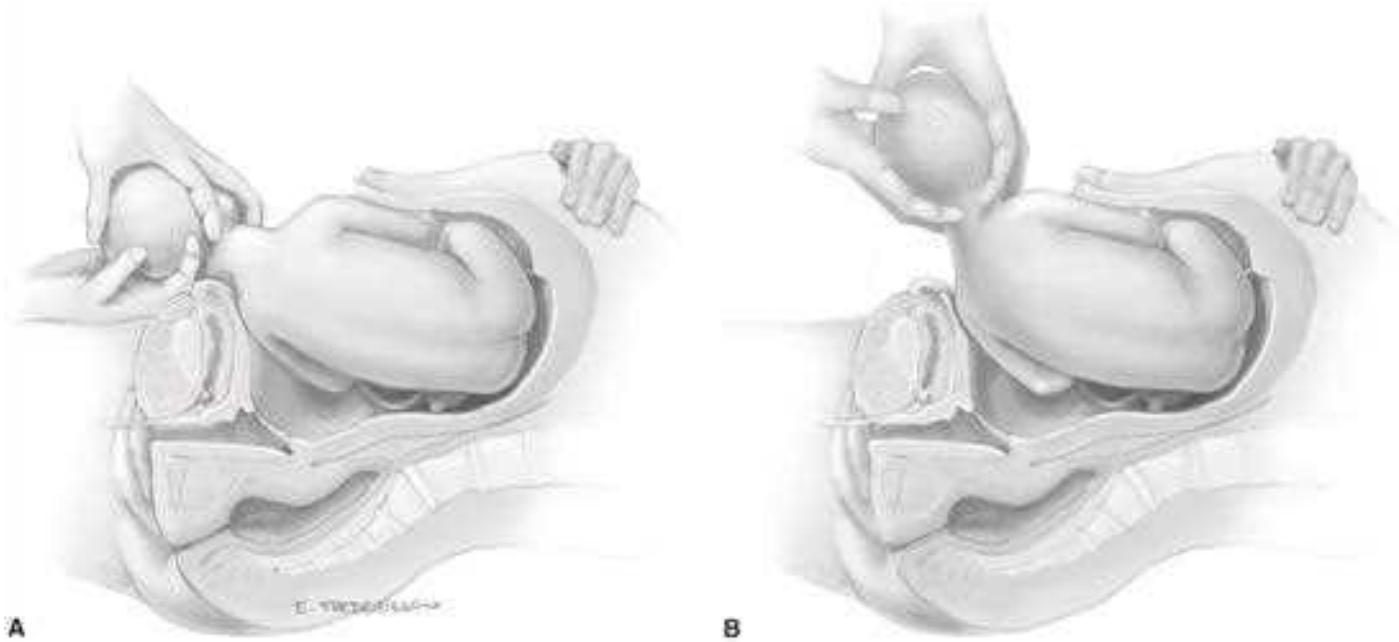
FIGURE 30-7

A. The first cesarean forceps blade is placed. **B.** Slight upward and outward traction is used to lift the head through the incision.



After head delivery, a finger should be passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops. If present, these are slipped over the head. The head is rotated to an occiput transverse position, which aligns the fetal bisacromial diameter vertically. The sides of the head are grasped with two hands, and gentle downward traction is applied until the anterior shoulder enters the hysterotomy incision (Fig. 30-8). Next, by upward movement, the posterior shoulder is delivered. During delivery, abrupt or powerful force is avoided to avert brachial plexus injury. With steady outward traction, the rest of the body then readily follows. Gentle fundal pressure may aid this.

FIGURE 30-8
The anterior **(A)** and then the posterior **(B)** shoulder are delivered.



With some exceptions, current American Heart Association neonatal resuscitation recommendations eschew suctioning immediately following birth, even with meconium present (Wyckoff, 2015). A fuller discussion of this and delayed umbilical cord clamping is found in Chapter 27 (Delivery of the Shoulders). The umbilical cord is clamped, and the newborn is given to the team member who will conduct resuscitative efforts as needed.

Comparing elective cesarean under neuraxial anesthesia and spontaneous vaginal deliveries, studies show that the need for neonatal resuscitation is not practically significant between the two (Atherton, 2006; Gordon, 2005; Jacob, 1997). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that “a qualified person who is skilled in neonatal resuscitation should be in the delivery room.” At Parkland Hospital, pediatric nurse practitioners attend uncomplicated, scheduled cesarean deliveries. Notably, as anticipated neonatal risks rise, so too should the resuscitative skills of the attendants (Wyckoff, 2015).

To promote breastfeeding, the American College of Obstetricians and Gynecologists (2017b) recommends skin-to-skin contact between newborn and mother in the delivery room. Although most randomized trials focus on vaginal birth, several small studies support such contact following cesarean delivery, and this our practice (Moore, 2016; Stevens, 2014).

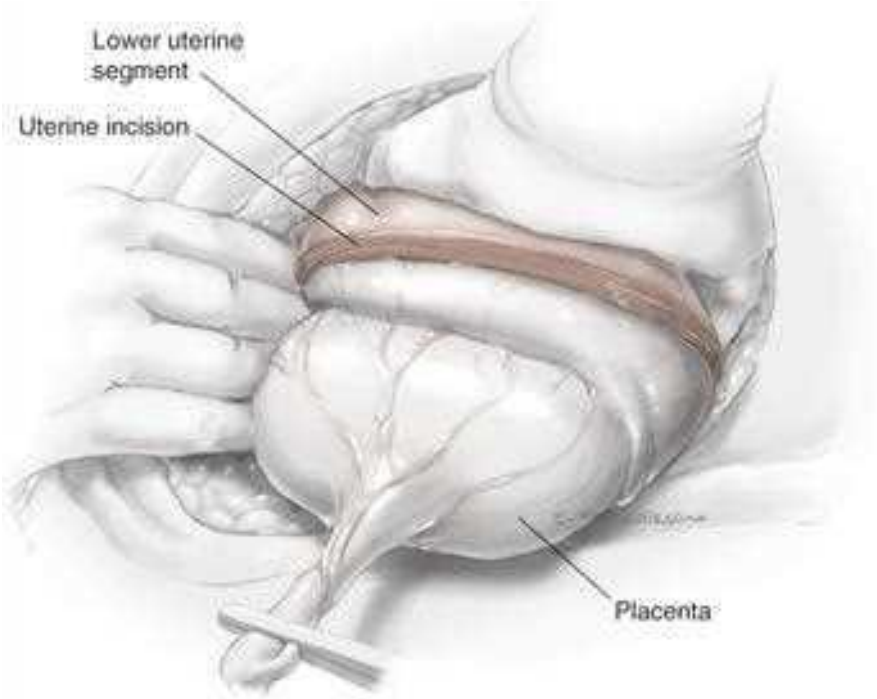
After birth, an intravenous infusion containing two ampules or 20 units of oxytocin per liter of crystalloid is infused at 10 mL/min. Some prefer higher infusion dosages, however, nondilute boluses are avoided because of associated hypotension (Roach, 2013). Once the uterus contracts satisfactorily, the rate can be reduced. An alternative is *carbetocin*—a longer-acting oxytocin derivative that is not available in the United States—that provides suitable, albeit more expensive, hemorrhage prophylaxis (Jin, 2016). Ergot-alkaloids are second-tier agents and carry hypertensive side effects. Carboprost, a 15-methyl derivative of prostaglandin $F_{2\alpha}$, is another second-tier agent used to treat uterine atony. Some but certainly not all studies indicate that misoprostol appears to perform similarly to oxytocin (Chaudhuri, 2014; Conde-Agudelo, 2013). Finally, some recommend the use of tranexamic acid added to a standard oxytocin infusion to decrease blood loss (Simonazzi, 2016; Wang, 2015). Its antifibrinolytic action and effects on thromboembolism rates in pregnant surgical patients are unclear. Larger trials are needed before widespread use. Additional discussions of all these agents are found in Chapter 41 (Risk Factors).

Delivery of the Placenta

The uterine incision is observed for any vigorously bleeding sites. These should be quickly clamped with Pennington or ring forceps. Although some surgeons may prefer manual removal of the placenta, spontaneous delivery prompted by some cord traction may reduce the risk of operative blood loss and infection (Anorlu, 2008; Baksu, 2005). Fundal massage may begin as soon as the fetus is delivered to hasten placental separation and delivery (Fig. 30-9).

FIGURE 30-9

Placenta bulging through the uterine incision as the uterus contracts. A hand gently massages the fundus to help aid spontaneous placental separation.



Immediately after delivery and quick gross inspection of the placenta, the uterine cavity is suctioned and wiped out with a gauze sponge to remove avulsed membranes, vernix, and clots. In the past, double-gloved fingers or ring forceps placed through the hysterotomy incision were used to dilate an ostensibly closed cervix. This practice does not reduce infection rates from potential hematometra and is not recommended (Kirscht, 2017; Liabsuetrakul, 2011).

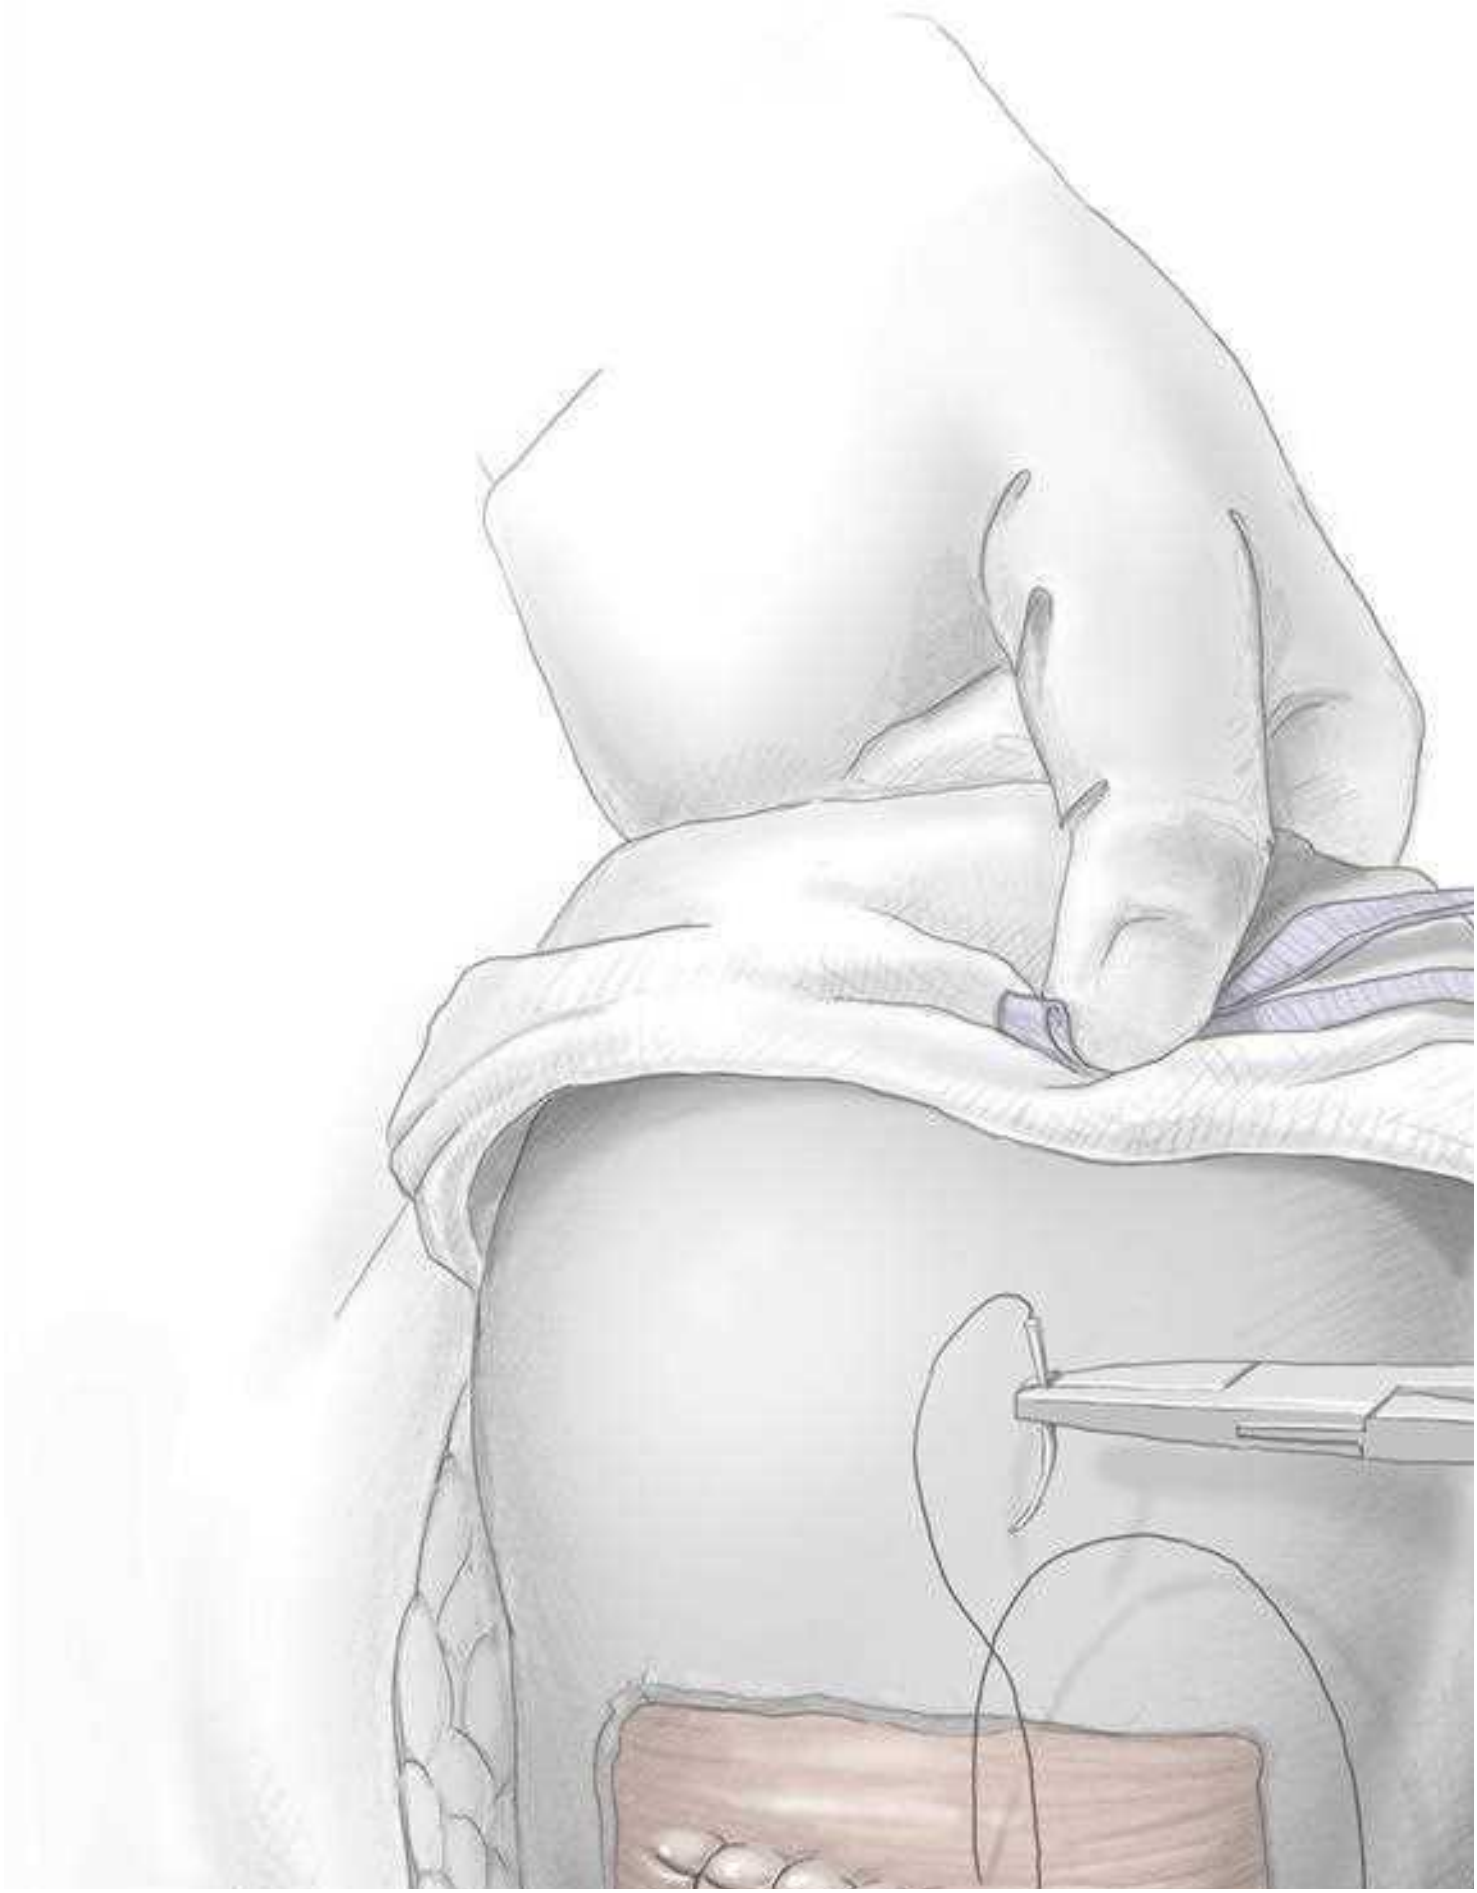
Uterine Repair

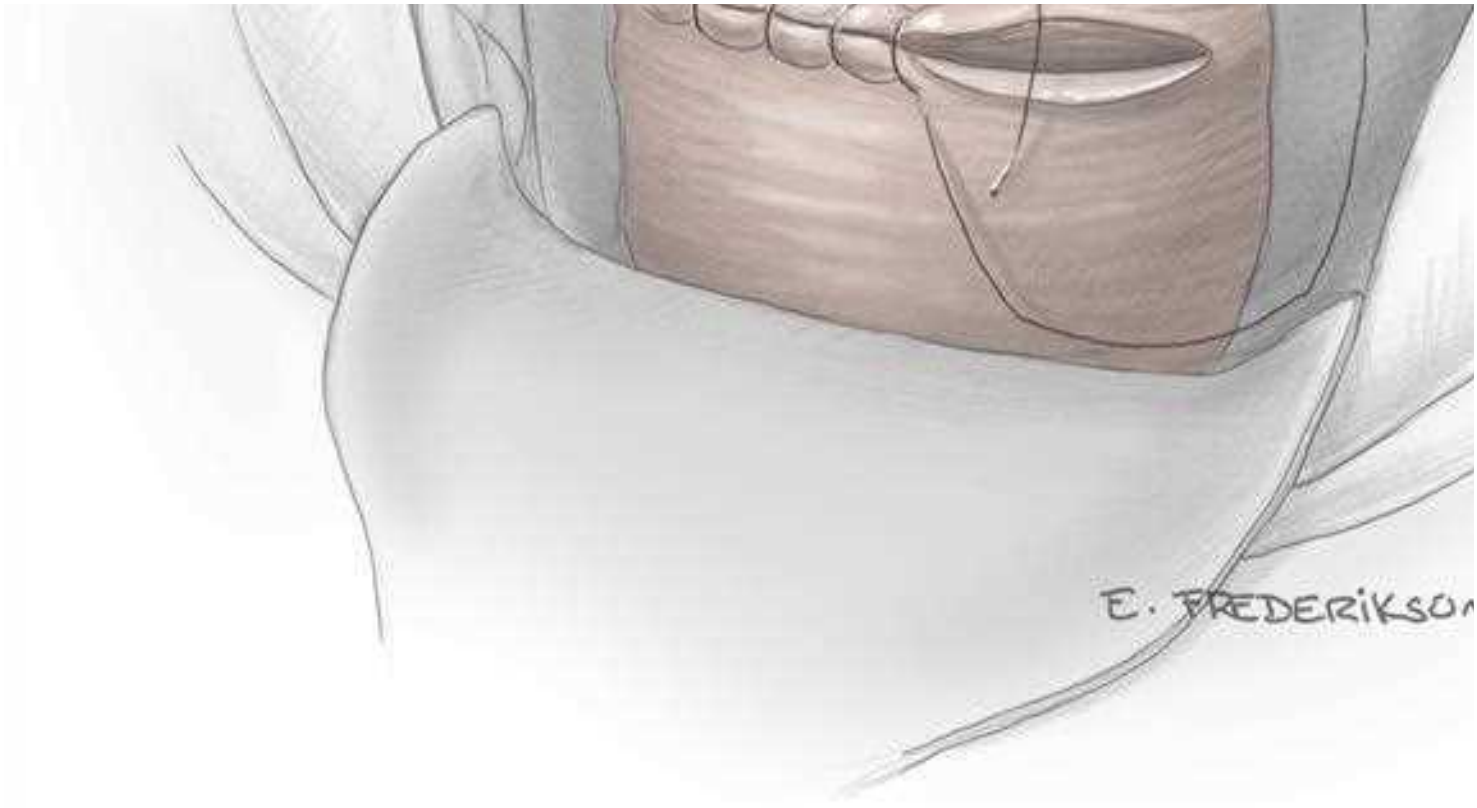
After placental delivery, the uterus is lifted through the incision and onto the draped abdominal wall, and the fundus is covered with a moistened laparotomy sponge. We favor this and believe a relaxed, atonic uterus can be recognized quickly and massage applied. Incision and bleeding points are more easily visualized and repaired, especially if there have been extensions. Adnexal exposure is superior, and thus, tubal sterilization is easier. Instead, some clinicians prefer to close the hysterotomy with the uterus in situ. Comparing these two approaches, febrile morbidity, pain, and blood loss are not significantly different (Walsh, 2009; Zaphiratos, 2015).

Before hysterotomy closure, previously clamped large vessels may be ligated separately or incorporated within the running incision closure. IUD insertion, if planned, is completed prior to hysterotomy closure (Chap. 38, Progestin Implants). One angle of the uterine incision is grasped to stabilize and maneuver the incision. The uterine incision is then closed with one or two layers of continuous 0- or no. 1 absorbable suture (Fig. 30-10). Chromic catgut suture is used by many, but some prefer synthetic delayed-absorbable polyglactin 910 (Vicryl). In subsequent pregnancy, neither suture type has been shown superior by mitigating against greater rates of adverse pregnancy outcomes such as uterine incision rupture (CORONIS Collaborative Group, 2016). Single-layer closure is typically faster and is not associated with higher rates of infection or transfusion (CAESAR Study Collaborative Group, 2010; Dodd, 2014; Roberge, 2014). Moreover, most studies observed that the number of layers does not significantly affect complication rates in the next pregnancy (Chapman, 1997; CORONIS Collaborative Group, 2016; Durnwald, 2003; Roberge, 2011).

FIGURE 30-10

The cut edges of the uterine incision are approximated with a running, locking suture.





At Parkland Hospital, we use a one-layer uterine closure with chromic catgut. The initial suture is placed just beyond one angle of the uterine incision. A continuous, locking suture line for hemostasis is then performed, with each suture penetrating the full thickness of the myometrium. The suture line then extends to a point just beyond the opposite incision angle. If approximation is not satisfactory after a single layer or if bleeding sites persist, then more sutures are required. Either another layer of running suture is placed to achieve approximation and hemostasis, or individual bleeding sites can be secured with targeted figure-of-eight or mattress stitches.

Traditionally, the peritoneum in the anterior cul-de-sac is approximated with a continuous 2–0 chromic catgut suture line. Multiple randomized trials suggest that omission of this step causes no postoperative complications (Grundsell, 1998; Irion, 1996; Nagele, 1996). If tubal sterilization is to be performed, it is completed as described in Chapter 39 (Puerperal Tubal Sterilization).

Adhesions

Following cesarean delivery, adhesions commonly form within the vesicouterine space or between the anterior abdominal wall and uterus. And, with each successive pregnancy, the percentage of affected women and adhesion severity rise (Morales, 2007; Tulandi, 2009). Adhesions can significantly lengthen incision-to-delivery time and total operative time (Rossouw, 2013; Sikirica, 2012). Although occurring infrequently, rates of cystotomy and bowel injury are also increased because of adhesive disease (Rahman, 2009; Silver, 2006).

Intuitively, scarring can be reduced by handling tissues delicately, achieving hemostasis, and minimizing tissue ischemia, infection, and foreign-body reaction. Most recent data on short- and long-term outcomes show no benefit to peritoneal closure (CAESAR Study Collaborative Group, 2010; CORONIS Collaborative Group, 2013, 2016; Kapustian, 2012). Similarly, most studies show no benefit from placement of an adhesion barrier at the hysterotomy site (Edwards, 2014; Kiefer, 2016).

Abdominal Closure

Any laparotomy sponges are removed, and the paracolic gutters and cul-de-sac are gently suctioned of blood and amnionic fluid. Some surgeons irrigate the gutters and cul-de-sac, especially in the presence of infection or meconium. Routine irrigation in low-risk women, however, leads to greater intraoperative nausea but not to lower postoperative infection rates (Eke, 2016; Viney, 2012).

Prior to abdominal closure, correct sponge and instrument counts are verified. The rectus abdominis muscle bellies are allowed to fall into place. With significant diastasis, the rectus muscles may be approximated with one or two figure-of-eight sutures of 0 or no. 1 chromic gut suture. The overlying rectus fascia is closed by a continuous, nonlocking technique with a delayed-absorbable suture. In patients with a higher risk for infection, there may be theoretical value in selecting a monofilament suture here rather than braided material.

The subcutaneous tissue usually need not be closed if it is less than 2 cm thick. With thicker layers, however, closure is recommended to minimize seroma and hematoma formation, which can lead to wound infection and/or disruption (Bohman, 1992; Chelmow, 2004). One recent metaanalysis found lower rates of seroma formation and of developing any wound complication with closure, but hematoma and wound infection rates were unaffected (Pergialiotis, 2017). Addition of a subcutaneous drain does not prevent significant wound complications (Hellums, 2007; Ramsey, 2005).

Skin is closed with a running subcuticular stitch of 4–0 delayed-absorbable suture, with adhesive glue, or with staples. In comparison, final cosmetic results and infection rates appear similar, skin suturing takes longer, but wound separation rates are higher with metal staples (Basha, 2010; Figueroa, 2013; Mackeen, 2014a, 2015). Poliglecaprone 25 (Monocryl) or polyglactin 910 (Vicryl) are both suitable (Tuuli, 2016b). Outcomes with 2-octyl cyanoacrylate adhesive (Dermabond) were equivalent to sutures for Pfannenstiel incisions (Daykan, 2017; Siddiqui, 2013). A sterile thin abdominal wound dressing is sufficient. In morbidly obese women, application of a prophylactic negative-pressure device atop the closed skin incision to prevent seroma and subsequent infection does not appear to lower wound complication rates (Hussamy, 2018; Smid, 2017).

Joel-Cohen and Misgav Ladach Techniques

The Pfannenstiel-Kerr technique just described has been used for decades. More recently, Joel-Cohen and Misgav Ladach techniques have been added (Holmgren, 1999). These differ from traditional Pfannenstiel-Kerr entry mainly by their initial incision placement and greater use of blunt dissection.

The Joel-Cohen technique creates a straight 10-cm transverse skin incision 3 cm below the level of the anterior superior iliac spines (Oloffson, 2015). The subcutaneous tissue layer is opened sharply 2 to 3 cm in the midline. This is carried down, without lateral extension, to the fascia. A small transverse incision is made in the fascia, and curved Mayo scissors are pushed laterally on each side and beneath intact subcutaneous fat to incise the fascia. With this incision completed, an index finger from each hand is inserted between the rectus abdominis muscle bellies and beneath the fascia. One finger is moved cranially and the other caudally, in opposition, to separate the bellies and further open the fascial incision. Then, a finger from each hand hooks under each belly to stretch the muscles laterally. The peritoneum is entered sharply, and this incision is sharply extended cephalocaudad. Entry with the Misgav Ladach technique differs in that the peritoneum is entered bluntly (Holmgren, 1999).

Modifications to the Joel-Cohen method abound. For emergency delivery, we begin along a line somewhat lower on the abdomen. For speed, we extend the fascial incision bluntly by hooking index fingers in the fascial incision's lateral angles and pulling laterally (Hofmeyr, 2009; Oloffson, 2015). Index fingers insinuated between the rectus bellies then move cephalocaudad in opposition to stretch the incision. Blunt index-finger dissection enters the peritoneum, and again, cranial and caudad opposing stretch opens this layer. Last, all the layers of the abdominal wall are grasped manually and pulled laterally in opposition to further open the operating space.

These techniques have been associated with shorter operative times and with lower rates of intraoperative blood loss and postoperative pain (Mathai, 2013). They may, however, prove difficult for women with anterior rectus fibrosis and peritoneal adhesions (Bolze, 2013).

Classical Cesarean Incision

Indications

This incision is usually avoided because it encompasses the active upper uterine segment and thus is prone to rupture with subsequent pregnancies. Some indications stem from difficulty in exposing or safely entering the lower uterine segment. For example, a densely adhered bladder from previous surgery is encountered; a *leiomyoma* occupies the lower uterine segment; the cervix has been invaded by cancer; or massive maternal obesity precludes safe access to the lower uterine segment. A classical incision is also preferred for placenta previa with anterior implantation, especially those complicated by placenta accrete syndromes. In extreme cases of this, the typical classical hysterotomy may be placed even higher in the uterine body or posteriorly to avoid the placenta. As such, fetuses with cephalic presentation are then delivered in a manner similar to total breech extraction (Chap. 28, Total Breech Extraction).

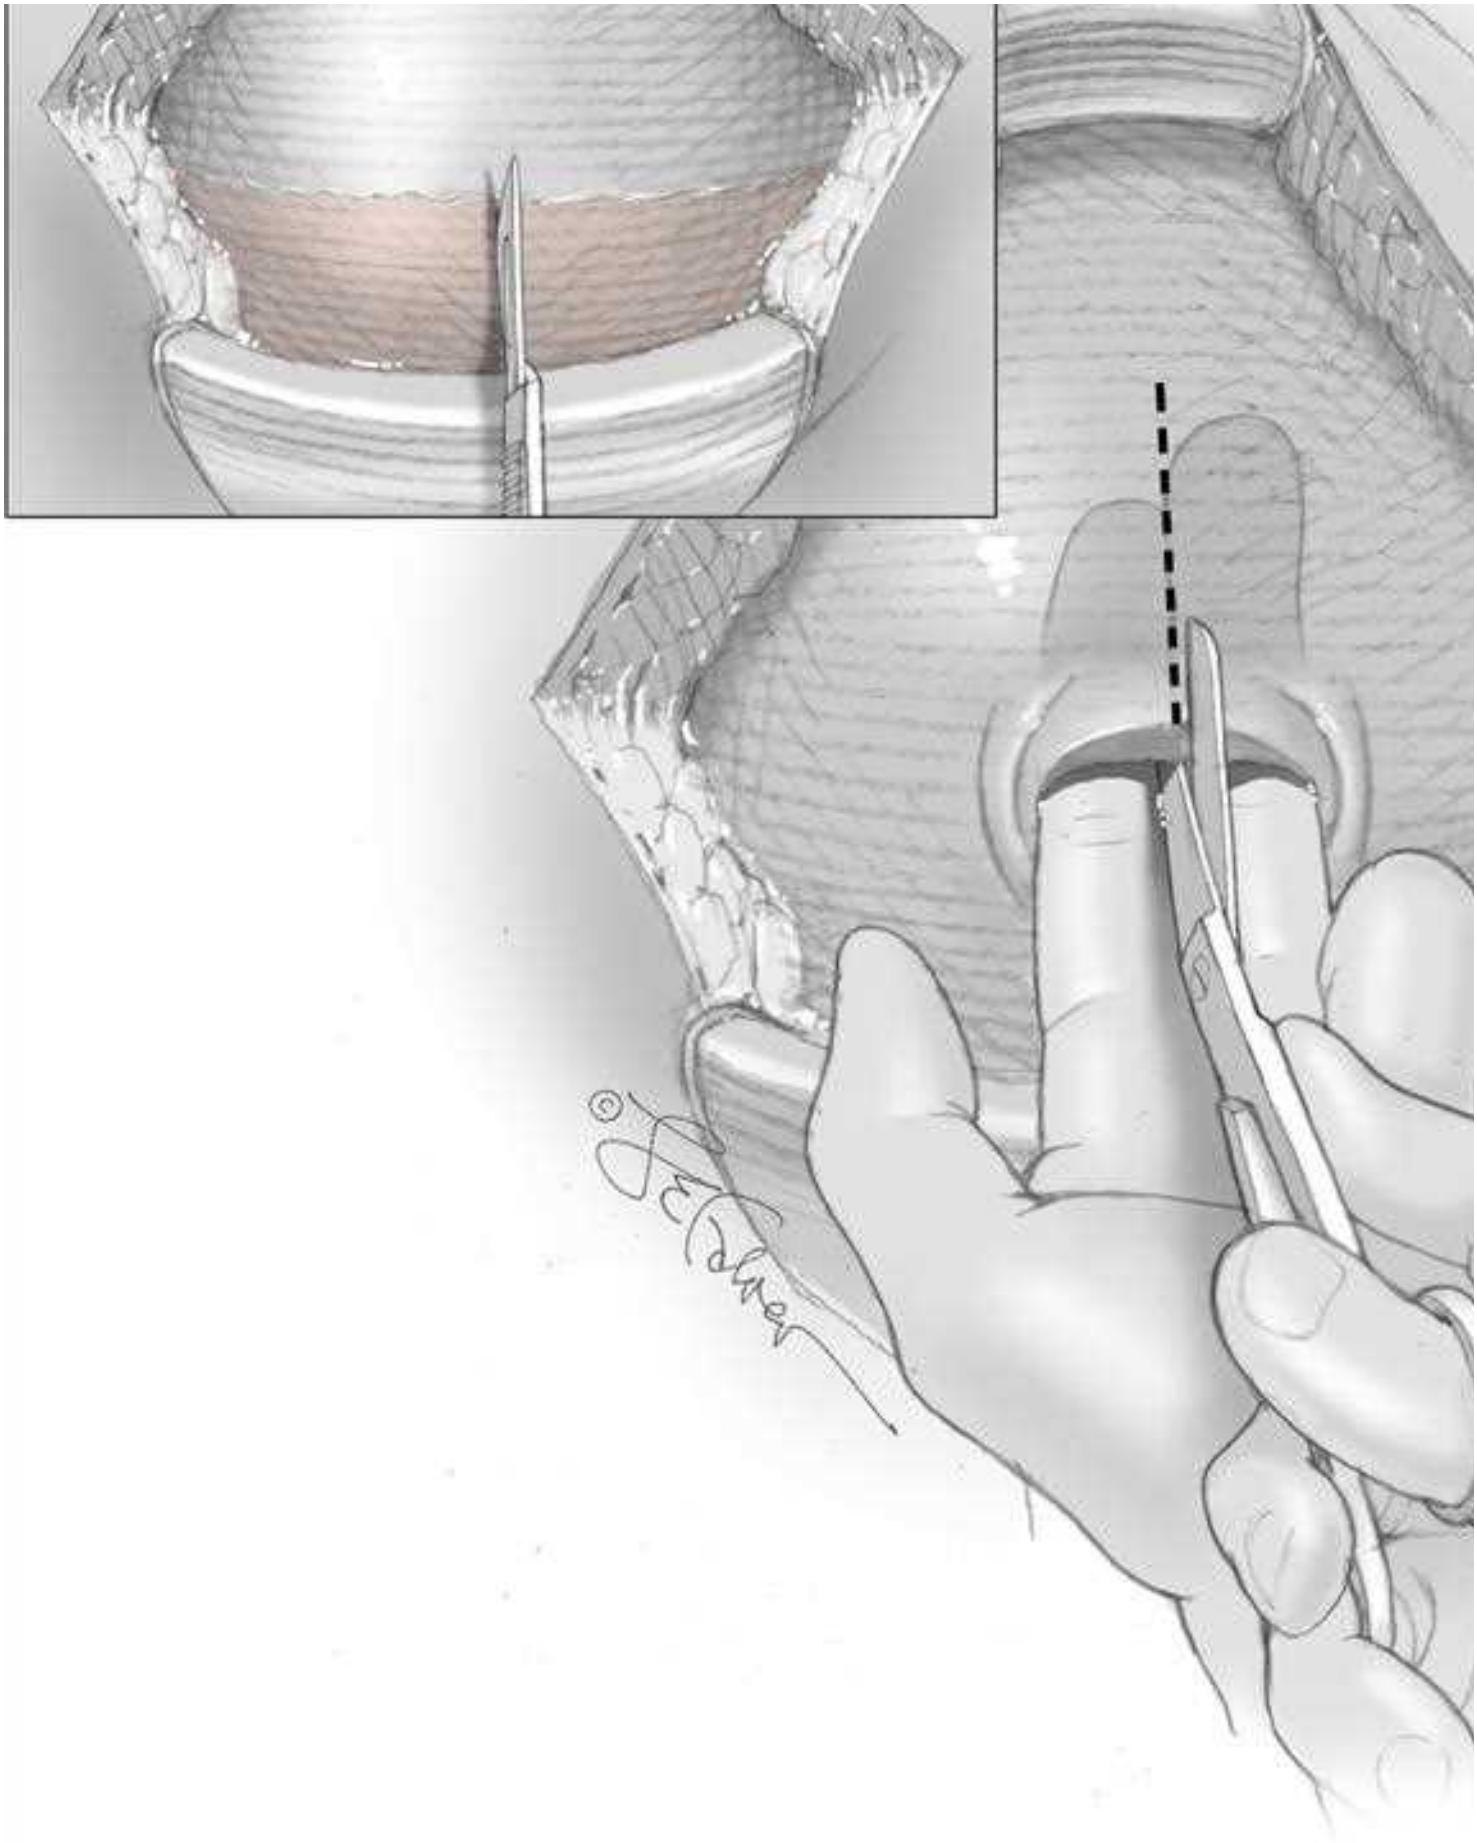
In other instances, fetal indications dictate the need. *Transverse lie of a large fetus*, especially if the membranes are ruptured and the shoulder is impacted in the birth canal, usually necessitates a classical incision. A fetus presenting as a back-down transverse lie is particularly difficult to deliver through a transverse uterine incision. In instances when the fetus is very small and breech, a classical incision may be preferable (Osmundson, 2013). In such cases, the poorly developed lower uterine segment provides inadequate space for the manipulations required for breech delivery. Or, less commonly, the small fetal head may become entrapped by a contracting uterine fundus following membrane rupture. Last, with multiple fetuses, a classical incision again may provide suitable room for extraction of fetuses that may be malpositioned or preterm (Osmundson, 2015).

Uterine Incision and Repair

A vertical uterine incision is initiated with a scalpel beginning as low as possible and preferably within the lower uterine segment (Fig. 30-11). If adhesions, insufficient exposure, a tumor, or placenta percreta preclude development of a bladder flap, then the incision is made above the level of the bladder. Once the uterus is entered with a scalpel, the incision is extended cephalad with bandage scissors until it is long enough to permit delivery of the fetus. With scissor use, the fingers of the nondominant hand are insinuated between the myometrium and fetus to prevent fetal laceration. As the incision is opened, numerous large vessels that bleed profusely are commonly encountered within the myometrium. The remainder of fetal and placental delivery mirrors that with a low transverse hysterotomy.

FIGURE 30-11

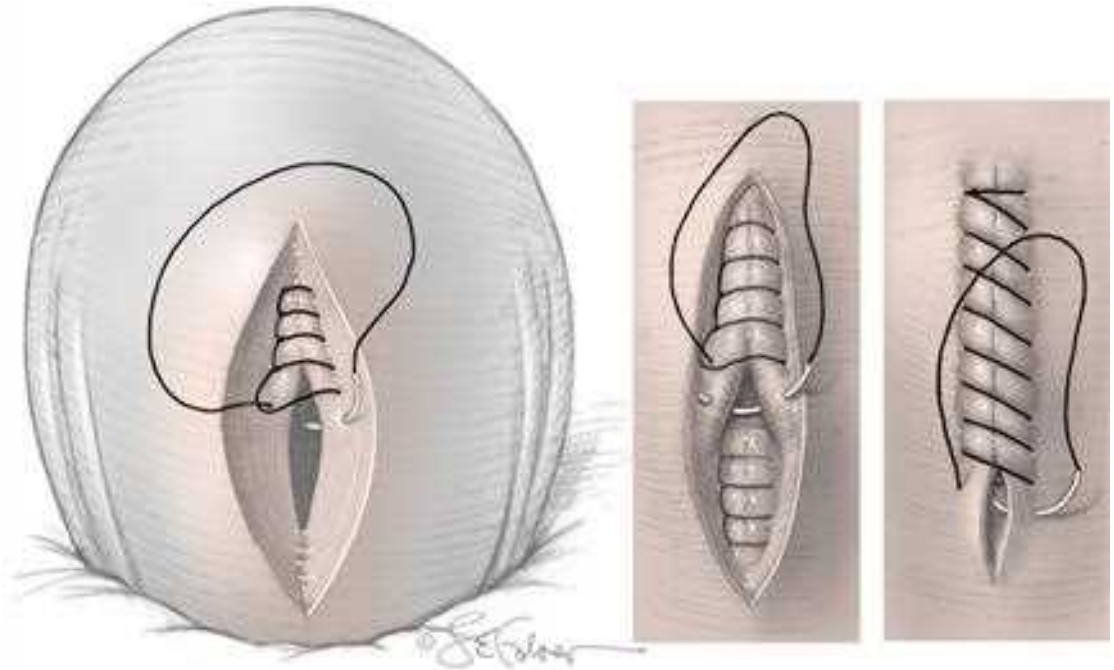
An initial small vertical hysterotomy incision is made in the lower uterine segment. Fingers are insinuated between the myometrium and fetus to avoid fetal laceration. Scissors extend the incision cephalad as needed for delivery. (Reproduced with permission from Johnson DD: Cesarean delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

For incision closure, one method employs a layer of 0- or no. 1 chromic catgut with a running stitch to approximate the deeper length of the incision (Fig. 30-12). The outer layer of myometrium is then closed along its length with similar suture and with a running suture line. To achieve good approximation and to prevent the suture from tearing through the myometrium, it is helpful to have an assistant compress the uterus on each side of the wound toward the midline as each stitch is placed.

FIGURE 30-12
Classical incision closure. The deeper half (*left*) and superficial half (*middle*) of the incision are closed in a running fashion. The serosa is then closed (*right*). New York, McGraw-Hill Education, 2017.)



PERIPARTUM HYSTERECTOMY

Indications

Hysterectomy is most commonly performed to arrest or prevent hemorrhage from intractable uterine atony or abnormal placentation (Bateman, 2012; Hernandez, 2012; Owolabi, 2013). It is more often completed during or after cesarean delivery but may be needed following vaginal birth. If all deliveries are considered, the peripartum hysterectomy rate in the United States approximates 1 per 1000 births and has risen significantly during the past few decades (Bateman, 2012; Govindappagari, 2016). During a 25-year period, the rate of peripartum hysterectomy at Parkland Hospital was 1.7 per 1000 births (Hernandez, 2012). Most of this rise is attributed to the increasing rates of cesarean delivery and its associated complications in subsequent pregnancy (Bateman, 2012; Bodelon, 2009; Flood, 2009; Orbach, 2011). Of hysterectomies, approximately one half to two thirds are total, whereas the remaining cases are supracervical (Rossi, 2010; Shellhaas, 2009).

Major complications of peripartum hysterectomy include greater blood loss and risk of urinary tract damage. Blood loss is usually appreciable because hysterectomy is being performed for hemorrhage that frequently is torrential, and the procedure itself is associated with substantial bleeding. Although many cases with hemorrhage cannot be anticipated, those with abnormal implantation are often identified antepartum. Preoperative preparations for placenta accreta are discussed in Chapter 41 (Management) and have also been outlined by the Society for Maternal-Fetal Medicine (2010) and American College of Obstetricians and Gynecologists (2017c).

An important factor affecting the cesarean hysterectomy complication rate is whether the operation is performed electively or emergently. With anticipated or planned cesarean hysterectomy, rates of blood loss, blood transfusion, and urinary tract complications are lower that with emergent procedures (Briery, 2007; Glaze, 2008).

Hysterectomy Technique

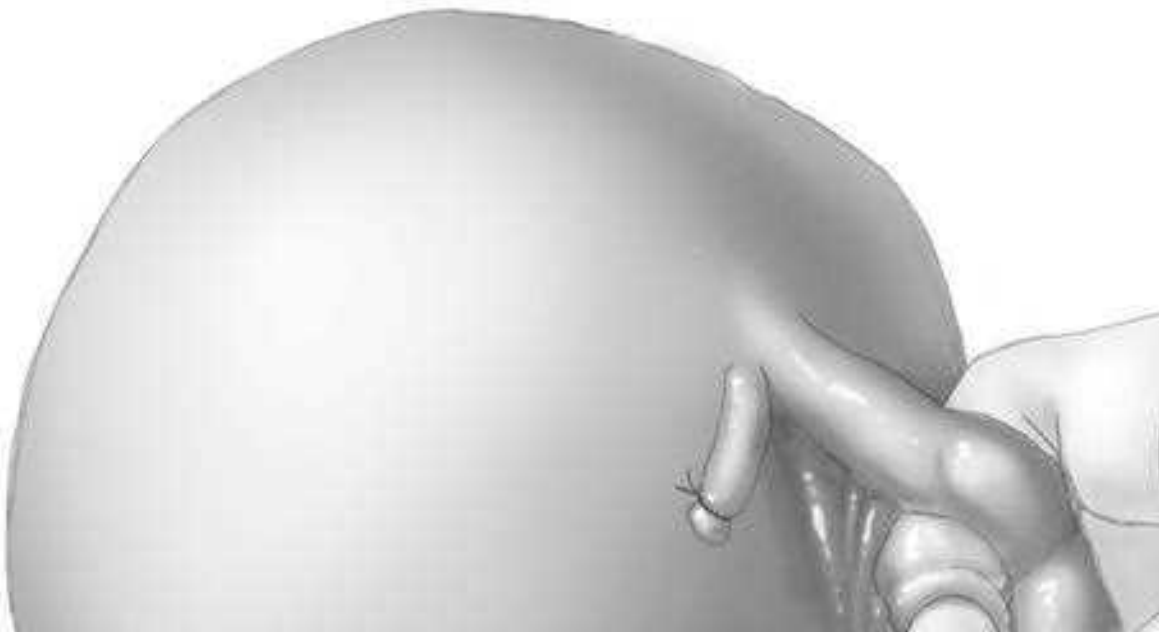
Total or supracervical hysterectomy is performed using standard operative techniques. Adequate exposure is essential, but initially, placement of a self-retaining retractor such as a Balfour is not necessary. Rather, satisfactory exposure is obtained with cephalad traction on the uterus by an assistant, along with handheld Richardson or Deaver retractors. The bladder flap is deflected downward to the level of the cervix if possible to permit total hysterectomy. In cases in which cesarean hysterectomy is planned or strongly suspected, extended bladder flap dissection is ideally completed before initial hysterotomy. Later attempts at bladder dissection may be obscured by bleeding, or excess blood may be lost while this dissection is performed.

After cesarean delivery, the placenta is typically removed. In cases of placenta accrete syndrome for which hysterectomy is already planned, the placenta is usually left undisturbed in situ. In either situation, if the hysterotomy incision is bleeding appreciably, it can be sutured or Pennington or sponge forceps can be applied for hemostasis. If bleeding is minimal, neither maneuver is necessary.

The round ligament is divided close to the uterus between clamps, and each pedicle is ligated (Fig. 30-13). Either 0 or no. 1 suture can be used in either chromic gut or delayed-absorbable material. The anterior leaf of the broad ligament is incised downward to meet the former bladder flap incision. The posterior leaf of the broad ligament adjacent to the uterus is bluntly or sharply perforated just beneath the fallopian tube, uteroovarian ligament, and ovarian vessels (Fig. 30-14). These structures together are then divided between sturdy clamps placed close to the uterus (Fig. 30-15). The lateral pedicle is doubly ligated. The medial clamp remains and is removed later with the entire uterine specimen. The posterior leaf of the broad ligament is incised toward the uterosacral ligaments (Fig. 30-16). Next, the bladder and attached peritoneal flap are further deflected and dissected as needed. If the bladder flap is unusually adhered, as it may be after previous hysterotomy incisions, careful sharp dissection may be necessary (Fig. 30-17).

FIGURE 30-13
The round ligaments are clamped, doubly ligated, and transected bilaterally.

FIGURE 30-14
The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, uteroovarian ligaments, and ovarian vessels.



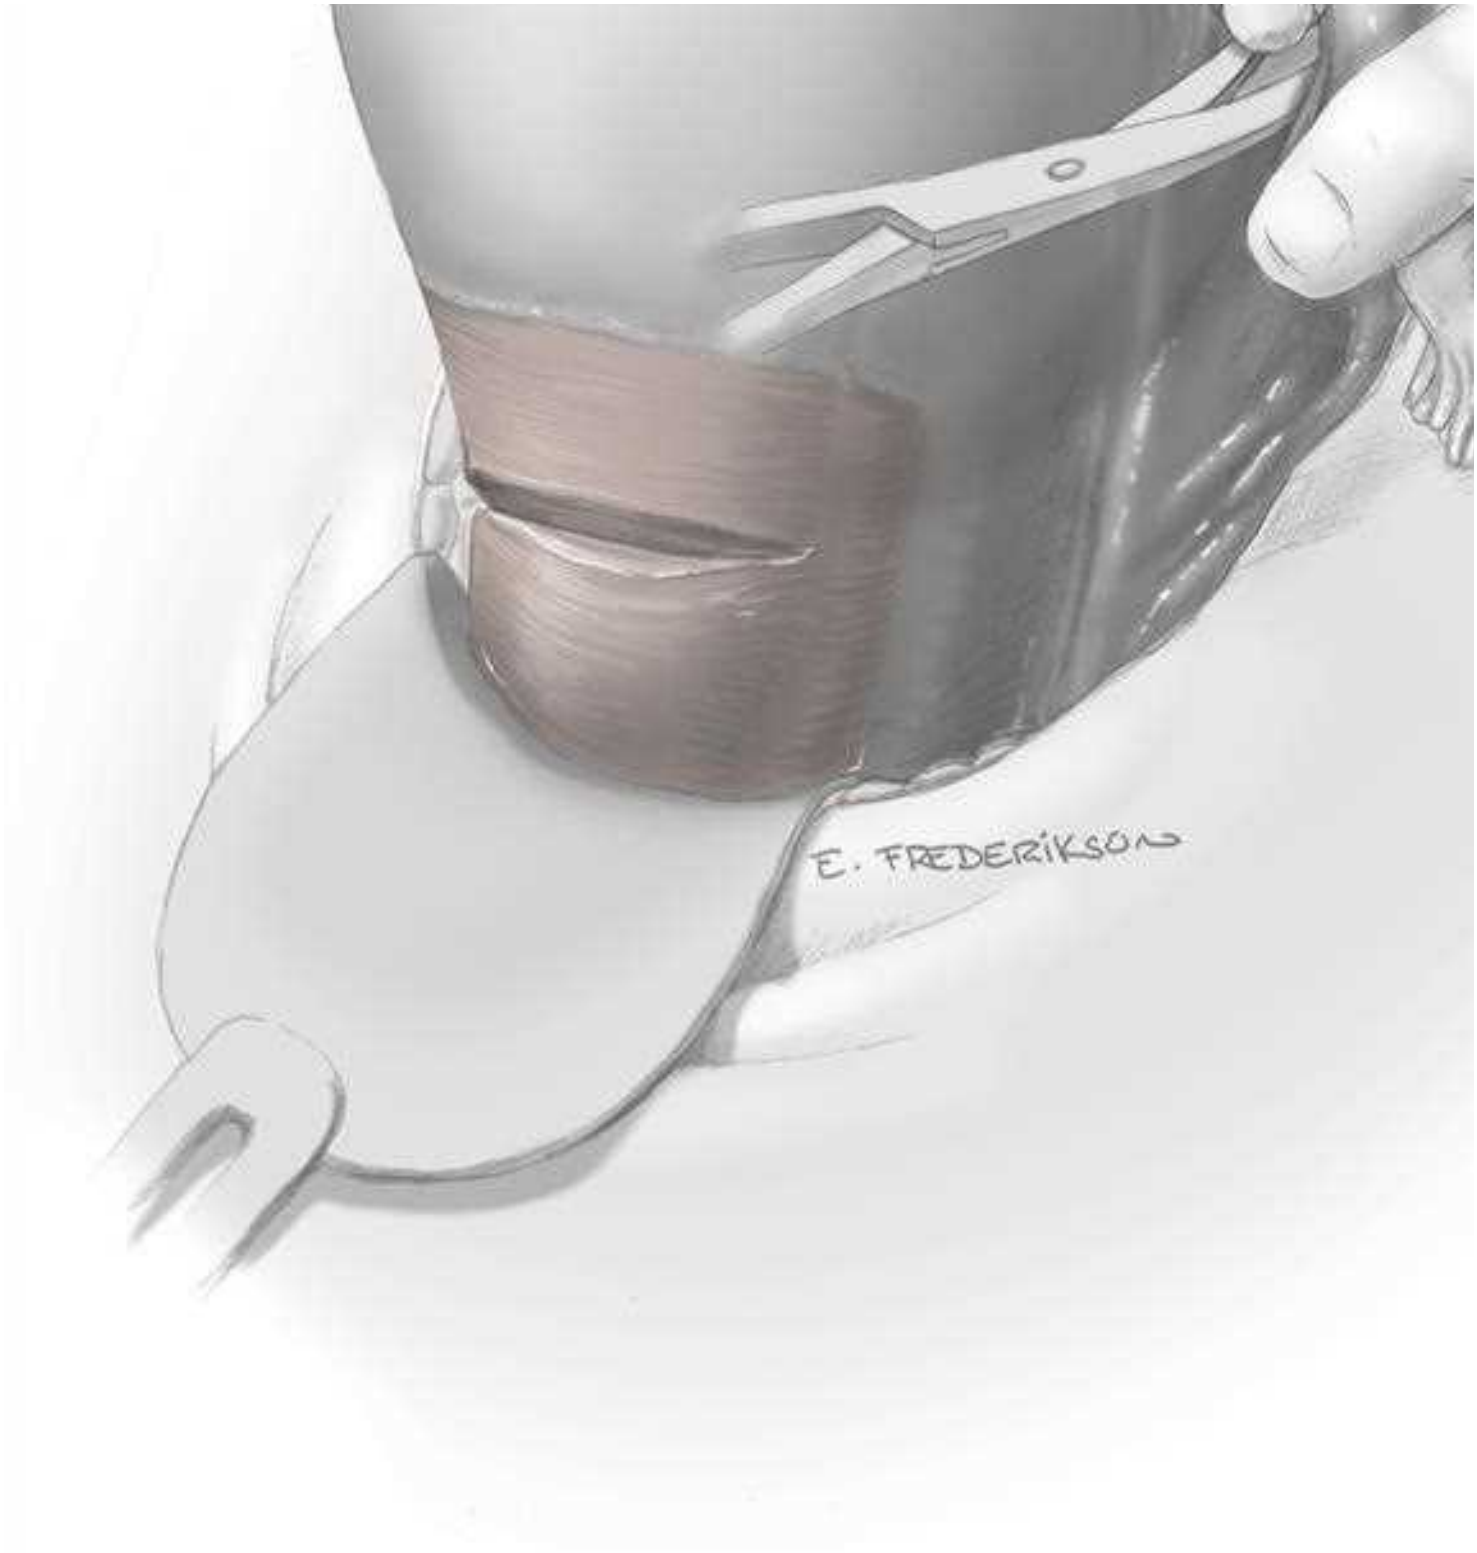


FIGURE 30-15

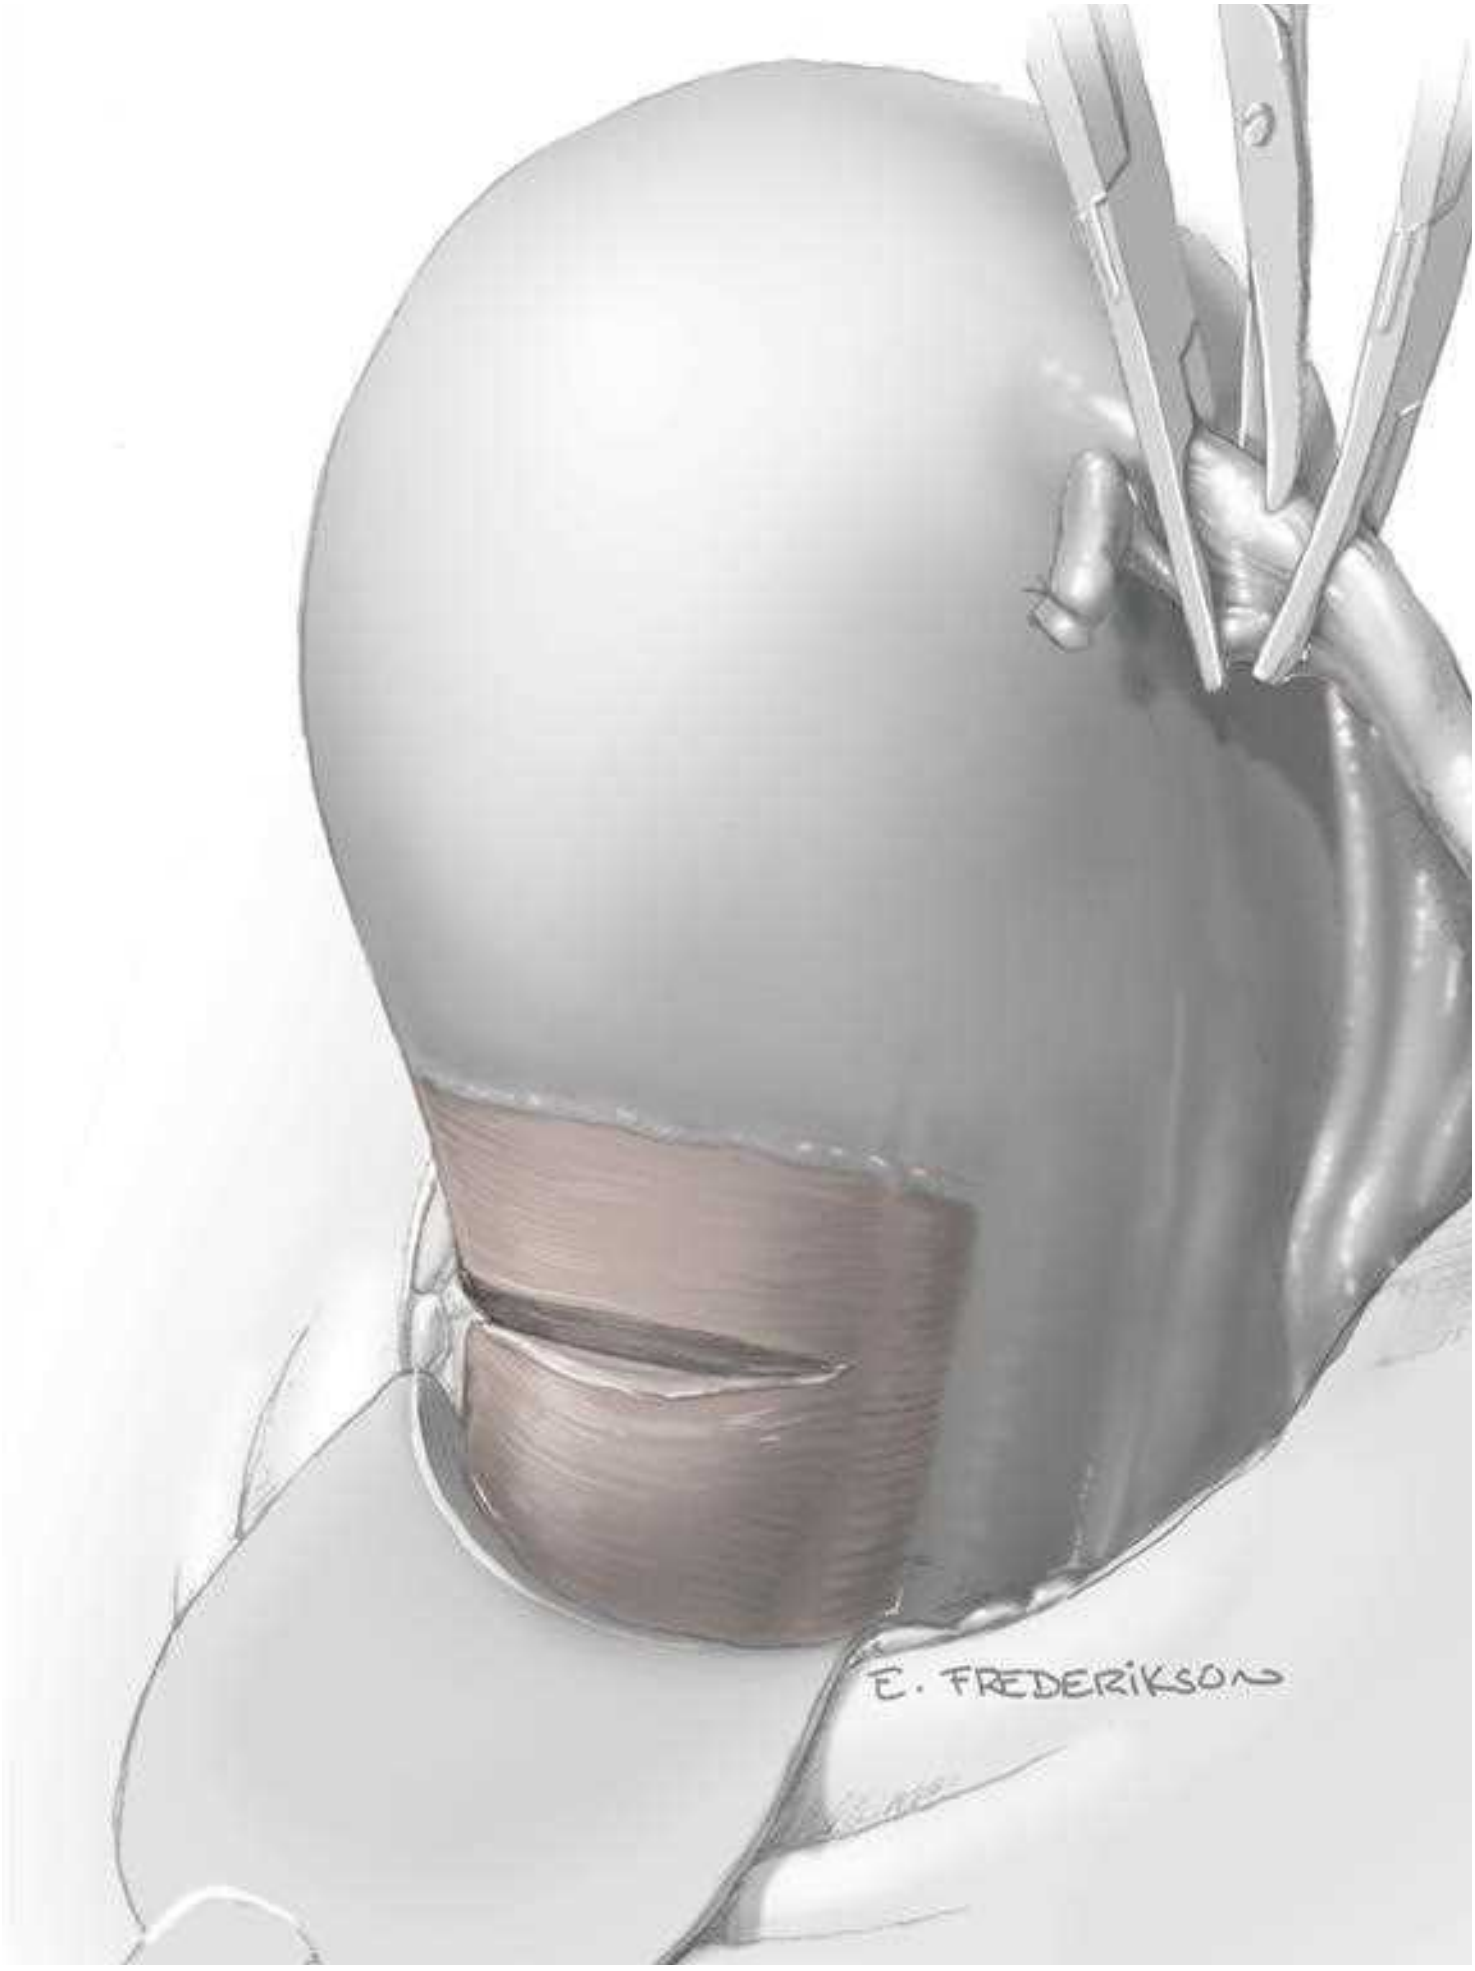
The uteroovarian ligament and fallopian tube are clamped and cut. The lateral pedicle is doubly ligated.



E. FREDERIKSON

FIGURE 30-16

The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligament.

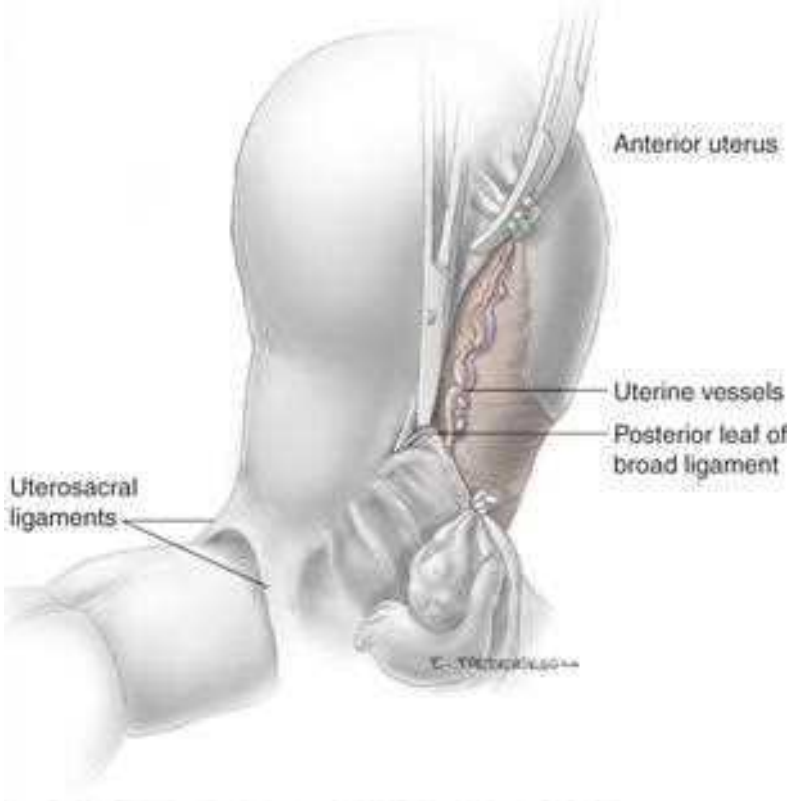


FIGURE 30-17

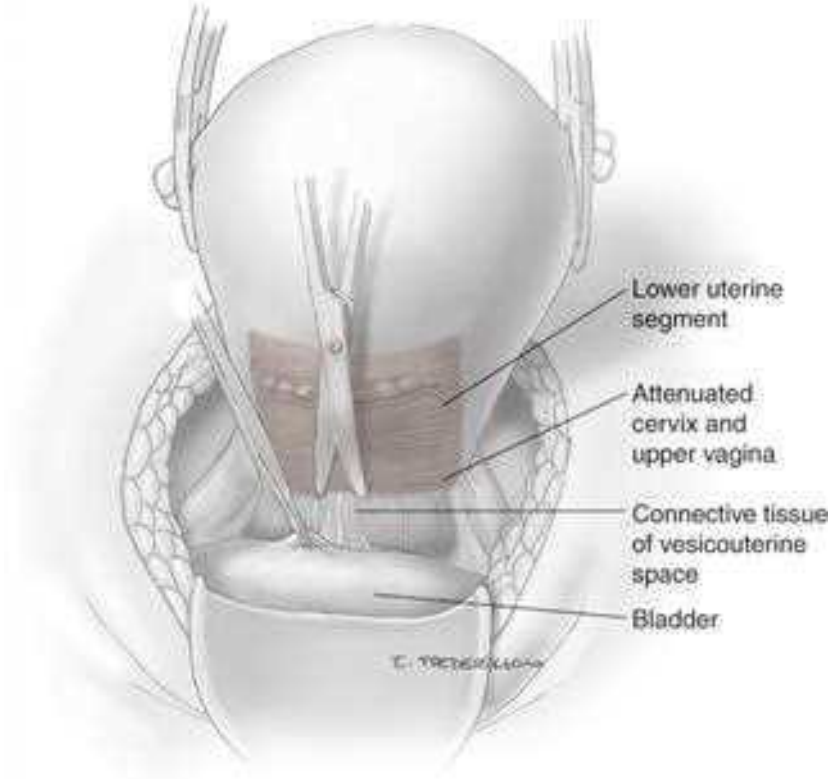
The bladder is dissected sharply from the lower uterine segment.



Special care is required from this point on to avoid injury to the ureters, which pass beneath the uterine arteries. To help accomplish this, an assistant places constant traction to pull the uterus in the direction away from the side on which the uterine vessels are being ligated. The ascending uterine artery and veins on either side are identified. These vessels are then clamped adjacent to the uterus. For security, some may prefer two lateral clamps as shown in Figure 30-18. The most medial clamp helps prevents back bleeding from the uterus and remains for later removal with the specimen. The uterine vessels are divided, and the lateral tissue pedicle is doubly suture ligated. After securing the uterine vessels on one side, the round ligament, adnexal pedicle, and uterine vessels are then addressed on the contralateral side.

FIGURE 30-18

The uterine vessels are clamped, and a third medial clamp helps prevent “back bleeding.” Once divided, the lateral vascular pedicle is doubly ligated to ensure hemostasis.

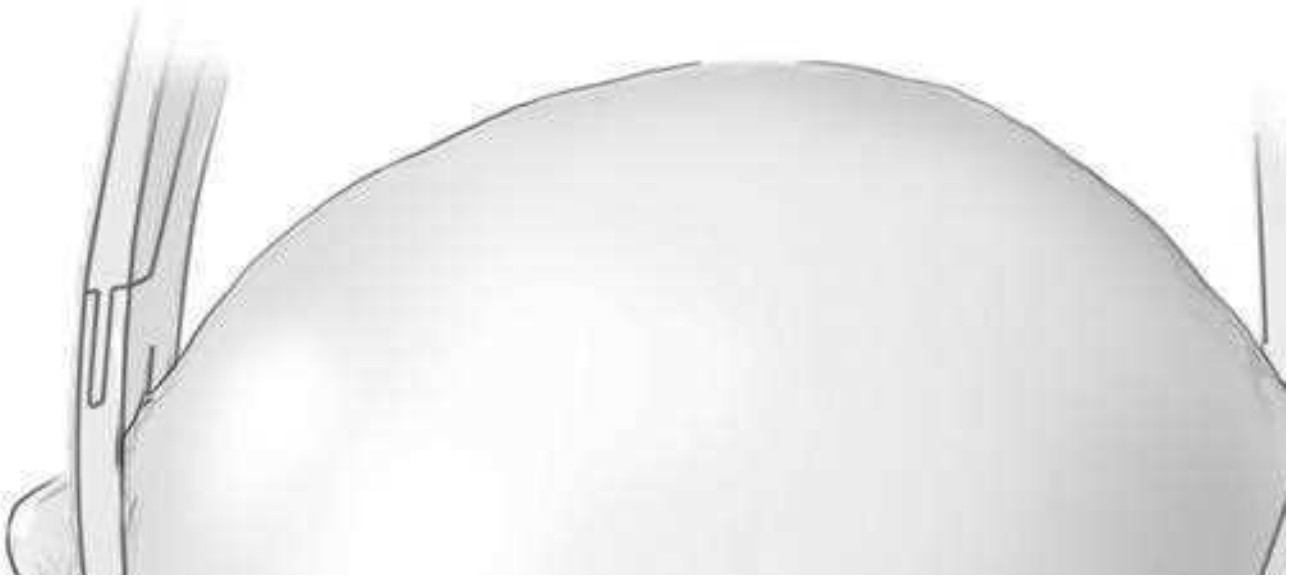
With cesarean hysterectomy, it may be more advantageous in cases of profuse hemorrhage to rapidly double clamp and divide all of the vascular pedicles between clamps to gain hemostasis. The surgical team can then return to ligate all of the pedicles.

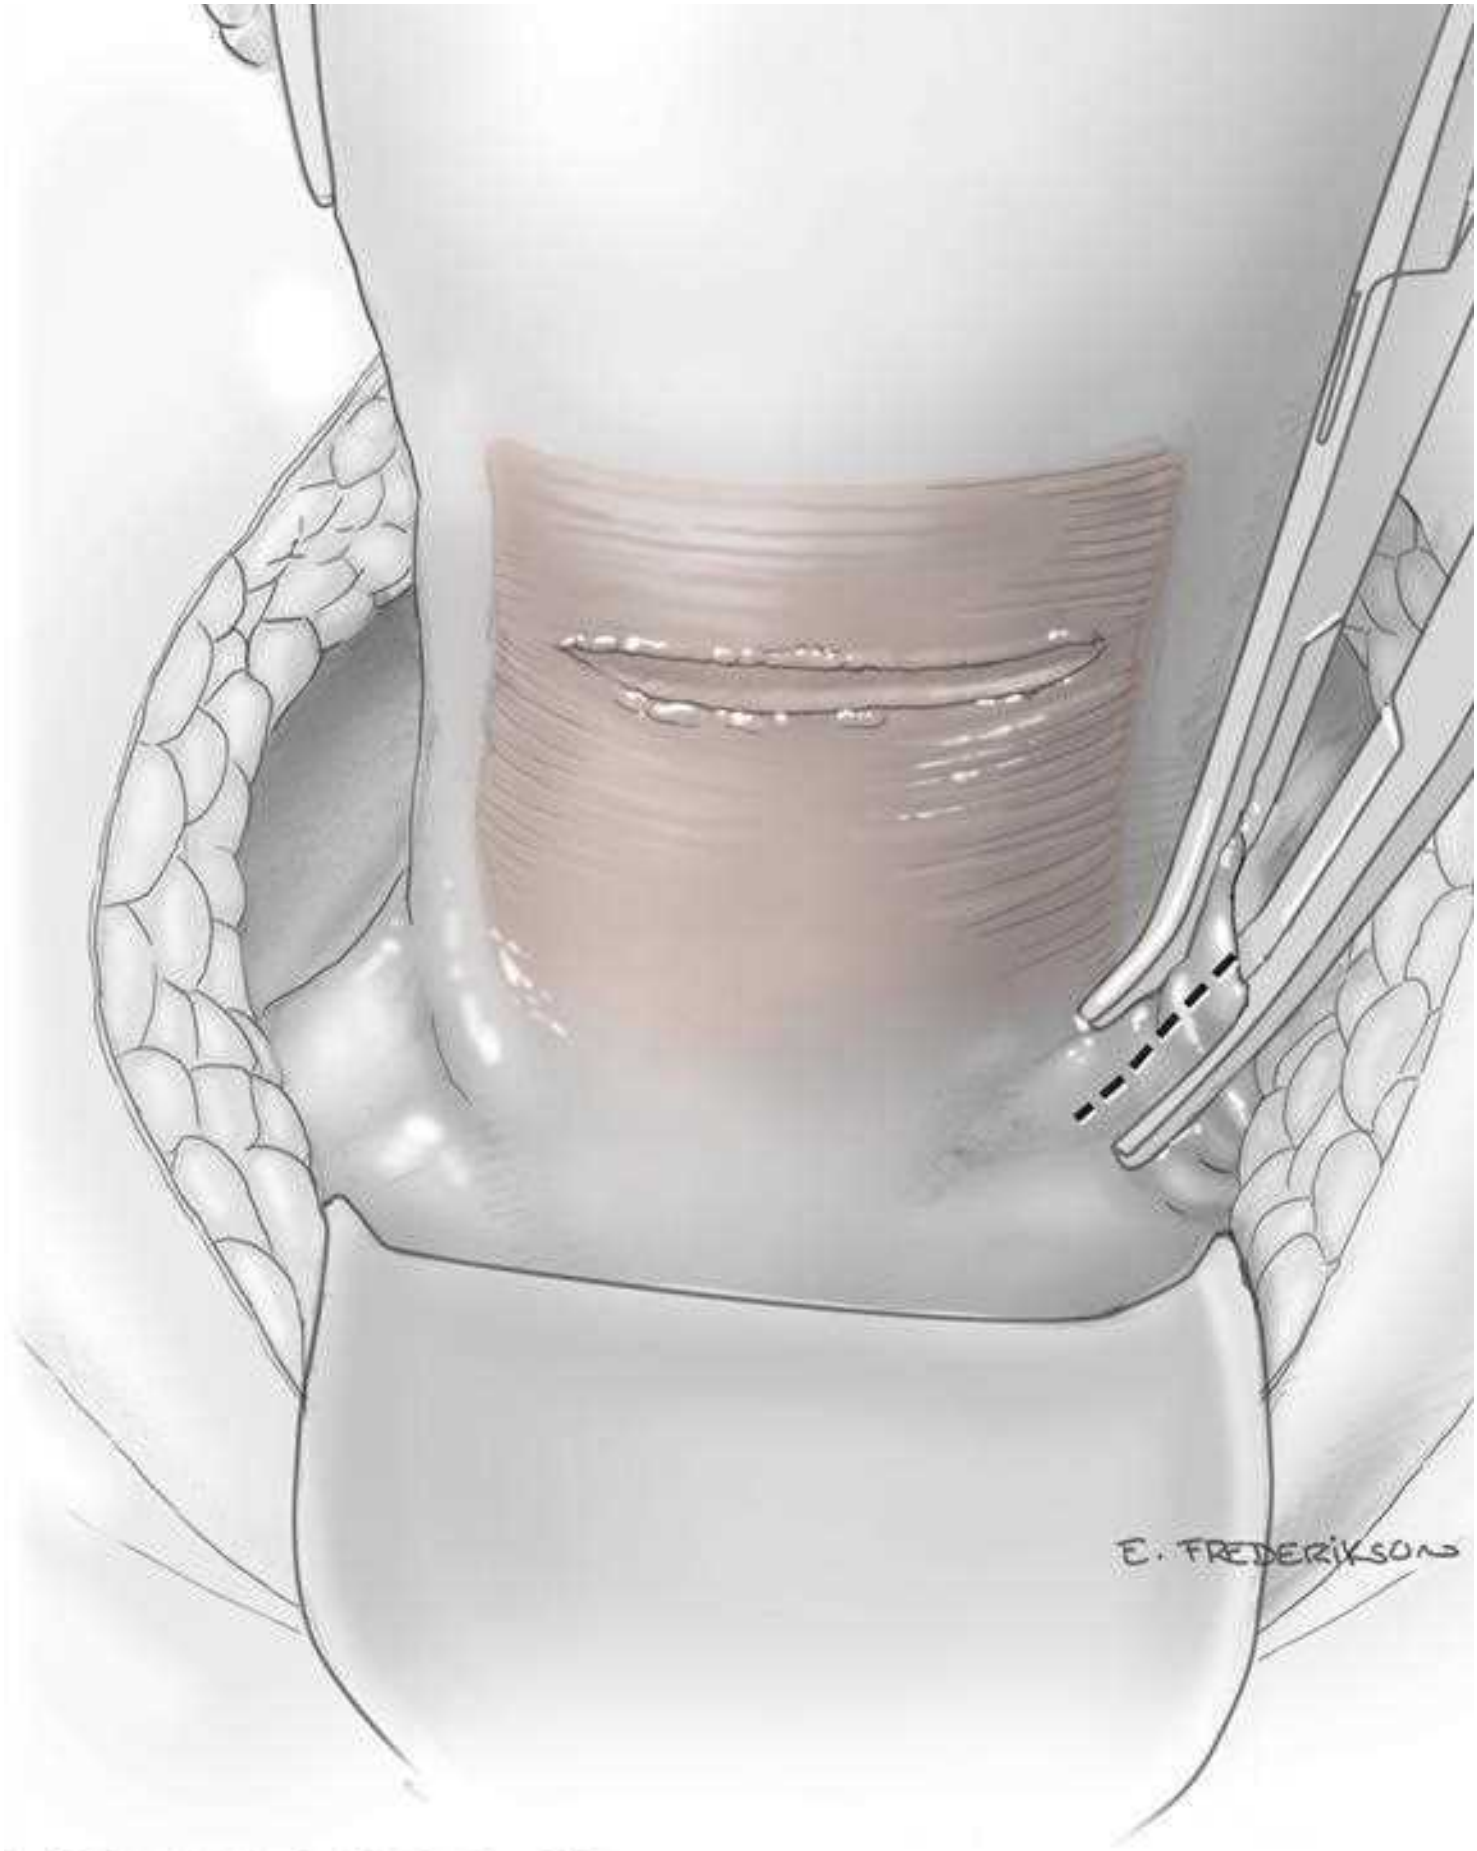
Total Hysterectomy

Even if total hysterectomy is planned, we find it technically easier in many cases to finish the operation after amputating the uterine fundus and placing Ochsner or Kocher clamps on the cervical stump for traction and hemostasis. Self-retaining retractors also may be placed at this time. To remove the cervix, the bladder is mobilized further if needed. This carries the ureters caudad as the bladder is retracted beneath the symphysis and will prevent laceration or suturing of the bladder during cervical excision and vaginal cuff closure.

The cardinal ligament, the uterosacral ligaments, and the many large vessels these ligaments contain are clamped systematically with sturdy Heaney-type curved or straight clamps (Fig. 30-19). The clamps are placed as close to the cervix as possible, taking care not to include excessive tissue in each clamp. The tissue between the pair of clamps is incised, and the lateral pedicle is suture ligated. These steps are repeated caudally and bilaterally until the level of the lateral vaginal fornix is reached on each side. In this way, the descending branches of the uterine vessels are clamped, cut, and ligated as the cervix is separated from the cardinal ligaments.

FIGURE 30-19
The cardinal ligaments are clamped, incised, and ligated.



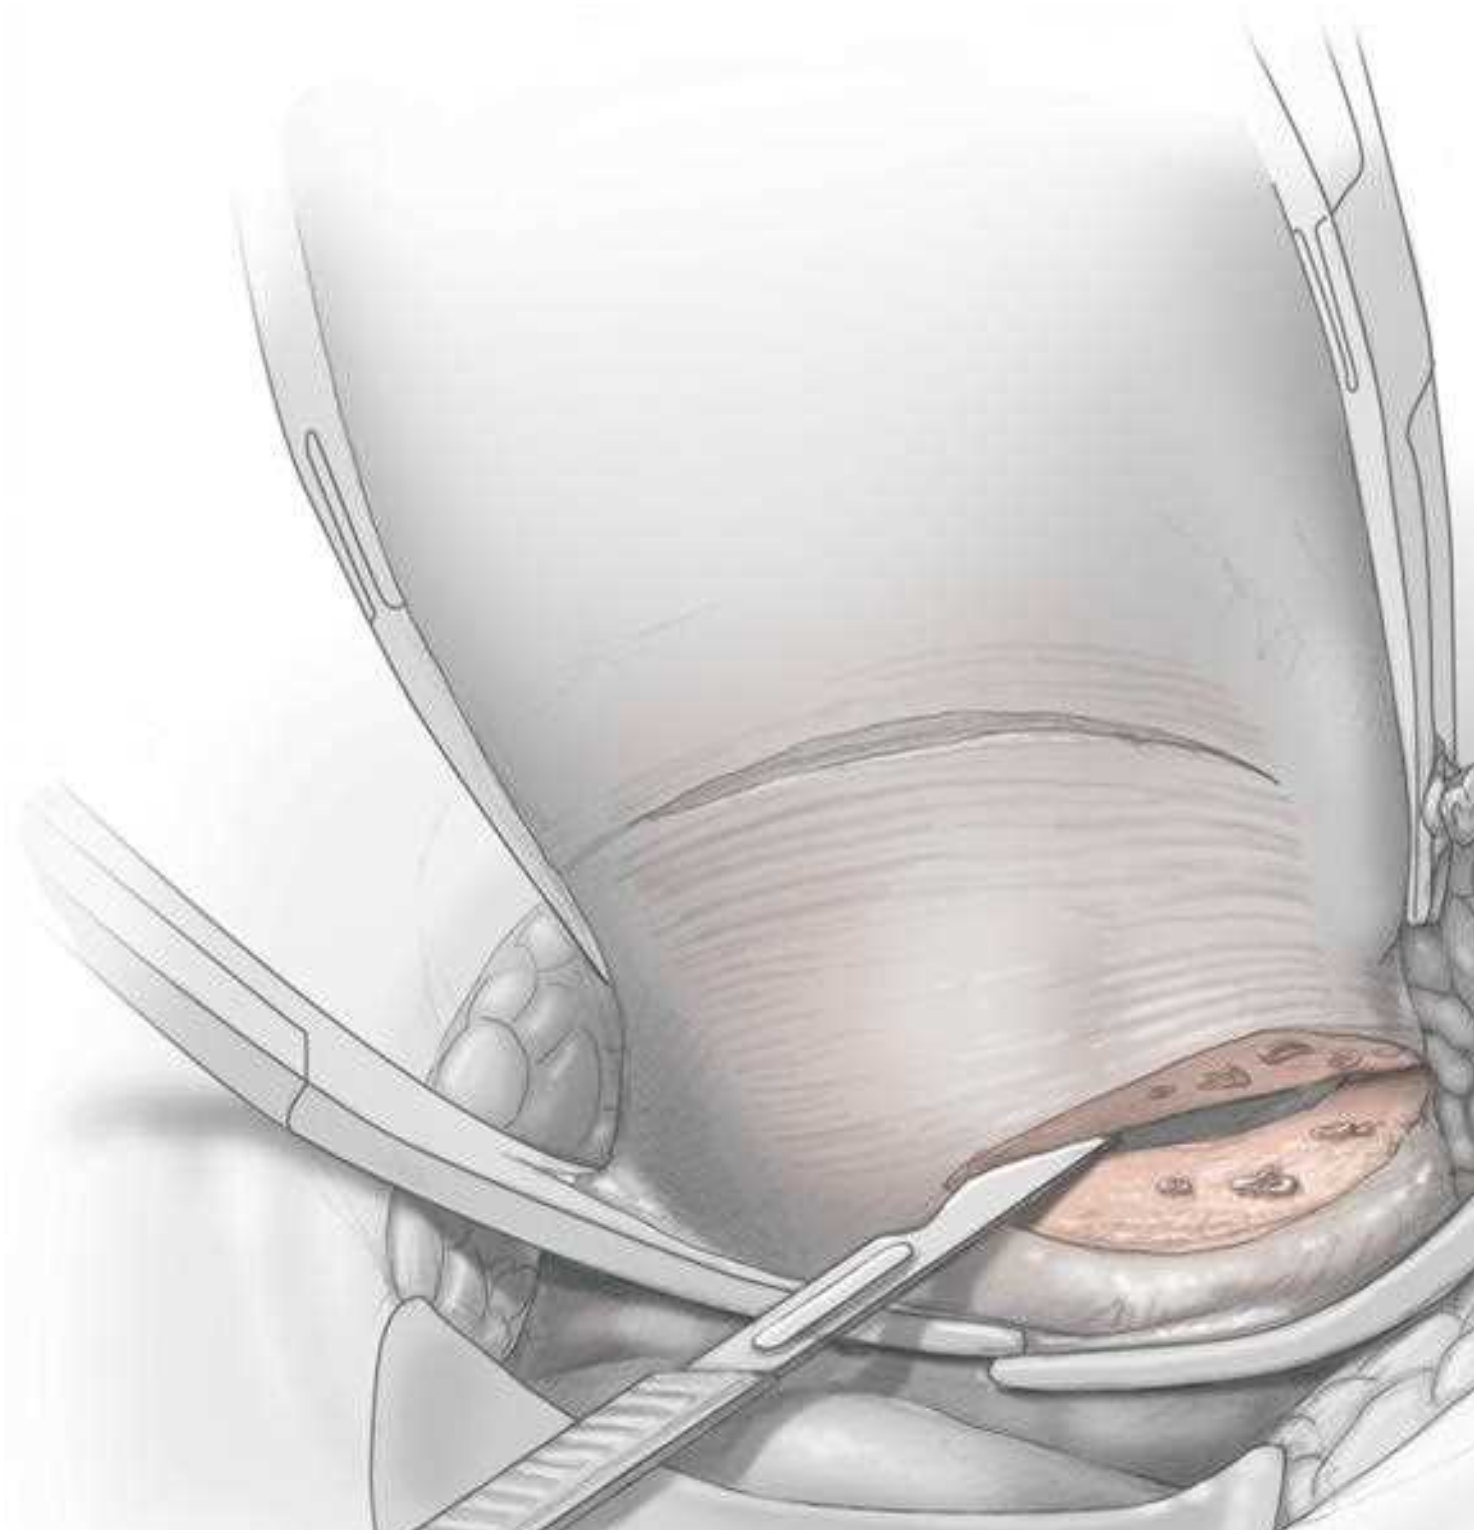


Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

If the cervix is effaced and dilated considerably, its softness may obscure palpable identification of the cervicovaginal junction. The junction location can be ascertained through a vertical uterine incision made anteriorly in the midline, either through the open hysterotomy incision or through an incision created at the level of the ligated uterine vessels. A finger is directed inferiorly through the incision to identify the free margin of the dilated, effaced cervix. The contaminated glove is replaced. Another useful method to identify the cervical margins in cases of planned hysterectomy is to transvaginally place four metal skin clips or brightly colored sutures at 12, 3, 6, and 9 o'clock positions on the cervical edges.

Immediately below the level of the cervix, a curved clamp is placed across the lateral vaginal fornix on each side, and the vagina is incised above the clamp (Fig. 30-20). The cervix is inspected to ensure that it has been completely removed. A transfixing suture is used for vaginal cuff closure as each clamp is removed. Interrupted stitches may be added to approximate the middle portion of the cuff. Each lateral vaginal fornix is secured to the uterosacral ligaments to mitigate later vaginal prolapse. For cuff closure, some surgeons instead prefer to close the vagina by apposing the anterior and posterior vaginal walls with interrupted figure-of-eight sutures or running suture line (Fig. 30-21).

FIGURE 30-20
A curved clamp is placed across the lateral vaginal fornix below the level of the cervix, and the tissue incised medially to the point of the clamp.



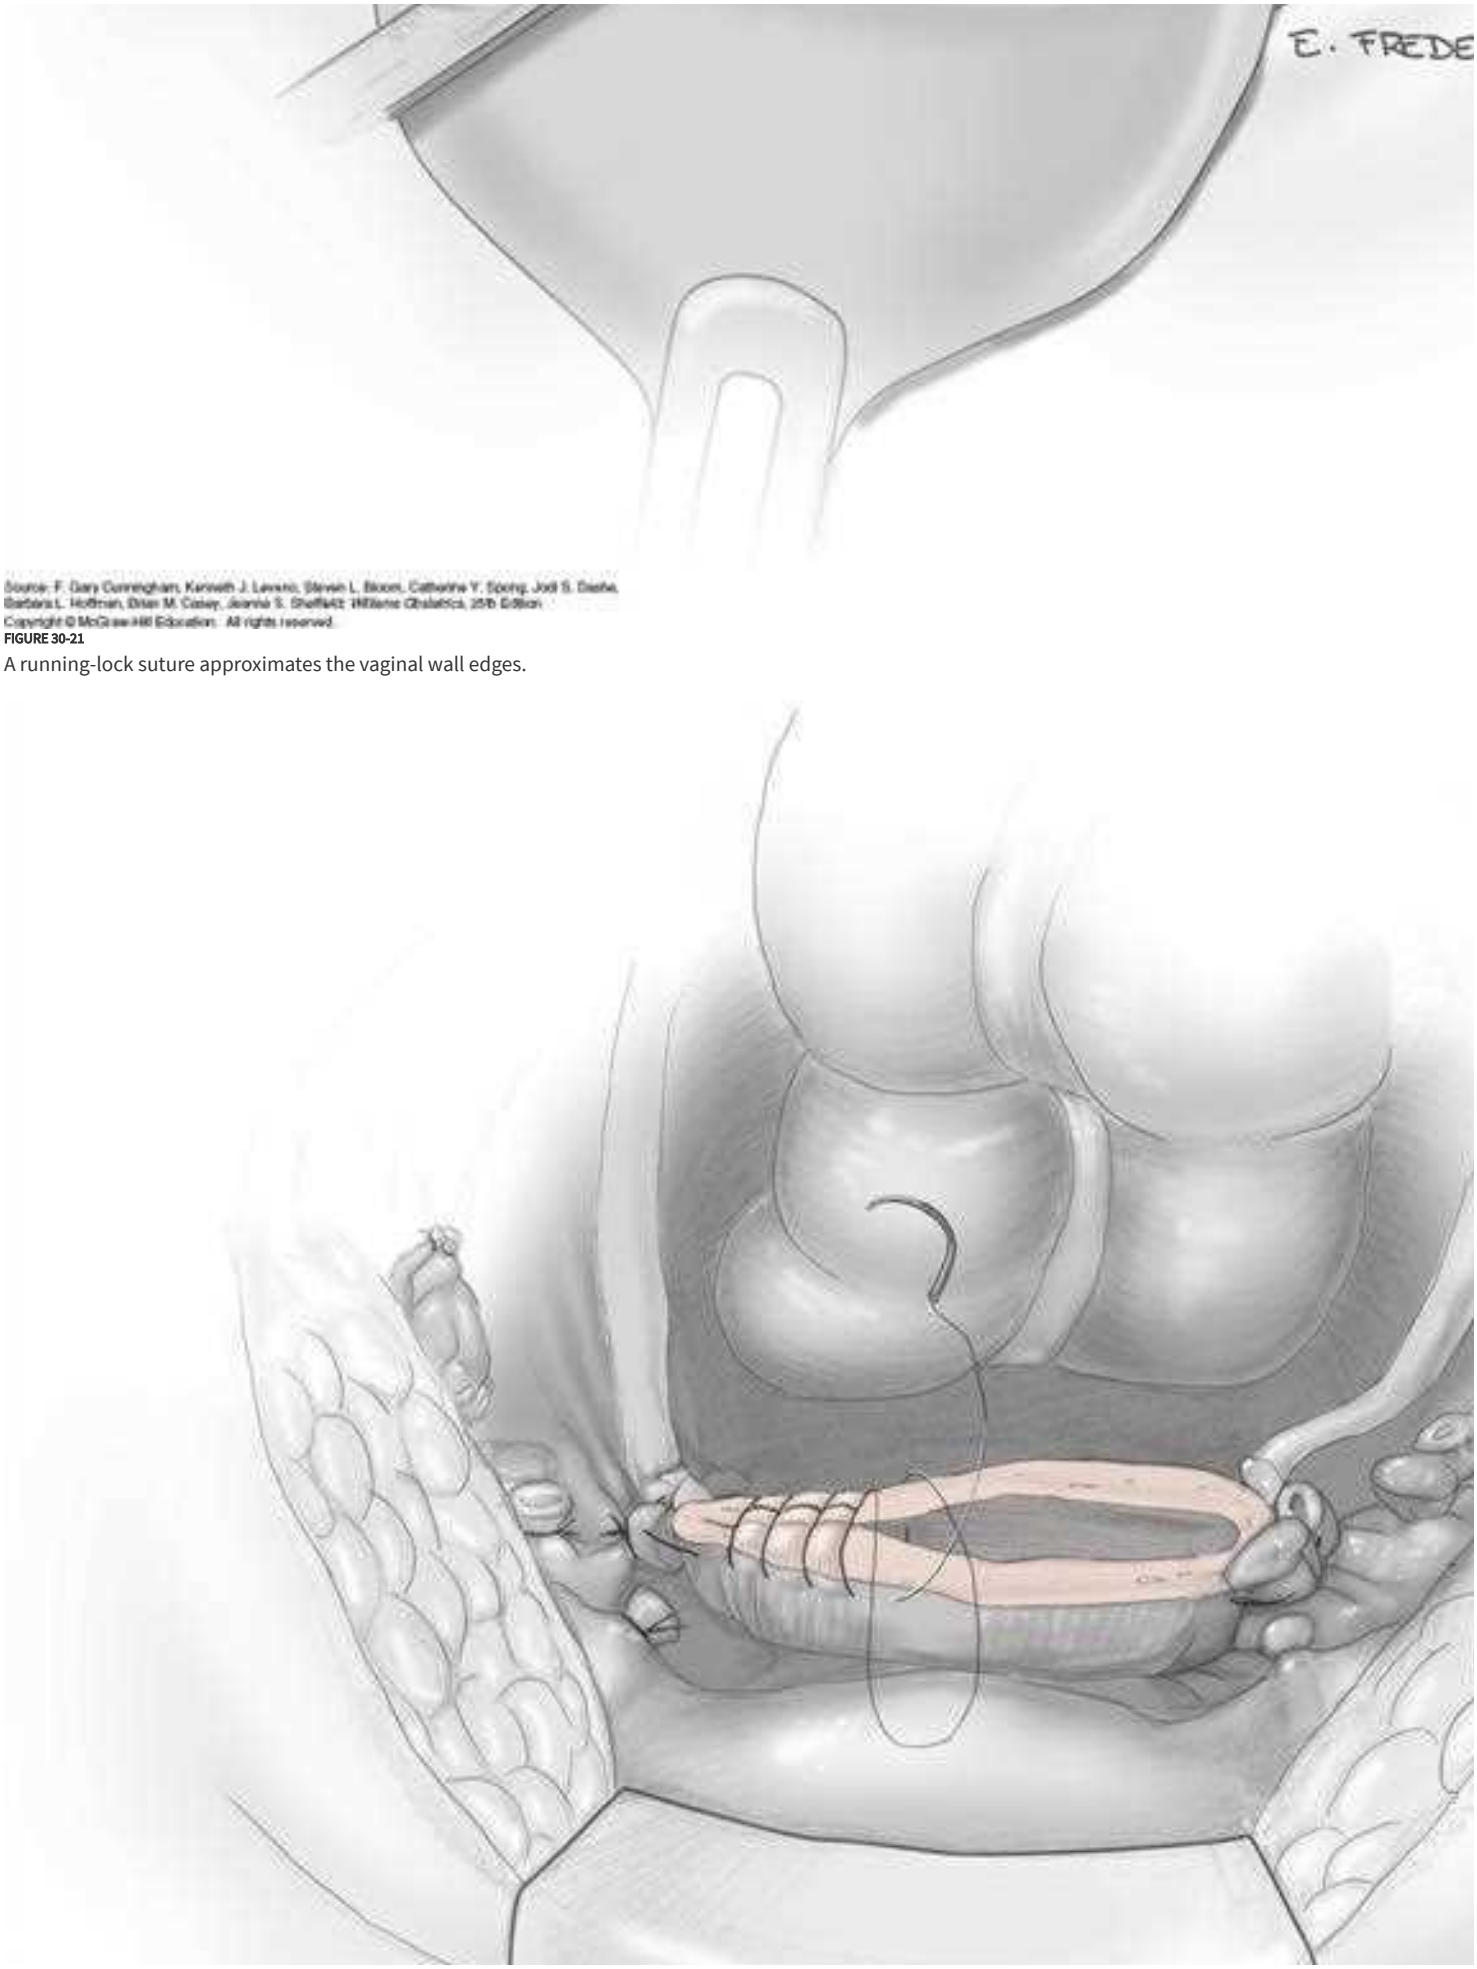


FIGURE 30-21

A running-lock suture approximates the vaginal wall edges.

All sites are examined carefully for bleeding. One technique is to perform a systematic bilateral survey from the fallopian tube and ovarian ligament pedicles to the vaginal vault and bladder flap. Bleeding sites are ligated with care to avoid the ureters. The abdominal wall normally is closed in layers, as previously described for cesarean delivery (Adhesions).

Supracervical Hysterectomy

To perform a subtotal hysterectomy, the uterine body is amputated immediately above the level of uterine artery ligation. The cervical stump may be closed with continuous or interrupted chromic catgut suture. Subtotal hysterectomy is often all that is necessary to stop hemorrhage. It may be preferred for women who would benefit from a shorter surgery or for those with extensive adhesions that threaten significant urinary tract injury.

Salpingo-oophorectomy

Because of the large adnexal vessels and their close proximity to the uterus, it may be necessary to remove one or both adnexa to obtain hemostasis. Briery and colleagues (2007) reported unilateral or bilateral oophorectomy in a fourth of cases. Preoperative counseling for anticipated hysterectomy should include this possibility.

Urinary Tract or Bowel Injury

These injuries are rare during cesarean delivery. The bladder laceration rate approximates 2 per 1000 cesarean deliveries, whereas that for ureteral trauma nears 0.3 per 1000 cases (Güngördük, 2010; Oliphant, 2014; Rajasekar, 1997). Bowel is damaged in about 1 in 1000 cesarean deliveries (Silver, 2006).

Cystotomy

Bladder laceration most commonly occurs during blunt or sharp dissection in the vesicouterine space to create the bladder flap, during peritoneal cavity entry, and during hysterotomy (Phipps, 2005; Rahman, 2009). Risks are prior cesarean delivery; emergency cesarean delivery; comorbid adhesive disease; cesarean hysterectomy, especially cases with morbidly adherent placenta; and surgery in second-stage labor compared with first-stage (Alexander, 2007; Silver, 2006; Yossepowitch, 2004).

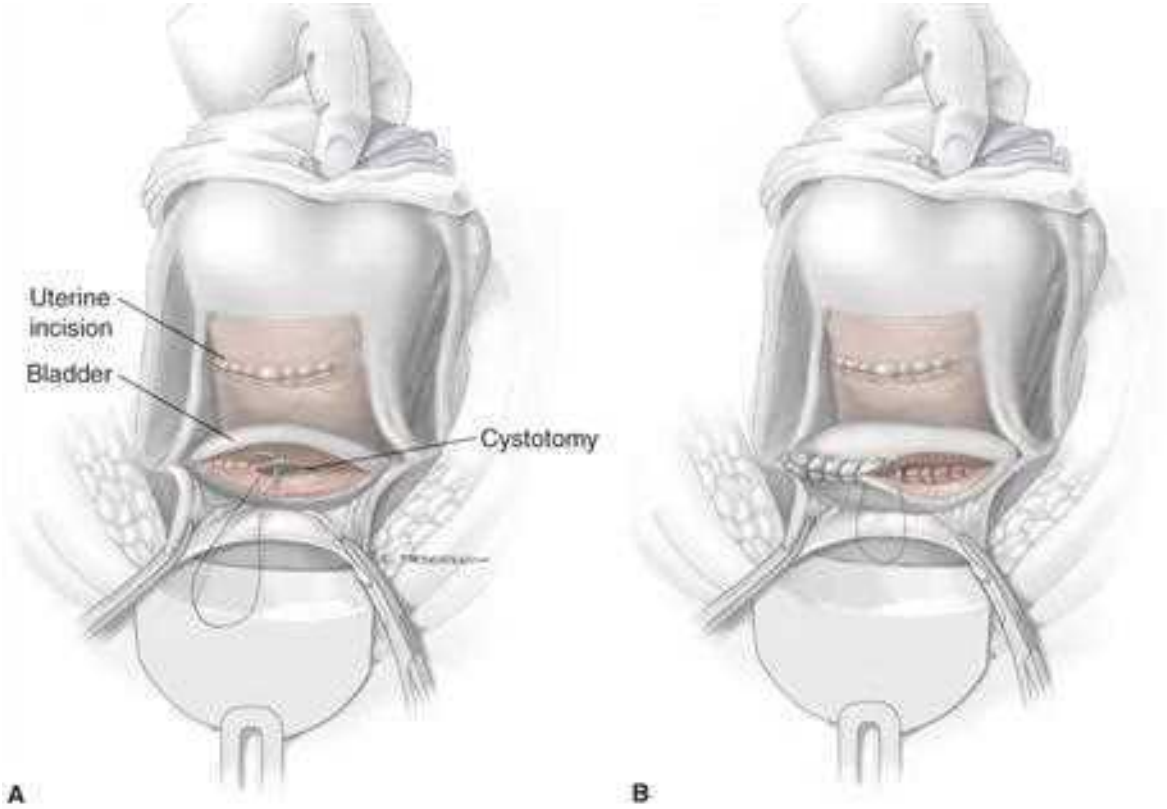
Bladder injury is typically identified intraoperatively, and initially, a clear-fluid gush or the Foley bulb may be seen. If cystotomy is suspected, it can be confirmed with retrograde instillation of infant formula or methylene-blue-stained saline through a Foley catheter into the bladder. Leakage of opaque milk or methylene blue aids in identification of the laceration as well as delineation of its borders. The dome is lacerated in 95 percent of cases, and injuries at the trigone form the remainder (Phipps, 2005).

Prior to cystotomy repair, ureters are examined, and surveillance for urine jets from each orifice follows. This can be done directly through the cystotomy, if at the dome, or through a separate diagnostic extraperitoneal or retropubic cystotomy, if injury nears the trigone. Jet visualization can be assisted by 50 mg of methylene blue administered intravenously.

Once ureteral patency is confirmed, the bladder may be closed with a two- or three-layer running closure using a 3–0 absorbable or delayed-absorbable suture (Fig. 30-22). The first layer inverts the mucosa into the bladder. The bladder is then filled with a marker fluid to demonstrate integrity of the repair. Leaking defects can be closed with interrupted reinforcing stitches. Subsequent layers reapproximate the bladder muscularis. Postoperative care requires continuous bladder drainage for 7 to 14 days to permit healing and minimize the risk of fistula formation. Uropathogen prophylaxis during this drainage is not required. Also, cystourethrography need not be routinely performed prior to catheter removal for a simple, single laceration (Davis, 1999).

FIGURE 30-22

Cystotomy repair. **A.** The primary layer inverts the bladder mucosa with running or interrupted sutures of 3–0 delayed-absorbable or absorbable suture. **B.** Second and possibly a third layer approximate the bladder muscularis to reinforce the incision closure.



Larger lacerations in or near the trigone require careful attention. Specialists may be consulted, and in preparation, ureteral stents can be assembled. In these cases, ureteral orifices are directly inspected to document jets from both. If not seen, then stents may be passed through the cystotomy and into each orifice to confirm patency. Once this is confirmed, repair should not disrupt the ureteral orifices, and stents may remain to ensure ureteral patency.

Unrepaired cystotomy can manifest as hematuria, oliguria, abdominal pain, ileus, ascites, peritonitis, fever, urinoma, or fistula. For diagnosis, retrograde cystography or abdominal computed tomography (CT) with cystography can be used (Tarney, 2013). Cystoscopy is also an option but may require an operating room. Once identified, prompt repair is indicated (Balgobin, 2017).

Ureteral Injury

These injuries occur most often during repair of hysterotomy extensions into the broad ligament or vagina (Eisenkop, 1982). If ureteral injury is suspected, methylene blue is administered. The pelvis is directly inspected for dye extravasation, which suggests ureteral transection. Next, brisk dye-stained urine jets are sought from each orifice to exclude ureteral kinking or ligation. Orifice viewing may be via cystoscopy, if available; through a comorbid traumatic cystotomy; or through a diagnostic cystotomy. With sluggish or absent jets, consultation with a specialist is typically requested. A ureteral catheter is first threaded to identify a potential obstruction site and guide ureterolysis. Kinked or ligated ureters can be relieved by release of ensnaring sutures. Crush injuries are inspected to ensure vital tissue. In these cases, stents are left to avert ureteral stricture. A Foley catheter remains for 7 to 10 days, and the ureteral catheters are removed via cystoscopy after 14 days. Intravenous pyelography (IVP) is usually not necessary before removal of the stent if it was placed as a precautionary measure after relatively minor injury (Davis, 1999).

Crush injuries with devascularization, thermal injury, or transection require more extensive repair. If a healthy-appearing ureter can be reimplanted into the bladder without undue tension, then ureteroneocystostomy is preferable. For more proximal injuries, ureteroureterostomy, psoas hitch, or Boari flap creation may be needed. An explanation of these more extensive procedures is found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Balgobin, 2017).

Unrecognized ureteral injury can mimic those of cystotomy with the addition of possible costovertebral angle tenderness. CT urography is a preferred initial diagnostic tool (Sharp, 2016). The duration of time from injury to identification directs repair. Those identified early are often suitable for immediate repair.

Bowel Injury

Serosal tears represent weak points in the small bowel. If obstruction develops postoperatively, these weak spots may perforate, leading to peritonitis. If serosal tears are few in number, they can be oversewn with either a fine absorbable or nonabsorbable suture (Davis, 1999). More significant lacerations are often repaired in consultation with a general surgeon or gynecologic oncologist.

