CHAPTER 1: Overview of Obstetrics

> *In the following pages I have attempted to set forth, as briefly as seemed to be consistent with thoroughness, the scientific basis for and the practical application of the obstetrical art. At the same time, I have endeavored to present the more practical aspects of obstetrics in such a manner as to be of direct service to the obstetrician at the bedside.*
>
> —J. Whitridge Williams (1903)

INTRODUCTION

So reads the introduction to Williams' first edition of this textbook, *Obstetrics—A Text-Book for the Use of Students and Practitioners.* In this 25th edition, we strive to follow the tenets described by Williams. And, each chapter begins with a quote from his original textbook.

The science and clinical practice of obstetrics is concerned with human reproduction. Through quality perinatal care, the specialty promotes the health and well-being of the pregnant woman and her fetus. Such care entails appropriate recognition and treatment of complications, supervision of labor and delivery, initial care of the newborn, and management of the puerperium. Postpartum care promotes health and provides family planning options.

The importance of obstetrics is reflected by the use of maternal and neonatal outcomes as an index of the quality of health and life among nations. Intuitively, indices that reflect poor obstetrical and perinatal outcomes would lead to the assumption that medical care for the entire population is lacking. With those thoughts, we now provide a synopsis of the current state of maternal and newborn health in the United States as it relates to obstetrics.

VITAL STATISTICS

The National Vital Statistics System of the United States is the oldest and most successful example of intergovernmental data sharing in public health. This agency collects statistics through vital registration systems that operate in various jurisdictions. These systems are legally responsible for registration of births, fetal deaths, deaths, marriages, and divorces. Legal authority resides individually with the 50 states; two regions—the District of Columbia and New York City; and five territories—American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the Virgin Islands.

The standard birth certificate was revised in 1989 to include more information on medical and lifestyle risk factors and obstetrical practices. In 2003, an extensively revised Standard Certificate of Live Birth was implemented in the United States. The enhanced data categories and specific examples of each are summarized in Table 1-1. By 2013, 35 states had implemented the revised birth certificate representing 76 percent of all births (MacDorman, 2015). Importantly, the 2003 version of the population death certificate contains a pregnancy checkbox to eventually be implemented by all states (Joseph, 2017).

TABLE 1-1

General Categories of New Information Added to the 2003 Revision of the Birth Certificate

Risk factors in pregnancy—Examples: prior preterm birth, prior eclampsia
Obstetrical procedures—Examples: tocolysis, cerclage, external cephalic version
Labor—Examples: noncephalic presentation, glucocorticoids for fetal lung maturation, antibiotics during labor
Delivery—Examples: unsuccessful operative vaginal delivery, trial of labor with prior cesarean delivery
Newborn—Examples: assisted ventilation, surfactant therapy, congenital anomalies

Definitions

The uniform use of standard definitions is encouraged by the World Health Organization as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017). Such uniformity allows data comparison not only between states or regions of the country but also between countries. Still, not all definitions are uniformly applied. For example, the American College of Obstetricians and Gynecologists recommends that reporting include all fetuses and neonates born weighing at minimum 500 g, whether alive or dead. But, not all states follow this recommendation. Specifically, 28 states stipulate that fetal deaths beginning at 20 weeks' gestation should be recorded as such; eight states report all products of conception as fetal deaths; and still others use a minimum birthweight of 350 g, 400 g, or 500 g to define fetal death. To further the confusion, the National Vital Statistics Reports tabulates fetal deaths from gestations that are 20 weeks or older (Centers for Disease Control and Prevention, 2016). This is problematic because the 50th percentile for fetal weight at 20 weeks approximates 325 to 350 g—considerably less than the 500-g definition. Indeed, a birthweight of 500 g corresponds closely with the 50th percentile for 22 weeks' gestation.

Definitions recommended by the National Center for Health Statistics and the Centers for Disease Control and Prevention are as follows:

Perinatal period. The interval between the birth of a neonate born after 20 weeks' gestation and the 28 completed days after that birth. When perinatal rates are based on birthweight, rather than gestational age, it is recommended that the perinatal period be defined as commencing at the birth of a 500-g neonate.

Birth. The complete expulsion or extraction from the mother of a fetus after 20 weeks' gestation. As described above, in the absence of accurate dating criteria, fetuses weighing <500 g are usually not considered as births but rather are termed *abortuses* for purposes of vital statistics.

Birthweight. The weight of a neonate determined immediately after delivery or as soon thereafter as feasible. It should be expressed to the nearest gram.

Birth rate. The number of live births per 1000 population.

Fertility rate. The number of live births per 1000 females aged 15 through 44 years.

Live birth. The term used to record a birth whenever the newborn at or sometime after birth breathes spontaneously or shows any other sign of life such as a heartbeat or definite spontaneous movement of voluntary muscles. Heartbeats are distinguished from transient cardiac contractions, and respirations are differentiated from fleeting respiratory efforts or gasps.

Stillbirth or fetal death. The absence of signs of life at or after birth.

Early neonatal death. Death of a liveborn neonate during the first 7 days after birth.

Late neonatal death. Death after 7 days but before 29 days.

Stillbirth rate or fetal death rate. The number of stillborn neonates per 1000 neonates born, including live births and stillbirths.

Neonatal mortality rate. The number of neonatal deaths per 1000 live births.

Perinatal mortality rate. The number of stillbirths plus neonatal deaths per 1000 total births.

Infant death. All deaths of liveborn infants from birth through 12 months of age.

Infant mortality rate. The number of infant deaths per 1000 live births.

Low birthweight. A newborn whose weight is <2500 g.

Very low birthweight. A newborn whose weight is <1500 g.

Extremely low birthweight. A newborn whose weight is <1000 g.

Term neonate. A neonate born any time after 37 completed weeks of gestation and up until 42 completed weeks of gestation (260 to 294 days). The American College of Obstetricians and Gynecologists (2016b) and Society for Maternal– Fetal Medicine endorse and encourage specific gestational age designations. *Early term* refers to neonates born at 37 completed weeks up to $38^{6/7}$ weeks. *Full term* denotes those born at 39 completed weeks up to $40^{6/7}$ weeks. Last, *late term* describes neonates born at 41 completed weeks up to $41^{6/7}$ weeks.

Preterm neonate. A neonate born before 37 completed weeks (the 259th day). A neonate born before 34 completed weeks is early preterm, whereas a neonate born between 34 and 36 completed weeks is late preterm.

Postterm neonate. A neonate born anytime after completion of the 42nd week, beginning with day 295.

Abortus. A fetus or embryo removed or expelled from the uterus during the first half of gestation—20 weeks or less, or in the absence of accurate dating criteria, born weighing <500 g.

Induced termination of pregnancy. The purposeful interruption of an intrauterine pregnancy that has the intention other than to produce a liveborn neonate and that does not result in a live birth. This definition excludes retention of products of conception following fetal death.

Direct maternal death. The death of the mother that results from obstetrical complications of pregnancy, labor, or the puerperium and from interventions, omissions, incorrect treatment, or a chain of events resulting from any of these factors. An example is maternal death from exsanguination after uterine rupture.

Indirect maternal death. A maternal death that is not directly due to an obstetrical cause. Death results from previously existing disease or a disease developing during pregnancy, labor, or the puerperium that was aggravated by maternal physiological adaptation to pregnancy. An example is maternal death from complications of mitral valve stenosis.

Nonmaternal death. Death of the mother that results from accidental or incidental causes not related to pregnancy. An example is death from an automobile accident or concurrent malignancy.

Maternal mortality ratio. The number of maternal deaths that result from the reproductive process per 100,000 live births. Used more commonly, but less accurately, are the terms *maternal mortality rate* or *maternal death rate.* The term *ratio* is more accurate because it includes in the numerator the number of deaths regardless of pregnancy outcome—for example, live births, stillbirths, and ectopic pregnancies—whereas the denominator includes the number of live births.

Pregnancy-associated death. The death of a woman, from any cause, while pregnant or within 1 calendar year of termination of pregnancy, regardless of the duration and the site of pregnancy.

Pregnancy-related death. A pregnancy-associated death that results from: (1) complications of pregnancy itself, (2) the chain of events initiated by pregnancy that led to death, or (3) aggravation of an unrelated condition by the physiological or pharmacological effects of pregnancy and that subsequently caused death.

PREGNANCY RATES IN THE UNITED STATES

According to the Centers for Disease Control and Prevention (CDC), the fertility rate of women aged 15 to 44 years in the United States in 2015 was 62.5 live births per 1000 women (Martin, 2017). This rate began slowly trending downward in 1990 and has now dropped below that for replacement births. This indicates a

population decline (Hamilton, 2012). There were 3.98 million births in 2015, and this constituted the lowest birth rate ever recorded for the United States—12.3 per 1000 population. The birth rate decreased for all major ethnic and racial groups, for adolescents and unmarried women, and for those aged 20 to 24 years. For women older than 30 years, the birth rate rose slightly. Almost half of newborns in 2010 in the United States were minorities: Hispanic—25 percent, African-American—14 percent, and Asian—4 percent (Frey, 2011).

The total number of pregnancies and their outcomes in 2015 are shown in Table 1-2. According to the Guttmacher Institute (2016b), 45 percent of births in the United States are unintended at the time of conception. Importantly, the overall proportion of unintended births has declined only slightly since 2001. Unmarried women, black women, and women with less education or income are more likely to have unplanned pregnancies.

TABLE 1-2

Total Pregnancies and Outcomes in the United States in 2015

Outcome	Number or Percent
Births	3,988,076
Cesarean deliveries	32.2%
Preterm births (<37 weeks)	9.5%
Low birthweight (<2500 g)	8.0%
Induced abortions	664,435
Total pregnancies[a]	4,652,511

[a]Excludes spontaneous abortions and ectopic pregnancies.

Data from Martin, 2017.

In Table 1-2, induced abortion information derives from CDC abortion surveillance data from 45 states combined with Guttmacher Institute data on induced abortion. These data have been collected beginning in 1976. Since *Roe v. Wade* legalization of abortion, more than 46 million American women have chosen legalized abortions. As discussed later, this provides a compelling argument for easily accessible family planning.

MEASURES OF OBSTETRICAL CARE

Perinatal Mortality

Several indices are used to assess obstetrical and perinatal outcomes as measures of medical care quality. As noted, the perinatal mortality rate includes the numbers of stillbirths and neonatal deaths per 1000 total births. In 2013, the perinatal mortality rate was 9.98 per 1000 births (Fig. 1-1) (MacDorman, 2015). There were 25,972 fetal deaths at gestational ages of 20 weeks or older. Fetal deaths at 28 weeks or more have been declining since 1990, whereas rates for those between 20 and 27 weeks are static (Fig. 1-2). By way of comparison, there were a total of 19,041 neonatal deaths in 2006—meaning that nearly 60 percent of the perinatal deaths in the United States were fetal.

Infant Deaths

There were 6.1 infant deaths per 1000 live births in 2013 compared with 6.8 in 2001 (MacDorman, 2015). The three leading causes of infant death—congenital malformations, low birthweight, and sudden infant death syndrome—accounted for almost half of all deaths (Heron, 2015). Infants born at the lowest gestational ages and birthweights add substantively to these mortality rates. For example, more than half of all infant deaths in 2005 were in the 2 percent of infants born before 32 weeks' gestation. Indeed, the percentage of infant deaths related to preterm birth increased from 34.6 percent in 2000 to 36.5 percent in 2005. When analyzed by birthweight, two thirds of infant deaths were in low-birthweight neonates. Of particular interest are infants with birthweights <500 g, for whom neonatal intensive care can now be offered.

Maternal Mortality

As shown in Figure 1-3, maternal mortality rates dropped precipitously in the United States during the 20th century. Pregnancy-related deaths are so uncommon as to be measured per 100,000 births. The CDC (2017a) has maintained data on pregnancy-related deaths since 1986 in its Pregnancy Mortality Surveillance System. In the latest report, Creanga and coworkers (2017) described 2009 pregnancy-related deaths during the period from 2011 to 2013. Approximately 5 percent were early-pregnancy deaths due to ectopic gestation or abortive outcomes. The deadly obstetrical triad of hemorrhage, preeclampsia, and infection has accounted for a third of all deaths (Fig. 1-4). Thromboembolism, cardiomyopathy, and other cardiovascular disease together accounted for another third. Other significant contributors were amnionic fluid embolism (5.3 percent) and cerebrovascular accidents (6.2 percent). Anesthesia-related deaths were at an all-time low—

only 0.7 percent. Similar causes were reported for selected cohorts for years 2008 to 2009 and 2013 to 2014 (MacDorman, 2017).

FIGURE 1-3

Maternal mortality rates for the United States, 1950–2003. (Data from Berg, 2010; Hoyert, 2007.)

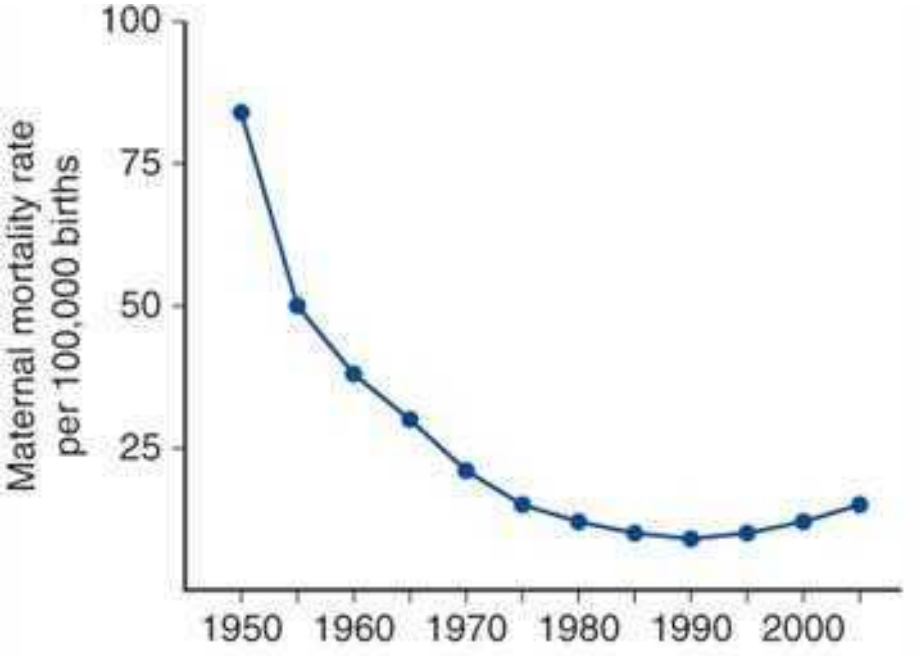

FIGURE 1-4

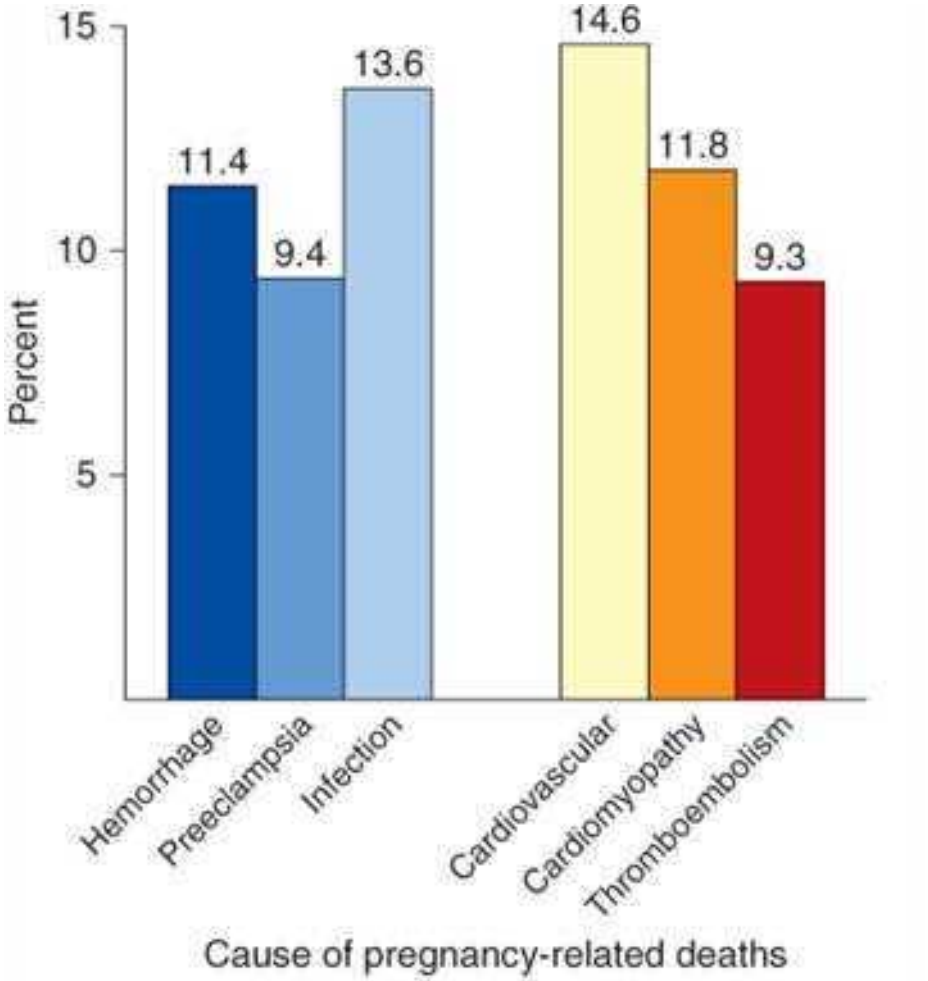
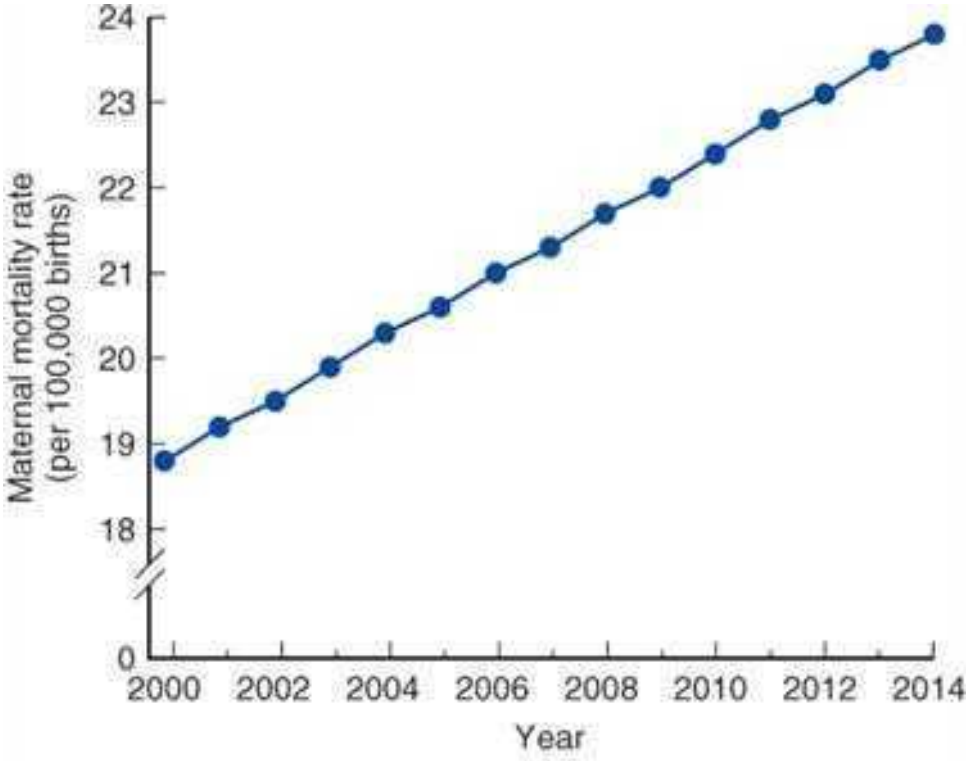
Six common causes of pregnancy–related deaths for the United States, 2006–2010. (Data from Creanga, 2015.)



Shown in Figure 1-5, the pregnancy-related mortality ratio of 23.8 per 100,000 live births in 2014 is the highest during the previous 40 years. And, according to the Institute of Health Metrics, it was 28 per 100,000 in 2013 (Tavernise, 2016). This rise simply may be that more women are dying, however, other factors explain this doubling of the rate from 1990 to 2013 (Joseph, 2017). The first is an artificial elevation caused by the International Statistical Classification of Diseases, 10th Revision (ICD-10), implemented in 1999. Second, improved reporting definitely contributes to the rise (MacDorman, 2016b, 2017). In the past, maternal deaths were notoriously underreported (Koonin, 1997). Third, and related to the second explanation, the rate of rise is at least partially due to the revised death certificate and its pregnancy checkbox described earlier (Main, 2015). Fourth, the number of pregnant women with severe chronic health conditions, which place women at higher risk, is greater (Centers for Disease Control and Prevention, 2017a). Finally, the increased proportion of births to women older than 40 years contribute to higher mortality rates (MacDorman, 2017).

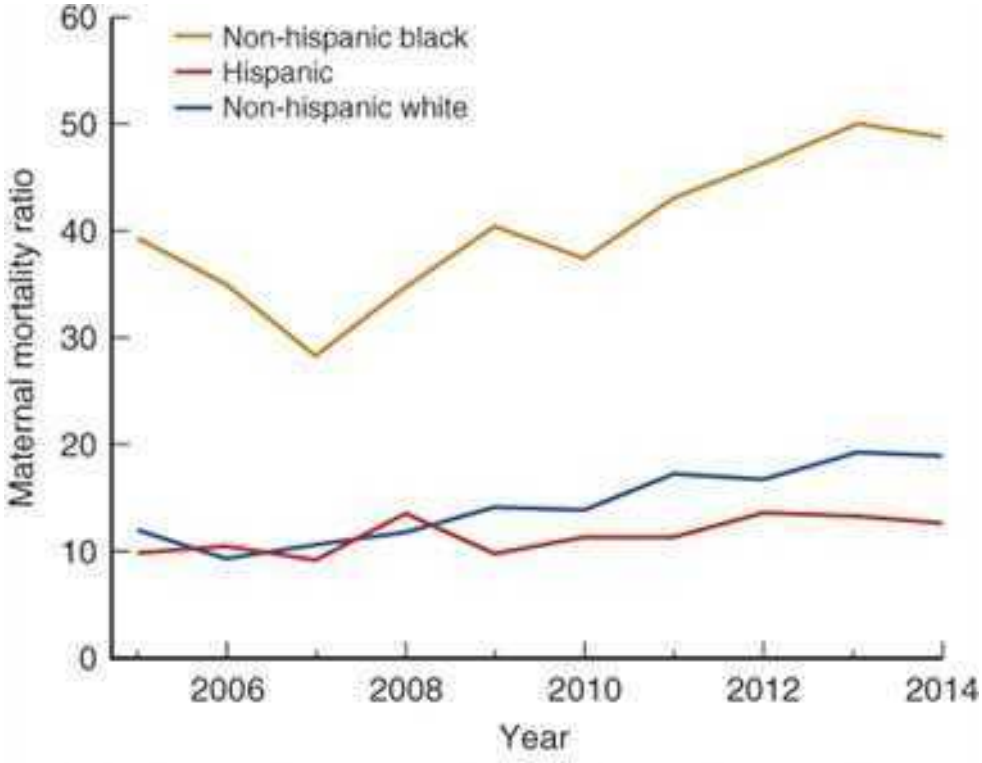
FIGURE 1-5
Estimated maternal mortality rates in 48 states and the District of Columbia. (Data from MacDorman, 2016.)



Whatever the cause, the apparent sharp rise of the maternal mortality rates has galvanized the obstetrical community to action (Chescheir, 2015). According to Barbieri (2015), the Joint Commission has recommended that birthing centers establish standardized protocols and implement simulation efforts. D'Alton and colleagues (2016) described efforts of a working group to lower morbidity and mortality rates.

Another consideration is the obvious disparity of higher mortality rates among black, Hispanic, and white women as shown in Figure 1-6. Racial disparities translate to health care availability, access, or utilization (Howell, 2016; Moaddab, 2016). And, maternal mortality is disparately high in rural compared with metropolitan areas (Maron, 2017).

FIGURE 1-6
Trends in maternal mortality ratio (per 100,000 live births) by race: United States, 2005–2014. (Data from Moaddab, 2016.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

Importantly, many of the reported maternal deaths are considered preventable. Berg and colleagues (2005) estimated that this may be up to a third of pregnancy-related deaths in white women and up to half of those in black women. In one evaluation of an insured cohort, 28 percent of 98 maternal deaths were judged preventable (Clark, 2008). Thus, although significant progress has been made, further efforts are imperative for obstetrics in the 21st century.

Severe Maternal Morbidity

This serves as another measure to guide prevention efforts. Lowering medical error rates serves to diminish risks for maternal mortality or severe maternal morbidity. The terms *near misses* or *close calls* were introduced and defined as unplanned events caused by error that do not result in patient injury but have the potential to do so (Institute for Safe Medication Practices, 2009). These are much more common than injury events, but for obvious reasons, they are more difficult to identify and quantify. Systems designed to encourage reporting have been installed in various institutions and allow focused safety efforts (Clark, 2012; Main, 2017; Shields, 2017). The American College of Obstetricians and Gynecologists and the Society for Maternal–Fetal Medicine (2016f) have provided lists of suggested screening topics for this purpose.

Several data systems now measure indicators of unplanned events caused by errors that have injurious potential. This evolution followed inadequacies in the ability of hospitalization coding to reflect the severity of maternal complications. Thus, coding indicators or modifiers are used to allow analysis of serious adverse clinical events (Clark, 2012; King, 2012). Such a system was implemented by the World Health Organization. It has been validated in Brazil and accurately reflects maternal death rates (Souza, 2012). Similar systems are in

use in Britain as the *UK Obstetric Surveillance System—UKOSS* (Knight, 2005, 2008). In the United States, one example is the National Partnership for Maternal Safety (D'Alton, 2016; Main, 2015).

To study severe morbidity, the CDC analyzed more than 50 million maternity records from the Nationwide Inpatient Sample from 1998 to 2009 (Callaghan, 2012). They used ICD-9-CM codes and reported that 129 per 10,000 of these gravidas had at least one indicator for severe morbidity (Table 1-3). Thus, for every maternal death, approximately 200 women experience severe morbidity. The CDC (2017b) estimates that 65,000 women per year have such maternal morbidity. These numbers are greatest in smaller hospitals with <1000 deliveries annually (Hehir, 2017). Finally, as with mortality rates, there are serious racial and ethnic disparities for severe maternal morbidity, and black women are disproportionately affected (Creanga, 2014).

TABLE 1-3

Severe Maternal Morbidity Indicators

Acute myocardial infarction
Acute renal failure
Adult respiratory distress syndrome
Amnionic fluid embolism
Cardiac arrest/ventricular fibrillation
Disseminated intravascular coagulation
Eclampsia
Heart failure during procedure
Injuries of thorax, abdomen, and pelvis
Intracranial injuries
Puerperal cerebrovascular disorders
Pulmonary edema
Severe anesthesia complications
Sepsis
Shock
Sickle-cell crisis
Thrombotic embolism
Cardiac monitoring
Conversion of cardiac rhythm
Hysterectomy

Cardiac surgery
Tracheostomy
Ventilation

Summarized from the Centers for Disease Control and Prevention, 2017b.

TIMELY TOPICS IN OBSTETRICS

Various topics have been in the forefront for obstetrical providers in the 4 years since the last edition of this textbook. In the following, we discuss several of these topics.

U.S. Health Care in Crisis

Obamacare and Medicaid

In a 2016 issue of the *Journal of the American Medical Association (JAMA),* then-President Barack Obama presented a summary of the Affordable Care Act (ACA), so-called Obamacare. He described the successes, the challenges ahead, and the policy implications of the policy (Bauchner, 2016). He summarized three lessons from his experiences with the ACA. First, change is especially difficult in the face of hyperpartisanship. Second, special interests pose a continued obstacle to change. Third, he stressed the importance of pragmatism. Here, he was referring to the pragmatism necessary when the ACA did not work effectively on day 1 of implementation.

At this same time, draconian cuts to Medicaid were being proposed, and President Obama ended his JAMA report with a quotation from John Kasich, the Republican governor of Ohio. “For those that live in the shadows of life, those who are the least among us, I will not accept the fact that the most vulnerable in our state should be ignored. We can help them.”

These potential effects to Medicaid ripple into the specialty of obstetrics. In 2010, it was estimated that Medicaid insured 48 percent of the births in the United States (Markus, 2013). Importantly, Medicaid covered a disproportionate number of complicated births. Specifically, Medicaid insured more than half of all hospital stays for preterm and low-birthweight infants and approximately 45 percent of infant hospital stays due to birth defects.

Repeal and Replace

The young, healthy Americans who were expected to financially bolster the ACA ultimately enrolled in insufficient numbers to ensure long-term ACA sustainability. Thus, long-term options included repair or repeal of the ACA. Throughout Donald Trump’s campaign for the presidency of the United States, he made repeal of the ACA a focus of his candidacy. As of this writing, both the United States House of Representatives and the Senate have grappled with “repeal and replace” for 6 months. According to the Congressional

Budget Office, this action would result in 23 million Americans losing health care insurance and cuts in Medicaid dollars (Fiedler, 2017). The latter was to be accomplished by transferring funding of Medicaid from the Federal government to the states. These potential outcomes have prompted considerable debate among voters, and "repeal and replace" has become politically charged. Currently, the Senate has been unable to recruit sufficient Republican votes for Senate passage of such a bill. We suggest that the health care crisis should be reframed and redirected instead to a critical analysis of health care costs and resource utilization.

Maternal and Infant Health Care Costs

The Centers for Medicare and Medicaid Services estimated that spending on health care in the United States in 2015 accounted for 17.8 percent of the gross domestic product—GDP (Voelker, 2010). The total amount of health-care spending—$3.2 trillion—equated to an estimated $10,000 per person. Moreover, compared with 12 other high-income countries, health-care spending in the United States as a proportion of GDP was approximately 50 percent more than the next highest country. Yet, health-care outcomes, which included infant mortality rates, were worse in the United States. And, approximately two thirds of U.S. infant deaths result from complications stemming from preterm births (Matthews, 2015). Indeed, in its 2010 annual global Premature Birth Report Card, the United States garnered a grade of "D" from the March of Dimes for its recognition and prevention of preterm labor in the more than 540,000 neonates born annually before 37 weeks' gestation.

Causes for the excessive health care costs in the United States are attributed, in part, to greater use of medical technology and excessive prices (Squires, 2017). Two recent studies demonstrate the detrimental effect of obstetrics on health care costs. The first report by Nelson and coworkers (2017) described the ineffectiveness of 17-alpha hydroxyprogesterone caproate (17-OHP-C) to prevent recurrent preterm birth. Methodology for this trial is presented in Chapter 42 (Progesterone Use without Prior Preterm Birth). Several lessons can be learned from this investigation. First, use of 17-OHP-C was legitimized in the United States by a national consensus committee using expert opinion. These opinions were promulgated, despite FDA reservations that the evidence was lacking in several important respects. However, once approved, 17-OHP-C was sold by one pharmaceutical company for $1500 for a single, 250-mg injectable dose. Remarkably, this same dose could be compounded and purchased for $25 from local pharmacies. In the subsequent price-gouging controversy, members of the United States Congress intervened to permit continued use of the less expensive 17-OHP-C.

The second study is a multisite prospective trial of the effectiveness of transvaginal sonography to screen for cervical-length shortening to predict preterm birth (Esplin, 2017). A total of 9410 nulliparous women were studied. The Society for Maternal-Fetal Medicine and the American College of Obstetricians and Gynecologists (2016d) both legitimized *universal* cervical-length screening in their joint Committee Opinion (Bloom, 2017). And, by 2015, one survey of 78 Maternal-Fetal Medicine fellowship programs showed that 68 percent were using universal cervical-length screening to predict preterm birth (Khalifeh, 2017). It was estimated that a modest Medicaid rate of $237 per cervical-length ultrasound would result in approximately $350 million in added health care costs. But, Esplin and associates (2017) found that *routine* screening for a short cervix was not beneficial. That is, a widely used intervention was actually ineffective. This is a clear example of how unproven technology can seep into widespread practice.

These two reports highlight a substantial problem in U.S. health care, namely, ineffective yet expensive interventions introduced into broad use without robust evidence. These two reports also speak to a demand for robust scientific evidence. Scrutiny of other ingredients in the health-care paradigm such as prices for hospitalization, prices for surgical procedures, and prices charged by health insurance companies may illuminate similar contributions to the health care fiscal crisis.

Cesarean Delivery Rate

In past editions of this textbook, the rising cesarean delivery rate was considered problematic. This rate has leveled, but there are still imperatives in progress to help lower this rate. One collateral source of cesarean delivery morbidity is from the growing incidence of morbidly adherent placentas encountered in women with a prior hysterotomy incision, discussed in Chapters 31 and 41.

Genomic Technology

Breakthroughs in fetal testing and diagnosis continue to stun. By 2012, prenatal gene microarray techniques were used for clinical management (Dugoff, 2012). The advantages of these techniques are outlined in Chapters 13 and 14. Wapner and coworkers (2012) compared chromosomal microarray analysis of maternal blood with karyotyping for chromosomal anomalies. Reddy and associates (2012) applied this technology to stillbirth evaluation and reported it to be superior to karyotyping. Another report by Talkowski and colleagues (2012) described whole-genome sequencing of a fetus using maternal blood.

Screening for fetal aneuploidy using cell-free DNA (cfDNA) was first introduced in 2011. The technique is described in Chapter 14 (Cell-Free DNA Screening), and it is based on isolation of free fetal (placental) DNA in maternal blood. In a landmark study, Norton and associates (2015) found that cfDNA had a higher sensitivity and specificity compared with standard prenatal screening for trisomy 21 fetuses. Still, invasive testing is currently necessary to confirm a positive cfDNA test result (Chitty, 2015; Snyder, 2015).

The Ob/Gyn Hospitalist

The term “hospitalist” was coined in the 1990s and referred to physicians whose primary professional focus was generalized care of hospitalized patients. From this concept came the obstetrical and gynecological hospitalist whose primary role was to care for hospitalized obstetrical patients and to help manage their emergencies. These physicians could also provide urgent gynecological care and emergency department consultation. Alternative terms include “obstetrical hospitalist” or “laborist,” but the preferred standardized term by the American College of Obstetricians and Gynecologists (2016e) is “Ob/Gyn hospitalist.”

Although not a recognized subspecialty of obstetrics and gynecology, the Ob/Gyn hospitalist movement has gained momentum. The Society of Ob-Gyn Hospitalists had 528 members in 2017 (Burkard, 2017). Various practice models are described to fit the needs of a wide spectrum of obstetrical volumes (McCue, 2016). In addition to providing lifestyle modifications, Ob/Gyn hospitalists are used by some hospitals to improve the quality and safety of their women’s services and to reduce adverse events. Aside from a possible lowering of

the labor induction rate, studies are needed to demonstrate improved outcomes with these providers (American College of Obstetricians and Gynecologists, 2016e; Srinivas, 2016).

Medical Liability

The American College of Obstetricians and Gynecologists periodically surveys its fellows concerning the effect of liability on their practice. The 2015 Survey on Professional Liability is the 12th such report since 1983 (Carpentieri, 2015). From this survey, it appears that there is still a "liability crisis," and the reasons for it are complex. Because it is largely driven by money and politics, a consensus seems unlikely. Although some interests are diametrically opposite, other factors contribute to the problem's complexity. For example, each state has its own laws and opinions on tort reform. In some states, annual premiums for obstetricians approach $300,000—expenses that at least partially are borne by the patient and certainly by the entire health-care system. In 2011, all tort costs in the United States totaled nearly $265 billion. This is an astounding 1.8 percent of the gross domestic product and averages to a cost of $838 per citizen (Towers Watson, 2015).

The American College of Obstetricians and Gynecologists (2016a,c) has taken a lead in adopting a fair system for malpractice litigation—or *maloccurrence litigation*. And nationally, there is the possibility of federal tort reform under the Trump administration (Lockwood, 2017; Mello, 2017).

Home Births

Following a slight decline from 1990 through 2004, the percentage of out-of-hospital births in the United States increased from 0.86 to 1.5 percent—almost 75 percent—through 2014 (MacDorman, 2016a). Of these home births, only a third are attended by nurse midwives certified by the American Midwife Certification Board (Grünebaum, 2015; Snowden, 2015).

Proponents of home births cite successes derived from laudatory observational data from England and The Netherlands (de Jonge, 2015; Van der Kooy, 2011). Data from the United States, however, are less convincing and indicate a higher incidence of perinatal morbidity and mortality (Grünebaum, 2014, 2015; Snowden, 2015; Wasden, 2014; Wax, 2010). These latter findings have led Chervenak and coworkers (2013, 2015) to question the ethics of participation in planned home births. Greene and Ecker (2015) take a broader view. Given data from these more recently cited studies, they are of the view that these data empower women to make a rational decision regarding home delivery. The American College of Obstetricians and Gynecologists (2017b) believes that hospitals and accredited birth centers offer the safest settings, but that each woman has the right to make a medically informed decision regarding delivery.

Family Planning Services

Politics and religion over the years have led to various governmental interferences with the reproductive rights of women. These intrusions have disparately affected indigent women and adolescents. This is despite all reports of the overwhelming success of such programs. One example is the exclusion of Planned

Parenthood affiliates from the Texas Medicaid fee-for-service family planning program. In some groups of women served, there was discontinuation of contraception and an increased rate of Medicaid births (Stevenson, 2016).

According to the Guttmacher Institute (2016a), publicly funded family planning services are needed by 20 million American women. In 2014, such services prevented nearly 2 million unintended pregnancies and 700,000 abortions in the United States. The fate of family planning services is not fully determined, while waiting for decisions regarding provisions within the 2017 American Health Care Act (AHCA), or "Trumpcare." In his response to news that the AHCA may dismantle contraceptive coverage, American College of Obstetricians and Gynecologists President Dr. Haywood Brown (2017) called this a deep disregard for women's health.

Opioid Abuse in Pregnancy

According to the CDC (2014), there were 259 million prescriptions written in 2012 for opioid medications. In 2013, more than a third of American adults reported prescription opioid use (Han, 2017). These freely available—albeit requiring a prescription—addictive drugs are associated with *opioid use disorders*. It remains uncertain if opioid use is teratogenic (Lind, 2017). Still, their abuse by pregnant women has caused an unprecedented rise in the *neonatal abstinence syndrome,* described further in Chapters 12 (Cocaine) and 33 (Neonatal Abstinence Syndrome). Treatment of opioid abuse in pregnancy and its sequelae result in $1.5 billion annually in hospital charges.

For obstetrical providers to better deal with opioid-addicted pregnant women and their fetus–newborns, the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development convened a workshop in 2016 to study many aspects of the problem (Reddy, 2017). The Workshop was cosponsored by the American College of Obstetricians and Gynecologists, the American Academy of Pediatrics, the Society for Maternal–Fetal Medicine, the CDC, and the March of Dimes. Several topics were addressed, and hopefully implementation of these findings will help improve maternal treatment and neonatal outcomes (American College of Obstetricians and Gynecologists, 2017a).

Brave New World

The bold new concept of in-vitro fertilization (IVF) produced the first IVF baby in Britain in 1978. This was soon followed in 1981 with an American success. After four decades, the Society for Assisted Reproductive Technology (SART) reports that more than 1 million babies have been born in the United States using assisted reproductive technologies (ART) offered by 440 clinics (Fox, 2017).

After 15 years of experimental preparation, the promise of a successful human uterine transplant was finally realized with an IVF-conceived liveborn neonate in Sweden (Brännström, 2015). During pregnancy, the mother was treated with tacrolimus, azathioprine, and corticosteroids and underwent cesarean delivery at 32 weeks for preeclampsia and abnormal fetal heart rate testing. This was followed by uterine transplantation programs at the Cleveland Clinic and Baylor Medical Center in Dallas (Flyckt, 2016, 2017;

Testa, 2017). In 2017, the Swedish team had completed a nine-patient trial, in which seven women had become pregnant and five had successful deliveries (Kuehn, 2017). Also, in Dallas, the first such newborn in the United States was born (Rice, 2017).

Meanwhile, researchers at Children's Hospital of Philadelphia pursued a 20-year goal in search of an artificial womb (Yuko, 2017). Using incubator technology, the team devised an artificial amnionic sac. Through this, the umbilical vessels were perfused and drained, and the blood was returned to systems that performed extracorporeal membrane oxygenation and dialysis. To date, lamb fetuses have been kept alive for as long as 1 month. Adverse effects of cerebrovascular hypotension and hypoxemia are conjectural but highly worrisome.

The ethical and legal challenges of these new technologies are daunting. Of those that arose from IVF, most are settled. For the other two endeavors, there are likely many years of ethical and legal milestones ahead.

CHAPTER 2: Maternal Anatomy

As the mechanism of labour is essentially a process of accommodation between the foetus and the passage through which it must pass, it is apparent that obstetrics lacked a scientific foundation until the anatomy of the bony pelvis and of the soft parts connected with it was clearly understood.

—J. Whitridge Williams (1903)

ANTERIOR ABDOMINAL WALL

Skin, Subcutaneous Layer, and Fascia

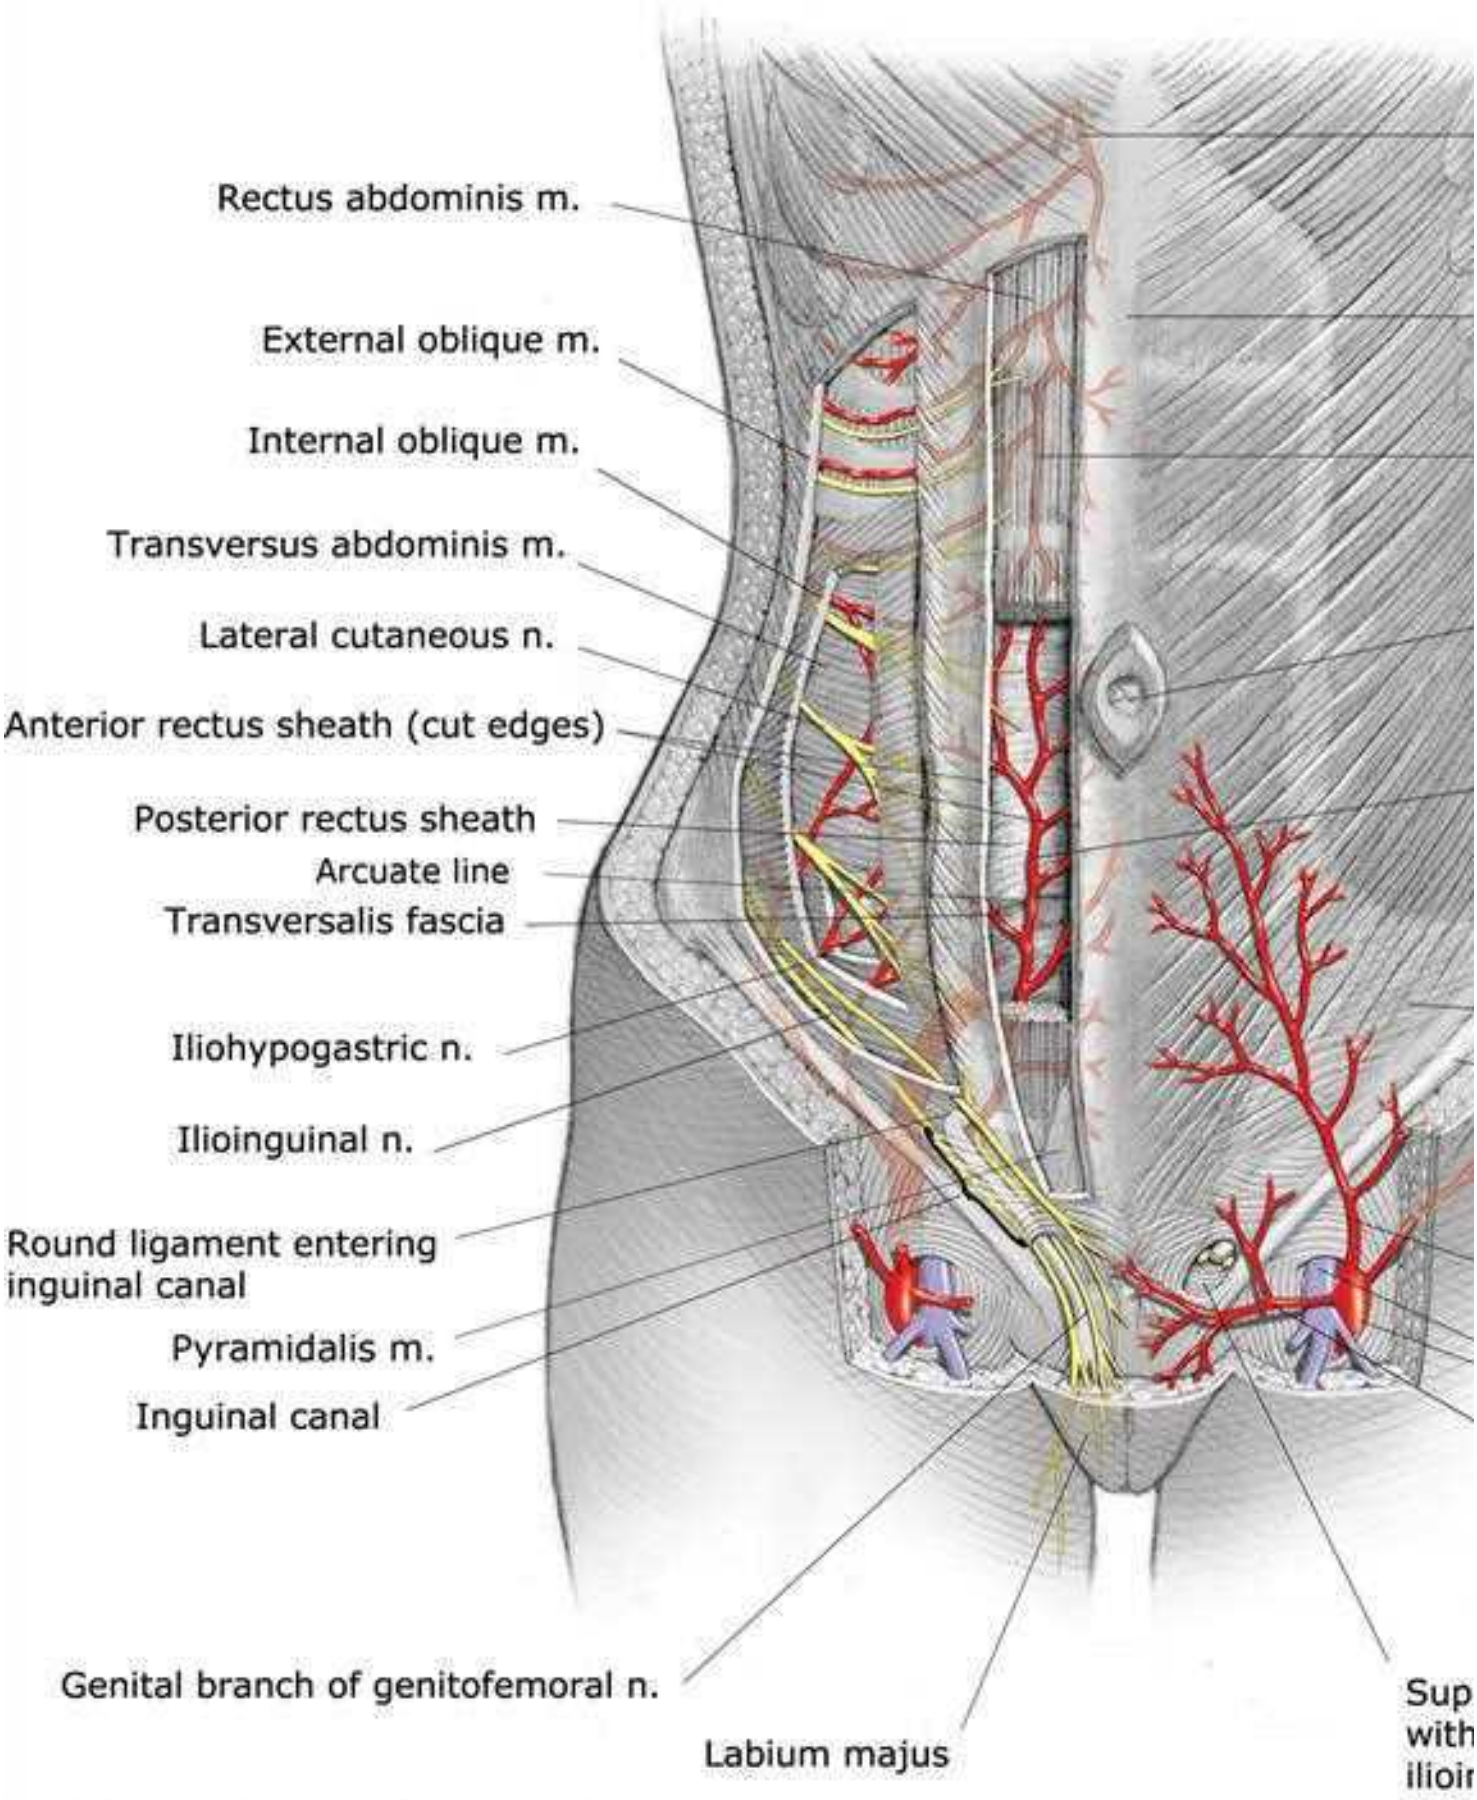
The anterior abdominal wall confines abdominal viscera, stretches to accommodate the expanding uterus, and provides surgical access to the internal reproductive organs. Thus, a comprehensive knowledge of its layered structure is required to surgically enter the peritoneal cavity.

Langer lines describe the orientation of dermal fibers within the skin. In the anterior abdominal wall, they are arranged transversely. As a result, vertical skin incisions sustain greater lateral tension and thus, in general, develop wider scars. In contrast, low transverse incisions, such as the Pfannenstiel, follow Langer lines and lead to superior cosmetic results.

The subcutaneous layer can be separated into a superficial, predominantly fatty layer—Camper fascia, and a deeper membranous layer—Scarpa fascia. Camper fascia continues onto the perineum to provide fatty substance to the mons pubis and labia majora and then to blend with the fat of the ischioanal fossa. Scarpa fascia continues inferiorly onto the perineum as Colles fascia, described in Perineum.

Beneath the subcutaneous layer, the anterior abdominal wall muscles consist of the midline rectus abdominis and pyramidalis muscles as well as the external oblique, internal oblique, and transversus abdominis muscles, which extend across the entire wall (Fig. 2-1). The fibrous aponeuroses of these three latter muscles form the primary fascia of the anterior abdominal wall. These fuse in the midline at the linea alba, which normally measures 10 to 15 mm wide below the umbilicus (Beer, 2009). An abnormally wide separation may reflect diastasis recti or hernia.

FIGURE 2-1
Anterior abdominal wall anatomy. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



These three aponeuroses also invest the rectus abdominis muscle as the rectus sheath. The construction of this sheath varies above and below a boundary, termed the arcuate line (see Fig. 2-1). Cephalad to this border, the aponeuroses invest the rectus abdominis bellies on both dorsal and ventral surfaces. Caudal to this line,

all aponeuroses lie ventral or superficial to the rectus abdominis muscle, and only the thin transversalis fascia and peritoneum lie beneath the rectus (Loukas, 2008). This transition of rectus sheath composition can be seen best in the upper third of a midline vertical abdominal incision.

The paired small triangular pyramidalis muscles originate from the pubic crest and insert into the linea alba. These muscles lie atop the rectus abdominis muscle but beneath the anterior rectus sheath.

Blood Supply

The superficial epigastric, superficial circumflex iliac, and superficial external pudendal arteries arise from the femoral artery just below the inguinal ligament within the femoral triangle (see Fig. 2-1). These vessels supply the skin and subcutaneous layers of the anterior abdominal wall and mons pubis. Of these three, the superficial epigastric vessels are surgically important to the obstetrician and course diagonally from their origin toward the umbilicus. With a low transverse skin incision, these vessels can usually be identified at a depth halfway between the skin and the anterior rectus sheath. They lie above Scarpa fascia and several centimeters from the midline. Ideally, these vessels are identified and surgically occluded.

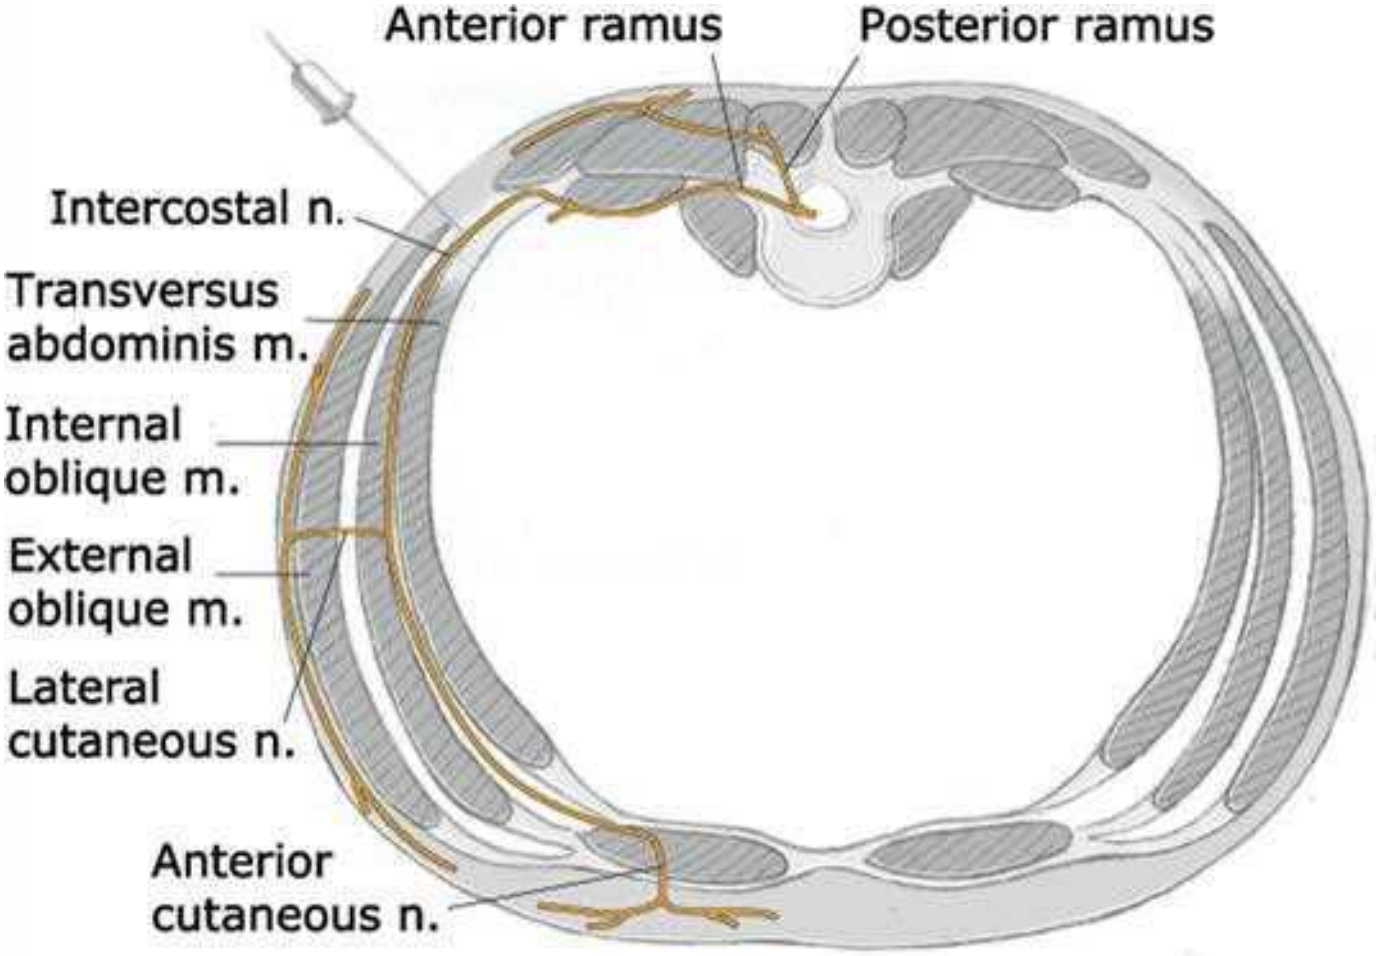
In contrast, the inferior “deep” epigastric vessels are branches of the external iliac vessels and supply anterior abdominal wall muscles and fascia. Of surgical relevance, the inferior epigastric vessels initially course lateral to, then posterior to the rectus abdominis muscles, which they supply. Above the arcuate line, these vessels course ventral to the posterior rectus sheath and lie between this sheath and the posterior surface of the rectus muscles. Near the umbilicus, the inferior epigastric vessels anastomose with the superior epigastric artery and vein, which are branches of the internal thoracic vessels. Clinically, when a Maylard incision is used for cesarean delivery, the inferior epigastric vessels may be lacerated lateral to the rectus belly during muscle transection. Preventively, identification and surgical occlusion are preferable. These vessels rarely may rupture following abdominal trauma and create a rectus sheath hematoma (Tolcher, 2010; Wai, 2015).

On each side of the lower anterior abdominal wall, Hesselbach triangle is the region bounded laterally by the inferior epigastric vessels, inferiorly by the inguinal ligament, and medially by the lateral border of the rectus abdominis muscle. Hernias that protrude through the abdominal wall in Hesselbach triangle are termed direct inguinal hernias. In contrast, indirect inguinal hernias do so through the deep inguinal ring, which lies lateral to this triangle, and then may exit out the superficial inguinal ring.

Innervation

The entire anterior abdominal wall is innervated by intercostal nerves ($T_{7–11}$), the subcostal nerve (T_{12}), and the iliohypogastric and the ilioinguinal nerves (L_1). Of these, the intercostal and subcostal nerves are anterior rami of the thoracic spinal nerves and run along the lateral and then anterior abdominal wall between the transversus abdominis and internal oblique muscles (Fig. 2-2). This space, termed the transversus abdominis plane, can be used for postcesarean analgesia blockade (Chap. 25, Postpartum Analgesia) (Fusco, 2015; Tawfik, 2017). Others report rectus sheath or ilioinguinal-iliohypogastric nerve blocks to decrease postoperative pain (Mei, 2011; Wolfson, 2012).

FIGURE 2-2
Intercostal and subcostal nerves are the anterior rami of spinal nerves. In this figure, an intercostal nerve extends ventrally between the transversus abdominis and internal oblique muscles. During this path, the nerve gives rise to lateral and anterior cutaneous branches, which innervate the anterior abdominal wall. As shown by the inserted needle, the transversus abdominis plane (TAP) block takes advantage of this anatomy. (Modified with permission from Hawkins JL: Anesthesia for the pregnant woman. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstraps’s Operative Obstetrics, 3rd ed. New York, McGraw Hill Education, 2017.)



Near the rectus abdominis lateral borders, anterior branches of the intercostal and subcostal nerves pierce the posterior sheath, rectus muscle, and then anterior sheath to reach the skin. Thus, these nerve branches may be severed during a Pfannenstiel incision creation during the step in which the overlying anterior rectus sheath is separated from the rectus abdominis muscle.

In contrast, the iliohypogastric and ilioinguinal nerves originate from the anterior ramus of the first lumbar spinal nerve. They emerge lateral to the psoas muscle and travel retroperitoneally across the quadratus lumborum inferomedially toward the iliac crest. Near this crest, both nerves pierce the transversus abdominis muscle and course ventromedially. At a site 2 to 3 cm medial to the anterior superior iliac spine, the nerves then pierce the internal oblique muscle and course superficial to it toward the midline (Whiteside, 2003). The iliohypogastric nerve perforates the external oblique aponeurosis near the lateral rectus border to provide sensation to the skin over the suprapubic area (see Fig. 2-1). The ilioinguinal nerve in its course medially travels through the inguinal canal and exits through the superficial inguinal ring, which forms by splitting of external abdominal oblique aponeurosis fibers. This nerve supplies the skin of the mons pubis, upper labia majora, and medial upper thigh.

The ilioinguinal and iliohypogastric nerves can be severed during a low transverse incision or entrapped during closure, especially if incisions extend beyond the lateral borders of the rectus abdominis muscle (Rahn, 2010). These nerves carry sensory information only, and injury leads to loss of sensation within the areas supplied. Rarely, chronic pain may develop (Whiteside, 2005).

The T_{10} dermatome approximates the level of the umbilicus. Analgesia to this level is suitable for labor and vaginal birth. Regional analgesia for cesarean delivery or for puerperal sterilization ideally extends to T_4.

EXTERNAL GENERATIVE ORGANS

Vulva

Mons Pubis, Labia, and Clitoris

The pudenda—commonly designated the vulva—includes all structures visible externally from the symphysis pubis to the perineal body. This includes the mons pubis, labia majora and minora, clitoris, hymen, vestibule, urethral opening, greater vestibular or Bartholin glands, minor vestibular glands, and paraurethral glands (Fig. 2-3). The vulva receives innervations and vascular support from the pudendal nerve (Pudendal Nerve).

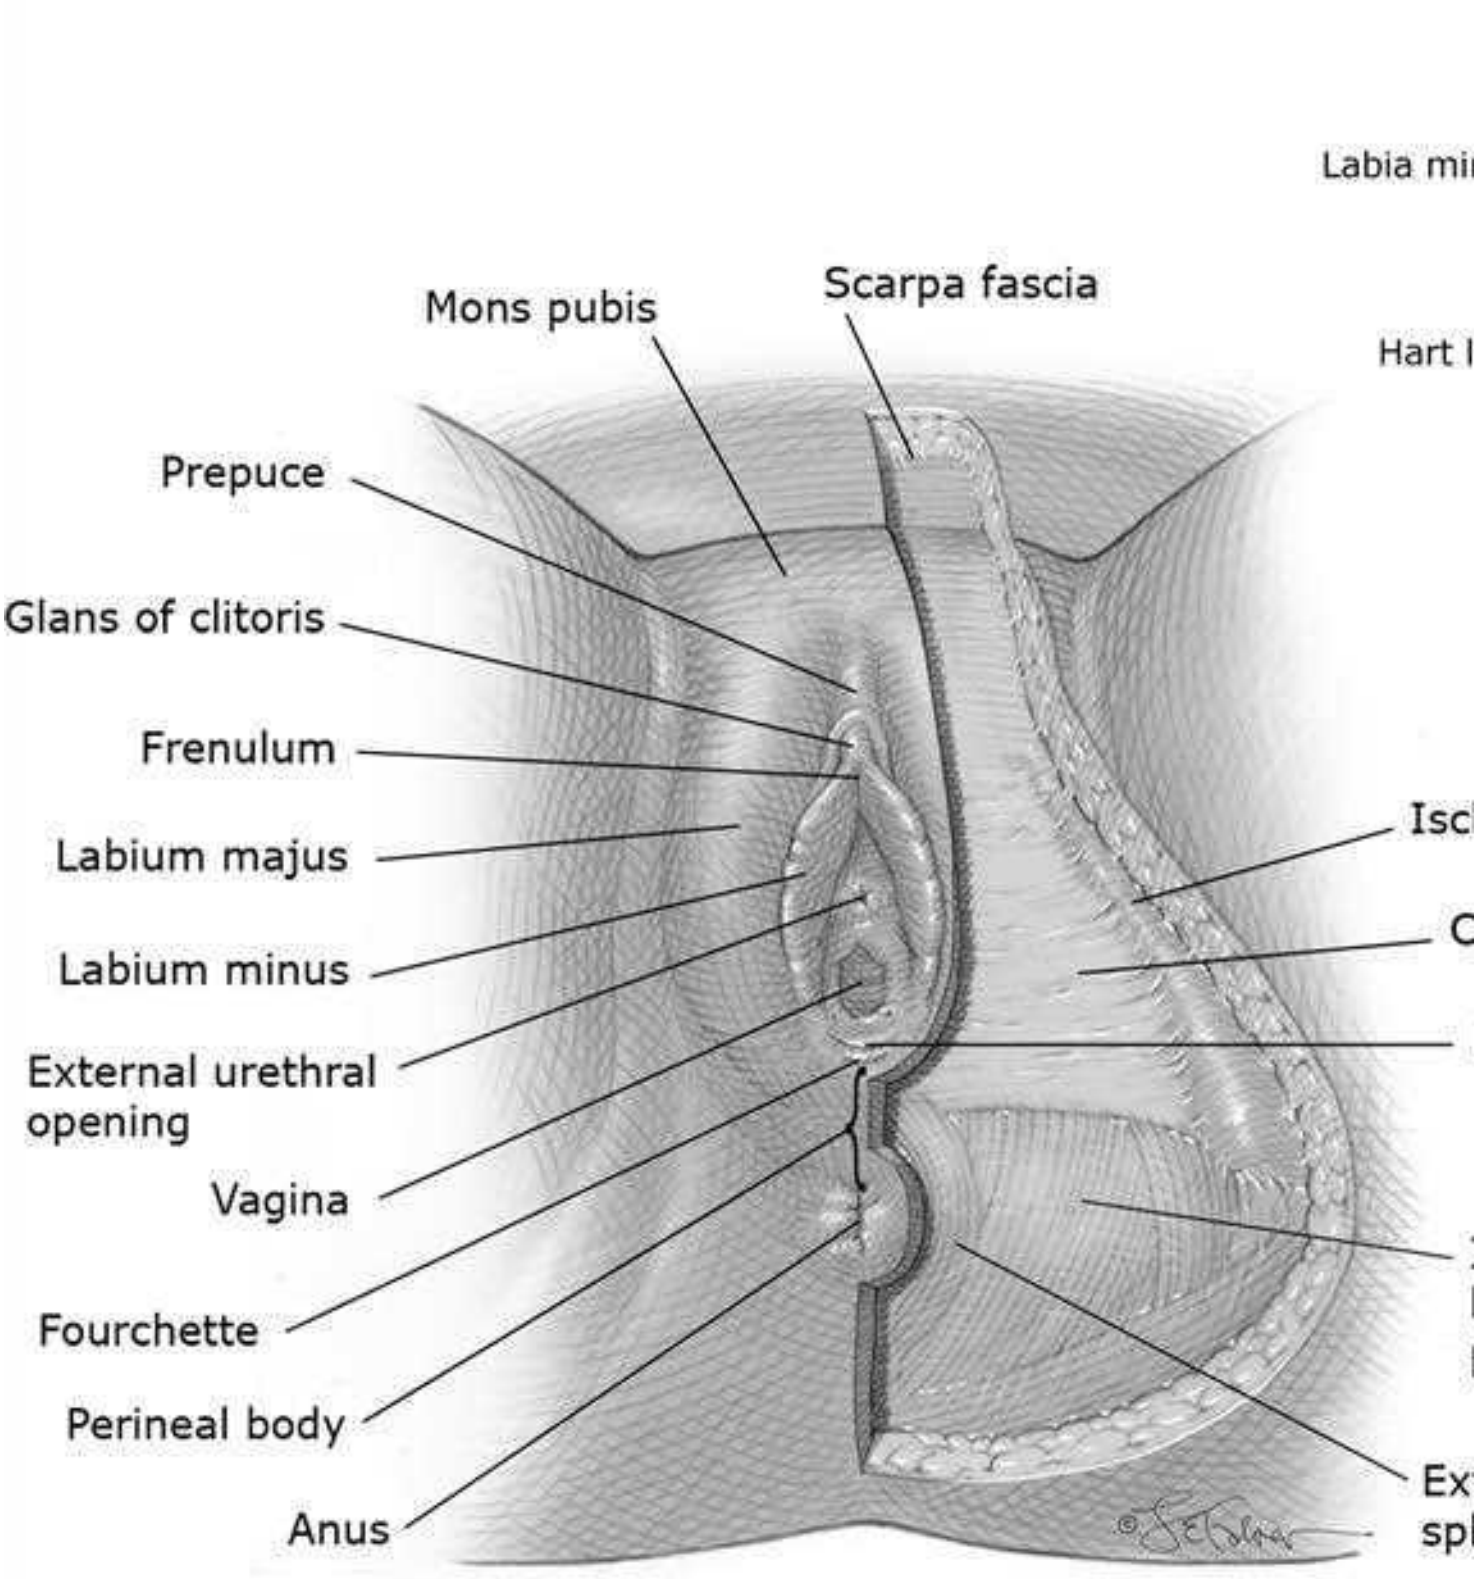
York, McGraw-Hill Education, 2016.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

The mons pubis is a fat-filled cushion overlying the symphysis pubis. After puberty, the mons pubis skin is covered by curly hair that forms the triangular escutcheon, whose base aligns with the upper margin of the symphysis pubis. In men and some hirsute women, the escutcheon extends farther onto the anterior abdominal wall toward the umbilicus.

Labia majora usually are 7 to 8 cm long, 2 to 3 cm wide, and 1 to 1.5 cm thick. They are continuous directly with the mons pubis superiorly, and the round ligaments terminate at their upper borders. Hair covers the labia majora, and apocrine, eccrine, and sebaceous glands are abundant. Beneath the skin, a dense connective tissue layer is nearly void of muscular elements but is rich in elastic fibers and fat. This fat mass provides bulk to the labia majora and is supplied with a rich venous

plexus. During pregnancy, this vasculature may develop varicosities, especially in multiparas, from increased venous pressure created by the enlarging uterus. They appear as engorged tortuous veins or as small grapelike clusters, but they are typically asymptomatic and require no treatment.

Each labium minus is a thin tissue fold that lies medial to each labium majus. The labia minora extend superiorly, where each divides into two lamellae. From each side, the lower lamellae fuse to form the frenulum of the clitoris, and the upper lamellae merge to form the prepuce (see Fig. 2-3). Inferiorly, the labia minora extend to approach the midline as low ridges of tissue that join to form the fourchette. The labia minora dimensions vary greatly among individuals, with lengths from 2 to 10 cm and widths from 1 to 5 cm (Lloyd, 2005).

Structurally, the labia minora are composed of connective tissue with numerous vessels, elastin fibers, and very few smooth muscle fibers. They are supplied with many nerve endings and are extremely sensitive (Ginger, 2011a; Schober, 2015). The epithelia of the labia minora differ with location. Thinly keratinized stratified squamous epithelium covers the outer surface of each labium. On their inner surface, the lateral portion is covered by this same epithelium up to a demarcating line, termed Hart line. Medial to this line, each labium is covered by squamous epithelium that is nonkeratinized. The labia minora lack hair follicles, eccrine glands, and apocrine glands. However, sebaceous glands are numerous (Wilkinson, 2011).

The clitoris is the principal female erogenous organ. It is located beneath the prepuce, above the frenulum and urethra, and projects downward and inward toward the vaginal opening. The clitoris rarely exceeds 2 cm in length and is composed of a glans, a corpus or body, and two crura (Verkauf, 1992). The glans is usually less than 0.5 cm in diameter, is covered by stratified squamous epithelium, and is richly innervated. The clitoral body contains two corpora cavernosa. Extending from the clitoral body, each corpus cavernosum diverges laterally to form a long, narrow crus. Each crus lies along the inferior surface of its respective ischiopubic ramus and deep to the ischiocavernosus muscle. The clitoral blood supply stems from branches of the internal pudendal artery. Specifically, the deep artery of the clitoris supplies the clitoral body, whereas the dorsal artery of the clitoris supplies the glans and prepuce.

Vestibule

In adult women, the vestibule is an almond-shaped area that is enclosed by Hart line laterally, the external surface of the hymen medially, the clitoral frenulum anteriorly, and the fourchette posteriorly (see Fig. 2-3). The vestibule is usually perforated by six openings: the urethra, the vagina, two Bartholin gland ducts, and two ducts of the largest paraurethral glands—the Skene glands. The posterior portion of the vestibule between the fourchette and the vaginal opening is called the fossa navicularis. It is usually observed only in nulliparas.

The bilateral Bartholin glands, also termed greater vestibular glands, measure 0.5 to 1 cm in diameter. On their respective side, each lies inferior to the vestibular bulb and deep to the inferior end of the bulbospongiosus muscle (former bulbocavernosus muscle). A duct extends medially from each gland, measures 1.5 to 2 cm long, and opens distal to the hymeneal ring—one at 5 and the other at 7 o'clock on the vestibule. Following trauma or infection, either duct may swell and obstruct to form a cyst or, if infected, an abscess. In contrast, the minor vestibular glands are shallow glands lined by simple mucin-secreting epithelium and open along Hart line.

The paraurethral glands are a collective arborization of glands whose numerous small ducts open predominantly along the entire inferior aspect of the urethra. The two largest are called Skene glands, and their ducts typically lie distally and near the urethral meatus. Clinically, inflammation and duct obstruction of any of the paraurethral glands can lead to urethral diverticulum formation. The urethral opening or meatus is in the midline of the vestibule, 1 to 1.5 cm below the pubic arch, and a short distance above the vaginal opening.

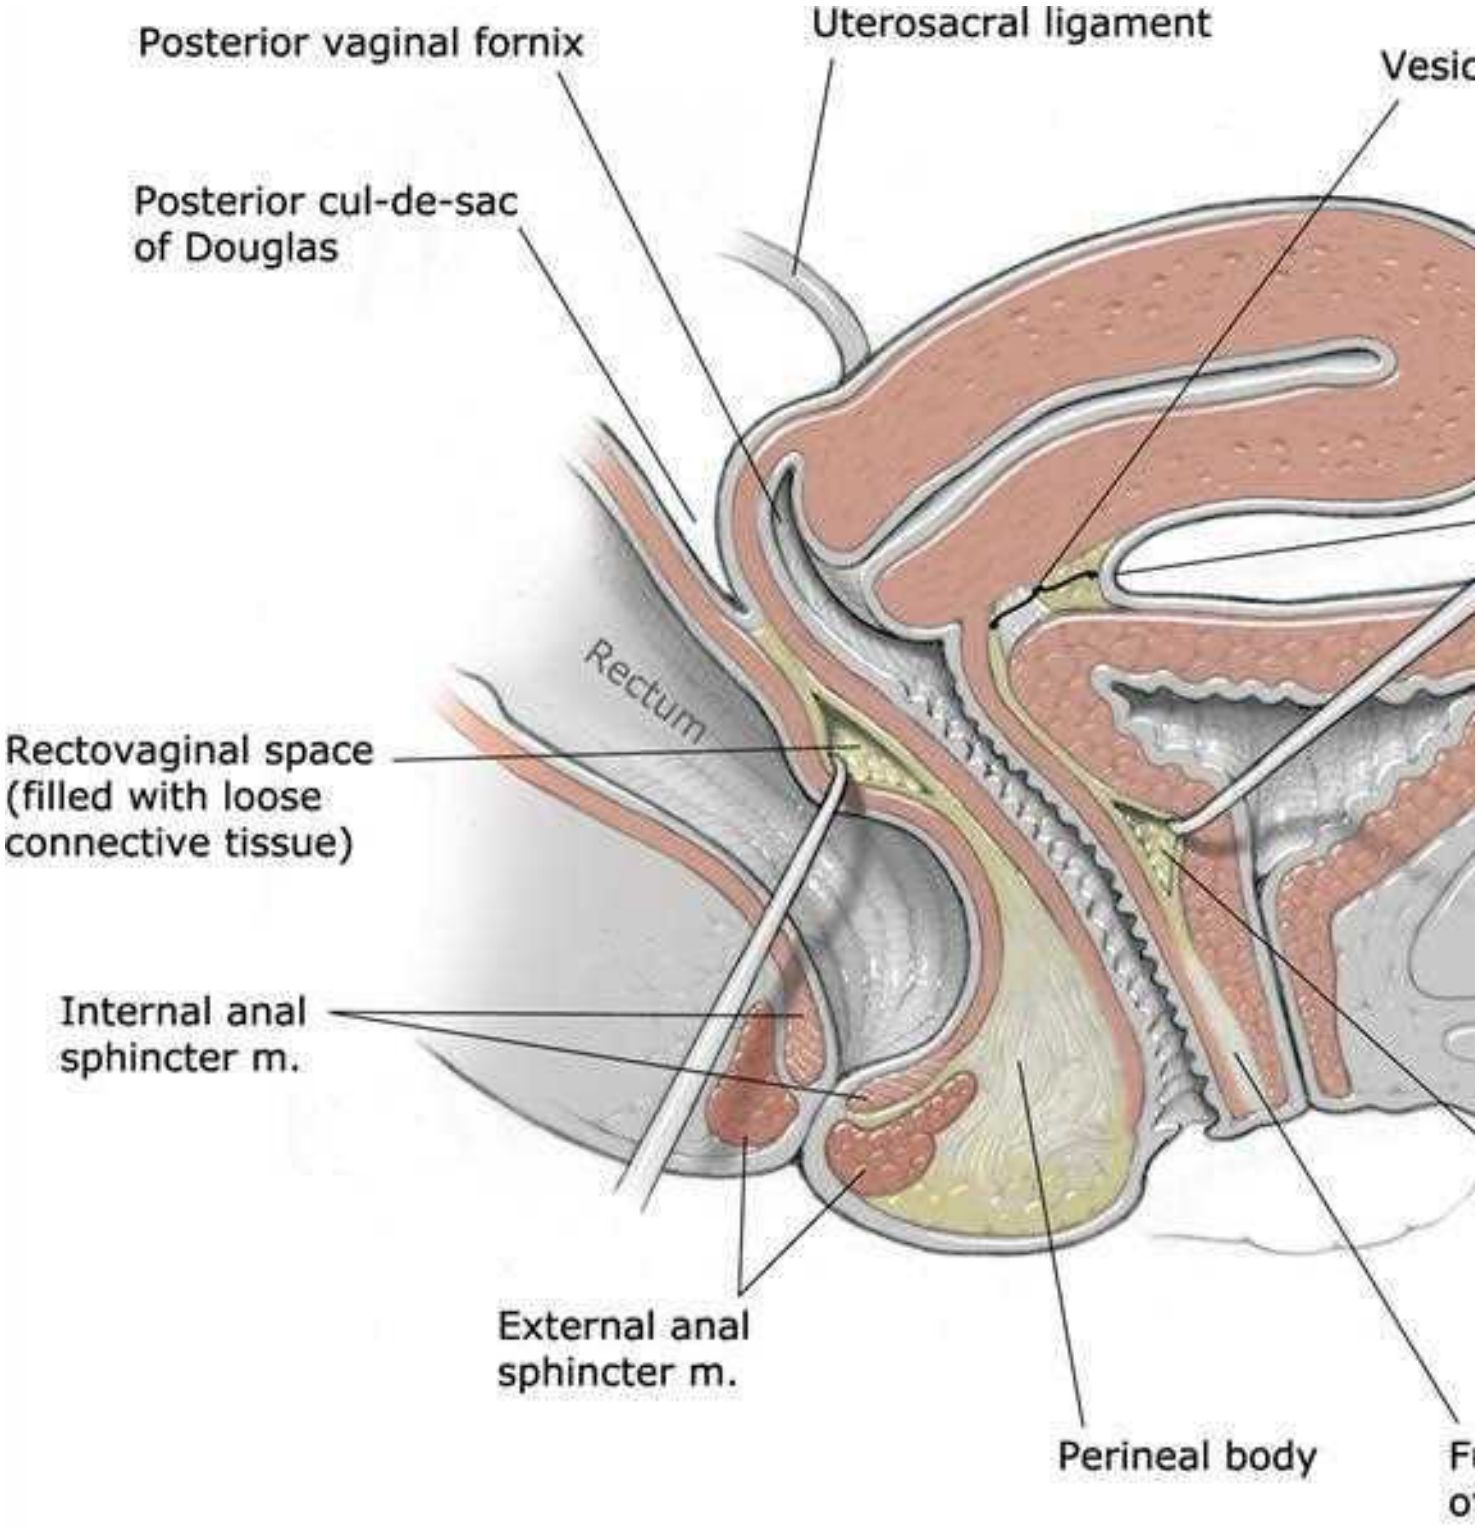
Vagina and Hymen

In adult women, the hymen is a membrane of varying thickness that surrounds the vaginal opening more or less completely. It is composed mainly of elastic and collagenous connective tissue, and both outer and inner surfaces are covered by nonkeratinized stratified squamous epithelium. The aperture of the intact hymen ranges in diameter from pinpoint to one that admits one or even two fingertips. As a rule, the hymen is torn at several sites during first coitus. However, identical tears may form by other penetration, for example, by tampons used during menstruation. The edges of the torn tissue soon reepithelialize. In pregnant women, the hymeneal epithelium is thick and rich in glycogen. Changes produced in the hymen by childbirth are usually readily recognizable. For example, over time, the hymen transforms into several nodules of various sizes, termed hymeneal or myrtiform caruncles.

Proximal to the hymen, the vagina is a musculomembranous tube that extends to the uterus and is interposed lengthwise between the bladder and the rectum (Fig. 2-4). Anteriorly, the vagina is separated from the bladder and urethra by connective tissue—the vesicovaginal septum. Posteriorly, between the lower portion of the vagina and the rectum, similar tissues together form the rectovaginal septum. The upper fourth of the vagina is separated from the rectum by the rectouterine pouch, also called the cul-de-sac or pouch of Douglas.

FIGURE 2-4

Vagina and surrounding anatomy. (Reproduced with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Normally, the anterior and posterior walls of the vaginal lumen lie in contact, with only a slight space intervening at the lateral margins. Vaginal length varies considerably, but commonly, the anterior wall measures 6 to 8 cm, whereas the posterior vaginal wall is 7 to 10 cm. The upper end of the vaginal vault is subdivided by the cervix into anterior, posterior, and two lateral fornices. Clinically, the internal pelvic organs usually can be palpated through the thin walls of these fornices.

The vaginal lining is composed of nonkeratinized stratified squamous epithelium and underlying lamina propria. In premenopausal women, this lining is thrown into numerous thin transverse ridges, known as rugae, which line the anterior and posterior vaginal walls along their length. Deep to this, a muscular layer contains smooth muscle, collagen, and elastin. Beneath this muscularis lies an adventitial layer consisting of collagen and elastin (Weber, 1997).

The vagina lacks glands. Instead, it is lubricated by a transudate that originates from the vaginal subepithelial capillary plexus and crosses the permeable epithelium (Kim, 2011). Due to increased vascularity during pregnancy, vaginal secretions are notably increased. At times, this may be confused with amnionic fluid leakage, and clinical differentiation of these two is described in Chapter 22 (Identification of Labor).

After birth-related epithelial trauma and healing, fragments of stratified epithelium occasionally are embedded beneath the vaginal surface. Similar to its native tissue, this buried epithelium continues to shed degenerated cells and keratin. As a result, epidermal inclusion cysts, which are filled with keratin debris, may form. These are a common vaginal cyst.

The vagina has an abundant vascular supply. The proximal portion is supplied by the cervical branch of the uterine artery and by the vaginal artery. The latter may variably arise from the uterine or inferior vesical artery or directly from the internal iliac artery. The middle rectal artery contributes supply to the posterior vaginal wall, whereas the distal walls receive contributions from the internal pudendal artery. At each level, vessels supplying each side of the vagina course medially across the anterior or posterior vaginal wall and form midline anastomoses.

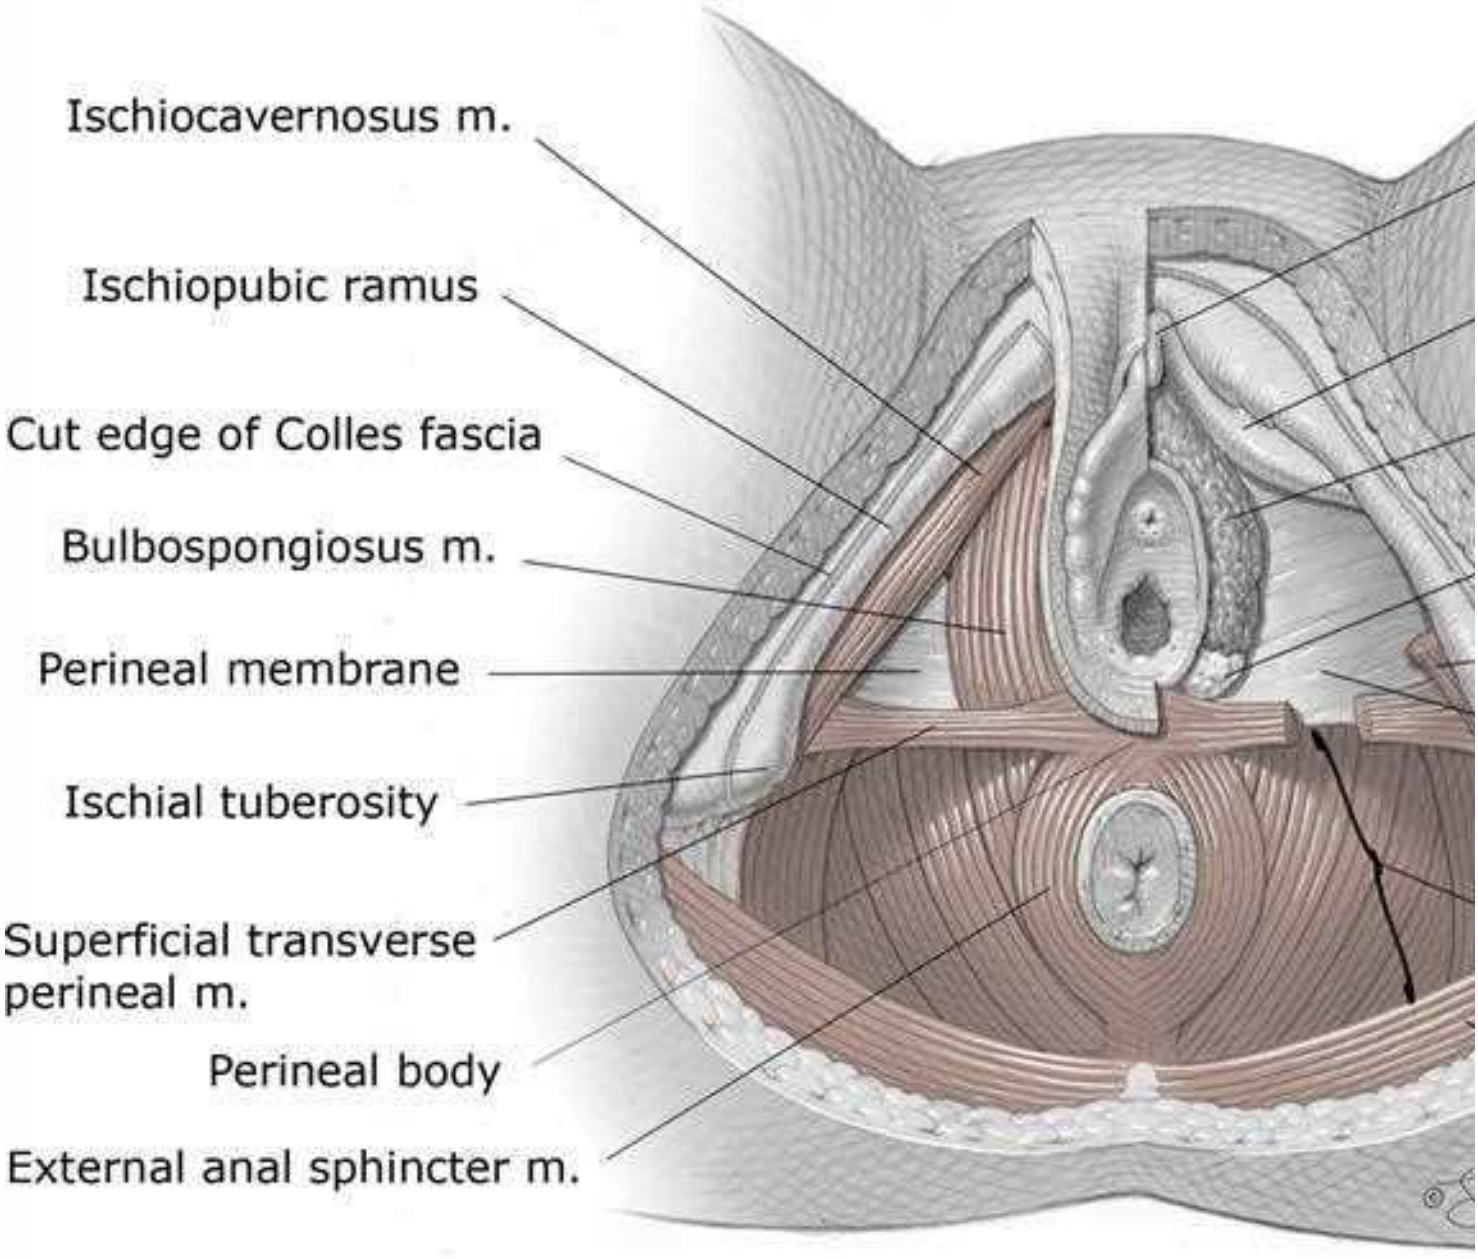
An extensive venous plexus also surrounds the vagina and follows the course of the arteries. Lymphatics from the lower third, along with those of the vulva, drain primarily into the inguinal lymph nodes. Those from the middle third drain into the internal iliac nodes, and those from the upper third drain into the external, internal, and common iliac nodes.

Perineum

This diamond-shaped area between the thighs has boundaries that mirror those of the bony pelvic outlet: the pubic symphysis anteriorly, ischiopubic rami and ischial tuberosities anterolaterally, sacrotuberous ligaments posterolaterally, and coccyx posteriorly. An arbitrary line joining the ischial tuberosities divides the perineum into an anterior triangle, also called the urogenital triangle, and a posterior triangle, termed the anal triangle.

The perineal body is a fibromuscular pyramidal mass found in the midline at the junction between these anterior and posterior triangles (Fig. 2-5). Also called the central tendon of the perineum, the perineal body sonographically measures 8 mm tall and 14 mm wide and thick (Santoro, 2016). It serves as the junction for several structures and provides significant perineal support (Shafik, 2007). Superficially, the bulbospongiosus, superficial transverse perineal, and external anal sphincter muscles converge on the perineal body. More deeply, the perineal membrane, portions of the pubococcygeus muscle, and internal anal sphincter contribute (Larson, 2010). The perineal body is incised by an episiotomy incision and is torn with second-, third-, and fourth-degree lacerations.

FIGURE 2-5
Superficial space of the anterior perineal triangle and posterior perineal triangle. Structures on the left side of the image can be seen after removal of Colles fascia. Those on the right side are noted after removal of the superficial muscles of the anterior triangle. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Superficial Space of the Anterior Triangle

This triangle is bounded by the pubic rami superiorly, the ischial tuberosities laterally, and the superficial transverse perineal muscles posteriorly. It is divided into superficial and deep spaces by the perineal membrane. This membranous partition is a dense fibrous sheet that was previously known as the inferior fascia of the urogenital diaphragm. The perineal membrane attaches laterally to the ischiopubic rami, medially to the distal third of the urethra and vagina, posteriorly to the perineal body, and anteriorly to the arcuate ligament of the pubis (see Fig. 2-5).

The superficial space of the anterior triangle is bounded deeply by the perineal membrane and superficially by Colles fascia. As noted earlier, Colles fascia is the continuation of Scarpa fascia onto the perineum. On the perineum, Colles fascia securely attaches laterally to the pubic rami and fascia lata of the thigh, inferiorly to the superficial transverse perineal muscle and inferior border of the perineal membrane, and medially to the urethra, clitoris, and vagina. As such, the superficial space of the anterior triangle is a relatively closed compartment.

This superficial pouch contains several important structures, which include the Bartholin glands, vestibular bulbs, clitoral body and crura, branches of the pudendal vessels and nerve, and the ischiocavernosus, bulbospongiosus, and superficial transverse perineal muscles. Of these muscles, the ischiocavernosus muscles each attach on their respective side to the medial aspect of the ischial tuberosity inferiorly and the ischiopubic ramus laterally. Anteriorly, each attaches to a clitoral crus and may help maintain clitoral erection by compressing the crus to obstruct venous drainage. The bilateral bulbospongiosus muscles overlie the vestibular bulbs and Bartholin glands. They attach to the body of the clitoris anteriorly and the perineal body posteriorly. The muscles constrict the vaginal lumen and aid release of secretions from the Bartholin glands. They also may contribute to clitoral erection by compressing the deep dorsal vein of the clitoris. The bulbospongiosus and ischiocavernosus muscles also pull the clitoris downward. Last, the superficial transverse perineal muscles are narrow strips that attach to the ischial tuberosities laterally and the perineal body medially. They may be attenuated or even absent, but when present, they contribute to the perineal body (Corton, 2016).

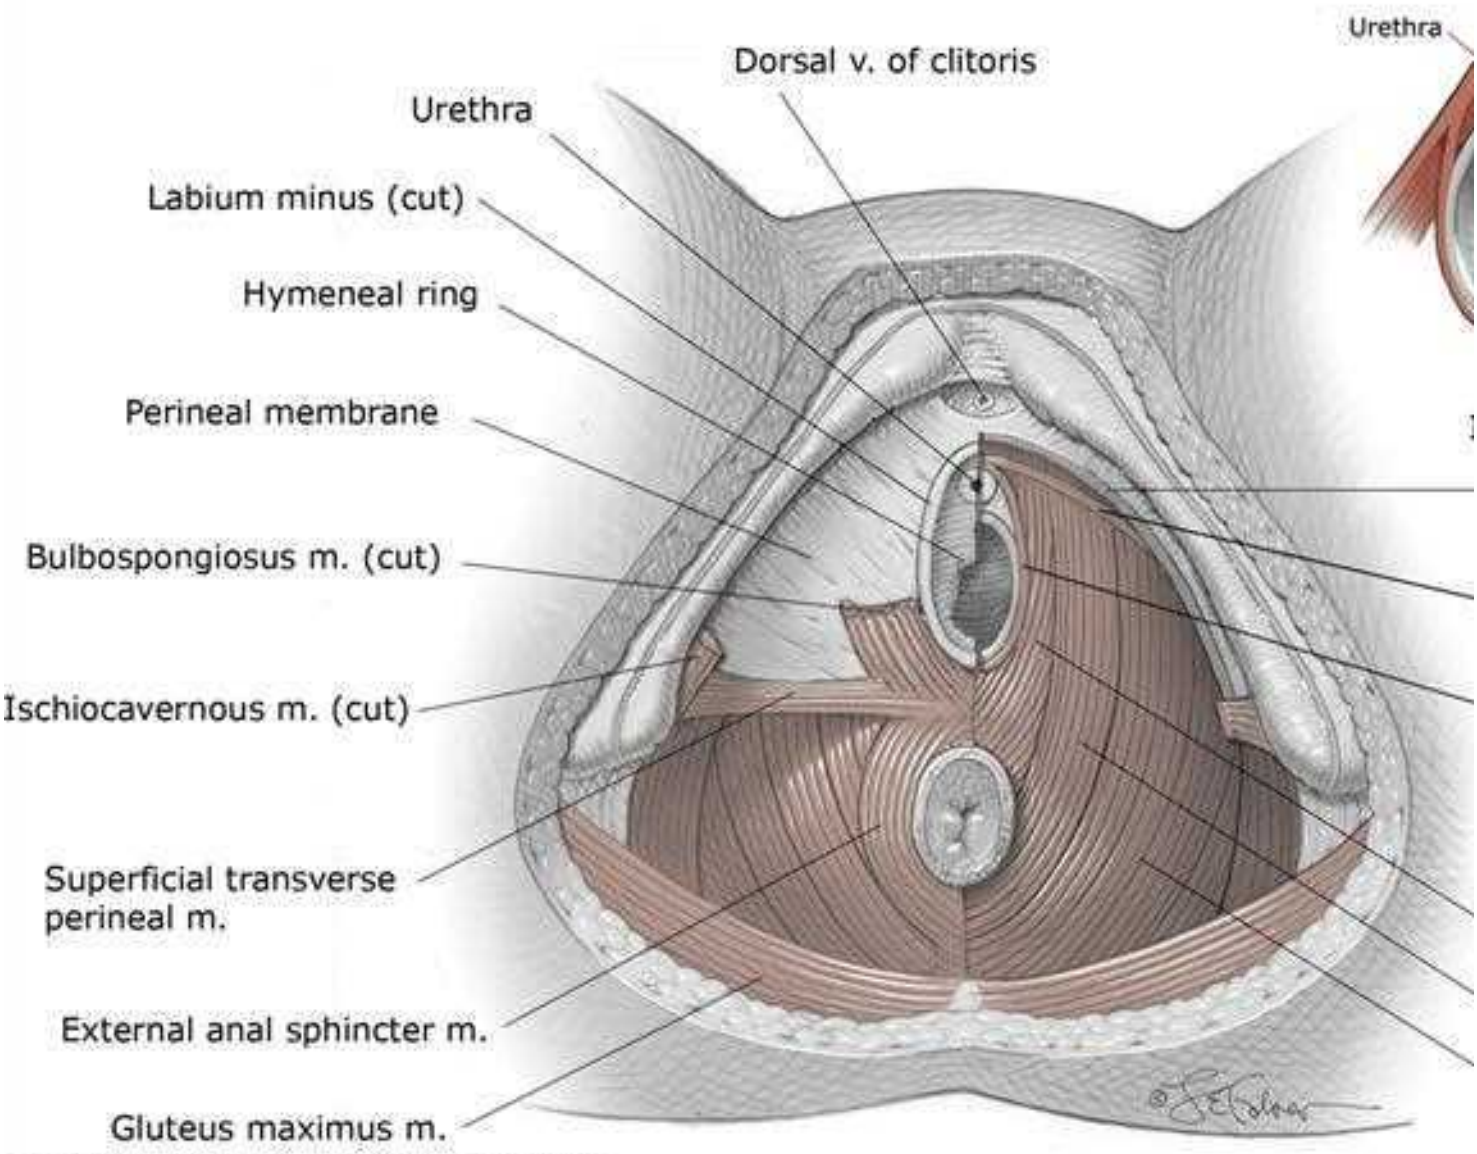
The vestibular bulbs are almond-shaped aggregations of veins that lie beneath the bulbospongiosus muscle on either side of the vestibule. They measure 3 to 4 cm long, 1 to 2 cm wide, and 0.5 to 1 cm thick. The bulbs terminate inferiorly at approximately the middle of the vaginal opening and extend upward toward the clitoris. Their anterior extensions merge in the midline, below the clitoral body. During childbirth, veins in the vestibular bulbs may be lacerated or even rupture to create a vulvar hematoma enclosed within the superficial space of the anterior triangle (Fig. 41-11).

Deep Space of the Anterior Triangle

This space lies deep to the perineal membrane and extends up into the pelvis (Mirilas, 2004). In contrast to the superficial perineal space, the deep space is continuous superiorly with the pelvic cavity (Corton, 2005). It contains portions of urethra and vagina, certain portions of internal pudendal artery branches, and muscles of the striated urogenital sphincter complex (Fig. 2-6).

FIGURE 2-6

Deep space of anterior triangle of the perineum. Structures on the right side of the image can be seen after removal of the perineal membrane. Also shown are structures that attach to the perineal body: bulbospongiosus, superficial transverse perineal, external anal sphincter, and puboperinealis muscles as well as perineal membrane. (Reproduced with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Urethra

The female urethra measures 3 to 4 cm and originates within the bladder trigone (Ovaries). The distal two thirds of the urethra are fused with the anterior vaginal wall. The epithelial lining of the urethra changes from transitional epithelium proximally to nonkeratinized stratified squamous epithelium distally. The walls of the urethra consist of two layers of smooth muscle, an inner longitudinal and an outer circular. This is in turn surrounded by a circular layer of skeletal muscle referred to

as the *sphincter urethrae* or *rhabdosphincter* (see Fig. 2-6). Approximately at the junction of the middle and lower third of the urethra, and just above or deep to the perineal membrane, two strap skeletal muscles called the *urethrovaginal sphincter* and *compressor urethrae* are found. Together with the sphincter urethrae, these constitute the *striated urogenital sphincter complex.* This complex supplies constant tonus and provides emergency reflex contraction to sustain continence.

Distal to the level of the perineal membrane, the walls of the urethra consist of fibrous tissue, serving as the nozzle that directs the urine stream. Here, the urethra has a prominent submucosal layer that is lined by hormonally sensitive stratified squamous epithelium. Within the submucosal layer on the dorsal (vaginal) surface of the urethra lie the paraurethral glands, described earlier (Vagina and Hymen).

The urethra receives its blood supply from branches of the inferior vesical, vaginal, or internal pudendal arteries. Although still controversial, the pudendal nerve is believed to innervate the most distal part of the striated urogenital sphincter complex. Somatic efferent branches from S_2–S_4 that course along the inferior hypogastric plexus variably innervate the sphincter urethrae.

Pelvic Diaphragm

Found deep to the anterior and posterior triangles, this broad muscular sling provides substantial support to the pelvic viscera. The pelvic diaphragm is composed of the levator ani and the coccygeus muscles. The levator ani, in turn, contains the pubococcygeus, puborectalis, and iliococcygeus muscles. The pubococcygeus muscle is also termed the pubovisceral muscle and is subdivided based on points of insertion and function. These include the pubovaginalis, puboperinealis, and puboanalis muscles, which insert into the vagina, perineal body, and anus, respectively (Kearney, 2004).

Vaginal birth conveys significant risk for damage to the levator ani or to its innervation (DeLancey, 2003; Weidner, 2006). Evidence supports that levator ani avulsion may predispose women to greater risk of pelvic organ prolapse (Dietz, 2008; Schwertner-Tiepelmann, 2012). For this reason, current research efforts are aimed at minimizing these injuries.

Posterior Triangle

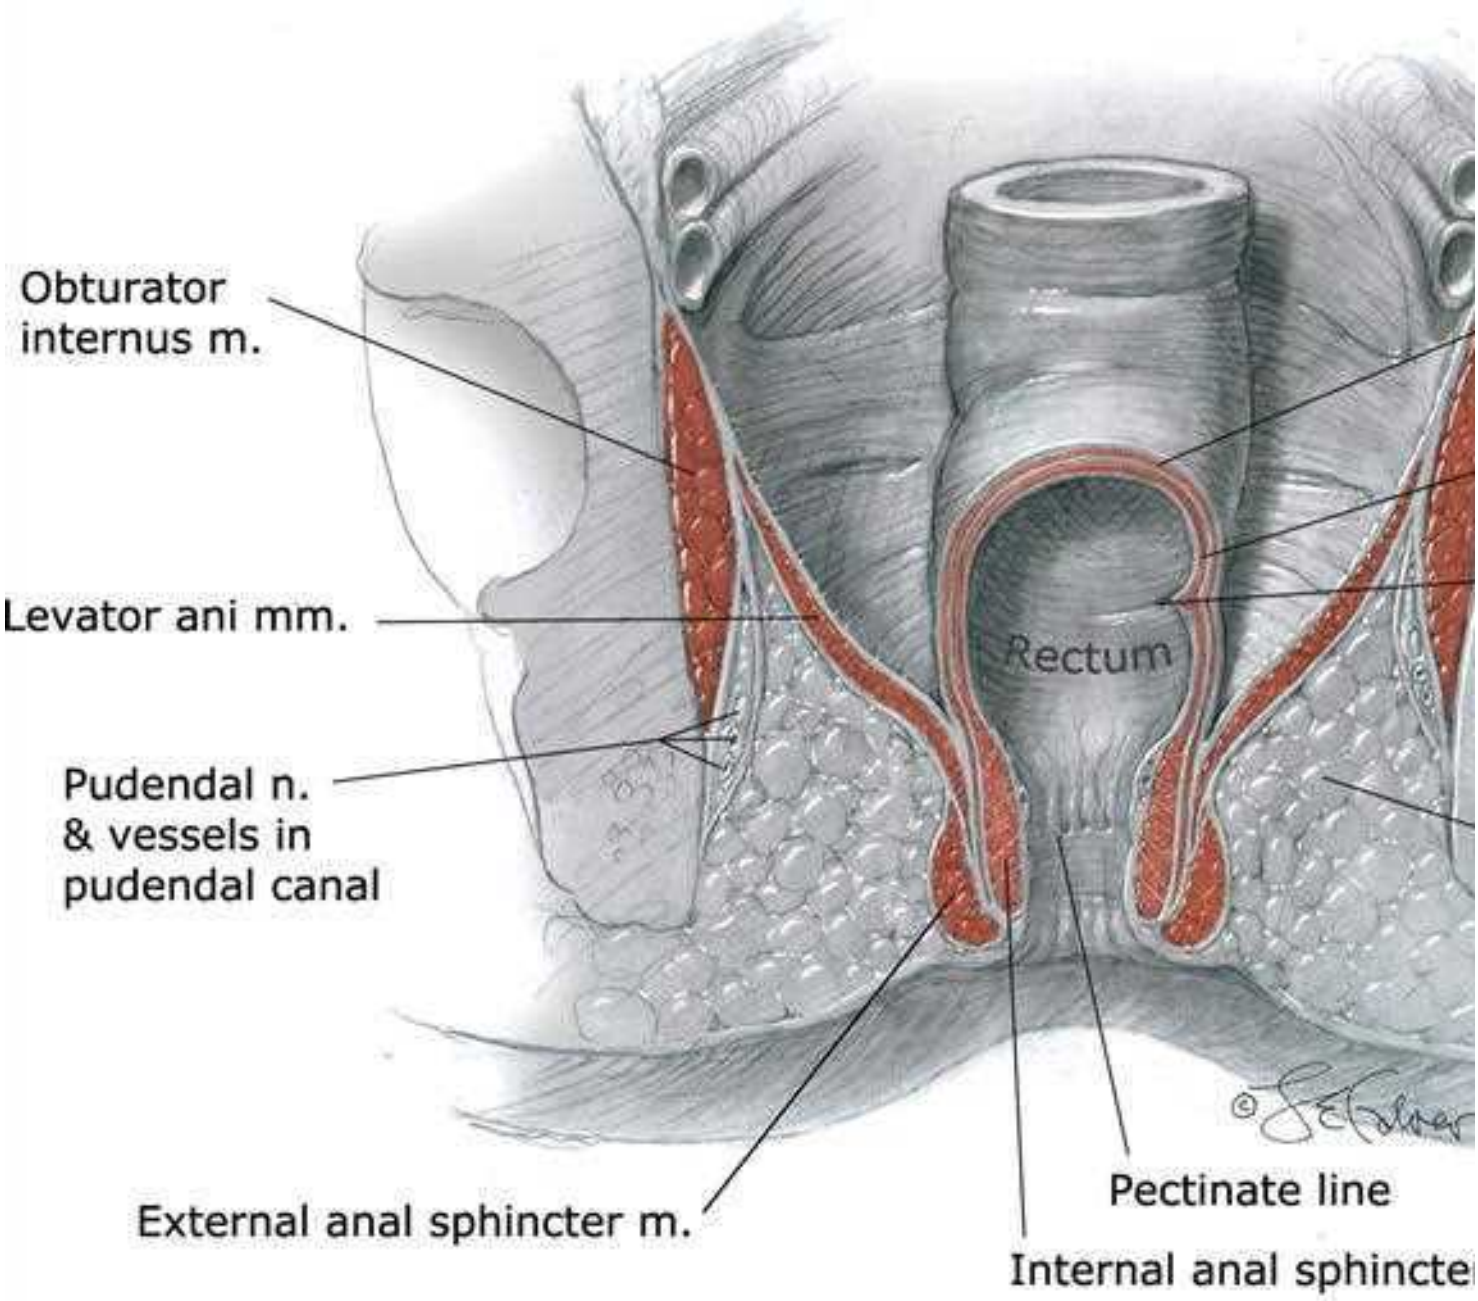
This triangle contains the ischioanal fossae, anal canal, and anal sphincter complex, which consists of the internal anal sphincter, external anal sphincter, and puborectalis muscle. Branches of the pudendal nerve and internal pudendal vessels are also found within this triangle.

Ischioanal Fossae

Also known as ischiorectal fossae, these two fat-filled wedge-shaped spaces are found on either side of the anal canal and comprise the bulk of the posterior triangle (Fig. 2-7). Each fossa has skin as its superficial base, whereas its deep apex is formed by the junction of the levator ani and obturator internus muscles. Other borders include: laterally, the obturator internus muscle fascia and ischial tuberosity; inferomedially, the anal canal and sphincter complex; superomedially, the inferior fascia of the downwardly sloping levator ani; posteriorly, the gluteus maximus muscle and sacrotuberous ligament; and anteriorly, the inferior border of the anterior triangle.

FIGURE 2-7

Anal canal and ischioanal fossa. (Reproduced with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



The fat found within each fossa provides support to surrounding organs yet allows rectal distention during defecation and vaginal stretching during delivery. Clinically, injury to vessels in the posterior triangle can lead to hematoma formation in the ischioanal fossa, and the potential for large accumulation in these easily distensible spaces. Moreover, the two fossae communicate dorsally, behind the anal canal. This can be especially important because an episiotomy infection or hematoma may extend from one fossa into the other.

Anal Canal

This distal continuation of the rectum begins at the level of levator ani attachment to the rectum and ends at the anal skin. Along this 4- to 5-cm length, the mucosa consists of columnar epithelium in the uppermost portion. However, at the pectinate line, also termed dentate line, simple stratified squamous epithelium begins and continues to the anal verge. At the verge, keratin and skin adnexa join the squamous epithelium.

The anal canal has several tissue layers (see Fig. 2-7). Inner layers include the anal mucosa, the internal anal sphincter, and an intersphincteric space that contains continuation of the rectum's longitudinal smooth muscle layer. An outer layer contains the puborectalis muscle as its cephalad component and the external anal sphincter caudally.

Within the anal canal, three highly vascularized submucosal arteriovenous plexuses, termed anal cushions, aid complete closure of the canal and fecal continence when apposed. Increasing uterine size, excessive straining, and hard stool create increased pressure that ultimately leads to degeneration and subsequent laxity of the cushion's supportive connective tissue base. These cushions then protrude into and downward through the anal canal. This leads to venous engorgement within the cushions—now termed hemorrhoids. Venous stasis results in inflammation, erosion of the cushion's epithelium, and then bleeding.

External hemorrhoids are those that arise distal to the pectinate line. They are covered by stratified squamous epithelium and receive sensory innervation from the inferior rectal nerve. Accordingly, pain and a palpable mass are typical complaints. Following resolution, a hemorrhoidal tag may remain and is composed of redundant anal skin and fibrotic tissue. In contrast, internal hemorrhoids are those that form above the pectinate line and are covered by insensitive anorectal mucosa. These may prolapse or bleed but rarely become painful unless they undergo thrombosis or necrosis.