POSTOPERATIVE CARE

Euvolemia Evaluation

During and after cesarean delivery, requirements for intravenous fluids can vary considerably. Administered fluids consist of either lactated Ringer solution or a similar crystalloid solution with 5-percent dextrose. Typically, at least 2 L is infused during surgery. Blood loss with uncomplicated cesarean delivery approximates 1000 mL. The average-sized woman with a hematocrit of 30 percent or more and with a normally expanded blood and extracellular fluid volume most often will tolerate blood loss up to 2000 mL without difficulty. Unappreciated bleeding through the vagina during the procedure, bleeding concealed in the uterus after its closure, or both commonly lead to underestimation.

Blood loss averages 1500 mL with elective cesarean hysterectomy, although this is variable (Pritchard, 1965). Most peripartum hysterectomies are unscheduled, and blood loss in these cases is correspondingly greater. Thus, in addition to close monitoring of vital signs and urine output, the hematocrit should be determined intra- or postoperatively as indicated.

Recovery Suite

The amount of vaginal bleeding is closely monitored for at least an hour in the immediate postoperative period. The uterine fundus is also identified frequently by palpation to ensure that the uterus remains firmly contracted. Unfortunately, as conduction analgesia fades or the woman awakens from general anesthesia, abdominal palpation is likely to produce pain. A patient-controlled analgesia (PCA) pump can be effective. Once regional analgesia begins to fade or the woman becomes fully awake following general anesthesia, criteria for transfer to the postpartum ward include minimal bleeding, stable vital signs, and adequate urine output.

Hospital Care until Discharge

Analgesia, Vital Signs, Intravenous Fluids

Several schemes are suitable for postoperative pain control. One PCA regimen uses intravenous morphine given as needed as a 1-mg dose with a 6-minute lockout interval and maximum dose of 30 mg in 4 hours. An additional 2-mg booster dose is permitted for a maximum of 2 doses. Alternatively, intramuscular (IM) meperidine, 50 to 75 mg every 3 to 4 hours, or IM morphine, 10 to 15 mg every 3 to 4 hours, is suitable. In a trial using these options, Yost and associates (2004) found that morphine provided superior pain relief to meperidine and was associated with significantly higher rates of breastfeeding and continuation of newborn rooming in. Breastfeeding can be initiated the day of surgery. If the mother elects not to breastfeed, a binder that supports the breasts without marked compression usually will minimize discomfort.

After transfer to her room, the woman is assessed at least hourly for 4 hours, and thereafter at intervals of 4 hours. Deep breathing and coughing are encouraged to prevent atelectasis. Vital signs, uterine tone, urine output, and bleeding are evaluated. The hematocrit is routinely measured the morning after surgery. It is checked sooner if there was unusual blood loss or if there is hypotension, tachycardia, oliguria, or other evidence to suggest hypovolemia. If the hematocrit is decreased significantly from the preoperative level, the measurement is repeated and a search is instituted to identify the cause. If the hematocrit stabilizes, the mother can be allowed to ambulate, and if there is little likelihood of further blood loss, iron therapy is preferred to transfusion.

Postpartum, the patient begins to mobilize and excrete her physiologically expanded extravascular volume. Thus, maintenance intravenous fluid proves adequate after surgery until consistent oral intake is reestablished. If urine output falls below 30 mL/hr, however, the woman should be reevaluated promptly. The cause of the oliguria can range from unrecognized blood loss to an antidiuretic effect from infused oxytocin.

Women undergoing unscheduled cesarean delivery may have pathological retention or constriction of the extracellular fluid compartment caused by severe preeclampsia, sepsis syndrome, vomiting, prolonged labor without adequate fluid intake, or increased blood loss. Women with these complications are generally observed in the recovery room until stabilization is assured.

Bladder and Bowel Function

The Foley catheter most often can be removed by 12 hours postoperatively, or more conveniently, the morning after surgery. The prevalence of urinary retention following cesarean delivery approximates 3 to 7 percent (Chap. 36, Perineal Care). Failure to progress in labor and postoperative narcotic analgesia are identified risks (Chai, 2008; Kandadai, 2014; Liang, 2007).

In uncomplicated cases, liquids or solid food may be offered within hours of surgery and advanced as tolerated (Guo, 2015). Some degree of adynamic ileus follows virtually every abdominal operation, but in most cases of cesarean delivery, it is negligible. Postoperative ileus symptoms include abdominal distention, gas pains, and an inability to pass flatus or stool. With persistent nausea and vomiting or with prolonged bowel function delay, radiological imaging may aid exclusion of bowel obstruction. A plain abdominal radiograph is a frequent first choice. However, in the general population, this study is diagnostic in only 50 to 60 percent of small bowel obstruction cases (Maglinte, 1997). Thus, a radiograph may best serve as a triage tool in cases in which ileus is the suspected diagnosis. Notably, an enlarged postpartum uterus can compress the rectosigmoid and prevent it from filling with gas. Thus, findings suggesting a distal colonic obstruction may confuse true cases

of transient ileus (Kammen, 2000). In comparison, CT with intravenous contrast provides greater accuracy for small bowel obstruction. Oral contrast is concurrently given when SBO is a consideration (Katz, 2013). Last, although uncommon, an unrecognized bowel injury may be responsible for otherwise unexplained fever and poor bowel function. Here, CT may be most diagnostic of potential etiologies.

As treatment of ileus, intravenous fluids compensate for poor oral intake and losses from emesis. Electrolyte imbalances are corrected to improve smooth muscle activity and avoid bowel edema. Nasogastric decompression is necessary only with persistent vomiting or severe distention.

For prevention, intraoperative goals strive to minimize bowel manipulation, avoid excess intravenous fluids or profound hypovolemia, and limit surgery length (Bragg, 2015). Postoperatively, gum chewing enhances early bowel function recovery by nearly 7 hours after cesarean delivery (Zhu, 2014). Among studies, chewing was initiated immediately or up to 12 hours later, lasted 15 to 60 minutes, and was repeated in at least three sessions daily (Pereira Gomes Morais, 2016).

Ambulation and Wound Care

As discussed earlier, women undergoing cesarean delivery have an increased risk of venous thromboembolism compared with those delivering vaginally. Early ambulation lowers the thromboembolism risk. Walking to the bathroom begins, initially with assistance. Brief walks are encouraged, and ambulation can be timed so that a recently administered analgesic will minimize discomfort.

Although not evidence based, we remove the surgical dressing after 24 hours and inspect the incision daily. One small randomized trial showed no wound healing differences if removed at 6 hours (Peleg, 2016). By the third postpartum day, showering is not harmful to the incision. Prior to this, a plastic cover can maintain dryness during showers. If used, staples often are removed on the fourth day. Once removed, dressing strips (Steri-Strips) can be placed as needed for 1 week to reinforce skin edge integrity. If there is concern for superficial wound separation, staples remain in place for 7 to 10 days.

Hospital Discharge

For uncomplicated cesarean delivery, the average hospitalization length is three to four days (Buie, 2010). Data from studies suggest that earlier discharge is feasible for properly selected women and newborns (Bayoumi, 2016; Tan, 2012). Protocols ideally include earlier reevaluation for neonatal jaundice.

Activities during the first week should be restricted to self-care and newborn care with assistance. Driving can be resumed when pain does not limit the ability to brake quickly and when narcotic medications are not in use. In women with cesarean delivery, intercourse was resumed in 44 percent by 6 weeks postpartum, in 81 percent by 3 months, and 97 percent at 1 year (McDonald, 2013). After the puerperium, the quality of sexual functioning does not differ between those undergoing spontaneous vaginal delivery or cesarean (Chang, 2015; Fehniger, 2013; Rogers, 2014). Return to work is variable. Six weeks is commonly cited, although many women use the Family and Medical Leave Act to allow up to 12 weeks for recovery and newborn bonding.

CHAPTER 31: Prior Cesarean Delivery

> *The occurrence of pregnancy after a Caesarean section, however, is not always devoid of danger, cases have been reported in which the uterine cicatrix ruptured in the latter part of a subsequent gestation. It is also stated that the adhesions that sometimes form between the uterus and the abdominal wall occasionally exert a deleterious influence in subsequent pregnancies.*
>
> —J. Whitridge Williams (1903)

INTRODUCTION

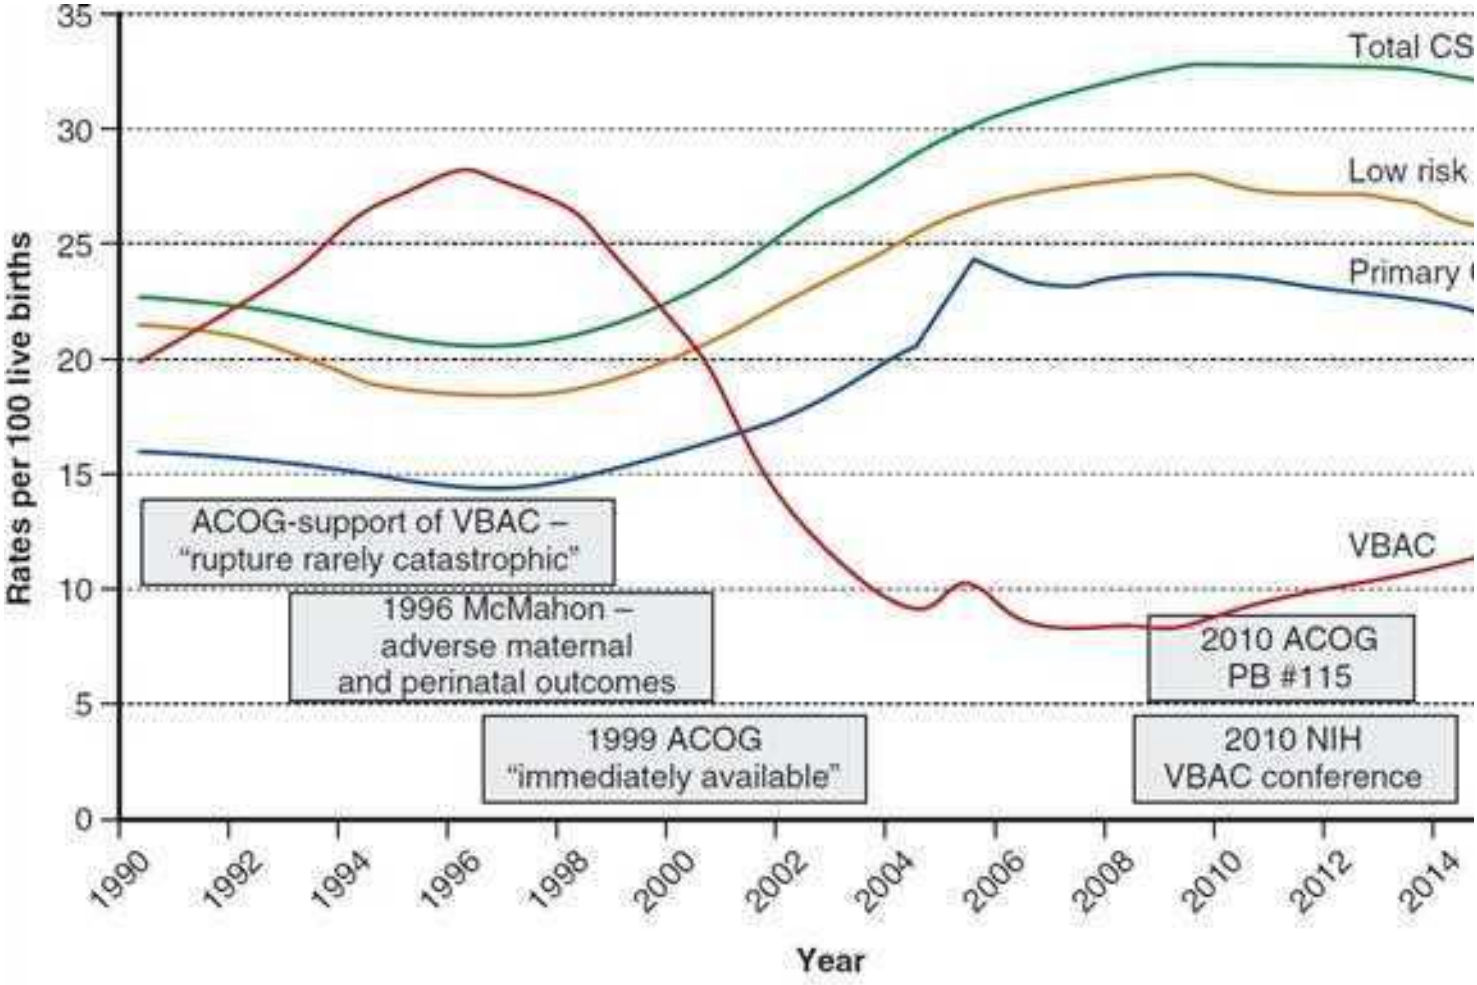
From the above, there was an early appreciation for some of the major problems encountered in women with a prior cesarean delivery. Few issues in modern obstetrics have been as controversial as the management of these women. Indeed, the dangers associated with uterine rupture led to the oft-quoted remark by Cragin in 1916: “Once a cesarean, always a cesarean.” As we reach the 100-year mark of Cragin’s pronouncement, the issue remains largely unsettled.

100 YEARS OF CONTROVERSY

By the beginning of the 20th century, cesarean delivery had become relatively safe. But, as women survived the first operation and conceived again, they were now at risk for rupture of the uterine scar. Still, the specter of rupture did not did not result in strict adherence to repeat cesarean delivery. Indeed, Eastman (1950) described a 30-percent postcesarean vaginal delivery rate at Johns Hopkins Hospital. The uterine rupture incidence was 2 percent and associated with a 10-percent maternal mortality rate. During the 1960s, observational studies suggested that vaginal delivery was a reasonable option (Pauerstein, 1966, Pauerstein, 1969). Germane to this is that through the 1960s, the overall cesarean delivery rate approximated only 5 percent. Since then, as the primary cesarean rate escalated, the rate for repeat cesarean delivery followed (Rosenstein, 2013).

During the 1980s, a National Institutes of Health (NIH) Consensus Development Conference (1981) was convened, and it questioned the necessity of routine repeat cesarean delivery. With support and encouragement from the American College of Obstetricians and Gynecologists (1988, 1994), enthusiastic attempts were begun to increase the use of *vaginal birth after cesarean—VBAC*. These attempts were highly successful, and VBAC rates increased from 3.4 percent in 1980 to a peak of 28.3 percent in 1996. These rates, along with a concomitant decline in total cesarean delivery rates for the United States, are shown in Figure 31-1.

FIGURE 31-1
Total, primary, and low-risk cesarean delivery (CS) rates and vaginal birth after previous cesarean (VBAC) rates in the United States, 1989–2015. Epochs denoted within rectangles represent contemporaneous ongoing events related to these rates. ACOG = American College of Obstetricians and Gynecologists; NIH = National Institutes of Health; PB = practice bulletin. (Data from Hamilton, 2015, 2016; National Institutes of Health: NIH Consensus Development Conference, 2010.)

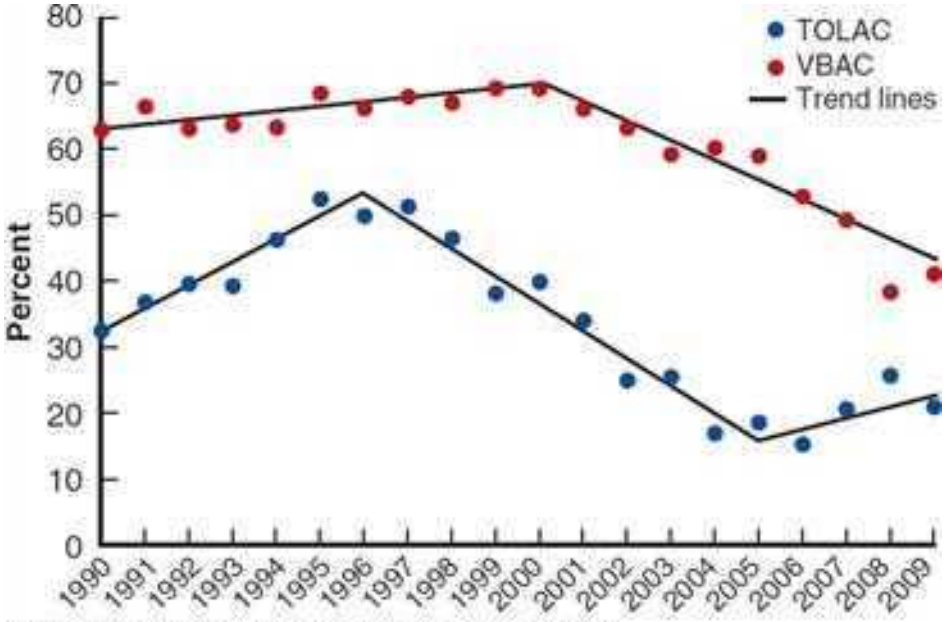


As the vaginal delivery rate increased, so did reports of uterine rupture-related maternal and perinatal morbidity and mortality (McMahon, 1996; Sachs, 1999). These complications dampened prevailing enthusiasm for a *trial of labor after cesarean section (TOLAC)* and stimulated the American College of Obstetricians and Gynecologists (1998) to caution that such trials should be attempted only in appropriately equipped institutions with physicians *readily available* to provide emergency care. Less than a year later, the College (1999) recommended that physicians should be *immediately available*. Many believe that this change of one word — from *readily* to *immediately* available—was in large part responsible for the decade-long decline in national VBAC rates illustrated in Figure 31-1 (Cheng, 2014; Leeman, 2013).

Uddin and colleagues (2013) reported the proportion of women with a prior cesarean delivery who underwent TOLAC. This number peaked in 1995, when slightly more than half of all of these women chose this option. Since that time, the proportion of women attempting TOLAC declined to a nadir in 2006 of about 16 percent and has subsequently increased to 20 to 25 percent through 2009. These investigators further reported that the percentage of VBACs reached its peak in 2000 with approximately 70 percent of women being successful, but this has subsequently declined to a nadir of 38 percent in 2008 (Fig. 31-2).

FIGURE 31-2

Percentage of births with trial of labor among all deliveries with a prior cesarean delivery and percentage of successful trials of labor among all trials of labor after caesarean delivery in the United States, 1990–2009. TOLAC = trial of labor after cesarean delivery; VBAC = vaginal birth after cesarean delivery. (Data from Uddin SFG, Simon AE: Rates and success rates of trial of labor after cesarean delivery in the United States, 1990–2009. Matern Child Health J 17:1309, 2013.)



In reality, several other interrelated factors—both medical and nonmedical—have undoubtedly contributed to declining VBAC rates. Because of their complexity and importance, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) and the Office of Medical Applications of Research (OMAR) convened an NIH Consensus Development Conference Panel (2010) to study the issues of VBAC. The panel report included a contemporaneous summary concerning the risks and benefits of repeat cesarean versus vaginal delivery. These findings are subsequently described along with summaries of current recommendations by various professional organizations. Importantly, data from California indicate that VBAC rates have not perceptibly increased since the 2010 NIH Consensus Conference (Barger, 2013).

INFLUENCING FACTORS

For the woman who has had a previous cesarean delivery, planning for future pregnancies and the delivery route should begin with preconceptional counseling and be addressed once again early in prenatal care. Importantly, any decision is subject to continuing revisions as dictated by exigencies that arise during pregnancy. Assuming no mitigating circumstances, there are two basic choices. First, a *TOLAC* offers the goal of achieving *VBAC*. If cesarean delivery becomes necessary during the trial, then it is termed a “failed trial of labor.” A second choice is *elective repeat cesarean delivery (ERCD)*. This includes scheduled cesarean delivery as well as unscheduled but planned cesarean delivery for spontaneous labor or another indication.

The ultimate decision should weigh clinical factors known to influence TOLAC success as well as benefits and risks. As expected, these rates vary between institutions and providers. Factors that influence a successful TOLAC are listed in Table 31-1. Finally, economic, staffing, and medicolegal factors may shape the decision to offer TOLAC.

TABLE 31-1

Some Factors That Influence a Successful Trial of Labor in a Woman with Prior Cesarean Delivery

Low-Risk	Favors Success	Increased Failure Rate	High-Risk[a]
Transverse incision Prior vaginal delivery Appropriate counseling Sufficient personnel and equipment	Teaching hospital White race Spontaneous labor Prior fetal malpresentation 1 or 2 prior transverse incisions Nonrecurrent indication Current preterm pregnancy	Single mother Increased maternal age Macrosomic fetus Obesity Breech Multifetal pregnancy Preeclampsia EGA >40 weeks Low-vertical incision Unknown incision Labor induction Medical disease Multiple prior cesarean deliveries Education <12 years Short interdelivery interval Liability concerns	Classical or T incision Prior rupture Patient refusal Transfundal surgery Obstetrical contraindication, e.g., previa Inadequate facilities

[a]Most consider these absolute contraindications.

EGA = estimated gestational age.

DELIVERY ROUTE RISKS

As evidence mounted that the risk of uterine rupture might be greater than expected, the American College of Obstetricians and Gynecologists (1988, 1998, 1999, 2017a) issued updated Practice Bulletins supporting labor trials but also urging a more cautious approach. It is problematic that both options have risks and benefits to mother and fetus but that these are not always congruent.

Maternal Risks

Rates of uterine rupture and associated complications clearly are increased with TOLAC. Uterine rupture typically is classified as either (1) *complete*, when all layers of the uterine wall are separated, or (2) *incomplete*, when the uterine muscle is separated but the visceral peritoneum is intact. Incomplete rupture is also commonly referred to as *uterine dehiscence*. It is these risks that underpin most of the angst in attempting TOLAC. Despite this, some have argued that these factors should weigh only minimally in the decision because their absolute risk is low. One systematic review by Guise and colleagues (2010) concluded that the risk of uterine rupture was significantly elevated in women undergoing TOLAC—absolute risk of 0.47 percent and relative risk of 20.7—compared with those choosing ERCD.

TABLE 31-2

Complications in Women with a Prior Cesarean Delivery Enrolled in the NICHD Maternal-Fetal Medicine Units Network, 1999–2002

Complication	Trial of Labor Group n = 17,898 No. (%)	Elective Repeat Cesarean Group n = 15,801 No. (%)	Odds Ratio (95% CI)	*p* value
Uterine rupture	124 (0.7)	0	NA	<.001
Uterine dehiscence	119 (0.7)	76 (0.5)	1.38 (1.04–1.85)	.03
Hysterectomy	41 (0.2)	47 (0.3)	0.77 (0.51–1.17)	.22

[a]Denominator is 15,338 for the trial of labor group and 15,014 for the elective repeat cesarean delivery group.

CI = confidence interval; HIE = hypoxic ischemic encephalopathy; NA = not applicable; NICHD = National Institute of Child Health and Human Development; NS = not significant.

Adapted from Landon, 2004.

The Maternal-Fetal Medicine Units Network conducted a prospective study at 19 academic centers (Landon, 2004). The outcomes of nearly 18,000 women attempting TOLAC were compared with more than 15,000 gravidas undergoing ERCD. The absolute risk of uterine rupture was 0.7 percent compared with no reported uterine ruptures in the ERCD cohort (Table 31-2). Most studies suggest that the maternal *mortality* rate does not differ significantly between these two groups (Landon, 2004; Mozurkewich, 2000). But, the aforementioned systematic review by Guise (2010) found the risk of maternal death to be significantly reduced for women undergoing TOLAC compared with ERCD. In a retrospective Canadian cohort study, the maternal death rate for women undergoing ERCD was 5.6 per 100,000 cases compared with 1.6 per 100,000 for those attempting TOLAC (Wen, 2005).

Estimates of maternal *morbidity* are also conflicting. The review by Guise (2010) observed no significant differences in the risk of hysterectomy or transfusion. But, another metaanalysis reported that women undergoing TOLAC were approximately half as likely to require a blood transfusion or hysterectomy compared with those undergoing ERCD (Mozurkewich, 2000). Conversely, in the Network study, investigators observed that the risks of transfusion and infection were significantly greater for women attempting TOLAC (Landon, 2004). This disparity is also found among other studies. Notably, compared with a successful TOLAC, the risk of these major complications was fivefold greater with an attempted vaginal delivery that failed (Babbar, 2013; Rossi, 2008).

Fetal and Neonatal Risks

TOLAC is associated with significantly higher *perinatal mortality* rates compared with ERCD. The perinatal rate with TOLAC is 0.13 compared with 0.05 percent for ERCD, and the neonatal mortality rates are 0.11 versus 0.06 percent, respectively (Guise, 2010). In another study of nearly 25,000 women with a prior cesarean delivery, the vaginal-delivery-related perinatal death risk was 1.3 per 1000 among 15,515 women electing TOLAC. Although this absolute risk is small, it is *11 times greater* than the risk found in 9014 women with ERCD (Smith, 2002).

TOLAC also appears to be associated with a higher risk of *hypoxic ischemic encephalopathy (HIE)* than ERCD. The Network study reported the incidence of HIE at term to be 46 per 100,000 TOLACs compared with zero cases in women undergoing ERCD (Landon, 2004).

In the systematic review, the absolute risk of *transient tachypnea of the newborn* was slightly higher with ERCD compared with TOLAC—4.2 versus 3.6 percent (Guise, 2010). But, neonatal bag and mask ventilation were used more often in newborns delivered following TOLAC than in those delivered by ERCD—5.4 versus 2.5 percent.

Finally, there are no significant differences in 5-minute Apgar scores or neonatal intensive care unit admission rates for newborns delivered by TOLAC compared with those delivered by ERCD. Birth trauma from lacerations is more commonly seen in neonates born by ERCD.

CANDIDATES FOR TRIAL OF LABOR

Few high-quality data are available to guide selection of TOLAC candidates. In a population-based cohort study of 41,450 women delivering in California hospitals, Gregory and colleagues (2008) reported a TOLAC success rate of 74 percent when no maternal, fetal, or placental complications were present. Several algorithms and nomograms have been developed to aid prediction, but none has demonstrated reasonable prognostic value (Grobman, 2007b, 2008, 2009; Macones, 2006; Metz, 2013; Srinivas, 2007). A predictive model for failed trial of labor, however, was found to be somewhat predictive of uterine rupture or dehiscence (Stanhope, 2013). Despite these limitations for precision, several points are pertinent to candidate evaluation and are described in the next sections. Current recommendations of the American College of Obstetricians and Gynecologists (2017a) are that most women with one previous low-transverse hysterotomy are candidates, and if appropriate, they should be counseled regarding TOLAC and ERCD options. Although not our practice, those with two prior low-transverse incisions may be considered.

Prior Uterine Incision

Prior Incision Type

The type and number of prior cesarean deliveries are overriding factors in recommending TOLAC. Women with one prior low-transverse hysterotomy have the lowest risk of symptomatic scar separation (Table 31-3). The highest risks are with prior vertical incisions extending into the fundus, such as that shown in Figure 31-3. Importantly, in some women, a classical scar will rupture before labor onset, and this can happen several weeks before term. In a review of 157 women with prior classical cesarean delivery, one woman had a complete uterine rupture before labor onset, whereas 9 percent had a uterine dehiscence (Chauhan, 2002).

TABLE 31-3

Types of Prior Uterine Incisions and Estimated Risks for Uterine Rupture

Prior Incision	Estimated Rupture Rate (%)
Classical	2–9
T-shaped	4–9
Low-vertical[a]	1–7
One low-transverse	0.2–0.9
Multiple low-transverse	0.9–1.8
Prior preterm cesarean delivery	“increased”
Prior uterine rupture	
Lower segment	2–6
Upper uterus	9–32

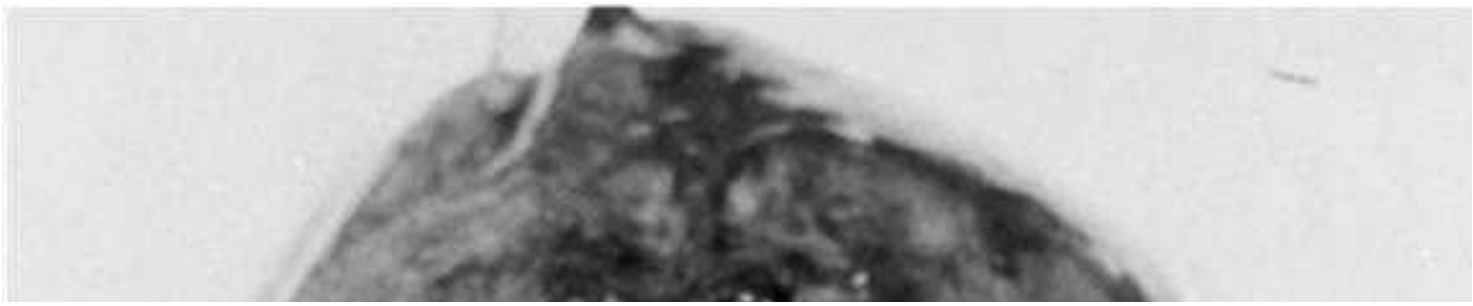
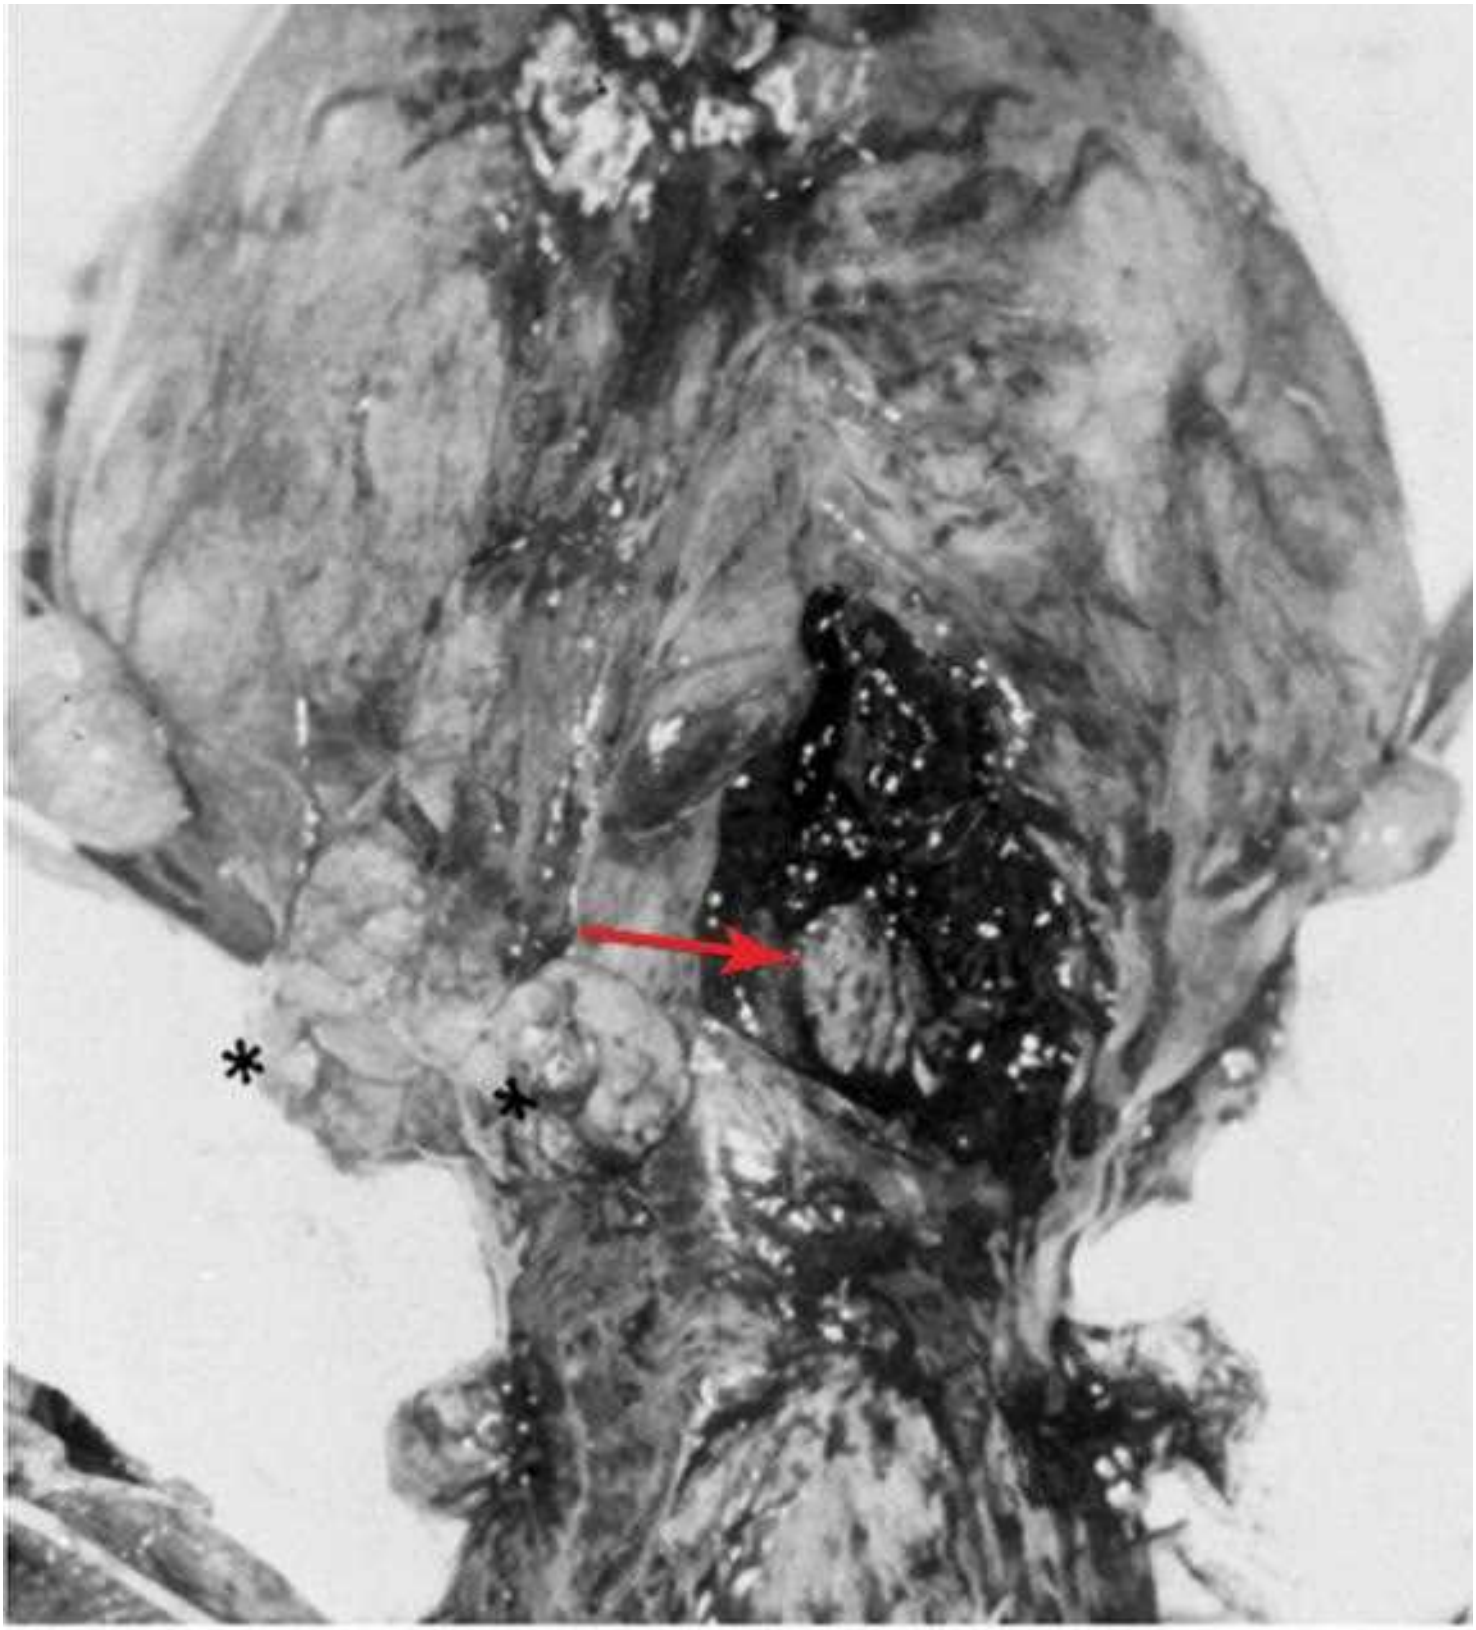
Data from the American College of Obstetricians and Gynecologists, 2017a; Cahill, 2010b; Chauhan, 2002; Landon, 2006; Macones, 2005a,b; Martin, 1997; Miller, 1994; Sciscione, 2008; Society for Maternal-Fetal Medicine, 2012; Tahseen, 2010.

FIGURE 31-3

Ruptured vertical cesarean delivery scar (*arrow*) identified at time of repeat cesarean delivery early in labor. The two black asterisks to the left indicate some sites of densely adhered omentum.





The risk of uterine rupture in women with a prior vertical incision that did not extend into the fundus is unclear. Martin (1997) and Shipp (1999) and their coworkers reported that these low-vertical uterine incisions did not have an increased risk for rupture compared with low-transverse incisions. The American College of Obstetricians and Gynecologists (2017a) concluded that although evidence is limited, women with a prior vertical incision in the lower uterine segment without fundal extension may be candidates for TOLAC. This is in contrast to prior classical or T-shaped uterine incisions, which are considered by most as contraindications to labor.

Although there are few indications for a primary classical incision, 53 percent of women undergoing cesarean delivery between $24^{0/7}$ weeks and $25^{6/7}$ weeks have such an incision (Osmundson, 2013). By 28 weeks' gestation, the risk drops to 35 percent and declines to <10 percent by 32 weeks. The likelihood of classical uterine

incision is also increased by noncephalic presentations. In those instances—for example, preterm breech fetus with an undeveloped lower segment—the "low vertical" incision almost invariably extends into the active segment. Prior preterm cesarean delivery may result in a twofold increased risk for rupture (Sciscione, 2008). This may be in part explained by the greater likelihood with a preterm fetus of upward uterine incision extension. Lannon and coworkers (2015) compared 456 women with a prior periviable cesarean delivery with more than 10,000 women whose prior cesarean delivery occurred at term. They observed uterine rupture in 1.8 percent in the prior periviable group versus 0.4 percent in the prior term group. Of the uterine ruptures in the periviable group, half were in women whose prior uterine incision was described as low transverse. Harper and associates (2009) did not confirm these findings.

There are also special considerations for women with uterine malformations who have undergone cesarean delivery. Earlier reports suggested that the uterine rupture risk in a subsequent pregnancy was greater than the risk in those with a prior low-transverse hysterotomy and normally formed uterus (Ravasia, 1999). But, in a study of 103 women with müllerian duct anomalies, there were no cases of uterine rupture (Erez, 2007). Given the wide range of risk for uterine rupture associated with the various uterine incision types, it is not surprising that most fellows of the American College of Obstetricians and Gynecologists consider the type of prior incision to be the most important factor when considering a TOLAC (Coleman, 2005).

Prior Incision Closure

As discussed in Chapter 30 (Uterine Repair), the low-transverse hysterotomy incision can be sutured in either one or two layers. A metaanalysis by Roberge and colleagues (2014) compared single- versus double-layer closure and locking versus unlocking suture for uterine closure. They reported that rates for uterine dehiscence or uterine rupture for these closures did not differ significantly. Single-layer closure and locked first layer, however, was associated with a reduced myometrial thickness during subsequent sonographic measurement. In contrast, Bennich and coworkers (2016) reported that a double-layer closure did not increase the residual myometrial thickness when saline contrast sonography was done several months postpartum. At Parkland Hospital, we routinely close the lower-segment incision with one running, locking suture line.

Number of Prior Cesarean Incisions

At least three studies report a doubling or tripling of the rupture rate in women with two compared with one prior transverse hysterotomy (Macones, 2005a; Miller, 1994; Tahseen, 2010). In contrast, analysis of the Network database by Landon and associates (2006) did not confirm this. Instead, they reported an insignificant difference in the uterine rupture rate in 975 women with multiple prior cesarean deliveries compared with 16,915 women with a single prior operation—0.9 versus 0.7 percent, respectively. As discussed in Multiple Repeat Cesarean Deliveries, other serious maternal morbidity increases along with the number of prior cesarean deliveries (Marshall, 2011).

Imaging of Prior Incision

Sonographic measurement of a prior hysterotomy incision has been used to predict the likelihood of rupture. Large defects in a nonpregnant uterus forecast a greater risk for subsequent rupture (Osser, 2011). Naji and coworkers (2013a,b) found that the *residual myometrial thickness* decreased as pregnancy progressed and that rupture correlated with a thinner scar. In a systematic review, women with a prior low-transverse cesarean incision underwent third-trimester sonographic evaluation (Jastrow, 2010a). Investigators concluded that the thickness of the lower uterine segment was a strong predictor for a uterine scar defect in women with prior cesarean delivery. They defined this segment as the smallest measurement between urine in the maternal bladder and amnionic fluid. That said, they could not find an ideal threshold value to recommend TOLAC. This same group subsequently recruited 1856 women contemplating vaginal birth after a single low-transverse incision, and they sonographically measured lower uterine segment thickness by between 34 weeks and 39 weeks (Jastrow, 2016). They grouped women into three risk categories for uterine rupture during TOLAC based on the measured segment value: high risk <2.0 mm; intermediate risk 2.0–2.4 mm; and low risk ≥2.5 mm. The TOLAC rates were 9, 42, and 61 percent in the three categories, respectively. Of the 984 TOLACs, there were no symptomatic uterine ruptures. Overall, data are limited, and this evaluation is currently not part of our routine practice.

Prior Uterine Rupture

Women who have previously sustained a uterine rupture are at greater risk for recurrence. As shown in Table 31-3, those with a previous low-segment rupture have up to a 6-percent recurrence risk, whereas prior upper segment uterine rupture confers a 9- to 32-percent risk (Reyes-Ceja, 1969; Ritchie, 1971). Fox and associates (2014) reported 14 women with prior uterine rupture and 30 women with prior uterine dehiscence. In 60 subsequent pregnancies, they reported no uterine ruptures or severe complications if women were managed in a standardized manner with cesarean delivery prior to labor onset.

Interdelivery Interval

Magnetic resonance imaging studies of myometrial healing suggest that complete uterine involution and restoration of anatomy may require at least 6 months (Dicle, 1997). To explore this further, Shipp and coworkers (2001) examined the relationship between interdelivery interval and uterine rupture in 2409 women with one prior cesarean delivery. There were 29 women with a uterine rupture—1.4 percent. Interdelivery intervals ≤18 months were associated with a threefold greater risk of symptomatic rupture during a subsequent TOLAC compared with intervals >18 months. Similarly, Stamilio and associates (2007) noted a threefold augmented risk of uterine rupture in women with an interpregnancy interval <6 months compared with one ≥6 months.

Prior Vaginal Delivery

Prior vaginal delivery, either before or after a cesarean birth, improves the prognosis for a subsequent vaginal delivery with either spontaneous or induced labor (Aviram, 2017; Grinstead, 2004; Hendler, 2004; Mercer, 2008). Prior vaginal delivery also lowers the risk of subsequent uterine rupture and other morbidities (Cahill, 2006; Hochler, 2014; Zelop, 1999).

Prior Cesarean Delivery Indication

Women with a nonrecurring indication—for example, breech presentation—have the highest VBAC rate of nearly 90 percent (Wing, 1999). Those with a prior cesarean delivery for fetal compromise have an approximately 80-percent VBAC rate, and for those done for labor arrest, VBAC rates approximate 60 percent (Bujold, 2001; Peaceman, 2006). Prior second-stage cesarean delivery can be associated with second-stage uterine rupture in a subsequent pregnancy (Jastrow, 2013).

Fetal Size and Lie

Most studies show that increasing fetal size is inversely related to VBAC rates. The risk for uterine rupture is less robustly linked. Zelop and associates (2001) studied outcomes of almost 2750 women undergoing TOLAC, and the rate of uterine rupture increased—albeit not significantly—with rising fetal weight. The rate was 1.0 percent for fetal weight <4000 g, 1.6 percent for >4000 g, and 2.4 percent for >4250 g. Similarly, Jastrow and colleagues (2010b) in a retrospective report of 2586 women with a prior low-transverse uterine incision, observed an elevated risk for a failed trial of labor, uterine rupture, shoulder dystocia, and perineal laceration associated with rising birthweights. Conversely, Baron and coworkers (2013) did not find higher uterine rupture rates with birthweights >4000 g. With a preterm fetus, women who attempt a TOLAC have higher VBAC rates and lower rupture rates (Durnwald, 2006; Quiñones, 2005).

Data supporting external cephalic version (ECV) for breech presentation are limited and are derived from small studies (Burgos, 2014; Weill, 2017). From these, ECV success and adverse event rates appear comparable to women without prior cesarean. The American College of Obstetricians and Gynecologists (2016) acknowledges this lack of robust data. At Parkland Hospital, we do not attempt ECV in those with a prior cesarean delivery.

Multifetal Gestation

Twin pregnancy does not appear to increase the risk of uterine rupture. Ford and associates (2006) analyzed 1850 women with twins and reported a 45-percent successful VBAC rate and a rupture rate of 0.9 percent. Similar studies by Cahill (2005) and Varner (2007) and their colleagues reported rupture rates of 0.7 to 1.1 percent and VBAC rates of 75 to 85 percent. According to the American College of Obstetricians and Gynecologists (2017a), women with twins and a prior low-transverse hysterotomy can safely undergo TOLAC.

Maternal Obesity

Multiple studies have reported an inverse relationship between prepregnancy body mass index (BMI) and VBAC rates. Hibbard and coworkers (2006) reported the following rates: 85 percent with a normal BMI, 78 percent with a BMI between 25 and 30, 70 percent with a BMI between 30 and 40, and 61 percent with a BMI ≥40. Similar findings were reported by Juhasz and associates (2005).

Fetal Death

Most women with a prior cesarean delivery and fetal death in the current pregnancy would prefer a vaginal delivery. Although fetal concerns are obviated, available data suggest that maternal risks are increased. Nearly 46,000 women with a prior cesarean delivery in the Network database had a total of 209 fetal deaths at an average gestational age of 32.8 weeks (Ramirez, 2010). There were 158 women who elected TOLAC, with a VBAC rate of 87 percent. In the entire TOLAC group, the uterine rupture rate was 2.4 percent. Of the 116 women who underwent an induction of labor, there were five uterine ruptures (3.4 percent).

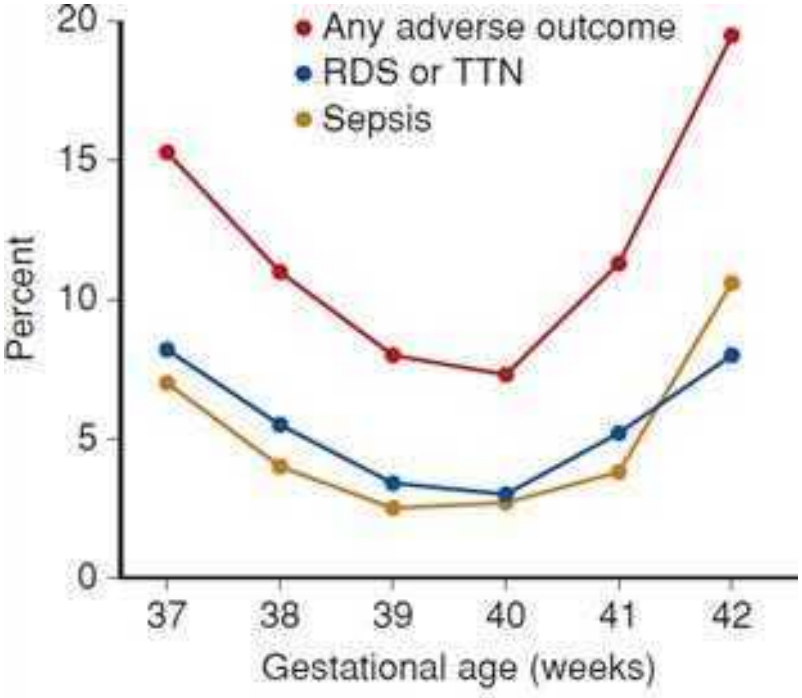
LABOR AND DELIVERY CONSIDERATIONS

Timing

The American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2017b) recommend delaying nonmedically indicated deliveries until 39 completed weeks of gestation or beyond. As shown in Figure 31-4, significant and appreciable adverse neonatal morbidity has been reported with elective delivery before 39 completed weeks (Chiossi, 2013; Clark, 2009). Thus, if ERCD is planned, it is essential that the fetus be mature.

FIGURE 31-4

Neonatal morbidity rates seen with 13,258 elective repeat cesarean deliveries. Any adverse outcome includes death. Sepsis includes suspected and proven. RDS = respiratory distress syndrome; TTN = transient tachypnea of the newborn. (Data from Tita AT, Landon MB, Spong CY, et al: Timing of elective repeat cesarean delivery at term and neonatal outcomes. N Engl J Med 360(2):111, 2009.)



The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) have established the following guidelines for timing an elective cesarean delivery, and accurate gestational dating is suitable using any of these criteria.

1. Sonographic measurements taken before 20 weeks' gestation support a gestational age ≥39 weeks.
2. Fetal heart sounds have been documented for 30 weeks by Doppler ultrasound.
3. A positive serum or urine β-human chorionic gonadotropin (hCG) test result has been documented for ≥36 weeks.

Intrapartum Care

Because of uterine rupture risks for women undergoing TOLAC, the American Academy of Pediatricians and the American College of Obstetricians and Gynecologists (2017) recommend that such trials be undertaken only in facilities with staff immediately available to provide emergency care. Moreover, these centers should have a plan and resources for managing uterine rupture. Some argue that these provisions deny women full access to choices. For example, in an earlier survey of Ohio hospitals, 15 percent of Level I, 63 percent of Level II, and 100 percent of Level III institutions met these requirements (Lavin, 2002). Moreover, an obstetrical anesthesia workforce survey reported that due to staffing limitations, TOLAC was allowed in only 88 percent of hospitals with ≥1500 annual deliveries, in 59 percent of those with 500 to 1499 deliveries, and in 43 percent of those with <500 deliveries (Traynor, 2016). In some cases, women choose to attempt TOLAC at a birthing center or at home (Shields, 2017).

Cervical Ripening and Labor Stimulation

Labor induction is associated with a higher failure rate during TOLAC. The risks for uterine rupture, however, are less clear with induction or augmentation, with the exception of prostaglandin E_1—misoprostol—which is contraindicated (American College of Obstetricians and Gynecologists, 2017a). Although most institutions are not so conservative, we do not induce or augment labor pharmacologically in women electing TOLAC at Parkland Hospital. Instead, we attempt induction only by amniotomy. Other considerations are to avoid induction or augmentation in women with an unknown prior incision type, an unfavorable cervix, or pregnancy >40 weeks.

Oxytocin

Induction or augmentation of labor with oxytocin has been *implicated* in increased rates of uterine rupture in women undergoing TOLAC (Zelop, 1999). In the Network study reported by Landon and colleagues (2004), uterine rupture was more frequent in women induced with oxytocin alone—1.1 percent—than in those in spontaneous labor—0.4 percent. Augmentation of labor was associated with uterine rupture in 0.9 percent. Among women in this trial without a prior vaginal delivery, the uterine rupture risk associated with oxytocin induction was 1.8 percent—a fourfold greater risk compared with spontaneous labor (Grobman, 2007a). In contrast, in one case-control study, induction was not associated with a higher risk for rupture (Harper, 2012a). Cahill (2008) and Goetzl (2001) and their coworkers reported a dose-related risk of rupture with oxytocin.

Prostaglandins

Various prostaglandin preparations commonly employed for cervical ripening or labor induction are discussed in Chapter 26 (Pharmacological Techniques). As a group, their safe use in women with a prior cesarean delivery is unclear because of conflicting data.

With misoprostol (PGE_1), Wing and colleagues (1998) compared it versus oxytocin for labor induction in women with a prior cesarean delivery. They terminated their trial after two of the first 17 women assigned to misoprostol developed a uterine rupture. Other studies confirmed this, and most consider misoprostol to be contraindicated (American College of Obstetricians and Gynecologists, 2017a).

Of other prostaglandins, studies to evaluate their use for induction are contradictory. Ravasia and coworkers (2000) compared uterine rupture in 172 women given PGE_2 gel with 1544 women in spontaneous labor. The rupture rate was significantly greater in women treated with PGE_2 gel—2.9 percent compared with 0.9 percent in those with spontaneous labor. Lydon-Rochelle and associates (2001) found similar results. However, in the Network study cited previously, the uterine rupture rate was 1.4 percent when any prostaglandin was used in combination with oxytocin (Landon, 2004). But, in the subgroup of 227 women in whom labor was induced with a prostaglandin alone, there were no ruptures. Similar findings were reported with intravaginal prostaglandins, which were not associated with a greater uterine rupture risk (Macones, 2005b). These latter investigators, along with Kayani and colleagues (2005), found that sequential use of a prostaglandin followed by oxytocin was associated with a threefold greater risk of rupture compared with spontaneous labor.

Mechanical Methods

Studies concerning the use of a transcervical Foley catheter for cervical ripening and induction of labor in women with a prior cesarean delivery are limited (Ben-Aroya, 2002; Jozwiak, 2014). In a retrospective study of 2479 women with prior cesarean delivery, the uterine rupture risk using a transcervical Foley catheter for labor induction (1.6 percent) was not significantly greater than that with spontaneous labor (1.1 percent) or with using amniotomy with or without oxytocin (1.2 percent) (Bujold, 2004). In contrast, Hoffman (2004) described 138 women who underwent preinduction cervical ripening with a Foley catheter compared with 536 women who entered labor spontaneously. They observed a significant and inordinately high uterine rupture risk during labor following Foley catheter cervical ripening compared with spontaneous onset of labor—6.5 versus 1.9 percent.

Epidural Analgesia

Concerns that epidural analgesia for labor might mask the pain of uterine rupture have not been verified. Fewer than 10 percent of women with scar separation experience pain and bleeding, and fetal heart rate decelerations are the most likely sign (Kieser, 2002). That said, Cahill and coworkers (2010a) documented that more frequent episodes of epidural dosing were associated with increasing uterine rupture rates. VBAC rates are similar, and in some cases higher, among women with labor epidural analgesia compared with those using other forms of analgesia (Aviram, 2017; Shmudi, 2017). Perhaps related, almost a fourth of VBAC deliveries were completed with either forceps or vacuum (Inbar, 2017). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) have concluded that epidural analgesia may safely be used during TOLAC.

Uterine Scar Exploration

Following VBAC, some clinicians routinely document the integrity of a prior scar by placing a hand through the dilated cervix and along the inner surface of the lower uterine segment. But routine uterine exploration is considered by others to be unnecessary. In a longitudinal study of 3469 women who had a VBAC, seven uterine dehiscences and one uterine rupture yielded an overall event rate of 0.23 percent (Silberstein, 1998). They concluded that transcervical evaluation need only be performed in symptomatic patients.

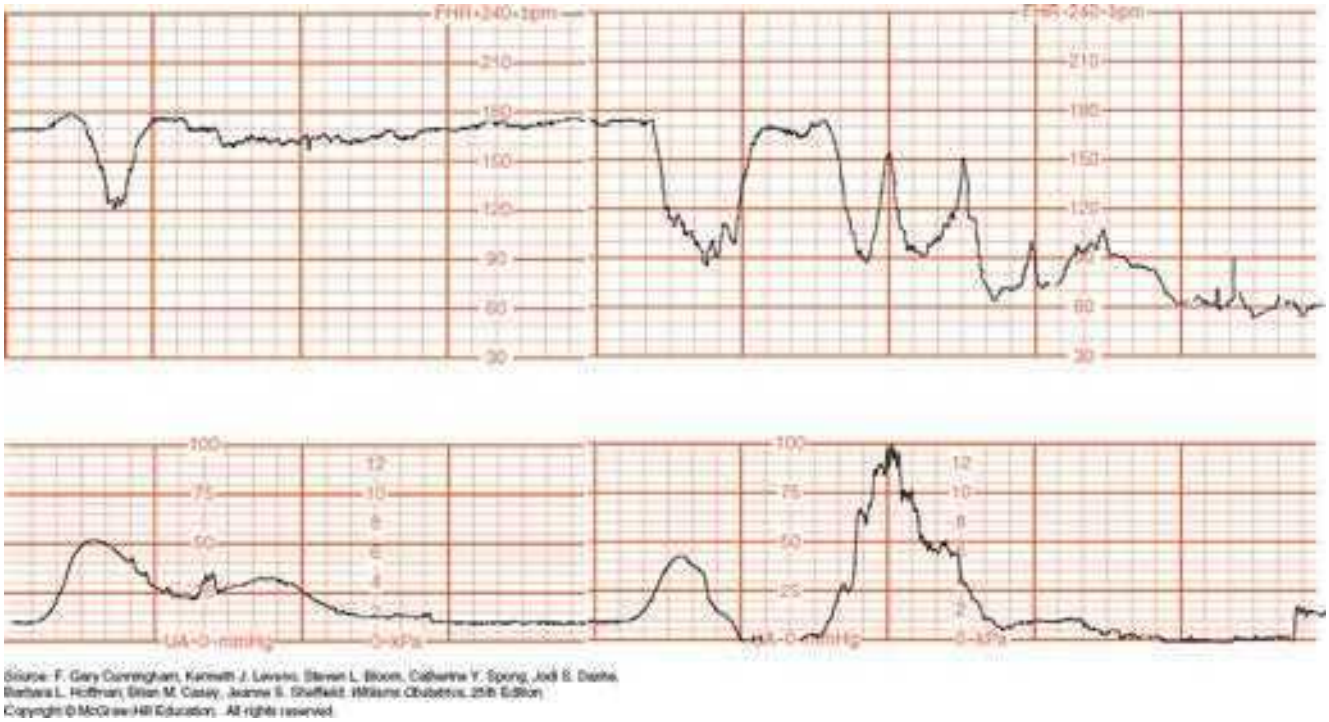
Currently, the benefits of routine scar evaluation in the asymptomatic woman are unclear, however, surgical correction of a dehiscence is necessary if significant bleeding is encountered. Our practice is to routinely examine these prior hysterotomy sites. Any decision for laparotomy and repair takes into consideration the extent of the tear, whether the peritoneal cavity has been entered, and the presence of active bleeding.

UTERINE SCAR RUPTURE

Diagnosis

Progress of labor in women attempting TOLAC is similar to normal labor, and no specific pattern presages uterine rupture (Graseck, 2012; Harper, 2012b; Sondgeroth, 2017). Before hypovolemic shock develops, symptoms and physical findings in women with uterine rupture may appear bizarre unless the possibility is kept in mind. For example, hemoperitoneum from a ruptured uterus may result in diaphragmatic irritation with pain referred to the chest. This may direct one to a diagnosis of pulmonary or amnionic fluid embolism instead of uterine rupture. As shown in Figure 31-5, the most common sign of uterine rupture is a nonreassuring fetal heart rate pattern with variable decelerations that may evolve into late decelerations and bradycardia. In 36 cases of such rupture during TOLAC, there were fetal signs of uterine rupture in 24, maternal signs in eight, and a combination of maternal and fetal in three (Holmgren, 2012). Few women experience cessation of contractions following uterine rupture, and the use of intrauterine pressure catheters does not assist reliably in the diagnosis (Rodriguez, 1989).

FIGURE 31-5
Fetal heart rate tracing in a woman whose uterus ruptured during labor while pushing. The rupture apparently stimulated a reflex push, after which uterine tone diminished and fetal bradycardia worsened.



In some women, the clinical appearance of uterine rupture mirrors that of placental abruption. In most, however, there is remarkably little appreciable pain or tenderness. Also, because most women in labor are treated for discomfort with either narcotics or epidural analgesia, pain and tenderness may not be readily apparent. The condition usually becomes evident because of fetal distress and occasionally because of maternal hypovolemia from concealed hemorrhage.

If the fetal presenting part has already entered the pelvis with labor, loss of station may be detected by pelvic examination. If the fetus is partly or totally extruded from the uterine rupture site, abdominal palpation or vaginal examination may be helpful to identify the presenting part, which will have moved away from the pelvic inlet. A firm contracted uterus may at times be felt alongside the fetus. Sonography may be helpful.

Decision-to-Delivery Time

With rupture and expulsion of the fetus into the peritoneal cavity, the chances for intact fetal survival are dismal, and reported mortality rates range from 50 to 75 percent. *Fetal condition depends on the degree to which placental implantation remains intact, although this can change within minutes.* With rupture, the only chance of fetal survival is afforded by immediate delivery—most often by laparotomy—otherwise, hypoxia is inevitable. If rupture is followed by total placental separation, then very few neurologically intact fetuses will be salvaged. *Thus, even in the best of circumstances, some fetal outcomes will be impaired.* The Utah experiences are instructive here (Holmgren, 2012). Of the 35 laboring patients with uterine rupture, the decision-to-delivery time was <18 minutes in 17, and none of these infants had an adverse neurological outcome. Of the 18 born >18 minutes from decision time, the three infants with long-term neurological impairments were delivered at 31, 40, and 42 minutes. There were no deaths, thus severe neonatal neurological morbidity developed in 8 percent of this group of 35 women with uterine rupture.

In a study using the Swedish Birth Registry, Kaczmarczyk and coworkers (2007) found that the risk of neonatal death following uterine rupture was 5 percent. In the Network study cited earlier, seven of the 114 uterine ruptures associated with TOLAC—6 percent—were complicated by development of neonatal HIE (Spong, 2007).

Maternal deaths from uterine rupture are uncommon. Of 2.5 million women who gave birth in Canada between 1991 and 2001, there were 1898 cases of uterine rupture, and four of these—0.2 percent—resulted in maternal death (Wen, 2005). In other regions of the world, however, maternal mortality rates are much higher. From rural India, the maternal mortality rate associated with uterine rupture was 30 percent (Chatterjee, 2007).

Management

With complete rupture during TOLAC, hysterectomy may be required. In selected cases, however, suture repair with uterine preservation may be performed. Sheth (1968) described outcomes from a series of 66 women in whom repair of a uterine rupture was elected rather than hysterectomy. Thirteen of the 41 mothers who did not have tubal sterilization had a total of 21 subsequent pregnancies. Uterine rupture recurred in four of these—approximately 20 percent. Usta and associates (2007) reported similar results. In another study, however, women with a uterine dehiscence were not more likely to have a subsequent uterine rupture (Baron, 2014).

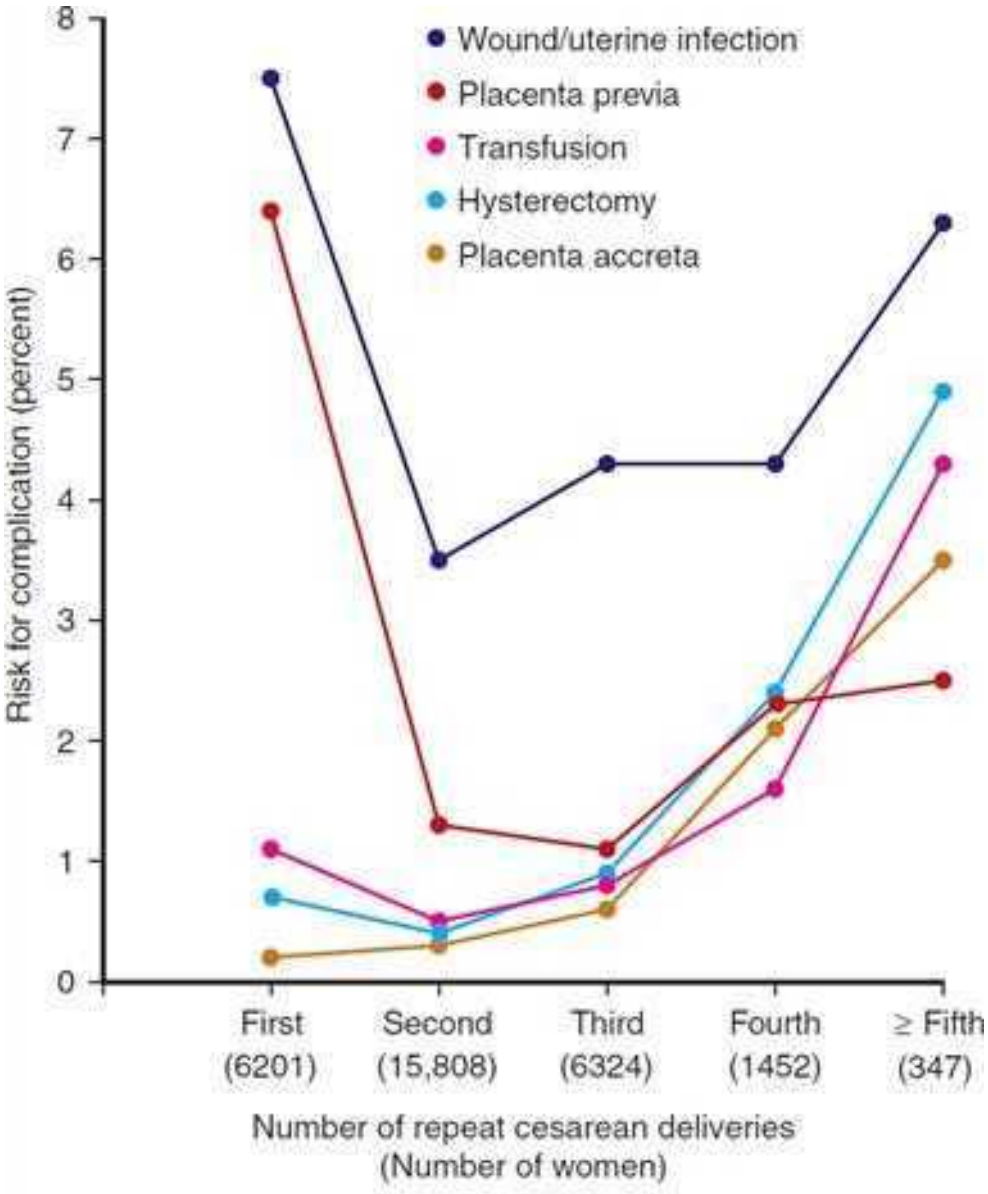
MULTIPLE REPEAT CESAREAN DELIVERIES

Because of the aforementioned concerns with TOLAC, most women in the United States undergo ERCD. This choice has several significant maternal complications, and rates of these rise in women who have multiple repeat operations. The incidences of some common complications for women with one prior transverse cesarean delivery who undergo an ERCD were shown in Table 31-2. Of note, half of cesarean hysterectomies done at Parkland Hospital are in women with one or more prior cesarean deliveries (Hernandez, 2013).

The Network addressed issues of increased morbidity in a cohort of 30,132 women who had from one to six repeat cesarean deliveries (Silver, 2006). The rates of some of the more frequent or serious complications are depicted in Figure 31-6. In addition, rates of bowel or bladder injury, admission to an intensive care unit or need for ventilator therapy, and maternal mortality, as well as operative and hospitalization length, showed significantly rising trends. Similar results have been reported by others (Nisenblat, 2006; Usta, 2005). More difficult to quantify are risks for bowel obstruction and pelvic pain from peritoneal adhesive disease, both of which increase with each successive cesarean delivery (Andolf, 2010; Mankuta, 2013).

FIGURE 31-6

Maternal-Fetal Medicine Units Network: rates of some complications with increasing number of repeat cesarean deliveries. (Data from Silver RM, Landon MB, Rouse DJ, et al: Maternal morbidity associated with multiple repeat cesarean deliveries. Obstet Gynecol 207:1226, 2006.)



Cook and colleagues (2013) from the United Kingdom Obstetric Surveillance System (UKOSS) described adverse sequelae of women with five or more cesarean deliveries. These women had significantly higher rates of morbidity. Namely, the major hemorrhage rate increased 18-fold; visceral damage, 17-fold; critical care admissions, 15-fold; and delivery <37 weeks, sixfold. Much of this morbidity was in the 18 percent who had a placenta previa or an accrete syndrome (Chap. 41, Placenta Previa).

VAGINAL BIRTH AFTER CESAREAN—2017

For providers and their patients, unfortunately, no large randomized trials have compared outcomes of women with an intent to pursue either TOLAC or ERCD. Most studies to date have compared *actual* routes of delivery rather than the *intended* route of delivery. Thus, we agree with Scott (2011) regarding a "common-sense" approach. The woman—and her partner if she wishes—are encouraged to actively participate with her provider in informed consent. Counseling should include documentation of the prior uterine incision and discussion of risks, benefits, and success rates of TOLAC or ERCD. This includes consideration of risks involving future pregnancies. Ideally, counseling begins preconceptionally and continues throughout pregnancy, with flexible options extending up to delivery. For women who desire TOLAC despite a factor that increases their specific risk, additions to the consent form are recommended by the American College of Obstetricians and

Gynecologists (2017a). Bonanno and colleagues (2011) have provided such an example. Brief synopses of professional society guidelines are shown in Table 31-4. Guidelines that tend to be more conservative are shown in Table 31-5.

TABLE 31-4

Some Recommendations of Professional Societies Concerning a Trial of Labor to Attempt VBAC

	Counseling	Facilities	Other
American College of Obstetricians and Gynecologists (2017a)	Offer to most women with one prior low-transverse incision; consider for two prior low-transverse incisions	Safest with ability for immediate cesarean delivery; patients should be allowed to accept increased risk when not available	Not precluded: twins, macrosomia, prior low-vertical or unknown type of incision
Society of Obstetricians and Gynaecologists of Canada (2005)	Offer to women with one prior transverse low-segment cesarean delivery; with >1 prior CD then VBAC likely successful but increased risks	Should deliver in hospital in which timely cesarean delivery is available; approximate timeframe of 30 minutes	Oxytocin or Foley catheter induction safe, but prostaglandins should not be used; macrosomia, diabetes, postterm pregnancy, twins are not contraindications
Royal College of Obstetricians and Gynaecologists (2007)	Discuss VBAC option with women with prior low-segment cesarean delivery; decision between obstetrician and patient	Suitable delivery suite with continuous care and monitoring; immediate cesarean delivery capability	Caution with twins and macrosomia

CD = cesarean delivery; VBAC = vaginal birth after cesarean.

TABLE 31-5

Conservative Guidelines to Approach a Trial of Labor Following Cesarean Delivery

Follow ACOG practice guidelines
Education and counseling Preconceptionally Provide ACOG patient pamphlet Early during prenatal care Develop preliminary plan Revisit at least each trimester Be willing to alter decision Have facilities availability
Risk assessment Review previous operative note(s) Review relative and absolute contraindications Reconsider risks as pregnancy progresses Tread carefully: >1 prior transverse CD, unknown incision, twins, macrosomia
Labor and delivery Cautions for induction—unfavorable cervix, high station Consider AROM Avoid prostaglandins Respect oxytocin—know when to quit Beware of abnormal labor progress Respect EFM pattern abnormalities Know when to abandon a trial of labor

ACOG = American College of Obstetricians and Gynecologists; AROM = artificial rupture of membranes; CD = cesarean delivery; EFM = electronic fetal monitoring.

CHAPTER 32: The Newborn

Normally the newly born child begins to cry almost immediately after its exit from the vulva. This act indicates the establishment of respiration, which is accompanied by important modifications in the circulatory system.

—J. Whitridge Williams (1903)

INTRODUCTION

In most instances at delivery, the newborn is healthy and vigorous, but at times, special care may be needed. For this reason, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017b) recommend that every birth should be attended by at least one qualified individual. This person should be skilled in the initial steps of newborn care and positive-pressure ventilation, and their only responsibility is management of the newborn. This usually is a pediatrician, nurse practitioner, anesthesiologist, nurse anesthetist, or specially trained nurse. However, in their absence, the responsibility for neonatal resuscitation falls to the obstetrical attendant. Thus, obstetricians should be well versed in measures for immediate care of the newborn.

The number and qualifications of personnel who attend the delivery will vary depending on the anticipated risk, the number of babies, and the hospital setting. A qualified team with full resuscitation skills should be present for high-risk deliveries and immediately available for every resuscitation (Wyckoff, 2015). This team should not be on call at home or in a remote area of the hospital. Moreover, team training through frequent simulation practice is recommended for all who may be called to attend deliveries (Perlman, 2015).

TRANSITION TO AIR BREATHING

Immediately following birth, the newborn must promptly convert from placental to pulmonary gas exchange. Pulmonary vascular resistance must fall, pulmonary perfusion must rapidly rise, and unique fetal vascular shunts must begin to close to separate the systemic and pulmonary circulations (Rudolph, 1979). These shunts include the patent ductus arteriosus and patent foramen ovale, described in Chapter 7 (Cardiovascular System). Lung aeration is not only critical for pulmonary gas exchange. Recent studies suggest that it is significantly responsible for initiating cardiovascular changes at birth (Hooper, 2016).

In utero, the fetal lungs are filled with amnionic fluid, which must be cleared quickly for air breathing. This clearance occurs through various means, and the contributions of these mechanisms may depend on gestational age and mode of delivery. First, a large release of fetal adrenaline late in labor stimulates pulmonary epithelial cells to stop secreting and instead to start reabsorbing lung liquid as a result of sodium-channel activation (te Pas, 2008). The contribution of this mechanism is unlikely to be major, as blockade of the receptors for sodium channel activation reduces or delays but does not prevent lung liquid clearance at birth (O'Brodovich, 1990).

As a second method, mechanical forces aid lung fluid clearance during labor. Early reports described compression of the fetal thorax and abdomen as they passed through the birth canal leading to lung liquid expulsion (Karlberg, 1962; Saunders, 1978). By this mechanism, up to a third of lung liquid is expelled in a jet of fluid from the nose and mouth once the respiratory tract is exposed to the lower outside pressure. However, it may be that uterine contractions force a change in fetal posture leading to compression of the thorax and increased intrathoracic pressures. This prompts expulsion of lung liquid early in labor more so than the "vaginal squeeze" theory (Lines, 1997; te Pas, 2008; Vyas, 1981).

In a third mechanism, a significant amount of lung liquid is cleared after birth (Hooper, 2016). In animal studies, most lung aeration occurs during inspiration—within three to five breaths after birth. But, no liquid clears between breaths (Hooper, 2007). Specifically, the transpulmonary pressure gradient during inspiration promotes movement of fluid into the interstitial tissue. From here, it is gradually cleared, probably by the pulmonary circulation and lymphatic vessls. It is possible for lung interstitial tissue pressure to rise to a point that fluid can actually move back into the airspaces during expiration unless positive end-expiratory pressure opposes liquid reentry (Siew, 2009a,b). This may be a contributing factor in the development of *transient tachypnea of the newborn*.

As fluid is replaced by air, compression of the pulmonary vasculature is reduced considerably, and in turn, resistance to blood flow is lowered. With the fall in pulmonary arterial blood pressure, the ductus arteriosus normally closes.

High, negative intrathoracic pressures are required to permit the initial entry of air into the fluid-filled alveoli. Normally, from the first breath after birth, progressively more residual air accumulates in the lung. And, with each successive breath, lower pulmonary opening pressure is required. In the normal mature newborn, by approximately the fifth breath, pressure-volume changes achieved with each respiration are very similar to those of the adult. Thus, the breathing pattern shifts from shallow episodic inspirations characteristic of the fetus to regular, deeper inhalations (Chap. 17, Fetal Breathing).

As a last mechanism, surfactant, which is synthesized by the type II pneumocytes, lowers alveolar surface tension and helps maintain lung inflation by preventing alveolar collapse. Insufficient surfactant, which is common in preterm neonates, leads promptly to respiratory distress syndrome (Chap. 34, Respiratory Distress Syndrome).

In utero, umbilical venous return is the main source of preload for the left ventricle, particularly as fetal pulmonary blood flow is very low due to high pulmonary vascular resistance and is unable to provide sufficient venous return to maintain left ventricular output (Hooper, 2015).

Clamping the umbilical cord reduces preload for the left ventricle and thus reduces cardiac output. Until the lungs aerate and pulmonary blood flow increases, the reduced cardiac output will manifest as bradycardia. If cord clamping is delayed until after the lungs have aerated, the transition is smoother and cardiac ouput does not fall (Bhatt, 2013). This understanding has led to interest in delayed (physiological) cord clamping, especially if it can be done after successful inflation of the lung. Randomized trials are currently underway.

CARE IN THE DELIVERY ROOM

The International Liaison Committee on Resuscitation (ILCOR) updated its scientific review for neonatal delivery room care and resuscitation (Perlman, 2015). The ILCOR scientific review is used by the American Academy of Pediatrics and the American Heart Association to develop the neonatal resuscitation guidelines for North America (Wyckoff, 2015).

Immediate Care

Before and during delivery, careful consideration must be given to several determinants of neonatal well-being. These include: (1) maternal health status; (2) prenatal complications, including any suspected fetal malformations; (3) gestational age; (4) labor complications; (5) duration of labor and ruptured membranes; (6) type and duration of anesthesia; (7) difficulty of delivery; and (8) medications given during labor and their dosages, administration routes, and timing.

When risk factors are present, neonatal resuscitation providers should be present for the delivery. This team readies equipment, ensures that adequate personnel are present, delegates roles and responsibilities, and considers contingency plans to stabilize the newborn. Four questions a neonatal provider will ask pertain to expected gestional age, amnionic fluid color, fetal number, and additional fetal risks. Several conditions are associated with a nonvigorous presentation. These may include immaturity, hypoxemia or acidosis from any cause, sepsis syndrome, recent drugs administered to the mother, and central nervous system developmental abnormalities. Those related to the respiratory tract are lung abnormalities, upper airway obstruction, pneumothorax, and meconium aspiration.

Umbilical Cord Clamping

Ideally, obstetrical and pediatric teams discuss plans regarding umbilical cord management. Delayed cord clamping provides transfusion of placental blood to the newborn. In term infants, delay of cord clamping by 30 to 60 seconds raises hemoglobin levels at birth, improves iron stores during infancy, and enhances neurodevelopment at 4 years of age (Katheria, 2017). As discussed in Chapter 33 (Neonatal Abstinence Syndrome), the only reported negative outcome of delayed cord clamping is hyperbilirubinemia, leading to a higher rate of phototherapy (American College of Obstetricians and Gynecologists, 2017a). In preterm neonates, delayed cord clamping reduces rates of blood transfusion, intraventricular hemorrhage, and necrotizing enterocolitis.

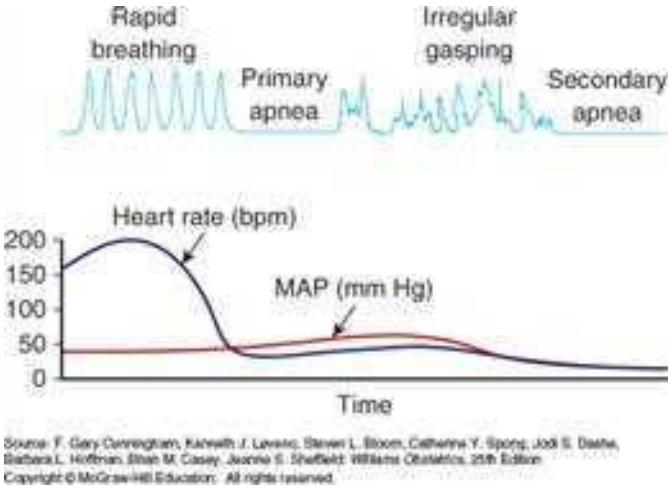
Delayed cord clamping should be performed in preterm and term newborns who do not require resuscitation at birth (American Academy of Pediatrics, 2017a; American College of Obstetricians and Gynecologists, 2017a; Perlman, 2015). There should be no delay if a newborn requires resuscitation or if the placental circulation is disrupted by abruption, cord avulsion, or bleeding placenta previa or vasa previa.

Newborn Resuscitation

Approximately 10 percent of newborns require some degree of active resuscitation to stimulate breathing, and 1 percent need extensive care. Perhaps not coincidentally, the risk of death for newborns delivered at home compared with those delivered in hospitals is increased two- to threefold (American College of Obstetricians and Gynecologists, 2017d).

When deprived of adequate gas exchange, either before or after birth, neonates demonstrate a well-defined sequence of events leading to apnea (Fig. 32-1). With oxygen deprivation and carbon dioxide (CO_2) elevation, there is a transient period of rapid breathing, and if it persists, breathing stops, which is termed *primary apnea.* This stage is accompanied by a fall in heart rate and loss of neuromuscular tone. Simple stimulation will usually reverse primary apnea. If oxygen deprivation and asphyxia persist, however, the newborn will develop deep gasping respirations, followed by *secondary apnea.* This latter stage is associated with a further decline in heart rate, fall in blood pressure, and loss of neuromuscular tone. Neonates in secondary apnea will not respond to stimulation and will not spontaneously resume respiratory efforts. Unless ventilation is assisted, death follows.

FIGURE 32-1
Physiological changes associated with primary and secondary apnea in the newborn. bpm = beats per minute; HR = heart rate; MAP = mean arterial pressure. (Adapted with permission from Kattwinkel J: Textbook of Neonatal Resuscitation, 6th ed. Elk Grove Village, American Academy of Pediatrics and American Heart Association, 2010.)



Clinically, primary and secondary apneas are indistinguishable, and thus, secondary apnea must be assumed. And, when a response to stimulation is not immediate, resuscitation with effective ventilation of the apneic newborn must be started quickly.

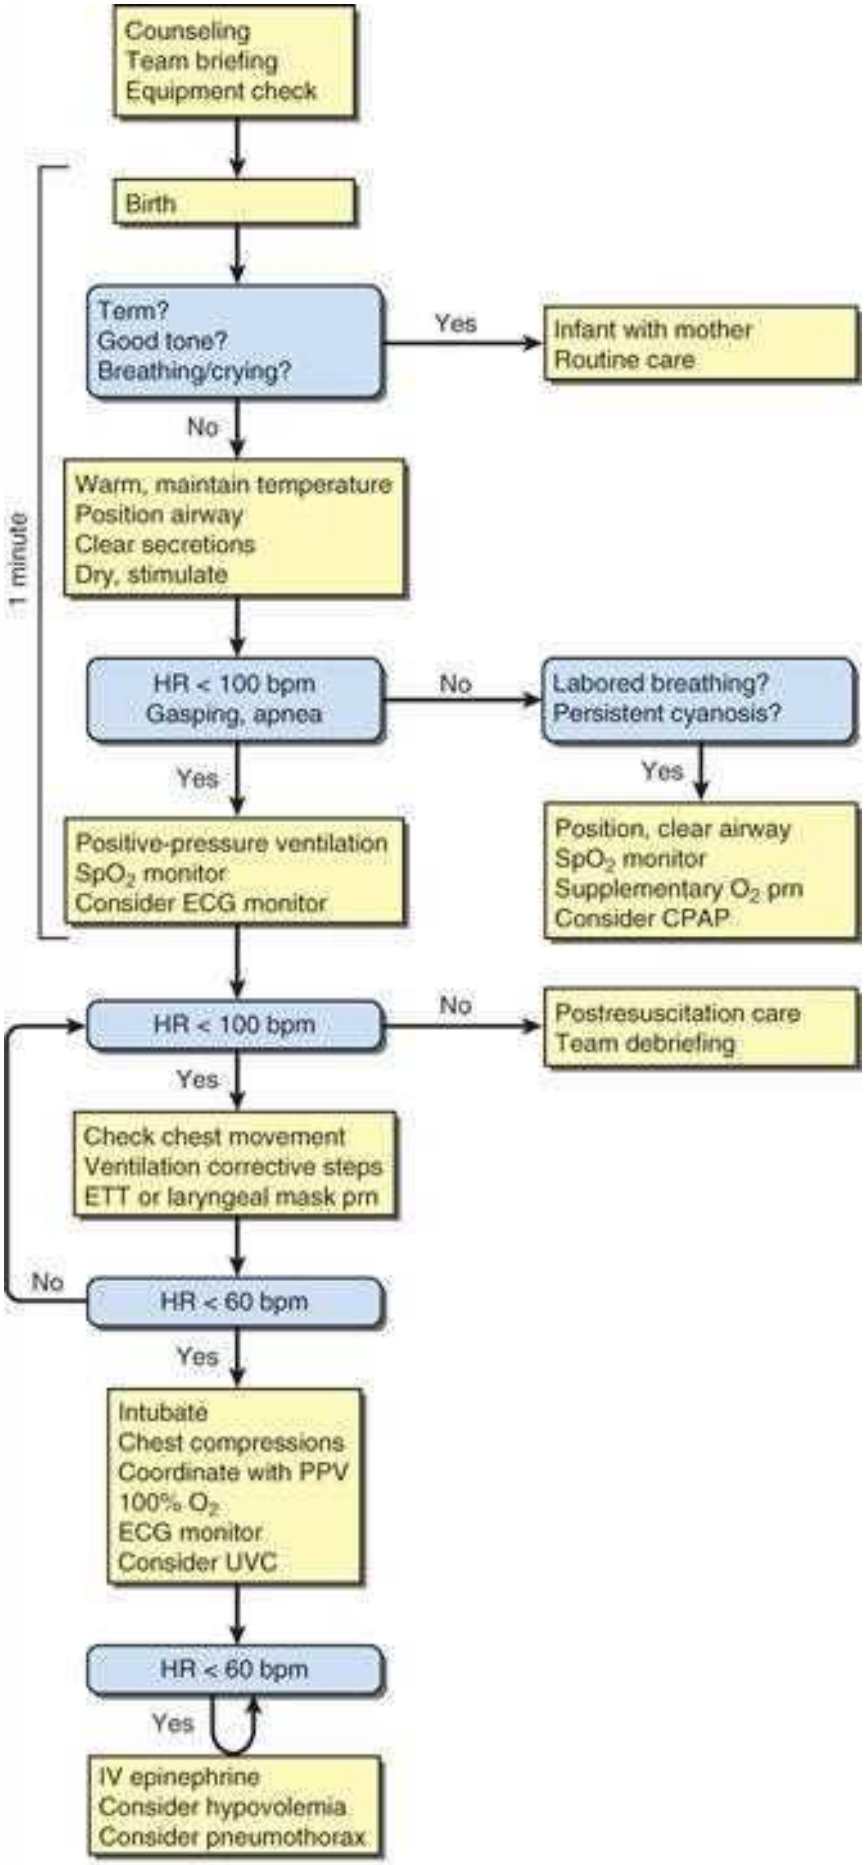
Resuscitation Protocol

Initial Assessment

Immediately after birth and usually during the delay for umbilical cord clamping, newborn tone, respiratory effort, and heart rate are evaluated (Fig. 32-2). Most term neonates are vigorous by 10 to 30 seconds after birth (Ersdal, 2012). For these, initial steps of warming the newborn can be done on the mother's chest or abdomen. Direct skin-to-skin contact with the mother and drying and covering the newborn with a warm blanket will help maintain euthermia (36.5 to 37.5°C). A vigorously crying newborn does not require routine oral suctioning (Carrasco, 1997; Gungor, 2006). Instead, bulb suctioning to remove secretions is best reserved for those who cannot clear secretions on their own due to apnea or copious secretions. Additional routine care steps include drying, gentle stimulation by rubbing the newborn's back, and continued observation during the transition period.

FIGURE 32-2

Algorithm for resuscitation of the newborn based on the International Liaison Committee on Resuscitation scientific review and recommended by the American Academy of Pediatrics and American Heart Association (Perlman, 2015; Wyckoff, 2015). bpm = beats per minute; CPAP = continuous positive airway pressure; ECG = electrocardiogram; ETT = endotracheal tube; HR = heart rate; IV = intravenous; PPV = positive-pressure ventilation; SpO_2= peripheral oxygen saturation; UVC = umbilical venous catheter.

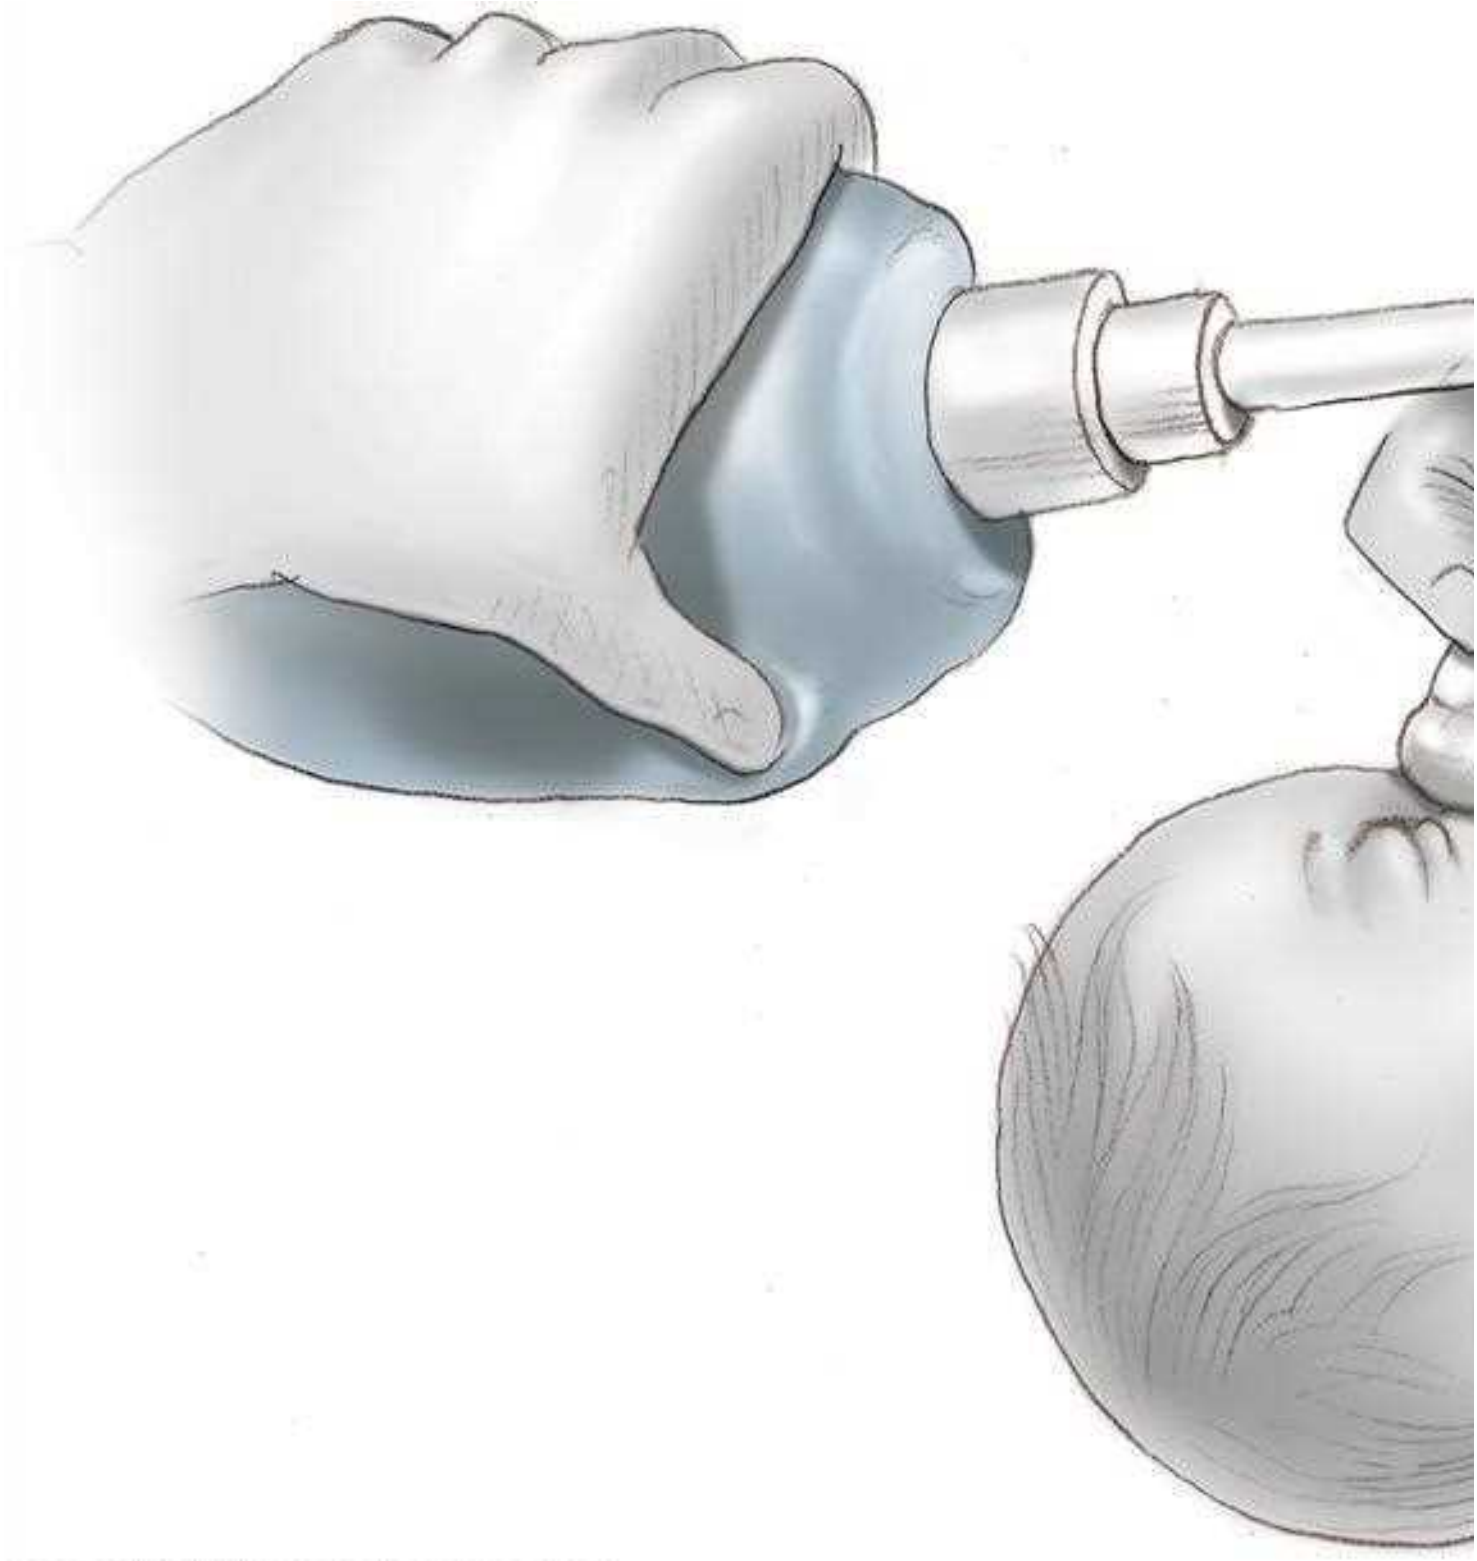


If not vigorous or if preterm, the neonate is carried to a prewarmed radiant warmer for the initial newborn care steps. The initial wet birth blanket is removed to allow newborn drying. Cold stress is associated with multiple neonatal morbidities and mortality. Preterm infants are particularly vulnerable, and special steps to maintain euthermia include providing a warmer delivery room (>25°C), covering the neonatal head with either a plastic or wool hat, application of polyethylene plastic "ponchos" or wraps to slow evaporative heat losses, use of chemically activated thermal mattresses to reduce conductive heat loss, and administration of warm, humidified respiratory gases during respiratory stabilization (Perlman, 2015).

At the radiant warmer, newborns must be positioned to maximally open the airway, with mild extension of the neck. If the newborn is apneic or has copious secretions that it cannot clear, a bulb syringe or suction catheter may be used to clear the mouth and then the nose. Routine intubation and suctioning of meconium-stained amnionic fluid is no longer recommended for the nonvigorous newborn (American College of Obstetricians and Gynecologists, 2017b; Perlman, 2015). Intubation and suction are reserved for suspected airway obstruction.

After completion of the initial stabilization steps, apnea, gasping respirations, or heart rate ≤100 beats per minute (bpm) should prompt immediate administration of positive-pressure ventilation with room air (Fig. 32-3). This should be started by 60 seconds of life, if not sooner, once the initial steps are completed.

FIGURE 32-3
Correct use of bag-and-mask ventilation. The head should be in a sniffing position with the tip of the nose pointing to the ceiling. The neck should not be hyperextended.



Mask Ventilation

Assisted ventilation by facemask at a rate of 40 to 60 breaths per minute is recommended. Oxygen saturation is monitored by pulse oximetry. Supplemental oxygen can be given in graduated, rising percentages to maintain oxygen saturation values within a normal range per minute of life. Adequate ventilation is best indicated by an improved heart rate. Colorimetric end-tidal carbon dioxide ($ETCO_2$) monitoring placed between the positive-pressure device and facemask serves as a helpful adjunct for detection of successful gas exchange during mask ventilation (Weiner, 2016).

If the heart rate remains ≤100 bpm after 5 to 10 positive pressure breaths, the attempted ventilation is inadequate and corrective steps must be taken. These can be remembered by the pneumonic MR. SOPA (Table 32-1). The two most common problems are mask leak due to an ineffective seal and malposition of the airway (Schmolzer, 2011). If corrective steps do not improve the heart rate, either intubation with an endotracheal tube or placement of a laryngeal mask airway is required.

TABLE 32-1

Ventilation Corrective Steps (MR. SOPA)

M—Mask adjustment	Check the seal of the mask and reapply if needed.
R—Reposition airway	Make sure the newborn is truly in the open airway (mild extension) position.
S—Suction mouth and nose	Remove obstructing secretions.
O—Open the mouth	In an effort to achieve a good seal, providers sometimes accidentally close the mouth. The higher resistance of the narrow-diameter nasal passages will limit effective ventilation.
P—Pressure increase	Try increasing the inflation pressure.
A—Advanced airway	If all prior steps fail to achieve chest rise, intubate or place a laryngeal mask.

Data from Weiner, 2016.

Alternative Airway

If mask ventilation is ineffective or prolonged, an alternative airway is placed. For tracheal intubation, a laryngoscope with a straight blade—size 0 for a preterm newborn and size 1 for a term neonate—is used. Gentle cricoid pressure may be useful. An increasing heart rate and $ETCO_2$ detection after several breaths are the primary methods of confirming intubation of the trachea and not the esophagus. One can also look for symmetrical chest wall motion; auscultate for equal breath sounds, especially in the axillae; and auscultate for the absence of breath sounds or gurgling over the stomach.

Once in place, the tube is used for tracheal suctioning only for a suspected obstructed airway. Otherwise, an appropriate positive-pressure device is attached to the endotracheal tube. Air puffs are delivered at a rate of 40 to 60 per minute with a force adequate to stabilize the heart rate. In term infants, opening pressures of 30 to 40 cm H_2O typically will expand the alveoli without causing barotrauma. Once the lung is inflated, less pressure is typically needed (20 to 25 cm H_2O). For preterm infants, pressures of 20 to 25 cm H_2O are typically used. An increase in heart rate and peripheral oxygen saturation (SpO_2) levels within acceptable ranges reflect a positive response.

Chest Compressions

Most commonly, effective ventilation is all that is required to stabilize the newborn in the delivery room. If the heart rate remains <60 bpm despite ventilation corrective steps, including placement of tracheal tube, chest compressions are initiated. Once the tracheal tube has been secured, compressions are done from the head of the bed rather than the side so that space is opened up for a provider to have umbilical venous access. When compressions are initiated, the oxygen concentration is increased to 100 percent. With the two-thumb compression method, hands encircle the chest, while the thumbs depress the sternum. Compressions are delivered on the lower third of the sternum at a depth sufficient to generate a palpable pulse. This is typically one third of the anterior-posterior diameter of the chest. Compared with other techniques, this method offers less provider fatigue over time, yields higher generated perfusion pressures, and lessens hand malpositioning that could cause traumatic injury (Kapadia, 2012).

A 3:1 compressions-to-ventilation ratio is recommended, and 90 compressions and 30 breaths achieve approximately 120 events each minute. Coordinated chest compressions and ventilations should continue until the spontaneous heart rate is ≥60 bpm.

Epinephrine

Intravenously administered epinephrine is indicated if the heart rate remains ≤60 bpm after adequate ventilation and chest compressions. The recommended intravenous dose is 0.01 to 0.03 mg/kg. Epinephrine may be given through the endotracheal tube if venous access has not been established, but its action is less reliable (Kapadia, 2017). If given through the endotracheal tube, higher doses are employed—0.05 to 0.1 mg/kg.

Discontinuation of Resuscitation

ILCOR concludes that it is reasonable to discontinue resuscitative efforts for a neonate who remains without a heartbeat despite at least 10 minutes of continuous and adequate resuscitative efforts. Notably, the decision to continue or discontinue resuscitative efforts must be individualized (Perlman, 2015).

EVALUATION OF NEWBORN CONDITION

Apgar Score

The scoring system described by Dr. Virginia Apgar in 1953 remains a useful clinical tool to classify newborn health immediately after birth and to assess the effectiveness of resuscitative measures (American Academy of Pediatrics, 2017). As shown in Table 32-2, each of five easily identifiable characteristics—heart rate, respiratory effort, muscle tone, reflex irritability, and color—is assessed and assigned a value of 0, 1, or 2. In the currently recommended expanded form, concurrent resuscitation interventions are also recorded over time. The total score, based on the sum of the five components, is determined in all neonates at 1 and 5 minutes after delivery. In those with a score <7, the score may be calculated at further 5-minute intervals until a 20-minute Apgar score is assigned or resuscitation efforts are halted.

TABLE 32-2

20-Minute Expanded Apgar Score

Sign	0 point	1 point	2 point	1 min	5 min	10 min	15 min	20 min
Color	Blue or pale	Acrocyanotic	Completely pink					
Heart rate	Absent	<100/min	>100/min					
Reflex irritability	No response	Grimace	Cry or active withdrawal					
Muscle tone	Limp	Some flexion	Active motion					
Respiration	Absent	Weak cry; hypo- ventilation	Good, crying					
			Total					
Comments:			**Resuscitation**					
			Minutes	1	5	10	15	20
			Oxygen					
			PPV/CPAP					
			ETT					
			Chest compressions					
			Epinephrine					

CPAP = continuous positive airway pressure; ETT = endotracheal tube; PPV = positive-pressure ventilation.

Data from Weiner, 2016.

In an analysis of more than 150,000 newborns delivered at Parkland Hospital, Casey and associates (2001b) assessed the significance of the 5-minute score for predicting survival during the first 28 days of life. They found that in term neonates, the risk of neonatal death was approximately 1 in 5000 for those with Apgar scores of 7 to 10. This risk compares with a mortality rate of 25 percent for term newborns with 5-minute scores ≤3. Low 5-minute scores were comparably predictive of neonatal death in preterm neonates. These investigators concluded that the Apgar scoring system remains relevant for the prediction of neonatal survival.

There have been attempts to use Apgar scores to define asphyxial injury and to predict subsequent neurological outcome—uses for which the Apgar score was never intended (Chap. 33, Neuroimaging Studies in Encephalopathy and Cerebral Palsy). Such associations are difficult to measure with reliability given that both asphyxial injury and low Apgar scores are infrequent outcomes. For example, according to United States birth certificate records for 2010, only 1.8 percent of newborns had a 5-minute score below 7 (Martin, 2012). Similarly, in a population-based study of more than 1 million term newborns in Sweden between 1988 and 1997, the incidence of 5-minute Apgar scores of ≤3 approximated 2 per 1000 (Thorngren-Jerneck, 2001).

Previously, many groups established erroneous definitions of asphyxia based solely on low Apgar scores. These prompted the American College of Obstetricians and Gynecologists and American Academy of Pediatrics (2017f) to issue a series of joint opinions with important caveats regarding Apgar score limitations. Certain elements of the Apgar score are partially dependent on the physiological maturity of the newborn, and a healthy, preterm neonate may receive a low score only because of immaturity. Other influencing factors include fetal malformations, maternal medications, and infection. Therefore, it is inappropriate to use an Apgar score alone to diagnose asphyxia. Moreover, the Apgar score alone cannot establish hypoxia as the cause of cerebral palsy, as discussed in Chapter 33 (Neuroimaging Studies in Encephalopathy and Cerebral Palsy).

Umbilical Cord Blood Acid–Base Studies

Blood taken from umbilical vessels may be used for acid–base studies to assess the metabolic status of the neonate. Blood collection is performed following delivery by immediately isolating a 10- to 20-cm segment of cord with two clamps placed near the neonate and another two clamps positioned nearer the placenta. The cord is then cut between the two proximal clamps and then the two distal clamps (Blickstein, 2007).

Arterial blood is drawn from the isolated cord segment into a 1- to 2-mL commercially prepared plastic syringe containing lyophilized heparin or a similar syringe that has been flushed with a heparin solution containing 1000 U/mL. Once sampling is completed, the needle is capped and the syringe transported, on ice, to the laboratory. Although efforts should be made for prompt transport, neither the pH nor partial pressure of CO_2 (pCO_2) values change significantly in blood kept at room temperature for up to 60 minutes (Lynn, 2007). Mathematical models have been developed that allow reasonable prediction of birth acid–base status in

properly collected cord blood samples analyzed as late as 60 hours after delivery (Chauhan, 1994). Acid–base measurements can show significant variances between different analyzing devices (Mokarami, 2012).

Fetal Acid–Base Physiology

The fetus produces both carbonic and organic acids. Carbonic acid (H_2CO_3) is formed by oxidative metabolism of CO_2. The fetus usually rapidly clears CO_2 through the placental circulation. If CO_2 clearance is lowered, then carbonic acid levels rise. This often follows impaired placental exchange. When H_2CO_3 accumulates in fetal blood and organic acids do not concurrently rise, the result is *respiratory acidemia*.

In contrast, organic acids primarily include lactic and β-hydroxybutyric acids. Levels of these increase with persistent placental exchange impairment, and they result from anaerobic glycolysis. These organic acids are cleared slowly from fetal blood. When they accumulate, without a concurrent increase in H_2CO_3, the result is *metabolic acidemia*. With the development of metabolic acidemia, bicarbonate (HCO_3^-) levels drop because it is used to buffer the organic acid. A rise in H_2CO_3 concentrations accompanied by greater organic acid levels, reflected by decreased HCO_3^- levels, causes *mixed respiratory-metabolic acidemia*.

In the fetus, respiratory and metabolic acidemia and ultimately tissue acidosis are most likely part of a progressively worsening continuum. This is different from adult pathophysiology, in which distinct conditions result either in respiratory acidosis—for example, pulmonary disease, or in metabolic acidosis—for example, diabetes. In the fetus, the placenta serves as both the lungs and, to a certain degree, the kidneys. One principal cause of fetal acidemia is a drop in uteroplacental perfusion. This creates retention of CO_2, that is, respiratory acidemia, and if protracted and severe enough, yields a mixed or metabolic acidemia.

Assuming that maternal pH and blood gases are normal, the actual pH of fetal blood is dependent on the proportion of carbonic and organic acids and the amount of bicarbonate, which is the major buffer in blood. This can best be illustrated by the Henderson–Hasselbalch equation:

$$pH = pK + \log \frac{[base]}{[acid]} \text{ or, } pH = pK + \log \frac{HCO_3^-}{H_2CO_3}$$

For clinical purposes, HCO_3^- represents the metabolic component and is reported in mEq/L. The H_2CO_3 concentration reflects the respiratory component and is reported as the pCO_2 in mm Hg. Thus:

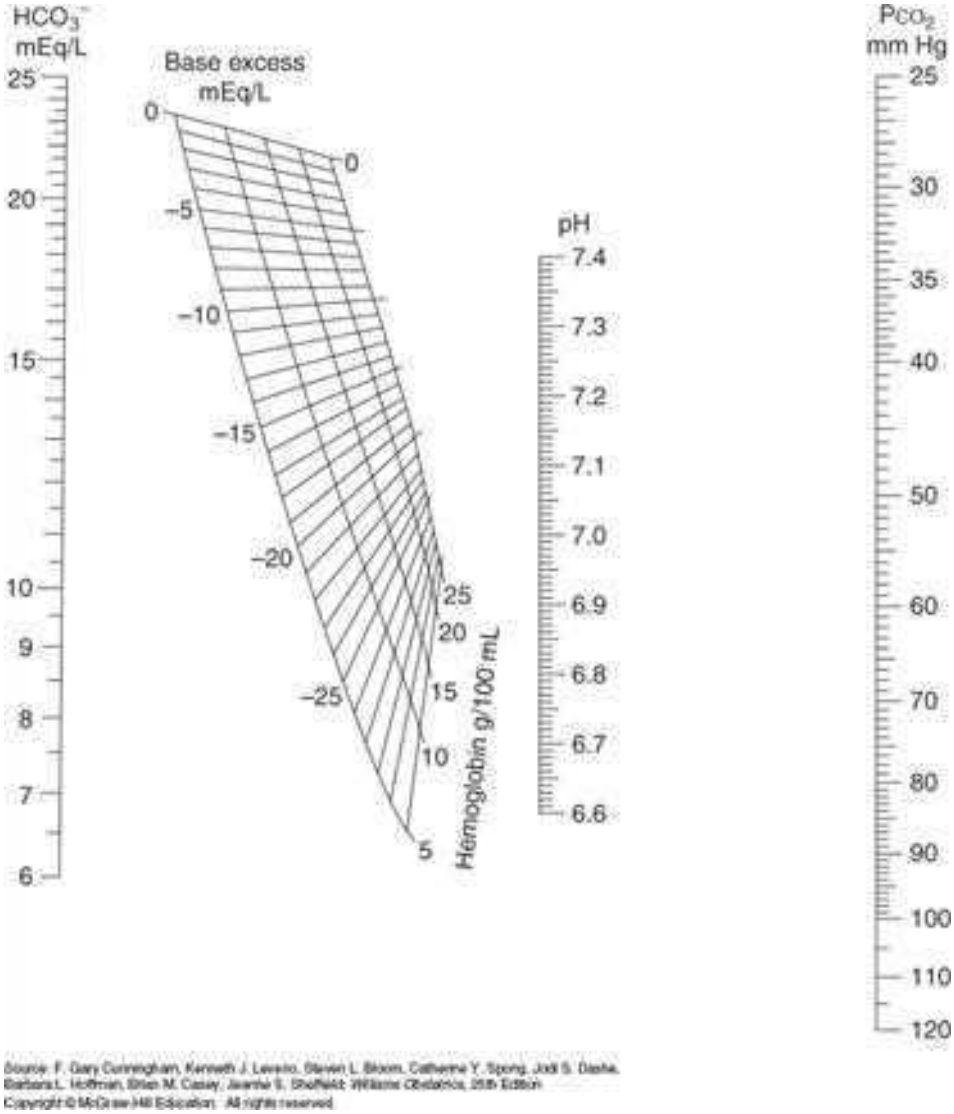
$$pH = pK + \log \frac{\text{metabolic } (HCO_3^- \text{ mEq/L})}{\text{respiratory } (Pco_2 \text{ mm Hg})}$$

The result of this equation is a pH value. Because pH is a logarithmic term, it does not give a linear measure of acid accumulation. For example, a change in hydrogen ion concentration associated with a fall in pH from 7.0 to 6.9 is almost twice that which is associated with a fall in pH from 7.3 to 7.2. For this reason, the change in base—termed delta base— offers a more linear measure of the degree of accumulation of metabolic acid (Armstrong, 2007). The delta base is a calculated number used as a measure of the change in buffering capacity of bicarbonate (HCO_3^-). The formula for calculating the base excess (BE) is as follows:

$$BE = 0.02786 \times pCO_2 \times 10^{(pH-6.1)} \times 13.77 \times pH - 124.58$$

Shown in Figure 32-4 is a nomogram developed from which these can be calculated if only two parameters are known. For example, the HCO_3^- concentration declines with a metabolic acidemia as it is consumed to maintain a normal pH. A base deficit develops when the HCO_3^- concentration drops below normal levels, and a base excess occurs when HCO_3^- values are above normal. Importantly, a mixed respiratory–metabolic acidemia with a large base deficit and a low HCO_3^-, for example 12 mmol/L, is more often associated with a depressed neonate than is a mixed acidemia with a minimal base deficit and a more nearly normal HCO_3^- level.

FIGURE 32-4
Nomogram for determining the delta base. (Adapted with permission from Siggaard- Anderson O: Blood acid–base alignment nomogram, Scand J Clin Lab Invest. 1963;15:211–7.)



Clinical Significance of Acidemia

Fetal oxygenation and pH generally decline during the course of normal labor. Normal umbilical cord blood pH and blood gas values at delivery in term newborns are summarized in Table 32-3. Similar values have been reported for preterm neonates (Dickinson, 1992; Ramin, 1989; Riley, 1993). The lower limits of normal pH in the newborn have been found to range from 7.04 to 7.10 (Thorp, 1996). Thus, these values should be considered to define neonatal acidemia. Even so, most fetuses will tolerate intrapartum acidemia with a pH as low as 7.00 without incurring neurological impairment (Freeman, 1988; Gilstrap, 1989). That said, in a study of newborns with a pH <7.0 from Parkland Hospital, there were inordinate proportions of neonatal deaths—8 percent, intensive care admissions—39 percent, intubations—14 percent, and seizures—13 percent (Goldaber, 1991). And, in a study from Oxford of more than 51,000 term newborns, the incidence of neonatal encephalopathy in those with a birth pH <7.0 was 3 percent (Yeh, 2012). Even those with who had normal 5-minute Apgar scores but an arterial cord pH values <7.0 had a significantly higher risk of morbidity that included respiratory distress, neonatal intensive care unit admission, and sepsis (Sabol, 2016). The speed of acidemia resolution after birth is associated with outcome (Casey, 2001a).

Respiratory Acidemia

Acute interruption in placental gas exchange is accompanied by subsequent CO_2 retention and respiratory acidemia. The most common antecedent factor is transient umbilical cord compression. Generally, respiratory acidemia is not harmful to the fetus (Low, 1994).

The degree to which pH is affected by pCO_2—the respiratory component of the acidosis—can be calculated. First, the upper normal neonatal pCO_2 of about 50 mm Hg is subtracted from the cord blood gas pCO_2 value. Each additional 10 mm Hg pCO_2 increment will lower the pH by 0.08 units (Eisenberg, 1987). Thus, in a mixed respiratory–metabolic acidemia, the benign respiratory component can be calculated. As an example, acute cord prolapse during labor prompts cesarean delivery of a neonate 20 minutes later. The umbilical artery blood gas pH was 6.95 and the pCO_2 was 90 mm Hg. The degree to which the cord compression and subsequent impairment of CO_2 exchange affected the pH is calculated using the relationship given earlier and shown below.

$$90 \text{ mm Hg} - 50 \text{ mm Hg} = 40 \text{ mm Hg excess } CO_2$$

$$\text{To correct pH: } (40 \div 10) \times 0.08 = 0.32;\ 6.95 + 0.32 = 7.27$$

Therefore, the pH before cord prolapse was approximately 7.27, well within normal limits. Thus, the low pH resulted from respiratory acidosis.

Metabolic Acidemia

The fetus begins to develop metabolic acidemia when oxygen deprivation is sufficiently long and severe to require anaerobic metabolism for cellular energy needs. Low and associates (1997) defined fetal acidosis as a base deficit ≥12 mmol/L, and severe fetal acidosis as a base deficit ≥16 mmol/L. In the Parkland study of more than 150,000 newborns cited earlier, metabolic acidemia was defined using umbilical cord blood gas thresholds that were two standard deviations below the mean (Casey, 2001b). Thus, metabolic acidemia was an umbilical artery blood pH <7.00 accompanied by a pCO_2 ≤76.3 mm Hg, with higher values indicating a respiratory

component; HCO_3^- concentration ≤17.7 mmol/L; and base deficit ≥10.3 mEq/L. From the standpoint of *possible* neurological injury, the American College of Obstetricians and Gynecologists (2014) defines metabolic acidosis as umbilical arterial pH <7.0 and a base deficit ≥12 mmol/L.

Metabolic acidemia is associated with a high rate of multiorgan dysfunction. In rare cases, such hypoxia-induced metabolic acidemia may be so severe that it causes subsequent neurological impairment—*hypoxic-ischemic encephalopathy* (Chap. 33, Neonatal Encephalopathy). In fact, a fetus without such acidemia cannot by definition have suffered recent hypoxic-induced injury. That said, severe metabolic acidosis is poorly predictive of subsequent neurological impairment in the term neonate (King, 1998; Socol, 1994). In very-low-birthweight neonates, that is, those <1000 g, newborn acid–base status may be more closely linked to intraventricular hemorrhage and possibly long-term neurological outcome (Lavrijsen, 2005; Salhab, 2005; Victory, 2003).

Casey and coworkers (2001b) described the association between metabolic acidemia, low Apgar scores, and neonatal death in term and preterm newborns. Regarding term neonates, the risk of neonatal death was more than 3200-fold greater in term neonates with metabolic acidemia and 5-minute scores ≤3 compared with those with a 5-minute Apgar score ≥7.

Recommendations for Cord Blood Gas Determinations

In some centers, cord gas analysis is performed in all neonates at birth (Casey, 2001b; Sabol, 2016). Cost-effectiveness analysis for universal cord blood gas measurements suggest benefit and potential cost savings (White, 2010, 2016). It seems reasonable to obtain cord blood gas determinations for intrapartum cases of cesarean delivery for fetal compromise, abnormal fetal heart rate tracing, fever, and low 5-minute Apgar score. Multifetal gestation and severely growth-restricted fetuses are others.

Although umbilical cord acid–base blood determinations are poorly predictive of either immediate or long-term adverse neurological outcome, they provide the most objective evidence of the fetal metabolic status at birth.

PREVENTIVE CARE

Eye Infection Prophylaxis

Ophthalmia neonatorum is mucopurulent conjunctivitis of newborns. Some form of conjunctivitis affects 1 to 12 percent of all neonates, and gonococcal and chlamydial infections are among the most common (Zuppa, 2011).

Neisseria gonorrhoeae infection acquired at birth was a common cause of childhood blindness in the past. However, the practice of instilling a 1-percent ophthalmic solution of silver nitrate largely eliminated this. Various other antimicrobial agents have also proven effective, and gonococcal prophylaxis is now mandatory for all neonates in most states (American Academy of Pediatrics, 2017b). For *prophylaxis* soon after delivery, recommendations include a single application of either 1-percent silver nitrate solution or 0.5-percent erythromycin ointment. In North America, a previously used 1-percent tetracycline ophthalmic ointment is no longer available (Mabry-Hernandez, 2010; Moore, 2015).

For a neonate born to a mother with untreated gonorrhea, *treatment* of presumptive neonatal gonococcal conjunctivitis is a single ceftriaxone dose, 100 mg/kg, given either intramuscularly or intravenously. Before treatment, testing for both gonococcal and chlamydia infections should be obtained.

With *chlamydial conjunctivitis,* adequate neonatal prophylaxis is complex. Ideally, prenatal screening and treatment for *Chlamydia trachomatis* obviates conjunctival infection (Hammerschlag, 2011). In neonates delivered vaginally of mothers with an active chlamydial infection, 12 to 25 percent will develop conjunctivitis up to 20 weeks after birth (Teoh, 2003). *Prophylactic topical eye treatments do not reliably reduce the incidence of chlamydial conjunctivitis.* In a study from Kenya, 2.5-percent povidone-iodine solution was reported to be superior to either 1-percent silver nitrate solution or 0.5-percent erythromycin ointment in preventing chlamydial conjunctivitis (Isenberg, 1995). In another study from Iran, povidone-iodine eye drops were twice as effective in preventing clinical conjunctivitis as erythromycin drops—9 versus 18 percent failure rate, respectively (Ali, 2007).

Conjunctivitis in a newborn up to age 3 months should prompt consideration for chlamydial infection (Moore, 2015). Treatment for pediatric chlamydial infection is with oral azithromycin for 5 days or oral erythromycin for 14 days.

Hepatitis B Immunization

Routine immunization with thimerosal-free vaccine against hepatitis B before hospital discharge is standard practice for all medically stable newborns with birthweights greater than 2000 g (American Academy of Pediatrics, 2017b). If the mother is seropositive for hepatitis B surface antigen, then the neonate is also passively immunized with hepatitis B immune globulin. As discussed in Chapter 55 (Pregnancy and Hepatitis B), some advocate treatment of high-risk or even all seropositive women with antiviral nucleoside or nucleotide analogues during pregnancy to minimize fetal transmission (Dusheiko, 2012; Tran, 2012).

Zika Virus

This virus is primarily spread by mosquito bites. Infection is asymptomatic in most people but can cause severe birth defects (Chap. 64, Coronavirus Infections). Screening begins with an interrogation for recent travel to endemic areas. For women at risk, serological screening is then completed. All newborns of mothers who have laboratory evidence of Zika virus infection during pregnancy should receive a comprehensive examination, a neurological assessment, postnatal head ultrasound, standard newborn hearing screen before hospital discharge, and Zika virus laboratory testing (Reynolds, 2017).

Vitamin K

Supplemental vitamin K injection will prevent vitamin K-dependent hemorrhagic disease of the newborn (Chap. 33, Polycythemia and Hyperviscosity). A single intramuscular dose of vitamin K, 0.5 to 1 mg, is given within 1 hour of birth (American Academy of Pediatrics, 2017b).

Newborn Screening

Numerous mass-screening tests are now available for 29 newborn conditions. Shown in Table 32-4, many are mandated by various state laws (American College of Obstetricians and Gynecologists, 2017c). Most states require that all tests in the core panel be performed. Supplemental conditions—*secondary targets*—are also listed on the Maternal and Child Health Bureau website. Some states require some of these in addition to their mandated core panel. Each practitioner should be familiar with their individual state requirements, which are available at http://genes-r-us.uthscsa.edu/resources/consumer/statemap.htm.

TABLE 32-4

Newborn Screening Core Panel

ROUTINE NEWBORN CARE

Gestational-Age Estimation

Newborn gestational age can be estimated very soon after delivery. The relationship between gestational age and birthweight can identify neonates at risk for complications. For example, neonates who are either small or large for gestational age are at greater risk for hypoglycemia and polycythemia, and measurements of blood glucose and hematocrit are indicated.

Care of Skin and Umbilical Cord

All excess vernix, blood, and meconium is gently wiped off after delivery while keeping the newborn warm. Any remaining vernix is readily absorbed and disappears within 24 hours. The first bath is postponed until the neonate's temperature is stable.

Aseptic precautions are observed in the immediate care of the cord. The American Academy of Pediatrics has concluded that keeping the cord dry is sufficient care (Stewart, 2016). The umbilical cord begins to lose water from Wharton jelly shortly after birth. Within 24 hours, the cord stump loses its characteristic bluish-white, moist appearance and soon becomes dry and black. Within several days to weeks, the stump sloughs and leaves a small, granulating wound, which after healing forms the umbilicus. Separation usually takes place within the first 2 weeks. The range is 3 to 45 days (Novack, 1988). The umbilical cord dries more quickly and separates more readily when exposed to air. Thus, a dressing is not recommended.

In resource-poor countries, local antimicrobial prophylaxis is reasonable (Salam, 2014). Triple-dye applied to the cord was reported to be superior to soap and water care in preventing colonization and exudate formation (Janssen, 2003). In a Nepalese study, cleaning the cord stump with 4-percent chlorhexidine reduced severe infection by 75 percent compared with soap and water (Mullany, 2006). Likewise, 0.1-percent chlorhexidine powder was superior to dry cord care (Kapellen, 2009). The World Health Organization (2014) recommends cleansing with chlorhexidine.

Despite precautions, a serious umbilical infection—*omphalitis*—sometimes develops. In a German study of more than 750 newborns with aseptic cord care, 1.3 percent suffered such infections (Kapellen, 2009). The most likely offending organisms are *Staphylococcus aureus, Escherichia coli,* and group B streptococcus.

Typical signs of cellulitis and stump discharge usually aid diagnosis. Mild erythema and some bleeding at the stump site with cord detachment is also common, but some cases present with no outward signs.

Feeding and Weight Loss

In 2016, 81 percent of U.S. newborns were initially breastfed, 52 percent were still breastfed at 6 months, and 31 percent at 1 year (Centers for Disease Control and Prevention, 2016). According to the American College of Obstetricians and Gynecologists (2017e), exclusive breastfeeding is preferred until 6 months. In many hospitals, breastfeeding begins in the delivery room. Most term newborns thrive best when fed 8 to 12 times daily for approximately 15 minutes each episode. Preterm or growth-restricted newborns require feedings at shorter intervals. Breastfeeding is discussed further in Chapter 36 (Lactation And Breastfeeding).

Because most neonates actually receive little nutriment for the first 3 or 4 days of life, they progressively lose weight until the flow of maternal milk is established or other feeding is instituted. Preterm neonates lose relatively more weight and regain their birthweight more slowly. Conversely, growth-restricted but otherwise healthy newborns regain their initial weight more quickly than those born preterm. With proper nourishment, birthweight of term newborns usually is regained by 10 days.

Stools and Urine

For the first 2 or 3 days after birth, the colon contains soft, brown-green meconium. This consists of desquamated epithelial cells from the intestinal tract, mucus, epidermal cells, and lanugo (fetal hair) that have been swallowed along with amnionic fluid. The characteristic color results from bile pigments. During fetal life and for a few hours after birth, the intestinal contents are sterile, but bacteria quickly colonize the bowel contents.

Meconium stooling is seen in 90 percent of newborns within the first 24 hours, and most of the rest within 36 hours. Usually, newborns first void shortly after birth but may not until the second day. Meconium and urine passage indicates patency of the gastrointestinal and urinary tracts, respectively. Failure of the newborn to stool or urinate after these times suggests a congenital defect, such as Hirschsprung disease, imperforate anus, or posterior urethral valve. After the third or fourth day, as a result of milk ingestion, meconium is replaced by light-yellow, softer, homogenous feces.

Neonatal Hyperbilirubinemia

Between the second and fifth day of life approximately one third of all neonates develop physiological jaundice of the newborn. It has special significance considering most hospitals have policies for early discharge. Guidelines regarding standard phototherapy equipment and monitoring, as well as treatment recommendations per gestational age, hour of life, and risk factors are used (Bhutani, 2011; Maisels, 2009). Hyperbilirubinemia is discussed further in Chapter 33 (Polycythemia and Hyperviscosity).

Male Circumcision

Indications

Neonatal circumcision of male infants has been a controversial topic in the United States for at least 30 years. Even so, scientific evidence supports several medical benefits that include prevention of phimosis, paraphimosis, and balanoposthitis. Circumcision also lowers the incidence of penile cancer and of cervical cancer among their sexual partners. Previously, the American Academy of Pediatrics Task Force on Circumcision (1999) concluded that existing evidence was insufficient to recommend *routine* neonatal circumcision. It seems that this policy has had only a negligible effect on practices in this country. Specifically, the Centers for Disease Control and Prevention (2011) estimated that the newborn male circumcision rate declined during a 12-year period from approximately 60 percent in 1999 to only 55 percent in 2010.

Other studies have endorsed health benefits of circumcision. In large randomized trials from regions of Africa with a high prevalence of human immunodeficiency virus (HIV), male circumcision was found to lower the risk of HIV acquisition in the adult by half (Bailey, 2007; Gray, 2007). And, male circumcision was also reported to decrease adult incidences of HIV, HPV, and herpes infections (Tobian, 2009). In its subsequent policy statement, the American Academy of Pediatrics Task Force on Circumcision (2012) concluded that health benefits of newborn male circumcision outweigh the risks. Thus, access to the procedure is justified for families who choose it. The Task Force stopped short of recommending circumcision for *all* newborns.

Surgical Technique

Circumcision is performed only in a healthy neonate. Other contraindications include any genital abnormalities such as hypospadias and a family history of a bleeding disorder, unless excluded in the newborn.

The Task Force (2012) recommends procedural analgesia. Various pain relief techniques include lidocaine-prilocaine topical cream, local analgesia infiltration, dorsal penile nerve block, or ring block (Arnett, 1990; Stang, 1988). The dorsal penile nerve block or the ring block is superior to topical analgesia (Hardwick-Smith, 1998; Lander, 1997; Taddio, 1997). The use of a pacifier dipped in sucrose is a useful adjunct to these methods (Kaufman, 2002).

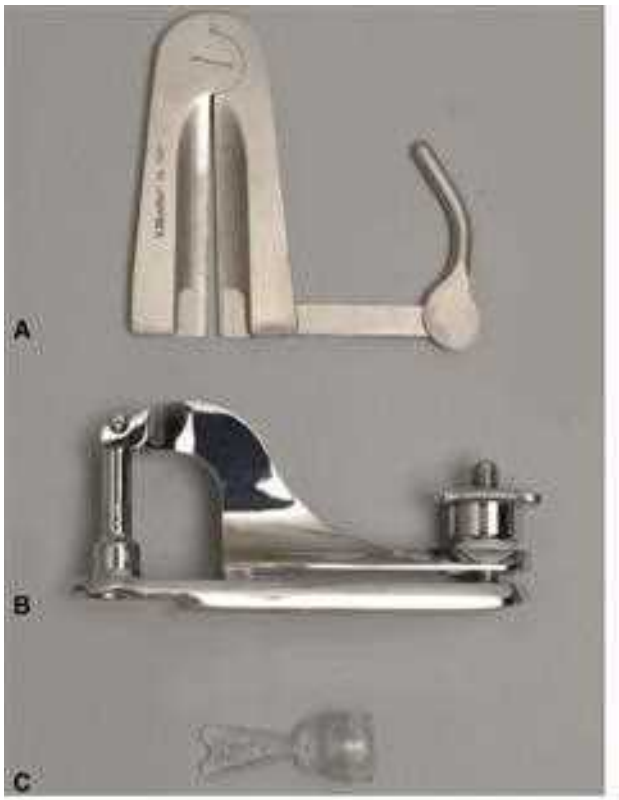
After appropriate penile cleansing, the ring block places a wheal of 1-percent lidocaine at the base of the penis and then advances the needle in a 180-degree arc around the base of the penis. The needle is advanced first to one side and then to the other to achieve a circumferential ring of analgesia. The maximum dose of lidocaine is 1.0 mL. *No vasoactive compounds such as epinephrine should ever be added to a local analgesic agent for circumcision.*

The most commonly used instruments are shown in Figure 32-5 and are Gomco and Mogen clamps and the Plastibell device. Compared with the Gomco procedure, Kaufman and colleagues (2002) reported that the Mogen technique required less time to perform and was associated with less apparent discomfort for the newborn. Regardless of the method used, the goal is to remove enough shaft skin and inner preputial epithelium so that the glans is exposed sufficiently to prevent phimosis. In all techniques: (1) the amount of external skin to be removed must be accurately estimated, (2) the preputial orifice must be dilated to visualize the glans and

ensure that it is normal, (3) the inner preputial epithelium must be freed from the glans epithelium, and (4) the circumcision device must be left in place long enough to produce hemostasis before amputating the prepuce (Lerman, 2001).

FIGURE 32-5

Three different tools used for circumcision. **A.** Mogen clamp. The arms of the clamp open to a 3-mm maximum width. **B.** Gomco clamp, assembled. **C.** Plastibell device.



The risks for bleeding, infection, and hematoma formation are low (Christakis, 2000). Unusual complications include distal glans amputation, acquisition of HIV infection or other sexually transmitted disease, meatal stenosis, penile denudation, penile destruction with electrosurgical coagulation, subsequent epidermal inclusion cyst and urethrocutaneous fistula, and ischemia following the inappropriate use of lidocaine with epinephrine (Amukele, 2003; Neulander, 1996; Nicoll, 1997; Pippi-Salle, 2013; Upadhyay, 1998).

Rooming In and Hospital Discharge

Hospital *rooming in* places newborns in their mothers' rooms instead of central nurseries. This practice attempts to make all phases of childbearing as natural as possible and to foster early mother-child relationships. By 24 hours, the mother is generally fully ambulatory. Thereafter, with rooming-in, she can usually provide routine care for herself and her newborn. An obvious advantage of this is her ability to assume full care when she arrives home.

Traditionally, the newborn is discharged with its mother, and in most cases, maternal stay has determined that of the neonate. From 1970 to the mid-1990s, average maternal postpartum length of stay declined steadily, and many mothers were discharged before 48 hours. The World Health Organization (2014) cites a minimal stay of only 24 hours. Although it is clear that most newborns can be safely discharged within 48 hours, this is not uniformly true. For example, in more than 2.1 million neonates in Canada, Liu and associates (2000) examined readmission rates following initial neonatal discharge. As the length of hospital stay dropped from 4.2 days in 1990 to 2.7 days in 1997, the readmission rate rose from 27 to 38 per 1000. Dehydration and jaundice accounted for most of these readmissions. Using Washington state data, Malkin and coworkers (2000) found that the 28-day mortality rate was increased fourfold in newborns discharged within 30 hours of birth, and the 1-year mortality rate grew twofold. Safe discharge for late-preterm newborns has special concerns (Whyte, 2012).

Because of the increased scrutiny regarding short hospital stays, federal legislation—*The Newborns' and Mothers' Health Protection Act of 1996*—was enacted to prohibit insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal delivery or 4 days for cesarean delivery. In an analysis of more than 662,000 births in California, Datar and Sood (2006) found that readmission rates declined by 9, 12, and 20 percent, respectively, at 1, 2, and 3 years after the legislation was implemented.

CHAPTER 33: Diseases and Injuries of the Term Newborn

In a small number of cases fractures of the skull are met with. This accident usually follows violent attempts at delivery, though occasionally it may occur spontaneously.

—J. Whitridge Williams (1903)

INTRODUCTION

In the first edition of this book, Williams wrote very little of the disorders of the term newborn. That said, it is well known that these neonates are susceptible to a wide variety of illnesses and injuries. In many instances, clinical manifestations of these disorders are extensions of pathological effects already incurred by the fetus. A common example is the newborn who is depressed and acidotic because of intrapartum septicemia. Because many of these disorders manifest differently, those more common in term newborns are considered here. Those more frequent in preterm neonates are discussed in Chapter 34. Specific disorders that are the direct consequence of maternal diseases are discussed in pertinent chapters.

RESPIRATORY DISTRESS

At the time of delivery, the newborn must convert rapidly to air breathing as described in Chapter 32 (Transition to Air Breathing). With inspiration, there is alveolar expansion, fluid clearance, and surfactant secretion by type II pneumocytes to prevent alveolar collapse. Interference with these functions can create respiratory insufficiency with hypoxemia and compensatory tachypnea, nasal flaring, retractions, and grunting (Reuter, 2014). In preterm infants, this is caused by lung immaturity and insufficient surfactant—*respiratory distress syndrome (RDS)*—and variants may be seen in severely ill older children and adults (Chap. 47, Acute Respiratory Distress Syndrome). All of these have some element of surfactant deficiency because the inciting agent damages alveolar epithelium. As fetuses approach term, surfactant deficiency as a cause of respiratory distress diminishes. The leading causes in term newborns are transient tachypnea of the newborn, RDS, meconium aspiration syndrome, pneumonia, persistent pulmonary hypertension, and hypoxic-ischemic encephalopathy (Lin, 2015).

Respiratory Distress Syndrome

In a report from Beijing that described 125 term infants with RDS, the most frequent causes were perinatal infection with sepsis syndrome in 50 percent, elective cesarean delivery in 27 percent, severe asphyxia in 10 percent, and meconium aspiration in 7 percent (Liu, 2010). Notably, even with a low incidence in term infants, RDS from surfactant deficiency is not rare (Berthelot-Ricou, 2012). Chorioamnionitis, male gender, and white race are independent risks (Anadkat, 2012; Higgins, 2016). Also, mutations of genes that encode for surfactant protein synthesis may augment the deficiency (Wambach, 2012). Regardless of etiology, when surfactant secretion is diminished, the pulmonary pathophysiology, clinical course, and management are similar to that for preterm infants. Treatment includes mechanical ventilation and replacement of surfactant (Chap. 34, Clinical Course). Evidence now supports that antenatal maternal corticosteroid treatment will enhance surfactant synthesis in late-preterm fetuses, that is, those 34 to 37 weeks' gestation (Gyamfi-Bannerman, 2016). At Parkland Hospital, corticosteroids are not given for this indication in the late-preterm period. Neonatal hypoglycemia is a concern with such treatment, and long-term effects are unknown. However, data indicate that hypoglycemia, if promptly treated, creates no adverse sequelae (McKinlay, 2015). The prognosis in term newborns with RDS largely depends on the cause, severity, and response to treatment.

Meconium Aspiration Syndrome

The physiology of meconium passage and amnionic fluid contamination is considered in Chapter 24 (Meconium in the Amnionic Fluid). In some instances, inhalation of meconium-stained fluid at or near delivery causes acute airway obstruction, chemical pneumonitis, surfactant dysfunction or inactivation, and pulmonary hypertension (Lee, 2016; Lindenskov, 2015). If severe, hypoxemia may lead to neonatal death or long-term neurological sequelae in survivors.

Given the high incidence—10 to 20 percent—of meconium-stained amnionic fluid in laboring women at term, one may reasonably assume that meconium aspiration must be relatively common. Fortunately, severe aspiration leading to overt respiratory failure is much less frequent. And although the exact incidence of meconium aspiration syndrome is unknown, Singh and associates (2009) reported it to complicate 1.8 percent of all deliveries. In a French study of nearly 133,000 term newborns, the prevalence of severe aspiration syndrome was 0.07 percent, and this rose progressively from 37 to 43 weeks' gestation (Fischer, 2012). Mortality rates depend on severity.

Fetal morbidity is more often associated with thicker meconium content. Presumably, in most cases, amnionic fluid is ample to dilute the meconium to permit prompt clearance by normal fetal physiological mechanisms. Meconium aspiration syndrome still occasionally develops with light staining. Many newborns are affected after a normal labor and uncomplicated delivery. However, some associated obstetrical factors include postterm pregnancy and fetal-growth restriction. These fetuses are at highest risk because diminished amnionic fluid and labor with cord compression or uteroplacental insufficiency are often comorbid. These can enhance the likelihood of meconium passage that is thick and undiluted (Leveno, 1984).

Prevention

Previously, aspiration was thought to be stimulated by fetal hypoxic episodes, and fetal heart rate tracing abnormalities were used to identify fetuses at greatest risk during labor. Unfortunately, this was found to be an unreliable predictor (Dooley, 1985). As another potential prevention, oropharyngeal suctioning was standard care for a time. However, this was abandoned when evidence failed to support a reduction in syndrome incidence or severity (Davis, 1985; Wiswell, 1990). At the same time, reports described that pulmonary hypertension caused by aspirated meconium was characterized by abnormal arterial muscularization beginning well before birth. These findings led some to conclude that only chronically asphyxiated fetuses developed meconium aspiration syndrome (Katz, 1992). But, correlation was not found between meconium aspiration and markers of *acute* asphyxia—for example, umbilical artery acidosis (Bloom, 1996; Richey, 1995). Others, however, have reported that thick meconium is an independent risk factor for neonatal acidosis (Maisonneuve, 2011).

In response to conflicting results regarding suctioning, an 11-center randomized trial was designed to compare suctioning with no suctioning (Vain, 2004). There was an identical 4-percent incidence of meconium aspiration syndrome in both groups. Subsequently, a committee that represented the American Heart Association updated its guidelines (Wyckoff, 2015). Adopted by the American College of Obstetricians and Gynecologists (2017c) and the World Health Organization (2012), these recommend *against* routine intrapartum oro- and nasopharyngeal suctioning at delivery. For vigorous newborns, no treatment is required. For depressed newborns, management includes intervention to support ventilation and oxygenation, and intubation is used as indicated (Chap. 32, Chest Compressions).

Intrapartum amnioinfusion has been used successfully in laboring women with diminished amnionic fluid volume and frequent variable fetal heart rate decelerations (Chap. 24, Management Options). Earlier, it was studied as a preventive measure in labors complicated by meconium staining. This practice failed to lower meconium aspiration syndrome rates because fetuses usually inhaled meconium before labor (Bryne, 1987; Wenstrom, 1995). To further settle this issue, a trial was conducted with almost 2000 women at 36 weeks' gestation or later and in whom labor was complicated by thick meconium (Fraser, 2005). The perinatal death rate with and without amnioinfusion was 0.05 percent in both groups. Rates of moderate or severe meconium aspiration were also not significantly different—4.4 percent with and 3.1 percent without amnioinfusion. Finally, cesarean delivery rates were similar—32 versus 29 percent, respectively. Currently, the American College of Obstetrics and Gynecologists (2016a) does not recommend amnioinfusion to reduce meconium aspiration syndrome.

Treatment

Ventilatory support and intubation are carried out as needed (Wyckoff, 2015). Because some aspects of meconium aspiration syndrome are caused by surfactant deficiency, replacement therapy is beneficial (Natarajan, 2016a). Also, inhaled corticosteroids may ameliorate the severity (Garg, 2016). *Extracorporeal membrane oxygenation—ECMO*—therapy is reserved for neonates who remain poorly oxygenated despite maximal ventilatory assistance (Hirakawa, 2017). In their review of randomized trials, El Shahed and colleagues (2014) found that surfactant replacement may reduce the need for ECMO but did not lower the mortality rate. The proportion that requires ECMO treatment varies. In a report by Singh and coworkers (2009), 1.4 percent of 7518 term newborns with the syndrome required such treatment, and these had a 5-percent mortality rate. Ramachandrappa and associates (2011) reported a higher mortality rate in late-preterm neonates with meconium aspiration compared with affected term newborns. Finally, pulmonary lavage with surfactant is being evaluated (Choi, 2012).

NEONATAL ENCEPHALOPATHY AND CEREBRAL PALSY

Few events evoke more apprehension in parents and obstetricians than the specter of "brain injury," which immediately prompts concerns for disabling cerebral palsy and intellectual disability. Although most brain disorders or injuries are less profound, history has helped to perpetuate the more dismal outlook. In his first edition of this textbook, Williams (1903) limited discussions of brain injury to those sustained from birth trauma. When later editions introduced the concept that *asphyxia neonatorum* was another cause of cerebral palsy, this too was linked to traumatic birth. Even as brain damage caused by traumatic delivery became uncommon during the ensuing decades, the belief—albeit erroneous—was that intrapartum events caused most neurological disability. This was a major reason for the escalating cesarean delivery rate beginning in the 1970s. Unfortunately, because in most cases the genesis of cerebral palsy occurs long before labor, this did little to mitigate risks for cerebral palsy (O'Callaghan, 2013).

These realizations stimulated scientific investigations to determine the etiopathogenesis of fetal brain disorders, including those leading to cerebral palsy. Seminal observations include those of Nelson and Ellenberg (1984, 1985, 1986a), discussed subsequently. These investigators are appropriately credited with proving that these neurological disorders are due to complex multifactorial processes caused by a combination of genetic, physiological, environmental, and obstetrical factors. Importantly, these studies showed that few neurological disorders were associated with peripartum events. Continuing international interest was garnered to codify the potential role of intrapartum events. In 2000, a task force of the American College of Obstetricians and Gynecologists was appointed to study the vicissitudes of neonatal encephalopathy and cerebral palsy. The multispecialty coalition reviewed contemporaneous data and provided criteria to define various neonatal brain disorders. Their findings were promulgated by the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2003).

Ten years later, a second task force of these organizations updated the findings (American College of Obstetricians and Gynecologists, 2014c). The 2014 Task Force findings are more circumspect in contrast to the earlier ones. Specifically, more limitations are cited in identifying cause(s) of peripartum *hypoxic-ischemic encephalopathy (HIE)* compared with other etiologies of neonatal encephalopathy. The 2014 Task Force recommends multidimensional assessment of each affected infant. They add the caveat that no one strategy is infallible, and thus, no single strategy will achieve 100-percent certainty in attributing a cause to neonatal encephalopathy.

Neonatal Encephalopathy

The 2014 Task Force defined neonatal encephalopathy as a syndrome of neurological dysfunction identified in the earliest days of life in neonates born at ≥35 weeks' gestation. It is manifested by subnormal levels of consciousness or seizures and often accompanied by difficulty with initiating and maintaining respiration and by depressed tone and reflexes. The incidence of encephalopathy has been cited to be 0.27 to 1.1 per 1000 term liveborn neonates, and it is much more frequent in

preterm newborns (Ensing, 2013; Plevani, 2013; Takenouchi, 2012; Wu, 2011). Although the 2014 Task Force concluded that there are many causes of encephalopathy and cerebral palsy, it focused on HIE and those that were thought to be incurred intrapartum. To identify affected infants, a thorough evaluation is necessary and includes maternal history, obstetrical antecedents, intrapartum factors, placental pathology, and newborn course. These are complemented by laboratory and neuroimaging findings.

There are three clinically defined levels. *Mild encephalopathy* is characterized by hyperalertness, irritability, jitteriness, and hypertonia and hypotonia. *Moderate encephalopathy* is manifest by lethargy, severe hypertonia, and occasional seizures. S*evere encephalopathy* is manifest by coma, multiple seizures, and recurrent apnea.

The 2014 Task Force also concluded that of the several forms of cerebral palsy, only the *spastic quadriplegic* type can result from acute peripartum ischemia. Other forms—*hemiparetic* or *hemiplegic cerebral palsy, spastic diplegia,* and *ataxia*—are unlikely to result from an intrapartum event. Purely dyskinetic or ataxic cerebral palsy, especially when accompanied by a learning disorder, usually has a genetic origin (Nelson, 1998).

Criteria for Hypoxic-Ischemic Encephalopathy

The 2014 Task Force radically revised its 2003 criteria used to define an acute peripartum event that is consistent with an HIE and neonatal encephalopathy. These are outlined in Table 33-1 and are considered with the following caveats.

TABLE 33-1

Findings Consistent with an Acute Peripartum or Intrapartum Event Leading to Hypoxic-Ischemic Encephalopathy

Neonatal Findings
Apgar score: <5 at 5 and 10 minutes
Umbilical arterial acidemia: pH <7.0 and/or base deficit ≥12 mmol/L
Neuroimaging evidence of acute brain injury: MR imaging or MRS consistent with HIE
Multisystem involvement consistent with HIE
Type and Timing of Contributing Factors
Sentinel hypoxic or ischemic event occurring immediately before or during delivery
Fetal heart rate monitor patterns consistent with an acute peripartum or intrapartum event

HIE = hypoxic ischemic encephalopathy; MR = magnetic resonance; MRS = magnetic resonance spectroscopy.

Summarized from the American College of Obstetricians and Gynecologists, 2014b.

First, *Apgar Scores* that are low at 5 and 10 minutes are associated with greater risk for neurological impairment. Low scores stem from many causes, and most of these infants will not develop cerebral palsy. With a 5-minute Apgar ≥7, it is unlikely that peripartum HIE caused cerebral palsy.

Acid-base study results define a second HIE criterion. Low pH and base deficit levels raise the likelihood that neonatal encephalopathy was caused by HIE. Decreasing levels form a continuum of increasing risk, but most acidemic neonates will be neurologically normal (Wayock, 2013). A cord artery pH ≥7.2 is very unlikely to be associated with HIE.

Magnetic resonance (MR) imaging or *MR spectroscopy (MRS)* is the best modality with which to visualize findings consistent with HIE. The 2014 Task Force concludes that cranial sonography and computed tomography (CT) lack sensitivity in the term newborn. Normal imaging findings after the first 24 hours of life, however, effectively exclude a hypoxic-ischemic cause of encephalopathy. MR imaging between 24 and 96 hours may be more sensitive for the timing of peripartum cerebral injury, and MR imaging at 7 to 21 days following birth is the best technique to delineate the full extent of cerebral injury.

Last, *multisystem involvement* of injury is consistent with HIE. These include renal, gastrointestinal, hepatic, or cardiac injury; hematological abnormalities; or combinations of these. The severity of neurological injury does not necessarily correlate with injuries to these other systems.

The 2014 Task Force also found that certain contributing factors may be consistent with an acute peripartum event. Of these, *sentinel events* are considered adverse obstetrical events that may lead to catastrophic clinical outcomes. Examples include ruptured uterus, severe placental abruption, cord prolapse, and amnionic fluid embolism. Martinez-Biarge and associates (2012) studied almost 58,000 deliveries and identified 192 cases with one of these sentinel events. Of these 192 fetus/newborns, 6 percent died intrapartum or in the early neonatal period, and 10 percent developed neonatal encephalopathy. Other risk factors for neonatal acidosis include prior or emergent cesarean delivery, maternal age ≥35 years, thick meconium, chorioamnionitis, and general anesthesia (Ahlin, 2016; Johnson, 2014; Nelson, 2014).

Differentiating an *abnormal fetal heart rate (FHR) tracing* on presentation versus one that develops subsequently was also emphasized by the 2014 Task Force. A category 1 or 2 FHR tracing associated with Apgar scores ≥7 at 5 minutes, normal cord gases (±1 SD), or both are not consistent with an acute HIE event (Graham, 2014). An FHR pattern at the time of presentation with persistently minimal or absent variability and lacking accelerations, with duration ≥60 minutes, and even without decelerations is suggestive of an already compromised fetus (Chap. 24, Cardiac Arrhythmia). The 2014 Task Force further recommended that if fetal well-being cannot be established with these findings present, the woman should be evaluated for the method and timing of delivery.

Prevention

Most prophylactic measures for neonatal encephalopathy have been evaluated in preterm infants (Chap. 42, Magnesium Sulfate for Neuroprotection). One of these—postnatally induced hypothermia—may prevent death and mitigate moderate to severe neurological disability in term newborns (Garfinkle, 2015; Nelson, 2014; Shankaran, 2012). MR imaging studies have demonstrated a slowing of diffusional abnormalities and fewer infarctions with hypothermia (Bednarek, 2012; Natarajan, 2016b). Most randomized trials have shown improved outcomes with induced hypothermia in those born at 36 weeks' gestation or older (Azzopardi, 2014; Guillet, 2012; Jacobs, 2011). In a metaanalysis of more than 1200 newborns, Tagin and colleagues (2012) concluded that hypothermia improves survival rates and neurodevelopment. Clinical trials to evaluate concomitant neonatal erythropoietin therapy for neuroprophylaxis have reported conflicting results (Fauchère, 2015; Malla, 2017). Preliminary data from one multicenter trial of maternal *allopurinol* therapy indicate some mitigation of cerebral damage caused by hypoxia and ischemia (Kaandorp, 2013).

Cerebral Palsy

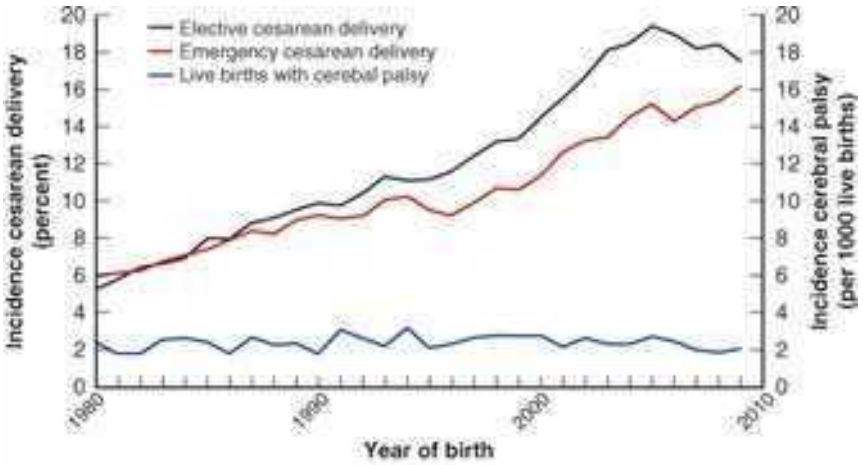
This term refers to a group of nonprogressive disorders of movement or posture caused by abnormal development or damage to brain centers for motor control. Cerebral palsy is further classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—and by the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. Together, the major types are s*pastic quadriplegia*—the most common—which has a strong association with mental retardation and seizure disorders; *diplegia,* which is common in preterm or low-birthweight infants; *hemiplegia; choreoathetoid types;* and *mixed varieties*. Although epilepsy and mental retardation frequently accompany cerebral palsy, these two disorders seldom are associated with perinatal asphyxia in the absence of cerebral palsy.

Incidence and Epidemiological Correlates

According to Nelson and coworkers (2015), the prevalence of cerebral palsy in the United States averages 2 of every 1000 children. *It is crucial to emphasize that this rate is derived from all children—including those born preterm.* Because of the remarkably greater survival rates of the latter currently, and despite the elevated cesarean delivery rate, the overall rate of cerebral palsy has remained essentially unchanged (Fig. 33-1). For example, follow-up studies of more than 900,000 Norwegian nonanomalous term infants cite an incidence of 1 per 1000, but the incidence was 91 per 1000 for those born at 23 to 27 weeks (Moster, 2008). Similar findings have been reported for Australian births (Smithers-Sheedy, 2016). In absolute numbers, term newborns comprise half of cerebral palsy cases because there are proportionately far fewer preterm births. It is again emphasized that most studies of cerebral palsy rates have not made distinctions between term and preterm infants.

FIGURE 33-1

Elective and emergency cesarean deliveries and live births with cerebral palsy. (Reproduced with permission from Nelson KB, Blair E: Prenatal factors in singletons with cerebral palsy born at or near term, N Engl J Med. 2015 Sep 3;373(10):946–953.)



As noted earlier, Nelson and Ellenberg (1984, 1985, 1986a) made many fundamental observations concerning cerebral palsy. Their initial studies emanated from data from the Collaborative Perinatal Project. This included children from almost 54,000 pregnancies who were followed until age 7. They found that the most frequently associated risk factors for cerebral palsy were: (1) evidence of genetic abnormalities such as maternal mental retardation or fetal congenital malformations; (2) birthweight <2000 g; (3) birth before 32 weeks; and (4) perinatal infection. They also found that obstetrical complications were not strongly predictive, and only a fifth of affected children had markers of perinatal asphyxia. *For the first time, there was solid evidence that the cause of most cases of cerebral palsy was unknown, and importantly, only a small proportion was caused by neonatal HIE.* Equally importantly, there was no foreseeable single intervention that would likely prevent a large proportion of cases.

Numerous studies have since confirmed many of these findings and identified an imposing list of other risk factors that are shown in Table 33-2. As expected, preterm birth continues to be the single most important risk factor (Nelson, 2015; Thorngren-Jerneck, 2006). Small-for-gestational-age neonates are also at higher risk. Stoknes and associates (2012) showed that in more than 90 percent of growth-restricted newborns, cerebral palsy was due to antepartum factors. Many other placental and neonatal risk factors have been correlated with neurodevelopmental abnormalities (Ahlin, 2013; Avagliano, 2010; Blair, 2011; Redline, 2008). Some placental factors are discussed further in Chapter 6 (Normal Placenta). One example is the substantively greater risk from chorioamnionitis (Gilbert, 2010; Shatrov, 2010). An example of a neonatal cause is arterial ischemic stroke, which may be associated with inherited fetal thrombophilias (Harteman, 2013; Kirton, 2011). Also, newborns with isolated congenital heart lesions have an elevated risk for microcephaly, possibly due to chronic fetal hypoxemia (Barbu, 2009). Other miscellaneous etiologies of cerebral palsy include fetal anemia, twin-twin transfusion syndrome, intrauterine transfusions, and fetal alcohol syndrome (DeJong, 2012; Lindenburg, 2013; O'Leary, 2012; Rossi, 2011; Spruijt, 2012).

TABLE 33-2

Perinatal Risk Factors Reported to Be Increased in Children with Cerebral Palsy

Risk Factors	Risk Ratio	95% CI
Hydramnios	6.9	1.0–49.3
Placental abruption	7.6	2.7–21.1
Interval between pregnancies <3 mo or >3 yr	3.7	1.0–4.4
Spontaneous preterm labor	3.4	1.7–6.7
Preterm delivery at 23–27 weeks	78.9	56.5–110
Breech or face presentation, transverse lie	3.8	1.6–9.1
Severe birth defect	5.6	8.1–30.0
Nonsevere birth defect	6.1	3.1–11.8
Time to cry >5 minutes	9.0	4.3–18.8
Obesity	1.2–2	1.1–2.8
Low placental weight	3.6	1.5–8.4
Placental infarction Chorioamnionitis	2.5	1.2–5.3
Clinical Histological	2.4 1.8	1.5–3.8 1.2–2.9
Others[a]	—	—

[a]Includes respiratory distress syndrome, meconium aspiration, emergent cesarean or operative vaginal delivery, hypoglycemia, gestational hypertension, hypotension, advanced maternal age, genetic factors, twins, thrombotic states, nighttime delivery, seizures, fetal-growth restriction, male gender, and nulliparity.

CI = confidence interval.

From Ahlin, 2013; Blair, 2011; McIntyre, 2013; Moster, 2008; Nelson, 2015; O'Callaghan, 2011; Shatrov, 2010; Takenouchi, 2012; Torfs, 1990; Villamor, 2017; Wu, 2012.

Apart from these causes, intrapartum hypoxemia was linked to only a minority of cerebral palsy cases by the National Collaborative Perinatal Project. However, because the study was carried out in the 1960s, there were inconsistent criteria to accurately assign cause. The contribution of HIE to subsequent neurological disorders is discussed in detail in Neonatal Encephalopathy. The 2003 Task Force applied these criteria to more contemporaneous outcomes and determined that only 1.6 cases of cerebral palsy per 10,000 deliveries are attributable solely to intrapartum hypoxia. This finding is supported by a study from Western Australia that spanned from 1975 to 1980 (Stanley, 1991). Other studies concluded that very few cases were due to intrapartum events and therefore preventable (Phelan, 1996; Strijbis, 2006).

Intrapartum Fetal Heart Rate Monitoring

Despite persistent attempts to validate continuous intrapartum electronic fetal monitoring as effective to prevent adverse perinatal outcomes, evidence does not support its ability to predict or reduce cerebral palsy risk (Clark, 2003; Thacker, 1995). Importantly, no specific fetal heart rate patterns predict cerebral palsy. Further, no relationship has been found between the clinician's response to abnormal patterns and neurological outcome. And, efforts using assisted computer analysis of

fetal heart tracings have not enhanced predictability (Alfirevic, 2017; INFANT Collaborative Group, 2017). Indeed, an abnormal heart rate pattern in fetuses that ultimately develop cerebral palsy may reflect a preexisting neurological abnormality (Phelan, 1994). Because of these studies, the American College of Obstetricians and Gynecologists (2017a,d) has concluded that electronic fetal monitoring does not reduce the incidence of long-term neurological impairment. This is discussed further in Chapter 24 (Benefits of Electronic Fetal Heart Rate Monitoring).

Apgar Scores

In general, 1- and 5-minute Apgar scores are poor predictors of long-term neurological impairment (American College of Obstetricians and Gynecologists, 2017e). When the 5-minute Apgar score is ≤3, however, neonatal death or the risk of neurological sequelae rises substantially (Dijxhoorn, 1986; Nelson, 1984). In a Swedish study, 5 percent of such children subsequently required special schooling (Stuart, 2011). In a Norwegian study, the incidence of these low Apgar scores was 0.1 percent in more than 235,000 newborns. Almost a fourth of those with such scores died, and 10 percent of survivors developed cerebral palsy (Moster, 2001).

Persistence past 5 minutes of these extremely low scores correlates strongly with a higher risk for neurological morbidity and death (Grünebaum, 2013). This of course is not absolute, and the 2003 Task Force cited a 10-percent risk for cerebral palsy for infants with 10-minute scores of 0 to 3. For 15-minute scores ≤2, there is a 53-percent mortality rate and a 36-percent cerebral palsy rate. For 20-minute scores ≤2, mortality rate is 60 percent, and a cerebral palsy rate is 57 percent. Some outcomes in the Norwegian Study of infants with these low 5-minute Apgar scores are shown in Table 33-3. Survivors who had Apgar scores of 0 at 10 minutes have even worse outcomes. In a review of 94 such newborns, 78 died, and *all* survivors assessed had long-term disabilities (Harrington, 2007).

TABLE 33-3

Comparison of Mortality and Morbidity in Norwegian Infants Weighing >2500 g According to 5-Minute Apgar Scores

Outcome	Apgar 0–3 (%)	Apgar 7–10 (%)	Relative Risk (95% CI)
Number	292	233, 500	
Mortality rates			
Neonatal	16.5	0.05	386 (270–552)
Infant	19.2	0.3	76 (56–103)
1–8 yr	3	0.2	18 (8–39)
Morbidity rates			
Cerebral palsy	6.8	0.09	81 (48–128)
Mental retardation	1.3	0.1	9 (3–29)
Other neurological	4.2	0.5	9 (5–17)
Non-neurological	3.4	2.0	2 (0.8–5.5)

CI = confidence interval.

Data from Moster, 2001.

Umbilical Cord Blood Gas Studies

As outlined in Neonatal Encephalopathy, objective evidence for metabolic acidosis—cord arterial blood pH <7.0 and base deficit ≥12 mmol/L—is a risk factor for encephalopathy and for cerebral palsy. The risk accrues as acidosis worsens. From their review of 51 studies, Malin and coworkers (2010) found that low cord arterial pH correlates with greater risk for neonatal encephalopathy and cerebral palsy. When used alone, however, these determinations are not accurate in predicting long-term neurological sequelae (Dijxhoorn, 1986; Yeh, 2012).

Data from several studies corroborate that a pH <7.0 is the threshold for clinically significant acidemia (Gilstrap, 1989; Goldaber, 1991). The likelihood of neonatal death grows as the cord artery pH falls to 7.0 or less. Casey and colleagues (2001) reported that when the pH was ≤6.8, the neonatal mortality rate rose 1400-fold. When the cord pH was ≤7.0 *and* the 5-minute Apgar score was 0 to 3, the risk of neonatal death was increased 3200-fold.

In the study from Oxford, adverse neurological outcomes were 0.36 percent with pH <7.1 and 3 percent with pH <7.0 (Yeh, 2012). As mentioned, newborn complication rates rise coincident with increasing severity of acidemia at birth. In a Swedish study, researchers observed that cord blood lactate levels may prove to be superior to base deficit for prognostication of neurological disorders (Wiberg, 2010).

Nucleated Red Blood Cells and Lymphocytes

Both immature red cells and lymphocytes enter the circulation of term newborns in response to hypoxia or hemorrhage. During the past two decades, quantification of these cells has been proposed as a measure of hypoxia, but most studies do not support this premise (Boskabadi, 2017; Silva, 2006; Walsh, 2011, 2013).

Neuroimaging Studies in Encephalopathy and Cerebral Palsy

Various neuroimaging techniques have provided important insight into the etiology and evolution of perinatal HIE and later cerebral palsy (Neonatal Encephalopathy). Importantly, findings are highly dependent on fetal age. The preterm neonatal brain responds quite differently to an ischemic episode compared with that of a term newborn. Other factors include insult severity and duration as well as restoration of cerebrovascular hypoperfusion. *Thus, precise timing of an injury with neuroimaging studies is not a realistic goal.* Moreover, the grade of neonatal encephalopathy, that is, mild, moderate, or severe, does not correlate with MR imaging findings (Walsh, 2017).

Neuroimaging in Neonatal Period

Regarding early use, the 2014 Task Force concluded that these imaging techniques provide the following information:

1. Sonographic studies are generally normal on the day of birth. With injury, increasing echogenicity in the thalami and basal ganglia is seen beginning at approximately 24 hours. This progresses over 2 to 3 days and persists for 5 to 7 days.
2. Computed tomography scans are usually normal the first day in term infants. With injury, decreased density in the thalami or basal ganglia is seen beginning at about 24 hours and persists for 5 to 7 days.
3. Magnetic resonance imaging will detect some abnormalities on the first day. Within 24 hours, MR imaging may show restricted water diffusion that peaks at approximately 5 days and disappears within 2 weeks. Acquisitions with T1- and T2-weighted images show variable abnormalities, which have an onset from less than 24 hours to several days. In a study of 175 term neonates with acute encephalopathy, it was reported that MR imaging showing basal ganglia lesions accurately predicted motor impairment at 2 years of age (Martinez-Biarge, 2012).

The 2014 Task Force concluded that for term newborns, imaging studies are helpful in timing an injury, but they provide only a window in time that is imprecise. In one study, the optimal range was 3 to 10 days (Lee, 2017).

Neuroimaging in Older Children with Cerebral Palsy

Imaging studies performed in children diagnosed with cerebral palsy frequently show abnormal findings. Wu and associates (2006) used CT or MR imaging to study 273 children who were born after 36 weeks' gestation and who were diagnosed later in childhood with cerebral palsy. Although a third of these studies were normal, focal arterial infarction was seen in 22 percent; brain malformations in 14 percent; and periventricular white-matter injuries in 12 percent. In another study of 351 children with cerebral palsy—approximately half were born near term—MR imaging findings were abnormal in 88 percent (Bax, 2006). Similar findings were reported in an Australian study (Robinson, 2008).

CT and MR imaging techniques have also been used in older children to help define the timing of fetal or perinatal cerebral injury. Wiklund and coworkers (1991a,b) studied 83 children between ages 5 and 16 years who were born at term and who developed hemiplegic cerebral palsy. Nearly 75 percent had abnormal CT findings, and these investigators concluded that more than half had CT changes that suggested a *prenatal injury.* Approximately 20 percent were attributed to a *perinatal injury*. In a similar study, Robinson and associates (2008) used MR imaging. They reported pathological findings in 84 percent of children with spastic quadriplegia. Remember, this is the neurological lesion that the 2014 Task Force concluded correlated with neonatal encephalopathy.

Intellectual Disability and Seizure Disorders

The term *intellectual disability* describes a spectrum of disabilities and seizure disorders that frequently accompany cerebral palsy. But, when either of these manifests alone, they are seldom caused by perinatal hypoxia (Nelson, 1984, 1986a,b). Severe mental disability has a prevalence of 3 per 1000 children, and its most frequent causes are chromosomal, gene mutation, and other congenital malformations. Finally, preterm birth is a common association for these (Moster, 2008).

The major predictors of seizure disorders are fetal malformations—cerebral and noncerebral; family history of seizures; and neonatal seizures (Nelson, 1986b). Neonatal encephalopathy causes a small proportion of seizure disorders. Reports from the Neonatal Research Network and other studies concluded that increasing severity of encephalopathy correlates best with seizures (Glass, 2011; Kwon, 2011).

Autism Spectrum Disorders

According to the Centers for Disease Control and Prevention, the frequency of autism spectrum disorders is 14.6 per 1000 in 8-year-old children (Christensen, 2016). Although these may be associated with maternal metabolic conditions, none has been linked convincingly to peripartum events (Krakowiak, 2012).

NEONATAL ABSTINENCE SYNDROME

This is a drug-withdrawal syndrome that most commonly follows in utero exposure to maternal opioids. It also may complicate exposure to ethanol or benzodiazepines. The syndrome is characterized by hypertonia, autonomic instability, irritability, poor sucking reflex, and seizures (Finnegan, 1975). The incidence of abstinence syndrome has risen six- to sevenfold during the past decade, coincidental with the growing opioid use described in Chapter 1 (Family Planning Services). For example, Tolia and colleagues (2015) reported that 4 percent of all neonatal intensive care unit (NICU) days in 2013 were attributed to care of these affected newborns.

Affected neonates undergo close observation, and pharmacotherapy is usually given. In addition to morphine and methadone, other treatment may include phenobarbital, benzodiazepines, and clonidine (Tolia, 2015). More recently, buprenorphine compared with morphine was reported to result in shorter lengths of stay (Kraft, 2017). Consensus is lacking regarding the most effective regimen. The American College of Obstetricians and Gynecologists and the American Society of Addiction Medicine (2017f) have taken the lead in screening, intervention, and treatment of opioid use disorders in pregnant women (Chap. 12, Cocaine).

HEMATOLOGICAL DISORDERS

There are a few neonatal disorders of erythrocytes, platelets, and coagulation with which the obstetrician should be familiar. As is the case for most other conditions manifest by the newborn shortly after birth, many of these hematological problems were manifest by the fetus and persist in the newborn.

Anemia

After 35 weeks' gestation, the mean cord hemoglobin concentration approximates 17 g/dL, and values below 14 g/dL are considered abnormal. The American College of Obstetricians and Gynecologists (2017b) now recommends a 30- to 60-second delay in cord clamping in all healthy newborns. A review of nearly 4000 deliveries found that this delayed cord clamping was associated with a mean neonatal hemoglobin rise of 1.5 g/dL (McDonald, 2013). At the same time, this practice almost doubled the incidence of hyperbilirubinemia requiring phototherapy.

Fetal anemia results from many causes (Colombatti, 2016; Yaish, 2017). Many of these are discussed in more detail in Chapter 15 (Fetal Anemia). Acute anemia with hypovolemia is seen with deliveries in which the placenta is cut or torn, if a fetal vessel is perforated or lacerated, if there is recent fetal-maternal hemorrhage, or if the newborn is held well above the level of the placenta for some time before cord clamping. Intracranial or extracranial injury or trauma to fetal intraabdominal organs can also cause hemorrhage with acute anemia (Akin, 2011; McAdams, 2017).

Polycythemia and Hyperviscosity

Neonatal polycythemia with hyperviscosity can be associated with chronic hypoxia in utero, twin-twin transfusion syndrome, placental- and fetal-growth restriction, fetal macrosomia from maternal diabetes, and transfusion at delivery. When the hematocrit rises above 65, blood viscosity markedly increases and may cause neonatal plethora, cyanosis, or neurological aberrations. Because of the shorter life span of macrocytic fetal erythrocytes, hyperbilirubinemia commonly accompanies polycythemia. Other findings include thrombocytopenia, fragmented erythrocytes, and hypoglycemia. Cui and associates (2017) reported a case of unilateral macular hemorrhage in a newborn with polycythemia and platelets of 1 million/μL. Partial exchange transfusion may be necessary in some neonates.

Hyperbilirubinemia

Even in term fetuses, hepatic maturation is not complete, and thus some unconjugated bilirubin—either albumin bound or free—is cleared by placental transfer to be conjugated in the maternal liver (Chap. 7, Urinary System). Fetal protection from unconjugated bilirubin is lost after delivery if not cleared rapidly. Because clearance is totally dependent on neonatal hepatic function, varying degrees of neonatal hyperbilirubinemia result. Even in the mature newborn, serum bilirubin levels usually rise for 3 to 4 days to reach up to 10 mg/dL. After this, concentrations usually fall rapidly. In one large study, 1 to 2 percent of neonates delivered at 35 weeks' gestation or later had a maximum serum bilirubin level >20 mg/dL (Eggert, 2006). Concomitant glucose-6-phosphate deficiency worsens hyperbilirubinemia (Chang, 2017). In approximately 15 percent of term newborns, bilirubin levels cause clinically visible skin yellowing termed *physiological jaundice* (Burke, 2009). As expected, in preterm neonates, the bilirubin elevation is greater and more prolonged.

Acute Bilirubin Encephalopathy and Kernicterus

Excessive serum bilirubin levels can be neurotoxic for newborns (Dijk, 2012; Watchko, 2013). The pathogenesis is complex, and toxicity has two forms. *Acute bilirubin encephalopathy* is encountered in the first days of life and is characterized by hypotonia, poor feeding, lethargy, and abnormal auditory-evoked responses (Kaplan, 2011). Immediate recognition and treatment will usually mitigate progressive neurotoxicity. The chronic form is termed *kernicterus*. With this, neurotoxicity follows bilirubin deposition and staining of the basal ganglia and hippocampus and is further characterized by profound neuronal degeneration. Survivors have spasticity, muscular incoordination, and varying degrees of mental deficiencies (Frank, 2017). Although there is a positive correlation between kernicterus and unconjugated bilirubin levels above 18 to 20 mg/dL, it can develop at much lower concentrations, especially in very preterm neonates (Sgro, 2011). Continuing hemolysis is a risk factor for kernicterus (El Houchi, 2017; Vandborg, 2012).

Prevention and Treatment

Various forms of phototherapy are used to prevent and treat neonatal hyperbilirubinemia (Ree, 2017). These "bili-lights" emit a spectrum of 460 to 490 nm, which augments bilirubin oxidation to enhance its renal clearance and lower serum levels. Sunlight filtered to remove ultraviolet light has been used in resource-poor countries (Slusher, 2015). Light that penetrates the skin also increases peripheral blood flow, which further enhances photo-oxidation. It is problematic that available devices are not standardized (Bhutani, 2011). Another advantage is that exchange transfusions are seldom required with phototherapy. Studies in both preterm and term newborns attest to phototherapy efficacy (Watchko, 2013). A Neonatal Research Network study reported that aggressive phototherapy in low-birthweight neonates reduced rates of neurodevelopmental impairment (Newman, 2006). Similar reductions were reported from Canada after implementation of 2007 guidelines (Sgro, 2016).

For term newborns, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) stress early detection and prompt phototherapy to prevent bilirubin encephalopathy. Despite these measures, bilirubin encephalopathy persists, and this is somewhat related to early hospital discharges (Gazzin, 2011; Kaplan, 2011; Sgro, 2011). According to Burke and coworkers (2009), hospitalizations for kernicterus in term newborns were 5.1 per 100,000

in 1988. Since then, however, this rate has dropped to 0.4 to 2.7 cases per 100,000 births (Watchko, 2013). This may be due in part to legislation, discussed in Chapter 36 (Immunizations), to minimize brief postpartum hospital stays.

Hemorrhagic Disease of the Newborn

This disorder is characterized by spontaneous internal or external bleeding beginning any time after birth. Most hemorrhagic disease results from abnormally low levels of the vitamin K-dependent clotting factors—V, VII, IX, X, prothrombin, and proteins C and S (Zipursky, 1999). Newborns whose mothers took anticonvulsant drugs are at higher risk because these suppress maternal hepatic synthesis of some of these factors. Classic hemorrhagic disease is usually apparent 2 to 5 days after birth in neonates not given vitamin K prophylaxis at delivery (Busfield, 2013). Delayed hemorrhage may occur at 2 to 12 weeks in exclusively breastfed infants because breast milk contains little vitamin K. Other causes of neonatal hemorrhage not related to vitamin K include hemophilia, congenital syphilis, sepsis, thrombocytopenia purpura, erythroblastosis, and intracranial hemorrhage.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend routine prophylaxis for hemorrhagic disease with a 0.5- to 1-mg dose of vitamin K_1 (phytonadione) given intramuscularly. Oral administration is not effective, and maternal vitamin K administration results in very little transport to the fetus (Sankar, 2016).

Thrombocytopenia

Abnormally low platelet concentrations in term newborns may be due to various etiologies such as immune disorders, infections, drugs, or inherited platelet defects, or they may be part of a congenital syndrome (American College of Obstetricians and Gynecologists, 2016b). In many, thrombocytopenia is an extension of a fetal disorder such as infection with B19 parvovirus, cytomegalovirus, toxoplasmosis, and others discussed in Chapters 64 and 65. Neonatal thrombocytopenia has been reported with maternal antiretroviral therapy for human immunodeficiency virus (HIV) infection (Smith, 2016). Term newborns admitted to NICUs, especially those with sepsis, have accelerated platelet consumption (Eissa, 2013).

Immune Thrombocytopenia

In women with an autoimmune disorder such as systemic lupus erythematosus or immunological thrombocytopenia, maternal antiplatelet IgG is transferred to the fetus and can cause accelerated platelet destruction. Most cases are mild, and platelet levels usually reach a nadir at 48 to 72 hours. Maternal corticosteroid therapy generally has no effect on fetal platelets. Fetal blood sampling for platelet determination is seldom necessary, and platelets are usually adequate to prevent fetal hemorrhage during delivery (Chap. 56, Platelet Disorders).

Alloimmune Thrombocytopenia

Alloimmune thrombocytopenia (AIT) or neonatal alloimmune thrombocytopenia (NAIT) is caused by maternal-fetal platelet antigen disparity. If maternal alloimmunization is stimulated, then transplacental antiplatelet IgG antibodies cause severe fetal thrombocytopenia and severe bleeding (Winkelhorst, 2017). This is considered in detail in Chapter 15 (Fetal Thrombocytopenia).

Preeclampsia Syndrome

Maternal platelet function and destruction can be severely affected in women with severe preeclampsia. That said, fetal or neonatal thrombocytopenia is rarely caused by the preeclampsia syndrome even when the mother has severe thrombocytopenia. Findings from the large study of mother-infant pairs delivered at Parkland Hospital dispelled earlier reports of an association of neonatal thrombocytopenia with preeclampsia (Pritchard, 1987). Instead, neonatal thrombocytopenia was found to be associated with preterm delivery and its numerous complications (Chap. 34, Respiratory Distress Syndrome).

INJURIES OF THE NEWBORN

Birth injuries can potentially complicate any delivery. Thus, although some are more likely associated with operative delivery by forceps or vacuum, others are seen with otherwise uncomplicated vaginal or cesarean delivery. In this section, some injuries are discussed in general, but specific injuries are described elsewhere in connection with their associated obstetrical complications.

Incidence

In three population studies that included more than 8 million term newborns, the overall incidence of birth trauma was 20 to 26 per 1000 deliveries (Baskett, 2007; Linder, 2012; Moczygemba, 2010). Data from Nova Scotia show an overall trauma risk of 19.5 per 1000 deliveries (Table 33-4). Only 1.6 cases of major trauma per 1000 were found, and these rates were highest with failed forceps or vacuum delivery and lowest with cesarean delivery without labor. Thus, most traumatic injuries were minor, and these had an incidence of 18 per 1000 deliveries.

TABLE 33-4

Incidence of Major and Minor Birth Trauma—Nova Scotia, 1988–2001

Type of Delivery (Trauma Rate per 1000)		Birth Trauma (Rate per 1000)	
	Number	Major[a]	Minor[b]
Spontaneous (14)	88,324	1.2	13
Assisted			
Vacuum (71)	3175	3.7	67
Forceps (58)	10,478	5.2	53
Failed assisted			
Vacuum (105)	609	8.3	100
Forceps (56)	714	7.0	50
Cesarean (8.6)	16,132	0.3	8.3
Labor (12)	10,731	0.4	11.9
No labor (1.2)	5401	0.2	1.1
All (19.5)	119,432	1.6	18

[a]Major trauma = depressed skull fracture, intracranial hemorrhage, brachial plexopathy, or combination.

[b]Minor trauma = linear skull fracture, other fractures, facial palsy, cephalohematoma, or combination.

Data from Baskett, 2007.

Trauma associated with cesarean delivery from a Maternal-Fetal Medicine Units Network study was described by Alexander and coworkers (2006). There were 400 injuries identified from a total of 37,100 operations—a rate of 11 per 1000 cesarean deliveries. Although skin lacerations predominated—7 per 1000—more serious injuries in these 400 infants included 88 cephalohematomas, 11 clavicular fractures, 11 facial nerve palsies, nine brachial plexopathies, and six skull fractures.

Cranial Injuries

Traumatic head injuries that are associated with labor or delivery can be *external* and obvious, such as a skull or mandibular fracture; they can be *intracranial*; and in some, they are *covert*. The fetal head has considerable plasticity and can undergo appreciable molding. Rarely, severe molding can result in tearing of veins. These may be the bridging cortical veins that empty into the sagittal sinus, the internal cerebral veins, the vein of Galen, or those of the tentorium itself. As a result, intracranial, subdural, and even epidural hemorrhage can be seen after an apparently uneventful vaginal delivery (Scheibl, 2012). Bleeding may also be asymptomatic. Conversely, subgaleal hemorrhages associated with forceps of vacuum delivery can be life threatening (Doumouchtsis, 2008; Swanson, 2012). In rare severe head trauma cases, fetal brain tissue can embolize to the heart or lungs (Cox, 2009).

Intracranial Hemorrhage

Most aspects of neonatal intracranial hemorrhage are related to gestational age. Specifically, most hemorrhage in the preterm neonate results from hypoxia and ischemia. However, in term newborns, trauma is the most frequent cause. Some varieties are shown in Table 33-5. *Importantly, in some newborns, a putative cause is not found.* Intracranial hemorrhage is asymptomatic in many cases. The reported incidence varies, but it is highest with operative deliveries—both vaginal and cesarean deliveries. In the study by Moczygemba and colleagues (2010), for more than 8 million singleton deliveries, the overall intracranial hemorrhage rate approximated 0.2 per 1000 births. In another study, Werner and associates (2011) cited a combined incidence in more than 120,000 nulliparous singleton operative deliveries of 0.12 percent, or about 1 in 750 procedures. The rates of intracranial hemorrhage were 1:385 with vacuum delivery; 1:515 with forceps, and 1:1210 with cesarean delivery. In another study, its incidence was nearly 1 percent following vacuum-assisted deliveries (Simonson, 2007).

TABLE 33-5

Major Types of Neonatal Intracranial Hemorrhage

Type	Etiology and Neuropathogenesis	Clinical Outcomes
Subdural	Trauma—tentorial, falx, or venous (sinus) laceration causing hematoma	Uncommon but potentially serious; symptom onset is variable depending on hematoma expansion, but usually <24 hours: irritability, lethargy, and brainstem compression
Primary subarachnoid	Possibly due to trauma or hypoxia—excludes SAH associated with subdural, intraventricular, intracerebral (AVM, aneurysm), or intracerebellar hemorrhage	Common but almost always benign
Intracerebellar	Trauma and perhaps hypoxia—most cases in preterm infants	Uncommon but serious
Intraventricular	Trauma and hypoxia (no discernible cause in 25 percent)—hemorrhage usually from choroid plexus	Uncommon but serious; symptoms as for subdural hemorrhage
Miscellaneous	Trauma with epidural or intracerebral hemorrhage Hemorrhagic infarction—embolism or thrombosis in artery or vein Coagulopathies—thrombocytopenia or inherited factor deficiencies Vascular defect—aneurysm or AVM	Depends on cause

AVM = arteriovenous malformation; SAH = subarachnoid hemorrhage.

Data from Volpe, 1995.

According to the American College of Obstetricians and Gynecologists (2015), the incidence of intracranial hemorrhage from birth trauma has been substantively lowered by elimination of difficult instrumented vaginal deliveries. This was verified in a report of carefully conducted Kielland forceps deliveries (Burke, 2012).

The prognosis after hemorrhage depends on its location and extent (see Table 33-5). For example, subdural and subarachnoid hemorrhage seldom results in neurological abnormalities, whereas large hematomas are serious. Any bleeding into the parenchyma from intraventricular or intracerebellar hemorrhage often causes serious permanent damage or death. Periventricular hemorrhage rarely causes the type of sequelae that are common in those born preterm (Chap. 34, Retinopathy of Prematurity).

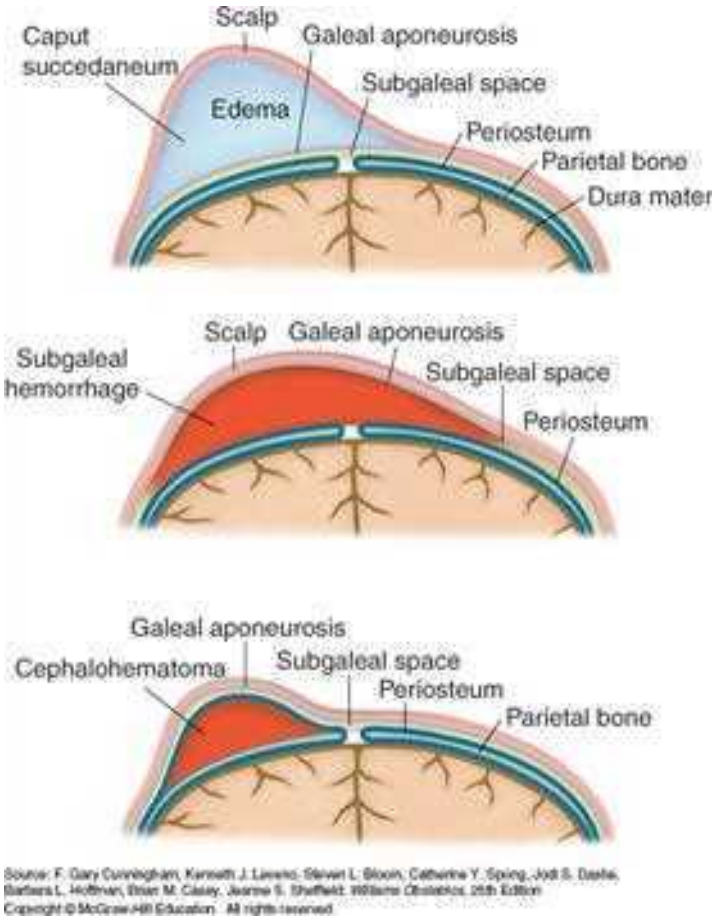
Newborns who have traumatic subdural or infratentorial hemorrhage tears will have neurological abnormalities from the time of birth (Volpe, 1995). Those most severely affected have stupor or coma, nuchal rigidity, and opisthotonos that worsen over minutes to hours. Some newborns who are born depressed appear to improve until about 12 hours of age, when drowsiness, apathy, feeble cry, pallor, failure to nurse, dyspnea, cyanosis, vomiting, and convulsions become evident.

Spontaneous intracranial hemorrhage has also been documented in healthy term neonates (Rutherford, 2012; Shah, 2016). In a prospective MR imaging study, Whitby and coworkers (2004) found that 6 percent of those delivered spontaneously and 28 percent of those delivered by forceps had a subdural hemorrhage. None of these had clinical findings, and hematomas resolved by 4 weeks in all infants.

Extracranial Hematomas

These blood collections accumulate outside the calvarium and are categorized as a *cephalohematoma* or *subgaleal hemorrhage* (Fig. 33-2). From its most superficial surface inward, the scalp is composed of skin, subcutaneous tissue, galea aponeurotica, subgaleal space, and calvarium periosteum. The galea aponeurotica is dense fibrous tissue, whereas the subgaleal space contains loose, fibroareolar tissue. Traversing across the subgaleal space are large, valveless *emissary veins*, which connect the dural sinuses inside the skull with superficial scalp veins. Both the galea aponeurotica and subgaleal space span across the occipital, parietal, and frontal bones. In contrast, periosteum invests each individual skull bone and does not cross suture lines.

FIGURE 33-2
Schematic of extracranial lesions in the neonate that include caput succedaneum, subgaleal hemorrhage, and cephalohematoma.



Cephalohematomas are cranial subperiosteal hematomas. These develop from shearing forces during labor and delivery that lacerate the emissary or diploic veins. Fortunately, the densely adhered periosteum impedes rapid enlargement and limits final hematoma size. Hemorrhage can be over one or both parietal bones, but palpable edges can be appreciated as the blood reaches the limits of the periosteum. These hematomas must be differentiated from *caput succedaneum*, also shown in Figure 33-2. A cephalohematoma may not be apparent until hours after delivery, when bleeding sufficient to raise the periosteum has occurred. After it is identified, it often grows larger and persists for weeks or even months, and bleeding may be sufficient to cause anemia as discussed in Neonatal Abstinence Syndrome. By contrast, with caput succedaneum, swelling of the scalp is from soft-tissue edema that overlies the periosteum. The caput is maximal at birth, rapidly grows smaller, and usually disappears within hours or a few days. Occasionally it becomes infected, and an abscess may form (Kersten, 2008).

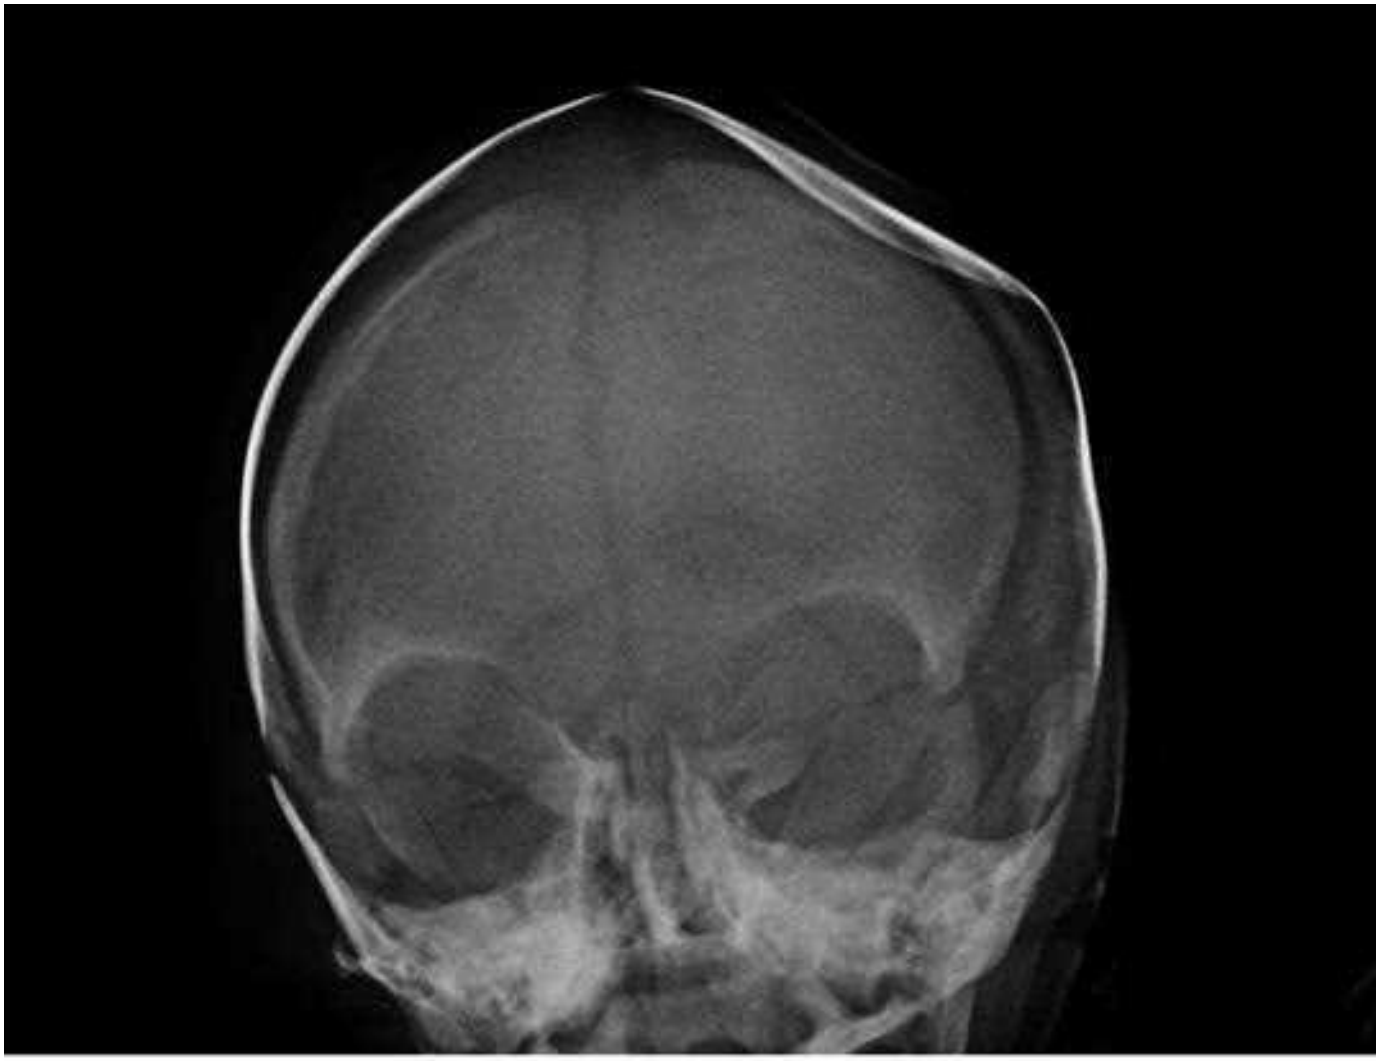
Cephalohematomas are common, and in the study from Nova Scotia shown in Table 33-3, these accounted for 80 percent of traumatic injuries with an incidence of 16 per 1000 (Baskett, 2007). They rarely develop in the absence of birth trauma, and an 11-percent incidence was reported in 913 term newborns delivered by vacuum extraction (Simonson, 2007). In the Network study of cesarean delivery outcomes cited above, the incidence of cephalohematoma was 2.4 per 1000 operations (Alexander, 2006). Others have reported lower incidences, although cephalohematoma is more common with vacuum compared with forceps deliveries—0.8 versus 2.7 per 1000 operative deliveries (Werner, 2011).

Subgaleal hemorrhage results from laceration of one of the emissary veins, with bleeding between the galea aponeurotica and the skull periosteum (Shah, 2016). Although most common with operative deliveries, cases with spontaneous vaginal delivery have been described (Liu, 2017). Because of its loose areolar tissue and large surface area, significant blood volumes can collect in this potential space and can extend from the neck to the orbits and laterally to the temporal fascia above the ears (Modanlou, 2016). Resulting hypotension can lead to significant morbidity, and cited mortality rates range from 12 to 18 percent (Chang, 2007; Kilani, 2006).

Skull Fractures

These are rare but are especially worrisome because of their association with the serious intracranial hemorrhages. Volpe (1995) considers three types of skull injuries to be fractures—linear and depressed fractures and occipital osteodiastasis. In a French study of nearly 2 million deliveries from 1990 to 2000, the incidence of skull fractures was reported to be 3.7 per 100,000 births, and 75 percent were associated with instrumented vaginal deliveries (Dupuis, 2005). These are occasionally seen with spontaneous or cesarean delivery (Fig. 33-3). These latter fractures are more common when the head is tightly wedged in the pelvis. In such cases, there are at least three possible causes. A fracture may result from skull compression against the sacral promontory, by hand pressure used to lift the head at cesarean delivery, or from transvaginally applied upward hand pressure by an assistant. Fractures are managed with surgical decompression, although spontaneous resolution can follow (Basaldella, 2011).

FIGURE 33-3
Depressed skull fracture evident immediately after cesarean delivery. Labor had progressed, and the head was deep in the pelvis. Dislodgment of the head from the birth canal was performed by an assistant using manual pressure upward through the vagina. (Used with permission from Dr. Kimberly M. Spoonts.)



Spinal Cord Injury

Overstretching of the spinal cord and associated hemorrhage and edema are rare. They are usually caused by excessive longitudinal or lateral traction of the spine or by torsion during delivery. In some cases, vertebrae are fractured or dislocated. Menticoglou and associates (1995) described 15 neonates with this type of high cervical spinal cord injury and found that all of the injuries were associated with forceps rotations. Spinal cord injury also can occur during breech delivery. Ross and coworkers (2006) described C_{5-6} vertebral dislocation associated with a Zavanelli maneuver done because of shoulder dystocia (Chap. 27, Shoulder Dystocia Drill).

Peripheral Nerve Injuries

Traumatic injuries to nerves can be serious and distressing, especially if permanent. Injury can involve a single nerve, or it can affect a nerve root, plexus, or trunk (Volpe, 1995).

Brachial Plexopathy

Injuries to the brachial plexus are relatively common. They are identified in 1 to 3 per 1000 term births (Baskett, 2007; Lindqvist, 2012; Wall, 2014). In the study reported by Moczygemba and colleagues (2010), the incidence of brachial nerve injury was 1.5 per 1000 vaginal deliveries and 0.17 per 1000 cesarean deliveries. The incidence among 366,408 neonates born at Parkland Hospital was 3.5 per 1000 births (Wall, 2014). Breech delivery and shoulder dystocia are risks for this trauma. However, severe plexopathy may also occur without risk factors (Torki, 2012).

With plexopathy, the injury damages the nerve roots that supply the brachial plexus—C_{5-8} and T_1. With hemorrhage and edema, axonal function may be temporarily impaired, but the recovery chances are good. However, with avulsion, the prognosis is poor. In 90 percent of cases, damage to the C_{5-6} nerve roots causes *Erb* or *Duchenne paralysis* (Volpe, 1995). Injuries with breech delivery are normally of this type, whereas the more extensive lesions follow difficult cephalic deliveries (Ubachs, 1995). The C_{5-6} roots join to form the upper trunk of the plexus, and injury leads to paralysis of the deltoid, infraspinatus, and flexor muscles of the forearm. The affected arm is held straight and internally rotated, the elbow is extended, and the wrist and fingers flexed. Finger function usually is retained. Because lateral

traction on the fetal head is frequently employed to effect delivery of the shoulders in normal vertex presentations, most cases of Erb paralysis follow deliveries that do not appear difficult.

Damage to the C_8-T_1 roots supplying the lower plexus results in *Klumpke paralysis,* in which the hand is flaccid. Total involvement of all brachial plexus nerve roots results in flaccidity of the arm and hand, and with severe damage, there may also be *Horner syndrome*.

Because of its importance, the American College of Obstetricians and Gynecologists (2014a) convened a task force to review extant studies. This Task Force concluded that shoulder dystocia cannot be accurately predicted, but in most cases, axonal death does not occur and the prognosis is good. Lindqvist and associates (2012) reported complete recovery in 86 percent of children with $C_{5–6}$ trauma, which was the most common injury, and in 38 percent of those with $C_{5–7}$ damage. However, those with global $C_{5–8}$–T_1 injuries always had permanent disability. Associated clavicular fracture is somewhat protective (Wall, 2014). Surgical exploration and possible repair may improve function if there is persistent paralysis (Malessy, 2009).

Facial Paralysis

Trauma to the facial nerve commonly occurs as it emerges from the stylomastoid foramen, and this can cause facial paralysis (Fig. 33-4). The incidence, which ranges from 0.2 to 7.5 per 1000 term births, is likely influenced by the vigor with which the diagnosis is sought (Al Tawil, 2010; Moczygemba, 2010). Facial paralysis may be apparent at delivery or may develop shortly after birth. It most frequently is associated with uncomplicated vaginal delivery. However, in one series, a fourth of cases followed cesarean delivery (Alexander, 2006; Al Tawil, 2010). Facial nerve damage is likely more common with low forceps (Levine, 1984). It is possible that damage is caused by pressure exerted by the posterior blade when forceps have been placed obliquely on the fetal head. In these cases, forceps marks indicate the cause of injury. Spontaneous recovery within a few days is the rule, however, permanent paralysis has been described (Al Tawil, 2010).

FIGURE 33-4
Left facial nerve injury. This was almost completely resolved two days after delivery.

Fractures

Most long-bone fractures follow difficult deliveries, however, this is not always the case. At minimum, palpation of the clavicles and long bones is indicated for all newborns after a difficult delivery. Crepitation or unusual irregularity should prompt radiographic examination.

Clavicular fractures are common, unpredictable, and unavoidable complications of normal birth. Their incidence averages 5 to 10 per 1000 live births (Linder, 2012; Moczygemba, 2010). Other than female gender, no specific risk factors—including birthweight and mode of delivery—have been identified. Clavicular fractures protect against brachial plexopathy when there is shoulder dystocia (Wall, 2014).

Humeral fractures are infrequent, and 70 percent follow an uneventful birth (Turpenny, 1993). Others are associated with difficult delivery of the shoulders in cephalic deliveries and of an extended arm in breech deliveries. Radiographically, they are often of the greenstick type, although complete fractures and distal

humeral epiphyseal fractures can occur (Tharakan, 2016).

Femoral fractures are rare and usually are associated with vaginal breech delivery. They occasionally follow cesarean delivery, and in one report, they were bilateral (Cebesoy, 2009). Because most breech-presenting fetuses now undergo cesarean delivery, most of these fractures are associated with this mode (Alexander, 2006; Cebesoy, 2009).

Mandibular fractures have been reported, are rare, and have been reviewed by Vasconcelos and coworkers (2009). The rare cases of *cervical vertebral dislocation* in fetuses delivered as breech or after the Zavanelli maneuver were discussed earlier (Ross, 2006). Finally, *rib fractures* are occasionally encountered (Khan, 2016).

Muscle Injuries

Sternocleidomastoid muscle injury in the past was usually seen with vaginal breech delivery. Hematomas of the muscle or the fascial sheath may resolve slowly with cicatricial contraction. With normal neck growth, the less-elastic damaged muscle does not elongate appropriately. As a result, the head is gradually turned toward the side of the injury—*torticollis.*

Soft Tissue Injuries

Conceivably, any fetal organ or part could be injured with either vaginal or cesarean delivery. Some of these include subcapsular hepatic hematomas that presented as inguinal and scrotal hematoma. In such cases, ecchymoses of the inguinal region are termed *Stabler sign,* and those of the scrotum are termed *Bryant sign* (Heyman, 2011; Saroha, 2015). Thymic gland traumatic hemorrhage in those with underlying hyperplasia or cyst has been described before, during, and after delivery (Eifinger, 2007; Saksenberg, 2001). Injuries to the sixth cranial nerve with resultant lateral rectus ocular muscle paralysis have also been reported (Galbraith, 1994).

Congenital Deformity Injuries

Several injuries create morphological defects sustained long before delivery. One is the amnionic band syndrome caused when a free strip of amnion forms a focal ring around an extremity or digit. Eventually, deformation or amputation may result. Occasionally, the amputated part may be found within the uterus. The genesis of such bands is debated and discussed in Chapter 6 (Amniochorion). A similar anomaly is a *limb-reduction defect* associated with chorionic villus sampling performed before 9 weeks' gestation (Chap. 14, Fetal Blood Sampling).

Various congenital postural anomalies form when a normally developed fetal structure becomes deformed by intrauterine mechanical factors. Examples of the latter include chronic oligohydramnios, as well as restricted fetal movement imposed by an abnormally shaped or small uterine cavity or by the presence of additional fetuses. Some mechanical deformations include talipes equinovarus (clubfoot), scoliosis, and hip dislocation (Miller, 1981). Talipes and other positional foot abnormalities are associated with membrane rupture from early amniocentesis between 11 and 13 weeks' gestation (Chap. 14, Chorionic Villus Sampling).

CHAPTER 34: The Preterm Newborn

> *The prognosis for the child depends, of course, upon the degree of development, as well as the pathological condition for which premature delivery is undertaken. Generally speaking, in the case of children born before the thirty-second week, the chances of surviving are very small.*
>
> —J. Whitridge Williams (1903)

INTRODUCTION

At the time of this textbook's first edition, preterm delivery of a living newborn was frequently followed by neonatal death. Contrast this with today's technological advances that have advanced the threshold of viability to 22 to 24 weeks' gestation. Even so, the preterm newborn is susceptible to various serious medical complications both early and later in life (Table 34-1). A less commonly cited cause of morbidity and mortality is congenital malformations, which are much more prevalent in preterm births.

TABLE 34-1

Complications of Prematurity

Respiratory distress syndrome (RDS)
Hyaline membrane disease (HMD)
Bronchopulmonary dysplasia (BPD)
Pneumothorax
Pneumonia/sepsis
Patent ductus arteriosus (PDA)
Necrotizing enterocolitis (NEC)
Retinopathy of prematurity (ROP)
Intraventricular hemorrhage (IVH)
Periventricular leukomalacia (PVL)
Cerebral palsy (CP)

These complications of prematurity can be placed in perspective in terms of overall neonatal outcomes. In 2009, two thirds of all infant deaths in the United States were in the 12 percent born before 37 weeks (Mathews, 2013). Fortunately, during the past decade, rates of preterm birth have declined from approximately 12 percent in 2007 to 10 percent in 2014. This is in part due to a decline in births to teen mothers (Ferré, 2016).

RESPIRATORY DISTRESS SYNDROME

The seminal complication of the preterm newborn is *respiratory distress syndrome (RDS)*. This results from immature lungs that are unable to sustain necessary oxygenation. Resulting hypoxia is an underlying associated cause of neurological damage such as cerebral palsy. In addition, hyperoxia, a side effect of RDS treatment, contributes to morbidities such as bronchopulmonary dysplasia, pulmonary hypertension, necrotizing enterocolitis, periventricular leukomalacia, and retinopathy of prematurity.

Etiopathogenesis

To provide blood gas exchange immediately following delivery, the lungs must rapidly fill with air while being cleared of fluid. Concurrently, pulmonary arterial blood flow must rise remarkably. Although some of the fluid is expressed as the chest is compressed during vaginal delivery, most is absorbed through the pulmonary lymphatics via complex mechanisms described in Chapter 32 (Transition to Air Breathing). Sufficient surfactant, synthesized by type II pneumocytes, is essential to stabilize the air-expanded alveoli. It lowers surface tension and thereby prevents lung collapse during expiration (Chap. 7, Respiratory System). If surfactant is inadequate, hyaline membranes form in the distal bronchioles and alveoli, and RDS develops. Although respiratory distress syndrome is generally a disease of preterm neonates, it does develop in term newborns, especially with sepsis or meconium aspiration. In these cases, surfactant can be inactivated by inflammation and/or presence of meconium (Chap. 33, Respiratory Distress).

With inadequate surfactant, alveoli are unstable, and low pressures cause collapse at end expiration. Pneumocyte nutrition is compromised by hypoxia and systemic hypotension. Partial persistence of the fetal circulation may lead to pulmonary hypertension and a relative right-to-left shunt. Eventually, alveolar cells undergo ischemic necrosis. When oxygen therapy is initiated, the pulmonary vascular bed dilates, and the shunt reverses. Protein-filled fluid leaks into the alveolar ducts, and the cells lining the ducts slough. Hyaline membranes composed of fibrin-rich protein and cellular debris line the dilated alveoli and terminal bronchioles. The epithelium underlying the membrane becomes necrotic. At autopsy, with hematoxylin-eosin staining of lung tissue, these membranes appear amorphous and eosinophilic, like hyaline cartilage. Because of this, respiratory distress syndrome is also termed *hyaline membrane disease.*

Clinical Course

In typical RDS, tachypnea develops, the chest wall retracts, and expiration is accompanied by nostril flaring and by grunting—in an attempt to provide a positive end-expiratory pressure to prevent lung collapse. Shunting of blood through nonventilated lung contributes to hypoxemia and to metabolic and respiratory acidosis. Poor peripheral circulation and systemic hypotension may be evident. The chest radiograph shows a diffuse reticulogranular infiltrate and an air-filled tracheobronchial tree—*air bronchogram*.

As discussed further in Chapter 33 Respiratory Distress, respiratory insufficiency can also be caused by sepsis, pneumonia, meconium aspiration, pneumothorax, persistent fetal circulation, heart failure, and malformations involving thoracic structures, such as diaphragmatic hernia. Common mutations in surfactant protein production and the phospholipid transporter (ABCA3) contribute to RDS (Beers, 2017; Tredano, 2003; Wert, 2009).

Treatment

An important factor influencing survival is neonatal intensive care. Although hypoxemia prompts supplemental oxygen, excess oxygen can damage the pulmonary epithelium, retina, and other immature tissues. Despite this, advances in mechanical ventilation technology have improved neonatal survival rates. For example, *continuous positive airway pressure (CPAP)* prevents the collapse of unstable alveoli. This allows high inspired-oxygen concentrations to be reduced, thereby minimizing its toxicity. In an attempt to

minimize the need for tracheal intubation and intermittent positive-pressure ventilation, CPAP has been studied in well-designed multicenter trials (Morley, 2008; SUPPORT Study Group, 2010b). An initial CPAP strategy with subsequent selective surfactant use is a beneficial alternative to immediate intubation and surfactant for many neonates of extremely early gestational age (American Academy of Pediatrics, 2014).

Mechanical ventilation has undoubtedly improved survival rates but is an important factor in the genesis of chronic lung disease of prematurity—*bronchopulmonary dysplasia (BPD)*. Namely, mechanical ventilation places a newborn at risk for barotrauma and volutrauma. Moreover, hyperoxia can create reactive oxygen species that trigger inflammation. Infection can also be contributory. In affected newborns, alveolar and pulmonary vascular development is disrupted and leads to hypoxia, hypercarbia, and chronic oxygen dependence (Davidson, 2017; Kair, 2012).

As prevention, *high-frequency oscillatory ventilation* has been evaluated. However, benefits and risks varied considerably between studies (Cools, 2015).

Treatment of the ventilator-dependent neonate with *glucocorticoids* was also used previously to prevent BPD. The American Academy of Pediatrics now recommends against routine steroid use because of limited benefits and greater rates of impaired motor and cognitive function and school performance in exposed neonates (Doyle, 2014a,b; Watterberg, 2010).

In other efforts for BPD prevention, early animal studies demonstrated significant improvements in lung function with weeks of *inhaled nitric oxide* (McCurnin, 2005). Despite initial enthusiasm, clinical trials failed to demonstrate a consistent benefit. A National Institutes of Health (NIH) consensus statement and the American Academy of Pediatrics (2014) concluded that the available data do not support its use to prevent or treat BPD (Cole, 2011).

Caffeine has been used widely to treat apnea of prematurity, but it also has bronchodilatory effects. One large randomized trial of caffeine versus placebo showed lower BPD rates, improved neurodevelopmental outcomes during early childhood, and good evidence of safety up to 11 years (Schmidt, 2006, 2012, 2017). This therapy is now widely used for newborns weighing ≤1250 g.

The antioxidant *vitamin A* is necessary for normal lung growth and the integrity of respiratory tract epithelial cells. Preterm newborns have low vitamin A levels at birth, and this has been associated with a greater risk of developing BPD. Randomized trials support the use of vitamin A to achieve a modest reduction in BPD rates for very-low-birthweight neonates weighing <1500 g (Darlow, 2016).

Surfactant Prophylaxis and Rescue

Exogenous surfactant products are delivered via endotracheal tube to help prevent RDS. They contain biological or animal surfactants such as bovine—*Survanta*, calf—*Infasurf*, or porcine—*Curosurf*. Synthetic surfactants such as first-generation *Exosurf* and second-generation *Surfaxin R* are equivalent but not superior to animal-derived surfactant (Moya, 2007). In a Cochrane review, Ardell and coworkers (2015) found that

animal-derived surfactants led to better outcomes than synthetic surfactants, which do not contain important surfactant proteins. There are currently no synthetic surfactants available.

Surfactant replacement was established decades ago as an effective and safe therapy for RDS. Treatment reduces rates of mortality and pneumothorax and improves survival without BPD (Polin, 2014). It has been used for *prophylaxis* of preterm, at-risk newborns and for *rescue* of those with established disease. Given together, antenatal corticosteroids and surfactant result in an even greater reduction in the overall death rate. However, randomized trials indicate that in populations with high use of antenatal steroids and routine use of CPAP in the delivery room, prophylactant surfactant is no longer beneficial and is associated with more risk of death or BPD (Rojas-Reyes, 2012; Sardesai, 2017). Exploration of different, less invasive ways to deliver rescue surfactant to spontaneously breathing preterm neonates is currently underway. Potential routes include surfactant application into the pharynx, surfactant nebulization, or application via laryngeal mask or via a thin catheter placed in the trachea (Kribs, 2016).

Prevention

Antenatal Corticosteroids

The NIH (1994, 2000) has concluded that a single course of antenatal corticosteroid therapy reduces RDS and intraventricular hemorrhage rates in preterm neonates born between 24 and 34 weeks' gestation (Cerebral Palsy). The American College of Obstetricians and Gynecologists (2016a) considers all women at risk for preterm birth in this gestational-age range to be potential candidates for therapy. It also may be considered for pregnant women starting at 23 weeks' gestation who are at risk of preterm delivery within 7 days. This is discussed further is Chapter 42 (Corticosteroids for Fetal Lung Maturation). More recently, administration of antenatal corticosteroids to women at risk for late-preterm delivery (34 to 36 weeks' gestation) was found to significantly reduce the rate of neonatal respiratory complications (Gyamfi-Bannerman, 2016).

Amniocentesis to Assess Fetal Lung Maturity

In some instances, when gestational age is uncertain, knowledge of fetal lung maturity may influence plans for delivery. One example is the woman with a prior classical cesarean delivery in whom repeat operation is planned and gestational age cannot be confirmed. Several tests are used to ensure fetal pulmonary maturity by analysis of amnionic fluid obtained by sonographically guided amniocentesis. At Parkland Hospital, we still find an occasional indication for such testing, however, the American College of Obstetricians and Gynecologists (2017a,b) counsels against its use in most of these cases. Instead the College recommends late-term delivery at "41 weeks' gestation" using the best clinical estimate of gestational age (Chap. 10 Gestational Age Assessment).

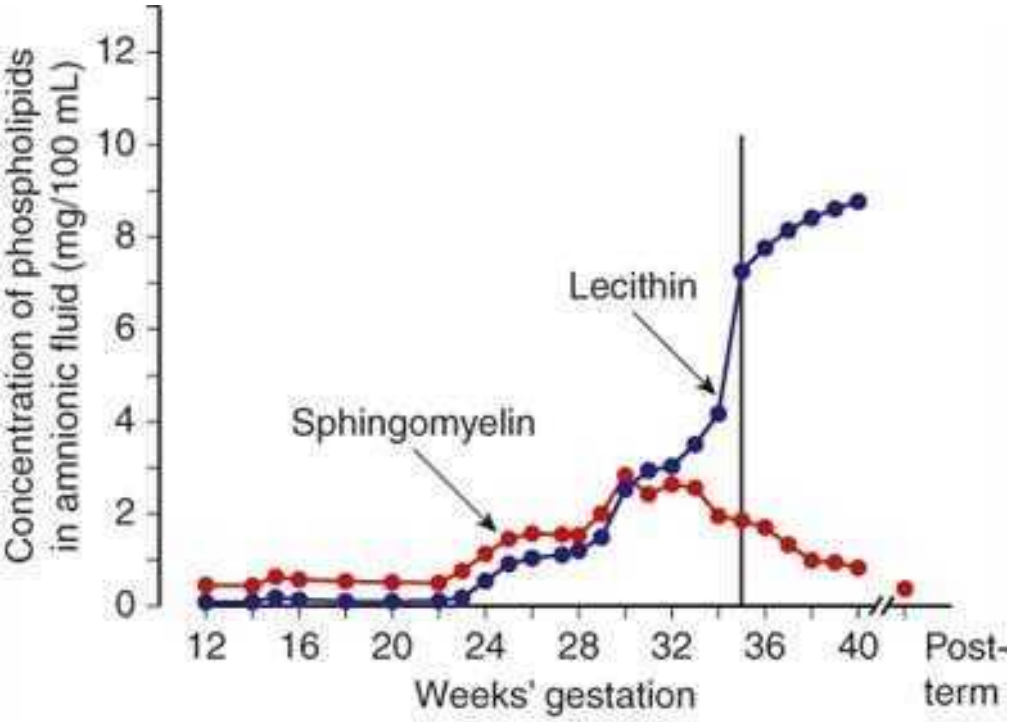
If amniocentesis is elected, fluid acquisition is similar to that described for second-trimester amniocentesis (Chap. 14, Technique). Complications requiring urgent delivery are rare (Zalud, 2008). Following analysis, the probability of RDS developing in a given newborn depends on the test used and fetal gestational age.

Importantly, administration of corticosteroids to induce pulmonary maturation has variable effects on some of these tests. Varner and colleagues (2013) have provided a review of testing options.

Of biochemical tests, the labor-intensive *lecithin-sphingomyelin (L/S) ratio* for many years was the gold-standard test. Dipalmitoylphosphatidylcholine (DPPC), that is, *lecithin*, and *sphingomyelin* are surfactant components. Before 34 weeks, both are present in amnionic fluid in similar concentrations. At 32 to 34 weeks, the concentration of lecithin relative to sphingomyelin begins to rise (Fig. 34-1). The risk of neonatal RDS is slight whenever the concentration of lecithin is at least twice that of sphingomyelin—L/S ratio >2 (Gluck, 1971). Previously, RDS was thought to develop despite an L/S ratio >2 in newborns of women with diabetes. Some recommend that *phosphatidylglycerol*, another surfactant phospholipid, be documented in amnionic fluid of these women. Based on current evidence, it is unclear if either diabetes, per se, or its level of control causes false-positive phospholipid test results for fetal lung maturity (De Luca, 2009).

FIGURE 34-1

Changes in mean concentrations of lecithin and sphingomyelin in amnionic fluid during gestation in normal pregnancy. (Modified with permission from Gluck L, Kulovich MV: Lecithin-sphingomyelin ratios in amniotic fluid in normal and abnormal pregnancy, Am J Obstet Gynecol. 1973 Feb 15;115(4):539–546.)



Of biophysical tests, the *fluorescence polarization test* is an automated assay that measures the surfactant-to-albumin ratio in uncentrifuged amnionic fluid and gives results in less than an hour. Investigators found the TDx-FLM to be equal or superior to the L/S ratio, foam stability index, or phosphatidylglycerol assessment. This included testing in diabetic pregnancies (Karcher, 2005; Varner, 2013). The modified *TDx-FLM II* is used by many hospitals as their primary test of pulmonary maturity. Thresholds vary by gestational age (Bennasar, 2009). The *foam stability* or *shake test* relies on the ability of surfactant in amnionic fluid, when mixed appropriately with ethanol, to generate stable foam at the air–liquid interface (Clements, 1972).

Problems include errors caused by slight contamination and frequent false-negative test results. Of other tests, the *Lumadex-FSI test, fluorescent polarization (microviscometry),* and *amnionic fluid absorbance at 650-nm wavelength* have all been used with variable success.

The *lamellar body count* is a rapid, simple, and accurate method of assessing fetal lung maturity and is comparable to TDx-FLM and L/S ratio accuracy (Karcher, 2005; Varner, 2013).

NECROTIZING ENTEROCOLITIS

This newborn bowel disorder has clinical findings that include abdominal distention, emesis, ileus, bilious gastric aspirates, and bloody stools. There is often radiological evidence of *pneumatosis intestinalis*—bowel wall gas derived from invading bacteria. Other classic imaging findings include hepatobiliary gas and pneumoperitoneum. Bowel perforation may prompt resection. Necrotizing enterocolitis (NEC) is seen primarily in low-birthweight newborns but occasionally is encountered in mature neonates. Various hypothesized causes include perinatal hypotension, hypoxia, sepsis, umbilical catheterization, exchange transfusions, blood transfusions, and the feeding of cow milk and hypertonic solutions (Neu, 2010). The pathophysiology is thought to be multifactorial, and genetic disposition, intestinal immaturity, imbalance in microvascular tone, abnormal microbial colonization in the intestine, exposure to enteral feeds, and highly immunoreactive intestinal mucosa play potential roles (Caplan, 2017; Neu, 2010).

Medical treatment includes abdominal decompression, bowel rest, broad-spectrum antibiotics, and parenteral nutrition. Surgery is reserved for neonates with intestinal perforation or deteriorating clinical or biochemical status. Possible surgical procedures include drain placement, exploratory laparotomy with resection of diseased bowel, or enterostomy with creation of a stoma (Neu, 2010).