Anal Sphincter Complex

Two sphincters surround the anal canal to provide fecal continence—the external and internal anal sphincters. Both lie near the vagina and may be torn during vaginal delivery. The internal anal sphincter (IAS) is a distal continuation of the rectal circular smooth muscle layer. It receives predominantly parasympathetic fibers, which pass through the pelvic splanchnic nerves. Along its length, this sphincter is supplied by the superior, middle, and inferior rectal arteries. The IAS contributes the bulk of anal canal resting pressure for fecal continence and relaxes prior to defecation. The IAS measures 3 to 4 cm in length, and at its distal margin, it overlaps the external sphincter for 1 to 2 cm (DeLancey, 1997). The distal site at which this overlap ends, called the intersphincteric groove, is palpable on digital examination.

In contrast, the external anal sphincter (EAS) is a striated muscle ring that anteriorly attaches to the perineal body and posteriorly connects to the coccyx via the anococcygeal ligament. The EAS maintains a constant resting contraction to aid continence, provides additional squeeze pressure when continence is threatened, yet relaxes for defecation. The external sphincter receives blood supply from the inferior rectal artery, which is a branch of the internal pudendal artery. Somatic motor fibers from the inferior rectal branch of the pudendal nerve supply innervation. Clinically, the IAS and EAS may be involved in third- and fourth-degree lacerations during vaginal delivery, and reunion of these rings is integral to defect repair (Chap. 27, Laceration and Episiotomy Repairs).

Pudendal Nerve

This is formed from the anterior rami of S_{2-4} spinal nerves. It courses between the piriformis and coccygeus muscles and exits through the greater sciatic foramen at a location posterior to the sacrospinous ligament and just medial to the ischial spine (Barber, 2002; Maldonado, 2015). Thus, when injecting local anesthetic for a pudendal nerve block, the ischial spine serves an identifiable landmark (Chap. 25, Central Nervous System Toxicity). The pudendal nerve then runs beneath the sacrospinous ligament and above the sacrotuberous ligament as it reenters the lesser sciatic foramen to course along the obturator internus muscle. Atop this muscle, the nerve lies within the pudendal canal, also known as Alcock canal, which is formed by splitting of the obturator internus investing fascia (Shafik, 1999). In general, the pudendal nerve is relatively fixed as it courses behind the sacrospinous ligament and within the pudendal canal. Accordingly, it may be at risk of stretch injury during downward displacement of the pelvic floor during childbirth (Lien, 2005).

The pudendal nerve leaves this canal to enter the perineum and divides into three terminal branches (Fig. 2-8). The first of these, the dorsal nerve of the clitoris, runs between the ischiocavernosus muscle and perineal membrane to supply the clitoral glans (Ginger, 2011b). Second, the perineal nerve runs superficial to the perineal membrane (Montoya, 2011). It divides into posterior labial branches and muscular branches, which serve the labial skin and the anterior perineal triangle muscles, respectively. Last, the inferior rectal branch runs through the ischioanal fossa to supply the external anal sphincter, the anal mucosa, and the perianal skin (Mahakkanukrauh, 2005). The major blood supply to the perineum is via the internal pudendal artery, and its branches mirror the divisions of the pudendal nerve.

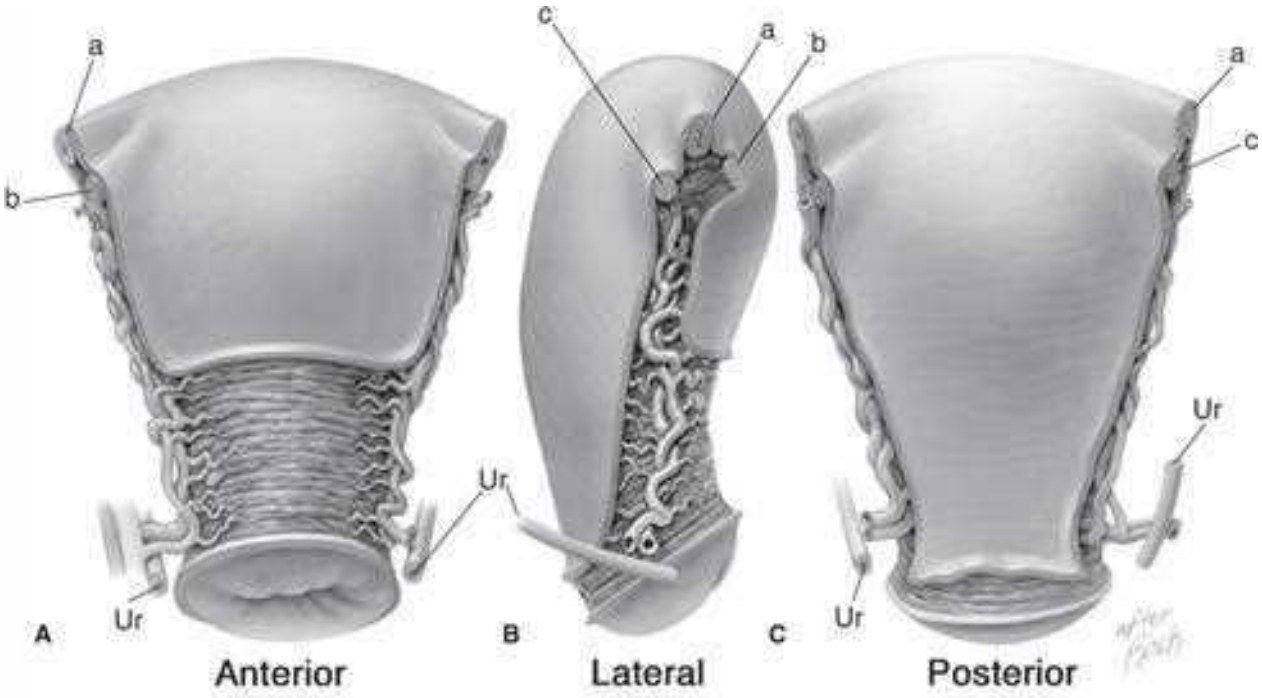
INTERNAL GENERATIVE ORGANS

Uterus

The nonpregnant uterus lies in the pelvic cavity between the bladder anteriorly and the rectum posteriorly. Almost the entire posterior wall of the uterus is covered by serosa, that is, visceral peritoneum (Fig. 2-9). The lower portion of this peritoneum forms the anterior boundary of the rectouterine cul-de-sac, or pouch of Douglas. Only the upper portion of the anterior uterine wall is covered by visceral peritoneum. At the caudal border of this portion, the peritoneum reflects forward onto the bladder dome to create the vesicouterine pouch. As a result, the lower portion of the anterior uterine wall is separated from the posterior wall of the bladder only by a well-defined loose connective tissue layer—the vesicouterine space. Clinically, during cesarean delivery, the peritoneum of the vesicouterine pouch is sharply incised, and the vesicouterine space is entered. Dissection caudally within this space lifts the bladder safely off the lower uterine segment for hysterotomy and delivery (Chap. 30, Hysterotomy).

FIGURE 2-9

Anterior **(A)**, right lateral **(B)**, and posterior **(C)** views of the uterus of an adult woman. a = oviduct; b = round ligament; c = ovarian ligament; Ur = ureter.



The uterus is pear shaped and consists of two major but unequal parts. The upper, larger portion is the body or corpus, whereas the lower smaller cervix projects into the vagina. The isthmus is the union site of these two. It is of special obstetrical significance because it forms the lower uterine segment during pregnancy. At each superolateral margin of the body is a uterine cornu, from which a fallopian tube emerges. This area also contains the origins of the round and ovarian ligaments. Between the points of fallopian tube insertion is the convex upper uterine segment termed the fundus.

The bulk of the uterine body, but not the cervix, is muscle. The inner surfaces of the anterior and posterior walls lie almost in contact, and the cavity between these walls forms a mere slit. The nulligravid uterus measures 6 to 8 cm in length compared with 9 to 10 cm in multiparas. The uterus averages 60 g and typically weighs more in parous women (Langlois, 1970; Sheikhazadi, 2010).

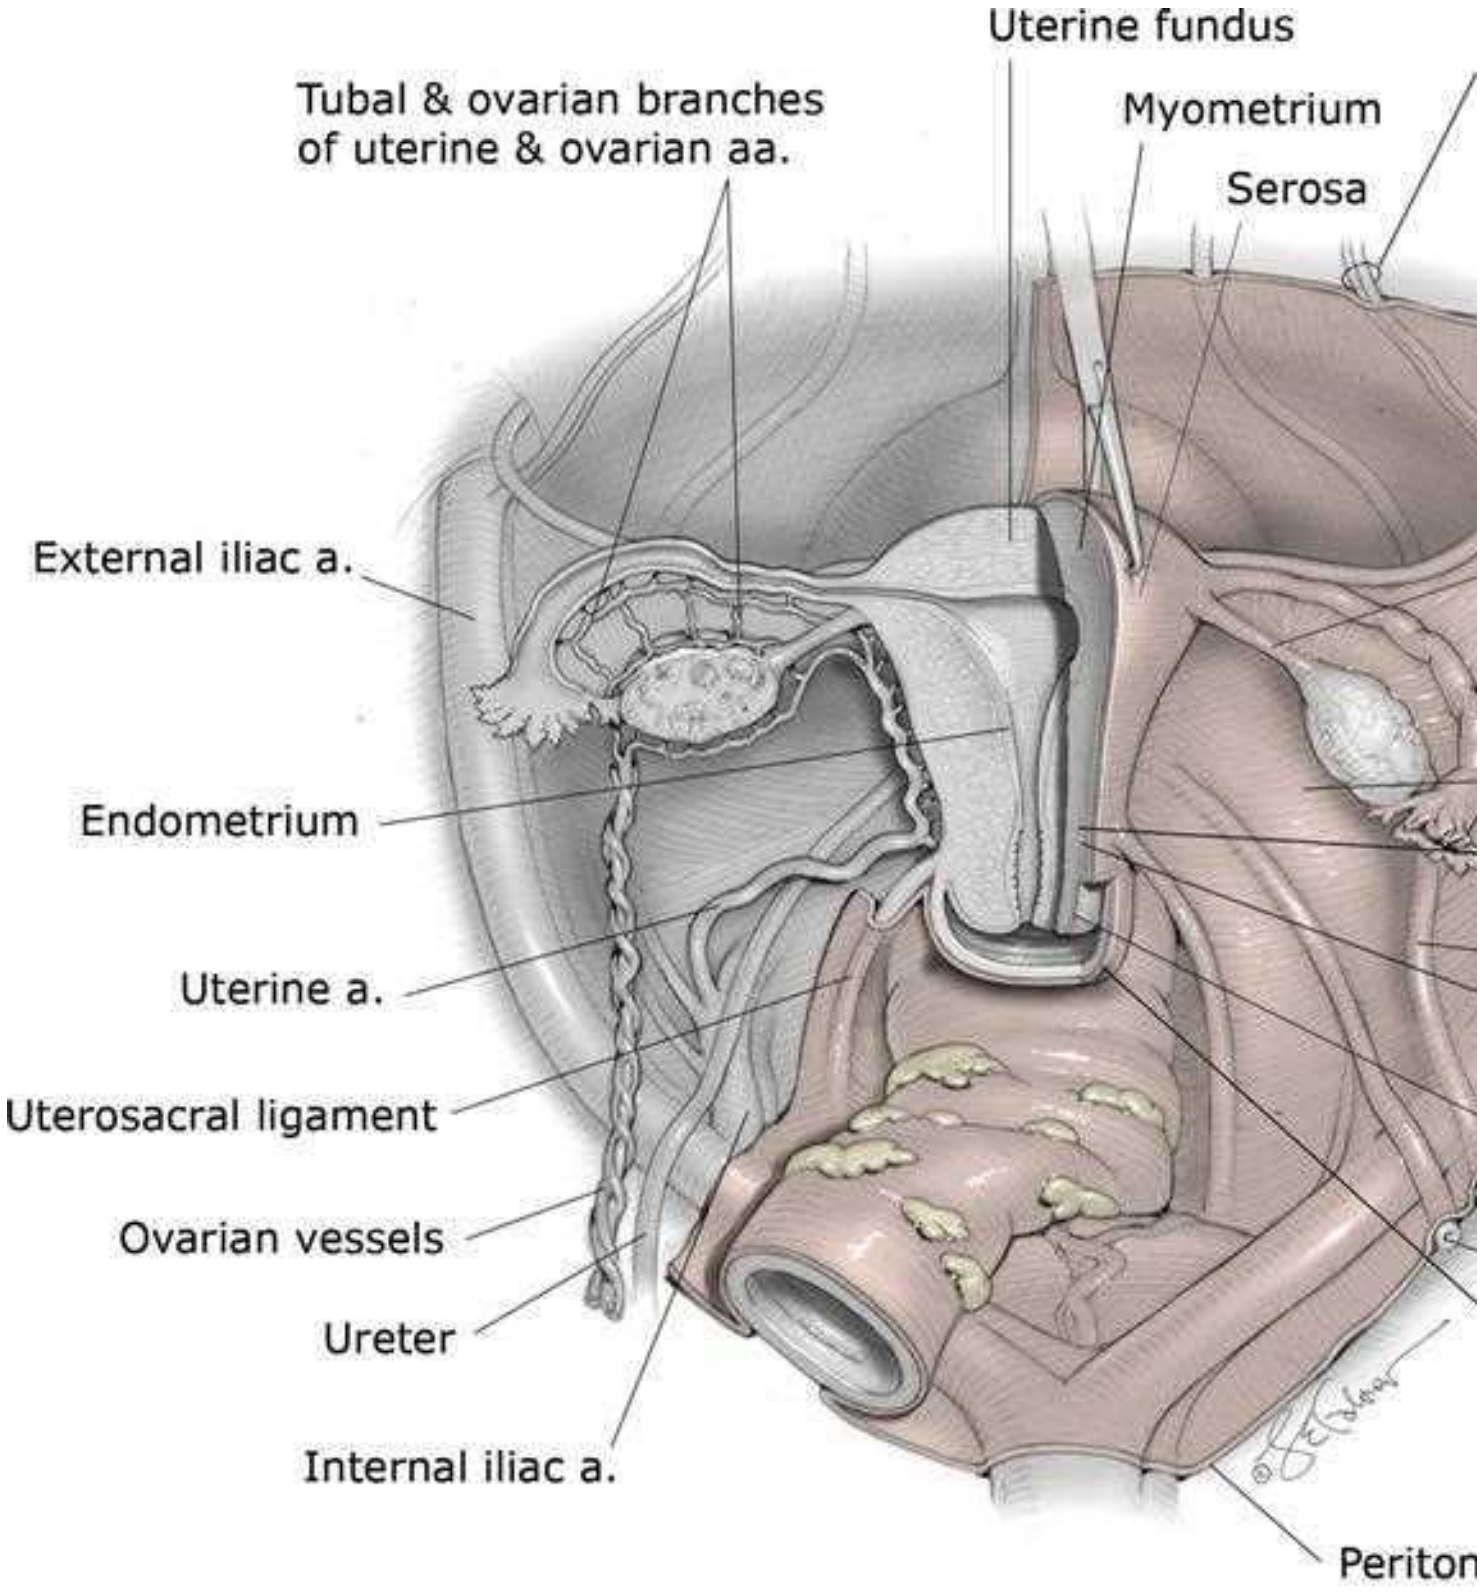
Pregnancy stimulates remarkable uterine growth due to muscle fiber hypertrophy. The uterine fundus, a previously flattened convexity between tubal insertions, now becomes dome shaped. Moreover, the round ligaments appear to insert at the junction of the middle and upper thirds of the organ. The fallopian tubes elongate, but the ovaries grossly appear unchanged.

Cervix

This portion of the uterus is cylindrical and has small apertures at each end—the internal and external cervical ora. The endocervical canal runs through the cervix and connects these ora. The cervix is divided into upper and lower portions by the vagina's attachment to its outer surface. The upper portion—the portio supravaginalis—begins at the internal os, which corresponds to the level at which the peritoneum is reflected up onto the bladder (Fig. 2-10). The lower cervical portion protrudes into the vagina as the portio vaginalis.

FIGURE 2-10

Uterus, adnexa, and associated anatomy. (Reproduced with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Before childbirth, the external cervical os is a small, regular, oval opening. After labor, especially vaginal childbirth, the orifice is converted into a transverse slit that is divided such that there are the so-called anterior and posterior cervical lips. If torn deeply during labor or delivery, the cervix may heal in such a manner that it appears irregular, nodular, or stellate (Fig. 36-1).

The cervical surface that radially surrounds the external os is called the ectocervix and is lined predominantly by nonkeratinized stratified squamous epithelium. In contrast, the endocervical canal is covered by a single layer of mucin-secreting columnar epithelium, which creates deep cleftlike infoldings or “glands.” Commonly during pregnancy, the endocervical epithelium moves out and onto the ectocervix in a physiological process termed eversion (Chap. 4, Cervix).

The cervical stroma is composed mainly of collagen, elastin, and proteoglycans, but very little smooth muscle. As described in Chapter 21 (Cervical Ripening), changes in the amount, composition, and orientation of these components lead to cervical ripening prior to labor onset. In early pregnancy, increased vascularity within the cervix stroma beneath the epithelium creates an ectocervical blue tint that is characteristic of Chadwick sign. Cervical edema leads to softening—Goodell sign, whereas isthmic softening is Hegar sign.

Myometrium and Endometrium

Most of the uterus is composed of myometrium, which contains smooth muscle bundles united by connective tissue with many elastic fibers. Interlacing myometrial fibers surround myometrial vessels and contract to compress these. This anatomy allows hemostasis at the placental site during the third stage of labor.

The number of myometrial muscle fibers varies by location (Schwalm, 1966). Levels progressively diminish caudally such that, in the cervix, muscle makes up only 10 percent of the tissue mass. The uterine body's inner wall has relatively more muscle than its outer layers. And, in the anterior and posterior walls, the muscle content is greater than in the lateral walls. During pregnancy, the upper myometrium undergoes marked hypertrophy, but cervical muscle content does not change significantly.

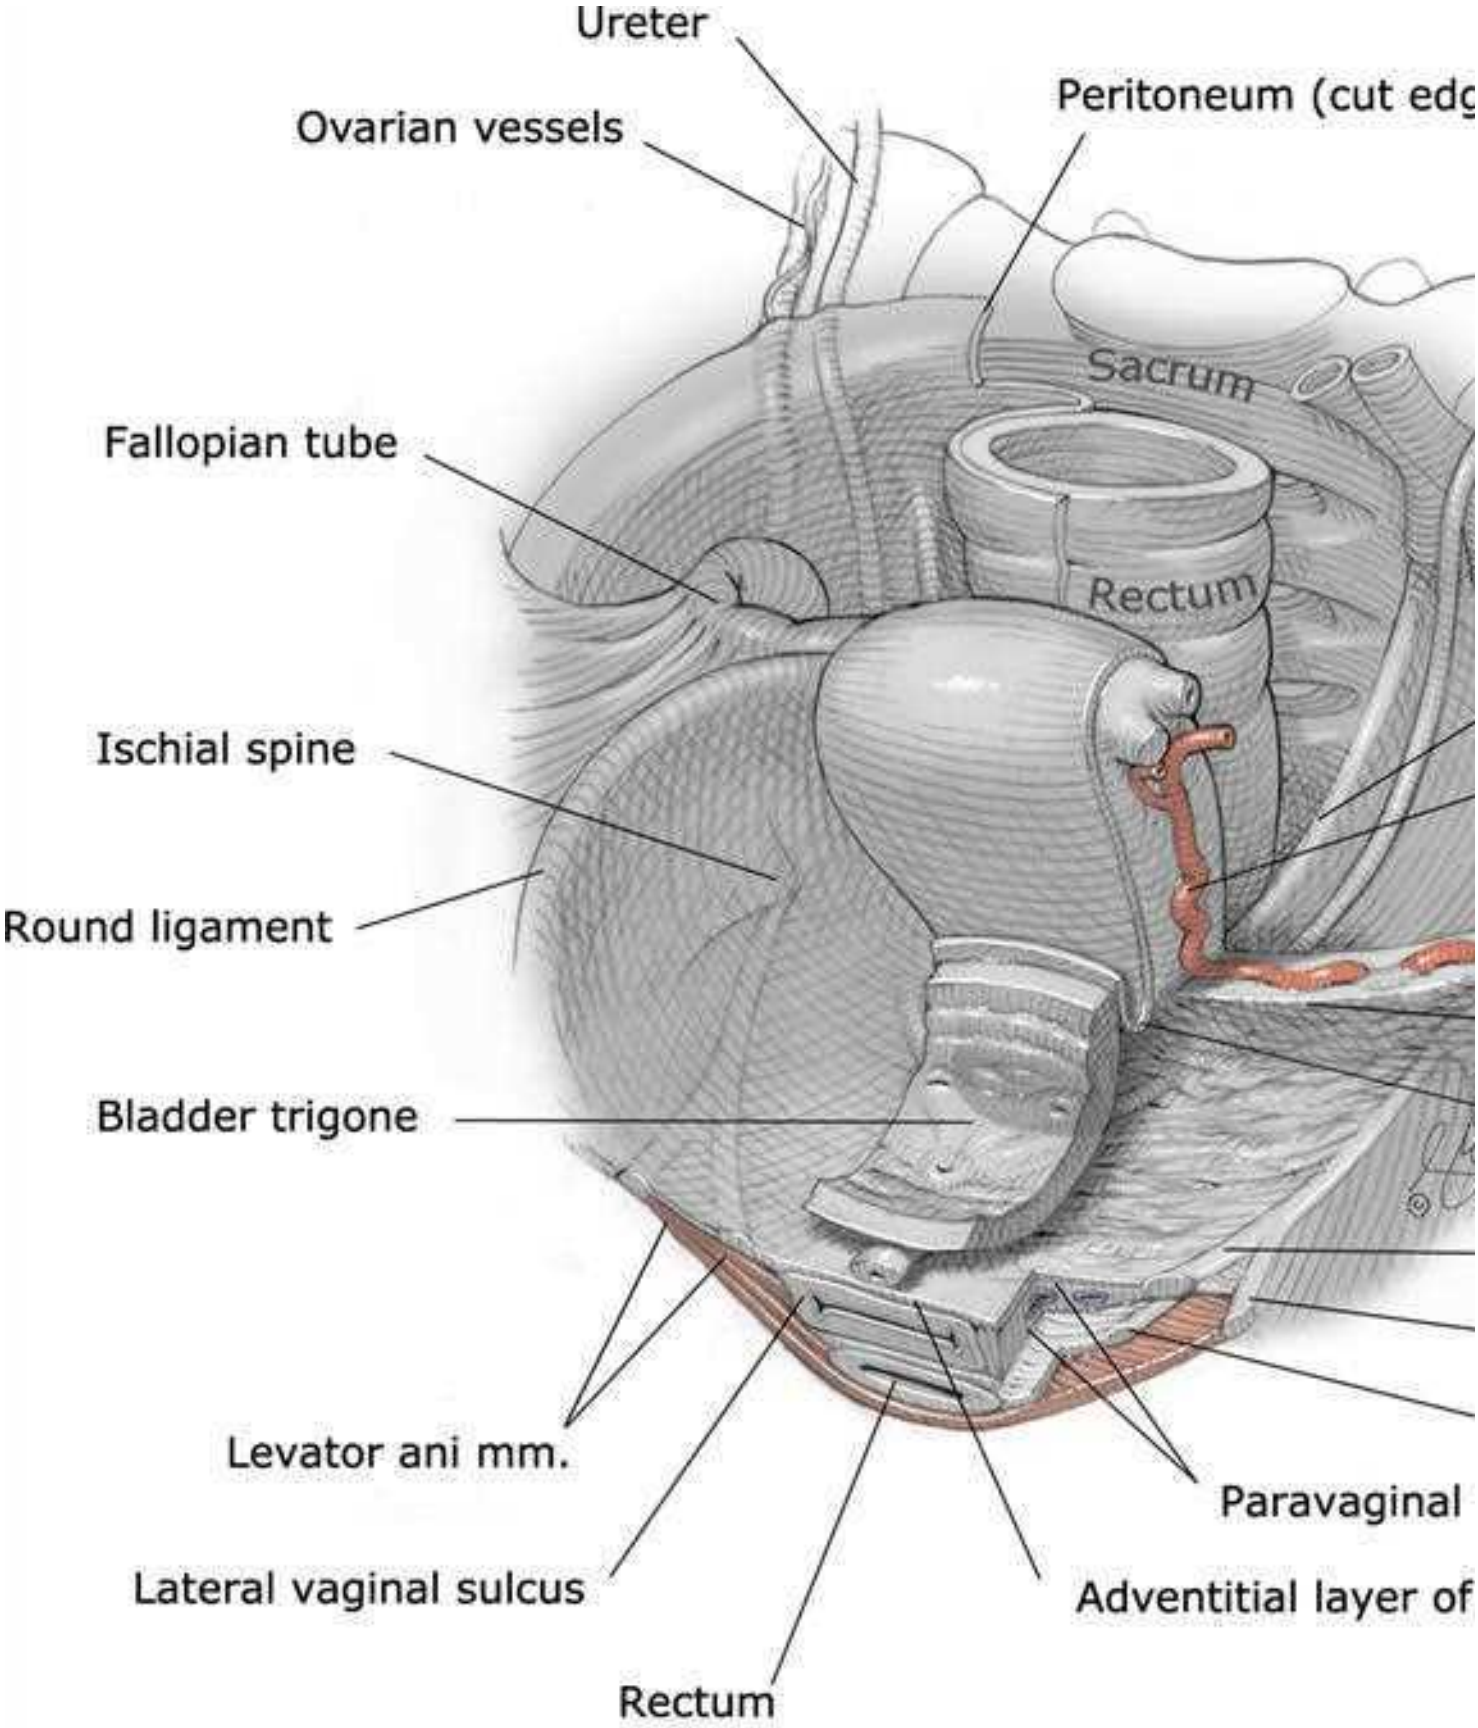
The uterine cavity is lined with endometrium, which is composed of an overlying epithelium, invaginating glands, and a supportive, vascular stroma. As discussed in Chapter 5 (Estrogen and Progesterone Action), the endometrium varies greatly throughout the menstrual cycle. This layer is divided into a functionalis layer, which is sloughed with menses, and a basalis layer, which serves to regenerate the functionalis layer following each menses. During pregnancy, the endometrium is termed decidua and undergoes dramatic hormonally driven alterations.

Ligaments

Several ligaments extend from the uterine surface toward the pelvic sidewalls and include the round, broad, cardinal, and uterosacral ligaments (Figs. 2-10 and 2-11). Despite their appellation, the round and broad ligaments provide no substantial uterine support, which contrasts with the cardinal and uterosacral ligaments.

FIGURE 2-11

Pelvic viscera and their connective tissue support. (Reproduced with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

The round ligament originates somewhat below and anterior to the origin of the fallopian tubes. Clinically, this orientation can aid fallopian tube identification during puerperal sterilization. This is important if pelvic adhesions limit tubal mobility and thus, hinder fimbria visualization and tubal confirmation prior to ligation. Each round ligament extends laterally and down into the inguinal canal, through which it passes, to terminate in the upper portion of the ipsilateral labium majus. Sampson artery, a branch of the uterine artery, runs within this ligament. In nonpregnant women, the round ligament varies from 3 to 5 mm in diameter and is

composed of smooth muscle bundles separated by fibrous tissue septa (Mahran, 1965). During pregnancy, these ligaments undergo considerable hypertrophy and increase appreciably in both length and diameter.

The broad ligaments are two winglike structures that extend from the lateral uterine margins to the pelvic sidewalls. Each broad ligament consists of a double-layer drape of peritoneum. The anterior and posterior layers of this drape are termed the anterior and posterior leaves, respectively. In forming the broad ligament, this peritoneum folds over structures extending from each cornu. Peritoneum that folds over the fallopian tube is termed the mesosalpinx, that around the round ligament is the mesoteres, and that over the ovarian ligament is the mesovarium. Peritoneum that extends beneath the fimbriated end of the fallopian tube toward the pelvic wall forms the suspensory ligament or the infundibulopelvic ligament of the ovary. This contains nerves and the ovarian vessels, and during pregnancy, these vessels, especially the venous plexuses, are dramatically enlarged. Specifically, the diameter of the ovarian vascular pedicle increases from 0.9 cm to reach 2.6 cm at term (Hodgkinson, 1953).

The cardinal ligament—also called the transverse cervical ligament or Mackenrodt ligament—anchors medially to the uterus and upper vagina. The cardinal ligament is the thick base of the broad ligament. As such, during cesarean hysterectomy, sturdy clamps and suture are required for its transection and ligation.

Each uterosacral ligament originates with a posterolateral attachment to the supravaginal portion of the cervix and inserts into the fascia over the sacrum, with some variations (Ramanah, 2012; Umek, 2004). These ligaments are composed of connective tissue, small bundles of vessels and nerves, and some smooth muscle. Covered by peritoneum, these ligaments form the lateral boundaries of the pouch of Douglas.

The term parametrium is used to describe the connective tissues adjacent and lateral to the uterus within the broad ligament. Paracervical tissues are those adjacent to the cervix, whereas paracolpium is that tissue lateral to the vaginal walls.

Pelvic Blood Supply

During pregnancy, there is marked hypertrophy of the uterine vasculature, which is supplied principally from the uterine and ovarian arteries (see Fig. 2-10). The uterine artery, a main branch of the internal iliac artery—previously called the hypogastric artery—enters the base of the broad ligament. The uterine artery courses medially to the lateral side of the uterus. Approximately 2 cm lateral to the cervix, the uterine artery crosses over the ureter. This proximity is of great surgical significance, as the ureter may be injured or ligated during hysterectomy when the uterine vessels are clamped and ligated.

Once the uterine artery has reached the supravaginal portion of the cervix, it divides. The smaller cervicovaginal artery supplies blood to the lower cervix and upper vagina. The main uterine artery branch turns abruptly upward and travels cephalad along the lateral margin of the uterus. Along its path, this main artery provides a branch of considerable size to the upper cervix and then numerous other medial branches serially penetrate the body of the uterus to form the arcuate arteries. As indicated by the name, each branch arches across the organ by coursing within the myometrium just beneath the serosal surface. Arcuate vessels from each side anastomose at the uterine midline. Radial artery branches originate at right angles from the arcuate arteries and travel inward through the myometrium, enter the endometrium/decidua, and branch there to become either basal arteries or coiled spiral arteries. The spiral arteries supply the functionalis layer. Also called the straight arteries, the basal arteries extend only into the basalis layer.

As the uterine artery courses cephalad, it gives rise to Sampson artery of the round ligament. Just before the main uterine artery vessel reaches the fallopian tube, it divides into three terminal branches. The ovarian branch of the uterine artery forms an anastomosis with the terminal branch of the ovarian artery; the tubal branch makes its way through the mesosalpinx and supplies part of the fallopian tube; and the fundal branch penetrates the uppermost uterus.

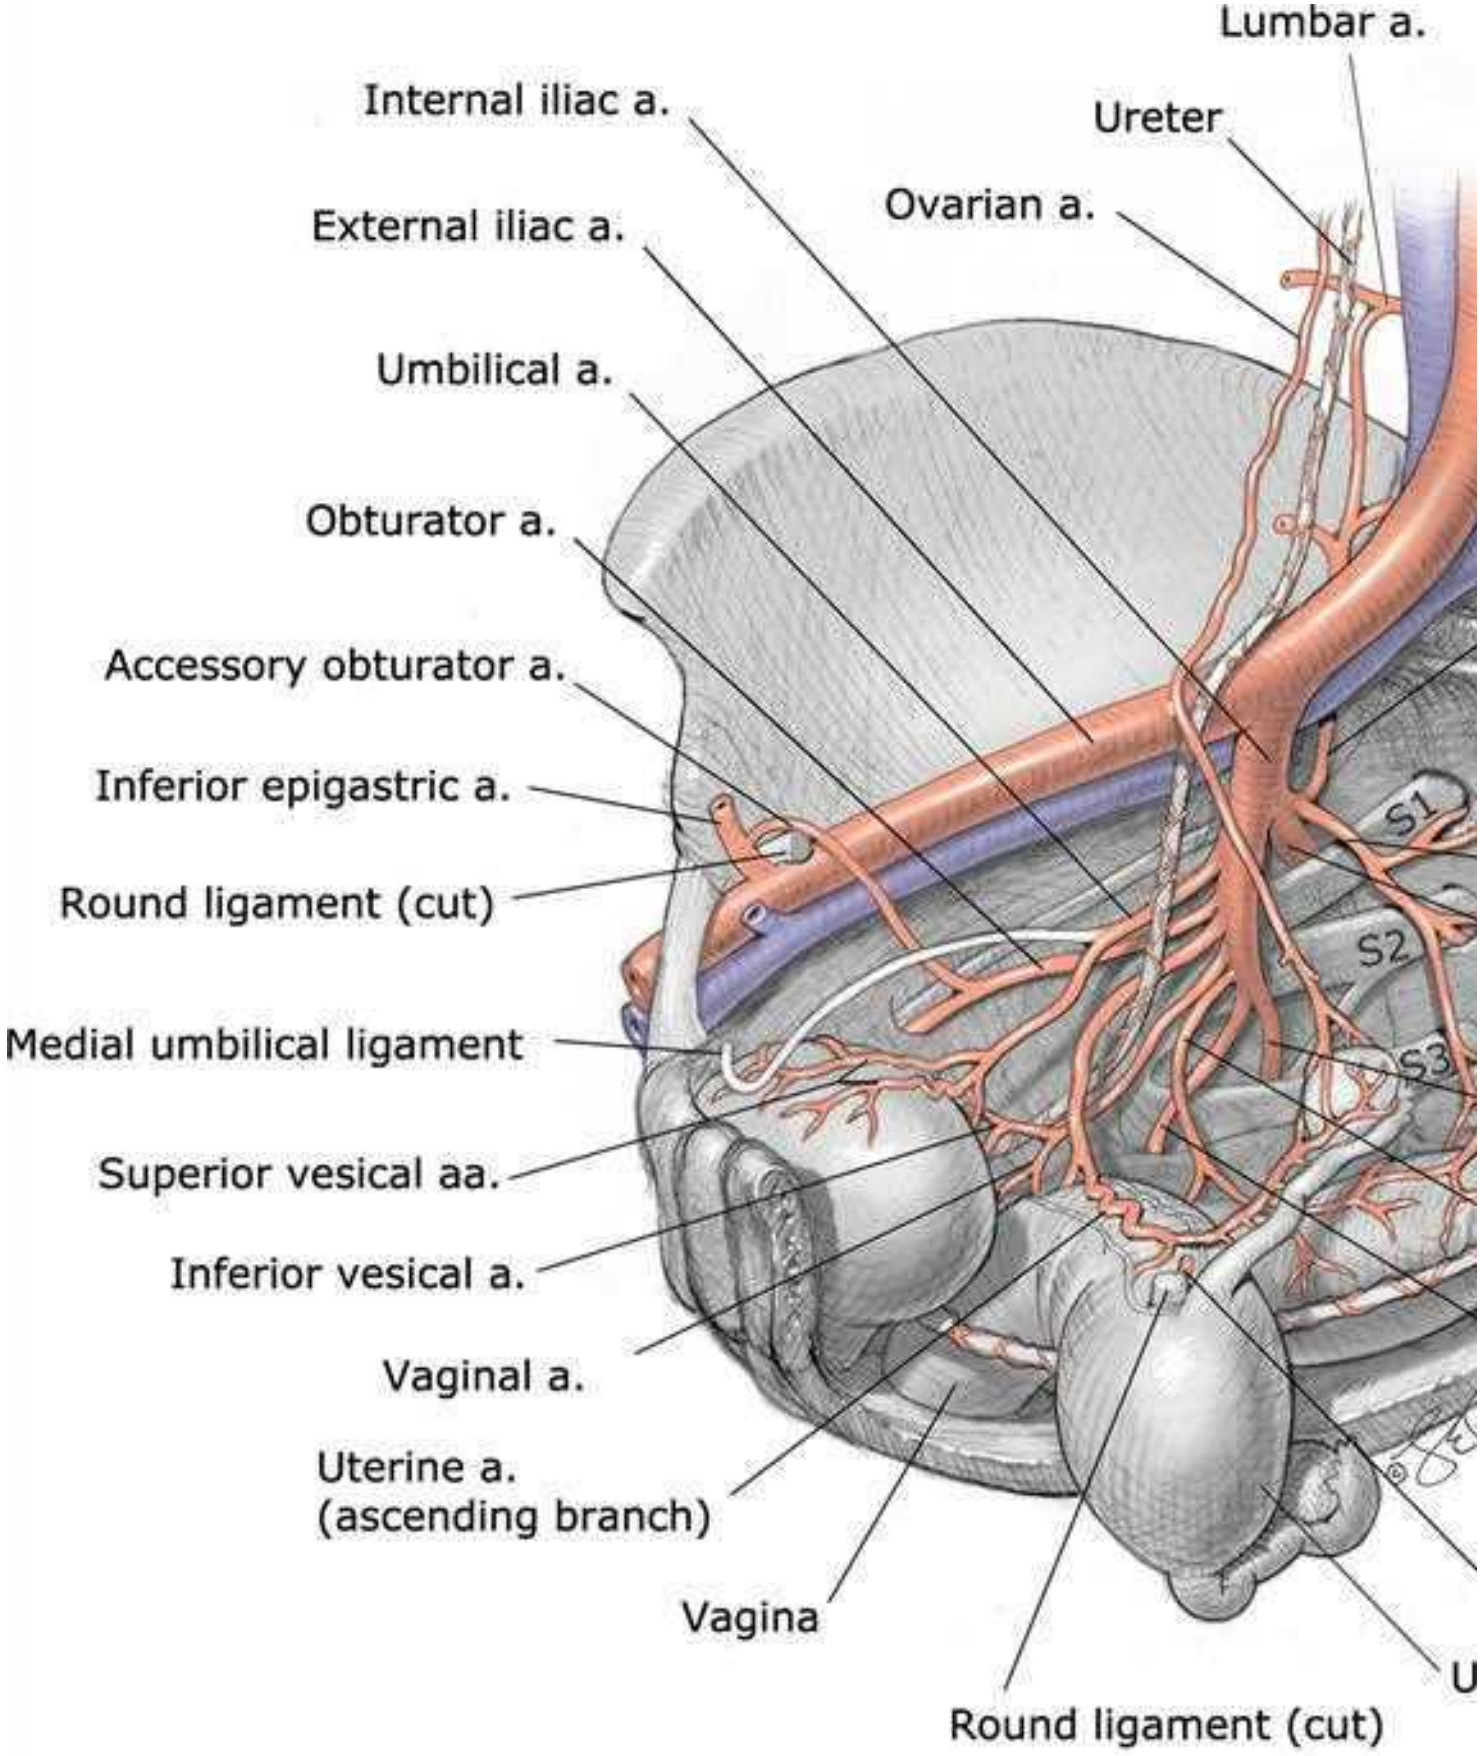
In addition to the uterine artery, the uterus receives blood supply from the ovarian artery (see Fig. 2-10). This artery is a direct branch of the aorta and enters the broad ligament through the infundibulopelvic ligament. At the ovarian hilum, it divides into smaller branches that enter the ovary. As the ovarian artery runs along the hilum, it also sends several branches through the mesosalpinx to supply the fallopian tubes. Its main stem, however, traverses the entire length of the broad ligament toward the uterine cornu. Here, it forms an anastomosis with the ovarian branch of the uterine artery. This dual uterine blood supply creates a vascular reserve to prevent uterine ischemia if ligation of the uterine or internal iliac artery is performed to control postpartum hemorrhage.

Uterine veins accompany their respective arteries. As such, the arcuate veins unite to form the uterine vein, which empties into the internal iliac vein and then the common iliac vein. Some of the blood from the upper uterus, the ovary, and the upper part of the broad ligament is collected by several veins. Within the broad ligament, these veins form the large pampiniform plexus that terminates in the ovarian vein. From here, the right ovarian vein empties into the vena cava, whereas the left ovarian vein empties into the left renal vein.

Blood supply to the pelvis is predominantly provided by branches of the internal iliac artery (Fig. 2-12). These branches are organized into anterior and posterior divisions, and subsequent branches are highly variable between individuals. The anterior division provides blood supply to the pelvic organs and perineum and includes the inferior gluteal, internal pudendal, middle rectal, vaginal, uterine, and obturator arteries, as well as the umbilical artery and its continuation as the superior vesical artery. The posterior division branches extend to the buttock and thigh and include the superior gluteal, lateral sacral, and iliolumbar arteries. For this reason, during internal iliac artery ligation, many advocate ligation distal to the posterior division to avoid compromised blood flow to the areas supplied by this division (Bleich, 2007).

FIGURE 2-12

Pelvic arteries. (Reproduced with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Pelvic Lymphatics

The lymphatics from the uterine corpus are distributed to two groups of nodes. One set of vessels drains into the internal iliac nodes. The other set, after joining lymphatics from the ovarian region, terminates in the paraaortic lymph nodes. Lymphatics from the cervix terminate mainly in the internal iliac nodes, which are situated near the bifurcation of the common iliac vessels.

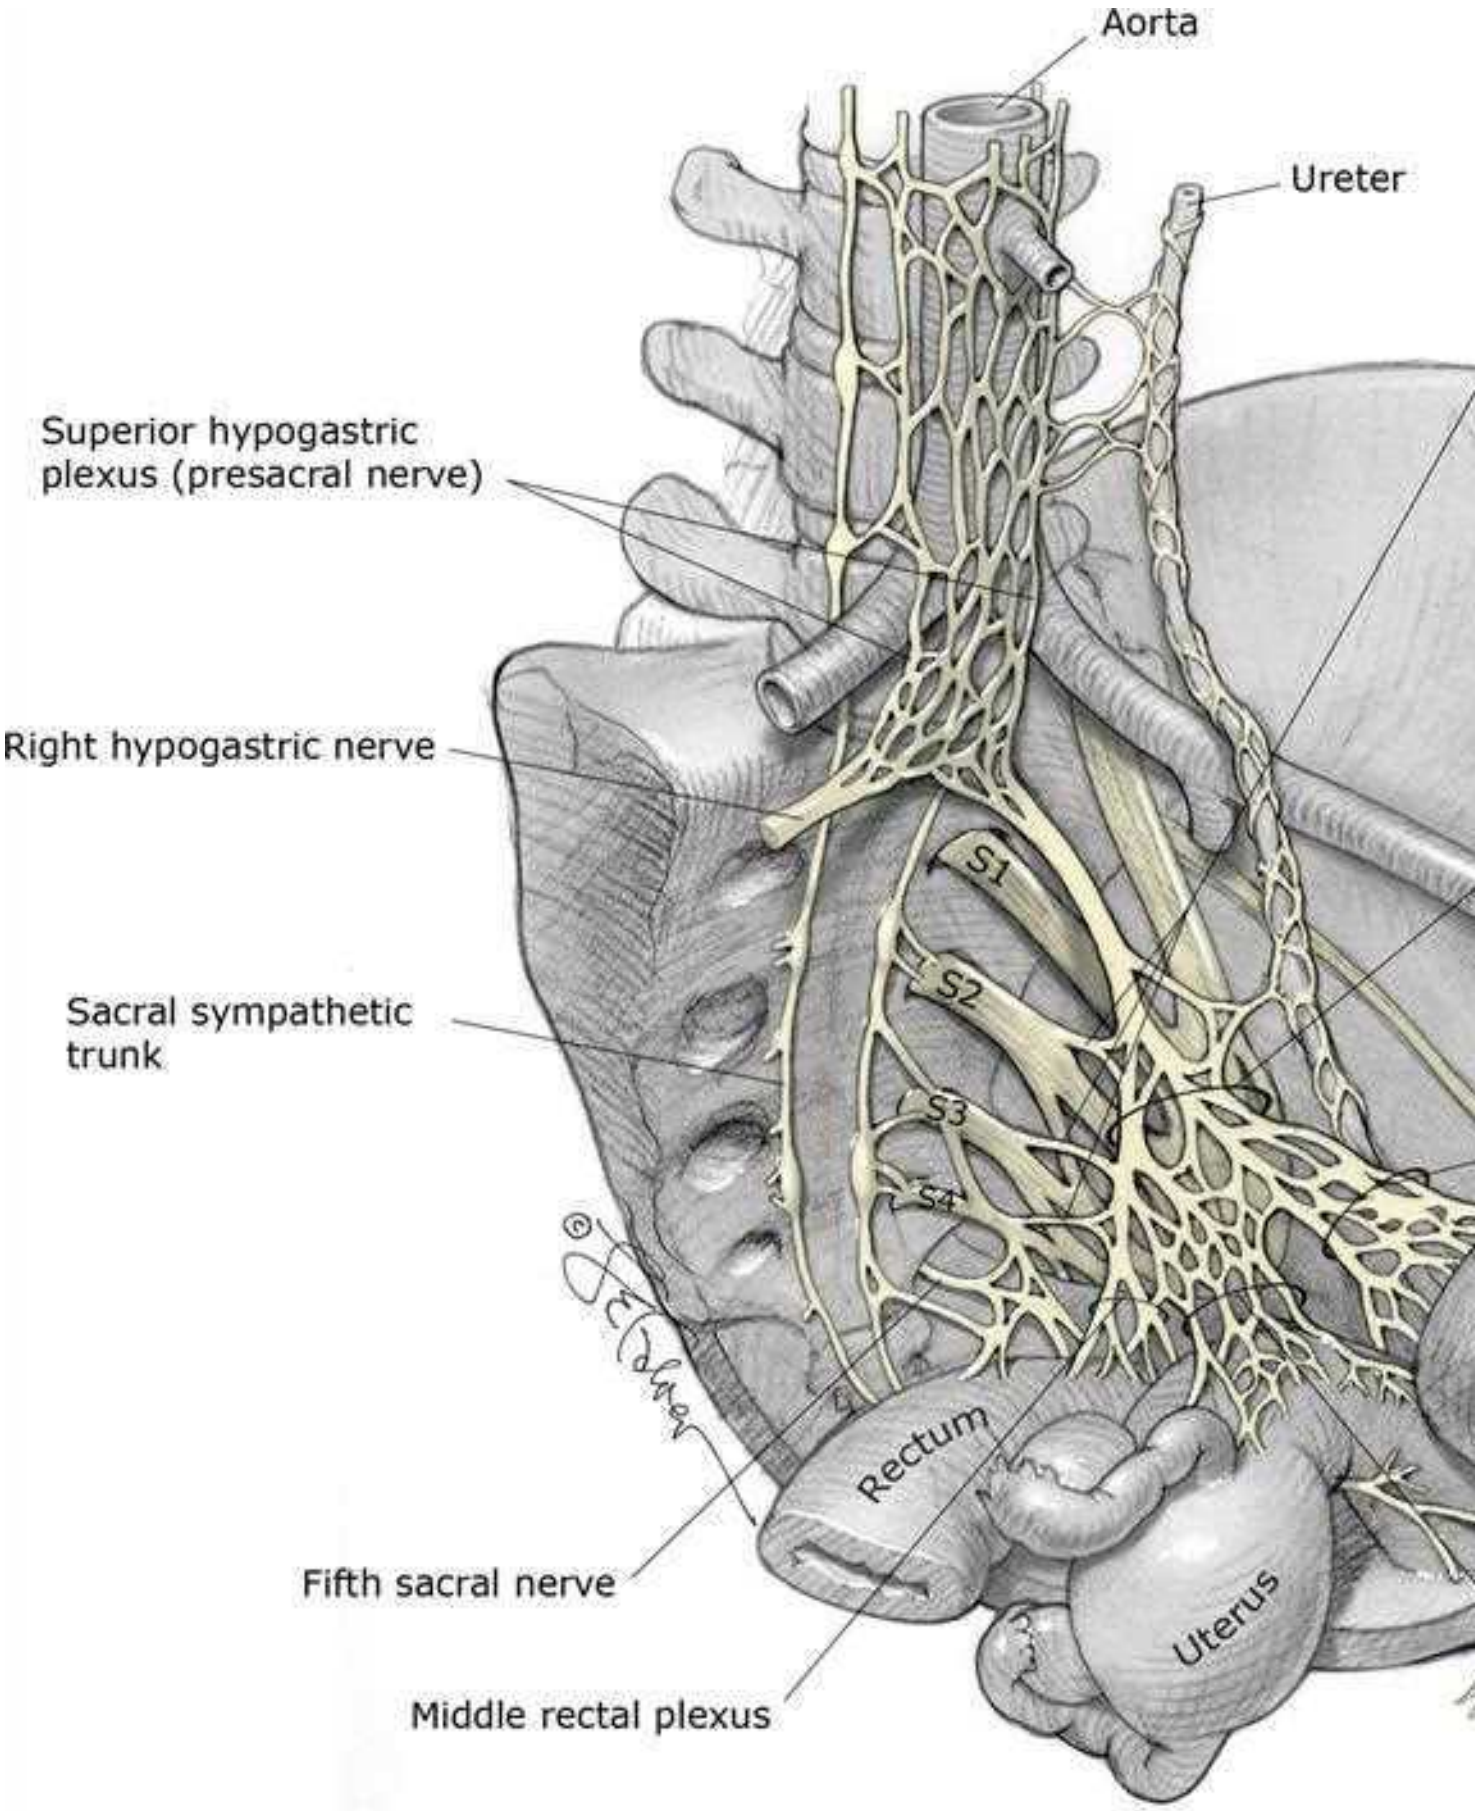
Pelvic Innervation

As a brief review, the peripheral nervous system is divided into a somatic division, which innervates skeletal muscle, and an autonomic division, which innervates smooth muscle, cardiac muscle, and glands. Pelvic visceral innervation is predominantly autonomic, which is further divided into sympathetic and parasympathetic components.

Sympathetic innervation to pelvic viscera begins with the superior hypogastric plexus, also termed the presacral nerve (Fig. 2-13). Beginning below the aortic bifurcation and extending downward retroperitoneally, this plexus is formed by sympathetic fibers arising from spinal levels T_{10} through L_2. At the level of the sacral promontory, this superior hypogastric plexus divides into a right and a left hypogastric nerve, which run downward along the pelvis sidewalls (Ripperda, 2015).

FIGURE 2-13

Pelvic innervation. (Reproduced with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



In contrast, parasympathetic innervation to the pelvic viscera derives from neurons at spinal levels S_2 through S_4. Their axons exit as part of the anterior rami of the spinal nerves for those levels. These combine on each side to form the pelvic splanchnic nerves, also termed nervi erigentes.

Blending of the two hypogastric nerves (sympathetic) and the two pelvic splanchnic nerves (parasympathetic) gives rise to the inferior hypogastric plexus, also termed the pelvic plexus. This retroperitoneal plaque of nerves lies at the S_4 and S_5 level (Spackman, 2007). From here, fibers of this plexus accompany internal iliac artery branches to their respective pelvic viscera. Thus, the inferior hypogastric plexus divides into three plexuses. The vesical plexus innervates the bladder, and the middle rectal plexus travels to the rectum. The uterovaginal plexus, also termed Frankenhäuser plexus, reaches the proximal fallopian tubes, uterus, and upper vagina. Extensions of the inferior hypogastric plexus also reach the perineum along the vagina and urethra to innervate the clitoris and vestibular bulbs (Montoya, 2011). Of these, the uterovaginal plexus is composed of variably sized ganglia, but particularly of a large ganglionic plate that is situated on either side of the cervix, proximate to the uterosacral and cardinal ligaments (Ramanah, 2012).

For the uterus, most of its afferent sensory fibers ascend through the inferior hypogastric plexus and enter the spinal cord via T_{10} through T_{12} and L_1 spinal nerves. These transmit the painful stimuli of contractions to the central nervous system. For the cervix and upper part of the birth canal, sensory nerves pass through the pelvic splanchnic nerves to the second, third, and fourth sacral nerves. Last, those from the lower portion of the birth canal pass primarily through the pudendal nerve. Anesthetic blocks used during delivery target these levels of innervation.

Ovaries

Along the pelvic sidewall, each ovary usually rests in the ovarian fossa of Waldeyer, which is a slight depression between the external and internal iliac vessels. During childbearing years, ovaries variably measure 2.5 to 5 cm in length, 1.5 to 3 cm in width, and 0.6 to 1.5 cm in thickness.

The ovarian ligament, also called the uteroovarian ligament, originates from the upper posterolateral portion of the uterus, just beneath the tubal insertion level, and extends to the uterine pole of the ovary (see Fig. 2-10). Measuring a few centimeters long and 3 to 4 mm in diameter, this ligament is made up of muscle and connective tissue and is covered by peritoneum—the mesovarium. Blood supply reaches the ovary through this double-layered mesovarium to enter the ovarian hilum.

The ovary consists of an outer cortex and inner medulla. In young women, the cortex is smooth, has a dull white surface, and is lined by single layer of cuboidal epithelium, the germinal epithelium of Waldeyer. This epithelium is supported by a connective tissue condensation, the tunica albuginea. Beneath this, the ovarian cortex contains oocytes and developing follicles. The medulla is composed of loose connective tissue, numerous arteries and veins, and a small amount of smooth muscle fibers.

The ovaries are supplied with both sympathetic and parasympathetic nerves. The sympathetic nerves are derived primarily from the ovarian plexus that accompanies the ovarian vessels and originates in the renal plexus. Others are derived from the plexus that surrounds the ovarian branch of the uterine artery. Parasympathetic input is from the vagus nerve. Sensory afferents follow the ovarian artery and enter at T_{10} spinal cord level.

Fallopian Tubes

Also called oviducts, these serpentine tubes extend laterally 8 to 14 cm from the uterine cornua. They are anatomically classified along their length as an interstitial portion, isthmus, ampulla, and infundibulum (Fig. 2-14). Most proximal, the interstitial portion is embodied within the uterine muscular wall. Next, the narrow 2- to 3-mm wide isthmus widens gradually into the 5- to 8-mm wide ampulla. Last, the infundibulum is the funnel-shaped fimbriated distal extremity of the tube, which opens into the abdominal cavity. These latter three extrauterine portions are covered by the mesosalpinx at the superior margin of the broad ligament.

FIGURE 2-14
The fallopian tube of an adult woman with cross-sectioned illustrations of the gross structure in several portions: **(A)** isthmus, **(B)** ampulla, and **(C)** infundibulum. Below these are photographs of corresponding histological sections. (Used with permission from Dr. Kelley S. Carrick.)

In cross section, the extrauterine fallopian tube contains a mesosalpinx, myosalpinx, and endosalpinx. The outer of these, the mesosalpinx, is a single-cell mesothelial layer functioning as visceral peritoneum. In the myosalpinx, smooth muscle is arranged in an inner circular and an outer longitudinal layer. The tubal musculature undergoes rhythmic contractions constantly, the rate of which varies with cyclical ovarian hormonal changes.

The tubal mucosa or endosalpinx is a single layer of columnar epithelium composed of ciliated, secretory, and intercalary cells resting on a sparse lamina propria. Clinically, its close proximity to the underlying myosalpinx contributes to easy invasion by ectopic trophoblast. The tubal mucosa is arranged in longitudinal folds that become progressively more complex toward the fimbria. In the ampulla, the lumen is occupied almost completely by the arborescent mucosa. The current produced by the tubal cilia is such that the direction of flow is toward the uterine cavity. Tubal peristalsis created by cilia and muscular layer contraction is believed to be an important factor in ovum transport (Croxatto, 2002).

The tubes are supplied richly with elastic tissue, blood vessels, and lymphatics. Their sympathetic innervation is extensive, in contrast to their parasympathetic innervation. This nerve supply derives partly from the ovarian plexus and partly from the uterovaginal plexus. Sensory afferent fibers ascend to T_{10} spinal cord levels.

LOWER URINARY TRACT STRUCTURES

Bladder

Anteriorly, the bladder rests against the inner surface of the pubic bones and then, as it fills, also against the anterior abdominal wall. Posteriorly, it rests against the vagina and cervix. The bladder is divided into a dome and a base approximately at the level of the ureteral orifices. The dome is thin walled and distensible, whereas the base is thicker and undergoes less distention during filling. The vesical trigone lies in the bladder base and contains both ureteral orifices and the internal urinary meatus (see Fig. 2-11). The urethral lumen begins at this meatus and then courses through the bladder base for less than 1 cm. This region where the urethral lumen traverses the bladder base is called the bladder neck.

The bladder wall consists of coarse bundles of smooth muscle known as the detrusor muscle, which extends into the proximal part of the urethra. A submucosal layer intervenes between this detrusor muscle and the mucosa. The bladder mucosa consists of transitional epithelium and underlying lamina propria.

The blood supply to the bladder arises from the superior vesical arteries, which are branches of the patent portion of the umbilical artery, and from the middle and inferior vesical arteries, which, when present, often arise from either the internal pudendal or the vaginal arteries (see Fig. 2-12). The nerve supply to the bladder arises from the vesical plexus, a component of the inferior hypogastric plexus (see Fig. 2-13).

Ureter

As the ureter enters the pelvis, it crosses over the bifurcation of the common iliac artery and passes just medial to the ovarian vessels (see Fig. 2-10). As the ureter descends into the pelvis, it lies medial to the internal iliac branches and anterolateral to the uterosacral ligaments. The ureter then traverses through the cardinal ligament approximately 1 to 2 cm lateral to the cervix. Near the level of the uterine isthmus, it courses below the uterine artery and travels anteromedially toward the bladder base. In this path, it runs close to the upper third of the anterior vaginal wall (Rahn, 2007). Finally, the ureter enters the bladder and travels obliquely for approximately 1.5 cm before opening at the ureteral orifices.

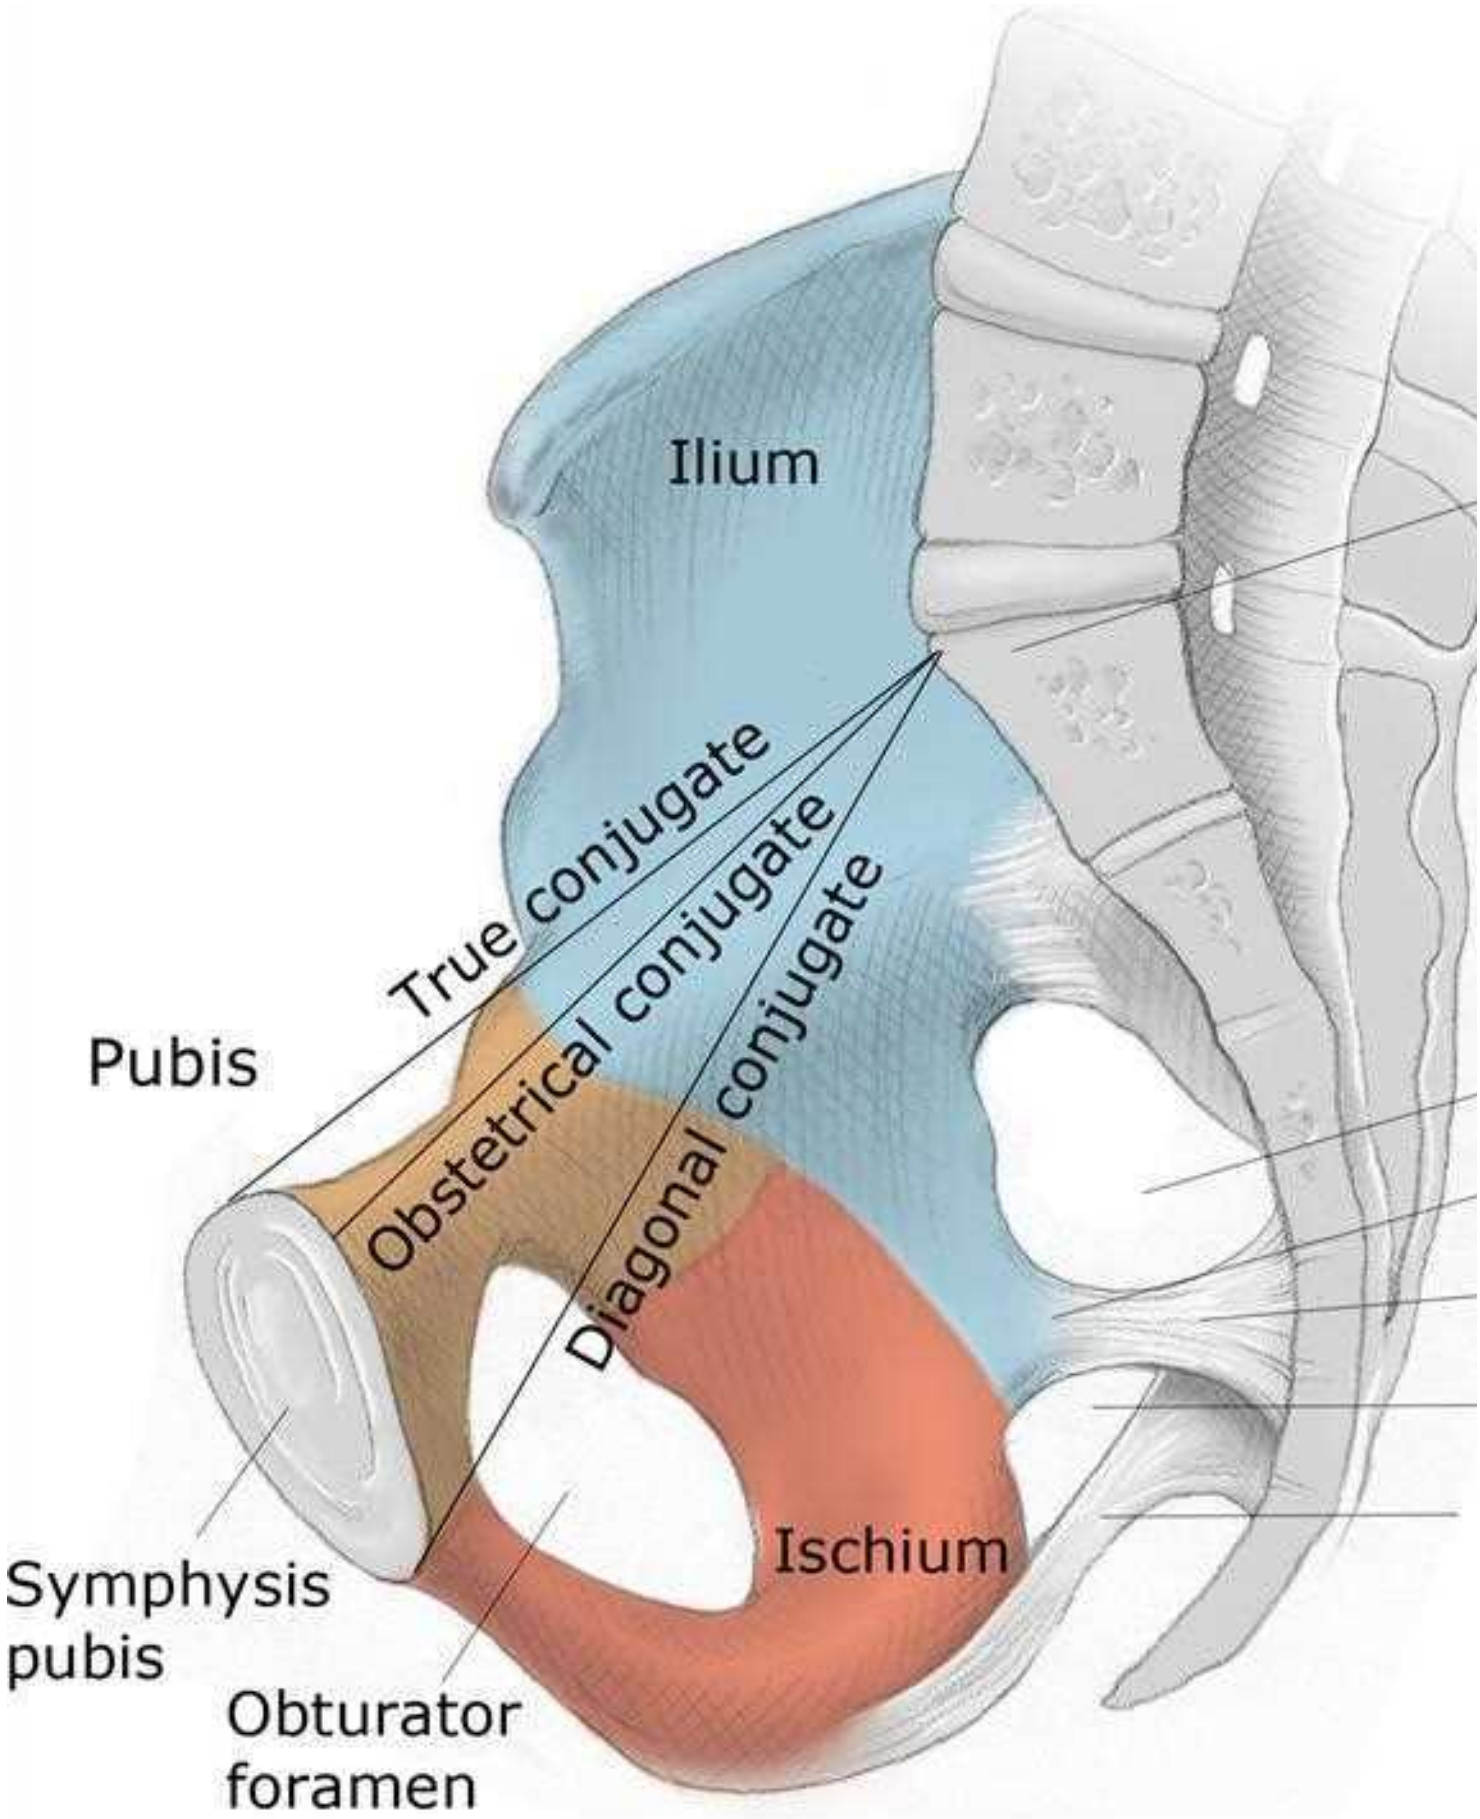
The pelvic ureter receives blood supply from the vessels it passes: the common iliac, internal iliac, uterine, and superior vesical vessels. The ureter's course runs medial to these vessels, and thus its blood supply reaches the ureter from lateral sources. This is important during ureteral isolation. Vascular anastomoses on the connective tissue sheath enveloping the ureter form a longitudinal network of vessels.

MUSCULOSKELETAL PELVIC ANATOMY

Pelvic Bones

The pelvis is composed of four bones—the sacrum, coccyx, and two innominate bones. Each innominate bone is formed by the fusion of three bones—the ilium, ischium, and pubis (Fig. 2-15). Both innominate bones are joined to the sacrum at the sacroiliac synchondroses and to one another at the symphysis pubis.

FIGURE 2-15
The innominate bone is composed of the pubis (*brown*), ischium (*red*), and ilium (*blue*). Of the three anteroposterior diameters of the pelvic inlet, only the diagonal conjugate can be measured clinically. The important obstetrical conjugate is derived by subtracting 1.5 cm from the diagonal conjugate.



Pelvic Joints

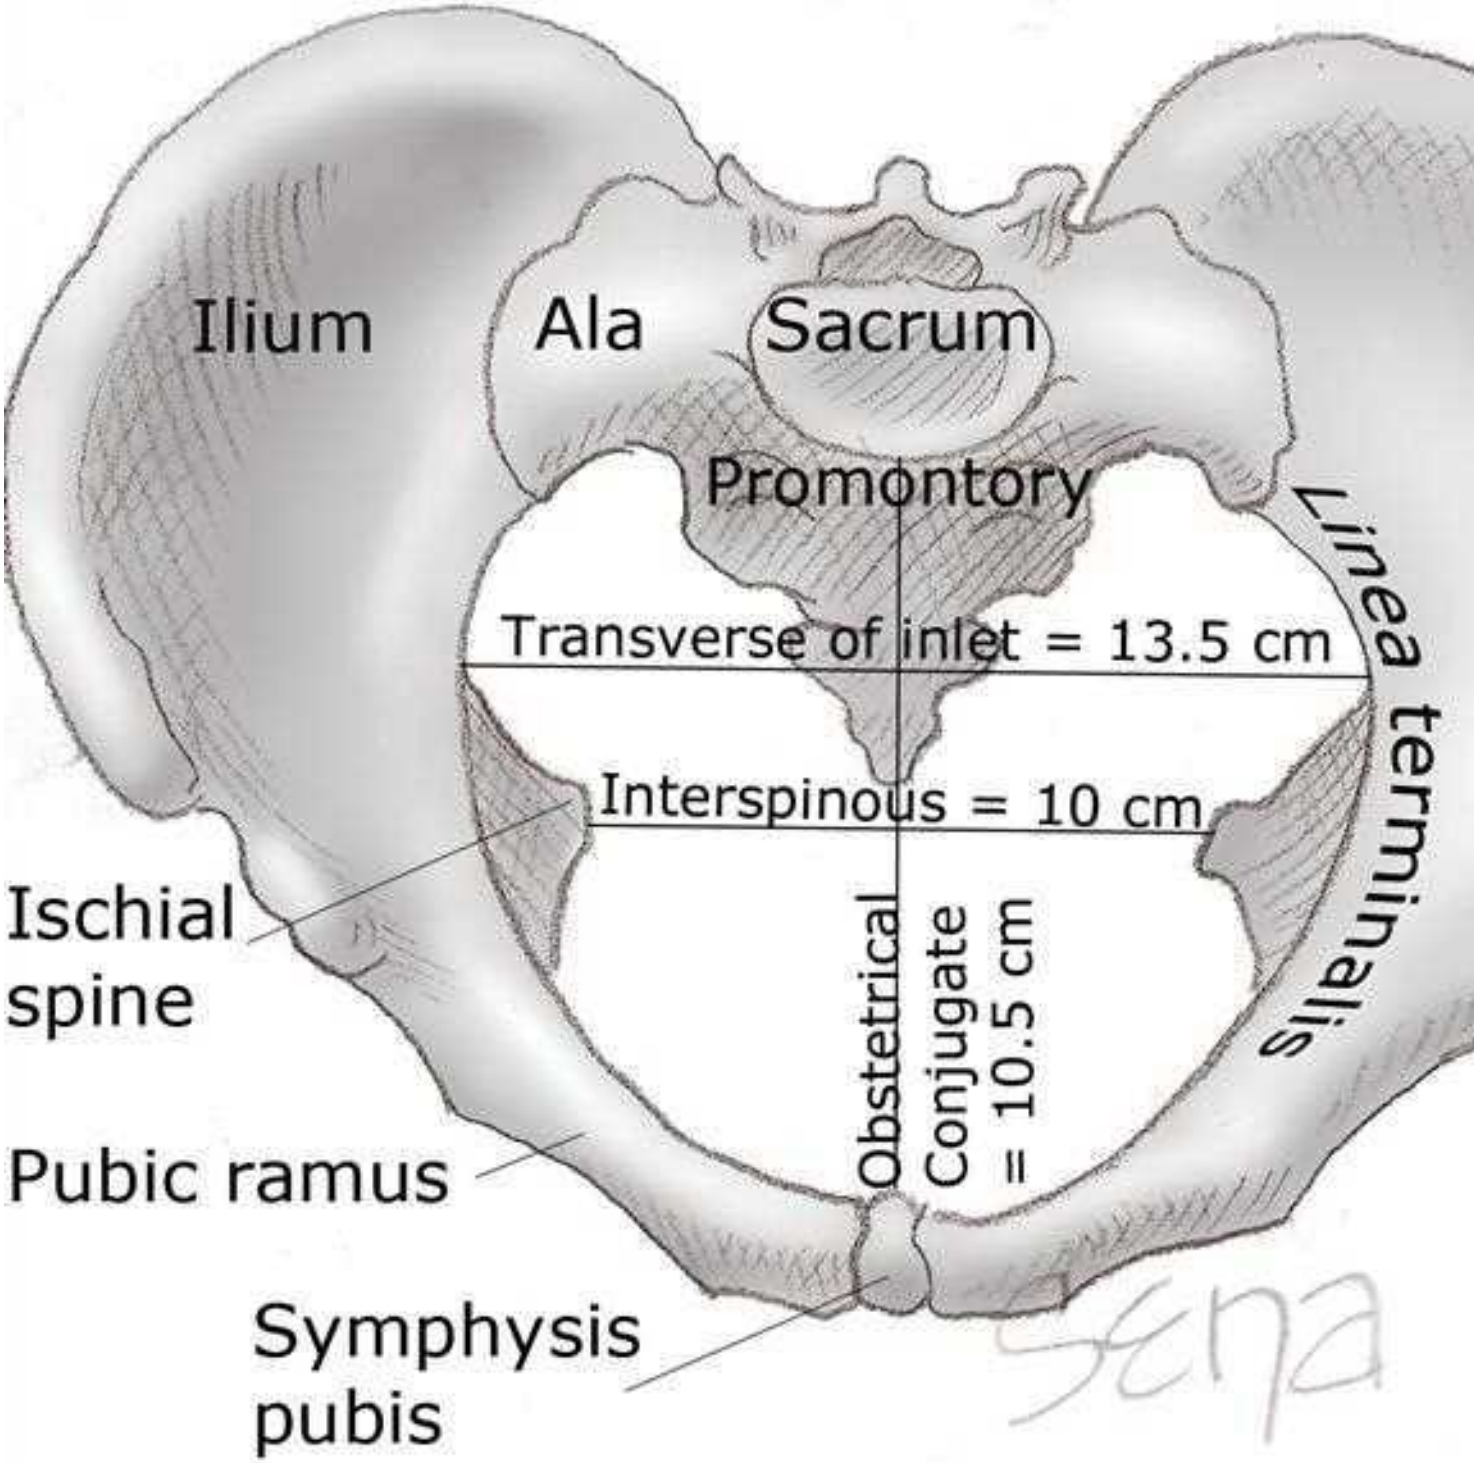
Anteriorly, the pelvic bones are joined together by the symphysis pubis. This structure consists of fibrocartilage and the superior and inferior pubic ligaments. The latter ligament is frequently designated the arcuate ligament of the pubis. Posteriorly, the pelvic bones are joined by articulations between the sacrum and the iliac portion of the innominate bones to form the sacroiliac joints.

The pelvic joints in general have a limited degree of mobility. However, during pregnancy, these joints relax remarkably at term. As one result, upward gliding of the sacroiliac joint, which is greatest in the dorsal lithotomy position, may increase the diameter of the outlet by 1.5 to 2.0 cm for delivery (Borell, 1957). Sacroiliac joint mobility also likely aids the McRoberts maneuver to release an obstructed shoulder in cases of shoulder dystocia (Chap. 27, Management). These changes may also contribute to the success of the modified squatting position to hasten second-stage labor (Gardosi, 1989). The squatting position may increase the interspinous diameter and the pelvic outlet diameter (Russell, 1969, 1982).

Planes and Diameters of the Pelvis

The pelvis is conceptually divided into false and true components. The false pelvis lies above the linea terminalis, and the true pelvis is below this boundary (Fig. 2-16). The false pelvis is bounded posteriorly by the lumbar vertebra and laterally by the iliac fossa. In front, the boundary is formed by the lower portion of the anterior abdominal wall.

FIGURE 2-16
Axial view of a normal female pelvis. The clinically important obstetrical conjugate and transverse diameter of the pelvic inlet are illustrated. The interspinous diameter of the midpelvis is also marked.



The pelvis is described as having four imaginary planes:

1. The plane of the pelvic inlet—the superior strait.
2. The plane of the pelvic outlet—the inferior strait.
3. The plane of the midpelvis—the least pelvic dimensions.
4. The plane of greatest pelvic dimension—of no obstetrical significance.

Pelvic Inlet

The pelvic inlet, also called the superior strait, is the superior plane of the true pelvis. It is bounded posteriorly by the promontory and alae of the sacrum, laterally by the linea terminalis, and anteriorly by the horizontal pubic rami and the symphysis pubis. During labor, fetal head engagement is defined by the fetal head's biparietal diameter passing through this plane.

Four diameters of the pelvic inlet are usually described: anteroposterior, transverse, and two oblique diameters. Of these, distinct anteroposterior diameters have been described using specific landmarks. Most cephalad, the anteroposterior diameter, termed the true conjugate, extends from the uppermost margin of the symphysis pubis to the sacral promontory (see Fig. 2-15). The clinically important obstetrical conjugate is the shortest distance between the sacral promontory and the symphysis pubis. Normally, this measures 10 cm or more, but unfortunately, it cannot be measured directly with examining fingers. Thus, the obstetrical conjugate is estimated indirectly by subtracting 1.5 to 2 cm from the diagonal conjugate. To measure the diagonal conjugate, a hand with the palm oriented laterally extends its index finger to the promontory. The distance from the fingertip to the point at which the lowest margin of the symphysis strikes the same finger's base is the diagonal conjugate.

The transverse diameter is constructed at right angles to the obstetrical conjugate and represents the greatest distance between the linea terminalis on either side (see Fig. 2-16). It usually intersects the obstetrical conjugate at a point approximately 5 cm in front of the promontory and measures approximately 13 cm.

Midpelvis and Pelvic Outlet

The midpelvis is measured at the level of the ischial spines, also called the midplane or plane of least pelvic dimensions (see Fig. 2-16). During labor, the degree of fetal head descent into the true pelvis may be described by station, and the midpelvis and ischial spines serve to mark zero station. The interspinous diameter is 10 cm or slightly greater and is usually the smallest pelvic diameter. The anteroposterior diameter through the level of the ischial spines normally measures at least 11.5 cm.

The pelvic outlet consists of two approximately triangular areas whose boundaries mirror those of the perineal triangle described earlier (Perineum). They have a common base, which is a line drawn between the two ischial tuberosities. The apex of the posterior triangle is the tip of the sacrum, and the lateral boundaries are the sacrotuberous ligaments and the ischial tuberosities. The anterior triangle is formed by the descending inferior rami of the pubic bones. These rami unite at an angle of 90 to 100 degrees to form a rounded arch under which the fetal head must pass. Unless there is significant pelvic bony disease, the pelvic outlet seldom obstructs vaginal delivery.

Pelvic Shapes

The Caldwell–Moloy (1933, 1934) anatomical classification of the pelvis is based on shape, and its concepts aid an understanding of labor mechanisms. Specifically, the greatest transverse diameter of the inlet and its division into anterior and posterior segments are used to classify the pelvis as gynecoid, anthropoid, android, or platypelloid. The posterior segment determines the type of pelvis, whereas the anterior segment determines the tendency. These are both determined because many pelves are not pure but are mixed types. For example, a gynecoid pelvis with an android tendency means that the posterior pelvis is gynecoid and the anterior pelvis is android shaped.

From viewing the four basic types in Figure 2-17, the configuration of the gynecoid pelvis would intuitively seem suited for delivery of most fetuses. Indeed, Caldwell (1939) reported that the gynecoid pelvis was found in almost half of women.

FIGURE 2-17

The four parent pelvic types of the Caldwell–Moloy classification. A line passing through the widest transverse diameter divides the inlets into posterior (P) and anterior (A) segments.

CHAPTER 3: Congenital Genitourinary Abnormalities

Abnormalities in the development or fusion of one or both Müllerian ducts may result in malformations which sometimes possess an obstetrical significance. Pregnancy may be associated with any one of these malformations, provided an ovum be cast off from the ovaries and no serious obstacle be opposed to the upward passage of the spermatozoa and their subsequent union with it.

—J. Whitridge Williams (1903)

GENITOURINARY TRACT DEVELOPMENT

In females, the external genitalia, gonads, and müllerian ducts each derive from different primordia and in close association with the urinary tract and hindgut. Abnormal embryogenesis during this process is thought to be multifactorial and can create sporadic anomalies. Several of these can lead to infertility, subfertility, miscarriage, or preterm delivery. Thus, knowledge of genitourinary system development is essential.

Embryology of the Urinary System

Between the 3rd and 5th gestational weeks, an elevation of intermediate mesoderm on each side of the fetus—the urogenital ridge—begins development into the urogenital tract. Subsequently, the urogenital ridge divides into the genital ridge, destined to become the ovary, and into the nephrogenic ridge (Fig. 3-1). The nephrogenic ridges develop into the mesonephros (mesonephric kidney) and paired mesonephric ducts, also termed wolffian ducts, which connect to the cloaca.

FIGURE 3-1

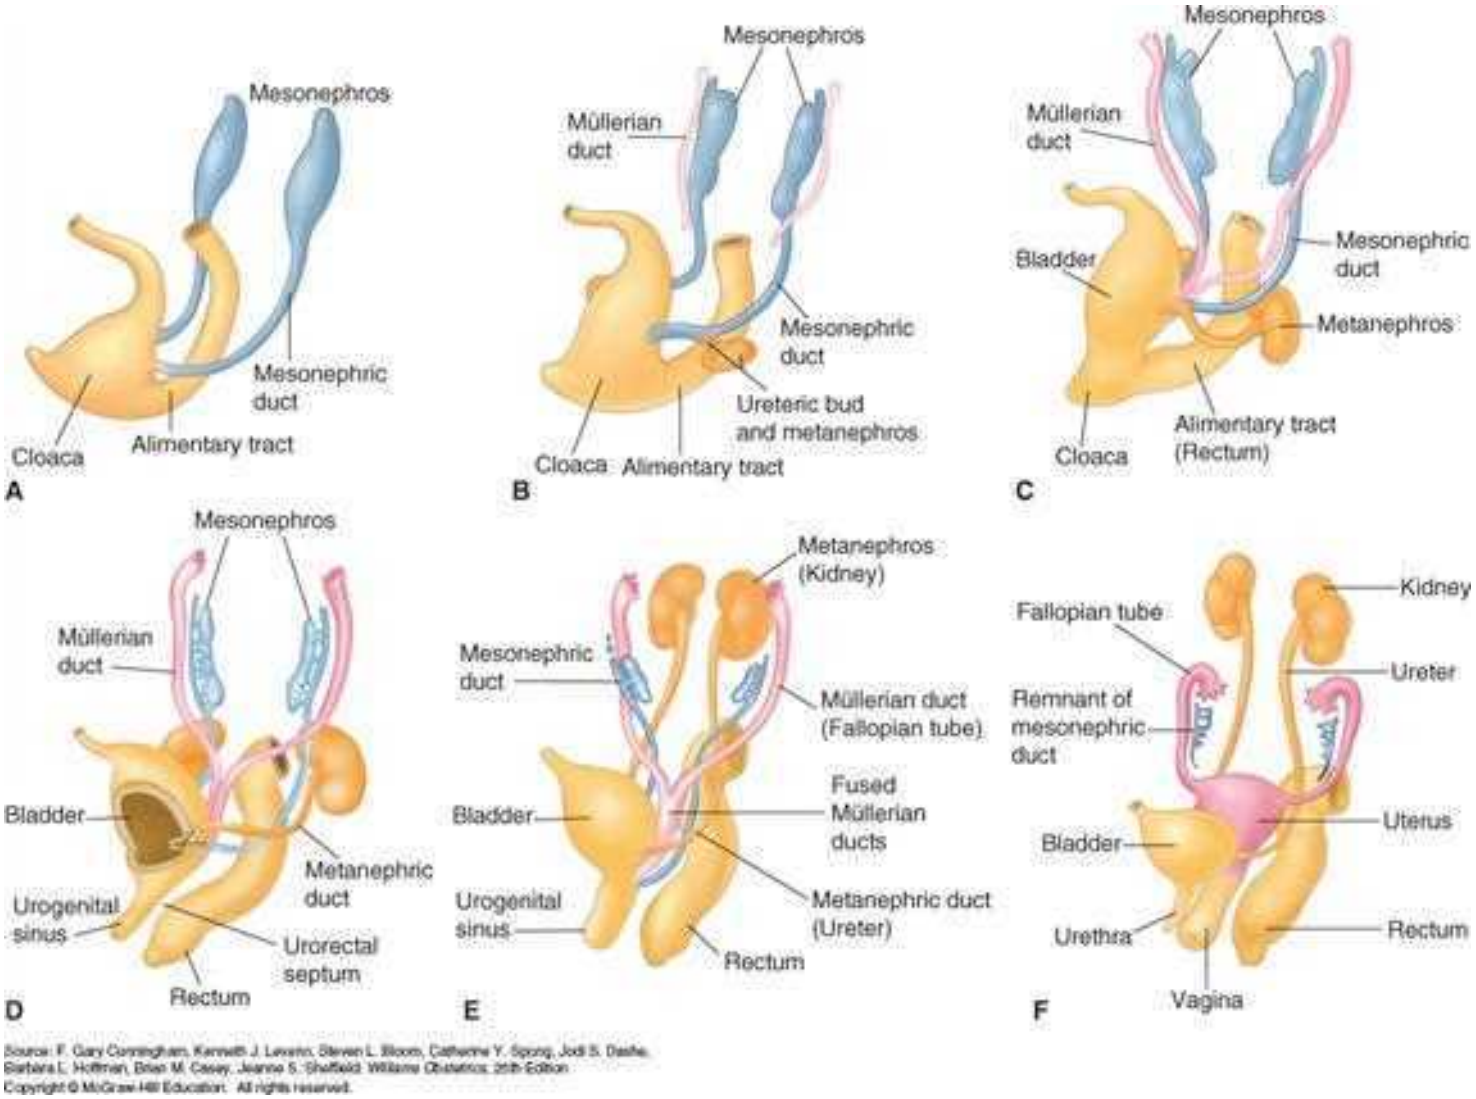
The early urinary tract develops from the mesonephros and its mesonephric ducts (Fig. 3-2A). Recall that evolution of the renal system passes sequentially through the pronephric and mesonephric stages to reach the permanent metanephric system. Between the 4th and 5th weeks, each mesonephric duct gives rise to a ureteric bud, which grows cephalad toward its respective mesonephros (Fig. 3-2B). As each bud lengthens, it induces differentiation of the

metanephros, which will become the final kidney (Fig. 3-2C). Each mesonephros degenerates near the end of the first trimester, and without testosterone, the mesonephric ducts regress as well.

FIGURE 3-2

Embryonic development of the female genitourinary tract **(A-F)**. (Reproduced with permission from Shatzkes DR, Haller JO, Velcek FT: Imaging of uterovaginal anomalies in the pediatric patient, Urol Radiol 1991;13(1):58–66.)



The cloaca begins as a common opening for the embryonic urinary, genital, and alimentary tracts. By the 7th week it becomes divided by the urorectal septum to create the rectum and the urogenital sinus (Fig. 3-2D). The urogenital sinus is considered in three parts: (1) the cephalad or vesicle portion, which forms the urinary bladder; (2) the middle or pelvic portion, which creates the female urethra; and (3) the caudal or phallic part, which gives rise to the distal vagina and to the greater vestibular (Bartholin) and paraurethral glands.

Embryology of the Genital Tract

The fallopian tubes, uterus, and upper vagina derive from the müllerian ducts, also termed paramesonephric ducts, which form adjacent to each mesonephros (see Fig. 3-2B). These ducts extend downward and then turn medially to meet and fuse together in the midline. The uterus is formed by this union of the two müllerian ducts at approximately the 10th week (Fig. 3-2E). Fusion to create the uterus begins in the middle and then extends both caudally and cephalad. With cellular proliferation at the upper portion, a thick wedge of tissue creates the characteristic piriform uterine shape. At the same time, dissolution of cells at the lower pole forms the first uterine cavity (Fig. 3-2F). As the upper wedge-shaped septum is slowly reabsorbed, the final uterine cavity is usually formed by the 20th week. If the two müllerian ducts fail to fuse, then two separate uterine horns remain. In contrast, resorption failure of the common tissue between them results in various degrees of persistent uterine septum.

As the distal end of the fused müllerian ducts contacts the urogenital sinus, this induces endodermal outgrowths from the sinus termed the sinovaginal bulbs. These bulbs proliferate and fuse to form the vaginal plate, which later resorbs to form the vaginal lumen. This vaginal canalization is generally completed by the 20th week. However, the lumen remains separated from the urogenital sinus by the hymeneal membrane. This membrane further degenerates to leave only the hymeneal ring.

The close association of the mesonephric (wolffian) and paramesonephric (müllerian) ducts explains the simultaneous abnormalities in their end organs. Kenney and colleagues (1984) showed that up to half of females with uterovaginal malformations have associated urinary tract defects. Anomalies most frequently associated with renal defects are unicornuate uterus, uterine didelphys, and agenesis syndromes, whereas arcuate and bicornuate are less commonly linked (Reichman, 2010). When müllerian anomalies are identified, the urinary system can be evaluated with magnetic resonance (MR) imaging, sonography, or intravenous pyelography (Hall-Craggs, 2013). With müllerian anomalies, ovaries are functionally normal but have a higher incidence of anatomical maldescent into the pelvis (Allen, 2012; Dabirashrafi, 1994).

As discussed, the mesonephric ducts usually degenerate, however, persistent remnants may become clinically apparent. Mesonephric or wolffian vestiges can persist as Gartner duct cysts. These are typically located in the proximal anterolateral vaginal wall but may be found at other sites along the vaginal length. They can be further characterized by MR imaging, which provides excellent image resolution at soft tissue interfaces. Most cysts are asymptomatic and benign and usually do not require surgical excision.

Intraabdominal wolffian remnants in the female include a few blind tubules in the mesovarium—the epoöphoron—and similar ones adjacent to the uterus—paroöphoron (see Fig. 3-2F) (Moore, 2013). The epoöphoron or paroöphoron may develop into clinically identifiable cysts in the adult.

Embryology of the Gonads

At approximately 4 weeks, gonads derive from coelomic epithelium covering the medial and ventral surface of the nephrogenic cord at a site between the eighth thoracic and fourth lumbar segments. Because of this separate gonadal and müllerian derivation, women with müllerian defects typically have functionally normal ovaries and are phenotypic females. The coelomic epithelium thickens to form the genital ridge, also known as the gonadal ridge. Strands of these epithelial cells extend into the underlying mesenchyme as the primary sex cords. By the sixth week, primordial germ cells have migrated from the yolk sac to enter the genital ridge mesenchyme (Fig. 3-3). The primordial germ cells are then incorporated into the primary sex cords.

FIGURE 3-3

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

In the seventh week, the sexes can be distinguished, and testes are recognized during microscopic sectioning by their well-defined radiating testis cords. These cords are separated from the coelomic epithelium by mesenchyme that is to become the tunica albuginea. The testis cords develop into the

seminiferous tubules and rete testis. The rete testis establishes connection with small tubes arising off the mesonephric duct. These small tubes become the efferent ducts that drain into the epididymis and then into the vas deferens, which are main mesonephric duct derivatives.

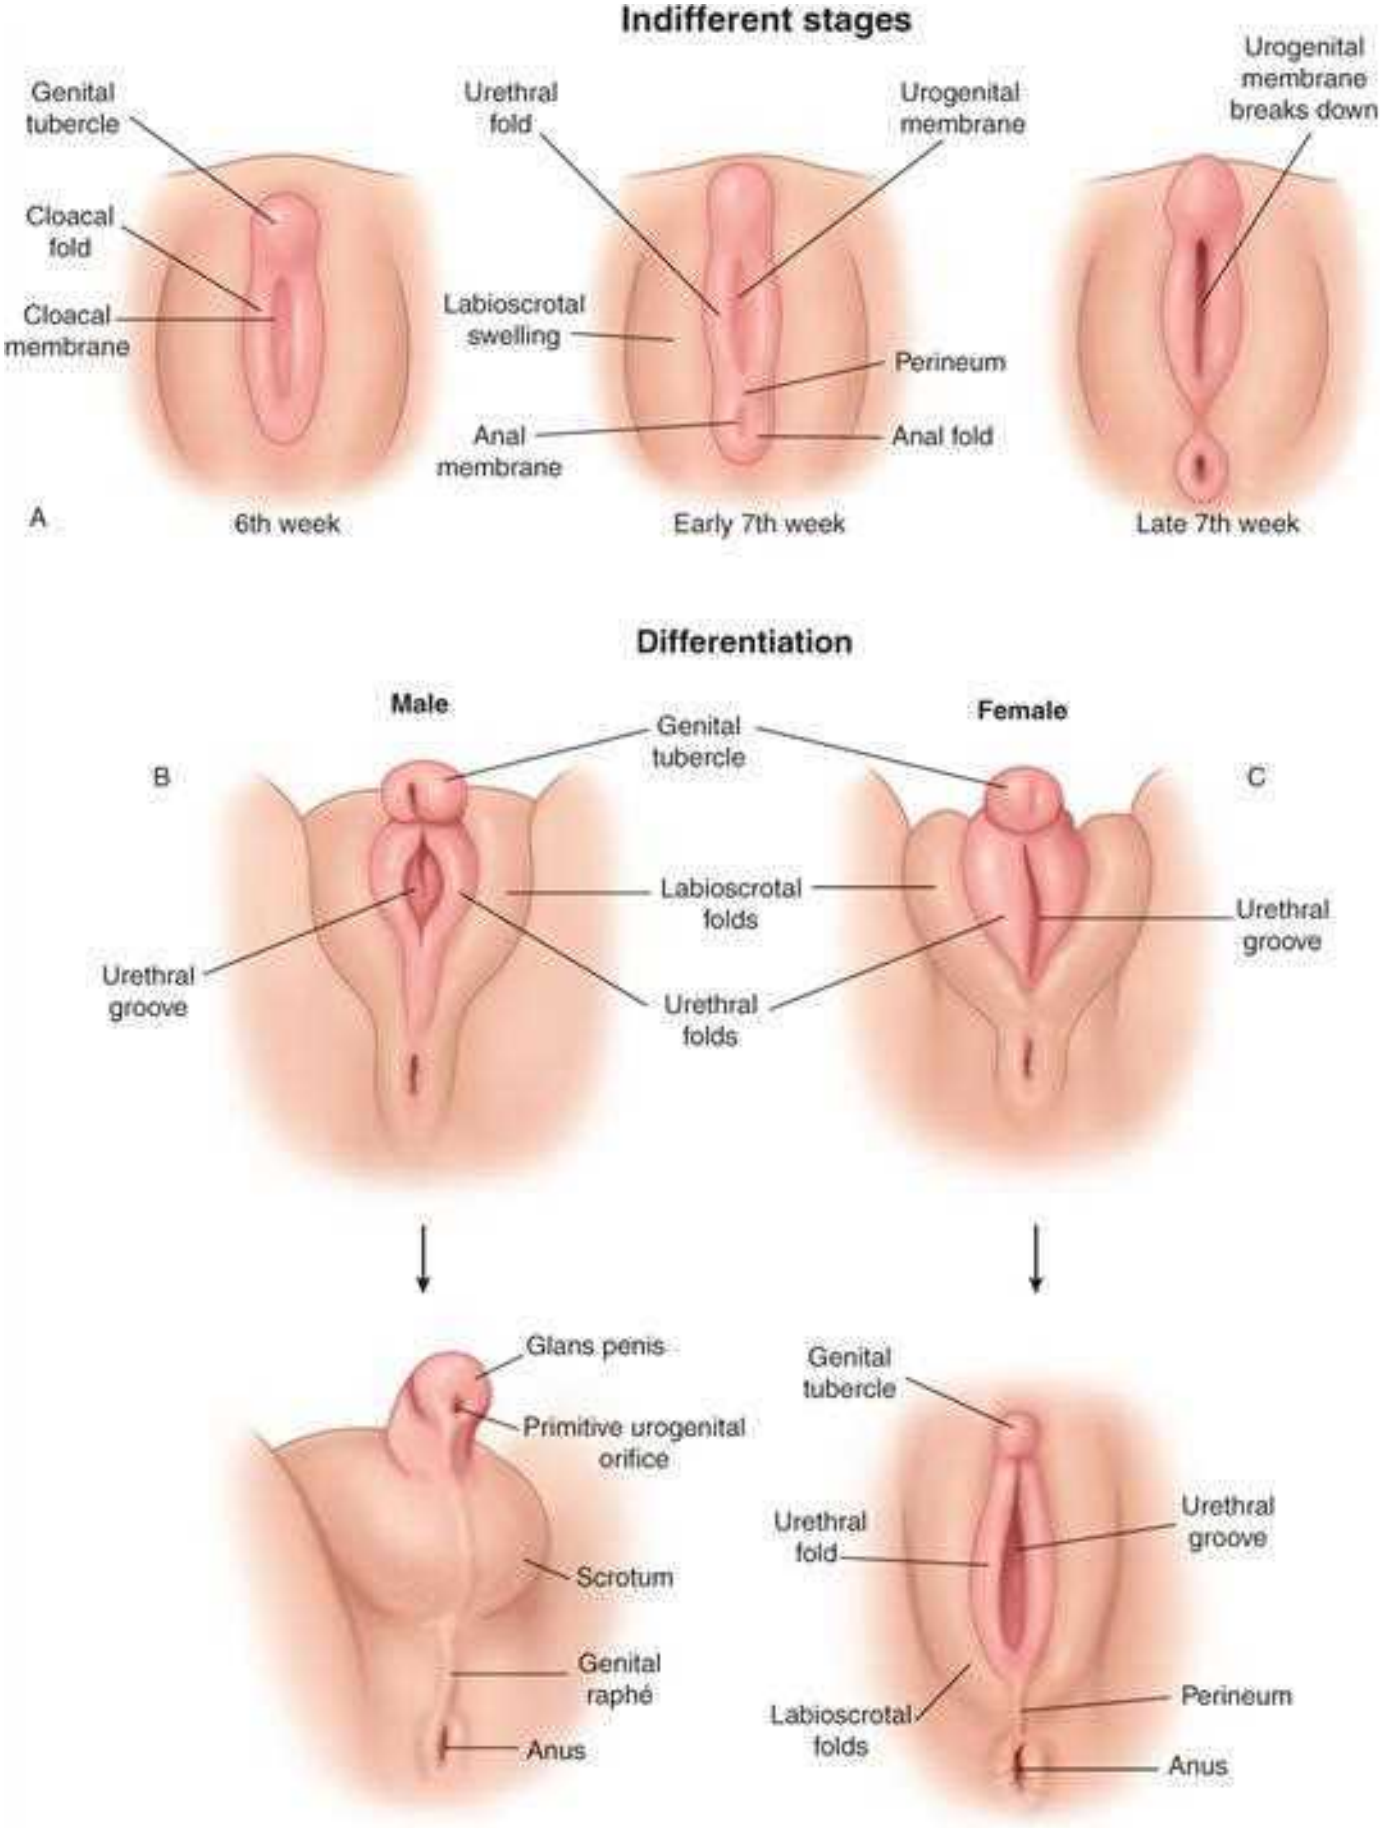
In the female embryo, the primary sex cords give rise to the medullary cords, which persist only for a short time. The coelomic epithelium again proliferates into the underlying mesenchyme, and these strands are the cortical cords. By the fourth month, the cortical cords begin to form isolated cell clusters called primordial follicles. These follicles contain the oogonia, which derive from primordial germ cells and are surrounded by a single layer of flattened follicular cells derived from the cortical cords. Follicular cells serve as supporting nutrient cells. By 8 months, the ovary has become a long, narrow, lobulated structure that is attached to the body wall by the mesovarium. The coelomic epithelium has been separated by a band of connective tissue—tunica albuginea—from the cortex. At this stage, the cortex contains follicles and is well defined from the inner medulla, which is composed of abundant blood vessels, lymphatic vessels, and nerve fibers.

Embryology of the External Genitalia

Early development of the external genitalia is similar in both sexes. By 6 weeks' gestation, three external protuberances have developed surrounding the cloacal membrane. These are the left and right cloacal folds, which meet ventrally to form the genital tubercle (Fig. 3-4). With division of the cloacal membrane into anal and urogenital membranes, the cloacal folds become the anal and urethral folds, respectively. Lateral to the urethral folds, genital swellings arise, and these become the labioscrotal folds. Between the urethral folds, the urogenital sinus extends onto the surface of the enlarging genital tubercle to form the urethral groove. By week 7, the urogenital membrane ruptures, exposing the cavity of the urogenital sinus to amnionic fluid.

FIGURE 3-4

Development of the external genitalia. **A.** Indifferent stage. **B.** Virilization of external genitalia. **C.** Feminization. (Reproduced with permission from Bradshaw KD: Anatomical disorders. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw Hill Education, 2016.)



The genital tubercle elongates to form the phallus in males and the clitoris in females. Still, it is not possible to visually differentiate between male and female external genitalia until week 12. In the male fetus, dihydrotestosterone (DHT) forms locally by the 5-α reduction of testosterone. DHT prompts the anogenital distance to lengthen, the phallus to enlarge, and the labioscrotal folds to fuse and form the scrotum.

In the female fetus, without DHT, the anogenital distance does not lengthen, and the labioscrotal and urethral folds do not fuse (Fig. 3-4C). The genital tubercle bends caudally to become the clitoris, and the urogenital sinus forms the vestibule of the vagina. The labioscrotal folds create the labia majora, whereas the urethral folds persist as the labia minora. Female external genital differentiation is complete by 11 weeks, whereas male external genital differentiation is complete by 14 weeks.

SEXUAL DIFFERENTIATION

Defining gender incorporates genetic gender, gonadal gender, and phenotypic gender. *Genetic gender*—XX or XY—is established at fertilization. However, for the first 6 weeks, development of male and female embryos is morphologically indistinguishable.

Gonadal gender is heralded by the differentiation of the primordial gonad into a testis or an ovary. If a Y chromosome is present, the gonad begins developing into a testis. Testis development is directed by a protein called the *testis-determining factor (TDF)*, which modulates the transcription of several genes involved in gonadal differentiation. TDF is encoded by the *sex-determining region (SRY) gene,* located on the short arm of the Y chromosome. But testis development is much more complex and requires other autosomal genes (Nistal, 2015a).

The importance of the *SRY* gene is demonstrated in several paradoxical conditions. First, 46,XX phenotypic males can result from translocation of the Y chromosome fragment containing *SRY* to the X chromosome during meiosis of male germ cells (Wu, 2014). Similarly, 46,XY individuals can appear phenotypically female if they carry a mutation in the *SRY* gene (Helszer, 2013).

Last, *phenotypic gender* begins at 8 weeks' gestation. Before this, urogenital tract development in both sexes is indistinguishable. Thereafter, differentiation of the internal and external genitalia to the male phenotype is dependent on testicular function. In the absence of a testis, female differentiation ensues irrespective of genetic gender (Table 3-1).

TABLE 3-1

Embryonic Urogenital Structures and Their Adult Homologues

Indifferent Structure	Female	Male
Genital ridge	Ovary	Testis
Primordial germ cells	Ova	Spermatozoa
Sex cords	Granulosa cells	Seminiferous tubules, Sertoli cells
Gubernaculum	Uteroovarian and round ligaments	Gubernaculum testis
Mesonephric tubules	Epoöphoron, paroöphoron	Efferent ductules, paradidymis
Mesonephric ducts	Gartner duct	Epididymis, ductus deferens, ejaculatory duct
Paramesonephric ducts	Uterus, fallopian tubes, upper vagina	Prostatic utricle, appendix of testis
Urogenital sinus	Bladder, urethra Vagina Paraurethral glands Greater (Bartholin) and lesser vestibular glands	Bladder, urethra Prostatic utricle Prostate glands Bulbourethral glands
Genital tubercle	Clitoris	Glans penis
Urogenital folds	Labia minora	Floor of penile urethra
Labioscrotal swellings	Labia majora	Scrotum

In males, the fetal testis secretes a protein called müllerian-inhibiting substance (MIS), also called antimüllerian hormone (AMH). It acts locally as a paracrine factor to cause müllerian duct regression. Thus, it prevents the development of uterus, fallopian tube, and upper vagina. AMH is produced by the Sertoli cells of the seminiferous tubules. Importantly, these tubules appear in fetal gonads and secrete AMH before differentiation of Leydig cells, which are the cellular

site of testosterone synthesis. AMH is secreted as early as 7 weeks, and müllerian duct regression is completed by 9 to 10 weeks. Because AMH acts locally near its site of formation, if a testis were absent on one side, the müllerian duct on that side would persist, and the uterus and fallopian tube would develop on that side.

Apparently through stimulation initially by human chorionic gonadotropin (hCG), and later by fetal pituitary luteinizing hormone (LH), the fetal testes secrete testosterone. This hormone acts directly on the wolffian duct to effect the development of the vas deferens, epididymis, and seminal vesicles. Testosterone also enters fetal blood and acts on the external genitalia anlage. In these tissues, testosterone is converted to 5α-DHT to cause virilization of the external genitalia.

DISORDERS OF SEX DEVELOPMENT

Definitions

As evident from the prior discussion, abnormal sex development may involve the gonads, internal duct system, or external genitalia. Rates vary and approximate 1 in every 1000 to 4500 births (Murphy, 2011; Ocal, 2011). The nomenclature used to describe disorders of sex development (DSDs) has evolved. Current classification of these disorders include: (1) sex chromosome DSDs, (2) 46,XY DSDs, and (3) 46,XX DSDs (Table 3-2) (Hughes, 2006).

TABLE 3-2

Disorders of Sex Development (DSD) Classification

Sex Chromosome DSD
45,X Turner[a]
47,XXY Klinefelter[a]
45,X/46,XY Mixed gonadal dysgenesis
46,XX/46,XY Ovotesticular DSD
46,XY DSD
Testicular development
Pure gonadal dysgenesis
Partial gonadal dysgenesis
Ovotesticular
Testis regression
Androgen production or action
Androgen synthesis
Androgen receptor
LH/hCG receptor
AMH
46,XX DSD
Ovary development
Ovotesticular
Testicular
Gonadal dysgenesis
Androgen excess
Fetal
Maternal
Placental

[a]And syndrome variants.

AMH = antimüllerian hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone.

Other important terms describe the abnormal phenotypic findings that can be found. First, some disorders of sexual development are associated with abnormal, underdeveloped gonads, that is, *gonadal dysgenesis*. With this, if a testis is poorly formed, it is called a *dysgenetic testis*, and if an ovary is poorly formed, it is called a *streak gonad*. In affected patients, the underdeveloped gonad ultimately fails, which is indicated by elevated gonadotropin levels. Another important clinical sequela is that patients bearing a Y chromosome are at high risk of developing a germ cell tumor in the dysgenetic gonad.

A second term, *ambiguous genitalia*, describes genitalia that do not appear clearly male or female. Abnormalities may include hypospadias, undescended testes, micropenis or enlarged clitoris, labial fusion, and labial mass.

Last, *ovotesticular* defines states characterized by ovarian and testicular tissue in the same individual. It was formerly termed true hermaphroditism. In these cases, different types of gonads can be paired. The types of gonads that may be paired include a normal testis, a normal ovary, a streak gonad, dysgenetic testis, or an ovotestis. In the latter, both ovarian and testicular elements are combined within the same gonad. With ovotesticular DSDs, the internal ductal system structure depends on the ipsilateral gonad and its degree of determination. Specifically, the amount of AMH and testosterone determines the degree to which the internal ductal system is masculinized or feminized. External genitalia are usually ambiguous and undermasculinized due to inadequate testosterone.

Sex Chromosome Disorders of Sex Development

Turner and Klinefelter Syndromes

Sex chromosome disorders of sexual development typically arise from an abnormal number of sex chromosomes. Of these, Turner and Klinefelter syndromes are most frequently encountered (Nielsen, 1990).

Turner syndrome is caused by de novo loss or severe structural abnormality of one X chromosome in a phenotypic female. Most affected fetuses are spontaneously aborted. However, in girls with Turner syndrome who survive, phenotype varies widely, but nearly all affected patients have short stature. Associated problems include cardiac anomalies (especially coarctation of the aorta), renal anomalies, hearing impairment, otitis media and mastoiditis, and an increased incidence of hypertension, achlorhydria, diabetes mellitus, and Hashimoto thyroiditis. It is the most common form of gonadal dysgenesis that leads to primary ovarian failure. In these cases, the uterus and vagina are normal and capable of responding to exogenous hormones (Matthews, 2017).

Another sex chromosome disorder is *Klinefelter syndrome* (47,XXY). These individuals tend to be tall, undervirilized males with gynecomastia and small, firm testes. They have significantly reduced fertility from hypogonadism due to gradual testicular cell failure. These men are at increased risk for germ cell tumors, osteoporosis, hypothyroidism, diabetes mellitus, breast cancer, cardiovascular abnormalities, and cognitive and psychosocial problems (Aksglaede, 2013; Calogero, 2017).

Chromosomal Ovotesticular DSD

Several karyotypes can create a coexistent ovary and testis, and thus ovotesticular DSD is found in all three DSD categories (see Table 3-2). In the sex chromosome group, ovotesticular DSD may arise from a 46,XX/46,XY karyotype. Here, an ovary, testis, or ovotestis may be paired. The phenotype in general mirrors that for ovotesticular disorders, which are described earlier on this page.

For others in the sex chromosome DSD group, ovotesticular disorder arises from a chromosomal mosaic such as 45,X/46,XY. With this karyotype, a picture of *mixed gonadal dysgenesis* shows a streak gonad on one side and a dysgenetic or normal testis on the other. The phenotypical appearance ranges from undervirilized male to ambiguous genitalia to Turner stigmata.

46,XY Disorders of Sex Development

Insufficient androgen exposure of a fetus destined to be a male leads to 46,XY DSD—formerly called male pseudohermaphroditism. The karyotype is 46,XY and testes are frequently present. The uterus is generally absent as a result of normal embryonic AMH production by Sertoli cells. These subjects are most often sterile from abnormal spermatogenesis and have a small phallus that is inadequate for sexual function. As seen in Table 3-2, etiology of 46,XY DSD may stem from abnormal testis development or from abnormal androgen production or action.

46,XY Gonadal Dysgenesis

This spectrum of abnormal gonad underdevelopment includes pure or complete, partial, or mixed 46,XY gonadal dysgenesis. These are defined by the amount of normal testicular tissue and by karyotype. Because of the potential for germ cell tumors in dysgenetic testes and intraabdominal testes, affected patients routinely have been advised to undergo gonadectomy (Jiang, 2016).

Of these, *pure gonadal dysgenesis* results from a mutation in the *SRY* gene or in other genes with testis-determining effects (Hutson, 2014). This leads to underdeveloped dysgenetic gonads that fail to produce androgens or AMH. Formerly named Swyer syndrome, the condition creates a normal prepubertal female phenotype and a normal müllerian system due to absent AMH.

Partial gonadal dysgenesis defines those with gonad development intermediate between normal and dysgenetic testes. Depending on the percentage of underdeveloped testis, wolffian and müllerian structures and genital ambiguity are variably expressed.

Mixed gonadal dysgenesis is one type of ovotesticular disorder of sexual differentiation. As discussed in Sex Chromosome Disorders of Sex Development, one gonad is streak, and the other is a normal or a dysgenetic testis. Of affected individuals, 15 percent have a 46,XY karyotype (Nistal, 2015b). The phenotype is wide ranging as with partial gonadal dysgenesis.