RETINOPATHY OF PREMATURITY

By 1950, this condition, formerly known as *retrolental fibroplasia,* became the largest single cause of blindness in this country. After the discovery that the disease resulted from hyperoxemia, its frequency declined but began to rise again with the increasing survival rates of extremely preterm newborns.

Normally, the fetal retina vascularizes centrifugally from the optic nerve starting at approximately the fourth month and continues until shortly after birth. During vascularization, excessive oxygen induces severe retinal vasoconstriction with endothelial damage and vessel obliteration. This is followed by subsequent aberrant neovascularization, in which the new vessels penetrate the retina and extend into the vitreous. Here, they are prone to leak proteins or burst with subsequent hemorrhage. Adhesions can form to detach the retina. Vascular endothelial growth factor (VEGF) plays an important role in normal angiogenesis and is upregulated during retinopathy of prematurity (ROP) development (Sharma, 2017). This understanding has opened new avenues of treatment with anti-VEGF therapies.

Precise levels of hyperoxemia that can be sustained without causing ROP are unknown. After birth, there is a “relative” hyperoxia compared with in utero oxygen content, even in newborns not exposed to higher

inspired oxygen concentrations. To better understand the oxygen saturation threshold necessary to minimize ROP without raising rates of other adverse outcomes, the Neonatal Research Network performed a randomized trial of oxygenation in 1316 neonates born between 24 and 27 weeks' gestation (SUPPORT Study Group, 2010a). The two target ranges of oxygen saturation were 85 to 89 percent in one arm and 91 to 95 percent in the other arm. These targets were both commonly employed in neonatal intensive care units. Death before discharge occurred significantly more frequently in the lower-oxygen saturation group—20 versus 16 percent. However, severe ROP among survivors developed significantly less often in the lower-oxygen saturation group—8.6 versus 17.9 percent.

BRAIN DISORDERS

Central nervous system injury usually creates different neuroanatomical sequelae in preterm newborns compared with those at term (Chap. 33, Neonatal Encephalopathy). In preterm neonates, cerebral lesions detected by neuroimaging include intraventricular hemorrhage, cerebellar hemorrhage, periventricular hemorrhagic infarction, cystic periventricular leukomalacia, and diffuse white matter injury. All of these are strongly associated with adverse neurodevelopmental outcomes (Kwon, 2014).

Cranial sonography remains the preferred approach for detecting frequently occurring brain abnormalities and acute events. It is readily available and reliable for detecting common abnormalities and monitoring brain growth. Because cystic injuries may take 2 to 5 weeks to evolve, serial scans are obtained during this time. In those whose findings are transient and resolve in the neonatal period, prognosis is improved compared with infants whose lesions remain and evolve. At the same time, however, between 4 and 10 percent of prematurely born children may develop cerebral palsy (CP) in the absence of lesions. Put another way, 90 to 96 percent of preterm newborns with CP have cerebral lesions that are detectable using cranial sonography.

Intracranial Hemorrhage

There are five major categories of intracranial hemorrhage in the neonate (Volpe, 2008). *Primary subarachnoid hemorrhage* is more common in those born preterm and is frequently benign. *Cerebellar hemorrhage* is also more frequent in preterm neonates and is increasingly recognized as a cause of serious sequelae. *Intraventricular hemorrhage (IVH)* is almost exclusively seen in preterm newborns, is relatively common, and can have serious effects. *Subdural hemorrhages* are more frequent in term newborns and can be serious. *Miscellaneous intraparenchymal hemorrhage* is also more frequent in those born at term and is of variable concern.

Periventricular–Intraventricular Hemorrhage

In preterm infants, the germinal matrix capillary network is fragile for several reasons. First, the subependymal germinal matrix provides poor support for the vessels coursing through it. Second, venous anatomy in this region causes stasis and congestion, which makes vessels susceptible to bursting if

intravascular pressure rises. Third, vascular autoregulation is impaired in the preterm neonate (Matsuda, 2006; Verhagen, 2014).

If fragile capillaries in the germinal matrix rupture, blood escapes into surrounding tissues and may extend into the ventricular system and brain parenchyma. This type of hemorrhage is common in preterm neonates, especially those born before 32 weeks. However, it can also develop at later gestational ages and even in term neonates. Most hemorrhages develop within 72 hours of birth, but they have been observed as late as 24 days (Whitelaw, 2011). Because IVH usually is recognized within 3 days of delivery, its genesis is often erroneously attributed to birth events. It is important to realize that *prelabor* IVH can also occur (Achiron, 1993; Nores, 1996).

The pathogenesis of IVH is multifactorial and includes hypoxic-ischemic events, carbon dioxide elevations, anatomical factors, blood pressure instability, coagulopathy, genetic factors, and many others (McCrea, 2008; Ment, 2016). Moreover, preterm birth is frequently associated with infection, which further predisposes to endothelial activation, platelet adherence, and thrombi (Redline, 2008). Respiratory distress and mechanical ventilation are commonly associated factors (Sarkar, 2009).

Almost half of hemorrhages are clinically silent. Most small germinal matrix hemorrhages and those confined to the cerebral ventricles resolve without impairment. But, nearly half do show some sign of neurological impairment (Patra, 2006). Survivors of extensive periventricular/intraventricular hemorrhage can have major neurodevelopmental handicaps (Mukerji, 2015). Large lesions can result in hydrocephalus or in degenerated cystic areas termed *periventricular leukomalacia (PVL)*, discussed below. Importantly, the extent of PVL correlates with CP risk (Bassan, 2006).

Incidence and Severity

Ventricular hemorrhage incidences depends on gestational age at birth. From the Neonatal Research Network, approximately 65 percent of all neonates born before 28 weeks' gestation demonstrated some evidence of hemorrhage or PVL (Stoll, 2010). The incidence ranged from 60 percent in those born at 23 weeks to only 23 percent in those at 28 weeks. Importantly, grade IV intraventricular hemorrhage was documented in 21 percent of 23-week-old neonates but in only 3 percent of those at 28 weeks.

The severity of IVH can be assessed by neuroimaging studies. Papile and coworkers (1978) devised the most widely used grading scheme to quantify the extent of a lesion and estimate prognosis:

Grade I—hemorrhage limited to the germinal matrix

Grade II—intraventricular hemorrhage

Grade III—hemorrhage with ventricular dilation

Grade IV—parenchymal extension of hemorrhage.

Antenatal Corticosteroids

If given at least 24 hours before delivery, corticosteroids prevent or reduce the incidence and severity of IVH (Wei, 2016). A Consensus Development Conference of the NIH (1994) concluded that such therapy reduced rates of mortality, RDS, and IVH in preterm neonates born between 24 and 32 weeks' gestation. A second consensus statement by the NIH (2000) recommended that repeated courses of corticosteroids not be given (Chap. 42, Corticosteroids for Fetal Lung Maturation).

Subsequently, the Maternal–Fetal Medicine Units Network reported that repeated corticosteroid courses were associated with some improved preterm neonatal outcomes, but also with reduced birthweight and increased risk for fetal-growth restriction (Wapner, 2006). Surveillance of this cohort through age 2 to 3 years found that children exposed to repeated versus single-dose steroid courses did not differ significantly in physical or neurocognitive measures (Wapner, 2007). It was worrisome, however, that there was a nonsignificant 5.7-fold relative risk of CP in infants exposed to multiple steroid courses.

At the same time, the 2-year follow-up of the Australian Collaborative Trial was reported by Crowther and coworkers (2007). In more than 1100 newborns, the incidence of CP was almost identical—4.2 versus 4.8 percent—in those given repeated versus single-course steroids, respectively. More recently, it was reported that for those born before 28 weeks' gestation, if 10 days or more had passed since betamethasone administration, the incidence of severe IVH was higher (Liebowitz, 2016).

The most recent recommendations from the American College of Obstetricians and Gynecologists (2016a) are for a single course of corticosteroids for pregnant women between $24^{0/7}$ weeks and $33^{6/7}$ weeks' gestation who are at risk for preterm delivery. They further note that those given their initial course more than 14 days prior and who have imminent risk of preterm delivery may receive a second "rescue" course. Antenatal corticosteroids are "considered" for $23^{0/7}$ to $23^{6/7}$ weeks and not recommended for pregnancies <23 weeks (American College of Obstetricians and Gynecologists, 2017c).

Other Preventive Methods

Although antenatal *magnesium sulfate* for those at risk for preterm delivery does not reduce the incidence of IVH, it does offer protection from neurodevelopmental impairment (Crowther, 2007; Doyle, 2009). The American College of Obstetricians and Gynecologists (2016b) recommends its use for this indication, as discussed further in Chapter 42 (Magnesium Sulfate for Neuroprotection). The efficacy of antenatal *vitamin K* and *phenobarbital*, as well as postnatal phenobarbital, have not been shown to consistently reduce the incidence of IVH (Crowther, 2010a,b; Smit, 2013). Although *vitamin E* reduced IVH rates, the associated risk for sepsis was increased (Brion, 2003). One metaanalysis of the many randomized trials of postnatal *indomethacin* showed a reduction in IVH rates, but no improvement in rates of death or neurodevelopmental impairment (Fowlie, 2010).

The benefits of cesarean delivery compared with vaginal birth to lower IVH rates remains controversial. One metaanalysis reported that cesarean delivery for very-low-birthweight neonates had no effect on rates of severe IVH but did reduce overall IVH rates (Barzilay, 2016). Delayed cord clamping compared with immediate cord clamping has been reported to reduce the risk for IVH in preterm newborns (Rabe, 2012).

Periventricular Leukomalacia

This pathological description refers to cystic areas deep in brain white matter that develop after hemorrhagic or ischemic infarction. Tissue ischemia leads to regional necrosis. Because brain tissue does not regenerate and the preterm neonate has minimal gliosis, these irreversibly damaged areas appear as echolucent cysts in neuroimaging studies. Generally, they require at least 2 weeks to form but may develop as long as 4 months after the initial insult. Thus, their presence at birth may help to determine the timing of an inciting event.

CEREBRAL PALSY

This term refers to a group of conditions that are characterized by chronic movement or posture abnormalities that are cerebral in origin, arise early in life, and are nonprogressive (Nelson, 2003). Epilepsy and mental retardation frequently accompany CP. Its cause(s) are different in preterm and term infants (Chap. 33, Cerebral Palsy).

CP is commonly classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—as well as the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. The major types and their frequencies were categorized by Freeman (1988) and Rosen (1992) and their associates:

Spastic quadriplegia, which has a strong association with developmental retardation and seizure disorders—20 percent

Diplegia, which is common in preterm or low-birthweight neonates—30 percent

Hemiplegia—30 percent

Choreoathetoid types—15 percent

Mixed varieties.

Incidence

According to the Centers for Disease Control and Prevention (2016), the prevalence of CP in the United States approximates 3 in 1000 children. In some countries, the incidence has risen because advances in care of very preterm newborns have improved their survival but not their neurological prognosis (O'Callaghan, 2011). For example, Moster and coworkers (2008) presented long-term follow-up of more than 900,000 births in Norway. The CP rate was 0.1 percent in nonanomalous term newborns but was 9.1 percent in those born at 23 to 27 weeks.

Risks

Intraventricular Hemorrhage

Various clinical and pathological data link CP with associated severe IVH (grade III or IV) and resulting PVL. In one study of nearly 1500 neonates born before ≤28 weeks, the rate of CP was fivefold greater in those who had grade III or IV hemorrhage compared with those who suffered no IVH (Bolisetty, 2014).

Ischemia

Preterm newborns are most susceptible to brain ischemia and PVL. Before 32 weeks' gestation, the vascular anatomy of the brain is composed of two systems. One penetrates into the cortex—the *ventriculopedal system.* The other reaches down to the ventricles, but then curves to flow outward—the *ventriculofugal system* (Weindling, 1995). There are no vascular anastomoses connecting these two systems. As a result, the area between these systems, through which the pyramidal tracts pass near the lateral cerebral ventricles, is a *watershed area* vulnerable to ischemia. Vascular insufficiency before 32 weeks leading to ischemia would affect this watershed area first. Resulting damage of the pyramidal tracts may cause spastic diplegia. After 32 weeks, vascular flow shifts toward the cortex, and hypoxic injury after this time primarily damages the cortical region.

Perinatal Infection/Inflammation

PVL is associated with infection and inflammation. Zupan and colleagues (1996) studied 753 infants born between 24 and 32 weeks, 9 percent of whom developed PVL. Those born before 28 weeks, those who had inflammatory events during the last days to weeks before delivery, and those who had both were at highest risk. In another study, PVL was strongly associated with prolonged membrane rupture, chorioamnionitis, and neonatal hypotension (Perlman, 1996). Bailis and coworkers (2008) reported that chronic—and not acute—placental inflammation was associated with PVL.

Fetal infection may be a key element in the pathway between preterm birth and CP (Burd, 2012; Leviton, 2010). As discussed in Chapter 42 (Cervical Dysfunction), chorioamnionitis is a major cause of spontaneous preterm delivery. In the pathway proposed in Figure 34-2, antenatal reproductive tract infection evokes the production of cytokines such as tumor necrosis factor and interleukins-1, -6, and -8. These in turn stimulate prostaglandin production and preterm labor. Preterm fetal intracranial blood vessels are susceptible to rupture and damage, and the cytokines that stimulate preterm labor also have direct toxic effects on oligodendrocytes and myelin. Vessel rupture, tissue hypoxia, and cytokine-mediated damage result in massive neuronal cell death. Glutamate is released, stimulating membrane receptors to allow excess calcium to enter the neurons. High intracellular calcium levels are toxic to white matter, and glutamate may be directly toxic to oligodendrocytes (Khwaja, 2008).

FIGURE 34-2

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

Many studies have shown that infection and cytokines can directly damage the immature brain (Chau, 2014; Yoon, 1997a). Tumor necrosis factor and interleukin-6 were more frequently found in the brains of infants who died with PVL (Yoon, 1997b). Cytokines are strongly linked to white matter lesions even when organisms cannot be demonstrated (Yoon, 2000).

Andrews and colleagues (2008) provided data that raise questions regarding a higher incidence of adverse neurodevelopmental outcomes related to exposure to chorioamnionitis. In a cohort born between 23 and 32 weeks, they studied several surrogate indicators and direct markers of in utero inflammation. These included clinical findings, cytokine levels, histological findings, and microbial culture results. Infants undergoing comprehensive psychoneurological testing had similar incidences of CP, intelligence quotient (IQ) scores <70, or both, regardless of these markers. The researchers interpreted their findings to support current practices that employ efforts to delay delivery with preterm pregnancies in the absence of overt intrauterine infection. Importantly, this does not apply to preterm pregnancy in which clinical chorioamnionitis is diagnosed. Of 3094 singletons born before 33 weeks' gestation, 15 percent had evidence of clinical chorioamnionitis (Soraisham, 2009). Compared with noninfected infants, cases complicated by infection had significantly higher rates of early-onset sepsis—4.8 versus 0.9 percent—and of IVH—22 versus 12 percent.

Prevention—Neuroprotection

The benefits of antenatal magnesium sulfate and corticosteroids have already been described. Few specific treatments have been identified to reduce or prevent brain injury in the vulnerable preterm newborn. One potential neuroprotective therapy is with erythropoiesis stimulating agents (ESAs) such as erythropoietin and darbepoetin. In addition to stimulating erythropoiesis, ESAs are protective in the developing brain in animal models (Wassink, 2017). Preliminary clinical studies are encouraging, and large trials are now underway (Beirer, 2014).

CHAPTER 35: Stillbirth

In the latter months of pregnancy, the disappearance of foetal movements usually directs the attention of the patient to the possibility of foetal death. The diagnosis of this condition, however, can be considered absolute only after repeated examinations, when one has failed to hear the foetal heart or perceive the movements of the child.

—J. Whitridge Williams (1903)

INTRODUCTION

In Williams' time, absolute documentation of fetal death was frustrating for both patient and obstetrician. Now, sonography provides prompt confirmation, which allows expedient induction of labor and delivery. However, epidemiologically, defining and reporting fetal deaths was—and continues to be—a challenge. In response, efforts to standardize the definition of stillbirth and analyze varying reports for application into clinical practice and public health policy are now being emphasized. Moreover, stillbirth research and prevention within the United States and abroad has expanded. Global public health efforts were stimulated in part by a six-part series in *The Lancet.* This compilation was considered a call to action after the recognition that an estimated 2.65 million stillbirths occur each year and that 98 percent of stillborn fetuses are from low- and middle-income countries (*The Lancet*'s Stillbirth Series Steering Committee, 2011a–f). Unfortunately, progress in improving these rates has been slow, as outlined in *The Lancet's* subsequent five-part progress report, which emphasized the need for dedicated leadership, measured effects of interventions, and investigation into knowledge gaps (The Lancet's Ending Preventable Stillbirths Series Study Group, 2016a–e).

In the United States, an estimated 1 million fetal losses are reported each year, and most occur before 20 weeks' gestation. Fetal mortality data from the National Vital Statistics system are usually presented for fetal deaths after the 20-week threshold (MacDorman, 2015). Using this definition, numbers of fetal deaths in the United States in 2013 slightly surpassed numbers of infant deaths (Fig. 35-1). As shown in Figure 35-2, fetal death rates are highest at the earliest and latest gestational ages, which suggests etiological differences.

FIGURE 35-1
Percent distribution of fetal deaths at 20 weeks' gestation or more and of infant deaths: United States, 2013. (Data from MacDorman MF, Reddy UM, Silver RM: Trends in stillbirth by gestational age in the United States, 2006–2012, Obstet Gynecol. 2015 Dec;126(6):1146–1150.)

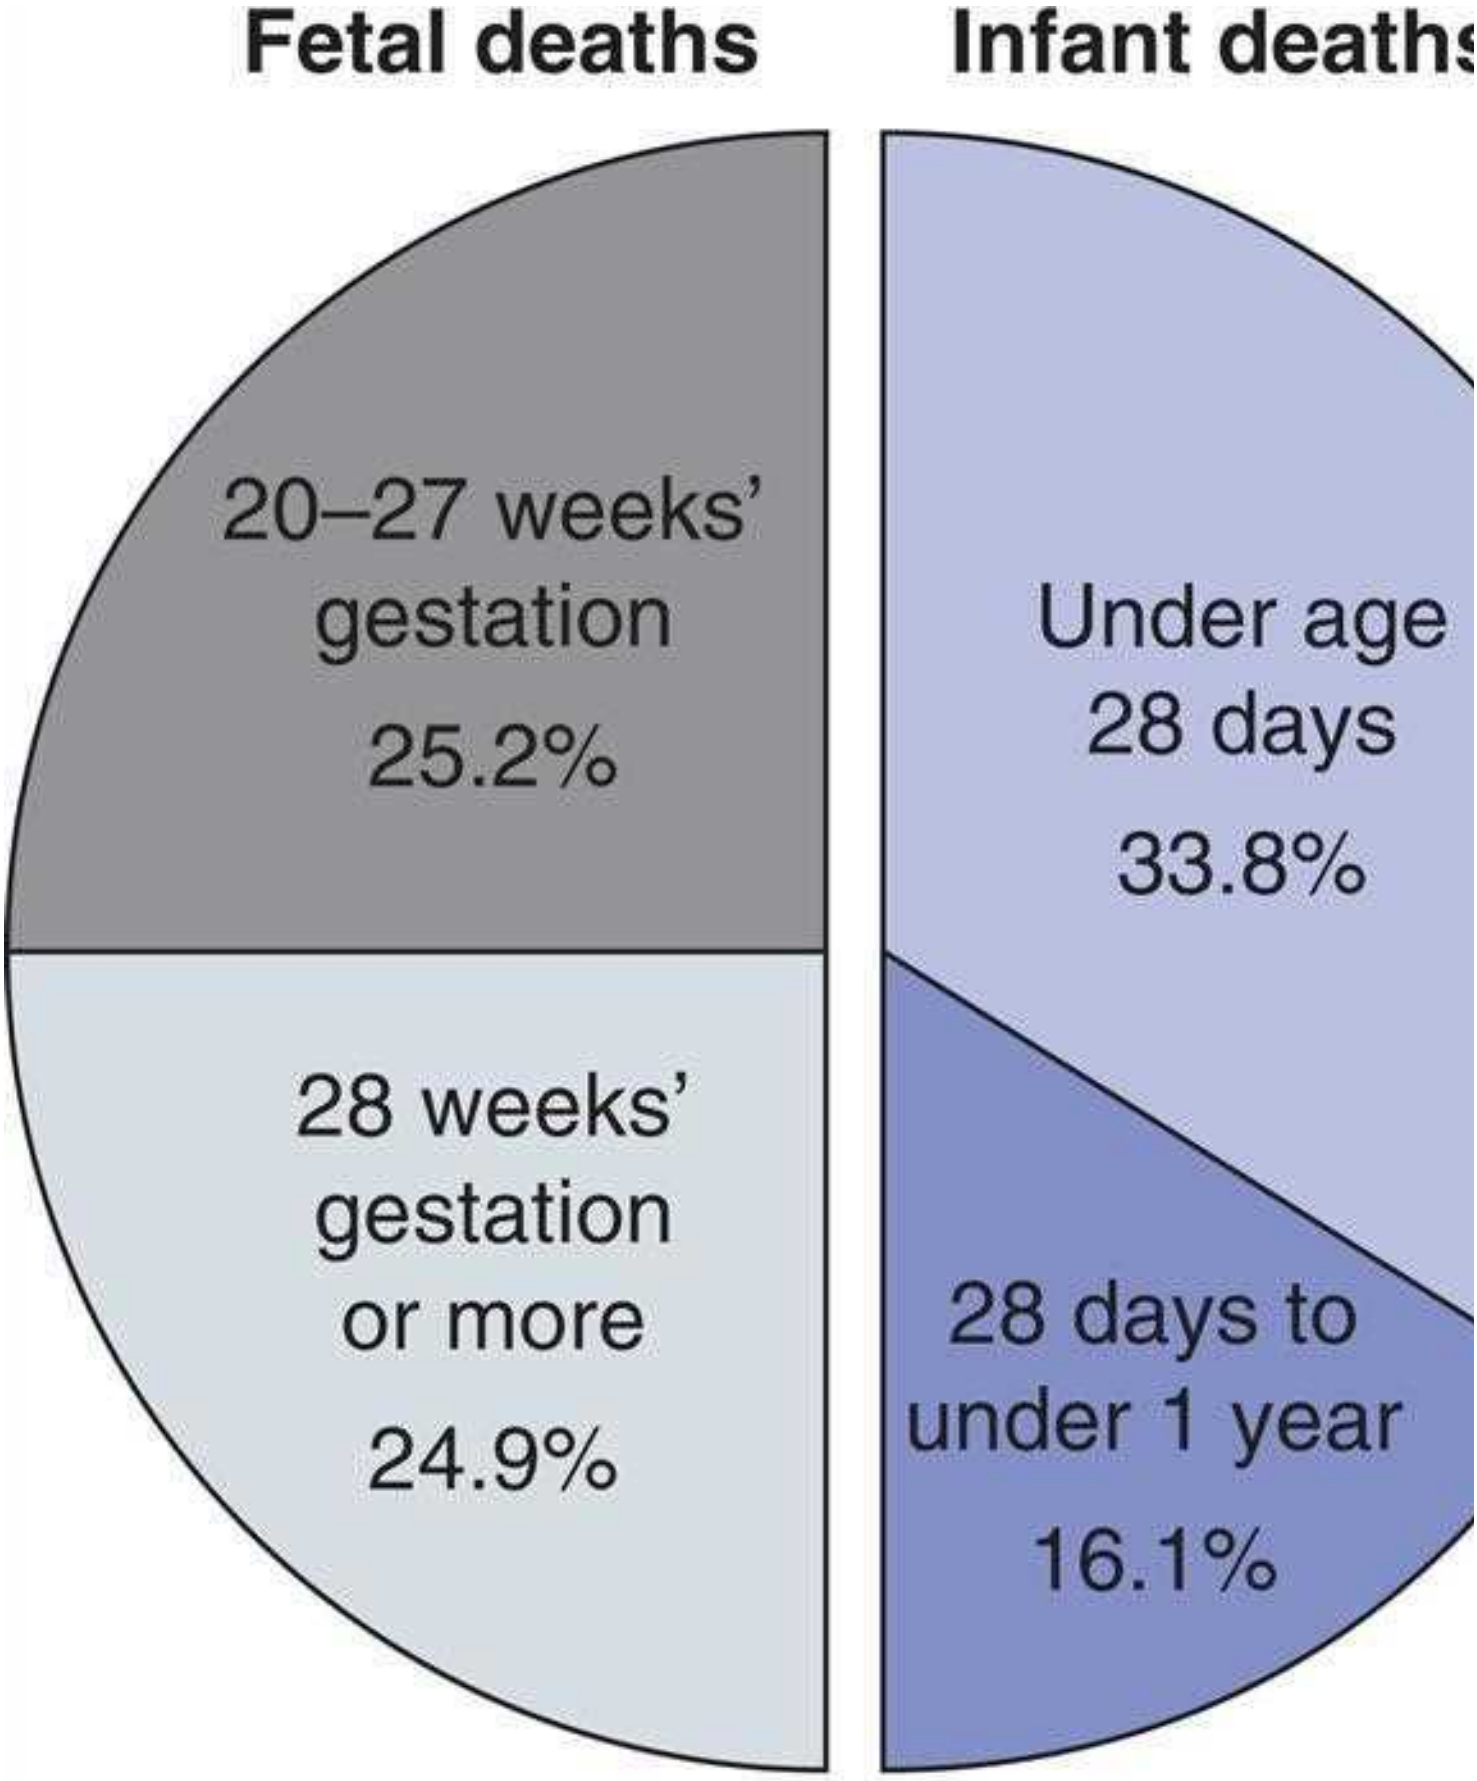

FIGURE 35-2

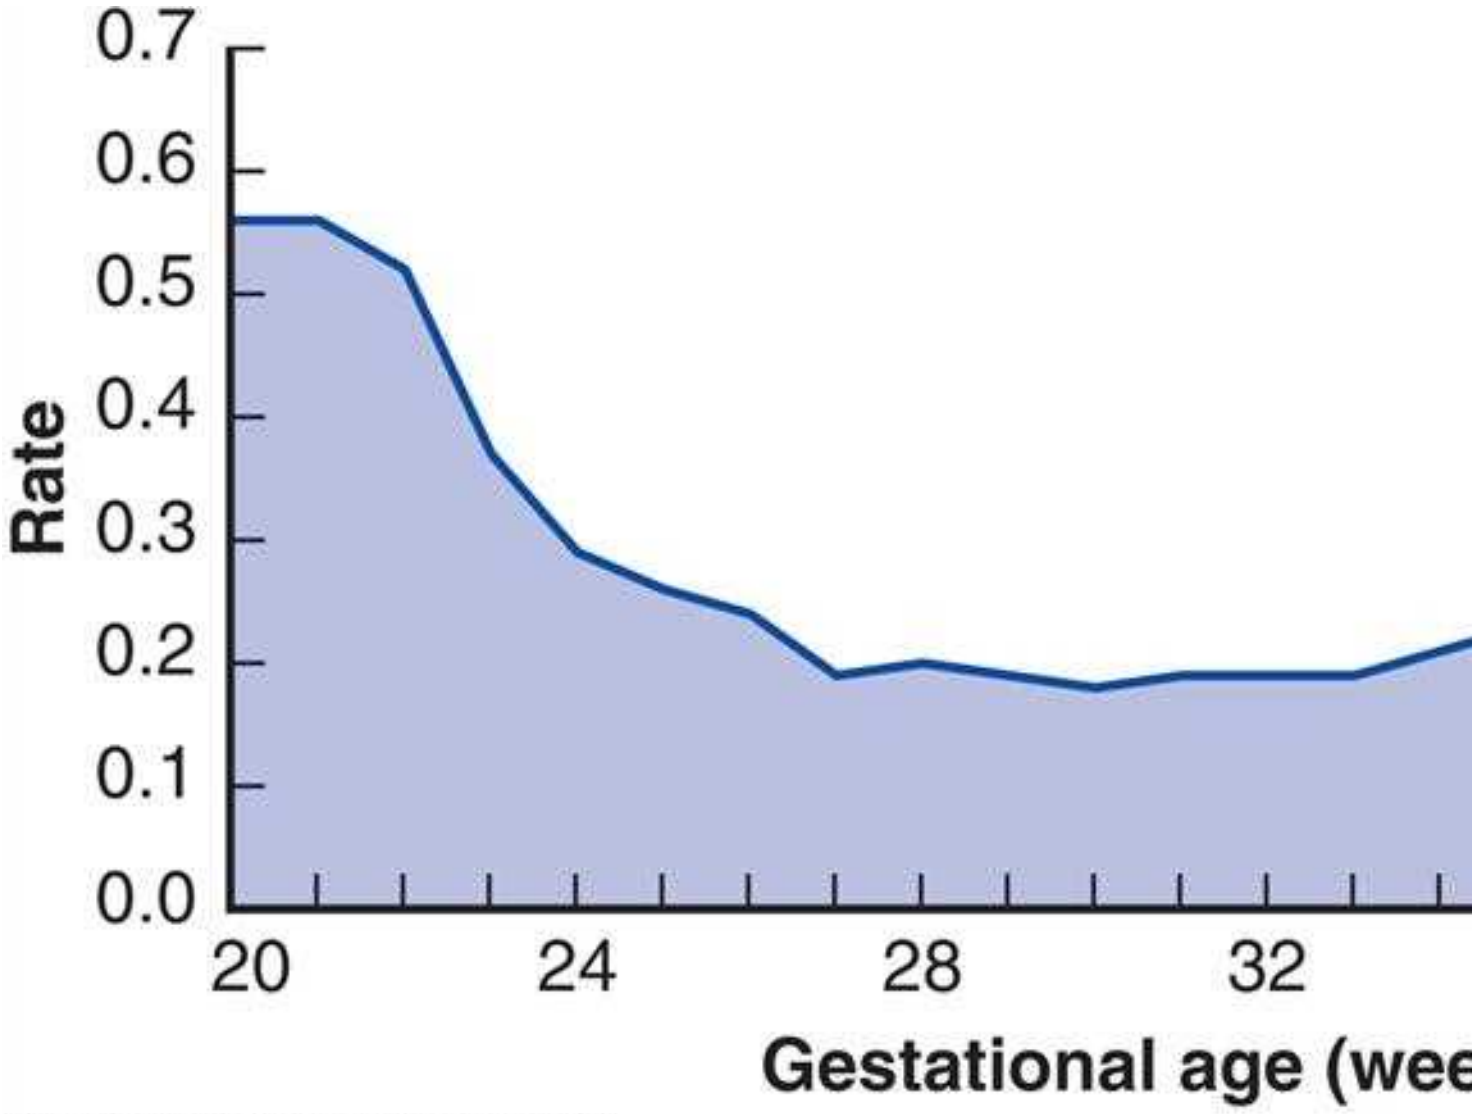
Prospective fetal mortality rate per 1000 births by weeks of gestation: United States, 2013. (Redrawn from MacDorman MF, Reddy UM, Silver RM: Trends in stillbirth by gestational age in the United States, 2006–2012, Obstet Gynecol. 2015 Dec;126(6): 1146–1150.)



DEFINITION OF FETAL MORTALITY

The current definition of fetal death adopted by the Centers for Disease Control and Prevention National Center for Health Statistics is based on a definition recommended by the World Health Organization (MacDorman, 2015). It states that "*Fetal death means death prior to complete expulsion or extraction from the mother of a product of human conception irrespective of the duration of pregnancy and which is not an induced termination of pregnancy. The death is indicated by the fact that after such expulsion or extraction, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles. Heartbeats are to be distinguished from transient cardiac contractions; respirations are to be distinguished from fleeting respiratory efforts or gasps.*"

Reporting requirements for fetal deaths in the United States are determined by each state, and thus, criteria differ significantly (Chap. 1, Definitions). Most states mandate reporting of deaths of fetuses that are 20 weeks' gestation or older or have a minimum birthweight of 350 g (roughly equivalent to 20 weeks) or some combination of these two. However, several states require reporting of fetal deaths at all periods of gestation, and one sets the threshold at 16 weeks. Alternatively, two states require reporting of deaths for fetuses with birthweights of 500 g, which approximates that at 22 weeks. There is substantial evidence that not all fetal deaths for which reporting is required are actually recorded (MacDorman, 2015). This is most likely for those at earlier gestational ages.

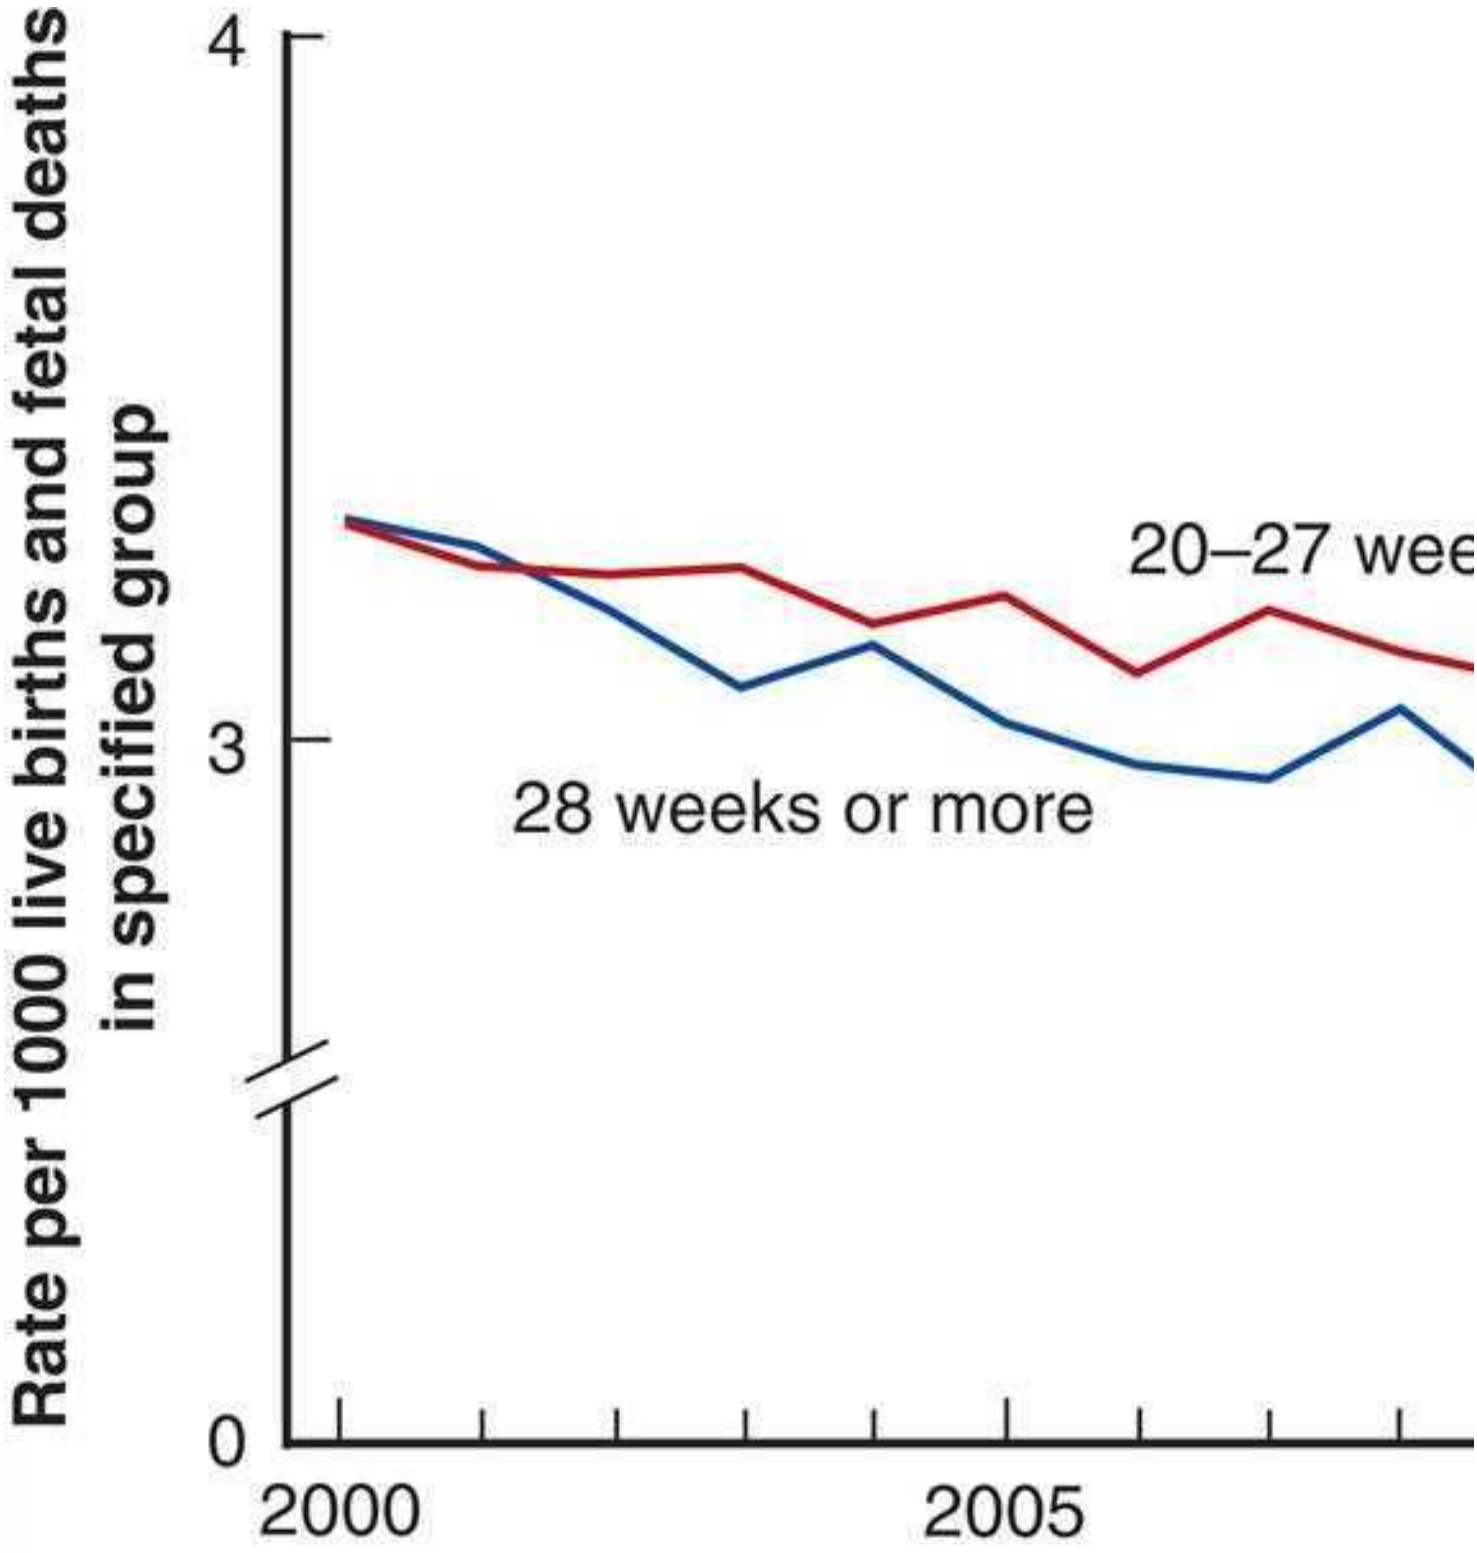
Comparisons of rates among countries are limited by incomplete fetal death data. Namely, internationally, less than 5 percent of neonatal deaths have formalized documentation (The Lancet's Ending Preventable Stillbirths Series Study Group, 2016d). Further, comparative analyses using birthweight versus gestational age among countries do not provide equivalent results. For example, in the United States, if stillbirth would be defined by a birthweight ≥500 g, the stillbirth rate would be reduced by 40 percent compared with a 22-week-age defined cohort (Blencowe, 2016). To address nomenclature differences, some have called for changes to the current definition (Joseph, 2015).

Overall, fetal mortality rates in the United States have remained relatively unchanged since 2006. However, the infant mortality rate has declined 11 percent, and both rates are now essentially equal (MacDorman, 2015). Three fetal mortality epochs are generally described: early (less than 20 completed weeks' gestation);

intermediate (20 to 27 weeks); and late (28 weeks or more). The fetal mortality rate at 20 to 27 weeks in 2013 declined 3 percent from the prior year. Between 2006 and 2012, rates were essentially unchanged in this age group. The late fetal mortality rate has been relatively unchanged since 2006 (Fig. 35-3).

FIGURE 35-3

Fetal mortality rates by period of gestation: United States, 2000–2013. (Data from MacDorman MF, Reddy UM, Silver RM: Trends in stillbirth by gestational age in the United States, 2006–2012, Obstet Gynecol. 2015 Dec;126(6):1146–1150.)



CAUSES OF FETAL DEATH

The *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) created the Stillbirth Collaborative Research Network to ascertain stillbirth causes in racially and geographically diverse populations in the United States. From this, the Stillbirth Collaborative Research Network Writing Group

(2011b) examined reasons for death at 20 weeks' gestation or later between 2006 and 2008 in 59 tertiary care and community hospitals in five states. Standardized evaluations included autopsy, placental histology, and testing of maternal or fetal blood/tissues, including fetal karyotyping. Evaluations were performed in 500 women with 512 stillbirths. Of these losses, 83 percent were before labor. Causes of stillbirth were divided into eight categories shown in Table 35-1. These categories were then classified as probable, possible, or unknown. As an example, diabetes was considered a *probable cause* if the fetus had diabetic embryopathy with lethal anomalies or the mother had diabetic ketoacidosis. It was a *possible cause* if the mother had poor glycemic control and the fetus had abnormal growth. *Overall, a probable or possible source was identified in 76 percent of cases.*

TABLE 35-1

Causes of 512 Stillbirths in the Stillbirth Collaborative Research Network Study

Cause	Percent	Examples
Obstetrical complications	29	Abruption, multifetal gestation, ruptured membranes at 20–24 weeks
Placental abnormalities	24	Uteroplacental insufficiency, maternal vascular disorders
Fetal malformations	14	Major structural abnormalities and/or genetic abnormalities
Infection	13	Involving the fetus or placenta
Umbilical cord abnormalities	10	Prolapse, stricture, thrombosis
Hypertensive disorders	9	Preeclampsia, chronic hypertension
Medical complications	8	Diabetes, antiphospholipid antibody syndrome
Undetermined	24	Not applicable

Percentages are rounded and total more than 100 percent because some stillbirths had more than one cause.

Overall, a cause was identified in 76 percent of stillbirths.

Data from Stillbirth Collaborative Research Network Writing Group, 2011b.

This Network study is unprecedented in the United States for several reasons. It was a population-based cohort of stillbirths, in which all underwent systematic and thorough evaluation. Each assigned cause of fetal death is reasonably straightforward and comprehensible except for "placental abnormalities." This category contains "uteroplacental insufficiency" and a few other less clearly defined placental entities. This aside, the leading reasons for fetal death were obstetrical and primarily included abruption, multifetal gestation complications, and spontaneous labor or ruptured membranes before viability. Importantly, this study illustrated that systematic evaluation may identify a likely cause in approximately three fourths of stillbirths. This rate is considerably higher than those in most prior analyses and serves to emphasize the importance of careful examination.

RISK FACTORS

Many factors are associated with an increased risk of stillbirth. Among others, these include advanced maternal age; African-American race; smoking; illicit drug use; maternal medical diseases—such as overt diabetes or chronic hypertension; assisted reproductive technology; nulliparity; obesity; and prior adverse pregnancy outcomes—such as prior preterm birth or growth-restricted newborn (Reddy, 2010; Varner, 2014).

Two major studies have assessed whether stillbirth risk factors could be identified either before or shortly after pregnancy confirmation. In the first, Reddy and colleagues (2010) analyzed data from the NICHD Consortium on Safe Labor. Briefly, the pregnancy outcomes of 206,969 women delivered between 2002 and 2008 at 19 hospitals in the United States were analyzed. When the distribution of stillbirths according to gestational age was studied, the tragedy of stillbirth occurred primarily in term pregnancies. These investigators concluded that their results did not support routine antenatal surveillance for any demographic risk factors.

The second analysis of stillbirth risk factors was included in the Stillbirth Collaborative Research Network study described earlier. The validity of stillbirth prediction was assessed based on risks identified in early pregnancy. They found that pregnancy factors known at the start of pregnancy accounted for only a small proportion of stillbirth risk. Except for prior stillbirth or pregnancy loss from causes such as preterm birth or fetal-growth restriction, other risks had limited predictive value (Stillbirth Collaborative Research Network Writing Group, 2011a). The importance of prior stillbirth as a risk for recurrence has been emphasized by Sharma and associates (2006). Specifically, the stillbirth risk was fivefold higher in women with a prior stillbirth. From another report, prior preterm birth, fetal-growth restriction, preeclampsia, and placental abruption were strongly associated with subsequent stillbirth (Rasmussen, 2009). Table 35-2 lists estimates of stillbirth risk according to maternal factors.

TABLE 35-2

Estimated Maternal Risk Factors and Risk of Stillbirth

Condition	Estimated Rate of Stillbirth (per 1000 births)	OR[a]
All pregnancies	6.4	1.0
Low-risk pregnancies	4.0–5.5	0.86
Hypertensive disorders		
Chronic hypertension	6–25	1.5–2.7
PIH		
Mild	9–51	1.2–4.0
Severe	12–29	1.8–4.4
Diabetes		
Diet alone	6–10	1.2–2.2
Insulin + diet	6–35	1.7–7.0
SLE	40–150	6–20
Renal disease	15–200	2.2–30
Thyroid disease	12–20	2.2–3.0
Thrombophilia	18–40	2.8–5.0
Cholestasis of pregnancy	12–30	1.8–4.4
Smoking >10 cigarettes	10–15	1.7–3.0
Obesity		
BMI 25–29.9 kg/m^2	12–15	1.9–2.7
BMI >30	13–18	2.1–2.8
Education (<12 yr vs ≥12 yr)	10–13	1.6–2.0
Prior IUGR (<10%)	12–30	2–4.6
Prior stillbirth	9–20	1.4–3.2
Multifetal gestation		
Twins	12	1.0–2.8
Triplets	34	2.8–3.7
Maternal age		
35–39 yr	11–14	1.8–2.2
≥40 yr	11–21	1.8–3.3
Black women compared with white women	12–14	2.0–2.2

[a]Odds ratio of the factor being present compared with the risk factor being absent.

BMI = body mass index; IUGR = intrauterine growth restriction; PIH = pregnancy-induced hypertension; SLE = systemic lupus erythematosus.

Adapted from Fretts, 2005.

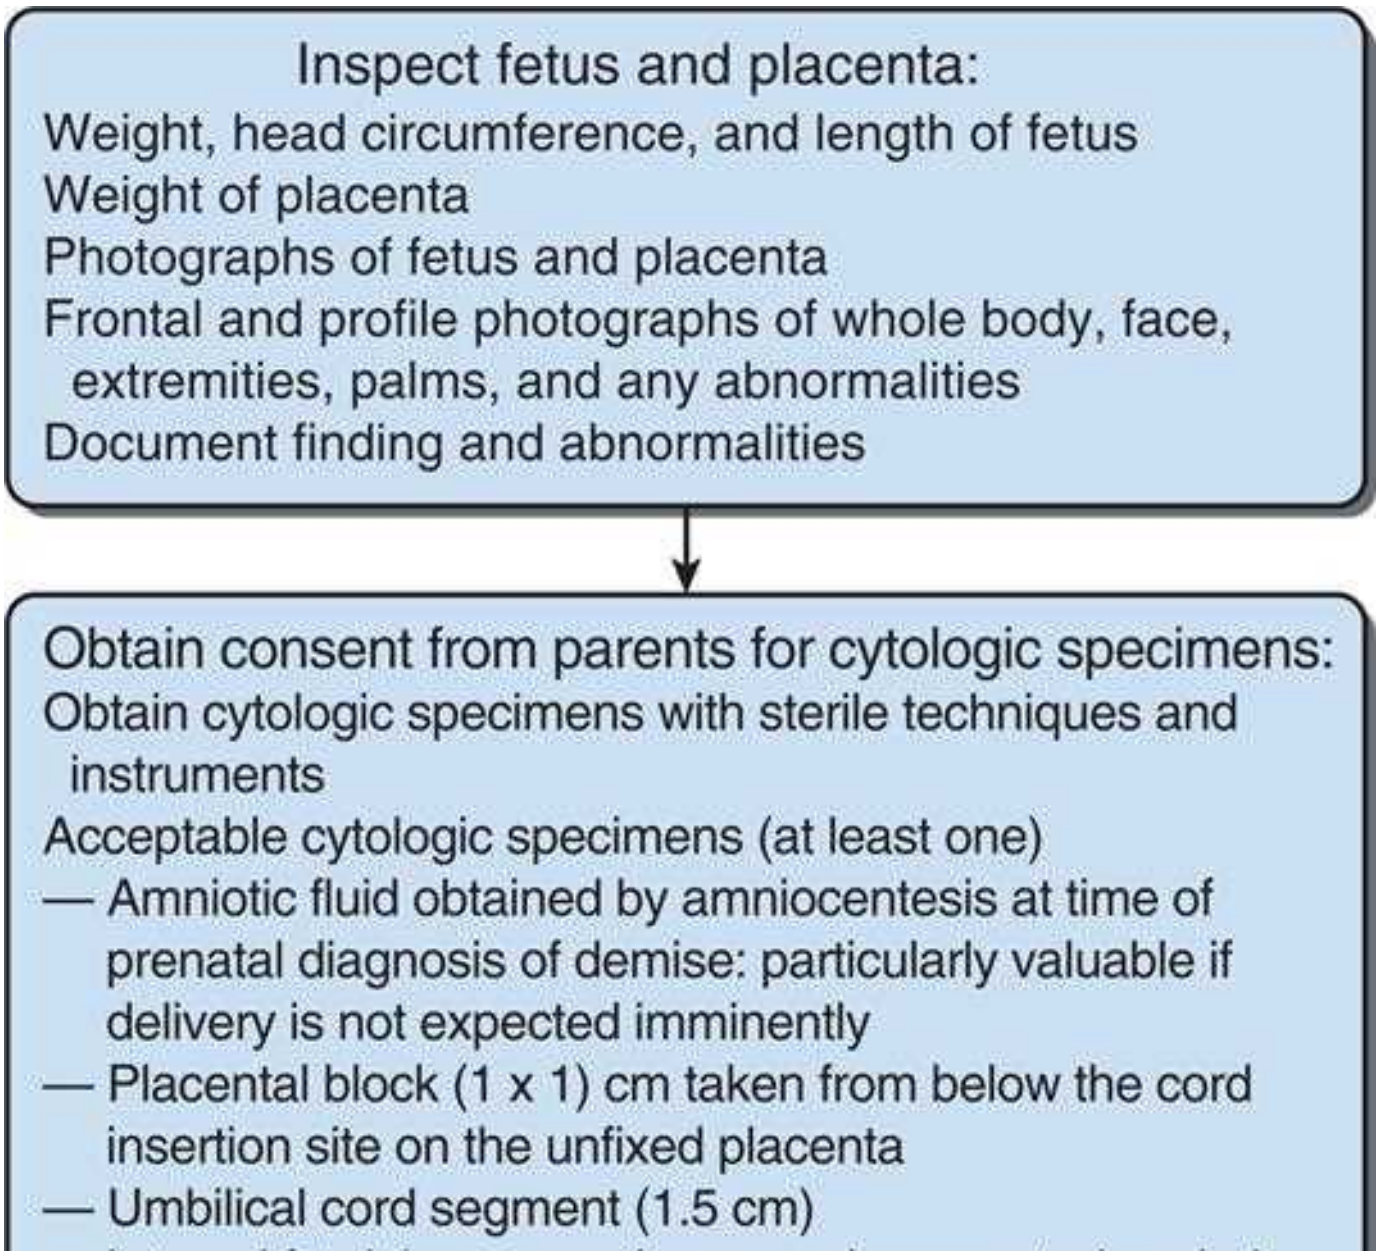
EVALUATION OF THE STILLBORN FETUS

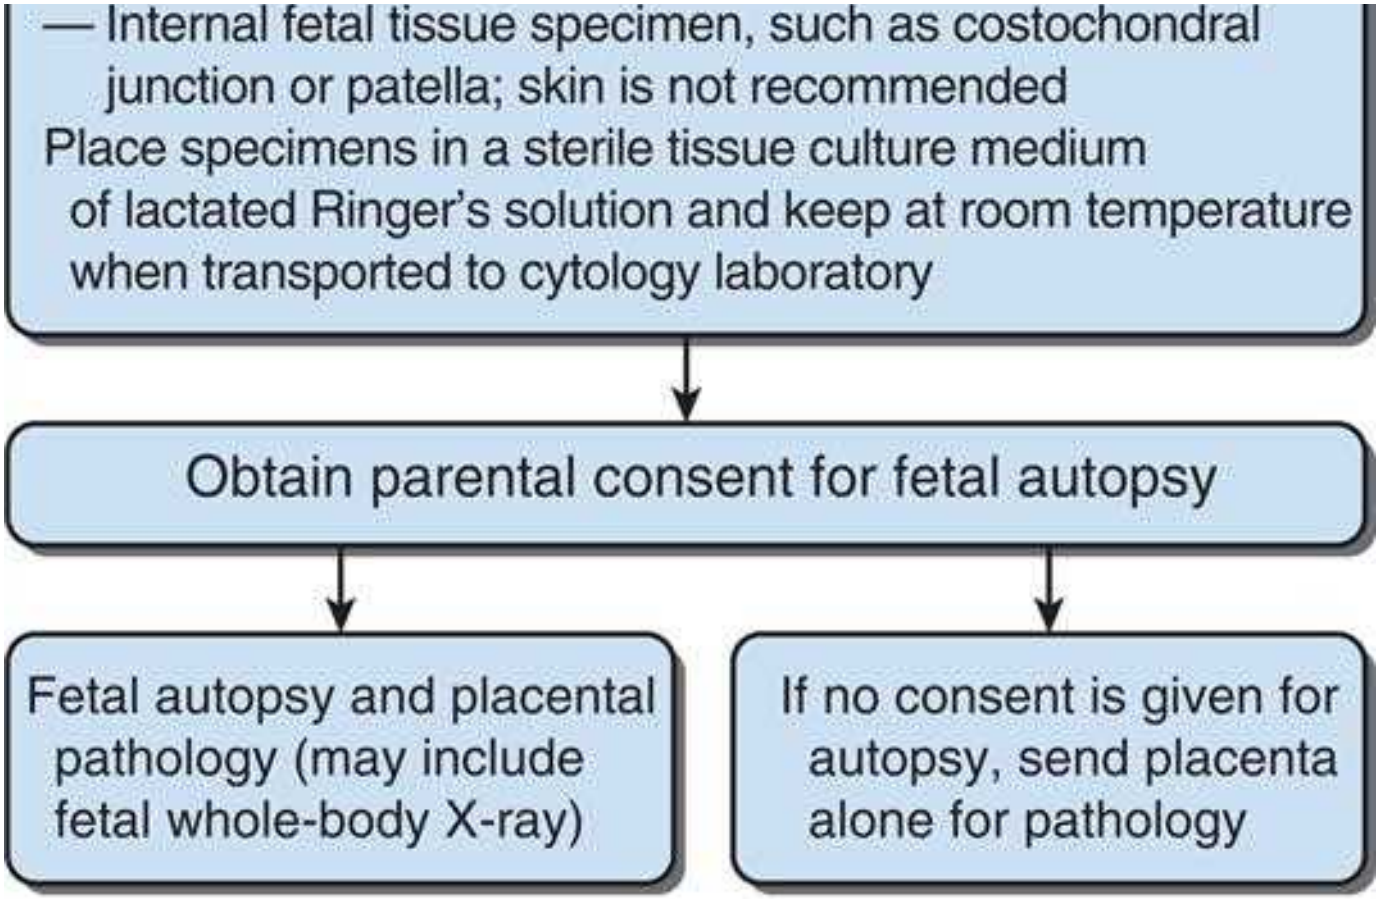
Determining the cause of fetal death aids maternal coping, helps assuage any perceived guilt, permits more accurate counseling regarding recurrence risk, and may prompt therapy or intervention to prevent a similar outcome in subsequent pregnancies (American College of Obstetricians and Gynecologists, 2016a). Identification of inherited syndromes also provides useful information for other family members.

Clinical Examination

Important tests in stillbirth evaluation are neonatal autopsy, chromosomal analysis, and examination of the placenta, cord, and chorioamnionic membranes (Pinar, 2014). Page and coworkers (2017) found placental pathology and fetal autopsy to be the most useful. One algorithm from the American College of Obstetricians and Gynecologists (2016a) is shown in Figure 35-4. Findings are documented in the medical record, and relevant prenatal events are delineated. Photographs are taken whenever possible, and a full radiograph of the fetus—a *fetogram*—may be performed. Postnatal magnetic resonance (MR) imaging or sonography may be especially important in providing anatomical information if parents decline a full autopsy (McPherson, 2017; Shruthi, 2017).

FIGURE 35-4
Flow chart for fetal and placental evaluation. (Modified with permission from ACOG Practice Bulletin No. 102: management of stillbirth, Obstet Gynecol. 2009 Mar;113(3):748–761.)





Laboratory Evaluation

If autopsy and chromosomal studies are performed, up to 35 percent of stillborn fetuses are discovered to have major structural anomalies (Faye-Petersen, 1999). Approximately 20 percent have dysmorphic features or skeletal anomalies, and 8 percent have chromosomal abnormalities (Pauli, 1994; Saller, 1995). In the absence of anatomic dysmorphology, up to 5 percent of stillborn fetuses will have a chromosomal abnormality (Korteweg, 2008). Although the American College of Obstetricians and Gynecologists (2016a) previously recommended karyotyping all stillborn fetuses, technological advancements of high-resolution, whole-genome sequencing—such as with *chromosomal microarray analysis (CMA)*—are now replacing standard karyotyping for chromosomal analysis of stillborn fetuses (Chap. 13, Chromosomal Microarray Analysis). CMA does not require dividing cells and is reported to be more useful in the evaluation of fetal death. This is especially true because the culturing of macerated fetal tissue is frequently unsuccessful (Reddy, 2012). Both the American College of Obstetricians and Gynecologists (2016c) and the Society for Maternal-Fetal Medicine (2016) now endorse the use of CMA for stillborn fetuses.

Appropriate consent must be obtained to take fetal samples, including tissue or fluid obtained postmortem by needle aspiration. As recently outlined by the American College of Obstetricians and Gynecologists (2016c), any type of fetal or placental tissue or amnionic fluid can be submitted for genetic testing by CMA. Contamination with maternal tissue or blood is ideally avoided. If fetal blood cannot be obtained from the umbilical cord or by cardiac puncture, the American College of Obstetricians and Gynecologists (2016a) recommends at least one of the following samples: (1) a placental block measuring about 1 × 1 cm taken below the cord insertion site in the unfixed specimen; (2) umbilical cord segment approximately 1.5 cm long; or (3) internal fetal tissue specimen such as costochondral junction or patella. Tissue is washed with sterile saline before being placed in lactated Ringer solution or sterile cytogenetic medium. Notably, placement in formalin or alcohol kills viable cells. If conventional karyotyping is the only test available and the timing of death is recent, amnionic fluid can be obtained by amniocentesis, as those cells obtained in a sterile fashion provide a greater likelihood of cell growth and eventual result compared with tissue obtained after delivery. Maternal blood is obtained for Kleihauer-Betke staining; for antiphospholipid antibody and lupus anticoagulant testing if indicated; and for serum glucose measurement to exclude overt diabetes (Silver, 2013).

In cases with significant growth restriction, with a family or personal history of thrombosis, or with severe placental pathology, testing for factor V Leiden mutation, prothrombin mutation, antithrombin level, and protein C and S activity may provide some information that could affect future pregnancy management (American College of Obstetricians and Gynecologists, 2016a). Our interpretation of relevant placental pathology includes derangements that stem from maternal vessel obstruction, which are described in Chapter 6. Although some have recommended routine evaluation of heritable thrombophilias, no evidence supports the clinical or financial efficiency of screening in an unselected population. Silver and colleagues (2016), with data from the Stillbirth Collaborative Research Network, found that most maternal and fetal thrombophilias were not associated with stillbirth and recommended against routine testing.

Autopsy

Parents are offered and encouraged to allow a full autopsy. That said, valuable information can still be obtained from limited studies. Pinar and coworkers (2012) described the autopsy protocol used by the Stillbirth Collaborative Research Network. As an alternative, gross external examination combined with photography, radiography, MR imaging, bacterial cultures, and selective use of chromosomal and histopathological studies often aids determination.

A complete autopsy is more likely to yield valuable data. An analysis of 400 consecutive fetal deaths in Wales showed that autopsy altered the presumed cause of death in 13 percent and provided new information in another 26 percent (Cartlidge, 1995). Other investigators have found that autopsy results changed the recurrence risk estimates and parental counseling in 25 to 50 percent of cases (Faye-Petersen, 1999; Silver, 2007). For example, Miller and associates (2016) recently demonstrated that placental examination with autopsy altered future medical management in 45 percent of cases.

According to the survey by Goldenberg and coworkers (2013), most hospitals do not audit stillbirths. In other centers, however, maternal records and autopsy findings are reviewed on a monthly basis by a stillbirth committee composed of obstetricians, maternal-fetal medicine specialists, neonatologists, clinical geneticists, and perinatal pathologists. If possible, the cause of death is assigned based on available evidence. Most importantly, parents are then contacted and offered counseling regarding the reason for the death, the potential recurrence risk, and possible strategies to avoid recurrence.

PSYCHOLOGICAL ASPECTS

Fetal death is psychologically traumatic for a woman and her family. Further stressors are an interval of more than 24 hours between the diagnosis of fetal death and labor induction, not seeing her infant for as long as she desires, having no tokens of remembrance, and poor communication (Radestad, 1996; Siassakos, 2017). The importance of seeing and holding a stillborn fetus for parental psychological well-being was recently summarized by Kingdon and colleagues (2015). As discussed in Chapter 61 (Postpartum Depression), a woman experiencing a stillbirth or early miscarriage is at increased risk for depression and should be closely monitored (Nelson, 2013).

Nuzum and coworkers (2014) reported that few obstetrical providers receive formal training in perinatal bereavement care. At Parkland Hospital, this care includes time with the infant, keepsake items, photographs, chaplaincy consultation, and bereavement support information. Care is coordinated through a dedicated nursing team affiliated with labor and delivery.

PRIOR STILLBIRTH

Table 35-3 lists an outlined approach for women with prior stillbirth. Importantly, these recommendations are based primarily on limited or inconsistent scientific evidence or on expert opinions. Unfortunately, few studies address management of affected women. Those with modifiable risk factors for stillbirth, such as hypertension or diabetes, warrant specific prevention strategies. Given that obesity has been identified as a risk factor for stillbirth and other obstetrical complications, preconceptional weight loss would seem prudent. Logically, women with a prior fetal death due to placental vascular events, that is, placental insufficiency, are also at increased risk for subsequent adverse perinatal outcomes (Monari, 2016). According to Reddy (2007), because almost half of fetal deaths are associated with growth restriction, fetal sonographic anatomical assessment beginning at midpregnancy is recommended. This is followed by serial growth studies beginning at 28 weeks. Supplementation with vitamin C or E in pregnancy has not been demonstrated to reduce the risk of fetal death (Rumbold, 2015a,b).

TABLE 35-3

Management of Subsequent Pregnancy after Stillbirth

Preconceptional or Initial Prenatal Visit
Detailed medical and obstetrical history
Review evaluation of prior stillbirth
Determination of recurrence risk
Discuss recurrence of comorbid obstetric complications
Smoking cessation
Preconceptional weight loss in obese women
Genetic counseling if family genetic condition exists
Diabetes screen
Thrombophilia screen: antiphospholipid antibodies (only if history indicates)
Support and reassurance
First Trimester
Dating sonography
First-trimester screen: pregnancy-associated plasma protein A, human chorionic gonadotropin, and nuchal translucency[a]
Support and reassurance
Second Trimester
Fetal sonographic anatomical survey at 18–20 weeks' gestation
Maternal serum screening (quadruple) *or* single-marker alpha fetoprotein if first-trimester screening elected[a]
Possible uterine artery Doppler studies at 22–24 weeks' gestation[a]
Support and reassurance
Third Trimester
Sonographic screening for fetal-growth restriction, starting at 28 weeks
Kick counts starting at 28 weeks
Antepartum fetal surveillance starting at 32 weeks *or* 1–2 weeks earlier than prior stillbirth
Support and reassurance
Delivery
Elective induction at 39 weeks
Delivery before 39 weeks only with documented fetal lung maturity by amniocentesis

[a]Provides risk modification but does not alter management.

Modified from Reddy, 2007.

Weeks and associates (1995) evaluated fetal biophysical testing in 300 women whose only indication was prior stillbirth. There was one subsequent stillbirth, and only three fetuses had abnormal testing results before 32 weeks. Notably, no relationship was found between the gestational age of the previous stillborn fetus and the incidence or timing of abnormal test results or fetal jeopardy in the subsequent pregnancy. These investigators concluded that antepartum surveillance should begin at 32 weeks or later in the otherwise healthy woman with a history of stillbirth. This recommendation is supported by the American College of Obstetricians and Gynecologists (2016a) with the caveat that it increases the iatrogenic preterm delivery rate. Although fetal movement counting strategies are routinely employed as described in Chapter 17 (Clinical Application), few data guide its use in clinical practice for those with a prior stillbirth (Mangesi, 2015).

Delivery at 39 weeks' gestation is recommended. Labor induction is suitable, and cesarean delivery is elected for those with a contraindication to induction. This timing minimizes fetal mortality rates, although the degree of risk reduction may be greater for older women (Page, 2013).

CHANGES IN STILLBIRTH RATES

Following declines between 2000 and 2006, the United States fetal mortality rate has been relatively unchanged since 2006 (MacDorman, 2015). Interpretation of these fetal mortality rates in the context of changing national healthcare strategies has spawned considerable debate. One example is the effort to prevent non-medically indicated deliveries before 39 weeks and its subsequent effect on term stillbirth rates. The value of this practice for neonatal outcome is described in Chapter 26 (Techniques). To analyze whether implementation of this "39-week rule" has altered the term stillbirth rate, Nicholson and coworkers (2016) examined data from 45 states and the District of Columbia during a 7-year period. The proportion of births before 39 weeks progressively declined from 2007 and 2013, but the term stillbirth rate rose. This suggested that the 39-week rule may cause unintended harm. MacDorman and associates (2015) also evaluated trends in stillbirth rates by gestational ages in the United States between 2006 and 2012. They used a "traditional stillbirth rate," which was calculated using a denominator composed of the live-birth number *plus* the stillbirth number at a given gestational age. They found increased rates at 24 to 27, 34 to 36, and 38 weeks' gestation. Alternatively, no

differences were found in “prospective stillbirth rates.” These rates were calculated using a denominator composed of the number of women who are pregnant at a given gestational age for weeks 21 through 42. The discrepancies in stillbirth rates appear to be primarily due to the decline in the number of births in the preterm and early-term gestational ages.

To summarize, implementation of the 39-week rule has reduced the number of elective births before 39 weeks’ gestation, although an unintended consequence may be an increase in term stillbirths—especially among women with medical complications. The importance of induction at less than 39 weeks in pregnant women with complications to prevent stillbirth is underscored by Little and colleagues (2015). These authors performed a retrospective multistate analysis of early-term deliveries ($37^{0/7}$ to $38^{6/7}$ weeks) from 2005 to 2011. They noted a decline in the number of early-term deliveries during this time but not a significant change in the term stillbirth rates. There was, however, a 25-percent rise in the rate of term, singleton stillbirths among women with diabetes, and this was attributed to clinicians misapplying early-term delivery policies to high-risk women. Undoubtedly, continued surveillance of stillbirth rates is warranted for both high- and low-risk pregnancies at a state and national level.

CHAPTER 36: The Puerperium

Although the changes occurring during the puerperium are considered as physiological, they border very closely upon the pathological, in as much as under no other circumstances does such marked and rapid tissue metabolism occur without a departure from a condition of health.

—J. Whitridge Williams (1903)

INTRODUCTION

The word *puerperium* is derived from Latin—*puer,* child + *parus,* bringing forth. Currently, it defines the time following delivery during which pregnancy-induced maternal anatomical and physiological changes return to the nonpregnant state. Its duration is understandably inexact, but is considered to be between 4 and 6 weeks. Although much less complex compared with pregnancy, the puerperium has appreciable changes as stated above by Williams (1903), and some of these may be either bothersome or worrisome for the new mother. Kanotra and colleagues (2007) analyzed challenges that women faced from 2 to 9 months following delivery. The Pregnancy Risk Assessment Surveillance System—PRAMS—of the Centers for Disease Control and Prevention (2016) listed concerns of new mothers that are shown in Table 36-1. At least a third of these women felt the need for social support, and 25 percent had concerns with breastfeeding.

TABLE 36-1

Pregnancy Risk Assessment Surveillance System—PRAMS[a] Concerns Raised by Women in the First 2–9 Months Postpartum

Concerns	Percent
Need for social support	32
Breastfeeding issues	24
Inadequate education about newborn care	21
Help with postpartum depression	10
Perceived need for extended hospital stay	8
Need for maternal insurance coverage postpartum	6

REPRODUCTIVE TRACT INVOLUTION

Birth Canal

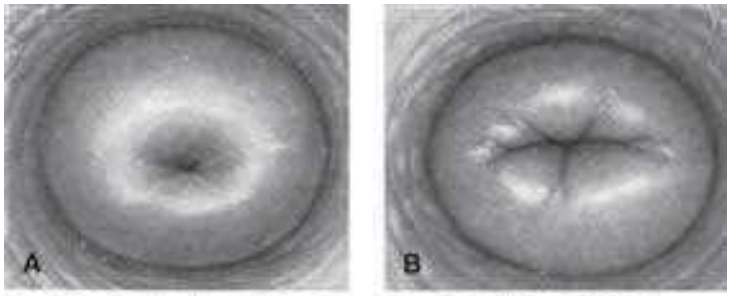
Return of the tissues in the birth canal to the nonpregnant state begins soon after delivery. The vagina and its outlet gradually diminish in size but rarely regain their nulliparous dimensions. Rugae begin to reappear by the third week but are less prominent than before. The hymen is represented by several small tags of tissue, which scar to form the *myrtiform caruncles.* The vaginal epithelium reflects the hypoestrogenic state, and it does not begin to proliferate until 4 to 6 weeks. This timing is usually coincidental with resumed ovarian estrogen production. Lacerations or stretching of the perineum during delivery can lead to vaginal outlet relaxation. Some damage to the pelvic floor may be inevitable, and parturition predisposes to urinary incontinence and pelvic organ prolapse.

Uterus

The massively increased uterine blood flow necessary to maintain pregnancy is made possible by significant hypertrophy and remodeling of pelvic vessels. After delivery, their caliber gradually diminishes to approximately that of the prepregnant state. Within the puerperal uterus, larger blood vessels become obliterated by hyaline changes. They are gradually resorbed and replaced by smaller ones. Minor vestiges of the larger vessels, however, may persist for years.

During labor, the margin of the dilated cervix, which corresponds to the external os, may be lacerated. The cervical opening contracts slowly, and for a few days immediately after labor, it readily admits two fingers. By the end of the first week, this opening narrows, the cervix thickens, and the endocervical canal re-forms. The external os does not completely resume its pregravid appearance. It remains somewhat wider, and typically, ectocervical depressions at the site of lacerations become permanent. These changes are characteristic of a parous cervix (Fig. 36-1). Cervical epithelium also undergoes considerable remodeling. This actually may be salutary because almost half of women have regression of high-grade dysplasia following delivery (Ahdoot, 1998; Kaneshiro, 2005).

FIGURE 36-1
Common appearance of nulliparous **(A)** and parous **(B)** cervices.



After delivery, the fundus of the contracted uterus lies slightly below the umbilicus. It consists mostly of myometrium covered by serosa and internally lined by decidua. The markedly attenuated lower uterine segment contracts and retracts, but not as forcefully as the uterine corpus. During the next few weeks, the lower segment is converted from a clearly distinct substructure large enough to accommodate the fetal head to a barely discernible uterine isthmus located between the corpus and internal cervical os. Immediately postpartum, the anterior and posterior walls, which lie in close apposition, are each 4 to 5 cm thick (Buhimschi, 2003). At this time, the uterus weighs approximately 1000 g.

Myometrial involution is a truly remarkable feat of destruction or deconstruction that begins as soon as 2 days after delivery (Williams, 1931). The total number of myocytes does not decrease appreciably—rather, their size decreases markedly. As emphasized by Hytten (1995), the quality of studies that describe the degree of decreasing uterine weight postpartum are poor. Best estimates show that the uterus weighs approximately 500 g by 1 week postpartum, about 300 g by 2 weeks, and at 4 weeks, involution is complete and the uterus weighs approximately 100 g. After each successive delivery, the uterus is usually slightly larger than before the most recent pregnancy.

Sonographic Findings

Uterine involution and rapid dissipation of size progresses in the first week (Fig. 36-2). Sonographically, the uterus and endometrium return to pregravid size by 8 weeks postpartum (Bae, 2012; Steinkeler, 2012). In a study of 42 normal puerperas, Tekay and Jouppila (1993) identified fluid in the endometrial cavity in 78 percent of women at 2 weeks, 52 percent at 3 weeks, 30 percent at 4 weeks, and 10 percent at 5 weeks. Belachew and coworkers (2012) used three-dimensional sonography and visualized intracavitary tissue matter in a third on day 1, in 95 percent on day 7, in 87 percent on day 14, and in 28 percent on day 28. By day 56, the small cavity was empty. Sohn and associates (1988) described Doppler ultrasound results showing continuously increasing uterine artery vascular resistance during the first 5 days postpartum. Weintraub and colleagues (2013) posited that uterine involution may be different in preeclamptic women because they more likely had early diastolic notches seen on uterine artery velocimetry.

FIGURE 36-2
Sonographic measurements of uterine involution during the first 9 days postpartum. AP = anteroposterior. (Data from Hytten F: The Clinical Physiology of the Puerperium. London, Farrand Press, 1995.)

Decidua and Endometrial Regeneration

Because separation of the placenta and membranes involves the spongy layer, the decidua basalis is not sloughed. The in situ decidua varies markedly in thickness, it has an irregular jagged border, and it is infiltrated with blood, especially at the placental site. Within 2 or 3 days after delivery, the remaining decidua becomes differentiated into two layers. The superficial layer becomes necrotic and is sloughed in the lochia. The basal layer adjacent to the myometrium remains intact and is the source of new endometrium.

Endometrial regeneration is rapid, except at the placental site. Within a week or so, the free surface becomes covered by epithelium, and Sharman (1953) identified fully restored endometrium in all biopsy specimens obtained from the 16th day onward. Histological endometritis is part of the normal reparative process. Moreover, microscopic inflammatory changes characteristic of acute salpingitis are seen in almost half of women between 5 and 15 days, however, these findings are not thought to reflect infection (Andrews, 1951).

Clinical Aspects

Afterpains

Several clinical findings arise with uterine involution. In primiparas, the uterus tends to remain tonically contracted following delivery. In multiparas, it often contracts vigorously at intervals and gives rise to *afterpains*, which are similar to but milder than labor contractions. These are more pronounced as parity increases and worsen when the newborn suckles, likely because of oxytocin release (Holdcroft, 2003). Usually, afterpains decrease in intensity and become mild by the third day. We have encountered unusually severe and persistent afterpains in women with postpartum uterine infections.

Lochia

Early in the puerperium, sloughing of decidual tissue results in a vaginal discharge of variable quantity. The discharge is termed *lochia* and contains erythrocytes, shredded decidua, epithelial cells, and bacteria. For the first few days after delivery, there is blood sufficient to color it red—*lochia rubra.* After 3 or 4 days, lochia becomes progressively pale in color—*lochia serosa.* After approximately the 10th day, because of an admixture of leukocytes and reduced fluid content, lochia assumes a white or yellow-white color—*lochia alba.* The average duration of lochial discharge ranges from 24 to 36 days (Fletcher, 2012). Because of this expected leukocyte component, saline preparations of lochia for microscopic evaluation in cases of suspected puerperal metritis are typically uninformative and not recommended.

Placental Site Involution

Complete extrusion of the placental site takes up to 6 weeks. Immediately after delivery, the placental site is approximately palm-sized. Within hours of delivery, it normally contains many thrombosed vessels that ultimately undergo organization. By the end of the second week, it is 3 to 4 cm in diameter.

Placental site involution is an exfoliation process, which is prompted in great part by undermining of the implantation site by new endometrial proliferation (Williams, 1931). Thus, involution is not simply absorption in situ. Exfoliation consists of both extension and “downgrowth” of endometrium from the margins of the placental site, as well as development of endometrial tissue from the glands and stroma left deep in the decidua basalis after placental separation. Anderson and Davis (1968) concluded that placental site exfoliation results from sloughing of infarcted and necrotic superficial tissues followed by a remodeling process.

Subinvolution

In some cases, uterine involution is hindered because of infection, retained placental fragments, or other causes. Such subinvolution is accompanied by varied intervals of prolonged lochia as well as irregular or excessive uterine bleeding. During bimanual examination, the uterus is larger and softer than would be expected. With bleeding, pelvic sonography may help exclude retained placenta or, less-commonly, vascular malformations as the source (Iraha, 2017). Methylergonovine (Methergine), 0.2 mg orally every 3 to 4 hours for 24 to 48 hours, is recommended by many, but its efficacy is questionable. If there is infection, antimicrobial therapy usually leads to a good response. In an earlier study, Wager and coworkers (1980) reported that a third of these late cases of postpartum metritis are caused by *Chlamydia trachomatis.* For mild infection, empirical therapy with azithromycin or doxycycline usually

prompts resolution regardless of bacterial etiology. At our institution, common oral options taken for 7 to 10 days include doxycycline, 100 mg twice daily; azithromycin, 500 mg twice daily; or ampicillin-clavulanate (Augmentin), 875 mg twice daily. Serious metritis is treated with intravenous broad-spectrum antibiotics listed in Table 37-2.

Another cause of subinvolution is incompletely remodeled uteroplacental arteries (Andrew, 1989; Kavalar, 2012). These noninvoluted vessels are filled with thromboses and lack an endothelial lining. Perivascular trophoblasts are also identified in the vessel walls, which suggests an aberrant interaction between uterine cells and trophoblasts.

Late Postpartum Hemorrhage

Secondary postpartum hemorrhage is defined as bleeding 24 hours to 12 weeks after delivery. Clinically worrisome uterine hemorrhage develops within 1 to 2 weeks in perhaps 1 percent of women. Such bleeding most often is the result of abnormal involution of the placental site. It occasionally is caused by retention of a placental fragment or by a uterine artery pseudoaneurysm. Usually, retained products undergo necrosis with fibrin deposition and may eventually form a so-called *placental polyp.* As the eschar of the polyp detaches from the myometrium, hemorrhage may be brisk. As discussed in Chapter 56 (Von Willebrand Disease), delayed postpartum hemorrhage may also be caused by von Willebrand disease or other inherited coagulopathies (Lipe, 2011).

In our experiences, few women with delayed hemorrhage are found to have retained placental fragments. Thus, we and others do not routinely perform curettage (Lee, 1981). Another concern is that curettage may worsen bleeding by avulsing part of the implantation site. Thus, in a stable patient, if sonographic examination shows an empty cavity, then oxytocin, methylergonovine, or a prostaglandin analogue is given. Suitable dosing is found in Table 20-2. Antimicrobials are added if uterine infection is suspected. If large clots are seen in the uterine cavity with sonography, then *gentle* suction curettage is considered. Otherwise curettage is carried out only if appreciable bleeding persists or recurs after medical management.

URINARY TRACT

Normal pregnancy-induced glomerular hyperfiltration persists during the puerperium but returns to prepregnancy baseline by 2 weeks (Hladunewich, 2004). Dilated ureters and renal pelves return to their prepregnant state by 2 to 8 weeks postpartum. Because of this dilated collecting system, coupled with residual urine and bacteriuria in a traumatized bladder, symptomatic urinary tract infection remains a concern in the puerperium.

Funnell and colleagues (1954) used cystoscopy immediately postpartum and described varying degrees of submucosal hemorrhage and edema. Bladder trauma is associated most closely with labor length and thus to some degree is a normal accompaniment of vaginal delivery. Postpartum, the bladder has an increased capacity and a relative insensitivity to intravesical pressure. Thus, overdistention, incomplete emptying, and excessive residual urine are frequent (Buchanan, 2014; Mulder, 2014). Acute urinary retention is also more common with narcotic analgesia (Kandadai, 2014). Their management is discussed in Perineal Care.

It is unusual for urinary incontinence to manifest during the puerperium. That said, much attention has been given to the potential for subsequent development of urinary incontinence and other pelvic floor disorders in the years following delivery. A more detailed discussion is found in Chapter 30 (Cesarean Delivery Risks).

PERITONEUM AND ABDOMINAL WALL

The broad and round ligaments require considerable time to recover from stretching and loosening during pregnancy. As a result of ruptured elastic fibers in the skin and prolonged distention by the pregnant uterus, the abdominal wall remains soft and flaccid. If the abdomen is unusually flabby or pendulous, an ordinary girdle is often satisfactory. An abdominal binder is another temporary measure. Several weeks are required for these structures to return to normal, and recovery is aided by exercise. These may be started anytime following vaginal delivery. After cesarean delivery, a 6-week interval to allow fascia to heal and abdominal soreness to diminish is reasonable. Silvery abdominal striae commonly develop as *striae gravidarum* (Chap. 4, Breasts). Except for these, the abdominal wall usually resumes its prepregnancy appearance. When muscles remain atonic, however, the abdominal wall also remains lax. Marked separation of the rectus abdominis muscles—*diastasis recti*—may result.

BLOOD AND BLOOD VOLUME

Hematological and Coagulation Changes

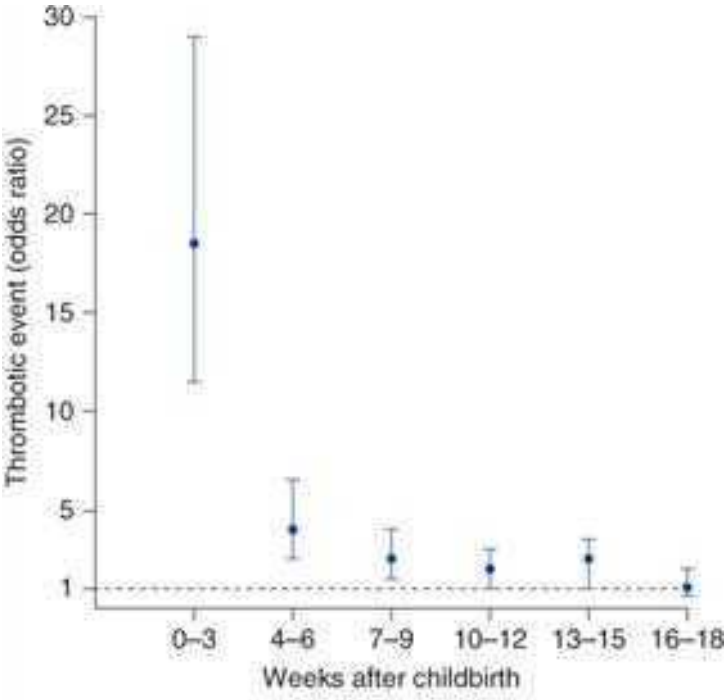
Marked leukocytosis and thrombocytosis may occur during and after labor. The white blood cell count sometimes reaches 30,000/µL, with the increase predominantly due to granulocytes. There is a relative lymphopenia and an absolute eosinopenia. Normally, during the first few postpartum days, hemoglobin concentration and hematocrit fluctuate moderately. We routinely check these on the first postpartum day or earlier if indicated. If they fall much below the levels present just before labor, a considerable amount of blood has been lost.

By the end of pregnancy, laboratory values that assess coagulation are altered (Kenny, 2014). These changes are discussed in Chapter 4 (Leukocytes and Lymphocytes) and listed in the Appendix (Serum and Blood Constituents). Many persist variably in the puerperium. For example, a markedly increased plasma fibrinogen level is maintained at least through the first week and hence so is an elevated sedimentation rate. Hypercoagulability appears to be

greater and is reflected by the likelihood of deep-vein thrombosis and pulmonary embolism in the 12 weeks following childbirth (Kamel, 2014). This is depicted in Figure 36-3 and is discussed further in Chapter 52 (Pathophysiology).

FIGURE 36-3

Risk of deep-vein thrombosis or pulmonary embolism following childbirth. (Data from Kamel H, Navi B, Sriram N, et al: Risk of a Thrombotic Event after the 6-week postpartum period. N Engl J Med 370:1307, 2014.)

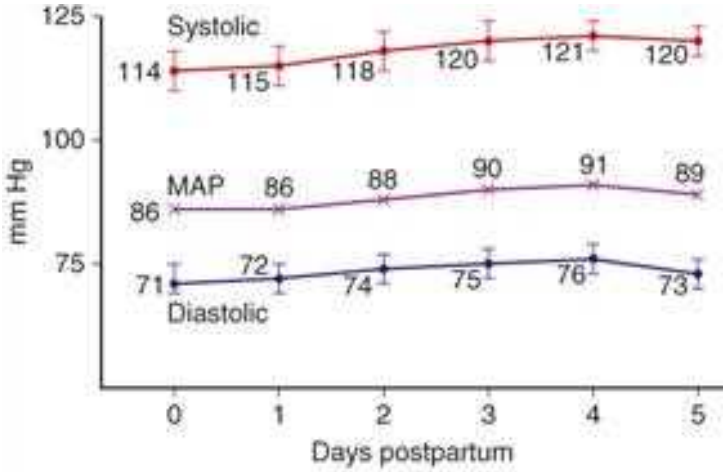


Pregnancy-Induced Hypervolemia

When the amount of blood attained by normal pregnancy hypervolemia is lost as postpartum hemorrhage, the woman almost immediately regains her nonpregnant blood volume (Chap. 41, Definition and Incidence). If less has been lost at delivery, blood volume generally nearly returns to its nonpregnant level by 1 week after delivery. Cardiac output usually remains elevated for 24 to 48 hours postpartum and declines to nonpregnant values by 10 days (Robson, 1987). Heart rate changes follow this pattern, and blood pressure similarly returns to nonpregnant values (Fig. 36-4). Correspondingly, systemic vascular resistance remains in the lower range characteristic of pregnancy for 2 days postpartum and then begins to steadily increase to normal nonpregnant values (Hibbard, 2014). Despite this, Morris and coworkers (2015) found that reduced arterial stiffness persists following pregnancy. They suggest a significant favorable effect of pregnancy on maternal cardiovascular remodeling, which may represent a mechanism by which preeclampsia risk is reduced in subsequent pregnancies.

FIGURE 36-4

During the early puerperium, blood pressure normally rises toward nonpregnant values. MAP = mean arterial pressure.



Postpartum Diuresis

Normal pregnancy is associated with an appreciable increase in extracellular sodium and water retention, and postpartum diuresis is a physiological reversal of this process. Chesley and coworkers (1959) demonstrated a decrease in sodium space of approximately 2 L during the first week postpartum. This also corresponds with loss of residual pregnancy hypervolemia. In preeclampsia, pathological retention of fluid antepartum and its diuresis postpartum may be prodigious (Chap. 40, Long-Term Consequences).

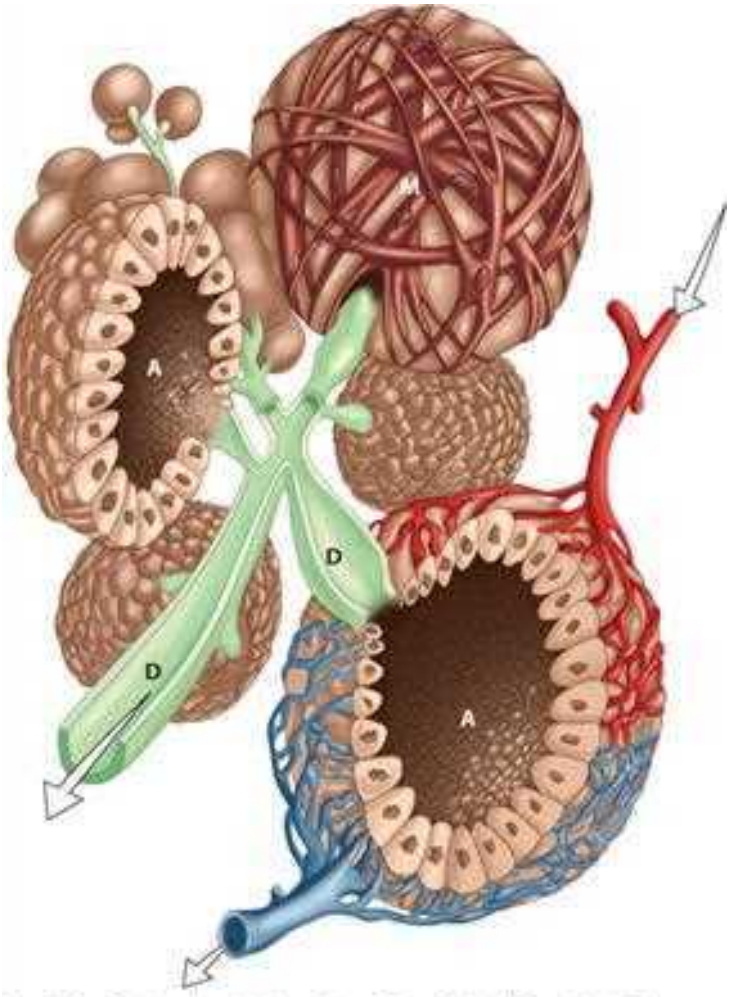
Postpartum diuresis results in relatively rapid weight loss of 2 to 3 kg, which is additive to the 5 to 6 kg incurred by delivery and normal blood loss. Weight loss from pregnancy itself is likely to be maximal by the end of the second week postpartum. It follows that any residual increased weight compared with prepregnancy values probably represents fat stores that will persist. According to Schauberger and associates (1992), women approach their self-reported prepregnancy weight 6 months after delivery but still retain an average surplus of 1.4 kg (3 lb).

LACTATION AND BREASTFEEDING

Breast Anatomy and Secretory Products

Each mature mammary gland or breast is composed of 15 to 25 lobes. They are arranged radially and are separated from one another by varying amounts of fat. Each lobe consists of several lobules, which in turn are composed of numerous alveoli. Each alveolus is provided with a small duct that joins others to form a single larger duct for each lobe as shown in Figure 36-5. These *lactiferous ducts* open separately on the nipple, where they may be distinguished as minute but distinct orifices. The alveolar secretory epithelium synthesizes the various milk constituents.

FIGURE 36-5
Schematic of the alveolar and ductal system during lactation. Note the myoepithelial fibers (*M*) that surround the outside of the uppermost alveolus. The secretions from the glandular elements are extruded into the lumen of the alveoli (*A*) and ejected by the myoepithelial cells into the ductal system (*D*), which empties through the nipple. Arterial blood supply to the alveolus is identified by the upper right arrow and venous drainage by the arrow beneath.



After delivery, the breasts begin to secrete *colostrum*, which is a deep lemon-yellow liquid. It usually can be expressed from the nipples by the second postpartum day. Compared with mature milk, colostrum is rich in immunological components and contains more minerals and amino acids (Ballard,

2013). It also has more protein, much of which is globulin, but less sugar and fat. Secretion persists for 5 days to 2 weeks, with gradual conversion from "transitional" to mature milk by 4 to 6 weeks. The colostrum content of immunoglobulin A (IgA) offers the newborn protection against enteric pathogens. Other host resistance factors found in colostrum and milk include complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes.

Mature milk is a complex and dynamic biological fluid that includes fat, proteins, carbohydrates, bioactive factors, minerals, vitamins, hormones, and many cellular products (Table 36-2). The concentrations and contents of human milk change even during a single feed and are influenced by maternal diet and by newborn age, health, and needs. A nursing mother easily produces 600 mL of milk daily, and maternal gestational weight gain has little impact on its quantity or quality. Milk is isotonic with plasma, and lactose accounts for half of the osmotic pressure. Essential amino acids are derived from blood, and nonessential amino acids are derived in part from blood or synthesized in the mammary gland. Most milk proteins are unique and include alpha-lactalbumin, beta-lactoglobulin, and casein. Fatty acids are synthesized in the alveoli from glucose and are secreted by an apocrine-like process. Most vitamins are found in human milk, but in variable amounts. Vitamin K is virtually absent, and thus, an intramuscular dose is given to the newborn (Chap. 33, Polycythemia and Hyperviscosity). Vitamin D content is low— 22 IU/mL, and newborn supplementation is also recommended by the American Academy of Pediatrics (Wagner, 2008).

TABLE 36-2

Average Composition of Human Breast Milk

Fat	g/100 mL
Total	4.2
Fatty Acids	Trace
PUFA	0.6
Cholesterol	0.016
Protein	g/100 mL
Total	1.1
Casein	0.3
α-Lactalbumin	0.3
Lactoferrin	0.2
Carbohydrate	g/100 mL
Lactose	7
Oligosaccharides	0.5

PUFA = Polyunsaturated fatty acids.

Whey is milk serum and has been shown to contain large amounts of interleukin-6 (Saito, 1991). Human milk has a whey-to-casein ratio of 60:40, considered ideal for absorption. *Prolactin* appears to be actively secreted into breast milk. *Epidermal growth factor (EGF)* has been identified, and because it is not destroyed by gastric proteolytic enzymes, it may be absorbed to promote growth and maturation of newborn intestinal mucosa (McCleary, 1991). Other critical components in human milk include lactoferrin, melatonin, oligosaccharides, and essential fatty acids.

Endocrinology of Lactation

The precise humoral and neural mechanisms involved in lactation are complex. Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the growth and development of the milk-secreting apparatus (Stuebe, 2014). With delivery, the maternal serum levels of progesterone and estrogen decline abruptly and profoundly. This drop removes the inhibitory influence of progesterone on alpha-lactalbumin production and stimulates lactose synthase to increase milk lactose. Progesterone withdrawal also allows prolactin to act unopposed in its stimulation of alpha-lactalbumin production. Activation of calcium-sensing receptors (CaSR) in mammary epithelial cells downregulates parathyroid hormone-related protein (PTHrP) and increases calcium transport into milk (Vanhouten, 2013). Serotonin is also produced in mammary epithelial cells and has a role in maintaining milk production (Collier, 2012).

The intensity and duration of subsequent lactation are controlled, in large part, by the repetitive stimulus of nursing and emptying of milk from the breast. Prolactin is essential for lactation, and women with extensive pituitary necrosis— *Sheehan syndrome*—do not lactate (Chap. 58, Acromegaly). Although plasma prolactin levels fall after delivery to levels lower than during pregnancy, each act of suckling triggers a rise in levels (Pang, 2007). Presumably a stimulus from the breast curtails the release of dopamine, also known as *prolactin-inhibiting factor*, from the hypothalamus. In turn, this transiently induces increased prolactin secretion.

The posterior pituitary secretes oxytocin in pulsatile fashion. This stimulates milk expression from a lactating breast by causing contraction of myoepithelial cells in the alveoli and small milk ducts (see Fig. 36-5). Milk ejection, or *letting down*, is a reflex initiated especially by suckling, which

stimulates the posterior pituitary to liberate oxytocin. The reflex may even be provoked by an infant cry and can be inhibited by maternal fright or stress (Stuebe, 2014).

Immunological Consequences of Breastfeeding

Human milk contains several protective immunological substances, including secretory IgA and growth factors. The antibodies in human milk are specifically directed against maternal environmental antigens such as *Escherichia coli* (Iyengar, 2012). According to the Centers for Disease Control and Prevention (Perrine, 2015), breastfeeding decreases the incidence of ear, respiratory, and gastrointestinal infections; necrotizing enterocolitis; and sudden infant death syndrome.

Much attention has been directed to the role of maternal breast milk lymphocytes in neonatal immunological processes. Milk contains both T and B lymphocytes, but the T lymphocytes appear to differ from those found in blood. Specifically, milk T lymphocytes are almost exclusively composed of cells that exhibit specific membrane antigens. These memory T cells appear to be an avenue for the neonate to benefit from the maternal immunological experience.

Nursing

Human milk is ideal food for newborns in that it provides age-specific nutrients, immunological factors, and antibacterial substances. Milk also contains factors that act as biological signals for promoting cellular growth and differentiation. A list of the advantages of breastfeeding is shown in Table 36-3. For both mother and infant, the benefits of breastfeeding are long-term. For example, women who breastfeed have a lower risk of breast and reproductive cancer, and their children have increased adult intelligence independent of a wide range of possible confounding factors (Jong, 2012; Kramer, 2008). Breastfeeding is associated with decreased postpartum weight retention (Baker, 2008). In addition, rates of sudden-infant-death syndrome are significantly lower among breastfed infants. Bartek and colleagues (2013) estimate that a 90-percent breastfeeding rate for 12 months would save more than $3 billion annually in excess infant and maternal morbidity costs. For all these reasons, the American Academy of Pediatrics (2017) and American College of Obstetricians and Gynecologists (2016a, 2017b) supports the World Health Organization (2011) recommendations of exclusive breastfeeding for up to 6 months.

The Surgeon General of the U.S. Department of Health and Human Services (2011) lists some barriers to breastfeeding and suggests practical means of overcoming them. Educational initiatives that include father and peer counseling may improve these rates (Pisacane, 2005; Wolfberg, 2004). The *Baby Friendly Hospital Initiative* is an international program to increase rates of exclusive breastfeeding and to extend its duration. It is based on the World Health Organization (1989) *Ten Steps to Successful Breastfeeding* (Table 36-4). Worldwide, almost 20,000 hospitals are designated as “baby-friendly,” however, only 10 to 15 percent of hospitals in the United States are so designated (Centers for Disease Control and Prevention, 2014; Perrine, 2015). Forrester-Knauss and coworkers (2013) described successful trends toward exclusive breastfeeding in Switzerland during 9 years in which a Baby-Friendly Hospital Initiative was implemented. In a large population-based study done in the United States, fewer than two thirds of term neonates were exclusively breastfed at the time of discharge (McDonald, 2012).

TABLE 36-4

Ten Steps to Successful Breastfeeding

1. Have a written breastfeeding policy that is regularly communicated to all health-care staff
2. Train all staff in skills necessary to implement this policy
3. Inform all pregnant women about the benefits and management of breastfeeding
4. Help mothers initiate breastfeeding within an hour of birth
5. Show mothers how to breastfeed and how to sustain lactation, even if they should be separated from their infants
6. Feed newborns nothing but breast milk, unless medically indicated, and under no circumstances provide breast milk substitutes, feeding bottles, or pacifiers free of charge or at low cost
7. Practice rooming-in, which allows mothers and newborns to remain together 24 hours a day
8. Encourage breastfeeding on demand
9. Give no artificial pacifiers to breastfeeding newborns
10. Help start breastfeeding support groups and refer mothers to them

Adapted with permission from World Health Organization: Protecting, promoting and supporting breast-feeding: the special role of maternity services. Geneva, World Health Organization, 1989.

Various individual resources available are available for breastfeeding mothers that include online information from the American Academy of Pediatrics (http://www.aap.org) and La Leche League International (http://www.llli.org).

Care of Breasts

The nipples require little attention other than cleanliness and attention to skin fissures. Fissured nipples render nursing painful, and they may have a deleterious influence on milk production. These cracks also provide a portal of entry for pyogenic bacteria. Because dried milk is likely to accumulate and irritate the nipples, washing the areola with water and mild soap is helpful before and after nursing. When the nipples are irritated or fissured, some recommend topical lanolin and a nipple shield for 24 hours or longer. Although specific evidence supporting this practice is lacking, nipple pain usually subsides by 10 days (Dennis, 2014). If fissuring is severe, the newborn should not be permitted to nurse on the affected side. Instead, the breast is emptied regularly with a pump until the lesions are healed. Poor latching of the neonate to the breast can create such fissures. For example, the newborn may take into its mouth only the nipple, which is then is forced against the hard palate during suckling. Ideally, the nipple and areola are both taken in to evenly distribute suckling forces. Moreover, the force of the hard palate against the lactiferous sinuses aids their efficient emptying, while the nipple is thereby positioned closer to the soft palate.

Contraindications to Breastfeeding

Nursing is contraindicated in women who take street drugs or do not control their alcohol use; have an infant with galactosemia; have human immunodeficiency virus (HIV) infection; have active, untreated tuberculosis; take certain medications; or are undergoing breast cancer treatment (American Academy of Pediatrics, 2017; Faupel-Badger, 2013). Breastfeeding has been recognized for some time as a mode of HIV transmission and is proscribed in developed countries in which adequate nutrition is otherwise available. Other viral infections do not contraindicate breastfeeding. For example, with maternal cytomegalovirus infection, both virus and antibodies are present in breast milk. And, although hepatitis B virus is excreted in milk, breastfeeding is not contraindicated if hepatitis B immune globulin is given to the newborns of affected mothers. Maternal hepatitis C infection is not a contraindication because breastfeeding has not been shown to transmit infection (Society for Maternal-Fetal Medicine, 2017). Women with active herpes simplex virus may suckle their infants if there are no breast lesions and if particular care is directed to hand washing before nursing.

Drugs Secreted in Milk

Most drugs given to the mother are secreted in breast milk, although the amount ingested by the infant typically is small. Many factors influence drug excretion and include plasma concentration, degree of protein binding, plasma and milk pH, degree of ionization, lipid solubility, and molecular weight (Rowe, 2013). The ratio of drug concentration in breast milk to that in maternal plasma is the *milk-to-plasma drug-concentration ratio*. Ideally, to minimize infant exposure, medication selection should favor drugs with a shorter half-life, poorer oral absorption, and lower lipid solubility. If multiple daily drug doses are required, then each is taken by the mother *after* the closest feed. Single daily-dosed drugs may be taken just before the longest infant sleep interval—usually at bedtime (Spencer, 2002).

Only a few drugs are absolutely contraindicated while breastfeeding (Berlin, 2013; Bertino, 2012). Cytotoxic drugs may interfere with cellular metabolism and potentially cause immune suppression or neutropenia, affect growth, and at least theoretically, increase the risk of childhood cancer. Examples include cyclophosphamide, cyclosporine, doxorubicin, methotrexate, and mycophenolate. If a medication presents a concern, then the importance of therapy should be ascertained. It should be determined whether there is a safer alternative or whether neonatal exposure can be minimized if the

medication dose is taken immediately after each breastfeeding (American Academy of Pediatrics, 2017). Finally, recreational drugs such as marijuana and alcohol should be avoided (American College of Obstetricians and Gynecologists, 2017a). Data on individual drugs are available through the National Institutes of Health website, LactMed, which can be found at toxnet.nlm.nih.gov.

Radioactive isotopes of copper, gallium, indium, iodine, sodium, and technetium rapidly appear in breast milk. Consultation with a nuclear medicine specialist is recommended before performing a diagnostic study with these isotopes (Chap. 46, Radiographic Contrast Agents). The goal is to use a radionuclide with the shortest excretion time in breast milk. The mother should pump her breasts before the study and store enough milk in a freezer to feed the infant. After the study, she should pump her breasts to maintain milk flow but discard all milk produced during the time that radioactivity is present. This ranges from 15 hours to 2 weeks, depending on the isotope used. Importantly, radioactive iodine concentrates and persists in the thyroid. Its special considerations are discussed in Chapter 63 (Thyroid Cancer).

Breast Engorgement

This is common in women who do not breastfeed. It is typified by milk leakage and breast pain, which peak 3 to 5 days after delivery (Spitz, 1998). Up to half of affected women require analgesia for breast pain relief, and as many as 10 percent report severe pain for up to 14 days.

Evidence is insufficient to firmly support any specific treatment (Mangesi, 2016). That said, breasts can be supported with a well-fitting brassiere, breast binder, or sports bra. Cool packs and oral analgesics for 12 to 24 hours aid discomfort. Pharmacological or hormonal agents are in general not recommended to suppress lactation.

Fever caused by breast engorgement was common before the renaissance of breastfeeding. In one study, Almeida and Kitay (1986) reported that 13 percent of puerperas had fever from engorgement that ranged from 37.8 to 39°C. Fever seldom persists for longer than 4 to 16 hours. The incidence and severity of engorgement and of the fever associated with it are much lower if women breastfeed. Other causes of fever, especially those due to infection, must be excluded. Of these, *mastitis* is infection of the mammary parenchyma. It is relatively common in lactating women and is discussed in Chapter 37 (Breast Infections).

Other Issues with Lactation

With *inverted nipples*, lactiferous ducts open directly into a depression at the center of the areola. With these depressed nipples, nursing is difficult. If the depression is not deep, milk sometimes can be drawn out by a breast pump. If instead the nipple is greatly inverted, daily attempts are made during the last few months of pregnancy to draw or “tease” the nipple out with the fingers.

Extra breasts—*polymastia*, or extra nipples—*polythelia*, may develop along the former embryonic mammary ridge. Also termed the *milk line*, this line extends from the axilla to the groin bilaterally. In some women, rests of accessory breast tissue can be found in the mons pubis or vulva (Wagner, 2013). In the general population, the incidence of accessory breast tissue ranges from 0.22 to 6 percent (Loukas, 2007). These breasts may be so small as to be mistaken for pigmented moles, or if without a nipple, for lymphadenopathy or lipoma. Polymastia has no obstetrical significance, although occasionally enlargement of these accessory breasts during pregnancy or engorgement postpartum may result in patient discomfort and anxiety.

Galactocele is a milk duct that becomes obstructed by inspissated secretions. The amount is ordinarily limited, but an excess may form a fluctuant mass—a galactocele—that may cause pressure symptoms and have the appearance of an abscess. It may resolve spontaneously or require aspiration.

Among individuals, the volume of milk secreted varies markedly. This depends not on general maternal health but on breast glandular development. Rarely, there is complete lack of mammary secretion—*agalactia*. Occasionally, mammary secretion is excessive—*polygalactia*.

HOSPITAL CARE

For 2 hours after delivery, blood pressure and pulse are taken every 15 minutes, or more frequently if indicated. Temperature is assessed every 4 hours for the first 8 hours and then at least every 8 hours subsequently (American Academy of Pediatrics, 2017). The amount of vaginal bleeding is monitored, and the fundus palpated to ensure that it is well contracted. If relaxation is detected, the uterus should be massaged through the abdominal wall until it remains contracted. Uterotonics are also sometimes required. Blood can accumulate within the uterus without external bleeding. This may be detected early by uterine enlargement during fundal palpation in the first postdelivery hours. Because the likelihood of significant hemorrhage is greatest immediately postpartum, even in normal births, the uterus is closely monitored for at least 1 hour after delivery. Postpartum hemorrhage is discussed in Chapter 41 (Uterine Atony). If regional analgesia or general anesthesia was used for labor or delivery, the mother should be observed in an appropriately equipped and staffed recovery area.

Women are out of bed within a few hours after delivery. An attendant should be present for at least the first time, in case the woman becomes syncopal. The many confirmed advantages of early ambulation include fewer bladder complications, less frequent constipation, and reduced rates of puerperal venous thromboembolism. As discussed in Peritoneum and Abdominal Wall, deep-vein thrombosis and pulmonary embolism are common in the puerperium (see Fig. 36-3). In an audit of puerperal women at Parkland Hospital, the frequency of venous thromboembolism was found to be 0.008

percent after a vaginal birth and 0.04 percent following cesarean delivery. We attribute this low incidence to early ambulation. Risk factors and other measures to diminish the frequency of thromboembolism are discussed in Chapter 52 (Pathophysiology).

There are no dietary restrictions for women who have been delivered vaginally. Two hours after uncomplicated vaginal delivery, a woman is allowed to eat. With breastfeeding, the level of calories and protein consumed during pregnancy are increased slightly as recommended by the Food and Nutrition Board of the National Research Council (Chap. 9, Dietary Reference Intakes—Recommended Allowances). If the mother does not breastfeed, dietary requirements are the same as for a nonpregnant woman. We recommend oral iron supplementation for at least 3 months after delivery and hematocrit evaluation at the first postpartum visit.

As noted earlier, profound drops in estrogen levels follow removal of the placenta. Reminiscent of the menopause, postpartum women may experience hot flushes, especially at night. Importantly, the patient's temperature is assessed to differentiate these physiological vasomotor events from infection.

In women with migraines, dramatic hypoestrogenism may trigger headaches. Importantly, severe headaches should be differentiated from spinal headache or hypertensive complications. Care varies depending on migraine severity. Mild headaches may respond to analgesics such as ibuprofen or acetaminophen. Alternatively, Midrin combines isometheptene mucate, which is a sympathomimetic agent; dichloralphenazone, which is a mild sedative; and acetaminophen and is compatible with breastfeeding. For more severe headaches, oral or systemic narcotics can be used. Instead of Midrin, a triptan, such as sumatriptan (Imitrex), can effectively relieve headaches by causing intracranial vasoconstriction.