Last, *testicular regression* can follow initial testis development. A broad phenotypic spectrum is possible and depends on the timing of testis failure.

Abnormal Androgen Production or Action

In some cases, 46,XY disorders of sexual differentiation stem from abnormalities in: (1) testosterone biosynthesis, (2) LH receptor function, (3) AMH function, or (4) androgen receptor action. First, the sex steroid biosynthesis pathway can suffer enzymatic defects that block testosterone production. Depending on the timing and degree of blockade, undervirilized males or phenotypic females may result. In contrast to these central enzymatic defects, peripheral defects may be causative. Namely, abnormal 5-α reductase type 2 enzyme action leads to impaired conversion of testosterone to DHT and thus to undervirilization.

Second, hCG/LH receptor abnormalities within the testes can lead to Leydig cell aplasia/hypoplasia and impaired testosterone production. In contrast, disorders of AMH and AMH receptors result in persistent müllerian duct syndrome (PMDS). Affected patients appear as males but have a persistent uterus and fallopian tubes due to failed AMH action.

Last, the androgen receptor may be defective and result in androgen-insensitivity syndrome (AIS). Resistance to androgens may be incomplete and associated with varying degrees of virilization and genital ambiguity. Milder forms have been described in men with severe male factor infertility and poor virilization.

Females with complete androgen-insensitivity syndrome (CAIS) appear as phenotypically normal females at birth. They often present at puberty with primary amenorrhea. External genitalia appear normal; scant or absent pubic and axillary hair are noted; the vagina is shortened or blind ending; and the uterus and fallopian tubes are absent. However, these individuals develop breasts during pubertal maturation due to abundant androgen to estrogen conversion. Testes may be palpable in the labia or inguinal area or may be found intraabdominally. Surgical excision of the testes after puberty is recommended to decrease the associated risk of germ cell tumors, which may be as high as 20 to 30 percent.

46,XX Disorders of Sex Development

As seen in Table 3-2, etiology of 46,XX disorders of sexual differentiation may stem from abnormal ovarian development or from excess androgen exposure.

Abnormal Ovarian Development

Disorders of ovarian development of those with a 46,XX complement include: (1) gonadal dysgenesis, (2) testicular DSD, and (3) ovotesticular DSD.

With *46,XX gonadal dysgenesis*, similar to Turner syndrome, streak gonads develop. These lead to hypogonadism, prepubertal normal female genitalia, and normal müllerian structures, but other Turner stigmata are absent.

With *46,XX testicular DSD*, several possible genetic mutations lead to testis-like formation within the ovary—streak gonad, dysgenetic testis, or ovotestis. Defects may stem from *SRY* translocation onto one X chromosome. In individuals without *SRY* translocation, other genes with testis-determining effects are most likely activated. Regardless, production of AMH prompts müllerian system regression, and androgens promote wolffian system development and external genitalia masculinization. Spermatogenesis, however, is absent due to a lack of needed genes on the long arm of the Y chromosome. These individuals are not usually diagnosed until puberty or during infertility evaluation.

With *46,XX ovotesticular DSD*, individuals possess a unilateral ovotestis with a contralateral ovary or testis, or bilateral ovotestes. Phenotypic findings depend on the degree of androgen exposures and mirror those for other ovotesticular DSDs discussed in Sex Chromosome Disorders of Sex Development.

Androgen Excess

Discordance between gonadal sex (46,XX) and the phenotypic appearance of external genitalia (masculinized) may also result from excessive fetal androgen exposure. This was previously termed female pseudohermaphroditism. In affected individuals, the ovaries and female internal ductal structures such as the uterus, cervix, and upper vagina are present. Thus, patients are potentially fertile. The external genitalia, however, are virilized to a varying degree depending on the amount and timing of androgen exposure. The three embryonic structures that are commonly affected by elevated androgen levels or ovarian development disorders are the clitoris, labioscrotal folds, and urogenital sinus. As a result, virilization may range from modest clitoromegaly to posterior labial fusion and development of a phallus with a penile urethra. Degrees of virilization can be described by the Prader score, which ranges from 0 for a normal-appearing female to 5 for a normal, virilized male.

Fetal, placental, or maternal sources can provide the excessive androgen levels. Maternally derived androgen excess may come from virilizing ovarian tumors such as luteoma and Sertoli-Leydig cell tumor or from virilizing adrenal tumors. Fortunately, these neoplasms infrequently cause fetal effects because of the tremendous ability of placental syncytiotrophoblast to convert C_{19} steroids—androstenedione and testosterone—to estradiol via the enzyme aromatase (Chap. 5, Placental Estrogen Production). As another source, drugs such as testosterone, danazol, and other androgen derivatives may cause fetal virilization.

Of fetal sources, exposure can arise from fetal congenital adrenal hyperplasia (CAH). This stems from a fetal enzyme deficiency in the steroidogenic pathway that leads to androgen accumulation. The most common defect is 21-hydroxylase deficiency. CAH is a frequent cause of virilization and has an incidence approximating 1 in 10,000 to 20,000 live births (Speiser, 2010).

With CAH, phenotypes depend on the location of the enzyme defect in the steroidogenic pathway and on the severity of the resulting enzymatic deficiency (Miller, 2011). With severe enzymatic deficiency, affected newborns have life-threatening salt wasting and virilization. Other mutations may prompt virilization alone (Auchus, 2015). The mildest abnormalities present later and are described as "nonclassic," "late-onset," or "adult-onset" CAH. In these patients, activation of the adrenal axis at puberty increases steroidogenesis and unmasks a mild enzymatic deficiency. Excess androgen provides negative feedback to gonadotropin-releasing hormone (GnRH) receptors in the hypothalamus. These patients often present with hirsutism, acne, and anovulation. Thus, late-onset CAH may mimic polycystic ovarian syndrome (McCann-Crosby, 2014). In some instances, CAH can be diagnosed antenatally. Early maternal dexamethasone therapy can dampen androgen excess to minimize virilization (Chap. 16, Congenital Adrenal Hyperplasia).

Of rare placental sources, placental aromatase deficiency from a fetal *CYP19* gene mutation causes an accumulation of placental androgen and underproduction of placental estrogens (Chap. 5, Placental Estriol Synthesis) (Jones, 2007). Consequently, both the mother and the 46,XX fetus are virilized.

Gender Assignment

Delivery of a newborn with a disorder of sexual differentiation is a potential medical emergency and can create possible long-lasting psychosexual and social ramifications for the individual and family. Ideally, as soon as the affected neonate is stable, parents are encouraged to hold the child. The newborn is referred to as "your baby," and suggested terms include "phallus," "gonads," "folds," and "urogenital sinus" to reference underdeveloped structures. The obstetrician explains that the genitalia are incompletely formed and emphasizes the seriousness of the situation and the need for rapid consultation and laboratory testing.

Because similar or identical phenotypes may have several etiologies, identification of a specific DSD may require several diagnostic tools (McCann-Crosby, 2015). Relevant neonatal physical examination evaluates: (1) ability to palpate gonads in the labioscrotal or inguinal regions, (2) ability to palpate uterus during rectal examination, (3) phallus size, (4) genitalia pigmentation, and (5) presence of other syndromic features. The newborn metabolic condition is assessed, as hyperkalemia, hyponatremia, and hypoglycemia may indicate CAH. The mother is examined for signs of hyperandrogenism. Other neonatal tests include genetic studies, hormone measurements, imaging, and in some cases endoscopic, laparoscopic, and gonadal biopsy. Sonography shows the presence or absence of müllerian/wolffian structures, can locate the gonads, and can identify associated malformations such as renal anomalies.

BLADDER AND PERINEAL ABNORMALITIES

Very early during embryo formation, a bilaminar cloacal membrane lies at the caudal end of the germinal disc and forms the infraumbilical abdominal wall. Normally, an ingrowth of mesoderm between the ectodermal and endodermal layers of the cloacal membrane leads to formation of the lower abdominal musculature and pelvic bones. Without this reinforcement, the cloacal membrane may prematurely rupture, and depending on the extent of the infraumbilical defect, cloacal exstrophy, bladder exstrophy, or epispadias may result.

Of these, *cloacal exstrophy* is rare. It includes the triad of omphalocele, bladder exstrophy, and imperforate anus.

Bladder exstrophy is uncommon and is characterized by an exposed bladder lying outside the abdomen. Associated findings often include abnormal external genitalia and a widened symphysis pubis. At the same time, however, the uterus, fallopian tubes, and ovaries are typically normal except for occasional müllerian duct fusion defects. Pregnancy with bladder exstrophy is associated with greater risk for antepartum pyelonephritis, urinary retention, ureteral obstruction, pelvic organ prolapse, preterm birth, and breech presentation. The American Urological Association has published management guidelines for pregnancy (Eswara, 2016). Due to the extensive adhesions from prior repair and altered anatomy typically encountered, some recommend planned cesarean delivery at a tertiary center (Deans, 2012; Dy, 2015; Greenwell, 2003).

Epispadias without bladder exstrophy is rare and develops in association with other anomalies such as a widened, patulous urethra; absent or bifid clitoris; nonfused labial folds; and flattened mons pubis. Vertebral abnormalities and pubic symphysis diathesis are also common.

Clitoral anomalies are unusual. One is clitoral duplication or bifid clitoris, which is rare and usually develops in association with bladder exstrophy or epispadias. With female phallic urethra, the urethra opens at the clitoral tip. Last, clitoromegaly noted at birth suggests fetal exposure to excessive androgens (46,XX Disorders of Sex Development). In other cases, congenital clitoromegaly in females born extremely premature is a rare but well-recognized finding thought to be due to transient androgen levels in these neonates (Greaves, 2008).

As noted, the hymen marks the embryological boundary between structures derived from the müllerian and urogenital sinus. *Hymeneal anomalies* include imperforate, microperforate, cribriform (sievelike), navicular (boat-shaped), and septate hymens. They result from failure of the inferior end of the vaginal plate—the hymeneal membrane—to canalize. Their incidences approximate 1 in 1000 to 2000 females (American College of Obstetricians and Gynecologists, 2016). During the neonatal period, significant amounts of mucus can be secreted due to maternal estrogen stimulation. With an imperforate hymen, secretions collect to form a bulging, translucent yellow-gray mass, termed hydro- or mucocolpos, at the vaginal introitus. Most are asymptomatic and resolve as mucus is reabsorbed and estrogen levels decrease, but rarely can cause perinatal urinary retention from their mass effects (Johal, 2009).

MÜLLERIAN ABNORMALITIES

Four principal deformities arise from defective müllerian duct embryological steps: (1) agenesis of both ducts, either focally or along the entire duct length; (2) unilateral maturation of one müllerian duct with incomplete or absent development of the opposite side; (3) absent or faulty midline fusion of the ducts; or (4) defective canalization. Various classifications have been proposed, and Table 3-3 shows the one from the American Fertility Society (1988). It separates anomalies into groups with similar clinical characteristics, prognosis for pregnancy, and treatment. It also includes one for abnormalities associated with fetal exposure to diethylstilbestrol (DES). Several other classification systems have been crafted, but this one is the most widely used (Acién, 2011; Di Spiezio Sardo, 2015; Oppelt, 2005).

TABLE 3-3

Classification of Müllerian Anomalies

I.	**Segmental müllerian hypoplasia or agenesis** a. Vaginal b. Cervical c. Uterine fundal d. Tubal e. Combined anomalies
II.	**Unicornuate uterus** a. Communicating rudimentary horn b. Noncommunicating horn c. No endometrial cavity d. No rudimentary horn
III.	**Uterine didelphys**
IV.	**Bicornuate uterus** a. Complete—division to internal os b. Partial
V.	**Septate uterus** a. Complete—septum to internal os b. Partial
VI.	**Arcuate**
VII.	**Diethylstilbestrol related**

Data from American Fertility Society: The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, Müllerian anomalies and intrauterine adhesions, Fertil Steril 1988 Jun;49(6):944–955.

Müllerian anomalies may be suspected by symptoms or physical findings such as vaginal septa, blind-ending vagina, or duplicated cervix. Amenorrhea may be an initial complaint for those with agenesis of a müllerian component. In those with outlet obstruction, pelvic pain from occult blood that accumulates and distends the vagina, uterus, or fallopian tubes may arise from functioning endometrium. Endometriosis and its associated dysmenorrhea, dyspareunia, and chronic pain are also frequent with outlet obstruction.

Müllerian Agenesis

Class I segmental defects are caused by müllerian hypoplasia or agenesis as shown in Figure 3-5. These developmental defects can affect the vagina, cervix, uterus, or fallopian tubes and may be isolated or may coexist with other müllerian defects.

Vaginal Abnormalities

Of all vaginal anomalies, vaginal agenesis is the most profound and may be isolated or associated with other müllerian anomalies. One example is the Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, in which upper vaginal agenesis is typically associated with uterine hypoplasia or agenesis. Less often, this syndrome also displays abnormalities of the renal, skeletal, and auditory systems. This triad is known by the acronym MURCS, which reflects müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia (Rall, 2015).

The obstetrical significance of vaginal anomalies depends greatly on the degree of obstruction. Complete vaginal agenesis, unless corrected operatively, precludes pregnancy by vaginal intercourse. With MRKH syndrome, a functional vagina can be created, but uterine agenesis proscribes childbearing. In these women, however, ova can be retrieved for in vitro fertilization (IVF) in a surrogate mother (Friedler, 2016). Uterine transplantation is currently experimental but holds future promise for these women (Johannesson, 2016).

Of other vaginal anomalies, congenital septa may form longitudinally or transversely, and each can arise from a fusion or resorption defect. Longitudinal septa divide the vagina into right and left portions. They may be complete and extend the entire vaginal length. Partial septa usually form high in the vagina but may develop at lower levels. Septa are typically associated with other müllerian anomalies (Haddad, 1997). During labor, a complete longitudinal vaginal septum usually does not cause dystocia because the vaginal side through which the fetus descends dilates satisfactorily. An incomplete or partially obstructed longitudinal septum, however, may interfere with descent. Occasionally, a woman with a distal longitudinal septum presents in labor. During second-stage labor, this septum usually becomes attenuated by pressure from the fetal head. After ensuring adequate analgesia, the inferior attachment of the septum is isolated, clamped, transected, and ligated. Following placenta delivery, the superior attachment can be transected while carefully avoiding urethral injury.

A transverse septum poses an obstruction of variable thickness. It may develop at any depth within the vagina, but most are in the lower third (Williams, 2014). These may or may not be perforate, and thus obstruction or infertility is variably present. In labor, perforate strictures may be mistaken for the upper limit of the vaginal vault, and the septal opening is misidentified as an undilated cervical os (Kumar, 2014). If encountered during labor, and after the external

os has dilated completely, the head impinges on the septum and causes it to bulge downward. If the septum does not yield, slight stretching pressure on its opening usually leads to further dilatation, but occasionally cruciate incisions are required to permit delivery (Blanton, 2003). If there is a thick transverse septum, however, cesarean delivery may be necessary.

Cervical Abnormalities

Developmental abnormalities of the cervix include partial or complete agenesis, duplication, and longitudinal septa. Uncorrected complete agenesis is incompatible with pregnancy, and in vitro fertilization with gestational surrogacy is an option. Surgical correction by uterovaginal anastomosis has resulted in successful pregnancy (Kriplani, 2012). Significant complications accompany this corrective surgery, and the need for clear preoperative anatomy delineation has been emphasized by Rock (2010) and Roberts (2011) and their colleagues. For this reason, they recommend hysterectomy for complete cervical agenesis and reserve reconstruction attempts for carefully selected patients with cervical dysgenesis.

Uterine Abnormalities

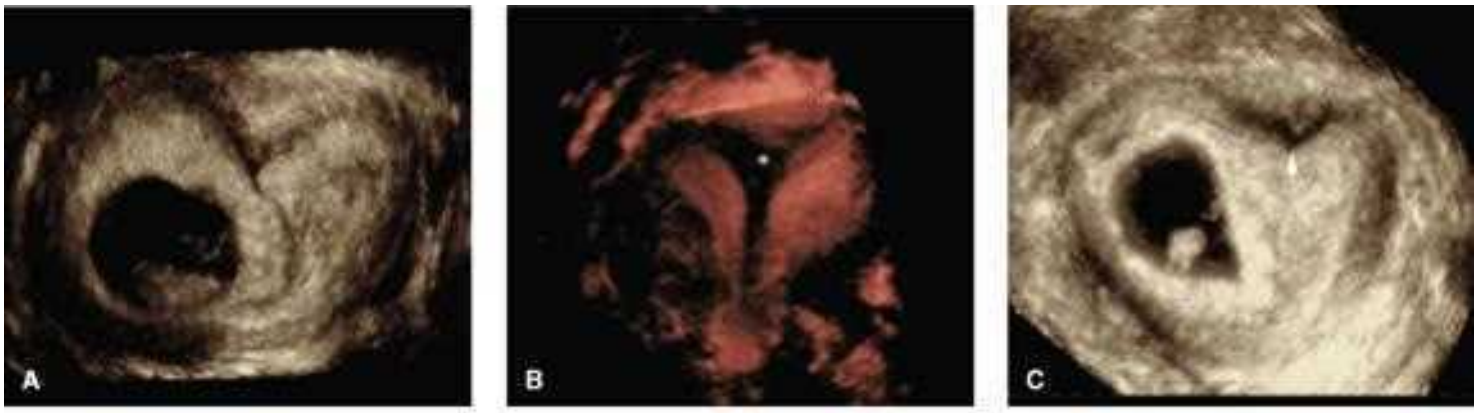
From a large variety, a few of the more common congenital uterine malformations are shown in Table 3-3. An accurate population prevalence of these is difficult to assess because the best diagnostic techniques are invasive. That said, the prevalence found with imaging ranges from 0.4 to 10 percent, and rates in women with recurrent miscarriage are significantly higher (Byrne, 2000; Dreisler, 2014; Saravelos, 2008). In a general population, the most common finding is arcuate uterus, followed in descending order by septate, bicornuate, didelphic, and unicornuate classes (Chan, 2011b).

Müllerian anomalies may be discovered during pelvic examination, cesarean delivery, tubal sterilization, or infertility evaluation. Depending on clinical presentation, diagnostic tools may include sonography, hysterosalpingography, magnetic-resonance imaging, laparoscopy, and hysteroscopy. Each has limitations, and these may be used in combination to completely define anatomy. In women undergoing fertility evaluation, hysterosalpingography (HSG) is commonly selected for uterine cavity and tubal patency assessment. It is contraindicated during pregnancy. HSG poorly defines the external uterine contour and can delineate only patent cavities. Regarding patency, remember that some unicornuate rudimentary horns lack a cavity. Also, outlet obstructions will preclude dye filling.

In most clinical settings, two-dimensional transvaginal sonography (2-D TVS) is initially performed. For this indication, the pooled accuracy for TVS is 90 to 92 percent (Pellerito, 1992). Saline infusion sonography (SIS) improves delineation of the endometrium and internal uterine morphology, but only with a patent endometrial cavity. It also is contraindicated in pregnancy. Three-dimensional (3-D) sonography is more accurate than 2-D sonography because it provides uterine images from virtually any angle. Thus, coronal images can be constructed as shown in Figure 3-6, and these are essential in evaluating both internal and external uterine contours (Grimbizis, 2016). Both 2-D and 3-D sonography are suitable for use in pregnancy.

FIGURE 3-6

Three-dimensional transvaginal sonographic images. **A.** Bicornuate uterus with an 8-week gestation. The external fundal contour (*red dotted line*) dips centrally below the intercornual line, and the endometrial cavities communicate. **B.** Septate uterus with a 5-week gestation. The external fundal contour is normal and convex (*yellow dotted line*), and the long septum (*asterisk*) extends caudad in the midline. **C.** Arcuate uterus with an 8-week gestation. The external fundal contour is normal and convex (*red dotted line*), but the fundal endometrial cavity is slightly indented (*arrow*).



Several studies have reported very good concordance between 3-D TVS and MR imaging of müllerian anomalies (Deutch, 2008; Graupera, 2015). MR imaging is often preferred for complex anatomy, especially cases for which corrective surgery is planned. MR imaging provides clear delineation of both the internal and external uterine anatomy and has a reported accuracy of up to 100 percent for müllerian anomaly evaluation (Bermejo, 2010; Pellerito, 1992). In addition, complex anomalies and commonly associated secondary diagnoses such as renal or skeletal anomalies can be concurrently evaluated. Precautions with MR imaging in pregnancy are discussed in Chapter 46 (Safety).

In some women undergoing an infertility evaluation, hysteroscopy and laparoscopy may be selected to assess for müllerian anomalies; screen for endometriosis, which is often coexistent; and exclude other tubal or uterine cavity pathologies (Puscheck, 2008; Saravelos, 2008). In pregnancy, these approaches are rarely used to diagnose müllerian anomalies, and hysteroscopy is contraindicated.

Unicornuate Uterus (Class II)

With this abnormality, the underdeveloped or rudimentary horn may be absent. If present, it may or may not communicate with the dominant horn and may or may not contain an endometrium-lined cavity (see Fig. 3-5). General population estimates cite an incidence of 1 in 4000 women (Reichman, 2009). This anomaly may be detected during fertility evaluation by HSG. But as noted, noncommunicating or noncavitary rudimentary horns may not fill with dye. If this anomaly is suspected, 3-D sonography increases diagnostic accuracy, but again MR imaging may be preferred. Importantly, 40 percent of affected women will have renal anomalies (Fedele, 1996).

This müllerian anomaly carries significant obstetrical risks, including first- and second-trimester miscarriage, malpresentation, fetal-growth restriction, fetal demise, prematurely ruptured membranes, and preterm delivery (Chan, 2011a; Hua, 2011; Reichman, 2009). Abnormal uterine blood flow, cervical incompetence, and diminished cavity size and muscle mass of the hemiuterus are postulated to underlie these risks (Donderwinkel, 1992).

Rudimentary horns also increase the risk for an ectopic pregnancy within the remnant, which may be disastrous. This risk includes noncommunicating cavitary rudiments, for which transperitoneal sperm migration permits ovum fertilization and pregnancy (Nahum, 2004). In a report of 70 such pregnancies, Rolen and associates (1966) found that the rudimentary uterine horn ruptured prior to 20 weeks in most. Nahum (2002) reviewed the literature from 1900 to 1999 and identified 588 rudimentary horn pregnancies. Half had uterine rupture, and 80 percent did so before the third trimester. Of the total 588, the neonatal survival rate was only 6 percent.

Imaging allows an earlier diagnosis of rudimentary horn pregnancy so that it can be treated either medically with methotrexate or surgically before rupture (Dove, 2017; Edelman, 2003; Khati, 2012; Worley, 2008). Although not emphasized in Figure 3-5, the attachment site between the rudimentary horn at times can be broad and vascular.

If diagnosed in a nonpregnant woman, most recommend prophylactic excision of a horn that has a cavity (Fedele, 2005; Rackow, 2007). Data regarding subsequent pregnancy after excision are scarce. In one series of eight women, all had a preterm cesarean delivery (Pados, 2014).

Uterine Didelphys (Class III)

This müllerian anomaly arises from a complete lack of fusion that results in two entirely separate hemiuteri, cervices, and usually two vaginas (see Fig. 3-5). It is common among marsupials, for example, the American possum—*Didelphys virginiana*. Most women have a double vagina or a longitudinal vaginal septum. Uterine didelphys may be isolated. Or, it may compose a triad with an obstructed hemivagina and with ipsilateral renal agenesis (OHVIRA), also known as Herlyn- Werner-Wunderlich syndrome (Tong, 2013).

These anomalies are suspected on pelvic examination by identification of a longitudinal vaginal septum and two cervices. During HSG for fertility evaluation, contrast shows two separate endocervical canals. These open into separate noncommunicating fusiform endometrial cavities that each ends with a solitary fallopian tube. In women without fertility issues, 2- or 3-D TVS is a logical initial imaging tool, and separate divergent uterine horns with a large intervening fundal cleft are seen. Endometrial cavities are uniformly separate. MR imaging may be valuable in cases without classic findings.

Adverse obstetrical outcomes associated with uterine didelphys are similar but less frequent than those seen with unicornuate uterus. Increased risks include miscarriage, preterm birth, and malpresentation (Chan, 2011a; Grimbizis, 2001; Hua, 2011).

Metroplasty for either uterine didelphys or bicornuate uterus involves resection of intervening myometrium and fundal recombination (Alborzi, 2015). These rarely performed surgeries are chosen for highly selected patients with otherwise unexplained miscarriages. Moreover, no evidence-based data confirm the efficacy of such surgical repair.

Bicornuate Uterus (Class IV)

This fusion anomaly results in two hemiuteri. As shown in Figure 3-5, the central myometrium runs either partially or completely to the cervix. A complete bicornuate uterus may extend to the internal cervical os and have a single cervix (bicornuate unicollis) or reach the external os (bicornuate bicollis). As with uterine didelphys, a coexistent longitudinal vaginal septum is not uncommon.

Radiological discrimination of a bicornuate uterus from a septate uterus can be challenging. This distinction, however, is important because septate uterus can be treated with hysteroscopic septal resection. HSG or 2-D TVS may initially suggest an anomaly, but further distinction is provided by 3-D TVS or MR imaging (see Fig. 3-6). With these, an intercornual angle greater than 105 degrees typifies a bicornuate uterus, whereas one less than 75 degrees indicates a septate uterus. Fundal contour also assists, and a straight line drawn between the imaged tubal ostia serves as the defining threshold. Referent to this, an intrafundal downward cleft measuring ≥1 cm or more is indicative of bicornuate uterus. A septate uterus shows a cleft depth <1 cm, or it may have a normal fundal contour.

Bicornuate uterus carries increased risks for adverse obstetrical outcomes that include miscarriage, preterm birth, and malpresentation. As discussed in the prior section, rare surgical correction by metroplasty is reserved for highly selected patients.

Septate Uterus (Class V)

With this anomaly, a resorption defect leads to a persistent complete or partial longitudinal uterine septum (see Fig. 3-5). Less often, a complete vaginocervicouterine septum is found (Ludwin, 2013). Many septate uteri are identified during evaluation of infertility or recurrent pregnancy loss. Although an abnormality may be identified with HSG or 2-D TVS, typically 3-D TVS or MR imaging is required to differentiate this from a bicornuate uterus (see Fig. 3-6).

Septate anomalies are associated with diminished fertility and increased risks for adverse pregnancy outcomes that include miscarriage, preterm delivery, and malpresentation (Chan, 2011a; Ghi, 2012). Hysteroscopic septal resection has been shown to improve pregnancy rates and outcomes (Mollo, 2009; Pabuçcu, 2004). From their metaanalysis, Valle and colleagues (2013) reported a 63-percent pregnancy rate and 50-percent live birth rate following resection.

Arcuate Uterus (Class VI)

This malformation is a mild deviation from the normally developed uterus. Although some studies report no increased adverse associated outcomes, others have found excessive second-trimester losses, preterm labor, and malpresentation (Chan, 2011a; Mucowski, 2010; Woelfer, 2001).

Treatment with Cerclage

Some women with uterine anomalies and repetitive pregnancy losses may benefit from transvaginal or transabdominal cervical cerclage (Golan, 1992; Groom, 2004). Others with partial cervical atresia or hypoplasia may also benefit (Hampton, 1990; Ludmir, 1991). Candidacy for cerclage is determined by the same criteria used for women without such defects, which is discussed in Chapter 18 (Management).

Diethylstilbestrol Reproductive Tract Abnormalities (Class VII)

During the 1960s, a synthetic nonsteroidal estrogen—diethylstilbestrol (DES)—was used to treat pregnant women for threatened abortion, preterm labor, preeclampsia, and diabetes. The treatment was remarkably ineffective. Later, it was also discovered that women exposed as fetuses had increased risks of developing several specific reproductive-tract abnormalities. These included vaginal clear cell adenocarcinoma, cervical intraepithelial neoplasia, small-cell cervical carcinoma, and vaginal adenosis. Affected women had identifiable structural variations in the cervix and vagina that include transverse septa, circumferential ridges, and cervical collars. Uteri potentially had smaller cavities, shortened upper uterine segments, or T-shaped and other irregular cavities (see Fig. 3-5) (Kaufman, 1984).

These women suffer impaired conception rates and higher rates of miscarriage, ectopic pregnancy, and preterm delivery, especially in those with structural abnormalities (Kaufman, 2000; Palmer, 2001). Now, more than 50 years after DES use was proscribed, most affected women are past childbearing age, but higher rates of earlier menopause, cervical intraepithelial neoplasia, and breast cancer are reported in exposed women (Hatch, 2006; Hoover, 2011; Troisi, 2016).

Fallopian Tube Abnormalities

The fallopian tubes develop from the unpaired distal ends of the müllerian ducts. Congenital anomalies include accessory ostia, complete or segmental tubal agenesis, and several embryonic cystic remnants. The most common is a small, benign cyst attached by a pedicle to the distal end of the fallopian tube—the hydatid of Morgagni. In other cases, benign paratubal cysts may be of mesonephric or mesothelial origin. Last, in utero exposure to DES is associated with various tubal abnormalities. Of these, short, tortuous tubes or ones with shriveled fimbria and small ostia are linked to infertility (DeCherney, 1981).

UTERINE FLEXION

The pregnant uterus may infrequently show exaggerated flexion. Mild or moderate flexion is typically inconsequential, but congenital or acquired extremes may lead to pregnancy complications.

Anteflexion describes forward angling of the uterine fundus in the sagittal plane relative to the cervix. Exaggerated degrees usually pose no problem in early pregnancy. Later, however, particularly when the abdominal wall is lax such as with diastasis recti or ventral hernia, the uterus may fall forward. In extreme cases, the fundus lies below the lower margin of the symphysis. Sometimes, this abnormal uterine position prevents proper transmission of labor contractions, but this is usually overcome by repositioning and application of an abdominal binder.

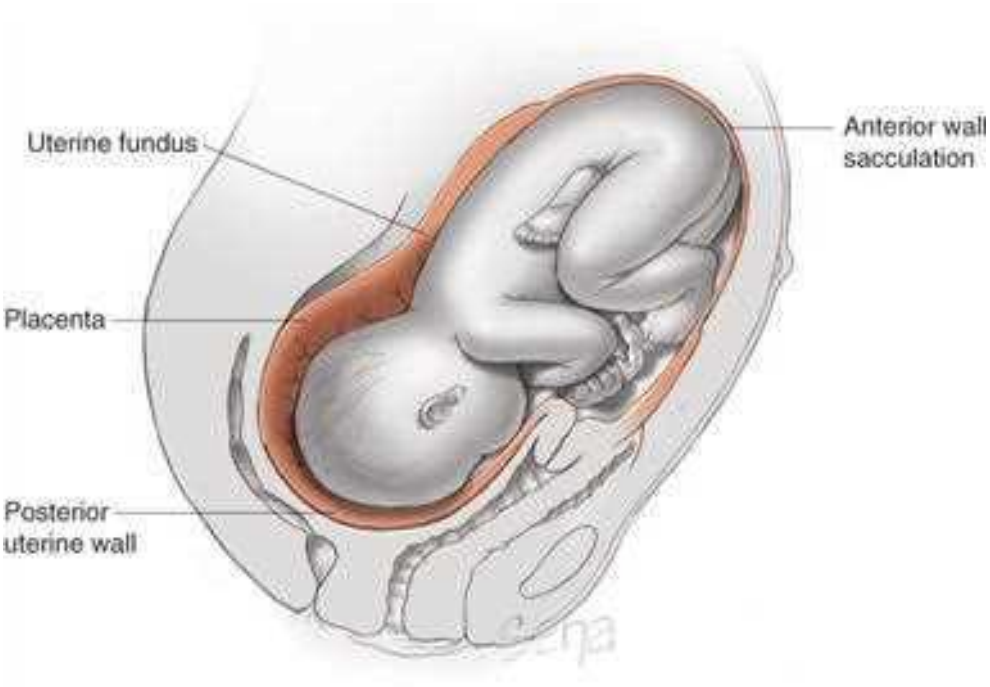
Retroflexion describes posterior uterine fundal angling in the sagittal plane. A growing retroflexed uterus will occasionally become incarcerated in the hollow of the sacrum. Symptoms include abdominal discomfort, pelvic pressure, and voiding dysfunction or retention. During bimanual pelvic examination, the cervix will be anterior and behind the symphysis pubis, whereas the uterus is appreciated as a mass wedged in the pelvis. Sonography or MR imaging can aid the clinical diagnosis (Gardner, 2013; Grossenburg, 2011; van Beekhuizen, 2003).

With continued uterine growth, the incarcerated uterus can spontaneously resolve over 1 to 2 weeks. An indwelling urinary catheter or intermittent self-catheterization may be needed in the interim to empty the bladder. Persistent cases require manual repositioning. For this, after bladder catheterization, the uterus can usually be pushed out of the pelvis when the woman is placed in a knee-chest position. Often, this is best accomplished by digital pressure applied through the rectum. Conscious sedation, spinal analgesia, or general anesthesia may be necessary. Following repositioning, the catheter is left in place until bladder tone returns. Insertion of a soft pessary for a few weeks usually prevents recurrent incarceration.

Lettieri and colleagues (1994) described seven cases of uterine incarceration not amenable to these simple procedures. In two women, laparoscopy was used at 14 weeks' gestation to reposition the uterus using the round ligaments for traction. Alternatively, in case series, advancing a colonoscope or colonoscopic insufflation was used to dislodge an incarcerated uterus (Dierickx, 2011; Newell, 2014; Seubert, 1999).

Rarely, *sacculation* may form as extensive lower uterine segment dilatation due to persistent entrapment of the pregnant uterus in the pelvis (Fig. 3-7). In these extreme cases, sonography and MR imaging are typically required to define anatomy (Gottschalk, 2008; Lee, 2008). Cesarean delivery is necessary when sacculation is marked, and Spearing (1978) stressed the importance of clarifying the distorted anatomy. An elongated vagina passing above the level of a fetal head that is deeply placed into the pelvis suggests a sacculation or an abdominal pregnancy. The Foley catheter is frequently palpated above the level of the umbilicus! Spearing (1978) recommended extending the abdominal incision above the umbilicus and delivering the entire uterus from the abdomen before hysterotomy. This will restore correct anatomical relationships and prevent inadvertent incisions into and through the vagina and bladder. Unfortunately, this may not always be possible (Singh, 2007). As a final caveat, a true uterine diverticulum has been mistaken for uterine sacculation (Rajiah, 2009).

FIGURE 3-7
Anterior sacculation of a pregnant uterus. Note the markedly attenuated anterior uterine wall and atypical location of the true uterine fundus.



The uterus commonly rotates to the maternal right during pregnancy. Rarely, uterine rotation exceeds 180 degrees to cause torsion. Most cases of torsion result from uterine leiomyomas, müllerian anomalies, fetal malpresentation, pelvic adhesions, or laxity of the abdominal wall or uterine ligaments. Jensen (1992) reviewed 212 cases and reported that associated symptoms may include obstructed labor, intestinal or urinary complaints, abdominal pain, uterine hypertonus, vaginal bleeding, and hypotension.

Most cases of uterine torsion are found at the time of cesarean delivery. In some women, torsion can be confirmed preoperatively with MR imaging, which shows a twisted vagina that appears X-shaped rather than its normal H-shape (Nicholson, 1995). As with uterine incarceration, during cesarean delivery, a severely displaced uterus should be repositioned anatomically before hysterotomy. In some cases, an inability to reposition or a failure to recognize the torsion may lead to a posterior hysterotomy incision (Albayrak, 2011; Picone, 2006; Rood, 2014).

CHAPTER 4: Maternal Physiology

The maternal organism reacts to a greater or lesser extent under the influence of pregnancy, but naturally the most characteristic changes are observed in the generative tract, and especially the uterus, which undergoes a very marked increase in size.

—J. Whitridge Williams (1903)

INTRODUCTION

In the first edition of this textbook, Williams devoted only 10 pages to the physiology of pregnancy, and half were focused on uterine growth. Many gestational changes begin soon after fertilization and continue throughout pregnancy. Equally astounding is that the woman is returned almost completely to her prepregnancy state after delivery and lactation. Most pregnancy-related changes are prompted by stimuli provided by the fetus and placenta. Virtually every organ system undergoes alterations, and these can appreciably modify criteria for disease diagnosis and treatment. Thus, an understanding of pregnancy adaptations is essential to avoid misinterpretation. Moreover, some physiological changes can unmask or worsen preexisting disease.

REPRODUCTIVE TRACT

Uterus

In the nonpregnant woman, the uterus weighs approximately 70 g and is almost solid, except for a cavity of 10 mL or less. During pregnancy, the uterus is transformed into a thin-walled muscular organ of sufficient capacity to accommodate the fetus, placenta, and amnionic fluid. The total volume of the contents at term averages 5 L but may be 20 L or more! Thus, by the end of pregnancy, the uterus has achieved a capacity that is 500 to 1000 times greater than the nonpregnant state. The corresponding increase in uterine weight is such that, by term, the organ weighs nearly 1100 g.

During pregnancy, uterine enlargement involves stretching and marked hypertrophy of muscle cells, whereas the production of new myocytes is limited. Fibrous tissue also accumulates, particularly in the external muscle layer, together with a considerable rise in elastic tissue content. The walls of the corpus considerably thicken and strengthen during the first few months of pregnancy but then gradually thin. By term, the myometrium is only 1 to 2 cm thick, and the fetus usually can be palpated through the soft, readily indentable uterine walls.

Uterine hypertrophy early in pregnancy probably is stimulated by the action of estrogen and perhaps progesterone. Thus, similar uterine changes can be observed with ectopic pregnancy. But after approximately 12 weeks' gestation, uterine growth is related predominantly to pressure exerted by the expanding products of conception.

Within the uterus, enlargement is most marked in the fundus. The extent of uterine hypertrophy is also influenced by the position of the placenta. Namely, the myometrium surrounding the placental site grows more rapidly than does the rest.

Myocyte Arrangement

The uterine musculature during pregnancy is arranged in three strata. The first is an outer hoodlike layer, which arches over the fundus and extends into the various ligaments. The middle layer is a dense network of muscle fibers perforated in all directions by blood vessels. Last is an internal layer, with sphincter-like fibers around the fallopian tube orifices and internal cervical os. Most of the uterine wall is formed by the middle layer. Here, each myocyte has a double curve so that the interlacing of any two cells forms a figure eight. This arrangement is crucial and permits myocytes to contract after delivery and constrict penetrating blood vessels to halt bleeding.

Uterine Shape and Position

For the first few weeks, the uterus maintains its original piriform or pear shape. But, as pregnancy advances, the corpus and fundus become globular and almost spherical by 12 weeks' gestation. Subsequently, the organ grows more rapidly in length than in width and becomes ovoid. By the end of 12 weeks, the enlarged uterus extends out of the pelvis. With this, it contacts the anterior abdominal wall, displaces the intestines laterally and superiorly, and ultimately reaches almost to the liver. With uterine ascent, it usually rotates to the right, and this dextrorotation likely is caused by the rectosigmoid on the left side of the pelvis. As the uterus rises, tension is exerted on the broad and round ligaments.

With the pregnant woman standing, the longitudinal axis of the uterus corresponds to an extension of the pelvic inlet axis. The abdominal wall supports the uterus and maintains this axis, unless the wall is lax. When the pregnant woman lies supine, the uterus falls back to rest on the vertebral column and the adjacent great vessels.

Uterine Contractility

Beginning in early pregnancy, the uterus contracts irregularly, and these may be perceived as mild cramps. During the second trimester, these contractions can be detected by bimanual examination. In 1872, J. Braxton Hicks first brought attention to these contractions, which now bear his name. These appear unpredictably and sporadically and are usually nonrhythmic. Their intensity varies between 5 and 25 mm Hg (Alvarez, 1950). Until near term, these *Braxton Hicks contractions* are infrequent, but their number rises during the last week or two. At this time, the uterus may contract as often as every 10 to 20 minutes and with some degree of rhythmicity. Correspondingly, uterine electrical activity is low and uncoordinated early in gestation, but becomes progressively more intense and synchronized by term (Garfield, 2005; Rabotti, 2015). This synchrony develops twice as fast in multiparas compared with nulliparas (Govindan, 2015). Late in pregnancy, these contractions may cause some discomfort and account for so-called false labor.

Uteroplacental Blood Flow

The delivery of most substances essential for fetal and placental growth, metabolism, and waste removal requires the placental intervillous space to be adequately perfused (Chap. 5, Breaks in the Placental "Barrier"). Placental perfusion depends on total uterine blood flow, but simultaneous measurement of uterine, ovarian, and collateral vessels is not yet possible, even using magnetic resonance (MR) angiography (Pates, 2010). Using ultrasound to study the uterine arteries, uteroplacental blood flow has been measured to increase progressively during pregnancy—from approximately 450 mL/min in the midtrimester to nearly 500 to 750 mL/min at 36 weeks (Flo, 2014; Wilson, 2007). These measures are similar to uterine artery blood flow estimates ascertained indirectly using clearance rates of androstenedione and xenon-133 (Edman, 1981; Kauppila, 1980). These values also mirror older ones—500 to 750 mL/min—obtained with invasive methods (Assali, 1953; Browne, 1953; Metcalfe, 1955). Logically, such massively increased uteroplacental blood flow requires adaptation of the uterine veins as well. The resultant increased venous caliber and distensibility can result in uterine vein varices that in rare instances may rupture (Lim, 2014).

As noted first from animal studies, uterine contractions, either spontaneous or induced, lower uterine blood flow proportionally to contraction intensity (Assali, 1968). A tetanic contraction yields a precipitous fall in uterine blood flow. In humans, three-dimensional power Doppler angiography has also demonstrated reduced uterine blood flow during contractions (Jones, 2009). Using a similar technique, resistance to blood flow in both maternal and fetal vessels was found to be greater during the second stage of labor compared with the first (Baron, 2015). Given that baseline uterine blood flow is diminished in pregnancies complicated by fetal-growth restriction, these fetuses may tolerate spontaneous labor less effectively (Ferrazzi, 2011; Simeone, 2017).

Uteroplacental Blood Flow Regulation

The vessels that supply the uterine corpus widen and elongate yet preserve their contractile function (Mandala, 2012). In contrast, the spiral arteries, which directly supply the placenta, vasodilate but completely lose contractility. This presumably results from endovascular trophoblast invasion that destroys the intramural muscular elements (Chap. 5, Endometrial Invasion). It is this vasodilation that allows maternal–placental blood flow to progressively rise during gestation. Given that blood flow increases proportionally to the fourth power of the radius of the vessel, small increases in vessel diameter result in tremendous augmentation of uterine artery blood flow. For example, in one study, the uterine artery diameter grew from only 3.3 mm to 3.7 mm between 22 and 29 weeks' gestation, but mean velocity increased 50 percent, from 29 to 43 cm/sec (Flo, 2010).

The downstream fall in vascular resistance is another key factor that accelerates flow velocity and shear stress in upstream vessels. In turn, shear stress leads to circumferential vessel growth. Nitric oxide—a potent vasodilator—appears to play a central role in regulating this process and is discussed later (Renin, Angiotensin II, and Plasma Volume). Indeed, endothelial shear stress and several hormones and growth factors all augment endothelial nitric oxide synthase (eNOS) and nitric oxide production (Grummer, 2009; Lim, 2015; Mandala, 2012; Pang, 2015). Factors include estrogen, progesterone, activin, placental growth factor (PlGF), and vascular endothelial growth factor (VEGF), which is a promoter of angiogenesis. As an important aside, VEGF and PlGF signaling is attenuated in response to excess placental secretion of their soluble receptor—*soluble FMS-like tyrosine kinase 1 (sFlt-1).* An elevated maternal sFlt-1 level inactivates and lowers circulating PlGF and VEGF concentrations and is important in preeclampsia pathogenesis (Chap. 40, Endothelial Cell Injury).

Normal pregnancy is also characterized by vascular refractoriness to the pressor effects of infused angiotensin II, and this raises uteroplacental blood flow (Rosenfeld, 1981, 2012). Other factors that augment uteroplacental blood flow include relaxin and certain adipocytokines (Vodstrcil, 2012). *Chemerin* is an adipocytokine secreted by several tissues, including the placenta (Garces, 2013; Kasher-Meron, 2014). Its concentration rises as gestation advances and serves to increase human umbilical eNOS activity, which mediates greater blood flow (Wang, 2015). Another adipocytokine–*visfatin*–raises VEGF secretion and VEGF receptor 2 expression in human epithelial cells derived from the placental amnion (Astern, 2013). Other adipocytokines include *leptin*, *resistin,* and *adiponectin*, which all enhance human umbilical vein endothelial cell proliferation (Połeć, 2014).

Last, certain microRNA species mediate vascular remodeling and uterine blood flow early in placentation (Santa, 2015). In particular, members of the miR-17–92 cluster and miR-34 are important in spiral artery remodeling and invasion. Abnormalities of micro-RNA function have been reported in preeclampsia, fetal-growth restriction, and gestational diabetes.

Cervix

As early as 1 month after conception, the cervix begins to soften and gain bluish tones. These result from increased vascularity and edema of the entire cervix, from changes in the collagen network, and from hypertrophy and hyperplasia of the cervical glands (Peralta, 2015; Straach, 2005). Although the cervix contains a small amount of smooth muscle, its major component is connective tissue. Rearrangement of this collagen-rich tissue aids the cervix in retention of the pregnancy until term, in dilatation to aid delivery, and in postpartum repair and reconstitution to permit a subsequent successful pregnancy (Myers, 2015). As detailed in Chapter 21 (Cervical Ripening), cervical ripening involves connective tissue remodeling that lowers collagen and proteoglycan concentrations and raises water content compared with the nonpregnant cervix.

Cervical glands undergo marked proliferation, and by the end of pregnancy, they occupy up to one half of the entire cervical mass. This normal pregnancy-induced change prompts an extension, or *eversion*, of the proliferating columnar endocervical glands onto the ectocervical portio (Fig. 4-1). This tissue appears red and

velvety and bleeds even with minor trauma, such as with Pap testing.

FIGURE 4-1
Cervical eversion of pregnancy as viewed through a colposcope. The eversion represents columnar epithelium on the portio of the cervix. (Used with permission from Dr. Claudia Werner.)

The endocervical mucosal cells produce copious amounts of tenacious mucus that obstruct the cervical canal soon after conception (Bastholm, 2017). This mucus is rich in immunoglobulins and cytokines and may act as an immunological barrier to protect the uterine contents against infection (Hansen, 2014; Wang, 2014). At labor onset, if not before, this *mucus plug* is expelled, resulting in a *bloody show.* Moreover, the cervical mucus consistency changes during pregnancy. Specifically, in most pregnant women, as a result of progesterone, when cervical mucus is spread and dried on a glass slide, it shows poor crystallization, termed *beading.* In some gravidas, as a result of amnionic fluid leakage, an arborization of ice-like crystals, called *fern*ing, is seen microscopically.

Histologically, basal cells near the squamocolumnar junction can be prominent in size, shape, and staining quality in pregnancy. These changes are considered to be estrogen induced. In addition, pregnancy is associated with both endocervical gland hyperplasia and hypersecretory appearance—the *Arias-Stella reaction*—which can make differentiating these from truly atypical glandular cells during Pap test evaluation particularly difficult (Rosai, 2015).

Ovaries

Ovulation ceases during pregnancy, and maturation of new follicles is suspended. The single corpus luteum found in gravidas functions maximally during the first 6 to 7 weeks of pregnancy—4 to 5 weeks postovulation. Thereafter, it contributes relatively little to progesterone production. Surgical removal of the corpus luteum before 7 weeks prompts a rapid fall in maternal serum progesterone levels and spontaneous abortion (Csapo, 1973). After this time, however, corpus luteum excision ordinarily does not cause abortion.

An extrauterine *decidual reaction* on and just beneath the ovarian surface is common in pregnancy and is usually observed at cesarean delivery. These slightly elevated clear or red patches bleed easily and may, on first glance, resemble freshly torn adhesions. Similar decidual reactions are seen on the uterine serosa and other pelvic, or even extrapelvic, abdominal organs (Bloom, 2010). These areas arise from subcoelomic mesenchyme or endometriotic lesions that have been stimulated by progesterone. They histologically appear similar to progestin-stimulated intrauterine endometrial stroma (Kim, 2015).

The enormous caliber of the ovarian veins viewed at cesarean delivery is startling. Hodgkinson (1953) found that the diameter of the ovarian vascular pedicle increased during pregnancy from 0.9 cm to approximately 2.6 cm at term. Again, recall that flow in a tubular structure increases exponentially as the diameter enlarges.

Relaxin

This protein hormone is secreted by the corpus luteum, the decidua, and the placenta in a pattern similar to that of human chorionic gonadotropin (hCG) (Chap. 5, Placental Progesterone Production). Relaxin is also expressed in brain, heart, and kidney. It is mentioned here because its secretion by the corpus luteum appears to aid many maternal physiological adaptations, such as remodeling of reproductive-tract connective tissue to accommodate labor (Conrad, 2013; Vrachnis, 2015). Relaxin also appears important in initiating augmented renal hemodynamics, lowering serum osmolality, and increasing arterial compliance, which are all associated with normal pregnancy (Conrad, 2014a). Despite its name, serum relaxin levels do not contribute to greater peripheral joint laxity or pelvic girdle pain during pregnancy (Aldabe, 2012; Marnach, 2003; Vøllestad, 2012).

Theca-Lutein Cysts

These benign ovarian lesions reflect exaggerated physiological follicle stimulation, which is termed *hyperreactio luteinalis.* These usually bilateral cystic ovaries are moderately to massively enlarged. The reaction is usually linked to markedly elevated serum hCG levels. Logically, theca-lutein cysts are found frequently with gestational trophoblastic disease (Fig. 20-3). They also can develop with the placentomegaly that can accompany diabetes, anti-D alloimmunization, and multifetal gestation (Malinowski, 2015). Hyperreactio luteinalis is associated with preeclampsia and hyperthyroidism, which may contribute to elevated risks for fetal-growth restriction and preterm birth (Cavoretto, 2014; Lynn, 2013; Malinowski, 2015). These cysts also are encountered in women with otherwise uncomplicated pregnancies. In these cases, an exaggerated response of the ovaries to normal levels of circulating hCG is suspected (Sarmento Gonçalves, 2015).

Although usually asymptomatic, hemorrhage into the cysts can cause acute abdominal pain (Amoah, 2011). Maternal virilization may be seen in up to 30 percent of women, however, virilization of the fetus has only rarely been reported (Malinowski, 2015). Maternal findings that include temporal balding, hirsutism, and clitoromegaly are associated with massively elevated levels of androstenedione and testosterone. The diagnosis typically is based on sonographic findings of bilateral enlarged ovaries containing multiple cysts in the appropriate clinical settings. The condition is self-limited and resolves following delivery. Its management is reviewed by Malinowski (2015) and discussed further in Chapter 63 (Pregnancy-Related Ovarian Tumors).

Fallopian Tubes

The fallopian tube musculature, that is, the *myosalpinx*, undergoes little hypertrophy during pregnancy. The epithelium of the *endosalpinx* somewhat flattens. Decidual cells may develop in the stroma of the endosalpinx, but a continuous decidual membrane is not formed.

Rarely, a fallopian tube may twist during uterine enlargement (Macedo, 2017). This torsion is more common with comorbid paratubal or ovarian cysts (Lee, 2015).

Vagina and Perineum

During pregnancy, greater vascularity and hyperemia develop in the skin and muscles of the perineum and vulva, and the underlying abundant connective tissue softens. This augmented vascularity prominently affects the vagina and cervix and results in the violet color characteristic of *Chadwick sign.* Within the vagina, the considerably elevated volume of cervical secretions during pregnancy forms a somewhat thick, white discharge. The pH is acidic, varying from 3.5 to 6. This pH results from increased production of lactic acid by *Lactobacillus acidophilus* during metabolism of glycogen energy stores in the vaginal epithelium. Pregnancy is associated with an elevated risk of vulvovaginal candidiasis, particularly during the second and third trimesters. Higher infection rates may stem from immunological and hormonal changes and from greater vaginal glycogen stores (Aguin, 2015).

The vaginal walls undergo striking changes in preparation for the distention that accompanies labor and delivery. These alterations include considerable epithelial thickening, connective tissue loosening, and smooth muscle cell hypertrophy.

Pelvic Organ Prolapse

Pelvic Organ Prolapse Quantification (POP-Q) and three-dimensional sonography studies show that vaginal support changes across pregnancy. In particular, vaginal lengthening, posterior vaginal wall and hiatal relaxation, increased levator hiatal area, and greater first-trimester vaginal elastase activity are all associated with uncomplicated spontaneous vaginal delivery (Oliphant, 2014). The larger hiatal area persists in women who deliver vaginally compared with women delivering by prelabor or early-labor cesarean delivery. However, all women show greater hiatal distensibility after delivery, which is potentially a factor in later pelvic floor dysfunction (van Veelen, 2015).

In women with apical vaginal prolapse, the cervix, and occasionally a portion of the uterine body, can protrude variably from the vulva during early pregnancy. With further growth, the uterus usually rises above the pelvis and can draw the cervix up with it. If the uterus persists in its prolapsed position, symptoms of incarceration may develop at 10 to 14 weeks' gestation (Chap. 3, Uterine Flexion). As a preventive measure, the uterus can be replaced early in pregnancy and held in position with a suitable pessary.

Attenuation of anterior vaginal wall support can lead to prolapse of the bladder, that is, a cystocele. Urinary stasis with a cystocele predisposes to infection. Pregnancy may also worsen coexistent *stress urinary incontinence (SUI)*, likely because urethral closing pressures do not rise sufficiently to compensate for altered bladder neck support. Urinary incontinence affects nearly 20 percent of women during the first trimester and nearly 40 percent during the third trimester. Most cases stem from SUI rather than urgency urinary incontinence (Abdullah, 2016a; Franco, 2014; Iosif, 1980). In primigravidas, maternal age greater than 30 years, obesity, smoking, constipation, and gestational diabetes mellitus are all risk factors associated with SUI development during pregnancy (Sangsawang, 2014).

Attenuation of posterior vaginal wall support can result in a rectocele. A large defect may fill with feces that occasionally can be evacuated only digitally. During labor, a cystocele or rectocele can block fetal descent unless they are emptied and pushed out of the way. Rarely, an enterocele of considerable size may bulge into the vagina. If the mass interferes with delivery, the hernia sac and its abdominal contents are gently reduced to permit fetal descent.

BREASTS

In early pregnancy, women often experience breast tenderness and paresthesias. After the second month, the breasts grow in size, and delicate veins are visible just beneath the skin. The nipples become considerably larger, more deeply pigmented, and more erectile. After the first few months, a thick, yellowish fluid—*colostrum*—can often be expressed from the nipples by gentle massage. During the same months, the areolae become broader and more deeply pigmented. Scattered through each areola are several small elevations, the *glands of Montgomery,* which are hypertrophic sebaceous glands. If breasts gain extensive size, skin striae similar to those observed in the abdomen may develop. Rarely, breasts can become pathologically enlarged—referred to as *gigantomastia*—which may require postpartum surgical reduction (Fig. 4-2) (Eler Dos Reis, 2014; Rezai, 2015).

FIGURE 4-2
Gigantomastia in a woman near term. (Used with permission from Dr. Patricia Santiago-Munoz.)

For most normal pregnancies, prepregnancy breast size and ultimate volume of breast milk do not correlate, as multiple factors influence milk production (Hartmann, 2007). These factors and gestation breast changes are further discussed in Chapter 36 (Lactation and Breastfeeding).

SKIN

Skin changes are common, and Fernandes and Amaral (2015) described dermatological changes in more than 900 pregnant women. They found at least one physiological cutaneous change in 89 percent of the women examined. Dermatologic pathologies during pregnancy are found in Chapter 62.

Abdominal Wall

Beginning after midpregnancy, reddish, slightly depressed streaks commonly develop in the abdominal skin and sometimes in the skin over the breasts and thighs. These are called *striae gravidarum* or *stretch marks.* In multiparas, glistening, silvery lines that represent the cicatrices of previous striae frequently coexist. In one study of 800 primiparas, 70 percent developed striae gravidarum on their abdomen; 33 percent on their breasts; and 41 percent on their hips and thighs (Picard, 2015). The strongest associated risk factors included younger maternal age, family history, and prepregnancy weight and weight gain during pregnancy. The etiology of striae gravidarum is unknown, and there are no preventive steps or definitive treatments (Korgavkar, 2015).

Occasionally, the muscles of the abdominal walls do not withstand the tension of the expanding pregnancy. As a result, rectus muscles separate in the midline, creating *diastasis recti* of varying extent. If severe, a considerable portion of the anterior uterine wall is covered by only a layer of skin, attenuated fascia, and peritoneum to form a ventral hernia.

Hyperpigmentation

This develops in up to 90 percent of women and is usually more accentuated in those with darker complexion (Ikino, 2015). Of specific sites, the pigmented skin line in the midline of the anterior abdominal wall—the *linea alba*—takes on dark brown-black pigmentation to form the *linea nigra.* Occasionally, irregular brownish patches of varying size appear on the face and neck, giving rise to *chloasma* or *melasma gravidarum*—the *mask of pregnancy*. Pigmentation of the areolae and genital skin may also be accentuated. After delivery, these pigmentary changes usually disappear or at least regress considerably. Oral contraceptives may cause similar alterations (Handel, 2014).

The etiology of these pigmentary changes is incompletely understood, however, hormonal and genetic factors play a role. For example, levels of melanocyte-stimulating hormone, a polypeptide similar to corticotropin, are elevated remarkably throughout pregnancy, and estrogen and progesterone also are reported to have melanocyte-stimulating effects.

Vascular Changes

Angiomas, called *vascular spiders,* are particularly common on the face, neck, upper chest, and arms. These are minute, red skin papules with radicles branching out from a central lesion. The condition is often designated as nevus, angioma, or telangiectasis. *Palmar erythema* is encountered during pregnancy. Both conditions lack clinical significance and disappear in most gravidas shortly after pregnancy. They are likely the consequence of hyperestrogenemia. In addition to these discrete lesions, increased cutaneous blood flow in pregnancy serves to dissipate excess heat generated by the augmented metabolism.

Hair Changes

Throughout life, the human hair follicle undergoes a pattern of cyclic activity that includes periods of hair growth (anagen phase), apoptosis-driven involution (catagen phase), and a resting period (telogen phase). Based on a study of 116 healthy pregnant women, the anagen phase lengthens during pregnancy and the telogen rate increases postpartum (Gizlenti, 2014). Neither is exaggerated in most gravidas, but excessive hair loss in the puerperium is termed *telogen effluvium*.

METABOLIC CHANGES

In response to the greater demands of the rapidly growing fetus and placenta, the pregnant woman undergoes metabolic changes that are numerous and intense. By the third trimester, maternal basal metabolic rate rises by 20 percent compared with that of the nonpregnant state (Berggren, 2015). This rate grows by an additional 10 percent in women with a twin gestation (Shinagawa, 2005). Viewed another way, the additional total pregnancy energy demand associated with normal pregnancy approximates 77,000 kcal (World Health Organization, 2004). This is stratified as 85, 285, and 475 kcal/d during the first, second, and third trimester, respectively (Table 4-1). Of note, Abeysekera and coworkers (2016) reported that women accrue fat mass during pregnancy despite the increased total energy expenditure and without significant change in energy intake. This suggests more efficient energy storage.

TABLE 4-1

Additional Energy Demands During Normal Pregnancy[a]

	Rates of Tissue Deposition			
	1st Trimester g/d	**2nd Trimester g/d**	**3rd Trimester g/d**	**Total Deposition g/280 d**
Weight gain	17	60	54	12,000
Protein deposition	0	1.3	5.1	597
Fat deposition	5.2	18.9	16.9	3741
Energy Cost of Pregnancy Estimated from Basal Metabolic Rate and Energy Deposition				
	1st Trimester kJ/d	**2nd Trimester kJ/d**	**3rd Trimester kJ/d**	**Total Energy Cost**
				MJ / **Kcal**
Protein deposition	0	30	121	14.1 / 3370
Fat deposition	202	732	654	144.8 / 34,600
Efficiency of energy utilization[b]	20	76	77	15.9 / 3800
Basal metabolic rate	199	397	993	147.8 / 35,130
Total energy cost of pregnancy	**421**	**1235**	**1845**	**322.6 / 77,100**

[a]Assumes an average gestational weight gain of 12 kg.

[b]Efficiency of food energy utilization for protein and fat deposition estimated as 0.90.

Adapted from the World Health Organization, 2004.

Weight Gain

Most of the normal weight gain in pregnancy is attributable to the uterus and its contents, the breasts, and expanded blood and extravascular extracellular fluid volumes. A smaller fraction results from metabolic alterations that promote accumulation of cellular water, fat, and protein, which are so-called maternal reserves. The average weight gain during pregnancy approximates 12.5 kg or 27.5 lb, and this value has remained consistent across studies and over time (Hytten, 1991; Jebeile, 2016). Weight gain is considered in further detail in Table 4-2 and in Chapter 9 (Nutritional Counseling).

TABLE 4-2

Weight Gain Based on Pregnancy-Related Components

	Cumulative Increase in Weight (g)			
Tissues and Fluids	**10 Weeks**	**20 Weeks**	**30 Weeks**	**40 Weeks**
Fetus	5	300	1500	3400
Placenta	20	170	430	650
Amnionic fluid	30	350	750	800
Uterus	140	320	600	970
Breasts	45	180	360	405
Blood	100	600	1300	1450
Extravascular fluid	0	30	80	1480
Maternal stores (fat)	310	2050	3480	3345
Total	**650**	**4000**	**8500**	**12,500**

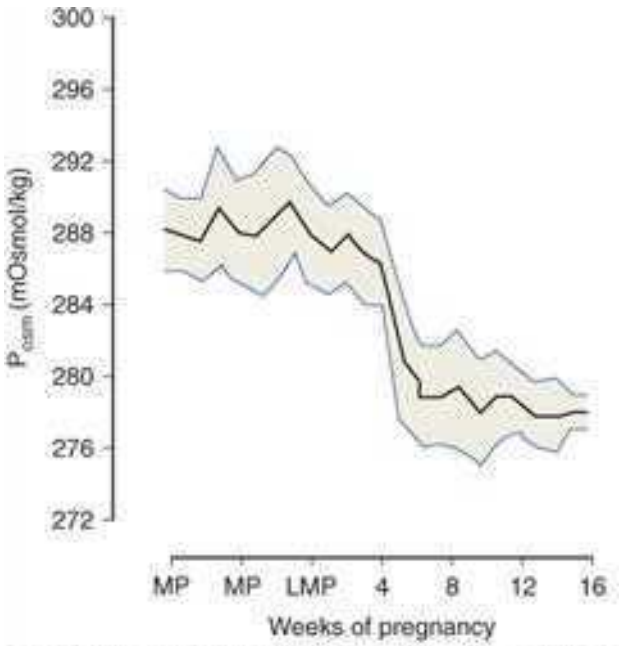
Modified from Hytten, 1991.

Water Metabolism

In pregnancy, greater water retention is normal and mediated in part by a drop in plasma osmolality of 10 mOsm/kg. This decline develops in early pregnancy and is induced by a reset of osmotic thresholds for thirst and vasopressin secretion (Fig. 4-3) (Davison, 1981; Lindheimer, 2001). Relaxin and other hormones are thought to play a role (Conrad, 2013).

FIGURE 4-3

Mean values (*black line*) ± standard deviations (*blue lines*) for plasma osmolality (P_{osm}) measured at weekly intervals in nine women from preconception to 16 weeks. LMP = last menstrual period; MP = menstrual period. (Redrawn with permission from Davison JM, Dunlop W: Renal hemodynamics and tubular function in normal human pregnancy. Kidney Int 18:152, 1980.)



At term, the water content of the fetus, placenta, and amnionic fluid approximates 3.5 L. Another 3.0 L accumulates from expanded maternal blood volume and from uterus and breast growth. Thus, the minimum amount of extra water that the average woman accrues during normal pregnancy approximates 6.5 L. This corresponds to 14.3 lb.

Clearly demonstrable pitting edema of the ankles and legs is seen in most pregnant women, especially at the end of the day. This fluid accumulation, which may amount to a liter or so, results from greater venous pressure below the level of the uterus as a consequence of partial vena cava occlusion. A decline in interstitial colloid osmotic pressure induced by normal pregnancy also favors edema late in pregnancy (Øian, 1985).

Longitudinal studies of body composition show a progressive accumulation of total body water and fat mass during pregnancy. These two components as well as initial maternal weight and weight gained during pregnancy are highly associated with neonatal birthweight (Lederman, 1999; Mardones-Santander, 1998). "Over-nourished" women are more likely to deliver oversized neonates, even when glucose tolerant (Di Benedetto, 2012).

Protein Metabolism

The products of conception, the uterus, and maternal blood are relatively rich in protein rather than fat or carbohydrate. At term, the normally grown fetus and placenta together weigh about 4 kg and contain approximately 500 g of protein, or about half of the total pregnancy increase. The remaining 500 g is added to the uterus as contractile protein, to the breasts primarily in the glands, and to maternal blood as hemoglobin and plasma proteins.

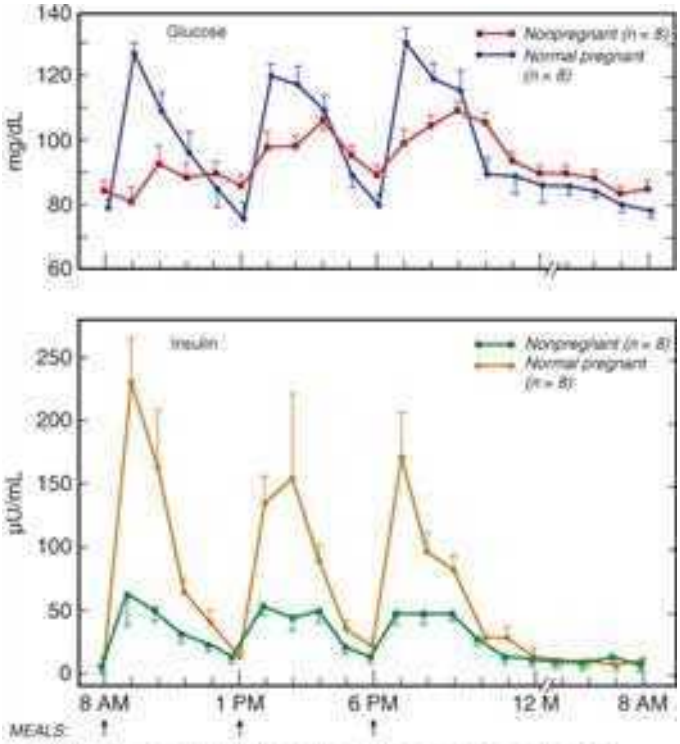
Amino acid concentrations are higher in the fetal than in the maternal compartment and generally result from facilitated transport across the placenta (Cleal, 2011; Panitchob, 2015). This greater concentration is largely regulated by the placenta through an incompletely understood process. In particular, placental transport is variable for individuals and for different amino acids. For example, tyrosine is a conditionally essential amino acid in the preterm neonate but not in the fetus (Van den Akker, 2010, 2011). The placenta concentrates amino acids into the fetal circulation and is also involved in protein synthesis, oxidation, and transamination of some nonessential amino acids (Galan, 2009).

Maternal protein intake does not appear to be a critical determinant for birthweight among well-nourished women (Chong, 2015). Still, recent data suggest that current recommendations for protein intake may be too low. These guidelines are extrapolated from nonpregnant adults and may underestimate actual needs. Stephens and colleagues (2015) prospectively analyzed maternal protein intake and metabolism. They estimated average requirements of 1.22 g/kg/d of protein for early pregnancy and 1.52 g/kg/d for late pregnancy. These levels are higher than the current recommendation of 0.88 g/kg/d. The daily requirements for dietary protein intake during pregnancy are discussed in Chapter 9 (Dietary Reference Intakes—Recommended Allowances).

Carbohydrate Metabolism

Normal pregnancy is characterized by mild fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia (Fig. 4-4). This elevated basal level of plasma insulin in normal pregnancy is associated with several unique responses to glucose ingestion. Specifically, after an oral glucose meal, gravidas demonstrate prolonged hyperglycemia and hyperinsulinemia and a greater suppression of glucagon (Phelps, 1981). This cannot be explained by an increased metabolism of insulin because its half-life during pregnancy is not changed appreciably (Lind, 1977). Instead, this response reflects a pregnancy-induced state of peripheral insulin resistance, which ensures a sustained postprandial supply of glucose to the fetus. Indeed, insulin sensitivity in late normal pregnancy is 30 to 70 percent lower than that of nonpregnant women (Lowe, 2014).

FIGURE 4-4
Diurnal changes in plasma glucose and insulin in normal late pregnancy. (Redrawn from Phelps, 1981.)



The mechanisms responsible for this reduced insulin sensitivity include numerous endocrine and inflammatory factors (Angueira, 2015). In particular, pregnancy-related hormones such as progesterone, placentally derived growth hormone, prolactin, and cortisol; cytokines such as tumor necrosis factor; and hormones derived from central adiposity, particularly leptin and its interplay with prolactin, all have a role in the insulin resistance of pregnancy. Even so, insulin resistance is not the only factor to elevate postprandial glucose values. Hepatic gluconeogenesis is augmented during both diabetic and nondiabetic pregnancies, particularly in the third trimester (Angueira, 2015).

Overnight, the pregnant woman changes from a postprandial state characterized by elevated and sustained glucose levels to a fasting state characterized by decreased plasma glucose and some amino acids. Plasma concentrations of free fatty acids, triglycerides, and cholesterol are also higher in the fasting state. This pregnancy-induced switch in fuels from glucose to lipids has been called *accelerated starvation.* Certainly, when fasting is prolonged in the pregnant woman, these alterations are exaggerated and ketonemia rapidly appears.

Fat Metabolism

The concentrations of lipids, lipoproteins, and apolipoproteins in plasma rise appreciably during pregnancy (Appendix, Serum and Blood Constituents). Increased insulin resistance and estrogen stimulation during pregnancy are responsible for the maternal hyperlipidemia. Augmented lipid synthesis and food intake contribute to maternal fat accumulation during the first two trimesters (Herrera, 2014). In the third trimester, however, fat storage declines or ceases. This is a consequence of enhanced lipolytic activity, and decreased lipoprotein lipase activity reduces circulating triglyceride uptake into adipose tissue. This transition to a catabolic state favors maternal use of lipids as an energy source and spares glucose and amino acids for the fetus.

Maternal hyperlipidemia is one of the most consistent and striking changes of lipid metabolism during late pregnancy. Triacylglycerol and cholesterol levels in very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs) are increased during the third trimester compared with those in nonpregnant women. During the third trimester, the average level of total serum cholesterol is 267 ± 30 mg/dL, of LDL-C is 136 ± 33 mg/dL, of HDL-C is 81 ± 17 mg/dL, and of triglycerides is 245 ± 73 mg/dL (Lippi, 2007). After delivery, the concentrations of these lipids, lipoproteins, and apolipoproteins decline. Breastfeeding drops maternal triglyceride levels but increases those of HDL-C. The effects of breastfeeding on total cholesterol and LDL-C levels are unclear (Gunderson, 2014).

Hyperlipidemia is theoretically a concern because it is associated with endothelial dysfunction. From studies, however, endothelium-dependent vasodilation responses actually improve across pregnancy (Saarelainen, 2006). This is partly because increased HDL-C concentrations likely inhibit LDL oxidation and thus protect the endothelium. These findings suggest that the increased cardiovascular disease risk in multiparas may be related to factors other than maternal hypercholesterolemia.

Leptin

This peptide hormone is primarily secreted by adipose tissue in nonpregnant humans. It plays a key role in body fat and energy expenditure regulation and in reproduction. For example, leptin is important for implantation, cell proliferation, and angiogenesis (Vazquez, 2015). Leptin deficiency is associated with anovulation and infertility, whereas certain leptin mutations cause extreme obesity (Tsai, 2015).

Among normal-weight pregnant women, serum leptin levels rise and peak during the second trimester and plateau until term in concentrations two to four times higher than those in nonpregnant women. Among obese women, leptin levels correlate with adiposity (Ozias, 2015; Tsai, 2015). In all cases, leptin levels fall after

delivery, reflecting the significant amounts produced by the placenta (Vazquez, 2015).

Leptin participates in regulating energy metabolism during pregnancy. Interestingly, despite the rise in leptin concentrations during pregnancy, reduced leptin sensitivity to food intake during pregnancy has been described (Chehab, 2014; Vazquez, 2015). This "leptin resistance" may serve to promote energy storage during pregnancy and for later lactation. Higher leptin levels during pregnancy may be disadvantageous under certain situations, such as in maternal obesity. Leptin functions as a proinflammatory cytokine in white adipose tissue, which may dysregulate the inflammatory cascade and lead to placental dysfunction in obese women (Vazquez, 2015). In addition, abnormally elevated leptin levels have been associated with preeclampsia and gestational diabetes (Bao, 2015; Taylor, 2015).

Fetal leptin is important for the development of several organs that include the pancreas, kidney, heart, and brain. Fetal levels correlate with maternal body mass index (BMI) and birthweight. Lower levels are linked to fetal-growth restriction (Briffa, 2015; Tsai, 2015).

Other Adipocytokines

Dozens of hormones with metabolic and/or inflammatory functions are produced by adipose tissue. *Adiponectin* is a peptide produced primarily in maternal fat but not in the placenta (Haghiac, 2014). Adiponectin levels inversely correlate with adiposity, and it acts as a potent insulin sensitizer. Despite reduced adiponectin levels in women with gestational diabetes, directed assays are not useful for predicting diabetes development (Hauguel-de Mouzon, 2013).

Ghrelin is a peptide secreted principally by the stomach in response to hunger. It cooperates with other neuroendocrine factors, such as leptin, in energy homeostasis modulation. Ghrelin is also expressed in the placenta and likely has a role in fetal growth and cell proliferation (González-Domínguez, 2016). Angelidis and associates (2012) have reviewed the many functions of ghrelin in the regulation of reproductive function.

Visfatin is a peptide that was first identified as a growth factor for B lymphocytes, but it is mainly produced within adipose tissue. Mumtaz and colleagues (2015) propose that elevated levels of visfatin and leptin impair uterine contractility. Such findings may provide a physiological basis for the observation that maternal obesity raises the risk for dysfunctional labor.

Electrolyte and Mineral Metabolism

During normal pregnancy, nearly 1000 mEq of *sodium* and 300 mEq of *potassium* are retained (Lindheimer, 1987). Although the glomerular filtration rate of sodium and potassium is increased, the excretion of these electrolytes is unchanged during pregnancy as a result of enhanced tubular resorption (Brown, 1986, 1988). Although total accumulations of sodium and potassium are elevated, their serum concentrations are diminished slightly (Appendix, Serum and Blood Constituents). Several mechanisms may explain these lower levels (Odutayo, 2012). In the case of potassium, it possibly involves the expanded plasma volume of pregnancy. With respect to sodium, osmoregulation is altered and the threshold for arginine vasopressin release is lowered. This promotes free water retention and diminished sodium levels.

Total serum *calcium* levels, which include both ionized and nonionized calcium, decrease during pregnancy. This reduction follows lowered plasma albumin concentrations and in turn a consequent decline in the amount of circulating protein-bound nonionized calcium. Serum ionized calcium levels, however, remain unchanged (Olausson, 2012).

The developing fetus imposes a significant demand on maternal calcium homeostasis. For example, the fetal skeleton accretes approximately 30 g of calcium by term, 80 percent of which is deposited during the third trimester. This demand is largely met by a doubling of maternal intestinal calcium absorption mediated partly by 1,25-dihydroxyvitamin D_3. These higher levels of vitamin D are possibly stimulated by a twofold rise in PTH-related peptide levels produced by several tissues including the placenta (Kovacs, 2006; Olausson, 2012). To help compensate, dietary intake of sufficient calcium is necessary to prevent excess depletion from the mother. A list of all recommended daily allowances is found in Table 9-5. This is especially important for pregnant adolescents, in whom bones are still developing. Unfortunately, a lack of robust data prevents drawing firm conclusions regarding the utility of calcium and vitamin D supplements during pregnancy (De-Regil, 2016).

Serum *magnesium* levels also decline during pregnancy. Bardicef and colleagues (1995) concluded that pregnancy is actually a state of extracellular magnesium depletion. Compared with nonpregnant women, both total and ionized magnesium concentrations are significantly lower during normal pregnancy (Rylander, 2014).

Serum *phosphate* levels lie within the nonpregnant range (Larsson, 2008). Although calcitonin is an important regulator of serum calcium and phosphate, the importance of calcitonin as it relates to pregnancy is poorly understood (Olausson, 2012).

Iodine requirements increase during normal pregnancy for several reasons (Moleti, 2014; Zimmermann, 2012). First, maternal thyroxine production rises to maintain maternal euthyroidism and to transfer thyroid hormone to the fetus prior to fetal thyroid functioning. Second, fetal thyroid hormone production increases during the second half of pregnancy. This contributes to greater maternal iodine requirements because iodide readily crosses the placenta. Third, the primary route of iodine excretion is through the kidney. Beginning in early pregnancy, the iodide glomerular filtration rate increases by 30 to 50 percent. In sum, because of greater thyroid hormone production, fetal iodine requirements, and augmented renal clearance, dietary iodine needs are higher during normal gestation. Although the placenta has the ability to store iodine, whether this organ functions to protect the fetus from inadequate maternal dietary iodine is currently unknown (Burns, 2011). Iodine deficiency is discussed later in this chapter (Parathyroid Glands) and in Chapter 58 (Iodine Deficiency). At the other extreme, maternal supplements containing excessive iodine have been associated with congenital hypothyroidism. This stems from autoregulation in the thyroid gland—known as the *Wolff-Chaikoff effect*—to curb thyroxine production in response to iodide overconsumption (Connelly, 2012).

With respect to most other minerals, pregnancy induces little change in their metabolism other than their retention in amounts equivalent to those needed for growth. An important exception is the considerably greater requirement for *iron,* which is discussed subsequently.

HEMATOLOGICAL CHANGES

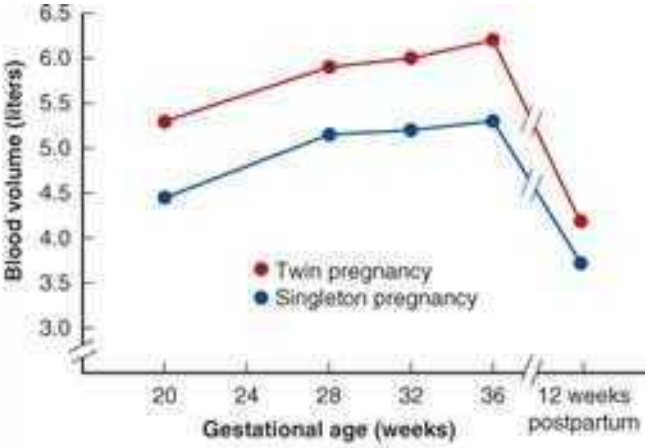
Blood Volume

The well-known hypervolemia associated with normal pregnancy averages 40 to 45 percent above the nonpregnant blood volume after 32 to 34 weeks' gestation (Pritchard, 1965; Zeeman, 2009). In individual women, expansion varies considerably. In some, accumulated volume rises only modestly, whereas in others blood volume nearly doubles. A fetus is not essential, as augmented blood volume develops in some with hydatidiform mole.

Pregnancy-induced hypervolemia serves several functions. First, it meets the metabolic demands of the enlarged uterus and its greatly hypertrophied vascular system. Second, it provides abundant nutrients and elements to support the rapidly growing placenta and fetus. Third, the expanded intravascular volume protects the mother, and in turn the fetus, against the deleterious effects of impaired venous return in the supine and erect positions. Last, it safeguards the mother against the adverse effects of parturition-associated blood loss.

Maternal blood volume begins to accrue during the first trimester. By 12 menstrual weeks, plasma volume expands by approximately 15 percent compared with that prior to pregnancy (Bernstein, 2001). Maternal blood volume grows most rapidly during the midtrimester, rises at a much slower rate during the third trimester, and reaches a plateau during the last several weeks of pregnancy (Fig. 4-5). Blood volume accrues even more dramatically in twin gestations. During blood volume expansion, plasma volume and erythrocyte number rise. Although more plasma than erythrocytes is usually added to the maternal circulation, the increase in erythrocyte volume is considerable and averages 450 mL (Pritchard, 1960). Moderate erythroid hyperplasia develops in the bone marrow, and the reticulocyte count is elevated slightly during normal pregnancy. These changes are almost certainly related to an elevated maternal plasma erythropoietin level.

FIGURE 4-5
Blood volume expansion during pregnancy in twins (n = 10) and singletons (n = 40). Data shown as medians. (Data from Thomsen, 1994.)



Hemoglobin Concentration and Hematocrit

Because of great plasma augmentation, both hemoglobin concentration and hematocrit decline slightly during pregnancy (Appendix, Serum and Blood Constituents). As a result, whole blood viscosity decreases (Huisman, 1987). Hemoglobin concentration at term averages 12.5 g/dL, and in approximately 5 percent of women it is below 11.0 g/dL. Thus, a hemoglobin concentration below 11.0 g/dL, especially late in pregnancy, is considered abnormal and usually due to iron-deficiency anemia rather than pregnancy hypervolemia.

Iron Metabolism

The total iron content of normal adult women ranges from 2.0 to 2.5 g, or approximately half that found normally in men. Most of this is incorporated in hemoglobin or myoglobin, and thus, iron stores of normal young women only approximate 300 mg (Pritchard, 1964). Although the lower iron levels in women may be partly due to menstrual blood loss, other factors have a role, particularly hepcidin–a peptide hormone that functions as a homeostatic regulator of systemic iron metabolism. Hepcidin levels rise with inflammation, but drop with iron deficiency and several hormones, including testosterone, estrogen, vitamin D, and possibly prolactin (Liu, 2016; Wang, 2015). Lower hepcidin levels are associated with greater absorption of iron via ferroportin in enterocytes (Camaschella, 2015).

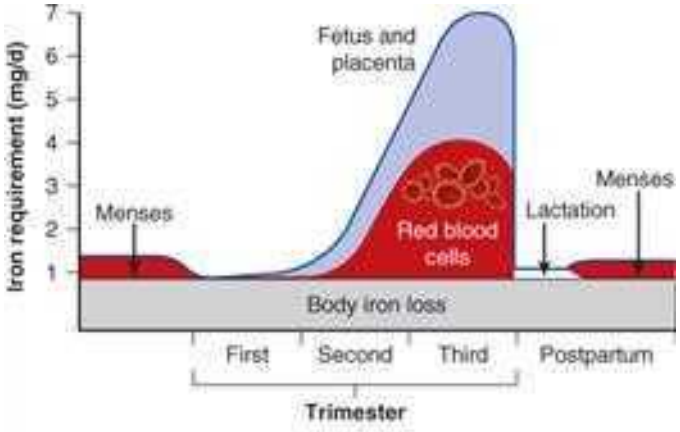
Iron Requirements

Of the approximate 1000 mg of iron required for normal pregnancy, about 300 mg is actively transferred to the fetus and placenta, and another 200 mg is lost through various normal excretion routes, primarily the gastrointestinal tract. These are obligatory losses and accrue even when the mother is iron deficient. The average increase in the total circulating erythrocyte volume—about 450 mL—requires another 500 mg. Recall that each 1 mL of erythrocytes contains 1.1 mg of iron.

As shown in Figure 4-6, because most iron is used during the latter half of pregnancy, the iron requirement becomes large after midpregnancy and averages 6 to 7 mg/d (Pritchard, 1970). In most women, this amount is usually not available from iron stores or diet. Thus, without supplemental iron, the optimal rise in maternal erythrocyte volume will not develop, and the hemoglobin concentration and hematocrit will fall appreciably as plasma volume rises. At the same time, fetal red cell production is not impaired because the placenta transfers iron even if the mother has severe iron-deficiency anemia. In severe cases, we have documented maternal hemoglobin values of 3 g/dL, and at the same time, fetuses had hemoglobin concentrations of 16 g/dL. The mechanisms of placental iron transport and regulation are complex (Koenig, 2014; McArdle, 2014).

FIGURE 4-6

Estimated daily iron requirements during pregnancy in a 55-kg woman. (Modified from Koenig, 2014.)



If the nonanemic pregnant woman is not given supplemental iron, then serum iron and ferritin concentrations decline after midpregnancy. Importantly, hepcidin levels drop early in pregnancy (Hedengran, 2016; Koenig, 2014). As noted, lower hepcidin levels aid iron transfer into the maternal circulation via ferroportin in enterocytes. Lower hepcidin levels also augment iron transport into the fetus via ferroportin in syncytiotrophoblast.

With normal vaginal delivery, 500 to 600 mL of blood is typically lost, and thus not all the maternal iron added in the form of hemoglobin is spent (Pritchard, 1965). The excess hemoglobin iron becomes stored iron.

Immunological Functions

Pregnancy is associated with suppression of various humoral and cell-mediated immunological functions (Chap. 5, Amnion). This permits accommodation of the "foreign" semiallogeneic fetal graft that contains antigens of both maternal and paternal origin (Redman, 2014). The tolerance that exists at the maternal-fetal interface remains a great unsolved medical mystery. This tolerance is complex and involves certain immune system adaptations and crosstalk among the maternal microbiome, uterine decidua, and trophoblast. In particular, areas of the uterus that were previously considered sterile are colonized with bacteria. In most cases, these microbes are believed to be commensal and play a tolerizing and protective role. Indeed, commensal organisms may inhibit the proliferation of certain pathogens. Several reviewers have described these relationships (Mor, 2015; Racicot, 2014; Sisti, 2016).

One immune adaptation that promotes tolerance and protection at the maternal-fetal interface involves the expression of special major histocompatibility complex (MHC) molecules on the trophoblast. Recall that all cells of the body express a "badge" that identifies "self" and therefore privilege against attack by immune responses. For most cells of the body, this "badge" is known as MHC Class Ia. However, it is uncommon for two unrelated individuals to share compatible MHC class Ia. This creates a potential problem for reproduction because half of the fetus is composed of paternally derived antigens. To circumvent this problem, trophoblast cells express a form of MHC that does not vary between individuals. This "nonclassic" MHC is known as human leukocyte antigen class Ib and includes HLA-E, HLA-F, and HLA-G. Recognition of these HLA class Ib proteins by natural killer cells residing within the decidua inhibits their activity and promotes immune quiescence (Djurisic, 2014).

Another immune adaptation that promotes tolerances stems from important changes in CD4 T lymphocyte subpopulations in pregnancy. First, Th1-mediated immunity shifts to Th2-mediated immunity. Indeed, an important antiinflammatory component of pregnancy involves suppression of T-helper (Th) 1 and T-cytotoxic (Tc) 1 cells, which lower secretion of interleukin-2 (IL-2), interferon-α, and tumor necrosis factor (TNF). Moreover, suppressed Th1 response is thought to be a requisite for pregnancy continuation. It also may explain pregnancy-related remission of some autoimmune disorders such as rheumatoid arthritis, multiple sclerosis, and Hashimoto thyroiditis—which are cell-mediated immune diseases stimulated by Th1 cytokines (Kumru, 2005). With suppression of Th1 cells, there is upregulation of Th2 cells to increase secretion of IL-4, IL-10, and IL-13 (Michimata, 2003). These Th2 cytokines promote humoral, or antibody-based, immunity. Thus, autoimmune diseases mediated mainly by autoantibodies, such as systemic lupus erythematosus, may flare if the disease is already active in early pregnancy. But, the transition to an antibody-mediated immunity is an important defense during pregnancy and early puerperium. In cervical mucus, peak levels of immunoglobulins A and G (IgA and IgG) are significantly higher during pregnancy, and the immunoglobulin-rich cervical mucus plug creates a barrier to ascending infection (Hansen, 2014; Wang, 2014). Similarly, IgG is transferred to the developing fetus in the third trimester as a form of passive immunity, ostensibly in anticipation of birth. Further, immunoglobulins secreted into breast milk during lactation augment neonatal defenses against infection.

Other subpopulations of CD4 T lymphocytes serve mucosal and barrier immunity. These specific CD4-positive cells are known as Th17 cells and Treg cells. Th17 cells are proinflammatory and express the cytokine IL-17 and the retinoic acid receptor-related orphan receptors (RORs). Treg cells express the transcription factor forkhead box protein-3 (FOXP3) and confer tolerizing activity. There is a shift toward Treg CD4 cells in the first trimester, which peaks during the second trimester and falls toward delivery (Figueiredo, 2016). This shift may promote tolerance at the maternal-fetal interface (La Rocca, 2014). In particular, failure of these CD4 T lymphocyte subpopulation alterations may be related to preeclampsia development (Vargas-Rojas, 2016).

Leukocytes and Lymphocytes

Normal leukocyte counts during pregnancy can be higher than nonpregnant values, and upper values approach 15,000/µL (Appendix, Serum and Blood Constituents). During labor and the early puerperium, values may become markedly elevated, attaining levels of 25,000/µL or greater. The cause is unknown, but the same response occurs during and after strenuous exercise. The leukocytosis possibly represents the reappearance of leukocytes previously shunted out of active circulation.

The distribution of lymphocyte cell types is also altered during pregnancy. Specifically, B lymphocytes numbers are unchanged, but the absolute numbers of T lymphocytes rise and create a relative increase. Concurrently, the ratio of CD4 to CD8 T lymphocytes does not change (Kühnert, 1998).

Inflammatory Markers

Many tests performed to diagnose inflammation cannot be used reliably during pregnancy. For example, *leukocyte alkaline phosphatase* levels—used to evaluate myeloproliferative disorders—are elevated beginning early in pregnancy. The concentration of *C-reactive protein,* an acute-phase serum reactant, rises rapidly in response to tissue trauma or inflammation. Median C-reactive protein levels in pregnancy and labor are higher than for nonpregnant women (Anderson, 2013; Watts, 1991). Of nonlaboring gravidas, 95 percent had levels of 1.5 mg/dL or less, and gestational age did not affect serum levels. Another marker of inflammation, the *erythrocyte sedimentation rate (ESR),* is increased in normal pregnancy because of elevated plasma globulins and fibrinogen levels. *Complement factors C3* and *C4* levels also significantly rise during the second and third trimesters (Gallery, 1981; Richani, 2005). Last, concentrations of *procalcitonin*, a normal precursor of calcitonin, increase at the end of the third trimester and through the first few postpartum days. Procalcitonin levels rise with severe bacterial infections but remain low in viral infections and nonspecific inflammatory disease. However, measured levels poorly predict development of overt or subclinical chorioamnionitis after premature rupture of membranes (Thornburg, 2016).

Coagulation and Fibrinolysis

During normal pregnancy, both coagulation and fibrinolysis are augmented but remain balanced to maintain hemostasis (Kenny, 2014). Evidence of activation includes increased concentrations of all clotting factors except factors XI and XIII (Table 4-3).

TABLE 4-3

Changes in Measures of Hemostasis During Normal Pregnancy

Parameter	Nonpregnant	Term Pregnant
Activated PTT (sec)	31.6 ± 4.9	31.9 ± 2.9
Fibrinogen (mg/dL)	256 ± 58	473 ± 72[a]
Factor VII (%)	99.3 ± 19.4	181.4 ± 48.0[a]
Factor X (%)	97.7 ± 15.4	144.5 ± 20.1[a]
Plasminogen (%)	105.5 ± 14.1	136.2 ± 19.5[a]
tPA (ng/mL)	5.7 ± 3.6	5.0 ± 1.5
Antithrombin III (%)	98.9 ± 13.2	97.5 ± 33.3
Protein C (%)	77.2 ± 12.0	62.9 ± 20.5[a]
Total protein S (%)	75.6 ± 14.0	49.9 ± 10.2[a]

[a] $p < .05$.

Data shown as mean ± standard deviation.

PTT = partial thromboplastin time; tPA = tissue plasminogen activator.

Data from Uchikova, 2005.

Of procoagulants, the level and rate of thrombin generation throughout gestation progressively increase (McLean, 2012). In normal nonpregnant women, plasma fibrinogen (factor I) averages 300 mg/dL and ranges from 200 to 400 mg/dL. During normal pregnancy, the fibrinogen concentration rises approximately 50 percent. In late pregnancy, it averages 450 mg/dL, with a range from 300 to 600 mg/dL. This contributes greatly to the striking increase in the ESR. Also, levels of factor XIII—*fibrin stabilizing factor*—significantly drop as normal pregnancy advances (Sharief, 2014).

The end product of the coagulation cascade is fibrin formation, and the main function of the fibrinolytic system is to remove excess fibrin (Fig. 41-29). Tissue plasminogen activator (tPA) converts plasminogen into plasmin, which causes fibrinolysis and produces fibrin-degradation products such as d-dimers. Although

somewhat conflicting, most evidence suggests that fibrinolytic activity is reduced in normal pregnancy (Kenny, 2014). As reviewed by Cunningham and Nelson (2015), these changes favor fibrin formation. Although this is countered by increased levels of plasminogen, the net result is that pregnancy is a procoagulant state. Such changes serve to ensure hemostatic control during normal pregnancy, particularly during delivery when a certain amount of blood loss is expected.

Regulatory Proteins

Several proteins are natural inhibitors of coagulation, including proteins C and S and antithrombin (Fig. 52-1). Inherited or acquired deficiencies of these and other natural regulatory proteins—collectively referred to as *thrombophilias*—account for many thromboembolic episodes during pregnancy. They are discussed in Chapter 52 (Inherited Thrombophilias).

Activated protein C, along with the cofactors protein S and factor V, functions as an anticoagulant by neutralizing the procoagulants factor Va and factor VIIIa. During pregnancy, resistance to activated protein C grows progressively and is related to a concomitant drop in free protein S levels and greater factor VIII concentrations. Between the first and third trimesters, activated protein C levels decline from 2.4 to 1.9 U/mL, and free protein S concentrations diminish from 0.4 to 0.16 U/mL (Cunningham, 2015; Walker, 1997). Antithrombin levels decrease by 13 percent between midpregnancy and term and fall 30 percent from this baseline until 12 hours after delivery. By 72 hours after delivery, there is a return to baseline (James, 2014).

Platelets

Normal pregnancy promotes platelet changes. In one study, the average platelet count declined slightly during pregnancy to 213,000/µL compared with 250,000/µL in nonpregnant controls (Boehlen, 2000). Thrombocytopenia defined as below the 2.5th percentile corresponded to a platelet count of 116,000/µL. Lower platelet concentrations are partially due to hemodilution. Also, platelet consumption is likely augmented and creates a greater proportion of younger and therefore larger platelets (Han, 2014; Valera, 2010). Further, levels of several markers of platelet activation rise with gestational age but drop postpartum (Robb, 2010). Because of splenic enlargement, there may be an element of "hypersplenism," in which platelets are prematurely destroyed (Kenny, 2014).

Spleen

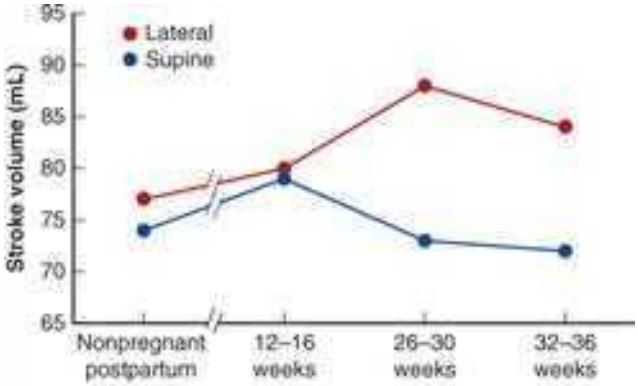
By the end of normal pregnancy, the spleen enlarges by up to 50 percent compared with that in the first trimester (Maymon, 2007). Moreover, Gayer and coworkers (2012) found that splenic size was 68-percent greater compared with that of nonpregnant controls. The cause of this splenomegaly is unknown, but it might follow the increased blood volume and/or the hemodynamic changes of pregnancy.

CARDIOVASCULAR SYSTEM

Changes in cardiac function become apparent during the first 8 weeks of pregnancy (Hibbard, 2014). Cardiac output is increased as early as the fifth week and reflects a reduced systemic vascular resistance and an increased heart rate. Compared with prepregnancy measurements, brachial systolic blood pressure, diastolic blood pressure, and central systolic blood pressure are all significantly lower 6 to 7 weeks from the last menstrual period (Mahendru, 2012). The resting pulse rate rises approximately 10 beats/min during pregnancy. Nelson and associates (2015) found that for both normal and overweight women, heart rate increased significantly between 12 and 16 weeks' and between 32 and 36 weeks' gestation. Between weeks 10 and 20, plasma volume expansion begins, and preload rises. This augmented preload results in significantly larger left atrial volumes and ejection fractions (Cong, 2015).

Ventricular performance during pregnancy is influenced by both the decrease in systemic vascular resistance and changes in pulsatile arterial flow. Multiple factors contribute to this overall altered hemodynamic function, which allows the physiological demands of the fetus to be met while maintaining maternal cardiovascular integrity (Hibbard, 2014). These changes during the last half of pregnancy and effects of maternal posture are summarized in Figure 4-7.

FIGURE 4-7
Left ventricular stroke volume across pregnancy compared with 12-week postpartum (nonpregnant) values for normal-weight women in the supine and lateral positions. (Data from Nelson, 2015.)



Heart

As the diaphragm becomes progressively elevated, the heart is displaced to the left and upward and is rotated on its long axis. As a result, the apex is moved somewhat laterally from its usual position and produces a larger cardiac silhouette in chest radiographs. Furthermore, gravidas normally have some degree of benign pericardial effusion, which may enlarge the cardiac silhouette (Enein, 1987). These factors make it difficult to precisely identify moderate degrees of cardiomegaly by simple radiographic studies.

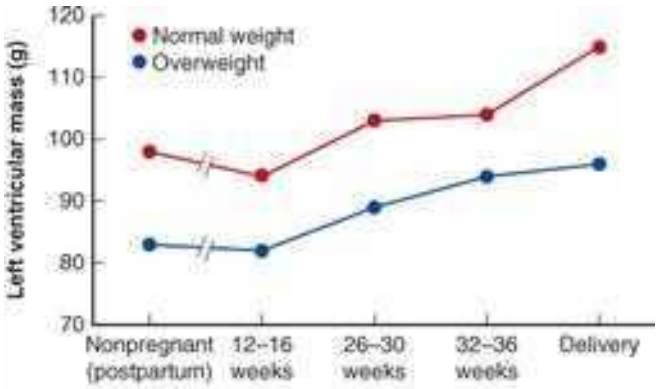
Normal pregnancy induces characteristic electrocardiographic changes, and the most common is slight left-axis deviation due to the altered heart position. Q waves in leads II, III and avF and flat or inverted T-waves in leads III, V1-V3 may also occur (Sunitha, 2014).

During pregnancy, many of the normal *cardiac sounds* are modified. These include: (1) an exaggerated splitting of the first heart sound and increased loudness of both components, (2) no definite changes in the aortic and pulmonary elements of the second sound, and (3) a loud, easily heard third sound (Cutforth, 1966). In 90 percent of gravidas, they also heard a systolic murmur that was intensified during inspiration in some or expiration in others and that disappeared shortly after delivery. A soft diastolic murmur was noted transiently in 20 percent, and continuous murmurs arising from the breast vasculature in 10 percent (Fig. 49-1).

Structurally, the expanding plasma volume seen during normal pregnancy is reflected by enlarging cardiac end-systolic and end-diastolic dimensions. Concurrently, however, septal thickness or ejection fraction does not change. This is because the dimensional changes are accompanied by substantive ventricular remodeling, which is characterized by left-ventricular mass expansion of 30 to 35 percent near term. In the nonpregnant state, the heart is capable of remodeling in response to stimuli such as hypertension and exercise. Such cardiac *plasticity* likely is a continuum that encompasses physiological growth—such as that in exercise, and pathological hypertrophy—such as with hypertension (Hill, 2008).

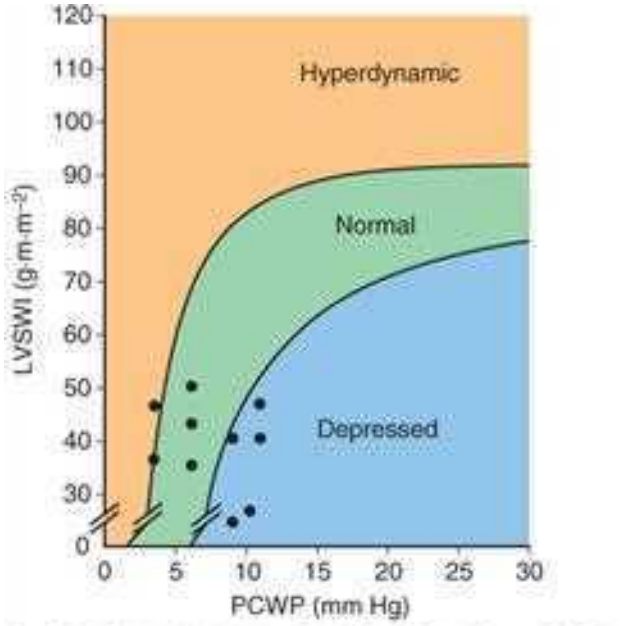
Stewart and colleagues (2016) used cardiac MR imaging to prospectively evaluate cardiac remodeling during pregnancy. Compared with the first trimester, left ventricular mass increased significantly beginning at 26 to 30 weeks' gestation, and this continued until delivery (Fig. 4-8). This remodeling is concentric and proportional to maternal size for both normal and overweight women and resolved within 3 months of delivery.

FIGURE 4-8
Left ventricular mass of normal-weight and overweight women across pregnancy compared with 12-week postpartum (nonpregnant) values. (Data from Stewart, 2016.)



Certainly for clinical purposes, ventricular function during pregnancy is normal, as estimated by the *Braunwald ventricular function* graph (Fig. 4-9). For the given filling pressures, cardiac output is appropriate and thus cardiac function during pregnancy is eudynamic. Of the metabolic changes that occur in the heart during pregnancy, the efficiency of cardiac work—which is the product of cardiac output × mean arterial pressure—is estimated to rise by approximately 25 percent. The associated increase in oxygen consumption is primarily accomplished via increased coronary blood flow rather than increased extraction (Liu, 2014).

FIGURE 4-9
Relationship between left ventricular stroke work index (LVSWI), cardiac output, and pulmonary capillary wedge pressure (PCWP) in 10 normal pregnant women in the third trimester. (Data from Clark, 1989.)



Cardiac Output

When measured in the lateral recumbent position at rest, cardiac output increases significantly beginning in early pregnancy. It continues to rise and remains elevated during the remainder of pregnancy. In a supine woman, a large uterus rather consistently compresses veins and diminishes venous return from the lower body. It also may compress the aorta (Bieniarz, 1968). In response, cardiac filling may be reduced and cardiac output lessened. Specifically, cardiac MR imaging shows that when a woman rolls from her back onto her left side, cardiac output at 26 to 30 weeks' gestation rises by approximately 20 percent and at 32 to 34 weeks by 10 percent (Nelson, 2015). Consistent with this, Simpson and James (2005) found that fetal oxygen saturation is approximately 10 percent higher if a laboring woman lies in a lateral recumbent position compared with supine. Upon standing, cardiac output falls to the same degree as in the nonpregnant woman (Easterling, 1988).

In multifetal pregnancies, compared with singletons, maternal cardiac output is augmented further by almost another 20 percent. Ghi and coworkers (2015) used transthoracic echocardiography to show that first-trimester cardiac output with twins (mean 5.50 L/min) was more than 20 percent greater than postpartum values. Cardiac output values in the second (6.31 L/min) and third (6.29 L/min) trimesters were increased an additional 15 percent compared with first-trimester output. Left atrial and left ventricular end-diastolic diameters are also longer with twins due to augmented preload (Kametas, 2003). The greater heart rate and inotropic contractility imply that cardiovascular reserve is reduced in multifetal gestations.

During first-stage labor, cardiac output rises moderately. During the second stage, with vigorous expulsive efforts, it is appreciably greater. The pregnancy-induced increase is lost after delivery, at times dependent on blood loss.

Hemodynamic Function in Late Pregnancy

Clark and associates (1989) conducted invasive studies to measure hemodynamic function late in pregnancy (Table 4-4). Right heart catheterization was performed in 10 healthy nulliparas at 35 to 38 weeks' gestation, and again at 11 to 13 weeks postpartum. Late pregnancy was associated with the expected increases in heart rate, stroke volume, and cardiac output. Systemic vascular and pulmonary vascular resistance both dropped significantly, as did colloid osmotic pressure. Pulmonary capillary wedge pressure and central venous pressure did not change appreciably. Thus, although cardiac output rises, left ventricular function as measured by stroke work index remains similar to the nonpregnant normal range (see Fig. 4-9). Put another way, normal pregnancy is not a continuous "high-output" state.

TABLE 4-4

Central Hemodynamic Changes in 10 Normal Nulliparous Women Near Term and Postpartum

	Pregnant[a] (35–38 wk)	Postpartum (11–13 wk)	Change[b]
Mean arterial pressure (mm Hg)	90 ± 6	86 ± 8	NSC
Pulmonary capillary wedge pressure (mm Hg)	8 ± 2	6 ± 2	NSC
Central venous pressure (mm Hg)	4 ± 3	4 ± 3	NSC
Heart rate (beats/min)	83 ± 10	71 ± 10	+17%
Cardiac output (L/min)	6.2 ± 1.0	4.3 ± 0.9	+43%
Systemic vascular resistance (dyn/sec/cm^{-5})	1210 ± 266	1530 ± 520	−21%
Pulmonary vascular resistance (dyn/sec/cm^{-5})	78 ± 22	119 ± 47	−34%
Serum colloid osmotic pressure (mm Hg)	18.0 ± 1.5	20.8 ± 1.0	−14%
COP-PCWP gradient (mm Hg)	10.5 ± 2.7	14.5 ± 2.5	−28%
Left ventricular stroke work index (g/m/m^2)	48 ± 6	41 ± 8	NSC

[a]Measured in lateral recumbent position.

[b]Changes significant unless NSC = no significant change.

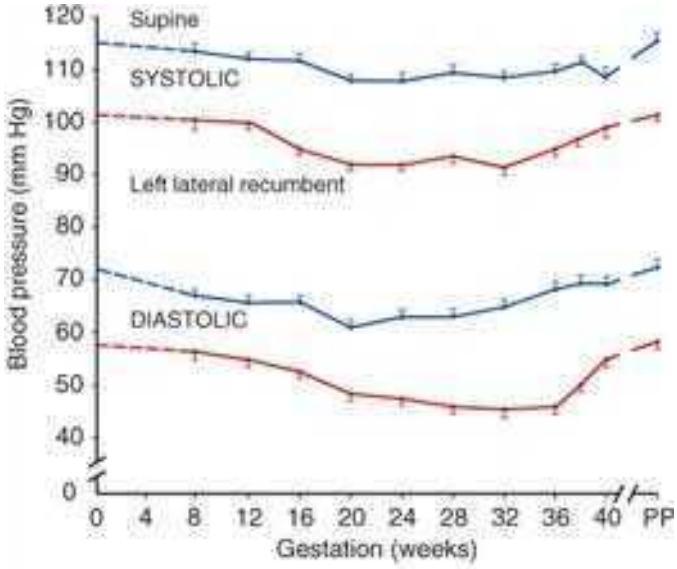
COP = colloid osmotic pressure; PCWP = pulmonary capillary wedge pressure.

Data from Clark, 1989.

Circulation and Blood Pressure

Changes in posture affect arterial blood pressure (Fig. 4-10). Brachial artery pressure when sitting is lower than that when in the lateral recumbent supine position (Bamber, 2003). Additionally, systolic blood pressure is lower in the lateral positions compared with either the flexed sitting or supine positions (Armstrong, 2011). Arterial pressure usually declines to a nadir at 24 to 26 weeks' gestation and rises thereafter. Diastolic pressure decreases more than systolic.

FIGURE 4-10
Sequential changes (±SEM) in blood pressure throughout pregnancy in 69 women in supine (*blue lines*) and left lateral recumbent positions (*red lines*). PP = postpartum. (Adapted from Wilson, 1980.)



Morris and associates (2015) studied measures of vascular compliance before pregnancy, during pregnancy, and postpartum. Compared with healthy nonpregnant controls, significant declines in mean arterial pressure and arterial stiffness, measured using pulse wave velocity, were observed between the prepregnant and the postpartum time periods. These findings suggest that pregnancy confers a favorable effect on maternal cardiovascular remodeling and may possibly help explain why the risk of preeclampsia is reduced in subsequent pregnancies.

Antecubital venous pressure remains unchanged during pregnancy. In the supine position, however, femoral venous pressure rises steadily, from approximately 8 mm Hg early in pregnancy to 24 mm Hg at term. Venous blood flow in the legs is retarded during pregnancy except when the lateral recumbent position is assumed (Wright, 1950). This tendency toward blood stagnation in the lower extremities during later pregnancy is attributable to occlusion of the pelvic veins and inferior vena cava by the enlarged uterus. The elevated venous pressure returns to normal when the pregnant woman lies on her side and immediately after delivery (McLennan, 1943). These alterations contribute to the dependent edema frequently experienced and to the development of varicose veins in the legs and vulva, as well as hemorrhoids. These changes also predispose to deep-vein thrombosis.

Supine Hypotension

In approximately 10 percent of women, supine compression of the great vessels by the uterus causes significant arterial hypotension, sometimes referred to as the *supine hypotensive syndrome* (Kinsella, 1994). Also when supine, uterine arterial pressure—and thus uterine blood flow—is significantly lower than that in the brachial artery. Evidence to support whether this directly affects fetal heart rate patterns in uncomplicated low-risk pregnancies is conflicting (Armstrong, 2011; Ibrahim, 2015; Tamás, 2007). Similar changes can also be seen with hemorrhage or with spinal analgesia.

Renin, Angiotensin II, and Plasma Volume

The renin-angiotensin-aldosterone axis is intimately involved in blood pressure control via sodium and water balance. All components of this system show increased levels in normal pregnancy. Renin is produced by both the maternal kidney and the placenta, and greater amounts of renin substrate (angiotensinogen) are produced by both maternal and fetal liver. Elevated angiotensinogen levels result, in part, from augmented estrogen production during normal pregnancy and are important in first-trimester blood pressure maintenance (Lumbers, 2014).

Gant and associates (1973) reported that nulliparas who remained normotensive became and stayed refractory to the pressor effects of infused angiotensin II. Conversely, those who ultimately became hypertensive developed, but then lost, this refractoriness. The diminished vascular responsiveness to angiotensin II may be progesterone related. Normally, pregnant women lose their acquired vascular refractoriness to angiotensin II within 15 to 30 minutes after the placenta is delivered. Large amounts of intramuscular progesterone given during late labor delay this diminishing refractoriness.