Perineal Care

The woman is instructed to clean the vulva from anterior to posterior—the vulva toward the anus. A cool pack applied to the perineum may help reduce edema and discomfort during the first 24 hours if there is a perineal laceration or an episiotomy. Most women also appear to obtain a measure of relief from the periodic application of a local anesthetic spray. *Severe perineal, vaginal, or rectal pain always warrants careful inspection and palpation*. Severe discomfort usually indicates a problem, such as a hematoma within the first day or so and infection after the third or fourth day (Chap. 37, Perineal Infections and Chap. 41, Puerperal Hematomas). Beginning approximately 24 hours after delivery, moist heat as provided by warm sitz baths can be used to reduce local discomfort. Tub bathing after uncomplicated delivery is allowed. The episiotomy incision normally is firmly healed and nearly asymptomatic by the third week.

Rarely, the cervix, and occasionally a portion of the uterine body, may protrude from the vulva following delivery. This is accompanied by variable degrees of anterior and posterior vaginal wall prolapse. Symptoms include a palpable mass at or past the introitus, voiding difficulties, or pressure. Puerperal procidentia typically improves with time as the weight of the uterus lessens with involution. As a temporizing measure in those with pronounced prolapse, the uterus can be replaced and held in position with a suitable pessary.

Hemorrhoidal veins are often congested at term. Thrombosis is common and may be promoted by second-stage pushing. Treatment includes topically applied anesthetics, warm soaks, and stool-softening agents. Nonprescription topical preparations containing corticosteroids, astringents, or phenylephrine are often used, but no randomized studies support their efficacy compared with conservative management.

Bladder Function

In most delivery units, intravenous fluids are infused during labor and for an hour or so after delivery. Oxytocin, in doses that have an antidiuretic effect, is typically infused postpartum, and rapid bladder filling is common. Moreover, both bladder sensation and capability to empty spontaneously may be diminished by local or conduction analgesia, by trauma to the bladder, by episiotomy or lacerations, or by operative vaginal delivery. Thus, urinary retention and bladder overdistention is common in the early puerperium. The incidence in more than 5500 women studied with a bladder scanner was 5.1 percent (Buchanan, 2014). In another study, Musselwhite and coworkers (2007) reported retention in 4.7 percent of women who had labor epidural analgesia. Risk factors that increased the likelihood of retention were primiparity, cesarean delivery, perineal laceration, oxytocin-induced or augmented labor, operative vaginal delivery, catheterization during labor, and labor duration >10 hours.

Prevention of bladder overdistention demands observation after delivery to ensure that the bladder does not overfill and that it empties adequately with each voiding. The enlarged bladder can be palpated suprapubically, or it is evident abdominally indirectly as it elevates the fundus above the umbilicus. The use of an automated bladder scanner sonography system has been studied to detect high bladder volumes and thus postpartum urinary retention (Buchanan, 2014; Van Os, 2006).

If a woman has not voided within 4 hours after delivery, it is likely that she cannot. If she has trouble voiding initially, she also is likely to have further trouble. An examination for perineal and genital-tract hematomas is completed. With an overdistended bladder, an indwelling catheter should be left in place until the factors causing retention have abated. Even without a demonstrable cause, it usually is best to leave the catheter in place for at least 24 hours. This prevents recurrence and allows recovery of normal bladder tone and sensation.

When the catheter is removed, a voiding trial is completed to demonstrate an ability to void appropriately. If a woman cannot void after 4 hours, she should be catheterized and the urine volume measured. If more than 200 mL, the bladder is not functioning appropriately, and the catheter is left for

another 24 hours. Although rare, if retention persists after a second voiding trial, an indwelling catheter and leg bag can be elected, and the patient returns in 1 week for an outpatient voiding trial. Intermittent self-catheterization is another option (Mulder, 2017).

During a voiding trial, if less than 200 mL of urine is obtained, the catheter can be removed and the bladder subsequently monitored clinically as described earlier. Harris and coworkers (1977) reported that 40 percent of such women develop bacteriuria, and thus a single dose or short course of antimicrobial therapy against uropathogens is reasonable after the catheter is removed.

Pain, Mood, and Cognition

Discomfort and its causes following cesarean delivery are considered in Chapter 30 (Postoperative Care). During the first few days after vaginal delivery, the mother may be uncomfortable because of afterpains, episiotomy and lacerations, breast engorgement, and at times, postdural puncture headache. Mild analgesics containing codeine, aspirin, or acetaminophen, preferably in combinations, are given as frequently as every 4 hours during the first few days.

It is important to screen the postpartum woman for depression (American College of Obstetricians and Gynecologists, 2016b). It is fairly common for a mother to exhibit some degree of depressed mood a few days after delivery. Termed *postpartum blues,* this likely is the consequence of several factors. These include emotional letdown that follows the excitement and fears experienced during pregnancy and delivery, discomforts of the early puerperium, fatigue from sleep deprivation, anxiety over the ability to provide appropriate newborn care, and body image concerns. In most women, effective treatment includes anticipation, recognition, and reassurance. This disorder is usually mild and self-limited to 2 to 3 days, although it sometimes lasts for up to 10 days. Should these moods persist or worsen, an evaluation for symptoms of major depression is done (Chap. 61, Postpartum Depression). Suicidal or infanticidal ideation is dealt with emergently. Because major postpartum depression recurs in at least a fourth of women in subsequent pregnancies, some recommend pharmacological prophylaxis beginning in late pregnancy or immediately postpartum.

Last, postpartum hormonal changes in some women may affect brain function. Bannbers and colleagues (2013) compared a measure of executive function in postpartum women and controls and observed a functional decline in postpartum subjects.

Neuromusculoskeletal Problems

Obstetrical Neuropathies

Pressure on branches of the lumbosacral nerve plexus during labor may manifest as complaints of intense neuralgia or cramp- like pains extending down one or both legs as soon as the head descends into the pelvis. If the nerve is injured, pain may continue after delivery, and variable degrees of sensory loss or muscle paralysis can result. In some cases, there is footdrop, which can be secondary to injury at the level of the lumbosacral plexus, sciatic nerve, or common fibular (peroneal) nerve (Bunch, 2014). Components of the lumbosacral plexus cross the pelvic brim and can be compressed by the fetal head or by forceps. The common fibular nerves may be externally compressed when the legs are positioned in stirrups, especially during prolonged second-stage labor.

Obstetrical neuropathy is relatively infrequent. Wong and associates (2003) evaluated more than 6000 puerperas and found that approximately 1 percent had a confirmed nerve injury. Lateral femoral cutaneous neuropathies were the most common (24 percent), followed by femoral neuropathies (14 percent). A motor deficit accompanied a third of injuries. Nulliparity, prolonged second-stage labor, and pushing for a long duration in the semi-Fowler position were risk factors. The median duration of symptoms was 2 months, and the range was 2 weeks to 18 months.

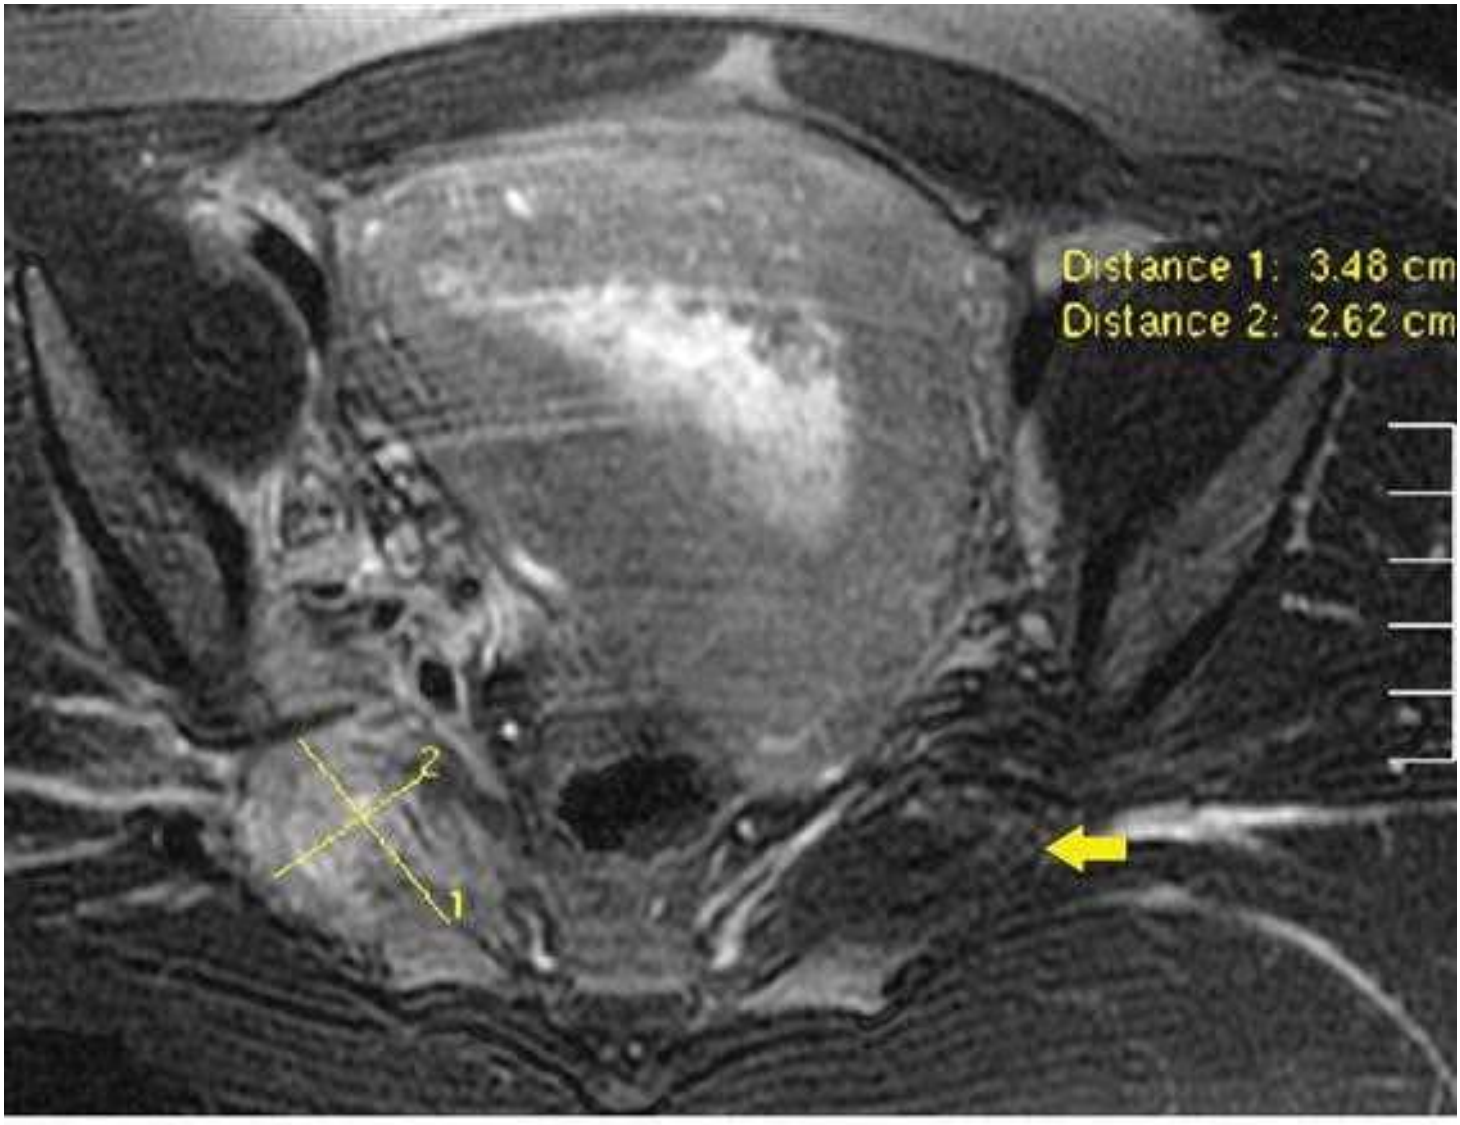
Nerve injuries with cesarean delivery include the iliohypogastric and ilioinguinal nerves (Rahn, 2010). These are discussed further in Chapter 2 (Innervation).

Musculoskeletal Injuries

Pain in the pelvic girdle, hips, or lower extremities may follow stretching or tearing injuries sustained at normal or difficult delivery. Magnetic resonance (MR) imaging is often informative (Miller, 2015). One example is the piriformis muscle hematoma shown in Figure 36-6. Most injuries resolve with antiinflammatory agents and physical therapy. Rarely, there may be septic pyomyositis such as with iliopsoas muscle abscess (Nelson, 2010; Young, 2010).

FIGURE 36-6

Inhomogeneous mass of the right piriformis muscle consistent with a hematoma (*yellow cursor measurements*) is compared with the normal-appearing left piriformis muscle (*yellow arrow*).



Separation of the symphysis pubis or one of the sacroiliac synchondroses during labor leads to pain and marked interference with locomotion (Fig. 36-7). Estimates of the frequency of this event vary widely from 1 in 600 to 1 in 30,000 deliveries (Reis, 1932; Taylor, 1986). In our experiences, symptomatic separations are uncommon. Their onset of pain is often acute during delivery, but symptoms may manifest either antepartum or up to 48 hours postpartum (Snow, 1997). In suspected cases, radiography is typically selected. The normal distance of the symphyseal joint is 0.4 to 0.5 cm, and symphyseal separation >1 cm is diagnostic for diastasis. Treatment is generally conservative, with rest in a lateral decubitus position and an appropriately fitted pelvic binder (Lasbleiz, 2017). Surgery is occasionally necessary in some symphyseal separations of more than 4 cm (Kharrazi, 1997). The recurrence risk is high in subsequent pregnancy, and Culligan and coworkers (2002) recommend consideration for cesarean delivery.

FIGURE 36-7

Pubic symphyseal separation found on the first postpartum day following vaginal delivery of a 2840-g newborn. The patient had pain over the pubic bone and pain with ambulation. A shuffling gait was noted, and she had difficulty with leg elevation when supine. The patient was treated with physical therapy and analgesics. A pelvic binder was applied, and a rolling walker was provided. She improved quickly and was discharged home on postoperative day 5.

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

In rare cases, fractures of the sacrum or pubic ramus are caused by even uncomplicated deliveries (Alonso-Burgos, 2007; Speziali, 2015). As discussed in Chapter 58 (Hypoparathyroidism), the latter are more likely with osteoporosis associated with heparin or corticosteroid therapy (Cunningham, 2005). In rare but serious cases, bacterial osteomyelitis—*osteitis pubis*—can be devastating. Lawford and coworkers (2010) reported such a case that caused massive vulvar edema.

Immunizations

The D-negative woman who is not isoimmunized and whose newborn is D-positive is given 300 µg of anti-D immune globulin shortly after delivery (Chap. 15, Prevention of Anti-D Alloimmunization). Women who are not already immune to rubella or varicella are excellent candidates for vaccination before discharge (Swamy, 2015). Those who have not received a tetanus/diphtheria or influenza vaccine should be given these (American College of Obstetricians and Gynecologists, 2017c). Morgan and colleagues (2015) reported that implementation of a best-practices alert in the electronic medical record was associated with a tetanus/diphtheria immunization rate of 97 percent at Parkland Hospital. Vaccination is also discussed in Chapter 9 (Automobile and Air Travel).

Hospital Discharge

Following uncomplicated vaginal delivery, hospitalization is seldom warranted for more than 48 hours. A woman should receive instructions concerning anticipated normal physiological puerperal changes, including lochia patterns, weight loss from diuresis, and milk let-down. She also should receive instructions concerning fever, excessive vaginal bleeding, or leg pain, swelling, or tenderness. Persistent headaches, shortness of breath, or chest pain warrant immediate concern.

Hospital-stay length following labor and delivery is now regulated by federal law (Chap. 32, Rooming In and Hospital Discharge). Currently, the norms are hospital stays up to 48 hours following uncomplicated vaginal delivery and up to 96 hours following uncomplicated cesarean delivery (American Academy

of Pediatrics, 2017; Blumenfield, 2015). Earlier hospital discharge is acceptable for appropriately selected women if they desire it.

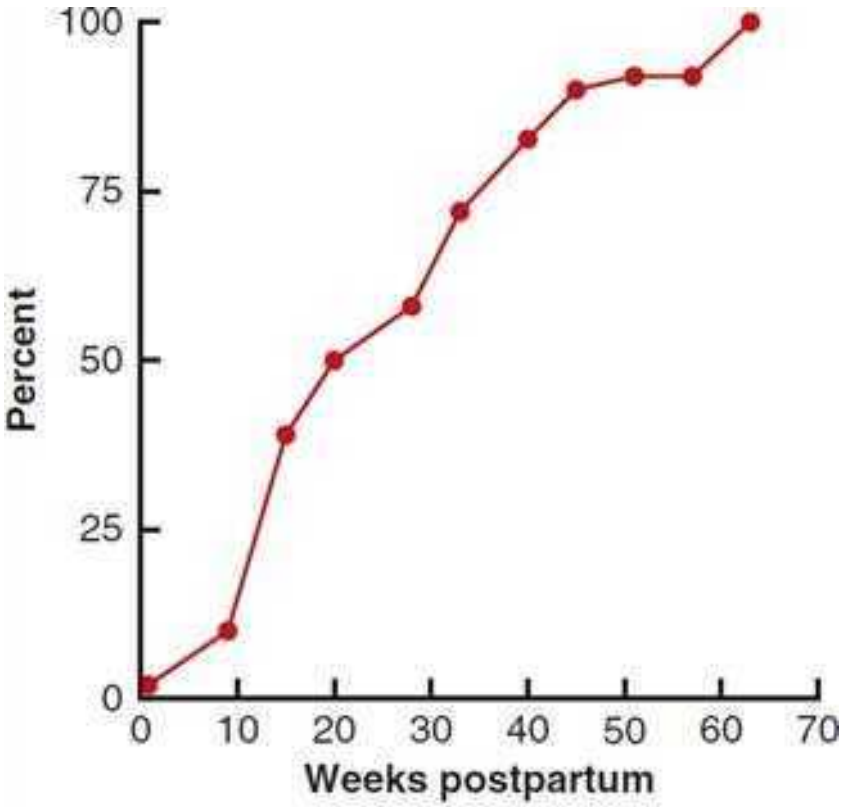
Contraception

During the hospital stay, a concerted effort is made to provide family planning education. Various forms of contraception are discussed throughout Chapter 38 and sterilization procedures in Chapter 39.

Women not breastfeeding have return of menses usually within 6 to 8 weeks. At times, however, it is difficult clinically to assign a specific date to the first menstrual period after delivery. A minority of women bleed small to moderate amounts intermittently, starting soon after delivery. Ovulation occurs at a mean of 7 weeks, but ranges from 5 to 11 weeks (Perez, 1972). That said, ovulation before 28 days has been described (Hytten, 1995). Thus, conception is possible during the artificially defined 6-week puerperium. *Women who become sexually active during the puerperium, and who do not desire to conceive, should initiate contraception*. Kelly and associates (2005) reported that by the third month postpartum, 58 percent of adolescents had resumed sexual intercourse, but only 80 percent of these were using contraception. Because of this, many recommend long-acting reversible contraceptives—LARC (Baldwin, 2013).

Women who breastfeed ovulate much less frequently compared with those who do not, but variation is great. Timing of ovulation depends on individual biological variation and the intensity of breastfeeding. Lactating women may first menstruate as early as the second or as late as the 18th month after delivery. Campbell and Gray (1993) analyzed daily urine specimens to determine the time of ovulation in 92 lactating women. As shown in Figure 36-8, breastfeeding in general delays resumption of ovulation, although as already emphasized, it does not invariably forestall it. Other findings in their study included the following:

FIGURE 36-8
Cumulative proportion of breastfeeding women who ovulated during the first 70 weeks following delivery. (Data from Campbell OM, Gray RH: Characteristics and determinants of postpartum ovarian function in women in the United States. Am J Obstet Gynecol 169:55, 1993.)



1. Resumption of ovulation was frequently marked by return of normal menstrual bleeding.
2. Breastfeeding episodes lasting 15 minutes seven times daily delayed ovulation resumption.
3. Ovulation can occur without bleeding.
4. Bleeding can be anovulatory.
5. The risk of pregnancy in breastfeeding women was approximately 4 percent per year.

For the breastfeeding woman, progestin-only contraceptives, such as progestin pills, depot medroxyprogesterone, or progestin implants, do not affect the quality or quantity of milk. Success with the progesterone-releasing vaginal ring has also been described (Carr, 2016). These may be initiated any time during the puerperium. Estrogen-progestin contraceptives likely reduce the quantity of breast milk, but under the proper circumstances, they too can be used by breastfeeding women. These hormonal methods are discussed in Chapter 38.

HOME CARE

Coitus

No evidence-based data guide resumption of coitus after delivery, and practices are individualized (Minig, 2009). After 2 weeks, coitus may be resumed *based on desire and comfort.* Barrett and colleagues (2000) reported that almost 90 percent of 484 primiparous women resumed sexual activity by 6 months. And although 65 percent of these reported problems, only 15 percent discussed them with a health-care provider.

Intercourse too soon may be unpleasant, if not frankly painful, and this may be related to episiotomy incisions or severe lacerations. In a study of women without an episiotomy, only 0.4 percent of those with a first- or second-degree tear had dyspareunia (Ventolini, 2014). Conversely, in primiparas with an episiotomy, 67 percent had sexual dysfunction at 3 months, 31 percent at 6 months, and 15 percent at 12 months (Chayachinda, 2015). Dyspareunia was also common following cesarean delivery (McDonald, 2015).

Postpartum, the vulvovaginal epithelium is thin, and very little lubrication follows sexual stimulation. This stems from the hypoestrogenic state following delivery, which lasts until ovulation resumes. It may be particularly problematic in breastfeeding women who are hypoestrogenic for many months postpartum (Palmer, 2003). For treatment, small amounts of topical estrogen cream can be applied daily for several weeks to vulvar tissues. Additionally, vaginal lubricants may be used with coitus.

This same thinning of the vulvovaginal epithelium can lead to dysuria. Topical estrogen can again be offered once cystitis is excluded.

Late Maternal Morbidity

Taken together, major and minor maternal morbidity are surprisingly common in the months following childbirth. In a survey of 1249 British mothers followed for up to 18 months, 3 percent required hospital readmission within 8 weeks (Glazener, 1995; Thompson, 2002). Milder health problems during the first 8 weeks were reported by 87 percent (Table 36-5). Moreover, almost three fourths continued to have various problems for up to 18 months. Practitioners should be aware of these potential issues in their convalescing patients.

TABLE 36-5

Puerperal Morbidity Reported by 8 Weeks

Morbidity	Percent[a]
Fatigue	59
Breast problems	36
Anemia	25
Backache	24
Hemorrhoids	23
Headache	22
“Blues”	21
Constipation	20
Suture breakdown	16
Vaginal discharge	15

[a]In 87 percent of all women, at least one symptom was reported.

Data from Glazener CM, Abdalla M, Stroud P, et al: Postnatal maternal morbidity: extent, causes, prevention and treatment. BJOG 102:282, 1995.

Follow-Up Care

By discharge, women who had an uncomplicated vaginal delivery can resume most activities, including bathing, driving, and household functions. Jimenez and Newton (1979) tabulated cross-cultural information on 202 societies from various international geographical regions. Following childbirth, most societies did not restrict work activity, and approximately half expected a return to full duties within 2 weeks. Wallace and coworkers (2013) reported that 80 percent of women who worked during pregnancy resume work by 1 year after delivery. Despite this, Tulman and Fawcett (1988) reported that only half of mothers regained their usual level of energy by 6 weeks. Women who delivered vaginally were twice as likely to have normal energy levels at this time compared with those with a cesarean delivery. Ideally, the care and nurturing of the infant should be provided by the mother with ample help from the father.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend a postpartum visit between 4 and 6 weeks. This has proven quite satisfactory to identify abnormalities beyond the immediate puerperium and to initiate contraceptive practices.

CHAPTER 37: Puerperal Complications

One cannot fail to be impressed with the very large proportion of patients whose troubles have originated from febrile affections during the puerperium, which in many cases were clearly due to the neglect of aseptic precautions on the part of the obstetrician or midwife.

—J. Whitridge Williams (1903)

INTRODUCTION

Although the woman who recently gave birth is susceptible to several potentially serious complications, pelvic infection continues to be the most important source of maternal morbidity and mortality. Other infections include mastitis and breast abscesses. That said, puerperal complications include many of those encountered during pregnancy. For example, as discussed in Chapter 52 (Pathophysiology), venous thromboembolism during the short 6-week puerperium is as frequent as during all 40 antepartum weeks. Other puerperal issues and care are discussed in Chapter 36.

PUERPERAL PELVIC INFECTION

Traditionally, the term *puerperal infection* describes any bacterial infection of the genital tract after delivery. These infections as well as preeclampsia and obstetrical hemorrhage formed the lethal triad of maternal death causes before and during the 20th century. Fortunately, because of effective antimicrobials, maternal mortality from infection has become uncommon. Creanga and associates (2017) reported results from the Pregnancy Mortality Surveillance System, which contained 2009 pregnancy-related maternal deaths in the United States from 2011 through 2013. Infection caused 12.7 percent of pregnancy-related deaths and was the second leading cause. In a similar analysis of the North Carolina population from 1991 through 1999, Berg and colleagues (2005) reported that 40 percent of infection-related maternal deaths were preventable.

Puerperal Fever

Several infective and noninfective factors can cause puerperal fever—a temperature of 38.0°C (100.4°F) or higher. *Most persistent fevers after childbirth are caused by genital tract infection.* Using this conservative definition of fever, Filker and Monif (1979) reported that only about 20 percent of women febrile within the first 24 hours after vaginal delivery were subsequently diagnosed with pelvic infection. This was in contrast to 70 percent of those after cesarean delivery. It must be emphasized that spiking fevers of 39°C or higher that develop within the first 24 hours postpartum may be associated with virulent pelvic infection caused by group A streptococcus, discussed in Uterine Infection.

Other causes of puerperal fever include breast engorgement; infections of the urinary tract, of perineal lacerations, and of episiotomy or abdominal incisions; and respiratory complications after cesarean delivery (Maharaj, 2007). Approximately 15 percent of women who do not breastfeed develop postpartum fever from *breast engorgement*. As discussed in Chapter 36 (Hospital Care), the incidence of fever is lower in breastfeeding women. “Breast fever” rarely exceeds 39°C in the first few postpartum days and usually lasts <24 hours. *Urinary infections* are uncommon postpartum because of the normal diuresis encountered then. *Acute pyelonephritis* has a variable clinical picture. The first sign of renal infection may be fever, followed later by costovertebral angle tenderness, nausea, and vomiting. *Atelectasis* following abdominal delivery is caused by hypoventilation and is best prevented by coughing and deep breathing on a fixed schedule following surgery. Fever associated with atelectasis is thought to stem from normal flora that proliferate distal to obstructing mucus plugs.

Uterine Infection

Postpartum uterine infection or puerperal sepsis has been called variously *endometritis, endomyometritis,* and *endoparametritis.* Because infection involves not only the decidua but also the myometrium and parametrial tissues, we prefer the inclusive term *metritis with pelvic cellulitis.*

Predisposing Factors

The route of delivery is the single most significant risk factor for the development of uterine infection (Burrows, 2004; Koroukian, 2004). In the French Confidential Enquiry on Maternal Deaths, Deneux-Tharaux and coworkers (2006) cited a nearly 25-fold increased infection-related mortality rate with cesarean versus vaginal delivery. Rehospitalization rates for wound complications and metritis were increased significantly in women undergoing a planned primary cesarean delivery compared with those having a planned vaginal birth (Declercq, 2007).

Women delivered vaginally at Parkland Hospital have a 1- to 2-percent incidence of metritis. For women at high risk for infection because of membrane rupture, prolonged labor, and multiple cervical examinations, the frequency of metritis after vaginal delivery is 5 to 6 percent. If intrapartum chorioamnionitis is present, the risk of persistent uterine infection increases to 13 percent (Maberry, 1991). These figures are similar to those reported from a cohort of more than 115,000 women by the Maternal Fetal Medicine Units Network in whom the overall pelvic infection rate approximated 5 percent (Grobman, 2015).

Because of the significant morbidity following hysterotomy, single-dose perioperative antimicrobial prophylaxis is recommended for all women undergoing cesarean delivery (American College of Obstetricians and Gynecologists, 2016b). Antimicrobial prophylaxis has done more to decrease the incidence and severity of

postcesarean delivery infections than any other intervention in the past 30 years. Such practices decrease the puerperal pelvic infection risk by 65 to 75 percent (Smaill, 2010).

The magnitude of the risk is exemplified from earlier reports that predate antimicrobial prophylaxis. Cunningham and associates (1978) described an overall incidence of 50 percent in all women undergoing cesarean delivery at Parkland Hospital. Important risk factors for infection following surgery included prolonged labor, membrane rupture, multiple cervical examinations, and internal fetal monitoring. Women with all these factors who were not given perioperative prophylaxis had a 90-percent serious postcesarean delivery pelvic infection rate (DePalma, 1982).

It is generally accepted that pelvic infection is more frequent in women of lower socioeconomic status (Maharaj, 2007). Except in extreme cases usually not seen in this country, it is likely uncommon that anemia or poor nutrition predispose to infection. *Bacterial colonization* of the lower genital tract with certain microorganisms—for example, group B streptococcus, *Chlamydia trachomatis, Mycoplasma hominis, Ureaplasma urealyticum*, and *Gardnerella vaginalis*—has been associated with an increased postpartum infection risk (Andrews, 1995; Jacobsson, 2002; Watts, 1990). Other factors associated with an increased infection risk include general anesthesia, cesarean delivery for multifetal gestation, young maternal age and nulliparity, prolonged labor induction, obesity, and meconium-stained amnionic fluid (Acosta, 2012; Leth, 2011; Siriwachirachai, 2014; Tsai, 2011).

Microbiology

Most female pelvic infections are caused by bacteria indigenous to the genital tract. Over the past 25 years, there have been reports of group A β-hemolytic streptococcus causing toxic shock-like syndrome and life-threatening infection (Castagnola, 2008; Nathan, 1994). Prematurely ruptured membranes are a prominent risk factor in these infections (Anteby, 1999). In reviews by Crum (2002) and Udagawa (1999) and their colleagues, women in whom group A streptococcal infection was manifested before, during, or within 12 hours of delivery had a maternal mortality rate of almost 90 percent and fetal mortality rate >50 percent. In the past 10 years, skin and soft-tissue infections due to community-acquired methicillin-resistant *Staphylococcus aureus (CA-MRSA)* have become common (Chap. 64, Listeriosis). Although this variant is not a frequent cause of puerperal metritis, it is often implicated in abdominal incisional infections (Anderson, 2007; Patel, 2007). Rotas and coworkers (2007) reported a woman with episiotomy cellulitis from CA-MRSA and hematogenously spread necrotizing pneumonia.

Common Pathogens

Bacteria responsible for most female genital tract infections are listed in Table 37-1. Most of these infections are polymicrobial, which enhances bacterial synergy. Other factors that promote virulence are hematomas and devitalized tissue. Although the cervix and vagina routinely harbor such bacteria, the uterine cavity is usually sterile before rupture of the amnionic sac. As the consequence of labor and delivery and associated manipulations, the amnionic fluid and uterus become contaminated with anaerobic and aerobic bacteria. Intraamnionic cytokines and C-reactive protein are also markers of infection (Combs, 2013; Marchocki, 2013). In studies done before the use of antimicrobial prophylaxis, Gilstrap and Cunningham (1979) cultured amnionic fluid obtained at cesarean delivery in women in labor with membranes ruptured more than 6 hours. All had bacterial growth, and on average, each specimen contained 2.5 organisms. Anaerobic and aerobic organisms were identified in 63 percent, anaerobes alone in 30 percent, and aerobes alone in only 7 percent. Anaerobes included *Peptostreptococcus* and *Peptococcus* species in 45 percent, *Bacteroides* species in 9 percent, and *Clostridium* species in 3 percent. Aerobes included *Enterococcus* in 14 percent, group B streptococcus in 8 percent, and *Escherichia coli* in 9 percent of isolates. Sherman and coworkers (1999) later showed that bacterial isolates at cesarean delivery correlated with those taken from women with metritis at 3 days postpartum. Group B streptococci, *E coli*, and enterococci are some of the more common blood culture isolates with metritis (Cape, 2013; O'Higgins, 2014). Although important because of the severity of infections they cause, clostridial species rarely cause puerperal infections (Chong, 2016).

TABLE 37-1

Bacteria Commonly Responsible for Female Genital Infections

Aerobes
Gram-positive cocci—group A, B, and D streptococci, enterococcus, *Staphylococcus aureus, Staphylococcus epidermidis*
Gram-negative bacteria—*Escherichia coli, Klebsiella, Proteus*
Gram-variable—*Gardnerella vaginalis*
Others
Mycoplasma and *Chlamydia, Neisseria gonorrhoeae*
Anaerobes
Cocci—*Peptostreptococcus* and *Peptococcus* species
Others—*Clostridium, Bacteroides, Fusobacterium, Mobiluncus*

The role of other organisms in the etiology of these infections is unclear. Observations of Chaim and colleagues (2003) suggest that when cervical colonization of *U urealyticum* is heavy, it may contribute to the development of metritis. To add evidence to these observations, Tita and associates (2016) recently reported that azithromycin-based extended-spectrum antimicrobial prophylaxis reduced postoperative cesarean delivery infections from 12 to 6 percent compared with β-lactam

agents given alone. Chlamydial infections have been implicated in late-onset, indolent metritis (Ismail, 1985). Finally, Jacobsson and associates (2002) reported a threefold risk of puerperal infection in a group of Swedish women in whom bacterial vaginosis was identified in early pregnancy (Chap. 65, Vaginitis).

Bacterial Cultures

Routine genital tract cultures obtained before treatment serve little clinical use and add significant costs. Similarly, routine blood cultures seldom modify care. In two earlier studies done before perioperative prophylaxis was used, blood cultures were positive in 13 percent of women with postcesarean metritis at Parkland Hospital and 24 percent in those at Los Angeles County Hospital (Cunningham, 1978; DiZerega, 1979). In a later Finnish study, Kankuri and associates (2003) identified bacteremia in only 5 percent of almost 800 women with puerperal sepsis. Blood cultures might be reasonable in women with exceedingly high temperature spikes that may signify virulent infection with group A streptococci.

Pathogenesis and Clinical Course

Puerperal infection following vaginal delivery primarily involves the placental implantation site, decidua and adjacent myometrium, or cervicovaginal lacerations. The pathogenesis of uterine infection following cesarean delivery is that of an infected surgical incision. Bacteria that colonize the cervix and vagina gain access to amnionic fluid during labor. Postpartum, they invade devitalized uterine tissue. Parametrial cellulitis next follows with infection of the pelvic retroperitoneal fibroareolar connective tissue. With early treatment, infection is contained within the parametrial and paravaginal tissue, but it may extend deeply into the pelvis.

Fever is the most important criterion for the diagnosis of postpartum metritis. Intuitively, the degree of fever is believed proportional to the extent of infection and sepsis syndrome. Temperatures commonly are 38 to 39°C. Chills that accompany fever suggest bacteremia or endotoxemia. Women usually complain of abdominal pain, and parametrial tenderness is elicited on abdominal and bimanual examination. Leukocytosis may range from 15,000 to 30,000 cells/μL, but recall that delivery itself increases the leukocyte count (Hartmann, 2000). Although an offensive odor may develop, many women have foul-smelling lochia without evidence for infection, and vice versa. Some other infections, notably those caused by group A β-hemolytic streptococci, may be associated with scant, odorless lochia (Anderson, 2014).

Treatment

If nonsevere metritis develops following vaginal delivery, then treatment with an oral or intramuscular antimicrobial agent may be sufficient (Meaney-Delman, 2015). For moderate to severe infections, however, intravenous therapy with a broad-spectrum antimicrobial regimen is indicated. Improvement follows in 48 to 72 hours in nearly 90 percent of women treated with one of several regimens discussed below. Persistent fever after this interval mandates a careful search for causes of refractory pelvic infection. These include a parametrial phlegmon—an area of intense cellulitis; an abdominal incisional or pelvic abscess or infected hematoma; and septic pelvic thrombophlebitis. In our experience, persistent fever is seldom due to antimicrobial-resistant bacteria or due to drug side effects. The woman may be discharged home after she has been afebrile for at least 24 hours, and further oral antimicrobial therapy is not needed (French, 2004; Mackeen, 2015).

Choice of Antimicrobials

Although therapy is empirical, initial treatment following cesarean delivery is directed against elements of the mixed flora shown in Table 37-1. For infections following vaginal delivery, as many as 90 percent of women respond to regimens such as ampicillin plus gentamicin. In contrast, anaerobic coverage is included for infections following cesarean delivery (Table 37-2).

TABLE 37-2

Antimicrobial Regimens for Pelvic Infections Following Cesarean Delivery

Regimen	Comments
Clindamycin + gentamicin	"Gold standard," 90–97% efficacy, once-daily gentamicin dosing acceptable ***PLUS*** Ampicillin added to regimen with sepsis syndrome or suspected enterococcal infection
Clindamycin + aztreonam	Gentamicin substitute for renal insufficiency
Extended-spectrum penicillins	Piperacillin, piperacillin tazobactam, ampicillin/sulbactam, ticarcillin/clavulanate
Cephalosporins	Cefotetan, cefoxitin, cefotaxime
Vancomycin	Added to other regimens for suspected *Staphylococcus aureus* infections
Metronidazole + ampicillin + gentamicin	Metronidazole has excellent anaerobic coverage
Carbapenems	Imipenem/cilastatin, meropenem, ertapenem reserved for special indications

In 1979, DiZerega and colleagues compared the effectiveness of clindamycin plus gentamicin with that of penicillin G plus gentamicin for treatment of pelvic infections following cesarean delivery. Women given the clindamycin-gentamicin regimen had a 95-percent response rate, and this regimen is still considered by most to be the standard by which others are measured (French, 2004; Mackeen, 2015). Because enterococcal cultures may be persistently positive despite this standard therapy, some add ampicillin to the clindamycin-gentamicin regimen, either initially or if there is no response by 48 to 72 hours (Brumfield, 2000).

Many authorities recommend that serum gentamicin levels be periodically monitored. At Parkland Hospital, we do not routinely do so if the woman has normal renal function. Once-daily dosing and multiple-dosing with gentamicin both provide adequate serum levels, and either method has similar cure rates (Livingston, 2003). Because of potential nephrotoxicity and ototoxicity with gentamicin in the event of diminished glomerular filtration, some have recommended a combination of clindamycin and a second-generation cephalosporin to treat such women. Others recommend a combination of clindamycin and aztreonam, which is a monobactam compound with activity similar to the aminoglycosides.

The spectra of *β-lactam antimicrobials* include activity against many anaerobic pathogens. Some examples include cephalosporins such as cefoxitin, cefotetan, cefotaxime, and ceftriaxone, as well as extended-spectrum penicillins such as piperacillin, ticarcillin, and mezlocillin. β-Lactam antimicrobials are inherently safe and, except for allergic reactions, are free of major toxicity. The *β-lactamase inhibitors* clavulanic acid, sulbactam, and tazobactam have been combined with ampicillin, amoxicillin, ticarcillin, and piperacillin to extend their spectra. *Metronidazole* has superior in vitro activity against most anaerobes. This agent given with ampicillin and an aminoglycoside provides coverage against most organisms encountered in serious pelvic infections. Metronidazole is also used to treat *Clostridium difficile* colitis.

Imipenem and similar antimicrobials are in the carbapenem family. These offer broad-spectrum coverage against most organisms associated with metritis. Imipenem is used in combination with *cilastatin*, which inhibits its renal metabolism. Preliminary findings with *ertapenem* indicated suboptimal outcomes (Brown, 2012). It seems reasonable from both a medical and an economic standpoint to reserve these drugs for serious nonobstetrical infections.

Vancomycin is a glycopeptide antimicrobial active against gram-positive bacteria. It is used in lieu of β-lactam therapy for a patient with a type 1 allergic reaction and given for suspected infections due to *Staphylococcus aureus* and to treat *C difficile* colitis (Chap. 54, Inflammatory Bowel Disease).

Perioperative Prophylaxis

The use of periprocedural antimicrobial prophylaxis is common in obstetrics. Even so, no rigorous studies have evaluated providing prophylaxis following operative vaginal delivery or manual removal of the placenta (Chongsomchai, 2014; Liabsuetrakul, 2017). But, as discussed, antimicrobial prophylaxis at the time of cesarean delivery has remarkably reduced the postoperative pelvic and wound infection rates. Numerous studies have shown that prophylactic antimicrobials reduce the pelvic infection rate by 70 to 80 percent (Chelmow, 2001; Dinsmoor, 2009; Smaill, 2014). The observed benefit applies to both elective and nonelective cesarean delivery and also includes a reduction in abdominal incision infection rates.

Single-dose prophylaxis with a 2-g dose of ampicillin or a first-generation cephalosporin is ideal. Both equal the efficacy of broad-spectrum agents or multiple-dose regimens (American College of Obstetricians and Gynecologists, 2016b). For obese women, evidence supports a 3-g dose of cefazolin to reach optimal tissue concentrations (Swank, 2015). Extended-spectrum prophylaxis with azithromycin added to standard single-dose prophylaxis further reduced postcesarean metritis rates (Sutton, 2015; Ward, 2016). As noted earlier, Tita and colleagues (2016) reported that postoperative uterine infection was decreased from 12 to 6 percent with the addition of azithromycin to cefazolin. Women known to be colonized with MRSA are given vancomycin in addition to a cephalosporin (Chap. 64, Listeriosis).

It is controversial whether the infection rate is lowered further if the antimicrobial is given before the skin incision compared with after umbilical cord clamping (Baaqeel, 2013; Macones, 2012; Sun, 2013). The American College of Obstetricians and Gynecologists (2016b) has concluded that the evidence favors predelivery administration. Abdominal preoperative skin preparation with chlorhexidine-alcohol is superior to iodine-alcohol for preventing surgical-site infections (Tuuli, 2016). Additive salutary effects may be gained by preoperative vaginal cleansing with povidone-iodine rinse or application of metronidazole gel (Haas, 2014; Reid, 2011; Yildirim, 2012).

Other Methods of Prophylaxis

Several studies have addressed the value of prenatal cervicovaginal cultures. These are obtained in the hope of identifying pathogens that might be eradicated to decrease incidences of preterm labor, chorioamnionitis, and puerperal infections. Unfortunately, treatment of asymptomatic vaginal infections has not been shown to prevent these complications. Carey and coworkers (2000) reported no beneficial effects for women treated for asymptomatic bacterial vaginosis. Klebanoff and colleagues (2001) reported a similar postpartum infection rate in women treated for second-trimester asymptomatic *Trichomonas vaginalis* infection compared with that of placebo-treated women.

Technical maneuvers done to alter the postpartum infection rate have been studied with cesarean delivery. For example, allowing the placenta to separate spontaneously compared with removing it manually lowers the infection risk. However, changing gloves by the surgical team after placental delivery does not (Atkinson, 1996). Exteriorizing the uterus to close the hysterotomy may decrease febrile morbidity (Jacobs-Jokhan, 2004). Postdelivery mechanical lower segment and cervical dilatation has not been shown to be effective (Liabsuetrakul, 2011). No differences were found in postoperative infection rates when single- and two-layer uterine closures were compared (Hauth, 1992). Similarly, infection rates are not appreciatively affected by closure versus nonclosure of the peritoneum (Bamigboye, 2014; Tulandi, 2003). Importantly, although closure of subcutaneous tissue in obese women does not lower the wound infection rate, it does decrease the wound separation incidence (Chelmow, 2004). Similarly, skin closure with staples versus suture has a higher incidence of noninfectious skin separation (Mackeen, 2012; Tuuli, 2011).

Complications of Uterine and Pelvic Infections

In more than 90 percent of women, metritis responds to antimicrobial treatment within 48 to 72 hours. In some of the remainder, any of several complications may arise. These include wound infections, complex pelvic infections such as phlegmons or abscesses, and septic pelvic thrombophlebitis (Jaiyeoba, 2012). As with other aspects of puerperal infections, the incidence and severity of these complications are remarkably decreased by perioperative antimicrobial prophylaxis.

Abdominal Incisional Infections

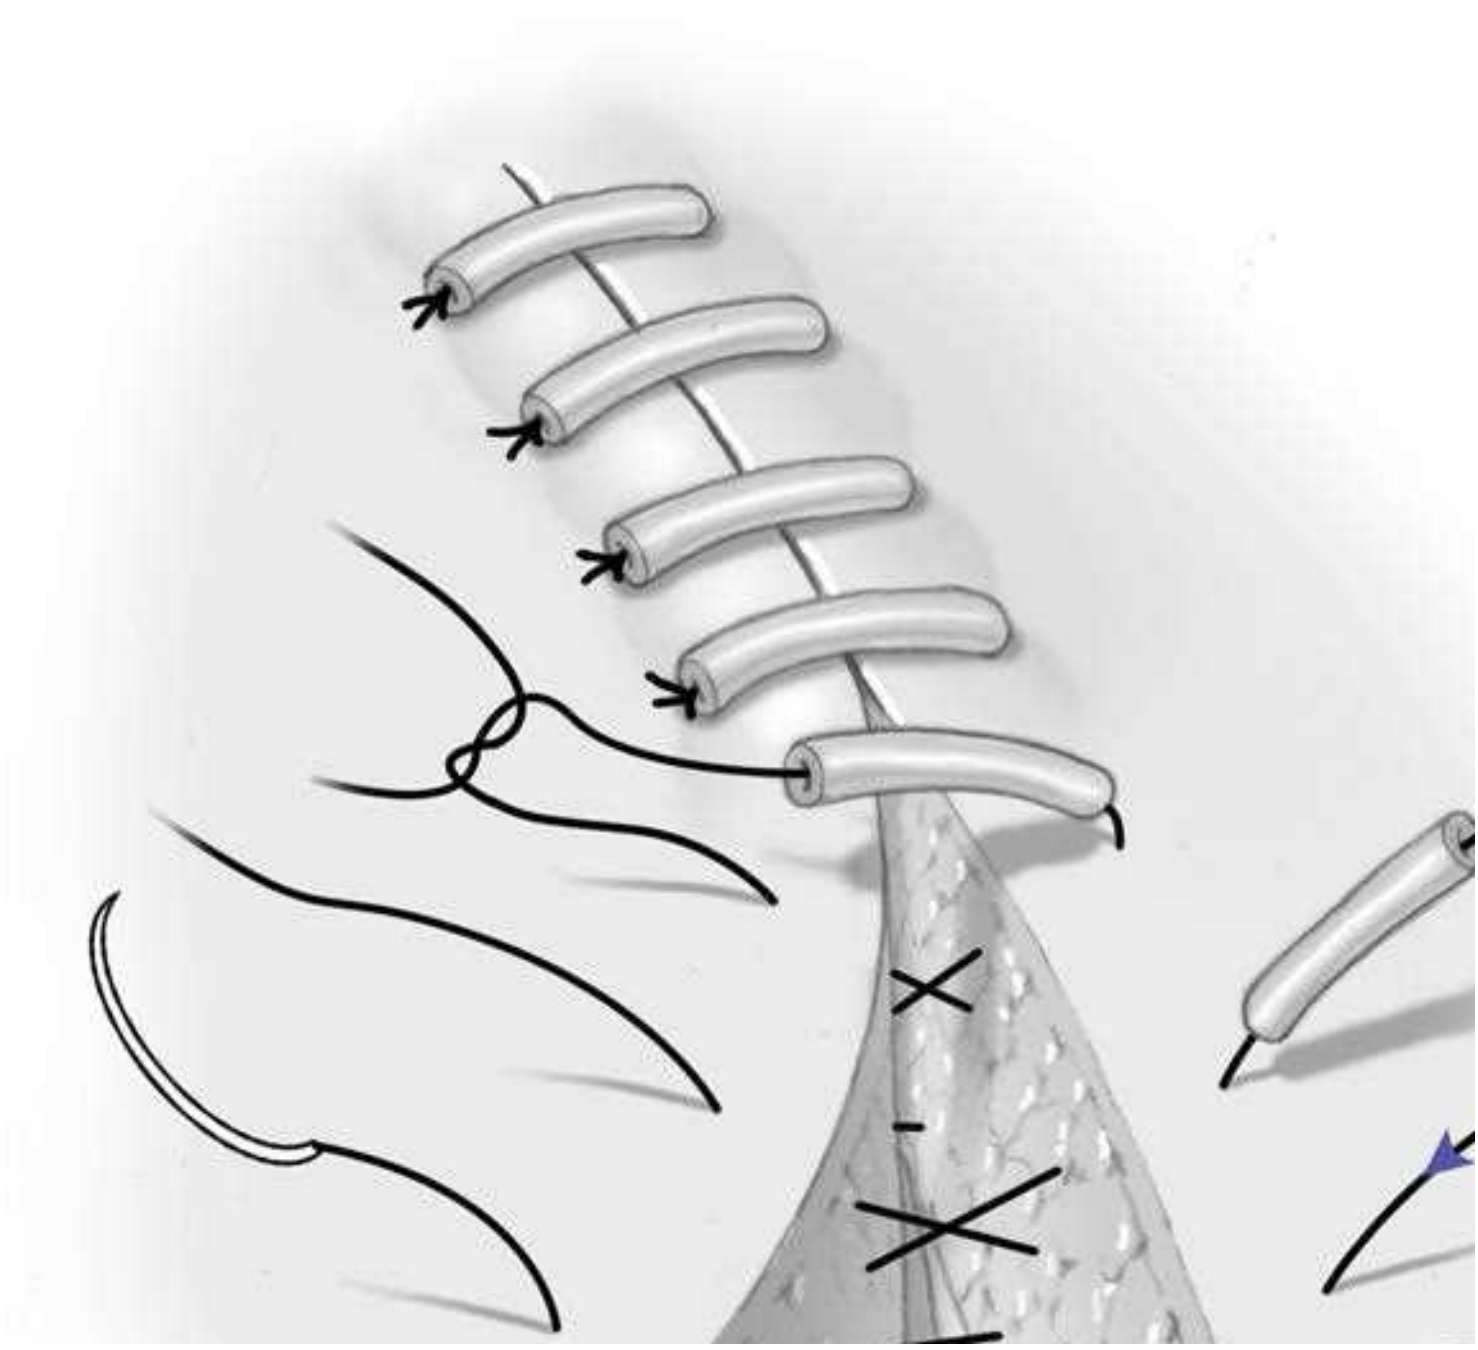
Wound infection is a common cause of persistent fever in women treated for metritis. Incisional infection risk factors include obesity, diabetes, corticosteroid therapy, immunosuppression, anemia, hypertension, and inadequate hemostasis with hematoma formation. If prophylactic antimicrobials are given, the incidence of abdominal wound infection following cesarean delivery ranges from 2 to 10 percent depending on risk factors (Andrews, 2003; Chaim, 2000). From our experiences at Parkland Hospital, the incidence is closer to 2 percent.

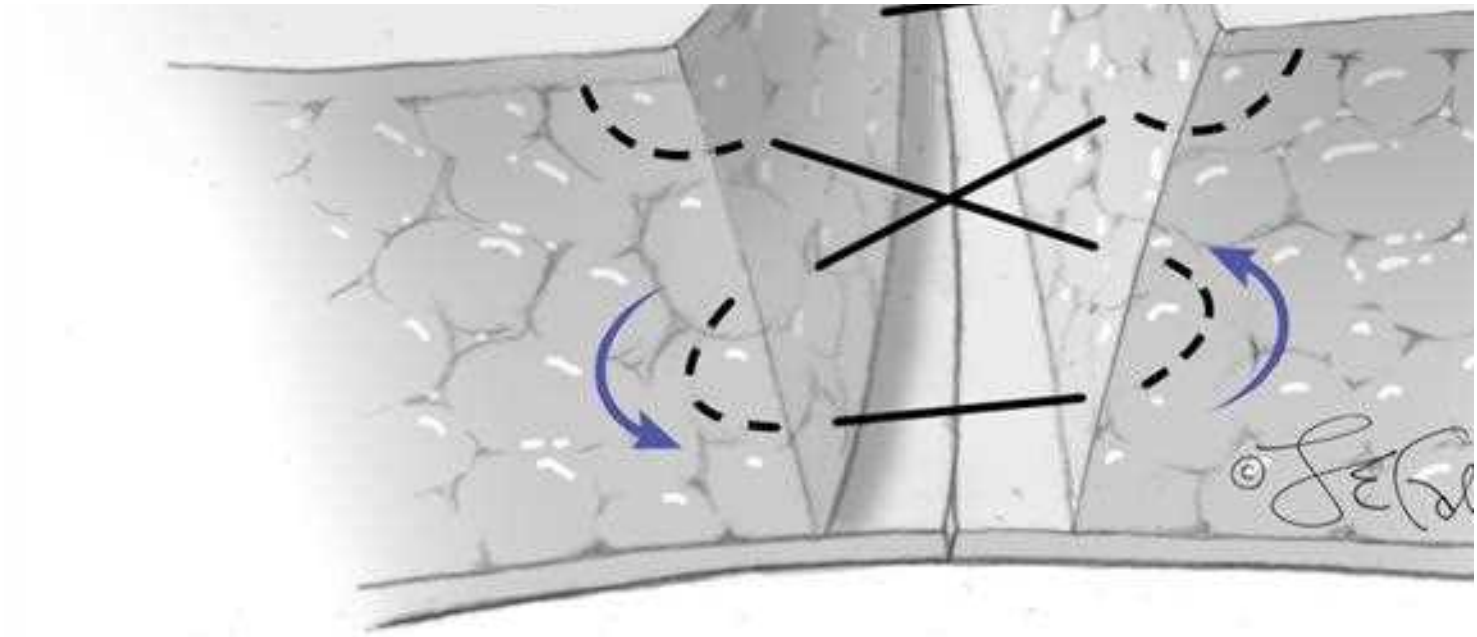
Incisional abscesses that develop following cesarean delivery usually cause persistent fever or fever that begins on about the fourth day. In many cases, antimicrobials had been given to treat pelvic infection, yet fever persisted. The wound is erythematous and drains pus. Although organisms that cause wound infections are generally the same as those isolated from amnionic fluid at cesarean delivery, hospital-acquired pathogens may also be causative (Owen, 1994).

Treatment includes antimicrobials and surgical drainage and debridement of devitalized tissue. This typically requires spinal analgesia or general anesthesia. The fascia is carefully inspected to document integrity. Local wound care thereafter is completed twice daily. Before each dressing change, procedural analgesia is tailored to wound size and location, and oral, intramuscular, or intravenous dosage routes are suitable. Topical lidocaine may also be added. Necrotic tissue is removed, and the wound is repacked with moist gauze. At 4 to 6 days, healthy granulation tissue is typically present, and secondary en bloc closure of the open layers can usually be accomplished (Wechter, 2005). As shown in Figure 37-1, a polypropylene or nylon suture of appropriate gauge enters 2 to 3 cm from one wound edge. It crosses the wound to incorporate the full wound thickness and emerges 3 cm from the other wound edge. These are placed in series to close the opening. In most cases, sutures may be removed on postprocedural day 10.

FIGURE 37-1

Secondary abdominal wound closure technique. (From Worley KC: Postoperative complications. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw Hill Education, 2017.)





Vacuum-Assisted Wound Closure

This system was designed to apply negative pressure to a foam-wound interface that would promote wound healing. The technique is variably referred to as *vacuum-assisted closure—VAC; topical negative pressure—TNP*; and *negative-pressure wound therapy—NPWT*. Several systems are available and widely accepted despite meager formal evidence for clinical efficacy (Echebiri, 2015; Rouse, 2015; Swift, 2015). In obstetrics, disrupted and infected abdominal wounds are a major indication for vacuum-assisted closure. Closure of perineal wounds resulting from infected episiotomies, hematomas, or abscesses is another (Aviki, 2015). These devices are also used for the "open surgical abdomen," which is occasionally encountered in obstetrics. Negative-pressure wound therapy has also been used to prevent wound infections in those closed to heal by primary intention.

Very few randomized trials have compared vacuum-assisted wound closure with conventional wound care (Semsarzadeh, 2015). Likewise, its cost effectiveness has not been thoroughly studied, although provider time is decreased substantially (Lewis, 2014). From their review, Mouës and colleagues (2011) are more circumspect about its use for disrupted abdominal wounds because of scarce data. Other reviewers conclude that vacuum therapy is the most efficient method of temporary abdominal closure for patients with open abdominal wounds (Bruhin, 2014; Quyn, 2012).

Wound Dehiscence

Wound disruption or dehiscence refers to separation of the fascial layer. This is a serious complication and requires secondary closure of the incision in the operating room. McNeeley and associates (1998) reported a fascial dehiscence rate of approximately 1 per 300 operations in almost 9000 women undergoing cesarean delivery. Other than wound infection, obesity may be a risk factor (Subramaniam, 2014). Most disruptions manifested on about the fifth postoperative day and were accompanied by a serosanguinous discharge. Two thirds of 27 fascial dehiscences identified in this study were associated with concurrent fascial infection and tissue necrosis.

Necrotizing Fasciitis

This uncommon, severe wound infection is associated with high mortality rates. In obstetrics, necrotizing fasciitis may involve abdominal incisions, or it may complicate episiotomy or other perineal lacerations. As the name implies, tissue necrosis is significant. Of the risk factors for fasciitis summarized by Owen and Andrews (1994), three of these—diabetes, obesity, and hypertension—are relatively common in gravidas. Like pelvic infections, these wound complications usually are polymicrobial and are caused by organisms that make up the normal vaginal flora. In some cases, however, infection is caused by a single virulent bacterial species such as group A β-hemolytic streptococcus (Anderson, 2014; Rimawi, 2012). Occasionally, necrotizing infections are caused by rarely encountered pathogens (Chong, 2016; Swartz, 2004).

Goepfert and coworkers (1997) reviewed their experiences with necrotizing fasciitis. Nine cases complicated more than 5000 cesarean deliveries, a frequency of 1.8 per 1000. In two women, the infection was fatal. In another report, Schorge and colleagues (1998) described five women with fasciitis following cesarean delivery. None of these women had predisposing risk factors, and none died.

Infection may involve skin, superficial and deep subcutaneous tissues, and any of the abdominopelvic fascial layers (Fig. 37-2). In some cases, muscle is also involved —*myofasciitis*. Although some virulent infections—for example, those caused by group A β-hemolytic streptococci—develop early postpartum, most of these necrotizing infections do not cause symptoms until 3 to 5 days after delivery. Clinical findings vary, and it is frequently difficult to differentiate more innocuous superficial wound infections from an ominous deep fascial one. A high index of suspicion, with surgical exploration if the diagnosis is uncertain, may be lifesaving (Goh, 2014). We aggressively pursue early exploration. Certainly, if myofasciitis progresses, the woman may become ill from septicemia (Chap. 47, Sepsis Syndrome).

FIGURE 37-2

Necrotizing fasciitis involving the abdominal wall and Pfannenstiel incision. The skin rapidly became dusky and gangrenous, and pus is seen exuding from the left angle of the incision. Extensive debridement and supportive therapy were lifesaving.

Early diagnosis, surgical debridement, antimicrobials, and intensive care are paramount to successfully treat necrotizing soft-tissue infections (Gallup, 2002; Goh, 2014). Surgery includes extensive debridement of all infected tissue, leaving wide margins of healthy bleeding tissue. This may include extensive abdominal or vulvar debridement with unroofing and excision of abdominal, thigh, or buttock fascia. Death is virtually universal without surgical treatment, and rates approach 25 percent even if extensive debridement is performed. With extensive resection, synthetic mesh may ultimately be required later to close the fascial incision (Gallup, 2002; McNeeley, 1998).

Adnexal Abscesses and Peritonitis

An *ovarian abscess* rarely develops in the puerperium. These are presumably caused by bacterial invasion through a rent in the ovarian capsule (Wetchler, 1985). The abscess is usually unilateral, and women typically present 1 to 2 weeks after delivery. Rupture is common, and peritonitis may be severe.

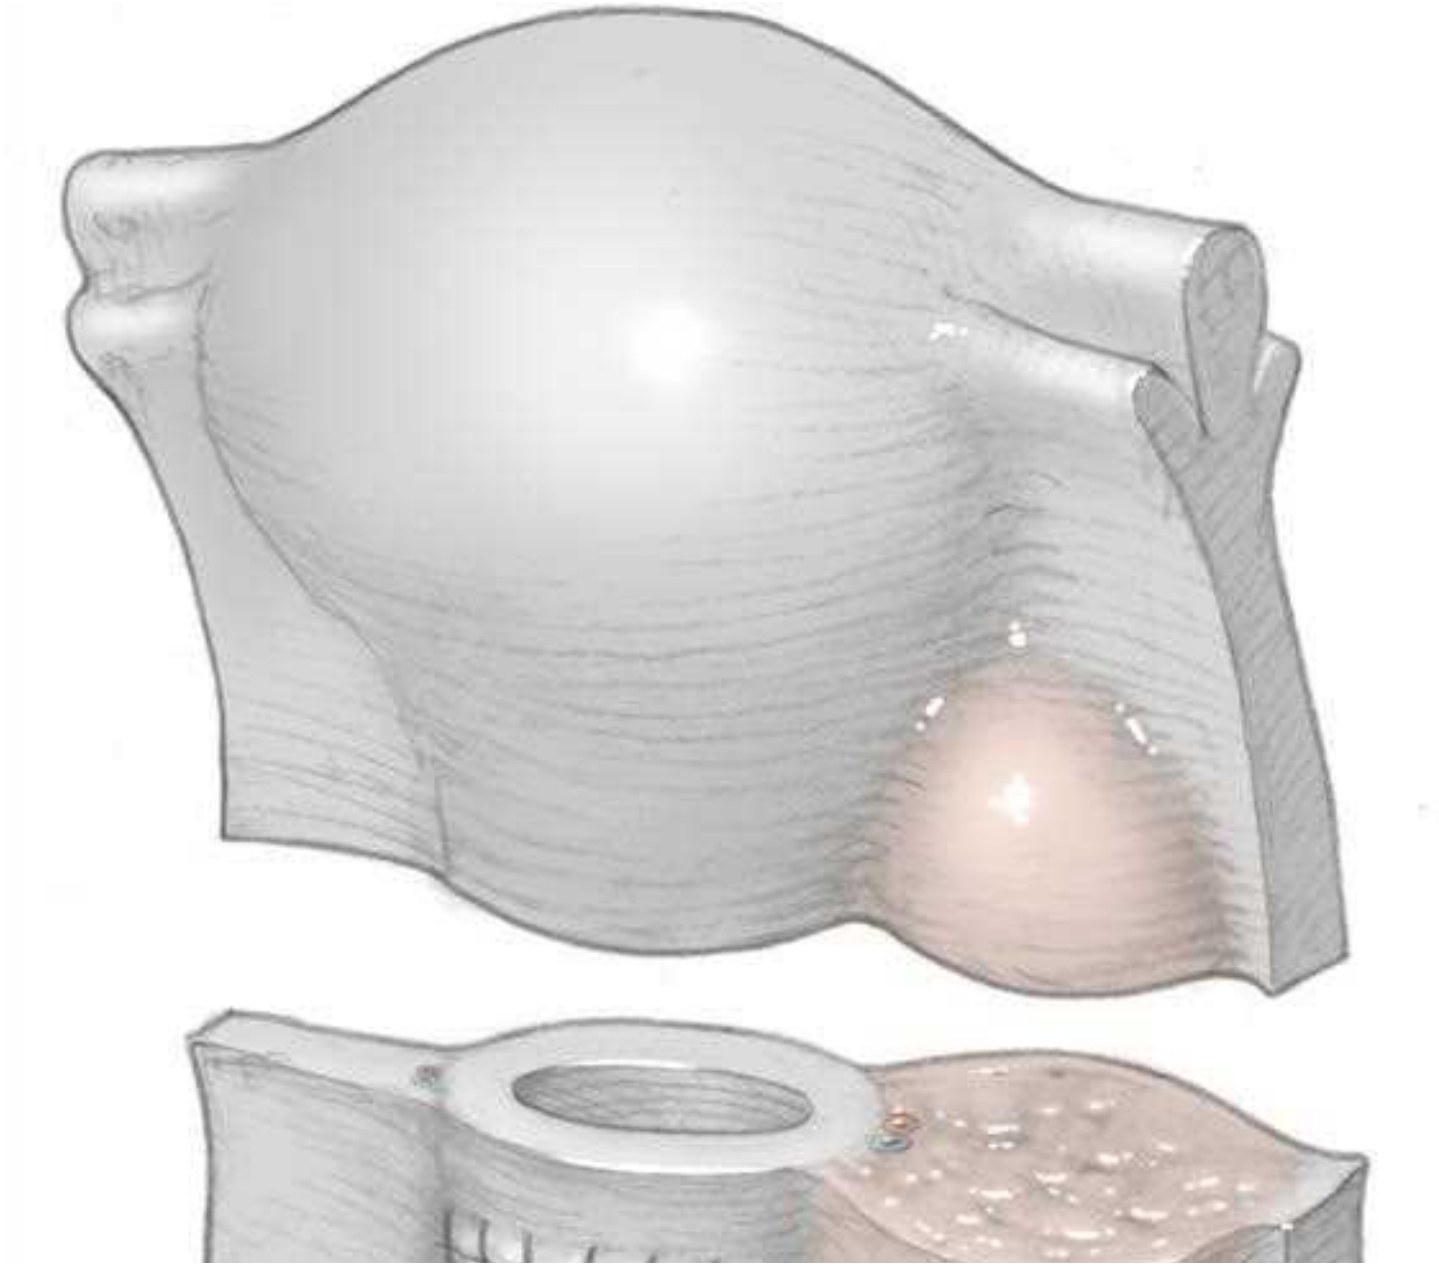
Peritonitis is infrequent following cesarean delivery. It almost invariably is preceded by metritis, especially cases with uterine incisional necrosis and dehiscence. However, it may stem from a ruptured adnexal abscess or an inadvertent intraoperative bowel injury.

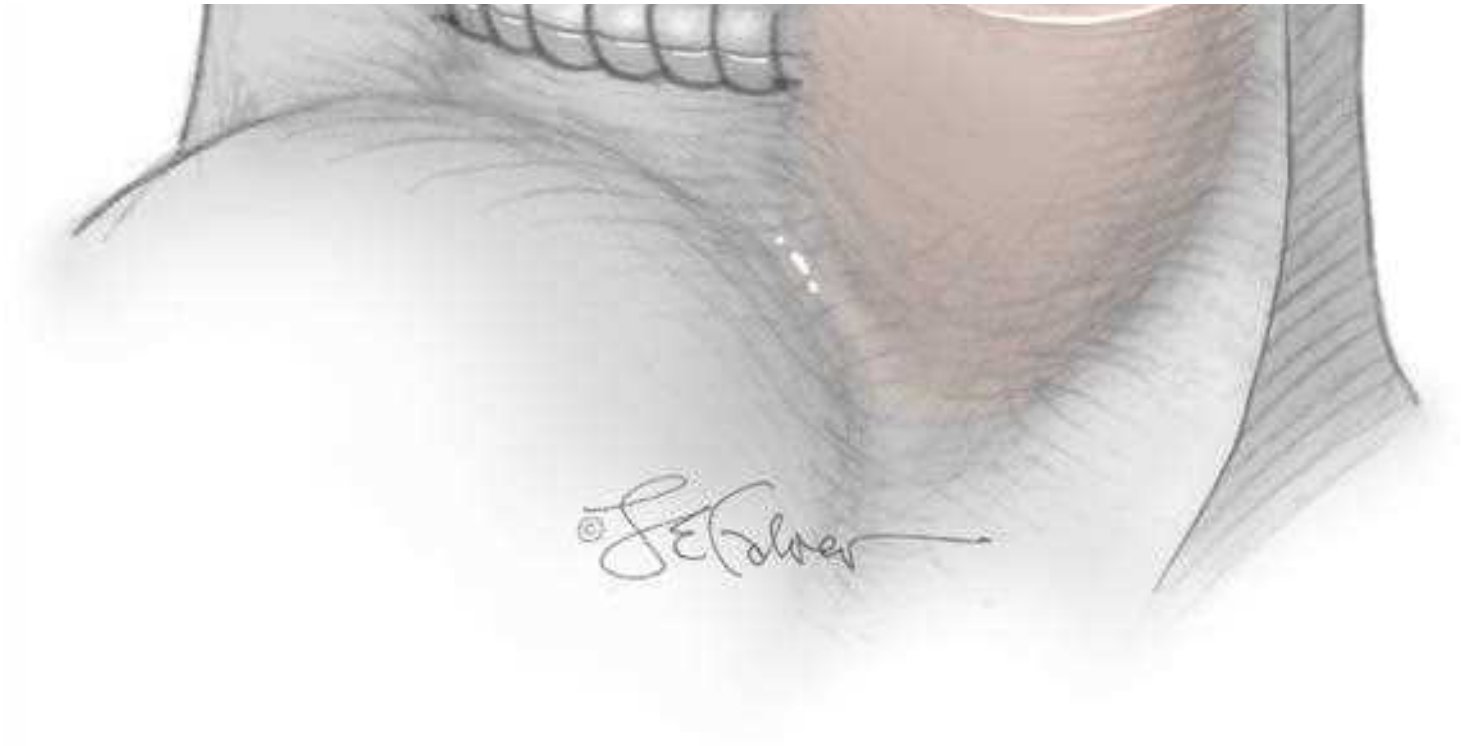
Peritonitis is rarely encountered after vaginal delivery, and many such cases are due to virulent strains of group A β-hemolytic streptococci or similar organisms. Importantly in postpartum women, abdominal rigidity may not be prominent with puerperal peritonitis because of physiological abdominal wall laxity from pregnancy. Pain may be severe, but frequently, the first symptoms of peritonitis are those of *adynamic ileus.* Marked bowel distention may develop, which is unusual after uncomplicated cesarean delivery. If the infection begins in an intact uterus and extends into the peritoneum, antimicrobial treatment alone usually suffices. Conversely, peritonitis caused by uterine incisional necrosis as discussed subsequently, or from bowel perforation, must be treated promptly with surgical intervention.

Parametrial Phlegmon

For some women in whom metritis develops following cesarean delivery, parametrial cellulitis is intensive and forms an area of induration—a *phlegmon*—within the leaves of the broad ligament (Fig. 37-3). These infections are considered when fever persists longer than 72 hours despite intravenous antimicrobial therapy (Brown, 1999; DePalma, 1982).

FIGURE 37-3
Left-sided parametrial phlegmon: cellulitis causes induration in the parametrium adjacent to the hysterotomy incision. (From Worley KC: Postoperative complications. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw Hill Education, 2017.)

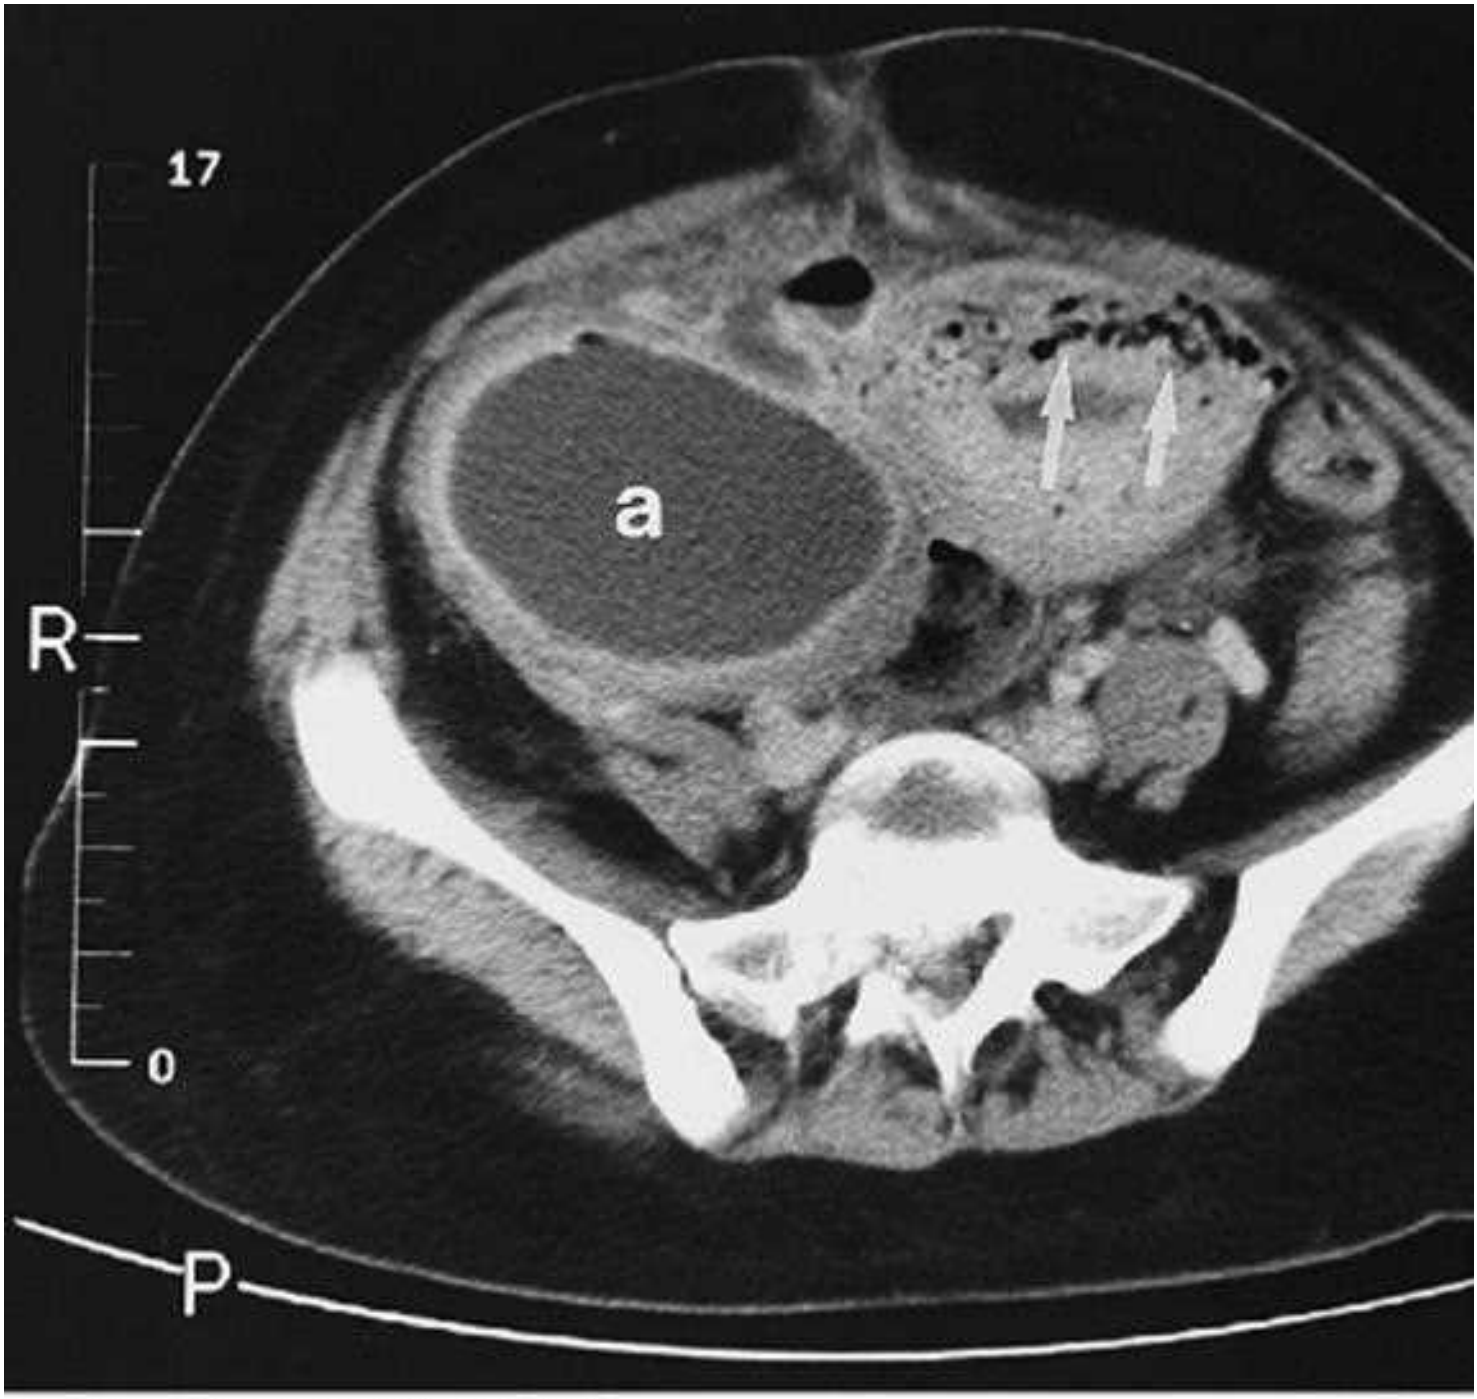




Phlegmons are usually unilateral, and they frequently are limited to the parametrium at the base of the broad ligament. If the inflammatory reaction is more intense, cellulitis extends along natural lines of cleavage. The most common form of extension is laterally along the broad ligament, with a tendency to extend to the pelvic sidewall. Occasionally, posterior extension may involve the rectovaginal septum, producing a firm mass posterior to the cervix. In most women with a phlegmon, clinical improvement follows continued treatment with a broad-spectrum antimicrobial regimen. Typically, fever resolves in 5 to 7 days, but in some cases, it persists longer. Absorption of the induration may require several days to weeks.

In some women, severe cellulitis of the uterine incision may ultimately lead to necrosis and separation (Treszezamsky, 2011). Extrusion of purulent material as shown in Figure 37-4 causes intraabdominal abscess formation and peritonitis as described above. Surgery is reserved for women in whom uterine incisional necrosis is suspected because of ileus and peritonitis. For most, hysterectomy and surgical debridement are needed and are predictably difficult because the cervix and lower uterine segment are involved with an intense inflammatory process that extends to the pelvic sidewall. The adnexa are seldom involved, and one or both ovaries can usually be conserved. Blood loss is often appreciable, and transfusion is usually necessary.

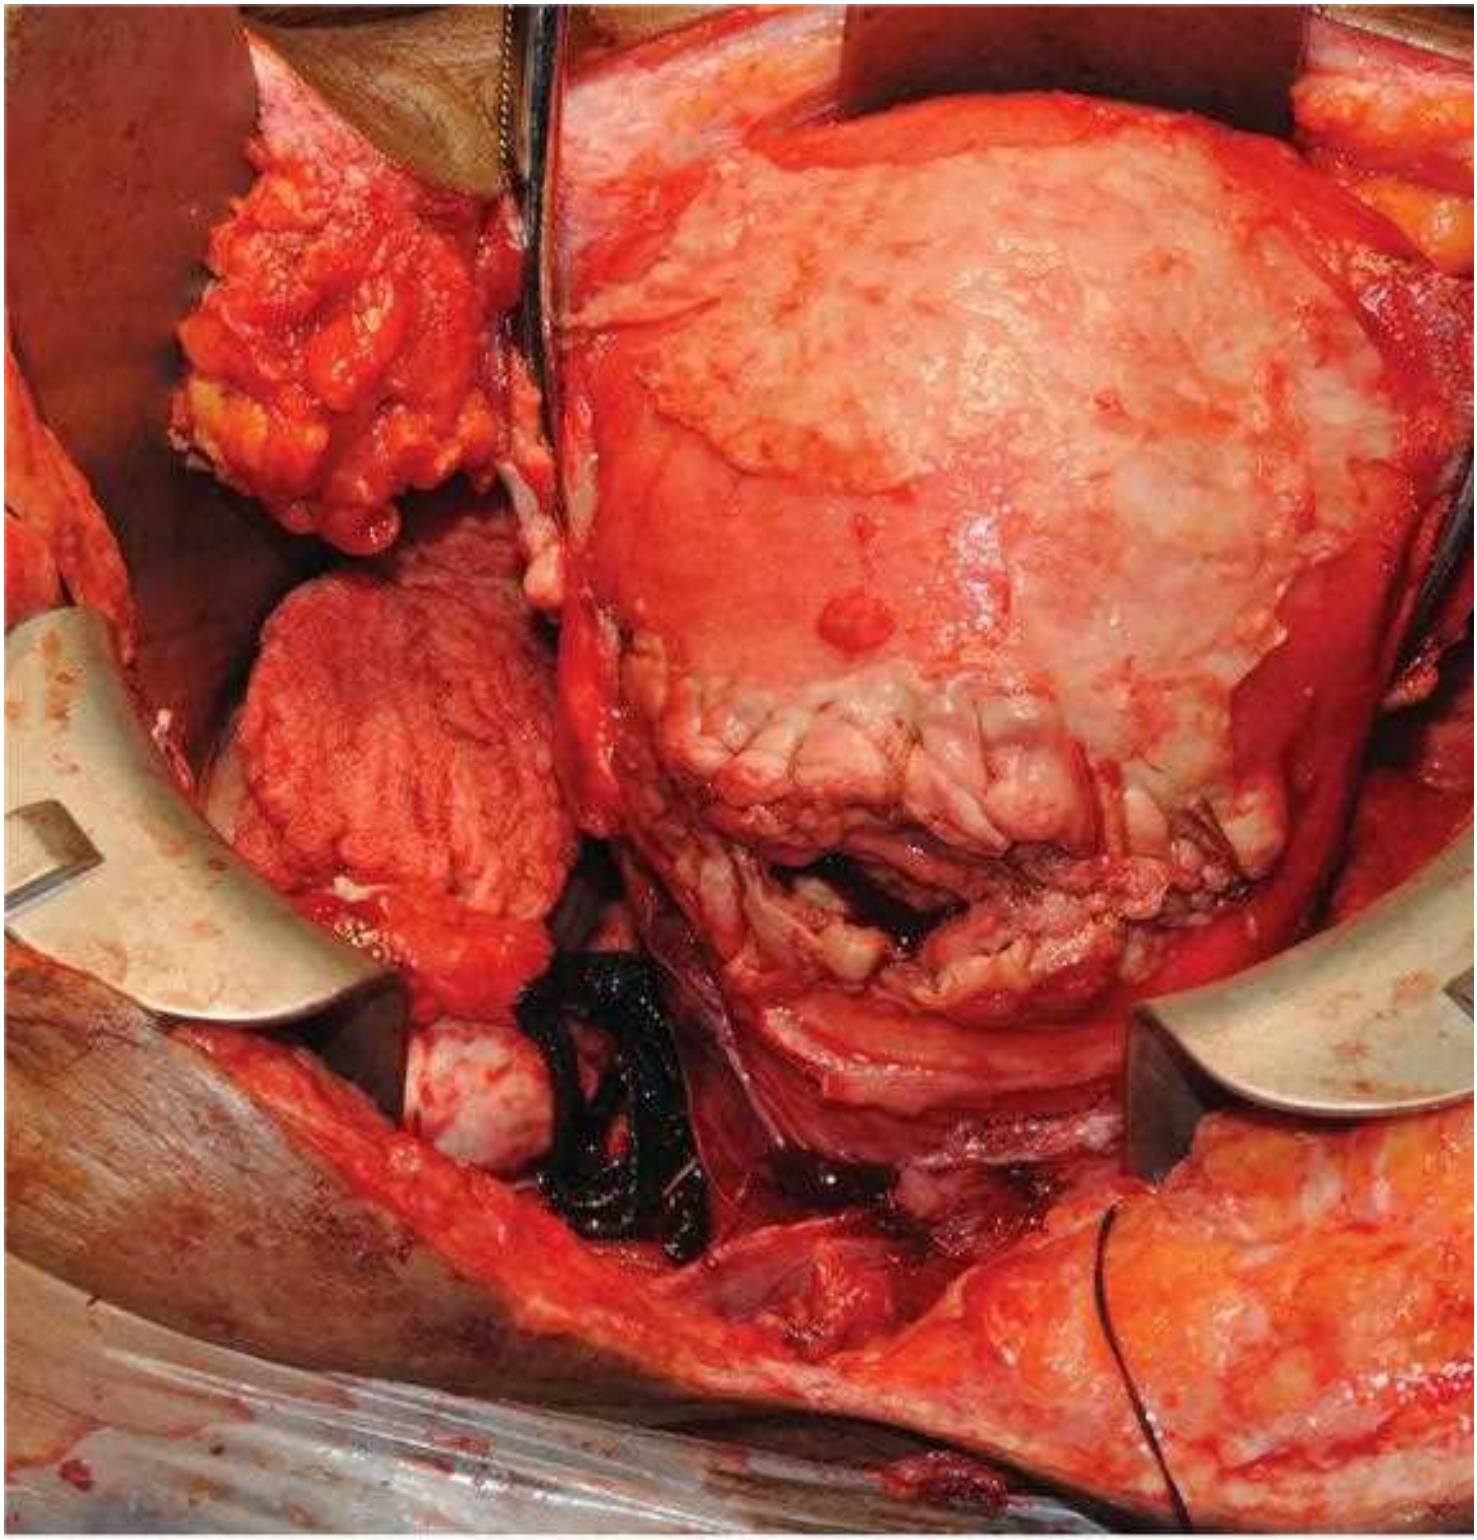
FIGURE 37-4
Pelvic computed tomography scan showing necrosis of the uterine incision with gas in the myometrium (*arrows*). There is also a large right-sided parametrial abscess (*a*).



Imaging Studies

Persistent puerperal infections can be evaluated using computed tomography (CT) or magnetic resonance (MR) imaging. Brown and associates (1991) used CT imaging in 74 women in whom pelvic infection was refractory to antimicrobial therapy given for 5 days. They found at least one abnormal radiological finding in 75 percent of these women, and in most, these were nonsurgical lesions. In most cases, imaging can be used to dissuade surgical exploration. Uterine incisional dehiscence such as shown in Figure 37-4 can sometimes be confirmed based on CT scanning images. These findings must be interpreted within the clinical context because apparent uterine incisional defects thought to represent edema can be seen even after uncomplicated cesarean delivery (Twickler, 1991). Shown in Figure 37-5 is a necrotic hysterotomy incision that leaked into the peritoneal cavity.

FIGURE 37-5
Necrotic hysterotomy infection. Severe cellulitis of the uterine incision resulted in dehiscence with subsequent leakage into the peritoneal cavity. Hysterectomy was required for sufficient debridement of necrotic tissue.



Occasionally, a parametrial phlegmon may suppurate, forming a fluctuant broad ligament mass that may point above the inguinal ligament. These abscesses can dissect anteriorly as shown in Figure 37-4 and be amenable to CT-directed needle drainage. Occasionally they dissect posteriorly to the rectovaginal septum, where surgical drainage is easily effected by colpotomy. A *psoas abscess* is rare, and despite antimicrobial therapy, percutaneous drainage may be required to effectively treat it (Shahabi, 2002; Swanson, 2008).

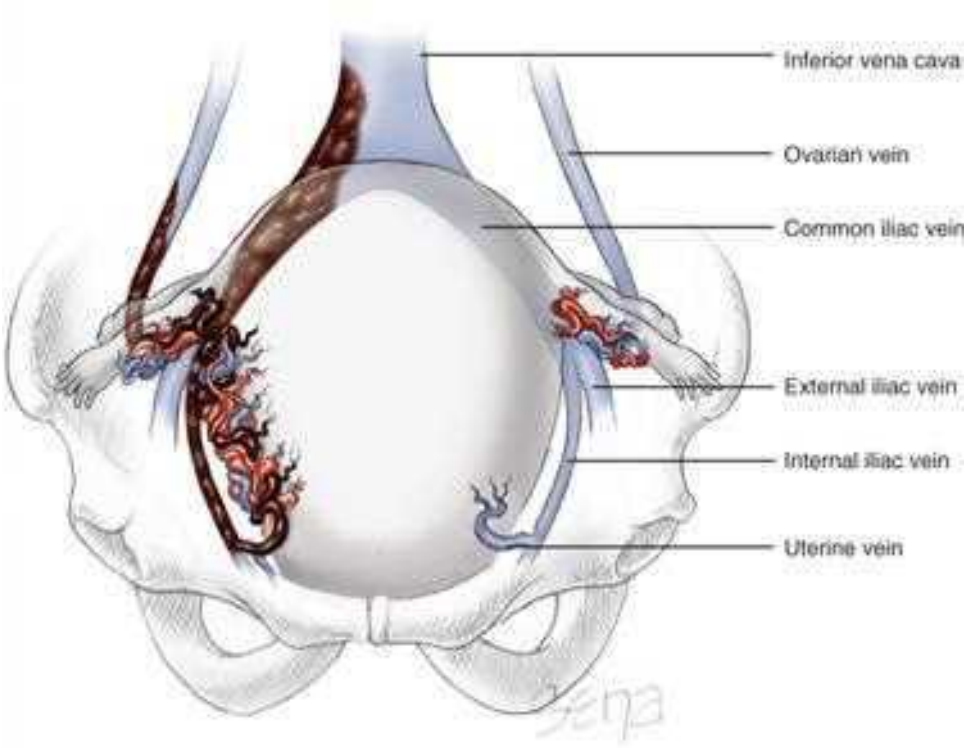
Septic Pelvic Thrombophlebitis

Suppurative thrombophlebitis was a frequent complication in the preantibiotic era, and septic embolization was common. However, with the advent of antimicrobial therapy, the mortality rate and need for surgical therapy for these infections diminished. Septic phlebitis arises as an extension along venous routes and may cause thrombosis as shown in Figure 37-6. Lymphangitis often coexists. The ovarian veins may then become involved because they drain the upper uterus and therefore the placental implantation site. The experiences of Witlin and Sibai (1995) and Brown and coworkers (1999) suggest that puerperal septic

thrombophlebitis is likely to involve one or both ovarian venous plexuses. In a fourth of women, the clot extends into the inferior vena cava and occasionally to the renal vein.

FIGURE 37-6

Septic pelvic thrombophlebitis: uterine and parametrial infection may extend to any pelvic vessel as well as the inferior vena cava. The clot in the right common iliac vein extends from the uterine and internal iliac veins and into the inferior vena cava. The ovarian vein septic thrombosis extends halfway to the vena cava.

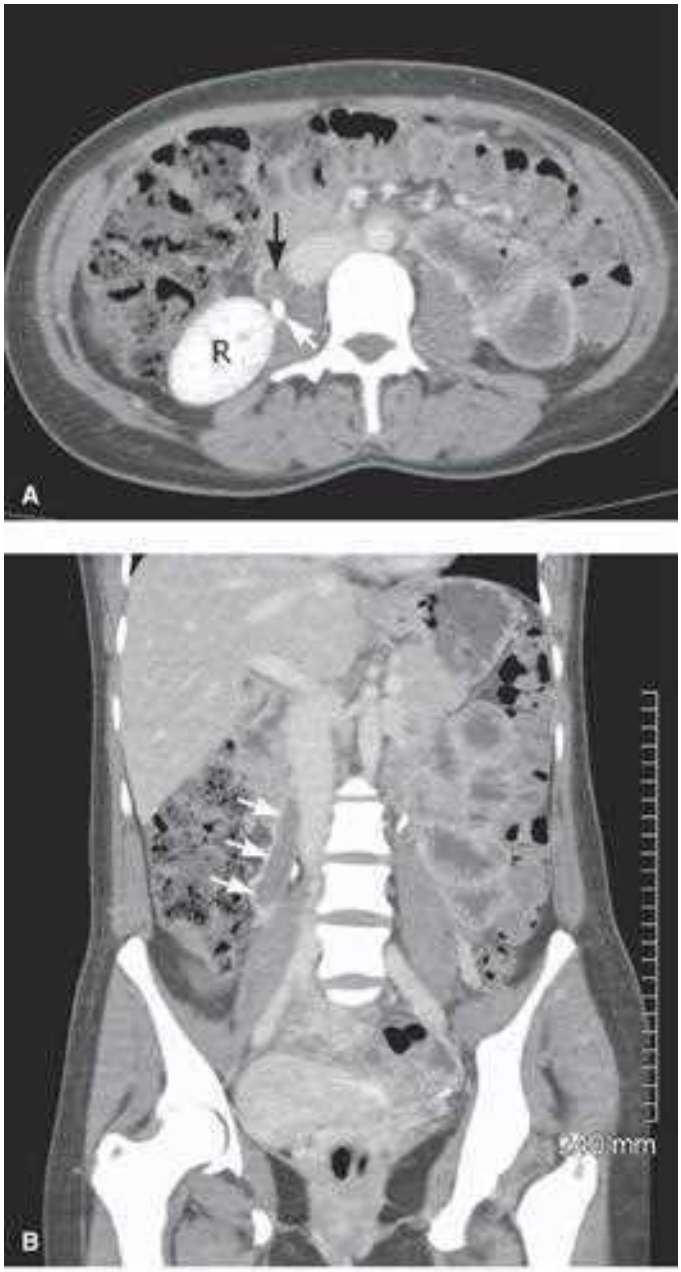


The incidence of septic phlebitis has varied in several reports. In a 5-year survey of 45,000 women who were delivered at Parkland Hospital, Brown and associates (1999) found an incidence of septic pelvic thrombophlebitis in 1 per 9000 gravidas following vaginal delivery and 1 per 800 after cesarean delivery. The overall incidence of 1 per 3000 deliveries was similar to the 1 per 2000 reported by Dunnihoo and colleagues (1991). In large studies of women with cesarean delivery, the incidence was 1 in 400 to 1 in 1000 surgeries (Dotters-Katz, 2017; Rouse 2004). Chorioamnionitis, endometritis, and wound complications were other risks.

Women with septic thrombophlebitis usually have symptomatic improvement with antimicrobial treatment, however, they continue to have fever. Although pain occasionally is noted in one or both lower quadrants, patients are usually asymptomatic except for chills. As shown in Figure 37-7, the diagnosis can be confirmed by pelvic CT or MR imaging (Klima, 2008). Using either, Brown and colleagues (1999) found that 20 percent of 69 women with metritis who had fever despite >5 days of appropriate antimicrobial therapy had septic pelvic thrombophlebitis.

FIGURE 37-7

Septic ovarian vein thrombosis—contrast-enhanced computed tomography scan. **A.** Enlarged right ovarian vein filled with low-density thrombus (*black arrow*). Contrast is seen in ureter (*white arrow*). *R* = lower pole, right kidney. **B.** Coronal image demonstrates enlarged right ovarian vein filled with low-density thrombus (*arrows*). (From Worley KC: Postoperative complications. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw Hill Education, 2017.)



It has been disproven that intravenous heparin causes fever to dissipate with septic phlebitis (Brown, 1986; Witlin, 1995). And although Garcia and coworkers (2006) and Klima and Snyder (2008) advocate heparin therapy, we do not recommend anticoagulation. In a randomized study of 14 women by Brown and associates (1999), the addition of heparin to antimicrobial therapy for septic pelvic thrombophlebitis did not hasten recovery or improve outcome. Certainly, no evidence supports long-term anticoagulation.

Perineal Infections

Episiotomy infections are not common because the operation is performed much less frequently now than in the past (American College of Obstetricians and Gynecologists, 2016a). Reasons for this are discussed further in Chapter 27 (Indications). In an older study, Owen and Hauth (1990) described only 10 episiotomy infections in 20,000 women delivered vaginally. With infection, however, dehiscence is a concern. Ramin and colleagues (1992) reported an episiotomy dehiscence rate of 0.5 percent at Parkland Hospital—80 percent of these were infected. Uygur and associates (2004) reported a 1-percent dehiscence rate and attributed two thirds to infection. No data suggest that dehiscence is related to faulty repair.

When the anal sphincter is disrupted at delivery, the subsequent infection rate is higher and is likely influenced by intrapartum antimicrobial treatment (Buppasiri, 2014; Stock, 2013). Lewicky-Gaupp and colleagues (2015) reported a 20-percent infection rate. Infection of a fourth-degree laceration can be even more serious. Goldaber and coworkers (1993) described fourth-degree lacerations in 390 parturients, of whom 5.4 percent had morbidity. In these women, 2.8 percent had infection and dehiscence, 1.8 percent had only dehiscence, and 0.8 percent only infection. Although life-threatening septic shock is rare, it may still occur as a result of an infected episiotomy. Occasionally also, necrotizing fasciitis develops as discussed in Necrotizing Fasciitis.

Pathogenesis and Clinical Course

Episiotomy dehiscence is most commonly associated with infection. Other factors include coagulation disorders, smoking, and human papillomavirus infection (Ramin, 1994). Local pain and dysuria, with or without urinary retention, are frequent symptoms. Ramin and colleagues (1992), evaluating a series of 34 women with episiotomy dehiscence, reported that the most common findings were pain in 65 percent, purulent discharge in 65 percent, and fever in 44 percent. In extreme cases, the entire vulva may become edematous, ulcerated, and covered with exudate.

Vaginal lacerations may also become infected directly or by extension from the perineum. The epithelium becomes red and swollen and may then become necrotic and slough. Parametrial extension can lead to lymphangitis. Cervical lacerations are common but seldom are noticeably infected, which may manifest as metritis. Deep lacerations that extend directly into the base of the broad ligament may become infected and cause lymphangitis, parametritis, and bacteremia.

Treatment

Infected episiotomies are managed similar to other infected surgical wounds. Drainage is established, and in most cases, sutures are removed and the infected wound debrided. In women with obvious cellulitis but no purulence, close observation and broad-spectrum antimicrobial therapy alone may be appropriate. With dehiscence, local wound care is continued along with intravenous antimicrobials.

Early Repair of Infected Episiotomy

Hauth and colleagues (1986) were the first to advocate early episiotomy repair after infection subsided, and other studies have confirmed the efficacy of this approach. Hankins and coworkers (1990) described early repair in 31 women with an average duration of 6 days from dehiscence to repair. All but two had a successful repair. Each of the two women with failures developed a pinpoint rectovaginal fistula that was treated successfully with a small rectal flap. With episiotomy dehiscence due to infection, Ramin and coworkers (1992) reported successful early repair in 32 of 34 women (94 percent), and Uygur and colleagues (2004) noted a similarly high percentage. Rarely, intestinal diversion may be required to allow healing (Rose, 2005).

Before performing early repair, diligent preparation is essential as outlined in Table 37-3. The surgical wound must be properly cleaned and cleared of infection. Once the surface of the episiotomy wound is free of infection and exudate and covered by pink granulation tissue, secondary repair can be accomplished. The tissue must be adequately mobilized, with special attention to identify and mobilize the anal sphincter muscle. Secondary closure of the episiotomy is accomplished in layers, as described for primary episiotomy closure (Chap. 27, Laceration and Episiotomy Repairs). Postoperative care includes local wound care, stool softeners, and nothing per vagina or rectum until healed.

TABLE 37-3

Preoperative Protocol for Early Repair of Episiotomy Dehiscence

Open wound, remove sutures, begin intravenous antimicrobials
Wound care
Sitz bath several times daily or hydrotherapy
Adequate analgesia or anesthesia—regional analgesia or general anesthesia may be necessary for the first few debridements
Scrub wound twice daily with a povidone-iodine solution
Debride necrotic tissue
Closure when afebrile and pink, healthy granulation tissue predominates
Bowel preparation for fourth-degree repair

Toxic Shock Syndrome

This acute febrile illness with severe multisystem derangement has a case-fatality rate of 10 to 15 percent. Fever, headache, mental confusion, diffuse macular erythematous rash, subcutaneous edema, nausea, vomiting, watery diarrhea, and marked hemoconcentration are usual findings. Renal failure followed by hepatic failure, disseminated intravascular coagulopathy, and circulatory collapse may follow in rapid sequence. During recovery, the rash-covered areas undergo desquamation. For some time, *Staphylococcus aureus* was recovered from almost all afflicted persons. Specifically, a staphylococcal exotoxin, termed *toxic shock syndrome toxin-1* (*TSST-1*), was found to cause the clinical manifestations by provoking profound endothelial injury. A very small amount of TSST-1 has been shown to activate T cells to create a “cytokine storm” as described by Que (2005) and Heying (2007) and their coworkers.

During the 1990s, sporadic reports of virulent group A β-hemolytic streptococcal infection began to appear (Anderson, 2014). Heavy colonization or infection is complicated in some cases by *streptococcal toxic shock syndrome,* which is produced when pyrogenic exotoxin is elaborated. Serotypes M1 and M3 are particularly virulent (Beres, 2004; Okumura, 2004). Finally, almost identical findings of toxic shock were reported by Robbie and associates (2000) in women with *Clostridium sordellii* colonization.

Thus, in some cases of toxic shock syndrome, infection is not apparent and colonization of a mucosal surface is the presumed source. At least 10 to 20 percent of pregnant women have vaginal colonization with *S aureus.* And *Clostridium perfringens* and *sordellii* are cultured from 3 to 10 percent of asymptomatic women (Chong, 2016). Thus, it is not surprising that the disease develops in postpartum women when growth of vaginal bacteria is luxuriant (Chen, 2006; Guerinot, 1982).

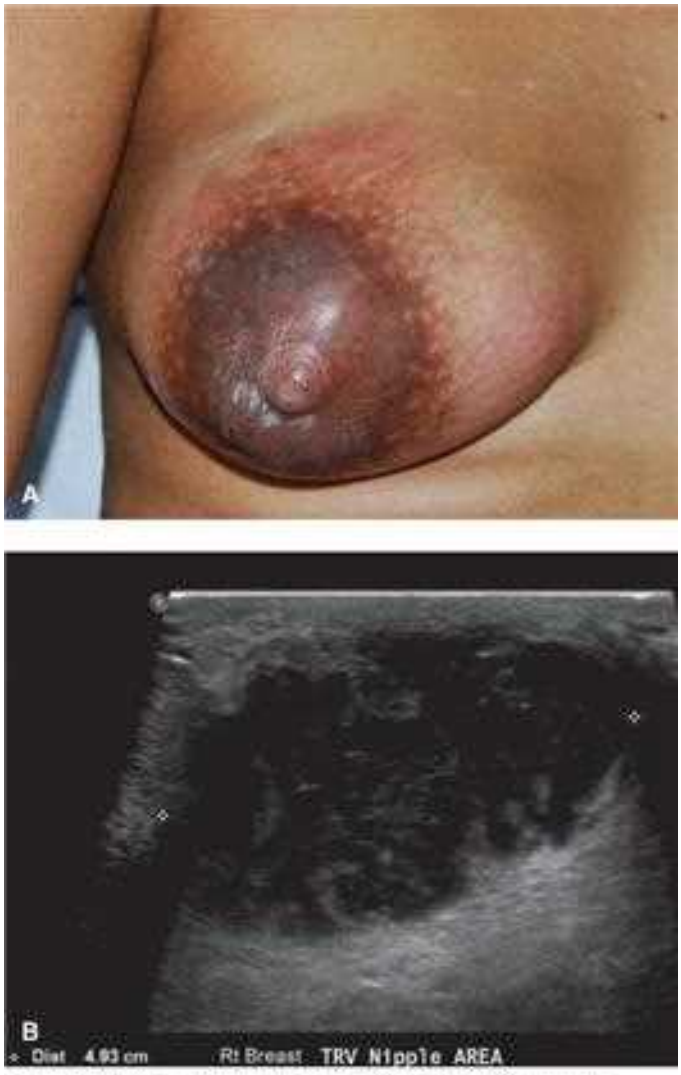
Delayed diagnosis and treatment may be associated with maternal mortality (Schummer, 2002). Crum and colleagues (2002) described a neonatal death following antenatal toxic shock syndrome. Principal therapy is supportive, while allowing reversal of capillary endothelial injury. Antimicrobial therapy that includes staphylococcal and streptococcal coverage is given. With evidence of pelvic infection, antimicrobial therapy must also include agents used for polymicrobial infections. Women with these infections may require extensive wound debridement and possibly hysterectomy. Because the toxin is so potent, the mortality rate is correspondingly high (Hotchkiss, 2003).

BREAST INFECTIONS

Parenchymal infection of the mammary glands is a rare antepartum complication but is estimated to develop in up to a third of breastfeeding women (Barbosa-Cesnik, 2003). Excluding breast engorgement, in our experiences, as well as that of Lee and associates (2010), the incidence of mastitis is much lower and probably approximates 3 percent. No evidence supports any of several prophylactic measures to prevent breast infection (Crepinsek, 2012). Risk factors include difficulties in nursing, cracked nipples, and oral antibiotic therapy (Branch-Elliman, 2012; Mediano, 2014). Symptoms of suppurative mastitis seldom appear before the end of the first week postpartum and, as a rule, not until the third or fourth week. Infection almost invariably is unilateral, and marked engorgement usually precedes inflammation. Symptoms include chills or actual rigors, which are soon followed by fever and tachycardia. Pain is severe, and the breast(s) becomes hard and red (Fig. 37-8). Approximately 10 percent of women with mastitis develop an abscess. Detection of fluctuation may be difficult, and sonography is usually diagnostic.

FIGURE 37-8

Puerperal mastitis with breast abscess. **A.** Photograph shows indurated, erythematous skin overlying area of right breast infection. **B.** Sonographic picture of this 5-cm abscess. (Used with permission from Dr. Emily Adhikari.)



Etiology

Staphylococcus aureus, especially MRSA, is the most commonly isolated organism in breast infections. Matheson and coworkers (1988) found it in 40 percent of women with mastitis. Other commonly isolated organisms are coagulase-negative staphylococci and viridans streptococci. The immediate source of organisms that cause mastitis is almost always the infant's nose and throat. Bacteria enter the breast through the nipple at fissures or small abrasions. The infecting organism can usually be cultured from milk. Toxic shock syndrome from mastitis caused by *S aureus* has been reported (Demey, 1989; Fujiwara, 2001).

At times, suppurative mastitis reaches epidemic levels among nursing mothers. Such outbreaks most often coincide with the appearance of a new strain of antibiotic-resistant staphylococcus. A contemporaneous example is CA-MRSA, which has rapidly become the most commonly isolated staphylococcal species in some areas (Berens, 2010; Klevens, 2007). At Parkland Hospital from 2000 to 2004, Laibl and associates (2005) reported that a fourth of CA-MRSA isolates were from pregnant or postpartum women with puerperal mastitis. Hospital-acquired MRSA may cause mastitis when the newborn becomes colonized after contact with nursery personnel who are colonized (Centers for Disease Control and Prevention, 2006). Stafford and colleagues (2008) found a higher incidence of recurrent abscess in those with CA-MRSA-associated mastitis.

Management

Provided that appropriate therapy for mastitis is started before suppuration begins, the infection usually resolves within 48 hours. As discussed, abscess formation is more common with *S aureus* infection (Matheson, 1988). Most recommend that milk be expressed from the affected breast onto a swab and cultured before therapy is begun. Bacterial identification and antimicrobial sensitivities provide information mandatory for a successful program of nosocomial infection surveillance (Lee, 2010).

The most effective treatment has not been reported (Jahanfar, 2013). Thus, the initial antimicrobial choice is influenced by the current experience with staphylococcal infections at a given institution. Dicloxacillin, 500 mg orally four times daily, may be started empirically. Erythromycin is given to women who are penicillin sensitive. If the infection is caused by resistant, penicillinase-producing staphylococci or if resistant organisms are suspected while awaiting the culture results, then vancomycin, clindamycin, or trimethoprim-sulfamethoxazole is given (Sheffield, 2013). Although clinical response may be prompt, treatment is recommended for 10 to 14 days.

Marshall and coworkers (1975) demonstrated the importance of continued breastfeeding. They reported that of 65 women with mastitis, the only three who developed abscesses were among the 15 women who quit breastfeeding. Vigorous milk expression may be sufficient treatment alone (Thomsen, 1984). Sometimes the infant will not nurse on the inflamed breast. This probably is not related to any changes in the milk taste but is secondary to engorgement and edema, which can make the areola harder to grip. Pumping can alleviate this. When nursing bilaterally, it is best to begin suckling on the uninvolved breast. This allows let-down to commence before moving to the tender breast.

In resource-poor countries, breastfeeding in women infected with the human immunodeficiency virus (HIV) is not contraindicated. In the setting of mastitis or breast abscess, it is recommended to stop feeding from the infected breast. This is because HIV RNA levels increase in affected breast milk. These levels return to baseline after symptoms resolve (Semrau, 2013).

Breast Abscess

In a population-based study of nearly 1.5 million Swedish women, the incidence of breast abscess was 0.1 percent (Kvist, 2005). An abscess should be suspected when defervescence does not follow within 48 to 72 hours of mastitis treatment or when a mass is palpable. Again, sonographic imaging is valuable. Breast abscesses can be large, and in one case report, 2 L of pus were released (Martic, 2012). Traditional therapy is surgical drainage, which usually requires general anesthesia. The incision ideally is placed along Langer skin lines for a cosmetic result (Stehman, 1990). In early cases, a single incision over the most dependent portion of fluctuation is usually sufficient. Multiple abscesses, however, require several incisions and disruption of loculations. The resulting cavity is loosely packed with gauze, which should be replaced at the end of 24 hours by a smaller pack.