Cardiac Natriuretic Peptides

At least two species of these—*atrial natriuretic peptide (ANP)* and *brain natriuretic peptide (BNP)*—are secreted by cardiomyocytes in response to chamber-wall stretching. These peptides regulate blood volume by provoking natriuresis, diuresis, and vascular smooth-muscle relaxation. In nonpregnant and pregnant patients, levels of BNP and of amino-terminal pro-brain natriuretic peptide (Nt pro-BNP), as well as newer analytes such as suppressor of tumorigenicity 2 (ST2), may be useful in screening for depressed left ventricular systolic function and determining chronic heart failure prognosis (Ghashghaei, 2016).

During normal pregnancy, plasma ANP and BNP levels are maintained in the nonpregnant range despite greater plasma volume (Yurteri-Kaplan, 2012). In one study, median BNP levels were stable across pregnancy with values <20 pg/mL (Resnik, 2005). BNP levels are increased in severe preeclampsia, and this may be caused by cardiac strain from increased afterload (Afshani, 2013). It would appear that ANP-induced physiological adaptations participate in extracellular fluid volume expansion and in the elevated plasma aldosterone concentrations characteristic of normal pregnancy.

Prostaglandins

Elevated prostaglandin production during pregnancy is thought to have a central role in control of vascular tone, blood pressure, and sodium balance. Renal medullary prostaglandin E_2 synthesis is markedly elevated during late pregnancy and is presumed to be natriuretic. Levels of prostacyclin (PGI_2), the principal prostaglandin of endothelium, also rise during late pregnancy. PGI_2 regulates blood pressure and platelet function. It helps maintain vasodilation during pregnancy, and its deficiency is associated with pathological vasoconstriction (Shah, 2015). Thus, the ratio of PGI_2 to thromboxane in maternal urine and blood is considered important in preeclampsia pathogenesis (Majed, 2012).

Endothelin

Several endothelins are generated in pregnancy. Endothelin-1 is a potent vasoconstrictor produced in endothelial and vascular smooth muscle cells and regulates local vasomotor tone (George, 2011; Lankhorst, 2016). Its production is stimulated by angiotensin II, arginine vasopressin, and thrombin. Endothelins, in turn, stimulate secretion of ANP, aldosterone, and catecholamines. Vascular sensitivity to endothelin-1 is not altered during normal pregnancy. Pathologically elevated levels may play a role in preeclampsia (Saleh, 2016).

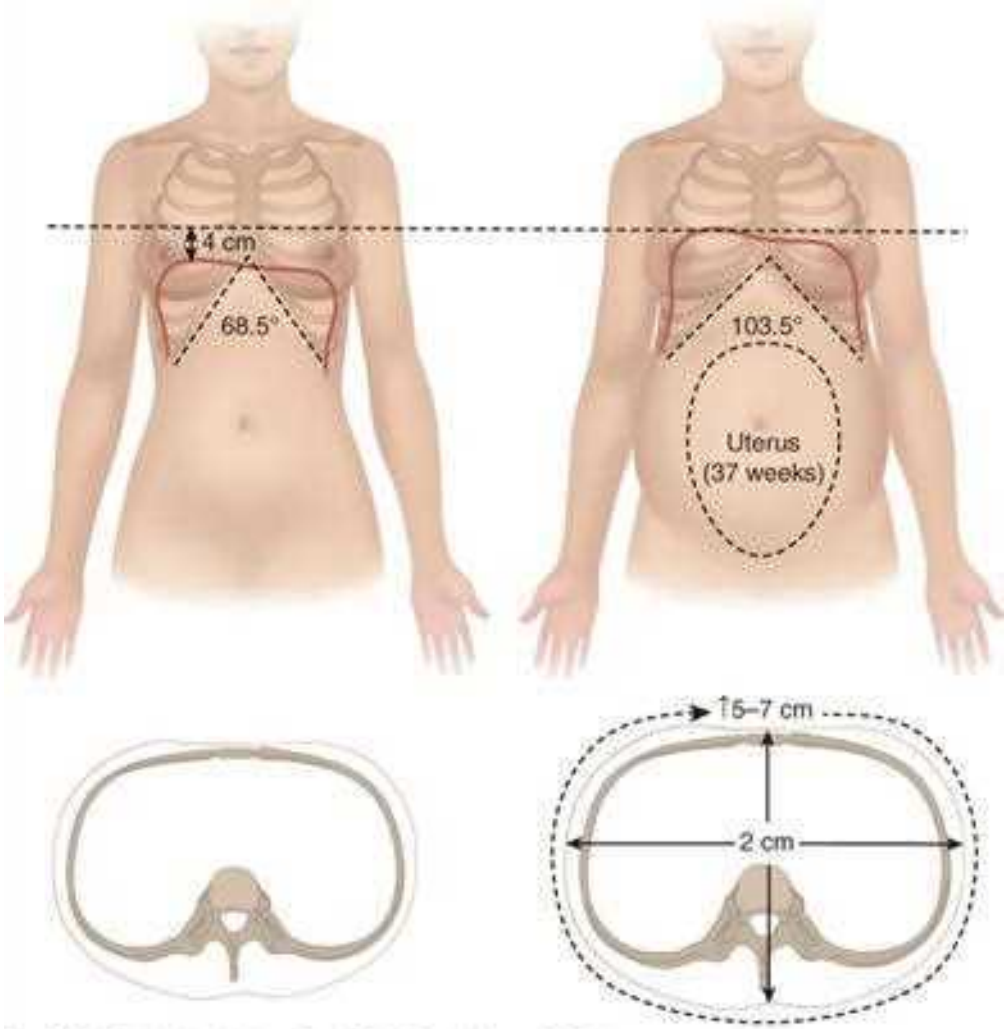
Nitric Oxide

This potent vasodilator is released by endothelial cells and may modify vascular resistance during pregnancy. Moreover, nitric oxide is an important mediator of placental vascular tone and development (Krause, 2011; Kulandavelu, 2013). Abnormal nitric oxide synthesis has been linked to preeclampsia development (Laskowska, 2015; Vignini, 2016).

RESPIRATORY TRACT

Of anatomic changes, the diaphragm rises approximately 4 cm during pregnancy (Fig. 4-11). The subcostal angle widens appreciably as the transverse diameter of the thoracic cage lengthens approximately 2 cm. The thoracic circumference increases about 6 cm, but not sufficiently to prevent reduced residual lung volumes created by the elevated diaphragm. Even so, diaphragmatic excursion is greater in pregnant than in nonpregnant women.

FIGURE 4-11
Chest wall measurements in nonpregnant (*left*) and pregnant women (*right*). The subcostal angle increases, as does the anteroposterior and transverse diameters of the chest wall and chest wall circumference. These changes compensate for the 4-cm elevation of the diaphragm so that total lung capacity is not significantly reduced. (Redrawn with permission from Hegewald MJ, Crapo RO: Respiratory physiology in pregnancy. Clin Chest Med 32(1):1, 2011.)

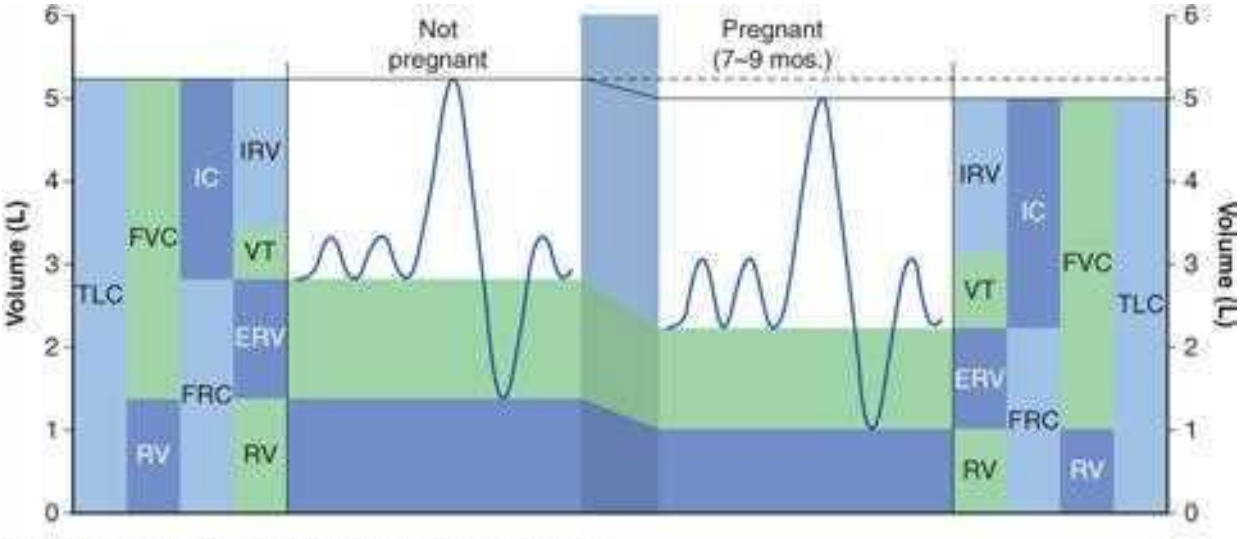


Pulmonary Function

Of physiological lung changes, *functional residual capacity (FRC)* decreases by approximately 20 to 30 percent or 400 to 700 mL during pregnancy (Fig. 4-12). This capacity is composed of *expiratory reserve volume*—which drops 15 to 20 percent or 200 to 300 mL—and *residual volume*—which decreases 20 to 25 percent or 200 to 400 mL. FRC and residual volume decline progressively across pregnancy due to diaphragm elevation. Significant reductions are observed by the sixth month. *Inspiratory capacity,* the maximum volume that can be inhaled from FRC, rises by 5 to 10 percent or 200 to 350 mL during pregnancy. *Total lung capacity*—the combination of FRC and inspiratory capacity—is unchanged or decreases by less than 5 percent at term (Hegewald, 2011).

FIGURE 4-12

Changes in lung volumes with pregnancy. The most significant changes are reduction in functional residual capacity (FRC) and its subcomponents, expiratory reserve volume (ERV) and residual volume (RV), as well as increases in inspiratory capacity (IC) and tidal volume (VT). (Redrawn with permission from Hegewald MJ, Crapo RO: Respiratory physiology in pregnancy. Clin Chest Med 32(1):1, 2011.)



The respiratory rate is essentially unchanged, but *tidal volume* and *resting minute ventilation* increase significantly as pregnancy advances. Kolarzyk and coworkers (2005) reported significantly greater mean tidal volumes—0.66 to 0.8 L/min—and resting minute ventilations—10.7 to 14.1 L/min—compared with those of nonpregnant women. The elevated minute ventilation is caused by several factors. These include enhanced respiratory drive primarily due to the stimulatory action of progesterone, low expiratory reserve volume, and compensated respiratory alkalosis (Heenan, 2003). Decreased plasma osmolality also results in less respiratory depression (Moen, 2014). This provides an additional mechanism for the increased minute ventilation seen in pregnancy, and one that is not dependent on progesterone.

Regarding pulmonary function, *peak expiratory flow rates* rise progressively as gestation advances (Grindheim, 2012). *Lung compliance* is unaffected by pregnancy. *Airway conductance* is increased and *total pulmonary resistance* reduced, possibly as a result of progesterone. The *maximum breathing capacity* and *forced* or *timed vital capacity* are not altered appreciably. It is unclear whether the critical *closing volume*—the lung volume at which airways in the dependent parts of the lung begin to close during expiration—is higher in pregnancy (Hegewald, 2011). Pulmonary function with a singleton pregnancy does not significantly differ from that with twins (McAuliffe, 2002; Siddiqui, 2014). Importantly, the greater oxygen requirements and perhaps the increased critical closing volume imposed by pregnancy make respiratory diseases more serious.

Demir and colleagues (2015) studied nasal physiology in 85 pregnant women. Although the minimal cross-sectional area decreased between the first and third trimesters, subjective reports of nasal congestion or total nasal resistance did not significantly differ among trimesters or compared with nonpregnant controls.

Oxygen Delivery

The amount of oxygen delivered into the lungs by the increased tidal volume clearly exceeds oxygen requirements imposed by pregnancy. Moreover, the total hemoglobin mass and, in turn, total oxygen-carrying capacity rise appreciably during normal pregnancy, as does cardiac output. Consequently, the *maternal arteriovenous oxygen* difference is diminished. Oxygen consumption grows approximately 20 percent during pregnancy, and it is approximately 10 percent higher in multifetal gestations (Ajjimaporn, 2014). During labor, oxygen consumption increases 40 to 60 percent (Bobrowski, 2010).

Acid–Base Equilibrium

A greater awareness of a desire to breathe is common even early in pregnancy (Milne, 1978). This may be interpreted as dyspnea, which may suggest pulmonary or cardiac abnormalities when none exist. This physiological dyspnea, which should not interfere with normal physical activity, is thought to result from greater tidal volume that lowers the blood P_{CO_2} slightly and paradoxically causes dyspnea. The increased respiratory effort during pregnancy, and in turn the reduction in the partial pressure of carbon dioxide in blood (P_{CO_2}), is likely induced in large part by progesterone and to a lesser degree by estrogen. Progesterone acts centrally, where it lowers the threshold and raises the sensitivity of the chemoreflex response to carbon dioxide (CO_2) (Jensen, 2005).

To compensate for the resulting respiratory alkalosis, plasma bicarbonate levels normally drop from 26 to 22 mmol/L. Although blood pH is increased only minimally, it does shift the oxygen dissociation curve to the left. This shift increases the affinity of maternal hemoglobin for oxygen—the *Bohr effect*—thereby lowering the oxygen-releasing capacity of maternal blood. This is offset because the slight pH rise also stimulates an increase in 2,3-diphosphoglycerate in maternal erythrocytes. This shifts the curve back to the right (Tsai, 1982). Thus, reduced P_{CO_2} from maternal hyperventilation aids CO_2 (waste) transfer from the fetus to the mother while also aiding oxygen release to the fetus.

URINARY SYSTEM

Kidney

The urinary system undergoes several remarkable changes in pregnancy (Table 4-5). *Kidney size* grows approximately 1.0 cm (Cietak, 1985). Both the *glomerular filtration rate (GFR)* and *renal plasma flow* increase early in pregnancy. The GFR rises as much as 25 percent by the second week after conception and 50 percent by the beginning of the second trimester. This hyperfiltration results from two principal factors. First, hypervolemia-induced hemodilution lowers the protein concentration and oncotic pressure of plasma entering the glomerular microcirculation. Second, renal plasma flow increases by approximately 80 percent before the end of the first trimester (Conrad, 2014b; Odutayo, 2012). As shown in Figure 4-13, elevated GFR persists until term, even though renal plasma flow declines during late pregnancy. Primarily as a consequence of this elevated GFR, approximately 60 percent of nulliparas during the third trimester experience urinary frequency, and 80 percent experience nocturia (Frederice, 2013).

TABLE 4-5

Renal Changes in Normal Pregnancy

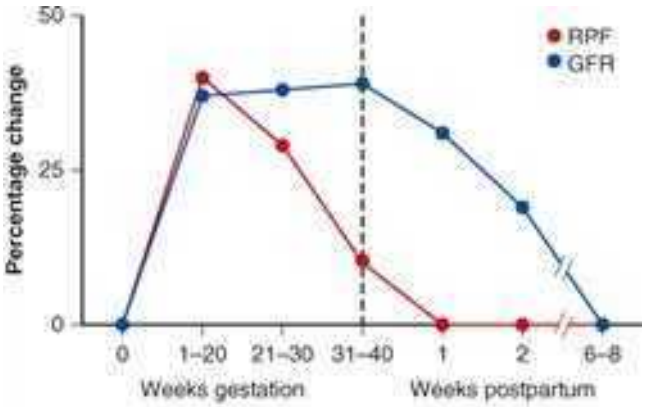
Parameter	Alteration	Clinical Relevance
Kidney size	Approximately 1 cm longer on radiograph	Size returns to normal postpartum
Dilatation	Resembles hydronephrosis on sonogram or IVP (more marked on right)	Can be confused with obstructive uropathy; retained urine leads to collection errors; renal infections are more virulent; may be responsible for "distention syndrome"; elective pyelography should be deferred to at least 12 weeks postpartum
Renal function	Glomerular filtration rate and renal plasma flow increase ~50%	Serum creatinine decreases during normal gestation; >0.8 mg/dL (>72 µmol/L) creatinine already borderline; protein, amino acid, and glucose excretion all increase
Maintenance of acid-base	Decreased bicarbonate threshold; progesterone stimulates respiratory center	Serum bicarbonate decreased by 4–5 mEq/L; P_{CO_2} decreased 10 mm Hg; a P_{CO_2} of 40 mm Hg already represents CO_2 retention
Plasma osmolality	Osmoregulation altered; osmotic thresholds for AVP release and thirst decrease; hormonal disposal rates increase	Serum osmolality decreases 10 mOsm/L (serum Na ~5 mEq/L) during normal gestation; increased placental metabolism of AVP may cause transient diabetes insipidus during pregnancy

AVP = vasopressin; IVP = intravenous pyelography; P_{CO_2}= partial pressure carbon dioxide.

Modified from Lindheimer, 2000.

FIGURE 4-13

Percentage increment in glomerular filtration rate (GFR) and renal plasma flow (RPF) across gestation and in the puerperium. (Data from Odutayo, 2012.)



During the puerperium, a marked GFR persists during the first postpartum day, principally from the reduced glomerular capillary oncotic pressure. A reversal of the gestational hypervolemia and hemodilution, still evident on the first postpartum day, eventuates by the second week postpartum (Odutayo, 2012).

Studies suggest that relaxin, discussed earlier (Fallopian Tubes), may mediate both increased GFR and renal blood flow during pregnancy (Conrad, 2014a; Helal, 2012). Relaxin boosts renal nitric oxide production, which leads to renal vasodilation and lowered renal afferent and efferent arteriolar resistance. This augments renal blood flow and GFR (Bramham, 2016). Relaxin may also increase vascular gelatinase activity during pregnancy, which leads to renal vasodilation, glomerular hyperfiltration, and reduced myogenic reactivity of small renal arteries (Odutayo, 2012).

As with blood pressure, maternal posture may considerably influence several aspects of renal function. Late in pregnancy, the sodium excretion rate in the supine position averages less than half that in the lateral recumbent position. The effects of posture on GFR and renal plasma flow vary.

One unusual feature of the pregnancy-induced changes in renal excretion is the remarkably increased amounts of some nutrients lost in the urine. Amino acids and water-soluble vitamins are excreted in much greater amounts (Shibata, 2013).

Renal Function Tests

Of renal function tests, serum creatinine levels decline during normal pregnancy from a mean of 0.7 to 0.5 mg/dL. *Values of 0.9 mg/dL or greater suggest underlying renal disease and prompt further evaluation.* Creatinine clearance in pregnancy averages 30 percent higher than the 100 to 115 mL/min in nonpregnant women. This is a useful test to estimate renal function, provided that complete urine collection is made during an accurately timed period. If this is not done precisely, results are misleading (Lindheimer, 2000, 2010). During the day, pregnant women tend to accumulate water as dependent edema, and at night, while recumbent, they mobilize this fluid with diuresis. This reversal of the usual nonpregnant diurnal pattern of urinary flow causes nocturia, and urine is more dilute than in nonpregnant women. Failure of a pregnant woman to excrete concentrated urine after withholding fluids for approximately 18 hours does not necessarily signify renal damage. In fact, the kidneys in these circumstances function perfectly normally by excreting mobilized extracellular fluid of relatively low osmolality.

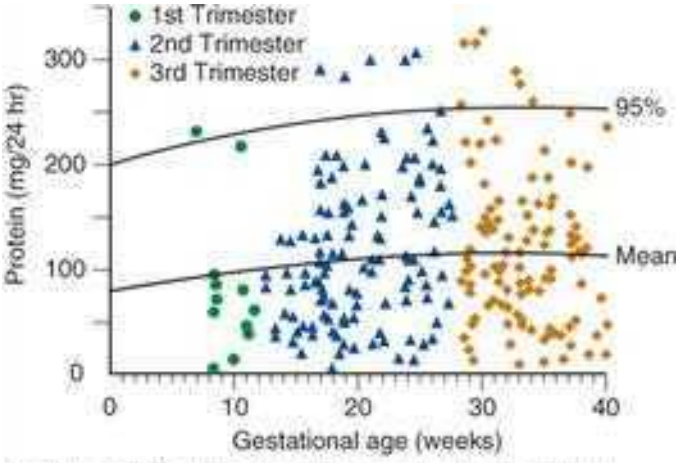
Urinalysis

Glucosuria during pregnancy may not be abnormal. The appreciably increased GFR, together with impaired tubular reabsorptive capacity for filtered glucose, accounts for most cases of glucosuria. Chesley (1963) calculated that about a sixth of pregnant women will spill glucose in the urine. That said, although common during pregnancy, when glucosuria is identified, a search for diabetes mellitus is pursued.

Hematuria frequently results from contamination during collection. If not, it most often suggests urinary tract disease or infection. Hematuria is common after difficult labor and delivery because of trauma to the bladder and urethra.

Proteinuria is typically defined in nonpregnant subjects as a protein excretion rate of more than 150 mg/d. Because of the aforementioned hyperfiltration and possible reduction of tubular reabsorption, proteinuria during pregnancy is usually considered significant once a protein excretion threshold of at least 300 mg/d is reached (Odutayo, 2012). Higby and coworkers (1994) measured protein excretion in 270 normal women throughout pregnancy (Fig. 4-14). Mean 24-hour excretion for all three trimesters was 115 mg, and the upper 95-percent confidence limit was 260 mg/d without significant differences by trimester. They showed that albumin excretion is minimal and ranges from 5 to 30 mg/d. Proteinuria increases with gestational age, which corresponds with the peak in GFR (see Fig. 4-13)(Odutayo, 2012).

FIGURE 4-14
Scatter plot of women showing 24-hour urinary total protein excretion by gestational age. Mean and 95-percent confidence limits are outlined. (Redrawn with permission from Higby K, Suiter CR, Phelps JY, et al: Normal values of urinary albumin and total protein excretion during pregnancy. Am J Obstet Gynecol 171:984, 1994.)



Measuring Urine Protein

The three most commonly employed approaches for assessing proteinuria are the qualitative classic dipstick, the quantitative 24-hour collection, and the albumin/creatinine or protein/creatinine ratio of a single voided urine specimen. The pitfalls of each approach have been reviewed by Conrad (2014b) and Bramham (2016) and their colleagues. The principal problem with dipstick assessment is that it fails to account for renal concentration or dilution of urine. For example, with polyuria and extremely dilute urine, a negative or trace dipstick could actually be associated with excessive protein excretion.

The 24-hour urine collection is affected by urinary tract dilatation, which is discussed in the next section. The dilated tract may lead to errors related both to retention—hundreds of milliliters of urine remaining in the dilated tract—and to timing—the remaining urine may have formed hours before the collection. To minimize these pitfalls, the patient is first hydrated and positioned in lateral recumbency—the definitive nonobstructive posture—for 45 to 60 minutes. After this, she is asked to void, and this specimen is discarded. Immediately following this void, her 24-hour collection begins. During the final hour of collection, the patient is again placed in the lateral recumbent position. But, at the end of this hour, the final collected urine is incorporated into the total collected volume (Lindheimer, 2010).

Last, the protein/creatinine ratio is a promising approach because data can be obtained quickly and collection errors are avoided. Disadvantageously, the amount of protein per unit of creatinine excreted during a 24-hour period is not constant, and the thresholds to define abnormal vary. Nomograms for urinary microalbumin and creatinine ratios during uncomplicated pregnancies have been developed (Waugh, 2003).

Ureters

After the uterus completely rises out of the pelvis, it rests on the ureters. This laterally displaces and compresses them at the pelvic brim. Above this level, elevated intraureteral tonus results, and ureteral dilatation is impressive (Rubi, 1968). It is right sided in 86 percent of women (Fig. 4-15) (Schulman, 1975). This unequal dilatation may result from cushioning provided the left ureter by the sigmoid colon and perhaps from greater right ureteral compression exerted by the dextrorotated uterus. The right ovarian vein complex, which is remarkably dilated during pregnancy, lies obliquely over the right ureter and may also contribute to right ureteral dilatation.

FIGURE 4-15
Hydronephrosis. Plain film from the 15-minute image of an intravenous pyelogram (IVP). Moderate hydronephrosis on the right (*arrows*) and mild hydronephrosis on the left (*arrowheads*) are both normal for this 35-week gestation.

Progesterone likely has some additional effect. Van Wagenen and Jenkins (1939) described continued ureteral dilatation after removal of the monkey fetus but with the placenta left in situ. The relatively abrupt onset of dilatation in women at midpregnancy, however, seems more consistent with ureteral compression.

Ureteral elongation accompanies distention, and the ureter is frequently thrown into curves of varying size, the smaller of which may be sharply angulated. These so-called kinks are poorly named, because the term connotes obstruction. They are usually single or double curves that, when viewed in a radiograph taken in the same plane as the curve, may appear as acute angulations. Another exposure at right angles nearly always identifies them to be gentle curves. Despite these anatomical changes, complication rates associated with ureteroscopy in pregnant and nonpregnant patients do not differ significantly (Semins, 2014).

Bladder

The bladder shows few significant anatomical changes before 12 weeks' gestation. Subsequently, however, increased uterine size, the hyperemia that affects all pelvic organs, and hyperplasia of bladder muscle and connective tissues elevate the trigone and thicken its intraureteric margin. Continuation of this process to term produces marked deepening and widening of the trigone. The bladder mucosa is unchanged other than an increase in the size and tortuosity of its blood vessels.

Bladder pressure in primigravidas increases from 8 cm H_2O early in pregnancy to 20 cm H_2O at term (Iosif, 1980). To compensate for reduced bladder capacity, absolute and functional urethral lengths increased by 6.7 and 4.8 mm, respectively. Concurrently, maximal intraurethral pressure rises from 70 to 93 cm H_2O, and thus continence is maintained. Still, at least half of women experience some degree of urinary incontinence by the third trimester (Abdullah, 2016a). Indeed, this is always considered in the differential diagnosis of ruptured membranes. Near term—particularly in nulliparas, in whom the presenting part often engages before labor—the entire base of the bladder is pushed ventral and cephalad. This converts the normally convex surface into a concavity. As a result, difficulties in diagnostic

and therapeutic procedures are greatly accentuated. Moreover, pressure from the presenting part impairs blood and lymph drainage from the bladder base, often rendering the area edematous, easily traumatized, and possibly more susceptible to infection.

GASTROINTESTINAL TRACT

As pregnancy progresses, the stomach and intestines are displaced cephalad by the enlarging uterus. Consequently, the physical findings in certain diseases are altered. The appendix, for instance, is usually displaced upward and somewhat laterally. At times, it may reach the right flank.

Pyrosis (heartburn) is common during pregnancy and is most likely caused by reflux of acidic secretions into the lower esophagus. Although the altered stomach position probably contributes to its frequency, lower esophageal sphincter tone also is decreased. In addition, intraesophageal pressures are lower and intragastric pressures higher in pregnant women. Concurrently, esophageal peristalsis has lower wave speed and lower amplitude (Ulmsten, 1978).

Gastric emptying time is unchanged during each trimester and compared with nonpregnant women (Macfie, 1991; Wong, 2002, 2007). During labor, however, and especially after administration of analgesics, gastric emptying time may be appreciably prolonged. As a result, one danger of general anesthesia for delivery is regurgitation and aspiration of either food-laden or highly acidic gastric contents.

Hemorrhoids are common during pregnancy (Shin, 2015). They are caused in large measure by constipation and elevated pressure in rectal veins below the level of the enlarged uterus.

Liver

Liver size does not enlarge during human pregnancy. Hepatic arterial and portal venous blood flow, however, increase substantively (Clapp, 2000).

Some laboratory test results of hepatic function are altered in normal pregnancy (Appendix, Serum and Blood Constituents). Total alkaline phosphatase activity almost doubles, but much of the rise is attributable to heat-stable placental alkaline phosphatase isozymes. Serum aspartate transaminase (AST), alanine transaminase (ALT), γ-glutamyl transpeptidase (GGT), and bilirubin levels are slightly lower compared with nonpregnant values (Cattozzo, 2013; Ruiz-Extremera, 2005).

The serum albumin concentration declines during pregnancy. By late pregnancy, albumin levels may be near 3.0 g/dL compared with approximately 4.3 g/dL in nonpregnant women (Mendenhall, 1970). Total body albumin levels rise, however, because of pregnancy-associated increased plasma volume. Serum globulin levels are also slightly higher.

Leucine aminopeptidase is a proteolytic liver enzyme whose serum levels may be increased with liver disease. Its activity is markedly elevated in pregnant women. The rise, however, results from a pregnancy-specific enzyme(s) with distinct substrate specificities (Song, 1968). Pregnancy-induced aminopeptidase has oxytocinase and vasopressinase activity that occasionally causes transient diabetes insipidus.

Gallbladder

During normal pregnancy, gallbladder contractility is reduced and leads to greater residual volume (Braverman, 1980). Progesterone potentially impairs gallbladder contraction by inhibiting cholecystokinin-mediated smooth muscle stimulation, which is the primary regulator of gallbladder contraction. Impaired emptying, subsequent stasis, and the increased cholesterol saturation of bile in pregnancy contribute to the increased prevalence of cholesterol gallstones in multiparas. In one study, approximately 8 percent of women had gallbladder sludge or stones when imaged at 18 and/or 36 weeks' gestation (Ko, 2014).

The pregnancy effects on maternal serum bile acid concentrations are still incompletely characterized. This is despite the long-acknowledged propensity for pregnancy to cause intrahepatic cholestasis and pruritus gravidarum from retained bile salts. Cholestasis of pregnancy is described in Chapter 55 (Intrahepatic Cholestasis of Pregnancy).

ENDOCRINE SYSTEM

Pituitary Gland

During normal pregnancy, the pituitary gland enlarges by approximately 135 percent (Gonzalez, 1988). This increase may sufficiently compress the optic chiasma to reduce visual fields. Impaired vision from this is rare and usually due to macroadenomas (Lee, 2014). Pituitary enlargement is primarily caused by estrogen-stimulated hypertrophy and hyperplasia of the lactotrophs (Feldt-Rasmussen, 2011). And, as discussed subsequently, maternal serum prolactin levels parallel the increasing size. Gonadotrophs decline in number, and corticotrophs and thyrotrophs remain constant. Somatotrophs are generally suppressed due to negative feedback by the placental production of growth hormone.

Peak pituitary size may reach 12 mm in MR images in the first days postpartum. The gland then involutes rapidly and reaches normal size by 6 months postpartum (Feldt-Rasmussen, 2011). The incidence of pituitary prolactinomas is not increased during pregnancy (Scheithauer, 1990). When these tumors are large before pregnancy—a macroadenoma measuring ≥10 mm—then growth during pregnancy is more likely (Chap. 58, Pituitary Disorders).

The maternal pituitary gland is not essential for pregnancy maintenance. Many women have undergone hypophysectomy, completed pregnancy successfully, and entered spontaneous labor while receiving compensatory glucocorticoids, thyroid hormone, and vasopressin.

Growth Hormone

During the first trimester, growth hormone is secreted predominantly from the maternal pituitary gland, and concentrations in serum and amnionic fluid lie within the nonpregnant range of 0.5 to 7.5 ng/mL (Kletzky, 1985). As early as 6 weeks' gestation, growth hormone secreted from the placenta becomes detectable, and by approximately 20 weeks, the placenta is the principal source of growth hormone secretion (Pérez-Ibave, 2014). Maternal serum values rise slowly from approximately 3.5 ng/mL at 10 weeks to plateau at about 14 ng/mL after 28 weeks. Growth hormone in amnionic fluid peaks at 14 to 15 weeks and slowly declines thereafter to reach baseline values after 36 weeks.

Placental growth hormone—which differs from pituitary growth hormone by 13 amino acid residues—is secreted by syncytiotrophoblast in a nonpulsatile fashion (Newbern, 2011). Its regulation and physiological effects are incompletely understood, but it influences fetal growth via upregulation of insulin-like growth factor 1 (IGF-1). Higher levels have been linked with development of preeclampsia (Mittal, 2007; Pérez-Ibave, 2014). Further, placental expression correlates positively with birthweight but negatively with fetal-growth restriction (Koutsaki, 2011). Maternal serum levels are associated with uterine artery resistance changes (Schiessl, 2007). That said, fetal growth still progresses in the complete absence of this hormone. Although not absolutely essential, the hormone may act in concert with placental lactogen to regulate fetal growth (Newbern, 2011).

Prolactin

Maternal plasma prolactin levels increase markedly during normal pregnancy. Concentrations are usually tenfold greater at term—about 150 ng/mL—compared with those of nonpregnant women. Paradoxically, plasma concentrations drop after delivery even in women who are breastfeeding. During early lactation, pulsatile bursts of prolactin secretion are a response to suckling.

The principal function of maternal prolactin is to ensure lactation. Early in pregnancy, prolactin acts to initiate DNA synthesis and mitosis of glandular epithelial cells and presecretory alveolar cells of the breast. Prolactin also augments the number of estrogen and prolactin receptors in these cells. Finally, prolactin promotes mammary alveolar cell RNA synthesis, galactopoiesis, and production of casein, lactalbumin, lactose, and lipids (Andersen, 1982). A woman with isolated prolactin deficiency failed to lactate after two pregnancies (Kauppila, 1987). This establishes prolactin as a requisite for lactation but not for pregnancy. Grattan (2015) has reviewed the numerous physiological roles of prolactin for facilitating maternal adaptations to pregnancy. A possible role is proposed for a prolactin fragment in the genesis of peripartum cardiomyopathy (Chap. 49, Dilated Cardiomyopathy) (Cunningham, 2012).

Prolactin is present in amnionic fluid in high concentrations. Levels of up to 10,000 ng/mL are found at 20 to 26 weeks' gestation. Thereafter, levels decline and reach a nadir after 34 weeks. Uterine decidua is the synthesis site of prolactin found in amnionic fluid. Although the exact function of amnionic fluid prolactin is unknown, impaired water transfer from the fetus into the maternal compartment to thereby prevent fetal dehydration is one suggestion.

Oxytocin and Antidiuretic Hormone

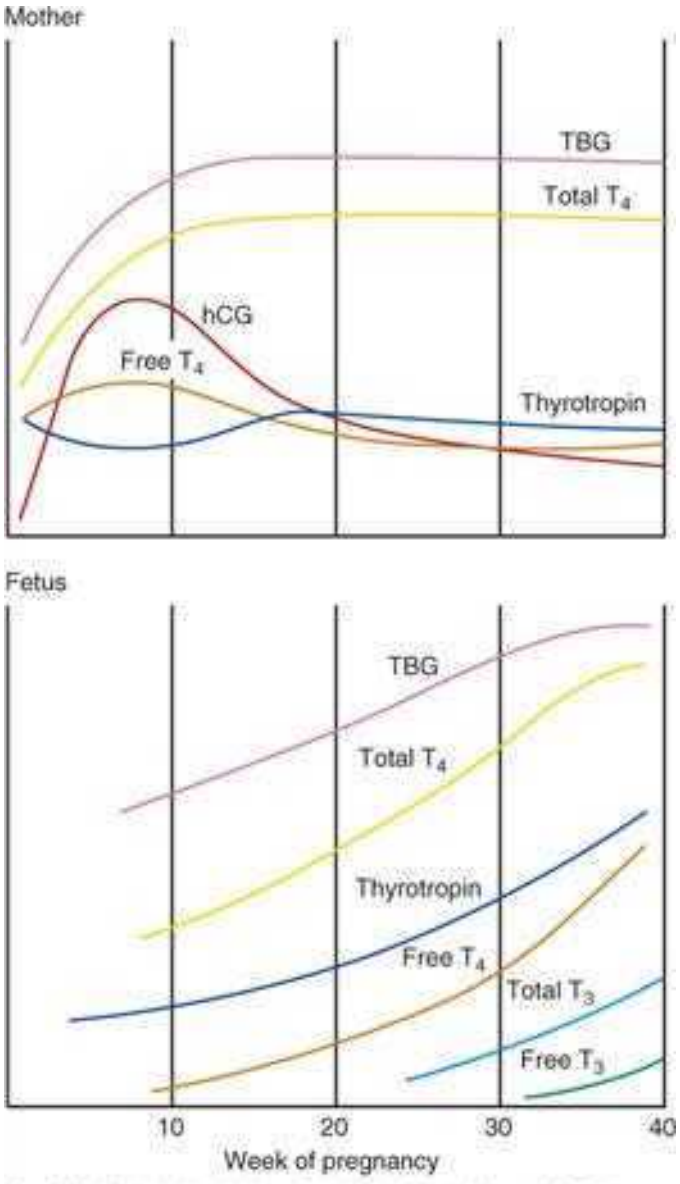
These two hormones are secreted from the posterior pituitary gland. The roles of oxytocin in parturition and lactation are discussed in Chapters 21 (Uterotonins in Parturition Phase 3) and 36 (Endocrinology of Lactation), respectively. Brown and colleagues (2013) have reviewed the complex mechanisms that promote quiescence of oxytocin systems during pregnancy. Levels of antidiuretic hormone, also called vasopressin, do not change during pregnancy.

Thyroid Gland

Thyrotropin-releasing hormone (TRH) is secreted by the hypothalamus and stimulates thyrotrope cells of the anterior pituitary to release *thyroid-stimulating hormone (TSH),* also called *thyrotropin.* TRH levels do not rise during normal pregnancy. However, TRH does cross the placenta and may serve to stimulate the fetal pituitary to secrete TSH (Thorpe-Beeston, 1991).

Serum TSH and hCG levels vary with gestational age (Fig. 4-16). As discussed in Chapter 5 (Placental Hormones), the α-subunits of the two glycoproteins are identical, whereas the β-subunits, although similar, differ in their amino acid sequence. As a result of this structural similarity, hCG has intrinsic thyrotropic activity, and thus, high serum hCG levels cause thyroid stimulation. Indeed, TSH levels in the first trimester decline in more than 80 percent of pregnant women, however, they still remain in the normal range for nonpregnant women

FIGURE 4-16
Relative changes in maternal and fetal thyroid function across pregnancy. Maternal changes include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of human chorionic gonadotropin (hCG). Increased TBG increases serum thyroxine (T_4) concentrations. hCG has thyrotropin-like activity and stimulates maternal free T_4 secretion. This transient hCG-induced increase in serum T_4 levels inhibits maternal secretion of thyrotropin. Except for minimally increased free T_4 levels when hCG peaks, these levels are essentially unchanged. Fetal levels of all serum thyroid analytes increase incrementally across pregnancy. Fetal triiodothyronine (T_3) does not increase until late pregnancy. (Modified from Burrow, 1994.)



The thyroid gland boosts production of thyroid hormones by 40 to 100 percent to meet maternal and fetal needs (Moleti, 2014). To accomplish this, the thyroid gland undergoes moderate enlargement during pregnancy caused by glandular hyperplasia and greater vascularity. Mean thyroid volume increases from 12 mL in the first trimester to 15 mL at term (Glinoer, 1990). That said, normal pregnancy does not typically cause significant thyromegaly, and thus any goiter warrants evaluation.

Early in the first trimester, levels of the principal carrier protein—*thyroid-binding globulin (TBG)*—rise, reach their zenith at about 20 weeks, and stabilize at approximately double baseline values for the remainder of pregnancy (see Fig. 4-16). The greater TBG concentrations result from both higher hepatic synthesis rates—due to estrogen stimulation—and lower metabolism rates due to greater TBG sialylation and glycosylation. These elevated TBG levels increase total serum thyroxine (T_4) and triiodothyronine (T_3) concentrations, but do not affect the physiologically important serum *free* T_4 and *free* T_3 levels. Specifically, total serum T_4 levels rise sharply beginning between 6 and 9 weeks' gestation and reach a plateau at 18 weeks. Serum free T_4 levels rise only slightly and peak along with hCG levels, and then they return to normal.

Interestingly, T_4 and T_3 secretion is not similar for all pregnant women (Glinoer, 1990). Approximately a third of women experience relative hypothyroxinemia, preferential T_3 secretion, and higher, albeit normal, serum TSH levels. Thus, thyroidal adjustments during normal pregnancy may vary considerably.

The fetus relies on maternal T_4, which crosses the placenta in small quantities to maintain normal fetal thyroid function (Chap. 58, Thyroid Disorders). Recall that the fetal thyroid does not begin to concentrate iodine until 10 to 12 weeks' gestation. The synthesis and secretion of thyroid hormone by fetal pituitary TSH ensues at approximately 20 weeks. At birth, approximately 30 percent of the T_4 in umbilical cord blood is of maternal origin (Leung, 2012).

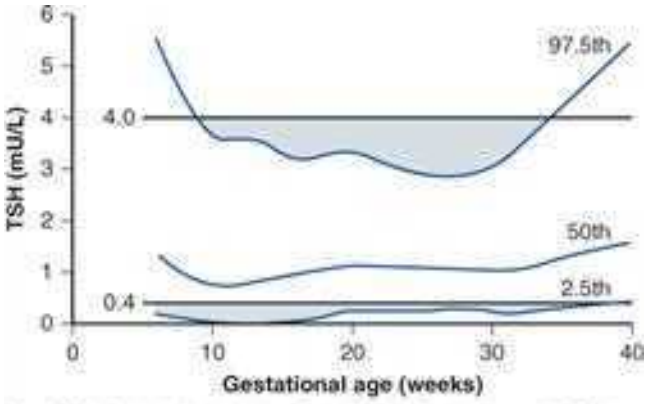
Thyroid Function Tests

Normal suppression of TSH during pregnancy may lead to a misdiagnosis of subclinical hyperthyroidism. Of greater concern is the potential failure to identify women with early hypothyroidism because of suppressed TSH concentrations. To mitigate the likelihood of such misdiagnoses, Dashe and coworkers (2005) conducted a

population-based study at Parkland Hospital to develop gestational-age-specific TSH normal curves for both singleton and twin pregnancies (Fig. 4-17). Similarly, Ashoor and associates (2010) established normal ranges for maternal TSH, free T_4, and free T_3 at 11 to 13 weeks' gestation.

FIGURE 4-17

Gestational age-specific thyroid-stimulating hormone (TSH) nomogram derived from 13,599 singleton pregnancies. The nonpregnant reference values of 4.0 and 0.4 mU/L are represented as solid black lines. Upper shaded area represents the 28 percent of singleton pregnancies with TSH values above the 97.5th percentile threshold that would not have been identified as abnormal based on the assay reference value of 4.0 mU/L. Lower shaded area represents singleton pregnancies that would have been (falsely) identified as having TSH suppression based on the assay reference value of 0.4 mU/L. (Data from Dashe, 2005.)



These complex alterations of thyroid regulation do not appear to alter maternal thyroid status as measured by metabolic studies. Although basal metabolic rate increases progressively by as much as 25 percent during normal pregnancy, most of this greater oxygen consumption can be attributed to fetal metabolic activity. If fetal body surface area is considered along with that of the mother, the predicted and observed basal metabolic rates are similar to those in nonpregnant women.

Iodine Status

Iodine requirements increase during normal pregnancy (Chap. 58, Congenital Hypothyroidism). In women with low or marginal intake, deficiency may manifest as low T_4 and higher TSH levels. Importantly, more than a third of the world population lives in areas where iodine intake is marginal. For the fetus, early exposure to thyroid hormone is essential for the nervous system, and despite public health programs to supplement iodine, severe iodine deficiency resulting in cretinism affects more than 2 million people globally (Syed, 2015).

Parathyroid Glands

In one longitudinal investigation of 20 women, all markers of bone turnover rose during normal pregnancy and failed to reach baseline levels by 12 months postpartum (More, 2003). Investigators concluded that the calcium needed for fetal growth and lactation may be drawn at least in part from the maternal skeleton. The factors affecting bone turnover yield a net result favoring fetal skeletal formation at the expense of the mother, such that pregnancy is a vulnerable period for osteoporosis (Sanz-Salvador, 2015). That said, prevention is difficult due to a paucity of identifiable risk factors.

Parathyroid Hormone

Acute or chronic declines in plasma calcium or acute drops in magnesium levels stimulate parathyroid hormone (PTH) release. Conversely, greater calcium and magnesium levels suppress PTH levels. The action of this hormone on bone resorption, intestinal absorption, and kidney reabsorption is to raise extracellular fluid calcium concentrations and lower phosphate levels.

Fetal skeleton mineralization requires approximately 30 g of calcium, primarily during the third trimester (Sanz-Salvador, 2015). Although this amounts to only 3 percent of the total calcium held within the maternal skeleton, the provision of calcium still challenges the mother. In most circumstances, augmented maternal calcium absorption provides the additional calcium. During pregnancy, the amount of calcium absorbed rises gradually and reaches approximately 400 mg/d in the third trimester. Greater calcium absorption appears to be mediated by elevated maternal 1,25-dihydroxyvitamin D concentrations. This occurs despite decreased PTH levels during early pregnancy, which is the normal stimulus for active vitamin D production within the kidney. Indeed, PTH plasma concentrations decline during the first trimester and then rise progressively throughout the remainder of pregnancy (Pitkin, 1979).

The increased production of active vitamin D is likely due to placental production of either PTH or a PTH-related protein (PTH-rP). Outside pregnancy and lactation, PTH-rP is usually detectable only in serum of women with hypercalcemia due to malignancy. During pregnancy, however, PTH-rP concentrations increase significantly. This protein is synthesized in both fetal tissues and maternal breasts.

Calcitonin

The C cells that secrete calcitonin are located predominantly in the perifollicular areas of the thyroid gland. Calcitonin opposes actions of PTH and vitamin D and protects the maternal skeleton during times of calcium stress. Pregnancy and lactation cause profound maternal calcium stress, ostensibly for the sake of the fetus.

Indeed, fetal calcitonin levels are at least twofold higher than maternal levels (Ohata, 2016). And although maternal levels fall during pregnancy, they generally rise postpartum (Møller, 2013).

Calcium and magnesium promote the biosynthesis and secretion of calcitonin. Various gastric hormones—gastrin, pentagastrin, glucagon, and pancreozymin—and food ingestion also increase calcitonin plasma levels.

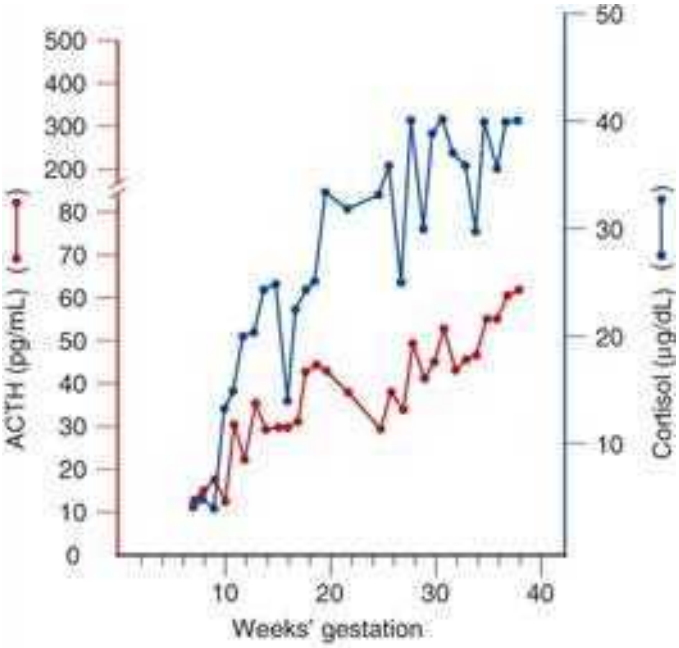
Adrenal Glands

Cortisol

In normal pregnancy, unlike their fetal counterparts, the maternal adrenal glands undergo little, if any, morphological change. The serum concentration of circulating cortisol rises, but much of it is bound by *transcortin*, the cortisol-binding globulin. The adrenal secretion rate of this principal glucocorticoid is not elevated, and probably it is lower than in the nonpregnant state. The metabolic clearance rate of cortisol, however, is diminished during pregnancy because its half-life is nearly doubled compared with that for nonpregnant women (Migeon, 1957). Administration of estrogen, including most oral contraceptives, causes changes in serum cortisol levels and transcortin similar to those of pregnancy (Jung, 2011).

During early pregnancy, the levels of circulating *adrenocorticotropic hormone* (*ACTH*), also known as *corticotropin*, are dramatically reduced. As pregnancy progresses, ACTH and free cortisol levels rise equally and strikingly (Fig. 4-18). This apparent paradox is not understood completely. Some suggest that greater free cortisol levels in pregnancy result from a "resetting" of the maternal feedback mechanism to higher thresholds (Nolten, 1981). This might result from *tissue refractoriness* to cortisol. Others assert that these incongruities stem from an antagonistic action of progesterone on mineralocorticoids (Keller-Wood, 2001). Thus, in response to elevated progesterone levels during pregnancy, an elevated free cortisol is needed to maintain homeostasis. Other theories include possible roles for higher free cortisol in preparation for the stress of pregnancy, delivery, and lactation. This pattern might also influence postpartum behavior and parenting roles (Conde, 2014).

FIGURE 4-18
Serial increases in serum cortisol (*blue line*) and adrenocorticotropic hormone (ACTH) (*red line*) across normal pregnancy. (Data redrawn from Carr, 1981.)



Aldosterone

As early as 15 weeks' gestation, the maternal adrenal glands secrete considerably increased amounts of aldosterone, the principal mineralocorticoid. By the third trimester, approximately 1 mg/d is released. If sodium intake is restricted, aldosterone secretion is even further elevated (Watanabe, 1963). Concurrently, levels of renin and angiotensin II substrate normally rise, especially during the latter half of pregnancy. This scenario promotes greater plasma levels of angiotensin II, which acts on the zona glomerulosa of the maternal adrenal glands and accounts for the markedly elevated aldosterone secretion. Some suggest the increased aldosterone secretion during normal pregnancy affords protection against the natriuretic effect of progesterone and atrial natriuretic peptide. Gennari-Moser and colleagues (2011) provide evidence that aldosterone, as well as cortisol, may modulate trophoblast growth and placental size.

Deoxycorticosterone

Maternal plasma levels of this potent mineralocorticosteroid progressively increase during pregnancy. Indeed, plasma levels of deoxycorticosterone rise to near 1500 pg/mL by term, a more than 15-fold increase (Parker, 1980). This marked elevation does not derive from adrenal secretion but instead represents augmented kidney

production resulting from estrogen stimulation. The levels of deoxycorticosterone and its sulfate in fetal blood are appreciably higher than those in maternal blood, which suggests transfer of fetal deoxycorticosterone into the maternal compartment.

Androgens

In balance, androgenic activity rises during pregnancy, and both maternal plasma levels of *androstenedione* and *testosterone* are increased. This finding is not totally explained by alterations in their metabolic clearance. Both androgens are converted to estradiol in the placenta, which increases their clearance rates. Conversely, greater plasma sex hormone-binding globulin levels in gravidas retard testosterone clearance. Thus, the production rates of maternal testosterone and androstenedione during human pregnancy are increased. The source of this higher C_{19}-steroid production is unknown, but it likely originates in the ovary.

Interestingly, little or no testosterone in maternal plasma enters the fetal circulation as testosterone. Even when massive testosterone levels are found in the circulation of pregnant women, as with androgen-secreting tumors, testosterone concentrations in umbilical cord blood are likely to be undetectable. This results from the near complete trophoblastic conversion of testosterone to 17β-estradiol.

Maternal serum and urine levels of *dehydroepiandrosterone sulfate* are lower during normal pregnancy. This stems from a greater metabolic clearance through extensive maternal hepatic 16α-hydroxylation and placental conversion to estrogen (Chap. 5, Placental Estrogen Production).

MUSCULOSKELETAL SYSTEM

Progressive lordosis is a characteristic feature of normal pregnancy. Compensating for the anterior position of the enlarging uterus, lordosis shifts the center of gravity back over the lower extremities. The sacroiliac, sacrococcygeal, and pubic joints have increased mobility during pregnancy. However, as discussed earlier (Fallopian Tubes), increased joint laxity and associated discomfort during pregnancy do not correlate with increased maternal serum levels of estradiol, progesterone, or relaxin (Aldabe, 2012; Marnach, 2003; Vøllestad, 2012). Most relaxation takes place in the first half of pregnancy. It may contribute to maternal posture alterations and in turn create lower back discomfort. As discussed in Chapter 36 (Pain, Mood, and Cognition), although some symphyseal separation likely accompanies many deliveries, those greater than 1 cm may cause significant pain (Shnaekel, 2015).

Aching, numbness, and weakness also occasionally are experienced in the upper extremities. This may result from the marked lordosis and associated anterior neck flexion and shoulder girdle slumping, which produce traction on the ulnar and median nerves (Crisp, 1964). The latter may give rise to symptoms mistaken for the *carpal tunnel syndrome* (Chap. 60, Spinal Cord Injury). Joint strengthening begins immediately following delivery and is usually complete within 3 to 5 months. Pelvic dimensions measured by MR imaging up to 3 months after delivery are not significantly different from prepregnancy measurements (Huerta-Enochian, 2006).

CENTRAL NERVOUS SYSTEM

Memory

Central nervous system changes are relatively few and mostly subtle. Women often report problems with attention, concentration, and memory throughout pregnancy and the early puerperium. Systematic studies of memory in pregnancy, however, are limited and often anecdotal. Keenan and associates (1998) longitudinally investigated memory in pregnant women and a matched control group. They found pregnancy-related memory decline that was limited to the third trimester. This decline was not attributable to depression, anxiety, sleep deprivation, or other physical changes associated with pregnancy. It was transient and quickly resolved following delivery. Others have found poorer verbal recall and processing speed and worse spatial recognition memory in pregnancy (Farrar, 2014; Henry, 2012).

Zeeman and coworkers (2003) used MR imaging to measure cerebral blood flow across pregnancy. They found that mean blood flow in the middle and posterior cerebral arteries declined progressively from 147 and 56 mL/min when nonpregnant to 118 and 44 mL/min late in pregnancy, respectively. Mechanisms and significance of the decline are unknown. Pregnancy does not affect cerebrovascular autoregulation (Bergersen, 2006; Cipolla, 2014).

Eyes

Intraocular pressure drops during pregnancy and is attributed partly to greater vitreous outflow. Corneal sensitivity is decreased, and the greatest changes are late in gestation. Most pregnant women demonstrate a measurable but slight increase in corneal thickness, thought to be due to edema. Consequently, they may have difficulty with previously comfortable contact lenses. Brownish-red opacities on the posterior surface of the cornea—*Krukenberg spindles*—are observed with a higher than expected frequency during pregnancy. Hormonal effects similar to those observed for skin lesions are believed to cause this increased pigmentation. Other than transient loss of accommodation reported with both pregnancy and lactation, visual function is unaffected by pregnancy. These changes during pregnancy and pathological eye aberrations were reviewed by Grant and Chung (2013).

Sleep

Beginning as early as 12 weeks' gestation and extending through the first 2 months postpartum, women have difficulty with falling asleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency (Pavlova, 2011). Abdullah and colleagues (2016b) concluded that sleep apnea is more common in pregnancy, especially in obese patients. The greatest disruption of sleep is encountered postpartum and may contribute to postpartum blues or to frank depression (Juulia Paavonen, 2017).

CHAPTER 5: Implantation and Placental Development

Almost immediately after the implantation of the ovum, its trophoblast begins to proliferate and invade the surrounding decidual tissue. As it does so, it breaks through the walls of the maternal capillaries, from which the blood escapes and forms cavities, which are bounded partly by trophoblast and partly by decidua. The maternal blood spaces established in this manner represent the earliest stages of the intervillous blood spaces of the future placenta.

—J. Whitridge Williams (1903)

INTRODUCTION

In 1903, the histopathological and embryological descriptions of ovum implantation and placental development had been extensively studied and described. However, the origins and functions of pregnancy hormones were largely unknown. Indeed, it was another 25 to 30 years before estrogen and progesterone were discovered. In the past 50 years, remarkable strides have followed to uncover the steps of implantation and placental structure and function.

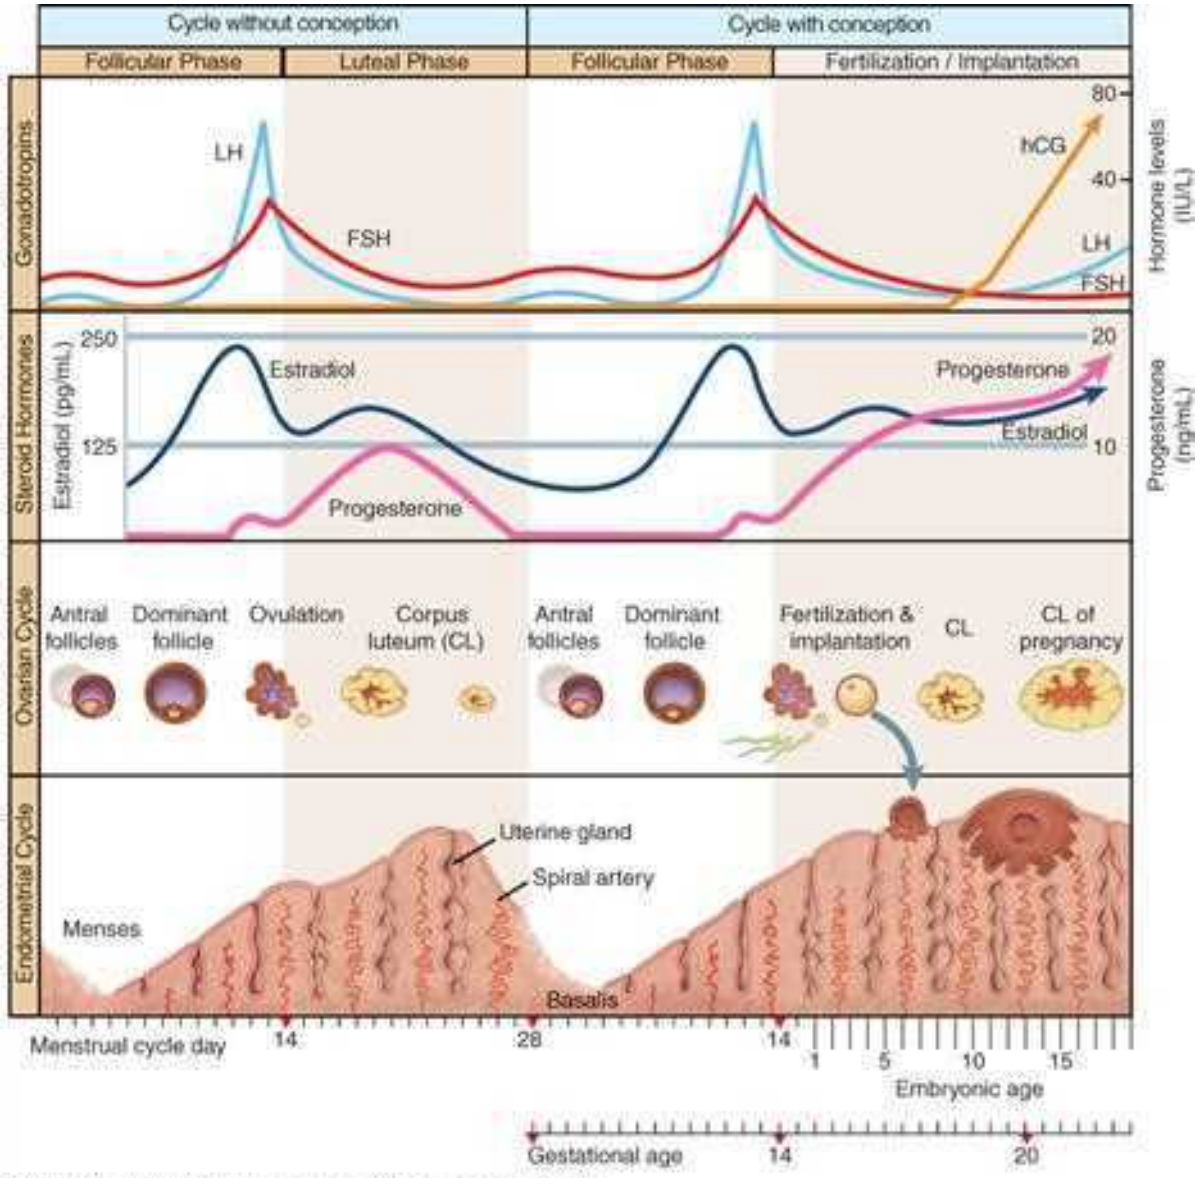
All obstetricians should understand the basic biological steps required for women to successfully achieve pregnancy. Several abnormalities can affect each of these and lead to infertility or pregnancy loss. In most women, spontaneous, cyclical ovulation continues during almost 40 years between menarche and menopause. Without contraception, there are approximately 400 opportunities for pregnancy, namely, the day of ovulation and its few preceding days. This narrow window for fertilization is controlled by tightly regulated production of ovarian steroids. Moreover, these hormones promote optimal endometrial regeneration after menstruation in preparation for the next implantation window.

If fertilization occurs, events that begin after blastocyst implantation persist until parturition. These derive from a unique interaction between fetal trophoblasts and the maternal endometrium, which has been transformed into the *decidua*. The ability of a mother and her fetus to coexist as two distinct immunological systems results from endocrine, paracrine, and immunological modification of fetal and maternal tissues in a manner not seen elsewhere. In addition, the placenta mediates a unique fetal–maternal communication system, which creates a hormonal environment that initially maintains pregnancy and eventually initiates events leading to parturition.

OVARIAN–ENDOMETRIAL CYCLE

Predictable, regular, cyclical, and spontaneous ovulatory menstrual cycles are regulated by complex interactions of the hypothalamic-pituitary-ovarian axis. Concurrently, cyclical changes in endometrial histology are faithfully reproduced (Fig. 5-1). Essentials players in this process include follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which are pituitary-derived gonadotropins, and the ovarian sex steroid hormones estrogen and progesterone.

FIGURE 5-1
Gonadotropin control of the ovarian and endometrial cycles. The ovarian-endometrial cycle has been structured as a 28-day cycle. The follicular phase (days 1 to 14) is characterized by rising estrogen levels, endometrial thickening, and selection of the dominant “ovulatory” follicle. During the luteal phase (days 14 to 21), the corpus luteum (CL) produces estrogen and progesterone, which prepare the endometrium for implantation. If implantation occurs, the developing blastocyst begins to produce human chorionic gonadotropin (hCG) and rescues the corpus luteum, thus maintaining progesterone production. FSH = follicle-stimulating hormone; LH = luteinizing hormone.



The average cycle duration approximates 28 days but ranges from 25 to 32 days, even for a given woman. The follicular or proliferative phase shows considerable phase-length variation. This contrasts with the luteal or secretory postovulatory phase of the cycle, which is remarkably constant at 12 to 14 days.

Ovarian Cycle

Follicular Phase

The human ovary contains 2 million oocytes at birth, and approximately 400,000 follicles are present at puberty onset (Baker, 1963). These are depleted at a rate of approximately 1000 follicles per month until age 35, when this rate accelerates (Faddy, 1992). Only 400 follicles are normally released during female reproductive life. Therefore, more than 99.9 percent of these undergo atresia through a process of cell death termed apoptosis (Gougeon, 1996; Kaipia, 1997).

Follicular development consists of several stages. Primordial follicles undergo gonadotropin-independent recruitment from the resting pool and then progress from primary and secondary follicles to the antral stage. This appears to be controlled by locally produced growth factors. Two members of the transforming growth factor-β family include growth differentiation factor 9 (GDF9) and bone morphogenetic protein 15 (BMP-15), which regulate granulosa cell proliferation and differentiation as primary follicles grow (Trombly, 2009; Yan, 2001). They also stabilize and expand the cumulus oocyte complex in the oviduct (Hreinsson, 2002). These factors are produced by oocytes, suggesting that the early steps in follicular development are, in part, oocyte controlled. As antral follicles develop, surrounding stromal cells are recruited, by a yet-to-be-defined mechanism, to become thecal cells.

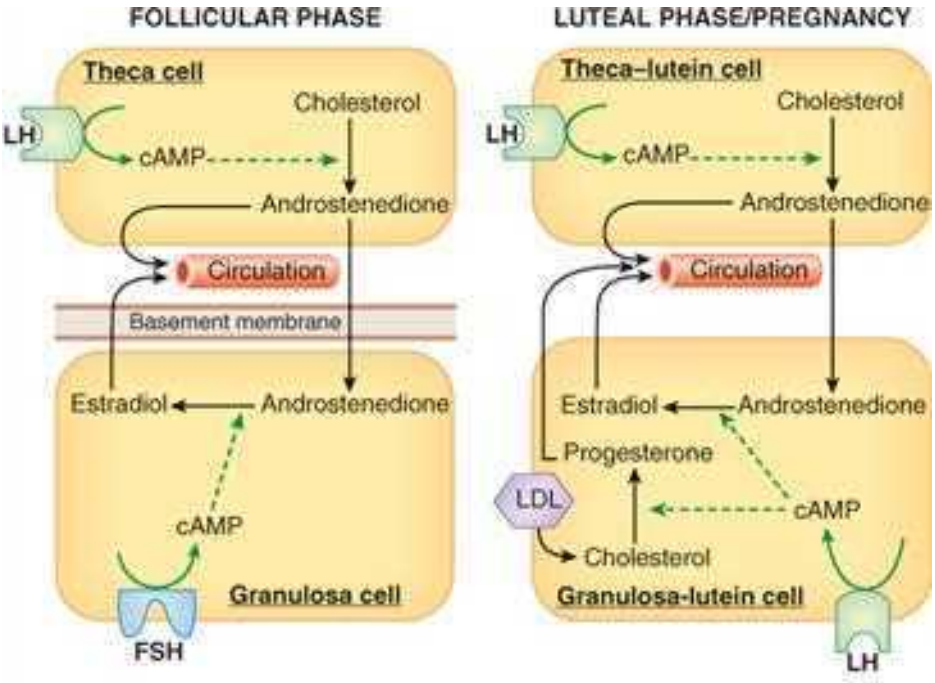
Although not required for early follicular maturation, FSH is required for further development of large antral follicles (Hillier, 2001). During each ovarian cycle, a group of antral follicles, known as a cohort, begins a phase of semisynchronous growth based on their maturation state during the FSH rise in the late luteal phase of the previous cycle. This FSH increase leading to further follicular development is called the *selection window* of the ovarian cycle (Macklon, 2001). Only follicles progressing to this stage develop the capacity to produce estrogen.

During the follicular phase, estrogen levels rise in proportion to growth of a dominant follicle and to the increase in its number of granulosa cells (see Fig. 5-1). These cells are the exclusive site of FSH receptor expression. The elevation of circulating FSH levels during the late luteal phase of the previous cycle stimulates an increase

in FSH receptors and subsequently, the ability of cytochrome P450 aromatase within granulosa cells to convert androstenedione into estradiol. The requirement for thecal cells, which respond to LH, and granulosa cells, which respond to FSH, represents the two-gonadotropin, two-cell hypothesis for estrogen biosynthesis (Short, 1962). As shown in Figure 5-2, FSH induces aromatase and expansion of the antrum of growing follicles. The follicle within the cohort that is most responsive to FSH is likely to be the first to produce estradiol and initiate expression of LH receptors.

FIGURE 5-2

The two-cell, two-gonadotropin principle of ovarian steroid hormone production. During the follicular phase (*left panel*), luteinizing hormone (LH) controls theca cell production of androstenedione, which diffuses into the adjacent granulosa cells and acts as precursor for estradiol biosynthesis. The granulosa cell capacity to convert androstenedione to estradiol is controlled by follicle-stimulating hormone (FSH). After ovulation (*right panel*), the corpus luteum forms and both theca-lutein and granulosa-lutein cells respond to LH. The theca-lutein cells continue to produce androstenedione, whereas granulosa-lutein cells greatly increase their capacity to produce progesterone and to convert androstenedione to estradiol. LH and hCG bind to the same LH-hCG receptor. If pregnancy occurs (*right panel*), human chorionic gonadotropin (hCG) rescues the corpus luteum through their shared LH-hCG receptor. Low-density lipoproteins (LDL) are an important source of cholesterol for steroidogenesis. cAMP = cyclic adenosine monophosphate.



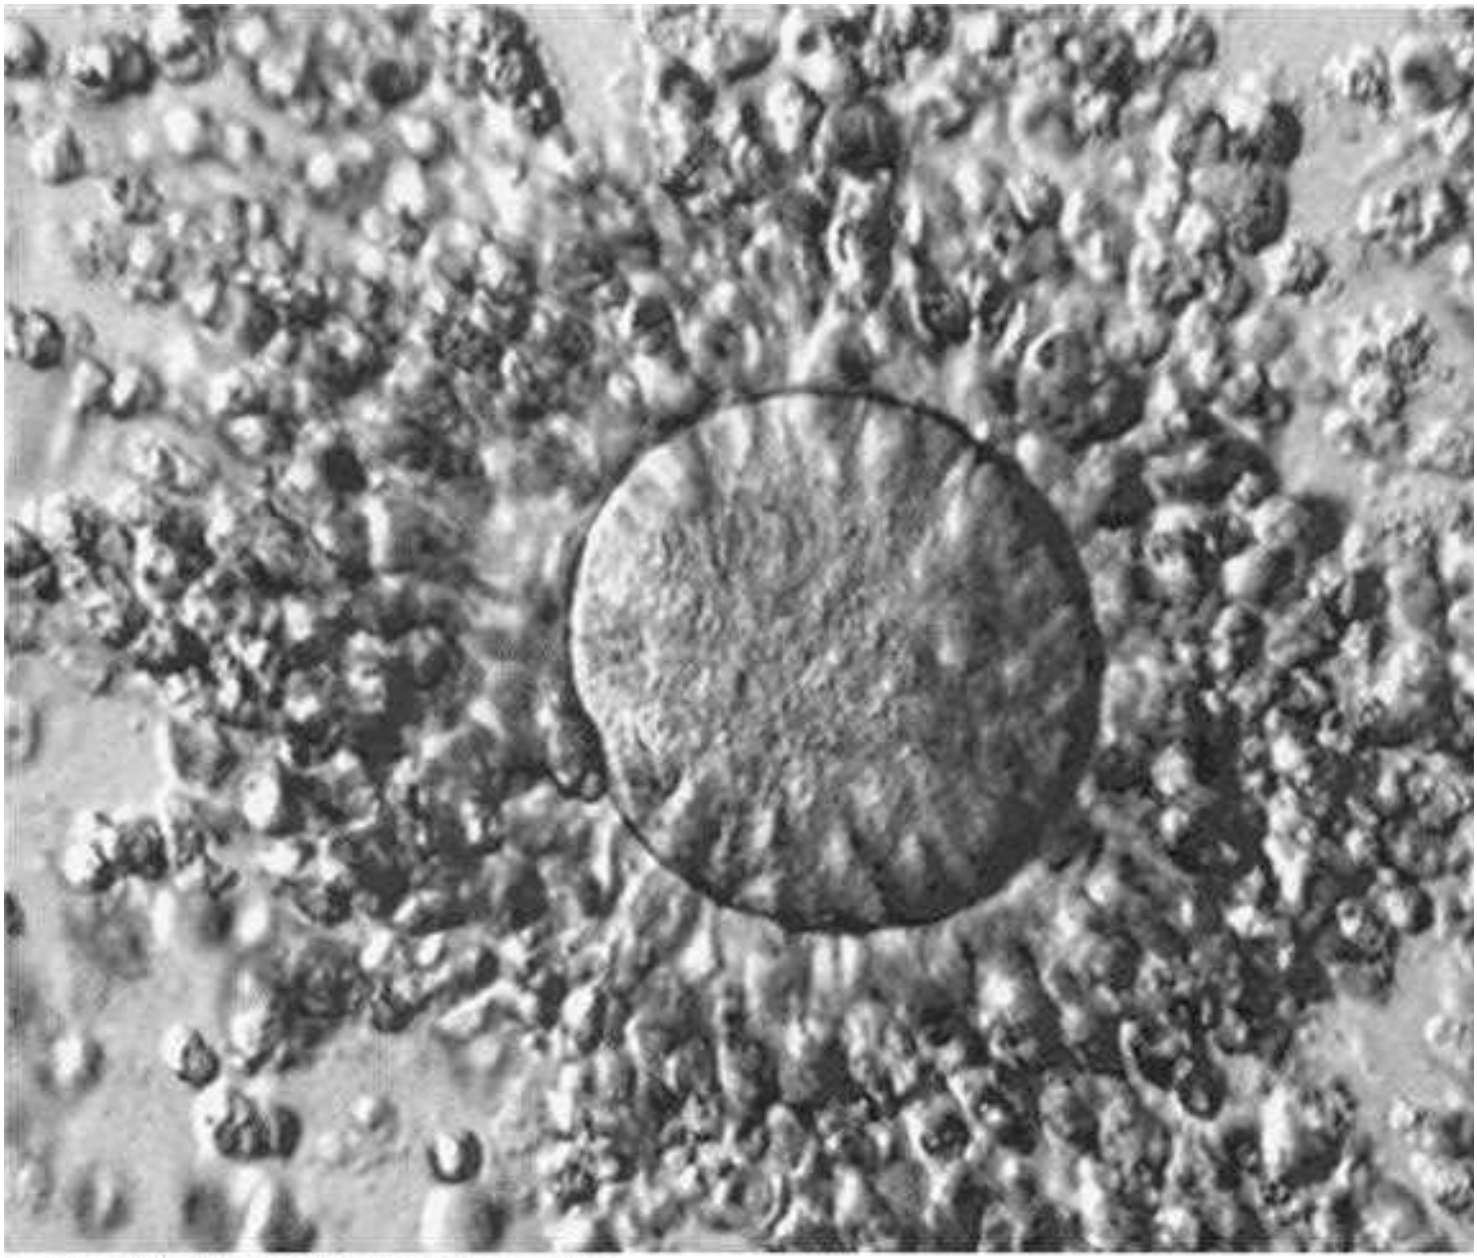
After the appearance of LH receptors, the preovulatory granulosa cells begin to secrete small quantities of progesterone. The preovulatory progesterone secretion, although somewhat limited, is believed to exert positive feedback on the estrogen-primed pituitary to either cause or augment LH release. In addition, during the late follicular phase, LH stimulates thecal cell production of androgens, particularly androstenedione, which are then transferred to the adjacent follicles where they are aromatized to estradiol (see Fig. 5-2). During the early follicular phase, granulosa cells also produce inhibin B, which can feed back on the pituitary to inhibit FSH release (Groome, 1996). As the dominant follicle begins to grow, estradiol and inhibin production rises and results in a decline of follicular-phase FSH. This drop in FSH levels is responsible for the failure of other follicles to reach preovulatory status—the Graafian follicle stage—during any one cycle. Thus, 95 percent of plasma estradiol produced at this time is secreted by the dominant follicle—the one destined to ovulate. Concurrently, the contralateral ovary is relatively inactive.

Ovulation

The onset of the gonadotropin surge resulting from increasing estrogen secretion by preovulatory follicles is a relatively precise predictor of ovulation. It occurs 34 to 36 hours before ovum release from the follicle (see Fig. 5-1). LH secretion peaks 10 to 12 hours before ovulation and stimulates resumption of meiosis in the ovum and release of the first polar body. Studies suggest that in response to LH, greater progesterone and prostaglandin production by the cumulus cells, as well as GDF9 and BMP-15 by the oocyte, activates expression of genes critical to formation of a hyaluronan-rich extracellular matrix by the cumulus complex (Richards, 2007). As seen in Figure 5-3, during synthesis of this matrix, cumulus cells lose contact with one another and move outward from the oocyte along the hyaluronan polymer—this process is called expansion. This results in a 20-fold augmentation of the cumulus complex volume and coincides with an LH-induced remodeling of the ovarian extracellular matrix. These allow release of the mature oocyte and its surrounding cumulus cells through the surface epithelium. Activation of proteases likely plays a pivotal role in weakening the follicular basement membrane and ovulation (Curry, 2006; Ny, 2002).

FIGURE 5-3

An ovulated cumulus–oocyte complex. An oocyte is at the center of the complex. Cumulus cells are widely separated from each other by the hyaluronan-rich extracellular matrix. (Used with permission from Dr. Kevin J. Doody.)



Luteal Phase

Following ovulation, the corpus luteum develops from the remains of the Graafian follicle in a process referred to as *luteinization*. The basement membrane separating the granulosa-lutein and theca-lutein cells breaks down, and by day 2 postovulation, blood vessels and capillaries invade the granulosa cell layer. The rapid neovascularization of the once-avascular granulosa may be due to angiogenic factors that include vascular endothelial growth factor (VEGF) and others produced by theca-lutein and granulosa-lutein cells in response to LH (Albrecht, 2003; Fraser, 2001). During luteinization, these cells undergo hypertrophy and increase their capacity to synthesize hormones.

LH is the primary luteotropic factor responsible for corpus luteum maintenance (Vande Wiele, 1970). Indeed, LH injections can extend the corpus luteum life span in normal women by 2 weeks (Segaloff, 1951).

The hormone secretion pattern of the corpus luteum differs from that of the follicle (see Fig. 5-1). As depicted in Figure 5-2, the greater capacity of granulosa-lutein cells to produce progesterone results from enhanced access to considerably more steroidogenic precursors through blood-borne, low-density lipoprotein (LDL)-derived cholesterol (Carr, 1981a). Ovarian progesterone production peaks at 25 to 50 mg/d during the midluteal phase. With pregnancy, the corpus luteum continues progesterone production in response to placental human chorionic gonadotropin (hCG), which binds to the same receptor as LH.

Estrogen levels follow a more complex pattern of secretion. Specifically, just after ovulation, estrogen levels decline, but then exhibit a secondary rise that reaches a peak production of 0.25 mg/d of 17β-estradiol in the midluteal phase. Toward the end of the luteal phase, estradiol production again drops.

The human corpus luteum is a transient endocrine organ that, in the absence of pregnancy, will rapidly regress 9 to 11 days after ovulation via apoptosis (Vaskivuo, 2002). The mechanisms that control luteolysis, that is, the regression of the corpus luteum, remain unclear. However, it results in part from dropping levels of

circulating LH in the late luteal phase and rising LH insensitivity by luteal cells (Duncan, 1996; Filicori, 1986). The role of other factors is less established. The dramatic drop in circulating estradiol and progesterone levels initiate molecular events that lead to menstruation.

Estrogen and Progesterone Action

Estrogen is the essential hormonal signal on which most events in the normal menstrual cycle depend. They function in many cell types to regulate follicular development, uterine receptivity, and blood flow. The most biologically potent naturally occurring estrogen is 17β-estradiol, which is secreted by granulosa cells of the dominant follicle and luteinized granulosa cells of the corpus luteum. Estradiol action is complex and appears to involve two classic nuclear hormone receptors designated estrogen receptor α (ERα) and β (ERβ) (Katzenellenbogen, 2001). These isoforms are the products of separate genes and can exhibit distinct tissue expression. Both estradiol-receptor complexes act as transcriptional factors that become associated with the estrogen-response element of specific genes. They share a robust activation by estradiol. However, differences in their binding affinities to other estrogens and their cell-specific expression patterns suggest that ERα and ERβ receptors may have both distinct and overlapping function (Saunders, 2005).

Most progesterone actions on the female reproductive tract are mediated through the nuclear hormone receptors, progesterone-receptor type A (PR-A) and B (PR-B). Progesterone enters cells by diffusion, and in responsive tissues it becomes associated with its receptors (Conneely, 2002). Progesterone-receptor isoforms arise from a single gene and regulate transcription of target genes. These receptors have unique actions. When PR-A and PR-B receptors are coexpressed, it appears that PR-A can inhibit PR-B gene regulation. The endometrial glands and stroma appear to have different expression patterns for progesterone receptors that vary during the menstrual cycle (Mote, 1999).

Progesterone can also evoke rapid responses, such as changes in intracellular free calcium levels, which cannot be explained by genomic mechanisms. G-protein–coupled membrane receptors for progesterone have been identified, but their role in the ovarian–endometrial cycle remains to be elucidated (Peluso, 2007).

Endometrial Cycle

Proliferative Phase

In the endometrium, epithelial cells line the endometrial glands and are supported by stromal cells. These cells and supplying blood vessels replicate rapidly and cyclically in reproductive-aged women and are regenerated each ovarian–endometrial cycle. The superficial endometrium, termed the *functionalis layer*, is shed and reconstructed from the deeper *basalis layer* (Fig. 5-4). There is no other example in humans of such cyclical shedding and regrowth of an entire tissue.

FIGURE 5-4

The endometrium consists of two layers, the functionalis layer and basalis layer. These are supplied by the spiral and basal arteries, respectively. Numerous glands also span these layers. As the menstrual cycle progresses, greater coiling of the spiral arteries and increased gland folding can be seen. Near the end of the menstrual cycle (day 27), the coiled arteries constrict, deprive blood supply to the functionalis layer, and lead to necrosis and sloughing of this layer.

Fluctuations in estrogen and progesterone levels produce striking effects on the endometrium. Follicular-phase estradiol production is the most important factor in endometrial recovery following menstruation, and both ERα and ERβ receptors are expressed here. Although up to two thirds of the functionalis endometrium is fragmented and shed with menses, reepithelialization begins even before menstrual bleeding has ceased. By the fifth day of the endometrial cycle—fifth day of menses-the epithelial surface of the endometrium has been restored, and revascularization has begun. The preovulatory endometrium is characterized by proliferation of glandular, stromal, and vascular endothelial cells. During the early part of the proliferative phase, the endometrium is usually less than 2 mm thick. The glands are narrow, tubular structures that pursue almost a straight and parallel course from the basalis layer toward the endometrial cavity. Mitotic figures,

especially in the glandular epithelium, are identified by the fifth cycle day. Mitotic activity in both epithelium and stroma persists until day 16 to 17, that is, 2 to 3 days after ovulation. Blood vessels are numerous and prominent.

Clearly, reepithelialization and angiogenesis are important to cessation of endometrial bleeding (Chennazhi, 2009; Rogers, 2009). These are dependent on tissue regrowth, which is estrogen regulated. Epithelial cell growth also is regulated in part by epidermal growth factor and transforming growth factor α (TGFα). Stromal cells proliferate through paracrine and autocrine actions of estrogen and greater local levels of fibroblast growth factor-9 (Tsai, 2002). Estrogens also raise local production of VEGF, which causes angiogenesis through vessel elongation in the basalis (Gargett, 2001; Sugino, 2002).

By the late proliferative phase, the endometrium thickens from both glandular hyperplasia and augmented stromal ground substance, which is edema and proteinaceous material. The loose stroma is especially prominent, and the glands in the functionalis layer are widely separated. This is compared with those of the basalis layer, in which the glands are more crowded and the stroma is denser.

At midcycle, as ovulation nears, glandular epithelium becomes taller and pseudostratified. The surface epithelial cells acquire numerous microvilli, which increase epithelial surface area, and develop cilia, which move endometrial secretions during the secretory phase (Ferenczy, 1976).

Secretory Phase

After ovulation, the estrogen-primed endometrium responds to rising progesterone levels in a highly predictable manner. By day 17, glycogen accumulates in the basal portion of glandular epithelium, creating subnuclear vacuoles and pseudostratification. These changes likely result from direct progesterone action through receptors expressed in glandular cells (Mote, 2000). On day 18, vacuoles move to the apical portion of the secretory nonciliated cells. By day 19, these cells begin to secrete glycoprotein and mucopolysaccharide contents into the gland lumen (Hafez, 1975). Glandular cell mitosis ceases with secretory activity due to rising progesterone levels, which antagonize the mitotic effects of estrogen. Estradiol action also diminishes because of glandular expression of the type 2 isoform of 17β-hydroxysteroid dehydrogenase. This converts estradiol to the less active estrone (Casey, 1996). On cycle days 21 to 24, the stroma becomes edematous. Next, on days 22 to 25, stromal cells surrounding the spiral arterioles begin to enlarge, and stromal mitosis becomes apparent. Days 23 to 28 are characterized by predecidual cells, which surround spiral arterioles.

Between days 22 and 25, the secretory-phase endometrium undergoes striking changes associated with predecidual transformation of the upper two thirds of the functionalis layer. The glands exhibit extensive coiling, and luminal secretions become visible. Changes within the endometrium also can mark the so-called window of implantation seen on days 20 to 24. Epithelial surface cells show fewer microvilli and cilia, but luminal protrusions appear on the apical cell surface (Nikas, 2003). These pinopodes help prepare for blastocyst implantation. They also coincide with changes in the surface glycocalyx that allow acceptance of a blastocyst (Aplin, 2003).

Another highlight of the secretory phase is the continuing growth and development of the spiral arteries. These vessels arise from the radial arteries, which are myometrial branches of the arcuate and, ultimately, uterine vessels (see Fig. 5-4). The morphological and functional properties of the spiral arteries are unique and essential to blood flow changes seen during menstruation or implantation. During endometrial growth, spiral arteries lengthen at a rate appreciably greater than the rate of endometrial tissue thickening. This growth discordance obliges even greater coiling. Spiral artery development reflects a marked induction of angiogenesis, with widespread vessel sprouting and extension. Such rapid angiogenesis is regulated, in part, through estrogen- and progesterone-regulated synthesis of VEGF (Ancelin, 2002; Chennazhi, 2009).

Menstruation

The midluteal–secretory phase of the endometrial cycle is a critical branch point in endometrial development and differentiation. With corpus luteum rescue and continued progesterone secretion, the endometrium is transformed into the decidua. With luteolysis and declining luteal progesterone production, events leading to menstruation are initiated (Critchley, 2006; Thiruchelvam, 2013).

In the late premenstrual-phase endometrium, the stroma is invaded by neutrophils to create a pseudoinflammatory appearance. These cells infiltrate primarily on the day or two immediately preceding menses onset. The endometrial stromal and epithelial cells produce interleukin-8 (IL-8), a chemotactic–activating factor for neutrophils (Arici, 1993). Similarly, monocyte chemotactic protein-1 (MCP-1) is synthesized by endometrium and promotes monocyte recruitment (Arici, 1995).

Leukocyte infiltration is considered key to both endometrial extracellular matrix breakdown and repair of the functionalis layer. The term “inflammatory tightrope” refers to the ability of macrophages to assume phenotypes that vary from proinflammatory and phagocytic to immunosuppressive and reparative. These are likely relevant to menstruation, in which tissue breakdown and restoration occur simultaneously (Evans, 2012; Maybin, 2015). Invading leukocytes secrete enzymes that are members of the matrix metalloprotease (MMP) family. These add to the proteases already produced by endometrial stromal cells and effectively initiate matrix degradation. During menses as tissue shedding is completed, microenvironment-regulated changes in macrophage phenotype then promote repair and resolution (Evans, 2012; Thiruchelvam, 2013).

The classic study by Markee (1940) described tissue and vascular alterations in endometrium before menstruation. With endometrial regression, spiral artery coiling becomes sufficiently severe that resistance to blood flow rises to cause endometrial hypoxia. Resultant stasis is the primary cause of endometrial ischemia and tissue degeneration. Intense spiral artery vasoconstriction precedes menstruation and also serves to limit menstrual blood loss.

Prostaglandins play a key role in the events leading to menstruation that include vasoconstriction, myometrial contractions, and upregulation of proinflammatory responses (Abel, 2002). Large amounts of prostaglandins are present in menstrual blood. Painful menstruation is common and likely caused by myometrial contractions and uterine ischemia. This response is believed to be mediated by prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)-induced spiral artery vasoconstriction, which render the uppermost endometrial zones hypoxic. The hypoxic environment is a potent inducer of angiogenesis and vascular permeability factors such as VEGF.

Progesterone withdrawal increases expression of cyclooxygenase 2 (COX-2), also called prostaglandin synthase 2, to synthesize prostaglandins. Withdrawal also lowers expression of 15-hydroxyprostaglandin dehydrogenase (PGDH), which degrades prostaglandins (Casey, 1980, 1989). The net result is higher prostaglandin

production by endometrial stromal cells and greater prostaglandin-receptor density on blood vessels and surrounding cells.

Actual menstrual bleeding follows rupture of spiral arterioles and consequent hematoma formation. With a hematoma, the superficial endometrium is distended and ruptures. Subsequently, fissures develop in the adjacent functionalis layer, and blood and tissue fragments are sloughed. Hemorrhage stops with arteriolar constriction. Changes that accompany partial tissue necrosis also serve to seal vessel tips.

The endometrial surface is restored by growth of flanges, or collars, that form the everted free ends of the endometrial glands (Markee, 1940). These flanges rapidly grow in diameter, and epithelial continuity is reestablished by fusion of the edges of these sheets of migrating cells.

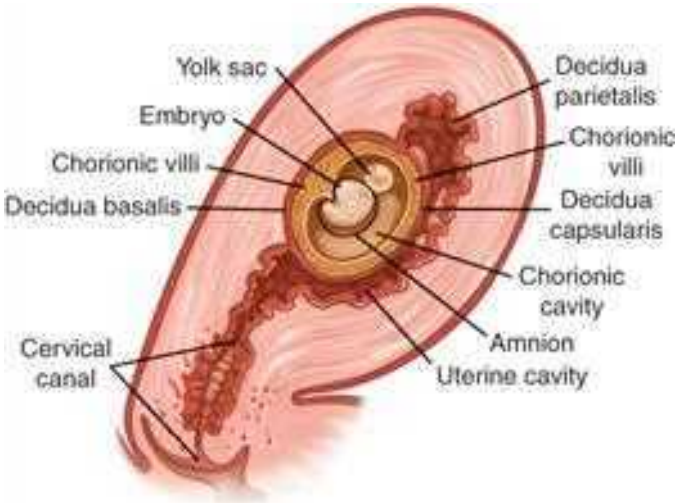
DECIDUA

This is a specialized, highly modified endometrium of pregnancy. It is essential for *hemochorial placentation*, that is, one in which maternal blood contacts trophoblasts. This relationship requires trophoblast invasion, and considerable research has focused on the interaction between decidual cells and invading trophoblasts. *Decidualization*, that is, transformation of proliferating endometrial stromal cells into specialized secretory cells, is dependent on estrogen, progesterone, androgens, and factors secreted by the implanting blastocyst (Gibson, 2016). The decidua produces factors that regulate endometrial receptivity and modulate immune and vascular cell functions within the maternal–fetal microenvironment. The special relationship existing between the decidua and the invading trophoblasts ensures success of the pregnancy semiallograft yet seemingly defies the laws of transplantation immunology.

Decidual Structure

The decidua is classified into three parts based on anatomical location. Decidua directly beneath blastocyst implantation is modified by trophoblast invasion and becomes the *decidua basalis*. The *decidua capsularis* overlies the enlarging blastocyst and initially separates the conceptus from the rest of the uterine cavity (Fig. 5-5). This portion is most prominent during the second month of pregnancy and consists of stromal decidual cells covered by a single layer of flattened epithelial cells. Internally, it contacts the avascular, extraembryonic fetal membrane—the chorion laeve. The remainder of the uterus is lined by *decidua parietalis*. During early pregnancy, there is a space between the decidua capsularis and parietalis because the gestational sac does not fill the entire uterine cavity. The gestation sac is the extraembryonic coelom and also called the chorionic cavity. By 14 to 16 weeks' gestation, the expanding sac has enlarged to completely fill the uterine cavity. The resulting apposition of the decidua capsularis and parietalis creates the *decidua vera*, and the uterine cavity is functionally obliterated.

FIGURE 5-5
Three portions of the decidua—the basalis, capsularis, and parietalis—are illustrated.



In early pregnancy, the decidua begins to thicken, eventually attaining a depth of 5 to 10 mm. With magnification, furrows and numerous small openings, representing the mouths of uterine glands, can be detected. Later in pregnancy, the decidua becomes thinner, presumably because of pressure exerted by the expanding uterine contents.

The decidua parietalis and basalis are composed of three layers. There is a surface or compact zone—*zona compacta*; a middle portion or spongy zone—*zona spongiosa*—with remnants of glands and numerous small blood vessels; and a basal zone—*zona basalis*. The zona compacta and spongiosa together form the *zona functionalis*. The basal zone remains after delivery and gives rise to new endometrium.

In human pregnancy, the decidual reaction is completed only with blastocyst implantation. Predecidual changes, however, commence first during the midluteal phase in endometrial stromal cells adjacent to the spiral arteries and arterioles. Thereafter, they spread in waves throughout the uterine endometrium and then from the implantation site. The endometrial stromal cells enlarge to form polygonal or round decidual cells. The nuclei become vesicular, and the cytoplasm becomes clear, slightly basophilic, and surrounded by a translucent membrane.

As a consequence of implantation, the blood supply to the decidua capsularis is lost as the embryo–fetus grows. Blood supply to the decidua parietalis through spiral arteries persists. These arteries retain a smooth-muscle wall and endothelium and thereby remain responsive to vasoactive agents.

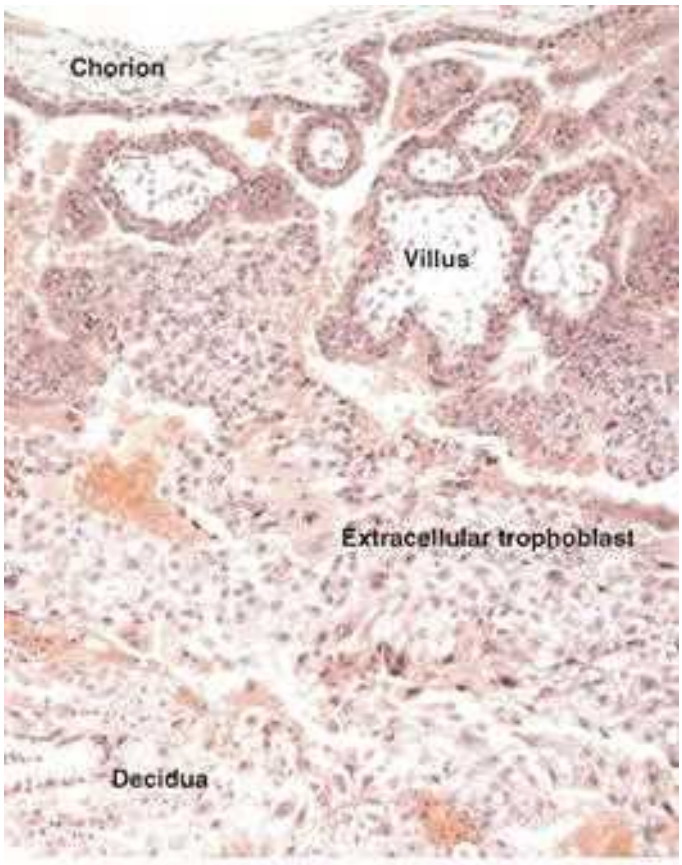
In contrast, the spiral arterial system that supplies the decidua basalis and ultimately the placental intervillous space is altered remarkably. These spiral arterioles and arteries are invaded by trophoblasts, and during this process, the vessel walls in the basalis are destroyed. Only a shell without smooth muscle or endothelial cells remains. Importantly, as a result, these vascular conduits of maternal blood—which become the uteroplacental vessels—are unresponsive to vasoactive agents. Conversely, the fetal chorionic vessels, which transport blood between the placenta and the fetus, contain smooth muscle and thus do respond to vasoactive agents.

Decidual Histology

Early in pregnancy, the zona spongiosa of the decidua consists of large distended glands, often exhibiting marked hyperplasia and separated by minimal stroma. At first, the glands are lined by typical cylindrical uterine epithelium with abundant secretory activity that contributes to blastocyst nourishment. With advanced pregnancy, the glandular elements largely disappear.

The decidua basalis contributes to formation of the placental basal plate (Fig. 5-6). The spongy zone of the decidua basalis consists mainly of arteries and widely dilated veins, and by term, glands have virtually disappeared. Also, the decidua basalis is invaded by many interstitial trophoblasts and trophoblastic giant cells. Although most abundant in the decidua, the giant cells commonly penetrate the upper myometrium. Their number and invasiveness can be so extensive as to resemble choriocarcinoma.

FIGURE 5-6
Section through a junction of chorion, villi, and decidua basalis in early first-trimester pregnancy. (Used with permission from Dr. Kurt Benirschke.)



The *Nitabuch layer* is a zone of fibrinoid degeneration in which invading trophoblasts meet the decidua basalis. If the decidua is defective, as in placenta accreta, the Nitabuch layer is usually absent (Chap. 41, Classification). There is also a more superficial, but inconsistent, deposition of fibrin—*Rohr stria*—at the bottom of the intervillous space and surrounding the anchoring villi. Decidual necrosis is a normal phenomenon in the first and probably second trimesters (McCombs, 1964). Thus, necrotic decidua obtained through curettage after spontaneous abortion in the first trimester should not necessarily be interpreted as either a cause or an effect of the pregnancy loss.

Both decidua types contain numerous cell groups whose composition varies with gestational stage (Loke, 1995). The primary cellular components are the true decidual cells, which differentiated from the endometrial stromal cells, and numerous maternal bone marrow-derived cells. Accumulation of lymphocytes with unique properties at the maternal–fetal interface is essential to evoke tolerance mechanisms that prevent maternal immune rejection of the fetus. These include regulatory T cells, decidual macrophages, and decidual natural killer cells. Collectively, these cells not only provide immunotolerance but also play an important role in trophoblast invasion and vasculogenesis (PrabhuDas, 2015).

Decidual Prolactin

In addition to placental development, the decidua potentially provides other functions. The decidua is the source of prolactin, which is present in enormous amounts in amnionic fluid (Golander, 1978; Riddick, 1979). Decidual prolactin is a product of the same gene that encodes for anterior pituitary prolactin, but the

exact physiological role of decidual prolactin is unknown. Notably, decidual prolactin is not to be confused with placental lactogen (hPL), which is produced only by syncytiotrophoblast.

Prolactin preferentially enters amnionic fluid, and little enters maternal blood. Consequently, prolactin levels in amnionic fluid are extraordinarily high and may reach 10,000 ng/mL at 20 to 24 weeks' gestation (Tyson, 1972). This compares with fetal serum levels of 350 ng/mL and maternal serum levels of 150 to 200 ng/mL. As a result, decidual prolactin is a classic example of paracrine function between maternal and fetal tissues.

IMPLANTATION AND EARLY TROPHOBLAST FORMATION

The fetus is dependent on the placenta for pulmonary, hepatic, and renal functions. These are accomplished through the anatomical relationship of the placenta and its uterine interface. In overview, maternal blood spurts from uteroplacental vessels into the placental intervillous space and bathes the outer syncytiotrophoblast. This allows exchange of gases, nutrients, and other substances with fetal capillary blood within the core of each villus. Thus, fetal and maternal blood does not normally mix in this hemochorial placenta. A paracrine system also links mother and fetus through the anatomical and biochemical juxtaposition of the maternal decidua parietalis and the extraembryonic chorion laeve, which is fetal. This is an extraordinarily important arrangement for communication between fetus and mother and for maternal immunological acceptance of the conceptus (Guzeloglu-Kayisli, 2009).

Fertilization

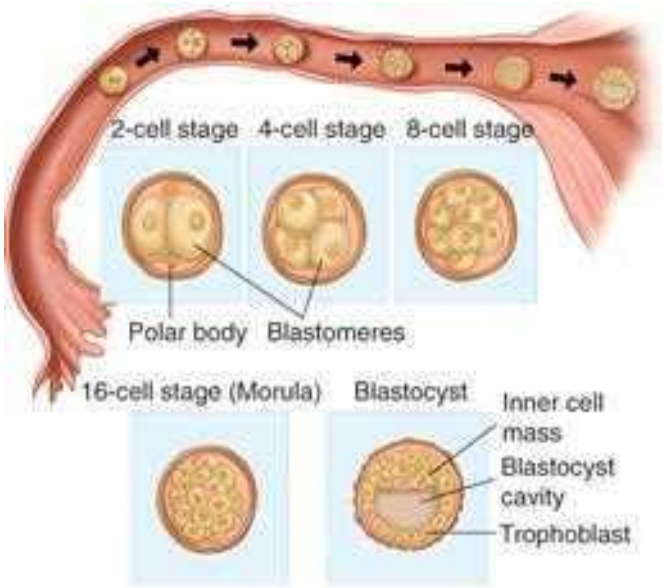
With ovulation, the secondary oocyte and adhered cells of the cumulus–oocyte complex are freed from the ovary. Although technically this mass of cells is released into the peritoneal cavity, the oocyte is quickly engulfed by the fallopian tube infundibulum. Further transport through the tube is accomplished by directional movement of cilia and tubal peristalsis. Fertilization, which normally occurs in the oviduct, must take place within a few hours, and no more than a day after ovulation. Because of this narrow window, spermatozoa must be present in the fallopian tube at the time of oocyte arrival. Almost all pregnancies result when intercourse occurs during the 2 days preceding or on the day of ovulation.

Fertilization is highly complex. Molecular mechanisms allow spermatozoa to pass between follicular cells; through the zona pellucida, which is a thick glycoprotein layer surrounding the oocyte cell membrane; and into the oocyte cytoplasm. Fusion of the two nuclei and intermingling of maternal and paternal chromosomes creates the *zygote*.

Early human development is described by days or weeks postfertilization, that is, postconceptional. By contrast, in most chapters of this book, clinical pregnancy dating is calculated from the first day of the last menstrual period (LMP). Thus, 1 week postfertilization corresponds to approximately 3 weeks from the LMP in women with regular 28-day cycles. As an example, 8 weeks' gestation refers to 8 completed weeks following the LMP.

After fertilization, the zygote—a diploid cell with 46 chromosomes—undergoes cleavage, and zygote cells produced by this division are called *blastomeres* (Fig. 5-7). In the two-cell zygote, the blastomeres and polar body continue to be surrounded by the zona pellucida. The zygote undergoes slow cleavage for 3 days while still remaining in the fallopian tube. As the blastomeres continue to divide, a solid mulberry-like ball of cells—the *morula*—is produced. The morula enters the uterine cavity approximately 3 days after fertilization. Gradual accumulation of fluid between the morula cells leads to formation of the early *blastocyst*.

FIGURE 5-7
Zygote cleavage and blastocyst formation. The morula period begins at the 12- to 16-cell stage and ends when the blastocyst forms, which occurs when there are 50 to 60 blastomeres present. The polar bodies, shown in the 2-cell stage, are small nonfunctional cells that soon degenerate.



Blastocyst

As early as 4 to 5 days after fertilization, the 58-cell blastula differentiates into five embryo-producing cells—the *inner cell mass* (see Fig. 5-7). The remaining 53 outer cells, called the *trophectoderm,* are destined to form *trophoblasts* (Hertig, 1962).

Interestingly, the 107-cell blastocyst is found to be no larger than the earlier cleavage stages, despite the accumulated fluid within the blastocyst cavity. At this stage, the eight formative, embryo-producing cells are surrounded by 99 trophoblastic cells. And, the blastocyst is released from the zona pellucida secondary to secretion of specific proteases from the secretory-phase endometrial glands (O'Sullivan, 2002).

Release from the zona pellucida allows blastocyst-produced cytokines and hormones to directly influence endometrial receptivity (Lindhard, 2002). IL-1α and IL-1β are secreted by the blastocyst, and these cytokines likely directly influence the endometrium. Embryos also have been shown to secrete hCG, which may influence endometrial receptivity (Licht, 2001; Lobo, 2001). The receptive endometrium is thought to respond by producing leukemia inhibitory factor (LIF), follistatin, and colony-stimulating factor-1 (CSF-1). LIF and follistatin activate signaling pathways that collectively inhibit proliferation and promote differentiation of the endometrial epithelia and stroma to enable uterine receptivity (Rosario, 2016b). At the maternal–fetal interface, CSF-1 has proposed immunomodulatory actions and proangiogenic actions that are required for implantation (Rahmati, 2015).

Implantation

Six or 7 days after fertilization, the blastocyst implants into the uterine wall. This process can be divided into three phases: (1) apposition—initial contact of the blastocyst to the uterine wall; (2) adhesion—increased physical contact between the blastocyst and decidua; and (3) invasion—penetration and invasion of syncytiotrophoblast and cytotrophoblasts into the decidua, inner third of the myometrium, and uterine vasculature.

Successful implantation requires a receptive endometrium appropriately primed with estrogen and progesterone by the corpus luteum. Such uterine receptivity is limited to days 20 to 24 of the cycle. Adherence is mediated by cell-surface receptors at the implantation site that interact with blastocyst receptors (Carson, 2002; Lessey, 2002; Lindhard, 2002). If the blastocyst approaches the endometrium after cycle day 24, the potential for adhesion is diminished because antiadhesive glycoprotein synthesis prevents receptor interactions (Navot, 1991).

At the time of its interaction with the endometrium, the blastocyst is composed of 100 to 250 cells. The blastocyst loosely adheres to the decidua by apposition. This most commonly occurs on the upper posterior uterine wall. Attachment of the blastocyst trophectoderm to the decidual surface by apposition and adherence appears to be closely regulated by paracrine interactions between these two tissues.

Successful endometrial blastocyst adhesion involves modification in expression of cellular adhesion molecules (CAMs). The integrins—one of four families of CAMs—are cell-surface receptors that mediate cell adhesion to extracellular matrix proteins (Lessey, 2002). Endometrial integrins are hormonally regulated, and a specific set of integrins is expressed at implantation (Lessey, 1995). Recognition-site blockade of integrins needed for binding will prevent blastocyst attachment (Kaneko, 2013).

Trophoblast Development

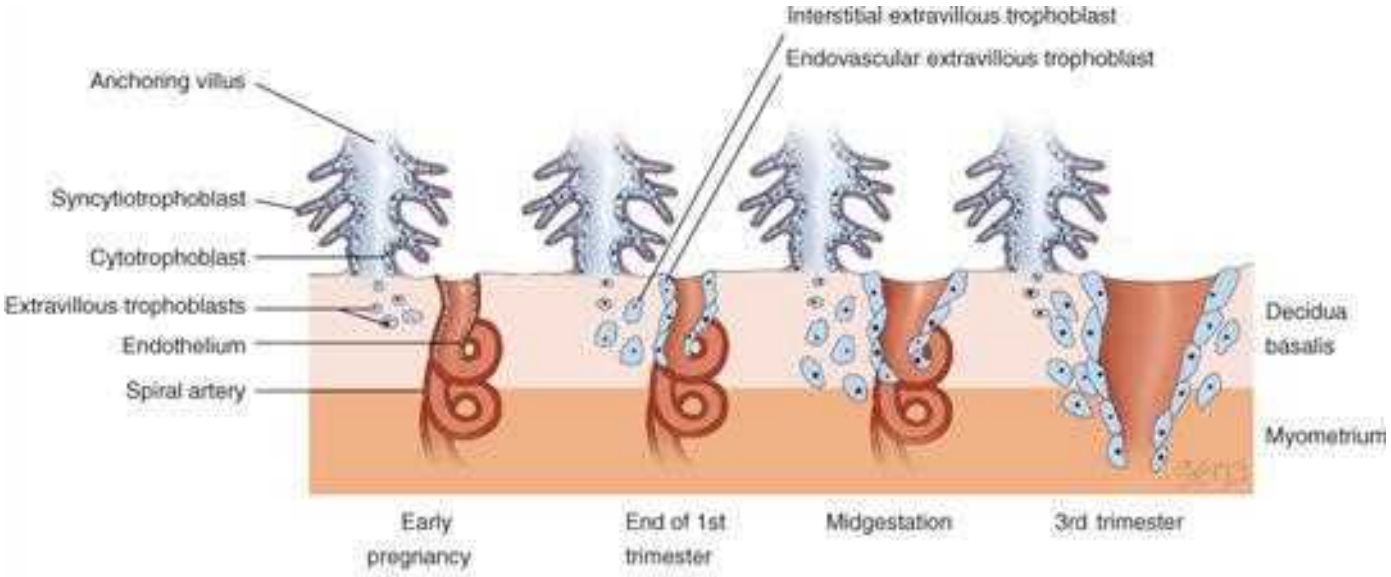
Human placental formation begins with the trophectoderm, which gives rise to a trophoblast cell layer encircling the blastocyst. From then until term, trophoblasts play a critical part at the fetal–maternal interface. Trophoblasts exhibit the most variable structure, function, and developmental pattern of all placental components. Their invasiveness promotes implantation, their nutritional role for the conceptus is reflected in their name, and their endocrine organ function is essential to maternal physiological adaptations and to pregnancy maintenance.

By the eighth day postfertilization, after initial implantation, trophoblasts have differentiated into an outer multinucleated syncytium—primitive *syncytiotrophoblast*, and an inner layer of primitive mononuclear cells—*cytotrophoblasts*. The latter are germinal cells for the syncytium. As cytotrophoblasts proliferate, their cell walls disappear, and the cells fuse to add to the expanding outer layer of syncytiotrophoblast. Each cytotrophoblast has a well-demarcated cell border, a single nucleus, and ability to undergo DNA synthesis and mitosis (Arnholdt, 1991). These are lacking in the syncytiotrophoblast, which provides transport functions of the placenta. It is so named because instead of individual cells, it has an amorphous cytoplasm without cell borders, nuclei that are multiple and diverse in size and shape, and a continuous syncytial lining. This configuration aids transport.

After implantation is complete, trophoblasts further differentiate along two main pathways, giving rise to villous and extravillous trophoblasts. As shown in Figure 5-8, both have distinct functions (Loke, 1995). *Villous trophoblasts* generate chorionic villi, which primarily transport oxygen, nutrients, and other compounds between the fetus and mother. *Extravillous trophoblasts* migrate into the decidua and myometrium and also penetrate maternal vasculature, thus coming into contact with various maternal cell types (Pijnenborg, 1994). Extravillous trophoblasts are further classified as *interstitial trophoblasts* and *endovascular trophoblasts.* The interstitial trophoblasts invade the decidua and eventually penetrate the myometrium to form placental-bed giant cells. These trophoblasts also surround spiral arteries. The endovascular trophoblasts penetrate the spiral artery lumens (Pijnenborg, 1983). These are both discussed in greater detail in subsequent sections.

FIGURE 5-8

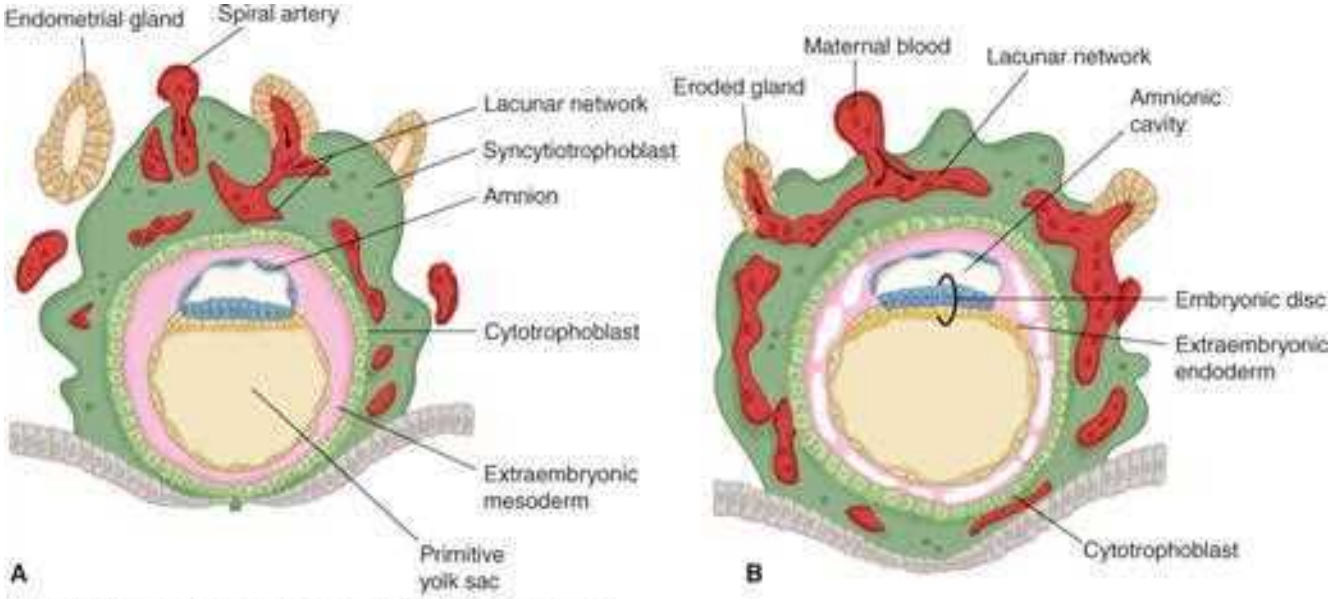
Extravillous trophoblasts are found outside the villus and can be subdivided into endovascular and interstitial categories. Endovascular trophoblasts invade and transform spiral arteries during pregnancy to create low-resistance blood flow that is characteristic of the placenta. Interstitial trophoblasts invade the decidua and surround spiral arteries.



Early Invasion

After gentle erosion between epithelial cells of the surface endometrium, invading trophoblasts burrow deeper. At 9 days of development, the blastocyst wall facing the uterine lumen is a single layer of flattened cells. By the 10th day, the blastocyst becomes totally encased within the endometrium (Fig. 5-9). The blastocyst wall opposite the uterine lumen is thicker and comprises two zones—the trophoblasts and the embryo-forming inner cell mass. As early as 7½ days postfertilization, the inner cell mass or embryonic disc differentiates into a thick plate of primitive ectoderm and an underlying layer of endoderm. Some small cells appear between the embryonic disc and the trophoblasts and enclose a space that will become the amnionic cavity.

FIGURE 5-9
Drawing of sections through implanted blastocysts. **A.** At 10 days. **B.** At 12 days after fertilization. This stage is characterized by the intercommunication of the lacunae filled with maternal blood. Note in **(B)** that large cavities have appeared in the extraembryonic mesoderm, forming the beginning of the extraembryonic coelom. Also note that extraembryonic endodermal cells have begun to form on the inside of the primitive yolk sac. (Redrawn and adapted from Moore KL, Persaud, TV, Torchia, MG (eds): The Developing Human. Clinically Oriented Embryology, 9th edition, Philadelphia, Saunders, 2013.)



Extraembryonic mesenchyme first appears as groups of isolated cells within the blastocyst cavity, and later this mesoderm completely lines the cavity. Spaces form and then fuse within the extraembryonic mesoderm to form the chorionic cavity (extraembryonic coelom). The *chorion* is composed of trophoblasts and mesenchyme. Some mesenchymal cells eventually will condense to form the body stalk. This stalk joins the embryo to the nutrient chorion and later develops into the umbilical cord. The body stalk can be recognized at an early stage at the caudal end of the embryonic disc (Fig. 7-3).

As the embryo enlarges, more maternal decidua basalis is invaded by syncytiotrophoblast. Beginning approximately 12 days after conception, the syncytiotrophoblast is permeated by a system of intercommunicating channels called trophoblastic lacunae. After invasion of superficial decidual capillary walls,

lacunae become filled with maternal blood. At the same time, the decidual reaction intensifies in the surrounding stroma. This is characterized by decidual stromal cell enlargement and glycogen storage.

Chorionic Villi

With deeper blastocyst invasion into the decidua, solid primary villi arise from buds of cytotrophoblasts that protrude into the primitive syncytium before 12 days postfertilization. Primary villi are composed of a cytotrophoblast core covered by syncytiotrophoblast. As the lacunae join, a complicated labyrinth is formed that is partitioned by these solid cytotrophoblastic columns. The trophoblast-lined channels form the intervillous space, and the solid cellular columns form the *primary villous stalks*.

Beginning on approximately the 12th day after fertilization, mesenchymal cords derived from extraembryonic mesoderm invade the solid trophoblast columns. These form *secondary villi*. Once angiogenesis begins in the mesenchymal cords, *tertiary villi* are formed. Although maternal venous sinuses are tapped early in implantation, maternal arterial blood does not enter the intervillous space until around day 15. By approximately the 17th day, however, fetal blood vessels are functional, and a placental circulation is established. The fetal–placental circulation is completed when the blood vessels of the embryo are connected with chorionic vessels. In some villi, angiogenesis fails from lack of circulation. They can be seen normally, but the most striking exaggeration of this process is seen with hydatidiform mole (Fig. 20-1).

Villi are covered by an outer layer of syncytiotrophoblast and an inner layer of cytotrophoblasts, which are also known as *Langhans cells*. Cytotrophoblast proliferation at the villous tips produces the trophoblastic cell columns that form anchoring villi. They are not invaded by fetal mesenchyme, and they are anchored to the decidua at the basal plate. Thus, the base of the intervillous space faces the maternal side and consists of cytotrophoblasts from cell columns, the covering shell of syncytiotrophoblast, and maternal decidua of the basal plate. The base of the chorionic plate forms the roof of the intervillous space. It consists of two layers of trophoblasts externally and fibrous mesoderm internally. The “definitive” chorionic plate is formed by 8 to 10 weeks as the amnionic and primary chorionic plate mesenchyme fuse together. This formation is accomplished by expansion of the amnionic sac, which also surrounds the connective stalk and the allantois and joins these structures to form the umbilical cord (Kaufmann, 1992).

Interpretation of the fine structure of the placenta came from electron microscopic studies of Wislocki and Dempsey (1955). There are prominent microvilli on the syncytial surface that correspond to the so-called brush border described by light microscopy. Associated pinocytotic vacuoles and vesicles are related to absorptive and secretory placental functions. Microvilli act to increase surface area in direct contact with maternal blood. This contact between the trophoblast and maternal blood is the defining characteristic of a hemochorial placenta (Fig. 5-10).

FIGURE 5-10

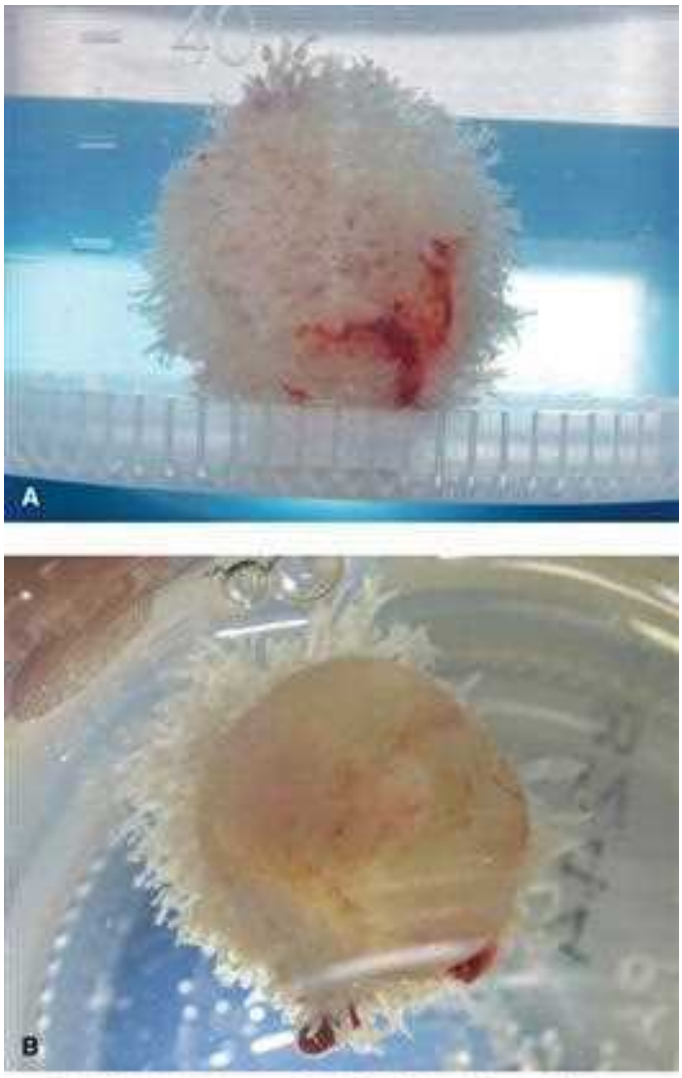
PLACENTA AND CHORION

Chorion Development

In early pregnancy, the villi are distributed over the entire periphery of the chorionic membrane (Fig. 5-11). As the blastocyst with its surrounding trophoblasts grows and expands into the decidua, one pole faces the endometrial cavity. The opposite pole will form the placenta. Here, chorionic villi in contact with the decidua basalis proliferate to form the *chorion frondosum*—or leafy chorion. As growth of embryonic and extraembryonic tissues continues, the blood supply to the chorion facing the endometrial cavity is restricted. Because of this, villi in contact with the decidua capsularis cease to grow and then degenerate. This portion of the chorion becomes the avascular fetal membrane that abuts the decidua parietalis and is called the *chorion laeve*—or smooth chorion. This smooth chorion is composed of cytotrophoblasts and fetal mesodermal mesenchyme.

FIGURE 5-11

Complete abortion specimens. **A.** Initially, the entire chorionic sac is covered with villi, and the embryo within is not visible **B.** With further growth, stretch and pressure prompt partial regression of the villi. Remaining villi form the future placenta, whereas the smooth portion is the chorion.



Until near the end of the third month, the chorion laeve is separated from the amnion by the exocoelomic cavity. Thereafter, they are in intimate contact to form an avascular amniochorion. These two structures are important sites of molecular transfer and metabolic activity. Moreover, they constitute an important paracrine arm of the fetal–maternal communication system.

Regulators of Trophoblast Invasion

Implantation and endometrial decidualization activate a unique population of maternal immune cells that infiltrate the uterus and play critical functions in trophoblast invasion, angiogenesis, spiral artery remodeling, and maternal tolerance to fetal alloantigens. Decidual natural killer cells (dNK) make up 70 percent of decidual leukocytes in the first trimester and are found in direct contact with trophoblasts. In contrast to natural killer cells in peripheral blood, these cells lack cytotoxic functions. They produce specific cytokines and angiogenic factors to regulate invasion of fetal trophoblasts and spiral artery remodeling (Hanna, 2006). These and other unique properties distinguish dNK cells from circulating natural killer cells and from natural killer cells in the endometrium before pregnancy (Fu, 2013; Winger, 2013). dNK cells express both IL-8 and interferon-inducible protein-10, which bind to receptors on invasive trophoblastic cells to promote their decidual invasion toward the spiral arteries. dNK cells also produce proangiogenic factors, including VEGF and placental growth factor (PlGF), which both promote vascular growth in the decidua.

Trophoblasts also secrete specific chemokines that attract the dNK cells to the maternal–fetal interface. Thus, both cell types simultaneously attract each other. Decidual macrophages account for approximately 20 percent of leukocytes in the first trimester and elicit an M2-immunomodulatory phenotype (Williams, 2009). Remember, M1 macrophages are proinflammatory, and M2 macrophages counter proinflammatory responses and promote tissue repair. In addition to a role in angiogenesis and spiral artery remodeling, dNK cells promote phagocytosis of cell debris (Faas, 2017). Concurrent with the critical role of maternal dNK cells and macrophages, T cell subsets aid tolerance toward the allogenic fetus. Regulatory T cells (Tregs) are essential for promoting immune tolerance. Other T cell subsets are present, such as Th1, Th2 and Th17, although their functions are tightly regulated (Ruocco, 2014).

Endometrial Invasion

Extravillous trophoblasts of the first-trimester placenta are highly invasive. This process occurs under low-oxygen conditions, and regulatory factors that are induced under hypoxic conditions are contributory (Soares, 2012). Invasive trophoblasts secrete numerous proteolytic enzymes that digest extracellular matrix and activate proteinases already present in the decidua. Trophoblasts produce urokinase-type plasminogen activator, which converts plasminogen into the broadly acting serine protease, plasmin. This in turn both degrades matrix proteins and activates MMPs. One member of the MMP family, MMP-9, appears to be critical. The timing and extent of trophoblast invasion is regulated by a balanced interplay between pro- and antiinvasive factors.

The relative ability to invade maternal tissue in early pregnancy compared with limited invasiveness in late pregnancy is controlled by autocrine and paracrine trophoblastic and decidual factors. Trophoblasts secrete insulin-like growth factor II that promotes invasion into the decidua. Decidual cells secrete insulin-like growth factor binding-protein type 4, which blocks this autocrine loop.

Low estradiol levels in the first trimester are critical for trophoblast invasion and remodeling of the spiral arteries. Animal studies suggest that the rise in second-trimester estradiol levels suppresses and limits vessel remodeling by reducing trophoblast expression of VEGF and specific integrin receptors (Bonagura, 2012). Namely, extravillous trophoblasts express integrin receptors that recognize the extracellular matrix proteins collagen IV, laminin, and fibronectin. Binding of these matrix proteins and integrin receptors initiates signals to promote trophoblast cell migration and differentiation. However, as pregnancy advances, rising estradiol levels downregulate VEGF and integrin receptor expression. This represses and controls the extent of uterine vessel transformation.

Spiral Artery Invasion

One of the most remarkable features of human placental development is the extensive modification of maternal vasculature by trophoblasts, which are by definition of fetal origin. These events occur in the first half of pregnancy and are considered in detail because of their importance to uteroplacental blood flow. They are also integral to some pathological conditions such as preeclampsia, fetal-growth restriction, and preterm birth. Spiral artery modifications are carried out by two populations of extravillous trophoblasts—endovascular trophoblasts, which penetrate the spiral-artery lumen, and interstitial trophoblasts, which surround the arteries (see Fig. 5-8).

Interstitial trophoblasts constitute a major portion of the placental bed. They penetrate the decidua and adjacent myometrium and aggregate around spiral arteries. Although less defined, their functions may include vessel preparation for endovascular trophoblast invasion.

Endovascular trophoblasts first enter the spiral artery lumens and initially form cellular plugs. They then destroy vascular endothelium via an apoptosis mechanism and invade and modify the vascular media. Thus, fibrinoid material replaces smooth muscle and connective tissue of the vessel media. Spiral arteries later regenerate endothelium. Invading endovascular trophoblasts can extend several centimeters along the vessel lumen, and they must migrate against arterial flow. Of note, invasion by trophoblasts involves only the decidual spiral arteries and not decidual veins.

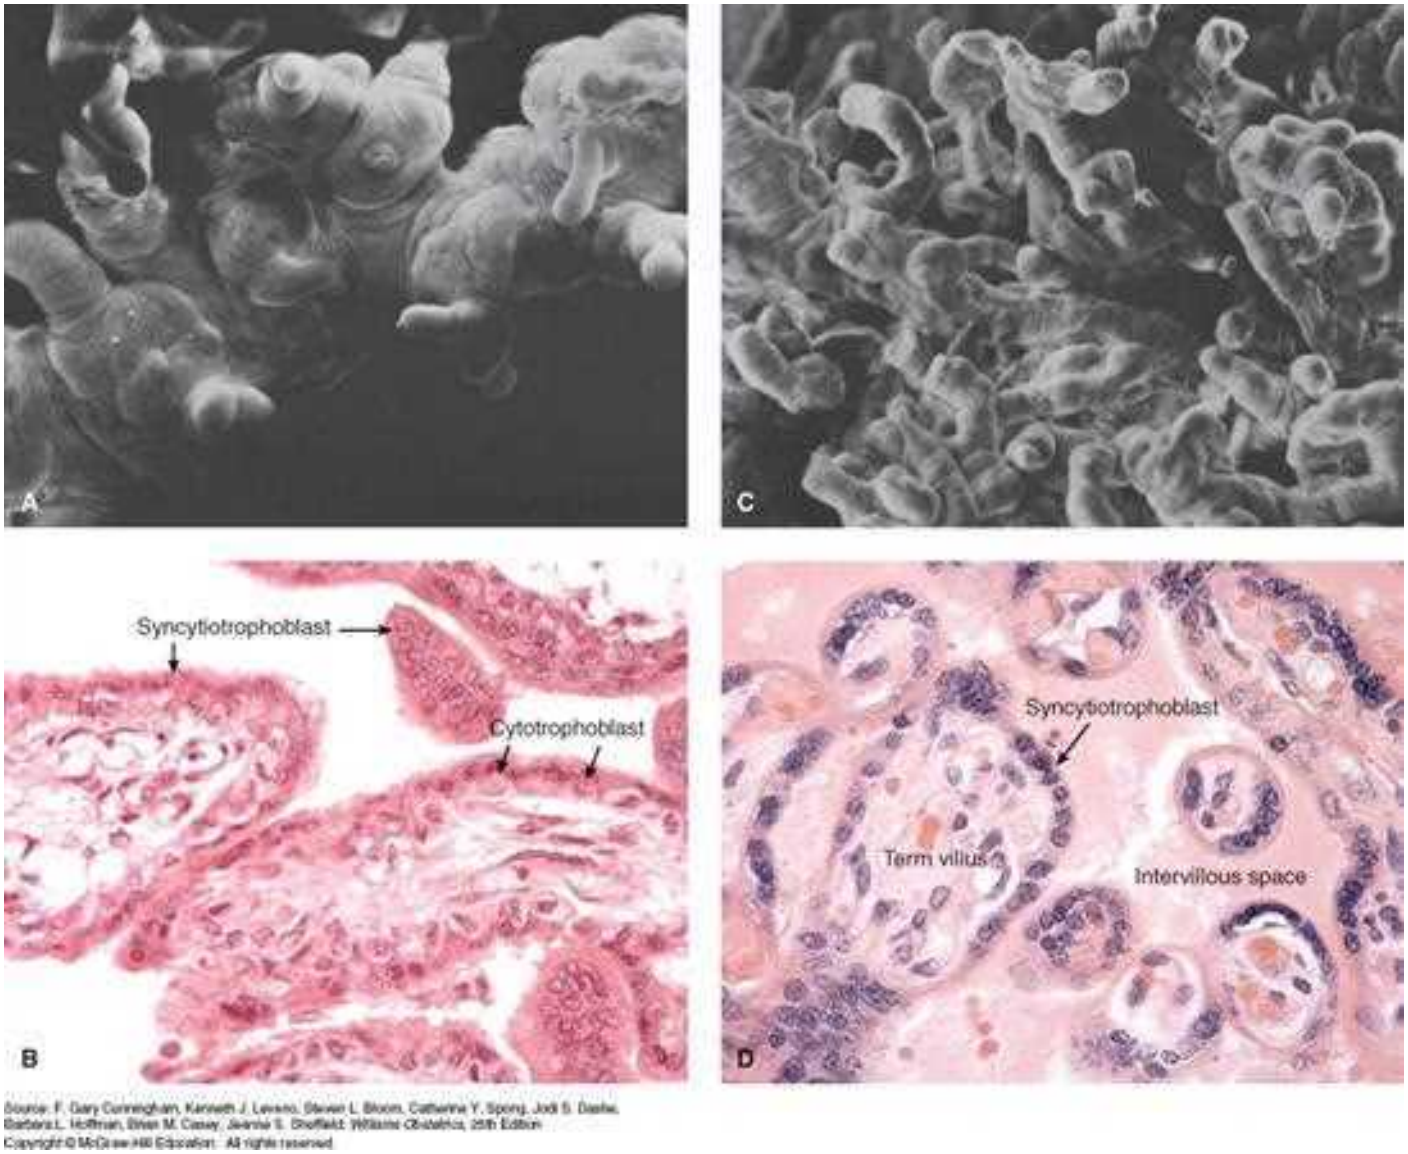
Uteroplacental vessel development proceeds in two waves or stages (Ramsey, 1980). The first occurs before 12 weeks' postfertilization, and spiral arteries are invaded and modified up to the border between the decidua and myometrium. The second wave, between 12 and 16 weeks, involves some invasion of the intramyometrial segments of spiral arteries. Remodeling converts narrow-lumen, muscular spiral arteries into dilated, low-resistance uteroplacental vessels. Molecular mechanisms of these crucial events, their regulation by cytokines, signaling pathways, and their significance in the pathogenesis of preeclampsia and fetal-growth restriction has been reviewed by several authors (Pereira de Sousa, 2017; Xie, 2016; Zhang, 2016).

Approximately 1 month after conception, maternal blood enters the intervillous space in fountain-like bursts from the spiral arteries. Blood is propelled outside of the maternal vessels and sweeps over and directly bathes the syncytiotrophoblast.

Villus Branching

Although certain villi of the chorion frondosum extend from the chorionic plate to the decidua to serve as anchoring villi, most villi arborize and end freely within the intervillous space. As gestation proceeds, the short, thick, early stem villi branch to form progressively finer subdivisions and greater numbers of increasingly smaller villi (Fig. 5-12). Each of the truncal or main stem villi and their ramifications constitutes a placental lobule, or cotyledon. Each lobule is supplied with a single chorionic artery. And each lobule has a single vein, so that lobules constitute the functional units of placental architecture.

FIGURE 5-12
Electron micrographs **(A, C)** and photomicrographs **(B, D)** of early and late human placentas. **A** and **B.** Limited branching of villi is seen in this early placenta. **C** and **D.** With placental maturation, increasing villous arborization is seen, and villous capillaries lie closer to the surface of each villus. (Photomicrographs used with permission from Dr. Kurt Benirschke. Electron micrographs reproduced with permission from King BF, Menton DN: Scanning electron microscopy of human placental villi from early and late in gestation. Am J Obstet Gynecol 122:824, 1975.)



Placental Growth and Maturation

In the first trimester, placental growth is more rapid than that of the fetus. But by approximately 17 weeks' gestation, placental and fetal weights are approximately equal. By term, placental weight is approximately one sixth of fetal weight.

The mature placenta and its variant forms are discussed in detail in Chapter 6 (Shape and Size Variants). Briefly, viewed from the maternal surface, the number of slightly elevated convex areas, called lobes, varies from 10 to 38. Lobes are incompletely separated by grooves of variable depth that overlie placental septa, which arise as upward projections of decidua. The total number of placental lobes remains the same throughout gestation, and individual lobes continue to grow—although less actively in the final weeks (Crawford, 1959). Although grossly visible lobes are commonly referred to as cotyledons, this is not accurate. Correctly used, lobules or cotyledons are the functional units supplied by each main stem villus.

As villi continue to branch and the terminal ramifications become more numerous and smaller, the volume and prominence of cytotrophoblasts decrease. As the syncytium thins, the fetal vessels become more prominent and lie closer to the surface (see Fig. 5-10). The villous stroma also exhibits changes as gestation progresses. In early pregnancy, the branching connective-tissue cells are separated by an abundant loose intercellular matrix. Later, the villous stroma becomes denser, and the cells are more spindly and closely packed.

Another change in the stroma involves the infiltration of *Hofbauer cells*, which are fetal macrophages. These are nearly round with vesicular, often eccentric nuclei and very granular or vacuolated cytoplasm. They grow in number and maturational state throughout pregnancy and appear to be important mediators of protection at the maternal–fetal interface (Johnson, 2012). These macrophages are phagocytic, have an immunosuppressive phenotype, can produce various cytokines, and are capable of paracrine regulation of trophoblastic functions (Cervar, 1999; Reyes, 2017). As discussed further in Chapter 64 (Coronavirus Infections), recent studies suggest that Zika virus can infect Hofbauer cells to allow fetal transmission (Simoni, 2017).

Some of the histological changes that accompany placental growth and maturation improve transport and exchange to meet advancing fetal metabolic requirements. Among these changes are a thinner syncytiotrophoblast, significantly reduced cytotrophoblast number, decreased stroma, and increased number of capillaries with close approximation to the syncytial surface. By 16 weeks' gestation, the apparent continuity of the cytotrophoblasts is lost. At term, villi may be

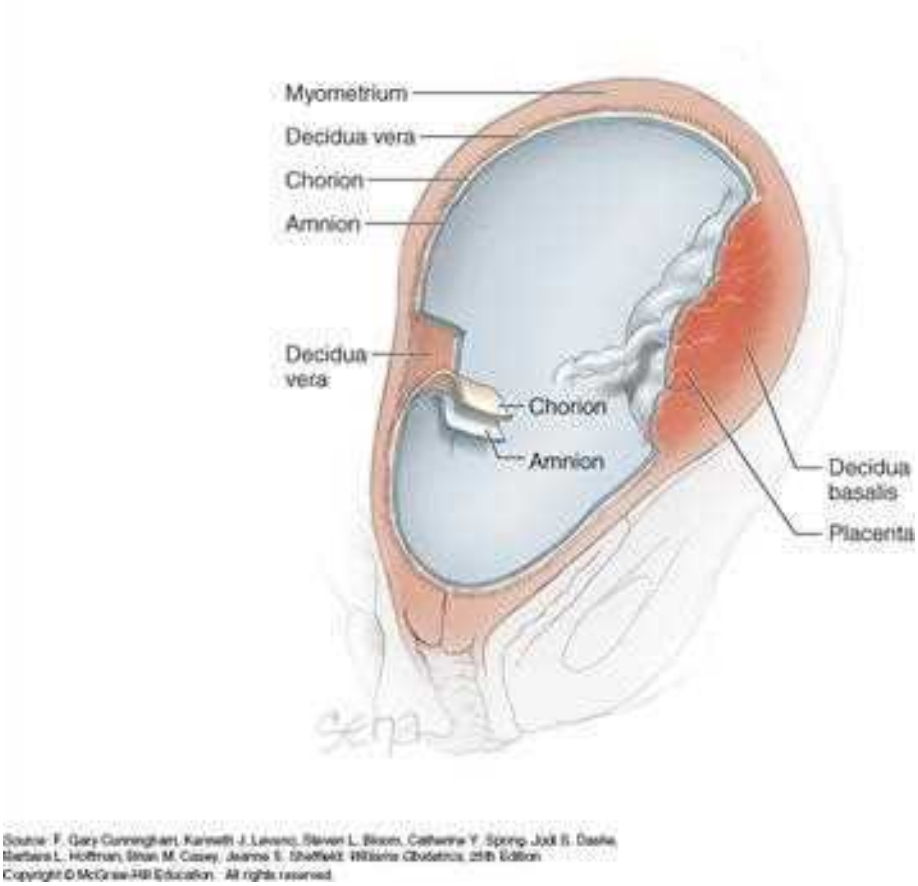
focally reduced to a thin layer of syncytium covering minimal villous connective tissue in which thin-walled fetal capillaries abut the trophoblast and dominate the villi.

There are some changes in placental architecture that can cause decreased placental exchange efficiency if they are substantive. These include thickening of the basal lamina of trophoblast or capillaries, obliteration of certain fetal vessels, greater villous stroma, and fibrin deposition on the villous surface.

Placental Circulation

Because the placenta is functionally an intimate approximation of the fetal capillary bed to maternal blood, its gross anatomy primarily concerns vascular relations. The fetal surface is covered by the transparent amnion, beneath which chorionic vessels course. A section through the placenta includes amnion, chorion, chorionic villi and intervillous space, decidual (basal) plate, and myometrium (Figs. 5-13 and 5-14).

FIGURE 5-13
Uterus showing a normal placenta and its membranes in situ.



Fetal Circulation

Deoxygenated venous-like fetal blood flows to the placenta through the two umbilical arteries. As the cord joins the placenta, these umbilical vessels branch repeatedly beneath the amnion as they run across the chorionic plate. Branching continues within the villi to ultimately form capillary networks in the terminal villous branches. Blood with significantly higher oxygen content returns from the placenta via a single umbilical vein to the fetus.

FIGURE 5-14

The branches of the umbilical vessels that traverse along the fetal surface of the placenta in the chorionic plate are referred to as the placental surface or chorionic vessels. These vessels are responsive to vasoactive substances, but anatomically, morphologically, histologically, and functionally, they are unique. Chorionic arteries always cross over chorionic veins. Vessels are most readily recognized by this interesting relationship, but they are difficult to distinguish by histological criteria.

Truncal arteries are perforating branches of the surface arteries that pass through the chorionic plate. Each truncal artery supplies one main stem villus and thus one cotyledon. As the artery penetrates the chorionic plate, its wall loses smooth muscle, and its caliber increases. The loss of muscle continues as the truncal arteries and veins branch into their smaller rami.

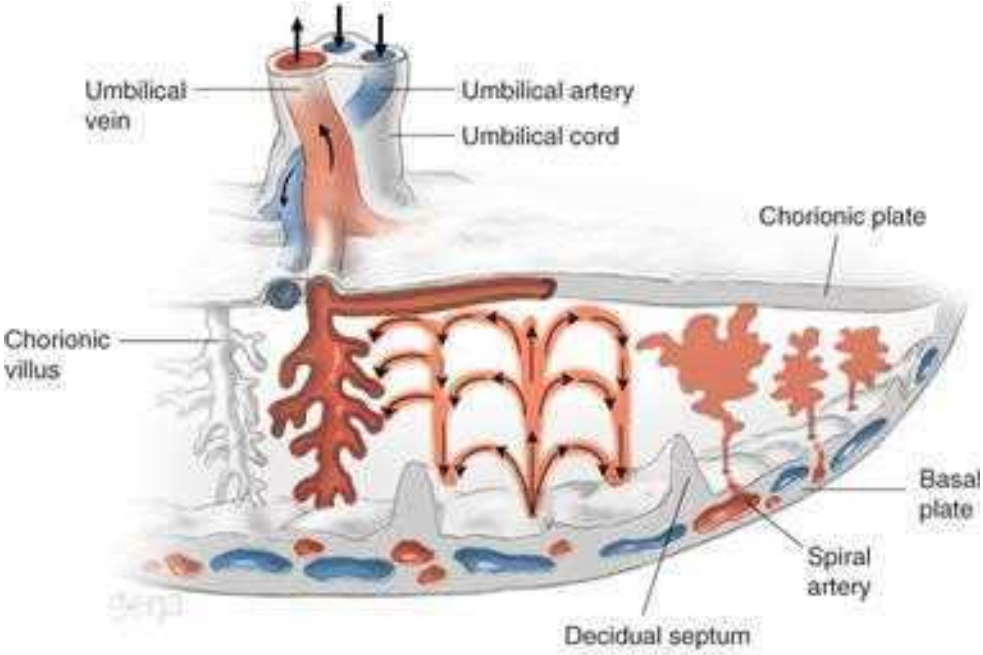
Before 10 weeks' gestation, there is no end-diastolic flow pattern within the umbilical artery at the end of the fetal cardiac cycle (Fisk, 1988; Loquet, 1988). After 10 weeks, however, end-diastolic flow appears and is maintained throughout normal pregnancy. Clinically, these flow patterns are studied with Doppler sonography to assess fetal well-being (Chap. 10, Doppler).

Maternal Circulation

Mechanisms of placental blood flow must allow blood to leave maternal circulation; flow into an amorphous space lined by syncytiotrophoblast, rather than endothelium; and return through maternal veins without producing arteriovenous-like shunts that would prevent maternal blood from remaining in contact with villi long enough for adequate exchange. For this, maternal blood enters through the basal plate and is driven high up toward the chorionic plate by arterial pressure before laterally dispersing (Fig. 5-15). After bathing the external microvillous surface of chorionic villi, maternal blood drains back through venous orifices in the basal plate and enters uterine veins. Thus, maternal blood traverses the placenta randomly without preformed channels. The previously described trophoblast invasion of the spiral arteries creates low-resistance vessels that can accommodate massive increase in uterine perfusion during gestation. Generally, spiral arteries are perpendicular to, but veins are parallel to, the uterine wall. This arrangement aids closure of veins during a uterine contraction and prevents the exit of maternal blood from the intervillous space. The number of arterial openings into the intervillous space is gradually reduced by cytotrophoblastic invasion. There are about 120 spiral arterial entries into the intervillous space at term (Brosens, 1963). These discharge blood in spurts that bathes the adjacent villi (Borell, 1958). After the 30th week, a prominent venous plexus lies between the decidua basalis and myometrium and helps develop the cleavage plane needed for placental separation after delivery.

FIGURE 5-15

Schematic drawing of a section through a full-term placenta. Maternal blood flows into the intervillous spaces in funnel-shaped spurts. Exchanges occur with fetal blood as maternal blood flows around the villi. Inflowing arterial blood pushes venous blood into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Note also that the umbilical arteries carry deoxygenated fetal blood to the placenta and that the umbilical vein carries oxygenated blood to the fetus. Placental lobes are separated from each other by placental (decidual) septa.



Both inflow and outflow are curtailed during uterine contractions. Bleker and associates (1975) used serial sonography during normal labor and found that placental length, thickness, and surface area grew during contractions. They attributed this to distention of the intervillous space by impairment of venous outflow compared with arterial inflow. During contractions, therefore, a somewhat larger volume of blood is available for exchange even though the rate of flow is decreased. Similarly, Doppler velocimetry has shown that diastolic flow velocity in spiral arteries is diminished during uterine contractions. Thus, principal factors regulating intervillous space blood flow are arterial blood pressure, intrauterine pressure, uterine contraction pattern, and factors that act specifically on arterial walls.

Breaks in the Placental "Barrier"

The placenta does not maintain absolute integrity of the fetal and maternal circulations. There are numerous examples of trafficking cells between mother and fetus in both directions. This situation is best exemplified clinically by erythrocyte D-antigen alloimmunization (Chap. 15, Red Cell Alloimmunization). Fetal cell admixtures likely are small in most cases, although rarely the fetus exsanguinates into the maternal circulation.

Fetal cells can also engraft in the mother during pregnancy and can be identified decades later. Fetal lymphocytes, CD34+ mesenchymal stem cells, and endothelial colony-forming cells all reside in maternal blood, bone marrow, or uterine vasculature (Nguyen, 2006; Piper, 2007; Sipos, 2013). Termed *microchimerism*, such residual stem cells have been implicated in the disparate female:male ratio of autoimmune disorders (Greer, 2011; Stevens, 2006). As discussed in Chapter 59 (Systemic Lupus Erythematosus), they are associated with the pathogenesis of lymphocytic thyroiditis, scleroderma, and systemic lupus erythematosus.

Fetal–Maternal Interface

Survival of the semiallogenic fetal graft requires complex interactions between fetal trophoblasts and maternal decidual immune cells. The fetal–maternal interface is not immunologically inert. Rather, it is an active hub of interactions that allows implantation and appropriate placental development and ensures immunotolerance of the fetus. Despite this, a functional immune system must be maintained to protect the mother.

Immunogenicity of the Trophoblasts

Trophoblastic cells are the only fetus-derived cells in direct contact with maternal tissues and blood. Fetal syncytiotrophoblast synthesizes and secretes numerous factors that regulate the immune responses of maternal cells both at the implantation site and systemically.

Human leukocyte antigens (HLAs) are the human analogue of the major histocompatibility complex (MHC) (Hunt, 1992). There are 17 HLA class I genes, including three classic genes, HLA-A, -B, and -C, that encode the major class I (class Ia) transplantation antigens. Three other class I genes, designated HLA-E, -F, and -G, encode class Ib HLA antigens. MHC class I and II antigens are absent from villous trophoblasts, which appear to be immunologically inert at all gestational stages (Weetman, 1999). Invasive extravillous cytotrophoblasts do express MHC class I molecules. Thus, the ability of these cells to bypass transplantation rejection is the focus of considerable study.

Moffett-King (2002) reasoned that normal implantation depends on controlled trophoblastic invasion of maternal decidua and spiral arteries. Such invasion must proceed far enough to provide for normal fetal growth and development, but a mechanism must regulate invasion depth. She suggests that dNK cells combined with unique expression of three specific HLA class I genes in extravillous cytotrophoblasts act in concert to permit and subsequently limit trophoblast invasion.

Class I antigens in extravillous cytotrophoblasts are accounted for by the expression of classic HLA-C and nonclassic class Ib molecules of HLA-E and HLA-G. HLA-G antigen is expressed only in humans, with expression restricted to extravillous cytotrophoblasts contiguous with maternal tissues. Embryos used for in vitro fertilization do not implant if they do not express a soluble HLA-G isoform (Fuzzi, 2002). Thus, HLA-G may be immunologically permissive of the maternal–fetal antigen mismatch (LeBouteiller, 1999). HLA-G has a proposed role in protecting extravillous trophoblasts from immune rejection via modulation of dNK functions

(Apps, 2011; Rajagopalan, 2012). Last, Goldman-Wohl and associates (2000) have provided evidence for abnormal HLA-G expression in extravillous trophoblasts from women with preeclampsia.

Decidual Immune Cells

Natural killer cells are the predominant population of leukocytes present in midluteal phase endometrium and in decidua throughout the first trimester (Johnson, 1999). By term, however, relatively few dNK cells are present in decidua. In first-trimester decidua, dNK cells lie close to extravillous trophoblasts, and there they purportedly serve to regulate invasion. These dNKs have a distinct phenotype characterized by a high surface density of CD56 or neural cell adhesion molecules (Manaster, 2008; Moffett-King, 2002). Their infiltration is increased by progesterone and by stromal cell production of IL-15 and decidual prolactin (Dunn, 2002; Gubbay, 2002). Although dNK cells have the capacity for cytotoxicity, they are not cytotoxic toward fetal trophoblasts. Their cytotoxic potential is prevented by molecular cues from decidual macrophages. In addition, the expression of specific HLA molecules protects against dNK killing. Also, dNK cells function to restrict trophoblast invasiveness to protect the mother.

Of other cell types, *decidual macrophages* are distinct from proinflammatory M1 or antiinflammatory M2 macrophages**.** Decidual macrophages express the complement receptor CD11c at high or low levels: CD11cHI and CD11cLO. These cells function to regulate adaptive T cell responses; control dNK differentiation, activation, and cytotoxicity; and produce antiinflammatory cytokines such as IL-10 to ensure fetal tolerance and inhibition of harmful immune responses.

Dendritic cells are cells that present antigens to T cells. They play an important role in the development of a receptive endometrium for implantation.

Maternal T cells, as part of the adaptive immune response, increase in number and function after encounter with a specific antigen. These cells subsequently retain the ability to respond rapidly in a subsequent encounter with the same antigen. Specific populations of Treg cells persist and can protect against aberrant immune responses. During pregnancy, there is a systemic expansion of maternal Treg cell populations. These cells are FOXP3+ cells with defined fetal specificity. They are immunosuppressive and play a role in fetal tolerance.

AMNION

At term, the amnion is a tough and tenacious but pliable membrane. This innermost avascular fetal membrane is contiguous with amnionic fluid and plays a role of incredible importance in human pregnancy. The amnion provides almost all tensile strength of the fetal membranes. Thus, its resilience to rupture is vitally important to successful pregnancy outcome. Indeed, preterm rupture of fetal membranes is a major cause of preterm delivery (Chap. 42, Management of Preterm Premature Rupture of Membranes).

Bourne (1962) described five separate amnion layers. The inner surface, which is bathed by amnionic fluid, is an uninterrupted, single layer of cuboidal epithelium (Fig. 5-16). This epithelium is attached firmly to a distinct basement membrane that is connected to an acellular compact layer composed primarily of interstitial collagens. On the outer side of the compact layer, there is a row of fibroblast-like mesenchymal cells, which are widely dispersed at term. There also are a few fetal macrophages in the amnion. The outermost amnion layer is the relatively acellular zona spongiosa, which is contiguous with the second fetal membrane, the chorion laeve. The human amnion lacks smooth muscle cells, nerves, lymphatics, and importantly, blood vessels.

FIGURE 5-16

Photomicrograph of fetal membranes. From left to right: AE = amnion epithelium; AM = amnion mesenchyme; S = zona spongiosa; CM = chorionic mesenchyme; TR = trophoblast; D = decidua. (Used with permission from Dr. Judith R. Head.)

Amnion Development

Early during implantation, a space develops between the embryonic cell mass and adjacent trophoblastic cells (see Fig. 5-9). Small cells that line this inner surface of trophoblasts have been called amniogenic cells—precursors of amnionic epithelium. The amnion is first identifiable on the 7th or 8th day of embryo development. It

is initially a minute vesicle, which then develops into a small sac that covers the dorsal embryo surface. As the amnion enlarges, it gradually engulfs the growing embryo, which prolapses into its cavity (Benirschke, 2012).

Distention of the amnionic sac eventually brings it into contact with the interior surface of the chorion laeve. Apposition of the chorion laeve and amnion near the end of the first trimester then causes an obliteration of the extraembryonic coelom. The amnion and chorion laeve, although slightly adhered, are never intimately connected and can be separated easily. Placental amnion covers the placental surface and thereby is in contact with the adventitial surface of chorionic vessels. Umbilical amnion covers the umbilical cord. With diamnionic-monochorionic placentas, there is no intervening tissue between the fused amnions. In the conjoined portion of membranes of diamnionic-dichorionic twin placentas, amnions are separated by fused chorion laeve.

Amnionic fluid fills this amnionic sac. Until about 34 weeks' gestation, the normally clear fluid increases in volume as pregnancy progresses. After this, the volume declines. At term, amnionic fluid averages 1000 mL, although this may vary widely in normal and especially abnormal conditions. The origin, composition, circulation, and function of amnionic fluid are discussed further in Chapter 11 (Normal Amnionic Fluid Volume).

Amnion Cell Histogenesis

Epithelial cells of the amnion derive from fetal ectoderm of the embryonic disc. They do not arise by delamination from trophoblasts. This is an important consideration from both embryological and functional perspectives. For example, HLA class I gene expression in amnion is more akin to that in embryonic cells than to that in trophoblasts.

The fibroblast-like mesenchymal cell layer of the amnion is likely derived from embryonic mesoderm. Early in human embryogenesis, the amnionic mesenchymal cells lie immediately adjacent to the basal surface of the amnion epithelium. At this time, the amnion surface is a two-cell layer with approximately equal numbers of epithelial and mesenchymal cells. Simultaneously with growth and development, interstitial collagens are deposited between these two cell layers. This marks formation of the amnion compact layer, which separates the two layers of amnion cells.

As the amnionic sac expands, the compactness of the mesenchymal cells is progressively reduced, and they become sparsely distributed. Early in pregnancy, amnionic epithelium replicates at a rate appreciably faster than mesenchymal cells. At term, these cells form a continuous uninterrupted epithelium on the fetal amnionic surface. Conversely, mesenchymal cells are widely dispersed, being connected by a fine lattice network of extracellular matrix with the appearance of long slender fibrils.

Amnion Epithelial Cells

The apical surface of the amnionic epithelium is replete with highly developed microvilli. This structure reflects its function as a major site of transfer between amnionic fluid and amnion. This epithelium is metabolically active, and its cells synthesize tissue inhibitor of MMP-1, prostaglandin E_2 (PGE_2), and fetal fibronectin (fFN) (Rowe, 1997). Although epithelia produce fFN, recent studies suggest that fibronectin functions in the underlying mesenchymal cells. Here, fFN promotes synthesis of MMPs that break down the strength-bearing collagens and enhance prostaglandin synthesis to prompt uterine contractions (Mogami, 2013). This pathway is upregulated in premature rupture of membranes induced by thrombin or infection-induced release of fFN (Chigusa, 2016; Mogami, 2014).

Epithelial cells may respond to signals derived from the fetus or the mother, and they are responsive to various endocrine or paracrine modulators. Examples include oxytocin and vasopressin, both of which increase PGE_2 production in vitro (Moore, 1988). They may also produce cytokines such as IL-8 during labor initiation (Elliott, 2001).

Amnionic epithelium also synthesizes vasoactive peptides, including endothelin and parathyroid hormone-related protein (Economos, 1992; Germain, 1992). The tissue produces brain natriuretic peptide (BNP) and corticotropin-releasing hormone (CRH), which are peptides that invoke smooth-muscle relaxation (Riley, 1991; Warren, 1995). BNP production is positively regulated by mechanical stretch in fetal membranes and is proposed to function in uterine quiescence. Epidermal growth factor, a negative regulator of BNP, is upregulated in the membranes at term and leads to a decline in BNP-regulated uterine quiescence (Carvajal, 2013). It seems reasonable that vasoactive peptides produced in amnion gain access to the adventitial surface of chorionic vessels. Thus, the amnion may be involved in modulating chorionic vessel tone and blood flow. Amnion-derived vasoactive peptides function in both maternal and fetal tissues in diverse physiological processes. After their secretion, these bioactive agents enter amnionic fluid and thereby are available to the fetus by swallowing and inhalation.

Amnion Mesenchymal Cells

Mesenchymal cells of the amnionic fibroblast layer are responsible for other major functions. Synthesis of interstitial collagens that compose the compact layer of the amnion—the major source of its tensile strength—takes place in mesenchymal cells (Casey, 1996). At term the generation of cortisol by 11β-hydroxysteroid dehydrogenase may contribute to membrane rupture via reduction of collagen abundance (Mi, 2017). Mesenchymal cells also synthesize cytokines that include IL-6, IL-8, and MCP-1. Cytokine synthesis rises in response to bacterial toxins and IL-1. This functional capacity of amnion mesenchymal cells is an important consideration in amnionic fluid study of labor-associated accumulation of inflammatory mediators (Garcia-Velasco, 1999). Finally, mesenchymal cells may be a greater source of PGE_2 than epithelial cells, especially in the case of premature membrane rupture (Mogami, 2013; Whittle, 2000).

Tensile Strength

During tests of tensile strength, the decidua and then the chorion laeve give way long before the amnion ruptures. Indeed, the membranes are elastic and can expand to twice normal size during pregnancy (Benirschke, 2012). The amnion tensile strength resides almost exclusively in the compact layer, which is composed of cross-linked interstitial collagens I and III and lesser amounts of collagens V and VI.

Collagens are the primary macromolecules of most connective tissues. Collagen I is the major interstitial collagen in tissues characterized by great tensile strength, such as bone and tendon. In other tissues, collagen III is believed to contribute to tissue integrity and provides both tissue extensibility and tensile strength. For

example, the ratio of collagen III to collagen I in the walls of a number of highly extensible tissues—amnionic sac, blood vessels, urinary bladder, bile ducts, intestine, and gravid uterus—is greater than that in nonelastic tissues (Jeffrey, 1991).

Amnion tensile strength is regulated in part by fibrillar collagen assembly. This process is influenced by the interaction fibrils with proteoglycans such as decorin and biglycan (Chap. 21, Cervical Ripening). Reduction of these proteoglycans is reported to perturb fetal membrane function (Horgan, 2014; Wu, 2014). Fetal membranes overlying the cervix have a regional shift in gene expression and lymphocyte activation that set in motion an inflammatory cascade (Marcellin, 2017). This change may contribute to tissue remodeling and loss of tensile strength in the amnion (Moore, 2009).

Metabolic Functions

The amnion is metabolically active, is involved in solute and water transport for amnionic fluid homeostasis, and produces an impressive array of bioactive compounds. The amnion is responsive both acutely and chronically to mechanical stretch, which alters amnionic gene expression (Carvajal, 2013; Nemeth, 2000). This in turn may trigger both autocrine and paracrine responses that include production of MMPs, IL-8, and collagenase (Bryant-Greenwood, 1998; Mogami, 2013). Such factors may modulate changes in membrane properties during labor.

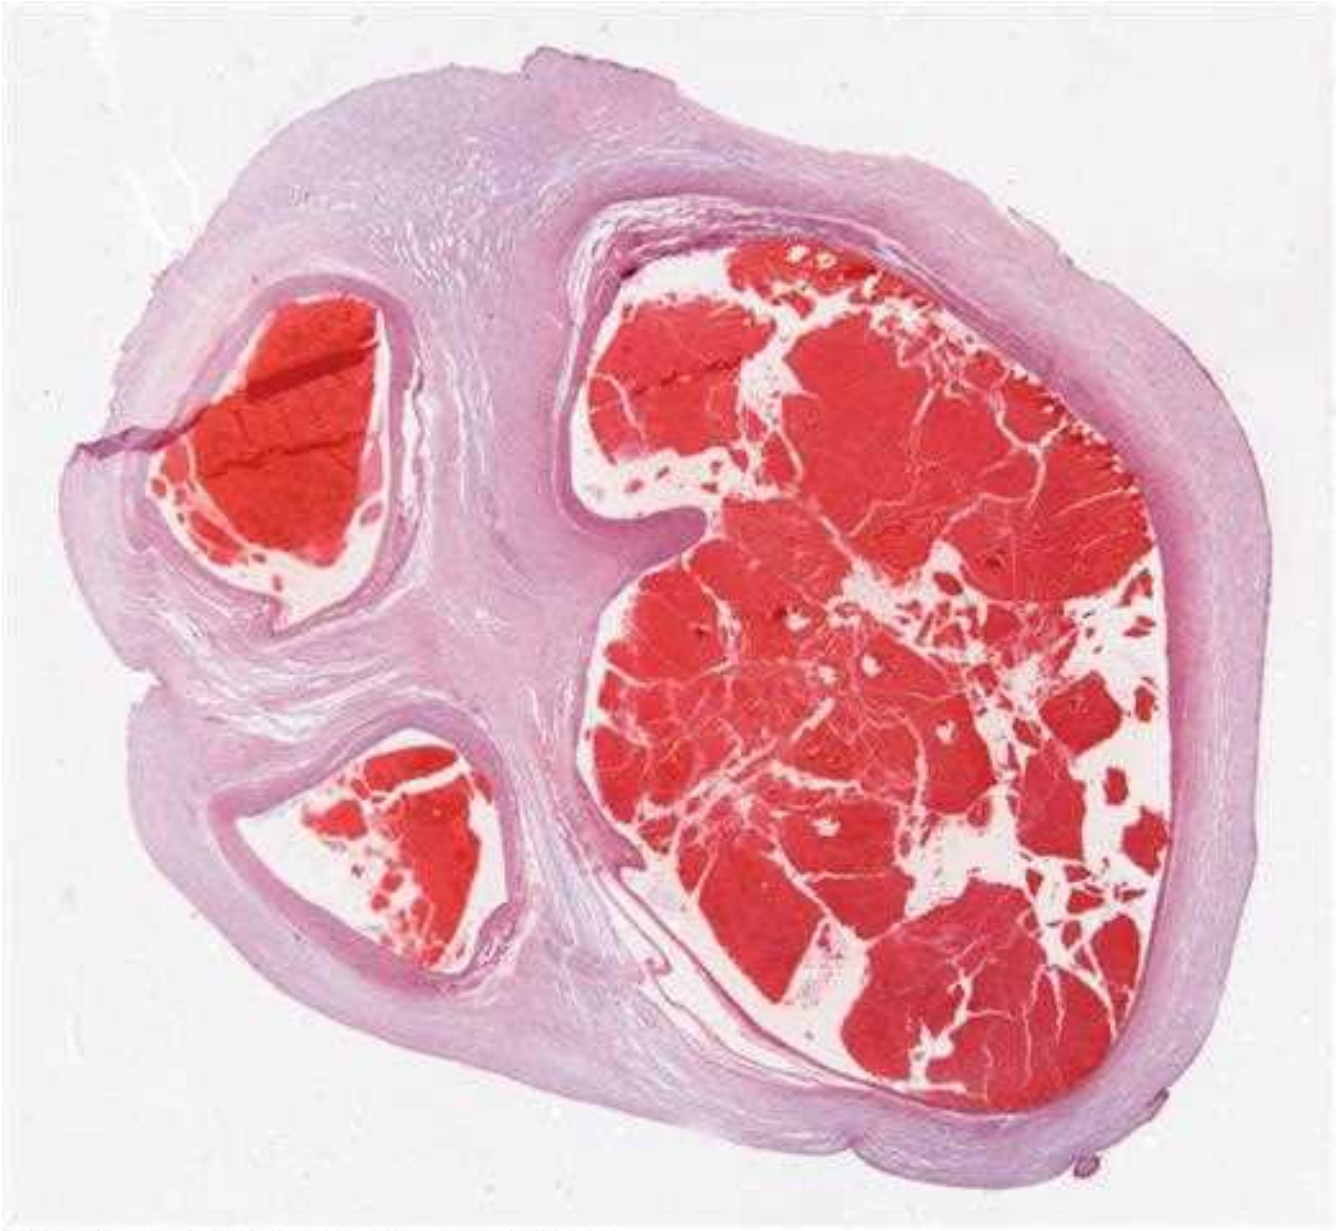
UMBILICAL CORD

The yolk sac and the umbilical vesicle into which it develops are prominent early in pregnancy. At first, the embryo is a flattened disc interposed between amnion and yolk sac (see Fig. 5-9). Its dorsal surface grows faster than the ventral surface, in association with the elongation of its neural tube. Thus, the embryo bulges into the amnionic sac, and the dorsal part of the yolk sac is incorporated into the embryo body to form the gut. The allantois projects into the base of the body stalk from the caudal wall of the yolk sac and later, from the anterior wall of the hindgut.

As pregnancy advances, the yolk sac becomes smaller and its pedicle relatively longer. By the middle of the third month, the expanding amnion obliterates the extraembryonic coelom, fuses with the chorion laeve, and covers the bulging placental disc and the lateral surface of the body stalk. The latter is then called the umbilical cord—or funis. A more detailed description of this cord and potential abnormalities is found in Chapter 6 (Umbilical Cord).

The cord at term normally has two arteries and one vein (Fig. 5-17). The right umbilical vein usually disappears early during fetal development, leaving only the original left vein.

FIGURE 5-17
Cross-section of umbilical cord. The large umbilical vein carries oxygenated blood to the fetus *(right)*. To its left are the two smaller umbilical arteries, carrying deoxygenated blood from the fetus to the placenta. (Used with permission from Dr. Mandolin S. Ziadie.)



The umbilical cord extends from the fetal umbilicus to the fetal surface of the placenta, that is, the chorionic plate. Blood flows from the umbilical vein toward the fetus. Blood then takes a path of least resistance via two routes within the fetus. One is the ductus venosus, which empties directly into the inferior vena cava (Fig. 7-9). The other route consists of numerous smaller openings into the hepatic circulation. Blood from the liver flows into the inferior vena cava via the hepatic vein. Resistance in the ductus venosus is controlled by a sphincter that is situated at the origin of the ductus at the umbilical recess and is innervated by a vagus nerve branch.

Blood exits the fetus via the two umbilical arteries. These are anterior branches of the internal iliac artery and become obliterated after birth to form the medial umbilical ligaments.

PLACENTAL HORMONES

The production of steroid and protein hormones by human trophoblasts is greater in amount and diversity than that of any single endocrine tissue in all of mammalian physiology. A compendium of average production rates for various steroid hormones in nonpregnant and in near-term pregnant women is given in Table 5-1. It is apparent that alterations in steroid hormone production that accompany normal human pregnancy are incredible. The human placenta also synthesizes an enormous amount of protein and peptide hormones, summarized in Table 5-2. Another remarkable feature is the successful physiological adaptations of pregnant women to the unique endocrine milieu, and this is discussed throughout Chapter 4 (Reproductive Tract).

TABLE 5-1

Steroid Production Rates in Nonpregnant and Near-Term Pregnant Women

	Production Rates (mg/24 hr)	
Steroid[a]	**Nonpregnant**	**Pregnant**
Estradiol-17β	0.1–0.6	15–20
Estriol	0.02–0.1	50–150
Progesterone	0.1–40	250–600
Aldosterone	0.05–0.1	0.250–0.600
Deoxycorticosterone	0.05–0.5	1–12
Cortisol	10–30	10–20

[a]Estrogens and progesterone are produced by placenta. Aldosterone is produced by the maternal adrenal in response to the stimulus of angiotensin II. Deoxycorticosterone is produced in extraglandular tissue sites by way of the 21-hydroxylation of plasma progesterone. Cortisol production during pregnancy is not increased, even though the blood levels are elevated because of decreased clearance caused by increased cortisol-binding globulin.

TABLE 5-2

Protein Hormones Produced by the Human Placenta

Hormone	Primary Non-placental Site of Expression	Shares Structural or Function Similarity	Functions
Human chorionic gonadotropin (hCG)	—	LH, FSH, TSH	Maintains corpus luteum function Regulates fetal testis testosterone secretion Stimulates maternal thyroid
Placental lactogen (PL)	—	GH, prolactin	Aids maternal adaptation to fetal energy requirements
Adrenocorticotropin (ACTH)	Hypothalamus	—	
Corticotropin-releasing hormone (CRH)	Hypothalamus	—	Relaxes smooth-muscle; initiates parturition? Promotes fetal and maternal glucocorticoid production
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	—	Regulates trophoblast hCG production
Thyrotropin (TRH)	Hypothalamus		Unknown
Growth hormone- releasing hormone (GHRH)	Hypothalamus	—	Unknown
Growth hormone variant (hGH-V)	—	GH variant not found in pituitary	Potentially mediates pregnancy insulin resistance
Neuropeptide Y	Brain		Potential regulates CRH release by trophoblasts
Parathyroid-releasing protein (PTH-rp)	—		Regulates transfer of calcium and other solutes; regulates fetal mineral homeostasis
Inhibin	Ovary/testis		Potentially inhibits FSH-mediated ovulation; regulates hCG synthesis
Activin	Ovary/testis		Regulates placental GnRH synthesis

GH = growth hormone; FSH = follicle-stimulating hormone; LH = luteinizing hormone; TSH = thyroid-stimulating hormone.

Human Chorionic Gonadotropin

Biosynthesis

Chorionic gonadotropin is a glycoprotein with biological activity similar to that of LH, and both act via the same LH-hCG receptor. hCG has with a molecular weight of 36,000 to 40,000 Da and has the highest carbohydrate content of any human hormone—30 percent. The carbohydrate component, and especially the terminal sialic acid, protects the molecule from catabolism. As a result, the 36-hour plasma half-life of intact hCG is much longer than the 2 hours for LH. The hCG molecule is composed of two dissimilar subunits termed α and β subunits. These are noncovalently linked and are held together by electrostatic and hydrophobic forces. Isolated subunits are unable to bind the LH-hCG receptor and thus lack biological activity.

hCG is produced almost exclusively in the placenta, but low levels are synthesized in the fetal kidney. Other fetal tissues produce either the β-subunit or intact hCG molecule (McGregor, 1981, 1983).

The hCG hormone is structurally related to three other glycoprotein hormones—LH, FSH, and TSH. All four glycoproteins share a common α-subunit. However, each of their β-subunits, although sharing certain similarities, is characterized by a distinctly different amino acid sequence.

Synthesis of the α- and β-chains of hCG is regulated separately. A single gene located on chromosome 6 encodes the α-subunit. Seven genes on chromosome 19 encode for the β-hCG–β-LH family of subunits. Six genes code for β-hCG and one for β-LH (Miller-Lindholm, 1997). Both subunits are synthesized as larger precursors, which are then cleaved by endopeptidases. Intact hCG is then assembled and rapidly released by secretory granule exocytosis (Morrish, 1987). There are multiple forms of hCG in maternal plasma and urine that vary enormously in bioactivity and immunoreactivity. Some result from enzymatic degradation, and others from modifications during molecular synthesis and processing.

Before 5 weeks, hCG is expressed both in the syncytiotrophoblast and in cytotrophoblasts (Maruo, 1992). Later, in the first trimester when maternal serum levels peak, hCG is produced almost solely in the syncytiotrophoblast (Beck, 1986; Kurman, 1984). At this time, mRNA concentrations of both α- and β-subunits in the syncytiotrophoblast are greater than at term (Hoshina, 1982). This may be an important consideration when hCG is used as a screening procedure to identify abnormal fetuses.

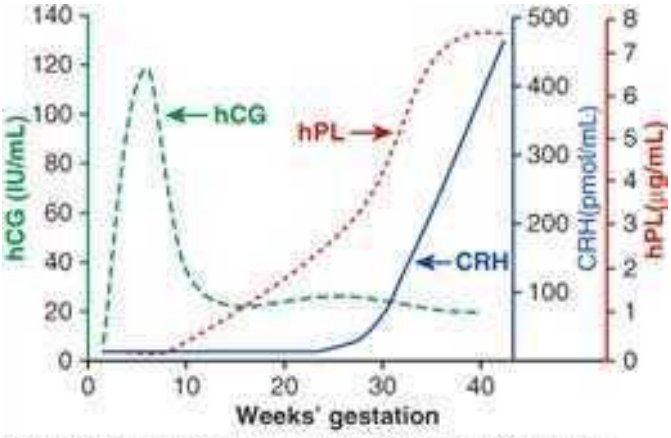
Circulating free levels of β-subunit are low to undetectable throughout pregnancy. In part, this is the result of its rate-limiting synthesis. Free α-subunits that do not combine with the β-subunit are found in placental tissue and maternal plasma. Levels of the α-subunit rise gradually and steadily until they plateau at approximately 36 weeks' gestation. At this time, they account for 30 to 50 percent of hormone (Cole, 1997). Thus, α-hCG secretion roughly corresponds to placental mass, whereas secretion of complete hCG molecules is maximal at 8 to 10 weeks.

Concentrations in Serum and Urine

The combined hCG molecule is detectable in plasma of pregnant women 7 to 9 days after the midcycle surge of LH that precedes ovulation. Thus, hCG likely enters maternal blood at the time of blastocyst implantation. Plasma levels rise rapidly, doubling every 2 days in the first trimester (Fig. 5-18). Appreciable fluctuations in levels for a given patient are observed on the same day.

FIGURE 5-18

Distinct profiles for the concentrations of human chorionic gonadotropin (hCG), human placental lactogen (hPL), and corticotropin-releasing hormone (CRH) in serum of women throughout normal pregnancy.



Intact hCG circulates as multiple highly related isoforms with variable cross-reactivity between commercial assays. Thus, calculated serum hCG levels can vary considerably among the more than a hundred available assays. This emphasizes the need to use the same assay type when clinically measuring serial hCG levels. Peak maternal plasma levels reach approximately 50,000 to 100,000 mIU/mL between the 60th and 80th days after menses. At 10 to 12 weeks' gestation, plasma levels begin to decline, and a nadir is reached by approximately 16 weeks. Plasma levels are maintained at this lower level for the remainder of pregnancy.

The pattern of hCG appearance in fetal blood is similar to that in the mother. Fetal plasma levels, however, are only about 3 percent of those in maternal plasma. Amnionic fluid hCG concentration early in pregnancy is similar to that in maternal plasma. As pregnancy progresses, hCG concentration in amnionic fluid declines, and near term the levels are approximately 20 percent of those in maternal plasma.

Maternal urine contains the same variety of hCG degradation products as maternal plasma. The principal urinary form is the terminal product of hCG degradation, namely, the β-core fragment. Concentrations of this fragment follow the same general pattern as that in maternal plasma, peaking at approximately 10 weeks' gestation. Importantly, the so-called β-subunit antibody used in most pregnancy tests reacts with both intact hCG—the major form in the plasma, and with fragments of hCG—the major forms found in urine.

hCG Regulation

Placental gonadotropin-releasing hormone (GnRH) is likely involved in the regulation of hCG formation. Both GnRH and its receptor are expressed by cytotrophoblasts and by the syncytiotrophoblast (Wolfahrt, 1998). GnRH administration elevates circulating hCG levels, and cultured trophoblasts respond to GnRH treatment and raise hCG secretion (Iwashita, 1993; Siler-Khodr, 1981). Pituitary GnRH production also is regulated by inhibin and activin. In cultured placental cells, activin stimulates and inhibin inhibits GnRH and hCG production (Petraglia, 1989; Steele, 1993).

Renal clearance of hCG accounts for 30 percent of its metabolic clearance. The remainder is likely cleared by metabolism in the liver (Wehmann, 1980). Clearances of β- and α-subunits are approximately 10- and 30-fold, respectively, greater than that of intact hCG. In pregnancies complicated by chronic renal disease, hCG clearance can be markedly decreased.

Biological Functions

Both hCG subunits are required for binding to the LH-hCG receptor in the corpus luteum and the fetal testis. LH-hCG receptors are present in various other tissues, but their roles there are less defined.

The best-known biological function of hCG is the so-called rescue and maintenance of corpus luteum function—that is, continued progesterone production. This is only an incomplete explanation for the physiological function of hCG in pregnancy. For example, maximum plasma hCG concentrations are attained well after hCG-

stimulated corpus luteum secretion of progesterone has ceased. Specifically, luteal progesterone synthesis begins to decline at about 6 weeks despite continued and increasing hCG production.

A second hCG role is stimulation of fetal testicular testosterone secretion. This is maximum approximately when hCG levels peak. Thus, at a critical time in male sexual differentiation, hCG enters fetal plasma from the syncytiotrophoblast. In the fetus, it acts as an LH surrogate to stimulate Leydig cell replication and testosterone synthesis to promote male sexual differentiation (Chap. 3, Embryology of the Gonads). Before approximately 110 days, there is no vascularization of the fetal anterior pituitary from the hypothalamus. Thus, pituitary LH secretion is minimal, and hCG acts as LH before this time. Thereafter, as hCG levels fall, pituitary LH maintains modest testicular stimulation.

The maternal thyroid gland is also stimulated by large quantities of hCG. In some women with gestational trophoblastic disease, biochemical and clinical evidence of hyperthyroidism sometimes develops (Chap. 20, Diagnosis). This once was attributed to formation of chorionic thyrotropins by neoplastic trophoblasts. It was subsequently shown, however, that some forms of hCG bind to TSH receptors on thyrocytes (Hershman, 1999). And, treatment of men with exogenous hCG increases thyroid activity. The thyroid-stimulatory activity in plasma of first-trimester pregnant women varies appreciably from sample to sample. Modifications of hCG oligosaccharides likely are important in the capacity of hCG to stimulate thyroid function. For example, acidic isoforms stimulate thyroid activity, and some more basic isoforms stimulate iodine uptake (Kraiem, 1994; Tsuruta, 1995; Yoshimura, 1994). Finally, the LH-hCG receptor is expressed by thyrocytes, which suggests that hCG stimulates thyroid activity via the LH-hCG receptor as well as by the TSH receptor (Tomer, 1992).

Other hCG functions include promotion of relaxin secretion by the corpus luteum (Duffy, 1996). LH-hCG receptors are found in myometrium and in uterine vascular tissue. It has been hypothesized that hCG may promote uterine vascular vasodilatation and myometrial smooth muscle relaxation (Kurtzman, 2001). Chorionic gonadotropin also regulates expansion of dNK cell numbers during early stages of placentation, thus ensuring appropriate establishment of pregnancy (Kane, 2009).

Abnormally High or Low Levels

There are several clinical circumstances in which substantively higher maternal plasma hCG levels are found. Some examples are multifetal pregnancy, erythroblastosis fetalis associated with fetal hemolytic anemia, and gestational trophoblastic disease. Relatively higher hCG levels may be found in women carrying a fetus with Down syndrome. This observation is used in biochemical screening tests (Chap. 14, Traditional Aneuploidy Screening Tests). The reason for the elevation is not clear, but reduced placental maturity has been speculated. Various malignant tumors also produce hCG, sometimes in large amounts—especially trophoblastic neoplasms (Chaps. 9 (Initial Prenatal Evaluation) and 20, Diagnosis).

Relatively lower hCG plasma levels are found in women with early pregnancy wastage, including ectopic pregnancy (Chap. 19, Multimodality Diagnosis). hCG is produced in very small amounts in normal tissues of men and nonpregnant women, perhaps primarily in the anterior pituitary gland. Nonetheless, the detection of hCG in blood or urine almost always indicates pregnancy (Chap. 9, Diagnosis of Pregnancy).

Human Placental Lactogen

Biosynthesis

This is a single, nonglycosylated polypeptide chain with a molecular weight of 22,279 Da. The sequences of hPL and of human growth hormone (hGH) are strikingly similar, with 96-percent homology. Also, hPL is structurally similar to human prolactin (hPRL), with a 67-percent amino acid sequence similarity. Because of these similarities, it was called human placental lactogen or chorionic growth hormone. Currently, human placental lactogen is used by most.

There are five genes in the growth hormone–placental lactogen gene cluster that are linked and located on chromosome 17. hPL is concentrated in syncytiotrophoblast, but similar to hCG, hPL is demonstrated in cytotrophoblasts before 6 weeks (Grumbach, 1964; Maruo, 1992). Within 5 to 10 days after conception, hPL is demonstrable in the placenta and can be detected in maternal serum as early as 3 weeks. Levels of mRNA for hPL in syncytiotrophoblast remain relatively constant throughout pregnancy. This finding supports the idea that the hPL secretion rate is proportional to placental mass. Levels rise steadily until 34 to 36 weeks' gestation. The hPL production rate near term—approximately 1 g/d—is by far the greatest of any known hormone in humans. The half-life of hPL in maternal plasma is between 10 and 30 minutes (Walker, 1991). In late pregnancy, maternal serum concentrations reach levels of 5 to 15 µg/mL (see Fig. 5-18).

Very little hPL is detected in fetal blood or in the urine of the mother or newborn. Amnionic fluid levels are somewhat lower than in maternal plasma. hPL is secreted primarily into the maternal circulation, with only very small amounts in cord blood. Thus, its role in pregnancy is believed to be mediated through actions in maternal rather than in fetal tissues. Nonetheless, interest continues for the possibility that hPL serves select functions in fetal growth.

Metabolic Actions

hPL has putative actions in several important metabolic processes. First, hPL promotes maternal lipolysis with increased circulating free fatty acid levels. This provides an energy source for maternal metabolism and fetal nutrition. In vitro studies suggest that hPL inhibits leptin secretion by term syncytiotrophoblast (Coya, 2005). Prolonged maternal starvation in the first half of pregnancy leads to higher hPL plasma concentrations.

Second, hPL may aid maternal adaptation to fetal energy requirements. For example, increased maternal insulin resistance ensures nutrient flow to the fetus. It also favors protein synthesis and provides a readily available amino acid source to the fetus. To counterbalance the greater insulin resistance and prevent maternal hyperglycemia, maternal insulin levels are increased. Both hPL and prolactin signal through the prolactin receptor to increase maternal beta cell proliferation to augment insulin secretion (Georgia, 2010). In animals, prolactin and hPL upregulate serotonin synthesis, which increases beta cell proliferation (Kim, 2010). Short-term changes in plasma glucose or insulin, however, have relatively little effect on plasma hPL levels. In vitro studies of syncytiotrophoblast suggest that hPL synthesis is stimulated by insulin and insulin-like growth factor-1 and inhibited by PGE_2 and $PGF_{2\alpha}$ (Bhaumick, 1987; Genbacev, 1977).

Last, hPL is a potent angiogenic hormone. It may serve an important function in fetal vasculature formation (Corbacho, 2002).

Other Placental Protein Hormones

The placenta has a remarkable capacity to synthesize numerous peptide hormones, including some that are analogous or related to hypothalamic and pituitary hormones. In contrast to their counterparts, some of these placental peptide/protein hormones are not subject to feedback inhibition.

Hypothalamic-Like Releasing Hormones

The known hypothalamic-releasing or -inhibiting hormones include GnRH, CRH, thyrotropin-releasing hormone (TRH), growth hormone-releasing hormone, and somatostatin. For each, there is an analogous hormone produced in the human placenta (Petraglia, 1992; Siler-Khodr, 1988).

GnRH in the placenta shows its highest expression in the first trimester (Siler-Khodr, 1978, 1988). Interestingly, it is found in cytotrophoblasts, but not syncytiotrophoblast. Placenta-derived GnRH functions to regulate trophoblast hCG production and extravillous trophoblast invasion via regulation of MMP-2 and MMP-9 (Peng, 2016). Placenta-derived GnRH is also the likely cause of elevated maternal GnRH levels in pregnancy (Siler-Khodr, 1984).

CRH is a member of a larger family of CRH-related peptides that includes CRH and urocortins (Dautzenberg, 2002). Maternal serum CRH levels increase from 5 to 10 pmol/L in the nonpregnant woman to approximately 100 pmol/L in the early third trimester of pregnancy and to almost 500 pmol/L abruptly during the last 5 to 6 weeks (see Fig. 5-18). Urocortin also is produced by the placenta and secreted into the maternal circulation, but at much lower levels than seen for CRH (Florio, 2002). After labor begins, maternal plasma CRH levels rise even further (Petraglia, 1989, 1990).

The biological function of CRH synthesized in the placenta, membranes, and decidua has been somewhat defined. CRH receptors are present in many tissues including placenta. Trophoblast, amniochorion, and decidua express both CRH-R1 and CRH-R2 receptors and several variant receptors (Florio, 2000). Both CRH and urocortin enhance trophoblast secretion of adrenocorticotropic hormone (ACTH), supporting an autocrine-paracrine role (Petraglia, 1999). Large amounts of trophoblast CRH enter maternal blood.

Other proposed biological roles include induction of smooth-muscle relaxation in vascular and myometrial tissue and immunosuppression. The physiological reverse, however, induction of myometrial contractions, has been proposed for the rising CRH levels seen near term. One hypothesis suggests that CRH may be involved with parturition initiation (Wadhwa, 1998). Some evidence suggests that urocortin 2 expression is induced at term and induces expression of proinflammatory markers and prostaglandin F receptor expression in the placenta and myometrium (Voltolini, 2015). Prostaglandin formation in the placenta, amnion, chorion laeve, and decidua is increased with CRH treatment (Jones, 1989b). These observations further support a potential action in parturition timing.

Glucocorticoids act in the hypothalamus to inhibit CRH release, but in the trophoblast, glucocorticoids stimulate CRH gene expression (Jones, 1989a; Robinson, 1988). Thus, there may be a novel positive feedback loop in the placenta by which placental CRH stimulates placental ACTH to stimulate fetal and maternal adrenal glucocorticoid production with subsequent stimulation of placental CRH expression (Nicholson, 2001; Riley, 1991).

G*rowth hormone-releasing hormone* has an unknown role (Berry, 1992). Ghrelin is another regulator of hGH secretion that is produced by placental tissue (Horvath, 2001). Trophoblast ghrelin expression peaks at midpregnancy and is a paracrine regulator of differentiation or is a potential regulator of human growth hormone variant production, described next (Fuglsang, 2005; Gualillo, 2001).

Pituitary-Like Hormones

ACTH, lipotropin, and β-endorphin, which are all proteolytic products of pro-opiomelanocortin, are recovered from placental extracts (Genazzani, 1975; Odagiri, 1979). The physiological action of placental ACTH is unclear. As discussed, placental CRH stimulates synthesis and release of chorionic ACTH.

A *human growth hormone variant (hGH-V)* that is not expressed in the pituitary is expressed in the placenta. The gene encoding hGH-V is located in the hGH–hPL gene cluster on chromosome 17. Sometimes referred to as placental growth hormone, hGH-V is a 191-amino-acid protein that differs in 15 amino acid positions from the sequence for hGH. Although hGH-V retains growth-promoting and antilipogenic functions similar to those of hGH, it has reduced diabetogenic and lactogenic functions relative to hGH (Vickers, 2009). Placental hGH-V presumably is synthesized in the syncytiotrophoblast. It is believed that hGH-V is present in maternal plasma by 21 to 26 weeks' gestation, rises in concentration until approximately 36 weeks, and remains relatively constant thereafter. There is a correlation between the levels of hGH-V in maternal plasma and those of insulin-like growth factor-1. Also, hGH-V secretion by trophoblast in vitro is inhibited by glucose in a dose-dependent manner (Patel, 1995). Overexpression of hGH-V in mice causes severe insulin resistance, making it a likely candidate to mediate insulin resistance of pregnancy (Liao, 2016).

Relaxin

Expression of relaxin has been demonstrated in human corpus luteum, decidua, and placenta (Bogic, 1995). This peptide is synthesized as a single, 105-amino-acid preprorelaxin molecule that is cleaved to A and B molecules. Relaxin is structurally similar to insulin and insulin-like growth factor. Two of the three relaxin genes—*H2* and *H3*—are transcribed in the corpus luteum (Bathgate, 2002; Hudson, 1983, 1984). Decidua, placenta, and membranes express *H1* and *H2* (Hansell, 1991).

The rise in maternal circulating relaxin levels seen in early pregnancy is attributed to corpus luteum secretion, and levels parallel those of hCG. Relaxin, along with rising progesterone levels, may act on myometrium to promote relaxation and the quiescence of early pregnancy (Chap. 21, Decidua). In addition, the production of relaxin and relaxin-like factors within the placenta and fetal membranes may play an autocrine-paracrine role in postpartum regulation of extracellular matrix remodeling (Qin, 1997a,b). One important relaxin function is enhancement of the glomerular filtration rate (Chap. 4, Renal Function Tests).

Parathyroid Hormone-Related Protein

In pregnancy, circulating parathyroid hormone-related protein (PTH-rP) levels are significantly elevated within maternal but not fetal circulation (Bertelloni, 1994; Saxe, 1997). Many functions of this hormone have been proposed. PTH-rP synthesis is found in several normal adult tissues, especially in reproductive organs that include myometrium, endometrium, corpus luteum, and lactating mammary tissue. PTH-rP is not produced in the parathyroid glands of normal adults. Placenta-derived PTH-rP may have an important function to regulate genes involved in transfer of calcium and other solutes. It also contributes to fetal mineral homeostasis in bone, amnionic fluid, and the fetal circulation (Simmonds, 2010).

Leptin

This hormone is normally secreted by adipocytes. It functions as an antiobesity hormone that decreases food intake through its hypothalamic receptor. It also regulates bone growth and immune function (Cock, 2003; La Cava, 2004). In the placenta, leptin is synthesized by both cytotrophoblasts and syncytiotrophoblast (Henson, 2002). Relative contributions of leptin from maternal adipose tissue versus placenta are currently not well defined, although recent evidence highlights a key regulatory role of placental leptin in placental amino acid transport and fetal growth (Rosario, 2016a). Maternal serum levels are significantly higher than those in nonpregnant women. Fetal leptin levels correlate positively with birthweight and likely function in fetal development and growth. Studies suggest that reductions in leptin availability contribute to adverse fetal metabolic programing in intrauterine growth-restricted offspring (Nusken, 2016).

Neuropeptide Y

This 36-amino-acid peptide is widely distributed in brain. It also is found in sympathetic neurons innervating the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. Neuropeptide Y has been isolated from the placenta and localized in cytotrophoblasts (Petraglia, 1989). Trophoblasts possess neuropeptide Y receptors, and treatment of these with neuropeptide Y causes CRH release (Robidoux, 2000).

Inhibin and Activin

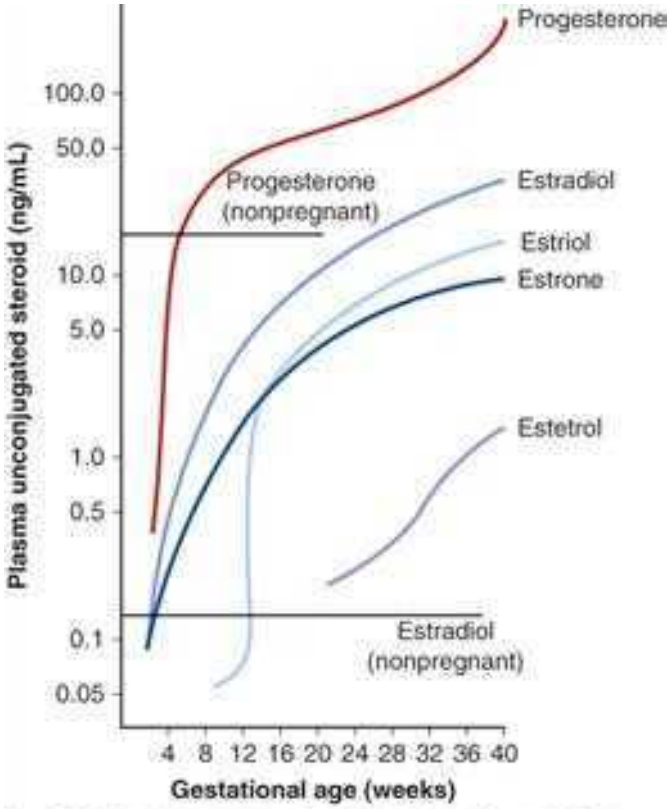
These glycoprotein hormones are expressed in male and female reproductive tissues and belong to the transforming growth factor-β family (Jones, 2006). Inhibin is a heterodimer made up of one α-subunit and one of two distinct β-subunits, either βA or βB. This yields either inhibin A or inhibin B, respectively. Activin is formed by the combination of the two β-subunits. Activin, inhibin, and their respective receptors are expressed in the placenta. Both activin and inhibin A have proposed functions during cytotrophoblast fusion into the syncytiotrophoblast (Debiève, 2000; Jones, 2006). Activin also stimulates production of placental hormones such as hCG, hPL, progesterone, and estrogen (Luo, 2002; Morrish, 1991; Petraglia, 1989; Song, 1996). Inhibin A opposes activin action in the placenta to inhibit production of hCG and steroidogenesis (Petraglia, 1989). Abnormal levels of inhibin or activin correlate with placental pathologies. For example, elevation in inhibin A levels in the second trimester is indicative of fetal Down syndrome. Further, low inhibin levels early in pregnancy may indicate pregnancy failure (Prakash, 2005; Wallace, 1996). Elevations in circulating inhibin and activin levels are reported in women with preeclampsia (Bersinger, 2003).

Placental Progesterone Production

After 6 to 7 weeks' gestation, little progesterone is produced in the ovary (Diczfalusy, 1961). Surgical removal of the corpus luteum or even bilateral oophorectomy during the 7th to 10th week does not decrease excretion rates of urinary pregnanediol, the principal urinary metabolite of progesterone. Before this time, however, corpus luteum removal will result in spontaneous abortion unless an exogenous progestin is given (Chap. 63, Diagnosis). After approximately 8 weeks, the placenta assumes progesterone secretion, resulting in a gradual increase in maternal serum levels throughout pregnancy (Fig. 5-19). By term, these levels are 10 to 5000 times those found in nonpregnant women, depending on the stage of the ovarian cycle.

FIGURE 5-19

Plasma levels of progesterone, estradiol, estrone, estetrol, and estriol in women during the course of gestation. (Modified and redrawn with permission from Mesiano S: The endocrinology of human pregnancy and fetoplacental neuroendocrine development. In Strauss JF, Barbieri RL (eds) Yen and Jaffe's Reproductive Endocrinology: Physiology, Pathophysiology, and Clinical Management, 6th ed. Philadephia, Saunders, 2009.)



The daily production rate of progesterone in late, normal, singleton pregnancies approximates 250 mg. In multifetal pregnancies, the daily production rate may exceed 600 mg. Progesterone is synthesized from cholesterol in a two-step enzymatic reaction. First, cholesterol is converted to pregnenolone within the

mitochondria, in a reaction catalyzed by cytochrome P450 cholesterol side-chain cleavage enzyme. Pregnenolone leaves the mitochondria and is converted to progesterone in the endoplasmic reticulum by 3β-hydroxysteroid dehydrogenase. Progesterone is released immediately through a process of diffusion.

Although the placenta produces a prodigious amount of progesterone, the syncytiotrophoblast has a limited capacity for cholesterol biosynthesis. Radiolabeled acetate is incorporated into cholesterol by placental tissue at a slow rate. The rate-limiting enzyme in cholesterol biosynthesis is 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. Because of this, the placenta must rely on an exogenous source, that is, maternal cholesterol, for progesterone formation. The trophoblast preferentially uses LDL cholesterol for progesterone biosynthesis (Simpson, 1979, 1980). This mechanism differs from placental production of estrogens, which relies principally on fetal adrenal precursors.

Although there is a relationship between fetal well-being and placental estrogen production, this is not the case for placental progesterone. Thus, placental endocrine function, including the formation of protein hormones such as hCG and progesterone biosynthesis, may persist for weeks after fetal demise.

The metabolic clearance rate of progesterone in pregnant women is similar to that found in men and nonpregnant women. During pregnancy, the plasma concentration of 5α-dihydroprogesterone disproportionately rises due to synthesis in syncytiotrophoblast from both placenta-produced progesterone and fetus-derived precursor (Dombroski, 1997). Thus, the concentration ratio of this progesterone metabolite to progesterone is elevated in pregnancy. The mechanisms for this are not defined completely. Progesterone also is converted to the potent mineralocorticoid deoxycorticosterone in pregnant women and in the fetus. The concentration of deoxycorticosterone is strikingly higher in both maternal and fetal compartments (see Table 5-1). The extraadrenal formation of deoxycorticosterone from circulating progesterone accounts for most of its production in pregnancy (Casey, 1982a,b).

Placental Estrogen Production

During the first 2 to 4 weeks of pregnancy, rising hCG levels maintain production of estradiol in the maternal corpus luteum. Production of both progesterone and estrogens in the maternal ovaries drops significantly by the 7th week of pregnancy. At this time, there is a luteal–placental transition. By the 7th week, more than half of estrogen entering maternal circulation is produced in the placenta (MacDonald, 1965a; Siiteri, 1963, 1966). Subsequently, the placenta produces a continually increasing magnitude of estrogen. Near term, normal human pregnancy is a hyperestrogenic state, and syncytiotrophoblast is producing estrogen in amounts equivalent to that produced in 1 day by the ovaries of no fewer than 1000 ovulatory women. This hyperestrogenic state terminates abruptly after delivery of the placenta.

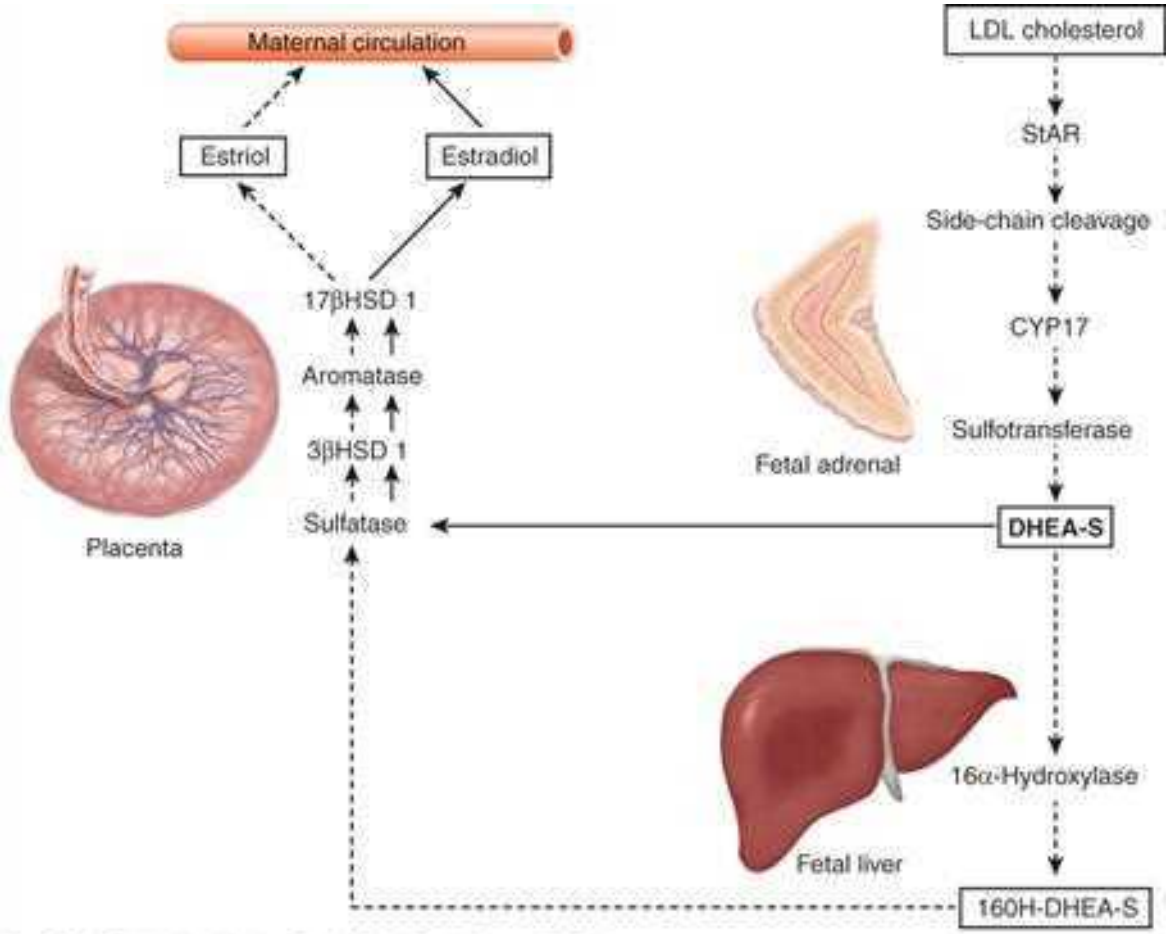
Biosynthesis

In human trophoblast, neither cholesterol nor, in turn, progesterone can serve as precursor for estrogen biosynthesis. This is because *steroid 17α-hydroxylase/17,20-lyase (CYP17A1)* is not expressed in the human placenta. This essential enzyme converts 17-OH progesterone (a C_{21} steroid) to androstenedione, which is a C_{19} steroid and an estrogen precursor. Consequently, the conversion of C_{21} steroids to C_{19} steroids is not possible.

However, dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S) are also C_{19} steroids and are produced by maternal and fetal adrenal glands. These two steroids can serve as estrogen precursors (Fig. 5-20). Ryan (1959a) found that the placenta had an exceptionally high capacity to convert appropriate C_{19} steroids to estrone and estradiol. The conversion of DHEA-S to estradiol requires placental expression of four key enzymes that are located principally in syncytiotrophoblast (Bonenfant, 2000; Salido, 1990). First, the placenta expresses high levels of steroid sulfatase (STS), which converts the conjugated DHEA-S to DHEA. DHEA is then acted upon by 3β-hydroxysteroid dehydrogenase type 1 (3βHSD) to produce androstenedione. Cytochrome P450 aromatase (CYP19) then converts androstenedione to estrone, which is then converted to estradiol by 17β-hydroxysteroid dehydrogenase type 1 (17βHSD1).

FIGURE 5-20

Schematic presentation of estrogen biosynthesis in the human placenta. Dehydroepiandrosterone sulfate (DHEAS), secreted in prodigious amounts by the fetal adrenal glands, is converted to 16α-hydroxydehydroepiandrosterone sulfate (16αOHDHEAS) in the fetal liver. These steroids, DHEAS and 16αOHDHEAS, are converted in the placenta to estrogens, that is, 17β-estradiol (E_2) and estriol (E_3). Near term, half of E_2 is derived from fetal adrenal DHEAS and half from maternal DHEAS. On the other hand, 90 percent of E_3 in the placenta arises from fetal 16αOHDHEAS and only 10 percent from all other sources.



DHEA-S is the major precursor of estrogens in pregnancy (Baulieu, 1963; Siiteri, 1963). However, maternal adrenal glands do not produce sufficient amounts of DHEA-S to account for more than a fraction of total placental estrogen biosynthesis. The fetal adrenal glands are quantitatively the most important source of placental estrogen precursors in human pregnancy. Thus, estrogen production during pregnancy reflects the unique interactions among fetal adrenal glands, fetal liver, placenta, and maternal adrenal glands.

Directional Secretion

More than 90 percent of estradiol and estriol formed in syncytiotrophoblast enters maternal plasma (Gurpide, 1966). And, 85 percent or more of placental progesterone enters maternal plasma, and little maternal progesterone crosses the placenta to the fetus (Gurpide, 1972).

This directional movement of newly formed steroid into the maternal circulation stems from basic characteristics of hemochorioendothelial placentation. In this system, steroids secreted from syncytiotrophoblast can enter maternal blood directly. Steroids that leave the syncytium do not enter fetal blood directly. They must first traverse the cytotrophoblast layer and then enter the stroma of the villous core and then fetal capillaries. From either of these spaces, steroids can reenter the syncytium. The net result of this hemochorial arrangement is that entry of steroids into the maternal circulation is substantially greater than that into fetal blood.

FETAL ADRENAL GLAND–PLACENTAL INTERACTIONS

Morphologically, functionally, and physiologically, the fetal adrenal glands are remarkable. At term, the fetal adrenal glands weigh the same as those of the adult. More than 85 percent of the fetal gland is composed of a unique fetal zone, which has a great capacity for steroid biosynthesis. Daily steroid production of fetal adrenal glands near term is 100 to 200 mg/d. This compares with resting adult steroid secretion of 30 to 40 mg/d.

The fetal zone is lost in the first year of life and is not present in the adult. In addition to ACTH, fetal adrenal gland growth is influenced by factors secreted by the placenta. This is exemplified by the continued growth of the fetal glands throughout gestation and by rapid involution immediately after birth and placental delivery.

Placental Estriol Synthesis

Estradiol is the primary placental estrogen product at term. In addition, significant levels of *estriol* and *estetrol* are found in the maternal circulation, and levels also rise, particularly late in gestation (see Fig. 5-19). These hydroxylated forms of estrogen derive from the placenta using substrates formed by the combined efforts of the fetal adrenal gland and fetal liver. For this, high levels of fetal hepatic 16α-hydroxylase act on adrenal-derived steroids. Ryan (1959b) and MacDonald and Siiteri (1965b) found that 16α-hydroxylated C_{19} steroids, particularly 16α-hydroxydehydroepiandrosterone (16-OHDHEA), were converted to estriol by placental tissue.

Thus, the disproportionate increase in estriol formation during pregnancy is accounted for by placental synthesis of estriol principally from plasma-borne 16-OHDHEA-sulfate. Near term, the fetus is the source of 90 percent of placental estriol and estetrol precursors in normal human pregnancy.

Maternal estriol and estetrol are produced almost solely by fetal steroid precursors. Thus, in the past, levels of these steroids were used as an indicator of fetal well-being. However, the low sensitivity and specificity of such tests have caused them to be discarded.

Fetal Adrenal Steroid Precursor

The precursor for fetal adrenal steroidogenesis is cholesterol. The steroid biosynthesis rate in the fetal gland is so great that its steroidogenesis alone is equivalent to a fourth of the total daily LDL cholesterol turnover in adults. Fetal adrenal glands synthesize cholesterol from acetate. All enzymes involved in cholesterol biosynthesis are elevated compared with those of the adult adrenal gland (Rainey, 2001). Thus, the de novo cholesterol synthesis rate by fetal adrenal tissue is extremely high. Even so, it is insufficient to account for the steroids produced by fetal adrenal glands. Therefore, cholesterol must be assimilated from the fetal circulation and mainly from LDL (Carr, 1980, 1981b, 1982; Simpson, 1979).

Most fetal plasma cholesterol arises by de novo synthesis in the fetal liver (Carr, 1984). The low LDL cholesterol level in fetal plasma is not the consequence of impaired fetal LDL synthesis, but instead results from the rapid use of LDL by the fetal adrenal glands for steroidogenesis (Parker, 1980, 1983).

Fetal Conditions Affecting Estrogen Production

Several fetal disorders alter the availability of substrate for placental steroid synthesis and thus highlight the interdependence of fetal development and placental function.

Fetal demise is followed by a striking reduction in urinary estrogen levels. Similarly, after ligation of the umbilical cord with the fetus and placenta left in situ, placental estrogen production declines markedly (Cassmer, 1959). However, as previously discussed, placental progesterone production is maintained. In sum, an important source of precursors of placental estrogen—but not progesterone—biosynthesis is eliminated with fetal death.

Anencephalic fetuses have markedly atrophic adrenal glands. This stems from absent hypothalamic-pituitary function, which precludes adrenal stimulation by ACTH. With absence of the adrenal cortex fetal zone, the placental formation of estrogen—especially estriol—is severely limited because of diminished availability of C_{19} steroid precursors. Indeed, urinary estrogen levels in women pregnant with an anencephalic fetus are only about 10 percent of those found in normal pregnancy (Frandsen, 1961). With an anencephalic fetus, almost all estrogens produced arise from placental use of maternal plasma DHEA-S.

Fetal adrenal cortical hypoplasia occurs in perhaps 1 in 12,500 births (McCabe, 2001). Estrogen production in these pregnancies is limited, which suggests the absence of C_{19} precursors.

Fetal–placental sulfatase deficiency is associated with very low estrogen levels in otherwise normal pregnancies (France, 1969). Namely, sulfatase deficiency precludes the hydrolysis of C_{19} steroid sulfates, the first enzymatic step in the placental use of these circulating prehormones for estrogen biosynthesis. This deficiency is an X-linked disorder, and thus all affected fetuses are male. Its estimated frequency is 1 in 2000 to 5000 births and is associated with delayed labor onset. It also is associated with the development of ichthyosis in affected males later in life (Bradshaw, 1986).

Fetal–placental aromatase deficiency is a rare autosomal recessive disorder in which individuals cannot synthesize endogenous estrogens (Grumbach, 2011; Simpson, 2000). To recall, fetal adrenal DHEA-S is converted in the placenta to androstenedione, but in cases of placental aromatase deficiency, androstenedione cannot be converted to estradiol. Rather, androgen metabolites of DHEA produced in the placenta, including androstenedione and some testosterone, are secreted into the maternal or fetal circulation, or both. This can cause virilization of the mother and the female fetus (Belgorosky, 2009; Harada, 1992; Shozu, 1991).

Trisomy 21—Down syndrome screening searches for abnormal levels of hCG, alpha-fetoprotein, and other analytes (Chap. 14, Traditional Aneuploidy Screening Tests). It was discovered that serum unconjugated estriol levels were low in women with Down syndrome fetuses (Benn, 2002). The likely reason for this is inadequate formation of C_{19} steroids in the adrenal glands of these trisomic fetuses.

Fetal erythroblastosis in some cases of severe fetal D-antigen alloimmunization can lead to elevated maternal plasma estrogen levels. A suspected cause is the greater placental mass from hypertrophy, which can be seen with such fetal hemolytic anemia (Chap. 15, Fetal Anemia).

Maternal Conditions Affecting Estrogen Production

Glucocorticoid treatment can cause a striking reduction in placental estrogen formation. Glucocorticoids inhibit ACTH secretion from the maternal and fetal pituitary glands. This diminishes maternal and fetal adrenal secretion of the placental estrogen precursor DHEA-S.

With *Addison disease,* pregnant women show lower estrogen levels, principally estrone and estradiol levels (Baulieu, 1956). The fetal adrenal contribution to estriol synthesis, particularly in later pregnancy, is quantitatively much more important.

Maternal *androgen-producing tumors* can present the placenta with elevated androgen levels. Fortunately, placenta is extraordinary efficient in the aromatization of C_{19} steroids. For example, Edman and associates (1981) found that virtually all androstenedione entering the intervillous space is taken up by syncytiotrophoblast and converted to estradiol. None of this C_{19} steroid enters the fetus. Second, a female fetus is rarely virilized if there is a maternal androgen-secreting tumor. The placenta efficiently converts aromatizable C_{19} steroids, including testosterone, to estrogens, thus precluding transplacental passage. Indeed, virilized female fetuses of women with an androgen-producing tumor may be cases in which a nonaromatizable C_{19} steroid androgen is produced by the tumor—for example, 5α-dihydrotestosterone. Another explanation is that testosterone is produced very early in pregnancy in amounts that exceed the placental aromatase capacity at that time.

Complete hydatidiform mole and *gestational trophoblastic neoplasias* lack a fetus and also a fetal adrenal source of C_{19} steroid precursors for trophoblast estrogen biosynthesis. Consequently, placental estrogen formation is limited to the use of C_{19} steroids from the maternal plasma, and therefore estradiol is principally produced (MacDonald, 1964, 1966).

CHAPTER 6: Placental Abnormalities

The placenta, as a rule, presents more or less rounded outlines, but now and again when inserted in the neighbourhood of the internal os it may take on a horseshoe-like appearance, its two branches running partially around the orifice.

—J. Whitridge Williams (1903)

INTRODUCTION

The placenta is a fantastic organ in its own right. As discussed in Chapter 5 (Blastocyst), it provides the indispensable interface between mother and fetus. Indeed, placental anatomy, physiology, and molecular structure remain some of the most intriguing and understudied topics in obstetrics.

Although a placental examination by the obstetrician is recommended, by consensus, routine pathological examination is not mandatory. Indeed, specific conditions that merit submission for detailed inspection are still debated. By way of example, the College of American Pathologists has recommended placental examination for an extensive list of indications (Langston, 1997). Data, however, are insufficient to support all of these. At minimum, the placenta and cord should be inspected in the delivery room. The decision to request pathological examination should be based on clinical and placental findings (Redline, 2008; Roberts, 2008). Listed in Table 6-1 are some of the indications at Parkland Hospital for placental anatomical and histopathological examination.

TABLE 6-1

Some Indications for Placental Pathological Examination[a]

Maternal Indications
Abruption
Antepartum infection with fetal risks
Anti-CDE alloimmunization
Cesarean hysterectomy
Oligohydramnios or hydramnios
Peripartum fever or infection
Preterm delivery
Postterm delivery
Severe trauma
Suspected placental injury
Systemic disorders with known effects
Thick or viscid meconium
Unexplained late pregnancy bleeding
Unexplained or recurrent pregnancy complications
Fetal and Neonatal Indications
Admission to an acute care nursery
Birth weight ≤10th or ≥95th percentile
Fetal anemia
Fetal or neonatal compromise
Neonatal seizures
Hydrops fetalis
Infection or sepsis
Major anomalies or abnormal karyotype
Multifetal gestation
Stillbirth or neonatal death
Vanishing twin beyond the first trimester
Placental Indications
Gross lesions
Marginal or velamentous cord insertion
Markedly abnormal placental shape or size
Markedly adhered placenta
Term cord <32 cm or >100 cm
Umbilical cord lesions

[a]Indications are organized alphabetically.

NORMAL PLACENTA

At term, the typical placenta weighs 470 g, is round to oval with a 22-cm diameter, and has a central thickness of 2.5 cm (Benirschke, 2012). It is composed of a placental disc, extraplacental membranes, and three-vessel umbilical cord. The disc surface that lies against the uterine wall is the *basal plate*, which is divided by clefts into portions—termed cotyledons. The fetal surface is the *chorionic plate*, into which the umbilical cord inserts, typically in the center. Large fetal vessels that originate from the cord vessels then spread and branch across the chorionic plate before entering stem villi of the placenta parenchyma. In tracing these, fetal arteries almost invariably cross over veins. The chorionic plate and its vessels are covered by thin amnion, which can be easily peeled away from a postdelivery specimen.

As recommended by the American Institute of Ultrasound in Medicine (2013), placental location and relationship to the internal cervical os are recorded during prenatal sonographic examinations. As visualized ultrasonically, the normal placenta is homogenous and 2 to 4 cm thick, lies against the myometrium, and indents into the amnionic sac. The retroplacental space is a hypoechoic area that separates the myometrium from the basal plate and measures less than 1 to 2 cm. The umbilical cord is also imaged, its fetal and placental insertion sites examined, and its vessels counted.

Many placental lesions can be identified grossly or sonographically, but other abnormalities require histopathological examination for clarification. A detailed description of these is beyond the scope of this chapter, and interested readers are referred to textbooks by Benirschke (2012), Fox (2007), and Faye-Petersen (2006) and their colleagues. Moreover, the placenta accrete syndrome and gestational trophoblastic disease are presented in detail in Chapters 20 and 41, respectively.

SHAPE AND SIZE VARIANTS

Of variants, placentas may infrequently form as separate, nearly equally sized discs. This *bilobate placenta* may also be called bipartite placenta or placenta duplex. In these, the cord inserts between the two placental lobes—either into a connecting chorionic bridge or into intervening membranes. A placenta containing three or more equivalently sized lobes is rare and termed *multilobate*. Unlike this equal distribution, one or more disparately smaller accessory lobes —*succenturiate lobes*—may develop in the membranes at a distance from the main placenta (Fig. 6-1). These lobes have vessels that course through the membranes. Of clinical importance, if these vessels overlie the cervix to create a vasa previa, dangerous fetal hemorrhage can follow vessel laceration (Remnants and Cysts). An accessory lobe can also be retained in the uterus after delivery to cause postpartum uterine atony and hemorrhage or later endometritis.

FIGURE 6-1

Succenturiate lobe. **A.** Vessels extend from the main placental disc to supply the small round succenturiate lobe located beneath it. (Used with permission from Dr. Jaya George.) **B.** Sonographic imaging with color Doppler shows the main placental disc implanted posteriorly (*asterisk*). The succenturiate lobe is located on the anterior uterine wall across the amnionic cavity. Vessels are identified as the long red and blue crossing tubular structures that travel within the membranes to connect these two portions of placenta.

Rarely, the placental surface area varies from the norm. With placenta membranacea, villi cover all or nearly all the uterine cavity. This may occasionally give rise to serious hemorrhage because of associated placenta previa or accreta (Greenberg, 1991; Pereira, 2013). A ring-shaped placenta may be a variant of placenta membranacea. This placenta is annular, and a partial or complete ring of placental tissue is present. These abnormalities appear to be associated with a greater likelihood of antepartum and postpartum bleeding and fetal-growth restriction (Faye-Petersen, 2006; Steemers, 1995). With placenta fenestrata, the central

portion of a placental disc is missing. In some instances, there is an actual hole in the placenta, but more often, the defect involves only villous tissue, and the chorionic plate remains intact. Clinically, it may erroneously prompt a search for a retained placental cotyledon.

During pregnancy, the normal placenta increases its thickness at a rate of approximately 1 mm per week. Although not measured as a component of routine sonographic evaluation, this thickness typically does not exceed 40 mm (Hoddick, 1985). *Placentomegaly* defines those thicker than 40 mm and commonly results from striking villous enlargement. This may be secondary to maternal diabetes or severe maternal anemia, or to fetal hydrops, anemia, or infection caused by syphilis, toxoplasmosis, parvovirus, or cytomegalovirus. In these conditions, the placenta is homogeneously thickened. Less commonly with placentomegaly, fetal parts are present, but villi are edematous and appear as small placental cysts, such as in cases of partial mole (Chap. 20, Diagnosis). Cystic vesicles are also seen with *placental mesenchymal dysplasia*. Vesicles in this rare condition correspond to enlarged stem villi, but unlike molar pregnancy, trophoblast proliferation is not excessive (Woo, 2011).

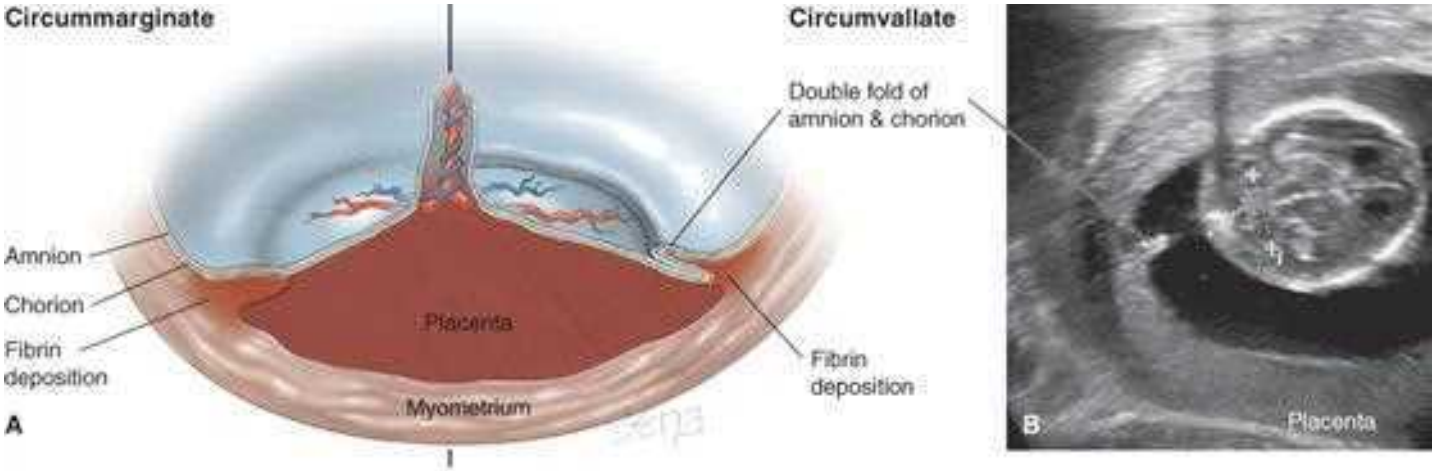
Rather than villous enlargement, placentomegaly often may result from collections of blood or fibrin, which impart heterogeneity to the placenta. Examples of this are discussed in Maternal Blood Flow Disruption and include massive perivillous fibrin deposition, intervillous or subchorionic thromboses, and large retroplacental hematomas.

EXTRACHORIAL PLACENTATION

The chorionic plate normally extends to the periphery of the placenta and has a diameter similar to that of the basal plate. With extrachorial placentation, however, the chorionic plate fails to extend to this periphery and leads to a chorionic plate that is smaller than the basal plate (Fig. 6-2). Circummarginate and circumvallate placentas are the two types. In a *circummarginate placenta*, fibrin and old hemorrhage lie between the placenta and the overlying sheer amniochorion. In contrast, with a *circumvallate placenta*, the chorion periphery is a thickened, opaque, gray-white circular ridge composed of a double fold of chorion and amnion. Sonographically, the double fold can be seen as a thick, linear band of echoes extending from one placental edge to the other. On cross section, however, it appears as two "shelves," with each lying above an opposing placental margin (see Fig. 6-2). This anatomy can help differentiate this shelf from amnionic bands and amnionic sheets, which are described in Amniochorion.

FIGURE 6-2

A. In this illustration, circummarginate (*left*) and circumvallate (*right*) varieties of extrachorial placentation are shown. A circummarginate placenta is covered by a single layer of amniochorion. **B.** This transabdominal gray-scale sonographic image shows a circumvallate placenta. The double fold of amnion and chorion creates a broad, opaque white ring and ridge on the fetal surface.