A more recently used technique that is less invasive is sonographically guided needle aspiration using local analgesia. This has an 80- to 90-percent success rate (Geiss, 2014; Schwarz, 2001). In a randomized trial, Naeem and colleagues (2012) compared surgical drainage and aspiration. They found aspiration resulted in quicker healing at 8 weeks, 77 versus 93 percent, respectively.

CHAPTER 38: Contraception

From the evidence available, it appears to be tolerably satisfactorily demonstrated that in women who copulate at frequent intervals the tube must be regarded as a species of receptaculum seminis, in which spermatozoa are always present and waiting for the ovum, and that fertilization usually occurs in the tubes and only rarely in the uterus.

—J. Whitridge Williams (1903)

INTRODUCTION

Nearly half of all pregnancies each year in the United States are unintended (Finer, 2016). These may follow contraceptive method failure or stem from lack of contraceptive use. In 2011 to 2013, 7 percent of sexually active fertile women in the United States not pursuing pregnancy did not use any birth control method (Daniels, 2015).

For those seeking contraception, effective contraceptive methods are available and variably selected (Table 38-1). With these methods, estimated failure rates of perfect and typical use during the first year differ widely. To reflect these failure rates, the World Health Organization (WHO) has grouped methods into efficacy tiers (see Table 38-1). Implants and intrauterine devices are found in the top tier. They effectively lower unintended pregnancy rates and are considered long-acting reversible contraception (LARC). The American College of Obstetricians and Gynecologists (2017c) recognizes these tiers, recommends counseling on *all* options, and encourages highly effective LARC for appropriate candidates.

TABLE 38-1

Contraceptive Failure Rates During the First Year of Method Use in Women in the United States

Method[a]	Perfect Use	Typical Use
Top Tier: Most Effective		
Intrauterine devices:		
Levonorgestrel system	0.2	0.2
T 380A copper	0.6	0.8
Levonorgestrel implants	0.05	0.05
Female sterilization	0.5	0.5
Male sterilization	0.1	0.15
Second Tier: Very Effective		
Combination pill	0.3	9
Vaginal ring	0.3	9
Patch	0.3	9
DMPA	0.2	6
Progestin-only pill	0.3	9
Third Tier: Effective		
Condom		
Male	2	18
Female	5	21
Diaphragm with spermicides	6	12
Fertility-awareness		24
Standard days	5	
Two day	4	
Ovulation	3	
Symptothermal	0.4	
Fourth Tier: Least Effective		
Spermicides	18	28
Sponge		
Parous women	20	24
Nulliparous women	9	12
No WHO Category		

Method[a]	Perfect Use	Typical Use
Withdrawal	4	22
No contraception	85	85

[a]Methods organized according to tiers of efficacy.

DMPA = depot medroxyprogesterone acetate; WHO = World Health Organization.

Data from Trussell, 2011a.

No contraceptive method is completely without side effects, but contraception usually poses less risk than pregnancy. However, some disorders or medications can raise the risks from certain contraceptives. The World Health Organization (2015) has provided and updated evidence-based guidelines, termed *Medical Eligibility Criteria*, for the use of all highly effective reversible contraceptive methods by women with various health conditions. Individual countries have subsequently modified these guidelines. The *United States Medical Eligibility Criteria (US MEC)* was updated in 2016 by the Centers for Disease Control and Prevention (Curtis, 2016b). These documents are available at: http://www.cdc.gov/reproductivehealth/UnintendedPregnancy/Contraception_Guidance.htm.

In the United States MEC, reversible contraceptive methods are organized into six groups by their similarity: combination hormonal contraceptives (CHCs), progestin-only pills (POPs), depot medroxyprogesterone acetate (DMPA), implants, levonorgestrel-releasing intrauterine system (LNG-IUS), and copper intrauterine devices (Cu-IUDs). For a given health condition, each method is categorized 1 through 4 (Table 38-2). The score describes the safety profile for a typical woman with that condition: (1) no restriction of method use, (2) method advantages outweigh risks, (3) method risks outweigh advantages, and (4) method poses an unacceptably high health risk.

TABLE 38-2

Contraindications and Cautions with Specific Contraceptive Methods

1 = no method restrictions
2 = method benefits outweigh risks
3 = method risks outweigh benefits
4 = method poses an unacceptably high health risk

In this table, a blank space indicates the method is category 1 or 2

Condition	CHC[a]	POP	DMPA	Implants	LNG-IUS	Cu-IUD
Postpartum <21 d/<30 d	4/3					
21–42 d	2/3[b]					
Postpregnancy infection					4	4
Smoking & age ≥35 yr	3/4[c]					
Active breast cancer	4	4	4	4	4	
Breast cancer disease free ≥5 yr	3	3	3	3	3	
Multiple cardiovascular risks	3/4[d]		3

SLE & severe thrombocytopenia			3			3/2
Complicated solid-organ transplant	4				3/2	3/2

[a]Combination hormone contraception (CHC) group includes pills, vaginal ring, and patch.

[b]Associated risks that increase category score include: age ≥35, transfusion at delivery, BMI ≥30, postpartum hemorrhage, cesarean delivery, smoking, preeclampsia.

[c]Smoking ≥15 cigarettes/day increases risk category to 4 in this age group.

[d]Risk category score is modified by associated risk factors and disease severity.

[e]Including superficial thrombosis.

[f]Oral agents only. Ring and patch are category 1.

[g]Benign hepatic adenoma or hepatocellular cancer. Focal nodular hyperplasia compatible with hormone use.

[h]These include phenytoin, barbiturates, carbamazepine, oxcarbazepine, primidone, topiramate.

[i]In those methods under Start/Continue columns, the first US MEC number refers to whether a method may be initiated in an affected patient. For patients who initially develop the condition while using a specific method, the second number refers to risks for continuing that method.

[j]Prior to evaluation.

[k]Those on chronic corticosteroids and at risk for bone fracture.

AIDS = acquired immunodeficiency syndrome; APA = antiphospholipid antibodies; ARV = antiretroviral; BP = blood pressure; BMI = body mass index; CHTN = chronic hypertension; Cu-IUD = copper intrauterine device; DM = diabetes mellitus; DMPA = depot medroxyprogesterone acetate; GC/CT = gonorrhea/chlamydial infection; GTD = gestational trophoblastic disease; ISHD = ischemic heart disease; LNG-IUS = levonorgestrel-releasing intrauterine system; MS = multiple sclerosis; PI = protease inhibitor; PID = pelvic inflammatory disease; POP = progestin-only pills; SLE = system lupus erythematosus; VTE = venous thromboembolism.

Compiled from Curtis, 2016b; Merck, 2015; Teva Women's Health, 2014.

Alternatively, depending on the underlying disorder or patient desire, male or female sterilization may be a preferred or recommended permanent contraceptive method (American College of Obstetricians and Gynecologists, 2017b). These options are fully discussed in Chapter 39.

INTRAUTERINE DEVICES

Globally, 14 percent of reproductive-aged women use intrauterine contraception, and in the United States, 10 percent of contracepting women use this method (Buhling, 2014; Daniels, 2015). The five intrauterine devices (IUDs) currently approved for use in the United States are *chemically active* and continually elute either copper or levonorgestrel. These all have a T-shaped frame of polyethylene that is compounded with barium to render them radiopaque. Of devices, *Mirena* and *Liletta* both measure 32 × 32 mm and contain a 52-mg levonorgestrel-releasing cylinder reservoir in the stem of the T (Fig. 38-1). Two trailing strings that are tan (*Mirena*) or blue (*Liletta*) are attached to the distal stem to aid eventual device removal. *Skyla*—known as *Jaydess* in some countries—contains 13.5 mg of levonorgestrel. It has smaller dimensions—28 × 30 mm—and was sized to more appropriately fit a nulliparous uterus (Gemzell-Danielsson, 2012). *Kyleena* has the same dimensions but contains 19.5 mg of the same progestin. Two trailing strings off *Skyla* are tan, and those off *Kyleena* are blue. *Skyla* and *Kyleena* can be differentiated from *Mirena* and *Liletta* visually and sonographically by a silver ring near the junction of their stem and arms. *Mirena* and *Kyleena* are currently approved for 5 years of use following insertion, whereas *Skyla* and *Liletta* are approved for 3 years.

FIGURE 38-1
Intrauterine devices (IUDs). **A.** *ParaGard T 380A* copper IUD. **B.** *Mirena* levonorgestrel-releasing intrauterine system. (Reproduced with permission from Stuart GS: Contraception and sterilization. In Hoffman BL, Schorge JO, Bradshaw KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Joanna S. Sheffield: Williams Obstetrics, 25th Edition

The third device, the T380A IUD named *ParaGard,* is wound with copper, and two strings extend from the stem base. Originally blue, the strings are now white. It is currently approved for 10 years of use following insertion (Teva Women's Health, 2014).

In addition to these five currently marketed IUDs, women may retain discontinued brands. A *Lippes Loop* has two "S" shapes stacked one on the other. The *Dalkon Shield* has a crab form, whereas a *Copper 7* mirrors that number. *Progestasert* is an early T-shaped progestin-releasing IUD. Last, various metal-eluting ring devices are common in Asia.

Contraceptive Action

All these IUDs are effective. Failure rates are well below 1 percent and similar overall to those of tubal sterilization (Thonneau, 2008; Trussell, 2011b). Their mechanisms have not been precisely defined, but prevention of fertilization is now favored.

With the LNG-IUS, long-term progestin release leads to endometrial atrophy, which hinders normal implantation (Silverberg, 1986). Moreover, progestins create scant viscous cervical mucus that obstructs sperm motility (Apter, 2014; Moraes, 2016). Within the uterus, an intense local endometrial inflammatory response is induced, especially by copper-containing devices. Cellular and humoral components of this inflammation are expressed in endometrial tissue and in fluid filling the uterine cavity and fallopian tubes. These lead to decreased sperm and egg viability (Ortiz, 2007). Also, in the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. Also, with the Cu-IUD specifically, copper levels rise in the cervical mucus of users and act to decrease sperm motility and viability (Jecht, 1973). The above effects are considered primary for contraception because ovulation inhibition is inconsistent with the LNG-IUS and lacking with the Cu-IUD (Nilsson, 1984).

Method-Specific Adverse Effects

Ectopic Pregnancy

Contraindications to IUD use are few and shown in Table 38-2. In the past, IUDs were perceived to increase the risk of ectopic pregnancy, but this has since been clarified. Specifically, IUDs provide effective contraception and lower the absolute number of ectopic pregnancies by half compared with the rate in noncontracepting women (World Health Organization, 1985, 1987). But, the IUD mechanisms of action are more effective in preventing *intrauterine* implantation. Thus, if an IUD fails, a higher proportion of pregnancies are likely to be ectopic (Backman, 2004; Furlong, 2002).

Lost Device

Expulsion of an IUD from the uterus is most common during the first month. Thus, women are examined approximately 1 month following IUD insertion, usually after menses, to identify the tails trailing from the cervix. Following this, a woman is instructed to palpate the strings each month after menses. Regardless of IUD type, the cumulative 3-year expulsion rate approximates 10 percent (Madden, 2014; Simonatto, 2016). This rate is higher in those ≤25 years (Jatlaoui, 2017).

If the tail of an IUD cannot be visualized, the device may have been expelled, may have perforated the uterus, or may be malpositioned. Alternatively, the device may be normally positioned with its tails folded within the endocervical canal or uterine cavity. To investigate, after excluding pregnancy, a cytological brush can be twirled within the endocervical canal to entangle the strings and bring them gently into the vagina. If unsuccessful, the uterine cavity is probed gently with a Randall stone clamp or with a specialized rod with a terminal hook to snare the strings or device.

One should not assume that a device has been expelled unless it was seen. Thus, if tails are not visible and the device is not felt by gentle probing of the uterine cavity, transvaginal sonography can be used to ascertain if the device lies within the uterus. Although traditional sonography will document IUD position adequately in most cases, three-dimensional sonography offers improved visualization, especially with the LNG-IUS (Moschos, 2011). If sonography is inconclusive or if no device is seen, then a plain radiograph of the abdominopelvis is taken. Computed tomography (CT) scanning or, less commonly, magnetic resonance (MR) imaging is an alternative (Boortz, 2012). It is safe to perform MR imaging at 1.5 and 3 Tesla (T) with an IUD in place (Ciet, 2015).

Perforation

During uterine sounding or IUD insertion, the uterus may be perforated, which is identified by the tool traveling farther than the expected uterine length based on initial bimanual examination. Rates approximate 1 per 1000 insertions, and risks include puerperal insertion, lactation, provider inexperience, and extremes of uterine flexion (Harrison-Woolrych, 2003; Heinemann, 2015). Although devices may migrate spontaneously into and through the uterine wall, most perforations occur, or at least begin, at the time of insertion (Ferguson, 2016).

With acute perforation, the fundus is the more common site, and bleeding is typically minimal due to myometrial contraction around the puncture hole. If no brisk or persistent bleeding is noted from the os following instrument or device removal, then patient observation alone is reasonable. Rarely, acute lateral perforations may lacerate the uterine artery, and subsequent brisk bleeding may prompt laparoscopy or laparotomy for control. Following any perforation, although this is not firmly evidence-based, a single dose of broad-spectrum antibiotic may mitigate infection.

With chronic perforation, a device can penetrate the muscular uterine wall to varying degrees. A patient may be asymptomatic but abdominal pain, uterine bleeding, or missing strings can be clues (Kaislasuo, 2013). Those with a predominantly intrauterine location are usually managed by hysteroscopic IUD removal. In contrast, devices that have nearly or completely perforated through the uterine wall are more easily removed laparoscopically. Notably, an extrauterine Cu-IUD frequently induces an intense local inflammatory reaction and adhesions (Kho, 2014). Laparotomy may be necessary, and bowel preparation is considered. Sigmoid and bladder perforations and small-bowel obstruction have been reported remote from insertion (Sano, 2017; Xu, 2015; Zeino, 2011).

Menstrual Changes

Dysmenorrhea and bleeding irregularities can complicate IUD use (Aoun, 2014; Grunloh, 2013). These can be treated with some degree of success by nonsteroidal antiinflammatory drugs (NSAIDs) or tranexamic acid, which is an antifibrinolytic (Godfrey, 2013; Madden, 2012; Sørdal, 2013). Of the two IUDs, heavy bleeding more often complicates Cu-IUD use and may cause iron-deficiency anemia, for which oral iron salts are given. With the LNG-IUS, irregular spotting for up to 6 months after placement often gives way to progressive amenorrhea, which is reported by 30 percent of women after 2 years and by 60 percent after 12 years (Ronnerdag, 1999). This is frequently associated with improved dysmenorrhea.

Infection

The risk of upper genital tract device-related infection is greatest during the first months following IUD insertion (Farley, 1992; Turok, 2016). Pathogens include *Neisseria gonorrhoeae, Chlamydia trachomatis,* and vaginal flora. Women at risk for sexually transmitted diseases (STDs) should be screened either before or at the time of IUD insertion (Centers for Disease Control and Prevention, 2015; Sufrin, 2012). That said, device insertion need not be delayed while awaiting sexually transmitted disease or Pap test results in asymptomatic women (Birgisson, 2015). If these bacteria are subsequently found and the patient is without symptoms, then the IUD may remain and treatment prescribed as detailed in Chapter 65 (Chlamydial Infections). Importantly, *routine* antimicrobial prophylaxis before insertion is not recommended (Grimes, 2012; Walsh, 1998). And the American Heart Association does not recommend bacterial endocarditis prophylaxis with insertion (Nishimura, 2014).

After the first month, infection risk is not increased in IUD users who would otherwise be at low risk of sexually transmitted infections. Correspondingly, IUDs appear to cause little, if any, increase in infertility rates in these low-risk patients (Hubacher, 2001). The American College of Obstetricians and Gynecologists (2015c, 2016a) recommends that women at low risk for STDs, including adolescents, be considered good candidates for IUDs. The IUD is also safe and effective in women infected with human immunodeficiency virus (HIV) and may be used in others who are immunosuppressed (Centers for Disease Control and Prevention, 2015; Tepper, 2016a).

If infection does develop, it may take several forms and typically requires broad-spectrum antimicrobials. *Pelvic inflammatory disease (PID)* without abscess is treated with antibiotics on an outpatient or inpatient basis, depending on infection severity. There are theoretical concerns that a coexistent IUD may worsen the infection or delay resolution. A provider may choose to remove an IUD in this setting, although some evidence supports allowing a device to remain during treatment in those hospitalized with mild or moderate PID (Centers for Disease Control and Prevention, 2015; Tepper, 2013). If infection fails to improve during 48 to 72 hours of treatment, the device is removed. *Tuboovarian abscess* can complicate PID and is treated aggressively with intravenous broad-spectrum antibiotics and IUD removal. Last, *septic abortion* mandates immediate uterine evacuation and antibiotics.

Actinomyces israelii is a gram-positive, slow-growing, anaerobic indigenous vaginal bacterium that rarely causes suppurative infection. Some have found it more frequently in the vaginal flora or on the Pap smears of IUD users (Curtis, 1981; Kim, 2014). Current recommendations advise that an asymptomatic woman may retain her IUD and does not require antibiotic treatment (American College of Obstetricians and Gynecologists, 2017c; Lippes, 1999; Westhoff, 2007a). However, if signs or symptoms of infection develop in a woman who harbors *Actinomyces* species, then the device is removed and antibiotics are given. Early findings with infection include fever, weight loss, abdominal pain, and abnormal uterine bleeding or discharge. *Actinomyces* species are sensitive to antibiotics with gram-positive coverage, notably the penicillins.

Pregnancy with an IUD

For women who conceive while using an IUD, ectopic pregnancy should be excluded. With intrauterine pregnancy, if the tail is seen, it should be grasped and the IUD removed by gentle outward traction. This action reduces complications such as abortion, chorioamnionitis, and preterm birth (Fulkerson Schaeffer, 2017; Kim, 2010). Specifically, in one cohort, a 54-percent abortion rate and 17-percent preterm delivery rate was noted if the device remained in situ. More favorably, rates of 25 percent and 4 percent, respectively, resulted from prompt Cu-IUD removal (Tatum, 1976). Few data guide management with the LNG-IUS, and most practice extrapolates from copper devices.

If the tail is not visible, attempts to locate and remove the device may result in abortion. Although not our practice, some case reports and small series describe sonography or hysteroscopy to assist in difficult device removals (Pérez-Medina, 2014; Schiesser, 2004). After fetal viability is reached, it is unclear whether it is better to remove an IUD whose strings are visible and accessible or to leave it in place. Fetal malformation rates are not greater with a device left in situ (Tatum, 1976; Vessey, 1979).

Second-trimester miscarriage with an IUD in place is more likely to be infected (Vessey, 1974). Sepsis may be fulminant and fatal. Pregnant women with a device in utero who demonstrate any evidence of pelvic infection are treated with broad-spectrum antibiotics and prompt uterine evacuation. Because of these risks, a woman should be given the option of early pregnancy termination if the device cannot be removed early in pregnancy. Last, in women who give birth with a device in place, appropriate steps should be taken at delivery to identify and remove the IUD.

IUD Insertion

Timing

To reduce expulsion rates and perforation risks, IUD insertion has traditionally followed complete uterine involution—at least 6 weeks after delivery. Women delivered at Parkland Hospital are seen 3 weeks postpartum, and IUDs are inserted 6 weeks postpartum or sooner if involution is complete.

Alternatively, immediately after miscarriage, surgical abortion, or delivery, an IUD may be inserted in the absence of overt infection (Lopez, 2015a; Okusanya, 2014). Also, “immediate” insertion 1 week after mifepristone and completed medical abortion has been described (Sääv, 2012; Shimoni, 2011). The risk of IUD expulsion is slightly higher if it is placed immediately following any of these recent pregnancies (Whitaker, 2017). However, in studies, the number of women in immediate-placement groups who ultimately receive and retain an IUD is greater than in groups scheduled for traditionally timed placement, some of whose members do not return for insertion (Bednarek, 2011; Chen, 2010).

With immediate insertion, techniques depend on uterine size. After first-trimester evacuation, the IUD can be placed using the manufacturer’s standard instructions. If the uterine cavity is larger, the IUD can be placed using ring forceps with sonographic guidance (Drey, 2009; Fox, 2011).

Immediately following vaginal or cesarean delivery, an IUD can be placed by a hand, by its inserter tube, or by ring forceps (Levi, 2015; Xu, 1996). With any of these methods, the arms of the IUD need not be folded into the inserter tube prior to insertion. During cesarean delivery placement, the hand or inserter travels through the unsutured open hysterotomy to deposit the device at the fundus. A second hand cupping the outer fundus can provide back pressure and stabilize the uterus during insertion. Strings are then gently directed toward the cervix. For instrumented insertion following vaginal delivery, the clinician resterilizes the vulva and

changes gloves after placental delivery but before perineal repairs. The anterior lip of the floppy cervix is held with ring forceps. A second ring forceps grasp the IUD stem and guides it through the uterine cavity to the fundus. For manual insertion following vaginal delivery, the provider secures the IUD between the index and middle fingers to deposit the device. In either case, back pressure against the fundus by an abdominal hand can guide positioning (Stuart, 2017; The ACQUIRE Project, 2008).

For placement not related to pregnancy, insertion near the end of normal menstruation, when the cervix is usually softer and somewhat more dilated, may be easier and also helps exclude early pregnancy. But, insertion is not limited to this time. For the woman who is sure she is not pregnant and does not want to be pregnant, insertion is done at any time.

Technique

Before insertion, contraindications are sought. Candidates are counseled, and written consent obtained. An oral NSAID, with or without codeine, can be used to allay cramps after insertion (Ngo, 2015). But NSAIDs, misoprostol, or even paracervical blockade do not consistently decrease discomfort experienced during device placement (Bednarek, 2015; Hubacher, 2006; Mody, 2012; Pergialiotis, 2014). Of topical lidocaine products, 2-percent gel is ineffective, but a newer gel and a spray both show promise (Aksoy, 2016; Lopez, 2015b; Tornblom-Paulander, 2015). Bimanual pelvic examination delineates uterine position and size. Abnormalities are evaluated, as they may contraindicate insertion. Mucopurulent cervicitis or significant vaginitis is appropriately treated and resolved before IUD insertion.

The cervical surface is cleansed with an antiseptic solution, and sterile instruments and a sterile IUD are used. A tenaculum is placed on the cervical lip, and the canal and uterine cavity are straightened by applying gentle outward traction. The cavity is then probed by a uterine sound to identify its direction and depth. Specific steps of ParaGard and Mirena insertion are shown in Figures 38-2 and 38-3 and outlined in their respective package inserts.

FIGURE 38-2

Insertion of the *Mirena* intrauterine system. Initially, threads from behind the slider are first released to hang freely. The slider found on the handle should be positioned at the top of the handle nearest the device. The IUD arms are oriented horizontally. A flange on the outside of the inserter tube is positioned from the IUD tip to reflect the depth found with uterine sounding. **A.** As both free threads are pulled, the *Mirena* IUD is drawn into the inserter tube. The threads are then tightly fixed from below into the handle's cleft. In these depictions, the inserter tube has been foreshortened. The inserter tube is gently inserted into the uterus until the flange lies 1.5 to 2 cm from the external cervical os to allow the arms to open. **B.** While holding the inserter steady, the IUD arms are released by pulling the slider back to reach the raised horizontal mark on the handle, but no further. **C.** The inserter is then gently guided into the uterine cavity until its flange touches the cervix. **D.** The device is released by holding the inserter firmly in position and pulling the slider down all the way. The threads will be released automatically from the cleft. The inserter may then be removed, and IUD strings trimmed. (Reproduced with permission from Stuart GS: Contraception and sterilization. In Hoffman BL, Schorge JO, Bradshaw KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)

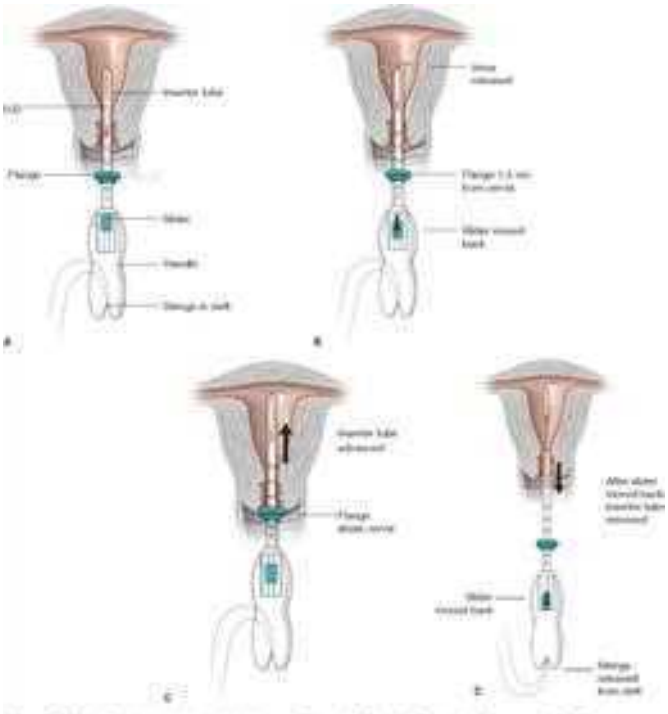

FIGURE 38-3

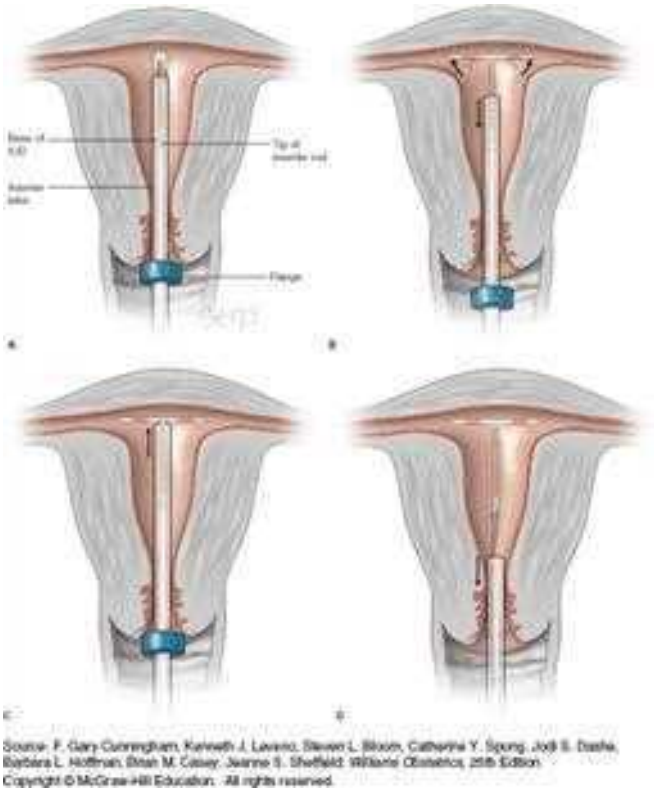
Insertion of *ParaGard T 380A*. The uterus is sounded, and the IUD is loaded into its inserter tube not more than 5 minutes before insertion. A blue plastic flange on the outside of the inserter tube is positioned from the IUD tip to reflect uterine depth. The IUD arms should lie in the same plane as the flat portion of the oblong blue flange. **A.** The inserter tube, with the IUD loaded, is passed into the endometrial cavity. A long, solid, white inserter rod abuts the base of the IUD. When the blue flange contacts the cervix, insertion stops. **B.** To release the IUD arms, the solid white rod within the inserter tube is held steady, while the inserter tube is withdrawn no more than 1 cm. **C.** The inserter tube, not the inserter rod, is then carefully moved upward toward the top of the uterus until slight resistance is felt. At no time during insertion is the inserter rod advanced forward. **D.** First, the solid white rod and then the inserter tube are withdrawn individually. At completion, only the

threads should be visible protruding from the cervix. These are trimmed to allow 3 to 4 cm to extend into the vagina. (Reproduced with permission from Stuart GS: Contraception and sterilization. In Hoffman BL, Schorge JO, Bradshaw KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Following insertion, only the threads should be visible trailing from the cervix. These are trimmed to allow 3 to 4 cm to protrude into the vagina, and their length is recorded. If improper device positioning is suspected, placement should be confirmed, using sonography if necessary. If the IUD is not positioned completely within the uterus, it is removed and replaced with a new device. An expelled or partially expelled device should not be reinserted.

PROGESTIN IMPLANTS

Etonogestrel Implant

Contraception can be provided by thin, pliable progestin-containing cylinders that are implanted subdermally and release hormone over many years. One of these, *Nexplanon* is a single-rod implant with 68 mg of etonogestrel covered by an ethylene vinyl acetate copolymer cover. The implant is placed subdermally on the medial surface of the upper arm 8 to 10 cm from the elbow in the biceps groove and is aligned with the long axis of the arm. It may be used as contraception for 3 years, removed, and then replaced at the same site or in the opposite arm (Merck, 2016a).

Nexplanon is radiopaque, and its inserter device is designed to assist with subdermal positioning and avert deeper placement. This device replaced *Implanon*, which is not radiopaque. A misplaced *Implanon* may be identified with sonography using a 10- to 15-MHz linear array transducer (Shulman, 2006). In some cases, MR imaging may be required if supplemental information is needed despite sonography (Correia, 2012). Both implants are similarly shaped and pharmacologically identical. They are highly effective, and the mechanism of action for progestin-only products is described later (Progestin-Only Contraceptives) (Croxatto, 1998; Mommers, 2012). *Implanon* is safe and still approved by the Food and Drug Administration (FDA), but it is no longer distributed by the manufacturer.

Levonorgestrel Implants

The first progestin implants contained levonorgestrel (LNG), and systems are still available outside the United States. *Jadelle*, originally named *Norplant-2*, provides LNG and contraception for 5 years through two subdermally implanted Silastic rods. After this time, rods may be removed and if desired, new rods inserted at the same site (Bayer Group, 2015). *Jadelle* is approved by the FDA, however, it is not marketed or distributed in the United States. Sino-implant II is a two-rod system with the same amount (150 mg) of LNG and same mechanism of action as *Jadelle* but provides 4 years of contraception. Sino-implant II is manufactured in China and approved for use by 20 countries in Asia and Africa (FHI 360, 2012).

Like the etonogestrel implant, these systems are placed subdermally on the inner arm approximately 8 cm from the elbow and have similar removal steps. Implants vary regarding their insertion technique, and manufacturer instructions should be consulted. Both implant systems are highly effective (Sivin, 1998; Steiner, 2010).

The forerunner of these implants was the *Norplant System,* which provided LNG in six Silastic rods implanted subdermally. The manufacturer stopped distributing the system in 2002.

Few data compare the LNG and etonogestrel implants. In one, efficacy and discontinuation rates by 2.5 years of use were similar (Bahamondes, 2015).

Method-Specific Adverse Effects

Unscheduled bleeding is common with progestin-only methods and described in Progestin-Only Contraceptives. Device-specific adverse effects derive mainly from malpositioning. First, branches of the medial antebrachial cutaneous nerve can be injured during implant or needle insertion that is too deep or during exploration for a lost implant. Clinically, numbness and paresthesia over the anteromedial aspect of the forearm are noted (Wechselberger, 2006). Second, nonpalpable devices are not uncommon and require radiological imaging for localization. As an adjunct, one group adopted the hook-wire tagging method used in breast tumor surgery to allow deep-lying implants to be marked prior to extraction (Nouri, 2013). If imaging fails to locate an implant, etonogestrel blood level determination can help verify that the implant is indeed in situ. This special assay must be coordinated with the manufacturer (1–877–467–5266).

Implant Insertion

Timing

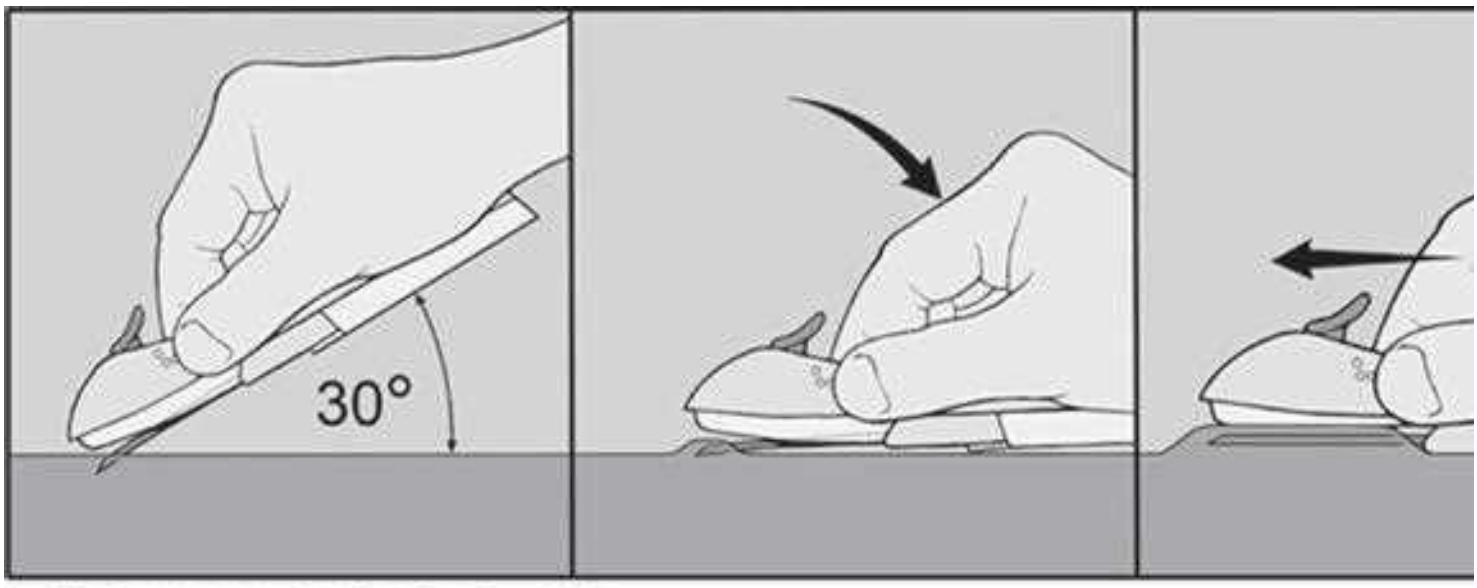
For those not currently using hormonal contraception, the etonogestrel implant is ideally inserted within 5 days of menses onset. With LNG-releasing implants, contraception is established within 24 hours if inserted within the first 7 days of the menstrual cycle (Sivin, 1997; Steiner, 2010). For transitioning methods, an implant is placed on the day of the first placebo combination oral contraceptive (COC) pill; on the day that the next depot-medroxyprogesterone injection would be due; or within 24 hours of taking the last POP (Merck, 2016a). In women certain that they are not pregnant, insertion at other times of the cycle is followed by alternative contraception for 7 days. Related to pregnancy, an implant may be inserted before discharge following delivery or abortion (Sothornwit, 2017).

Nexplanon Insertion Technique

With the patient lying down, her nondominant arm, forearm, and hand are outstretched on the bed with the inner aspects of each exposed upward, and the elbow is flexed. The insertion site is marked with a sterile pen 8 to 10 cm proximal to the medial condyle of the humerus. A second mark is placed 4 cm proximally and delineates the final path of the implant. The Nexplanon is inserted using sterile technique. The area is cleansed aseptically, and a 1-percent lidocaine anesthetic track is injected beneath the skin along the planned insertion path. The implant is then placed as shown in Figure 38-4. After placement, both patient and provider should palpate and identify both ends of the 4-cm implant. To minimize bruising at the site, a pressure bandage is created around the arm and is removed the following day.

FIGURE 38-4

Nexplanon insertion. A sterile pen marks the insertion site, which is 8 to 10 cm proximal to the medial humeral condyle. A second mark is placed 4 cm proximally along the arm's long axis. The area is cleaned aseptically, and a 1-percent lidocaine anesthetic track is injected along the planned insertion path. **A.** The insertion device is grasped at its gripper bubbles found on either side, and the needle cap is removed outward. The device can be seen within the needle bore. The needle bevel then pierces the skin at a 30-degree angle. **B.** Once the complete bevel is subcutaneous, the needle is quickly angled downward to lie horizontally. **C.** Importantly, the skin is tented upward by the needle as the needle is slowly advanced horizontally and subdermally. **D.** Once the needle is completely inserted, the lever on the top of the device is pulled backward toward the operator. This retracts the needle and thereby deposits the implant. The device is then lifted away from the skin. After placement, both patient and operator should palpate the 4-cm implant.



With implant extraction, the removal site is first cleansed with antiseptic. The proximal end of the implant is depressed with a finger to allow the distal end to bulge up toward the skin. After anesthetizing the skin over this bulge, the skin is incised 2 mm toward the elbow along the long axis of the arm. The proximal butt of the implant is then pushed toward this incision. Once visible, the distal end of the implant is grasped with a hemostat and removed. If present, superficial adhesions surrounding an implant may be dissected away with hemostat tips placed into the incision.

PROGESTIN-ONLY CONTRACEPTIVES

Actions and Side Effects

Progestin-only contraceptives include the implants just described, injectables, and pills. As their primary contraceptive action, these progestins suppress luteinizing hormone (LH) and in turn block ovulation. As other effects, cervical mucus is thickened to retard sperm passage, and atrophy renders the endometrium unfavorable for implantation. Fertility is restored rapidly following cessation of progestin-only contraception. An exception is DMPA, as described in Barrier Methods (Mansour, 2011).

For all progestin-only methods, irregular or heavy uterine bleeding is a distinct disadvantage. It is the most frequently reported adverse event leading to method discontinuation. Often, counseling and reassurance is sufficient. Troublesome bleeding may be improved by one to two cycles of combination oral contraceptives, by a 1- to 3-week course of estrogen alone, or by a short course of NSAIDs combined with the established method (Abdel-Aleem, 2013). Fortunately, with prolonged use, progestins induce endometrial atrophy, which leads to sustained amenorrhea. For the well-counseled patient, this is often an advantage.

Most progestin-only contraceptive methods do not significantly affect lipid metabolism, glucose levels, hemostatic factors, liver function, thyroid function, or blood pressure (Dorflinger, 2002). However, the increased low-density lipoprotein (LDL) cholesterol and decreased high-density lipoprotein (HDL) cholesterol levels seen with DMPA may be less desirable for women with cardiac or vascular disease risks (Kongsayreepong, 1993).

Progestin-only methods do not impair milk production and are an excellent choice for lactating women. There are no increased risks of genital tract, liver, or breast neoplasia (Samson, 2016; Wilailak, 2012; World Health Organization, 1991a,b, 1992). Weight gain and bone fracture are not prominent side effects of this contraceptive group, except for depot progesterone, discussed in Barrier Methods (Lopez, 2012a, 2013a). Functional ovarian cysts develop with a greater frequency in women using progestin-only agents, although they do not usually necessitate intervention (European Society of Human Reproduction and Embryology, 2001; Hidalgo, 2006; Nahum, 2015). Last, an association between depression and DMPA or POPs is unclear (Civic, 2000; Pagano, 2016; Svendal, 2012; Westhoff, 1995). Women with depression may be prescribed these methods, but surveillance following initiation is reasonable.

Progestin Contraindications

These methods are ideal for most women, but contraindications and cautions are associated with a few conditions listed in Table 38-2. Current breast cancer and pregnancy are the only two absolute contraindications. In a few instances, manufacturer restrictions differ from the US MEC. First, manufacturer prescribing information lists thrombosis or thromboembolic disorders as contraindications (Merck, 2016a; Pfizer, 2015a,b). However, for individuals with these disorders, US MEC considers progestin-containing methods category 2. Moreover, evidence does not link progestin-only methods with thromboembolism, stroke, or cardiovascular disease (Mantha, 2012; Tepper, 2016b; World Health Organization, 1998). Second, for many progestin products, manufacturers note prior ectopic pregnancy as a contraindication. This is secondary to progesterone's effect of slowing fallopian tube motility and thereby delaying fertilized egg transport to the endometrial cavity. That said, effective contraception lowers pregnancy rates overall. Thus, for those with prior ectopic pregnancy, US MEC considers progestin injectables and implants category 1, and progestin-only pills are category 2.

HORMONAL CONTRACEPTIVES

These currently are available in forms that contain both estrogen and progestin or contain only progestin. Progestin-only injectables and pills are considered very effective, yet second-tier agents, due to the need for increased patient compliance. Similarly, products containing both estrogen and progestin, often termed combination hormonal contraception (CHC), are considered in this tier. These may be supplied as pills, transvaginal rings, or transdermal patches.

Combination Hormonal Contraceptives Mechanism of Action

Actions of combination hormonal contraceptives are multiple, but the most important effect is suppression of hypothalamic gonadotropin-releasing factors. This in turn blocks pituitary secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and thereby inhibits ovulation. The progestin component of CHCs provides ovulation prevention by suppressing LH; it thickens cervical mucus and thereby retards sperm passage; and it renders the endometrium unfavorable for implantation. Estrogen blocks ovulation by suppressing FSH release. To promote cycle control, estrogen stabilizes the endometrium, which prevents intermenstrual bleeding—also known as *breakthrough bleeding*. The net effect is an extremely effective yet highly reversible method (Mansour, 2011).

Combination Oral Contraceptive Pills

Composition

These pills are the most frequently used reversible birth control method in the United States. In a 2006 to 2010 survey, 16 percent of contracepting women in the United States were using these (Daniels, 2015). COCs are marketed in a wide variety of estrogen and progestin combinations. Most are available as generics, and the FDA (2016) confirms the bioequivalence of COC generics. The American College of Obstetricians and Gynecologists (2015a) supports the use of either branded or generic preparations.

Pharmacologically, ethinyl estradiol is the most common estrogen present in COC formulations in the United States. Less frequently, mestranol or estradiol valerate is used. Unwanted effects most often attributed to the estrogen component include breast tenderness, weight gain, nausea, and headache.

COCs also contain one of several progestins that are structurally related to progesterone, testosterone, or spironolactone. Thus, these progestins bind variably to progesterone, androgen, glucocorticoid, and mineralocorticoid receptors. These affinities explain many pill-related side effects and are often used to compare one progestin with another.

Most progestins used in COCs are related to testosterone and may impart androgenic side affects such as acne and adverse HDL and LDL levels. To avoid these effects, antiandrogenic progestins have been introduced and include *dienogest* and *nomegestrol acetate*. The latter is used in a COC approved outside the United

States. Despite these pharmacological differences, the true advantage of one progestin over another is less apparent clinically (Lawrie, 2011; Moreau, 2007).

Another progestin, *drospirenone*, is structurally similar to spironolactone. The doses in currently marketed COCs have effects similar to 25 mg of this diuretic (Seeger, 2007). Drospirenone displays antiandrogenic activity, provides an antialdosterone action to minimize water retention, and has antimineralocorticoid properties that may, in theory, cause potassium retention and hyperkalemia (Krattenmacher, 2000). Thus, it is avoided in women with renal or adrenal insufficiency or with hepatic dysfunction. Moreover, serum potassium level monitoring is recommended in the first month for patients chronically treated concomitantly with any drug associated with potassium retention. These include NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II antagonists, heparin, aldosterone antagonists, and potassium-sparing diuretics (Bayer HealthCare Pharmaceuticals, 2015).

Since the development of COCs, their estrogen and progestin content has dropped remarkably to minimize adverse effects. Currently, the lowest acceptable dose is limited by the ability to prevent pregnancy and to avoid unacceptable breakthrough bleeding. Thus, the daily estrogen content varies from 10 to 50 µg of ethinyl estradiol, and most contain 35 µg or less.

In a few COCs, inert placebo pills have been replaced by tablets containing iron. These have the suffix Fe added to their name. In addition, *Beyaz* has a form of folate —levomefolate calcium—within both its active and placebo pills.

With COCs termed *monophasic pills*, the progestin dose remains constant throughout the cycle. In others, the dose frequently is varied, and term *biphasic, triphasic,* or *quadriphasic pill* is used depending on the number of dose changes within the cycle. In some formulations, the estrogen dose also varies. In general, phasic pills were developed to reduce the total progestin content per cycle without sacrificing contraceptive efficacy or cycle control. The theoretical advantage of a lower total progesterone dose per cycle, however, has not been borne out clinically (Moreau, 2007). Cycle control also appears to be comparable among mono- through triphasic pills (van Vliet, 2011a,b,c).

Administration

Hormones are taken daily for a specified time (21 to 81 days) and then replaced by placebo for a specified time (4 to 7 days), which is called the “pill-free interval.” During these pill-free days, withdrawal bleeding is expected.

With the trend toward lower estrogen doses to minimize side effects, follicular development and ovulation may occur. To counter this, the active-pill duration in some formulations is extended to 24 days. In comparison, these 24/4 regimens perform similarly to higher-estrogen-dose 21/7 regimens (Anttila, 2011; Marr, 2012).

Alternatively, longer durations of active hormone, designed to minimize the number of withdrawal episodes, have similar efficacy and safety profiles as more traditional administration (Edelman, 2014). These extended-cycle products produce a 13-week cycle, that is, 12 weeks of hormone use, followed by a week for withdrawal menses. The product *Amethyst* provides continuous active hormone pills for 365 days each year. Such extended or continuous regimens may be especially suited for women with significant menstrual symptoms (Mendoza, 2014).

For general initiation, women ideally begin COCs on the first day of a menstrual cycle. In such cases, a supplementary contraceptive method is unnecessary. With the more traditional “Sunday start,” women begin pills on the first Sunday that follows menses onset, and an additional method is needed for 1 week to prevent conception. If menses begin on a Sunday, then pills are begun that day and no supplemental method is required. Alternatively, with the “quick start” method, COCs are started on any day, commonly the day prescribed, regardless of cycle timing. An additional method is used during the first week (Westhoff, 2002, 2007b). If the woman is unknowingly already pregnant during quick start initiation, COCs are not teratogenic (Lammer, 1986; Rothman, 1978; Savolainen, 1981). However, a missed menses following COC initiation should prompt pregnancy testing. Similar same-day initiation can be implemented with the contraceptive vaginal ring or patch (Murthy, 2005; Schafer, 2006).

For maximum efficiency, pills are best taken at the same time each day. If one dose is missed, the missed pill is taken immediately; the scheduled dose for that day is taken on time; and then daily pills are continued. If two or more doses are missed, the most recent missed pill is taken immediately; the scheduled dose for that day is taken on time; and an effective barrier technique used for 7 days while daily pills are then continued (Curtis, 2016a). If withdrawal bleeding fails to occur during the pill-free interval, a woman should continue her pills but seek attention to exclude pregnancy.

With initiation of COCs, spotting or bleeding is common. It does not reflect contraceptive failure and typically resolves within one to three cycles. If unscheduled bleeding persists, those with bleeding during the first part of a pill pack may benefit from an increase in the estrogen dose, whereas those with bleeding during the second part may improve with a higher progestin dose (Nelson, 2011).

Method-Specific Effects

Altered Drug Efficacy

Some drugs decrease COC effectiveness, and choosing another contraceptive method is preferable. However, if a COC is selected for concurrent use in these instances, a preparation containing a minimum of 30 µg ethinyl estradiol is ideally chosen. Conversely, some COCs interfere with the actions of certain drugs (see Table 38-2).

In obese women, COCs are effective (Lopez, 2016). Some studies point to lowered hormone bioavailability, but overall efficacy remains high (Nakajima, 2016; Westhoff, 2010; Yamazaki, 2015). With the transdermal patch method, however, evidence is more robust that obesity may alter pharmacokinetics and lower efficacy, as discussed in Transdermal Patch.

Metabolic Changes

Combination oral contraceptives alter lipid synthesis and in general raise serum levels of triglycerides and of total cholesterol, HDL, and very-low density lipoprotein (VLDL) cholesterol. Estrogen lowers LDL cholesterol concentrations. Oral contraceptives are not atherogenic, and their effect on lipids is clinically inconsequential for most women (Wallach, 2000). In women with dyslipidemias, limited data suggest that COCs increase the risk for myocardial infarction and minimally so for venous thromboembolism or stroke (Dragoman, 2016). For those with multiple additional risk factors for vascular disease, alternative contraceptive methods are recommended.

With COCs, protein metabolism is affected, and estrogens boost hepatic production of various globulins. First, fibrinogen and many of the clotting factor levels rise in direct proportion to the estrogen dose and may lead to thrombosis. Angiotensinogen production is also augmented by COCs, and its conversion by renin to angiotensin I may be associated with "pill-induced hypertension," discussed subsequently. Last, COCs elevate sex hormone-binding globulin (SHBG) levels, which in turn lower concentrations of bioavailable testosterone and lessen androgenic side effects.

Regarding carbohydrate metabolism, current low-dose formulations have minimal effects in women who do not have diabetes (Lopez, 2014). And, the risk of developing diabetes is not increased (Kim, 2002). For diabetic women, COCs may be used in nonsmokers with disease duration <20 years and without associated vascular disease, nephropathy, retinopathy, or neuropathy (Curtis, 2016b).

Of other metabolic changes, thyroid-binding globulin and thyroid-stimulating hormone (TSH) levels are elevated, but free plasma thyroxine (FT_4) levels are unchanged (Raps, 2014). Studies have not supported a connection between COCs and weight gain (Gallo, 2014).

Cardiovascular Effects

Despite increased plasma angiotensinogen (renin substrate) levels, women using low-dose COC formulations rarely develop clinically significant hypertension (Chasan-Taber, 1996). However, it is common practice for patients to return 8 to 12 weeks after COC initiation for evaluation of blood pressure and other symptoms.

During initial contraception selection, a history of gestational hypertension does not preclude subsequent COC use. Among women with well-controlled hypertension, COC use is linked to greater risks than nonusers for stroke, acute myocardial infarction, and peripheral arterial disease, and in these women, COCs are considered US MEC category 3 (Curtis, 2016b). Severe forms of hypertension, especially those with end-organ involvement, preclude COC use.

For nonsmoking women younger than 35, the risk of stroke is extremely low (World Health Organization, 1996). COCs are associated with a small increased risk for ischemic stroke (Chan, 2004; Lidegaard, 2012). Rates increase significantly for women who have hypertension, who smoke, or who have migraine headaches with visual aura or other focal neurological changes *and* use COCs (MacClellan, 2007; Tepper, 2016c). The evidence for stroke risk in migraineurs without aura is less clear (Etminan, 2005; Schürks, 2009). COC initiation may be considered for women with preexisting migraines without aura if they are otherwise healthy, younger, normotensive nonsmokers. For women with prior stroke, COCs should not be considered due to risks for repeat events.

For women with prior myocardial infarction, COCs should not be considered. Also, in women with multiple cardiovascular risk factors, which include smoking, hypertension, older age, and diabetes, the risk for myocardial infarction outweighs the benefits of this method. However, for those without these risks, low-dose oral contraceptives are not associated with an increased risk of myocardial infarction (Margolis, 2007; World Health Organization, 1997).

The risks for deep-vein thrombosis and pulmonary embolism are increased in women who use COCs (Stadel, 1981). These clearly are estrogen-dose related, and rates have substantively declined with lower-dose formulations containing 10 to 35 µg of ethinyl estradiol. The general-population risk of venous thromboembolism (VTE) is 4 to 5 events per 100,000 woman-years. The incidence of VTE with COC use increases three- to fivefold compared with nonusers (Shaw, 2013; van Hylckama Vlieg, 2009). Obesity raises the VTE risk, which is compounded by COCs (Horton, 2016; Suchon, 2016). Accordingly, in an obese woman, COCs are considered a US MEC category 2. VTEs are significantly increased in women older than 35 years who smoke, and COCs are not recommended. Those most at risk for VTE include women with thrombophilias (ESHRE Capri Workshop Group, 2013). Moreover, COC use during the month before a major operative procedure appears to double the risk for postoperative VTE (Robinson, 1991). Thus, the American College of Obstetricians and Gynecologists (2016d) recommends balancing the risks of VTE and the degree of postoperative immobility with the risk of unintended pregnancy during the 4 to 6 weeks required to reverse the thrombogenic effects of COCs before surgery. In the early puerperium, VTE risks are also increased, and COCs are not recommended for women within the first 4 weeks after delivery.

Certain progestins within COC are linked with greater rates of thromboembolism. A slightly higher VTE risk with drospirenone-containing COCs has been shown in two studies. In response, an assessment of benefits and VTE risks in users of these pills has been emphasized (Food and Drug Administration, 2012; Jick, 2011; Parkin, 2011). Desogestrel and gestodene are also implicated and carry similarly elevated risks (Stegeman, 2013; Vinogradova, 2015).

Neoplasia

Most studies indicate that COCs overall are not associated with an increased risk of cancer (Cibula, 2010). In fact, a protective effect against ovarian and endometrial cancer has been shown (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008; Tsilidis, 2011). As an exception, the relative risk of cervical dysplasia and cervical cancer is higher in current COC users, but this declines after use is discontinued. Following 10 or more years, risk returns to that of never users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007). It is unclear whether COCs contribute to breast cancer development. Major studies show no risk or a small risk among current users, which drops with time following cessation (Collaborative Group on Hormonal Factors in Breast Cancer, 1996; Hannaford, 2007; Marchbanks, 2002).

Although COC use in the past was linked to development of hepatic *focal nodular hyperplasia* and *benign hepatic adenoma*, large studies do not support this (Heinemann, 1998). Moreover, no evidence supports concern for greater risk of hepatocellular cancer (Maheshwari, 2007). For women with known tumors, COCs may be used in those with focal nodular hyperplasia, but avoided in those with benign hepatic adenoma and hepatocellular carcinoma (Kapp, 2009b). Rates of colorectal cancer appear to be reduced in ever users (Bosetti, 2009; Luan, 2015).

Other Effects

Cholestasis and cholestatic jaundice are uncommon, but they resolve when COCs are discontinued. In women who have active hepatitis, COCs should not be initiated, but these may be continued in women who experience a flare of their liver disease while already taking COCs. Use of progestin-only contraception in these women is not restricted. Moreover, there is no reason to withhold COCs from women who have recovered. Mild compensated cirrhosis does not limit the use of COCs or progestin-only methods. But in those with severe decompensated disease, all hormonal methods are avoided (Kapp, 2009a).

Chloasma, which is hyperpigmentation of the face and forehead, is more likely in women who demonstrated such a change during pregnancy (Chap. 4, Breasts). This is less common with low-dose estrogen formulations. Although previously used for treating functional ovarian cysts, low-dose COC formulations have been shown to have no effects related to cyst resolution or prevention (European Society of Human Reproduction and Embryology, 2001; Grimes, 2014).

Many noncontraceptive benefits are associated with COC use (American College of Obstetricians and Gynecologists, 2016c). And indeed, COCs may be used for these effects, even in those without contraceptive needs. Dysmenorrhea and heavy menstrual bleeding lessen with COC use. Another action is to improve androgenic conditions such as acne and hirsutism. For women with premenstrual dysphoric disorder (PMDD), several studies have shown symptom improvement in those who use the drospirenone-containing COC *Yaz* (Lopez, 2012b; Pearlstein, 2005; Yonkers, 2005).

Transdermal Patch

The *Ortho Evra* patch contains ethinyl estradiol and the progestin norelgestromin. It has an inner layer containing an adhesive and hormone matrix, and a water-resistant outer layer. Thus, women can wear the patch in bathtubs, showers, swimming pools, saunas, and whirlpools without decreased efficacy. The patch may be applied to buttocks, upper outer arm, lower abdomen, or upper torso, but the breasts are avoided. Because the hormones are combined with the adhesive, improper skin adherence will lower hormone absorption and efficacy. Therefore, if a patch is so poorly adhered that it requires reinforcement with tape, it should be replaced.

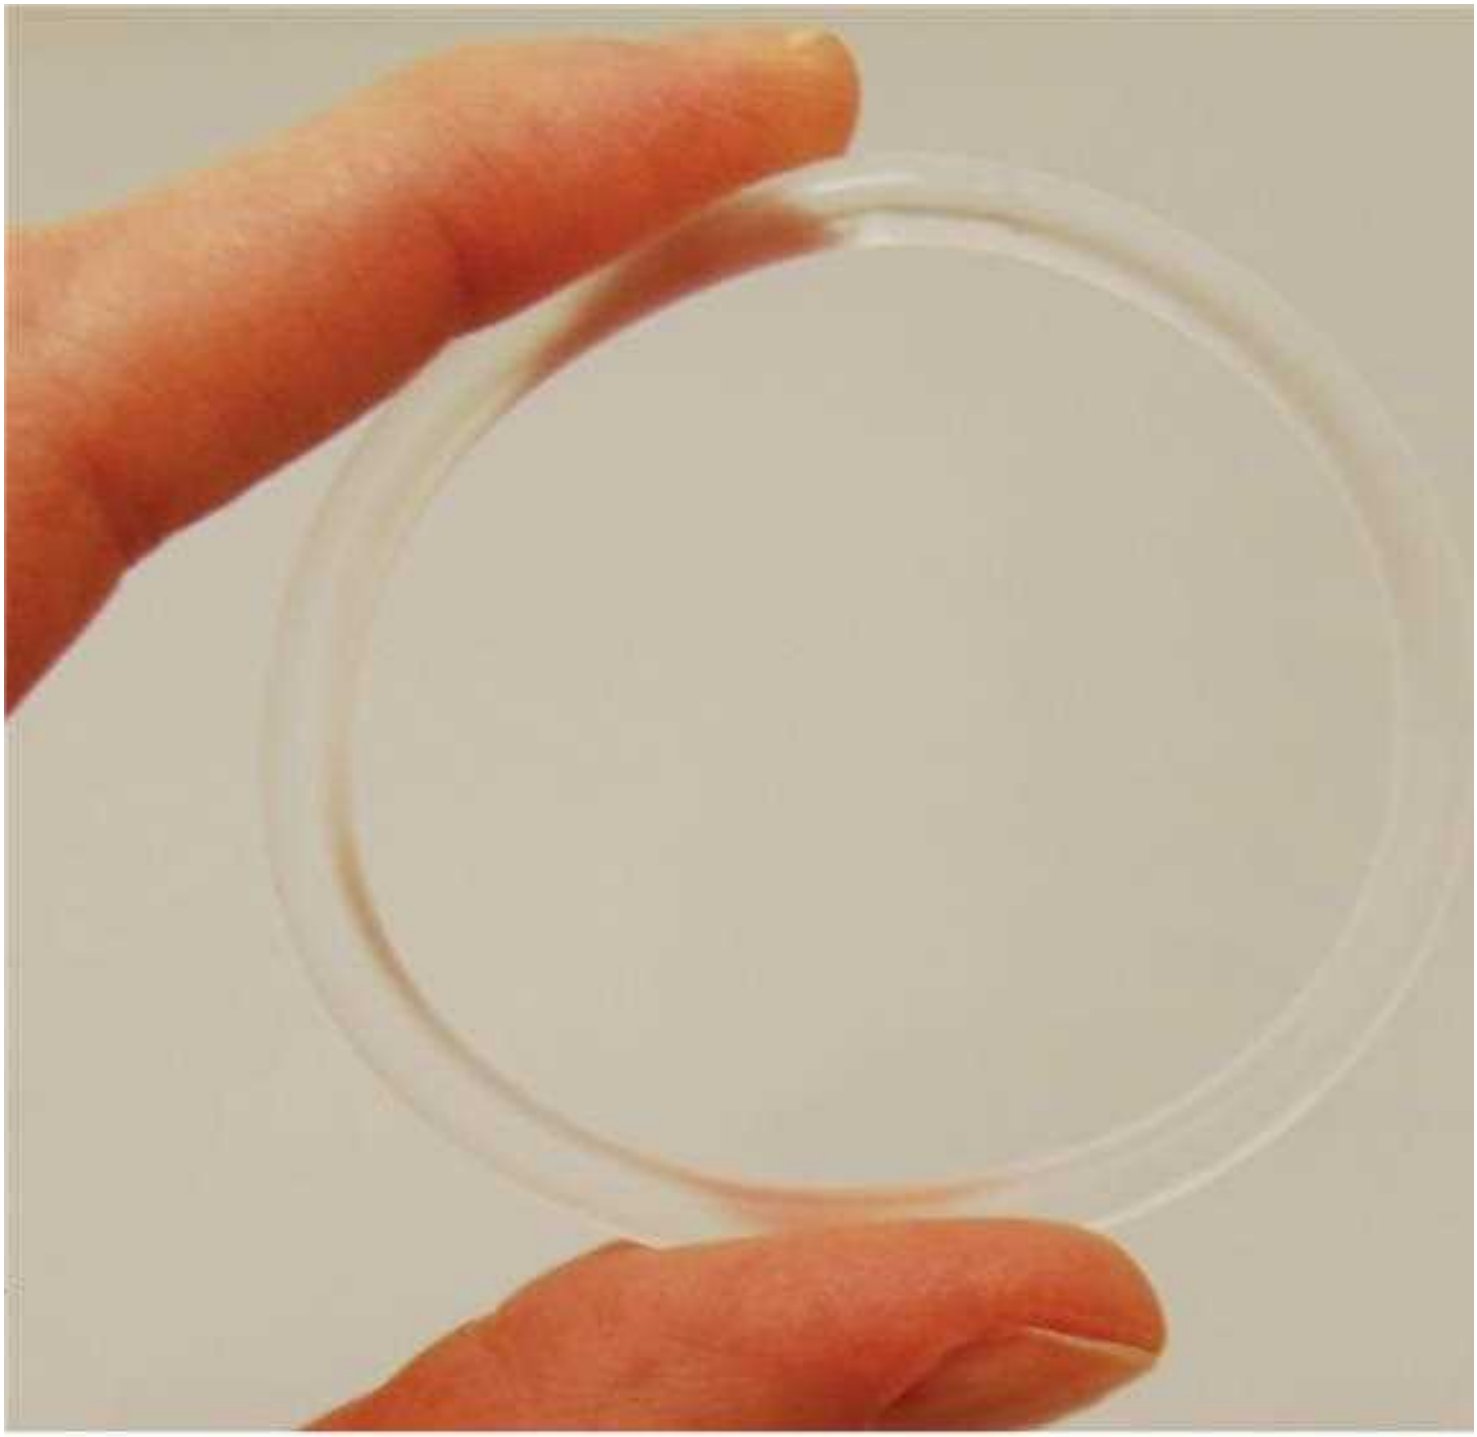
Initiation of the patch is the same as for COCs, and a new patch is applied weekly for 3 weeks, followed by a patch-free week to allow withdrawal bleeding. Although a patch is ideally worn no longer than 7 days, hormone levels remain in an effective range for up to 9 days. This affords a 2-day window for patch-change delays (Abrams, 2001).

In general, the transdermal patch and vaginal ring produce metabolic changes, side effects, and efficacy rates comparable to those with COC pills. However, the patch has been associated with a higher thromboembolism risk in some but not all studies (Cole, 2007; Jick, 2010; Lidegaard, 2011). In response, the Food and Drug Administration (2015b) approved labeling for the patch to state that the risk for VTE may be increased compared with other COCs, and relative risk estimates range from 1.2 to 2.2. Obesity—90 kg or greater—may be associated with a higher risk for patch contraceptive failure (Janssen Pharmaceuticals, 2015; Zieman, 2002). Finally, application-site reaction and breast tenderness are more frequent during initial cycles in patch wearers (Urdl, 2005).

Transvaginal Ring

The *NuvaRing* is yet another form of combination hormonal contraception and is a flexible intravaginal ring. The ring is constructed of ethinyl vinyl acetate, and it measures 54 mm in diameter and 4 mm in cross section (Fig. 38-5). During insertion, the ring is compressed and threaded into the vagina, but no specific final orientation within the vagina is required. Its core releases ethinyl estradiol and the progestin etonogestrel, which are absorbed across the vaginal epithelium. Before being dispensed, the rings are refrigerated, and once dispensed, their shelf life is 4 months. The ring is placed within 5 days of menses onset and, after 3 weeks of use, is removed for 1 week to allow withdrawal bleeding. Contraception will still be afforded if a ring is left in place for a fourth week (Merck, 2016b).

FIGURE 38-5
NuvaRing: estrogen-progestin–releasing vaginal contraceptive ring.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Ellen M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Patient satisfaction is high with this method, although vaginitis, ring-related events, and leukorrhea are more common (Lopez, 2013b; Oddsson, 2005). Despite this, no deleterious affect on lower reproductive tract or endometrial epithelia has been found (Lete, 2013; Veres, 2004). A ring may be used concurrently with vaginal medications or with a tampon (Haring, 2003; Verhoeven, 2004a,b). Approximately 70 percent of partners feel the ring during intercourse (Dieben, 2002). If this is bothersome, the ring may be removed for intercourse but should be replaced within 3 hours to maintain efficacy.

Injectable Progestin Contraceptives

Both intramuscular depot medroxyprogesterone acetate—Depo-Provera (DMPA)—150 mg every 3 months, and norethisterone enanthate, 200 mg every 2 months, are injectable progestin contraceptives used worldwide. Of the two, DMPA is available in the United States. DMPA is injected into the deltoid or gluteus muscle, but massage is avoided to ensure that the drug is released slowly. Alternatively, a subcutaneous version, *depo-subQ provera 104*, is also available and is injected into the subcutaneous tissue of the anterior thigh or abdomen every 3 months.

DMPA is effective, and as with other progestin-only methods, contraception is provided by ovulation inhibition, greater cervical mucus viscosity, and creation of an endometrium unfavorable for ovum implantation. Initial injection is given within the first 5 days following menses onset. Serum levels sufficient for contraception are observed by 24 hours. Thus, no additional contraceptive method is required for initiation within this window. Alternatively, limited data support a “quick wtart,”

or initiation of DMPA regardless of cycle day. If so implemented, investigators recommend an initial negative pregnancy test result before injection, a supplemental contraceptive method during the 7 days following injection, and a second pregnancy test after 3 to 6 weeks to identify an early pregnancy (Rickert, 2007; Sneed, 2005). Pregnancies conceived during DMPA use are not associated with a higher risk of fetal malformation (Katz, 1985). For women who present for intramuscular DMPA reinjection more than 13 weeks or for subcutaneous DMPA reinjection more than 14 weeks after the prior dose, the manufacturer recommends exclusion of pregnancy before reinjection (Pfizer, 2015a,b).

Actions and Side Effects

Injected progestins offer the convenience of a 3-month dosing schedule, contraceptive efficacy comparable with or better than COCs, and minimal to no lactation impairment. Iron-deficiency anemia is less likely in long-term users because of amenorrhea, which develops in up to 50 percent after 1 year and in 80 percent after 5 years.

Similar to other progestin-only contraceptive, irregular menstrual bleeding is common, and a fourth of women discontinued DMPA in the first year because of this (Cromer, 1994). Unique to DMPA, prolonged anovulation can follow discontinuation, which results in delayed fertility resumption. After injections are stopped, a fourth of patients do not resume regular menses for up to 1 year (Gardner, 1970). Accordingly, DMPA may not be ideal for women who plan to use birth control only briefly before attempting conception.

As with other progestins, DMPA has not been associated with cardiovascular events or stroke in otherwise healthy women. However, in those with severe hypertension, a higher risk of stroke has been found in DMPA users (World Health Organization, 1998). Moreover, the US MEC authors express concerns regarding hypoestrogenic effects and reduced HDL levels from DMPA in women with vascular disease or multiple risks for cardiovascular disease.

Weight gain is generally attributed to DMPA, and these increases are comparable between the two depot forms (Bahamondes, 2001; Vickery, 2013; Westhoff, 2007c). In long-term users, loss of bone mineral density is also a potential problem (Petitti, 2000; Scholes, 1999). In 2004, the FDA added a black box warning to DMPA labeling, which notes that this concern is probably most relevant for adolescents, who are building bone mass, and perimenopausal women, who will soon have increased bone loss during menopause. That said, World Health Organization (1998) and American College of Obstetricians and Gynecologists (2016b) believe that DMPA should not be restricted in those high-risk groups. And, it seems prudent to reevaluate overall risks and benefits during extended use. It is somewhat reassuring that bone loss appears to be reversible after discontinuation of therapy, although reversal is still not complete after 18 to 24 months (Clark, 2006; Scholes, 2002).

Progestin-Only Pills

So-called *mini-pills* are progestin-only contraceptives that are taken daily. These contraceptives have not achieved widespread popularity and are used by only 0.4 percent of reproductive-aged American women (Hall, 2012). Unlike COCs, they do not reliably inhibit ovulation. Rather, their effectiveness depends more on cervical mucus thickening and endometrial atrophy. Because mucus changes are not sustained longer than 24 hours, mini-pills should be taken at the same time every day to be maximally effective. If a progestin-only pill is taken even 4 hours late, a supplemental form of contraception must be used for the next 48 hours. Progestin-only pills are contraindicated in women with known breast cancer or pregnancy. Other cautions are listed in Table 38-2.

BARRIER METHODS

Male Condom

For many years, male and female condoms, vaginal diaphragms, and periodic abstinence have been used for contraception with variable success (see Table 38-2). When used properly, condoms provide considerable but not absolute protection against a broad range of sexually transmitted diseases, including HIV (Eaton, 2014). Contraceptive efficacy of the male condom is enhanced appreciably by a reservoir tip and probably by the addition of a spermicide. Such agents, as well as those used for lubrication, should be water-based because oil-based products degrade latex condoms and diaphragms.

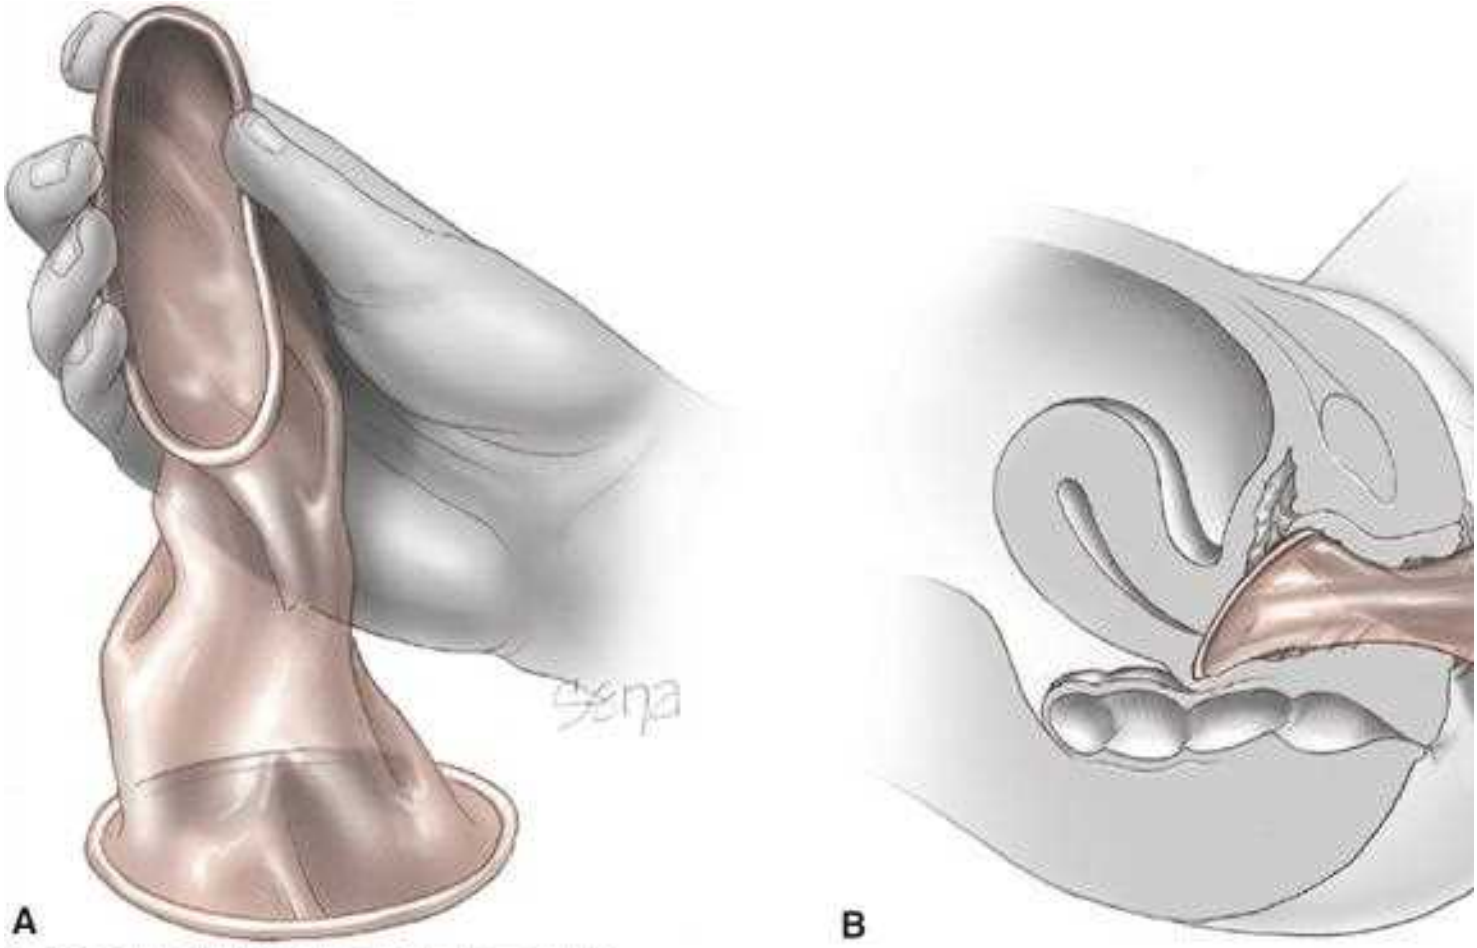
For individuals sensitive to latex, condoms made from lamb intestines are effective, but they do not provide infection protection. Fortunately, nonallergenic condoms have been developed that are made of polyurethane or of synthetic elastomers. Polyurethane condoms are effective against STDs but have a higher breakage and slippage rate compared with latex condoms (Gallo, 2012a).

Female Condom

The only female condom available in the United States is marketed as the *FC2 Female Condom*. It is a synthetic nitrile sheath with one flexible polyurethane ring at each end. Its open ring remains outside the vagina, whereas its closed internal ring is fitted under the symphysis like a diaphragm (Fig. 38-6). The female condom can be used with both water-based and oil-based lubricants. Male condoms should not be used concurrently because simultaneous use may cause friction that leads to condom slipping, tearing, and displacement. Following use, the female condom outer ring should be twisted to seal the condom so that no semen spills. As an added value, the female condom may offer some protection against STDs (Minnis, 2005).

FIGURE 38-6

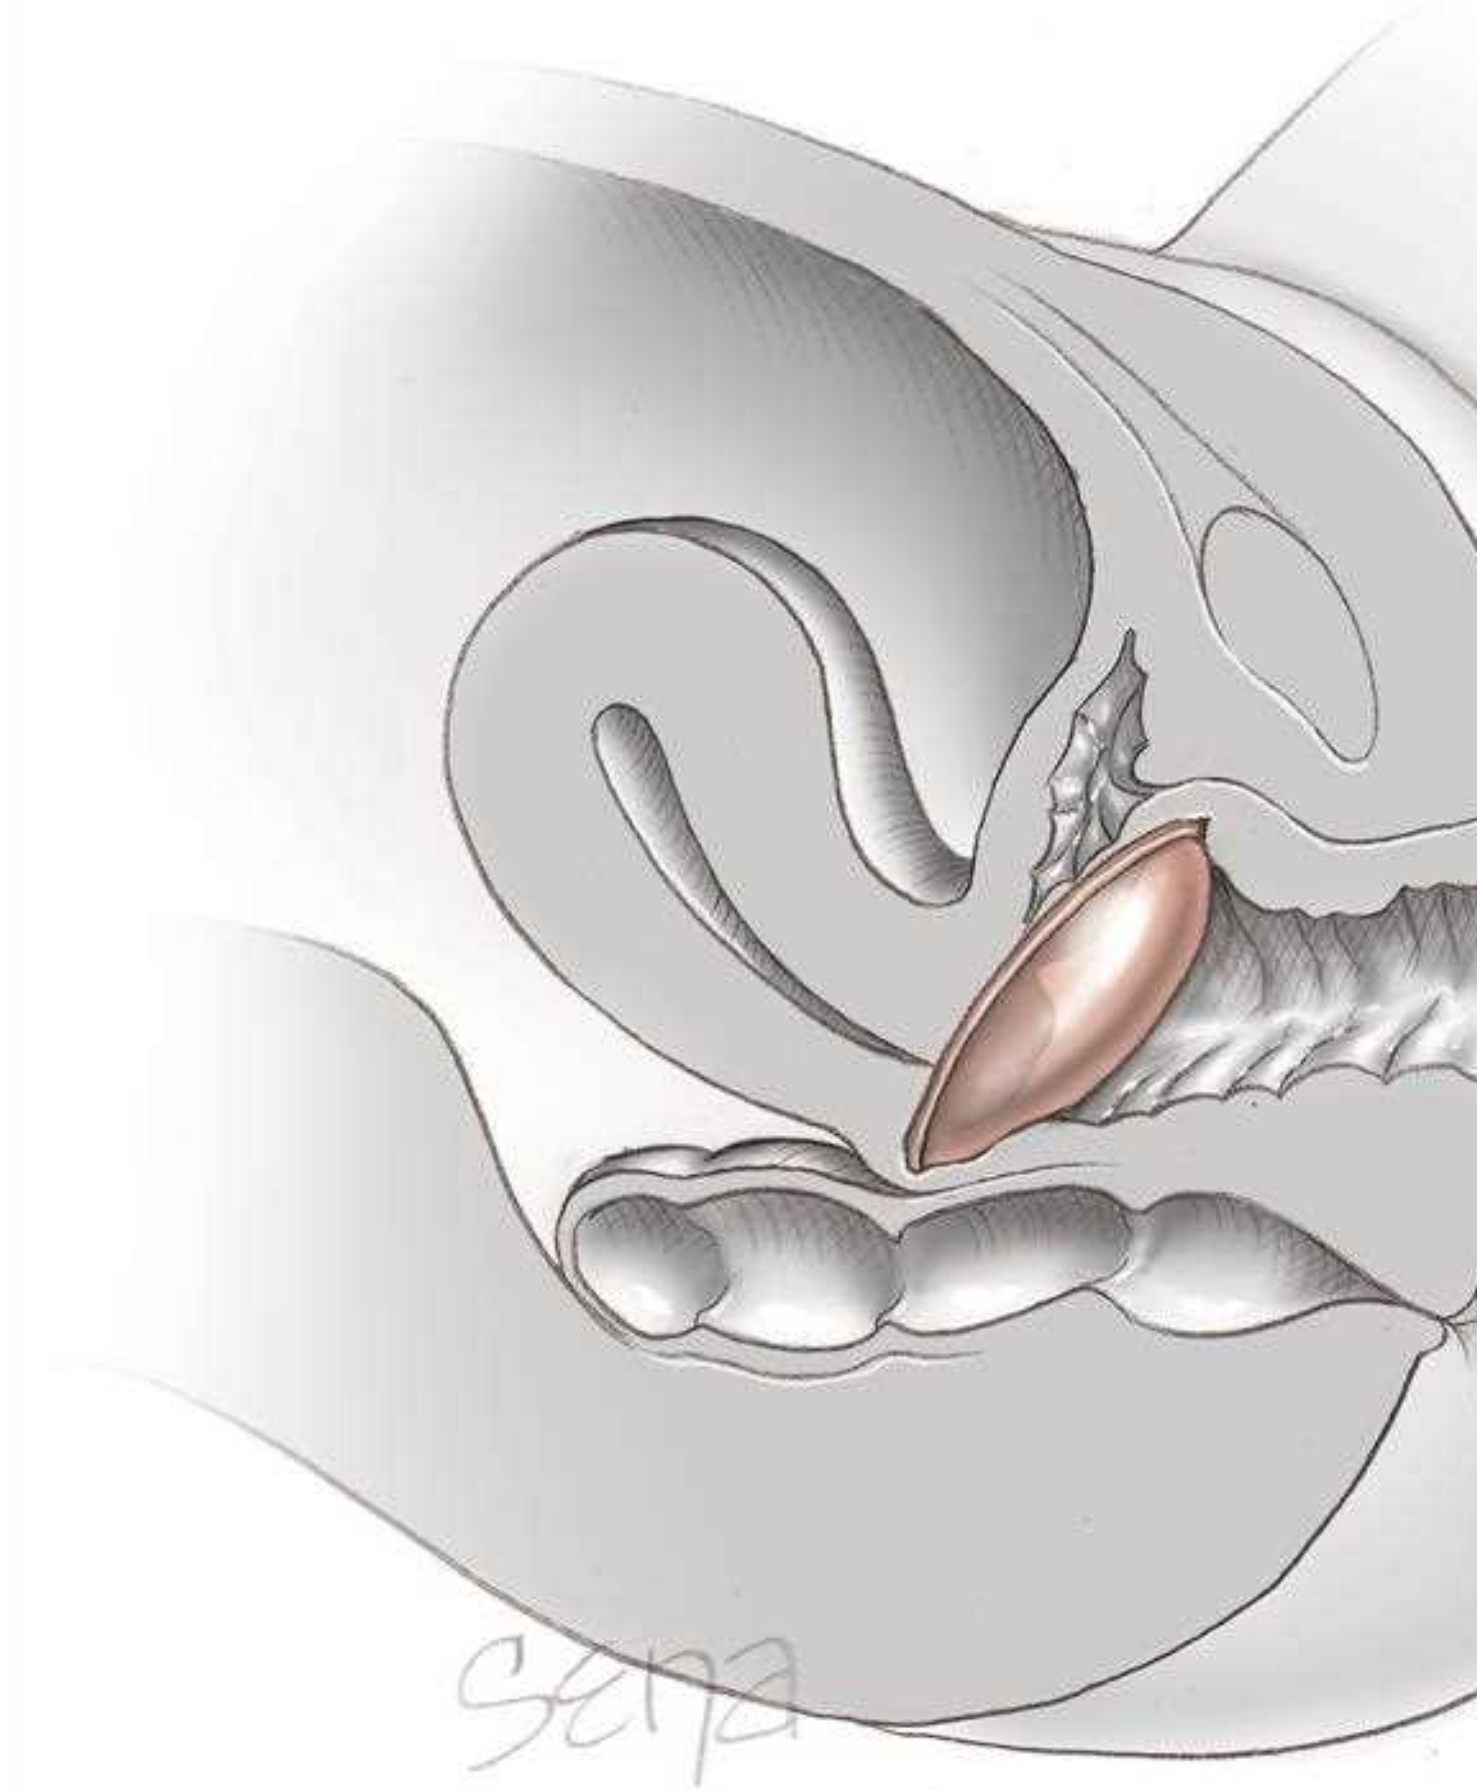
FC2 Female Condom insertion and positioning. **A.** The inner ring is squeezed for insertion. The sheath is inserted similarly to a diaphragm. **B.** The inner ring is pushed inward with an index finger.



Diaphragm Plus Spermicide

The diaphragm consists of a circular latex dome of variable diameter supported by a circumferential latex-covered metal spring. It is effective when used in combination with spermicidal jelly or cream. The spermicide is applied into the dome cup and along the device rim. The diaphragm is then positioned so that the cup faces the cervix and that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. In this fashion, the centrally placed spermicide is held against the cervix. When appropriately positioned, one rim is lodged deep in the posterior vaginal fornix, and the opposite rim fits behind the inner surface of the symphysis and immediately below the urethra (Fig. 38-7). If a diaphragm is too small, it will not remain in place. If it is too large, it is uncomfortable when forced into position. A coexistent cystocele or uterine prolapse typically leads to instability and expulsion. Because size and spring flexibility must be individualized, the diaphragm is fitted by providers and available only by prescription.

FIGURE 38-7
A diaphragm in place creates a physical barrier between the vagina and cervix.



For use, the diaphragm and spermicide can be inserted hours before intercourse. If more than 6 hours elapse, the diaphragm can remain but additional spermicide is placed in the upper vagina for maximum protection. Spermicide is reapplied before each subsequent coital episode. The diaphragm is not removed for at least 6 hours after intercourse. Because toxic shock syndrome has been described following its use, it may be worthwhile to remove the diaphragm at 6 hours, or at least the

next morning, to minimize this rare event. Diaphragm use is associated with a slightly greater rate of urinary infections, presumably from urethral irritation by the ring under the symphysis.

Cervical Cap

FemCap is currently the only available cervical cap in the United States. Made of silicone rubber, it has a sailor-cap shape with a dome that covers the cervix and a flared brim, which allows the cap to be held in place by the muscular walls of the upper vagina. Available in 22-, 26-, and 30-mm sizes, it is used with a spermicide applied once at insertion to both sides of the dome cup. For contraception, it should remain in place for 6 hours following coitus and may remain for up to 48 hours. Even with proper fitting and correct use, pregnancy rates with this method are higher that with the diaphragm (Gallo, 2012b; Mauck, 1999).

FERTILITY AWARENESS-BASED METHODS

These family planning methods attempt to identify the fertile days each cycle and advise sexual abstinence during these days. Their major drawback is their limited efficacy, which is shown in Table 38-1. Common forms of these fertility awareness-based (FAB) methods include Standard Days, Temperature Rhythm, Cervical Mucus, and Symptothermal Methods. Some smartphone applications aim to assist these practices (Fehring, 2013).

The *Standard Days Method* counsels women to avoid unprotected intercourse during cycle days 8 through 19. For successful use, women must have regular monthly cycles of 26 to 32 days. Those who use this method can mark a calendar or can use *Cycle-Beads*, which is a ring of counting beads, to keep track of their days.

The *Temperature Rhythm Method* relies on a sustained 0.4°F rise in the basal body temperature, which usually precedes ovulation. For maximum efficacy, the woman must abstain from intercourse from the first day of menses through the third day after the temperature increase.

The *Cervical Mucus Method*, also called the Two-Day Method or Billings Method, relies on awareness of vaginal “dryness” and “wetness.” These reflect changes in the amount and quality of cervical mucus at different times in the menstrual cycle. With the Billings Method, abstinence is required from the beginning of menses until 4 days after slippery mucus is identified. With the Two-Day Method, intercourse is considered safe if a woman did not note mucus on the day of planned intercourse or the day prior.

The *Symptothermal Method* combines changes in cervical mucus—onset of fertile period; changes in basal body temperature—end of fertile period; and calculations to estimate the time of ovulation. This method is more complex to learn and apply, but it does not appreciably improve efficacy.

SPERMICIDES

These contraceptives are marketed variously as creams, jellies, suppositories, films, and aerosol foam. Most can be purchased without a prescription. They are considered a less effective method (see Table 38-1). If pregnancy does occur, they are not teratogenic (Briggs, 2015).

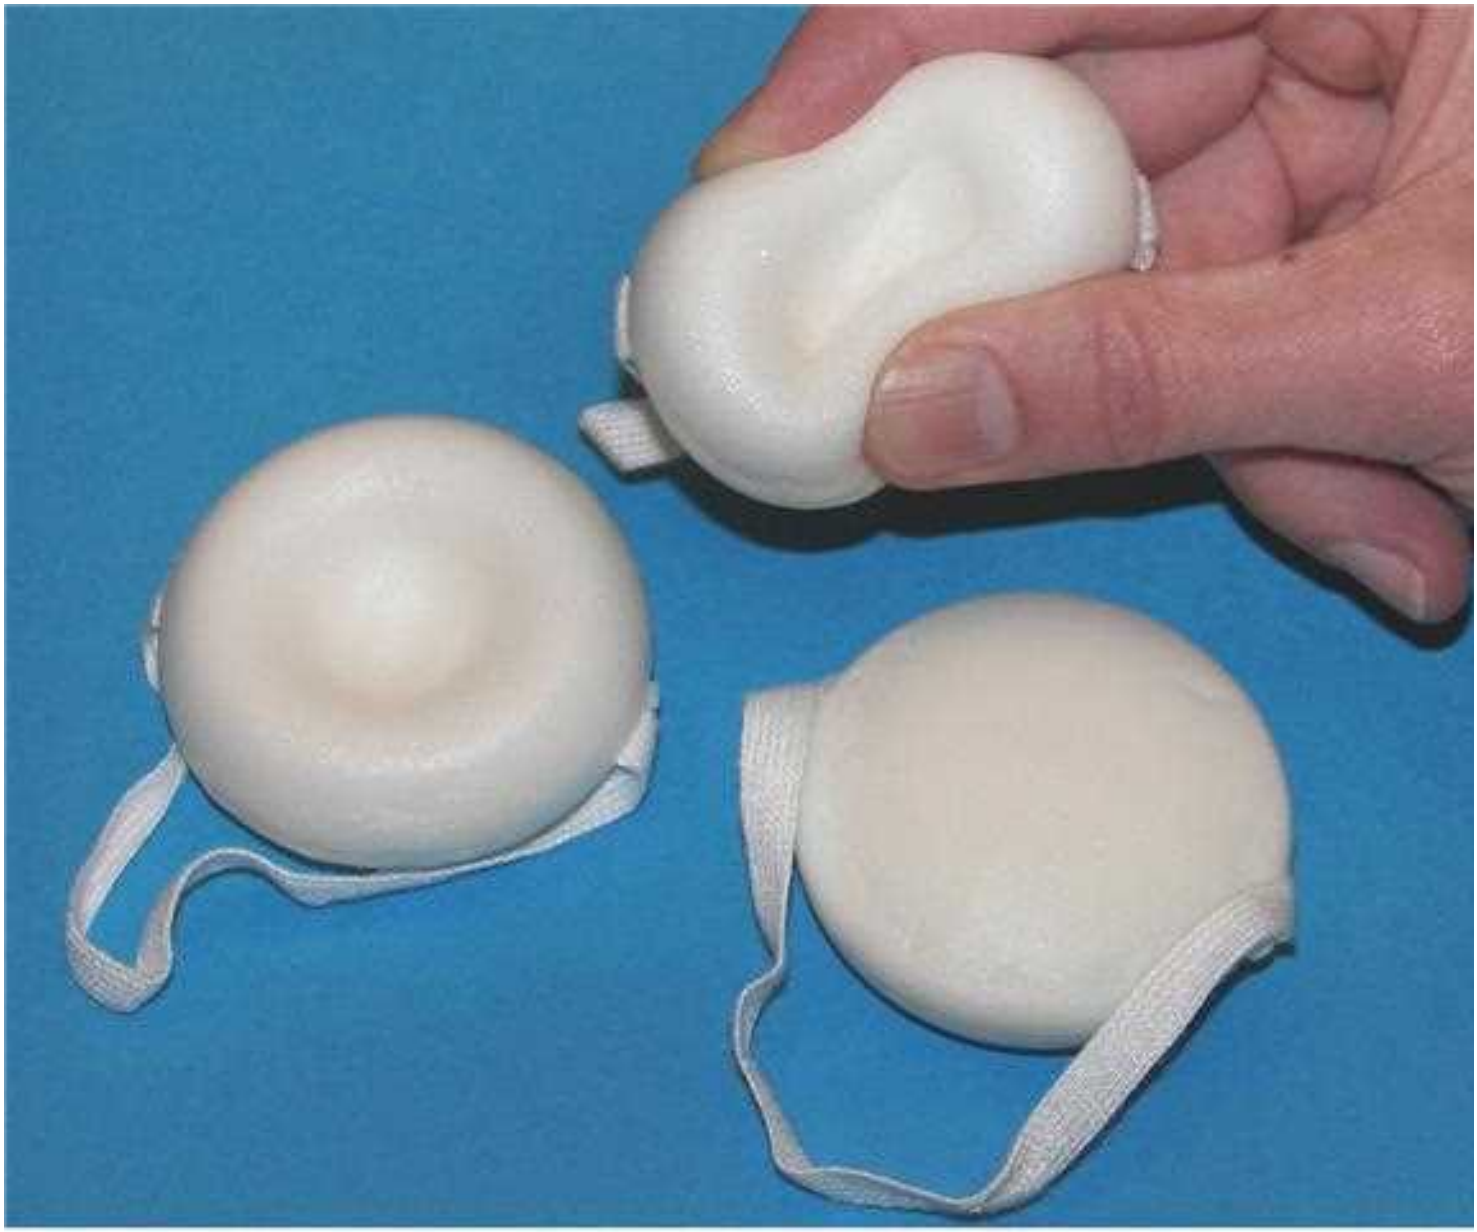
Typically, spermicides function by providing a physical barrier to sperm penetration and a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9. Although these are spermicidal, they do not provide STD protection. Ideally, spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse. Their duration of maximal effectiveness is usually no more than 1 hour, and thereafter, they must be reinserted before repeat intercourse. Douching is avoided for at least 6 hours after coitus.

Contraceptive Sponge

The *Today* contraceptive sponge is an over-the-counter, one-size-fits-all device. The nonoxynol-9–impregnated polyurethane disc is 2.5 cm thick and 5.5 cm wide and has a dimple on one side and satin loop on the other (Fig. 38-8). The sponge can be inserted up to 24 hours prior to intercourse, and while in place, it provides contraception regardless of coital frequency. It should remain in place for 6 hours after intercourse. Pregnancy is prevented primarily by the spermicide nonoxynol-9 and to a lesser extent by covering the cervix and absorbing semen.

FIGURE 38-8

Today sponges. The sponge is moistened with tap water and gently squeezed to create light suds. It is then positioned with the dimple directly against the cervix. The fabric loop trails within the vagina and can be hooked with a finger to later extract the sponge.



Although the sponge is possibly more convenient than the diaphragm or condom, it is less effective than either (Kuyoh, 2013). Most common causes for method discontinuance are pregnancy, irritation, discomfort, or vaginitis (Beckman, 1989). Although toxic shock syndrome has been reported with the contraceptive sponge, it is rare, and evidence suggests that the sponge may actually limit production of the responsible staphylococcal exotoxin (Remington, 1987). Still, it is recommended that the sponge not be used during menses or the puerperium.

EMERGENCY CONTRACEPTION

Following unprotected sexual intercourse, many women present for contraceptive care. Several emergency contraception (EC) regimens substantially lower the likelihood of an unwanted pregnancy when used correctly. Current methods include COCs, progestins, progesterone antagonists, and copper-containing IUDs (Table 38-3). Overall, the IUD is most effective, and ulipristal acetate is the most efficient oral regimen (American College of Obstetricians and Gynecologists, 2017a). Patients can obtain information regarding emergency contraception by calling 1–888-NOT-2-LATE or accessing The Emergency Contraception Website: http://not-2-late.com.

TABLE 38-3

Methods Available for Use as Emergency Contraception

Method	Formulation	Pills per Dose	Number of Doses[a]
Progestin-Only Pill			
Plan B One-Step Next Choice One Dose	150 mg LNG	1	1
PRM Pill			
Ella	30 mg ulipristal acetate	1	1
COC Pills[b,c]			
Ogestrel	0.05 mg EE + 0.5 mg norgestrel	2	2
Cryselle, Low-Ogestrel	0.03 mg EE + 0.3 mg norgestrel	4	2
Enpresse (orange), Trivora (pink)	0.03 mg EE + 0.125 mg LNG	4	2
Levora, Seasonale	0.03 mg EE + 0.15 mg LNG	4	2
Aviane, LoSeasonique (orange)	0.02 mg EE + 0.1 mg LNG	5	2
Copper-Containing IUD	Paragard T 380A		

[a]Doses taken 12 hours apart if multiple.

[b]Other COC brands with formulations identical to those above may also be used.

[c]Use of an antiemetic agent before taking the medication will lessen the risk of nausea, which is a common side effect.

COC = combination oral contraceptive; EE = ethinyl estradiol; IUD = intrauterine device; LNG = levonorgestrel; PRM = progesterone-receptor modulator.

Hormonal Emergency Contraception

Except for allergy to a particular component, no conditions in the US MEC contraindicate hormonal EC methods. With progestin-only regimens, levonorgestrel is taken as a single, one-time 1.5-mg dose (Arowojolu, 2002). This is now recommended instead of two 0.75-mg doses separated by 12 or 24 hours (Ngai, 2005). Dosing begins ideally within 72 hours of unprotected coitus but may be given up to 120 hours. Notably, the single-dose regimen is available over-the-counter without a prescription to all reproductive-aged women (Food and Drug Administration, 2013, 2015a).

One progesterone-receptor modulator currently available for EC is ulipristal acetate and is marketed as *Ella.* It is taken as a single 30-mg tablet up to 120 hours after unprotected intercourse (Brache, 2010; Watson, 2010).

Also known as the *Yuzpe method*, this older EC method provides a minimum of 100 µg of ethinyl estradiol and 0.5 mg of levonorgestrel in each of two doses. As shown in Table 38-3, a sufficient dose may be achieved by two or more pills. The first dose is taken ideally within 72 hours of intercourse but may be given up to 120 hours. The initial dose is followed 12 hours later by a second equivalent dose.

The major mechanism with all hormonal regimens is inhibition or delay of ovulation. Of oral methods, failure rates are lowest with ulipristal (1 to 2 percent) and greatest with the Yuzpe method (2 to 3.5 percent) (Cleland, 2014). If EC fails to prevent pregnancy or is mistimed, no associations with major congenital malformation or pregnancy complications have been noted with these hormonal methods (Jatlaoui, 2016; Levy, 2014).

With EC administration, nausea and vomiting can be an important side effect (American College of Obstetricians and Gynecologists, 2015b; Gemzell-Danielsson, 2013). Accordingly, an oral antiemetic may be prescribed at least 1 hour before each dose (Rodriguez, 2013). If a woman vomits within 2 hours of a dose, the dose is repeated.

Copper-Containing Intrauterine Devices

For women who are candidates, Cu-IUD insertion is the most effective emergency contraceptive method and provides an effective 10-year method of contraception (Cheng, 2012). If an IUD is placed up to 5 days after unprotected coitus, the failure rate approximates only 0.1 percent (Cleland, 2012; Wu, 2010).

PUERPERAL CONTRACEPTION

For mothers who are nursing exclusively, ovulation during the first 10 weeks after delivery is unlikely. Nursing, however, is not a reliable method of family planning for women whose infants are on a daytime-only feeding schedule. Moreover, waiting for first menses involves a risk of pregnancy, because ovulation usually antedates menstruation. Certainly, after the first menses, contraception is essential unless the woman desires pregnancy.

As shown in Table 38-2, all methods may be suitable for nursing mothers after the initial weeks, during which thromboembolism risks are still great. With all hormonal methods, very small quantities are excreted in breast milk, but no adverse effects on infants have been reported (Phillips, 2015; World Health Organization, 1988). Although not robust, some older studies link decreased infant weight gain or milk volume with early initiation of combination oral contraceptives before 6 weeks postpartum (Lopez, 2015c; Tepper, 2016a).

CHAPTER 39: Sterilization

In order, therefore, to render a woman permanently sterile by an operation upon the tubes, they must be excised by wedge-shaped incisions at the cornua of the uterus and the wounds closed by sutures.

—J. Whitridge Williams (1903)

INTRODUCTION

Sterilization is a popular choice of contraception for millions of men and women. Among women using contraception, one third rely on either male or female sterilization (Daniels, 2015). This procedure is indicated in those requesting sterilization and who clearly understand its permanence and its difficult and often unsuccessful reversal. All persons considering sterilization should also be counseled regarding alternative contraceptive choices (American College of Obstetricians and Gynecologists, 2017a,c).

Female sterilization is usually accomplished by occlusion, excision, or division of the fallopian tubes. *Puerperal sterilization* procedures follow cesarean or vaginal delivery and approximately 7 percent of all live births in the United States (Moniz, 2017). *Nonpuerperal tubal sterilization* is done at a time unrelated to recent pregnancy and is also termed interval sterilization.

PUERPERAL TUBAL STERILIZATION

Timing

For several days postpartum, the uterine fundus lies at the level of the umbilicus, and fallopian tubes are accessible directly beneath the abdominal wall. Moreover, abdominal laxity allows easy repositioning of the incision over each uterine cornu.

On our service, puerperal tubal ligation is performed by a surgical team dedicated to this role the morning after delivery. This timing minimizes hospital stay but lowers the likelihood that postpartum hemorrhage would complicate recovery following surgery. In addition, the status of the newborn can be better ascertained before surgery. In contrast, some prefer to perform sterilization immediately following delivery and use neuraxial analgesia already placed for labor. In this model, barriers to sterilization can be lessened by designating these postpartum surgeries as urgent, especially in high-volume labor and delivery units, which usually prioritize limited operating-room availability for intrapartum procedures (American College of Obstetricians and Gynecologists, 2016; Potter, 2013).

Technique

Various techniques are now used to disrupt tubal patency. In general, a midtubal segment of fallopian tube is excised, and the severed ends seal by fibrosis and peritoneal regrowth. Commonly used methods of puerperal sterilization include the Parkland, Pomeroy, and modified Pomeroy techniques (American College of Obstetricians and Gynecologists, 2017a). Less often, Filshie clips are used (Madari, 2011). Irving and Uchida techniques or Kroener fimbriectomy are rarely used because of their increased required dissection or unfavorably high failure rates. Also, in the absence of uterine or other pelvic disease, hysterectomy solely for sterilization at the time of cesarean delivery, early in the puerperium, or even remote from pregnancy is difficult to justify. It carries significantly increased surgical morbidity compared with tubal sterilization.

Evidence suggests that the fallopian tube may be the origin of pelvic serous carcinomas, especially those of the ovary. With this knowledge, the Society of Gynecologic Oncologists (2013) and American College of Obstetricians and Gynecologists (2017b) recommend consideration of salpingectomy to lower cancer risks. Specifically, for women at average risk of ovarian cancer, risk-reducing salpingectomy should be discussed and considered with patients at the time of abdominal or pelvic surgery, at hysterectomy, or in lieu of tubal ligation.

Spinal analgesia is typically selected for cases scheduled for the first postpartum day. If done more proximate to delivery, the same epidural catheter used for labor analgesia can be used for sterilization analgesia. Notably, for those with preeclampsia, HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome, or gestational thrombocytopenia, platelet levels should be >100,000 for spinal blockade (Chap. 25, Contraindications). General anesthesia may be less desirable due to residual pregnancy-related airway vulnerabilities (Bucklin, 2003). The bladder is emptied before surgery to avoid its laceration. A full bladder can also push the fundus above the umbilicus.

A small infraumbilical incision is ideal for several reasons. As noted, the fundus in most cases lies near the umbilicus. Second, the umbilicus usually remains the thinnest portion of the anterior abdominal wall and requires less subcutaneous dissection to reach the linea alba fascia. Third, an infraumbilical incision offers fascia with sufficient integrity to provide a closure that has minimal risk for later incisional hernia. Last, incisions that follow the natural curve of the lower umbilical skin fold yield suitable cosmesis. A 2- to 4-cm transverse or vertical skin incision is usually sufficient for normal-weight women. For obese women, a 4- to 6-cm incision may be needed for adequate abdominal access.

Beneath this incision, the subcutaneous tissue is bluntly separated to reach the linea alba fascia. For this, an Allis clamp can be opened and closed as downward pressure is exerted. Similarly, the blades of two army-navy retractors both pulling in downward yet opposite directions can part the subcutaneous layer. Clearing this

fatty tissue away from the fascia isolates the fascia for incision and for later closure without intervening fat, which may impede wound healing.

The fascial incision may be transverse or vertical and follows the same orientation of the skin incision. For this, once the linea alba is reached, it is grasped with two Allis clamps—one placed on either side of the planned fascial incision. The purchase of tissue with each clamp should be substantial and creates a small roll of fascia to be incised. Often, the peritoneum is incorporated simultaneously and entered. If not, the peritoneum is grasped with two hemostats and sharply cut. Others may prefer to bluntly enter with a single index finger. Notably, if the initial fascial incision is too small, it can be extended with curved Mayo scissors.

Adequate exposure is critical, and army-navy or appendiceal retractors are suitable. For obese women, a slightly larger incision and narrow deeper retractors may be required. If bowel or omentum is obstructing, Trendelenburg position can help displace these cephalad. Digitally packing with a single, moist, fanned-out piece of surgical gauze can also be used, but a hemostat should always be attached to the distal end to avert its retention. At times, tilting the entire table to the opposite side of the tube being exposed assists tube isolation.

The fallopian tube is identified and grasped at its midportion with a Babcock clamp, and the distal fimbria confirmed. This prevents confusing the round ligament with the midportion of the tube. A common reason for sterilization failure is ligation of the wrong structure, typically the round ligament. Therefore, identification and isolation of the distal tube prior to ligation is necessary. Whenever the tube is inadvertently dropped, it is mandatory to repeat this identification process. Surgical steps for ligation are outlined in Figures 39-1 and 39-2.