In relatively small observational studies of circumvallate placenta diagnosed postpartum, it was associated with increased risk for antepartum bleeding, abruption, fetal demise, and preterm birth (Lademacher, 1981; Suzuki, 2008; Taniguchi, 2014). In a prospective sonographic investigation of 17 cases, however, Shen and associates (2007a) found most circumvallate placentas to be transient. Persistent cases were benign. In general, most otherwise uncomplicated pregnancies with either type of extrachorial placentation have normal outcomes, and no increased surveillance is usually required.

CIRCULATORY DISTURBANCES

Functionally, placental perfusion disorders can be grouped into: (1) those in which maternal blood flow to or within the intervillous space is disrupted, and (2) those with disturbed fetal blood flow through the villi. These lesions are frequently identified in the normal, mature placenta. Although they can limit maximal placental blood flow, functional reserve within the placental prevents harm in most cases. Indeed, some estimate that up to 30 percent of placental villi can be lost without untoward fetal effects (Fox, 2007). If extensive, however, these lesions can profoundly limit fetal growth.

Lesions that disrupt perfusion are frequently seen grossly or sonographically, whereas smaller lesions are seen only histologically. With sonography, many of these, such as subchorionic fibrin deposition, perivillous fibrin deposition, and intervillous thrombosis, appear as focal sonolucencies within the placenta. Importantly, in the absence of maternal or fetal complications, isolated placental sonolucencies are considered incidental findings.

Maternal Blood Flow Disruption

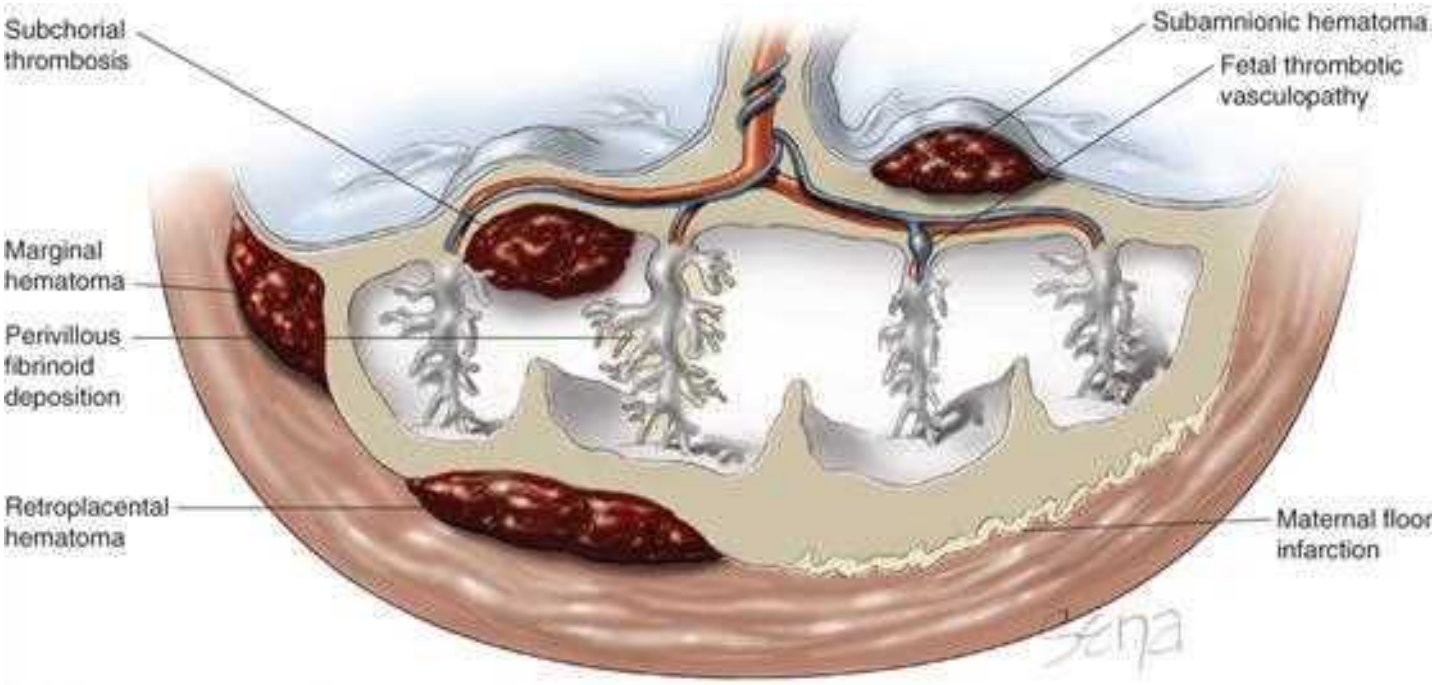
Subchorionic Fibrin Deposition

These collections are caused by slowing of maternal blood flow within the intervillous space. In the portion of this space near the chorionic plate, blood stasis is prominent and leads to subsequent fibrin deposition. In viewing the placental fetal surface, subchorionic lesions are commonly seen as white or yellow, firm, round, elevated plaques just beneath the chorionic plate.

Perivillous Fibrin Deposition

Stasis of maternal blood flow around an individual villus also results in fibrin deposition and can lead to diminished villous oxygenation and necrosis of syncytiotrophoblast (Fig. 6-3). These small yellow-white placental nodules are grossly visible within the parenchyma of a sectioned placenta. Within limits, these reflect normal placental aging.

FIGURE 6-3
Potential sites of maternally and fetally related placental circulatory disturbances. (Adapted from Faye-Petersen, 2006.)



Maternal Floor Infarction

This extreme variant of perivillous fibrin deposition is a dense fibrinoid layer within the placental basal plate and is erroneously termed an infarction. *Maternal floor infarction* has a thick, yellow or white, firm corrugated surface that impedes normal maternal blood flow into the intervillous space. In specific cases that extend beyond the basal plate to entrap villi and obliterate the intervillous space, the term *massive perivillous fibrin deposition* is used. The etiopathogenesis is unclear, but maternal auto- or alloimmunity appears contributory (Faye-Peterson, 2017; Romero, 2013). Antiphospholipid antibody syndrome and angiogenic factors involved with preeclampsia have also been implicated (Sebire, 2002, 2003; Whitten, 2013).

These lesions are not reliably imaged with prenatal sonography, but they may create a thicker basal plate. Affected pregnancies are associated with miscarriage, fetal-growth restriction, preterm delivery, and stillbirth (Andres, 1990; Mandsager, 1994). Importantly, these adverse outcomes can recur in subsequent pregnancies.

Intervillous Thrombus

This is a collection of coagulated maternal blood normally found in the intervillous space mixed with fetal blood from a break in a villus. Grossly, these round or oval collections vary in size up to several centimeters. They appear red if recent or white-yellow if older, and they develop at any placental depth. Intervillous thrombi are common and typically not associated with adverse fetal sequelae. Because there is potential for a communication between maternal and fetal circulations, large lesions can cause elevated maternal serum alpha-fetoprotein levels (Salafia, 1988).

Infarction

Chorionic villi themselves receive oxygen solely from maternal circulation supplied to the intervillous space. Any uteroplacental disease that diminishes or obstructs this supply can result in infarction of an individual villus. These are common lesions in mature placentas and are benign in limited numbers. If

numerous, however, placental insufficiency can develop. When they are thick, centrally located, and randomly distributed, they may be associated with preeclampsia or lupus anticoagulant.

Hematoma

As depicted in Figure 6-3, the maternal-placental-fetal unit can develop several hematoma types. These include: (1) retroplacental hematoma—between the placenta and its adjacent decidua; (2) marginal hematoma—between the chorion and decidua at the placental periphery—known clinically as subchorionic hemorrhage; (3) subamnionic hematoma—these are of fetal vessel origin and found beneath the amnion but above the chorionic plate, and (4) subchorial thrombus along the roof of the intervillous space and beneath the chorionic plate. With this last type, *massive subchorionic hematomas* are also known as a *Breus mole.*

Sonographically, hematomas evolve with time and appear hyperechoic to isoechoic in the first week after hemorrhage, hypoechoic at 1 to 2 weeks, and finally, anechoic after 2 weeks. Most subchorionic hematomas visible sonographically are fairly small and of no clinical consequence. However, extensive retroplacental, marginal, and subchorial collections have been associated with higher rates of miscarriage, stillbirth, placental abruption, and preterm delivery (Ball, 1996; Fung, 2010; Madu, 2006; Tuuli, 2011). In essence, placental abruption is a large, clinically significant retroplacental hematoma.

Fetal Blood Flow Disruption

Fetal Thrombotic Vasculopathy

Placental lesions that arise from fetal circulatory disturbances are also depicted in Figure 6-3. Deoxygenated fetal blood flows from the two umbilical arteries into arteries within the chorionic plate that divide and send branches out across the placental surface. These eventually supply individual stem villi, and their thrombosis will obstruct fetal blood flow. Distal to the obstruction, affected portions of the villus become nonfunctional. Thrombi in limited numbers are normally found in mature placentas. If many villi are affected, which can be seen with preeclampsia, the fetus may suffer growth restriction, stillbirth, or nonreassuring fetal heart rate patterns (Chisholm, 2015; Lepais, 2014; Saleemuddin, 2010).

Villous Vascular Lesions

There is a spectrum of villous capillary lesions. *Chorangiosis* describes an increased number of capillaries within terminal villi. Its definition requires ≥10 capillaries to be present in ≥10 villi in ≥10 fields viewed through a 10× microscope lens (Altshuler, 1984). Clinically, long-standing hypoperfusion or hypoxia is thought to be causative (Stanek, 2016). It is often associated with maternal diabetes mellitus (Ogino, 2000). *Chorangiomatosis* describes increased capillary number in stem villi, but terminal villi are spared. This finding has been linked with fetal-growth restriction and anomalies (Bagby, 2011). Despite these associations, the clinical significance of both vascular conditions remains unclear. *Chorioangiomas* are described subsequently.

Subamnionic Hematoma

As indicated earlier, these hematomas lie between the chorionic plate and amnion. They most often are acute events during third-stage labor when cord traction ruptures a vessel near the cord insertion.

Large chronic antepartum lesions may cause fetomaternal hemorrhage or fetal-growth restriction (Deans, 1998). They also may be confused with other placental masses such as chorioangioma. In most cases, Doppler interrogation will show absent internal blood flow within a hematoma and permit differentiation (Sepulveda, 2000).

PLACENTAL CALCIFICATION

Calcium salts can be deposited throughout the placenta but are most common on the basal plate. Calcification accrues with advancing gestation, and greater degrees are associated with smoking and increasing maternal serum calcium levels (Bedir Findik, 2015; Klesges, 1998; McKenna, 2005). These hyperechoic deposits can easily be seen sonographically, and a grading scale from 0 to 3 reflects increasing calcification with increasing numerical grade (Grannum, 1979). Following this scheme, a grade 0 placenta is homogeneous, lacks calcification, and displays a smooth, flat chorionic plate. A grade 1 placenta has scattered echogenicities and subtle chorionic plate undulations. Grade 2 shows echogenic stippling at the basal plate. Large, echogenic comma shapes originate from an indented chorionic plate, but their curve falls short of the basal plate. Last, a grade 3 placenta has echogenic indentations extending from the chorionic plate to the basal plate, which create discrete components that resemble cotyledons. Basal plate densities also increase.

As a predictor, this grading scale is not useful for neonatal outcome near term (Hill, 1983; McKenna, 2005; Montan, 1986). However, data from two small studies link grade 3 placenta prior to 32 weeks with stillbirth and some other adverse pregnancy outcomes (Chen, 2011, 2015).

PLACENTAL TUMORS

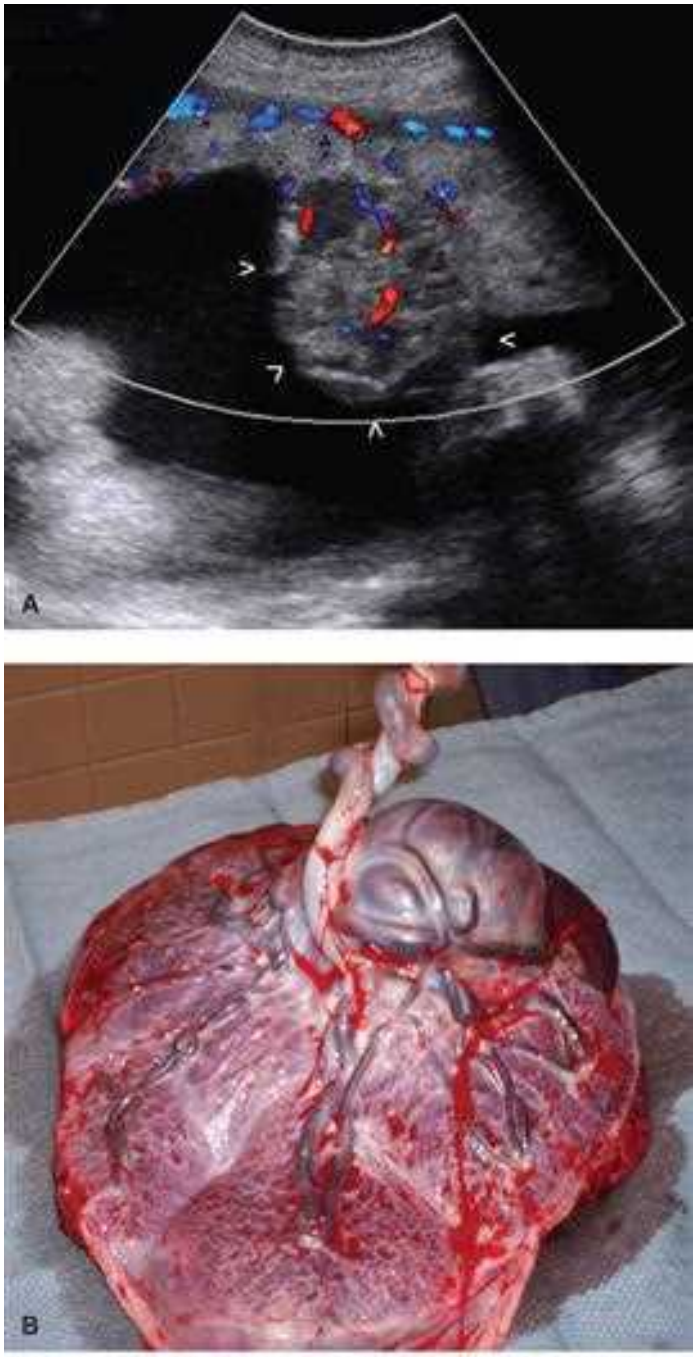
Chorioangioma

These benign tumors have components similar to blood vessels and stroma of the chorionic villus. Also called chorangiomas, these placental tumors occur with an incidence of approximately 1 percent (Guschmann, 2003). In some cases, fetal-to-maternal hemorrhage across tumor capillaries leads to elevated levels of maternal serum alpha-fetoprotein (MSAFP), prompting sonographic evaluation. Their characteristic sonographic appearance shows a well-circumscribed,

rounded, predominantly hypoechoic lesion lying near the chorionic plate and protruding into the amnionic cavity (Fig. 6-4). Documenting increased blood flow by color Doppler helps to distinguish these lesions from other placental masses such as hematoma, partial hydatidiform mole, teratoma, metastases, and leiomyoma (Prapas, 2000). Although rare, *chorangiocarcinoma* tumors clinically mirror chorangiomas (Huang, 2015).

FIGURE 6-4

Placental chorioangioma. **A.** Color Doppler imaging displays blood flow through a large chorioangioma with its border outlined by white arrows. **B.** Grossly, the chorioangioma is a round, well-circumcised mass protruding from the fetal surface.



Small chorioangiomas are usually asymptomatic. Large tumors, typically those measuring >4 cm, can create significant arteriovenous shunting within the placenta to cause high-output heart failure, hydrops, and fetal death (Al Wattar, 2014). Compression of fetal erythrocytes within tumor vessels can lead to hemolysis and microangiopathic anemia (Bauer, 1978). Hydramnios, preterm delivery, and fetal-growth restriction are other sequelae. Rare cases include tumor vessel rupture, hemorrhage, and fetal death (Batukan, 2001). At the other extreme, rare tumor infarction can lead to symptom reversal (Zalel, 2002).

Gray-scale and color Doppler interrogation of the placenta and amnionic fluid volume are used to identify these tumors. Diagnostic tools that can affirm associated fetomaternal hemorrhage include MSAFP level and Kleihauer-Betke stain. With fetal concern, echocardiography assesses cardiac function, whereas middle cerebral artery interrogation is used to identify fetal anemia.

Several fetal therapies interfere with the vascular supply to the tumor and reverse fetal heart failure. At specialized perinatal centers, endoscopic laser ablation of feeder vessels to the tumor is most frequently used and is associated with favorable fetal outcomes (Hosseinzadeh, 2015). Of other therapy, fetal transfusion can treat serious anemia, amnioreduction can temporize hydramnios, and digoxin therapy can assist fetal heart failure.

Metastatic Tumors

Maternal malignant tumors rarely metastasize to the placenta. Of those that do, melanomas, leukemias and lymphomas, and breast cancer are the most common (Al-Adnani, 2007). Tumor cells usually are confined within the intervillous space. As a result, metastasis to the fetus is uncommon but is most often seen with melanoma (Alexander, 2003).

Similarly, cases in which fetal malignancy metastasizes to the placenta are rare (Reif, 2014). These are predominantly fetal neuroectodermal tumors, and only one case in the literature describes transplantation of tumor to the maternal uterus (Nath, 1995).

AMNIOCHORION

Chorioamnionitis

Normal genital-tract flora can colonize and infect the membranes, umbilical cord, and eventually the fetus. Bacteria most commonly ascend after prolonged membrane rupture and during labor to cause infection. Organisms initially infect the chorion and adjacent decidua in the area overlying the internal os. Subsequently, progression leads to full-thickness involvement of the membranes—chorioamnionitis. Organisms often then spread along the chorioamnionic surface to colonize and replicate in amniotic fluid. Inflammation of the chorionic plate and of the umbilical cord—*funisitis*—may follow (Kim, 2015; Redline, 2012).

Most commonly, there is microscopic or occult chorioamnionitis, which is caused by a wide variety of microorganisms. This is frequently cited as a possible explanation for many otherwise unexplained cases of ruptured membranes, preterm labor, or both as discussed in Chapter 42 (Cervical Dysfunction). In some cases, gross infection is characterized by membrane clouding and is sometimes accompanied by a foul odor that depends on bacterial species.

Other Membrane Abnormalities

Amnion nodosum is a condition characterized by numerous small, light-tan nodules on the amnion overlying the chorionic plate. These may be scraped off the fetal surface and contain deposits of fetal squames and fibrin that reflect prolonged and severe oligohydramnios (Adeniran, 2007).

Two notable bandlike structures can be formed by the fetal membranes. Of these, *amnionic band sequence* is an anatomical disruption sequence in which amnion bands tether, constrict, or amputate fetal parts. Amnionic bands commonly cause limb-reduction defects, facial clefts, or encephalocele (Barzilay, 2015; Guzmán-Huerta, 2013). Umbilical cord compromise is another sequela (Barros, 2014; Heifetz, 1984b). Severe defects of the spine or ventral wall that accompany amnionic bands suggest a *limb-body wall complex*, described in Chapter 10 (Gastrointestinal Tract).

Clinically, sonography often first identifies the sequelae of this sequence rather than the bands themselves. As with any fetal anomaly, targeted sonography is indicated. Identification of a limb-reduction defect, an encephalocele in an atypical location, or an extremity with edema or positional deformity should prompt careful evaluation for amnionic bands.

Management depends on the degree of anatomic deformity. Fetoscopic laser interruption of the band may be suitable in highly selected antepartum cases (Javadian, 2013; Mathis, 2015).

In contrast, an *amnionic sheet* is formed by normal amniochorion draped over a preexisting uterine synechia. Generally, these sheets pose little fetal risk, although slightly higher rates of preterm membrane rupture and placental abruption have been described (Korbin, 1998; Nelson, 2010; Tuuli, 2012).

UMBILICAL CORD

Length

Most umbilical cords at delivery are 40 to 70 cm long, and very few measure <30 cm or >100 cm. Cord length is influenced positively by both amnionic fluid volume and fetal mobility (Miller, 1982). In retrospective studies, short cords have been linked with congenital malformations and intrapartum distress (Baergen, 2001; Krakowiak, 2004; Yamamoto, 2016). Excessively long cords are linked with cord entanglement or prolapse and with fetal anomalies (Olaya-C, 2015; Rayburn, 1981).

Because antenatal determination of cord length is technically limited, cord diameter has been evaluated as a predictive marker for fetal outcomes. Some have linked lean cords with poor fetal growth and large-diameter cords with macrosomia (Proctor, 2013). However, the clinical utility of this parameter is still unclear (Barbieri, 2008; Cromi, 2007; Raio, 1999b, 2003).

Coiling

Cord coiling characteristics have been reported but are not currently part of standard sonographic evaluation. Usually the umbilical vessels spiral through the cord in a sinistral, that is, left-twisting direction (Fletcher, 1993; Lacro, 1987). The number of complete coils per centimeter of cord length is termed the *umbilical*

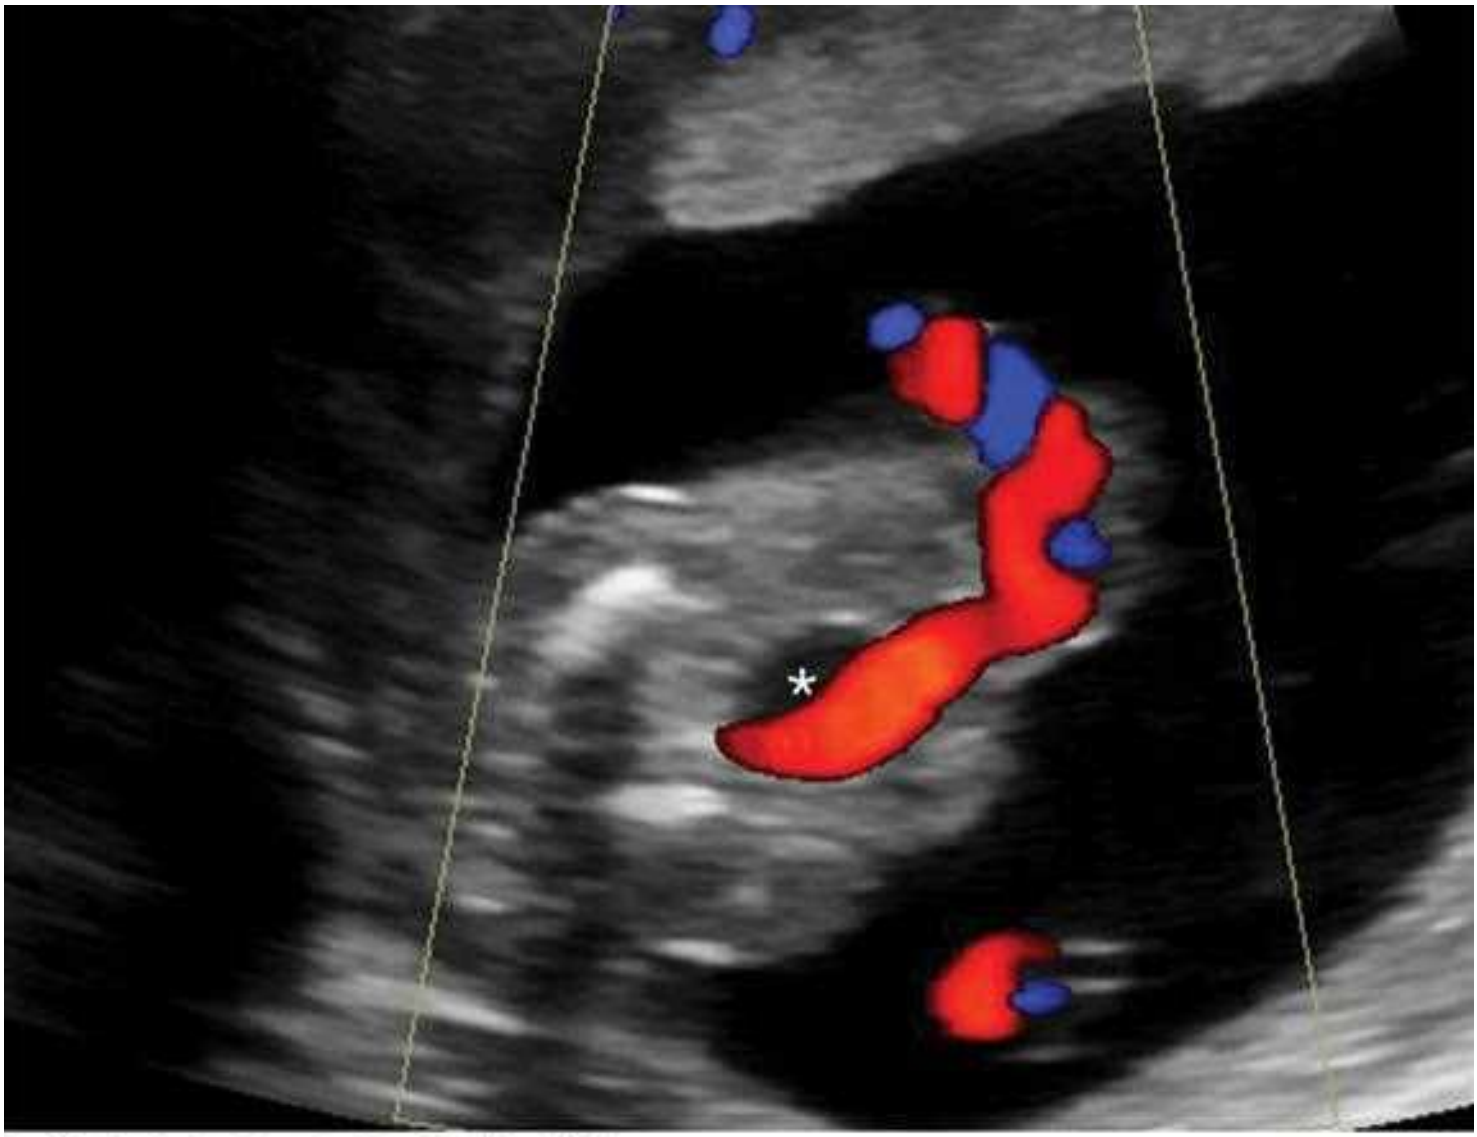
coiling index—UCI (Strong, 1994). A normal, antepartum, sonographically derived UCI is 0.4, and this contrasts with a normal, postpartum, physically measured value of 0.2 (Sebire, 2007). UCIs <10th percentile are considered *hypocoiled,* and those >90th percentile are *hypercoiled.* Clinically, the significance of coiling extremes is controversial. Some studies evaluating large, unselected cohorts find no associations between UCI values and poor neonatal outcome (Jessop, 2014; Pathak, 2010). In others, extremes are linked with various adverse outcomes but most consistently with intrapartum fetal heart rate abnormalities, preterm labor, or fetal-growth restriction (Chitra, 2012; de Laat, 2006; Predanic, 2005; Rana, 1995).

Vessel Number

Counting cord vessel number is a standard component of anatomical evaluation during fetal sonographic examination and immediately after delivery (Fig. 6-5). Embryos initially have two umbilical veins. In the first trimester, the right vein typically atrophies to leave one large vein to accompany the two, thick-walled umbilical arteries. Four-vessel cords are rare and often associated with congenital anomalies (Puvabanditsin, 2011). If it is an isolated finding, however, prognosis can be good (Avnet, 2011).

FIGURE 6-5

Two umbilical arteries are typically documented sonographically in the second trimester. They encircle the fetal bladder (*asterisk*) as extensions of the superior vesical arteries. In this color Doppler sonographic image, a single umbilical artery, shown in red, runs along the bladder wall before joining the umbilical vein (blue) in the cord. Below this, the two vessels of the cord, seen as a larger red and smaller blue circle, are also seen floating in a cross section of a cord segment.



The most common aberration is that of a single umbilical artery (SUA), with a cited incidence of 0.63 percent in liveborn neonates, 1.92 percent with perinatal deaths, and 3 percent in twins (Heifetz, 1984a). Fetuses with major malformations frequently have a single artery. Thus, its identification often prompts consideration for targeted sonography and possibly fetal echocardiography. The most frequent anomalies are cardiovascular and genitourinary (Hua, 2010; Murphy-Kaulbeck, 2010). In an anomalous fetus, a single artery greatly increases the aneuploidy risk, and amniocentesis is recommended (Dagklis, 2010; Lubusky, 2007).

If target sonography finds otherwise normal anatomy, an isolated single artery in an otherwise low-risk pregnancy does not significantly increase the fetal aneuploidy risk. However, as in isolated finding, it has been associated with fetal-growth restriction and perinatal death in some but not all studies (Chetty-John, 2010; Gutvirtz, 2016; Hua, 2010; Murphy-Kaulbeck, 2010; Voskamp, 2013). Thus, while clinical monitoring of growth is reasonable, the value of sonographic surveillance is unclear.

A rare anomaly is that of a fused umbilical artery with a shared lumen. It arises from failure of the two arteries to split during embryological development. The common lumen may extend through the entire cord, but, if partial, it is typically found near the placental insertion site (Yamada, 2005). In one report, these were associated with a higher incidence of marginal or velamentous cord insertion, but not congenital fetal anomalies (Fujikura, 2003).

Found in most placentas, the *Hyrtl anastomosis* is a connection between the two umbilical arteries and lies near the cord insertion into the placenta. This anastomosis acts as a pressure-equalizing system between the arteries (Gordon, 2007). As a result, redistribution of pressure gradients and blood flow improves placental perfusion, especially during uterine contractions or during compression of one umbilical artery. Fetuses with a single umbilical artery lack this safety valve (Raio, 1999a, 2001).

Remnants and Cysts

Several structures are housed in the umbilical cord during fetal development, and their remnants may be seen when the mature cord is viewed transversely. Indeed, Jauniaux and colleagues (1989) sectioned 1000 cords, and in one fourth of the specimens, they found remnants of vitelline duct, allantoic duct, and embryonic vessels. These were not associated with congenital malformations or perinatal complications.

Cysts occasionally are found along the course of the cord. They are designated according to their origin. *True cysts* are epithelium-lined remnants of the allantoic or vitelline ducts and tend to be located closer to the fetal insertion site. In contrast, the more common *pseudocysts* form from local degeneration of Wharton jelly and occur anywhere along the cord. Both have a similar sonographic appearance. Single umbilical cord cysts identified in the first trimester tend to resolve completely, however, multiple cysts may portend miscarriage or aneuploidy (Ghezzi, 2003; Hannaford, 2013). Cysts persisting beyond this time are associated with a risk for structural defects and chromosomal anomalies (Bonilla, 2010; Zangen, 2010).

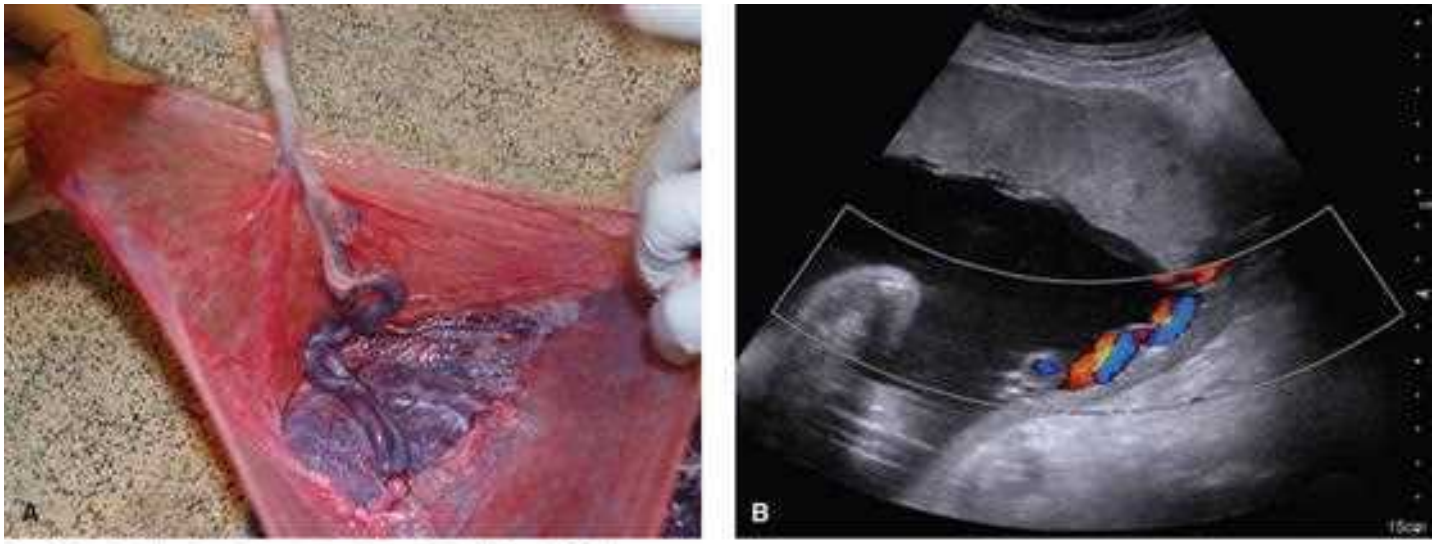
Insertion

The cord normally inserts centrally into the placental disc, but eccentric, marginal, or velamentous insertions are variants. Of these, eccentric insertions in general pose no identifiable fetal risk. Marginal insertion is a common variant—sometimes referred to as a *battledore placenta*—in which the cord anchors at the placental margin. In one population-based study, the rate was 6 percent in singleton gestations and 11 percent in twins (Ebbing, 2013). This common insertion variant rarely causes problems, but it and velamentous insertion occasionally result in the cord being pulled off during delivery of the placenta (Ebbing, 2015; Luo, 2013). In monochorionic twins, this insertion may be associated with weight discordance (Kent, 2011).

With velamentous insertion, the umbilical vessels characteristically travel within the membranes before reaching the placental margin (Fig. 6-6) The incidence of velamentous insertion approximates 1 percent but is 6 percent with twins (Ebbing, 2013). It is more commonly seen with placenta previa (Papinniemi, 2007; Räisänen, 2012). Antenatal diagnosis is possible sonographically, and with velamentous insertion, cord vessels are seen traveling along the uterine wall before entering the placental disc. Clinically, vessels are vulnerable to compression, which may lead to fetal hypoperfusion and acidemia. Higher associated rates of low Apgar scores, stillbirth, preterm delivery, and small for gestational age have been noted (Ebbing, 2017; Esakoff, 2015; Heinonen, 1996; Vahanian, 2015). Accordingly, monitoring of fetal growth is reasonable either clinically or sonographically (Vintzileos, 2015).

FIGURE 6-6

Velamentous cord insertion. **A.** The umbilical cord inserts into the membranes. From here, the cord vessels branch and are supported only by membrane until they reach the placental disc. **B.** When viewed sonographically and using color Doppler, the cord vessels appear to lie against the myometrium as they travel to insert marginally into the placental disc, which lies at the top of this image.



Last, with the very uncommon furcate insertion, umbilical vessels lose their protective Wharton jelly shortly before they insert. As a result, they are covered only by an amnion sheath and prone to compression, twisting, and thrombosis.

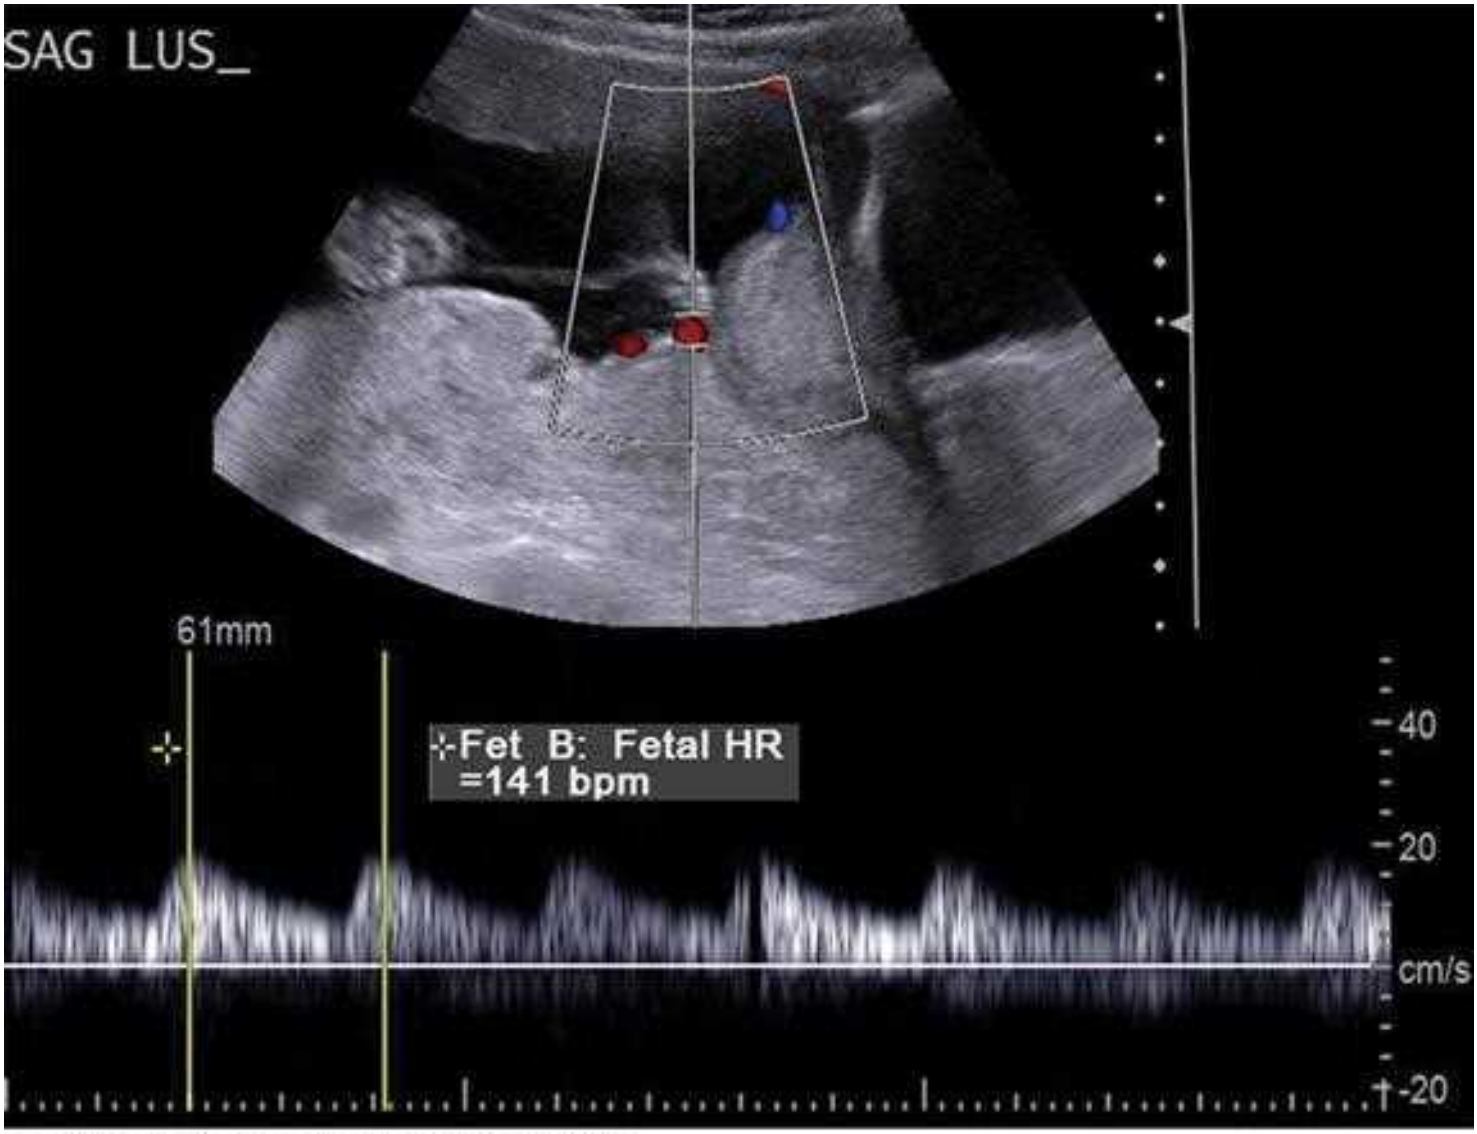
Vasa Previa

With this condition, vessels travel within the membranes and overlie the cervical os. There, they can be torn with cervical dilatation or membrane rupture, and laceration can lead to rapid fetal exsanguination. Over the cervix, vessels can also be compressed by a presenting fetal part. Fortunately, vasa previa is uncommon and has an incidence of 2 to 6 per 10,000 pregnancies (Ruiter, 2016; Sullivan, 2017). Vasa previa is classified as type 1, in which vessels are part of a velamentous cord insertion, and type 2, in which involved vessels span between portions of a bilobate or a succenturiate placenta (Catanzarite, 2001). Two other risks are conception with in vitro fertilization and second-trimester placenta previa, with or without later migration (Baulies, 2007; Schachter, 2003).

Compared with intrapartum diagnosis, antepartum diagnosis greatly improves the perinatal survival rate, which ranges from 97 to 100 percent (Oyelese, 2004; Rebarber, 2014; Swank, 2016). Thus, vasa previa is ideally identified early, although this is not always possible. Clinically, an examiner is occasionally able to palpate or directly see a tubular fetal vessel in the membranes overlying the presenting part. Effective screening for vasa previa begins during scheduled midtrimester sonographic examination. In suspicious cases, transvaginal sonography is added and shows cord vessels inserting into the membranes—rather than directly into the placenta—and vessels running above the cervical internal os (Fig. 6-7). Routine color Doppler interrogation of the placental cord insertion site, particularly in cases of placenta previa or low-lying placenta, may aid its detection. With this, the vessel waveform reflects the fetal heart rate. In one systematic review, the median prenatal detection rate was 93 percent (Ruiter, 2015).

FIGURE 6-7

Vasa previa. Using color Doppler, an umbilical vessel (*red circle*) is seen overlying the internal os. At the bottom, the Doppler waveform seen with this vasa previa has the typical appearance of an umbilical artery, with a pulse rate of 141 beats per minute.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Once vasa previa is identified, subsequent imaging is reasonable because 6 to 17 percent of cases ultimately resolve (Rebarber, 2015; Swank, 2016). Bed rest apparently has no added advantage. Antenatal corticosteroids can be provided as indicated or given prophylactically at 28 to 32 weeks' gestation to cover possible urgent preterm delivery. Antenatal hospitalization may be considered at 30 to 34 weeks to permit surveillance and expedited delivery for labor, bleeding, or rupture of membranes. Data supporting this is limited, and admission may best serve women with risk factors that portend early delivery (Society for Maternal-Fetal Medicine, 2015). A few cases of antepartum fetoscopic surgery with vessel laser ablation are described (Hosseinzadeh, 2015; Johnston, 2014). However, current practice is early scheduled cesarean delivery. Robinson and Grobman (2011) performed a decision analysis and recommend elective cesarean delivery at 34 to 35 weeks' gestation to balance the risks of perinatal exsanguination versus preterm birth morbidity. The Society for Maternal-Fetal Medicine (2015) considers planned cesarean delivery at 34 to 37 weeks' gestation reasonable.

At delivery, the fetus is expeditiously delivered after the hysterotomy incision in case a vessel is lacerated during uterine entry. Delayed cord clamping is not encouraged.

In all pregnancies, otherwise unexplained vaginal bleeding either antepartum or intrapartum should prompt consideration of vasa previa and a lacerated fetal vessel. In many cases, bleeding is rapidly fatal, and infant salvage is not possible. With less hemorrhage, however, it may be possible to distinguish fetal versus maternal bleeding. Various tests may be used, and each relies on the increased resistance of fetal hemoglobin to denaturing by alkaline or acid reagents (Odunsi, 1996; Oyelese, 1999).

Knots, Strictures, and Loops

Various mechanical abnormalities in the cord can impede blood flow and sometimes cause fetal harm. Of these, *true knots* are found in approximately 1 percent of births. These form from fetal movement, and associated risks include hydramnios and diabetes (Hershkovitz, 2001; Räisänen, 2013). Knots are especially common and dangerous in monoamnionic twins, which are discussed in Chapter 45 (Unique Fetal Complications). When true knots are associated with singleton fetuses, the stillbirth risk is increased four- to tenfold (Airas, 2002; Sørnes, 2000).

Knots can be found incidentally during antepartum sonography, and a “hanging noose” sign is suggestive (Ramon y Cajal, 2006). Three-dimensional and color Doppler aid diagnostic accuracy (Hasbun, 2007). With these knots, optimal fetal surveillance is unclear but may include umbilical artery Doppler velocimetry, nonstress testing, or subjective fetal movement monitoring (Rodriguez, 2012; Scioscia, 2011). Allowing vaginal delivery is suitable, but abnormal intrapartum fetal heart rate tracings are more often encountered. That said, cesarean delivery rates are not increased, and cord blood acid-base values are usually normal (Airas, 2002; Maher, 1996).

In contrast, *false knots* form from focal redundancy and folding of an umbilical cord vessel. These lack clinical significance.

Cord strictures are focal narrowings of the diameter that usually develop near the fetal cord insertion site (Peng, 2006). Characteristic pathological features include an absence of Wharton jelly and stenosis or obliteration of cord vessels at the narrow segment (Sun, 1995). In most instances, the fetus is stillborn (French, 2005). Even less common is a cord stricture caused by an amnionic band.

Cord loops are frequently encountered and are caused by coiling around various fetal parts during movement. A cord around the neck—a *nuchal cord*—is common, and vaginal delivery is suitable. One loop is reported in 20 to 34 percent of deliveries; two loops in 2.5 to 5 percent; and three loops in 0.2 to 0.5 percent (Kan, 1957; Sørnes, 1995; Spellacy, 1966). During labor, up to 20 percent of fetuses with a nuchal cord have moderate to severe variable heart rate decelerations, and these are associated with a lower umbilical artery pH (Hankins, 1987). Cords wrapped around the body can have similar effects (Kobayashi, 2015). Despite their frequency, nuchal cords are not associated with greater rates of adverse perinatal outcome (Henry, 2013; Sheiner, 2006).

Last, a *funic presentation* describes when the umbilical cord is the presenting part in labor. These are uncommon and most often are associated with fetal malpresentation (Kinugasa, 2007). A funic presentation in some cases is identified with placental sonography and color flow Doppler (Ezra, 2003). Overt or occult cord prolapse can complicate labor. Thus, once identified at term, cesarean delivery is typically recommended.

Vascular

Cord hematomas are rare and generally follow rupture of an umbilical vessel, usually the vein, and bleeding into the Wharton jelly. Hematomas have been associated with abnormal cord length, umbilical vessel aneurysm, trauma, entanglement, umbilical vessel venipuncture, and funisitis (Gualandri, 2008). Most are identified postpartum, but hematomas are recognized sonographically as hypoechoic masses that lack blood flow (Chou, 2003). Sequelae include stillbirth or intrapartum abnormal fetal heart rate pattern (Abraham, 2015; Barbati, 2009; Sepulveda, 2005; Towers, 2009).

Umbilical cord vessel thromboses are rare in utero events and seldom diagnosed antepartum. Approximately 70 percent are venous, 20 percent are venous and arterial, and 10 percent are arterial thromboses (Heifetz, 1988). These all have high associated rates of stillbirth, fetal-growth restriction, and intrapartum fetal distress (Minakami, 2001; Sato, 2006; Shilling, 2014). If these are identified antepartum as hypoechoic masses without blood flow, data from case reports support consideration of prompt delivery if of viable age (Kanenishi, 2013).

An *umbilical vein varix* can complicate either the intraamnionic or fetal intraabdominal portion of the umbilical vein. Sonographically and complemented by color Doppler, rare intraamnionic varices show cystic dilatation of the umbilical vein that is contiguous with a normal-caliber portion. Of complications, an intraamnionic varix may compress an adjacent umbilical artery or can rupture or thrombose. In cases without these, White and colleagues (1994) recommend fetal surveillance and delivery once fetal maturity is confirmed. However, data are limited and derived from case reports.

The rare *umbilical artery aneurysm* is caused by congenital thinning of the vessel wall with diminished support from Wharton jelly. Indeed, most form at or near the cord placental insertion site, where this support is absent. These are associated with single umbilical artery, trisomy 18, amnionic fluid volume extremes, fetal-growth restriction, and stillbirth (Hill, 2010; Vyas, 2016). At least theoretically, these aneurysms could cause fetal compromise and death by compression of the umbilical vein. These aneurysms may appear sonographically as a cyst with a hyperechoic rim. Within the aneurysm, color flow and spectral Doppler interrogation demonstrate either low-velocity or turbulent nonpulsatile flow (Olog, 2011; Sepulveda, 2003; Shen, 2007b). Although not codified, management may include fetal karyotyping, antenatal fetal surveillance, and early delivery to prevent stillbirth (Doehrman, 2014).

CHAPTER 7: Embryogenesis and Fetal Development

Our knowledge concerning the physiology of the foetus has been markedly enriched during recent years; nevertheless, when compared with the adult, it offers many points concerning which we are but slightly informed or profoundly ignorant.

—J. Whitridge Williams (1903)

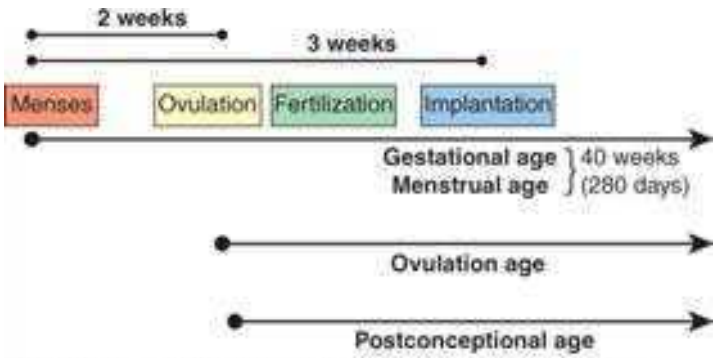
INTRODUCTION

Since these words were written by Williams in 1903, great strides in the understanding of fetal organogenesis and physiology have been gained. Contemporary obstetrics incorporates physiology and pathophysiology of the fetus, its development, and its environment. An important result is that fetal status has been elevated to that of a patient who, in large measure, can be given the same meticulous care that obstetricians provide for gravidas. In our 25th edition, the entirety of Section 5 is dedicated to the fetal patient, as are individual chapters in other sections. Indeed, virtually every aspect of obstetrics can affect the developing fetus.

GESTATIONAL AGE

Several terms define pregnancy duration and thus fetal age (Fig. 7-1). *Gestational age* or *menstrual age* is the time elapsed since the first day of the last menstrual period (LMP), a time that actually precedes conception. This starting time, which is usually approximately 2 weeks before ovulation and fertilization and nearly 3 weeks before blastocyst implantation, has traditionally been used because most women know their approximate last period. Embryologists describe embryofetal development in *ovulation age,* or the time in days or weeks from ovulation. Another term is *postconceptional age,* which is nearly identical to ovulation age.

FIGURE 7-1
Terminology used to describe pregnancy duration.



Until recently, clinicians customarily calculated menstrual age with term pregnancy averaging approximately 280 days, or 40 weeks between the first day of the LMP and birth. This corresponds to 9 and 1/3 calendar months. However, menstrual cycle length variability among women renders many of these calculations inaccurate. This realization, combined with the frequent use of first-trimester sonography, has led to more accurate gestational age determination (Duryea, 2015). Much of this change hinges on the accuracy of early sonographic measurement. As a result, the American College of Obstetricians and Gynecologists, the American Institute of Ultrasound in Medicine, and the Society for Maternal-Fetal Medicine (Reddy, 2014) together recommend the following:

1. First-trimester sonography is the most accurate method to establish or reaffirm gestational age.
2. In conceptions achieved with assisted-reproductive technology, this gestational age is used.
3. If available, the gestational ages calculated from the LMP and from first-trimester sonography are compared, and the estimated date of confinement (EDC) recorded and discussed with the patient.
4. The best obstetrical estimate of gestational age at delivery is recorded on the birth certificate.

The embryofetal crown-rump length in the first trimester is accurate ±5 to 7 days. Thus, if sonographic assessment of gestational age differs by more than 5 days prior to 9 weeks' gestation, or by more than 7 days later in the first trimester, the estimated delivery date is changed.

Naegele Rule

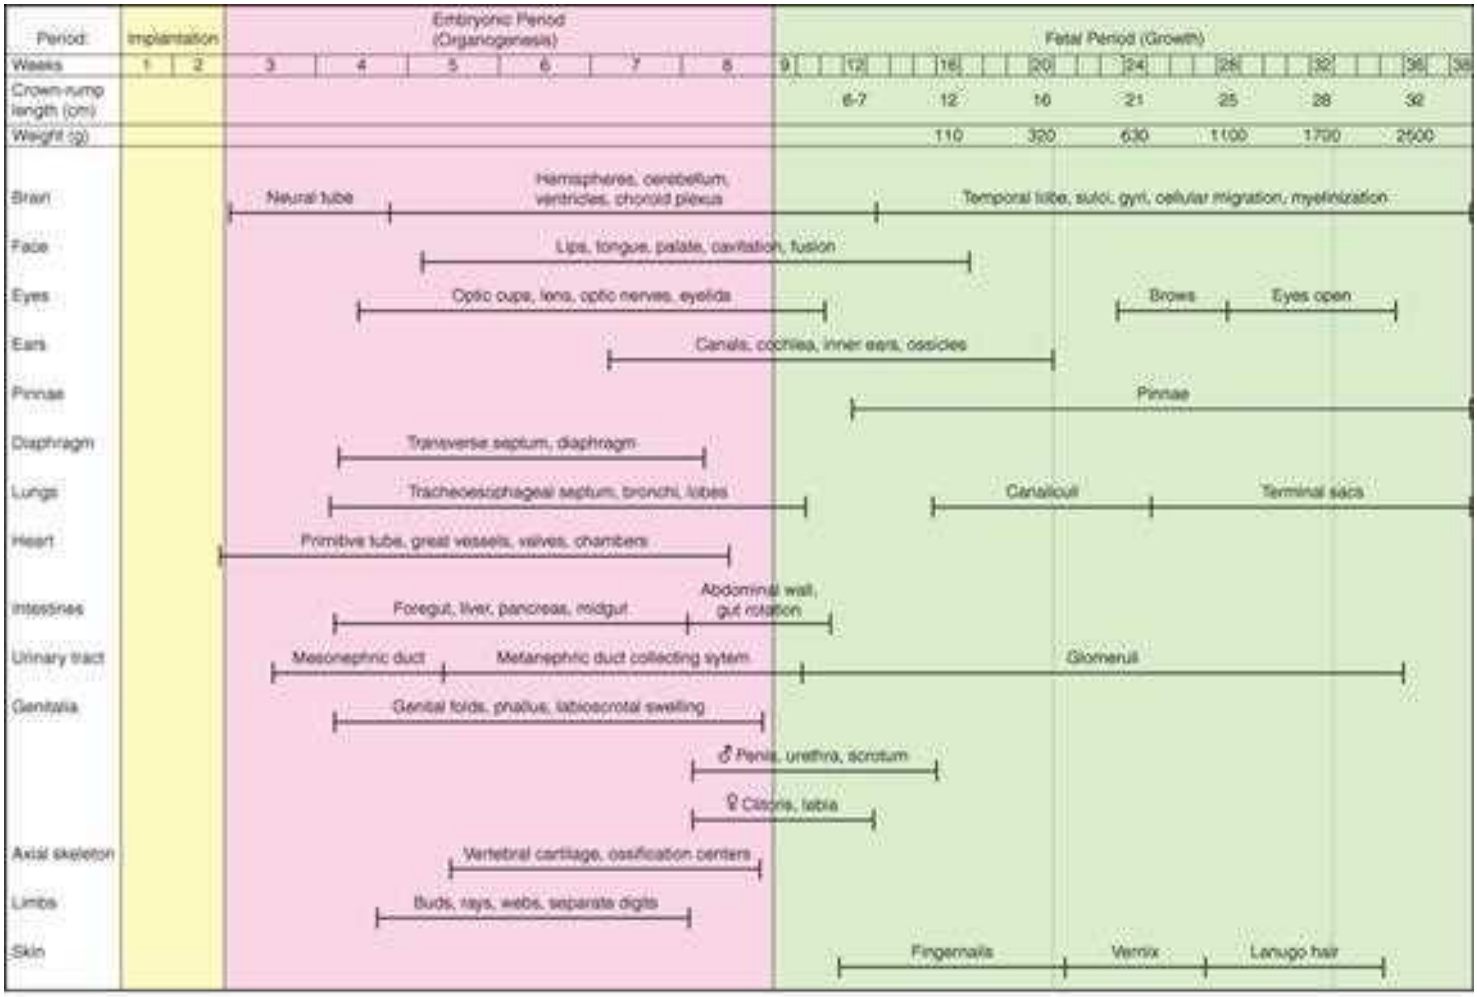
An EDC based on LMP can be quickly estimated as follows: add 7 days to the first day of the LMP and subtract 3 months. For example, if the first day of the LMP was October 5, the due date is 10–05 minus 3 (months) plus 7 (days) = 7–12, or July 12 of the following year. This calculation has been termed the *Naegele rule*. The period of gestation can also be divided into three units of approximately 14 weeks each. These three *trimesters* are important obstetrical milestones.

In addition to estimating the EDC with either Naegele rule or pregnancy "wheels," calculator tools in the electronic medical record and smartphone applications can provide a calculated EDC and gestational age. For example, the American College of Obstetricians and Gynecologists (2016) has developed a calculator application that incorporates sonographic criteria and the LMP or embryo transfer date. This is discussed further in Chapter 10 (Gestational Age Assessment).

EMBRYONIC DEVELOPMENT

The complexity of embryofetal development is almost beyond comprehension. Figure 7-2 shows a developmental sequence of various organ systems. New information regarding organ development continues to accrue. For example, imaging techniques help unravel the contributions of gene regulation and tissue interaction to eventual three-dimensional organ morphology (Anderson, 2016; Mohun, 2011). Others have described the sequence of gene activation that underlies cardiac development.

FIGURE 7-2
Embryofetal development according to gestational age determined by the first day of the last menses. Times are approximate.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

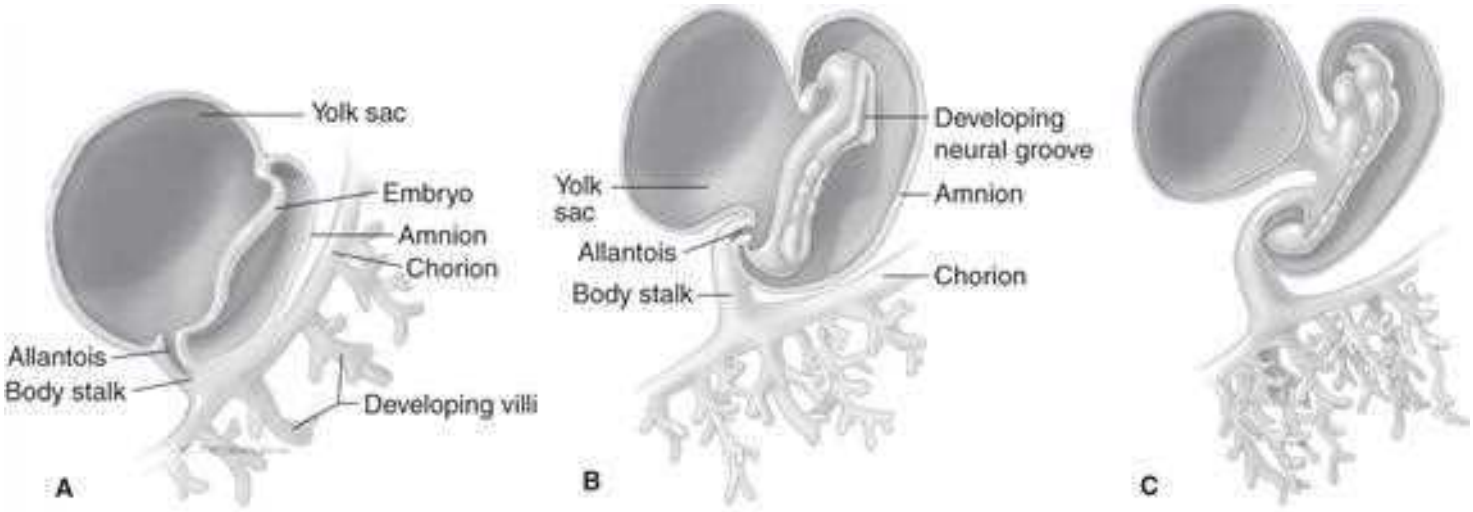
Zygote and Blastocyst Development

During the first 2 weeks after ovulation and then fertilization, the zygote—or preembryo—develops to the blastocyst stage. The blastocyst implants 6 or 7 days following fertilization. The 58-cell blastocyst differentiates into five embryo-producing cells—*the inner cell mass*—and the remaining 53 cells form placental trophoblast. Details of implantation and early development of the blastocyst and placenta are described in Chapter 5 (Implantation and Early Trophoblast Formation).

Embryonic Period

The conceptus is termed an embryo at the beginning of the third week after ovulation and fertilization. Primitive chorionic villi form, and this coincides with the expected day of menses. The embryonic period, during which time organogenesis takes place, lasts 6 weeks. It begins the third week from the LMP through the eighth week. The embryonic disc is well defined, and most pregnancy tests that measure human chorionic gonadotropin (hCG) become positive by this time. As shown in Figure 7-3, the body stalk is now differentiated. There are villous cores in which angioblastic chorionic mesoderm can be distinguished and a true intervillous space that contains maternal blood.

FIGURE 7-3
Early human embryos. Ovulation ages: **A.** 19 days (presomite). **B.** 21 days (7 somites). **C.** 22 days (17 somites). (After drawings and models in the Carnegie Institute.)



During the third week, fetal blood vessels in the chorionic villi appear. In the fourth week, a cardiovascular system has formed (Fig. 7-4). Thereby, a true circulation is established both within the embryo and between the embryo and the chorionic villi. Partitioning of the primitive heart begins. Also in the fourth week, the neural plate forms, and it subsequently folds to form the neural tube. By the end of the fifth menstrual week, the chorionic sac measures approximately 1 cm in diameter. The embryo is 3 mm long and can be measured sonographically. Arm and leg buds have developed, and the amnion is beginning to ensheathe the body stalk, which thereafter becomes the umbilical cord. At the end of the sixth week, the embryo measures approximately 9 mm long, and the neural tube has closed (Fig. 7-5). Cardiac motion is almost always discernable sonographically (Fig. 7-6). The cranial end of the neural tube closes by 38 days from the LMP, and the caudal end closes by 40 days. Thus, the neural tube has closed by the end of the sixth week. And by the end of the eighth week, the crown-rump length approximates 22 mm. Fingers and toes are present, and the arms bend at the elbows. The upper lip is complete, and the external ears form definitive elevations on either side of the head. Three-dimensional images and videos of human embryos from the MultiDimensional Human Embryo project are found at: http://embryo.soad.umich.edu/index.html.

FIGURE 7-4
Three- to four-week-old embryos. **A, B.** Dorsal views of embryos during 22 to 23 days of development showing 8 and 12 somites, respectively. **C–E.** Lateral views of embryos during 24 to 28 days, showing 16, 27, and 33 somites, respectively. (Redrawn from Moore KL: The Developing Human: Clinically Oriented Embryology, 4th ed. Philadelphia, Saunders, 1988.)

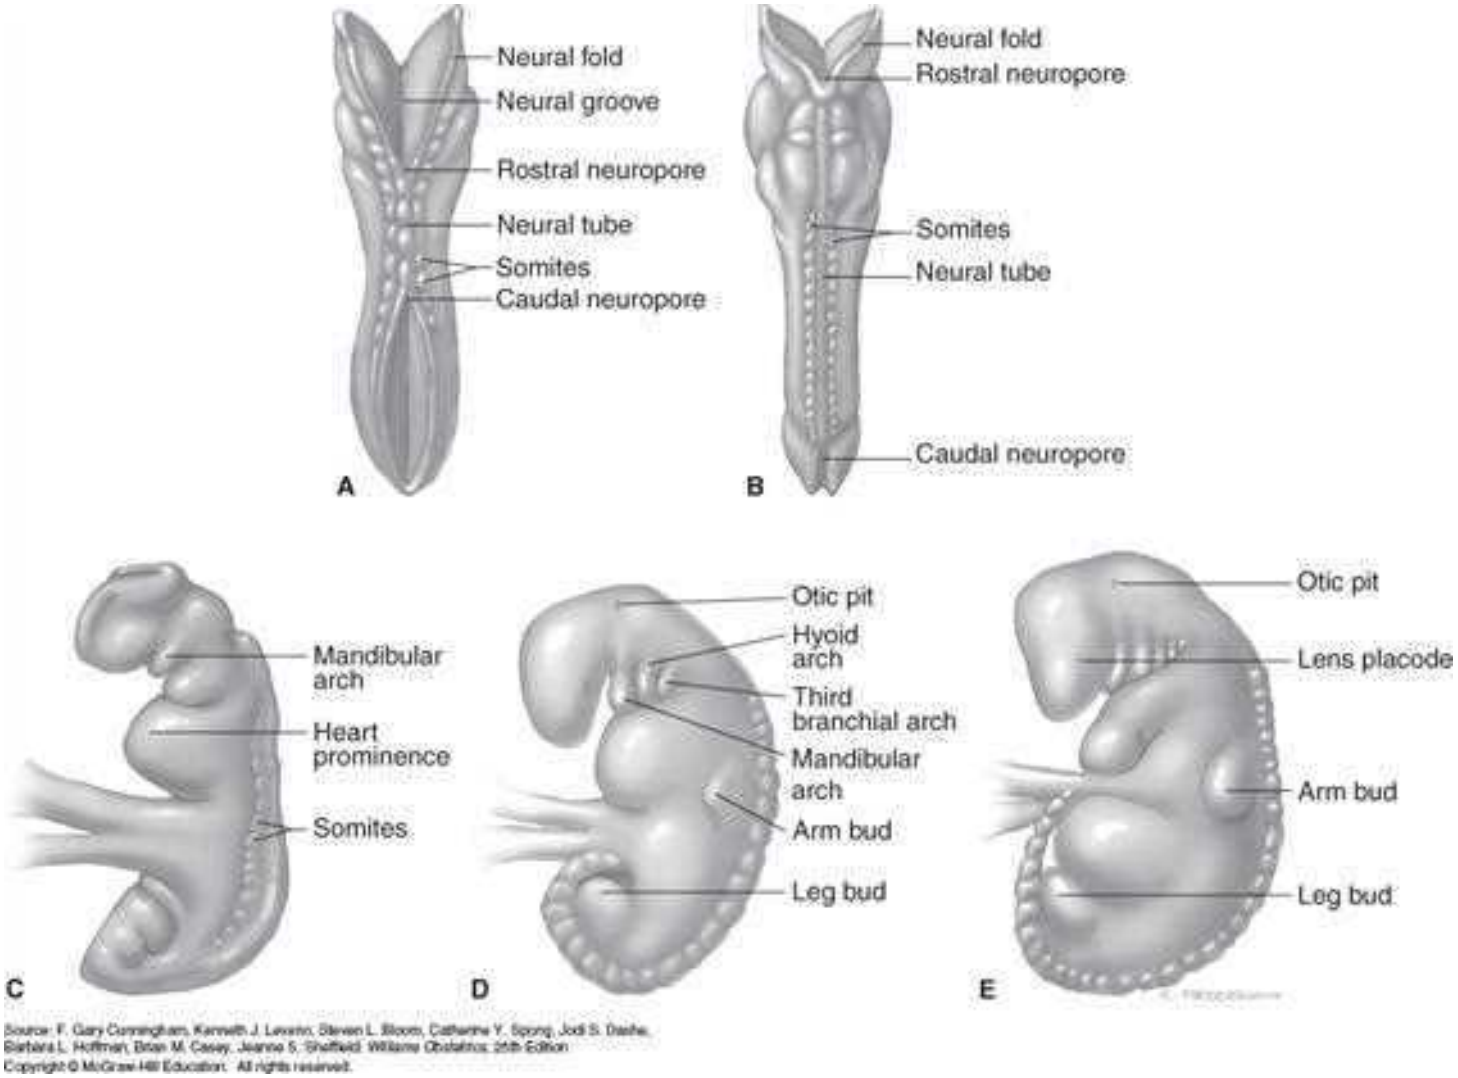


FIGURE 7-5

Embyro photographs. **A.** Dorsal view of an embryo at 24 to 26 days and corresponding to Figure 7-4C. **B.** Lateral view of an embryo at 28 days and corresponding to Figure 7-4D. **C.** Lateral view of embryofetus at 56 days, which marks the end of the embryonic period and the beginning of the fetal period. The liver is within the white, halo circle. (From Werth B, Tsiaras A: From Conception to Birth: A Life Unfolds. New York, Doubleday, 2002.)

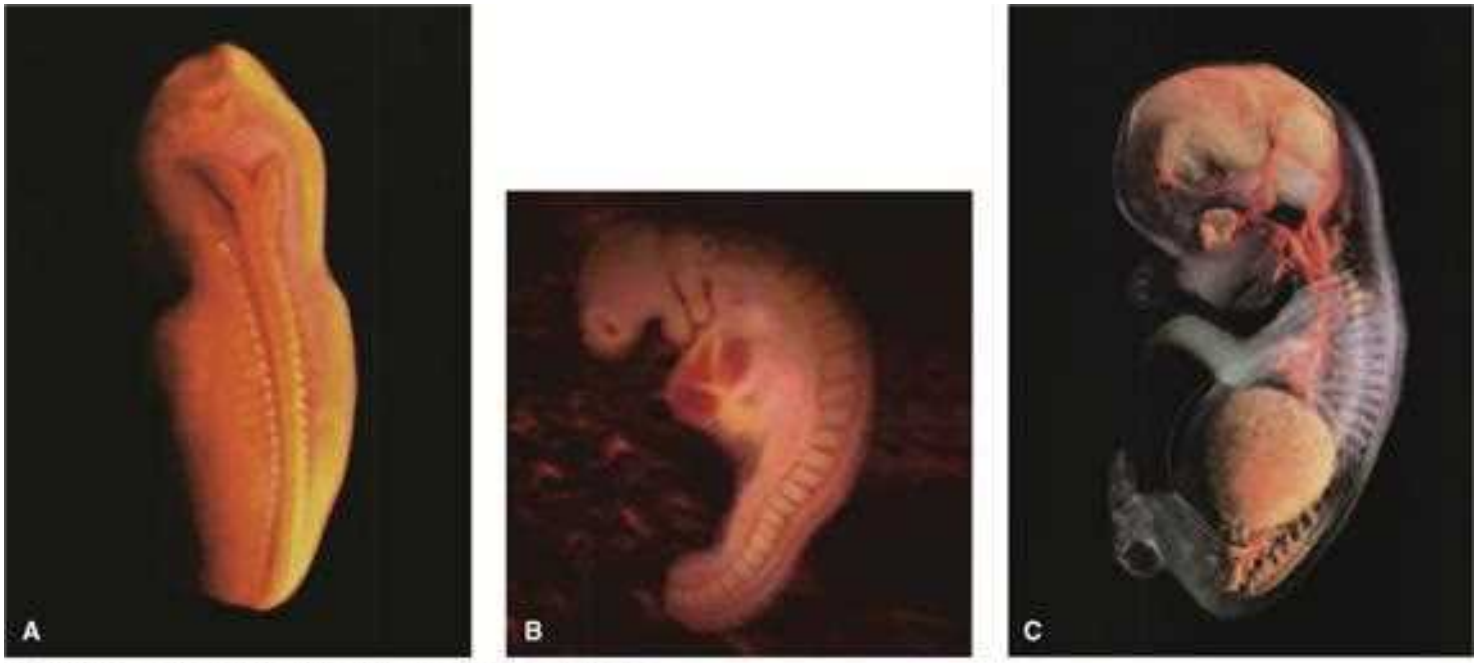

FIGURE 7-6

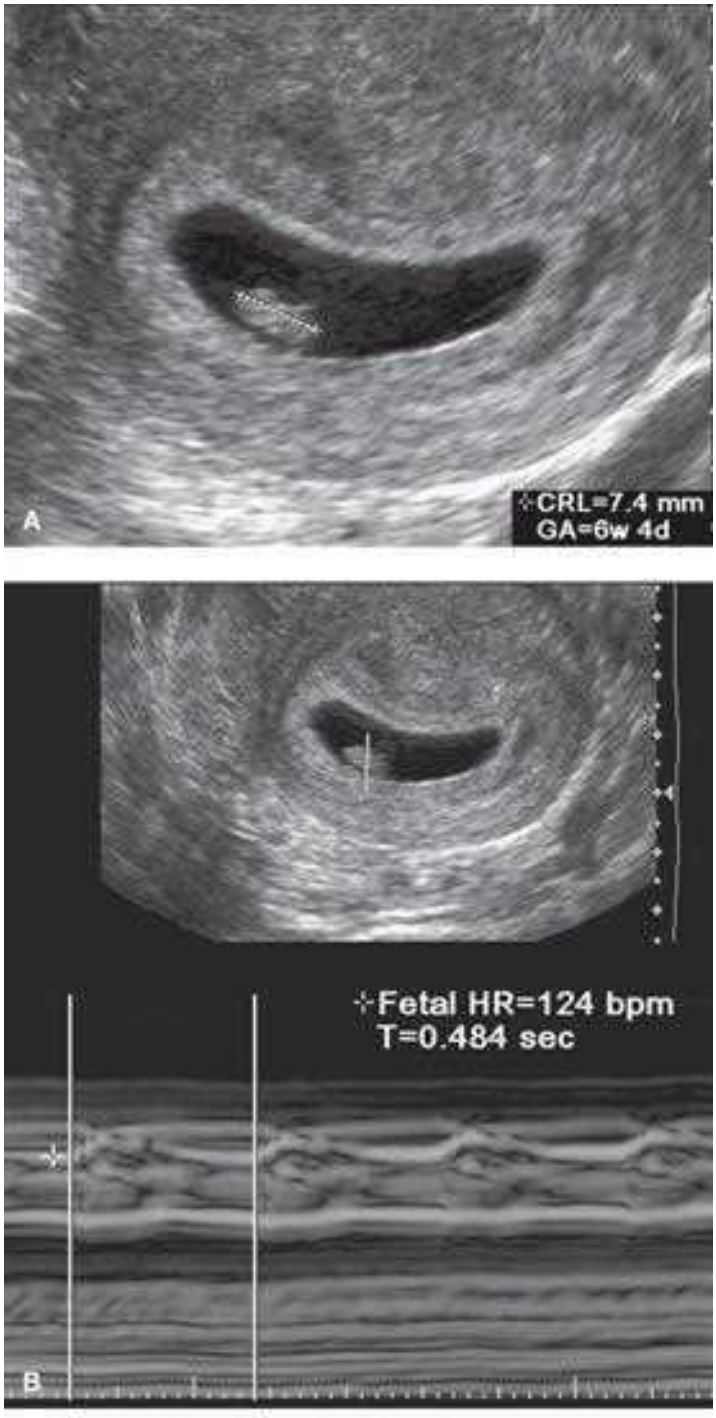
A. This image of a 6-week, 4-day embryo depicts measurement of the crown-rump length, which is 7.4 mm at this gestational age. **B.** Despite the early gestational age, M-mode imaging readily demonstrates embryonic cardiac activity. The heart rate in this image is 124 beats per minute.



FETAL DEVELOPMENT AND PHYSIOLOGY

Fetal Period Epochs

Transition from the embryonic period to the fetal period occurs at 7 weeks after fertilization, corresponding to 9 weeks after onset of the last menses. At this time, the fetus approximates 24 mm in length, most organ systems have developed, and the fetus enters a period of growth and maturation. These phases are outlined in Figure 7-2.

12 Gestational Weeks

The uterus usually is just palpable above the symphysis pubis. Fetal growth is rapid, and the fetal crown-rump length is 5 to 6 cm (Fig. 7-7). Centers of ossification have appeared in most fetal bones, and the fingers and toes have become differentiated. Skin and nails develop, and scattered rudiments of hair appear. The external genitalia are beginning to show definitive signs of male or female gender. The fetus begins to make spontaneous movements.

FIGURE 7-7

This image of a 12-week, 3-day embryo depicts measurement of the crown-rump length. The fetal profile, cranium, and a hand and foot are also visible in this image.

16 Gestational Weeks

Fetal growth slows at this time. The crown-rump length is 12 cm, and the fetal weight approximates 150 g (Hadlock, 1991). Practically speaking, the sonographic crown-rump length is not measured beyond 13 weeks, which corresponds to approximately 8.4 cm. Instead, biparietal diameter, head circumference, abdominal circumference, and femur length are measured. Fetal weight in the second and third trimesters is estimated from a combination of these measurements (Chap. 10, Gestational Age Assessment).

Eye movements begin at 16 to 18 weeks, coinciding with midbrain maturation. By 18 weeks in the female fetus, the uterus is formed and vaginal canalization begins. By 20 weeks in the male, testicles start to descend.

20 Gestational Weeks

This is the midpoint of pregnancy as estimated from the LMP. The fetus now weighs somewhat more than 300 g, and weight increases substantially in a linear manner. From this point onward, the fetus moves approximately every minute and is active 10 to 30 percent of the day (DiPietro, 2005). Brown fat forms, and the fetal skin becomes less transparent. Downy lanugo covers its entire body, and some scalp hair can be seen. Cochlear function develops between 22 and 25 weeks, and its maturation continues for 6 months after delivery.

24 Gestational Weeks

The fetus now weighs almost 700 g (Duryea, 2014). The skin is characteristically wrinkled, and fat deposition begins. The head is still comparatively large, and eyebrows and eyelashes are usually recognizable. By 24 weeks, the secretory type II pneumocytes have initiated surfactant secretion (Chap. 32, Care in the Delivery Room). The canalicular period of lung development, during which the bronchi and bronchioles enlarge and alveolar ducts develop, is nearly completed. Despite this, a fetus born at this time will attempt to breathe, but many will die because the terminal sacs, required for gas exchange, have not yet formed. The overall survival rate at 24 weeks is barely above 50 percent, and only approximately 30 percent survive without severe morbidity (Rysavy, 2015). By 26 weeks, the eyes open. Nociceptors are present over all the body, and the neural pain system is developed (Kadic, 2012). The fetal liver and spleen are important sites for hemopoiesis.

28 Gestational Weeks

The crown-rump length approximates 25 cm, and the fetus weighs about 1100 g. The thin skin is red and covered with **vernix caseosa**. The pupillary membrane has just disappeared from the eyes. Isolated eye blinking peaks at 28 weeks. The bone marrow becomes the major site of hemopoiesis. The otherwise normal neonate born at this age has a 90-percent chance of survival without physical or neurological impairment.

32 and 36 Gestational Weeks

At 32 weeks, the fetus has attained a crown-rump length approximating 28 cm and a weight of about 1800 g. The skin surface is still red and wrinkled. In contrast, by 36 weeks, the fetal crown-rump length averages about 32 cm, and the weight approximates 2800 g (Duryea, 2014). Because of subcutaneous fat deposition, the body has become more rotund, and the previous wrinkled facies is now fuller. Normal fetuses have nearly 100-percent survival rate.

40 Gestational Weeks

This is considered term, and the fetus is now fully developed. The average crown-rump length measures about 36 cm, and the average weight approximates 3500 g.

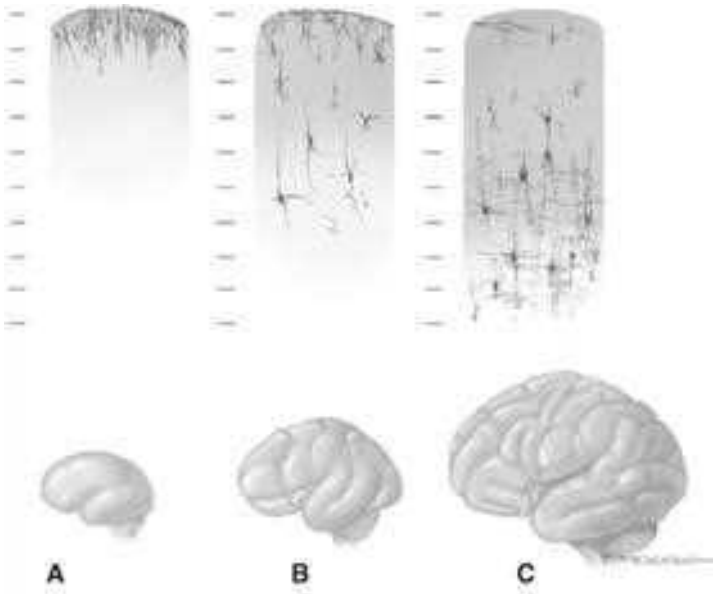
Central Nervous System Development

Brain Development

The cranial end of the neural tube closes by 38 days from the LMP, and the caudal end closes by 40 days. Hence, folic acid supplementation to prevent neural-tube defects must be in place before this point to be efficacious (Chap. 9, Pragmatic Nutritional Surveillance). The walls of the neural tube form the brain and spinal cord. The lumen becomes the ventricular system of the brain and the central canal of the spinal cord. During the sixth week, the cranial end of the neural tube forms three primary vesicles. In the seventh week, five secondary vesicles develop: the telencephalon—future cerebral hemispheres; diencephalon—thalami; mesencephalon—midbrain; metencephalon—pons and cerebellum; and myelencephalon—medulla. Meanwhile, flexures develop and fold the brain into its typical configuration. The end of the embryonic period signifies completion of primary and secondary neuralization.

At 3 to 4 months' gestation, *neuronal proliferation* peaks. As expected, disorders in this cerebral development phase profoundly worsen function (Volpe, 2008). *Neuronal migration* occurs almost simultaneously and peaks at 3 to 5 months. This process is characterized by movement of millions of neuronal cells from their ventricular and subventricular zones to areas of the brain in which they reside for life (Fig. 7-8). Upregulation of gene expression for neuronal migration has been described (Iruretagoyena, 2014). Noninvasive methods to study fetal neurodevelopment have also been reported (Goetzl, 2016).

FIGURE 7-8
Neuronal proliferation and migration are complete at 20 to 24 weeks. During the second half of gestation, organizational events proceed with gyral formation and proliferation, differentiation, and migration of cellular elements. Approximate gestational ages are shown. **A.** 20 weeks. **B.** 35 weeks. **C.** 40 weeks.



As gestation progresses, the fetal brain appearance steadily changes. Thus, it is possible to identify fetal age from its external appearance (Volpe, 2008). Neuronal proliferation and migration proceed along with gyral growth and maturation (see Fig. 7-8). Sequential maturation studies by Manganaro (2007) and Dubois (2014) and their colleagues have characterized the developing fetal brain image using magnetic resonance (MR) imaging. Other recent investigations that also used MR imaging have quantified development of subcortical brain structures from 12 to 22 weeks (Meng, 2012).

Myelination of the ventral roots of the cerebrospinal nerves and brainstem begins at approximately 6 months, but most myelination progresses after birth. This lack of myelin and incomplete skull ossification permit fetal brain structure to be seen sonographically throughout gestation.

Spinal Cord

Whereas the superior two thirds of the neural tube give rise to the brain, the inferior third forms the spinal cord. In the embryo, the spinal cord extends along the entire vertebral column length, but after that it lags behind vertebral growth. Ossification of the entire sacrum is visible sonographically by approximately 21 weeks (Chap. 10, Normal and Abnormal Fetal Anatomy). By 24 weeks, the spinal cord extends to S_1, at birth to L_3, and in the adult to L_1. Spinal cord myelination begins at midgestation and continues through the first year of life. Synaptic function is sufficiently developed by the eighth week to demonstrate flexion of the neck and trunk (Temiras, 1968). During the third trimester, integration of nervous and muscular function proceeds rapidly.

Cardiovascular System

The embryology of the heart is complex. At its earliest stages of formation, the fetal heart undergoes molecular programming, and more than a hundred genes and molecular factors are integral to its morphogenesis. To summarize, the straight cardiac tube is formed by the 23rd day during an intricate morphogenetic sequence, during which each *segment* arises at a unique time. The tube then undergoes *looping,* and the chambers then fuse and form septa (Manner, 2009). The valves develop, and the aortic arch forms by vasculogenesis. For a complete description, refer to Chapter 9 in *Hurst's The Heart* (Keller, 2013).

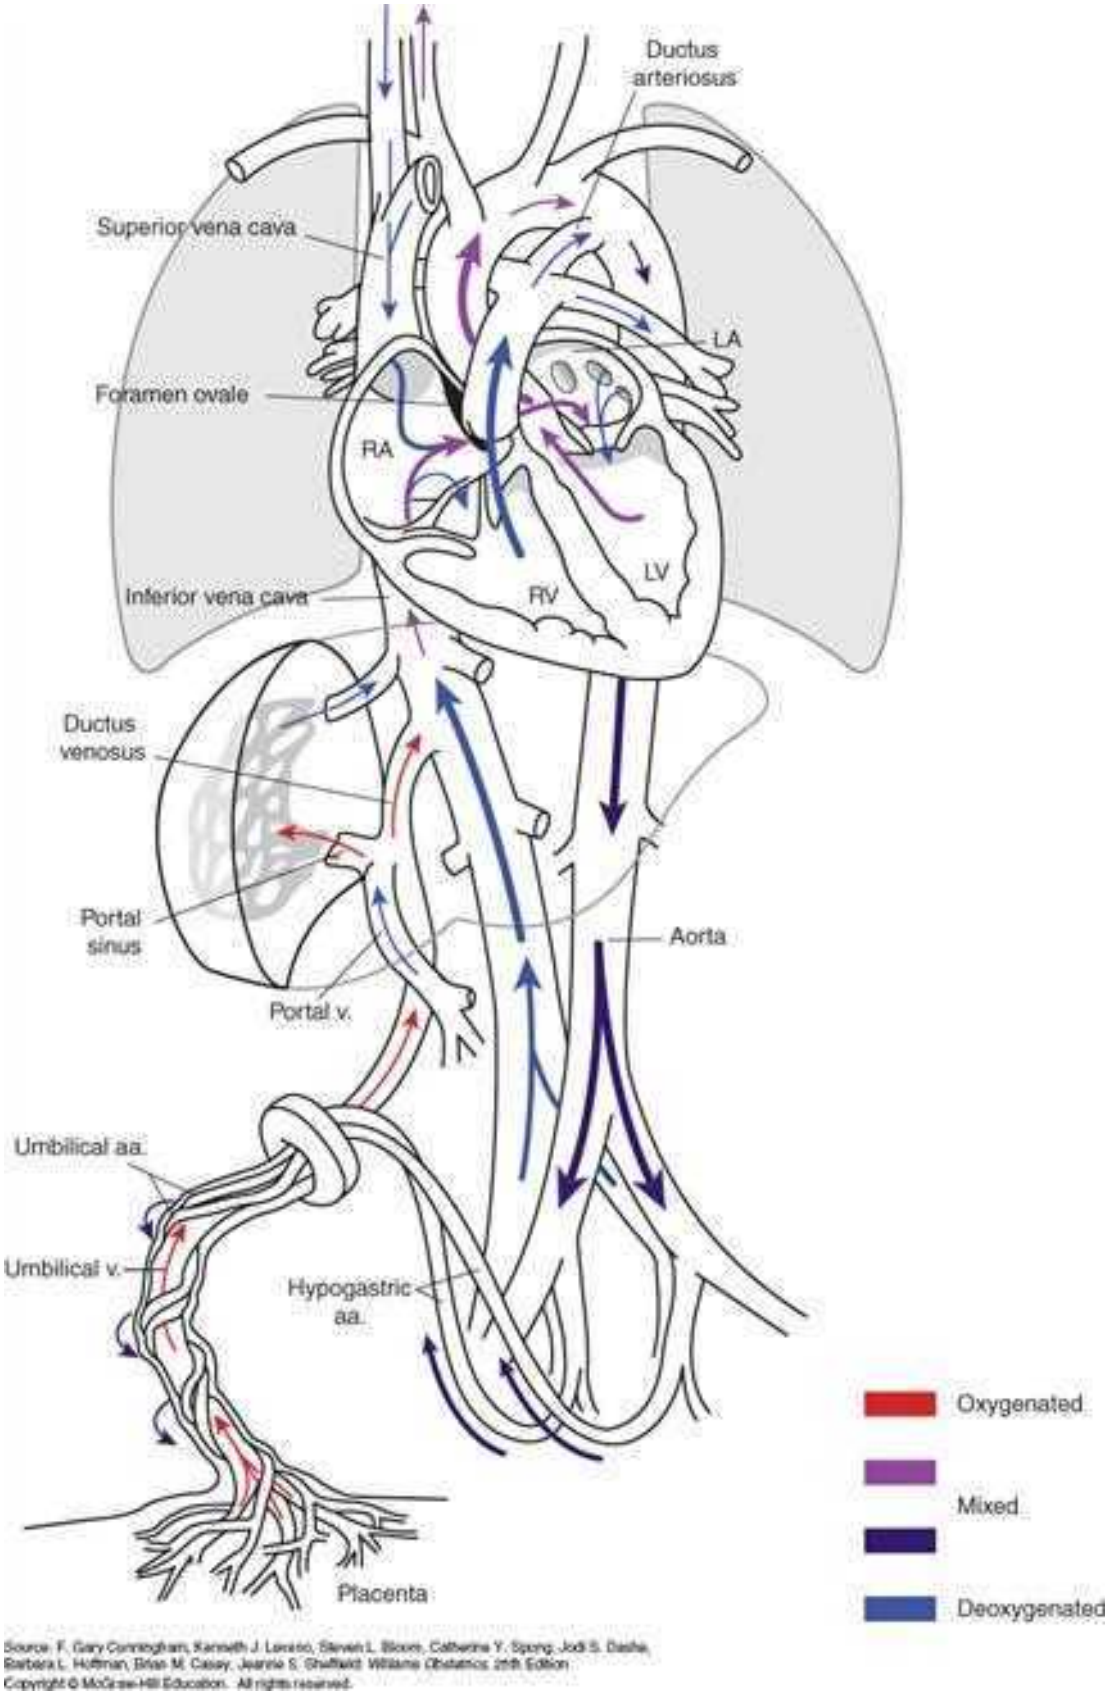
Fetal Circulation

This unique circulation is substantially different from that of the adult and functions until birth, when it changes dramatically. For example, because fetal blood does not need to enter the pulmonary vasculature to be oxygenated, most of the right ventricular output bypasses the lungs. In addition, the fetal heart chambers work in parallel, not in series, which effectively supplies the brain and heart with more highly oxygenated blood than the rest of the body.

Oxygen and nutrient materials required for fetal growth and maturation are delivered from the placenta by the single umbilical vein (Fig. 7-9). The vein then divides into the ductus venosus and the portal sinus. The ductus venosus is the major branch of the umbilical vein and traverses the liver to enter the inferior vena cava directly. Because it does not supply oxygen to the intervening tissues, it carries well-oxygenated blood directly to the heart. In contrast, the portal sinus carries blood to the hepatic veins primarily on the left side of the liver, and oxygen is extracted. The relatively deoxygenated blood from the liver then flows back into the inferior vena cava, which also receives more deoxygenated blood returning from the lower body. Blood flowing to the fetal heart from the inferior vena cava, therefore, consists of an admixture of arterial-like blood that passes directly through the ductus venosus and less well-oxygenated blood that returns from most of the veins below the level of the diaphragm. The oxygen content of blood delivered to the heart from the inferior vena cava is thus lower than that leaving the placenta.

FIGURE 7-9

The intricate nature of the fetal circulation is evident. The degree of blood oxygenation in various vessels differs appreciably from that in the postnatal state. aa = arteries; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle; v = vein.



As discussed, the ventricles of the fetal heart work in parallel, not in series. Well-oxygenated blood enters the left ventricle, which supplies the heart and brain, and less oxygenated blood enters the right ventricle, which supplies the rest of the body. These two separate circulations are maintained by the right atrial structure, which effectively directs entering blood to either the left atrium or the right ventricle, depending on its oxygen content. This separation of blood according to its oxygen content is aided by the pattern of blood flow in the inferior vena cava. The well-oxygenated blood tends to course along the medial aspect of the inferior vena cava and the less oxygenated blood flows along the lateral vessel wall. This aids their shunting into opposite sides of the

heart. Once this blood enters the right atrium, the configuration of the upper interatrial septum—the *crista dividens*—preferentially shunts the well-oxygenated blood from the medial side of the inferior vena cava and the ductus venosus through the foramen ovale into the left heart and then to the heart and brain (Dawes, 1962). After these tissues have extracted needed oxygen, the resulting less oxygenated blood returns to the right atrium through the superior vena cava.

The less oxygenated blood coursing along the lateral wall of the inferior vena cava enters the right atrium and is deflected through the tricuspid valve to the right ventricle. The superior vena cava courses inferiorly and anteriorly as it enters the right atrium, ensuring that less well-oxygenated blood returning from the brain and upper body also will be shunted directly to the right ventricle. Similarly, the ostium of the coronary sinus lies just superior to the tricuspid valve so that less oxygenated blood from the heart also returns to the right ventricle. As a result of this blood flow pattern, blood in the right ventricle is 15 to 20 percent less saturated than blood in the left ventricle.

Almost 90 percent of blood exiting the right ventricle is shunted through the ductus arteriosus to the descending aorta. High pulmonary vascular resistance and comparatively lower resistance in the ductus arteriosus and the umbilical–placental vasculature ensure that only about 8 percent of right ventricular output goes to the lungs (Fineman, 2014). Thus, one third of the blood passing through the ductus arteriosus is delivered to the body. The remaining right ventricular output returns to the placenta through the two hypogastric arteries. These two arteries course from the level of the bladder along the abdominal wall to the umbilical ring and into the cord as the umbilical arteries. In the placenta, this blood picks up oxygen and other nutrients and is recirculated through the umbilical vein.

Circulatory Changes at Birth

After birth, the umbilical vessels, ductus arteriosus, foramen ovale, and ductus venosus normally constrict or collapse. With the functional closure of the ductus arteriosus and the expansion of the lungs, blood leaving the right ventricle preferentially enters the pulmonary vasculature to become oxygenated before it returns to the left heart (Hillman, 2012). Virtually instantaneously, the ventricles, which had worked in parallel in fetal life, now effectively work in series. The more distal portions of the hypogastric arteries undergo atrophy and obliteration within 3 to 4 days after birth. These become the umbilical ligaments, whereas the intraabdominal remnants of the umbilical vein form the ligamentum teres. The ductus venosus constricts by 10 to 96 hours after birth and is anatomically closed by 2 to 3 weeks. This ultimately forms the ligamentum venosum (Fineman, 2014).

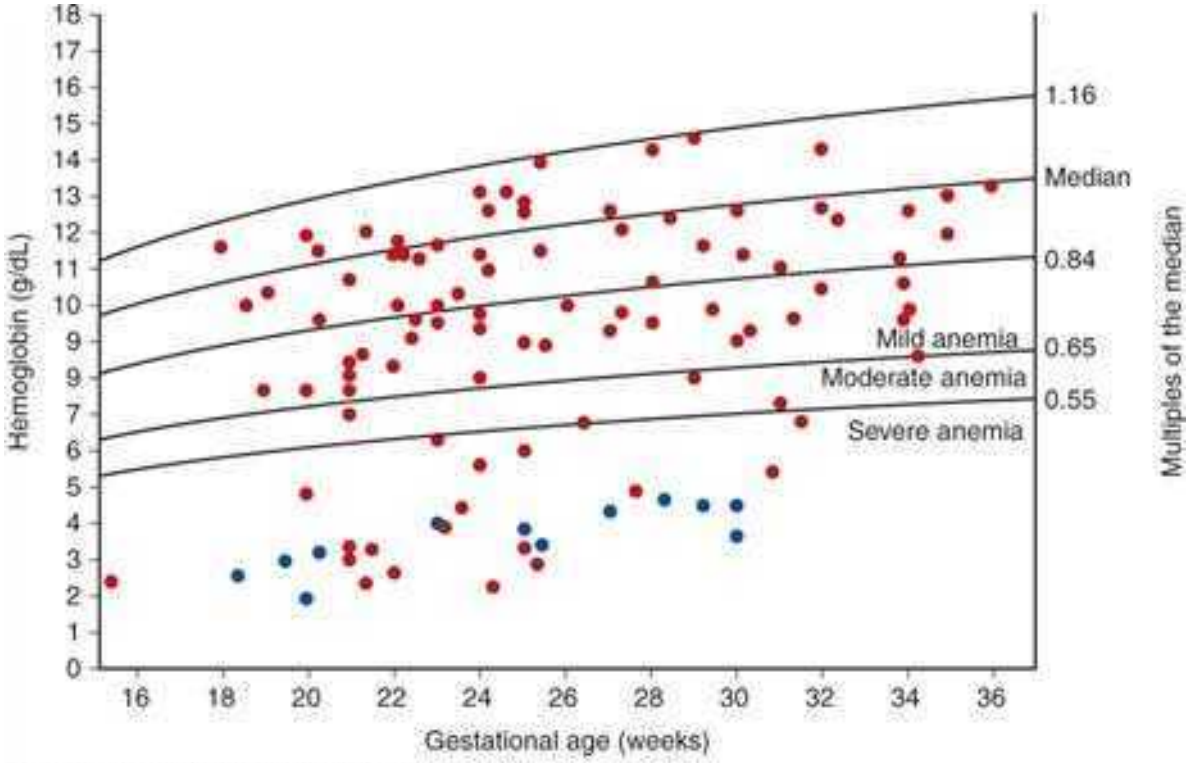
Fetoplacental Blood Volume

Although precise measurements of human fetoplacental blood volume are lacking, Usher and associates (1963) reported values in term normal newborns to average 78 mL/kg when immediate cord clamping was conducted. Gruenwald (1967) found the fetal blood volume contained in the placenta after prompt cord clamping to average 45 mL/kg of fetal weight. Thus, fetoplacental blood volume at term is approximately 125 mL/kg of fetal weight. This is important when assessing the magnitude of fetomaternal hemorrhage as discussed in Chapter 15 (Fetal Thrombocytopenia).

Hemopoiesis

In the early embryo, hemopoiesis is demonstrable first in the yolk sac, followed by the liver, and finally spleen and bone marrow. Both myeloid and erythroid cells are continually produced by progenitors that are from hematopoietic stem cells (Golub, 2013; Heinig, 2015). The first erythrocytes released into the fetal circulation are nucleated and macrocytic. The mean cell volume is at least 180 fL in the embryo and decreases to 105 to 115 fL at term. The erythrocytes of aneuploid fetuses generally do not undergo this maturation and maintain high mean cell volumes—130 fL on average (Sipes, 1991). As fetal development progresses, more and more of the circulating erythrocytes are smaller and nonnucleated. With fetal growth, both the blood volume in the common fetoplacental circulation and hemoglobin concentration increase. As shown in Figure 7-10, fetal hemoglobin concentrations rise across pregnancy. The Society for Maternal-Fetal Medicine (2015) recommends a cutoff hematocrit value of 30 percent to define anemia.

FIGURE 7-10
Relationship between fetal hemoglobin across gestational age. Blue dots indicate fetuses with hydrops. (Reproduced with permission from Mari G, Deter RL, Carpenter RL, et al: Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses (Level II-I), N Engl J Med 2000 Jan 6;342(1):9–14.)



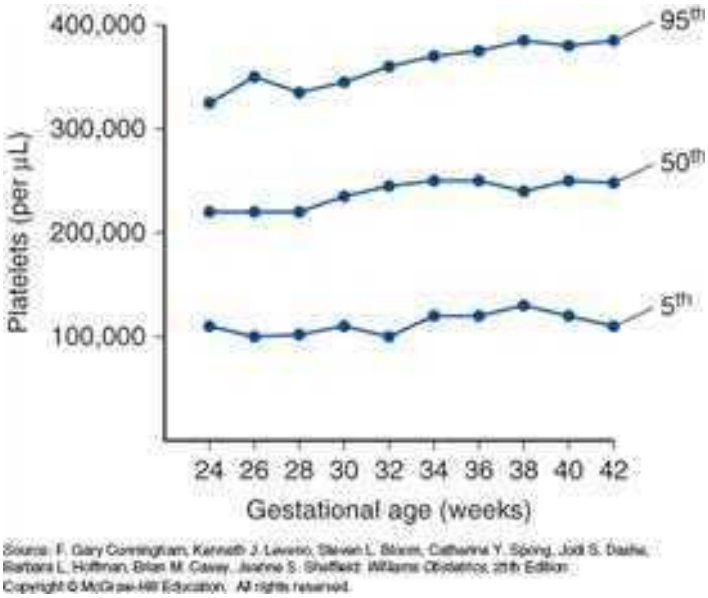
Because of their large size, fetal erythrocytes have a short life span, which progressively lengthens to approximately 90 days at term (Pearson, 1966). As a consequence, red blood cell production rises. Reticulocytes are initially present at high levels, but decrease to 4 to 5 percent of the total at term. Fetal erythrocytes differ structurally and metabolically from those in the adult (Baron, 2012). They are more deformable, which serves to offset their higher viscosity. They also contain several enzymes with appreciably different activities.

Erythropoiesis is controlled primarily by fetal erythropoietin because maternal erythropoietin does not cross the placenta. Fetal hormone production is influenced by testosterone, estrogen, prostaglandins, thyroid hormone, and lipoproteins (Stockman, 1992). Serum erythropoietin levels rise with fetal maturity. Although the exact production site is disputed, the fetal liver appears to be an important source until renal production begins. There is a close correlation between the erythropoietin concentration in amnionic fluid and that in umbilical venous blood obtained by cordocentesis. After birth, erythropoietin normally may not be detectable for up to 3 months.

In contrast, platelet production reaches stable levels by midpregnancy, although there is some variation across gestation (Fig. 7-11). The fetal and neonatal platelet count is subject to various agents as discussed in Chapter 15 (Fetal Thrombocytopenia).

FIGURE 7-11

Platelet counts by gestational age obtained the first day of life. Mean values and 5th and 95th percentiles are shown. (Data from Christensen RD, Henry E, Antonio DV: Thrombocytosis and thrombocytopenia in the NICU: incidence, mechanisms and treatments, J Matern Fetal Neonatal Med 2012 Oct;25 Suppl 4:15–17)



Fetal Hemoglobin

This tetrameric protein is composed of two copies of two different peptide chains, which determine the type of hemoglobin produced. Normal adult hemoglobin A is made of α and β chains. During embryonic and fetal life, various α and β chain precursors are produced. This results in the serial production of several different embryonic hemoglobins. Genes for β-type chains are on chromosome 11, and those for α-type chains on chromosome 16. Each of these genes is turned on and then off during fetal life, until α and β genes, which direct the production of adult hemoglobin A, are permanently activated.

The timing of production of each of these early hemoglobins corresponds to the site of hemoglobin production. Fetal blood is first produced in the yolk sac, where hemoglobins Gower 1, Gower 2, and Portland are made. Erythropoiesis then moves to the liver, where fetal hemoglobin F is produced. When hemopoiesis finally moves to the bone marrow, adult-type hemoglobin A appears in fetal red blood cells and is present in progressively greater amounts as the fetus matures (Pataryas, 1972).

The final adult version of the α chain is produced exclusively by 6 weeks. After this, there are no functional alternative versions. If an α-gene mutation or deletion occurs, no alternate α-type chain can be substituted to form functional hemoglobin. In contrast, at least two versions of the β chain—δ and γ—remain in production throughout fetal life and beyond. In the case of a β-gene mutation or deletion, these two other versions of the β chain often continue to be produced, resulting in hemoglobin A_2 or hemoglobin F, which substitute for the abnormal or missing hemoglobin.

Genes are turned off by methylation of their control region, which is discussed in Chapter 13 (DNA Triplet Repeat Expansion—Anticipation). In some situations, methylation does not occur. For example, in newborns of diabetic women, hemoglobin F may persist due to hypomethylation of the γ gene (Perrine, 1988). With sickle cell anemia, the γ gene remains unmethylated, and large quantities of fetal hemoglobin continue to be produced. As discussed in Chapter 56 (Polycythemias), elevated hemoglobin F levels are associated with fewer sickle-cell disease symptoms, and pharmacological modification of these levels by hemoglobin F-inducing drugs is one approach to treatment.

As discussed in Placental Transfer, there is a functional difference between hemoglobins A and F. At any given oxygen tension and at identical pH, fetal erythrocytes that contain mostly hemoglobin F bind more oxygen than do those that contain nearly all hemoglobin A (Fig. 47-2). This is because hemoglobin A binds 2,3-diphosphoglycerate (2,3-DPG) more avidly than does hemoglobin F, thus lowering the affinity of hemoglobin A for oxygen. During pregnancy, maternal 2,3-DPG levels are greater, and because fetal erythrocytes have lower concentrations of 2,3-DPG, the latter has increased oxygen affinity.

The amount of hemoglobin F in fetal erythrocytes begins to decrease in the last weeks of pregnancy. At term, approximately three fourths of total hemoglobin levels are hemoglobin F. During the first 6 to 12 months of life, the hemoglobin F proportion continues to decline and eventually reaches the low levels found in adult erythrocytes.

Coagulation Factors

With the exception of fibrinogen, there are no embryonic forms of the various hemostatic proteins. The fetus starts producing normal, adult-type procoagulant, fibrinolytic, and anticoagulant proteins by 12 weeks. Because they do not cross the placenta, their concentrations at birth are markedly below the levels that develop within a few weeks of life (Corrigan, 1992). In normal neonates, the levels of factors II, VII, IX, X, XI, and of protein S, protein C, antithrombin, and plasminogen all approximate 50 percent of adult levels. In contrast, levels of factors V, VIII, XIII, and fibrinogen are closer to adult values (Saracco, 2009). Without prophylactic treatment, the levels of vitamin K-dependent coagulation factors usually decrease even further during the first few days after birth. This decline is amplified in breastfed infants and may lead to newborn hemorrhage (Chap. 33, Polycythemia and Hyperviscosity).

Fetal fibrinogen, which appears as early as 5 weeks, has the same amino acid composition as adult fibrinogen, however, it has different properties (Klagsbrun, 1988). It forms a less compressible clot, and the fibrin monomer has a lower degree of aggregation (Heimark, 1988). Although plasma fibrinogen levels at birth are less than those in nonpregnant adults, the protein is functionally more active than adult fibrinogen (Ignjatovic, 2011).

Levels of functional fetal factor XIII—fibrin stabilizing factor—are significantly reduced compared with those in adults (Henriksson, 1974). Nielsen (1969) described low levels of plasminogen and elevated fibrinolytic activity in cord plasma compared with that of maternal plasma. Platelet counts in cord blood are in the normal range for nonpregnant adults (see Fig. 7-11).

Despite this relative reduction in procoagulants, the fetus appears to be protected from hemorrhage, and fetal bleeding is rare. Even after invasive fetal procedures such as cordocentesis, excessive bleeding is uncommon. Ney and coworkers (1989) have shown that amnionic fluid thromboplastins and a factor(s) in Wharton jelly combine to aid coagulation at the umbilical cord puncture site.

Various *thrombophilias* may cause thromboses and pregnancy complications in adults (Chap. 52, Acquired Thrombophilias). If the fetus inherits one of these mutations, thrombosis and infarction can develop in the placenta or fetal organs. This is usually seen with homozygous inheritance. One example is homozygous protein C mutation, which causes *purpura fulminans*.

Plasma Proteins

Liver enzymes and other plasma proteins are produced by the fetus, and these levels do not correlate with maternal levels (Weiner, 1992). Concentrations of plasma proteins, which include albumin, lactic dehydrogenase, aspartate aminotransferase, γ-glutamyl transpeptidase, and alanine transferase, all rise. Conversely, prealbumin levels decline with gestational age (Fryer, 1993). At birth, mean total plasma protein and albumin concentrations in fetal blood are similar to maternal levels. This is important because albumin binds unconjugated bilirubin to prevent *kernicterus* in the newborn (Chap. 33, Polycythemia and Hyperviscosity).

Respiratory System

Lung maturation and biochemical indices of functional fetal lung maturity are important predictors of early neonatal outcome. Morphological or functional immaturity at birth leads to the development of the *respiratory distress syndrome* (Chap. 34, Respiratory Distress Syndrome). A sufficient amount of surface-active materials—collectively referred to as *surfactant*—in the amnionic fluid is evidence of fetal lung maturity. As Liggins (1994) emphasized, however, the structural and morphological maturation of fetal lung also is extraordinarily important to proper lung function.

Anatomical Maturation

The limits of viability appear to be determined by the usual process of pulmonary growth. Like the branching of a tree, lung development proceeds along an established timetable that apparently cannot be hastened by antenatal or neonatal therapy. Within this framework, four essential lung development stages are described by Moore (2000). First, the ***pseudoglandular stage*** entails growth of the intrasegmental bronchial tree between the 5th and 17th weeks. During this period, the lung looks microscopically like a gland. Second, during the ***canalicular stage***, from 16 to 25 weeks, the bronchial cartilage plates extend peripherally. Each terminal bronchiole gives rise to several respiratory bronchioles, and each of these in turn divides into multiple saccular ducts. Third, the ***terminal sac stage*** begins after 25 weeks. During this stage, alveoli give rise to primitive pulmonary alveoli, that is, the terminal sacs. Simultaneously, an extracellular matrix develops from proximal to distal lung segments until term. Finally, the alveolar stage begins during the late fetal period and continues well into childhood. An extensive capillary network is built, the lymph system forms, and type II pneumocytes begin to produce surfactant. At birth, only approximately 15 percent of the adult number of alveoli is present. Thus, the lung continues to grow, adding more alveoli for up to 8 years.

Various insults can upset this process, and their timing determines the sequelae. One example is fetal renal agenesis, in which amnionic fluid is absent at the beginning of lung growth, and major defects occur in all four developmental stages. In another instance, the fetus with membrane rupture and subsequent oligohydramnios before 20 weeks usually exhibits nearly normal bronchial branching and cartilage development but has immature alveoli. In contrast, membrane rupture after 24 weeks may have minimal long-term effect on pulmonary structure. In another example, various growth factors are expressed abnormally in the fetus with a diaphragmatic hernia (Candilira, 2015). Finally, vitamin D is thought to be important for several aspects of lung development (Hart, 2015; Lykkedegn, 2015).

Pulmonary Surfactant

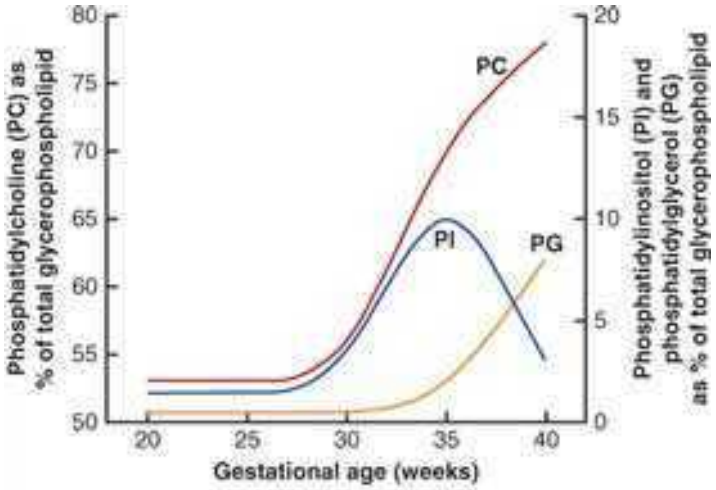
After the first breath, the terminal sacs must remain expanded despite the pressure imparted by the tissue-to-air interface, and surfactant keeps them from collapsing. Surfactant is formed in type II pneumonocytes that line the alveoli. These cells are characterized by multivesicular bodies that produce the lamellar bodies in which surfactant is assembled. During late fetal life, at a time when the alveolus is characterized by a water-to-tissue interface, the intact lamellar bodies are secreted from the lung and swept into the amnionic fluid during respiratory-like movements that are termed fetal breathing. At birth, with the first breath, an air-to-tissue interface is established in the lung alveolus. Surfactant uncoils from the lamellar bodies and spreads to line the alveolus to prevent alveolar collapse during expiration. Thus, the fetal lungs' capacity to produce surfactant establishes lung maturity.

Surfactant Composition

Gluck (1972) and Hallman (1976) and their coworkers approximated that 90 percent of surfactant's dry weight is lipid, specifically glycerophospholipids. Proteins account for the other 10 percent. Nearly 80 percent of the glycerophospholipids are phosphatidylcholines (lecithins). The principal active

component that constitutes half of surfactant is a specific lecithin, which is dipalmitoylphosphatidylcholine (DPPC or PC). Phosphatidylglycerol (PG) accounts for another 8 to 15 percent. Its precise role is unclear because newborns without PG usually do well. The other major constituent is phosphatidylinositol (PI). The relative contributions of each component are shown in Figure 7-12.

FIGURE 7-12
Relationship between the levels of lecithin— dipalmitoyl phosphatidylcholine (PC), phosphatidylinositol (PI), and phosphatidylglycerol (PG) in amnionic fluid.



Surfactant Synthesis

Biosynthesis takes place in the type II pneumocytes. The apoproteins are produced in the endoplasmic reticulum, and the glycerophospholipids are synthesized by cooperative interactions of several cellular organelles. Phospholipid is the primary surface tension-lowering component of surfactant, whereas the apoproteins aid the forming and reforming of a surface film.

The major apoprotein is surfactant A (SP-A), which is a glycoprotein with a molecular weight of 28,000 to 35,000 Da (Whitsett, 1992). It is synthesized in the type II cells, and its content in amnionic fluid increases with gestational age and fetal lung maturity. *SP-A* gene expression is demonstrable by 29 weeks (Mendelson, 2005). Specifically, *SP-A1* and *SP-A2* are two separate genes on chromosome 10, but their regulation is distinctive and different (McCormick, 1994).

Several smaller apoproteins such as SP-B and SP-C are likely important in optimizing the action of surfactant. For example, deletions in *SP-B* gene are incompatible with survival despite production of large amounts of surfactant (Hallman, 2013).

Corticosteroids and Fetal Lung Maturation

Since Liggins (1969) observed accelerated lung maturation in lamb fetuses given glucocorticosteroids prior to preterm delivery, many suggested that fetal cortisol stimulates lung maturation and surfactant synthesis. It is unlikely that corticosteroids are the only stimulus for augmented surfactant formation. However, when these are administered at certain critical times, they may improve preterm fetal lung maturation. As fetal lung therapy, antenatal betamethasone and dexamethasone use and neonatal replacement surfactant therapy are discussed in Chapter 34 (Clinical Course).

Breathing

Fetal respiratory muscles develop early, and chest wall movements are detected sonographically as early as 11 weeks (Koos, 2014). From the beginning of the fourth month, the fetus engages in respiratory movement sufficiently intense to move amnionic fluid in and out of the respiratory tract. Some extrauterine events have effects on fetal breathing, for example, maternal exercise stimulates it (Sussman, 2016).

Digestive System

After its embryogenic formation from the yolk sac as the primordial gut, the digestive system forms the intestines and various appendages. The foregut gives rise to the pharynx, lower respiratory system, esophagus, stomach, proximal duodenum, liver, pancreas, and biliary tree. The midgut gives rise to the distal duodenum, jejunum, ileum, cecum, appendix, and the right colon. The hindgut develops into the left colon, rectum, and the superior portion of the anal canal. Numerous malformations develop in these structures from improper rotation, fixation, and partitioning.

Swallowing begins at 10 to 12 weeks, coincident with the ability of the small intestine to undergo peristalsis and actively transport glucose (Koldovsky, 1965). As a correlate, neonates born preterm may have swallowing difficulties because of immature gut motility (Singendonk, 2014). Much of the water in swallowed fluid is absorbed, and unabsorbed matter is propelled to the lower colon. Gitlin (1974) demonstrated that late in pregnancy, approximately 800 mg of soluble protein is ingested daily by the fetus. The stimulus for swallowing is unclear, but the fetal neural analogue of thirst, gastric emptying, and change in the amnionic fluid composition are potential factors (Boyle, 1992). The fetal taste buds may play a role because saccharin injected into amnionic fluid increases swallowing, whereas injection of a noxious chemical inhibits it (Liley, 1972).

Fetal swallowing appears to have little effect on amnionic fluid volume early in pregnancy because the volume swallowed is small compared with the total. However, term fetuses swallow between 200 and 760 mL per day—an amount comparable to that of the term neonate (Pritchard, 1966). Thus at term, amnionic fluid volume regulation can be substantially altered by fetal swallowing. For example, as discussed in Chapter 11 (Hydramnios), if swallowing is inhibited, hydramnios is common.

Hydrochloric acid and some digestive enzymes are present in the stomach and small intestine in minimal amounts in the early fetus. Intrinsic factor is detectable by 11 weeks, and pepsinogen by 16 weeks. The preterm neonate, depending on its gestational age, may have transient deficiencies of these enzymes (Lebenthal, 1983).

Stomach emptying appears to be stimulated primarily by volume. Movement of amnionic fluid through the gastrointestinal system may enhance growth and development of the alimentary canal. That said, other regulatory factors likely are involved. For example, anencephalic fetuses, in which swallowing is limited, often have normal amnionic fluid volume and normal-appearing gastrointestinal tract.

Meconium

Fetal bowel contents consist of various products of secretion, such as glycerophospholipids from the lung, desquamated fetal cells, lanugo, scalp hair, and vernix. It also contains undigested debris from swallowed amnionic fluid. The dark greenish-black color forms from bile pigments, especially biliverdin. Meconium can pass from normal bowel peristalsis in the mature fetus or from vagal stimulation. It can also pass when hypoxia stimulates arginine vasopressin (AVP) release from the fetal pituitary gland. AVP stimulates colonic smooth muscle to contract, resulting in intraamnionic defecation (deVane, 1982; Rosenfeld, 1985). Meconium is toxic to the respiratory system, and its inhalation can result in *meconium aspiration syndrome* (Chap. 33, Neonatal Encephalopathy and Cerebral Palsy).

Liver

The hepatic diverticulum is an outgrowth of the endodermal lining of the foregut. Epithelial liver cords and primordial cells differentiate into hepatic parenchyma. Serum liver enzyme levels increase with gestational age. Still, the fetal liver has a gestational-age-related diminished capacity for converting free unconjugated bilirubin to conjugated bilirubin (Morioka, 2015). Because of hepatic immaturity, the preterm newborn is at particular risk for hyperbilirubinemia (Chap. 33, Polycythemia and Hyperviscosity). And because the life span of normal fetal macrocytic erythrocytes is shorter than that of the adult, relatively more unconjugated bilirubin is produced. As just noted, the fetal liver conjugates only a small fraction, and this is excreted into the intestine and ultimately oxidized to biliverdin. Most of the unconjugated bilirubin is excreted into the amnionic fluid after 12 weeks and transferred across the placenta (Bashore, 1969).

Importantly, placental bilirubin transfer is bidirectional. Thus, a woman with severe hemolysis from any cause has excess unconjugated bilirubin that readily passes to the fetus and then into the amnionic fluid. Conversely, conjugated bilirubin is not exchanged to any significant degree between mother and fetus.

Most fetal cholesterol derives from hepatic synthesis, which satisfies the large demand for low-density lipoprotein (LDL) cholesterol by the fetal adrenal glands. Hepatic glycogen is present in low concentration during the second trimester, but near term, levels rise rapidly and markedly to reach concentrations that are two- to threefold higher than those in the adult liver. After birth, glycogen content falls precipitously.

Pancreas

This organ arises from dorsal and ventral pancreatic buds from the endoderm of the foregut. Gene regulation of its development was recently reviewed (Jennings, 2015). Insulin-containing granules can be identified by 9 to 10 weeks, and insulin is detectable in fetal plasma at 12 weeks (Adam, 1969). The pancreas responds to hyperglycemia by secreting insulin (Obenshain, 1970). Glucagon has been identified in the fetal pancreas at 8 weeks. Although hypoglycemia does not cause an increase in fetal glucagon levels, similar stimuli do so by 12 hours after birth (Chez, 1975). At the same time, however, fetal pancreatic α cells do respond to L-dopa infusions (Epstein, 1977). Therefore, unresponsiveness to hypoglycemia is likely the consequence of failed glucagon release rather than inadequate production. This is consistent with developmental expression of pancreatic genes in the fetus (Mally, 1994).

Most pancreatic enzymes are present by 16 weeks. Trypsin, chymotrypsin, phospholipase A, and lipase are found in the 14-week fetus, and their concentrations increase with gestational age (Werlin, 1992). Amylase has been identified in amnionic fluid at 14 weeks (Davis, 1986). The exocrine function of the fetal pancreas is limited. Physiologically important secretion occurs only after stimulation by a secretagogue such as acetylcholine, which is released locally after vagal stimulation (Werlin, 1992). Cholecystokinin normally is released only after protein ingestion and thus ordinarily would not be found in the fetus.

Urinary System

Renal development involves interaction between pluripotential stem cells, undifferentiated mesenchymal cells, and epithelial components (Fanos, 2015). Two primitive urinary systems—the pronephros and the mesonephros—precede development of the metanephros, which forms the final kidney (Chap. 3, Genitourinary Tract Development). The pronephros involutes by 2 weeks, and the mesonephros produces urine at 5 weeks and degenerates by 11 to 12 weeks. Failure of these two structures either to form or to regress may result in anomalous urinary system development. Between 9 and 12 weeks, the

ureteric bud and the nephrogenic blastema interact to produce the metanephros. The kidney and ureter develop from intermediate mesoderm. The bladder and urethra develop from the urogenital sinus. The bladder also develops in part from the allantois.

By week 14, the loop of Henle is functional and reabsorption occurs (Smith, 1992). New nephrons continue to be formed until 36 weeks. In preterm neonates, their formation continues after birth. Although the fetal kidneys produce urine, their ability to concentrate and modify the pH is limited even in the mature fetus. Fetal urine is hypotonic with respect to fetal plasma and has low electrolyte concentrations.

Renal vascular resistance is high, and the filtration fraction is low compared with adult values (Smith, 1992). Fetal renal blood flow and thus urine production are controlled or influenced by the renin-angiotensin system, the sympathetic nervous system, prostaglandins, kallikrein, and atrial natriuretic peptide. The glomerular filtration rate increases with gestational age from less than 0.1 mL/min at 12 weeks to 0.3 mL/min at 20 weeks. In later gestation, the rate remains constant when corrected for fetal weight (Smith, 1992). Hemorrhage or hypoxia generally results in a decrease in renal blood flow, glomerular filtration rate, and urine output.

Urine usually is found in the bladder even in small fetuses. The fetal kidneys start producing urine at 12 weeks. By 18 weeks, they are producing 7 to 14 mL/day, and at term, this increases to 650 mL/day (Wladimiroff, 1974). Maternally administered furosemide increases fetal urine formation, whereas uteroplacental insufficiency, fetal growth restriction, and other fetal disorders can lower it. Obstruction of the urethra, bladder, ureters, or renal pelves can damage renal parenchyma and distort fetal anatomy (Müller Brochut, 2014). Kidneys are not essential for survival in utero but influence control of amnionic fluid composition and volume. Thus, abnormalities that cause chronic fetal anuria are usually accompanied by oligohydramnios and pulmonary hypoplasia. Pathological correlates and prenatal therapy of urinary tract obstruction are discussed in Chapter 16 (Urinary Shunts).

Endocrine Gland Development

Pituitary Gland

The fetal endocrine system is functional for some time before the central nervous system reaches maturity (Mulchahey, 1987). The anterior pituitary gland develops from oral ectoderm—*Rathke pouch*, whereas the posterior pituitary gland derives from neuroectoderm. As with other organ systems, embryonic development involves a complex and highly spatiotemporally regulated network of signaling molecules and transcription factors (Bancalari, 2012; de Moraes, 2012).

Anterior and Intermediate Lobes

The adenohypophysis, or anterior pituitary, differentiates into five cell types that secrete six protein hormones. Of these types, lactotropes produce prolactin (PRL), somatotropes produce growth hormone (GH), corticotropes produce adrenocorticotropic hormone (ACTH), thyrotropes produce thyroid-stimulating hormone (TSH), and gonadotropes produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

ACTH is first detected in the fetal pituitary gland at 7 weeks, and GH and LH have been identified by 13 weeks. By the end of the 17th week, the fetal pituitary gland synthesizes and stores all pituitary hormones. Moreover, the fetal pituitary is responsive to tropic hormones and is capable of secreting these early in gestation (Grumbach, 1974). The fetal pituitary secretes β-endorphin, and cord blood levels of β-endorphin and β-lipotrophin rise with fetal P_{CO_2} (Browning, 1983).

The intermediate lobe in the fetal pituitary gland is well developed. The cells of this structure begin to disappear before term and are absent from the adult pituitary. The principal secretory products of the intermediate lobe cells are α-melanocyte–stimulating hormone (α-MSH) and β-endorphin.

Neurohypophysis

The posterior pituitary gland or neurohypophysis is well developed by 10 to 12 weeks, and oxytocin and arginine vasopressin are demonstrable. Both hormones probably function in the fetus to conserve water by actions directed largely at the lung and placenta rather than kidney. Vasopressin levels in umbilical cord plasma are increased strikingly compared with maternal levels (Chard, 1971).

Thyroid Gland

This gland arises from the endoderm of the second pharyngeal pouch. The thyroid migrates to its final position and the obliterated thyroglossal duct connects to the foramen cecum of the tongue. The pituitary–thyroid system is functional by the end of the first trimester. The thyroid gland is able to synthesize hormones by 10 to 12 weeks, and thyrotropin, thyroxine, and thyroid-binding globulin (TBG) have been detected in fetal serum as early as 11 weeks (Bernal, 2007). The placenta actively concentrates iodide on the fetal side, and by 12 weeks and throughout pregnancy, the fetal thyroid concentrates iodide more avidly than does the maternal thyroid. Thus, maternal administration of either radioiodide or appreciable amounts of ordinary iodide is hazardous after this time (Chap. 58, Fetal and Neonatal Effects). Normal fetal levels of free thyroxine (T_4), free triiodothyronine (T_3), and thyroxin-binding globulin increase steadily throughout gestation (Ballabio, 1989). Compared with adult levels, by 36 weeks, fetal serum concentrations of TSH are higher, total and free T_3 concentrations are lower, and T_4 is similar. This suggests that the fetal pituitary may not become sensitive to feedback until late pregnancy (Thorpe-Beeston, 1991).

Fetal thyroid hormone plays a role in the normal development of virtually all fetal tissues, especially the brain (Forhead, 2014; Rovet, 2014). Its influence is illustrated by congenital hyperthyroidism, which develops when maternal thyroid-stimulating antibody crosses the placenta to stimulate the fetal gland to secrete thyroxine (Donnelley, 2015). These fetuses develop large goiters as shown in Figure 58-3. They also display tachycardia, hepatosplenomegaly,

hematological abnormalities, craniosynostosis, and growth restriction. As children, they have perceptual motor difficulties, hyperactivity, and reduced growth (Wenstrom, 1990). Fetal thyroid disease and its treatment are discussed in Chapter 16 (Surgical Therapy). Neonatal effects of fetal thyroid deficiency are discussed in Chapter 58 (Iodine Deficiency).

The placenta prevents substantial passage of maternal thyroid hormones to the fetus by rapidly deiodinating maternal T_4 and T_3 to form reverse T_3, a relatively inactive thyroid hormone (Vulsma, 1989). Several antithyroid antibodies cross the placenta when present in high concentrations (Pelag, 2002). Those include the long-acting thyroid stimulators (LATS), LATS-protector (LATS-P), and thyroid-stimulating immunoglobulin (TSI). It was previously believed that normal fetal growth and development, which occurred despite fetal hypothyroidism, provided evidence that T_4 was not essential for fetal growth. It is now known, however, that growth proceeds normally because small quantities of maternal T_4 prevent antenatal cretinism in fetuses with thyroid agenesis (Forhead, 2014; Vulsma, 1989). The fetus with congenital hypothyroidism typically does not develop stigmata of cretinism until after birth (Abduljabbar, 2012). Because administration of thyroid hormone will prevent this, by state law, all newborns are tested for high serum levels of TSH (Chap. 32, Routine Newborn Care).

Immediately after birth, thyroid function and metabolism undergo major change. Cooling to room temperature evokes sudden and marked increase in TSH secretion. This in turn causes a progressive increase in serum T_4 levels that are maximal 24 to 36 hours after birth. There are nearly simultaneous elevations of serum T_3 levels.

Adrenal Glands

These glands develop from two separate tissues. The medulla derives from neural crest ectoderm, whereas the fetal and adult cortex arise from intermediate mesoderm. The gland grows rapidly through cell proliferation and angiogenesis, cellular migration, hypertrophy, and apoptosis (Ishimoto, 2011). Fetal glands are much larger in relation to total body size than in adults. The bulk is made up of the inner or fetal zone of the adrenal cortex and involutes rapidly after birth. This zone is scant to absent in rare instances in which the fetal pituitary gland is congenitally absent. The function of the fetal adrenal glands is discussed in detail in Chapter 5 (Fetal Adrenal Gland–placental Interactions).

Immunological System

Infections in utero have provided an opportunity to examine mechanisms of the fetal immune response. Evidence of immunological competence has been reported as early as 13 weeks (Kohler, 1973; Stabile, 1988). In cord blood at or near term, the average level for most components is approximately half that of the adult values (Adinolfi, 1977).

B cells differentiate from pluripotent hemopoietic stem cells that migrate to the liver (Melchers, 2015; Muzzio, 2013). Despite this, in the absence of a direct antigenic stimulus such as infection, fetal plasma immunoglobulins consist almost totally of transferred maternal immunoglobulin G (IgG). Thus, antibodies in the newborn are most often reflective of maternal immunological experiences (American College of Obstetricians and Gynecologists, 2017). The interaction between maternal and fetal T cells is described in detail in Chapter 5 (Amnion).

Immunoglobulin G

Maternal IgG transport to the fetus begins at approximately 16 weeks and increases thereafter. The bulk of IgG is acquired during the last 4 weeks of pregnancy (Gitlin, 1971). Accordingly, preterm neonates are poorly endowed with protective maternal antibodies. Newborns begin to slowly produce IgG, and adult values are not attained until age 3 years. In certain situations, the transfer of IgG antibodies from mother to fetus can be harmful rather than protective to the fetus. The classic example is hemolytic disease of the fetus and newborn resulting from Rh-antigen alloimmunization (Chap. 15, Red Cell Alloimmunization).

Immunoglobulins M and A

In the adult, production of immunoglobulin M (IgM) in response to an antigenic stimulus is superseded in a week or so predominantly by IgG production. In contrast, very little IgM is produced by normal fetuses. With infection, the IgM response is dominant in the fetus and remains so for weeks to months in the newborn. And, because IgM is not transported from the mother, any IgM in the fetus or newborn is that which it produced. Thus, specific IgM levels in umbilical cord blood may be useful in fetal infection diagnosis. According to the American College of Obstetricians and Gynecologists (2017), elevated levels of IgM are usually found in newborns with congenital infection such as rubella, cytomegalovirus infection, or toxoplasmosis. In infants, adult levels of IgM are normally attained by age 9 months.

Immunoglobulin A (IgA) ingested in colostrum provides mucosal protection against enteric infections. This may explain the small amount of fetal secretory IgA found in amnionic fluid (Quan, 1999).

Lymphocytes and Monocytes

The immune system develops early, and B lymphocytes appear in fetal liver by 9 weeks and in blood and spleen by 12 weeks. T lymphocytes begin to leave the thymus at approximately 14 weeks. Despite this, the newborn responds poorly to immunization, and especially poorly to bacterial capsular

polysaccharides. This immature response may stem from a deficient response of newborn B cells to polyclonal activators or from a lack of T cells that proliferate in response to specific stimuli (Hayward, 1983). In the newborn, monocytes are able to process and present antigen when tested with maternal antigen-specific T cells. DNA methylation patterns are developmentally regulated during monocyte-macrophage differentiation and contribute to the antiinflammatory phenotype in macrophages (Kim, 2012).

Musculoskeletal System

The origin of most muscles and bones is mesodermal. The skeleton arises from condensed mesenchyme—embryonic connective tissue—which eventually forms hyaline cartilage models of the bones. By the end of the embryonic period, ossification centers have developed, and bones harden by endochondral ossification. The limb buds appear by the fourth week. Most skeletal muscle derives from myogenic precursor cells in the somites.

ENERGY AND NUTRITION

Because of the small amount of yolk in the human ovum, growth of the embryofetus is dependent on maternal nutrients during the first 2 months. During the first few days after implantation, blastocyst nutrition comes from the interstitial fluid of the endometrium and the surrounding maternal tissue.

Maternal adaptations to store and transfer nutrients to the fetus are discussed in Chapter 4 and summarized here. Three major maternal storage depots are the liver, muscle, and adipose tissue. These maternal depots and the storage hormone insulin are intimately involved in the metabolism of the nutrients absorbed from the gut. Maternal insulin secretion is sustained by increased serum levels of glucose and amino acids. The net effect is maternal storage of glucose as glycogen primarily in liver and muscle, retention of some amino acids as protein, and storage of the excess as fat. Storage of maternal fat peaks in the second trimester and then declines as fetal energy demands rise in the third trimester (Pipe, 1979). Interestingly, the placenta appears to act as a nutrient sensor, altering transport based on the maternal supply and environmental stimuli (Fowden, 2006; Jansson, 2006b).

During times of fasting, glucose is released from glycogen, but maternal glycogen stores cannot provide an adequate amount of glucose to meet requirements for maternal energy and fetal growth. Augmentation is provided by cleavage of triacylglycerols, stored in adipose tissue, which result in free fatty acids and activation of lipolysis.

Glucose and Fetal Growth

Although dependent on the mother for nutrition, the fetus also actively participates in providing its own nutrition. At midpregnancy, fetal glucose concentration is independent of maternal levels and may exceed them (Bozzetti, 1988). Glucose is the major nutrient for fetal growth and energy. Logically, mechanisms exist during pregnancy to minimize maternal glucose use so that the limited maternal supply is available to the fetus. Human placental lactogen (hPL), a hormone normally abundant in the mother but not the fetus, has an insulin antagonist effect. It blocks the peripheral uptake and use of glucose, while promoting mobilization and use of free fatty acids by maternal tissues (Chap. 5, Human Placental Lactogen). This hormone is also diabetogenic as discussed in Chapter 57 (Gestational Diabetes).

Glucose Transport

The transfer of d-glucose across cell membranes is accomplished by a carrier-mediated, stereospecific, nonconcentrating process of facilitated diffusion. There are 14 glucose transport proteins (GLUTs) encoded by the *SLC2A* gene family and characterized by tissue-specific distribution (Leonce, 2006). GLUT-1 and GLUT-3 primarily facilitate glucose uptake by the placenta and are located in the plasma membrane of the syncytiotrophoblast microvilli (Acosta, 2015). DNA methylation regulates expression of placental *GLUT* genes, with epigenetic modification across gestation (Novakovic, 2013). It increases as pregnancy advances and is induced by almost all growth factors (Frolova, 2011). GLUT-3 expression is upregulated with fetal growth restriction (Janzen, 2013).

Lactate is a product of glucose metabolism and transported across the placenta also by facilitated diffusion. By way of cotransport with hydrogen ions, lactate is probably transported as lactic acid.

Fetal Macrosomia

The precise biomolecular events in the pathophysiology of fetal macrosomia are not defined. Nonetheless, fetal hyperinsulinemia is clearly one driving force (Luo, 2012). As discussed in Chapter 44 (Normal Birthweight), insulin-like growth factor, fibroblast growth factor, and corticotropin-releasing hormone (CRH) and are important regulators of placental development and function (Gao, 2012; Giudice, 1995). Maternal obesity begets fetal macrosomia (Chap. 44, Definition). In addition, it is hypothesized that maternal obesity affects fetal cardiomyocyte growth that may result in fetal cardiomyopathy or even congenital heart disease (Roberts, 2015).

Leptin

This polypeptide hormone was originally identified as a product of adipocytes and a regulator of energy homeostasis by curbing appetite. It also contributes to angiogenesis, hemopoiesis, osteogenesis, pulmonary maturation, and neuroendocrine, immune, and reproductive functions (Briffa, 2015; Maymó, 2009). Leptin is produced by the mother, fetus, and placenta. It is expressed in syncytiotrophoblast and fetal vascular endothelial cells. Of placental production, 5

percent enters the fetal circulation, whereas 95 percent is transferred to the mother (Hauguel-de Mouzon, 2006). Leptin concentrations peak in amnionic fluid at midpregnancy (Scott-Finley, 2015).

Fetal leptin levels begin rising at approximately 34 weeks and are correlated with fetal weight. This hormone is involved in the development and maturation of the heart, brain, kidneys, and pancreas, and its levels are decreased with fetal growth restriction (Briffa, 2015). Abnormal levels have been associated with fetal growth disorders, gestational diabetes, and preeclampsia (Fasshauer, 2014). Postpartum, leptin levels decline in both the newborn and mother. Perinatal leptin is associated with the development of metabolic syndromes later in life (Briffa, 2015; Granado, 2012).

Free Fatty Acids and Triglycerides

The newborn has a large proportion of fat, which averages 15 percent of body weight (Kimura, 1991). Thus, late in pregnancy, a substantial part of the substrate transferred to the human fetus is stored as fat. Although maternal obesity raises placental fatty acid uptake and fetal fat deposition, it does not appear to affect fetal organ growth (Dubé, 2012). Neutral fat in the form of triglycerides does not cross the placenta, but glycerol does. Despite this, evidence supports that abnormal maternal concentrations of triglycerides—both low and high levels—are associated with major congenital anomalies (Nederlof, 2015).

There is preferential placental-fetal transfer of long-chain polyunsaturated fatty acids (Gil-Sanchez, 2012). Lipoprotein lipase is present on the maternal but not on the fetal side of the placenta. This arrangement favors hydrolysis of triacylglycerols in the maternal intervillous space yet preserves these neutral lipids in fetal blood. Fatty acids transferred to the fetus can be converted to triglycerides in the fetal liver.

The placental uptake and use of LDL is an alternative mechanism for fetal assimilation of essential fatty acids and amino acids (Chap. 5, Placental Estrogen Production). LDL binds to specific receptors in the coated-pit regions of the syncytiotrophoblast microvilli. The large LDL particle, measuring about 250,000 Da, is taken up by a process of receptor-mediated endocytosis. The apoprotein and cholesterol esters of LDL are hydrolyzed by lysosomal enzymes in the syncytium to yield: (1) cholesterol for progesterone synthesis; (2) free amino acids, including essential amino acids; and (3) essential fatty acids, primarily linoleic acid.

Amino Acids

The placenta concentrates many amino acids in the syncytiotrophoblast, which are then transferred to the fetal side by diffusion. Based on data from cordocentesis blood samples, the amino acid concentration in umbilical cord plasma is greater than in maternal venous or arterial plasma (Morriss, 1994). Transport system activity is influenced by gestational age and environmental factors. These include heat stress, hypoxia, under- and overnutrition, and hormones such as glucocorticoids, growth hormone, and leptin (Briffa, 2015; Fowden, 2006). Trophoblastic mammalian target of rapamycin complex 1 (mTORC1) regulates placental amino acid transporters and modulates transfer across the placenta (Jansson, 2012). In vivo studies suggest an upregulation of transport for certain amino acids and a greater delivery rate of these to the fetuses of women with gestational diabetes associated with fetal overgrowth (Jansson, 2006a).

Proteins

Placental transfer of larger proteins is limited, but there are exceptions. IgG crosses the placenta in large amounts via endocytosis and trophoblast Fc receptors. IgG transfer depends on maternal levels of total IgG, gestational age, placental integrity, IgG subclass, and antigenic potential (Palmeira, 2012). Conversely, the larger immunoglobulins—IgA and IgM—of maternal origin are effectively excluded from the fetus.

Ions and Trace Metals

Calcium and phosphorus are actively transported from mother to fetus. Calcium is transferred for fetal skeletal mineralization (Olausson, 2012). A calcium-binding protein is produced in placenta. Parathyroid hormone-related protein (PTH-rP), as the name implies, acts as a surrogate PTH in many systems (Chap. 5, Placental Progesterone Production). PTH is not found in fetal plasma, but PTH-rP is present, suggesting that PTH-rP is the fetal parathormone. The expression of PTH-rP in cytotrophoblasts is modulated by the extracellular concentration of Ca^{2+} (Hellman, 1992). It seems possible, therefore, that PTH-rP synthesized in decidua, placenta, and other fetal tissues is important in fetal Ca^{2+} transfer and homeostasis.

Iodide transport is clearly attributable to a carrier-mediated, energy-requiring active process. And indeed, the placenta concentrates iodide. The concentrations of zinc in the fetal plasma also are greater than those in maternal plasma. Conversely, copper levels in fetal plasma are less than those in maternal plasma. This fact is of particular interest because important copper-requiring enzymes are necessary for fetal development.

Placental Sequestration of Heavy Metals

The heavy metal–binding protein metallothionein-1 is expressed in human syncytiotrophoblast. This protein binds and sequesters a host of heavy metals, including zinc, copper, lead, and cadmium. Despite this, fetal exposure is variable (Caserta, 2013). For example, lead enters the fetal environment at a level 90 percent of maternal concentrations. In contrast, placental transfer of cadmium is limited (Kopp, 2012). The most common source of environmental cadmium is cigarette smoke.

Metallothionein also binds and sequesters copper (Cu^{2+}) in placental tissue. This accounts for the low levels of Cu^{2+} in cord blood (Iyengar, 2001). It is possible that cadmium provokes metallothionein synthesis in the amnion. This may cause Cu^{2+} sequestration, a pseudo–copper deficiency, and in turn, diminished tensile strength of the amnion.

Vitamins

The concentration of vitamin A (retinol) is greater in fetal than in maternal plasma and is bound to retinol-binding protein and to prealbumin. Retinol-binding protein is transferred from the maternal compartment across the syncytiotrophoblast. The transport of vitamin C—ascorbic acid—from mother to fetus is accomplished by an energy-dependent, carrier-mediated process. Levels of principal vitamin D metabolites, including 1,25-dihydroxycholecalciferol, are greater in maternal plasma than in fetal plasma. The 1β-hydroxylation of 25-hydroxyvitamin D_3 is known to take place in placenta and in decidua.

PLACENTAL ROLE IN EMBRYOFETAL DEVELOPMENT

The placenta is the organ of transfer between mother and fetus. Within this maternal-fetal interface, oxygen and nutrients transfer from the mother to the fetus, whereas CO_2 and metabolic wastes are directed from fetus to mother. Fetal blood, which is contained in the fetal capillaries of the chorionic villi, has no direct contact with maternal blood, which remains in the intervillous space. Instead, bidirectional transfer depends on processes that allow or aid the transport through the syncytiotrophoblast that lines chorionic villi.

Over the past few years, it has become apparent that breaks in the chorionic villi permit escape of fetal cells and other blood-borne material into the maternal circulation. This leakage is the mechanism by which some D-negative women become sensitized by the erythrocytes of their D-positive fetus (Chap. 15, Red Cell Alloimmunization). In fact, after 10 weeks, 10 to 15 percent of cell-free DNA (cfDNA) in maternal plasma is placental in origin, that is, trophoblastic DNA (Norton, 2012). The escape of fetal cells can also lead to fetal microchimerism from entrance of allogeneic fetal cells, including trophoblast, into maternal blood and other organs (Rijnik, 2015). Volumes are estimated to range from 1 to 6 cells/mL at midpregnancy. Some fetal cells become “immortal” in that they persist in the maternal circulation and organs following pregnancy. As discussed in Chapter 59 (Systemic Lupus Erythematosus), the clinical corollary is that some maternal autoimmune diseases may be provoked by such microchimerism.

The Intervillous Space

Maternal blood within the intervillous space is the primary source of maternal–fetal transfer. Blood from the maternal spiral arteries directly bathes the trophoblast layer that surrounds the villi. Substances transferred from mother to fetus first enter the intervillous space and are then transported to the syncytiotrophoblast. As such, the chorionic villi and intervillous space function together as the fetal lung, gastrointestinal tract, and kidney.

Circulation within the intervillous space is described in Chapter 5 (Breaks in the Placental “Barrier”). Intervillous and uteroplacental blood flow increases throughout the first trimester of normal pregnancies (Mercé, 2009). At term, the residual volume of the intervillous space approximates 140 mL. Moreover, uteroplacental blood flow near term is estimated to be 700 to 900 mL/min, and most of this blood apparently goes to the intervillous space (Pates, 2010).

Active labor contractions reduce blood flow into the intervillous space to a degree that depends on contraction intensity. Blood pressure within the intervillous space is significantly less than uterine arterial pressure, but somewhat greater than venous pressure. The latter, in turn, varies depending on several factors, including maternal position (Nelson, 2015). When supine, for example, pressure in the lower part of the inferior vena cava is elevated, and consequently, pressure in the uterine and ovarian veins, and in turn in the intervillous space, is increased.

Placental Transfer

Substances that pass from maternal to fetal blood must first traverse the syncytiotrophoblast, the attenuated cytotrophoblast layer, the villous stroma, and finally, the fetal capillary wall. Although this histological barrier separates maternal and fetal circulations, it is not a simple physical barrier. First, throughout pregnancy, syncytiotrophoblast actively or passively permits, facilitates, and adjusts the amount and rate of substance transfer to the fetus. The maternal-facing syncytiotrophoblast surface is characterized by a complex microvillous structure. The fetal-facing basal cell membrane is the site of transfer to the intravillous space. Finally, the villous capillaries are an additional site for transport from the intravillous space into fetal blood, or vice versa. In determining the effectiveness of the human placenta as an organ of transfer, several variables are important and shown in Table 7-1. Zhao and coworkers (2014) have provided a review of the pharmacology of these interactions.

TABLE 7-1

Variables of Maternal-Fetal Substance Transfer

Maternal plasma concentration and carrier-protein binding of the substance
Maternal blood flow rate through the intervillous space
Trophoblast surface area size available for exchange
Physical trophoblast properties to permit simple diffusion
Trophoblast biochemical machinery for active transport
Substance metabolism by the placenta during transfer
Fetal intervillous capillary surface area size for exchange
Fetal blood concentration of the substance
Specific binding or carrier proteins in the fetal or maternal circulation
Villous capillary blood flow rate

Mechanisms of Transfer

Most substances with a molecular mass <500 Da pass readily through placental tissue by simple diffusion. These include oxygen, CO_2, water, most electrolytes, and anesthetic gases (Carter, 2009). Some low-molecular-weight compounds undergo transfer facilitated by syncytiotrophoblast. These are usually those that have low concentrations in maternal plasma but are essential for normal fetal development.

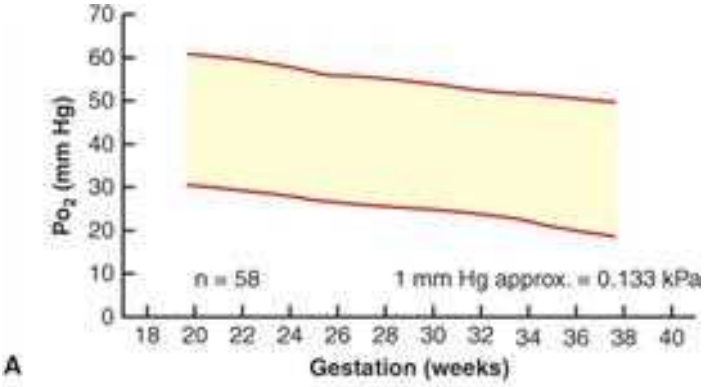
Insulin, steroid hormones, and thyroid hormones cross the placenta, but very slowly. The hormones synthesized in situ in the syncytiotrophoblast enter both the maternal and fetal circulations, but not equally (Chap. 5, Placental Hormones). Examples are hCG and hPL concentrations, which are much lower in fetal plasma than in maternal plasma. High-molecular-weight substances usually do not traverse the placenta, but there are important exceptions. One is immunoglobulin G—molecular weight 160,000 Da—which is transferred by way of a specific trophoblast receptor–mediated mechanism (Stach, 2014).

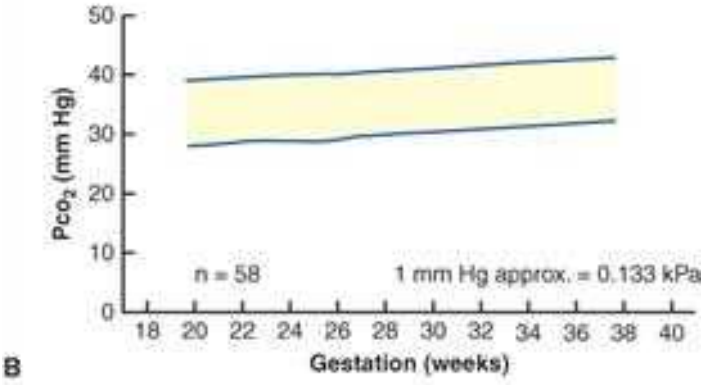
Transfer of Oxygen and Carbon Dioxide

Placental oxygen transfer is blood flow limited. Using estimated uteroplacental blood flow, Longo (1991) calculated oxygen delivery to be approximately 8 mL O_2/min/kg of fetal weight. Normal values for oxygen and CO_2 are presented in Figure 7-13. Because of the continuous passage of oxygen from maternal blood in the intervillous space to the fetus, its oxygen saturation resembles that in maternal capillaries. The average oxygen saturation of intervillous blood is estimated to be 65 to 75 percent, with a partial pressure (Po_2) of 30 to 35 mm Hg. The oxygen saturation of umbilical vein blood is similar but has a somewhat lower oxygen partial pressure. Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin. This is illustrated by the oxyhemoglobin disassociation curve, which is described in Chapter 47 (Positive End-Expiratory Pressure).

FIGURE 7-13

Umbilical venous cordocentesis samples obtained in fetuses being evaluated for possible intrauterine infections or hemolysis, but who were found to be healthy. **A.** Oxygen pressure (Po_2). **B.** Carbon dioxide pressure (Pco_2). Shaded areas represent 5th to 95th percentiles. (Modified from Ramsey, MM: Normal Values in Pregnancy. Ramsay MM, James DK, Steer PJ, et al (eds). London, Elsevier, 1996, p 106.)





The placenta is highly permeable to CO_2, which traverses the chorionic villus by diffusion more rapidly than oxygen. Near term, the partial pressure of carbon dioxide (Pco_2) in the umbilical arteries averages 50 mm Hg, which is approximately 5 mm Hg higher than in the maternal intervillous blood. Fetal blood has less affinity for CO_2 than does maternal blood, thereby favoring CO_2 transfer from fetus to mother. Also, mild maternal hyperventilation results in a fall in Pco_2 levels, favoring a transfer of CO_2 from the fetal compartment to maternal blood.

Selective Transfer and Facilitated Diffusion

Although simple diffusion is an important method of placental transfer, the trophoblast and chorionic villus unit demonstrate enormous selectivity in transfer. This results in different metabolite concentrations on the two sides of the villus. Importantly, the levels of many substances that are not synthesized by the fetus are several times higher in fetal than in maternal blood. Ascorbic acid is one example. This relatively low-molecular-weight substance might be expected to traverse the placenta by simple diffusion. The concentration of ascorbic acid, however, is two to four times higher in fetal plasma than in maternal plasma (Morriss, 1994). Another example is the unidirectional transfer of iron. Typically, maternal plasma iron concentration is much lower than that in her fetus. Even with severe maternal iron-deficiency anemia, the fetal hemoglobin mass is normal.

CHAPTER 8: Preconceptional Care

Pregnancy may be associated with certain diseases that existed before the inception of pregnancy. As a rule, all diseases which subject the organism to a considerable strain are much more serious when occurring in a pregnant woman.

—J. Whitridge Williams (1903)

INTRODUCTION

The Centers for Disease Control and Prevention (CDC) (2015) defines preconceptional care as "a set of interventions that aim to identify and modify biomedical, behavioral, and social risks to a woman's health or pregnancy outcome through prevention and management." To achieve this goal, the CDC has developed an action plan for preconceptional health care in the United States (Johnson, 2006). The American College of Obstetricians and Gynecologists (2017e) and the Society for Maternal-Fetal Medicine (2014) also reaffirm the importance of preconceptional care, and the following objectives have been established for advancing it:

1. Improve knowledge, attitudes, and behaviors of men and women related to preconceptional health
2. Assure that all childbearing-aged women receive preconceptional care services—including evidence-based risk screening, health promotion, and interventions—that will enable them to enter pregnancy in optimal health
3. Reduce risks indicated by a previous adverse pregnancy outcome through interconceptional interventions to prevent or minimize recurrent adverse outcomes
4. Reduce the disparities in adverse pregnancy outcomes

To illustrate potentially modifiable conditions, data that describe the health status of women who delivered liveborn neonates in the United States in 2004 are reviewed. Table 8-1 demonstrates the high prevalence of many conditions that may be amenable to intervention during the preconceptional and interpregnancy periods. To be successful, however, strategies that mitigate these potential pregnancy risks must be provided before conception. By the time most women realize they are pregnant—usually 1 to 2 weeks after the first missed period—the embryo has already begun to form. Thus, many preventive steps—for example, folic acid to avoid neural-tube defects—will be ineffective if initiated at this time. Importantly, up to half of all pregnancies in the United States in 2008 were unplanned according to the Guttmacher Institute (2015), and often these are at greatest risk.

TABLE 8-1

Prevalence of Prepregnancy Maternal Behaviors, Experiences, Health Conditions, and Previous Poor Birth Outcomes[a]

Factor	Prevalence (%)
Tobacco use	23
Alcohol use	50
Multivitamin use	35
Contraceptive nonuse[b]	53
Dental visit	78
Health counseling	30
Physical abuse	4
Stress	19
Underweight	13
Overweight	13
Obesity	22
Diabetes	2
Asthma	7
Hypertension	2
Heart problem	1
Anemia	10
Prior low-birthweight neonate	12
Prior preterm neonate	12

[a]In the United States in 2004.

[b]Among women who were not trying to become pregnant.

Data from D'Angelo D, Williams L, Morrow B, et al: Preconception and interconception health status of women who recently gave birth to a live-born infant—Pregnancy Risk Assessment Monitoring System (PRAMS), United States, 26 reporting areas, 2004. MMWR 56(10):1, 2007.

Few randomized trials evaluate preconceptional counseling efficacy, in part because withholding such counseling would be unethical. Also, pregnancy outcomes are dependent on the interaction of various maternal, fetal, and environmental factors. Thus, ascribing a salutary outcome to a specific intervention is difficult (Moos, 2004; Temel, 2014). However, prospective observational and case-control studies have demonstrated the successes of preconceptional counseling (American College of Obstetrics and Gynecologists, 2016b). Moos and coworkers (1996) assessed the effectiveness of a preconceptional counseling program administered during routine health care provision to reduce unintended pregnancies. The 456 counseled women had a 50-percent greater likelihood of subsequent pregnancies that they considered "intended" compared with 309 uncounseled women. Moreover, compared with another group of women who had no health care before pregnancy, the counseled group had a 65-percent higher rate of intended pregnancy. Interesting ethical aspects of *paternal* lifestyle modification were reviewed by van der Zee and associates (2013).

COUNSELING SESSION

Gynecologists, internists, family practitioners, and pediatricians have the best opportunity to provide preventive counseling during periodic health maintenance examinations. The occasion of a negative pregnancy test is also an excellent time for education. Jack and colleagues (1995) administered a comprehensive preconceptional risk survey to 136 such women, and almost 95 percent reported at least one problem that could affect a future pregnancy. These included medical or reproductive problems—52 percent; family history of genetic disease—50 percent; increased risk of human immunodeficiency virus infection—30 percent; increased risk of hepatitis B and illegal substance abuse—25 percent; alcohol use—17 percent; and nutritional risks—54 percent. Counselors should be knowledgeable regarding relevant medical diseases, prior surgery, reproductive disorders, or genetic conditions and must be able to interpret data and recommendations provided by other specialists (Simpson, 2014). If the practitioner is uncomfortable providing guidance, the woman or couple should be referred to an appropriate counselor.

Women presenting specifically for preconceptional evaluation should be advised that information collection may be time consuming, depending on the number and complexity of factors that require assessment. The intake evaluation includes a thorough review of the medical, obstetrical, social, and family histories. Useful information is more likely to be obtained by asking specific questions regarding each of these histories and each family member than by asking general, open-ended questions. Some important information can be obtained by questionnaires that address these topics. Answers are reviewed with the couple to ensure appropriate follow-up, including obtaining relevant medical records.

MEDICAL HISTORY

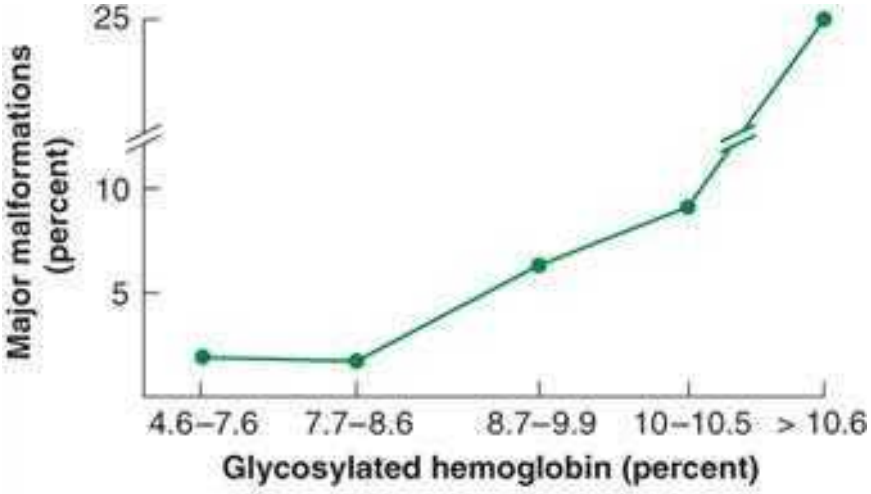
With specific medical conditions, general points include how pregnancy will affect maternal health and how a high-risk condition might affect the fetus. Afterward, advice for improving outcome is provided. Some chronic conditions that may affect pregnancy outcomes include treated or active cancer, prior peripartum cardiomyopathy, and systemic lupus erythematosus (Amant, 2015; Buyon, 2015; McNamara, 2015). Importantly, psychological health should be considered (Lassi, 2014). Detailed preconceptional information regarding a few exemplary conditions is found in the next sections and in the other topic-specific chapters of this text.

Diabetes Mellitus

Because maternal and fetal pathology associated with hyperglycemia is well known, diabetes is the prototype of a condition for which preconceptional counseling is beneficial. Diabetes-associated risks to both mother and fetus are discussed in detail in Chapter 57 (Impact on Pregnancy). Many of these complications can be avoided if glucose control is optimized before conception. Another important aspect of counseling pertains to the frequent use of teratogenic angiotensin-converting enzyme inhibitors in this population (Podymow, 2015).

The American College of Obstetricians and Gynecologists (2016a) has concluded that preconceptional counseling for women with pregestational diabetes is both beneficial and cost-effective and should be encouraged. The American Diabetes Association has promulgated consensus recommendations for preconceptional care for diabetic women (Kitzmiller, 2008). These guidelines advise obtaining a thorough inventory of disease duration and related complications and completing a clinical and laboratory examination for end-organ damage. Perhaps most essential, they encourage a preconceptional goal of the lowest hemoglobin A_{1c} level possible without undue hypoglycemic risk to the mother. In addition to assessing diabetic control during the preceding 6 weeks, hemoglobin A_{1c} measurement can also be used to estimate risks for major anomalies as shown in Figure 8-1. Although these data are from women with severe overt diabetes, the incidence of fetal anomalies in women who have gestational diabetes with fasting hyperglycemia is increased fourfold compared with that in normal women (Sheffield, 2002).

FIGURE 8-1
Relationship between first-trimester glycosylated hemoglobin values and risk for major congenital malformations in 320 women with insulin-dependent diabetes. (Data from Kitzmiller JL, Gavin LA, Gin GD, et al: Preconception care of diabetics. JAMA 265:731, 1991.)



Such counseling in diabetic women has been shown to be effective. Leguizamón and associates (2007) identified 12 studies that included more than 3200 pregnancies in women with insulin-dependent diabetes. Of the 1618 women without preconceptional counseling, 8.3 percent had a fetus with a major congenital anomaly, and this compared with a rate of 2.7 percent in the 1599 women who did have counseling. Tripathi and coworkers (2010) compared outcomes in 588 women with pregestational diabetes in whom approximately half had preconceptional counseling. Those women who received counseling had improved glycemic control before pregnancy and in the first trimester. This group also had higher folate intake rates preconceptionally, and they experienced lower rates of adverse outcomes—defined as a perinatal death or major congenital anomaly. These cited benefits are accompanied by reduced health-care costs in diabetic women. From their review, Reece and Homko (2007) found that each $1 expended for a preconceptional care program saved between $1.86 and $5.19 in averted medical costs. Despite such benefits, the proportion of diabetic women receiving preconceptional care is suboptimal. In their study of approximately 300 diabetic women in a managed-care plan, Kim and colleagues (2005) found that only approximately one half had preconceptional counseling. Counseling rates are undoubtedly much lower among uninsured and indigent women.

Epilepsy

Compared with unaffected women, those with a seizure disorder carry an undisputed augmented risk of having neonates with structural anomalies (Chap. 12, Antiepileptic Medications). Some early reports indicated that epilepsy conferred an elevated a priori risk for congenital malformations that was independent of anticonvulsant treatment effects. Although more recent publications have largely failed to confirm this increased risk in untreated women, it is difficult to refute entirely because

women who are controlled without medication generally have less severe disease (Cassina, 2013; Vajda, 2015). Fried and associates (2004) conducted a metaanalysis of studies comparing epileptic women, both treated and untreated, with controls. In this study, greater malformation rates could only be demonstrated in the offspring of women who had been exposed to anticonvulsant therapy. Veiby and coworkers (2009) used the Medical Birth Registry of Norway and identified an increased malformation risk only in women who were exposed to valproic acid (5.6 percent) or polytherapy (6.1 percent). Untreated women had anomaly rates that were similar to those of nonepileptic controls. Risks for miscarriage and stillbirths in exposed epileptic women do not appear elevated (Aghajanian, 2015; Bech, 2014).

Ideally, seizure control is optimized preconceptionally. For example, Vajda and colleagues (2008) analyzed data from the Australian Register of Antiepileptic Drugs in Pregnancy. They found the seizure risk during pregnancy was 50- to 70-percent lower in women without a seizure in the year preceding pregnancy compared with a group experiencing seizures in this preceding year. No further advantages accrued if the seizure-free period exceeded a year.

Treatment goals attempt to achieve seizure control with monotherapy and with medications considered less teratogenic (Aguglia, 2009; Tomson, 2009). As discussed in detail in Chapter 60 (Preconceptional Counseling) and shown in Table 8-2, some one-drug regimens are more teratogenic than others. Valproic acid, in particular, is avoided if possible, as this medication has consistently been associated with a greater risk for major congenital malformations than other antiepileptic drugs (Jentink, 2010; Vajda, 2015). Trimethadione is contraindicated (Aghajanian, 2015). The American Academy of Neurology recommends consideration of antiseizure medication discontinuation before pregnancy in suitable candidates (Jeha, 2005). These include women who satisfy the following criteria: (1) have been seizure-free for 2 to 5 years, (2) display a single seizure type, (3) have a normal neurological examination and normal intelligence, and (4) show electroencephalogram results that have normalized with treatment.

TABLE 8-2

First-Trimester Antiepileptic Monotherapy and the Associated Major Malformation Risk

Antiepileptic (n)	Malformations (%)	Relative Risk (95% CI)[a]
Unexposed controls (442)	1.1	Reference
Lamotrigine (1562)	2.0	1.8 (0.7–4.6)
Carbamazepine (1033)	3.0	2.7 (1.0–7.0)
Phenytoin (416)	2.9	2.6 (0.9–7.4)
Levetiracetam (450)	2.4	2.2 (0.8–6.4)
Topiramate (359)	4.2	3.8 (1.4–10.6)
Valproate (323)	9.3	9.0 (3.4–23.3)
Phenobarbital (199)	5.5	5.1 (1.8–14.9)
Oxcarbazepine (182)	2.2	2.0 (0.5–7.4)
Gabapentin (145)	0.7	0.6 (0.07–5.2)
Clonazepam (64)	3.1	2.8 (0.5–14.8)

[a]Risk compared with that of the unexposed reference population of nonepileptic women.

Data from Hernández-Díaz S, Smith CR, Shen A, et al: Comparative safety of antiepileptic drugs during pregnancy. Neurology 78:1692, 2012.

Epileptic women should be advised to daily take a 4-mg folic acid supplement. Even so, it is not entirely clear that folate supplementation reduces the fetal malformation risk in pregnant women taking anticonvulsant therapy. In one case-control study, Kjær and associates (2008) reported that the congenital abnormality risk was reduced by maternal folate supplementation in fetuses exposed to carbamazepine, phenobarbital, phenytoin, and primidone. Conversely, from the United Kingdom Epilepsy and Pregnancy Register, Morrow and coworkers (2009) compared fetal outcomes of women who received preconceptional folic acid with those who did not receive it until later in pregnancy or not at all. In this study, a paradoxical *increase* in the number of major congenital malformations was observed in the group who received preconceptional folate. These investigators concluded that folate metabolism may be only a part of the mechanism by which malformations are induced in women taking these medications.

Immunizations

Preconceptional counseling includes assessment of immunity against common pathogens. Also, depending on health status, travel plans, and time of year, other immunizations may be indicated as discussed in Chapter 9 (Table 9-7). Vaccines that contain toxoids such as tetanus are suitable before or during gestation. Also, those containing killed bacteria or viruses—such as influenza, pneumococcus, hepatitis B, meningococcus, and rabies vaccines—are not associated with adverse fetal outcomes and are not contraindicated preconceptionally or during pregnancy. Conversely, live-virus vaccines are not recommended

during pregnancy. Examples are vaccines against varicella-zoster, measles, mumps, rubella, polio, chickenpox, and yellow fever. Moreover, 1 month or longer should ideally pass between vaccination and conception attempts. That said, inadvertent administration of measles, mumps, rubella (MMR) or varicella vaccines during pregnancy should not generally be considered indications for pregnancy termination. Most reports indicate that the fetal risk is only theoretical. Immunization to smallpox, anthrax, and other bioterrorism diseases should be discussed if clinically appropriate (Chap. 64, Mycotic Infections).

With some infections, vaccines are unavailable. One recent example is the Zika virus (Brasil, 2016). For this virus, the CDC has issued travel advisories for pregnant women (Petersen, 2016; Schuler-Faccini, 2016).

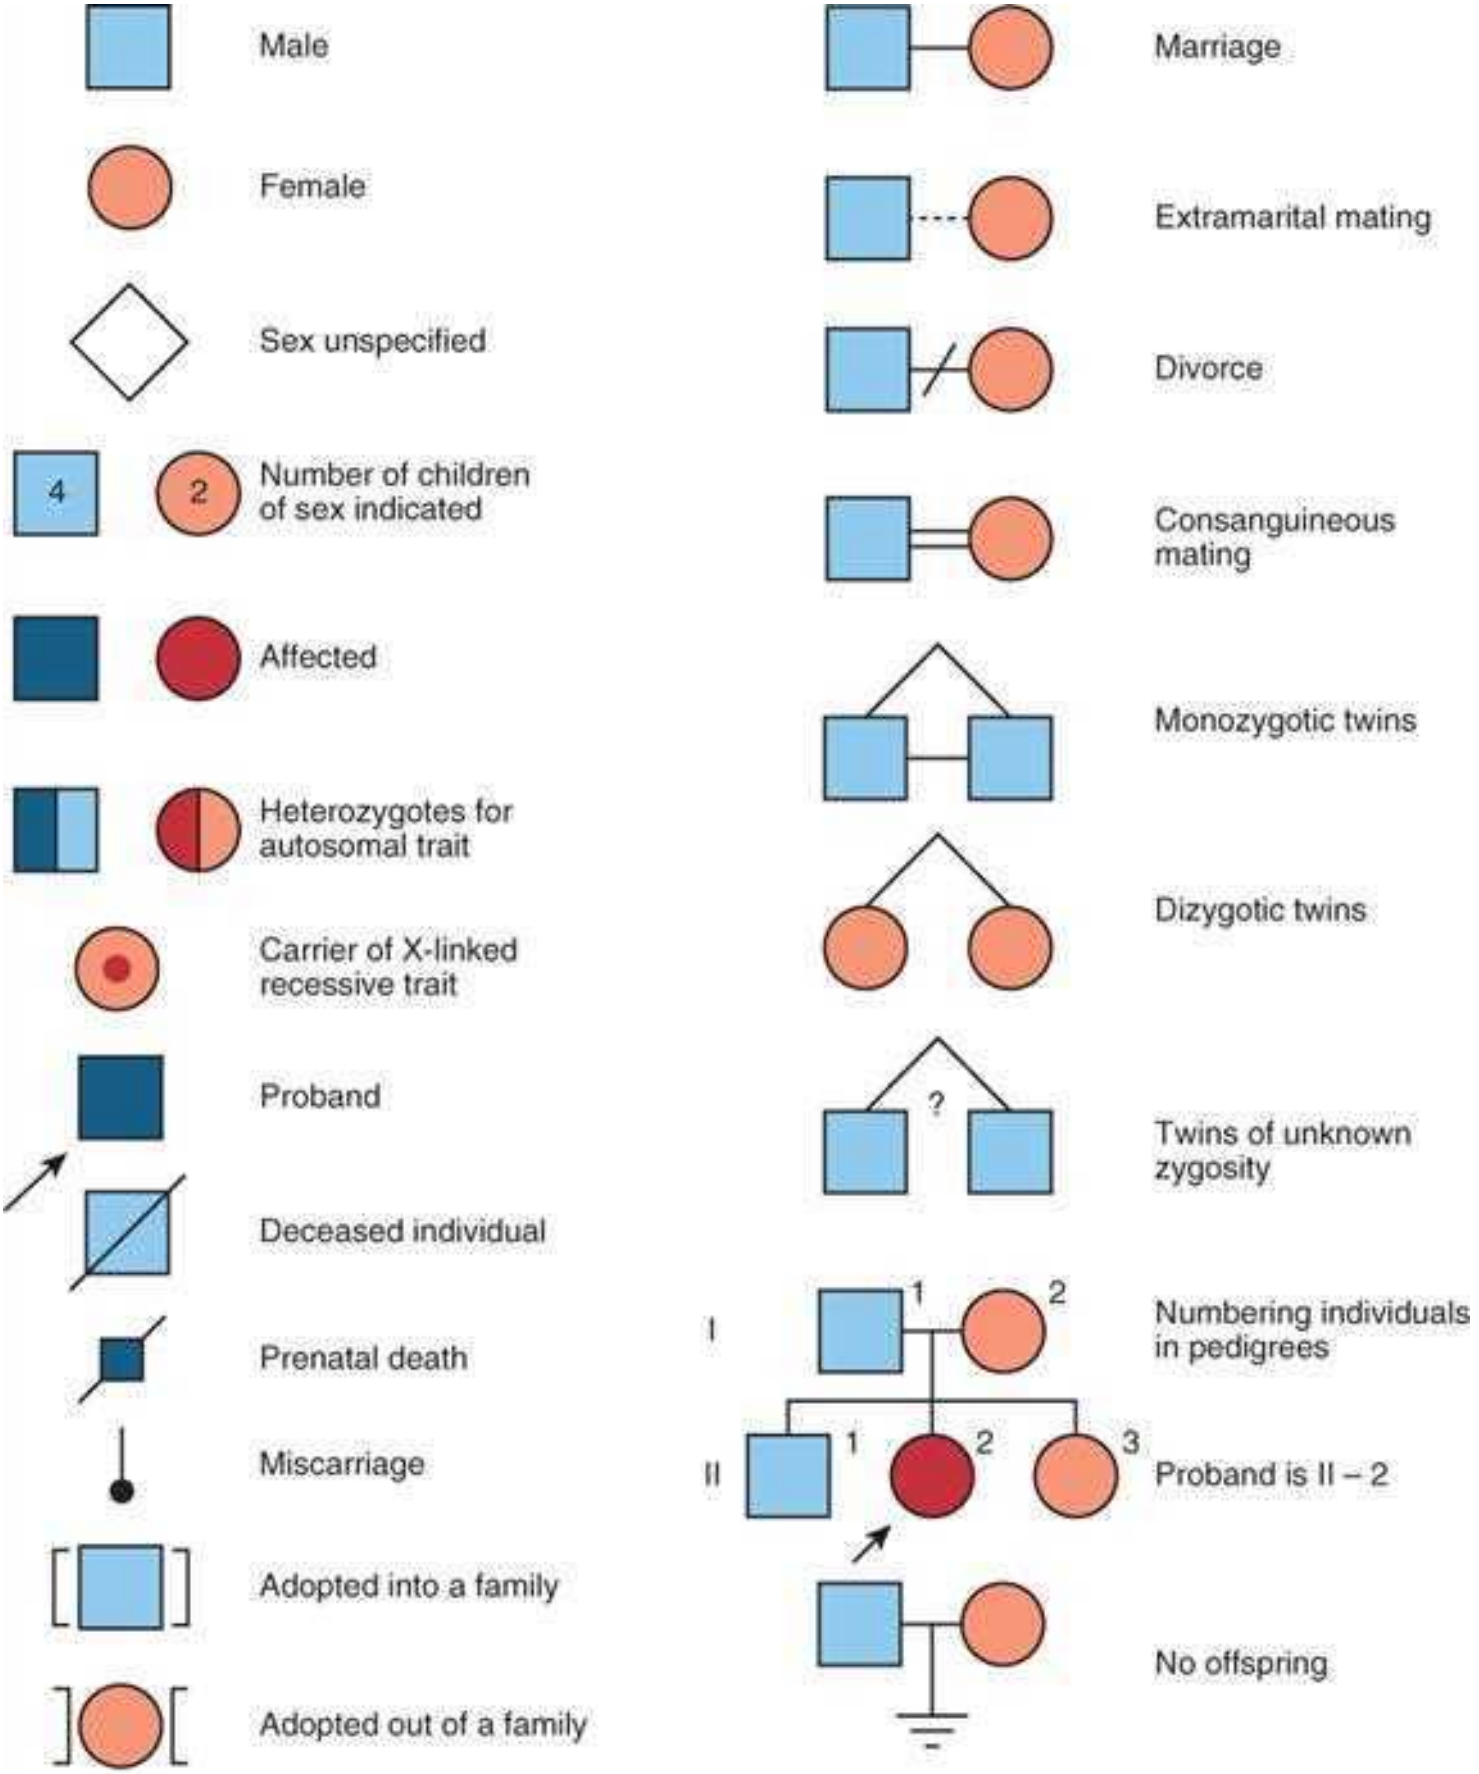
GENETIC DISEASES

The CDC (2016) estimates that 3 percent of neonates born each year in the United States will have at least one birth defect. Importantly, such defects are the leading cause of infant mortality and account for 20 percent of deaths. The benefits of preconceptional counseling usually are measured by comparing the incidence of new cases before and after initiation of a counseling program. Congenital conditions that clearly benefit from patient education include neural-tube defects, phenylketonuria, thalassemias, and other genetic diseases more common in individuals of Eastern European Jewish descent.

Family History

Pedigree construction using the symbols shown in Figure 8-2 is the most thorough method for obtaining a family history as a part of genetic screening. The health and reproductive status of each “blood relative” should be individually reviewed for medical illnesses, mental retardation, birth defects, infertility, and pregnancy loss. Certain racial, ethnic, or religious backgrounds may indicate elevated risk for specific recessive disorders.

FIGURE 8-2
Symbols used for pedigree construction. (Modified with permission from Thompson MW, McInnes RR, Huntington FW (eds): Genetics in Medicine, 5th ed. Philadelphia, Saunders, 1991.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catharine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

Although most women can provide some information regarding their history, their understanding may be limited. For example, several studies have shown that pregnant women often fail to report a birth defect in the family or they report it incorrectly.

Thus, any disclosed defect or genetic disease should be confirmed by reviewing pertinent medical records or by contacting affected relatives for additional information.

Neural-Tube Defects

The incidence of neural-tube defects (NTDs) is 0.9 per 1000 live births, and they are second only to cardiac anomalies as the most frequent structural fetal malformation (Chap. 13, Genetic Tests). Some NTDs, as well as congenital heart defects, are associated with specific mutations. One example is the 677C → T substitution in the gene that encodes methylene tetrahydrofolate reductase. For this and similar gene defects, the trial conducted by the Medical Research Council Vitamin Study Research Group (1991) showed that preconceptional folic acid therapy significantly reduced the risk for a recurrent NTD by 72 percent. More importantly, because more than 90 percent of neonates with NTDs are born to women at low risk, Czeizel and Dudas (1992) showed that supplementation reduced the a priori risk of a first NTD occurrence. It is currently recommended, therefore, that all women who may become pregnant take daily 400 to 800 µg of folic acid orally before conception and through the first trimester (U.S Preventive Services Task Force, 2009). Folate fortification of cereal grains has been mandatory in the United States since 1998, and this practice has also resulted in decreased neural-tube defect rates (Williams, 2015). Despite the demonstrated benefits of folate supplementation, only half of women have taken folic acid supplementation periconceptionally (de Jong-van den Berg, 2005; Goldberg, 2006). The strongest predictor of use appears to be consultation with a health-care provider before conception.

Phenylketonuria

More than 600 mutations have been identified in the phenylalanine hydroxylase gene. The inherited defect in phenylalanine metabolism exemplifies diseases in which the fetus may not be at risk to inherit the disorder but may be damaged by maternal disease. Specifically, mothers with phenylketonuria (PKU) who eat an unrestricted diet have abnormally high blood phenylalanine levels. This amino acid readily crosses the placenta and can damage developing fetal organs, especially neural and cardiac tissues (Table 8-3).

TABLE 8-3

Frequency of Complications in the Offspring of Women with Untreated Phenylketonuria

Complication	Frequency (%)
Spontaneous abortion	24
Developmental delays	92
Microcephaly	73
Congenital heart disease	12
Fetal-growth restriction	40

Data from American Academy of Pediatrics: Maternal phenylketonuria, Pediatrics 2008 Aug;122(2):445–449.

With appropriate preconceptional counseling and adherence to a phenylalanine-restricted diet before pregnancy, the incidence of fetal malformations is dramatically reduced (Camp, 2014; Vockley, 2014). Therefore, the phenylalanine concentration is ideally normalized 3 months before conception and then maintained throughout pregnancy (American College of Obstetricians and Gynecologists, 2017b). The target phenylalanine blood concentration is 120 to 360 µmol/L (Camp, 2014).

Thalassemias

These disorders of globin-chain synthesis are the most common single-gene disorders worldwide (Forget, 2013; Vichinsky, 2013). As many as 200 million people carry a gene for one of these hemoglobinopathies, and hundreds of mutations are known to cause thalassemia syndromes (Chap. 56, Thalassemia Syndromes). In endemic areas such as Mediterranean and Southeast Asian countries, counseling and other prevention strategies have reduced the incidence of new cases by up to 80 percent (Cao, 2013).

The American College of Obstetricians and Gynecologists (2015a) recommends that individuals of high-risk ancestry be offered carrier screening to allow them informed decision making regarding reproduction and prenatal diagnosis. One method of early prenatal diagnosis is *preimplantation genetic diagnosis (PGD),* which is coupled with assisted reproductive technologies. Described in Chapter 14 (Preimplantation Genetic Testing), PGD is available for patients at risk for certain thalassemia syndromes (Kuliev, 2011).

Individuals of Eastern European Jewish Descent

Most individuals of Jewish ancestry in North America are descended from Ashkenazi Jewish communities and are at increased risk for having offspring with one of several autosomal recessive disorders. These include Tay-Sachs disease, Gaucher disease, cystic fibrosis, Canavan disease, familial dysautonomia, mucolipidosis IV, Niemann-Pick disease type A, Fanconi anemia group C, and Bloom syndrome. The American College of Obstetricians and Gynecologists (2016c, 2017a) recommends preconceptional counseling and screening for these in this population. Carrier frequency and features of these conditions are discussed in Chapter 14 (Sickle Hemoglobinopathies).

REPRODUCTIVE HISTORY

During preconceptional screening, information is sought regarding infertility; abnormal pregnancy outcomes that may include miscarriage, ectopic pregnancy, and recurrent pregnancy loss; and obstetrical complications such as cesarean delivery, preeclampsia, placental abruption, and preterm delivery (Stubblefield, 2008). As discussed in Chapter 35 (Risk Factors), details involving a prior stillbirth are especially important. For example, Korteweg and associates (2008) identified chromosomal abnormalities in 13 percent of stillborns who underwent karyotyping. Reddy and colleagues (2012) confirmed that chromosomal microarray analysis (CMA) yielded better detection of genetic abnormalities than did standard karyotyping, primarily because nonviable tissue can be used for the analysis. CMA is described and illustrated in Chapter 13 (Chromosomal Microarray Analysis). Identification of a genetic abnormality in a stillborn can help determine the recurrence risk and aid in the preconceptional or prenatal management in subsequent pregnancies.

PARENTAL AGE

Maternal Age

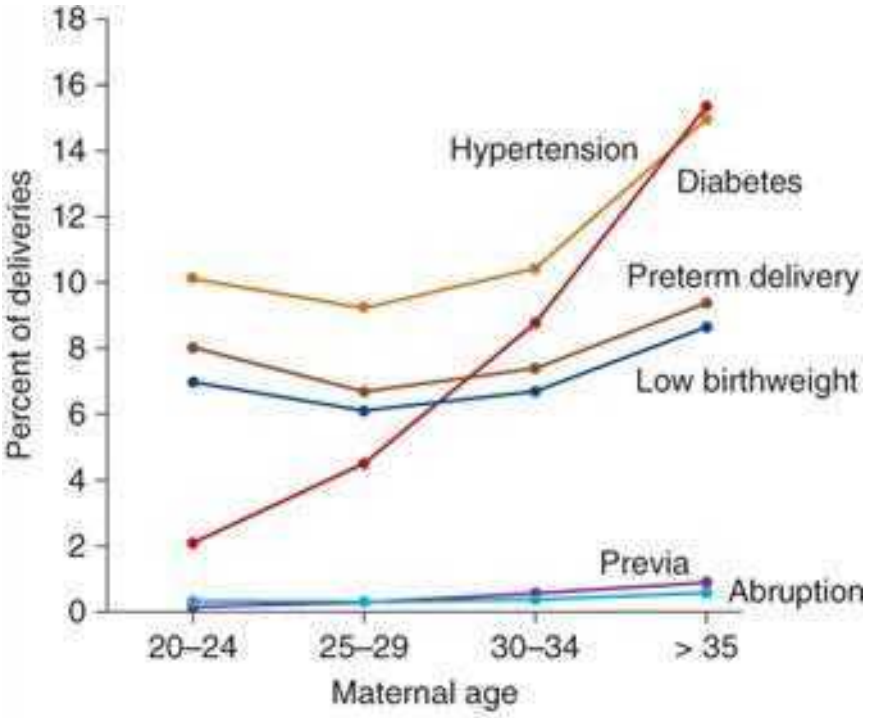
Women at both ends of the reproductive-age spectrum have unique outcomes to be considered. First, according to the CDC, in 2010, 3.4 percent of births in the United States were in women between the ages of 15 and 19 years (Martin, 2012). These adolescents are at increased risk for anemia, preterm delivery, and preeclampsia compared with women aged 20 to 35 years (Usta, 2008). The incidence of sexually transmitted diseases—common in adolescents—is even higher during pregnancy (Niccolai, 2003). Unfortunately, because most of their pregnancies are unplanned, adolescents rarely seek preconceptional counseling.

Conceptions after age 35 currently comprise approximately 15 percent of pregnancies in the United States (Martin, 2012). By contrast, these older women are more likely to request preconceptional counseling, either because of postponed pregnancy with a desire to optimize outcomes or because of plans to undergo infertility treatment. Some studies—including data from

Parkland Hospital presented in Figure 8-3— indicate that after age 35, the risks for obstetrical complications and for perinatal morbidity and mortality rise (Cunningham, 1995; Waldenström, 2015). The older woman who has a chronic illness or who is in poor physical condition usually has readily apparent risks. For the physically fit woman without medical problems, however, the risks are much lower than previously reported.

FIGURE 8-3

Incidence of selected pregnancy complications in relation to maternal age among 295,667 women delivered at Parkland Hospital.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

Overall, the maternal mortality rate is higher in women aged 35 and older. Compared with women in their 20s, women aged 35 to 39 are 2.5 times more likely and women aged 40 or older are 5.3 times more likely to suffer pregnancy-related mortality (Geller, 2006). Creanga and coworkers (2015) analyzed pregnancy-related deaths in the United States for 2006 through 2010. Although women older than 35 years contributed less than 15 percent of all live births, they constituted 27 percent of maternal deaths. For the fetus, maternal age-related risks primarily stem from: (1) indicated preterm delivery for maternal complications such as hypertension and diabetes, (2) spontaneous preterm birth, (3) fetal growth disorders related to chronic maternal disease or multifetal gestation, (4) fetal aneuploidy, and (5) pregnancies resulting from assisted reproductive technology.

Assisted Reproductive Technologies

Recall that older women have subfertility problems. And although the incidence of dizygotic twinning increases with maternal age, the more important cause of multifetal gestation in older women follows the use of assisted reproductive technology (ART) and ovulation induction. Indeed, according to the CDC, 30 to 40 percent of all multifetal gestations in the United States in 2012 were conceived with the use of ART (Sunderan, 2015). Morbidity and mortality with multifetal pregnancies stem from preterm delivery. Other obstetrical morbidities, such as placenta previa, abruption, and preeclampsia, are also risks associated with these conceptions (Lukes, 2017; Qin, 2016).

Finally, experience has accrued that links ART to higher major congenital malformation rates. Davies and colleagues (2012) reported that of 308,974 births in South Australia, 8.3 percent of neonates conceived by ART had major birth defects. In this analysis, after adjustment for maternal age and other risk factors, intracytoplasmic injection continued to be associated with a significantly elevated risk for malformations, but in vitro fertilization did not.

Paternal Age

Parental history and experiences—paternal and maternal—can exert effects through epigenomic information not contained in the DNA sequence. Examples include variations in sperm and oocyte cytosine methylation and other mechanisms (Cedars, 2015; Lane, 2014). Perhaps one example is the possible link between increasing paternal age and complex neuropsychiatric conditions (Malaspina, 2015). Finally, the incidence of genetic diseases in offspring caused by new autosomal-dominant mutations in older men is increased. Still, the incidence is low (Chap. 13, Autosomal Dominant Inheritance). Accordingly, targeted sonographic examination performed solely for advanced maternal or paternal age is controversial.

SOCIAL HISTORY

Recreational Drugs and Smoking

Fetal risks associated with alcohol, marijuana, cocaine, amphetamines, and heroin are discussed in Chapter 12 (Known and Suspected Teratogens). The first step in preventing drug-related fetal risk is an honest assessment of use by the patient (American College of Obstetricians and Gynecologists, 2017c). Toward this end, questioning should be nonjudgmental. Screening for at-risk drinking can be accomplished using several validated tools. One is the well-studied TACE questions (American College of Obstetricians and Gynecologists, 2013). This is a series of four questions concerning *tolerance* to alcohol, being *annoyed* by comments about their drinking, attempts to *cut down*, and a history of drinking early in the morning—the *eye opener*.

In a Canadian study of more than 1000 postpartum patients, Tough and coworkers (2006) found that a high percentage of women reported alcohol use concurrent with conception attempts. Specifically, nearly half of those planning for pregnancy reported a mean of 2.2 drinks daily during early gestation and before they recognized their pregnancy. Of note, Bailey and associates (2008) found that rates of binge drinking and marijuana use by men were unaffected by their partner's pregnancy. The frequency and pattern of such behaviors clearly underscore the opportunity for preconceptional counseling.

Currently 20 million women in the United States smoke cigarettes (Centers for Disease Control and Prevention, 2014). Smoking in pregnancy has been consistently associated with numerous adverse perinatal outcomes, listed in Chapter 12 (Tobacco). These risks are largely mitigated by cessation before pregnancy, highlighting the importance of screening for tobacco use in the preconceptional period and during prenatal care as outlined in Chapter 9 (Normal Pregnancy Duration).

Environmental Exposures

Contact with environmental substances is inescapable. Thus, it is fortunate that only a few agents have been shown to cause adverse pregnancy outcomes (Windham, 2008). Exposures to infectious diseases have myriad deleterious effects, and these are detailed in Chapters 64 and 65. Likewise, contact with some chemicals may impart significant maternal and fetal risks. As discussed in Chapters 9 and 12 (Common Concerns and Immunosuppressant Medications), excess exposure to methyl mercury or lead is associated with neurodevelopmental disorders.

In the past, some concerns were raised over common everyday exposure to *electromagnetic fields* such as those emanated by high-voltage power lines, electric blankets, microwave ovens, and cellular phones. Fortunately, no human or animal evidence links these and adverse fetal outcomes (Robert, 1999). The effects of *electrical shock* are discussed in Chapter 47 (Thermal Injury).

Diet

Pica is the craving for and consuming of ice, laundry starch, clay, dirt, or other nonfood items. It should be discouraged due to its inherent replacement of healthful food with nutritionally empty products (Chap. 9, Caffeine). In some cases, it may represent an unusual physiological response to iron deficiency. Many *vegetarian diets* are protein deficient but can be corrected by

increasing egg and cheese consumption. *Anorexia* and *bulimia* increase maternal risks of nutritional deficiencies, electrolyte disturbances, cardiac arrhythmias, and gastrointestinal pathology (Becker, 1999). As discussed in Chapter 61 (Schizophrenia Spectrum Disorders), pregnancy-related complications with these disorders include greater risks of low birthweight, smaller head circumference, microcephaly, and small-for-gestational-age newborns (Kouba, 2005).

In contrast to these perinatal morbidities, *obesity* is linked with several maternal complications. As discussed in Chapter 48 (Maternal Morbidity), these include preeclampsia, gestational diabetes, labor abnormalities, cesarean delivery, and operative complications (American College of Obstetricians and Gynecologists, 2015b). Obesity also appears to be associated with a range of structural fetal anomalies (Stothard, 2009).

Exercise

Conditioned pregnant women usually can continue to exercise throughout gestation (American College of Obstetricians and Gynecologists, 2017d). As discussed in Chapter 9 (Common Concerns), no data suggest that exercise is harmful during pregnancy. One caveat is that as pregnancy progresses, balance problems and joint relaxation may predispose to orthopedic injury. A woman is advised not to exercise to exhaustion, and she should augment heat dissipation and fluid replacement. Further avoidances include prolonged supine position, activities requiring good balance, and extreme weather conditions.

Intimate Partner Violence

Pregnancy can exacerbate interpersonal problems and is a time of elevated risk from an abusive partner. According to the American College of Obstetricians and Gynecologists (2012), approximately 324,000 pregnant women are abused each year. As discussed in Chapter 47 (Trauma), intimate partner violence has been associated with greater risk for several pregnancy-related complications, including hypertension, vaginal bleeding, hyperemesis, preterm delivery, and low-birthweight neonates (Silverman, 2006). Because domestic violence can escalate during pregnancy, even to the point of homicide, the preconceptional period provides an ideal time for screening and if indicated, intervention (Cheng, 2010). As detailed in Chapter 9 (Alcohol), the American College of Obstetricians and Gynecologists (2012) provides recommendations and resources for screening both pregnant and nonpregnant women for domestic violence.

SCREENING TESTS

Certain laboratory tests may help assess the risk for and prevent some pregnancy complications. These include basic tests that are usually performed during prenatal care and are enumerated in Chapter 9. More specific tests may assist evaluation of women with certain chronic medical diseases. Examples of some chronic diseases that ideally would be assessed before conception are highlighted in Table 8-4. With several of these, optimizing maternal condition before conception will improve pregnancy outcomes. Cox and coworkers (1992) reviewed pregnancy outcomes in 1075 high-risk women who received such evaluation. They reported that the 240 women with hypertension, asthma, or renal, thyroid, or cardiac disease had better outcomes compared with the outcomes from their prior pregnancies.

TABLE 8-4

Selected Preconceptional Counseling Topics

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Environmental exposure	Chap. 9, Common Concerns Chap. 12, Immunosuppressant Medications	*Methyl mercury:* Avoid shark, swordfish, king mackerel, and tile fish. Ingest no more than 12 ounces or 2 servings of canned tuna and no more than 6 ounces of albacore per week. *Lead:* Blood lead testing if a risk factor is identified; treat if indicated according to recommendations.
Abnormal weight	Chap. 48, General Considerations Chap. 61, Schizophrenia Spectrum Disorders	Calculate BMI yearly from Figure 48-1 *BMI* ≥*25 kg/m*^{2}: Counsel on diet. Test for diabetes and metabolic syndrome if indicated. Consider weight loss prior to conception. *BMI* ≤*18.5 kg/m*^{2}: Assess for eating disorder.
Cardiovascular disease	Chap. 49, Peripartum Management Considerations Chap. 12, Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs, Warfarin	Counsel on cardiac risks during pregnancy; discuss situations in which pregnancy is contraindicated. Optimize cardiac function. Discuss medication teratogenicity (warfarin, ACE inhibitor, ARB) and, if possible, switch to less dangerous agent when conception planned. Offer genetic counseling to those with congenital cardiac anomalies (Table 49-4).
Chronic hypertension	Chap. 50, Definition and Classification	Counsel on specific risks during pregnancy. Assess those with long-standing HTN for ventricular hypertrophy, retinopathy, and renal disease. Optimize blood pressure control. If medications indicated, select or switch to an agent appropriate for pregnancy.
Asthma	Chap. 51, Asthma	Counsel on asthma risks during pregnancy. Optimize pulmonary function preconceptionally. Treat women with pharmacological step therapy for chronic asthma.
Thrombophilia	Chap. 52, Inherited Thrombophilias	Question for personal or family history of thrombotic events or recurrent poor pregnancy outcomes. If a thrombophilia is found or known, counsel and offer appropriate anticoagulation regimen.

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Renal disease	Chap. 53, Pregnancy-Induced Urinary Tract Changes Chap. 12, Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs	Counsel on specific risks during pregnancy. Optimize blood pressure control before conception. Counsel women taking ACE inhibitors and ARBs about teratogenicity and the need to switch agents before pregnancy.
Gastrointestinal disease	Chap. 54, Inflammatory Bowel Disease and Fertility Chap. 12, Antimicrobial Drugs, Immunosuppressant Medications	*Inflammatory bowel disease:* Counsel affected women on subfertility risks and risks of adverse pregnancy outcomes. Discuss teratogenicity of methotrexate and the other immunomodulators. Offer effective contraception during their use and switch agents, if possible, before conception.
Hepatobiliary disease	Chap. 55, Pregnancy and Hepatitis B	*Hepatitis B:* Vaccinate all high-risk women before conception (Table 9-7). Counsel chronic carriers on transmission prevention to partners and fetus. Treat if indicated. *Hepatitis C:* Screen high-risk women. Counsel affected women on risks of disease and transmission. If treatment indicated, discuss ramifications and appropriateness of pregnancy.
Hematological disease	Chap. 56, Anemias	*Iron-deficiency anemia:* Iron supplementation. *Sickle-cell disease:* Screen all black women. Counsel those with trait or disease. Test partner if desired. *Thalassemias:* Screen women of Southeast Asian or Mediterranean ancestry.
Diabetes	Chap. 57, Diabetic Neuropathy	Optimize glycemic control to minimize teratogenicity of hyperglycemia. Evaluate for end-organ damage such as retinopathy, nephropathy, hypertension, and others. Discontinue ACE inhibitors.
Thyroid disease	Chap. 58, Thyroid Disorders	Screen those with thyroid disease symptoms. Ensure iodine-sufficient diet. Treat overt hyper- or hypothyroidism. Counsel on risks to pregnancy outcome.
Connective tissue disease	Chap. 59, Immune-Mediated Connective Tissue Diseases Chap. 12, Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs	*RA:* Counsel on flare risk after pregnancy. Discuss methotrexate and leflunomide teratogenicity, as well as possible effects of other immunomodulators. Switch these agents before conception. Stop NSAIDs by 27 weeks' gestation. *SLE:* Counsel on risks during pregnancy. Optimize disease before conception. Discuss mycophenolate mofetil and cyclophosphamide teratogenicity as well as possible effects of newer immunomodulators. Switch these agents before conception.

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Psychiatric disorders	Chap. 61, Treatment Considerations	*Depression:* Screen for symptoms of depression. Counsel on risks of treatment and of untreated illness and the high risk of exacerbation during pregnancy and the puerperium.
Neurological disorders	Chap. 60, Preconceptional Counseling	*Seizure disorder:* Optimize seizure control using monotherapy if possible.
Dermatological disease	Chap. 12, Selective Serotonin- and Norepinephrine-Reuptake Inhibitors	Discuss isotretinoin and etretinate teratogenicity and effective contraception during their use; switch agents before conception.
Cancer	Chap. 63, Fertility and Pregnancy after Cancer Therapy	Counsel on fertility preservation options before cancer therapy and on decreased fertility following certain agents. Discuss appropriateness of pregnancy balanced with need for ongoing cancer therapy and prognosis of the disease state.
Infectious diseases	Chap. 64, Maternal and Fetal Immunology	*Influenza:* Vaccinate all women who will be pregnant during flu season. Vaccinate high-risk women prior to flu season. *Malaria:* Counsel to avoid travel to endemic areas during conception. If unable, offer effective contraception during travel or provide chemoprophylaxis for those planning pregnancy. *Zika virus:* See travel restrictions by CDC. *Rubella:* Screen for rubella immunity. If nonimmune, vaccinate and counsel on the need for effective contraception during the subsequent month. *Tdap: tetanus, diphtheria, pertussis*: Update vaccination in all reproductive-aged women. *Varicella:* Question regarding immunity. If nonimmune, vaccinate.
STDs	Chap. 65, Syphilis	*Gonorrhea, syphilis, chlamydial infection:* Screen high-risk women and treat as indicated. *HIV:* Screen at-risk women. Counsel affected women on risks during pregnancy and on perinatal transmission. Discuss initiation of treatment before pregnancy to decrease transmission risk. Offer effective contraception to those not desiring conception. *HPV:* Provide Pap smear screening per guidelines (Chap. 63, Epithelial Neoplasia). Vaccinate candidate patients. *HSV:* Provide serological screening to asymptomatic women with affected partners. Counsel affected women on risks of perinatal transmission and on preventative measures during the third trimester and labor.

ACE = angiotensin-converting enzyme; ACOG = American College of Obstetricians and Gynecologists; ARB = angiotensin-receptor blocker; BMI = body mass index; CDC = Centers for Disease Control and Prevention; HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus; HTN = hypertension; NSAID = nonsteroidal antiinflammatory drug; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; STD = sexually transmitted disease.

CHAPTER 9: Prenatal Care

The borderline between health and disease is less distinctly marked during gestation, and therefore, it accordingly becomes necessary to keep pregnant patients under strict supervision, and to be constantly on the alert for the appearance of untoward symptoms.

—J. Whitridge Williams (1903)

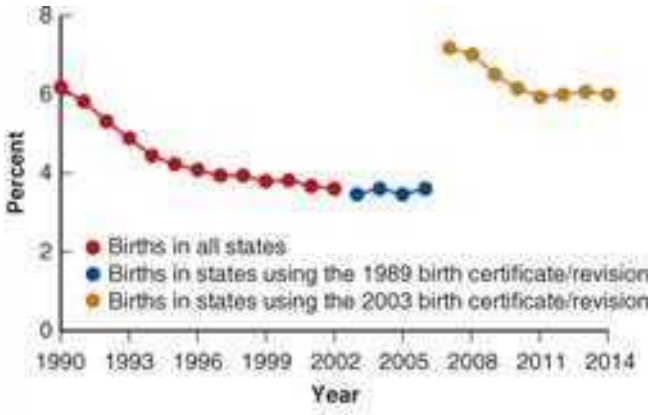
INTRODUCTION

As emphasized above by Williams, prenatal care is important. According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) a comprehensive antepartum program is defined as: "a coordinated approach to medical care, continuous risk assessment, and psychological support that optimally begins before conception and extends throughout the postpartum period and interconceptional period."

PRENATAL CARE IN THE UNITED STATES

Almost a century after its introduction, prenatal care has become one of the most frequently used health services in the United States. In 2001, there were approximately 50 million prenatal visits. The median was 12.3 visits per pregnancy, and many women had 17 or more visits. Still, as seen from Figure 9-1, 6 to 7 percent of women in this country have late or no prenatal care. In 2014, the percentages of non-Hispanic white, Hispanic, and African-American women who received inadequate or no prenatal care were 4.3, 7.5, and 9.7, respectively (Child Trends, 2015).

FIGURE 9-1
Percentage of births to mothers who received late or no prenatal care—United States, 1990–2014. (Data from Child Trends, 2015.)



The Centers for Disease Control and Prevention (CDC) (2000) analyzed birth certificate data and found that half of women with delayed or no prenatal care wanted to begin care earlier. Barriers to care varied by social and ethnic group, age, and payment method. The most common reason cited was late recognition of pregnancy by the patient. The second most commonly cited obstacle was lack of money or insurance. The third was inability to obtain an appointment.

Prenatal Care Effectiveness

Care designed during the early 1900s focused on lowering the extremely high maternal mortality rate. Prenatal care undoubtedly contributed to the dramatic decline in this mortality rate from 690 deaths per 100,000 births in 1920 to 50 per 100,000 by 1955 (Loudon, 1992). And, the low current maternal mortality rate of 10 to 15 per 100,000 is likely associated with the high utilization of this care (Xu, 2010). Indeed, data from 1998 to 2005 from the Pregnancy Mortality Surveillance System identified a fivefold increased risk for maternal death in women who received no prenatal care (Berg, 2010).

Other reports also attest to prenatal care efficacy. In a study of almost 29 million births, the risk for preterm birth, stillbirth, early and late neonatal death, and infant death rose linearly with decreasing prenatal care (Partridge, 2012). Similarly, Leveno and associates (2009) found that a significant decline in preterm births at Parkland Hospital correlated closely with increased use of prenatal care by medically indigent women. Moreover, National Center for Health Statistics data showed that women with prenatal care had an overall stillbirth rate of 2.7 per 1000 compared with 14.1 per 1000 for women without this care (Vintzileos, 2002).

Evaluating the format of care, Ickovics and coworkers (2016) compared individual prenatal care and group prenatal care. The latter provided traditional pregnancy surveillance in a group setting with special focus on support, education, and active health-care participation. Women enrolled in group prenatal care had significantly better pregnancy outcomes. Carter and colleagues (2016) cited similar results. Childbirth education classes are also reported to result in better

pregnancy outcomes (Afshar, 2017). Adolescent pregnancies carry special risk, and guidelines have been developed that focus on this subgroup (Fleming, 2015). Few data are available to recommend the practice of offering tangible incentives to improve prenatal care attendance (Till, 2015).

DIAGNOSIS OF PREGNANCY

Pregnancy is usually identified when a woman presents with symptoms and possibly a positive home urine pregnancy test result. Typically, these women receive confirmatory testing of urine or blood for human chorionic gonadotropin (hCG). Further, presumptive signs or diagnostic findings of pregnancy may be found during examination. Sonography is often used, particularly if miscarriage or ectopic pregnancy is a concern.

Symptoms and Signs

Amenorrhea in a healthy reproductive-aged woman who previously has experienced spontaneous, cyclical, predictable menses is highly suggestive of pregnancy. Menstrual cycles vary appreciably in length among women and even in the same woman (Chap. 5, Ovarian Cycle). Thus, amenorrhea is not a reliable pregnancy indicator until 10 days or more after expected menses have passed. Occasionally, uterine bleeding that mimics menstruation is noted after conception. During the first month of pregnancy, these episodes are likely the consequence of blastocyst implantation. Still, first-trimester bleeding should generally prompt evaluation for an abnormal pregnancy.

Of other symptoms, maternal perception of fetal movement depends on factors such as parity and habitus. In general, after a first successful pregnancy, a woman may first perceive fetal movements between 16 and 18 weeks' gestation. A primigravida may not appreciate fetal movements until approximately 2 weeks later. At about 20 weeks, depending on maternal habitus, an examiner can begin to detect fetal movements.

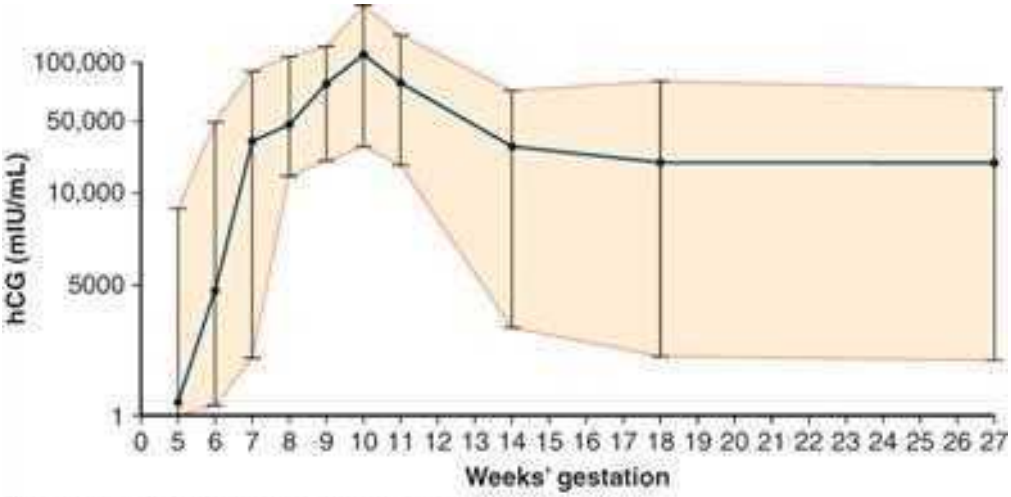
Of pregnancy signs, changes in the lower reproductive tract, uterus, and breasts develop early. These are described in detail in Chapter 4 (Reproductive Tract).

Pregnancy Tests

Detection of hCG in maternal blood and urine is the basis for endocrine assays of pregnancy. Syncytiotrophoblast produces hCG in amounts that increase exponentially during the first trimester following implantation. A main function of hCG is to prevent involution of the corpus luteum, which is the principal site of progesterone formation during the first 6 weeks of pregnancy.

With a sensitive test, the hormone can be detected in maternal serum or urine by 8 to 9 days after ovulation. The doubling time of serum hCG concentration is 1.4 to 2.0 days. As shown in Figure 9-2, serum levels range widely and increase from the day of implantation. They reach peak levels at 60 to 70 days. Thereafter, the concentration declines slowly until a plateau is reached at approximately 16 weeks' gestation.

FIGURE 9-2
Mean concentration (95% CI) of human chorionic gonadotropin (hCG) in serum of women throughout normal pregnancy.



Measurement of hCG

This hormone is a glycoprotein with high carbohydrate content. The general structure of hCG is a heterodimer composed of two dissimilar subunits, designated α and β, which are noncovalently linked. The α-subunit is identical to those of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH), but the β-subunit is structurally distinct among these. Thus, antibodies were developed with high specificity for the hCG β-subunit. This specificity allows its detection, and numerous commercial immunoassays are available for measuring serum and urine hCG levels. Although each immunoassay detects a slightly different mixture of hCG variants, its free subunits, or its metabolites, all are appropriate for pregnancy testing (Braunstein, 2014). Depending on the assay used, the sensitivity for the laboratory detection limit of hCG in serum is 1.0 mIU/mL or even lower (Wilcox, 2001).

False-positive hCG test results are rare (Braunstein, 2002). A few women have circulating serum factors that may bind erroneously with the test antibody directed to hCG in a given assay. The most common factors are heterophilic antibodies. These are produced by an individual and bind to the animal-derived test antibodies used in a given immunoassay. Thus, women who have worked closely with animals are more likely to develop these antibodies, and alternative laboratory techniques are available (American College of Obstetricians and Gynecologists, 2017a). Elevated hCG levels may also reflect molar pregnancy and its associated cancers (Chap. 20, Diagnosis). Other rare causes of positive assays without pregnancy are: (1) exogenous hCG injection used for weight loss, (2) renal failure with impaired hCG clearance, (3) physiological pituitary hCG, and (4) hCG-producing tumors that most commonly originate from gastrointestinal sites, ovary, bladder, or lung (Montagnana, 2011).

Home Pregnancy Tests

Over-the-counter pregnancy test kits have been available since the early 1970s, and millions are sold annually in the United States. More than 60 such tests are available in this country (Grenache, 2015). Unfortunately, many of these are not as accurate as advertised (Johnson, 2015). For example, Cole and associates (2011) found that a detection limit of 12.5 mIU/mL would be required to diagnose 95 percent of pregnancies at the time of missed menses, but they reported that only one brand had this degree of sensitivity. Two other brands gave false-positive or invalid results. In fact, with an hCG concentration of 100 mIU/mL, clearly positive results were displayed by only 44 percent of brands. Accordingly, only about 15 percent of pregnancies could be diagnosed at the time of the missed menses. Some manufacturers of even newer home urine assays claim >99-percent accuracy of tests done on the day of—and some up to 4 days before—the expected day of menses. Again, careful analysis suggests that these assays are often not as sensitive as advertised (Johnson, 2015).

Sonographic Recognition of Pregnancy

Transvaginal sonography has revolutionized early pregnancy imaging and is commonly used to accurately establish gestational age and confirm pregnancy location. A *gestational sac*—a small anechoic fluid collection within the endometrial cavity—is the first sonographic evidence of pregnancy. It may be seen with transvaginal sonography by 4 to 5 weeks' gestation. A fluid collection, however, can also be seen within the endometrial cavity with an ectopic pregnancy and is termed a *pseudogestational sac* or *pseudosac* (Fig. 19-4). Thus, further evaluation may be warranted if this is the only sonographic finding, particularly in a woman with pain or bleeding. A normal gestational sac implants eccentrically in the endometrium, whereas a pseudosac is seen in the midline of the endometrial cavity. Other potential indicators of early intrauterine pregnancy are an anechoic center surrounded by a single echogenic rim—the *intradecidual sign*—or two concentric echogenic rings surrounding the gestational sac—the *double decidual sign* shown in Figure 9-3. If sonography yields equivocal findings, the term *pregnancy of unknown location (PUL)* is applied. In these cases, serial serum hCG levels and transvaginal sonograms can help differentiate a normal intrauterine pregnancy from an extrauterine pregnancy or an early miscarriage (Chap. 19, Multimodality Diagnosis).

FIGURE 9-3

Transvaginal sonogram of a first-trimester intrauterine pregnancy. The double decidual sign is noted surrounding the gestational sac and is defined by the decidua parietalis (*white asterisk*) and the decidua capsularis (*yellow asterisk*). The arrow notes the yolk sac, and the crown-rump length of the embryo is marked with measuring calipers. (Used with permission from Dr. Elysia Moschos.)

If the *yolk sac*—a brightly echogenic ring with an anechoic center—is seen within the gestational sac, an intrauterine location for the pregnancy is confirmed. The yolk sac can normally be seen by the middle of the fifth week. As shown in Figure 9-3, after 6 weeks, an embryo is seen as a linear structure immediately adjacent to the yolk sac. Cardiac motion is typically noted at this point. Up to 12 weeks' gestation, the crown-rump length is predictive of gestational age within 4 days (Chap. 10, Gestational Age Assessment).

INITIAL PRENATAL EVALUATION

Prenatal care is ideally initiated early. Major goals are to: (1) define the health status of the mother and fetus, (2) estimate the gestational age, and (3) initiate a plan for continued obstetrical care. Typical components of the initial visit are summarized in Table 9-1. Subsequent care may range from relatively infrequent routine visits to prompt hospitalization because of serious maternal or fetal disease.

Tuberculosis screening	Chap. 51, Diagnosis				

[a]First-trimester aneuploidy screening may be offered between 11 and 14 weeks.

A Performed at 28 weeks, if indicated.

B Test should be offered.

C High-risk women should be retested at the beginning of the third trimester.

D High-risk women should be screened at the first prenatal visit and again in the third trimester.

E Rectovaginal culture should be obtained between 35 and 37 weeks.

HIV = human immunodeficiency virus.

Prenatal Record

Use of a standardized record within a perinatal health-care system greatly aids antepartum and intrapartum management. Standardizing documentation allows communication and care continuity between providers and enables objective measures of care quality to be evaluated over time and across different clinical settings (Gregory, 2006). A prototype is provided by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) in their *Guidelines for Perinatal Care*, 8th edition.

Definitions

Several definitions are pertinent to establishment of an accurate prenatal record.

1. *Nulligravida*—a woman who currently is not pregnant and has never been pregnant.
2. *Gravida*—a woman who currently is pregnant or has been in the past, irrespective of the pregnancy outcome. With the establishment of the first pregnancy, she becomes a *primigravida,* and with successive pregnancies, a *multigravida*.
3. *Nullipara*—a woman who has never completed a pregnancy beyond 20 weeks' gestation. She may not have been pregnant or may have had a spontaneous or elective abortion(s) or an ectopic pregnancy.
4. *Primipara*—a woman who has been delivered only once of a fetus or fetuses born alive or dead with an estimated length of gestation of 20 or more weeks. In the past, a 500-g birthweight threshold was used to define parity. This threshold is now controversial because many states still use this weight to differentiate a stillborn fetus from an abortus (Chap. 1, Definitions). However, the survival of neonates with birthweights <500 g is no longer uncommon.
5. *Multipara*—a woman who has completed two or more pregnancies to 20 weeks' gestation or more. Parity is determined by the number of pregnancies reaching 20 weeks. It is not increased to a higher number if multiples are delivered in a given pregnancy. Moreover, stillbirth does not lower this number. In some locales, the obstetrical history is summarized by a series of digits connected by dashes. These refer to the number of term infants, preterm infants, abortuses younger than 20 weeks, and children currently alive. For example, a woman who is para 2–1–0–3 has had two term deliveries, one preterm delivery, no abortuses, and has three living children. Because these are nonconventional, it is helpful to specify the outcome of any pregnancy that did not end normally.

Normal Pregnancy Duration

The normal duration of pregnancy calculated from the first day of the last normal menstrual period is very close to 280 days or 40 weeks. In a study of 427,581 singleton pregnancies from the Swedish Birth Registry, Bergsjø and coworkers (1990) found that the mean pregnancy duration was 281 days with a standard deviation of 13 days. However, menstrual cycle length varies among women and renders many of these calculations inaccurate. This, combined with the frequent use of first-trimester sonography, has changed the method of determining an accurate gestational age (Duryea, 2015).

The American College of Obstetricians and Gynecologists (2017e), the American Institute of Ultrasound in Medicine, and the Society for Maternal-Fetal Medicine have concluded that first-trimester ultrasound is the most accurate method to establish or reaffirm gestational age. For pregnancies conceived by assisted reproductive technology, embryo age or transfer date is used to assign gestational age. If available, the gestational ages calculated from the last menstrual period and from first-trimester ultrasound are compared, and this estimated date of delivery is recorded. This is discussed in further detail in Chapter 7 (Gestational Age) and in Table 10-1 (Gestational Age Assessment).

A quick estimate of a pregnancy due date based on menstrual data can be made as follows: add 7 days to the first day of the last period and subtract 3 months. For example, if the first day of the last menses was October 5, the due date is 10–05 minus 3 (months) plus 7 (days) = 7–12, or July 12 of the following year. This calculation is the *Naegele rule* (American College of Obstetricians and Gynecologists, 2017e).

Trimesters

It has become customary to divide pregnancy into three equal epochs or trimesters of approximately 3 calendar months. Historically, the first trimester extends through completion of 14 weeks, the second through 28 weeks, and the third includes the 29th through 42nd weeks of pregnancy. Thus, there are three periods of 14 weeks each. Certain major obstetrical problems tend to cluster in each of these time periods. For example, most spontaneous abortions take place during the first trimester, whereas most women with hypertensive disorders due to pregnancy are diagnosed during the third trimester.

In modern obstetrics, the clinical use of trimesters to describe a specific pregnancy is imprecise. For example, it is inappropriate in cases of uterine hemorrhage to categorize the problem temporally as "third-trimester bleeding." Appropriate management for the mother and her fetus will vary remarkably depending on whether bleeding begins early or late in the third trimester (Chap. 41, Risks). Because precise knowledge of fetal age is imperative for ideal obstetrical management, the clinically appropriate unit is *weeks of gestation completed.* And more recently, clinicians designate gestational age using completed weeks and days, for example, $33^{4/7}$ weeks or 33 + 4, for 33 completed weeks and 4 days.

Previous and Current Health Status

As elsewhere in medicine, history taking begins with queries concerning medical or surgical disorders. Also, detailed information regarding previous pregnancies is essential as many obstetrical complications tend to recur in subsequent pregnancies. The *menstrual* and *contraceptive histories* are also important. Gestational or menstrual age is the number of weeks since the onset of the last menstrual period in women with menstrual cycles lasting 28 to 30 days. For those with irregular menses, sonography in early pregnancy will clarify gestational age. Last, some methods of birth control favor ectopic implantation following method failure (Chap. 38, Method-Specific Adverse Effects and Progestin-Only Contraceptives).

Psychosocial Screening

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) define psychosocial issues as nonbiomedical factors that affect mental and physical well-being. Women should be screened regardless of social status, education level, race, or ethnicity. Such screening should seek barriers to care, communication obstacles, nutritional status, unstable housing, desire for pregnancy, safety concerns that include intimate-partner violence, depression, stress, and use of substances such as tobacco, alcohol, and illicit drugs. This screening is performed on a regular basis, at least once per trimester, to identify important issues and reduce adverse pregnancy outcomes. Coker and colleagues (2012) compared pregnancy outcomes in women before and after implementation of a universal psychosocial screening program and found that screened women were less likely to have preterm or low-birthweight newborns, as well as other adverse outcomes. Specific screens for depression are presented in Chapter 61 (The Puerperium).

Cigarette Smoking

Data on this practice have been included on the birth certificate since 1989. The number of pregnant women who smoke continues to decline. From 2000 to 2010, the prevalences were 12 to 13 percent (Tong, 2013). Based on the Pregnancy Risk Assessment Monitoring System, these women were more likely younger, had less education, and were either Alaska Natives or American Indians (Centers for Disease Control and Prevention, 2013a).

Numerous adverse outcomes have been linked to smoking during pregnancy (U.S. Department of Health and Human Services, 2000). Potential teratogenic effects are reviewed in Chapter 12 (Tobacco). Notable among these are greater rates of miscarriage, stillbirth, low birthweight, and preterm delivery (Man, 2006; Tong, 2013). There is also a twofold risk of placenta previa, placental abruption, and premature membrane rupture compared with nonsmokers. Thus, the U.S. Preventive Services Task Force recommends that clinicians offer counseling and effective intervention options to pregnant smokers at the first and subsequent prenatal visits (Siu, 2015). Although benefits are greatest if smoking ceases early in pregnancy or preferably preconceptionally, quitting at any stage of pregnancy can improve perinatal outcomes (Fiore, 2008).

Person-to-person psychosocial interventions are significantly more successful in achieving smoking abstinence in pregnancy than is simply advising the woman to quit (Fiore, 2008). One example is a brief counseling session covering the "5As" of smoking cessation (Table 9-2). This approach can be accomplished in 15 minutes or less and is effective when initiated by health-care providers (American College of Obstetricians and Gynecologists, 2017i).

TABLE 9-2

Five A's of Smoking Cessation

ASK about smoking at the first and subsequent prenatal visits.
ADVISE with clear, strong statements that explain the risks of continued smoking to the woman, fetus, and newborn.
ASSESS the patient's willingness to attempt cessation.
ASSIST with pregnancy-specific, self-help smoking cessation materials. Offer a direct referral to the smoker's quit line (1–800-QUIT NOW) to provide ongoing counseling and support.
ARRANGE to track smoking abstinence progress at subsequent visits.

Adapted from Fiore, 2008.

Behavioral interventions and nicotine replacement products are successful in reducing smoking rates (Patnode, 2015). That said, nicotine replacement has not been sufficiently evaluated to determine its effectiveness and safety in pregnancy. Trials evaluating such therapy have yielded conflicting evidence (Coleman, 2015; Pollak, 2007; Spindel, 2016). Two recent randomized trials also produced nonconclusive results. In the Smoking and Nicotine in Pregnancy (SNAP) trial, Cooper and associates (2014) reported a temporary cessation of smoking that may have been associated with improved infant development. In the Study of Nicotine Patch in Pregnancy (SNIPP) trial, Berlin and coworkers (2014) found no differences in smoking cessation rates or birthweights.

Because of limited available evidence to support pharmacotherapy for smoking cessation in pregnancy, the American College of Obstetricians and Gynecologists (2017i) has recommended that if nicotine replacement therapy is used, it should be done with close supervision and after careful consideration of the risks of smoking versus nicotine replacement.