FIGURE 39-1

Parkland method. **A.** An avascular site in the mesosalpinx adjacent to the fallopian tube is perforated with a small hemostat. The jaws are opened to separate the fallopian tube from the adjacent mesosalpinx for approximately 2.5 cm. **B.** The freed fallopian tube is ligated proximally and distally with 0-chromic suture. The intervening segment of approximately 2 cm is excised, and the excision site is inspected for hemostasis. This method was designed to avoid the initial intimate proximity of the cut ends of the fallopian tube inherent with the Pomeroy procedure. (Reproduced with permission from Hoffman BL, Corton MM: Surgeries for benign gynecologic conditions. In Hoffman BL, Schorge JO, Bradshaw KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)

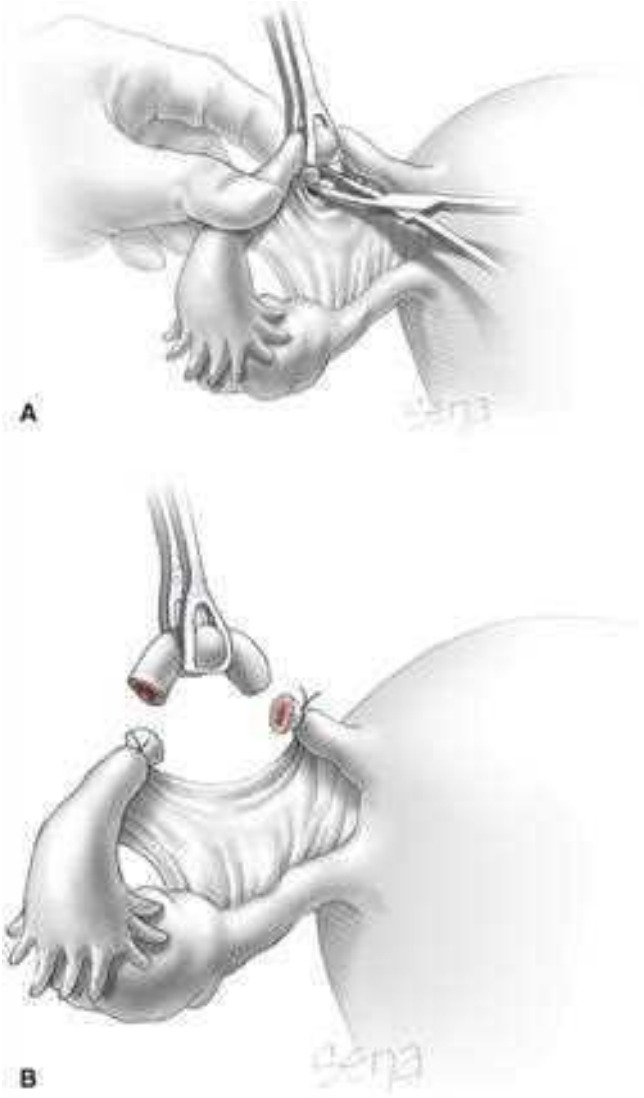

FIGURE 39-2

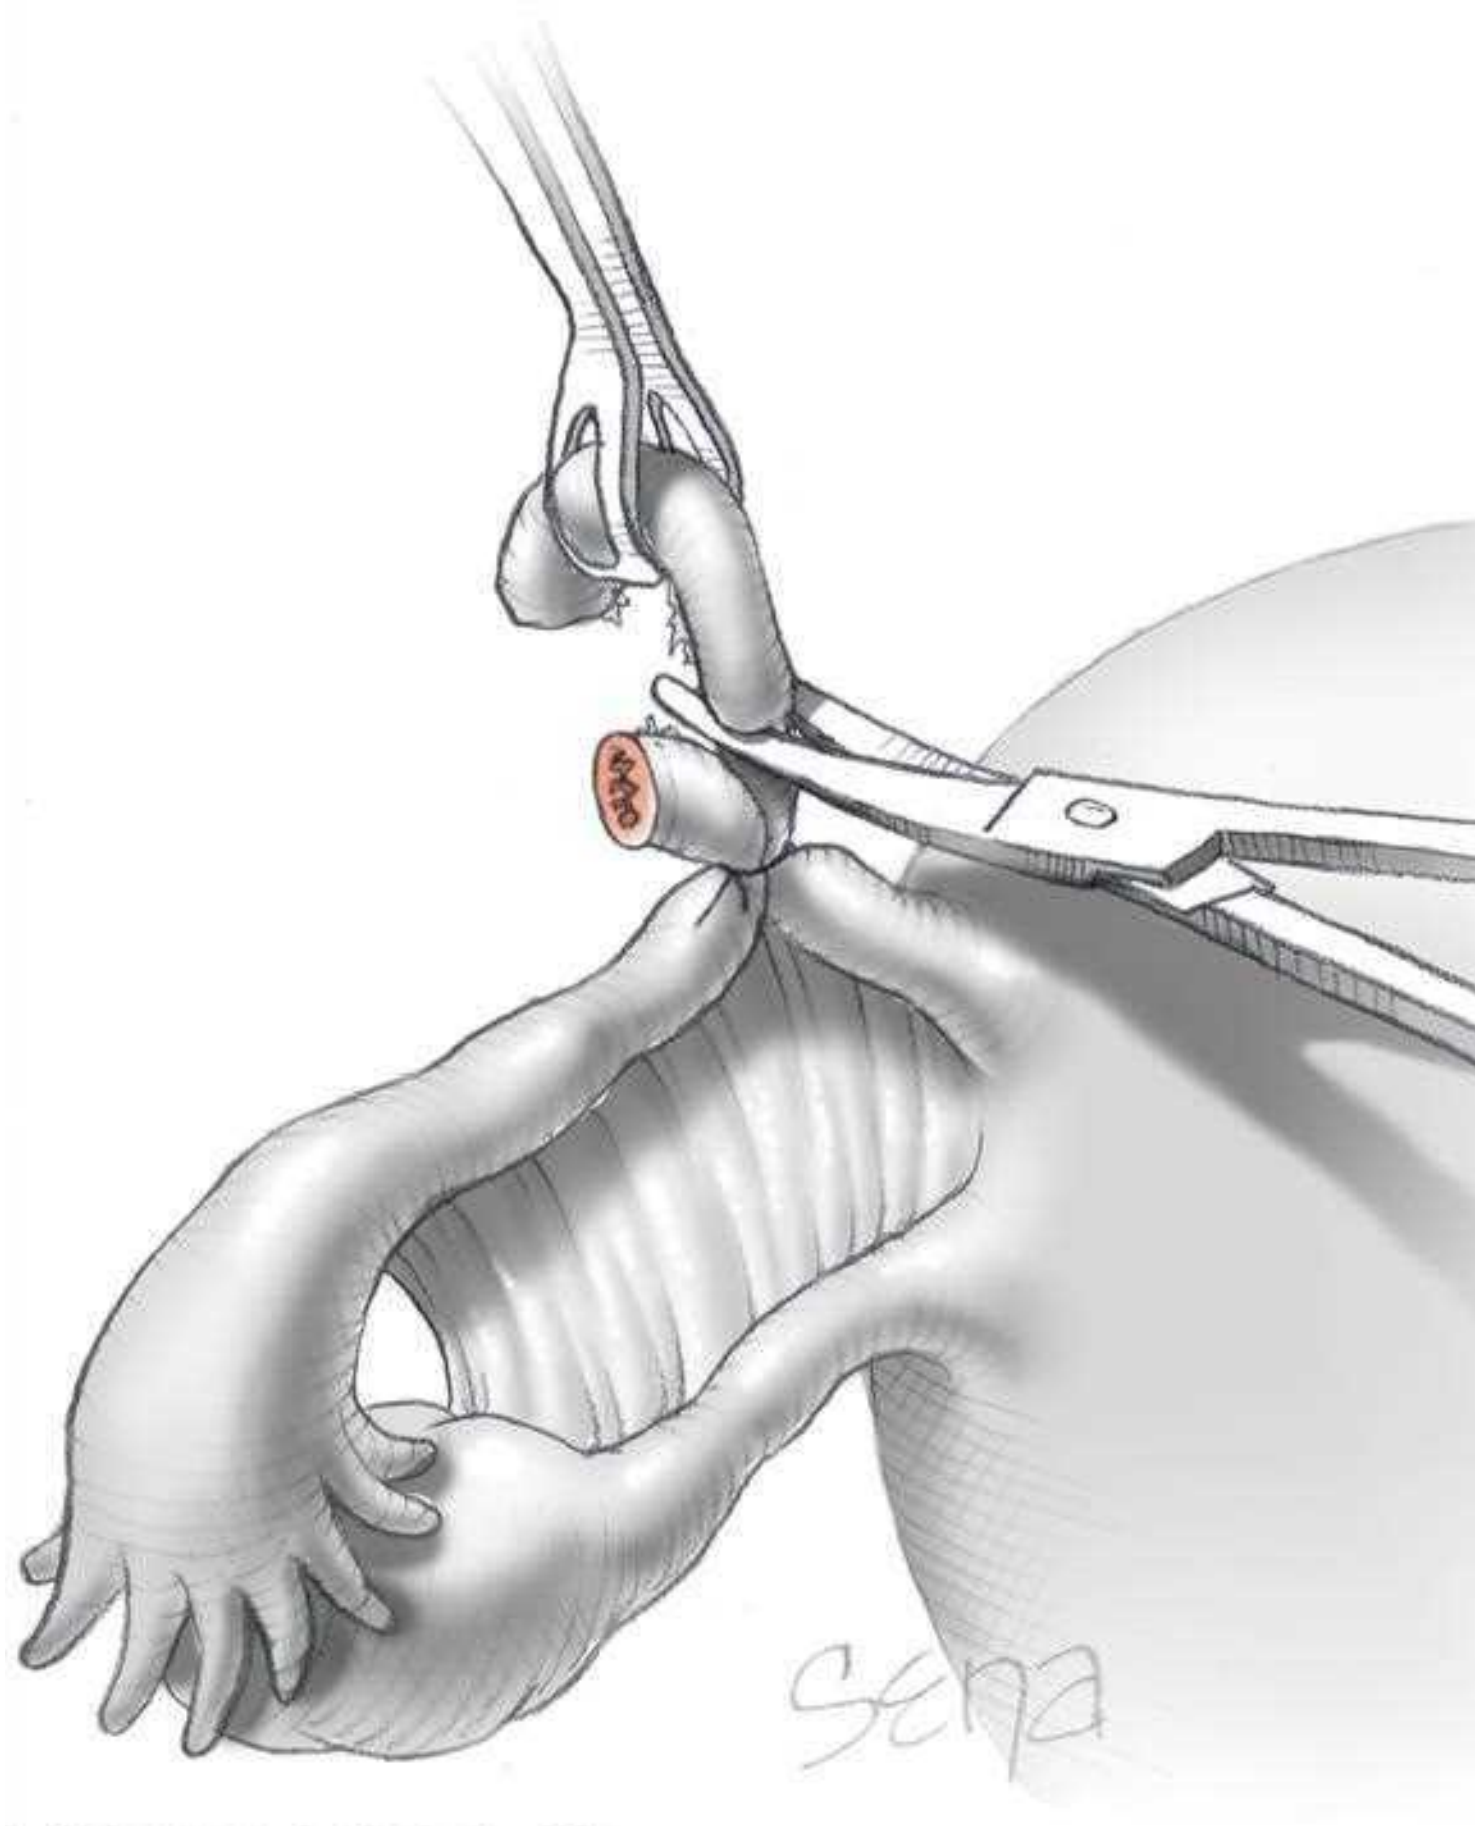
Pomeroy method. During ligation of a midsegment tubal loop, plain catgut is used to ensure prompt absorption of the ligature and subsequent separation of the severed tubal ends. (Reproduced with permission from Hoffman BL, Corton MM: Surgeries for benign gynecologic conditions. In Hoffman BL, Schorge JO, Bradshaw

KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Steps of salpingectomy are shown in Figure 39-3. The umbilical incision generally will need to be larger to allow an adequate view of the tube and mesosalpinx and to place clamps. With total salpingectomy, the entire mesosalpinx must be divided to free the fallopian tube.In two small cohorts undergoing salpingectomy after vaginal birth, surgical times were longer than for tubal occlusion, and in one report, blood loss was increased (Danis, 2016; Powell, 2017). With salpingectomy and cesarean delivery, total blood loss rates were not statistically higher (Powell, 2017; Shinar, 2017).

FIGURE 39-3

A. With salpingectomy, the mesosalpinx is sequentially clamped, cut, and ligated. **B.** At the cornu, clamps are placed across the fallopian tube and its adjacent mesosalpinx prior to tubal transection. New York, McGraw-Hill, 2017.)

After surgery, diet is given as tolerated. Ileus is infrequent and should prompt concern for bowel injury, albeit rare. Most women have an uncomplicated course and are discharged on the first postoperative day.

NONPUERPERAL TUBAL STERILIZATION

These techniques and other modifications basically consist of (1) ligation and resection at laparotomy as described earlier for puerperal sterilization; (2) application of permanent rings, clips, or inserts to the fallopian tubes by laparoscopy or hysteroscopy; or (3) electrocoagulation of a tubal segment, usually through a laparoscope. A detailed description and illustration of these can be found in *Williams Gynecology, 3rd edition* (Thompson, 2016).

In the United States, a laparoscopic approach to interval tubal sterilization is the most common. The procedure is frequently performed in an ambulatory surgical setting under general anesthesia. In almost all cases, the woman can be discharged within several hours. Minilaparotomy using a 3-cm suprapubic incision is also popular, especially in resource-poor countries. Major morbidity is rare with either minilaparotomy or laparoscopy. Although not often used, the peritoneal cavity can be entered through the posterior vaginal fornix via colpotomy to perform tubal interruption.

LONG-TERM COMPLICATIONS

Contraceptive Failure

Pregnancy following sterilization is infrequent. The Collaborative Review of Sterilization (CREST) study followed 10,863 women who had undergone tubal sterilization from 1978 through 1986 (Peterson, 1996). The cumulative failure rate for the various tubal procedures was 18.5 per 1000 or approximately 0.5 percent. The study found puerperal sterilization to be highly effective. The 5-year failure rate was 5 per 1000, and for 12 years, it was 7 per 1000.

Puerperal sterilization fails for two major reasons. First, surgical errors occur and include transection of the round ligament or only partial transection of the tube. For this reason, both tubal segments are submitted for pathological confirmation. Second, a fistulous tract or spontaneous reanastomosis may form between the severed tubal stumps.

Approximately 30 percent of pregnancies that follow a failed tubal sterilization procedure are ectopic. This rate is 20 percent for those following a postpartum procedure (Peterson, 1996, 1997). Thus, any symptoms of pregnancy in a woman after tubal sterilization must be investigated, and an ectopic pregnancy excluded.

Other Effects

Overall, risks for ovarian cancer decline and for breast cancer are unaffected following sterilization (Gaudet, 2013; Pearce, 2015). Women who have undergone tubal sterilization are highly unlikely to subsequently have salpingitis (Levgur, 2000). For menorrhagia and intermenstrual bleeding following tubal sterilization, most studies of the risk have found no association (DeStefano, 1985; Peterson, 2000; Shy, 1992).

Less objective but important psychological sequelae of sterilization have also been evaluated. In the CREST study, Costello (2002) found that tubal ligation did not change sexual interest or pleasure in 80 percent of women. In most of the 20 percent of women who did report a change, positive effects were 10 to 15 times more likely.

Invariably, a number of women express regrets regarding sterilization, and this is especially true if it is performed at a younger age (Curtis, 2006; Kelekçi, 2005). In the CREST study, Jamieson (2002) reported that 7 percent of women who had undergone tubal ligation had regrets by 5 years. This is not limited to their own sterilization, because 6.1 percent of women whose husbands had undergone vasectomy had similar regrets.

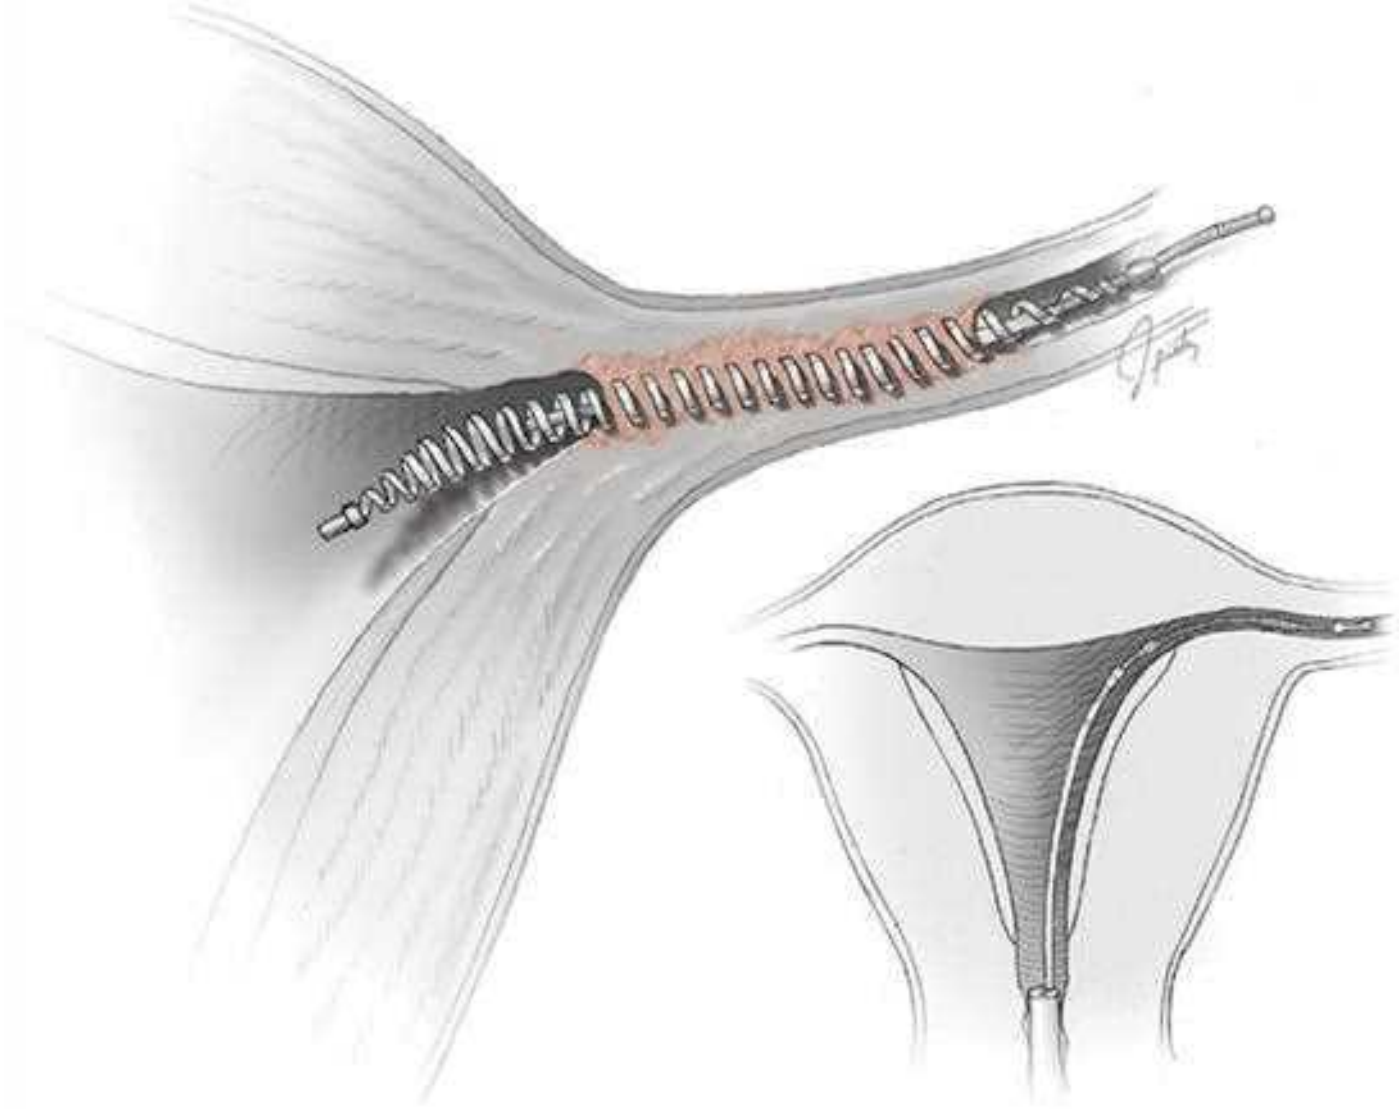
Tubal Sterilization Reversal

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed either by surgery or by assisted reproductive techniques. Both approaches are technically difficult, expensive, and not always successful. In general, pregnancy rates after tubal reversal favor women with age younger than 35 years, with 7 cm of remaining tube, with a short time from antecedent sterilization, and with isthmic–isthmic repairs. With reanastomosis via laparotomy, rates of live births range from 44 to 82 percent (Deffieux, 2011; Malacova, 2015). The rate of ectopic pregnancy is 2 to 10 percent after reanastomosis (American Society for Reproductive Medicine, 2015). With reanastomosis to reverse *Essure* sterilization, only 27 percent of women had subsequent live births (Monteith, 2014).

TRANSCERVICAL STERILIZATION

Devices can be inserted via hysteroscopy to occlude the proximal fallopian tubes. The *Essure* microinsert has a fine stainless-steel inner coil enclosed in polyester fibers and an expandable outer coil of Nitinol—a nickel and titanium alloy (Fig. 39-4). The outer coil expands after placement, allowing the inner fibers to expand. These synthetic fibers incite a chronic inflammatory response to prompt local tissue ingrowth that leads to complete tubal lumen occlusion. For hysteroscopic placement, sedation, paracervical block, or both may be used, and in-office insertion is often elected. Devices cannot be placed in all women, and some do not tolerate the procedure while awake (Duffy, 2005). Bilateral placement is achieved in 81 to 98 percent of cases on a first attempt (la Chapelle, 2015).

FIGURE 39-4
Essure microinsert placement hysteroscopically and ingrowth of tissue. (Reproduced with permission from Thompson M, Kho K: Minimally invasive surgery. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill, 2016.)



Since the introduction of *Essure*, cited adverse events include abnormal bleeding, perforation of the uterus or fallopian tubes from device migration, and allergy or hypersensitivity reactions, especially to the nickel component (Al-Safi, 2013; Mao, 2015). Some events resulted in device removal that requires abdominal surgery (Casey, 2016; Lazorwitz, 2017). To provide more information of the risks and benefits, the Food and Drug Administration (2016) has drafted a black box warning and patient-decision checklist to aid counseling.

Because complete tubal blockage is not 100 percent, it must be confirmed by hysterosalpingography (HSG) 3 months following surgery (Bayer Healthcare, 2002). With such confirmation, efficacy rates for these devices reach 98 to 99 percent (Chudnoff, 2015; Munro, 2014). In real-world settings, pregnancies following transcervical sterilization are most frequently attributed to conception before insertion or HSG and to noncompliance with HSG or its misinterpretation. Although data are limited to small case series, pregnancies conceived with *Essure* in place do not appear to be at increased risk from the device (Arora, 2014; Veersema, 2014).

Another insert, *Adiana,* also stimulates tissue ingrowth for tubal occlusion using a cylindrical, nonabsorbent silicone elastomer matrix. However, for financial reasons, production of this device has now been discontinued by the manufacturer (Hologic, 2012). That said, patients with these inserts may be encountered and can consider their device effective.

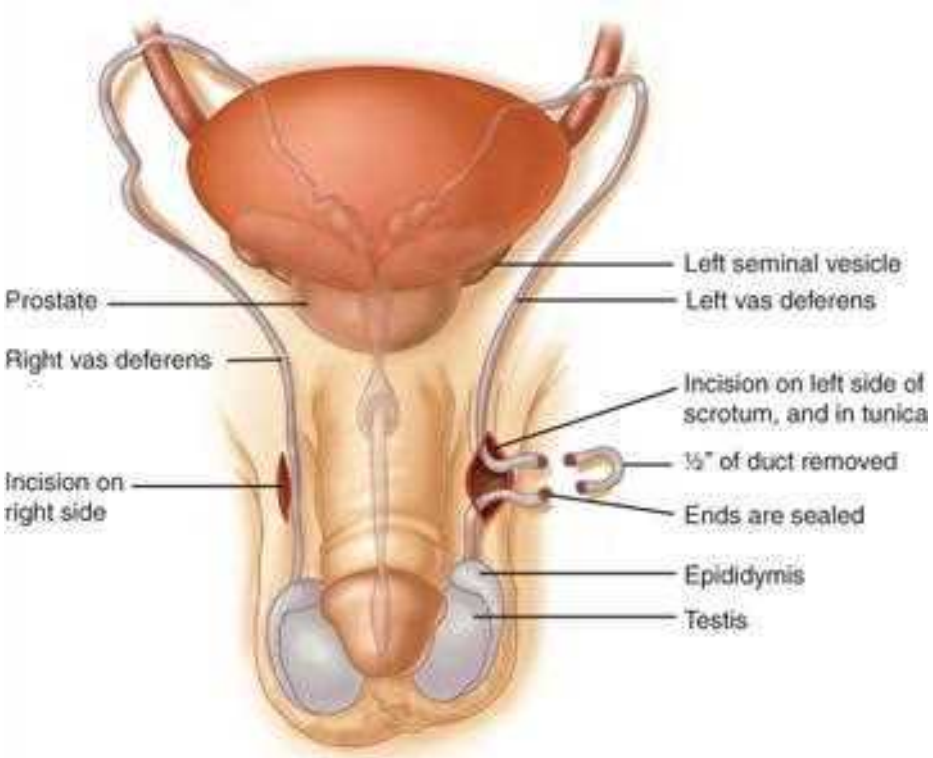
Although not currently available in the United States, *quinacrine pellets* cause sclerosis at the tubal ostia. Placement at the uterine fundus with an IUD-type inserter method allows pellet migration into the tubal ostia. Of drawbacks, prior cancer associations have been disproved (Sokal, 2010a,b). Efficacy appears enhanced by technique modification. In one early cohort of 1335 treated women, pregnancy rates at 10 years were 12 percent (Sokal, 2008). Following insertion technique improvement, a 2-year failure rate of 1.2 percent was calculated by Lippes (2015).

VASECTOMY

Currently, up to a half million men in the United States undergo vasectomy each year (Barone, 2006; Eisenberg, 2010). And 5 percent of women rely on this method for contraception (Daniels, 2015). For sterilization, the vas deferens lumen is disrupted to block the passage of sperm from the testes. Most commonly, a *no-scalpel vasectomy (NSV)* accomplishes this with one specialized instrument that grasps the vas deferens and surrounding skin together. A second dissector tool punctures the skin and then isolates the vas (Rogers, 2013). As clarified by the American Urological Association, *minimally invasive vasectomy* includes any vas isolation

procedure, including the no-scalpel technique, which uses a skin incision measuring ≤1 cm and requires minimal vas dissection (Fig. 39-5) (Sharlip, 2012). Compared with *conventional vasectomy* that employs incisions >1 cm and greater dissection, the no-scalpel technique is associated with fewer minor surgical complications, but each is equally effective (Cook, 2014).

FIGURE 39-5
Anatomy of male reproductive system showing procedure for vasectomy.



Vasectomy is safer than tubal sterilization because it is less invasive and is performed with local analgesia (American College of Obstetricians and Gynecologists, 2017a). In a review to compare the two, Hendrix and associates (1999) found that, compared with vasectomy, female tubal sterilization has a 20-fold increased complication rate, a 10- to 37-fold failure rate, and costs three times as much.

One disadvantage is that sterilization following vasectomy is not immediate. Complete release of sperm stored in the reproductive tract beyond the interrupted vas deferens takes approximately 3 months or 20 ejaculations. The American Urological Association recommends a postprocedural semen analysis at 8 to 16 weeks to document sterility (Sharlip, 2012). During the period before azoospermia is documented, another form of contraception should be used.

The failure rate for vasectomy during the first year is 9.4 per 1000 procedures and 11.4 per 1000 at 2, 3, and 5 years (Jamieson, 2004). Failures result from unprotected intercourse too soon after ligation, incomplete occlusion of the vas deferens, or recanalization (Awsare, 2005; Deneux-Tharaux, 2004).

Other than regrets, long-term consequences are rare. One is troublesome chronic scrotal pain, which develops in up to 15 percent of men (Leslie, 2007; Manikandan, 2004). Previous concerns for atherogenesis, immune-complex mediated disease, testicular cancer, and prostate cancer have been allayed by a number of investigators (Bernal-Delgado, 1998; Giovannucci, 1992; Goldacre, 1983; Møller, 1994).

Reanastomosis of the vas deferens can be completed most effectively using microsurgical techniques. In general, conception rates following reversal are adversely affected by longer duration from vasectomy, poor sperm quality found at reversal, and type of reversal procedure required (American Society for Reproductive Medicine, 2008).

CHAPTER 40: Hypertensive Disorders

An eclamptic convulsion sometimes occurs without warning, "like a bolt from a clear sky", in women who are apparently in perfect health. In the majority of cases, however, the outbreak is preceded for a longer or shorter period by premonitory symptoms indicative of toxemia of pregnancy, among the more common being oedema, headache, epigastric pain, and possibly disturbances of vision.

—J. Whitridge Williams (1903)

INTRODUCTION

At the time of this textbook's first edition, it was accepted that "toxemia" preceded most cases of eclampsia. The central role of hypertension had not yet been discovered, and after many years, it became apparent that preeclampsia was a syndrome of which hypertension was only one important facet. Still, the mechanisms by which pregnancy incites or aggravates hypertension remain unsolved. Indeed, hypertensive disorders remain among the most significant and intriguing unsolved problems in obstetrics. These disorders complicate 5 to 10 percent of all pregnancies, and together they are one of the deadly triad—along with hemorrhage and infection—that contributes greatly to maternal morbidity and mortality rates. Of hypertensive disorders, the *preeclampsia syndrome*, either alone or superimposed on chronic hypertension, is the most dangerous. As subsequently discussed, new-onset hypertension during pregnancy—termed *gestational hypertension*—is followed by signs and symptoms of preeclampsia almost half the time, and preeclampsia is identified in 4 to 5 percent of all pregnancies (Martin, 2012).

The World Health Organization (WHO) systematically reviews maternal mortality worldwide, and in developed countries, 16 percent of maternal deaths were attributed to hypertensive disorders (Khan, 2006). In the United States from 2011 to 2013, 7.4 percent of 2009 pregnancy-related maternal deaths were caused by preeclampsia or eclampsia (Creanga, 2017). A similar rate was 10 percent in France from 2003 through 2007 (Saucedo, 2013). Importantly, more than half of these hypertension-related deaths were deemed preventable (Berg, 2005).

TERMINOLOGY AND DIAGNOSIS

To update and codify the terminology and classification of hypertensive disorders of pregnancy, a Task Force of the American College of Obstetricians and Gynecologists (2013) has provided evidence-based recommendations for clinical practice. The previous basic classification was retained and describes four types of hypertensive disease:

1. Preeclampsia and eclampsia syndrome
2. Chronic hypertension of any etiology
3. Preeclampsia superimposed on chronic hypertension
4. Gestational hypertension—definitive evidence for the preeclampsia syndrome does not develop and hypertension resolves by 12 weeks postpartum.

Importantly, this classification differentiates the preeclampsia syndrome from other hypertensive disorders because it is potentially more ominous.

Diagnosis of Hypertensive Disorders

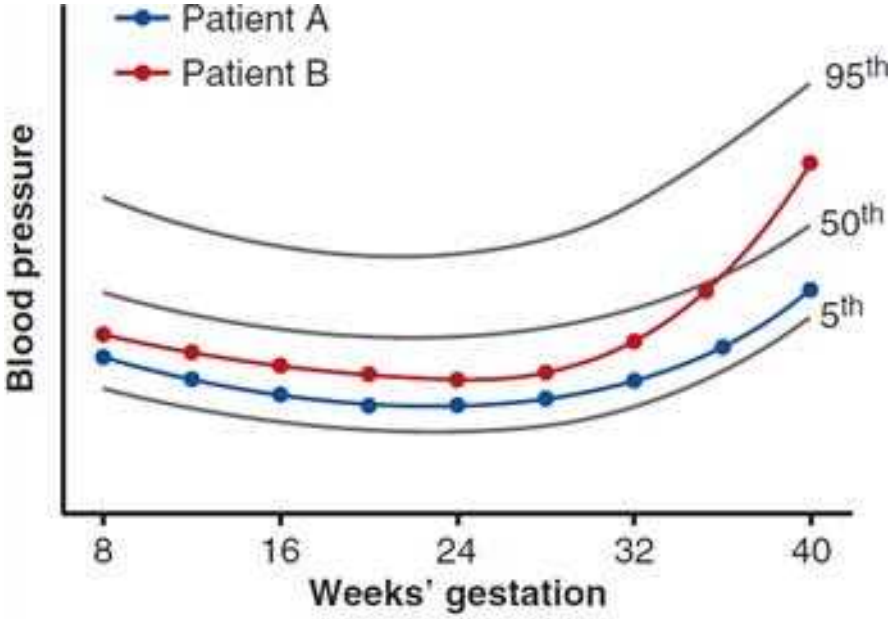
Hypertension is diagnosed empirically when appropriately taken blood pressure exceeds 140 mm Hg systolic or 90 mm Hg diastolic. Korotkoff phase V is used to define diastolic pressure. Previously, incremental increases of 30 mm Hg systolic or 15 mm Hg diastolic above blood pressure values taken at midpregnancy had also been used as diagnostic criteria, even when absolute values were <140/90 mm Hg. These incremental changes are no longer used to define hypertension, but it is recommended that such women be observed more closely because eclamptic seizures develop in some whose blood pressures have stayed below 140/90 mm Hg (Alexander, 2006). Also, a sudden rise in mean arterial pressure but still in a normal range—"delta hypertension"—may signify preeclampsia (Macdonald-Wallis, 2012; Zeeman, 2007).

Concept of "Delta Hypertension"

The systolic and diastolic blood pressure levels of 140/90 mm Hg have been arbitrarily used since the 1950s to define "hypertension" in nonpregnant individuals. However, these levels were selected by insurance companies to characterize a group of middle-aged men. It seems more realistic to define normal-range blood pressures that fall between an upper and lower limit for a particular population—such as young, healthy, pregnant women. A schematic example using arbitrary mean arterial blood pressure readings is shown in Figure 40-1. Data curves for both women show blood pressure measurements near the 25th percentile until 32 weeks. These begin to rise in patient B, who by term has substantively higher blood pressures. However, her pressures are still <140/90 mm Hg, and thus she is considered to be "normotensive." We use the term *delta hypertension* to describe this rather acute rise in blood pressure. Some of these women will go on to have obvious preeclampsia, and some even develop eclamptic seizures or HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome while still normotensive.

FIGURE 40-1

Schematic shows normal reference ranges for mean arterial blood pressure changes across pregnancy. Patient A (*blue*) has mean blood pressures near the 20th percentile throughout pregnancy. Patient B (*red*) has a similar pattern with mean pressures at the 25th percentile until approximately 36 weeks when her blood pressure begins to rise. By term, it is substantively higher and in the 75th percentile, but she is still considered "normotensive."



Gestational Hypertension

This diagnosis is made in women whose blood pressures reach 140/90 mm Hg or greater for the first time after midpregnancy, but in whom *proteinuria is not identified.* Almost half of these women subsequently develop preeclampsia syndrome. Even so, when blood pressure increases appreciably, it is dangerous to both mother and fetus to ignore this rise only because proteinuria has not yet developed. As Chesley (1985) emphasized, 10 percent of eclamptic seizures develop before overt proteinuria can be detected. Finally, gestational hypertension is reclassified by some as *transient hypertension* if evidence for preeclampsia does not develop and the blood pressure returns to normal by 12 weeks postpartum.

Preeclampsia Syndrome

Preeclampsia is best described as a pregnancy-specific syndrome that can affect virtually every organ system. In addition, it heralds a higher incidence of cardiovascular disease later in life (Long-Term Consequences). Although preeclampsia is much more than simply gestational hypertension with proteinuria, appearance of proteinuria remains an important diagnostic criterion. Thus, proteinuria is an *objective* marker and reflects the system-wide endothelial leak that characterizes the preeclampsia syndrome.

In some women with the preeclampsia syndrome, neither overt proteinuria nor fetal-growth restriction are features (Sibai, 2009). Because of this, the Task Force (2013) suggests other diagnostic criteria, which are shown in Table 40-1. Evidence of multiorgan involvement may include thrombocytopenia, renal dysfunction, hepatocellular necrosis, central nervous system perturbations, or pulmonary edema.

TABLE 40-1

Classification and Diagnosis of Pregnancy-Associated Hypertension

Condition	Criteria Required
Gestational hypertension	BP >140/90 mm Hg after 20 weeks in previously normotensive women
Preeclampsia: Hypertension plus	
Proteinuria	• ≥300 mg/24 h, or • Urine protein: creatinine ratio ≥0.3, or • Dipstick 1+ persistent[a]
or	
Thrombocytopenia	• Platelet count <100,000/**μL**
Renal insufficiency	• Creatinine level >1.1 mg/dL or doubling of baseline[b]
Liver involvement Cerebral symptoms	• Serum transaminase levels[c] twice normal • Headache, visual disturbances, convulsions
Pulmonary edema	—

[a]Recommended only if sole available test.

[b]No prior renal disease.

[c]AST (aspartate transaminase) or ALT (alanine transaminase).

BP = blood pressure.

Modified with permission from American College of Obstetricians and Gynecologists; Task Force on Hypertension in Pregnancy: Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy, Obstet Gynecol. 2013 Nov;122(5):1122–31

Indicators of Preeclampsia Severity

The markers listed in Table 40-1 are also used to classify preeclampsia syndrome severity. Although many use a dichotomous "mild" and "severe" classification, the Task Force (2013) discourages the use of "mild preeclampsia." It is problematic that there are criteria for the diagnosis of "severe" preeclampsia, but the default classification is either implied or specifically termed as "mild," "less severe," or "nonsevere" (Alexander, 2003; Lindheimer, 2008b). There are no generally agreed-on criteria for "moderate" preeclampsia—an elusive third category. We use the criteria listed in Table 40-2, which are categorized as "severe" versus "nonsevere."

TABLE 40-2

Indicators of Severity of Gestational Hypertensive Disorders[a]

Abnormality	Nonsevere[b]	Severe
Diastolic BP	<110 mm Hg	≥110 mm Hg
Systolic BP	<160 mm Hg	≥160 mm Hg
Proteinuria[c]	None to positive	None to positive
Headache	Absent	Present
Visual disturbances	Absent	Present
Upper abdominal pain	Absent	Present
Oliguria	Absent	Present
Convulsion (eclampsia)	Absent	Present
Serum creatinine	Normal	Elevated
Thrombocytopenia (<100,000/μL)	Absent	Present
Serum transaminase elevation	Minimal	Marked
Fetal-growth restriction	Absent	Present
Pulmonary edema	Absent	Present
Gestational age	Late	Early

[a]Compare with criteria in Table 40-1.

[b]Includes "mild" and "moderate" hypertension not specifically defined.

[c]Most disregard degrees of proteinuria to classify nonsevere or severe.

BP = blood pressure.

Some symptoms are considered ominous. *Headaches* or *visual disturbances* such as scotomata can precede *eclampsia*, which is a convulsion not attributable to another cause. The seizures are generalized and may appear before, during, or after labor. The proportion that develops seizures later, after 48 hours postpartum, approximates 10 percent (Sibai, 2005; Zwart, 2008). Another symptom, *epigastric or right upper quadrant pain*, frequently accompanies hepatocellular necrosis, ischemia, and edema that ostensibly stretches Glisson capsule. This characteristic pain is frequently accompanied by elevated serum hepatic transaminase levels. Finally, *thrombocytopenia* also signifies worsening preeclampsia. It represents platelet activation and aggregation as well as microangiopathic hemolysis. Other factors indicative of severe preeclampsia include renal or cardiac involvement, obvious fetal-growth restriction, and early-onset disease.

The more profound these signs and symptoms, the less likely it is that they can be temporized, and the more likely that delivery will be required. *A caveat is that differentiation between nonsevere and severe gestational hypertension or preeclampsia can be misleading because what might be apparently mild disease may progress rapidly to severe disease.*

Preeclampsia Superimposed on Chronic Hypertension

Regardless of its cause, any chronic hypertensive disorder predisposes a woman to develop superimposed preeclampsia syndrome. Chronic underlying hypertension is diagnosed in women with documented blood pressures >140/90 mm Hg before pregnancy or before 20 weeks' gestation, or both. Hypertensive disorders can create difficult problems with diagnosis and management in women who are not first seen until after midpregnancy. This is because blood pressure normally drops during the second and early third trimesters in both normotensive and chronically hypertensive women (see Fig. 40-1). Thus, a woman with previously undiagnosed chronic vascular disease who is seen before 20 weeks frequently has blood pressures within normal range. During the third trimester, however, as blood pressures return to their originally hypertensive levels, it may be difficult to determine whether hypertension is chronic or induced by pregnancy. Even a careful search for evidence of preexisting end-organ damage may be futile, as many of these women have mild disease and no evidence of ventricular hypertrophy, retinal vascular changes, or renal dysfunction.

In some with chronic hypertension, blood pressure rises to obviously abnormal levels, typically after 24 weeks' gestation. If new-onset or worsening baseline hypertension is accompanied by new-onset proteinuria or other findings listed in Table 40-1, then superimposed preeclampsia is diagnosed. Compared with "pure" preeclampsia, superimposed preeclampsia commonly develops earlier in pregnancy. It also tends to be more severe and more often is accompanied by fetal-growth restriction. The same criteria shown in Table 40-2 are also used to further characterize severity of superimposed preeclampsia.

INCIDENCE AND RISK FACTORS

Young and nulliparous women are particularly vulnerable to developing preeclampsia, whereas older women are at greater risk for chronic hypertension with superimposed preeclampsia. The incidence is markedly influenced by race and ethnicity—and thus by genetic predisposition. In one study by the Maternal-Fetal Medicine Units (MFMU) Network, the incidence of preeclampsia was 5 percent in white, 9 percent in Hispanic, and 11 percent in African-American women (Myatt, 2012a,b). In addition, black women have greater morbidity (Shahul, 2015). In several worldwide studies reviewed by Staff and coworkers (2015), the incidence of preeclampsia in nulliparous populations ranged from 3 to 10 percent. The incidence of preeclampsia in multiparas also varies and ranges from 1.4 to 4 percent (Fisher, 2015).

Bartsch and associates (2016) extracted data from more than 25 million pregnancies and calculated relative risks for several clinical factors shown in Table 40-3. Others include the metabolic syndrome and hyperhomocysteinemia (Karumanchi, 2016a; Masoudian, 2016; Scholten, 2013). Pregnancies with a male fetus are also at slightly higher risk (Jaskolka, 2017). Although smoking during pregnancy causes various adverse pregnancy outcomes, ironically, it carries a *reduced risk* for hypertension during pregnancy (Bainbridge, 2005; Kraus, 2014). Other factors are human immunodeficiency virus (HIV) seropositivity and sleep-disordered breathing (Facco, 2017; Sansone, 2016).

TABLE 40-3

Selected Clinical Risk Factors for Preeclampsia

Risk Factor	Pregnancies (millions)	Pooled Unadjusted Relative Risk (95% CI)
SLE	2.43	2.5 (1.0–6.3)
Nulliparity	2.98	2.1 (1.9–2.4)
Age >35	5.24	1.2 (1.1–1.3)
Prior stillbirth	0.063	2.4 (1.7–3.4)
CKD	0.97	1.8 (1.5–2.1)
ART	1.46	1.8 (1.6–2.1)
BMI >30	5.92	2.8 (2.6–3.1)
Multifetal	7.31	2.9 (2.6–3.1)
Prior abruption	0.29	2.0 (1.4–2.7)
Diabetes	2.55	3.7 (3.1–4.3)
Prior preeclampsia	3.72	8.4 (7.1–9.9)
CHTN	6.59	5.1 (4.0–6.5)
APA	0.22	2.8 (1.8–4.3)

APA = antiphospholipid antibody; ART = assisted reproductive technology; BMI = body mass index; CHTN = chronic hypertension; CKD = chronic kidney disease; SLE = systemic lupus erythematosus.

Data from Bartsch, 2016.

For eclampsia, the incidence has declined in areas where health care is more readily available. In the United States in 1998, it affected 1 in 3250 births (Ventura, 2000). Except for Iceland, which has an extremely low rate, in countries with adequate resources the incidence averages 1 in 2000 to 3000 deliveries (Andersgaard, 2006; Jaatinen, 2016; O'Connor, 2013; Royal College of Obstetricians and Gynaecologists, 2006; Zwart, 2008).

ETIOPATHOGENESIS

Any satisfactory theory concerning the origins of preeclampsia must account for the observation that gestational hypertensive disorders are more likely to develop in women with the following characteristics:

Are exposed to chorionic villi for the first time

Are exposed to a superabundance of chorionic villi, as with twins or hydatidiform mole

Have preexisting conditions associated with endothelial cell activation or inflammation, such as diabetes, obesity, cardiovascular or renal disease, immunological disorders, or hereditary influences

Are genetically predisposed to hypertension developing during pregnancy.

A fetus is not a requisite for preeclampsia to develop. And, although chorionic villi are essential, they need not be intrauterine. For example, preeclampsia can develop with an abdominal pregnancy (Worley, 2008). *Regardless of precipitating etiology, the cascade of events leading to the preeclampsia syndrome is characterized by abnormalities that result in systemic vascular endothelial damage with resultant vasospasm, transudation of plasma, and ischemic and thrombotic sequelae.*

Phenotypic Expression of Preeclampsia Syndrome

The preeclampsia syndrome varies widely in its clinical phenotypic expression. But, at least two major subtypes are differentiated by whether or not remodeling of uterine spiral arterioles by endovascular trophoblasts is defective. This concept has given rise to the “two-stage disorder” theory of preeclampsia pathogenesis. According to Redman and coworkers (2015a), stage 1 is caused by faulty endovascular trophoblastic remodeling that downstream causes the stage 2 clinical syndrome. Importantly, stage 2 can be modified by preexisting maternal conditions that are also manifest by endothelial cell activation or inflammation and are listed in the third prior bullet.

Such staging is artificial, and it seems logical that preeclampsia syndrome presents clinically as a spectrum of worsening disease. Moreover, evidence is accruing that many “isoforms” exist as discussed subsequently. Examples include differences in maternal and fetal characteristics, placental findings, and early- versus late-onset disease (Phillips, 2010; Valensise, 2008; van der Merwe, 2010).

Etiology

An imposing number of mechanisms have been proposed to explain the cause of preeclampsia. Those currently considered important include:

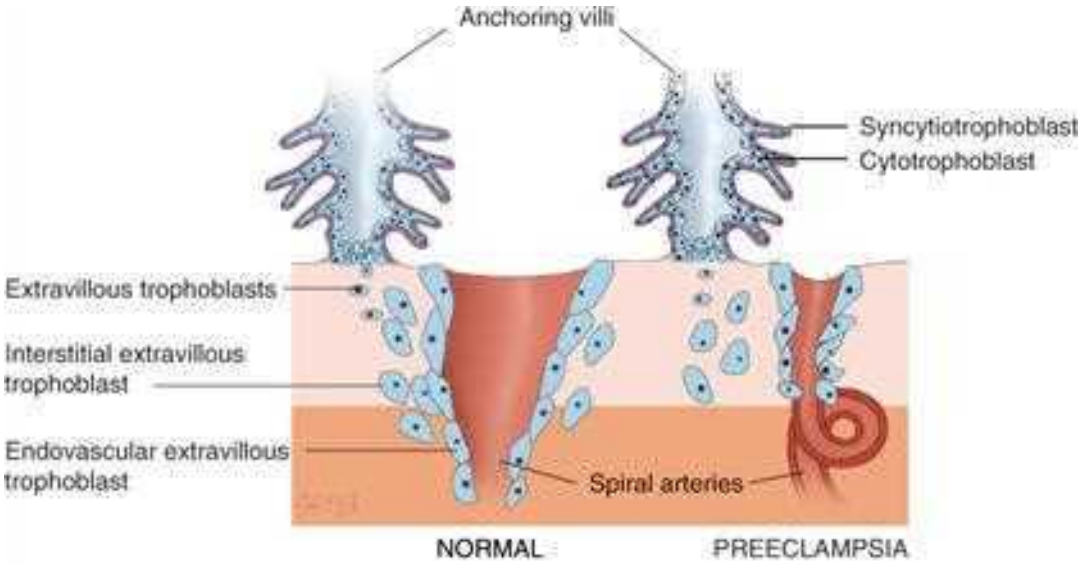
1. Placental implantation with abnormal trophoblastic invasion of uterine vessels
2. Immunological maladaptive tolerance between maternal, paternal (placental), and fetal tissues
3. Maternal maladaptation to cardiovascular or inflammatory changes of normal pregnancy
4. Genetic factors including inherited predisposing genes and epigenetic influences.

Abnormal Trophoblastic Invasion

Discussed in Chapter 5 (Blastocyst), normal implantation is characterized by extensive remodeling of the spiral arterioles within the decidua basalis (Fig. 40-2). Endovascular trophoblasts replace the vascular endothelial and muscular linings to enlarge the vessel diameter (Zhou, 1997). The veins are invaded only superficially.

FIGURE 40-2

Schematic representation of normal placental implantation shows proliferation of extravillous trophoblasts from an anchoring villus. These trophoblasts invade the decidua and extend into the walls of the spiral arteriole to replace the endothelium and muscular wall to create a dilated low-resistance vessel. With preeclampsia, defective implantation is characterized by incomplete invasion of the spiral arteriolar wall by extravillous trophoblasts. This results in a small-caliber vessel with high resistance to flow.



In some cases of preeclampsia, however, trophoblastic invasion may be incomplete. With this, decidual vessels, but not myometrial vessels, become lined with endovascular trophoblasts. The deeper myometrial arterioles thus do not lose their endothelial lining and musculoelastic tissue, and their mean external diameter is only half that of corresponding vessels in normal placentas (Fisher, 2015). In general, the magnitude of defective trophoblastic invasion correlates with the severity of the hypertensive disorder (Madazli, 2000). And importantly, it is more prevalent in women with early-onset preeclampsia (Khodzhaeva, 2016). McMahon and associates (2014) found that lower levels of soluble antiangiogenic growth factors may be involved in this faulty endovascular remodeling.

From placental electron microscopy studies, early preeclamptic changes include endothelial damage, insudation of plasma constituents into vessel walls, proliferation of myointimal cells, and medial necrosis (De Wolf, 1980). Hertig (1945) referred to lipid accumulation in myointimal cells and macrophages as *atherosis*. These findings are more common in placentas from women diagnosed with preeclampsia before 34 weeks (Nelson, 2014b). Acute placental vascular atherosis may also identify a group of women at greater risk for later atherosclerosis and cardiovascular disease (Staff, 2015). In pregnancy, the abnormally narrow lumen of spiral arterioles likely impairs placental blood flow. Diminished perfusion and a hypoxic environment eventually lead to release of *placental debris* or *microparticles.*

At this point, these changes incite a systemic inflammatory response, which is stage 2 of the preeclampsia syndrome (Lee, 2012; Redman, 2012). Defective placentation is posited to further cause the susceptible woman to develop gestational hypertension, the preeclampsia syndrome, preterm delivery, a growth-restricted fetus, and/or placental abruption (Brosens, 2011; Labarrere, 2017; Nelson, 2014b).

Immunological Factors

Maternal immune tolerance to paternally derived placental and fetal antigens is discussed in Chapter 5 (Fetal–Maternal Interface). Loss of this tolerance is another cited theory for preeclampsia (Erlebacher, 2013). Certainly, the histological changes at the maternal-placental interface are suggestive of acute graft rejection.

Inferential data also suggest that preeclampsia is an immune-mediated disorder. For example, the risk of preeclampsia is appreciably enhanced in circumstances in which formation of blocking antibodies to placental antigenic sites *might* be impaired. In this scenario, the first pregnancy would carry a higher risk. Tolerance dysregulation might also explain an elevated risk when the paternal antigenic load is increased, that is, with two sets of paternal chromosomes—a "double dose." Namely, women with molar pregnancies have a high incidence of early-onset preeclampsia. Women with a trisomy 13 fetus also have a 30- to 40-percent incidence of preeclampsia. These women have elevated serum levels of antiangiogenic factors. The gene for one of these factors, *soluble fms-like tyrosine kinase 1*, is on chromosome 13 (Bdolah, 2006). Conversely, women previously exposed to paternal antigens, such as a prior pregnancy with the *same* partner, are "immunized" against preeclampsia. This phenomenon is not as apparent in women with a prior abortion (Strickland, 1986). Multiparas impregnated by a new consort have a greater risk of preeclampsia (Mostello, 2002).

Redman and colleagues (2015a) reviewed the possible role of *immune maladaptation* in preeclampsia pathophysiology. In women destined to be preeclamptic, extravillous trophoblasts early in pregnancy express reduced amounts of immunosuppressive nonclassic human leukocyte antigen G (HLA G). Black women more commonly have the 1597ΔC gene allele that further predisposes to preeclampsia (Loisel, 2013). These changes may contribute to the defective placental vascularization in stage 1 of the preeclampsia syndrome. As discussed in Chapter 4 (Leukocytes and Lymphocytes), T-helper (Th) lymphocytes during normal pregnancy are produced so that type 2 activity is increased in relation to type 1—so-called *type 2 bias* (Redman, 2012, 2015a). Th2 cells promote humoral immunity, whereas Th1 cells stimulate inflammatory cytokine secretion. Beginning in the early second trimester in women who develop preeclampsia, Th1 action is increased.

Endothelial Cell Activation

Inflammatory changes are believed to be a continuation of stage 1 alterations. In response to ischemia or other inciting causes, placental factors are released and begin a cascade of events (Davidge, 2015). Thus, antiangiogenic and metabolic factors and other inflammatory leukocyte mediators are thought to provoke systemic endothelial cell injury, which is used synonymously here with *endothelial cell activation* or *dysfunction*.

Endothelial cell dysfunction may result from an extreme activated state of leukocytes in the maternal circulation (Faas, 2000; Gervasi, 2001). Briefly, cytokines such as tumor necrosis factor-α (TNF-α) and the interleukins may contribute to the systemic oxidative stress associated with preeclampsia. This is characterized by reactive oxygen species and free radicals that lead to formation of self-propagating lipid peroxides (Manten, 2005). These peroxides in turn generate highly toxic

radicals that injure systemic vascular endothelial cells, modify nitric oxide production by these cells, and interfere with prostaglandin balance. Other consequences of oxidative stress include production of the lipid-laden macrophage foam cells seen in placental atherosis, activation of systemic microvascular coagulation manifested by thrombocytopenia, and greater systemic capillary permeability reflected by edema and proteinuria.

Genetic Factors

Preeclampsia appears to be a multifactorial, polygenic disorder. In one study of almost 1.2 million Swedish births, a genetic association for gestational hypertension and for preeclampsia was found (Nilsson, 2004). Ward and Taylor (2015) cite an incident risk for preeclampsia of 20 to 40 percent for daughters of preeclamptic mothers; 11 to 37 percent for sisters of preeclamptic women; and 22 to 47 percent for twins. Ethnoracial factors are important, as evidenced by the high incidence of preeclampsia in African-American women. It may be that Latina women have a lower incidence because of interactions of American Indian and white race genes (Shahabi, 2013).

The hereditary predisposition for preeclampsia likely stems from interactions of literally hundreds of inherited genes—both maternal and paternal—that control myriad enzymatic and metabolic functions throughout every organ system (Triche, 2014). Plasma-derived factors may induce some of these genes in preeclampsia (Mackenzie, 2012). Thus, the clinical manifestation in any given woman with the preeclampsia syndrome will occupy a spectrum. In this regard, phenotypic expression will differ among similar genotypes depending on interactions with environmental components (Yang, 2013).

Hundreds of genes have been studied for their possible association with preeclampsia (Buurma, 2013; Sakowicz, 2016; Ward, 2015). Several that may have a significant association with the syndrome are listed in Table 40-4. However, because of the complex phenotypic expression of preeclampsia, it is doubtful that any *one* candidate gene will be found responsible. Indeed, Majander and associates (2013) have linked preeclampsia predisposition to even *fetal* genes on chromosome 18.

TABLE 40-4

Genes with Possible Associations with Preeclampsia Syndrome

Gene (Polymorphism)	Function Affected
MTHFR (C677T)	Methylene tetrahydrofolate reductase
F5 (Leiden)	Factor V_{Leiden}
AGT (M235T)	Angiotensinogen
HLA (Various)	Human leukocyte antigens
NOS3 (Glu 298 Asp)	Endothelial nitric oxide
F2 (G20210A)	Prothrombin (factor II)
ACE (I/D^{at}Intron 16)	Angiotensin-converting enzyme
CTLA4	Cytotoxic T-lymphocyte-associated protein
LPL	Lipoprotein lipase
SERPINE1	Serine peptidase inhibitor
GNA promoter	Decreased methylation

Data from Buurma, 2013; Staines-Urias, 2012; Triche, 2014; Ward, 2014; Ye, 2016.

Pathogenesis

Vasospasm

The concept of vasospasm with preeclampsia has been advanced for a century (Volhard, 1918). Systemic endothelial activation causes vasospasm that elevates resistance to produce subsequent hypertension. Concurrently, systemic endothelial cell injury promotes interstitial leakage, and blood constituents, including platelets and fibrinogen, are deposited subendothelially. Endothelial junctional proteins are also disrupted, and the subendothelial region of resistance arteries undergoes ultrastructural change (Suzuki, 2003; Wang, 2002). The much larger venous circuit is similarly involved.

With diminished blood flow because of maldistribution from vasospasm and interstitial leakage, ischemia of the surrounding tissues can lead to necrosis, hemorrhage, and other end-organ disturbances characteristic of the syndrome. One important clinical correlate to this is the markedly attenuated blood volume seen in women with severe preeclampsia (Zeeman, 2009).

Endothelial Cell Injury

Injury to systemic endothelial cells is now a centerpiece of preeclampsia pathogenesis (Davidge, 2015). In this scheme, protein factor(s)—likely placental—are secreted into the maternal circulation and provoke activation and dysfunction of the systemic vascular endothelium. Many facets of the clinical syndrome of preeclampsia are thought to result from these widespread endothelial cell changes.

Intact endothelium has anticoagulant properties. Also, systemic endothelial cells, by releasing nitric oxide, blunt the response of vascular smooth muscle to agonists. Injured or activated endothelial cells may produce less nitric oxide and may secrete substances that promote coagulation and greater sensitivity to vasopressors. Further evidence of endothelial activation includes the characteristic changes in glomerular capillary endothelial morphology, greater capillary permeability, and elevated blood concentrations of substances associated with endothelial activation. Likely, multiple factors in the plasma of preeclamptic women combine to exert these vasoactive effects (Myers, 2007; Walsh, 2009).

Increased Pressor Responses

As discussed in Chapter 4 (Renin, Angiotensin II, and Plasma Volume), pregnant women normally develop refractoriness to infused vasopressors (Abdul-Karim, 1961). Women with early preeclampsia, however, have enhanced vascular reactivity to infused norepinephrine and angiotensin II (Raab, 1956; Talledo, 1968). Moreover, increased sensitivity to angiotensin II clearly precedes the onset of gestational hypertension (Gant, 1974). Paradoxically, women who develop preterm preeclampsia have lower circulating levels of angiotensin II (Chase, 2017).

Several prostaglandins are thought to be central to preeclampsia syndrome pathophysiology. Specifically, the blunted pressor response seen in normal pregnancy is at least partially due to diminished vascular responsiveness mediated by endothelial prostaglandin synthesis. For example, compared with normal pregnancy, endothelial prostacyclin (PGI_2) production is lower in preeclampsia. This action appears to be mediated by phospholipase A_2 (Davidge, 2015). At the same time, thromboxane A_2 secretion by platelets is increased, and the prostacyclin:thromboxane A_2 ratio declines. The net result favors greater sensitivity to infused angiotensin II and, ultimately, vasoconstriction (Spitz, 1988). These changes are apparent as early as 22 weeks' gestation in gravidas who later develop preeclampsia (Chavarria, 2003).

Nitric oxide is a potent vasodilator synthesized from L-arginine by endothelial cells. Inhibition of nitric oxide synthesis raises mean arterial pressure, lowers heart rate, and reverses the pregnancy-induced refractoriness to vasopressors. In humans, nitric oxide likely is the compound that maintains the normal low-pressure vasodilated state characteristic of fetoplacental perfusion (Myatt, 1992; Weiner, 1992). The effects of nitric oxide production in preeclampsia are unclear. It appears that the syndrome is associated with decreased endothelial nitric oxide synthase expression, thus resulting in lower nitric oxide activity (Davidge, 2015).

Endothelins are 21-amino-acid peptides and potent vasoconstrictors. Endothelin-1 (ET-1) is the primary isoform produced by human endothelium (Karumanchi, 2016b). Plasma ET-1 levels are elevated in normotensive pregnant women, but women with preeclampsia have even higher levels (Ajne, 2003). According to Taylor and Roberts (1999), the placenta is not the source of increased ET-1 concentrations, and they likely arise from systemic endothelial activation. Interestingly, treatment of preeclamptic women with magnesium sulfate lowers ET-1 concentrations (Sagsoz, 2003). And, in animal studies, sildenafil reduces ET-1 concentrations (Gillis, 2016).

Angiogenic and Antiangiogenic Proteins

Placental vasculogenesis is evident by 21 days after conception. The list of pro- and antiangiogenic substances involved in placental vascular development is extensive, and the families of vascular endothelial growth factor (VEGF) and angiopoietin are the most studied. *Angiogenic imbalance* describes excessive amounts of antiangiogenic factors, which are thought to be stimulated by worsening hypoxia at the uteroplacental interface. Trophoblast of women destined to develop preeclampsia overproduces at least two antiangiogenic peptides that enter the maternal circulation (Karumanchi, 2016a).

First, *soluble fms-like tyrosine kinase 1 (sFlt-1)* is a receptor for VEGF. As depicted in Figure 40-3, elevated maternal sFlt-1 levels inactivate and reduce circulating free placental growth factor (PlGF) and VEGF concentrations, leading to endothelial dysfunction (Maynard, 2003). Importantly, sFlt-1 levels begin to rise in maternal serum months before preeclampsia is evident (Fig. 40-4). These high levels in the second trimester are associated with a doubling of the risk for preeclampsia (Haggerty, 2012). This divergence from normal levels appears to develop even sooner with early-onset preeclampsia (Vatten, 2012). These factors are also operative in pregnancies complicated by fetal-growth restriction (Herraiz, 2012).

FIGURE 40-3

Schematic of the receptor blocking action of sFlt-1 (soluble fms-like tyrosine kinase 1) and soluble endoglin (sEng).

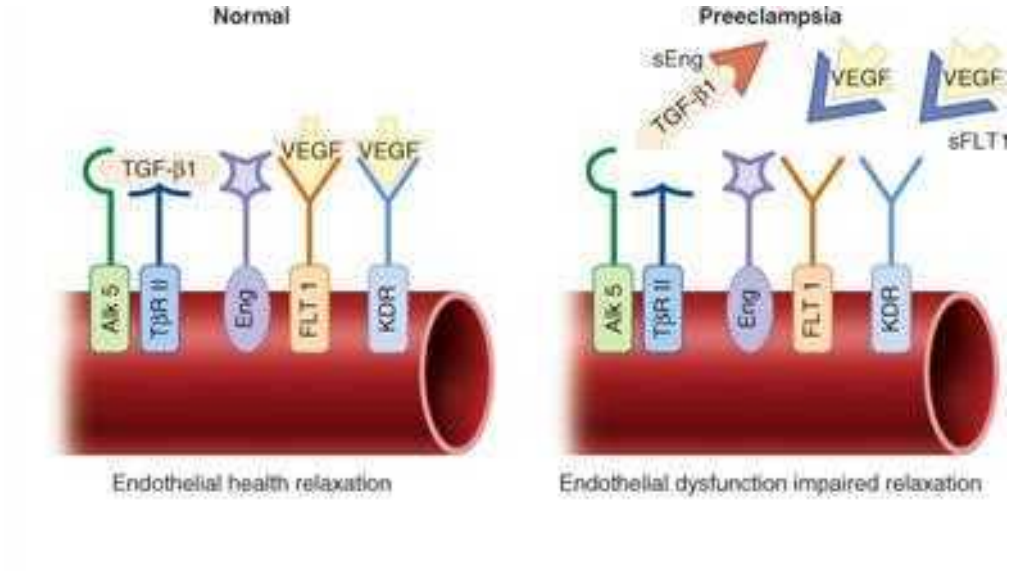


FIGURE 40-4

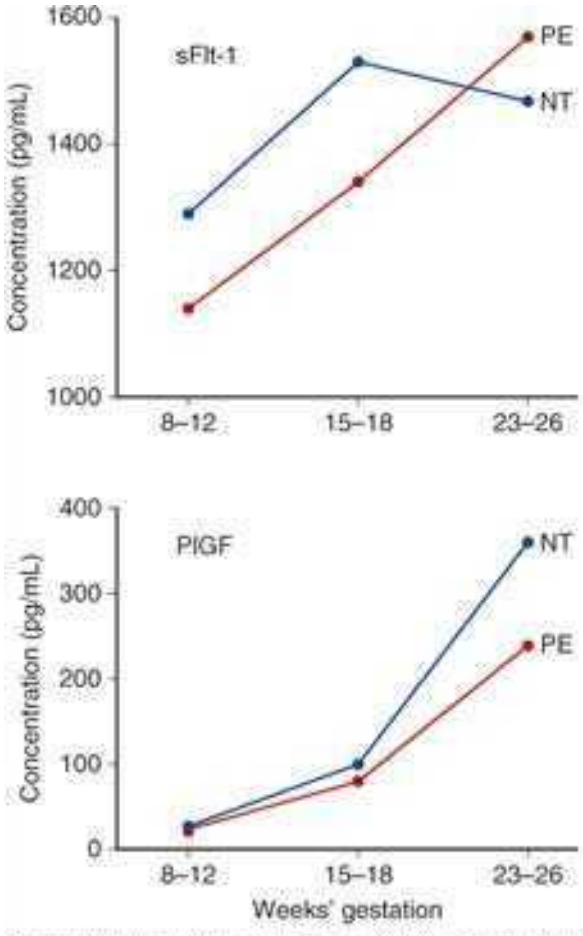
Angiogenic and antiangiogenic factors in normotensive (NT) and preeclamptic (PE) women across pregnancy. Both pairs of factors are significantly divergent by 23 to 26 weeks' gestation. sFlt = soluble fms-like tyrosine kinase 1; PlGF = placental growth factor. (Data from Myatt, 2013.)



A second antiangiogenic peptide, soluble endoglin (sEng), inhibits various transforming growth factor beta (TGF-β) isoforms from binding to endothelial receptors (see Fig. 40-3). Endoglin is one of these receptors. Decreased binding to endoglin diminishes endothelial nitric oxide-dependent vasodilatation. Serum levels of sEng also begin to rise months before clinical preeclampsia develops (Haggerty, 2012). Interestingly, metformin reduces antiangiogenic secretion from human tissues (Brownfoot, 2016).

In one systematic review, third-trimester elevation of sFlt-1 levels and lower PlGF concentrations correlate with preeclampsia development after 25 weeks' gestation (Widmer, 2007). Subsequently, Haggerty and coworkers (2012) reported that doubling of expressions of sFlt-1 and sEng increased the preeclampsia risk by 39 and 74

percent, respectively. The cause of placental overproduction of antiangiogenic proteins remains an enigma. There is a racial-ethnic difference in their secretion (Yang, 2016). Concentrations of the soluble forms are not higher in fetal circulation or amnionic fluid of preeclamptic women, and their levels in maternal blood dissipate after delivery (Staff, 2007).

Clinical research aims to employ antiangiogenic proteins in the prediction and diagnosis of preeclampsia. One preliminary report described therapeutic apheresis to reduce sFlt-1 levels (Thadhani, 2016).

PATHOPHYSIOLOGY

Evidence for preeclampsia manifestation begins early in pregnancy with covert pathophysiological changes that gain momentum across gestation and eventually become clinically apparent. Unless delivery supervenes, these changes ultimately lead to multiorgan involvement with a clinical spectrum ranging from meager findings to one of cataclysmic deterioration. As discussed, these are thought to be a consequence of endothelial dysfunction, vasospasm, and ischemia. Although the many maternal consequences of the preeclampsia syndrome are usually described in terms of individual organ systems, they frequently are multiple and overlap.

Cardiovascular System

Cardiovascular disturbances are common with preeclampsia syndrome. These are related to: (1) greater cardiac afterload caused by hypertension; (2) cardiac preload, which is reduced by a pathologically diminished volume expansion during pregnancy and which is increased by intravenous crystalloid or oncotic solutions; and (3) endothelial activation leading to interendothelial extravasation of intravascular fluid into the extracellular space and, importantly, into the lungs.

Hemodynamic Changes and Cardiac Function

The cardiovascular aberrations of pregnancy-related hypertensive disorders vary depending on several modifiers. These factors include preeclampsia severity, hypertension severity, presence of underlying chronic disease, and the part of the clinical spectrum in which these are studied. In some women, these cardiovascular changes may precede hypertension (De Paco, 2008; Easterling, 1990; Khalil, 2012; Melchiorre, 2013). Nevertheless, with the clinical onset of preeclampsia, cardiac output declines, due at least in part to greater peripheral resistance. When assessing cardiac function in preeclampsia, consideration is given to echocardiographic measures of *myocardial function* and to clinically relevant *ventricular function*.

Myocardial Function

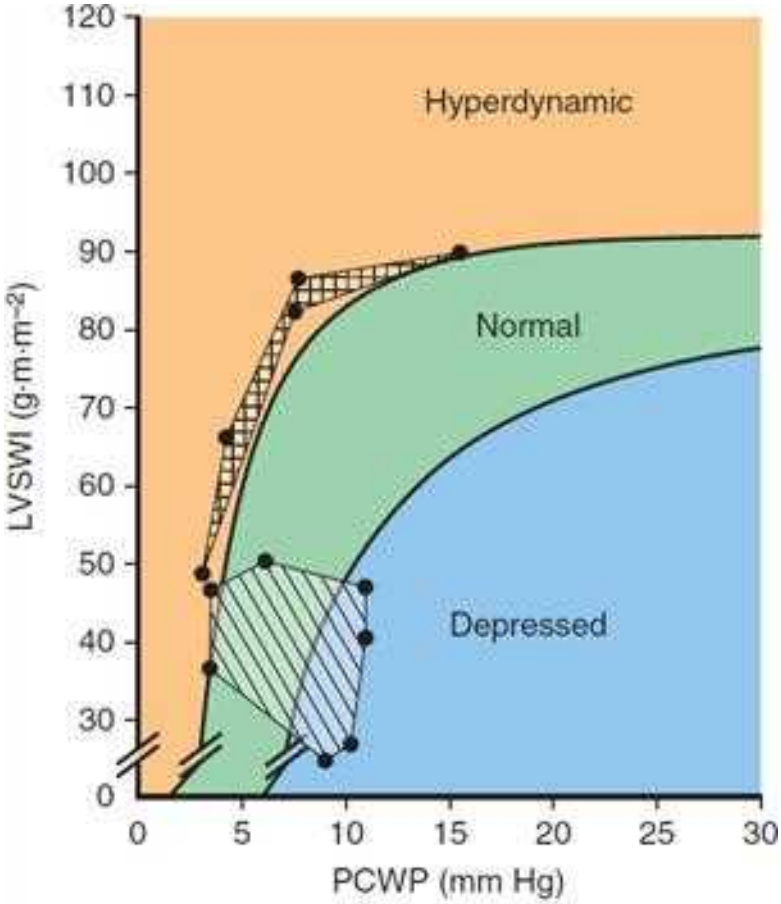
Of women with preeclampsia, serial echocardiographic studies document diastolic dysfunction in 40 to 45 percent (Guirguis, 2015; Melchiorre, 2012). With this dysfunction, ventricles do not properly relax and cannot fill properly. In some of these women, functional differences persist up to 4 years after delivery (Evans, 2011; Orabona, 2017). Diastolic dysfunction stems from ventricular remodeling, which is judged to be an adaptive response to maintain normal contractility despite the increased afterload of preeclampsia. High levels of antiangiogenic proteins may be contributory (Shahul, 2016). In the otherwise healthy pregnant woman, these changes are usually clinically inconsequential. But when combined with underlying ventricular dysfunction—for example, concentric ventricular hypertrophy from chronic hypertension—further diastolic dysfunction may cause cardiogenic pulmonary edema (Wardhana, 2017). This is discussed further in Chapters 47 (Acute Respiratory Distress Syndrome) and 49 (Heart Failure).

Ventricular Function

Despite the relatively high frequency of diastolic dysfunction with preeclampsia, clinical cardiac function in most affected women is appropriate (Hibbard, 2015). In some preeclamptic women, cardiac troponin levels are slightly elevated, and amino-terminal pro-brain natriuretic peptide (Nt pro-BNP) levels are elevated with severe preeclampsia (Pergialiotis, 2016; Zachary, 2017). Importantly, both normally pregnant women and those with preeclampsia syndrome can have normal or slightly hyperdynamic ventricular function (Fig. 40-5). Thus, both have a cardiac output that is appropriate for left-sided filling pressures. Filling pressures are dependent on the volume of intravenous fluids. Thus, aggressive hydration results in overtly *hyperdynamic* ventricular function. This is accompanied by elevated pulmonary capillary wedge pressures, and pulmonary edema may develop despite normal ventricular function. This is because of an alveolar endothelial-epithelial leak, and it is compounded by decreased oncotic pressure from a low serum albumin concentration. In sum, aggressive fluid administration to otherwise normal women with severe preeclampsia substantially elevates normal left-sided filling pressures and raises a physiologically normal cardiac output to hyperdynamic levels.

FIGURE 40-5

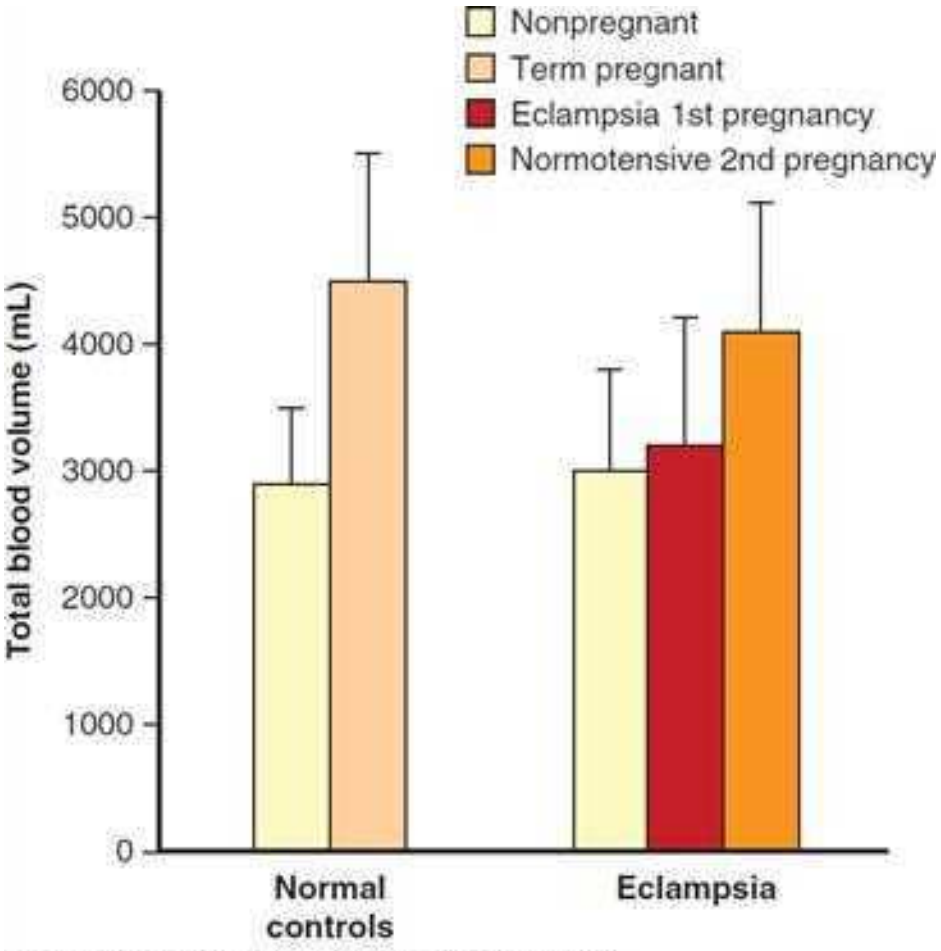
Ventricular function in normally pregnant women (*striped area*) and in women with eclampsia (*boxed area*) is plotted on a Braunwald ventricular function curve. Normal values are from Clark (1989), and those for eclampsia are from Hankins (1984). PCWP = pulmonary capillary wedge pressure; LVSWI = left ventricular stroke work index.



Blood Volume

Hemoconcentration is a hallmark of eclampsia. This concept was precisely quantified by Zeeman and colleagues (2009), who expanded the prior observations of Pritchard and associates (1984). They showed in *eclamptic* women that the normally expected pregnancy blood volume expansion is severely curtailed (Fig. 40-6). Women of average size have a blood volume of 3000 mL, and during the last several weeks of a normal pregnancy, this averages 4500 mL. With *eclampsia*, however, much or all of the anticipated 1500 mL excess is lost. Such hemoconcentration results from generalized vasospasm that follows endothelial activation and leakage of plasma into the interstitial space. In women with *preeclampsia*, and depending on its severity, hemoconcentration is usually not as marked.

FIGURE 40-6
Total blood volumes in normotensive women compared with those with eclampsia. The vertical extensions are one standard deviation from the mean. In eclamptic women, blood volume is minimally increased compared with a subsequent normotensive pregnancy. (Data from Zeeman, 2009.)



These changes have substantial clinical consequences. Importantly, women with severe hemoconcentration are unduly sensitive to blood loss at delivery that otherwise may be considered normal. Vasospasm and endothelial leakage of plasma persist for a variable time after delivery as the endothelium is restored to normalcy. As this takes place, vasoconstriction reverses, and as the blood volume reexpands, the hematocrit usually falls. *Importantly, a substantive cause of this fall in hematocrit, however, is usually the blood loss incurred at delivery.* Anemia may also partially result from greater erythrocyte destruction as subsequently described.

Maternal Thrombocytopenia

The platelet count is routinely measured in women with any form of gestational hypertension. Decreased platelet concentrations with eclampsia were described more than 100 years ago. The frequency and intensity of thrombocytopenia vary and are dependent on the severity and duration of the preeclampsia syndrome (Heilmann, 2007; Hupuczi, 2007). Overt thrombocytopenia—defined by a platelet count <100,000/μL—indicates severe disease (see Table 40-2). In general, the lower the platelet count, the higher the rates of maternal and fetal morbidity and mortality (Leduc, 1992). In most cases, delivery is advisable because worsening thrombocytopenia usually ensues. After delivery, the platelet count may continue to decline for the first day or so. It then usually rises progressively to reach a normal level within 3 to 5 days. As discussed later (Brain), in some instances with HELLP syndrome, the platelet count continues to fall after delivery. If these do not reach a nadir until 48 to 72 hours, then preeclampsia syndrome may be incorrectly attributed to one of the thrombotic microangiopathies discussed in Chapter 56 (Thrombotic Microangiopathies).

Myriad other platelet alterations are attributed to the preeclampsia syndrome. These were reviewed by Kenny and coworkers (2015) and include platelet activation with increased α-degranulation producing β-thromboglobulin, factor 4, and enhanced clearance. Paradoxically, in most studies, in vitro platelet aggregation is reduced compared with the normal increase that is characteristic of pregnancy. This likely is due to platelet "exhaustion" following in vivo activation. Although the cause is unknown, immunological processes or simply platelet deposition at sites of endothelial damage may be implicated. Levels of platelet-bound and circulating platelet-bindable immunoglobulins are elevated, which suggests platelet surface alterations.

Abnormally low platelets do not develop in the fetuses or neonates born to preeclamptic women despite severe maternal thrombocytopenia (Kenny, 2015; Pritchard, 1987). *Thus, maternal thrombocytopenia in a hypertensive woman is not a fetal indication for cesarean delivery.*

Hemolysis

Severe preeclampsia is frequently accompanied by hemolysis, which manifests as elevated serum lactate dehydrogenase levels and reduced haptoglobin levels. Other evidence comes from schizocytosis, spherocytosis, and reticulocytosis in peripheral blood (Cunningham, 1985; Pritchard, 1954, 1976). These derangements result in part from *microangiopathic hemolysis* caused by endothelial disruption with platelet adherence and fibrin deposition. Cunningham and coworkers (1995)

postulated that erythrocyte morphology was partially caused by serum lipid alterations. Related, substantively decreased long-chain fatty acid content is found in erythrocytes of preeclamptic women (Mackay, 2012).

After early reports of hemolysis and thrombocytopenia with severe preeclampsia, descriptions were added of abnormally elevated serum liver transaminase levels that indicated hepatocellular necrosis (Chesley, 1978). Weinstein (1982) referred to this combination of events as the *HELLP syndrome*—and this term now is used worldwide. Also, facets of the HELLP syndrome are included in criteria that differentiate severe from nonsevere preeclampsia (see Table 40-2). The HELLP syndrome is discussed further in that section (Brain).

Coagulation Changes

Subtle changes consistent with intravascular coagulation, and less often erythrocyte destruction, commonly are found with preeclampsia and especially eclampsia (Cunningham, 2015; Kenny, 2015). Some of these changes include elevated factor VIII consumption, increased levels of fibrinopeptides A and B and of d-dimers, and reduced levels of regulatory proteins—antithrombin III and proteins C and S. Coagulation aberrations generally are mild and are seldom clinically significant (Kenny, 2015; Pritchard, 1984). Unless placental abruption is comorbid, plasma fibrinogen levels do not differ remarkably from levels found in normal pregnancy. Fibrin degradation products such as d-dimers are minimally elevated. As preeclampsia worsens, so do abnormal findings with *thromboelastography* (Pisani-Conway, 2013). Despite these changes, routine laboratory assessments of coagulation, such as prothrombin time (PT), activated partial thromboplastin time (aPTT), and plasma fibrinogen level, are not required in the management of pregnancy-associated hypertensive disorders.

Endocrine and Hormonal Alterations

Plasma levels of *renin, angiotensin II, angiotensin 1–7, aldosterone, deoxycorticosterone,* and *atrial natriuretic peptide (ANP)* are substantively augmented during normal pregnancy. ANP is released during atrial wall stretching from blood volume expansion, and it responds to cardiac contractility (Chap. 4, Renin, Angiotensin II, and Plasma Volume). Levels of serum ANP rise in pregnancy, and its secretion is further enhanced in women with preeclampsia (Luft, 2009). Levels of its precursor—*proatrial natriuretic peptide*—are also increased in preeclampsia (Sugulle, 2012). *Vasopressin* levels are similar in nonpregnant, normally pregnant, and preeclamptic women even though the metabolic clearance is elevated in the latter two (Dürr, 1999).

Fluid and Electrolyte Alterations

In women with severe preeclampsia, the volume of *extracellular fluid,* manifest as edema, is usually much greater than that in normal pregnant women. As discussed, the mechanism responsible for pathological fluid retention is endothelial injury (Davidge, 2015). In addition to generalized edema and proteinuria, these women have reduced plasma oncotic pressure. This reduction creates a filtration imbalance and further displaces intravascular fluid into the surrounding interstitium. Electrolyte concentrations do not differ appreciably in women with preeclampsia compared with those of normal pregnant women.

Following an eclamptic convulsion, the *serum pH* and *bicarbonate* concentration are lowered due to lactic acidosis and compensatory respiratory loss of carbon dioxide. The intensity of acidosis relates to the amount of lactic acid produced—metabolic acidosis—and the rate at which carbon dioxide is exhaled—respiratory acidosis.

Kidney

During normal pregnancy, renal blood flow and glomerular filtration rate rise appreciably (Chap. 4, Urinary System). With preeclampsia, several reversible anatomical and pathophysiological changes ensue. Of clinical importance, renal perfusion and glomerular filtration are reduced. Levels that are much less than normal nonpregnant values are infrequent and are the consequence of severe disease. Most of the decrement in glomerular filtration is from higher renal afferent arteriolar resistance that may be elevated up to fivefold (Conrad, 2015; Cornelis, 2011). Morphological changes are characterized by *glomerular endotheliosis*, which blocks the barrier that allows filtration. Diminished filtration causes serum creatinine levels to rise to values seen in nonpregnant individuals, that is, 1 mg/mL, and sometimes higher (Lindheimer, 2008a). Abnormal values usually begin to normalize 10 days or later after delivery (Cornelis, 2011; Spaan, 2012a).

In most preeclamptic women, the urine sodium concentration is elevated. Urine osmolality rises, urine:plasma creatinine ratio is elevated, and fractional excretion of sodium is low, which all indicated that a prerenal mechanism is involved. Sodium-containing crystalloid infusion raises left ventricular filling pressure, and although oliguria temporarily improves, rapid infusions may cause clinically apparent pulmonary edema. Intensive intravenous fluid therapy is not indicated as “treatment” for preeclamptic women with oliguria unless urine output is diminished from hemorrhage or fluid loss from vomiting or fever.

Plasma uric acid concentration is typically elevated in preeclampsia. The elevation exceeds that attributable to the reduction in glomerular filtration rate and likely is also due to enhanced tubular reabsorption (Chesley, 1945). At the same time, preeclampsia is associated with diminished urinary excretion of calcium, perhaps because of greater tubular reabsorption (Taufield, 1987).

Proteinuria

As shown in Table 40-1, detection of proteinuria helps to establish the diagnosis of preeclampsia. Abnormal protein excretion is empirically defined by 24-hour urinary excretion exceeding 300 mg; a urine protein:creatinine ratio ≥0.3; or persistent protein values of 30 mg/dL (1+ dipstick) in random urine samples. Although worsening or nephrotic-range proteinuria has been considered by most to be a sign of severe disease, this does not appear to be the case (Airoldi, 2007). Certainly, this concept was not accepted by the 2013 Task Force.

Problematically, the optimal method of establishing abnormal levels of either urine protein or albumin remains to be defined. For a 24-hour quantitative specimen, the “consensus” threshold value used is ≥300 mg/24 h (American College of Obstetricians and Gynecologists, 2013). Using a urinary protein excretion threshold of 165 mg in a 12-hour sample shows equivalent efficacy (Stout, 2015; Tun, 2012).

Determination of urinary protein:creatinine ratio may supplant the cumbersome 24-hour quantification (Kyle, 2008; Morris, 2012). Chen and associates (2008) found that clean-catch and catheterized urine specimens correlate well. In one systematic review, random urine protein:creatinine ratios below 130 to 150 mg/g, that is, 0.13 to 0.15, indicate a low likelihood of proteinuria exceeding 300 mg/d (Papanna, 2008). Ratios <0.08 or >1.19 have negative- or positive-predictive values of 86 and 96 percent, respectively (Stout, 2013). However, midrange ratios, that is, 300 mg/g or 0.3, have poor sensitivity and specificity. Thus, many recommend that with midrange ratio values, 24-hour protein excretion should be quantified.

With urine dipstick assessment, determinations depend on urine concentration and are notorious for false-positive and -negative results. Thus, assessment may show a dipstick value of 1+ to 2+ from concentrated urine specimens from women who excrete <300 mg/d.

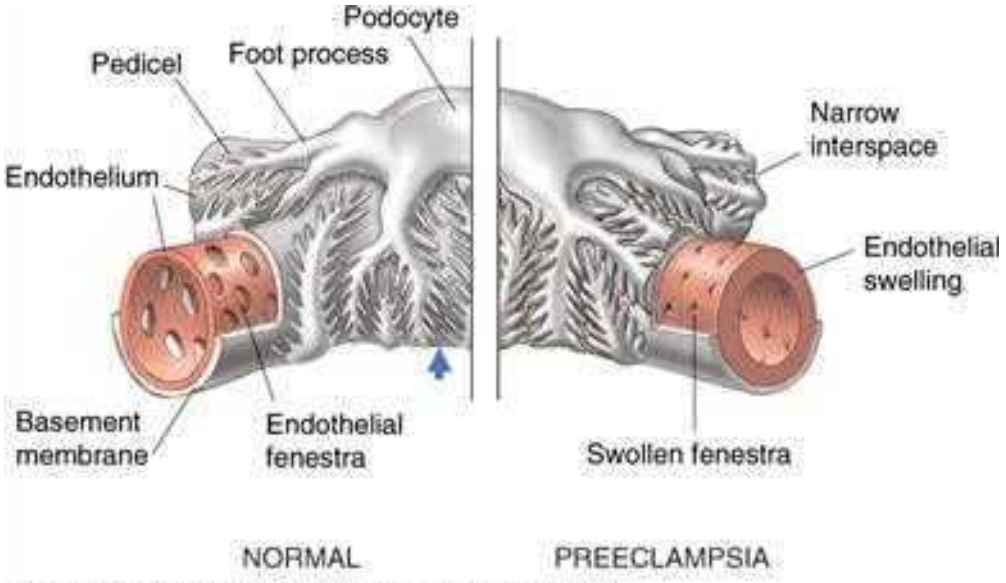
Importantly, proteinuria may develop late, and some women may already be delivered or have had an eclamptic convulsion before it appears. For example, 10 to 15 percent of women with HELLP syndrome do not have proteinuria at presentation (Sibai, 2004). In one report, 17 percent of eclamptic women did not have proteinuria by the time of seizures (Zwart, 2008).

Anatomical Changes

Sheehan and Lynch (1973) frequently found changes identifiable at autopsy by light and electron microscopy in the kidneys of eclamptic women. Glomeruli are enlarged by approximately 20 percent, they are "bloodless," and capillary loops variably are dilated and contracted. Endothelial cells are swollen—termed *glomerular capillary endotheliosis* (Spargo, 1959). Endothelial cells are often so swollen that they block or partially block the capillary lumens (Fig. 40-7) (Hecht, 2017). Homogeneous subendothelial deposits of proteins and fibrin-like material are seen.

FIGURE 40-7

Schematic showing glomerular capillary endotheliosis. The capillary of the normal glomerulus shown on the left has wide endothelial fenestrations, and the pedicels emanating from the podocytes are widely spaced (*arrow*). The illustration on the right is of a glomerulus with changes induced by the preeclampsia syndrome. The endothelial cells are swollen and their fenestrae narrowed, as are the pedicels that now abut each other.



Endothelial swelling may result from angiogenic protein "withdrawal" caused by the complexing of free angiogenic proteins with a compatible circulating antiangiogenic protein receptor (see Fig. 40-3). The angiogenic proteins are crucial for podocyte health, and their inactivation leads to podocyte dysfunction and endothelial swelling (Conrad, 2015; Karumanchi, 2009). Also, eclampsia is characterized by greater excretion of these epithelial podocytes (Wagner, 2012; White, 2014).

Acute Kidney Injury

Although mild degrees of acute kidney injury are encountered, clinically apparent *acute tubular necrosis* is almost invariably induced by comorbid hemorrhage with hypovolemia and hypotension (Chap. 41, General Considerations). This is usually caused by severe obstetrical bleeding—especially placental abruption—coupled with inadequate blood replacement. Drakeley and coworkers (2002) described 72 women with preeclampsia and renal failure. Half had HELLP syndrome, and a third had placental abruption. In one review of 183 women with HELLP syndrome, 5 percent had kidney injury (Haddad, 2000). Of those with renal injury, half had placental abruption, and most had postpartum hemorrhage. Last, irreversible *renal cortical necrosis* develops rarely (Chap. 53, Lower Genital Tract Lesions).

Liver

The characteristic hepatic lesions with eclampsia are regions of periportal hemorrhage in the liver periphery (Hecht, 2017). However, lesions as extensive as those shown in Figure 40-8 are unusual. Sheehan and Lynch (1973) described that some degree of hepatic infarction accompanied hemorrhage in almost half of women who died with eclampsia. These findings corresponded with reports during the 1960s that described elevated serum hepatic transaminase levels. Along with the earlier observations by Pritchard and associates (1954), who described hemolysis and thrombocytopenia with eclampsia, this constellation of hemolysis, hepatocellular necrosis, and thrombocytopenia was later termed *HELLP syndrome*.

FIGURE 40-8

Gross liver specimen from a woman with preeclampsia who died from aspiration pneumonitis. Periportal hemorrhagic necrosis was seen microscopically. (Reproduced with permission from Cunningham FG: Liver disease complicating pregnancy. Williams Obstetrics, 19th ed. (Suppl 1), Norwalk, Appleton & Lange, 1993.)

Liver involvement with preeclampsia may clinically display at least three manifestations. First, pain is considered a sign of severe disease. It typically manifests by moderate-to-severe right upper quadrant or midepigastric pain and tenderness. Such women usually have elevated serum aspartate transaminase (AST) or alanine transaminase (ALT) levels. In some cases, however, the amount of hepatic tissue involved with infarction may be surprisingly extensive yet still clinically insignificant (Nelson, 2017). In our experiences, infarction may be worsened by hypotension from obstetrical hemorrhage, and it occasionally causes hepatic failure—also called shock liver (Alexander, 2009; Yoshihara, 2016).

Second, elevations of serum AST and ALT levels are markers for severe preeclampsia. Values seldom exceed 500 U/L, but levels reaching more than 2000 U/L have been reported (Chap. 55, Hepatic Disorders). In general, serum concentrations inversely follow platelet levels, and they both usually normalize within 3 days following delivery.

As a third presentation, hemorrhagic infarction may extend to form a hepatic hematoma. This in turn can extend to form a subcapsular hematoma that may rupture. Computed tomography (CT) scanning or magnetic resonance (MR) imaging greatly aids diagnosis (Fig. 40-9). Unruptured hematomas are probably more common than clinically suspected and are more likely to be found with HELLP syndrome. Although once considered a surgical condition, current management of a hepatic hematoma usually consists of observation unless bleeding is ongoing. In some cases, however, prompt surgical intervention or angiographic embolization may be lifesaving. In one review of 180 cases of hepatic hematoma or rupture, 94 percent of affected gravidas had HELLP syndrome, and in 90 percent of the total, the capsule had ruptured (Vigil-De Gracia, 2012). The maternal mortality rate was 22 percent, and the perinatal mortality rate was 31 percent. In rare cases, liver transplantation is necessary (Hunter, 1995; Wicke, 2004).

FIGURE 40-9

Abdominal CT imaging performed postpartum in a woman with severe HELLP syndrome and right-upper quadrant pain. A large subcapsular hematoma (*asterisk*) is seen confluent with intrahepatic infarction and hematoma (*arrowhead*). Numerous flame-shaped hemorrhages are seen at the hematoma interface (*arrows*).

Acute fatty liver of pregnancy is sometimes confused with preeclampsia (Nelson, 2013; Sibai, 2007a). It too has an onset in late pregnancy, and often there is accompanying hypertension, elevated serum transaminase and creatinine levels, and thrombocytopenia. However, the hallmark of acute fatty liver is significant liver dysfunction, and Table 55-1 highlights these clinical differences.

Last, no convincing data link pancreatic involvement with preeclampsia syndrome (Sheehan, 1973). Thus, the occasional case of concurrent hemorrhagic pancreatitis is likely unrelated (Lynch, 2015; Swank, 2012). In our experiences from Parkland Hospital, amylase levels were seldom elevated in preeclamptic women (Nelson, 2014a).

HELLP Syndrome

There is no universally accepted strict definition of HELLP syndrome, and thus its incidence varies by investigator. In the previously noted study of 183 women with HELLP syndrome, 40 percent had adverse outcomes, and two mothers died (Haddad, 2000). Complications included eclampsia in 6 percent, placental abruption—10 percent, acute kidney injury—5 percent, and pulmonary edema—10 percent. Stroke, hepatic hematoma, coagulopathy, acute respiratory distress syndrome, and sepsis were other serious complications.

Women with preeclampsia and HELLP syndrome typically have worse outcomes than preeclamptic women without the HELLP constellation (Kozic, 2011; Martin, 2012, 2013). In one review of 693 women with HELLP syndrome, 10 percent had concurrent eclampsia (Keiser, 2011). Sep and associates (2009) described a significantly higher risk for complications in women with HELLP syndrome compared with those with "isolated preeclampsia." These included eclampsia—15 versus 4 percent; preterm birth—93 versus 78 percent; and perinatal mortality rate—9 versus 4 percent, respectively. Because of these marked clinical differences, it has been postulated that HELLP syndrome has a distinct pathogenesis (Reimer, 2013; Vaught, 2016).

Brain

Headaches and visual symptoms are common with severe preeclampsia, and associated convulsions define eclampsia. The earliest anatomical descriptions of brain involvement came from autopsy specimens, but CT and MR imaging and Doppler studies have added many important insights.

Neuroanatomical Lesions

From early anatomical descriptions, brain pathology accounted for only about a third of fatal cases such as the one shown in Figure 40-10. In fact, most deaths were from pulmonary edema, and brain lesions were coincidental. Thus, although gross intracerebral hemorrhage was seen in up to 60 percent of eclamptic women, it

was fatal in only half of these (Melrose, 1984; Richards, 1988; Sheehan, 1973). As shown in Figure 40-11, other principal lesions found at autopsy of eclamptic women were cortical and subcortical petechial hemorrhages. The classic microscopic vascular lesions consist of fibrinoid necrosis of the arterial wall and perivascular microinfarcts and hemorrhages. Other frequently described major lesions include subcortical edema, multiple nonhemorrhagic areas of "softening" throughout the brain, and hemorrhagic areas in the white matter (Hecht, 2017). There also may be hemorrhage in the basal ganglia or pons, sometimes with rupture into the ventricles.

FIGURE 40-10

Cerebrovascular Pathophysiology

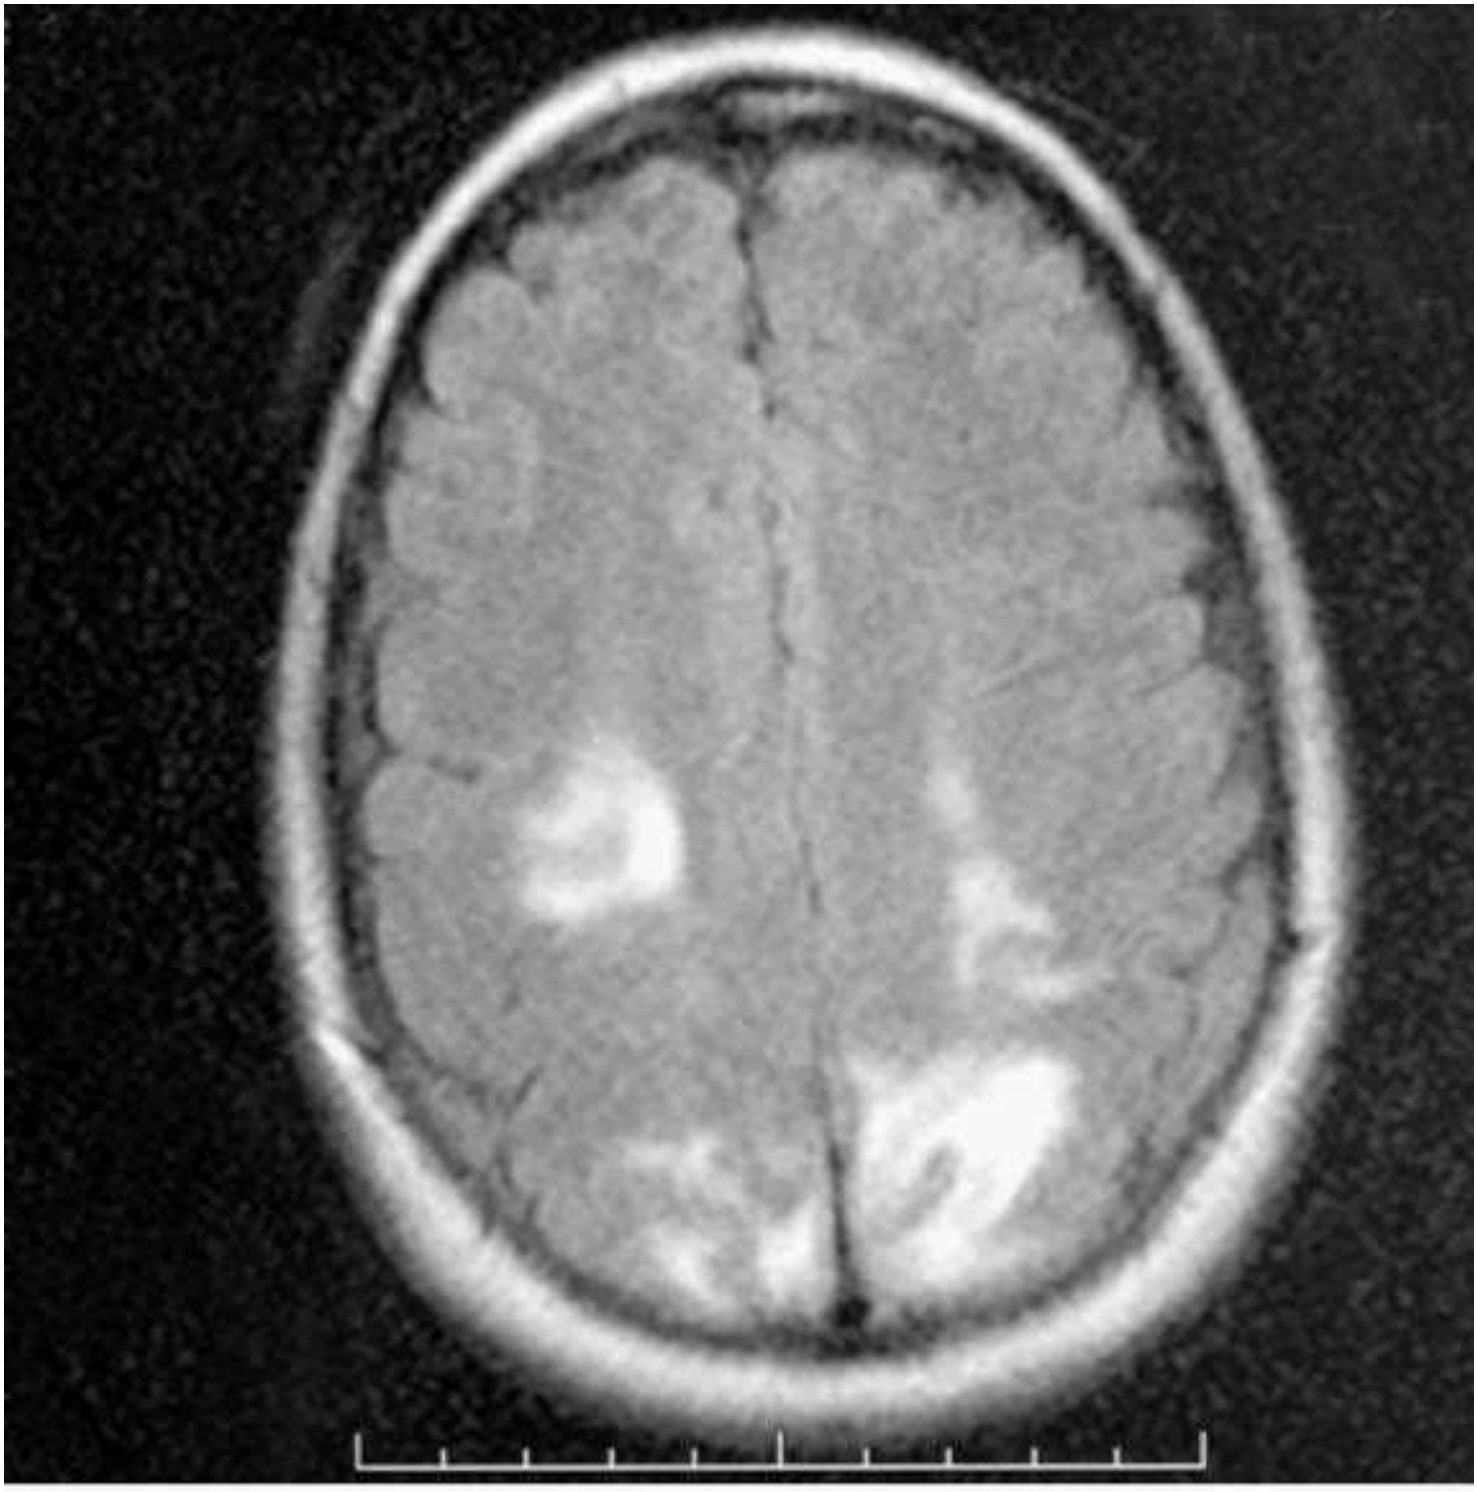
Clinical, pathological, and neuroimaging findings have led to two general theories to explain cerebral abnormalities with eclampsia. Importantly, endothelial cell dysfunction that characterizes the preeclampsia syndrome likely is a key in both. The first theory suggests that in response to acute and severe hypertension, cerebrovascular overregulation leads to vasospasm (Trommer, 1988). In this scheme, diminished cerebral blood flow is hypothesized to result in ischemia, cytotoxic edema, and eventually tissue infarction. Little objective evidence supports this mechanism.

The second theory is that sudden elevations in systemic blood pressure exceed the normal cerebrovascular autoregulatory capacity (Hauser, 1988; Schwartz, 2000). Regions of forced vasodilation and vasoconstriction develop, especially in arterial boundary zones. At the capillary level, disruption of end-capillary pressure causes increased hydrostatic pressure, hyperperfusion, and extravasation of plasma and red cells through endothelial tight-junction openings. This leads to *vasogenic edema*. The recent description of a central nervous system lymphatic vasculature lends credibility to this theory (Louveau, 2015).

The most likely mechanism is a combination of the two. Thus, a preeclampsia-associated interendothelial cell leak develops at blood pressure (hydraulic) levels much lower than those that usually cause vasogenic edema and is coupled with a loss of upper-limit autoregulation (Fugate, 2015; Zeeman, 2009). With imaging studies, these manifest as the *posterior reversible encephalopathy syndrome* (Fig. 40-12) (Fugate, 2015; Hinchey, 1996). The lesions of this syndrome principally involve the posterior brain—the occipital and parietal cortices. But, in at least a third of cases, other areas are involved (Edlow, 2013; Zeeman, 2004a).

FIGURE 40-12

Cranial magnetic-resonance imaging in a nullipara with eclampsia. Multilobe T2-FLAIR high-signal lesions are apparent. FLAIR = fluid-attenuated inversion recovery. (Used with permission from Dr. Gerda Zeeman.)



Cerebral Blood Flow

Autoregulation is the mechanism by which cerebral blood flow remains relatively constant despite alterations in cerebral perfusion pressure. Remember that cerebral perfusion pressure is the difference between mean arterial pressure and intracranial pressure. In nonpregnant individuals, this autoregulation protects the brain from hyperperfusion when mean arterial pressures rise to as high as 160 mm Hg. These are pressures far greater than those seen in all but a very few women with eclampsia. Thus, to explain eclamptic seizures, it was theorized that autoregulation must be altered by pregnancy. Studies by Cipolla and colleagues (2007, 2009, 2015) have convincingly shown that autoregulation is unchanged across pregnancy in rodents. But, some investigators have provided evidence of impaired autoregulation in women with preeclampsia (Janzarik, 2014; van Veen, 2013).

Zeeman and associates (2003) showed that cerebral blood flow during the first two trimesters of normal pregnancy is similar to nonpregnant values. But during the last trimester, flow significantly drops by 20 percent. This group also found greater cerebral blood flow in this trimester in women with severe preeclampsia compared with that in normotensive pregnant women (Zeeman, 2004b). Taken together, these findings suggest that eclampsia occurs when cerebral hyperperfusion forces capillary fluid interstitially because of endothelial damage. This leak leads to perivascular edema characteristic of the preeclampsia syndrome.

Neurological Manifestations

Several neurological manifestations typify the preeclampsia syndrome. Each signifies severe involvement and requires immediate attention.

First, *headache and scotomata* are thought to arise from cerebrovascular hyperperfusion that has a predilection for the occipital lobes. Up to 75 percent of women have headaches, and 20 to 30 percent have visual changes preceding eclamptic convulsions (Sibai, 2005; Zwart, 2008). The headaches may be mild to severe and intermittent to constant. In our experiences, they are unique in that they do not usually respond to traditional analgesia, but they frequently improve after magnesium sulfate infusion.

Convulsions are diagnostic for eclampsia. These are caused by excessive release of excitatory neurotransmitters—especially glutamate; massive depolarization of network neurons; and bursts of action potentials (Meldrum, 2002). Clinical and experimental evidence suggests that extended seizures can cause significant brain injury and later brain dysfunction.

Blindness is rare with preeclampsia alone, but it complicates eclamptic convulsions in up to 15 percent of women (Cunningham, 1995). Blindness may develop up to a week or more following delivery (Chambers, 2004). There are at least two types of blindness, as discussed subsequently.

Generalized cerebral edema may develop and is usually manifest by mental status changes that vary from confusion to coma. This situation is particularly dangerous because fatal transtentorial herniation can result.

Last, women with eclampsia have been shown to have some cognitive decline when studied 5 to 10 years following an eclamptic pregnancy. This is discussed further in the final section (Renal Sequelae).

Neuroimaging Studies

With CT imaging, localized hypodense lesions at the gray- and white-matter junction, primarily in the parietooccipital lobes, are typically found in eclampsia. Such lesions may also be seen in the frontal and inferior temporal lobes, the basal ganglia, and thalamus (Brown, 1988). These hypodense areas correspond to petechial hemorrhages and local edema. Edema of the occipital lobes or diffuse cerebral edema may cause symptoms such as blindness, lethargy, and confusion (Cunningham, 2000). Widespread edema can appear as marked compression or even obliteration of the cerebral ventricles. Such women may develop signs of impending life-threatening transtentorial herniation.

Several MR imaging acquisitions are used to study eclamptic women. Common findings are hyperintense T2 lesions—namely, posterior reversible encephalopathy syndrome (PRES)—in the subcortical and cortical regions of the parietal and occipital lobes (see Fig. 40-12). Also, the basal ganglia, brainstem, and cerebellum are relatively commonly involved (Brewer, 2013; Zeeman, 2004a). Again, these lesions represent focal cerebral edema. Although these PRES lesions are almost universal in women with eclampsia, their incidence in women with preeclampsia approximates 20 percent (Mayama, 2016). Lesions are more likely in women who have severe disease and who have neurological symptoms. And although usually reversible, a fourth of these hyperintense lesions represent cerebral infarctions that have persistent findings (Loureiro, 2003; Zeeman, 2004a).

Visual Changes and Blindness

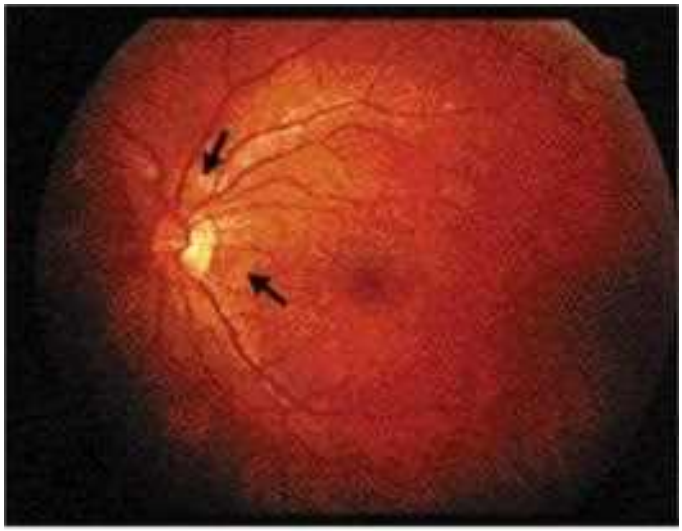
Scotomata, blurred vision, or diplopia are common with severe preeclampsia and eclampsia. These usually improve with magnesium sulfate therapy and/or lowered blood pressure. Blindness is less common, is usually reversible, and may arise from three potential areas. These are the visual cortex of the occipital lobe, the lateral geniculate nuclei, and the retina. In the retina, pathological lesions may be ischemia, infarction, or detachment (Handor, 2014; Roos, 2012).

Occipital blindness is also called *amaurosis*—from the Greek *dimming*. With imaging, affected women usually have evidence of extensive occipital lobe vasogenic edema. Of 15 women cared for at Parkland Hospital, occipital blindness lasted from 4 hours to 8 days, but it resolved completely in all cases (Cunningham, 1995). Rarely, extensive cerebral infarctions may result in total or partial visual defects.

Blindness from retinal lesions is caused either by serous retinal detachment or rarely by retinal infarction, which is termed *Purtscher retinopathy* (Fig. 40-13). *Serous retinal detachment* is usually unilateral and seldom causes total visual loss. In fact, asymptomatic serous retinal detachment is relatively common with preeclampsia (Saito, 1998). In most cases of eclampsia-associated blindness, visual acuity subsequently improves. However, if blindness is caused by retinal artery occlusion, vision may be permanently impaired (Lara-Torre, 2002; Moseman, 2002; Roos, 2012).

FIGURE 40-13

Purtscher retinopathy caused by choroidal ischemia and infarction in preeclampsia syndrome. Ophthalmoscopy shows scattered yellowish, opaque lesions of the retina (*arrows*). (Reproduced with permission from Lam DS, Chan W: Images in clinical medicine. Choroidal ischemia in preeclampsia. N Engl J Med 344(10):739, 2001.)



Cerebral Edema

Clinical manifestations suggesting widespread cerebral edema are worrisome. During 13 years at Parkland Hospital, 10 of 175 women (6 percent) with eclampsia were diagnosed with symptomatic cerebral edema (Cunningham, 2000). Symptoms ranged from lethargy, confusion, and blurred vision to obtundation and coma. In most cases, symptoms waxed and waned. Mental status changes generally correlated with the degree of involvement seen with CT and MR imaging studies. *These women are very susceptible to sudden and severe blood pressure elevations, which can acutely worsen the already widespread vasogenic edema.* Thus, careful blood pressure control is essential. In the 10 women with generalized edema, three became comatose and had imaging findings of transtentorial herniation, from which one died. Consideration is given for treatment with mannitol or dexamethasone.

Uteroplacental Perfusion

Compromised uteroplacental perfusion is almost certainly a major culprit in the greater perinatal morbidity and mortality rates seen with preeclampsia (Harmon, 2015). Defects in endovascular trophoblastic invasion with the preeclampsia syndrome were discussed earlier (Etiology). Thus, measurement of uterine, intervillous, and placental blood flow would likely be informative. Attempts to assess these in humans have been hampered by several obstacles that include inaccessibility of the placenta, the complexity of its venous effluent, and the need for radioisotopes or invasive techniques.

Measurement of uterine artery blood flow velocity has been used to estimate resistance to uteroplacental blood flow (Chap. 17, Amnionic Fluid Volume). Vascular resistance is estimated by comparing arterial systolic and diastolic velocity waveforms. By the completion of placentation, impedance of uterine artery blood flow is markedly decreased, but with abnormal placentation, abnormally high resistance persists (Everett, 2012; Ghidini, 2008; Napolitano, 2012). Earlier studies were done to assess this by measuring peak systolic:diastolic velocity ratios from uterine and umbilical arteries in preeclamptic pregnancies. In some cases, but certainly not all, there was higher resistance (Fleischer, 1986; Trudinger, 1990).

Another Doppler waveform—uterine artery "notching"—has been associated with elevated risks for preeclampsia or fetal-growth restriction (Groom, 2009). In the MFMU Network study reported by Myatt and colleagues (2012a), however, notching had a low predictive value except for early-onset severe disease.

Resistance in *uterine spiral arteries* has also been measured. Impedance was higher in peripheral than in central vessels—a "ring-like" distribution (Matijevic, 1999). Mean resistance values were greater in all women with preeclampsia compared with those in normotensive controls. One study used MR imaging and other techniques to assess placental perfusion ex vivo in myometrial arteries removed from women with preeclampsia or fetal-growth restriction (Ong, 2003). In both conditions, myometrial arteries exhibited endothelium-dependent vasodilatory response. Moreover, other pregnancy conditions are also associated with increased resistance (Urban, 2007). One major adverse effect, fetal-growth restriction, is discussed in Chapter 44 (Fetal-Growth Restriction).

de Almeida Pimenta and colleagues (2014) assessed placental vascularity using a three-dimensional power Doppler histogram and described a *placental vascularity index.* This index value was reduced in women with any pregnancy-associated hypertensive disorders—11.1 percent compared with 15.2 percent in normal controls.

Despite these findings, evidence for compromised uteroplacental circulation is found in only a few women who go on to develop preeclampsia. Indeed, when preeclampsia develops during the third trimester, only a third of women with severe disease have abnormal uterine artery velocimetry (Li, 2005). In a study of 50 women with HELLP syndrome, only a third had abnormal uterine artery waveforms (Bush, 2001). In general, the extent of abnormal waveforms correlates with severity of fetal involvement (Ghidini, 2008; Groom, 2009).

PREDICTION

Various biological markers implicated in the preeclampsia syndrome have been measured to help predict its development. Although most have been evaluated in the first half of pregnancy, some have been tested as predictors of severity in the third trimester (Chaiworapongsa, 2013; Lai, 2013; Mosimann, 2013). Others have been used to forecast recurrent preeclampsia (Demers, 2014; Eichelberger, 2015). Some of these tests are listed in Table 40-5, which is by no means all inclusive.

TABLE 40-5

Predictive Tests for Development of the Preeclampsia Syndrome

Testing Related To:	Examples
Placental perfusion/vascular resistance	Roll-over test, isometric handgrip or cold pressor test, pressor response to aerobic exercise, angiotensin-II infusion, midtrimester mean arterial pressure, platelet angiotensin-II binding, renin, 24-hour ambulatory blood pressure monitoring, uterine artery or fetal transcranial Doppler velocimetry
Fetal-placental unit endocrine dysfunction	Human chorionic gonadotropin (hCG), alpha-fetoprotein (AFP), estriol, pregnancy-associated protein A (PAPP A), inhibin A, activin A, placental protein 13, procalcitonin, corticotropin-releasing hormone, A disintegrin, ADAM-12, kisspeptin
Renal dysfunction	Serum uric acid, microalbuminuria, urinary calcium or kallikrein, microtransferrinuria, *N*-acetyl-β-glucosaminidase, cystatin C, podocyturia, podocalyxin
Endothelial dysfunction/oxidant stress	Platelet count and activation, fibronectin, endothelial adhesion molecules, prostaglandins, prostacyclin, MMP-9, thromboxane, C-reactive protein, cytokines, endothelin, neurokinin B, homocysteine, lipids, insulin resistance, resistin, antiphospholipid antibodies, plasminogen activator-inhibitor (PAI), leptin, p-selectin, angiogenic and antiangiogenic factors such as placental growth factor (PlGF), vascular endothelial growth factor (VEGF), fms-like tyrosine kinase receptor-1 (sFlt-1), endoglin
Others	Antithrombin-III(AT-3), atrial natriuretic peptide (ANP), β_2-microglobulin, haptoglobin, transferrin, ferritin, 25-hydroxyvitamin D, genetic markers, cell-free fetal DNA, serum and urine proteomics and metabolomic markers, hepatic aminotransferases

ADAM12 = ADAM metallopeptidase domain 12; MMP = matrix metalloproteinase.

Adapted from Conde-Agudelo, 2015, Duckworth, 2016.

Overall, these efforts have resulted in testing strategies with poor sensitivity and with poor positive-predictive values for preeclampsia (Conde-Agudelo, 2015; Odibo, 2013). *Currently, no screening tests for preeclampsia are predictably reliable, valid, and economical.* However, combinations of tests, some yet to be adequately evaluated, may be promising (Gallo, 2016; Olsen, 2012).

Vascular Resistance Testing and Placental Perfusion

Most tests in this category are cumbersome, time consuming, and overall inaccurate. To evaluate blood pressure changes, three tests assess the blood pressure rise in response to a stimulus. In one, women at 28 to 32 weeks' gestation rest in the left lateral decubitus position and then roll to the supine position. With this *roll-over test,* increased blood pressure with this maneuver signifies a positive test. The *isometric exercise test* employs the same principle by squeezing a handball. The *angiotensin II infusion test* is performed by giving incrementally increasing doses intravenously, and the hypertensive response is quantified. In an updated metaanalysis, sensitivities of all three tests were reported to range from 55 to 70 percent, and specificities approximated 85 percent (Conde-Agudelo, 2015).

Uterine artery Doppler velocimetry is posited to reflect faulty trophoblastic invasion of the spiral arteries. This failure results in diminished placental perfusion and upstream greater uterine artery resistance. Increased uterine artery velocimetry determined by Doppler ultrasound in the first two trimesters might provide indirect evidence of this process and thus serve as a predictive test for preeclampsia (Dar, 2010; Groom, 2009). Elevated flow resistance results in an abnormal vessel waveform represented by an exaggerated *diastolic notch.* These findings have value for prediction of fetal-growth restriction but not preeclampsia (American College of Obstetricians and Gynecologists, 2015). Several flow velocity waveforms have been investigated for preeclampsia prediction, however, none is suitable for clinical use (Conde-Agudelo, 2015; Kleinrouweler, 2012; Myatt, 2012a).

Fetal-Placental Unit Endocrine Function

Several serum analytes have been proposed to help predict preeclampsia (see Table 40-5). Newer ones are continually added. In general, none of these tests are clinically beneficial for hypertension prediction.

Renal Function Tests

Hyperuricemia likely results from reduced uric acid clearance from diminished glomerular filtration, increased tubular reabsorption, and decreased secretion. Cnossen and coworkers (2006) reported that its sensitivity to detect preeclampsia ranged from 0 to 55 percent, and specificity was 77 to 95 percent.

Isolated gestational proteinuria is a risk factor for preeclampsia (Jayaballa, 2015; Morgan, 2016; Yamada, 2016). As a predictive test for preeclampsia, microalbuminuria has sensitivities that range from 7 to 90 percent and specificities that span 29 to 97 percent (Conde-Agudelo, 2015).

Endothelial Dysfunction and Oxidant Stress

Endothelial activation and inflammation are major participants in the pathophysiology of the preeclampsia syndrome. As a result, compounds such as those listed in Table 40-5 are found to be elevated in circulating blood of affected women, and some have been assessed for their predictive value.

First, fibronectins are high-molecular-weight glycoproteins released from endothelial cells and extracellular matrix following endothelial injury. However, in one systematic review, neither cellular nor total fibronectin levels were clinically useful to predict preeclampsia (Leeflang, 2007).

Thrombocytopenia and platelet dysfunction are integral features of preeclampsia. Platelet activation causes augmented destruction and lower concentrations. Mean platelet volume rises because of platelet immaturity (Kenny, 2015). Although markers of coagulation activation, described earlier (Maternal Thrombocytopenia), are elevated, the substantive overlap with levels in normotensive pregnant women stultifies their predictive value.

Markers of oxidative stress were also hoped to predict preeclampsia. Namely, associated higher levels of lipid peroxides coupled with decreased antioxidant activity raised this possibility. Other markers include iron, transferrin, and ferritin; resistin; hyperhomocysteinemia; blood lipids, including triglycerides, free fatty acids, and lipoproteins; and antioxidants such as ascorbic acid and vitamin E (Christiansen, 2015; Conde-Agudelo, 2015; D'Anna, 2004; Mackay, 2012; Mignini, 2005). However, these have not been found to be predictive.

Last, an imbalance in antiangiogenic factors is linked to preeclampsia etiopathogenesis. For example, serum levels of VEGF and PlGF begin to drop before clinical preeclampsia develops. And, recall from Figure 40-4 that at the same time, levels of some antiangiogenic factors, such as sFlt-1 and sEng, begin to rise (Karumanchi, 2016a; Maynard, 2008). With some of these factors, sensitivities for all cases of preeclampsia ranged from 30 to 50 percent, and specificity approximated 90 percent (Conde-Agudelo, 2015). Their predictive accuracy is higher for early-onset preeclampsia (Redman, 2015b; Tsiakkas, 2016). Determination of the sFlt-1/PlGF ratio in women admitted near 37 weeks' gestation to exclude preeclampsia was useful as a predictive factor (Baltajian, 2016; Zeisler, 2016a,b). These results suggest a clinical role for preeclampsia prediction, especially later in pregnancy (Duckworth, 2016; Gallo, 2016). They may also predict adverse pregnancy outcomes in women with lupus and comorbid antiphospholipid antibodies (Kim, 2016).

Other Markers

As discussed in Chapter 13 (Fetal DNA in the Maternal Circulation), cell-free DNA (cfDNA) can be detected in maternal plasma. It is hypothesized that cfDNA is released in preeclampsia by accelerated apoptosis of cytotrophoblasts (DiFederico, 1999). One MFMU Network study found no correlation between total cfDNA levels and preeclampsia (Silver, 2017).

Proteomic, metabolomic, and transcriptomic technologies can be employed to study serum and urinary proteins and cellular metabolites. These have opened new vistas for preeclampsia prediction, and preliminary studies indicate that these may become useful (Bahado-Singh, 2013; Carty, 2011; Ma, 2014; Myers, 2013).

PREVENTION

Various strategies used to prevent or modify preeclampsia severity have been evaluated. Some are listed in Table 40-6. In general, none of these has been found to be convincingly and reproducibly effective.

TABLE 40-6

Some Methods to Prevent Preeclampsia That Have Been Evaluated in Randomized Trials

Dietary manipulation—low-salt diet, calcium or fish oil supplementation
Exercise—physical activity, stretching
Cardiovascular drugs—diuretics, antihypertensive drugs
Antioxidants—ascorbic acid (vitamin C), α-tocopherol (vitamin E), vitamin D
Antithrombotic drugs—low-dose aspirin, aspirin/dipyridamole, aspirin + heparin, aspirin + ketanserin

Modified from Staff, 2015.

Dietary and Lifestyle Modifications

Dietary "treatment" for preeclampsia has produced some interesting abuses (Chesley, 1978). A *low-salt diet* was one of the earliest research efforts to prevent preeclampsia (De Snoo, 1937). This was followed by years of inappropriate diuretic therapy. Although these practices were discarded, it ironically was not until relatively recently that the first randomized trial was done and showed that a sodium-restricted diet was ineffective in preventing preeclampsia (Knuist, 1998).

Regular exercise during pregnancy is linked to a lower risk of developing preeclampsia (Barakat, 2016; Morris, 2017). Also, in one systematic review, a trend toward risk reduction with exercise was noted (Kasawara, 2012). Only a few studies have been randomized, and thus, more research is needed (Staff, 2015).

Somewhat related, Abenhaim and coworkers (2008) reported a retrospective cohort study of 677 nonhypertensive women hospitalized for bed rest because of threatened preterm delivery. When outcomes of these women were compared with those of the general obstetrical population, bed rest was associated with a

significantly reduced relative risk—0.27—of developing preeclampsia. From two small randomized trials, prophylactic bed rest for 4 to 6 hours daily at home was successful in significantly lowering the incidence of preeclampsia in women with normal blood pressures (Meher, 2006).

Calcium supplementation has been studied in several trials, including one by the National Institute of Child Health and Human Development (NICHD) that included more than 4500 low-risk nulliparas (Levine, 1997). Calcium supplementation did not prevent preeclampsia or pregnancy-associated hypertension. In one metaanalysis, increased calcium intake in high-risk women lowered the risk for preeclampsia (Patrelli, 2012). However, in aggregate, most of these trials have shown that unless women are calcium deficient, supplementation has no salutary effects (Sanchez-Ramos, 2017; Staff, 2015).

Cardioprotective fatty acids found in some fatty fishes are plentiful in diets of Scandinavians and American Eskimos. Because supplementation with these fatty acids likely prevents inflammatory-mediated atherogenesis, it was posited that they might also prevent preeclampsia. Unfortunately, randomized trials conducted thus far have shown no such benefits from fish oil supplementation (Makrides, 2006; Olafsdottir, 2006; Zhou, 2012).

Antihypertensive Drugs

Because of the putative effects of sodium restriction for preeclampsia prevention, diuretic therapy became popular with the introduction of chlorothiazide in 1957 (Finnerty, 1958; Flowers, 1962). In one metaanalysis of nine randomized trials with more than 7000 pregnancies, women given diuretics had a lower incidence of edema and hypertension but not of preeclampsia (Churchill, 2007). Because women with chronic hypertension are at high risk for preeclampsia, several randomized trials have evaluated various antihypertensive drugs to reduce the incidence of superimposed preeclampsia (Chap. 50, Management During Pregnancy). A critical analysis of these trials by Staff and coworkers (2015) failed to demonstrate benefits for this goal.

Antioxidants

Data imply that an imbalance between oxidant and antioxidant activity plays a role in preeclampsia pathogenesis. Thus, naturally occurring antioxidants—vitamins C, D, and E—might reduce such oxidation. Several randomized studies have assessed antioxidant vitamin supplementation for women at high risk for preeclampsia (Poston, 2006; Rumbold, 2006; Villar, 2009). The Combined Antioxidant and Preeclampsia Prediction Studies (CAPPS) by the MFMU Network included almost 10,000 low-risk nulliparas (Roberts, 2010). None of these studies showed reduced preeclampsia rates in women provided vitamins C and E compared with those given placebo.

Statins were proposed to prevent preeclampsia because they stimulate hemoxygenase-1 expression, which inhibits sFlt-1 release. Preliminary animal data suggest that statins may prevent hypertensive disorders of pregnancy (Lewis, 2017). The MFMU Network plans a randomized trial to test pravastatin for this purpose (Costantine, 2013, 2016).

Metformin inhibits *hypoxic inducible factor 1α* by lowering mitochondrial electron transport chain activity. It reduces sFlt-1 and sEng activity and thus has potential to prevent preeclampsia (Brownfoot, 2016). However, clinical studies are lacking.

Antithrombotic Agents

As noted earlier (Pathogenesis), preeclampsia is characterized by vasospasm, endothelial cell dysfunction, and inflammation, as well as activation of platelets and the coagulation-hemostasis system. Other sequelae include placental infarction and spiral artery thrombosis (Nelson, 2014b). Thus, antithrombotic agents have been evaluated to reduce the incidence of preeclampsia.

Low-molecular-weight heparin for prophylaxis has been studied in several randomized trials. Rodger and colleagues (2016) performed a metaanalysis using individual patient data from 963 women. The risk for recurrent preeclampsia, abruption, or fetal-growth restriction was similar in women receiving heparin or placebo.

Aspirin, in low oral doses of 50 to 150 mg daily, effectively inhibits platelet thromboxane A_2 biosynthesis but has minimal effects on vascular prostacyclin production (Wallenburg, 1986). Still, several clinical trials have shown limited benefits in preeclampsia prevention. For example, a randomized trial from the MFMU Network found that risks for adverse outcomes were not significantly reduced with aspirin therapy (Caritis, 1998). Some combined reports, however, are more favorable. The Paris Collaborative Group performed a metaanalysis that included 31 randomized trials involving 32,217 women (Askie, 2007). For women assigned to receive antiplatelet agents, the relative risk for preeclampsia, superimposed preeclampsia, preterm delivery, or any adverse pregnancy outcome was significantly decreased by 10 percent. Other metaanalyses report marginal benefits of low-dose aspirin for prevention of severe preeclampsia (Roberge, 2012; Villa, 2013). Recently, one randomized trial of more than 1600 women at high risk for preterm preeclampsia provided low-dose aspirin from 11 to 14 weeks' gestation until 36 weeks to prevent recurrence. The rate of preterm recurrence was 1.6 percent in the aspirin group compared with 4.3 percent in the placebo arm (Rolnik, 2017).

In recent dueling metaanalyses, Roberge and colleagues (2017) found that aspirin prophylaxis initiated before 16 weeks' gestation was associated with a significant risk reduction—about 60 percent–for preeclampsia and fetal-growth restriction. Moreover, they found a dose-response effect. At the same time, Meher and associates (2017) performed an individual participant data metaanalysis and reported a much lower—about 10 percent—risk reduction that was significant whether therapy was initiated before or after 16 weeks.

Meanwhile, the U.S. Preventive Services Task Force recommends low-dose aspirin prophylaxis for women at high risk for preeclampsia (Henderson, 2014). Because of this, the American College of Obstetricians and Gynecologists (2016b) issued a Practice Advisory that recommends low-dose aspirin be given between 12 and 28 weeks' gestation to help prevent preeclampsia in high-risk women. This includes those with a history of preeclampsia and those with twins, chronic hypertension, overt diabetes, renal disease, and autoimmune disorders. These results have also raised the question as to whether *all* pregnant women should be given aspirin (Mone, 2017). At this time, our answer is "no."

Low-dose aspirin coupled with heparin mitigates thrombotic sequelae in women with lupus anticoagulant (Chap. 59, Adverse Pregnancy Outcomes). Because of a similarly high prevalence of placental thrombotic lesions found with severe preeclampsia, trials have assessed the possible merits of such treatments for women with prior preeclampsia. In two randomized trials, women with a history of early-onset preeclampsia were given an aspirin therapy or an enoxaparin plus aspirin regimen (Groom, 2017; Haddad, 2016). Outcomes were similar. From their reviews, Sergis and associates (2006) reported better pregnancy outcomes in women with prior severe preeclampsia given low-molecular-weight heparin plus low-dose aspirin compared with those given low-dose aspirin alone. Similar findings were reported by de Vries and coworkers (2012).

PREECLAMPSIA

Pregnancy complicated by gestational hypertension is managed based on its severity, presence of preeclampsia, and gestational age. Preeclampsia cannot always be diagnosed definitively. Thus, the Task Force (2013) recommends more frequent prenatal visits if preeclampsia is "suspected." *Increases in systolic and diastolic blood pressure can be either normal physiological changes or signs of developing pathology*. Heightened surveillance permits more prompt recognition of ominous changes in blood pressure, critical laboratory findings, and clinical signs and symptoms (Macdonald-Wallis, 2015).

The basic management objectives for any pregnancy complicated by preeclampsia are: (1) termination of pregnancy with the least possible trauma to mother and fetus, (2) birth of a healthy newborn that subsequently thrives, and (3) complete restoration of health to the mother. In many women with preeclampsia, especially those at or near term, all three objectives are served equally well by induction of labor. *One of the most important clinical questions for successful management is precise knowledge of fetal age.*

Early Diagnosis of Preeclampsia

Traditionally, the frequency of prenatal visits is increased during the third trimester, and this aids early detection of preeclampsia. *Women without overt hypertension, but in whom early developing preeclampsia is suspected during routine prenatal visits, are seen more frequently*. For many years at Parkland Hospital, women with new-onset diastolic blood pressures >80 mm Hg but <90 mm Hg or with sudden abnormal weight gain of more than 2 pounds per week have, at minimum, returned for visits at 7-day intervals. Outpatient surveillance is continued unless overt hypertension, proteinuria, headache, visual disturbances, or epigastric pain supervenes.

Women with overt new-onset hypertension—either diastolic pressures ≥90 mm Hg or systolic pressures ≥140 mm Hg—are admitted to determine if the increase is due to preeclampsia, and if so, to evaluate its severity.

Evaluation

With hospitalization, a systematic evaluation is instituted to include:

Detailed examination, which is coupled with daily scrutiny for clinical findings such as headache, visual disturbances, epigastric pain, and rapid weight gain

Daily weight measurement

Quantification of proteinuria or urine protein:creatinine ratio on admittance and at least every 2 days thereafter

Blood pressure readings with an appropriate-size cuff every 4 hours, except between 2400 and 0600 unless previous readings are elevated

Measurements of plasma or serum creatinine and hepatic transaminase levels and a hemogram that includes a platelet count. The frequency of testing is determined by hypertension severity. Although some recommend measurement of serum uric acid and lactate dehydrogenase levels and coagulation studies, their value has been questioned (Conde-Agudelo, 2015; Thangaratinam, 2006).

Evaluation of fetal size and well-being and amnionic fluid volume, by either physical examination or sonography.

Reduced physical activity throughout much of the day is likely beneficial, but as the 2013 Task Force concluded, absolute bed rest is not desirable. Ample protein and calories are included in the diet, and sodium and fluid intake are not limited or forced.

In sum, goals of evaluation include early identification of preeclampsia or worsening of the syndrome and development of a management plan for timely delivery. Fortunately, many cases are sufficiently mild and near enough to term that they can be managed conservatively until labor commences spontaneously or until the cervix becomes favorable for labor induction. *Complete abatement of all signs and symptoms, however, is uncommon until after delivery*. If severe preeclampsia is diagnosed using the criteria in Table 40-2, further management is subsequently described.

Consideration for Delivery

Termination of pregnancy is the only cure for preeclampsia. Headache, visual disturbances, or epigastric pain are indicative that convulsions may be imminent, and oliguria is another ominous sign. Severe preeclampsia demands anticonvulsant and often antihypertensive therapy, followed by delivery. Treatment for eclampsia is identical. The prime objectives are to forestall convulsions, to prevent intracranial hemorrhage and serious damage to other vital organs, and to deliver a healthy newborn.

This is true even when the cervix is unfavorable (Tajik, 2012). Labor induction is carried out, usually with preinduction cervical ripening with a prostaglandin or osmotic dilator (Chap. 26, Preinduction Cervical Ripening).

Concerns stemming from an unfavorable cervix, a perceived sense of urgency because of preeclampsia severity, and a need to coordinate neonatal intensive care have led some to advocate cesarean delivery. Alexander and colleagues (1999) reviewed 278 singleton liveborn neonates weighing 750 to 1500 g delivered of women with severe preeclampsia at Parkland Hospital. In half of the women, labor was induced, and the remainder underwent cesarean delivery without labor. Induction was successful in accomplishing vaginal delivery in a third, and it was not harmful to very-low-birthweight neonates. Others have reported similar observations (Alanis, 2008; Roland, 2017). However, whenever it appears that induction almost certainly will not succeed or attempts have failed, then cesarean delivery is indicated.

For a woman near term, with a soft, partially effaced cervix, even a milder degree of preeclampsia probably carries more risk to the mother and her fetus-newborn than does induction of labor (Tajik, 2012). A randomized trial of 756 women with mild preeclampsia supported delivery after 37 weeks' gestation (Koopmans, 2009).

When the fetus is preterm, the tendency is to temporize in the hope that additional weeks in utero will reduce the risk of neonatal death or serious morbidity from prematurity. Such a policy certainly is justified in milder cases. Assessments of fetal well-being and placental function are performed, especially when the fetus is immature. Most recommend frequent performance of nonstress testing or biophysical profiles to assess fetal well-being (American College of Obstetricians and Gynecologists, 2016a). Several tests can be used to provide evidence of lung maturity (Chap. 34, Necrotizing Enterocolitis). An sFlt-1/PlGF ratio <38 is predictive of the short-term absence of preeclampsia, but this ratio testing is still investigational (Zeisler, 2016a,b). Also, women with higher ratios tend to have more adverse outcomes (Baltajian, 2016).

The decision to deliver late-preterm fetuses is less clear. Barton and coworkers (2011) reported excessive neonatal morbidity in women delivered before 38 weeks despite having stable, mild, nonproteinuric hypertension. The Netherlands study of 4316 newborns delivered between $34^{0/7}$ and $36^{6/7}$ weeks also described substantive neonatal morbidity in these cases (Langenveld, 2011). Another Dutch study—HYPITAT-II—randomly assigned women with nonsevere hypertension between 34 and 37 weeks to immediate delivery or to expectant management (Broekhuijsen, 2015). Immediate delivery reduced the risks for adverse maternal outcomes—1.1 versus 3.1 percent. However, it increased the risk for neonatal respiratory distress syndrome—5.7 versus 1.7 percent.

Hospitalization versus Outpatient Management

For women with mild-to-moderate stable hypertension—whether or not preeclampsia has been confirmed—monitoring is continued. During surveillance, reduced physical activity throughout much of the day, at least intuitively, seems beneficial. That said, complete bed rest is not recommended by the 2013 Task Force. First, this is pragmatically unachievable because of the severe restrictions it places on otherwise well women. Also, it likely predisposes to thromboembolism (Knight, 2007). To reduce activity, several studies have addressed the benefits of inpatient care and outpatient management.

The concept of prolonged hospitalization for women with hypertension arose during the 1970s. At Parkland Hospital, an inpatient antepartum unit was established in 1973 by Dr. Peggy Whalley in large part to provide care for such women. Initial results from this unit were reported by Hauth (1976) and Gilstrap (1978) and their coworkers. Most hospitalized women have a beneficial response characterized by amelioration or improvement of hypertension. *These women are not "cured," and nearly 90 percent have recurrent hypertension before or during labor.* By 2016, more than 10,000 nulliparas with mild-to-moderate, early-onset hypertension during pregnancy had been managed successfully in this unit. Provider costs—*not charges*—for this relatively simple physical facility, modest nursing care, no drugs other than iron and folate supplements, and few essential laboratory tests are minimal compared with the cost of neonatal intensive care for a preterm neonate. Importantly, none of these women have suffered thromboembolic disease.

Many clinicians believe that further hospitalization is not warranted if hypertension abates within a few days, and this has legitimized third-party payers to deny hospitalization reimbursement. Consequently, many women with mild-to-moderate hypertension are managed at home. Outpatient management may continue as long as preeclampsia syndrome does not worsen and fetal jeopardy is not suspected. Sedentary activity throughout the greater part of the day is recommended. These women are instructed in detail to report symptoms. Home blood pressure and urine protein monitoring or frequent evaluations by a visiting nurse may prove beneficial.

To assess this approach, 1182 nulliparas with mild gestational hypertension—20 percent had proteinuria—were managed with home health care (Barton, 2002). Their mean gestational ages were 32 to 33 weeks at enrollment and 36 to 37 weeks at delivery. Severe preeclampsia developed in approximately 20 percent, about 3 percent developed HELLP syndrome, and two women had eclampsia. Perinatal outcomes were generally good. In approximately 20 percent, there was fetal-growth restriction, and the perinatal mortality rate was 4.2 per 1000 births.

Several studies have compared continued hospitalization and outpatient care. In a pilot study from Parkland Hospital, 72 nulliparas with new-onset hypertension from 27 to 37 weeks were assigned either to continued hospitalization or to outpatient care (Horsager, 1995). The only significant difference was that women in the home care group developed severe preeclampsia significantly more frequently than hospitalized women—42 versus 25 percent. In another trial, after hospital evaluation, 218 women with mild gestational nonproteinuric hypertension were similarly divided (Crowther, 1992). As shown in Table 40-7, the mean hospital duration was 22.2 days for women with inpatient management compared with only 6.5 days in the home care group. Preterm delivery before 34 and before 37 weeks' gestation was increased twofold in the outpatient group. However, maternal and newborn outcomes were otherwise similar.

TABLE 40-7

Randomized Clinical Trials Comparing Hospitalization versus Routine Care for Women with Mild Gestational Hypertension or Preeclampsia

	Maternal Characteristics—Admission					Maternal Characteristics—Delivery				Perinatal Outcomes		
Study Groups	No.	$Para_0$ (%)	Chronic HTN (%)	EGA (wk)	Prot (%)	EGA (wk)	<37 wk (%)	< 34 wk (%)	Mean Hosp (d)	Mean BW (g)	SGA (%)	PMR (%)
Crowther (1992)	218[a]											
Hospitalization	110	13	14	35.3	0	38.3	12	1.8	22.2	3080	14	0
Outpatient	108	13	17	34.6	0	38.2	22	3.7	6.5	3060	14	0
Tuffnell (1992)	54											
Day Unit	24	57	23	36	0	39.8	—	—	1.1	3320	—	0
Usual Care	30	54	21	36.5	21	39	—	—	5.1	3340	—	0
Turnbull (2004)	374[b]											
Hospitalization	125	63	0	35.9	22	39	—	—	8.5	3330	3.8	0
Day Unit	249	62	0	36.2	22	39.7	—	—	7.2	3300	2.3	0

[a]Excluded women with proteinuria at study entry.

[b]Included women with ≤1+ proteinuria.

BW = birthweight; EGA = estimated gestational age; HTN = hypertension; $Para_0$= nulliparas; PMR = perinatal mortality rate; Prot = proteinuria; SGA = small for gestational age.

Another approach, popular in Europe, is day care (Milne, 2009). In one study, 54 women with hypertension after 26 weeks' gestation were assigned to either day care or routine outpatient management (see Table 40-7) (Tuffnell, 1992). Progression to overt preeclampsia and labor inductions were significantly greater in the routine outpatient management group. In another, 395 women participated in either day care or inpatient management (Turnbull, 2004). Almost 95 percent had mild-to-moderate hypertension. Of enrolled women, 288 lacked proteinuria, and 86 had ≥1+ proteinuria. There were no perinatal deaths, and none of the women developed eclampsia or HELLP syndrome. Costs for either scheme were not significantly different, and general satisfaction favored day care.

In sum, either inpatient or close outpatient management is appropriate for a woman with mild de novo hypertension, including those with nonsevere preeclampsia. Most of these studies were carried out in academic centers with dedicated management teams. That said, the key to success is close surveillance and a conscientious patient with good home support.

Antihypertensive Therapy for Mild-to-Moderate Hypertension

The use of antihypertensive drugs to prolong pregnancy or modify perinatal outcomes in pregnancies complicated by various hypertensive disorders has been of considerable interest. Treatment for women with chronic hypertension complicating pregnancy is discussed in detail in Chapter 50 (Management During Pregnancy).

Drug treatment for early mild preeclampsia has been disappointing (Table 40-8). Sibai and colleagues (1987a) reported that women given labetalol had significantly lower mean blood pressures. However, mean pregnancy prolongation, gestational age at delivery, and birthweight did not differ between groups. The cesarean delivery rate and the number of newborns admitted to special-care nurseries were also similar. *The frequency of growth-restricted neonates was doubled in women given labetalol—19 versus 9 percent.* The three other studies listed in Table 40-8 compared labetalol or the calcium-channel blockers nifedipine and isradipine against placebo. Except for fewer episodes of severe hypertension, none of these studies showed any benefits from antihypertensive treatment (Magee, 2015). Similar conclusions were reached by Abalos and associates (2014), who reviewed 49 randomized trials of active antihypertensive therapy compared with either no treatment or placebo given to women with mild-to-moderate gestational hypertension.

TABLE 40-8

Randomized Placebo-Controlled Trials of Antihypertensive Therapy for Early Mild Gestational Hypertension

Study	Study Drug (No.)	Pregnancy Prolonged (d)	Severe HTN[a] (%)	Cesarean Delivery (%)	Placental Abruption (%)	Mean Birthweight (g)	Growth Restriction (%)	Neonatal Deaths (No.)
Sibai (1987a)[a] 200 inpatients	Labetalol (100)	21.3	5	36	2	2205	19[c]	1
	Placebo (100)	20.1	15[c]	32	0	2260	9	0
Sibai (1992)[b] 200 outpatients	Nifedipine (100)	22.3	9	43	3	2405	8	0
	Placebo (100)	22.5	18[c]	35	2	2510	4	0

	Placebo (74)	23.1	10	26	NS	NS	NS	NS
Wide-Swensson (1995)	Isradipine (54)	23.1	22	26	NS	NS	NS	0
111 outpatients	Placebo (57)	29.8	29	19	NS	NS	NS	0

[a]All women had preeclampsia.

[b]Includes postpartum hypertension.

[c]$p < .05$ when study drug compared with placebo.

HTN = hypertension; NS = not stated.

Delayed Delivery

Up through the early 1990s, the prevailing practice was that women with severe preeclampsia were usually delivered without delay. However, another approach for women with preterm severe preeclampsia has also been advocated. This approach calls for “conservative” or “expectant” management with the aim of improving neonatal outcome without compromising maternal safety. Aspects of such management always include careful daily—and usually more frequent—inpatient monitoring of the mother and her fetus.

Expectant Management of Preterm Severe Preeclampsia

Theoretically, antihypertensive therapy has potential application when severe preeclampsia develops before intact neonatal survival is likely. Such management is controversial, and it may be dangerous. In one of the first studies, Sibai and the Memphis group (1985) attempted to prolong pregnancy because of fetal immaturity in 60 women with severe preeclampsia between 18 and 27 weeks. The results were disastrous. *The perinatal mortality rate was 87 percent. Although no mothers died, 13 suffered placental abruption, 10 had eclampsia, three developed renal failure, two had hypertensive encephalopathy, one had an intracerebral hemorrhage, and another had a ruptured hepatic hematoma.*

Because of their early study, the Memphis group redefined criteria and performed a randomized trial of aggressive versus expectant management for 95 women who had severe preeclampsia but with more advanced gestations of 28 to 32 weeks (Sibai, 1994). *Women with HELLP syndrome were excluded from this trial.* Aggressive management included glucocorticoid administration for fetal lung maturation followed by delivery in 48 hours. Expectantly managed women were observed at bed rest and given either labetalol or nifedipine orally for severe hypertension. In this study, pregnancy was prolonged for a mean of 15.4 days in the expectant management group. An overall improvement in neonatal outcomes was also reported.

Following these experiences, expectant management became more commonly practiced, but with the caveat that women with HELLP syndrome or growth-restricted fetuses were usually excluded. But in a subsequent follow-up observational study, the Memphis group compared outcomes in 133 preeclamptic women with and 136

without HELLP syndrome who presented between 24 and 36 weeks (Abramovici, 1999). Women were subdivided into three study groups. The first group included those with *complete HELLP syndrome*. The second group included women with *partial HELLP syndrome*—defined as either one or two but not all three of the defining laboratory values. The third group included women who had severe preeclampsia without HELLP syndrome. Perinatal outcomes were similar in each group, and importantly, outcomes were not improved with procrastination. Despite this, the investigators concluded that women with partial HELLP syndrome and those with severe preeclampsia alone could be managed expectantly. Those with fetal-growth restriction generally have shorter interval-to-delivery durations (McKinney, 2016).

Sibai and Barton (2007b) reviewed expectant management of severe preeclampsia from 24 to 34 weeks. More than 1200 women were included, and although the average time gained ranged from 5 to 10 days, the maternal morbidity rates were formidable. Serious complications in some of these and in later studies included placental abruption, HELLP syndrome, pulmonary edema, renal failure, and eclampsia (Table 40-9). Moreover, perinatal mortality rates averaged 90 per 1000 births. Fetal-growth restriction was common, and in the studies from The Netherlands, it was an astounding 94 percent (Ganzevoort, 2005a,b). Perinatal mortality rates are disproportionately high in these growth-restricted neonates, but maternal outcomes are not appreciably different (Haddad, 2007; Shear, 2005). The MEXPRE Latin Study was a multicenter trial that randomly assigned 267 women with severe preeclampsia at 28 to 32 weeks to prompt delivery or to expectant management (Vigil-De Gracia, 2013). The perinatal mortality rate approximated 9 percent in each group, the composite neonatal morbidity outcome was not improved with expectant management. On the other hand, fetal-growth restriction—22 versus 9 percent—and placental abruption—7.6 versus 1.5 percent—were significantly higher in the group managed expectantly.

TABLE 40-9

Maternal and Perinatal Outcomes Reported since 2005 with Expectant Management of Severe Preeclampsia from 24 to 34 Weeks

			Maternal Outcomes (%)					Perinatal Outcomes (%)	
Study	**No.**	**Days Gained**	**Placental Abruption**	**HELLP**	**Pulm. Edema**	**AKI**	**Eclampsia**	**FGR**	**PMR**

[a]Includes one maternal death.

AKI = acute kidney injury; EGA = estimated gestational age; FGR = fetal-growth restriction; HELLP = hemolysis, elevated liver enzyme levels, low platelet count syndrome; NS = not stated; PMR = perinatal mortality rate; Pulm. = pulmonary.

Expectant Management of Midtrimester Severe Preeclampsia

Several small studies have focused on expectant management of severe preeclampsia syndrome *before 28 weeks*. In their review, Bombrys and coworkers (2008) found eight such studies that included nearly 200 women with severe preeclampsia with an onset <26 completed weeks. Maternal complications were common. Because no neonates survived when delivered before 23 weeks, the Task Force (2013) recommends pregnancy termination in these cases. For women with slightly more advanced pregnancies, however, the decision is less clear. For example, at 23 weeks' gestation, the perinatal survival rate was 18 percent, but long-term perinatal morbidity is yet unknown. For women with pregnancies at 24 to 26 weeks, perinatal survival approached 60 percent, and it averaged almost 90 percent for those at 26 weeks.

At least five observational studies of women with severe midtrimester preeclampsia who were managed expectantly have been published since 2005 (Abdel-Hady, 2010; Belghiti, 2011; Bombrys, 2008; Budden, 2006; Gaugler-Senden, 2006). Maternal complications developed in 60 percent, and there was one maternal death. The perinatal mortality rate was 650 per 1000 births. At this time, no comparative studies attest to perinatal benefits of such expectant treatment versus early delivery in the face of serious maternal complications, which approach rates of 50 percent. We do not recommend such management.

Glucocorticoids for Lung Maturation

To enhance fetal lung maturation, glucocorticoids have been administered to women with severe hypertension who are remote from term. Treatment does not seem to worsen maternal hypertension, and a lower incidence of respiratory distress and improved fetal survival rates have been cited. That said, only one randomized trial has evaluated corticosteroids given to hypertensive women for fetal lung maturation. This trial included 218 women with severe preeclampsia between 26 and 34 weeks' gestation who were randomly assigned to betamethasone or placebo administration (Amorim, 1999). Rates of neonatal complications that included respiratory distress, intraventricular hemorrhage, and death were reduced significantly when betamethasone was given compared with placebo. *On the heavily*

weighted negative side, there were two maternal deaths and 18 stillbirths. We add these findings to buttress our unenthusiastic acceptance of attempts to prolong gestation in many of these women (Alexander, 2015; Bloom, 2003).

Expectant Management Recommendations

Taken in toto, these studies do not show overwhelming benefits compared with maternal risks for expectant management of severe preeclampsia in women with gestations from 24 to 32 weeks. Despite these caveats, the Society for Maternal-Fetal Medicine (2011) has determined that such management is a reasonable alternative in selected women with severe preeclampsia before 34 weeks (Fig. 40-14). The Task Force (2013) supports this recommendation. As shown in Table 40-10, such management calls for in-hospital maternal and fetal surveillance with delivery prompted by evidence for worsening severe preeclampsia or maternal or fetal compromise. Although attempts are made for vaginal delivery in most cases, the likelihood of cesarean delivery rises with decreasing gestational age.

FIGURE 40-14

Clinical management algorithm for severe preeclampsia at <34 weeks. HELLP = hemolysis, elevated liver enzyme levels, low platelet count; L&D = labor and delivery; $MgSO_4$= magnesium sulfate; UOP = urine output. (Adapted from the Society for Maternal-Fetal Medicine, 2011.)

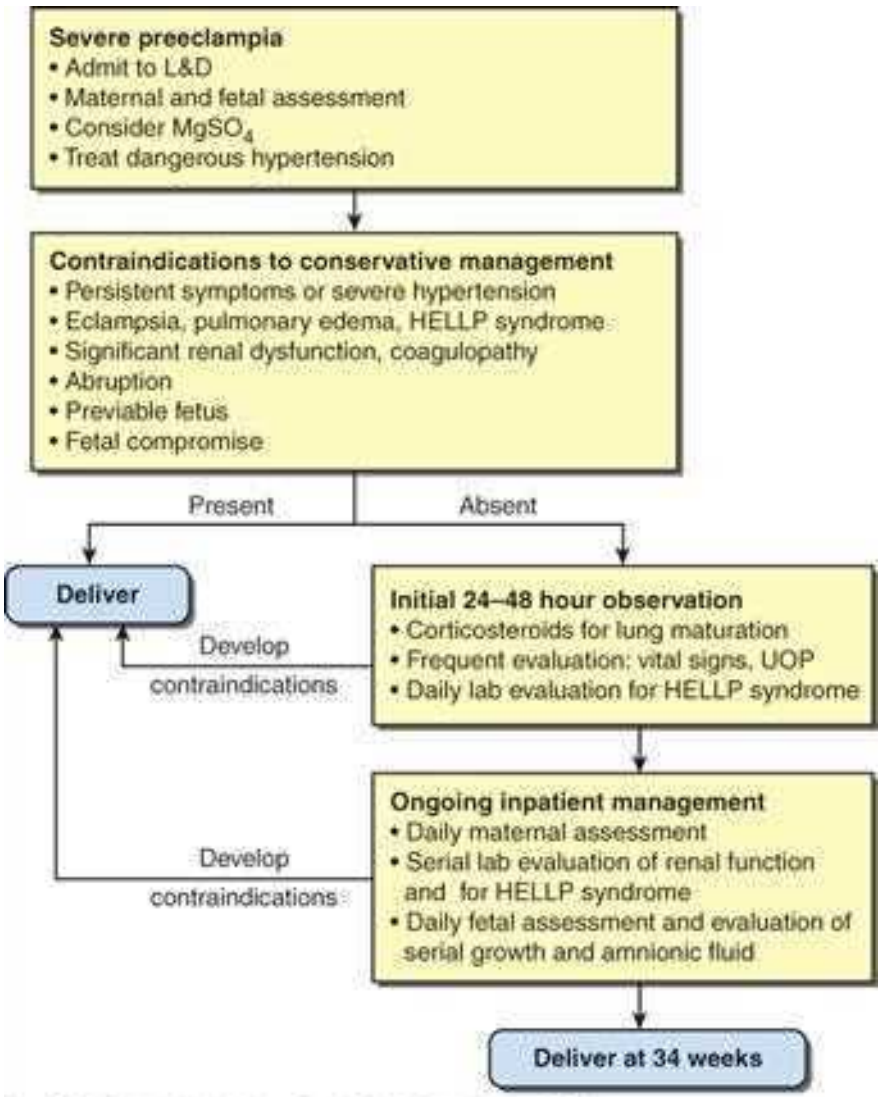

TABLE 40-10

Indications for Delivery in Women <34 Weeks' Gestation Managed Expectantly

Corticosteroid Therapy for Lung Maturation[a] and Delivery after Maternal Stabilization:
Uncontrolled severe hypertension
Eclampsia
Pulmonary edema
Placental abruption
Disseminated intravascular coagulation
Nonreassuring fetal status
Fetal demise
Corticosteroid Therapy for Lung Maturation—Delay Delivery 48 hr If Possible:
Preterm ruptured membranes or labor
Thrombocytopenia <100,000/μL
Hepatic transaminase levels twice upper limit of normal
Fetal-growth restriction
Oligohydramnios
Reversed end-diastolic Doppler flow in umbilical artery
Worsening renal dysfunction

[a]Initial dose only, do not delay delivery.

From the Society for Maternal-Fetal Medicine, 2011, and the Task Force of the American College of Obstetricians and Gynecologists, 2013.

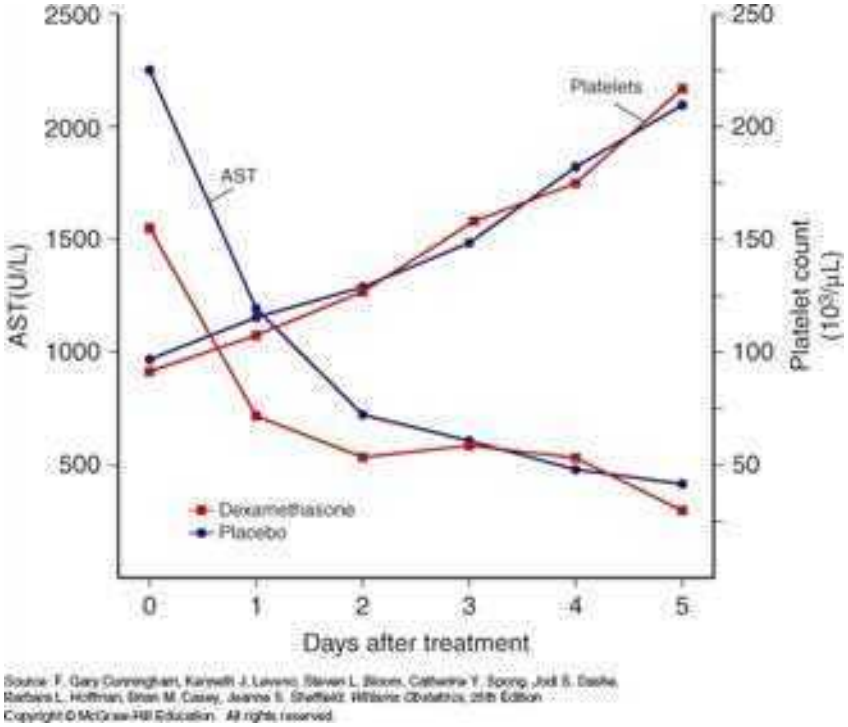
Our view is more conservative. Undoubtedly, the overriding reason to terminate pregnancies with severe preeclampsia is maternal safety. Indeed, it seems obvious that a delay to prolong gestation in women with severe preeclampsia may have serious maternal consequences (see Table 40-9). These observations are even more pertinent when considered with the absence of convincing evidence that perinatal outcomes are markedly improved by the average prolongation of pregnancy by approximately 1 week. If undertaken, the caveats that mandate delivery shown in Table 40-10 should be strictly heeded.

Corticosteroids to Ameliorate HELLP Syndrome

At least three randomized trials have evaluated the benefits of glucocorticoids given to improve the laboratory abnormalities associated with HELLP syndrome. First, Fonseca and associates (2005) randomly assigned 132 women with HELLP syndrome to either dexamethasone or placebo administration. Outcomes assessed included hospitalization length, recovery time of abnormal laboratory test results, resolution of clinical parameters, and complications that included acute renal failure, pulmonary edema, eclampsia, and death. None of these was significantly different between the two groups. In another study, 105 postpartum women with HELLP syndrome were assigned to dexamethasone or placebo treatment (Katz, 2008). Outcomes were analyzed similarly to the Fonseca study, and no advantage to dexamethasone was found (Fig. 40-15). In the third study, preeclamptic women were given either placebo or methylprednisolone if their platelet count was between 50,000 and 150,000/μL (Pourrat, 2016). No benefits were gained from corticosteroid therapy. Because of these findings, the 2013 Task Force does not recommend corticosteroid treatment for thrombocytopenia with HELLP syndrome.

FIGURE 40-15

Recovery times for platelet counts and serum aspartate transaminase (AST) levels in women with HELLP syndrome assigned to receive treatment with dexamethasone or placebo. (Data from Katz, 2008.)



Experimental Therapies

In several preliminary studies, therapies have attempted to lower serum levels or mitigate the action of antiangiogenic factors. Some of these include *therapeutic apheresis*, done to lower sFlt-1 levels (Thadhani, 2016). *Pravastatin* has been given for preeclampsia prevention (Cleary, 2014). *Sildenafil citrate*, a phosphodiesterase inhibitor, has been provided to promote vasodilation (Trapani, 2016; Vigil-De Gracia, 2016). In a recent randomized trial of 120 women with early-onset preeclampsia, an *recombinant antithrombin infusion* compared with saline afforded the same interval-to-delivery timing (Sibai, 2017).

ECLAMPSIA

Preeclampsia complicated by generalized tonic-clonic convulsions appreciably raises the risk to both mother and fetus. In an earlier report, Mattar and Sibai (2000) described outcomes in 399 consecutive women with eclampsia from 1977 through 1998. Major maternal complications included placental abruption—10 percent, neurological deficits—7 percent, aspiration pneumonia—7 percent, pulmonary edema—5 percent, cardiopulmonary arrest—4 percent, and acute renal failure— 4 percent. Moreover, 1 percent of these women died. Several subsequent reports similarly described excessive maternal morbidity and mortality rates with eclampsia that also included HELLP syndrome, pulmonary embolism, and stroke (Andersgaard, 2006; Knight, 2007). In The Netherlands, there were three maternal deaths among 222 eclamptic women (Zwart, 2008). Data from Ireland and Australia are similar (O'Connor, 2013; Thornton, 2013). In perspective, this is a thousand-fold increase above the overall maternal death rates for these countries.

Almost without exception—but at times unnoticed—preeclampsia precedes the convulsion onset. Eclampsia is most common in the last trimester and becomes increasingly frequent as term approaches. In more recent years, the incidence of postpartum eclampsia has declined. This is presumably related to improved access to prenatal care, earlier detection of antepartum preeclampsia, and prophylactic use of magnesium sulfate (Chames, 2002). Importantly, other diagnoses should be considered in women with convulsions more than 48 hours postpartum or in women with focal neurological deficits, prolonged coma, or atypical eclampsia (Sibai, 2012).

Clinical Findings with Eclampsia

Eclamptic seizures may be violent, and the woman must be protected, especially her airway. So forceful are the muscular movements that the woman may throw herself out of her bed, and if not protected, her tongue is bitten by the violent action of the jaws (Fig. 40-16). This phase, in which the muscles alternately contract and relax, may last approximately a minute. Gradually, the muscular movements become smaller and less frequent, and finally the woman lies motionless.

FIGURE 40-16
Hematoma of tongue from laceration during an eclamptic convulsion. Thrombocytopenia may have contributed to the bleeding.

After a seizure, the woman is postictal, but in some, a coma of variable duration ensues. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. In severe cases, coma persists from one convulsion to another, and death may result. In rare instances, a single convulsion may be followed by coma from which the woman may never emerge. As a rule, however, death does not occur until after frequent convulsions. Finally and also rarely, convulsions continue unabated—*status epilepticus*—and require deep sedation and even general anesthesia to obviate anoxic encephalopathy.

The respiratory rate after an eclamptic convulsion is usually increased and may reach 50 or more per minute in response to hypercarbia, lactic acidemia, and transient hypoxia. Cyanosis may be observed in severe cases. High fever is a grave sign as it likely emanates from cerebrovascular hemorrhage.

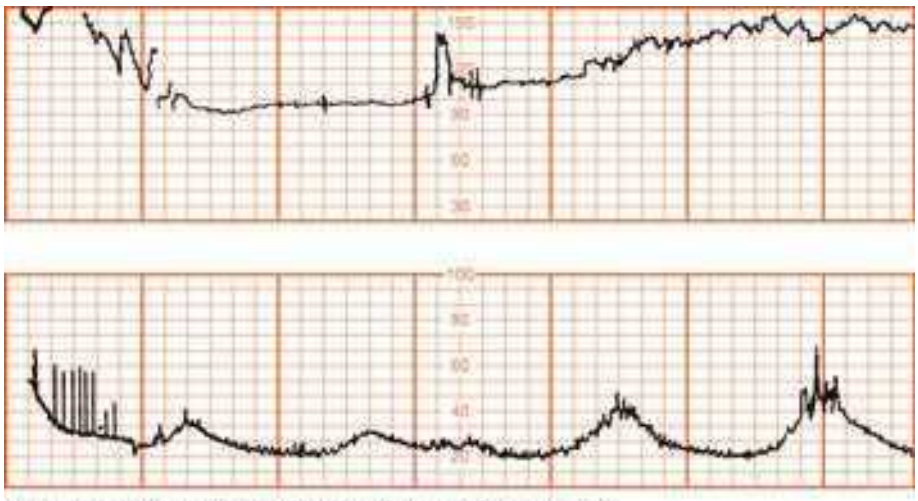
Proteinuria is usually, but not always, present as discussed earlier (Kidney). Urine output may be diminished appreciably, and occasionally anuria develops. There may be hemoglobinuria, but hemoglobinemia is rare. Often, facial and peripheral edema is pronounced, but it may be absent (Fig. 40-17).

FIGURE 40-17
Severe edema in a young nullipara with antepartum preeclampsia. (Used with permission from Dr. Nidhi Shah.)

As with severe preeclampsia, urinary output rises after delivery and is usually an early sign of improvement. With renal dysfunction, serum creatinine levels are serially monitored. Proteinuria and edema ordinarily disappear within a week postpartum. In most cases, blood pressure returns to normal within a few days to 2 weeks after delivery (Berks, 2009). As subsequently discussed, persisting and severe hypertension likely predicts underlying chronic vascular disease (Podymow, 2010).

In antepartum eclampsia, labor may begin spontaneously shortly after convulsions ensue and may progress rapidly. If the convulsions occur during labor, contractions may increase in frequency and intensity, and the duration of labor may be shortened. Because of maternal hypoxemia and lactic acidemia caused by convulsions, fetal bradycardia often follows a seizure (Fig. 40-18). The fetal heart rate usually recovers within 2 to 10 minutes (Ambia, 2018). If it persists more than about 10 minutes, another cause of bradycardia, such as placental abruption or imminent delivery, should be considered.

FIGURE 40-18
Fetal heart rate tracing shows fetal bradycardia following an intrapartum eclamptic convulsion. Bradycardia resolved and beat-to-beat variability returned approximately 5 minutes following the seizure.



Pulmonary edema may follow shortly after eclamptic convulsions or up to several hours later. This usually is caused by aspiration pneumonitis from gastric-content inhalation during vomiting that frequently accompanies convulsions. In some women, pulmonary edema may be caused by ventricular failure from increased afterload that results from severe hypertension. Both pulmonary edema and hypertension can be further aggravated by vigorous intravenous fluid administration (Dennis, 2012b). Such pulmonary edema from ventricular failure is more common in morbidly obese women and in those with previously unappreciated chronic hypertension.

Occasionally, sudden death occurs synchronously with an eclamptic convulsion, or it follows shortly thereafter. Most often in these cases, a massive cerebral hemorrhage is the cause (see Fig. 40-10). Hemiplegia may result from sublethal hemorrhage. Cerebral hemorrhages are more likely in older women with underlying chronic hypertension.

In approximately 10 percent of eclamptic women, some degree of blindness follows a seizure. The causes of blindness or impaired vision were discussed earlier (Uteroplacental Perfusion). Blindness with severe preeclampsia without convulsions usually stems from retinal detachment (Vigil-De Gracia, 2011). Conversely, blindness with eclampsia is typically due to occipital lobe edema (Cunningham, 1995). In both instances, however, the prognosis for return to normal function is good and is usually complete within 1 to 2 weeks postpartum.

Up to 5 percent of women with eclampsia have substantively altered consciousness, including persistent coma, following a seizure. This is due to extensive cerebral edema, and associated transtentorial herniation may cause death (Cerebrovascular Pathophysiology).

Rarely, eclampsia is followed by psychosis, and the woman becomes violent. This may last for several days to 2 weeks. The prognosis for return to normal function is good, provided there was no preexisting mental illness. It is presumed to be similar to postpartum psychosis discussed in Chapter 61 (Anxiety Disorders). Antipsychotic medications have proven effective in the few cases of posteclampsia psychosis treated at Parkland Hospital.

Generally, eclampsia is more likely to be diagnosed too frequently rather than overlooked. Epilepsy, encephalitis, meningitis, brain tumor, neurocysticercosis, amnionic fluid embolism, postdural puncture cephalalgia, and ruptured cerebral aneurysm during late pregnancy or in the puerperium may simulate eclampsia. Until other such causes are excluded, however, all pregnant women with convulsions should be considered to have eclampsia.

Management of Eclampsia

Magnesium sulfate is highly effective to prevent convulsions in women with preeclampsia and to stop them in those with eclampsia. In his review, Chesley (1978) cited observational data by Pritchard and colleagues (1955, 1975) from Parkland Hospital and from his own institution. At that time, most eclampsia regimens in the United States adhered to a similar philosophy, and it is still in use today:

1. Control of convulsions using an intravenously administered loading dose of magnesium sulfate that is followed by a maintenance dose, usually intravenous, of magnesium sulfate
2. Intermittent administration of an antihypertensive medication to lower blood pressure whenever it is considered dangerously high
3. Avoidance of diuretics unless pulmonary edema is obvious, limitation of intravenous fluid administration unless fluid loss is excessive, and avoidance of hyperosmotic agents
4. Delivery of the fetus to resolve preeclampsia.

Magnesium Sulfate to Control Convulsions

Magnesium sulfate administered parenterally is an effective anticonvulsant that avoids producing central nervous system depression. It may be given intravenously by continuous infusion or intramuscularly by intermittent injection (Table 40-11). The dosages for severe preeclampsia are the same as for eclampsia. Because labor and delivery is a more likely time for convulsions to develop, women with preeclampsia-eclampsia usually are given magnesium sulfate during labor and for 24 hours postpartum.

TABLE 40-11

Magnesium Sulfate Dosage Schedule for Severe Preeclampsia and Eclampsia

Continuous Intravenous (IV) Infusion
Give 4- to 6-g loading dose of magnesium sulfate diluted in 100 mL of IV fluid administered over 15–20 min Begin 2 g/hr in 100 mL of IV maintenance infusion. Some recommend 1 g/hr Monitor for magnesium toxicity: Assess deep tendon reflexes periodically Some measure serum magnesium level at 4–6 hr and adjust infusion to maintain levels between 4 and 7 mEq/L (4.8 to 8.4 mg/dL) Measure serum magnesium levels if serum creatinine ≥1.0 mg/dL Magnesium sulfate is discontinued 24 hr after delivery
Intermittent Intramuscular Injections
Give 4 g of magnesium sulfate ($MgSO_4 \cdot 7H_2O$ USP) as a 20% solution intravenously at a rate not to exceed 1 g/min Follow promptly with 10 g of 50% magnesium sulfate solution, one half (5 g) injected deeply in the upper outer quadrant of each buttock through a 3-inch-long 20-gauge needle. (Addition of 1.0 mL of 2% lidocaine minimizes discomfort.) If convulsions persist after 15 min, give up to 2 g more intravenously as a 20% solution at a rate not to exceed 1 g/min. If the woman is large, up to 4 g may be given slowly. Every 4 hr thereafter, give 5 g of a 50% solution of magnesium sulfate injected deeply in the upper outer quadrant of alternate buttocks, but only after ensuring that: The patellar reflex is present, Respirations are not depressed, and Urine output the previous 4 hr exceeded 100 mL Magnesium sulfate is discontinued 24 hr after delivery

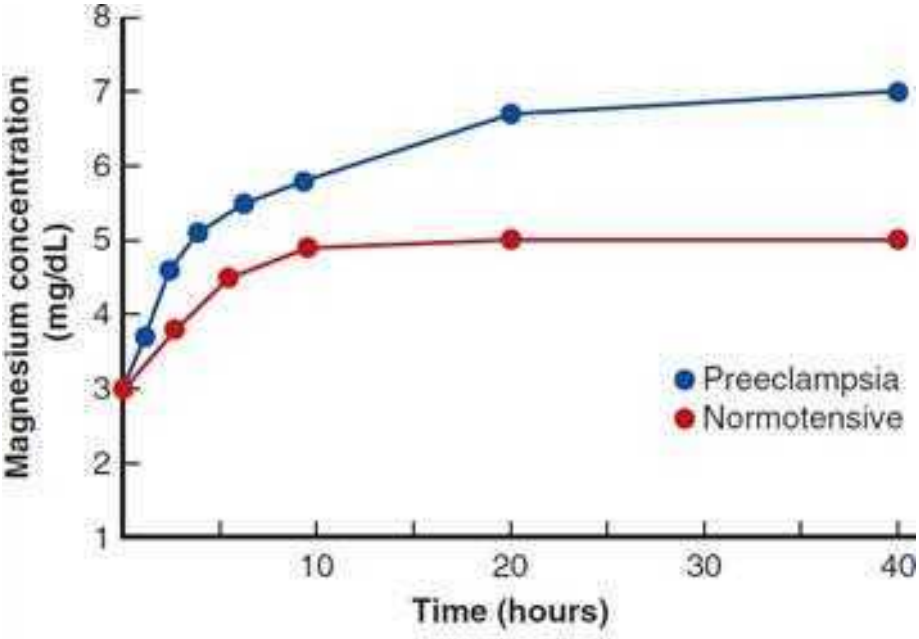
In the United States, magnesium sulfate is almost universally administered intravenously. Of concern, magnesium sulfate solutions, although inexpensive to prepare, are not readily available in all parts of the developing world. And even when the solutions are available, the technology to infuse them may not be. Therefore, it should not be overlooked that the drug can be administered intramuscularly and that this route is as effective as intravenous administration (Salinger, 2013). In two reports from India, intramuscular regimens were nearly equivalent in preventing recurrent convulsions and maternal deaths in women with eclampsia (Chowdhury, 2009; Jana, 2013). These observations comport with earlier ones from Parkland Hospital (Pritchard, 1975, 1984).

Magnesium sulfate is not given to treat hypertension. Magnesium most likely exerts a specific anticonvulsant action on the cerebral cortex. Typically, the mother stops convulsing after the initial 4-g loading dose. By an hour or two, she regains consciousness sufficiently to be oriented to place and time.

The magnesium sulfate dosage regimens presented in Table 40-11 usually result in plasma magnesium levels illustrated in Figure 40-19. When magnesium sulfate is given to arrest eclamptic seizures, 10 to 15 percent of women will have a subsequent convulsion. If so, an additional 2-g dose of magnesium sulfate in a 20-percent solution is slowly administered intravenously. In a small woman, this additional 2-g dose may be used once, but it can be given twice if needed in a larger woman. In only 5 of 245 women with eclampsia at Parkland Hospital was it necessary to use alternative supplementary anticonvulsant medication to control convulsions (Pritchard, 1984). For these, an intravenous barbiturate is given slowly. Midazolam or lorazepam may also be given in a small single dose, but prolonged use is avoided because it is associated with a higher mortality rate from aspiration pneumonia (Royal College of Obstetricians and Gynaecologists, 2006).

FIGURE 40-19

Serum magnesium concentration in normotensive and preeclamptic women following a 4-g loading dose of magnesium sulfate and 2 g/h infusion. (Data from Brookfield, 2016.)



Maintenance magnesium sulfate therapy has traditionally been continued for 24 hours after delivery. For eclampsia that develops postpartum, magnesium sulfate is administered for 24 hours after the onset of convulsions. A few investigators have truncated this therapy duration to 12 hours and found no seizures (Anjum, 2016; Ehrenberg, 2006; Kashanian, 2016). And more recently, Ludmir and colleagues (2017) described salutary outcomes when magnesium sulfate therapy was stopped after delivery. That said, these studies are small, and the abbreviated magnesium regimen needs further study before being routinely implemented.

Pharmacology and Toxicology

Using United States Pharmacopeia (USP) standards, magnesium sulfate USP is $MgSO_4 \cdot 7H_2O$, and it contains 8.12 mEq magnesium per 1 g. Parenterally administered magnesium is cleared almost totally by renal excretion, and magnesium intoxication is unusual when the glomerular filtration rate is normal or only slightly reduced. Adequate urine output *usually* correlates with preserved glomerular filtration rates. That said, magnesium excretion is not urine flow dependent, and urinary volume per unit time does not, per se, predict renal function. *Thus, serum creatinine levels must be measured to detect a decreased glomerular filtration rate.*

Eclamptic convulsions are almost always prevented or arrested by plasma magnesium levels maintained at 4 to 7 mEq/L, 4.8 to 8.4 mg/dL, or 2.0 to 3.5 mmol/L. But, one review of magnesium pharmacokinetics showed that most regimens result in much lower serum magnesium levels (Okusanya, 2016). This was especially true if only 1 g/hr was infused (Yefet, 2017). Importantly, the obesity epidemic has affected these observations (Cunningham, 2016). Tudela and colleagues (2013) described our observations from Parkland Hospital with magnesium administration to obese women. More than 60 percent of women whose body mass index (BMI) exceeded 30 kg/m^2 and who were receiving the 2 g/hr dose had subtherapeutic levels at 4 hours. Thus, obese women would require 3 g/hr to maintain effective plasma levels. That said, most currently do not recommend routine magnesium level measurements (American College of Obstetricians and Gynecologists, 2013; Royal College of Obstetricians and Gynaecologists, 2006).

Patellar reflexes disappear when the plasma magnesium level reaches 10 mEq/L—about 12 mg/dL—presumably because of a curariform action. This sign serves to warn of impending magnesium toxicity. When plasma levels rise above 10 mEq/L, breathing becomes weakened. At 12 mEq/L or higher levels, respiratory paralysis and respiratory arrest follow (Somjen, 1966). *Treatment with calcium gluconate or calcium chloride, 1 g intravenously, along with discontinuation of further magnesium sulfate, usually reverses mild-to-moderate respiratory depression.* One of these agents should be readily available whenever magnesium is being infused. Unfortunately, the effects of intravenously administered calcium may be short-lived if there is a steady-state toxic level. For severe respiratory depression and arrest, prompt tracheal intubation and mechanical ventilation are lifesaving. Direct toxic effects on the myocardium from high levels of magnesium are uncommon (McCubbin, 1981; Morisaki, 2000).

Because magnesium is cleared almost exclusively by renal excretion, the dosages described will become excessive if glomerular filtration is substantially decreased. The initial 4-g loading dose of magnesium sulfate can be safely administered regardless of renal function. It is important to administer the standard loading dose and not to reduce it under the mistaken conception that diminished renal function requires it. This is because after distribution, a loading dose *achieves* the desired therapeutic level, and the infusion *maintains* the steady-state level. *Thus, only the maintenance infusion rate should be altered with diminished glomerular filtration rate.* Renal function is estimated by measuring plasma creatinine. Whenever plasma creatinine levels are >1.0 mg/mL, serum magnesium levels are determined to guide the infusion rate.

After a 4-g intravenous dose administered over 15 minutes, mean arterial pressure falls slightly, accompanied by a 13-percent rise in cardiac index (Cotton, 1986b). Thus, magnesium lowers systemic vascular resistance and mean arterial pressure. At the same time, cardiac output is increased. These findings are coincidental with transient nausea and flushing, and the cardiovascular effects persist for only 15 minutes despite continued magnesium infusion.

Thurnau and associates (1987) showed that magnesium therapy led to a small but significant rise in the total magnesium concentration in the cerebrospinal fluid. The magnitude of the elevation was directly proportional to the corresponding serum concentration.

Other Effects

Magnesium has anticonvulsant and neuroprotective effects in several animal models. Some proposed mechanisms of action include: (1) reduced presynaptic release of the neurotransmitter glutamate, (2) blockade of glutamatergic *N*-methyl-d-aspartate (NMDA) receptors, (3) potentiation of adenosine action, (4) improved calcium buffering by mitochondria, and (5) blockage of calcium entry via voltage-gated channels (Arango, 2008; Wang, 2012).

In the uterus, relatively high serum magnesium concentrations depress myometrial contractility both in vivo and in vitro. With the suggested regimen, myometrial depression has not been observed, except for a transient decline in activity during and immediately after the initial intravenous loading dose (Leveno, 1998; Szal, 1999; Witlin, 1997). Blood loss at delivery is not increased by standard magnesium treatment (Graham, 2016). However, inhibition of uterine contractility is magnesium dose dependent, and serum levels of at least 8 to 10 mEq/L are necessary to inhibit uterine contractions (Watt-Morse, 1995).

Fetal and Neonatal Effects

Magnesium administered parenterally promptly crosses the placenta to achieve equilibrium in fetal serum and less so in amnionic fluid (Hallak, 1993). Levels in amnionic fluid rise with the duration of maternal infusion (Gortzak-Uzan, 2005). Magnesium sulfate has small but significant effects on the fetal heart rate pattern—specifically beat-to-beat variability (Hallak, 1999). Duffy and associates (2012) reported a lower heart rate baseline that was within the normal range; decreased variability; and fewer prolonged decelerations. They noted no adverse outcomes.

Overall, maternal magnesium therapy appears safe for perinates (Drassinower, 2015). One MFMU Network study of more than 1500 exposed preterm neonates found no association between the need for neonatal resuscitation and cord blood magnesium levels (Johnson, 2012). Still, a few neonatal adverse events are associated with its use. In a Parkland Hospital study of 6654 mostly term, exposed newborns, 6 percent had hypotonia (Abbassi-Ghanavati, 2012). In addition, exposed neonates had lower 1- and 5-minute Apgar scores, a higher intubation rate, and more admissions to the special care nursery. The study showed that neonatal depression occurs only if hypermagnesemia at delivery is severe.

Observational studies suggest a protective effect of magnesium against the development of cerebral palsy in very-low-birthweight newborns (Nelson, 1995; Schendel, 1996). At least five randomized trials have also assessed neuroprotective effects in preterm neonates. These findings are discussed in detail in Chapter 42 (Magnesium Sulfate for Neuroprotection). Nguyen and colleagues (2013) expanded this possibility to include term newborn neuroprotection, but data were insufficient to draw conclusions.

Last, in cases of preterm labor, magnesium has been given for several days for tocolysis (Chap. 42, β-Adrenergic Receptor Agonists). Administration in these instances has been associated with neonatal osteopenia (American College of Obstetricians and Gynecologists, 2016c).

Maternal Safety and Efficacy

The multinational Eclampsia Trial Collaborative Group study (1995) involved 1687 women with eclampsia randomly allocated to one of three different anticonvulsant regimens: magnesium sulfate, diazepam, or phenytoin (Table 40-12). In aggregate, magnesium sulfate therapy was associated with a significantly lower incidence of recurrent seizures (9.7 percent) compared with women given phenytoin (28 percent) or diazepam (17 percent). Importantly, the aggregate maternal death rate of 3.2 percent with magnesium sulfate was significantly lower than that of 5.2 percent for the other two regimens.

TABLE 40-12

Randomized Comparative Trials of Magnesium Sulfate Versus Phenytoin and Diazepam to Prevent Recurrent Eclamptic Convulsions

	Magnesium Sulfate	Phenytoin	Diazepam
Recurrent seizures[a]	60/453 (13%)	126/452 (28%)	—
	22/388 (5.6%)	—	66/389 (17%)
Maternal deaths[b]	10/388 (2.6%)	20/387 (5.2%)	—
	17/453 (3.8%)	—	24/452 (5.3%)

[a]All comparisons $p < 0.01$.

[b]Individual comparisons nonsignificant, combined comparison $p < .05$.

Data from Eclampsia Trial Collaborative Group, 1995.

In their review of more than 9500 treated women, Smith and coworkers (2013) reported the overall rate of absent patellar tendon reflexes to be 1.6 percent; respiratory depression, 1.3 percent; and calcium gluconate administration, 0.2 percent. Only one mother died due to magnesium toxicity. Our experiences are similar. In the more than 60 years of magnesium use at Parkland Hospital, only one woman has died from an overdose (Pritchard, 1984).

MANAGEMENT CONSIDERATIONS

Severe Hypertension Management

Dangerous hypertension can cause cerebrovascular hemorrhage and hypertensive encephalopathy, and it can trigger eclamptic convulsions in women with preeclampsia. Other complications include placental abruption and congestive heart failure induced by elevated hypertensive afterload.

Because of these serious sequelae, the working group for the National High Blood Pressure Education Program (NHBPEP)(2000) and the 2013 Task Force recommend treatment to lower systolic pressures to or below 160 mm Hg and diastolic pressures to or below 110 mm Hg. Martin and associates (2005, 2016) reported provocative observations that highlight the importance of treating systolic hypertension. They described 28 selected women with severe preeclampsia who suffered an associated stroke. Most (93 percent) were hemorrhagic strokes, and all women had systolic pressures >160 mm Hg before suffering their stroke. By contrast, only 20 percent of these same women had diastolic pressures >110 mm Hg.

From other observations, it seems likely that at least half of serious hemorrhagic strokes associated with preeclampsia are in women with chronic hypertension (Cunningham, 2005). Long-standing hypertension results in development of *Charcot-Bouchard aneurysms* in the deep penetrating arteries of the lenticulostriate branch of the middle cerebral arteries. These vessels supply the basal ganglia, putamen, thalamus, and adjacent deep white matter, as well as the pons and deep cerebellum. These unique aneurysmal weakenings predispose these small arteries to rupture during sudden hypertensive episodes.

Several drugs are available to rapidly lower dangerously elevated blood pressure in women with pregnancy-associated hypertension. The three most commonly employed are hydralazine, labetalol, and nifedipine. For years, parenteral hydralazine was the only one of these three available. But when parenteral labetalol was later introduced, it was proven to be equally effective for obstetrical use. Orally administered nifedipine has since also gained popularity. All three of these are recommended as first-line agents by the American College of Obstetricians and Gynecologists (2017a).

Hydralazine

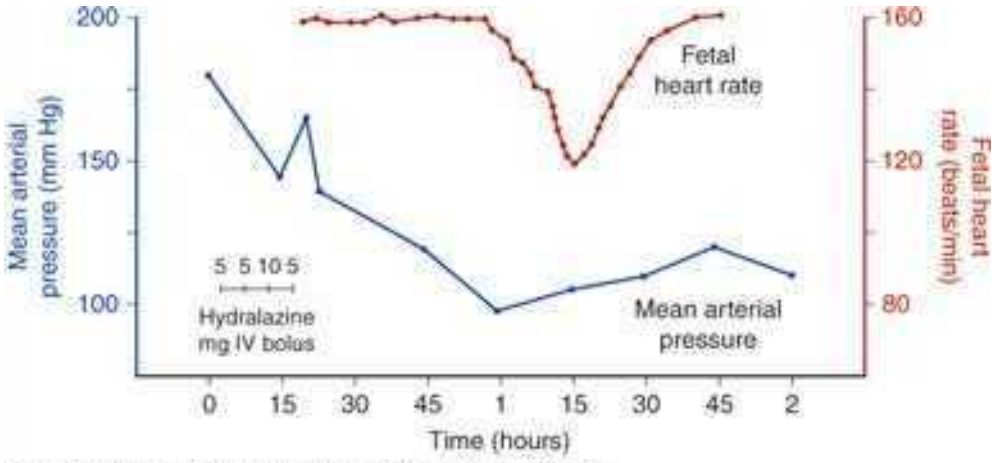
This is probably still the most commonly used antihypertensive agent in the United States for treatment of women with severe gestational hypertension. Hydralazine is administered intravenously with a 5- to 10-mg initial dose, and this is followed by 10-mg doses at 15- to 20-minute intervals until a satisfactory response is achieved. Although we will administer a third dose, the American College of Obstetricians and Gynecologists (2017a) recommends labetalol therapy if severe hypertension persists after the second dose. Antepartum or intrapartum, the target response is a decline in systolic pressure to <160 mm Hg and diastolic blood pressure to 90 to 110 mm Hg. Lower diastolic pressures risk compromised placental perfusion. Hydralazine has proven remarkably effective to prevent cerebral hemorrhage. Its onset of action can be as rapid as 10 minutes. Although repeated administration every 15 to 20 minutes may theoretically lead to undesirable hypotension, this has not been our experience when given in these 5- to 10-mg increments.

At Parkland Hospital, between 5 and 10 percent of all women with intrapartum hypertensive disorders are given a parenteral antihypertensive agent. Antepartum, we usually give hydralazine as described. We do not limit the total dose, and seldom is a second antihypertensive agent needed. We estimate that nearly 6000 women have been so treated at our facility during the past 50 years. Although less popular in Europe, hydralazine is used in some centers according to the Royal College of Obstetricians and Gynaecologists (2006).

For higher blood pressures, there is a tendency to give a larger initial dose of hydralazine. But, this must be avoided. The response to even 5- to 10-mg doses cannot be predicted by hypertension severity. Thus, our protocol is to always administer 5 mg as the initial dose. An adverse response to exceeding this initial dose is shown in Figure 40-20. This woman had chronic hypertension complicated by severe superimposed preeclampsia, and hydralazine was injected more frequently than recommended. Her blood pressure in less than 1 hour dropped from 240–270/130–150 mm Hg to 110/80 mm Hg. Fetal heart rate decelerations characteristic of uteroplacental insufficiency became evident. Decelerations persisted until her blood pressure was increased with rapid crystalloid infusion. In some cases, this fetal response to diminished uterine perfusion may be confused with placental abruption and may result in unnecessary and potentially dangerous emergency cesarean delivery.

FIGURE 40-20

Hydralazine was given at 5-minute intervals instead of 15-minute intervals. The mean arterial pressure dropped from 180 to 90 mm Hg within 1 hour and was associated with fetal bradycardia. Rapid crystalloid infusion raised the mean pressure to 115 mm Hg, and the fetus recovered.



Labetalol

This effective intravenous antihypertensive agent is an α- and nonselective β-blocker. Some prefer its use over hydralazine because of fewer side effects. At Parkland Hospital, we give 10 mg intravenously initially. If the blood pressure has not decreased to the desirable level in 10 minutes, then 20 mg is given. The next 10-minute incremental dose is 40 mg and is followed by another 40 mg if needed. If a salutary response is not achieved, then an 80-mg dose is given. Sibai (2003) recommends 20 to 40 mg every 10 to 15 minutes as needed and a maximum dose of 220 mg per treatment cycle. The American College of Obstetricians and Gynecologists (2017a)

recommends starting with a 20-mg intravenous bolus. If not effective within 10 minutes, this is followed by 40 mg, then 80 mg every 10 minutes. If hypertension persists, hydralazine is then given.

Comparative studies of hydralazine versus labetalol show equivalent results (Umans, 2015). In one trial, labetalol lowered blood pressure more rapidly, and associated tachycardia was minimal. But, hydralazine lowered mean arterial pressures to safe levels more effectively (Mabie, 1987). In another trial, maternal and neonatal outcomes were similar (Vigil-De Gracia, 2007). Hydralazine causes significantly more maternal tachycardia and palpitations, whereas labetalol more frequently leads to maternal hypotension and bradycardia. Both drugs have been associated with a reduced frequency of fetal heart rate accelerations (Cahill, 2013). Labetalol is not given to asthmatic women.

Nifedipine

This orally administered calcium-channel blocking agent has become popular because of its efficacy to control acute pregnancy-related hypertension. The American College of Obstetricians and Gynecologists (2017a), the NHBPEP Working Group (2000), and the Royal College of Obstetricians and Gynaecologists (2006) recommend a 10-mg initial immediate-release oral dose to be followed in 20 to 30 minutes with 10 to 20 mg if necessary. If not satisfactory, this is followed by labetalol. *Nifedipine given sublingually is no longer recommended.* This route is associated with dangerously rapid and extensive effects. Randomized trials that compared nifedipine with labetalol found neither drug definitively superior, but nifedipine lowered blood pressure more quickly (Scardo, 1999; Shekhar, 2016; Vermillion, 1999). Finally, nifedipine does not potentiate magnesium-related effects (Magee, 2015).

Other Antihypertensive Agents

A few other generally available antihypertensive agents have been tested in clinical trials but are not widely used (Umans, 2015). These include verapamil, nitroglycerin, nitroprusside, ketanserin, nicardipine, and nimodipine (Belfort, 1990, 2003; Bolte, 2001; Cornette, 2016). There are also experimental antihypertensive drugs that may become useful for preeclampsia treatment (Lam, 2013).

Diuretics

Potent loop diuretics can further compromise placental perfusion. Immediate effects include redistribution of the intravascular volume, which most often is already reduced in severe preeclampsia (Blood Volume). Therefore, before delivery, diuretics are not used to lower blood pressure (Zeeman, 2009; Zondervan, 1988). We use *antepartum* furosemide or similar drugs solely to treat pulmonary edema.

Fluid Therapy

Lactated Ringer solution is administered routinely at a rate between 60 and 125 mL per hour, unless fluid loss is unusual from vomiting, diarrhea, or diaphoresis, or, more likely, excessive blood loss with delivery. Oliguria is common with severe preeclampsia. Thus, coupled with the knowledge that maternal blood volume is likely constricted compared with that of normal pregnancy, it is tempting to administer intravenous fluids more vigorously. But controlled, conservative fluid administration is preferred for the typical woman with severe preeclampsia who already has excessive extracellular fluid that is inappropriately distributed between intravascular and extravascular spaces. Infusion of large fluid volumes enhances the maldistribution and thereby appreciably elevates the risk of pulmonary and cerebral edema (Dennis, 2012a; Sciscione, 2003; Zinaman, 1985). Thus, for preeclamptic women with anuria, small incremental boluses can be given to maintain urine output above 30 mL per hour. Diminished intravascular volume from hemorrhage or fluid loss from vomiting or fever can similarly be replaced by gradual incremental boluses. For labor analgesia with neuraxial analgesia, crystalloid solutions are infused slowly in graded amounts (Chap. 25, Safety).

Pulmonary Edema

Women with severe preeclampsia who develop pulmonary edema most often do so postpartum (Cunningham, 1986, 2012; Zinaman, 1985). With suspected pulmonary edema in the eclamptic woman, aspiration of gastric contents, which may be the result of convulsions, anesthesia, or oversedation, should be excluded. There are three common causes of pulmonary edema in women with severe preeclampsia syndrome—pulmonary capillary permeability edema, cardiogenic edema, or a combination of the two.

Some women with severe preeclampsia—especially if given vigorous fluid replacement—will have mild pulmonary congestion secondary to permeability edema. This is caused by normal pregnancy changes magnified by the preeclampsia syndrome. Importantly, plasma oncotic pressure drops appreciably in normal term pregnancy because of decreased serum albumin concentration, and oncotic pressure falls even more with preeclampsia (Zinaman, 1985). Moreover, both increased extravascular fluid oncotic pressure and increased capillary permeability are found in women with preeclampsia (Brown, 1989; Øian, 1986).

Invasive Hemodynamic Monitoring

Knowledge concerning cardiovascular and hemodynamic pathophysiological alterations associated with severe preeclampsia-eclampsia has accrued from studies done using invasive monitoring and a flow-directed pulmonary artery catheter (see Fig. 40-5). Two conditions frequently cited as indications are preeclampsia associated with oliguria and that associated with pulmonary edema (Clark, 2010). Somewhat ironically, it is usually vigorous treatment of the former that results in most cases of the latter. The Task Force (2013) recommends against routine invasive monitoring. Such monitoring is best reserved for severely preeclamptic women with accompanying cardiac disease, renal disease, or both or with refractory hypertension, oliguria, and pulmonary edema.

Plasma Volume Expansion

Because the preeclampsia syndrome is associated with hemoconcentration, some have infused various fluids, starch polymers, albumin concentrates, or combinations thereof to expand blood volume (Ganzevoort, 2004). Older observational studies describe serious complications—especially pulmonary edema—with volume expansion (Benedetti, 1985; López-Llera, 1982; Sibai, 1987b).

The Amsterdam randomized study reported by Ganzevoort and coworkers (2005a,b) was a well-designed investigation done to evaluate volume expansion. A total of 216 women with severe preeclampsia were enrolled between 24 and 34 weeks' gestation. The study included women whose preeclampsia was complicated by HELLP syndrome, eclampsia, or fetal-growth restriction. In the group randomly assigned to volume expansion, each woman was given 250 mL of 6-percent

hydroxyethyl starch infused over 4 hours twice daily. Their outcomes were compared with a control group, and none of these outcomes were significantly different (Table 40-13). Importantly, serious maternal morbidity and a substantive perinatal mortality rate accompanied their "expectant" management (see Table 40-9).

TABLE 40-13

Maternal and Perinatal Outcomes after Enrollment in a Randomized Trial of Plasma Volume Expansion versus Saline Infusion in 216 Women with Severe Preeclampsia between 24 and 34 Weeks

Outcomes	Control Group[a] (n = 105)	Treatment Group[a] (n = 111)
Maternal Outcomes (%)		
Eclampsia	1.9	1.8
HELLP	19.0	17.0
Pulmonary edema	2.9	4.5
Placental abruption	3.8	1.0
Perinatal Outcomes		
Fetal deaths (%)	7	12
Prolongation of pregnancy (mean)	11.6 d	6.7 d
EGA at death (mean)	26.7 wk	26.3 wk
Birthweight (mean)	625 g	640 g
Live births (%)	93	88
Prolongation of pregnancy (mean)	10.5 d	7.4 d
EGA at delivery (mean)	31.6 wk	31.4 wk
RDS (%)	30	35
Neonatal death (%)	7.6	8.1
Perinatal mortality rate (n per 1000)	142/1000	207/1000

[a]All comparisons $p > 0.05$.

EGA = estimated gestational age; HELLP = hemolysis, elevated liver enzyme levels, low platelet count; RDS = respiratory distress syndrome.

Data from Ganzevoort, 2005a, b.

Neuroprophylaxis—Prevention of Seizures

Several randomized trials have tested the efficacy of seizure prophylaxis for women with gestational hypertension, with or without proteinuria. In most of these, magnesium sulfate was compared with another anticonvulsant or with a placebo. *In all studies, magnesium sulfate was reported to be superior to the comparator agent to prevent eclampsia*. Four of the larger studies are summarized in Table 40-14. In the study from Parkland Hospital, magnesium sulfate therapy was superior to phenytoin to prevent eclamptic seizures in women with gestational hypertension or preeclampsia (Lucas, 1995). In another, magnesium sulfate and nimodipine—a calcium-channel blocker with specific cerebral vasodilator activity—were compared in 1650 women with severe preeclampsia (Belfort, 2003). The rate of eclampsia was more than threefold higher for women allocated to the nimodipine group—2.6 versus 0.8 percent.

TABLE 40-14

Randomized Comparative Trials of Prophylaxis with Magnesium Sulfate and Placebo or Another Anticonvulsant in Women with Gestational Hypertension

	No. with Seizures/Total No. Treated (%)		
Study/Inclusions	**Magnesium Sulfate**	**Control**	**Comparison[a]**
Lucas et al (1995)		Phenytoin	
Gestational hypertension[b]	0/1049 (0)	10/1089 (0.9)	$p < 0.001$
Coetzee et al (1998)		Placebo	
Severe preeclampsia	1/345 (0.3)	11/340 (3.2)	RR = 0.09 (0.1–0.69)
Magpie Trial (2002)[c]		Placebo	
Severe preeclampsia	40/5055 (0.8)	96/5055 (1.9)	RR = 0.42 (0.26–0.60)
Belfort et al (2003)		Nimodipine	
Severe preeclampsia	7/831 (0.8)	21/819 (2.6)	RR = 0.33 (0.14–0.77)

[a]All comparisons significant $p < 0.05$.

[b]Included women with and without proteinuria and those with all severities of preeclampsia.

[c]Magpie Trial Collaboration Group, 2002.

RR = relative risk.

The largest comparative study was *Magnesium Sulfate for Prevention of Eclampsia* reported by the Magpie Trial Collaboration Group (2002). More than 10,000 women with severe preeclampsia from 33 countries were randomly allocated to treatment with magnesium sulfate or placebo. Women given magnesium had a 58-percent significantly lower risk of eclampsia than those given placebo. In follow-up data of infants born to these mothers given magnesium sulfate, child behavior at approximately 18 months did not differ in those exposed compared with those not exposed to magnesium sulfate (Smyth, 2009).

Who Should Be Given Magnesium Sulfate?

Magnesium will prevent proportionately more seizures in women with correspondingly worse disease. However, severity is difficult to quantify, and thus deciding which individual woman might benefit most from neuroprophylaxis is difficult. *The 2013 Task Force recommends that women with either eclampsia or severe preeclampsia should be given magnesium sulfate prophylaxis.* Again, criteria that establish "severity" are not totally uniform (see Table 40-2). At the same time, however, the 2013 Task Force suggests that women with "mild" preeclampsia do not need magnesium sulfate neuroprophylaxis. The conundrum is whether or not to give neuroprophylaxis to any of these women with "nonsevere" gestational hypertension or preeclampsia (Alexander, 2006).

In most other countries, and principally following dissemination of the Magpie Trial Collaboration Group (2002) study results, magnesium sulfate is now recommended for women with severe preeclampsia. In some, however, debate continues concerning whether therapy should be reserved for women who have an eclamptic seizure. We believe that eclamptic seizures are dangerous (Brain and Renal Sequelae). Maternal mortality rates of up to 5 percent have been reported even in recent studies. Moreover, perinatal mortality rates are substantially increased (Abd El Aal, 2012; Knight, 2007; Ndaboine, 2012; Schutte, 2008; von Dadelszen, 2012). Finally, the possibility of adverse long-term neuropsychological and vision-related sequelae of eclampsia have raised additional concerns that eclamptic seizures are not "benign."

Selective versus Universal Prophylaxis

Because of the foregoing, there is uncertainty about which women with *nonsevere* gestational hypertension should be given magnesium sulfate neuroprophylaxis. An opportunity to address these questions was afforded by a change in our prophylaxis protocol at Parkland Hospital. Before this time, the risk of eclampsia without magnesium prophylaxis was approximately 1 in 100 for women with *mild preeclampsia* (Lucas, 1995). Up until 2000, all women with gestational hypertension were given magnesium prophylaxis intramuscularly. After 2000, we instituted a standardized protocol for intravenously administered magnesium sulfate (Alexander, 2006). At the same time, we also changed our practice of universal seizure prophylaxis for all women with gestational hypertension to one of selective prophylaxis given only to women who met our criteria for severe gestational hypertension. These criteria, shown in Table 40-15, included women with ≥2+ proteinuria measured by dipstick in a catheterized urine specimen.

TABLE 40-15

Selective versus Universal Magnesium Sulfate Prophylaxis: Parkland Hospital Criteria to Define Severe Gestational Hypertension or Preeclampsia

In a woman with new-onset proteinuric hypertension, at least one of the following criteria is required:
Systolic BP ≥160 or diastolic BP ≥110 mm Hg
Proteinuria ≥2+ by dipstick in a catheterized urine specimen
Serum creatinine >1.1 mg/dL
Platelet count <100,000/μL
Aspartate aminotransferase (AST) elevated two times above upper limit of normal range
Persistent headache or scotomata
Persistent midepigastric or right-upper quadrant pain

BP = blood pressure.

Criteria based on those from National High Blood Pressure Education Program Working Group, 2000; American College of Obstetricians and Gynecologists, 2012; cited by Alexander, 2006.

Following this protocol change, 60 percent of 6518 women with gestational hypertension during a 4½-year period were given magnesium sulfate neuroprophylaxis. The remaining 40 percent with nonsevere hypertension were not treated, and of these, 27 women developed eclamptic seizures—1 in 92. The seizure rate was only 1 in 358 for 3935 women with criteria for severe disease who were given magnesium sulfate, and thus these cases were treatment failures.

To assess morbidity, outcomes in 87 eclamptic women were compared with outcomes in all 6431 noneclamptic severely hypertensive women (Alexander, 2006). Although most maternal outcomes were similar, almost a fourth of women with eclampsia who underwent emergent cesarean delivery required general anesthesia. This is a great concern because eclamptic women have laryngotracheal edema and are at a higher risk for failed intubation, gastric acid aspiration, and death. Neonatal outcomes were also a concern because the composite morbidity was increased tenfold in eclamptic compared with noneclamptic women—12 versus 1 percent, respectively. These outcomes included cord artery pH <7.0; 5-minute Apgar score <4; or unanticipated admission of a term newborn to an intensive care nursery.

Thus, if one uses the Parkland criteria for nonsevere gestational hypertension, approximately 1 of 100 such women who are not given magnesium sulfate prophylaxis can be expected to have an eclamptic seizure. A fourth of these women likely will require emergent cesarean delivery with attendant maternal and perinatal morbidity and mortality from general anesthesia. From this, the major question regarding management of nonsevere gestational hypertension remains whether it is acceptable to avoid unnecessary treatment of 99 women to risk eclampsia in one? The answer appears to be yes as suggested by the 2013 Task Force. At Parkland Hospital, we only give magnesium neuroprophylaxis to women with severe criteria.

Analgesia and Anesthesia

During the past 20 years, the use of conduction analgesia for women with preeclampsia syndrome has proven ideal. Initial problems with this method included hypotension and diminished uterine perfusion caused by sympathetic blockade in preeclamptic women, with already attenuated hypervolemia. But pulmonary edema was mitigated by techniques that used slow induction of epidural analgesia with dilute solutions of anesthetic agents. This countered the need for rapid infusion of large volumes of crystalloid or colloid to correct maternal hypotension from neural blockade (Hogg, 1999; Wallace, 1995). These techniques are described in detail in Chapter 25 (Safety). Importantly, epidural blockade avoids general anesthesia, in which the stimulation of tracheal intubation may cause sudden severe hypertension. Such blood pressure spikes, in turn, can cause pulmonary edema, cerebral edema, or intracranial hemorrhage. Finally, tracheal intubation may be particularly difficult and thus hazardous in women with airway edema due to preeclampsia (American College of Obstetricians and Gynecologists, 2017b).

At least three randomized studies have been performed to compare these methods of analgesia and anesthesia. Wallace and colleagues (1995) studied 80 women at Parkland Hospital with severe preeclampsia who were to undergo cesarean delivery. They had not been given labor epidural analgesia and were randomly assigned to receive general anesthesia, epidural analgesia, or combined spinal-epidural analgesia. Their average preoperative blood pressures approximated 170/110 mm Hg, and all had proteinuria. Maternal and perinatal outcomes in each group were similar. Maternal hypotension resulting from regional analgesia was managed with judicious intravenous fluid administration. In women undergoing general anesthesia, maternal blood pressure was managed to avoid severe hypertension. There were no serious maternal or fetal complications attributable to any of the three anesthetic methods. It was concluded that all three are acceptable for use in women with pregnancies complicated by severe preeclampsia if steps are taken to ensure a careful approach to the selected method.

Another randomized study included 70 women with severe preeclampsia receiving spinal analgesia versus general anesthesia for cesarean delivery (Dyer, 2003). Their maternal and fetal outcomes were equivalent. In a third study, 116 women with severe preeclampsia received either epidural or patient-controlled intravenous meperidine analgesia during labor (Head, 2002). More women—9 percent—from the group assigned to epidural analgesia required ephedrine for hypotension. As

expected, pain relief was superior in the epidural group. Maternal and neonatal complications were similar between groups, and one woman in each group developed pulmonary edema. Importantly, epidural analgesia is not considered *treatment* of preeclampsia (Lucas, 2001; Ray, 2017).

Judicious fluid administration is essential in severely preeclamptic women who receive regional analgesia. Vigorous crystalloid infusion with epidural blockade in women with severe preeclampsia elevates pulmonary capillary wedge pressures (Newsome, 1986). Aggressive volume replacement in preeclamptic women raises their risk for pulmonary edema, especially in the first 72 hours postpartum (Clark, 1985; Cotton, 1986a). Finally, most cases of pharyngolaryngeal edema are related to aggressive volume therapy (Heller, 1983).

Blood Loss at Delivery

Hemoconcentration or lack of normal pregnancy-induced hypervolemia is an almost predictable feature of severe preeclampsia-eclampsia (see Fig. 40-7) (Zeeman, 2009). *These women, who consequently lack normal pregnancy hypervolemia, are much less tolerant of even normal blood loss than are normotensive pregnant women.* Importantly, an appreciable fall in blood pressure soon after delivery most often means excessive blood loss and not sudden resolution of vasospasm and endothelial damage. When oliguria follows delivery, the hematocrit should be evaluated frequently to help detect excessive blood loss. If identified, hemorrhage should be treated appropriately by crystalloid and blood transfusion.

Persistent Severe Postpartum Hypertension

Although severe postpartum hypertension usually follows labor and delivery complicated by hypertension, 8 percent of women develop de novo hypertension postpartum (Goel, 2015). In either case, if difficulty arises in controlling severe hypertension or if intravenous hydralazine or labetalol are being used repeatedly, then oral regimens can be given. Examples include labetalol or another β-blocker, or nifedipine or another calcium-channel blocker (Sharma, 2017). Women so treated are less likely to require readmission (Hirshberg, 2016). Persistent or refractory hypertension is likely aggravated by mobilization of pathological interstitial fluid and redistribution into the intravenous compartment, underlying chronic hypertension, or usually both (Sibai, 2012; Tan, 2002). Chronic, but not sporadic, administration of some nonsteroidal antiinflammatory drugs, namely ibuprofen, may aggravate postpartum hypertension in those with preeclampsia (Vigil-De Gracia, 2017; Viteri, 2017). In women with chronic hypertension and left-ventricular hypertrophy, severe postpartum hypertension can cause pulmonary edema from cardiac failure (Cunningham, 1986, 2012; Sibai, 1987a).

Furosemide

Because persistence of severe hypertension corresponds to the onset and length of diuresis and extracellular fluid mobilization, it seems logical that furosemide-augmented diuresis might serve to hasten blood pressure control. One randomized trial included 264 postpartum preeclamptic women who, after onset of spontaneous diuresis, were assigned to 20-mg oral furosemide given daily or to no therapy (Ascarelli, 2005). Women with mild disease had similar blood pressure control regardless of whether they received treatment or placebo. However, after 2 days, women with severe preeclampsia who were treated, compared with those receiving placebo, had a lower mean systolic blood pressure—142 versus 153 mm Hg. They also less frequently required supplemental antihypertensive therapy during the remainder of hospitalization—14 versus 26 percent, respectively. In a recent randomized study, Veena and colleagues (2017) treated severe postpartum eclampsia with nifedipine plus furosemide or nifedipine alone. They reported that this prophylactic therapy significantly lowered the need for an additional antihypertensive—26 versus 8 percent, respectively.

We use a simple method to estimate excessive extracellular/interstitial fluid. The *postpartum weight* is compared with the most recent *prenatal weight*, either from the last clinic visit or on admission for delivery. Typically, soon after delivery, maternal weight should be reduced by at least 10 to 15 pounds depending on newborn and placental weight, amnionic fluid volume, and blood loss. Because of various interventions, especially intravenous crystalloid infusions given with labor epidural analgesia or during operative vaginal or cesarean delivery, women with severe preeclampsia often have an immediate postpartum weight *in excess of their last prenatal weight*. If this weight increase is associated with severe persistent postpartum hypertension, then diuresis with intravenous furosemide is usually helpful in controlling blood pressure.

Plasma Exchange

Occasionally, women have an atypical syndrome in which severe preeclampsia-eclampsia persists despite delivery. Martin and colleagues (1995) described 18 such women whom they encountered during a 10-year period. They advocate single or multiple plasma exchange for these women. In some cases, 3 L of plasma was exchanged three times—a 36- to 45-donor unit exposure for each patient—before a response was forthcoming. Others have described plasma exchange performed in postpartum women with HELLP syndrome (Förster, 2002; Obeidat, 2002). In all of these cases, however, the distinction between HELLP syndrome and thrombotic thrombocytopenic purpura or hemolytic uremic syndrome was not clear (Tsai, 2016).

In our experiences with more than 50,000 women with gestational hypertension among nearly 450,000 pregnancies cared for at Parkland Hospital through 2017, we have encountered very few women with persistent postpartum hypertension, thrombocytopenia, and renal dysfunction who were diagnosed as having a thrombotic microangiopathy (Dashe, 1998). These latter syndromes complicating pregnancy were reviewed by Martin (2008) and George (2013) and their colleagues, who conclude that a rapid diagnostic test for ADAMTS-13 enzyme activity might be helpful to differentiate most of these syndromes.

Reversible Cerebral Vasoconstriction Syndrome

This is another cause of persistent hypertension, “thunderclap” headaches, seizures, and central nervous system findings. It is a form of postpartum angiopathy. *Reversible cerebral vasoconstriction syndrome* is characterized by diffuse segmental constriction of cerebral arteries and may be associated with ischemic and hemorrhagic strokes. This syndrome has several inciting causes that include pregnancy, and particularly preeclampsia (Ducros, 2012). It is more common in women, and in some cases, vasoconstriction may be so severe as to cause cerebral ischemia and infarction. The appropriate management is not known at this time (Edlow, 2013).

LONG-TERM CONSEQUENCES

Future Pregnancies

Defective remodeling of the spiral arteries in some placentas is posited as a cause of at least one preeclampsia phenotype. Specifically, lack of deep placentation is linked with preeclampsia, placental abruption, fetal-growth restriction, and preterm birth (Wikström, 2011). With this type of "overlap syndrome," hypertensive disorders may serve as markers for subsequent preterm labor and fetal-growth restriction. For example, even in subsequent nonhypertensive pregnancies, women who had preterm preeclampsia are at higher risk for preterm birth and growth-restricted neonates (Bramham, 2011; Connealy, 2014; Palatnik, 2016).

In addition, women who have had either gestational hypertension or preeclampsia risk developing hypertension in future pregnancies (Lykke, 2009b). Generally, the earlier preeclampsia is diagnosed during the index pregnancy, the greater the likelihood of recurrence. And, the recurrence risk for preeclampsia is elevated further in women with the metabolic syndrome (Stekkinger, 2015). Sibai and colleagues (1986, 1991) found that nulliparas diagnosed with preeclampsia before 30 weeks had a recurrence risk as high as 40 percent during a subsequent pregnancy. In a prospective study of 500 women previously delivered for preeclampsia at 37 weeks, the recurrence rate in a subsequent gestation was 23 percent (Bramham, 2011).

As perhaps expected, women with HELLP syndrome have a substantive risk for recurrence in subsequent pregnancies. In two studies, the risk ranged from 5 to 26 percent, but the true recurrence risk likely lies between these two extremes (Habli, 2009; Sibai, 1995). Even if HELLP syndrome does not recur with subsequent pregnancies, again incidences of preterm delivery, fetal-growth restriction, placental abruption, and cesarean delivery are increased (Habli, 2009; Hnat, 2002).

Long-Term Morbidity and Mortality

Evidence has accrued that the preeclampsia syndrome is a marker for subsequent long-term cardiovascular and related morbidity and mortality (Table 40-16). Thus, women with hypertension identified during pregnancy should be evaluated during the first several months postpartum. The working group of the NHBPEP (2000) concluded that hypertension attributable to pregnancy should resolve within 12 weeks of delivery. Hypertension persisting beyond this time is considered chronic (Chap. 50, Definition and Classification). The Magpie Trial Follow-Up Collaborative Group (2007) reported that 20 percent of 3375 preeclamptic women seen at a median of 26 months postpartum had hypertension. Importantly, even if hypertension does not persist in the short term, convincing evidence suggests a higher risk for long-term cardiovascular morbidity.

TABLE 40-16

Some Long-Term Consequences in Women with Preeclampsia Syndrome

Cardiovascular
Chronic hypertension
Ischemic heart disease
Atherosclerosis
Coronary artery calcification
Cardiomyopathy
Thromboembolism
Neurovascular
Stroke

Cardiovascular Morbidity

Any hypertension during pregnancy is a risk marker for morbidity and mortality in later life (American College of Obstetricians and Gynecologists, 2013; Bellamy, 2007). In a case-control study from Iceland, Arnadottir and associates (2005) reported the prevalences of *ischemic heart disease*—24 versus 15 percent, and *stroke*—9.5 versus 6.5 percent, were significantly increased in women who had gestational hypertension compared with normotensive controls. In a Swedish population study of more than 400,000 women, those with recurrent preeclampsia have systolic dysfunction and a greater incidence of ischemic heart disease (Valensise, 2016). Diastolic dysfunction is also more common (Bokslag, 2017). Preeclampsia is also a risk for coronary artery calcification and idiopathic cardiomyopathy (Behrens, 2016; White, 2016).

Lykke and associates (2009a) cited findings from a Danish registry of more than 780,000 nulliparas. After a mean follow-up of almost 15 years, the incidence of *chronic hypertension* was fivefold higher in those who had gestational hypertension, 3.5-fold greater after mild preeclampsia, and sixfold higher after severe preeclampsia. After two hypertensive pregnancies, this incidence rose sixfold. Moreover, these women with pregnancy-associated hypertension are at increased risk for *type 2 diabetes* (Rice, 2016). And, preeclampsia is a risk factor for later diabetic retinopathy and retinal detachment (Auger, 2017; Beharier, 2016).

As emphasized by several investigators, other cofactors or comorbidities are related to acquisition of these long-term adverse outcomes (Gastrich, 2012; Harskamp, 2007; Hermes, 2012; Spaan, 2012b). These include the metabolic syndrome, diabetes, obesity, dyslipidemia, and atherosclerosis (Kajantie, 2017; Orabona, 2016; Stekkinger, 2015).

Individuals who are born preterm have greater ventricular mass later in life (Lewandowski, 2013). And, women who have preeclampsia and who develop chronic hypertension later in life have an increased ventricular mass index before they become hypertensive (Ghossein-Doha, 2013). Finally, in at least some of these women, hypertensive cardiovascular pathologies appear to have begun near the time of *their own* births. A similar phenomenon is associated with preterm birth and with fetal-growth disorders.

Renal Sequelae

Preeclampsia is also a marker for subsequent renal disease. Almost 15 percent of previously preeclamptic women have renal dysfunction (Lopes van Balen, 2017). In a 40-year study of Norwegian birth and end-stage renal disease linked registries, although the absolute risk of renal failure was small, preeclampsia was associated with a fourfold greater risk (Vikse, 2008). Women with recurrent preeclampsia had an even higher risk. These data need to be considered in light of the findings that 15 to 20 percent of women with preeclampsia who undergo renal biopsy have evidence of chronic renal disease (Chesley, 1978). In another long-term study, Spaan and coworkers (2009) compared formerly preeclamptic women with a cohort of women who were normotensive at delivery. At 20 years following delivery, preeclamptic women were significantly more likely to be chronically hypertensive—55 versus 7 percent—compared with control women. They also had higher peripheral vascular and renovascular resistance and decreased renal blood flow. These data do not permit conclusions as to cause versus effect.

Central Nervous System Sequelae

Until recently, eclamptic seizures were believed to have no significant long-term sequelae. However, this may not be the case (Theilen, 2016). Recall that almost all eclamptic women have multifocal areas of perivascular edema, and approximately a fourth also have areas of cerebral infarction (Zeeman, 2004a).

In several long-term follow-up studies in women with severe preeclampsia and eclampsia, brain white-matter lesions that followed eclamptic convulsions persist (Aukes, 2007, 2009, 2012). Specifically, when studied with MR imaging at a mean of 7 years, 40 percent of formerly eclamptic women had more numerous and larger aggregate white matter lesions compared with 17 percent of normotensive control women. These investigators later also observed these white-matter lesions in preeclamptic women without convulsions (Aukes, 2012). And, Siepmann and associates (2017) documented temporal lobe white matter changes and reduced cortical volume in previously preeclamptic women. In studies designed to assess clinical relevance, formerly eclamptic women had subjectively impaired cognitive functioning (Postma, 2014). Wiegman and associates (2012) reported that formerly eclamptic women at approximately 10 years had lower vision-related quality of life compared with control subjects. This likely coincides with an elevated risk for retinopathy described by Auger and colleagues (2017). Because no baseline studies were done before these women suffered from preeclampsia or eclampsia, the investigators appropriately concluded that a cause versus an effect of these white-matter lesions remains unknown.

CHAPTER 41: Obstetrical Hemorrhage

A profuse hemorrhage occurring prior to or shortly after the birth of the child is always dangerous and not infrequently a fatal complication.

—J. Whitridge Williams (1903)