Alcohol

Ethyl alcohol or ethanol is a potent teratogen that causes a fetal syndrome characterized by growth restriction, facial abnormalities, and central nervous system dysfunction. As discussed in Chapter 12 (Known and Suspected Teratogens), women who are pregnant or considering pregnancy should abstain from using any alcoholic beverages. The CDC analyzed data from the Behavioral Risk Factor Surveillance System from 2011 to 2013 and estimated that 10 percent of pregnant women used alcohol. It is estimated that 3.3 million women are at risk for such exposure (Green, 2016). The American College of Obstetricians and Gynecologists (2016b) in collaboration with the CDC has developed the *Fetal Alcohol Spectrum Disorders (FASD) Prevention Program*, which provides resources for providers and is available at: http://www.acog.org/alcohol.

Illicit Drugs

It is estimated that 10 percent of fetuses are exposed to one or more illicit drugs. Agents may include heroin and other opiates, cocaine, amphetamines, barbiturates, and marijuana (American Academy of Pediatrics, 2017; American College of Obstetricians and Gynecologists, 2015a, 2017d). As discussed in Chapter 12 (Warfarin), chronic use of most of these in large quantities is harmful to the fetus (Metz, 2015). Well-documented sequelae include fetal-growth restriction, low birthweight, and drug withdrawal soon after birth. Adverse effects of marijuana are less convincing. Women who use such drugs frequently do not seek prenatal care, which in itself is associated with risks for preterm and low-birthweight newborns (El-Mohandes, 2003; Eriksen, 2016).

For women who abuse heroin, methadone maintenance can be initiated within a registered methadone treatment program to reduce complications of illicit opioid use and narcotic withdrawal, to encourage prenatal care, and to avoid drug culture risks (American College of Obstetricians and Gynecologists, 2017f). Available programs can be found through the treatment locator of the Substance Abuse and Mental Health Services Administration at www.samhsa.gov. Methadone dosages usually are initiated at 10 to 30 mg daily and titrated as needed. In some women, careful methadone taper may be an appropriate option (Stewart, 2013). Although less commonly used, buprenorphine alone or in combination with naloxone may also be offered and managed by physicians with specific credentialing.

Intimate-Partner Violence

This term refers to a pattern of assault and coercive behavior that may include physical injury, psychological abuse, sexual assault, progressive isolation, stalking, deprivation, intimidation, and reproductive coercion (American College of Obstetricians and Gynecologists, 2012). Such violence has been recognized as a major public health problem. Unfortunately, most abused women continue to be victimized during pregnancy. With the possible exception of preeclampsia, domestic violence is more prevalent than any major medical condition detectable through routine prenatal screening (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2017). The prevalence during pregnancy is estimated to range between 4 and 8 percent. Intimate-partner violence is associated with an increased risk of several adverse perinatal outcomes including preterm delivery, fetal-growth restriction, and perinatal death (Chap. 47, Trauma).

The American College of Obstetricians and Gynecologists (2012) has provided methods for domestic violence screening and recommends their use at the first prenatal visit, then again at least once per trimester, and again at the postpartum visit. Such screening should be done privately and away from family members and friends. Patient self-administered or computerized screenings appear to be as effective for disclosure as clinician-directed interviews (Ahmad, 2009; Chen, 2007). Physicians should be familiar with state laws that may require reporting of intimate-partner violence. Coordination with social services can be invaluable in these cases. The National Domestic Violence Hotline (1–800–799-SAFE [7233]) is a nonprofit telephone referral service that provides individualized information regarding city-specific shelter locations, counseling resources, and legal advocacy.

Clinical Evaluation

A thorough, general physical examination should be completed at the initial prenatal encounter. Pelvic examination is performed as part of this evaluation. The cervix is visualized employing a speculum lubricated with warm water or water-based lubricant gel. Bluish-red passive hyperemia of the cervix is characteristic, but not of itself diagnostic, of pregnancy. Dilated, occluded cervical glands bulging beneath the ectocervical mucosa—*nabothian cysts*—may be prominent. The cervix is not normally dilated except at the external os. To identify cytological abnormalities, a Pap test is performed according to current guidelines noted in Chapter 63 (Epithelial Neoplasia). Specimens for identification of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are also obtained when indicated.

Bimanual examination is completed by palpation, with special attention given to the consistency, length, and dilatation of the cervix; to uterine and adnexal size; to the bony pelvic architecture; and to any vaginal or perineal anomalies. Later in pregnancy, fetal presentation often can also be determined. Lesions of the cervix, vagina, or vulva are further evaluated as needed by colposcopy, biopsy, culture, or dark-field examination. The perianal region is visualized, and digital rectal examination performed as required for complaints of rectal pain, bleeding, or mass.

Gestational Age Assessment

Precise knowledge of gestational age is one of the most important aspects of prenatal care because several pregnancy complications may develop for which optimal treatment will depend on fetal age. As discussed earlier and in Chapter 7 (Gestational Age), first-trimester sonographic assessment is best correlated with menstrual history. That said, gestational age can also be estimated with considerable precision by carefully performed clinical uterine size examination that is coupled with knowledge of the last menses. Uterine size similar to a small orange roughly correlates with a 6-week gestation; a large orange, with an 8-week pregnancy; and a grapefruit, with one at 12 weeks (Margulies, 2001).

Laboratory Tests

Recommended routine tests at the first prenatal encounter are listed in Table 9-1. Initial blood tests include a complete blood count, a determination of blood type with Rh status, and an antibody screen. The Institute of Medicine recommends universal human immunodeficiency virus (HIV) testing, with patient notification and right of refusal, as a routine part of prenatal care. The CDC (Branson, 2006) as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2016f, 2017) continue to support this practice. If a woman declines testing, this is recorded in the prenatal record. All pregnant women are also screened for hepatitis B virus infection, syphilis, and immunity to rubella at the initial visit. Based on their prospective investigation of 1000 women, Murray and coworkers (2002) concluded that in the absence of hypertension, routine urinalysis beyond the first prenatal visit was not necessary. A urine culture is recommended by most because treating bacteruria significantly reduces the likelihood of developing symptomatic urinary tract infections in pregnancy (Chap. 53, Urinary Tract Infections).

Cervical Infections

Chlamydia trachomatis is isolated from the cervix in 2 to 13 percent of pregnant women. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that all women be screened for chlamydia during the first prenatal visit, with additional third-trimester testing for those at increased risk. Risk factors include unmarried status, recent change in sexual partner or multiple concurrent partners, age younger than 25 years, inner-city residence, history or presence of other sexually transmitted diseases, and little or no prenatal care. For those testing positive, treatment described in Chapter 65 (Chlamydial Infections) is followed by a second testing—a *test of cure*—3 to 4 weeks after treatment completion.

Neisseria gonorrhoeae typically causes lower genital tract infection in pregnancy. It also may cause septic arthritis (Bleich, 2012). Risk factors for gonorrhea are similar to those for chlamydial infection. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that pregnant women with risk factors or those living in an area of high *N gonorrhoeae* prevalence be screened at the initial prenatal visit and again in the third trimester. Treatment is given for gonorrhea and simultaneously for possible coexisting chlamydial infection (Chap. 65, Chlamydial Infections). Test of cure is also recommended following treatment.

Pregnancy Risk Assessment

Many factors can adversely affect maternal and fetal well-being. Some are evident at conception, but many become apparent during the course of pregnancy. The designation of “high-risk pregnancy” is overly vague for an individual woman and probably is best avoided if a more specific diagnosis can be assigned. Some common risk factors for which consultation is recommended by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) are shown in Table 9-3. Some conditions may require the involvement of a maternal-fetal medicine subspecialist, geneticist, pediatrician, anesthesiologist, or other medical specialist in the evaluation, counseling, and care of the woman and her fetus.

TABLE 9-3

Conditions for Which Maternal-Fetal Medicine Consultation May Be Beneficial

Medical History and Conditions
Cardiac disease—moderate to severe disorders
Diabetes mellitus with evidence of end-organ damage or uncontrolled hyperglycemia
Family or personal history of genetic abnormalities
Hemoglobinopathy
Chronic hypertension if uncontrolled or associated with renal or cardiac disease
Renal insufficiency if associated with significant proteinuria (≥500 mg/24 hour), serum creatinine ≥1.5 mg/dL, or hypertension
Pulmonary disease if severe restrictive or obstructive, including severe asthma
Human immunodeficiency virus infection
Prior pulmonary embolus or deep-vein thrombosis
Severe systemic disease, including autoimmune conditions
Bariatric surgery
Epilepsy if poorly controlled or requires more than one anticonvulsant
Cancer, especially if treatment is indicated in pregnancy
Obstetrical History and Conditions
CDE (Rh) or other blood group alloimmunization (excluding ABO, Lewis)
Prior or current fetal structural or chromosomal abnormality
Desire or need for prenatal diagnosis or fetal therapy
Periconceptional exposure to known teratogens
Infection with or exposure to organisms that cause congenital infection
Higher-order multifetal gestation
Severe disorders of amnionic fluid volume

SUBSEQUENT PRENATAL VISITS

These are traditionally scheduled at 4-week intervals until 28 weeks, then every 2 weeks until 36 weeks, and weekly thereafter. Women with complicated pregnancies—for example, with twins or diabetes—often require return visits at 1- to 2-week intervals (Luke, 2003; Power, 2013). In 1986, the Department of Health and Human Services convened an expert panel to review the content of prenatal care. This report was subsequently reevaluated and revised in 2005 (Gregory, 2006). The panel recommended, among other things, early and continuing risk assessment that is patient specific. It also endorsed flexibility in clinical visit spacing; health promotion and education, including preconceptional care; medical and psychosocial interventions; standardized documentation; and expanded prenatal care objectives—to include family health up to 1 year after birth.

The World Health Organization conducted a multicenter randomized trial with almost 25,000 women comparing routine prenatal care with an experimental model designed to minimize visits (Villar, 2001). In the new model, women were seen once in the first trimester and screened for certain risks. Those without anticipated complications—80 percent of those screened—were seen again at 26, 32, and 38 weeks. Compared with routine prenatal care, which required a median of eight visits, the new model required a median of only five. No disadvantages were attributed to the regimen with fewer visits, and these findings were consistent with other randomized trials (Clement, 1999; McDuffie, 1996).

Prenatal Surveillance

At each return visit, the well-being of mother and fetus are assessed (see Table 9-1). Fetal heart rate, growth, and activity and amnionic fluid volume are evaluated. Maternal blood pressure and weight and their extent of change are examined. Symptoms such as headache, altered vision, abdominal pain, nausea and vomiting, bleeding, vaginal fluid leakage, and dysuria are sought. After 20 weeks' gestation, uterine examination measures size from the symphysis to the fundus. In late pregnancy, vaginal examination often provides valuable information that includes confirmation of the presenting part and its station, clinical estimation of pelvic capacity and configuration, amnionic fluid volume adequacy, and cervical consistency, effacement, and dilatation (Chap. 22, Identification of Labor).

Fundal Height

Between 20 and 34 weeks' gestation, the height of the uterine fundus measured in centimeters correlates closely with gestational age in weeks (Jimenez, 1983). This measurement is used to monitor fetal growth and amnionic fluid volume. It is measured along the abdominal wall from the top of the symphysis pubis to the top of the fundus. Importantly, the bladder must be emptied before fundal measurement (Worthen, 1980). Obesity or the presence of uterine masses such as

leiomyomas may also limit fundal height accuracy. Moreover, using fundal height alone, fetal-growth restriction may be undiagnosed in up to a third of cases (American College of Obstetricians and Gynecologists, 2015b; Haragan, 2015).

Fetal Heart Sounds

Instruments incorporating Doppler ultrasound are often used to easily detect fetal heart action, and in the absence of maternal obesity, heart sounds are almost always detectable by 10 weeks with such instruments (Chap. 10, Doppler). The fetal heart rate ranges from 110 to 160 beats per minute and is typically heard as a double sound. Using a standard nonamplified stethoscope, the fetal heart is audible by 20 weeks in 80 percent of women, and by 22 weeks, heart sounds are expected to be heard in all (Herbert, 1987). Because the fetus moves freely in amnionic fluid, the site on the maternal abdomen where fetal heart sounds can be heard best will vary.

Additionally, with ultrasonic auscultation, one may hear the *funic souffle,* which is a sharp, whistling sound that is synchronous with the fetal pulse. It is caused by the rush of blood through the umbilical arteries and may not be heard consistently. In contrast, the *uterine souffle* is a soft, blowing sound that is synchronous with the maternal pulse. It is produced by the passage of blood through the dilated uterine vessels and is heard most distinctly near the lower portion of the uterus.

Sonography

Sonography provides invaluable information regarding fetal anatomy, growth, and well-being, and most women in the United States have at least one prenatal sonographic examination during pregnancy (American College of Obstetricians and Gynecologists, 2016h). Continuing trends suggest that the number of these examinations performed per pregnancy is increasing. Siddique and associates (2009) reported that the average number rose from 1.5 in 1995 through 1997 to 2.7 almost 10 years later. This trend was noted in both high- and low-risk pregnancies. The actual clinical utility of this increased use in pregnancy has not been demonstrated, and it is unclear that the cost-benefit ratio is justified (Washington State Health Care Authority, 2010). The American College of Obstetricians and Gynecologists (2016h) has concluded that sonography should be performed only when there is a valid medical indication and under the lowest possible ultrasound exposure setting. The College further states that a physician is not obligated to perform sonography without a specific indication in a low-risk patient, but that if she requests sonographic screening, it is reasonable to honor her request.

Subsequent Laboratory Tests

If initial results were normal, most tests need not be repeated. Hematocrit or hemoglobin determination, along with serology for syphilis if it is prevalent in the population, is repeated at 28 to 32 weeks (Hollier, 2003; Kiss, 2004). For women at increased risk for HIV acquisition during pregnancy, repeat testing is recommended in the third trimester, preferably before 36 weeks (American College of Obstetricians and Gynecologists, 2016f). Similarly, women who engage in behaviors that place them at high risk for hepatitis B virus infection are retested at the time of hospitalization for delivery. Women who are D (Rh) negative and are unsensitized should have an antibody screening test repeated at 28 to 29 weeks, and anti-D immunoglobulin is given if they remain unsensitized (Chap. 15, Prevention of Anti-D Alloimmunization).

Group B Streptococcal Infection

The CDC (2010b) recommends that vaginal and rectal group B streptococcal (GBS) cultures be obtained in all women between 35 and 37 weeks' gestation, and the American College of Obstetricians and Gynecologists (2016g) has endorsed this recommendation. Intrapartum antimicrobial prophylaxis is provided to those whose culture results are positive. Women with GBS bacteriuria or a previous infant with invasive disease are given empirical intrapartum prophylaxis. Trials are in progress to test an investigational vaccine (Donders, 2016; Schrag, 2016). These infections are described further in Chapter 64 (Bacterial Infections).

Gestational Diabetes

All pregnant women are screened for gestational diabetes mellitus, whether by history, clinical factors, or routine laboratory testing. Although laboratory testing between 24 and 28 weeks' gestation is the most sensitive approach, there may be pregnant women at low risk who are less likely to benefit from testing (American College of Obstetricians and Gynecologists, 2017c). Gestational diabetes is discussed in Chapter 57 (Gestational Diabetes).

Neural-Tube Defect and Genetic Screening

Serum screening for neural-tube defects is offered at 15 to 20 weeks. Fetal aneuploidy screening may be performed at 11 to 14 weeks' gestation and/or at 15 to 20 weeks, depending on the protocol selected (Rink, 2016). Additionally, screening for certain genetic abnormalities is offered to women at increased risk based on family history, ethnic or racial background, or age (American College of Obstetricians and Gynecologists, 2017h). These are discussed in greater detail in Chapter 14 (Historical Perspective). Some examples include testing for Tay-Sachs disease for persons of Eastern European Jewish or French Canadian ancestry; β-thalassemia for those of Mediterranean, Southeast Asian, Indian, Pakistani, or African ancestry; α-thalassemia for individuals of Southeast Asian or African ancestry; sickle-cell anemia for people of African, Mediterranean, Middle Eastern, Caribbean, Latin American, or Indian descent; and trisomy 21 for those with advanced maternal age.

NUTRITIONAL COUNSELING

Weight Gain Recommendations

In 2009, the Institute of Medicine and National Research Council revised guidelines for weight gain in pregnancy and continued to stratify suggested weight gain ranges based on prepregnancy body mass index (BMI) (Table 9-4). The new guidelines included a specific, relatively narrow range of recommended weight gains for obese women. Also, the same recommendations apply to adolescents, short women, and women of all racial and ethnic groups. The American College of Obstetricians and Gynecologists (2016i) has endorsed these measures.

TABLE 9-4

Recommendations for Total and Rate of Weight Gain During Pregnancy

Category (BMI)	Total Weight Gain Range (lb)[a]	Weight Gain in 2nd and 3rd Trimesters Mean in lb/wk (range)
Underweight (<18.5)	28–40	1 (1–1.3)
Normal weight (18.5–24.9)	25–35	1 (0.8–1)
Overweight (25.0–29.9)	15–25	0.6 (0.5–0.7)
Obese (≥30.0)	11–20	0.5 (0.4–0.6)

[a]Empirical recommendations for weight gain in twin pregnancies include: normal BMI, 37–54 lb; overweight women, 31–50 lb; and obese women, 25–42 lb.

BMI = body mass index.

Modified from the Institute of Medicine and National Research Council, 2009.

When the Institute of Medicine guidelines were formulated, concern focused on low-birthweight newborns, however, current emphasis is directed to the obesity epidemic (Catalano, 2007). This explains renewed interest in *lower* weight gains during pregnancy. Obesity is associated with significantly greater risks for gestational hypertension, preeclampsia, gestational diabetes, macrosomia, cesarean delivery, and other complications (Chap. 48, Maternal Morbidity). The risk appears "dose related" to prenatal weight gain. In a population-based cohort of more than 120,000 obese pregnant women, those who gained *<15 lb* had the lowest rates of preeclampsia, large-for-gestational age neonates, and cesarean delivery (Kiel, 2007). Among 100,000 women with normal prepregnancy BMI, DeVader and colleagues (2007) found that those who gained <25 lb during pregnancy had a lower risk for preeclampsia, failed induction, cephalopelvic disproportion, cesarean delivery, and large-for-gestational age neonates. This cohort, however, had an increased risk for small-for-gestational age newborns. Lifestyle intervention during pregnancy can result in less weight gain (Sagedal, 2017).

There is irrefutable evidence that maternal weight gain during pregnancy influences birthweight. Martin and coworkers (2009) studied this using birth certificate data for 2006. Approximately 60 percent of women gained 26 lb or more during pregnancy, and maternal weight gain positively correlated with birthweight. Moreover, women with the greatest risk— 14 percent—for delivering a newborn weighing <2500 g were those with weight gain <16 lb. Nearly 20 percent of births to women with such low weight gains were preterm.

Severe Undernutrition

Meaningful studies of nutrition in human pregnancy are exceedingly difficult to design because experimental dietary deficiency is not ethical. In those instances in which severe nutritional deficiencies have been induced as a consequence of social, economic, or political disaster, coincidental events have often created many variables, the effects of which are not amenable to quantification. Some past experiences suggest, however, that in otherwise healthy women, a state of near starvation is required to establish clear differences in pregnancy outcome.

During the severe European winter of 1944 to 1945, nutritional deprivation of known intensity prevailed in a well-circumscribed area of The Netherlands occupied by the German military (Kyle, 2006). At the lowest point during this Dutch Hunger Winter, rations reached 450 kcal/d, with generalized rather than selective malnutrition. Smith (1947) analyzed the outcomes of pregnancies that were in progress during this 6-month famine. Median neonatal birthweights declined approximately 250 g and rose again after food became available. This indicated that birthweight can be influenced significantly by starvation during later pregnancy. The perinatal mortality rate, however, was not altered. Moreover, the incidence of fetal malformations or preeclampsia did not rise significantly. Parenthetically, weight loss in obese women during pregnancy is also associated with an increased risk for low-birthweight neonates (Cox Bauer, 2016).

Evidence of impaired brain development has been obtained in some animal fetuses whose mothers had been subjected to intense dietary deprivation. Subsequent intellectual development was studied by Stein and associates (1972) in young male adults whose mothers had been starved during pregnancy in the aforementioned Hunger Winter. The comprehensive study was made possible because all males at age 19 underwent compulsory examination for military service. It was concluded that severe dietary deprivation during pregnancy caused no detectable effects on subsequent mental performance.

Several studies of the long-term consequences to this cohort of children born to nutritionally deprived women have been performed and have been reviewed by Kyle and Pichard (2006). Progeny deprived in mid to late pregnancy were lighter, shorter, and thinner at birth, and they had a higher incidences of subsequent hypertension, reactive airway disease, dyslipidemia, diminished glucose tolerance, and coronary artery disease. Early pregnancy deprivation was associated with greater obesity rates in adult women but not men. Early starvation was also linked to higher rates of central nervous system anomalies, schizophrenia, and schizophrenia-spectrum personality disorders.

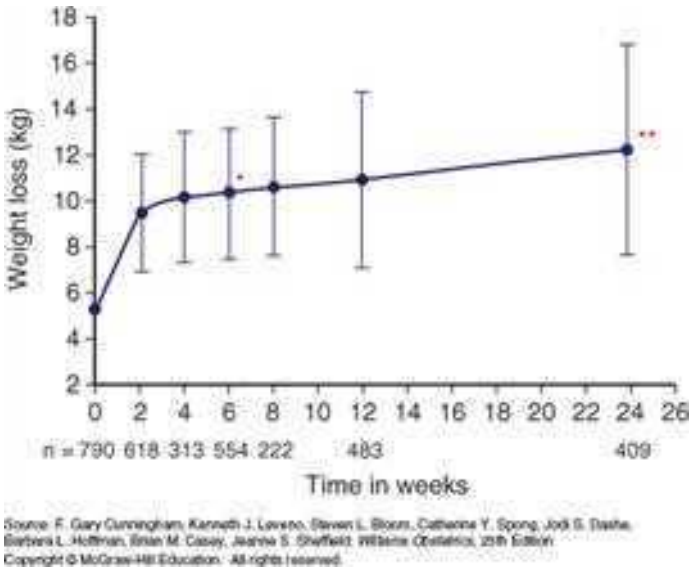
These observations and others have led to the concept of *fetal programming* by which adult morbidity and mortality are related to fetal health. Known widely as the *Barker hypothesis*, as promulgated by Barker and colleagues (1989), this concept is discussed in Chapter 44 (Placental Abnormalities).

Weight Retention after Pregnancy

Not all the weight gained during pregnancy is lost during and immediately after delivery. Schauberger and coworkers (1992) studied prenatal and postpartum weights in 795 women. Their average weight gain was 28.6 lb or 12.9 kg. As shown in Figure 9-4, most maternal weight loss was at delivery—approximately 12 lb or 5.4 kg—and in the ensuing 2 weeks—approximately 9 lb or 4 kg. An additional 5.5 lb or 2.5 kg was lost between 2 weeks and 6 months postpartum. Thus, average retained pregnancy weight was 2.1 lb or 1 kg. Excessive weight gain is manifest by accrual of fat and may be partially retained as long-term fat (Berggren, 2016; Widen, 2015). Overall, the more weight that was gained during pregnancy, the more that was lost postpartum. Interestingly, there is no relationship between prepregnancy BMI or prenatal weight gain and weight retention.

FIGURE 9-4

Cumulative weight loss from last antepartum visit to 6 months postpartum. *Significantly different from 2-week weight loss; **Significantly different from 6-week weight loss. (Redrawn from Schauberger CW, Rooney BL, Brimer LM: Factors that influence weight loss in the puerperium. Obstet Gynecol 79:424, 1992.)



Dietary Reference Intakes—Recommended Allowances

Periodically, the Institute of Medicine (2006, 2011) publishes recommended dietary allowances, including those for pregnant or lactating women. The latest recommendations are summarized in Table 9-5. Certain prenatal vitamin–mineral supplements may lead to intakes well in excess of the recommended allowances. Moreover, the use of excessive supplements, which often are self-prescribed, has led to concern regarding nutrient toxicities during pregnancy. *Those with potentially toxic effects include iron, zinc, selenium, and vitamins A, B_6, C, and D.*

TABLE 9-5

Recommended Daily Dietary Allowances for Pregnant and Lactating Women

	Pregnant	Lactating
Fat-Soluble Vitamins		
Vitamin A	770 µg	1300 µg
Vitamin D[a]	15 µg	15 µg
Vitamin E	15 mg	19 mg
Vitamin K[a]	90 µg	90 µg
Water-Soluble Vitamins		
Vitamin C	85 mg	120 mg
Thiamine	1.4 mg	1.4 mg
Riboflavin	1.4 mg	1.6 mg
Niacin	18 mg	17 mg
Vitamin B_6	1.9 mg	2 mg
Folate	600 µg	500 µg
Vitamin B_{12}	2.6 µg	2.8 µg
Minerals		
Calcium[a]	1000 mg	1000 mg
Sodium[a]	1.5 g	1.5 g
Potassium[a]	4.7 g	5.1 g
Iron	27 mg	9 mg
Zinc	11 mg	12 mg
Iodine	220 µg	290 µg
Selenium	60 µg	70 µg
Other		
Protein	71 g	71 g
Carbohydrate	175 g	210 g
Fiber[a]	28 g	29 g

[a]Recommendations measured as adequate intake.

From the Institute of Medicine, 2006, 2011.

Calories

As shown in Figure 9-5, pregnancy requires an additional 80,000 kcal, mostly during the last 20 weeks. To meet this demand, a caloric increase of 100 to 300 kcal/d is recommended during pregnancy (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2017). This greater intake, however, should not be divided equally during the course of pregnancy. The Institute of Medicine (2006) recommends adding 0, 340, and 452 kcal/d to the estimated nonpregnant energy requirements in the first, second, and third trimesters, respectively. The addition of 1000 kcal/d or more results in fat accrual (Jebeile, 2015).

FIGURE 9-5
Cumulative kilocalories required for pregnancy. (Redrawn from Chamberlain G, Broughton-Pipkin F (eds): Clinical Physiology in Obstetrics, 3rd ed. Oxford, Blackwell Science, 1998.)

Calories are necessary for energy. Whenever caloric intake is inadequate, protein is metabolized rather than being spared for its vital role in fetal growth and development. Total physiological requirements during pregnancy are not necessarily the sum of ordinary nonpregnant requirements plus those specific to pregnancy. For example, the additional energy required during pregnancy may be compensated in whole or in part by reduced physical activity (Hytten, 1991).

Protein

Protein requirements rise to meet the demands for growth and remodeling of the fetus, placenta, uterus, and breasts, and for increased maternal blood volume (Chap. 4, Protein Metabolism). During the second half of pregnancy, approximately 1000 g of protein are deposited, amounting to 5 to 6 g/d (Hytten, 1971). To accomplish this, protein intake that approximates 1 g/kg/d is recommended (see Table 9-5). Data suggest this should be doubled in late gestation (Stephens, 2015). Most amino-acid levels in maternal plasma fall markedly, including ornithine, glycine, taurine, and proline (Hytten, 1991). Exceptions during pregnancy are glutamic acid and alanine, the concentrations of which rise.

Preferably, most protein is supplied from animal sources, such as meat, milk, eggs, cheese, poultry, and fish. These furnish amino acids in optimal combinations. Milk and dairy products are considered nearly ideal sources of nutrients, especially protein and calcium, for pregnant or lactating women. Ingestion of specific fish and potential methylmercury toxicity are discussed in Common Concerns.

Minerals

The intakes recommended by the Institute of Medicine (2006) for various minerals are listed in Table 9-5. With the exception of iron and iodine, practically all diets that supply sufficient calories for appropriate weight gain will contain enough minerals to prevent deficiency.

Iron requirements are greatly increased during pregnancy, and reasons for this are discussed in Chapter 4 (Iron Metabolism). Of the approximately 300 mg of iron transferred to the fetus and placenta and the 500 mg incorporated into the expanding maternal hemoglobin mass, nearly all is used after midpregnancy. During that time, iron requirements imposed by pregnancy and maternal excretion total approximately 7 mg/d (Pritchard, 1970). Few women have sufficient iron stores or dietary intake to supply this amount. Thus, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) endorse the recommendation by the National Academy of Sciences that at least 27 mg of elemental iron be supplemented daily to pregnant women. This amount is contained in most prenatal vitamins.

Scott and coworkers (1970) established that as little as 30 mg of elemental iron, supplied as ferrous gluconate, sulfate, or fumarate and taken daily throughout the latter half of pregnancy, provides sufficient iron to meet pregnancy requirements and protect preexisting iron stores. This amount will also provide for iron requirements of lactation. The pregnant woman may benefit from 60 to 100 mg of elemental iron per day if she is large, has a multifetal gestation, begins supplementation late in pregnancy, takes iron irregularly, or has a somewhat depressed hemoglobin level. The woman who is overtly anemic from iron deficiency responds well to oral supplementation with iron salts. In response, serum ferritin levels rise more than the hemoglobin concentration (Daru, 2016).

Iodine is also needed, and the recommended iodine allowance is 220 µg/d (see Table 9-5). The use of iodized salt and bread products is recommended during pregnancy to offset the increased fetal requirements and maternal renal losses of iodine. Despite this, iodine intake has declined substantially in the past 15 years, and in some areas it is probably inadequate (Casey, 2017). Severe maternal iodine deficiency predisposes offspring to endemic cretinism, which is

characterized by multiple severe neurological defects. In parts of China and Africa where this condition is common, iodide supplementation very early in pregnancy prevents some cretinism cases (Cao, 1994). To obviate this, many prenatal supplements now contain various quantities of iodine.

Calcium is retained by the pregnant woman during gestation and approximates 30 g. Most of this is deposited in the fetus late in pregnancy (Pitkin, 1985). This amount of calcium represents only approximately 2.5 percent of total maternal calcium, most of which is in bone and can readily be mobilized for fetal growth. As another potential use, routine calcium supplementation to prevent preeclampsia has not proved effective (Chap. 40, Antihypertensive Drugs).

Zinc deficiency if severe may lead to poor appetite, suboptimal growth, and impaired wound healing. During pregnancy, the recommended daily intake approximates 12 mg. But, the safe level of zinc supplementation for pregnant women has not been clearly established. Vegetarians have lower zinc intakes (Foster, 2015). The bulk of studies support zinc supplementation only in zinc-deficient women in poor-resource countries (Nossier, 2015; Ota, 2015).

Magnesium deficiency as a consequence of pregnancy has not been recognized. Undoubtedly, during prolonged illness with no magnesium intake, the plasma level might become critically low, as it would in the absence of pregnancy. We have observed magnesium deficiency during pregnancies in some with previous intestinal bypass surgery. As a preventive agent, Sibai and coworkers (1989) randomly assigned 400 normotensive primigravid women to 365-mg elemental magnesium supplementation or placebo tablets from 13 to 24 weeks' gestation. Supplementation did not improve any measures of pregnancy outcome.

Trace metals include copper, selenium, chromium, and manganese, which all have important roles in certain enzyme functions. In general, most are provided by an average diet. Selenium deficiency is manifested by a frequently fatal cardiomyopathy in young children and reproductive-aged women. Conversely, selenium toxicity resulting from oversupplementation also has been observed. Selenium supplementation is not needed in American women.

Potassium concentrations in maternal plasma decline by approximately 0.5 mEq/L by midpregnancy (Brown, 1986). Potassium deficiency develops in the same circumstances as in nonpregnant individuals—a common example is hyperemesis gravidarum.

Fluoride metabolism is not altered appreciably during pregnancy (Maheshwari, 1983). Horowitz and Heifetz (1967) concluded that no additional offspring benefits accrued from maternal ingestion of fluoridated water if the newborn ingested such water from birth. Sa Roriz Fonteles and associates (2005) studied microdrill biopsies of deciduous teeth and concluded that antenatal fluoride provided no additional fluoride uptake compared with postnatal fluoride alone. Finally, supplemental fluoride ingested by lactating women does not raise the fluoride concentration in breast milk (Ekstrand, 1981).

Vitamins

The increased requirements for most vitamins during pregnancy shown in Table 9-5 usually are supplied by any general diet that provides adequate calories and protein. The exception is folic acid during times of unusual requirements, such as pregnancy complicated by protracted vomiting, hemolytic anemia, or multiple fetuses. That said, in impoverished countries, routine multivitamin supplementation reduced the incidence of low-birthweight and growth-restricted fetuses, but did not alter preterm delivery or perinatal mortality rates (Fawzi, 2007).

Folic acid supplementation in early pregnancy can lower neural-tube defect risks (Chap. 13, Genetic Tests). Namely, the CDC (2004) estimated that the number of affected pregnancies had decreased from 4000 pregnancies per year to approximately 3000 per year after mandatory fortification of cereal products with folic acid in 1998. Perhaps more than half of all neural-tube defects can be prevented with daily intake of 400 µg of folic acid throughout the periconceptional period. Evidence also suggests that folate insufficiency has a global effect on brain development (Ars, 2016). Putting 140 µg of folic acid into each 100 g of grain products may increase the folic acid intake of the average American woman of childbearing age by 100 µg/d. Because nutritional sources alone are insufficient, however, folic acid supplementation is still recommended (American College of Obstetricians and Gynecologists, 2016e). Likewise, the U.S. Preventive Services Task Force (2009) recommends that all women planning or capable of pregnancy take a daily supplement containing 400 to 800 µg of folic acid.

A woman with a prior child with a neural-tube defect can reduce the 2- to 5-percent recurrence risk by more than 70 percent with a daily 4-mg folic acid supplement taken during the month before conception and during the first trimester. As emphasized by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017), this dose should be consumed as a separate supplement and not as multivitamin tablets. This practice avoids excessive intake of fat-soluble vitamins.

Vitamin A, although essential, has been associated with congenital malformations when taken in high doses (>10,000 IU/d) during pregnancy. These malformations are similar to those produced by the vitamin A derivative isotretinoin (Accutane*)*, which is a potent teratogen (Chap. 12, Retinoids). Beta-carotene, the precursor of vitamin A found in fruits and vegetables, has not been shown to produce vitamin A toxicity. Most prenatal vitamins contain vitamin A in doses considerably below the teratogenic threshold. Dietary intake of vitamin A in the United States appears to be adequate, and additional supplementation is not routinely recommended. In contrast, vitamin A deficiency is an endemic nutritional problem in the developing world (McCauley, 2015). Vitamin A deficiency, whether overt or subclinical, is associated with night blindness and with an increased risk of maternal anemia and spontaneous preterm birth (West, 2003).

Vitamin B_{12} plasma levels drop in normal pregnancy, mostly as a result of reduced plasma levels of their carrier proteins—*transcobalamins*. Vitamin B_{12} occurs naturally only in foods of animal origin, and strict vegetarians may give birth to neonates whose B_{12} stores are low. Likewise, because breast milk of a vegetarian mother contains little vitamin B_{12}, the deficiency may become profound in the breastfed infant (Higginbottom, 1978). Excessive ingestion of vitamin C also can lead to a functional deficiency of vitamin B_{12}. Although its role is still controversial, vitamin B_{12} deficiency preconceptionally, similar to folate, may elevate the risk of neural-tube defects (Molloy, 2009).

Vitamin B_6, which is pyridoxine, does not require supplementation in most gravidas (Salam, 2015). For women at high risk for inadequate nutrition, a daily 2-mg supplement is recommended. As discussed in Caffeine, vitamin B_6, when combined with the antihistamine *doxylamine,* is helpful in many cases of nausea and vomiting of pregnancy.

Vitamin C allowances during pregnancy are 80 to 85 mg/d—approximately 20 percent more than when nonpregnant (see Table 9-5). A reasonable diet should readily provide this amount, and supplementation is not necessary (Rumbold, 2015). Maternal plasma levels decline during pregnancy, whereas cord-blood levels are higher, a phenomenon observed with most water-soluble vitamins.

Vitamin D is a fat-soluble vitamin. After being metabolized to its active form, it boosts the efficiency of intestinal calcium absorption and promotes bone mineralization and growth. Unlike most vitamins that are obtained exclusively from dietary intake, vitamin D is also synthesized endogenously with exposure to sunlight. Vitamin D deficiency is common during pregnancy. This is especially true in high-risk groups such as women with limited sun exposure, vegetarians, and ethnic minorities—particularly those with darker skin (Bodnar, 2007). Maternal deficiency can cause disordered skeletal homeostasis, congenital rickets, and fractures in the newborn (American College of Obstetricians and Gynecologists, 2017k). Vitamin D supplementation to women with asthma may decrease the likelihood of childhood asthma in their fetuses (Litonjua, 2016). The Food and Nutrition Board of the Institute of Medicine (2011) established that an adequate intake of vitamin D during pregnancy and lactation was 15 µg/d (600 IU/d). In women suspected of having vitamin D deficiency, serum levels of 25-hydroxyvitamin D can be obtained. Even then, the optimal levels in pregnancy have not been established (De-Regil, 2016).

Pragmatic Nutritional Surveillance

Although researchers continue to study the ideal nutritional regimen for the pregnant woman and her fetus, basic tenets for the clinician include:

1. Advise the pregnant woman to eat food types she wants in reasonable amounts and salted to taste.
2. Ensure that food is amply available for socioeconomically deprived women.
3. Monitor weight gain, with a goal of approximately 25 to 35 lb in women with a normal BMI.
4. Explore food intake by dietary recall periodically to discover the occasional nutritionally errant diet.
5. Give tablets of simple iron salts that provide at least 27 mg of elemental iron daily. Give folate supplementation before and in the early weeks of pregnancy. Provide iodine supplementation in areas of known dietary insufficiency.
6. Recheck the hematocrit or hemoglobin concentration at 28 to 32 weeks' gestation to detect significant anemia.

COMMON CONCERNS

Employment

More than half of the children in the United States are born to working mothers. Federal law prohibits employers from excluding women from job categories on the basis that they are or might become pregnant. The Family and Medical Leave Act of 1993 requires that covered employers must grant up to 12 work weeks of unpaid leave to an employee for the birth and care of a newborn child (Jackson, 2015). In the absence of complications, most women can continue to work until the onset of labor (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2017).

Some types of work, however, may increase pregnancy complication risks. Mozurkewich and colleagues (2000) reviewed 29 studies that involved more than 160,000 pregnancies. With physically demanding work, women had 20- to 60-percent higher rates of preterm birth, fetal-growth restriction, or gestational hypertension. In a prospective study of more than 900 healthy nulliparas, women who worked had a fivefold risk of preeclampsia (Higgins, 2002). Newman and coworkers (2001) reported outcomes in more than 2900 women with singleton pregnancies. Occupational fatigue—estimated by the number of hours standing, intensity of physical and mental demands, and environmental stressors—was associated with an increased risk of preterm premature membrane rupture. For women reporting the highest degrees of fatigue, the risk was 7.4 percent.

Thus, any occupation that subjects the gravida to severe physical strain should be avoided. Ideally, no work or play is continued to the extent that undue fatigue develops. Adequate periods of rest should be provided. It seems prudent to advise women with prior pregnancy complications that commonly recur to minimize physical work.

Exercise

In general, pregnant women do not need to limit exercise, provided they do not become excessively fatigued or risk injury (Davenport, 2016). Clapp and associates (2000) reported that both placental size and birthweight were significantly greater in women who exercised. Duncombe and coworkers (2006) reported similar findings in 148 women. In contrast, Magann and colleagues (2002) prospectively analyzed exercise behavior in 750 healthy women and found that working women who exercised had smaller infants and more dysfunctional labors.

The American College of Obstetricians and Gynecologists (2017g) advises a thorough clinical evaluation before recommending an exercise program. In the absence of contraindications listed in Table 9-6, pregnant women are encouraged to engage in regular, moderate-intensity physical activity for at least 150 minutes each week. Each activity should be reviewed individually for its potential risk. Examples of safe activities are walking, running, swimming, stationary

cycling, and low-impact aerobics. However, they should refrain from activities with a high risk of falling or abdominal trauma. Similarly, scuba diving is avoided because the fetus is at increased risk for decompression sickness.

TABLE 9-6

Some Contraindications to Exercise During Pregnancy

Significant cardiovascular or pulmonary disease
Significant risk for preterm labor: cerclage, multifetal gestation, significant bleeding, threatened preterm labor, prematurely ruptured membranes
Obstetrical complications: preeclampsia, placenta previa, anemia, poorly controlled diabetes or epilepsy, morbid obesity, fetal-growth restriction

Summarized from American College of Obstetricians and Gynecologists, 2017g.

In the setting of certain pregnancy complications, it is wise to abstain from exercise and even limit physical activity. For example, some women with pregnancy-associated hypertensive disorders, preterm labor, placenta previa, or severe cardiac or pulmonary disease may gain from being sedentary. Also, those with multiple or suspected growth-restricted fetuses may be served by greater rest.

Seafood Consumption

Fish are an excellent source of protein, are low in saturated fats, and contain omega-3 fatty acids. The Avon Longitudinal Study of Parents and Children reported beneficial effects on pregnancy outcomes in women who consumed 340 g or more of seafood weekly (Hibbeln, 2007). Because nearly all fish and shellfish contain trace amounts of mercury, pregnant and lactating women are advised to avoid specific types of fish with potentially high methylmercury levels. These include shark, swordfish, king mackerel, and tile fish. It is further recommended that pregnant women ingest 8 to 12 ounces of fish weekly, but no more than 6 ounces of albacore or "white" tuna (U.S. Environmental Protection Agency, 2014). If the mercury content of locally caught fish is unknown, then overall fish consumption should be limited to 6 ounces per week (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2017).

Lead Screening

Maternal lead exposure has been associated with several adverse maternal and fetal outcomes across a range of maternal blood lead levels (Taylor, 2015). These include gestational hypertension, miscarriage, low birthweight, and neurodevelopmental impairments in exposed pregnancies (American College of Obstetricians and Gynecologists, 2016c). The levels at which these risks rise remains unclear. However, recognizing that such exposure remains a significant health issue for reproductive-aged women, the CDC (2010a) has issued guidance for screening and managing exposed pregnant and lactating women. These guidelines, which have been endorsed by the American College of Obstetricians and Gynecologists (2016c), recommend blood lead testing only if a risk factor is identified. If the levels are >5 µg/dL, then counseling is completed, and the lead source is sought and removed. Subsequent blood levels are obtained. Blood lead levels >45 µg/dL are consistent with lead poisoning, and women in this group may be candidates for chelation therapy. Affected pregnancies are best managed in consultation with lead poisoning treatment experts. National and state resources are available at the CDC website: www.cdc.gov/nceh/lead/.

Automobile and Air Travel

Pregnant women are encouraged to wear properly positioned three-point restraints as protection against automobile crash injury (Chap. 47, Other Blunt Trauma). The lap portion of the restraining belt is placed under the abdomen and across her upper thighs. The belt should be comfortably snug. The shoulder belt also is firmly positioned between the breasts. Airbags should not be disabled for the pregnant woman.

In general, air travel in a properly pressurized aircraft has no harmful effect on pregnancy (Aerospace Medical Association, 2003). Thus, in the absence of obstetrical or medical complications, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2016a, 2017) have concluded that pregnant women can safely fly up to 36 weeks' gestation. It is recommended that pregnant women observe the same precautions for air travel as the general population. Seatbelts are used while seated. Periodic lower extremity movement and at least hourly ambulation help lower the venous thromboembolism threat. Significant risks with travel, especially international travel, are infectious disease acquisition and development of complications remote from adequate health-care resources (Ryan, 2002).

Coitus

In healthy pregnant women, sexual intercourse usually is not harmful. Whenever miscarriage, placenta previa, or preterm labor threatens, however, coitus is avoided. Nearly 10,000 women enrolled in a prospective investigation by the Vaginal Infection and Prematurity Study Group were interviewed regarding sexual activity (Read, 1993). They reported a decreased frequency of coitus with advancing gestation. By 36 weeks, 72 percent had intercourse less than once weekly. The decline is attributed to lower desire and fear of harming the pregnancy (Bartellas, 2000; Staruch, 2016).

Intercourse specifically late in pregnancy is not harmful. Grudzinskas and coworkers (1979) noted no association between gestational age at delivery and coital frequency during the last 4 weeks of pregnancy. Sayle and colleagues (2001) reported no increased—and actually a decreased—risk of delivery within 2 weeks of

intercourse. Tan and associates (2007) studied women scheduled for nonurgent labor induction and found that spontaneous labor ensued at equal rates in groups either participating in or abstaining from intercourse.

Oral-vaginal intercourse is occasionally hazardous. Aronson and Nelson (1967) described a fatal air embolism late in pregnancy as a result of air blown into the vagina during cunnilingus. Other near-fatal cases have been described (Bernhardt, 1988).

Dental Care

Examination of the teeth is included in the prenatal examination, and good dental hygiene is encouraged. Indeed, periodontal disease has been linked to preterm labor. Unfortunately, although its treatment improves dental health, it does not prevent preterm birth (Michalowicz, 2006). Dental caries are not aggravated by pregnancy. Importantly, pregnancy is not a contraindication to dental treatment including dental radiographs (Giglio, 2009).

Immunization

Current recommendations for immunization during pregnancy are summarized in Table 9-7. Well-publicized concerns regarding a causal link between childhood exposure to the thimerosal preservative in some vaccines and neuropsychological disorders have led to some parents to vaccine prohibition. Although controversy continues, these associations have proven groundless (Sugarman, 2007; Thompson, 2007; Tozzi, 2009). Thus, many vaccines may be used in pregnancy. The American College of Obstetricians and Gynecologists (2016b) stresses the importance of integrating an effective vaccine strategy into the care of both obstetrical and gynecological patients. The College further emphasizes that information on the safety of vaccines given during pregnancy is subject to change, and recommendations can be found on the CDC website at www.cdc.gov/vaccines.

TABLE 9-7

Recommendations for Immunization During Pregnancy

Immunobiological Agent	Indications for Immunization During Pregnancy	Dose Schedule	Comments
Live Attenuated Virus Vaccines			
Measles	Contraindicated—see immune globulins	Single dose SC, preferably as MMR[a]	Vaccinate susceptible women postpartum. Breastfeeding is not a contraindication
Mumps	Contraindicated	Single dose SC, preferably as MMR	Vaccinate susceptible women postpartum
Rubella	Contraindicated, but congenital rubella syndrome has never been described after vaccine	Single dose SC, preferably as MMR	Teratogenicity of vaccine is theoretical and not confirmed to date; vaccinate susceptible women postpartum
Poliomyelitis oral = live attenuated; injection = enhanced-potency inactivated virus	Not routinely recommended for women in the United States, except women at increased risk of exposure[b]	Primary: Two doses of enhanced-potency inactivated virus SC at 4- to 8-week intervals and a 3rd dose 6–12 months after 2nd dose Immediate protection: One dose oral polio vaccine (in outbreak setting)	Vaccine indicated for susceptible women traveling in endemic areas or in other high-risk situations
Yellow fever	Travel to high-risk areas	Single dose SC	Limited theoretical risk outweighed by risk of yellow fever
Varicella	Contraindicated, but no adverse outcomes reported in pregnancy	Two doses needed: 2nd dose given 4–8 weeks after 1st dose	Teratogenicity of vaccine is theoretical. Vaccination of susceptible women should be considered postpartum
Smallpox (vaccinia)	Contraindicated in pregnant women and in their household contacts	One dose SC, multiple pricks with lancet	Only vaccine known to cause fetal harm
Other			
Influenza	All pregnant women, regardless of trimester during flu season (October–May)	One dose IM every year	Inactivated virus vaccine
Rabies	Indications for prophylaxis not altered by pregnancy; each case considered individually	Public health authorities to be consulted for indications, dosage, and route of administration	Killed-virus vaccine
Human papillomavirus	Not recommended	Three-dose series IM at 0, 1, and 6 months	Polyvalent vaccines available containing inactivated virus. No teratogenicity has been observed
Hepatitis B	Preexposure and postexposure for women at risk of infection, e.g., chronic liver or kidney disease	Three-dose series IM at 0, 1, and 6 months	Used with hepatitis B immune globulin for some exposures. Exposed newborn needs birth-dose vaccination and immune globulin as soon as possible. All infants should receive birth dose of vaccine
Hepatitis A	Preexposure and postexposure if at risk (international travel); chronic liver disease	Two-dose schedule IM, 6 months apart	Inactivated virus
Inactivated Bacterial Vaccines			

Immunobiological Agent	Indications for Immunization During Pregnancy	Dose Schedule	Comments
Pneumococcus	Indications not altered by pregnancy. Recommended for women with asplenia; metabolic, renal, cardiac, or pulmonary diseases; immunosuppression; or smokers	In adults, one dose only; consider repeat dose in 6 years for high-risk women	Polyvalent polysaccharide vaccine; safety in the first trimester has not been evaluated
Meningococcus	Indications not altered by pregnancy; vaccination recommended in unusual outbreaks	One dose; tetravalent vaccine; two doses for asplenia	Antimicrobial prophylaxis if significant exposure
Typhoid	Not recommended routinely except for close, continued exposure or travel to endemic areas	Killed Primary: 2 injections IM 4 weeks apart Booster: One dose; schedule not yet determined	Killed, injectable vaccine or live attenuated oral vaccine. Oral vaccine preferred
Anthrax	Chapter 64 (Mycotic Infections)	Six-dose primary vaccination, then annual booster vaccination	Preparation from cell-free filtrate of *B anthracis*. No dead or live bacteria. Teratogenicity of vaccine theoretical
Toxoids			
Tetanus-diphtheria-acellular pertussis (Tdap)	Recommended in every pregnancy, preferably between 27 and 36 weeks to maximize passive antibody transfer	Primary: Two doses IM at 1–2 month interval with 3rd dose 6–12 months after the 2nd Booster: Single dose IM every 10 years, as a part of wound care if ≥ 5 years since last dose, or once per pregnancy	Combined tetanus-diphtheria toxoids with acellular pertussis (Tdap) preferred. Updating immune status should be part of antepartum care
Specific Immune Globulins			
Hepatitis B	Postexposure prophylaxis	Depends on exposure (Chap. 55, Pregnancy and Hepatitis B)	Usually given with hepatitis B virus vaccine; exposed newborn needs immediate prophylaxis
Rabies	Postexposure prophylaxis	Half dose at injury site, half dose in deltoid	Used in conjunction with rabies killed-virus vaccine
Tetanus	Postexposure prophylaxis	One dose IM	Used in conjunction with tetanus toxoid
Varicella	Should be considered for exposed pregnant women to protect against maternal, not congenital, infection	One dose IM within 96 hours of exposure	Indicated also for newborns or women who developed varicella within 4 days before delivery or 2 days following delivery
Standard Immune Globulins			
Hepatitis A: Hepatitis A virus vaccine should be used with hepatitis A immune globulin	Postexposure prophylaxis and those at high risk	0.02 mL/kg IM in one dose	Immune globulin should be given as soon as possible and within 2 weeks of exposure; infants born to women who are incubating the virus or are acutely ill at delivery should receive one dose of 0.5 mL as soon as possible after birth

[a]Two doses necessary for students entering institutions of higher education, newly hired medical personnel, and travel abroad.

[b]Inactivated polio vaccine recommended for nonimmunized adults at increased risk.

ID = intradermally; IM = intramuscularly; MMR = measles, mumps, rubella; PO = orally; SC = subcutaneously.

From the Centers for Disease Control and Prevention, 2011; Kim, 2016.

The frequency of pertussis infection has substantially risen in the United States. Young infants are at increased risk for death from pertussis and are entirely dependent on passive immunization from maternal antibodies until the infant vaccine series is initiated at age 2 months. For this reason, a three-agent tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine is recommended and is safe for pregnant women (Centers for Disease Control and Prevention, 2013b, 2016; Morgan, 2015). However, as demonstrated by Healy and coworkers (2013), maternal antipertussis antibodies are relatively short-lived, and Tdap administration before pregnancy—or even in the first half of the current pregnancy—is not likely to provide a high level of newborn antibody protection. Thus, to maximize passive antibody transfer to the fetus, a dose of Tdap is ideally given to gravidas between 27 and 36 weeks' gestation (American College of Obstetricians and Gynecologists, 2017j; Centers for Disease Control and Prevention, 2013b, 2016).

All women who will be pregnant during influenza season should be offered vaccination, regardless of gestational age. Those with underlying medical conditions that increase the risk for influenza complications are provided the vaccine before flu season starts. In addition to maternal protection against infection, prenatal maternal vaccination in one study reduced the infant influenza incidence in the first 6 months of life by 63 percent (Zaman, 2008). Moreover, it reduced all febrile respiratory illnesses in these infants by a third.

Women who are susceptible to rubella during pregnancy should receive measles, mumps, rubella (MMR) vaccination postpartum. Although this vaccine is not recommended during pregnancy, congenital rubella syndrome has never resulted from its inadvertent use. Breastfeeding is compatible with MMR vaccination (Centers for Disease Control and Prevention, 2011).

Caffeine

Whether adverse pregnancy outcomes are related to caffeine consumption is somewhat controversial. As summarized from Chapter 18 (Paternal Factors), heavy intake of coffee each day—about five cups or 500 mg of caffeine—slightly raises the miscarriage risk. Studies of "moderate" intake—less than 200 mg daily—did not find a higher risk.

It is unclear if caffeine consumption is associated with preterm birth or impaired fetal growth. Clausson and coworkers (2002) found no association between moderate caffeine consumption of less than 500 mg/d and low birthweight, fetal-growth restriction, or preterm delivery. Bech and associates (2007) randomly assigned more than 1200 pregnant women who drank at least three cups of coffee per day to caffeinated versus decaffeinated coffee. They found no difference in birthweight or gestational age at delivery between groups. The CARE Study Group (2008), however, evaluated 2635 low-risk pregnancies and reported a 1.4-fold risk for fetal-growth restriction among those whose daily caffeine consumption was >200 mg/d compared with those who consumed <100 mg/d. The American College of Obstetricians and Gynecologists (2016d) concludes that moderate consumption of caffeine—less than 200 mg/d—does not appear to be associated with miscarriage or preterm birth, but that the relationship between caffeine consumption and fetal-growth restriction remains unsettled. The American Dietetic Association (2008) recommends that caffeine intake during pregnancy be limited to less than 300 mg/d, which approximates three 5-oz cups of percolated coffee.

Nausea and Heartburn

Nausea and vomiting are common complaints during the first half of pregnancy. These vary in severity and usually commence between the first and second missed menstrual period and continue until 14 to 16 weeks' gestation. Although nausea and vomiting tend to be worse in the morning—thus erroneously termed *morning sickness*—both symptoms frequently continue throughout the day. Lacroix and coworkers (2000) found that nausea and vomiting were reported by three fourths of pregnant women and lasted an average of 35 days. Half had relief by 14 weeks, and 90 percent by 22 weeks. In 80 percent of these women, nausea lasted all day.

Treatment of pregnancy-associated nausea and vomiting seldom provides complete relief, but symptoms can be minimized. Eating small meals at frequent intervals is valuable. One systematic literature search reported that the herbal remedy ginger was likely effective (Borrelli, 2005). Mild symptoms usually respond to vitamin B_6 given along with doxylamine, but some women require phenothiazine or H_1-receptor blocking antiemetics (American College of Obstetricians and Gynecologists, 2015c). In some with *hyperemesis gravidarum,* vomiting is so severe that dehydration, electrolyte and acid-base disturbances, and starvation ketosis become serious problems.

Heartburn is another common complaint of gravidas and is caused by gastric content reflux into the lower esophagus. The greater frequency of regurgitation during pregnancy most likely results from upward displacement and compression of the stomach by the uterus, combined with relaxation of the lower esophageal sphincter. Avoiding bending over or lying flat is preventive. In most pregnant women, symptoms are mild and relieved by a regimen of more frequent but smaller meals. Antacids may provide considerable relief (Phupong, 2015). Specifically, aluminum hydroxide, magnesium trisilicate, or magnesium hydroxide is given alone or in combination. Management of heartburn or nausea that does not respond to simple measures is discussed in Chapter 54 (Management).

Pica and Ptyalism

The craving of pregnant women for strange foods is termed pica. Worldwide, its prevalence is estimated to be 30 percent (Fawcett, 2016). At times, nonfoods such as ice—pagophagia, starch—amylophagia, or clay—geophagia may predominate. This desire is considered by some to be triggered by severe iron deficiency. Although such cravings usually abate after deficiency correction, not all pregnant women with pica are iron deficient. Indeed, if strange "foods" dominate the diet, iron deficiency will be aggravated or will develop eventually.

Patel and coworkers (2004) prospectively completed a dietary inventory on more than 3000 women during the second trimester. The prevalence of pica was 4 percent. The most common nonfood items ingested were starch in 64 percent, dirt in 14 percent, sourdough in 9 percent, and ice in 5 percent. The prevalence of

anemia was 15 percent in women with pica compared with 6 percent in those without it. Interestingly, the rate of spontaneous preterm birth before 35 weeks was twice as high in women with pica.

Women during pregnancy are occasionally distressed by profuse salivation—*ptyalism*. Although usually unexplained, ptyalism sometimes appears to follow salivary gland stimulation by the ingestion of starch.

Headache or Backache

At least 5 percent of pregnancies are estimated to be complicated by new-onset or new-type headache (Spierings, 2016). Common headaches are virtually universal. Acetaminophen is suitable for most of these, and an in-depth discussion is found in Chapter 60 (Headache).

Low back pain to some extent is reported by nearly 70 percent of gravidas (Liddle, 2015; Wang, 2004). Minor degrees follow excessive strain or significant bending, lifting, or walking. It can be reduced by squatting rather than bending when reaching down, by using a back-support pillow when sitting, and by avoiding high-heeled shoes. Back pain complaints increase with progressing gestation and are more prevalent in obese women and those with a history of low back pain. In some cases, troublesome pain may persist for years after the pregnancy (Norén, 2002).

Severe back pain should not be attributed simply to pregnancy until a thorough orthopedic examination has been conducted. Severe pain has other uncommon causes that include pregnancy-associated osteoporosis, disc disease, vertebral osteoarthritis, or septic arthritis (Smith, 2008). More commonly, muscular spasm and tenderness are classified clinically as acute strain or fibrositis. Although evidence-based clinical research directing care in pregnancy is limited, low back pain usually responds well to analgesics, heat, and rest. Acetaminophen may be used chronically as needed. Nonsteroidal antiinflammatory drugs may also be beneficial but are used only in short courses to avoid fetal effects (Chap. 12, Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs). Muscle relaxants that include cyclobenzaprine or baclofen may be added when needed. Once acute pain is improved, stabilizing and strengthening exercises provided by physical therapy help improve spine and hip stability, which is essential for the increased load of pregnancy. For some, a support belt that stabilizes the sacroiliac joint may be helpful (Gutke, 2015).

Varicosities and Hemorrhoids

Venous leg varicosities have a congenital predisposition and accrue with advancing age. They can be aggravated by factors that raise lower extremity venous pressures, such as an enlarging uterus. Femoral venous pressures in the supine gravida rise from 8 mm Hg in early pregnancy to 24 mm Hg at term. Thus, leg varicosities typically worsen as pregnancy advances, especially with prolonged standing. Symptoms vary from cosmetic blemishes and mild discomfort at the end of the day to severe discomfort that requires prolonged rest with feet elevation. Treatment is generally limited to periodic rest with leg elevation, elastic stockings, or both. Surgical correction during pregnancy generally is not advised, although rarely the symptoms may be so severe that injection, ligation, or even stripping of the veins is necessary.

Vulvar varicosities frequently coexist with leg varicosities, but they may appear without other venous pathology. Uncommonly, they become massive and almost incapacitating. If these large varicosities rupture, blood loss can be severe. Treatment is with specially fitted pantyhose that will also minimize lower extremity varicosities. With particularly bothersome vulvar varicosities, a foam rubber pad suspended across the vulva by a belt can be used to exert pressure on the dilated veins.

Hemorrhoids are rectal vein varicosities and may first appear during pregnancy as pelvic venous pressures rise. Commonly, they are recurrences of previously encountered hemorrhoids. Up to 40 percent of pregnant women develop these (Poskus, 2014). Pain and swelling usually are relieved by topically applied anesthetics, warm soaks, and stool-softening agents. With thrombosis of an external hemorrhoid, pain can be considerable. This may be relieved by incision and removal of the clot following injection of a local anesthetic.

Sleeping and Fatigue

Beginning early in pregnancy, many women experience fatigue and need greater amounts of sleep. This likely is due to the soporific effect of progesterone but may be compounded in the first trimester by nausea and vomiting. In the latter stages, general discomforts, urinary frequency, and dyspnea can be additive. Sleep duration may be related to obesity and gestational weight gain (Facco, 2016; Lockhart, 2015). Moreover, sleep efficiency appears to progressively diminish as pregnancy advances. Wilson and associates (2011) performed overnight polysomnography and observed that women in the third trimester had poorer sleep efficiency, more awakenings, and less of both stage 4 (deep) and rapid-eye movement sleep. Women in the first trimester were also affected, but to a lesser extent. Daytime naps and mild sedatives at bedtime such as diphenhydramine (Benadryl) can be helpful.

Cord Blood Banking

Since the first successful cord blood transplantation in 1988, more than 25,000 umbilical cord blood transplantations have been performed to treat hemopoietic cancers and various genetic conditions (Butler, 2011). There are two types of cord blood banks. Public banks promote allogeneic donation, for use by a related or unrelated recipient, similar to blood product donation (Armson, 2015). Private banks were initially developed to store stem cells for future autologous use and charged fees for initial processing and annual storage. The American College of Obstetricians and Gynecologists (2015d) has concluded that if a woman requests information on umbilical cord banking, information regarding advantages and disadvantages of public versus private banking should be explained. Some states have passed laws that require physicians to inform patients about cord blood banking options. Importantly, few transplants have been performed by using cord blood stored in the absence of a known indication in the recipient (Screnci, 2016). The likelihood that cord blood would be used for the child or family member of

the donor couple is considered remote, and it is recommended that directed donation be considered when an immediate family member carries the diagnosis of a specific condition known to be treatable by hemopoietic transplantation (Chap. 56, Anemias).

CHAPTER 10: Fetal Imaging

After discovery of the Roentgen ray and the demonstration of the various uses to which it might be put, it was thought possible that it might also afford a valuable method of investigating the shape and size of the pelvis.

—J. Whitridge Williams (1903)

INTRODUCTION

X-ray techniques were just on the horizon when the first edition of this textbook was published. The first application focused on the maternal pelvis without attention to the fetus. Thus, congenital abnormalities were routinely not discovered until birth. Subsequent radiographic efforts to evaluate the fetus were later replaced by ultrasonography and more recently by magnetic resonance (MR) imaging, techniques which have become increasingly sophisticated. The subspecialty of fetal medicine has developed only because of these advances, and today's practitioner can hardly imagine obstetrical care without them.

SONOGRAPHY IN OBSTETRICS

Prenatal sonography can be used to accurately assess gestational age, fetal number, viability, and placental location, and it can aid diagnosis of many fetal abnormalities. With improvements in resolution and image display, anomalies are increasingly detected in the first trimester, and Doppler is used to manage pregnancies complicated by growth impairment or anemia. The American College of Obstetricians and Gynecologists (2016) recommends that prenatal sonography be performed in all pregnancies and considers it an important part of obstetrical care in the United States.

Technology and Safety

The real-time image on the ultrasound screen is produced by sound waves that are reflected back from fluid and tissue interfaces of the fetus, amnionic fluid, and placenta. Sector array transducers contain groups of piezoelectric crystals working simultaneously in arrays. These crystals convert electrical energy into sound waves, which are emitted in synchronized pulses. Sound waves pass through tissue layers and are reflected back to the transducer when they encounter an interface between tissues of different densities. Dense tissue such as bone produces high-velocity reflected waves, which are displayed as bright echoes on the screen. Conversely, fluid generates few reflected waves and appears dark. Digital images generated at 50 to more than 100 frames per second undergo postprocessing that yields the appearance of real-time imaging.

Ultrasound refers to sound waves traveling at a frequency above 20,000 hertz (cycles per second). Higher-frequency transducers yield better image resolution, whereas lower frequencies penetrate tissue more effectively. Transducers use wide-bandwidth technology to perform within a range of frequencies. In early pregnancy, a 5- to 10-megahertz (MHz) transvaginal transducer usually provides excellent resolution, because the early fetus is close to the transducer. And, in the first and second trimesters, a 4- to 6-MHz transabdominal transducer is similarly close enough to the fetus to yield precise images. By the third trimester, however, a lower frequency 2- to 5-MHz transducer may be needed for tissue penetration—particularly in obese patients—and this can lead to compromised resolution.

Fetal Safety

Sonography should be performed only for a valid medical indication, using the lowest possible exposure setting to gain necessary information—the *ALARA* principle—*a*s *l*ow *a*s *r*easonably *a*chievable. Examinations are performed only by those trained to recognize fetal abnormalities and artifacts that may mimic pathology, using techniques to avoid ultrasound exposure beyond what is considered safe for the fetus (American College of Obstetricians and Gynecologists, 2016; American Institute of Ultrasound in Medicine, 2013b). No causal relationship has been demonstrated between diagnostic ultrasound and any recognized adverse effect in human pregnancy. The International Society of Ultrasound in Obstetrics and Gynecology (2016) further concludes that there is no scientifically proven association between ultrasound exposure in the first or second trimesters and autism spectrum disorder or its severity.

All sonography machines are required to display two indices: the *thermal index* and the *mechanical index*. The thermal index is a measure of the relative probability that the examination may raise the temperature, potentially high enough to induce injury. That said, fetal damage resulting from commercially available ultrasound equipment in routine practice is extremely unlikely. The potential for temperature elevation is higher with longer examination time and is greater near bone than in soft tissue. Theoretical risks are higher during organogenesis than later in gestation. The thermal index for soft tissue, *Tis*, is used before 10 weeks' gestation, and that for bone, *Tib*, is used at or beyond 10 weeks' (American Institute of Ultrasound in Medicine, 2013b). The thermal index is higher with pulsed Doppler applications than with routine B-mode scanning (Doppler). In the first trimester, if pulsed Doppler is clinically indicated, the thermal index should be ≤0.7, and the exposure time should be as brief as possible (American Institute of Ultrasound in Medicine, 2016). To document the embryonic or fetal heart rate, motion-mode (M-mode) imaging is used instead of pulsed Doppler imaging.

The mechanical index is a measure of the likelihood of adverse effects related to rarefactional pressure, such as cavitation—which is relevant only in tissues that contain air. Microbubble ultrasound contrast agents are not used in pregnancy for this reason. In mammalian tissues that do not contain gas bodies, no adverse effects have been reported over the range of diagnostically relevant exposures. Because fetuses cannot contain gas bodies, they are not considered at risk.

The use of sonography for any nonmedical purpose, such as "keepsake fetal imaging," is considered *contrary to responsible medical practice* and is not condoned by the Food and Drug Administration (2014), the American Institute of Ultrasound in Medicine (2012, 2013b), or the American College of Obstetricians and Gynecologists (2016).

Operator Safety

The reported prevalence of work-related musculoskeletal discomfort or injury among sonographers approximates 70 percent (Janga, 2012; Roll, 2012). The main risk factors for injury during transabdominal ultrasound examinations are awkward posture, sustained static forces, and various pinch grips used while maneuvering the transducer (Centers for Disease Control and Prevention, 2006). Maternal habitus can be contributory because more force is often employed when imaging obese patients.

The following guidelines may help avert injury:

1. Position the patient close to you on the examination table. As a result, your elbow is close to your body, shoulder abduction is less than 30 degrees, and your thumb is facing up.
2. Adjust the table or chair height so that your forearm is parallel to the floor.
3. If seated, use a chair with back support, support your feet, and keep ankles in neutral position. Do not lean toward the patient or monitor.
4. Face the monitor squarely and position it so that it is viewed at a neutral angle, such as 15 degrees downward.
5. Avoid reaching, bending, or twisting while scanning.
6. Frequent breaks may prevent muscle strain. Stretching and strengthening exercises can be helpful.

Gestational Age Assessment

The earlier that sonography is performed, the more accurate the gestational age assessment. Specific criteria for "re-dating" a pregnancy, that is, reassigning the gestational age and estimated date of delivery using initial sonogram findings, are shown in Table 10-1. The only exception to revising the gestational age based on early sonography is if the pregnancy resulted from assisted reproductive technology, in which case accuracy of gestational age assessment is presumed.

TABLE 10-1

Sonographic Gestational Age Assessment

Gestational Age	Parameter(s)	Threshold to Revise[a]
<9 wks	CRL	>5 d
9 to <14 wks	CRL	>7 d
14 to <16 wks	BPD, HC, AC, FL	>7 d
16 to <22 wks	BPD, HC, AC, FL	>10 d
22 to <28 wks	BPD, HC, AC, FL	>14 d
≥28 weeks	BPD, HC, AC, FL	>21 d

[a]Sonographic gestational age should be used when the LMP-derived gestational age differs from that obtained with sonography by the threshold value.

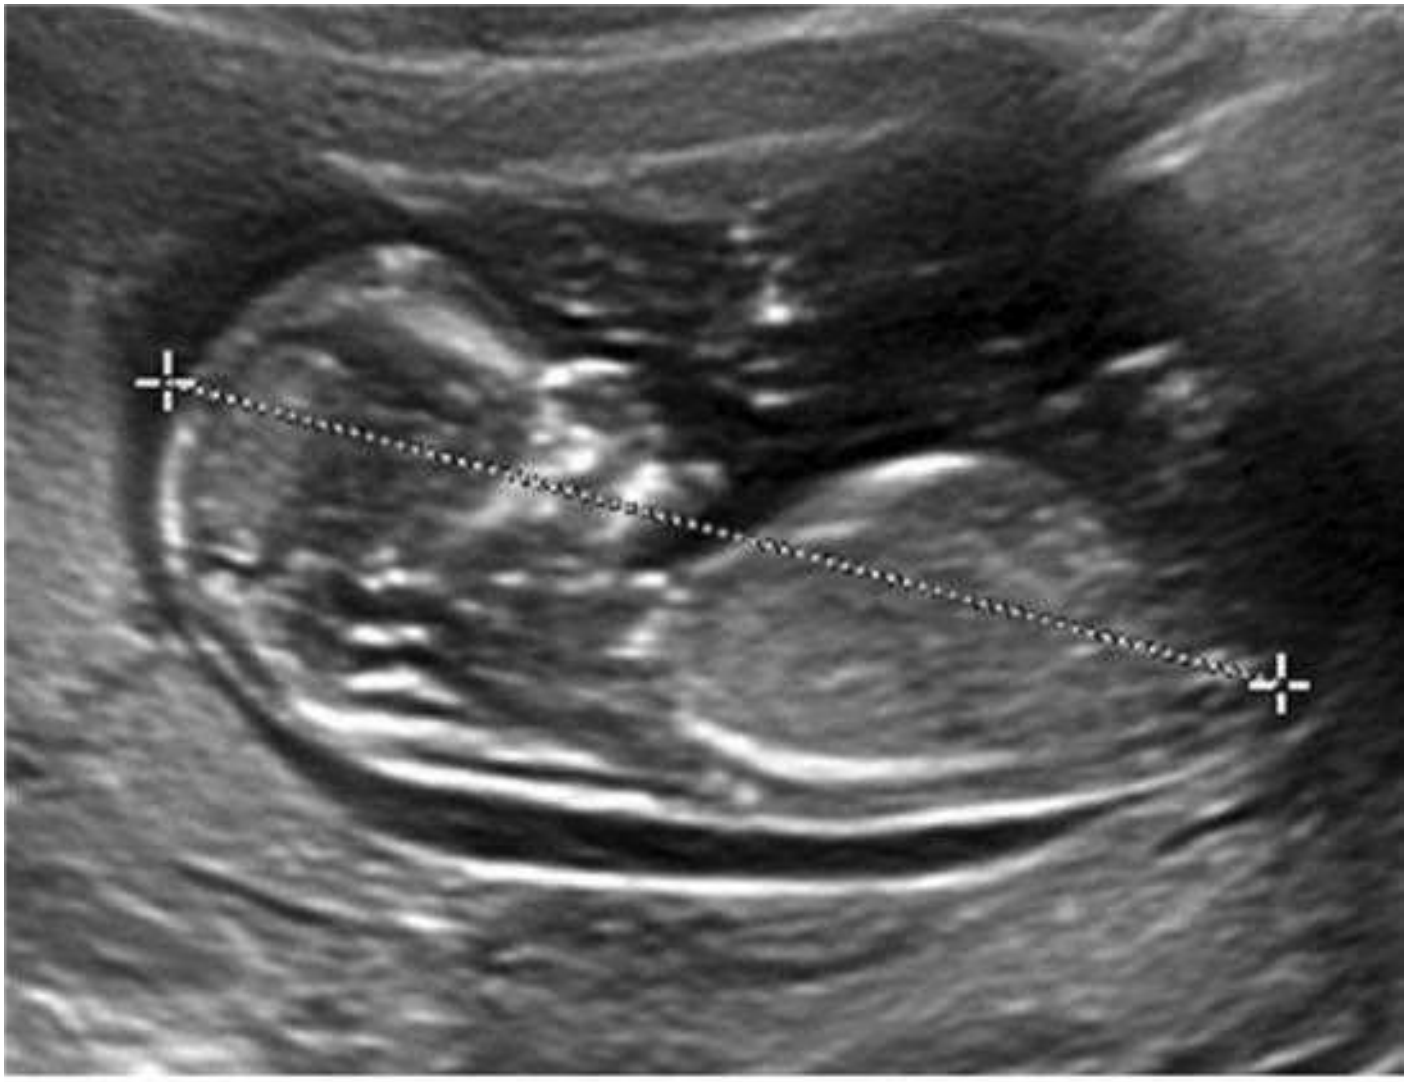
AC = abdominal circumference; BPD = biparietal diameter; CRL = crown-rump length; FL = femur length; HC = head circumference; LMP = last menstrual period.

Modified from American College of Obstetricians and Gynecologists, 2017b.

Sonographic measurement of the crown-rump length (CRL) is the most accurate method to establish or confirm gestational age (Appendix, Fetal Sonographic Measurements). As noted, transvaginal imaging typically yields higher resolution images. The CRL is measured in the midsagittal plane with the embryo or fetus in a neutral, nonflexed position so that its length can be measured in a straight line (Fig. 10-1). The measurement should include neither the yolk sac nor a limb bud. The mean of three discrete measurements is used. Until $13^{6/7}$ weeks' gestation, the CRL is accurate to within 5 to 7 days (American College of Obstetricians and Gynecologists, 2017b).

FIGURE 10-1

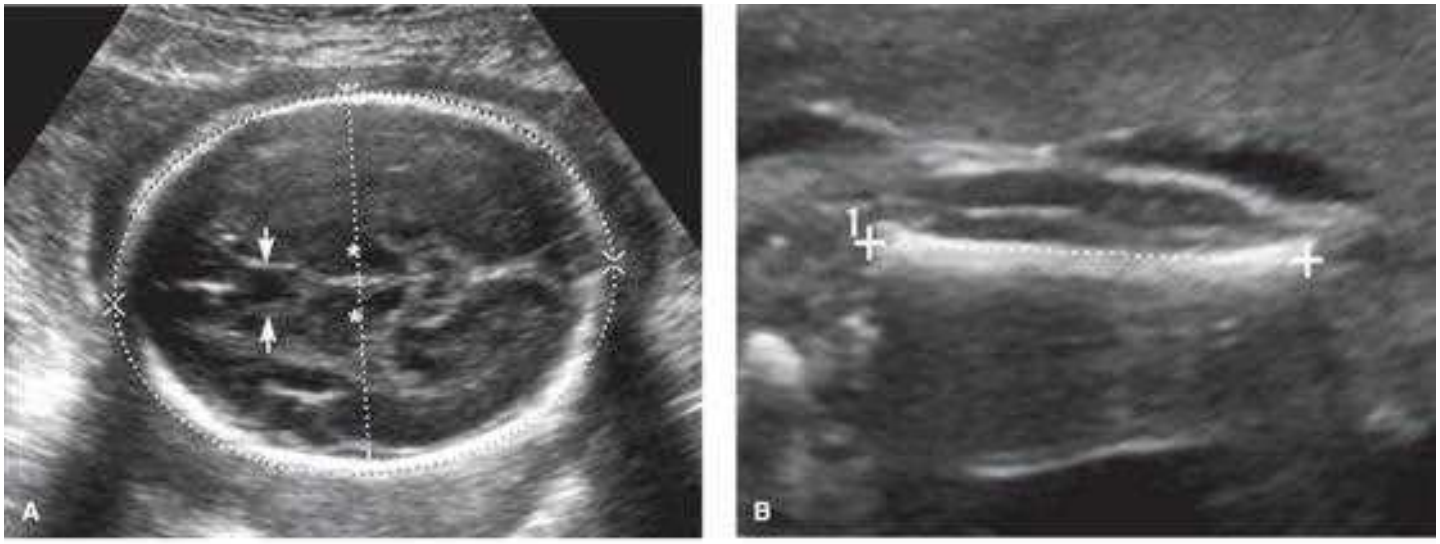
The measured crown-rump length in this 12-week 3-day fetus approximates 6 cm.



Starting at $14^{0/7}$ weeks, equipment software formulas calculate estimated gestational age and fetal weight from measurements of the biparietal diameter, head and abdominal circumference, and femur length (Fig. 10-2). The estimates are most accurate when multiple parameters are used but may over- or underestimate fetal weight by up to 20 percent (American College of Obstetricians and Gynecologists, 2016). Various nomograms for other fetal structures, including the cerebellar diameter, ear length, ocular distances, thoracic circumference, and lengths of kidney, long bones, and feet, may be used to address specific questions regarding organ system abnormalities or syndromes (Appendix, Fetal Sonographic Measurements).

FIGURE 10-2

Fetal biometry. **A.** Transthalamic view. A transverse (axial) image of the head is obtained at the level of the cavum septum pellucidum (*arrows*) and thalami (*asterisks*). The biparietal diameter is measured perpendicular to the sagittal midline, from the outer edge of the skull in the near field to the inner edge of the skull in the far field. By convention, the near field is that which is closer to the sonographic transducer. The head circumference is measured circumferentially around the outer border of the skull. **B.** Femur length. The femur is measured perpendicular to the femoral shaft, from each diaphyseal end, excluding the epiphysis. **C.** Abdominal circumference. This is a transverse measurement at the level of the stomach (*S*). The J-shaped structure (*arrowheads*) indicates the confluence of the umbilical vein and the right portal vein. Ideally, only one rib is visible on each side of the abdomen, indicating that the image was not taken at an oblique angle.



The biparietal diameter (BPD) most accurately reflects gestational age, with a variation of 7 to 10 days in the second trimester. The BPD is measured perpendicular to the midline falx in the *transthalamic view*, at the level of the thalami and cavum septum pellucidum (CSP) (see Fig. 10-2A). Calipers are placed from the outer edge of the skull in the near field to the inner edge of the skull in the far field. The head circumference (HC) is also measured in the transthalamic view. An ellipse is placed around the outer edge of the skull or the circumference is calculated using BPD and occipital-frontal diameter (OFD) values. The *cephalic index*, which is the BPD divided by the OFD, is normally 70 to 86 percent.

If the head shape is flattened—*dolichocephaly,* or rounded—*brachycephaly,* the HC is more reliable than the BPD. These head shape variants may be normal or can be secondary to fetal position or oligohydramnios. But, dolichocephaly can occur with neural-tube defects, and brachycephaly may be seen in fetuses with Down syndrome. Also, with abnormal skull shape, *craniosynostosis* and other craniofacial abnormalities are a consideration.

The femur length (FL) correlates well with both BPD and gestational age. It is measured with the beam perpendicular to the long axis of the shaft. Calipers are placed at each end of the calcified diaphysis and exclude the epiphysis. For gestational age estimation, it has a variation of 7 to 11 days in the second trimester (see Fig. 10-2B). A femur measurement that is <2.5th percentile for gestational age or that is shortened to ≤90 percent of that expected based on the measured BPD is a minor marker for Down syndrome (Chap. 14, Second-Trimester Markers—"Soft Signs"). The normal range for the FL to abdominal circumference (AC) ratio is generally 20 to 24 percent. A dramatically foreshortened FL or a FL-to-AC ratio below 18 percent prompts evaluation for a skeletal dysplasia (Skeletal Abnormalities).

Of biometric parameters, AC is most affected by fetal growth. Thus, for gestational age estimation, AC has the greatest variation, which can reach 2 to 3 weeks in the second trimester. To measure the AC, a circle is placed outside the fetal skin in a transverse image that contains the stomach and the confluence of the umbilical vein with the portal sinus (see Fig. 10-2C). The image should appear as round as possible and ideally contains no more than 1 rib on each side of the abdomen. The kidneys should not be visible in the image.

Variability of the sonographic gestational age estimate increases with advancing gestation. Accordingly, pregnancies not imaged prior to 22 weeks to confirm or revise gestational age are considered *suboptimally dated* (American College of Obstetricians and Gynecologists, 2017a). Although the estimate is improved by averaging multiple parameters, if one parameter differs significantly from the others, consideration should be given to excluding it from the calculation. The

outlier may result from poor visibility, but it could also indicate a fetal abnormality or growth problem. Reference tables such as the one in the Appendix (Fetal Sonographic Measurements) may be used to estimate fetal weight percentiles.

First-Trimester Sonography

Indications for sonography before 14 weeks' gestation are listed in Table 10-2. Early pregnancy can be evaluated using transabdominal or transvaginal sonography, or both. The components listed in Table 10-3 should be assessed. First-trimester sonography can reliably diagnose anembryonic gestation, embryonic demise, ectopic pregnancy, and gestational trophoblastic disease. The first trimester is also the ideal time to evaluate the uterus, adnexa, and cul-de-sac. Determination of chorionicity in a multifetal gestation is most accurate in the first trimester (Chap. 45, Sonographic Determination).

TABLE 10-2

Some Indications for First-Trimester Ultrasound Examination

Confirm an intrauterine pregnancy
Evaluate a suspected ectopic pregnancy
Define the cause of vaginal bleeding
Evaluate pelvic pain
Estimate gestational age
Diagnose or evaluate multifetal gestations
Confirm cardiac activity
Assist chorionic villus sampling, embryo transfer, and localization and removal of an intrauterine device
Assess for certain fetal anomalies, such as anencephaly, in high-risk patients
Evaluate maternal pelvic masses and/or uterine abnormalities
Measure nuchal translucency when part of a screening program for fetal aneuploidy
Evaluate suspected gestational trophoblastic disease

Modified from the American Institute of Ultrasound in Medicine, 2013a.

TABLE 10-3

Components of Standard Ultrasound Examination by Trimester

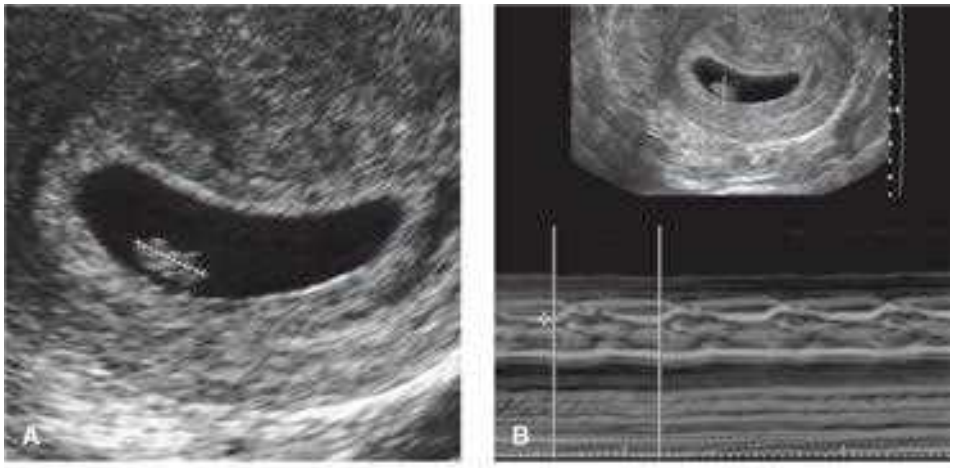
First Trimester	Second and Third Trimester
Gestational sac size, location, and number	Fetal number, including amnionicity and chorionicity of multifetal gestations
Embryo and/or yolk sac identification	Fetal cardiac activity
Crown-rump length	Fetal presentation
Fetal number, including amnionicity and chorionicity of multifetal gestations	Placental location, appearance, and relationship to the internal cervical os, with documentation of placental cord insertion site when technically possible
Embryonic/fetal cardiac activity	Amnionic fluid volume
Assessment of embryonic/fetal anatomy appropriate for the first trimester	Gestational age assessment
Evaluation of the maternal uterus, adnexa, and cul-de-sac	Fetal weight estimation
Evaluation of the fetal nuchal region, with consideration of fetal nuchal translucency assessment	Fetal anatomical survey, including documentation of technical limitations
	Evaluation of the maternal uterus, adnexa, and cervix when appropriate

Modified from the American Institute of Ultrasound in Medicine, 2013a.

An intrauterine gestational sac is reliably visualized with transvaginal sonography by 5 weeks, and an embryo with cardiac activity by 6 weeks (Fig. 10-3). The embryo should be visible transvaginally once the mean sac diameter has reached 25 mm—otherwise the gestation is *anembryonic*. Cardiac motion is usually visible with transvaginal imaging when the embryo length reaches 5 mm. In embryos <7 mm without cardiac activity, subsequent examination may be needed to determine viability (American College of Obstetricians and Gynecologists, 2016). At Parkland hospital, first-trimester demise is diagnosed if the embryo has reached 10 mm and lacks cardiac motion. Other criteria for this diagnosis are found in Chapter 18 (Table 18-3).

FIGURE 10-3

A. The measured crown-rump length is approximately 7 mm in this 6-week embryo. **B.** M-mode demonstrates embryonic cardiac activity and a heart rate of 124 beats per minute.



Nuchal Translucency

Nuchal translucency (NT) evaluation is a component of first-trimester aneuploidy screening, discussed in Chapter 14 (Traditional Aneuploidy Screening Tests). It represents the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck. NT is measured in the sagittal plane between 11 and 14 weeks' gestation using precise criteria (Table 10-4). When the NT measurement is increased, the risk for fetal aneuploidy and various structural anomalies—in particular heart defects—is significantly elevated.

TABLE 10-4

Guidelines for Nuchal Translucency (NT) Measurement

The margins of NT edges must be clear enough for proper caliper placement
The fetus must be in the midsagittal plane
The image must be magnified so that it is filled by the fetal head, neck, and upper thorax
The fetal neck must be in a neutral position, not flexed and not hyperextended
The amnion must be seen as separate from the NT line
Electronic calipers must be used to perform the measurement
The + calipers must be placed on the inner borders of the nuchal space with none of the horizontal crossbar itself protruding into the space
The calipers must be placed perpendicular to the long axis of the fetus
The measurement must be obtained at the widest space of the NT

Fetal Anomaly Detection

Assessment for selected fetal abnormalities in an at-risk pregnancy is done with first-trimester sonography (see Table 10-2). Research in this area has focused on anatomy visible at 11 to 14 weeks' gestation, to coincide with sonography performed as part of aneuploidy screening. *With current technology, it is not realistic to expect that all major abnormalities detectable in the second trimester may be visualized in the first trimester.* Thus, first-trimester scanning should not replace second-trimester anatomical evaluation (American College of Obstetricians and Gynecologists, 2016).

As examples, in one study of more than 40,000 pregnancies undergoing sonographic aneuploidy screening between 11 and 14 weeks, basic anatomical evaluation yielded a detection rate of approximately 40 percent for structural abnormalities (Syngelaki, 2011). Bromley and colleagues (2014) similarly found that late first-trimester sonography identified major abnormalities in 0.5 percent of pregnancies, representing approximately 40 percent of pregnancies with anomalies detected prenatally. Detection rates are very high for anencephaly, alobar holoprosencephaly, and ventral wall defects. But, in one analysis of more than 60,000 pregnancies with these early scans, only a third of major cardiac anomalies were identified, and *no* cases of microcephaly, agenesis of the corpus callosum, cerebellar abnormalities, congenital pulmonary airway malformations, or bowel obstruction were detected (Syngelaki, 2011). In another study of low-risk or unselected pregnancies, 32 percent of anomalies were detected, whereas in pregnancies described as high-risk, anomaly detection exceeded 60 percent (Karim, 2017).

Second- and Third-Trimester Sonography

It is recommended that sonography be routinely offered to all pregnant women between 18 and 22 weeks' gestation (American College of Obstetricians and Gynecologists, 2016). This time interval permits accurate assessment of gestational age, fetal anatomy, placental location, and cervical length. Recognizing that the gestational age at which abnormalities are identified may affect pregnancy management options, providers may opt to perform the examination prior to 20 weeks. The many additional indications for second- and third-trimester sonography are listed in Table 10-5. The three examination types are *standard*, *specialized*—which includes targeted sonography, and *limited*.

TABLE 10-5

Some Indications for Second- or Third-Trimester Ultrasound Examination

Maternal Indications
Vaginal bleeding
Abdominal/pelvic pain
Pelvic mass
Suspected uterine abnormality
Suspected ectopic pregnancy
Suspected molar pregnancy
Suspected placenta previa and subsequent surveillance
Suspected placental abruption
Preterm premature rupture of membranes and/or preterm labor
Cervical insufficiency
Adjunct to cervical cerclage
Adjunct to amniocentesis or other procedure
Adjunct to external cephalic version
Fetal Indications
Gestational age estimation
Fetal-growth evaluation
Significant uterine size/clinical date discrepancy
Suspected multifetal gestation
Fetal anatomical evaluation
Fetal anomaly screening
Assessment for findings that raise the aneuploidy risk
Abnormal biochemical markers
Fetal presentation determination
Suspected hydramnios or oligohydramnios
Fetal well-being evaluation
Follow-up evaluation of a fetal anomaly
History of congenital anomaly in prior pregnancy
Suspected fetal death
Fetal condition evaluation in late registrants for prenatal care

Adapted from the American Institute of Ultrasound in Medicine, 2013a.

The standard sonogram includes evaluation of fetal number and presentation, cardiac activity, amnionic fluid volume, placental position, fetal biometry, and fetal anatomy (American Institute of Ultrasound in Medicine, 2013b). When technically feasible, the maternal cervix and adnexa are examined as clinically appropriate. Components are found in Table 10-3, and the fetal anatomical structures that should be evaluated are listed in Table 10-6. With twins or other multiples, documentation also includes the number of chorions and amnions, comparison of fetal sizes, estimation of amnionic fluid volume within each sac, and fetal sex determination (Chap. 45, Sonographic Determination).

TABLE 10-6

Components of Standard and Targeted Fetal Anatomic Surveys

Standard Sonogram	Additional Targeted (Detailed) Sonogram Components
Head, face, and neck Lateral cerebral ventricles Choroid plexus Midline falx Cavum septum pellucidum Cerebellum Cisterna magna Upper lip Consideration of nuchal skin fold measurement at 15–20 weeks	**Head, face, and neck** Integrity and shape of cranium Third ventricle[a] Fourth ventricle[a] Corpus callosum[a] Cerebellar lobes, vermis Brain parenchyma Profile Coronal nose, lips, lens[a] Palate[a], maxilla, mandible, and tongue[a] Ear position and size[a] Orbits[a] Neck
Chest Cardiac activity Four-chamber view of the heart Left ventricular outflow tract Right ventricular outflow tract	**Chest** Aortic arch Superior/inferior venae cavae 3-vessel view 3-vessel and trachea view Lungs Integrity of diaphragm Ribs[a]

Fetal sex In multifetal gestations and when medically indicated	

[a]When medically indicated (determined on case-by-case basis).

Modified from the American Institute of Ultrasound in Medicine, 2013a; Wax, 2014.

The *targeted* sonogram is a type of *specialized* examination. It is performed when the risk for a fetal anatomical or genetic abnormality is elevated because of history, screening test result, or abnormal finding during standard examination (Table 10-7). Targeted sonograms include a detailed anatomical survey, the components of which are shown in Table 10-6. Because it carries the CPT code 76811, this sonogram is colloquially called the “76811 examination.” It is intended

to be indication-driven and should not be repeated later in the absence of an extenuating circumstance. Physicians who perform or interpret targeted sonograms should have expertise in fetal imaging, through both training and ongoing experience (Wax, 2014). For many of the targeted examination components, the physician determines on a case-by-case basis whether assessment is needed (American College of Obstetricians and Gynecologists, 2016). Other types of specialized examinations include fetal echocardiography, Doppler evaluation, and the biophysical profile, which is described in Chapter 17 (Acoustic Stimulation Tests).

TABLE 10-7

Indications for Targeted Fetal Anatomical Ultrasound Examination

Prior fetus or neonate with a structural or genetic/chromosomal abnormality
Current pregnancy with known or suspected fetal abnormality or confirmed growth abnormality
Increased risk for fetal structural anomaly in current pregnancy
Maternal diabetes diagnosed before 24 weeks' gestation
Assisted reproductive technology to achieve conception
Maternal prepregnancy body mass index >30 kg/m^2
Multifetal gestation (Chap. 45, Mechanisms of Multifetal Gestations)
Abnormal serum alpha-fetoprotein or estriol levels
Teratogen exposure
Nuchal translucency measurement ≥3.0 mm
Increased risk for fetal genetic/chromosomal abnormality in current pregnancy
Parental carriage of genetic/chromosomal abnormality
Maternal age ≥35 at delivery
Abnormal aneuploidy screening test result
Minor aneuploidy marker (on standard sonogram)
Nuchal translucency measurement ≥3.0 mm
Other condition affecting the fetus
Congenital infection (Chaps. 64 and 65)
Drug dependence
Alloimmunization (Chap. 15, Red Cell Alloimmunization)
Amnionic fluid abnormality (Chap. 11, Hydramnios)

Modified from Wax, 2014, 2015.

A *limited* sonogram is performed to address a specific clinical question. Examples include evaluation of fetal presentation, viability, amnionic fluid volume, or placental location. In the absence of an emergency, a limited examination is only performed if a standard sonogram has already been completed. Otherwise, provided that the gestational age is at least 18 weeks, a standard sonogram is recommended.

Fetal Anomaly Detection

With current advances in imaging technology, approximately 50 percent of major fetal abnormalities overall are detected with standard sonography (Rydberg, 2017). The sensitivity of sonography for detecting fetal anomalies varies according to factors such as gestational age, maternal habitus, fetal position, equipment features, examination type, operator skill, and the specific abnormality in question. For example, maternal obesity has been associated with a 20-percent reduction in the anomaly detection rate (Dashe, 2009).

Detection also varies considerably according to the abnormality. For example, population-based data from 18 registries comprise the EUROCAT network. Between 2011 and 2015, EUROCAT (2017) prenatal detection rates for selected fetal anomalies—excluding genetic conditions—were as follows: anencephaly, 99 percent; spina bifida, 89 percent; hydrocephaly, 78 percent; cleft lip/palate, 68 percent; hypoplastic left heart, 87 percent; transposition of the great vessels, 64 percent; diaphragmatic hernia, 74 percent; gastroschisis, 94 percent; omphalocele, 92 percent; bilateral renal agenesis, 94 percent; posterior urethral valves, 79 percent; limb-reduction defects, 57 percent; and clubfoot, 57 percent.

Importantly, however, the overall anomaly detection rate, excluding aneuploidy, was *below 40 percent.* This reflects inclusion of anomalies with minimal or no sonographic detection in the second trimester, such as microcephaly, choanal atresia, cleft palate, Hirschsprung disease, anal atresia, and congenital skin disorders. These are mentioned because clinicians tend to focus on abnormalities amenable to sonographic detection, whereas those not readily detectable may be equally devastating to families. *Therefore, every sonographic examination should include a frank discussion of examination limitations.*

Most anomalous neonates are born to women whose pregnancies are otherwise considered low-risk, that is, without an indication for targeted sonography. Thus, for standard sonographic examinations, accurate documentation and quality assurance are essential to optimize detection rates. Practice guidelines and standards established by organizations such as the American Institute of Ultrasound in Medicine (2013b) and the International Society of Ultrasound in Obstetrics and Gynecology (Salomon, 2011) have undoubtedly contributed to improvements in anomaly detection rates. Ultrasound practice accreditation is a process offered by the American Institute of Ultrasound in Medicine and the American College of Radiology that was developed to improve imaging quality and adherence to guidelines. It includes review of images and their storage, ultrasound equipment, report generation, and the qualifications of physicians and sonographers.

The Society for Maternal-Fetal Medicine (2013) recommends that whenever possible, obstetrical ultrasound examinations by maternal-fetal medicine subspecialists be performed by accredited practices.

Amnionic Fluid Volume

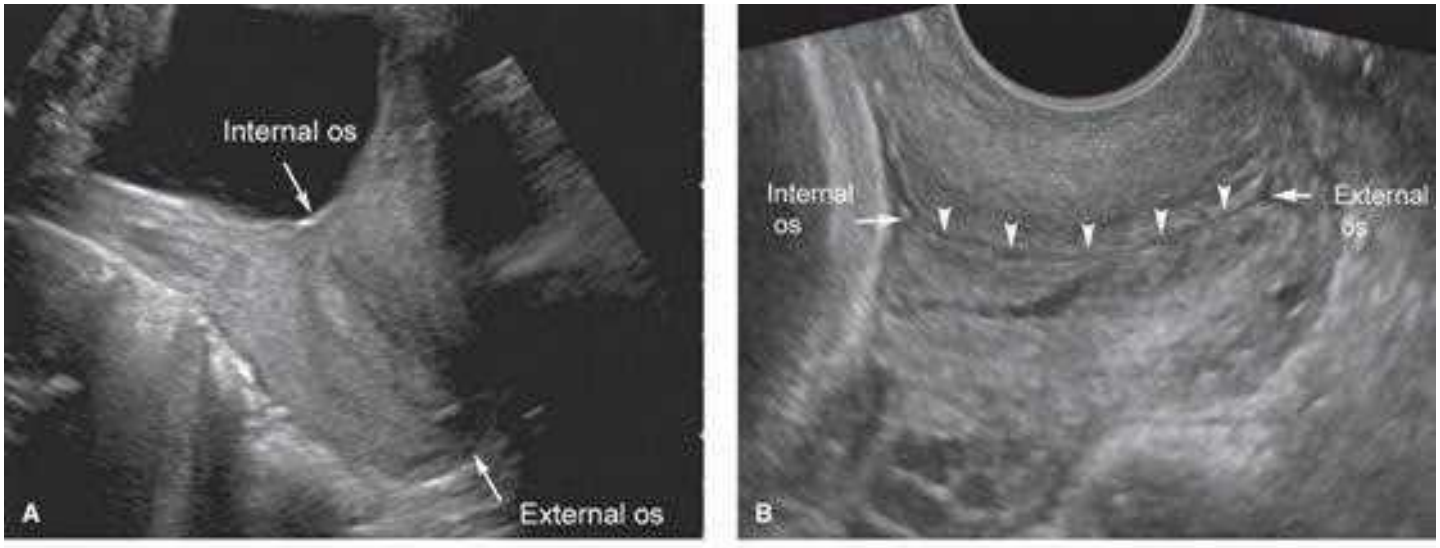
Evaluation of amnionic fluid volume is a component of every second- or third-trimester sonogram, and volumes vary with gestational age. *Oligohydramnios* indicates an amnionic fluid volume below normal range, and subjective crowding of the fetus is often noted. *Hydramnios*—also called *polyhydramnios*—defines a volume above a given normal threshold. Amnionic fluid volume is usually assessed semiquantitatively. Measurements include either the single deepest vertical fluid pocket or the sum of the deepest vertical pockets from each of four equal uterine quadrants—the *amnionic fluid index* (Phelan, 1987). Reference ranges have been established for both measurements from 16 weeks' gestation onward. The single deepest vertical pocket is normally between 2 and 8 cm, and the amnionic fluid index normally ranges between 8 and 24 cm. A further discussion and images are provided in Chapter 11 (Hydramnios).

Cervical Length Assessment

Evaluation of the relationship between the placenta and the internal cervical os is an essential component of the standard sonogram. Abnormalities of the placenta and umbilical cord are reviewed in Chapter 6 (Normal Placenta). Although the cervix may be imaged transabdominally (Fig. 10-4), this is often limited by technical factors that include maternal habitus, cervical position, or shadowing by the fetal presenting part. In addition, the maternal bladder or pressure from the transducer may artificially elongate the appearance of the cervix. As a result, values from transabdominal or transvaginal measurement of the cervix can differ significantly.

FIGURE 10-4

A. Transabdominal image of the cervix depicting the internal os and external os. **B.** Transvaginal imaging provides a more accurate evaluation of the cervix and should be used for medical decision-making. In this image, arrowheads mark the endocervical canal. (Reproduced with permission from Dr. Emily Adhikari.)



If the cervix appears shortened or if it cannot be adequately visualized during transabdominal evaluation, transvaginal assessment is considered (American Institute of Ultrasound in Medicine, 2013b). Only cervical length measurements obtained transvaginally at or beyond 16 weeks' gestation are considered sufficiently accurate for clinical decision-making (see Fig. 10-4). A foreshortened cervix is associated with an elevated risk for preterm birth, particularly in the setting of prior preterm birth, and the degree of risk rises proportionally with the degree of cervical shortening (Chap. 42, Preterm Birth Prevention).

To measure the cervix transvaginally, the imaging criteria shown in Table 10-8 are followed. The endocervical canal should be visible in its entirety, and images ideally are obtained over several minutes to allow for dynamic change. During examination, visible funneling or debris is sought. Funneling is a protrusion of amnionic membranes into a portion of the endocervical canal that has dilated (Fig. 10-5). Funneling is not an independent predictor of preterm birth, however, it is associated with cervical shortening, and transvaginal assessment is recommended if a funnel is suspected transabdominally. The cervical length is measured distal to the funnel, because the base of the funnel becomes the functional internal os. If the cervix is dilated, as with cervical insufficiency, the membranes may prolapse through the endocervical canal and into the vagina, producing an hourglass appearance. Sludge or debris represents an aggregate of particulate matter within the amnionic sac, close to the internal os. In pregnancies at risk for preterm birth, sludge is associated with a further increased risk.

TABLE 10-8

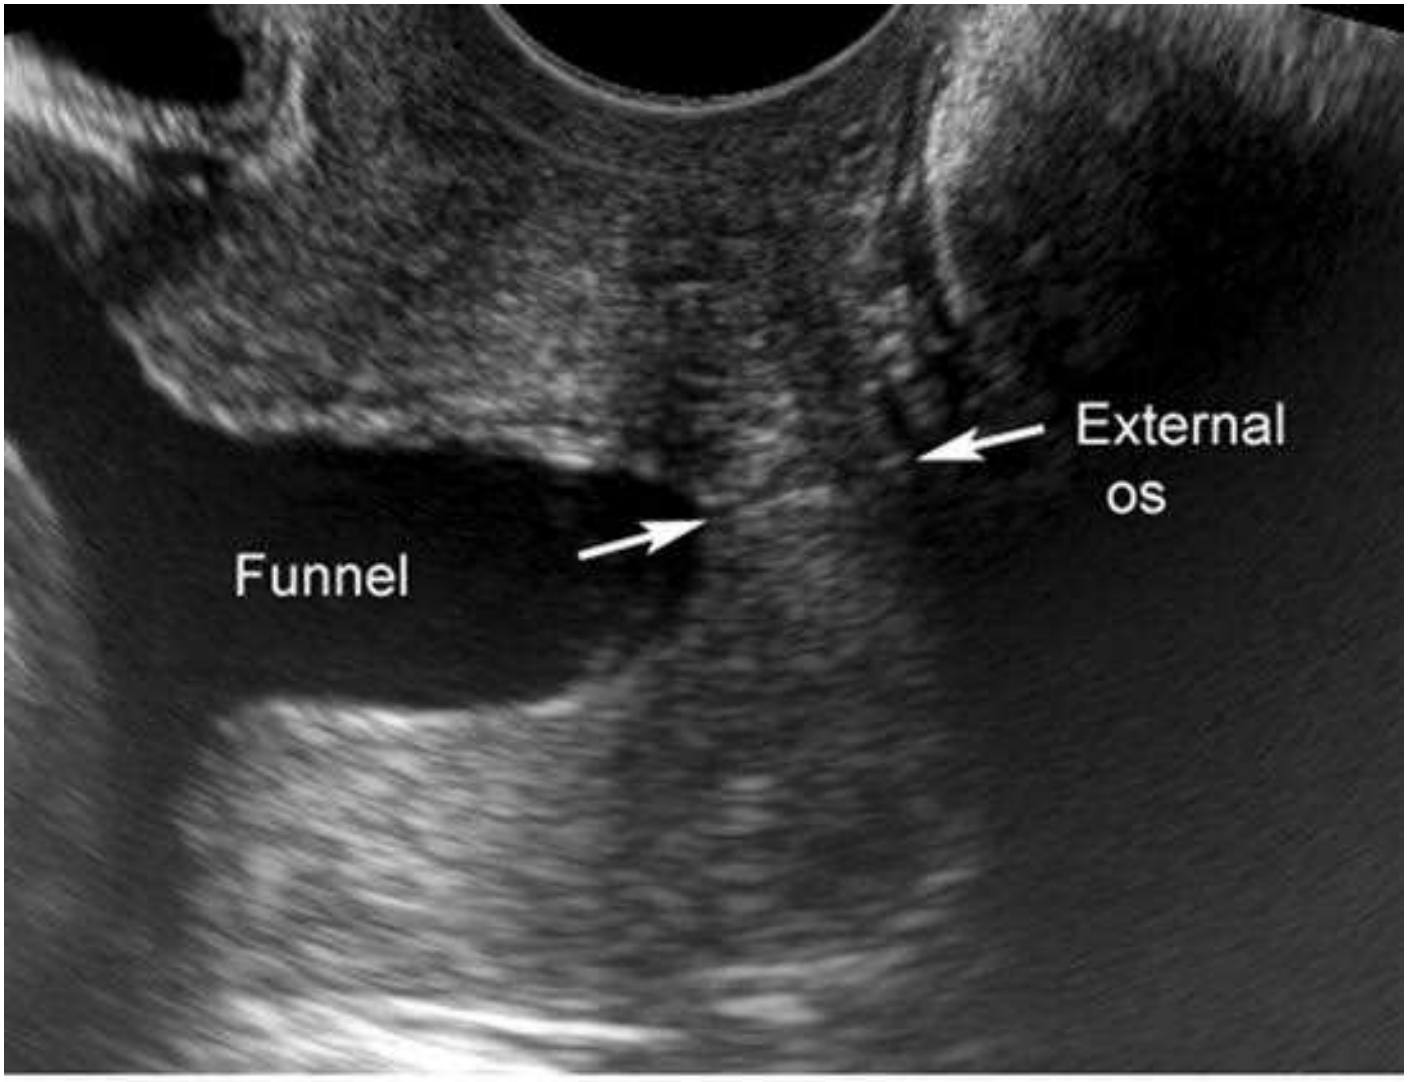
Criteria for Transvaginal Evaluation of the Cervix

Imaging the Cervix
Maternal bladder should be empty.
Transducer is inserted under real-time observation, identifying midsagittal plane, internal os, and then external os, while keeping the internal os in view.
Internal os, external os, and entire endocervical canal should be visible. The internal os may appear as a small triangular indentation at the junction of the amnionic cavity and endocervical canal.
Image is enlarged so that the cervix fills approximately 75% of the screen.
Anterior and posterior width of the cervix should be approximately equal.
Transducer is pulled back slightly until the image begins to blur, ensuring that pressure is not placed on the cervix, then inserted only enough to restore a clear image.
Images should be obtained with and without fundal or suprapubic pressure, to assess for dynamic change–or shortening on real-time imaging.
Measuring the Cervix
Calipers are placed where anterior and posterior walls of cervix meet.
Endocervical canal appears as a faint, linear echodensity.
If canal has a curved contour, a straight line between the internal and external os will deviate from the path of the endocervical canal.
If midpoint of the line between the internal and external canal deviates by ≥3 mm from the endocervical canal, measure the cervical length in two linear segments.
Funneling, sludge (debris), or dynamic change is noted.
At least three separate images are measured during a period of at least 3 minutes to allow for dynamic change. Visualization of cervical shortening on real-time imaging, with or without fundal or suprapubic pressure, raises preterm birth risks.
Shortest cervical length image that meets all criteria should be used.

Modified from Iams, 2013.

FIGURE 10-5

Transvaginal image depicting a foreshortened cervix with funneling. Funneling is a protrusion of amnionic membranes into a portion of the endocervical canal that has dilated. The distal protruding edge of the funnel becomes the functional internal os (*left arrow*). Thus, the measured cervical length, which lies between the arrows, should not include the funnel. (Reproduced with permission from Dr. Emily Adhikari.)



NORMAL AND ABNORMAL FETAL ANATOMY

Many fetal anomalies and syndromes may be characterized with targeted sonography, and selected abnormalities are discussed subsequently. This list is not intended to be comprehensive but covers abnormalities commonly detected with standard sonography and those that are potentially amenable to fetal therapy. Sonographic features of chromosomal abnormalities are reviewed in Chapters 13 and 14, and fetal therapy is discussed in Chapter 16.

Brain and Spine

Standard sonographic evaluation of the fetal brain includes three transverse (axial) views. The *transthalamic view* is used to measure the BPD and HC and includes the midline falx, cavum septum pellucidum (CSP), and thalami (see Fig. 10-1A). The CSP is the space between the two laminae that separate the frontal horns of the lateral ventricles. Inability to visualize a normal CSP may indicate a midline brain abnormality such as agenesis of the corpus callosum, lobar holoprosencephaly, or septo-optic dysplasia (de Morsier syndrome). The *transventricular view* includes the lateral ventricles, which contain the echogenic choroid plexus (Fig. 10-6). The ventricles are measured at their atrium, which is the confluence of the temporal and occipital horns. The *transcerebellar view* is obtained by angling the transducer back through the posterior fossa (Fig. 10-7). In this view, the cerebellum and cisterna magna are measured, and between 15 and about 20 weeks, the nuchal skinfold thickness may also be measured. From 15 until 22 weeks' gestation, the cerebellar diameter in millimeters is roughly equivalent to the gestational age in weeks (Goldstein, 1987). The cisterna magna normally measures between 2 and 10 mm. Effacement of the cisterna magna is present in the *Chiari II malformation*, discussed later (Ventriculomegaly).

FIGURE 10-6
The transventricular view depicts the lateral ventricles, which contain the echogenic choroid plexus (*CP*). The lateral ventricle is measured at the *atrium* (*arrows*), which is the confluence of the temporal and occipital horns. A normal measurement is between 5 and 10 mm throughout the second and third trimesters. The atria measured 6 mm in this 21-week fetus.

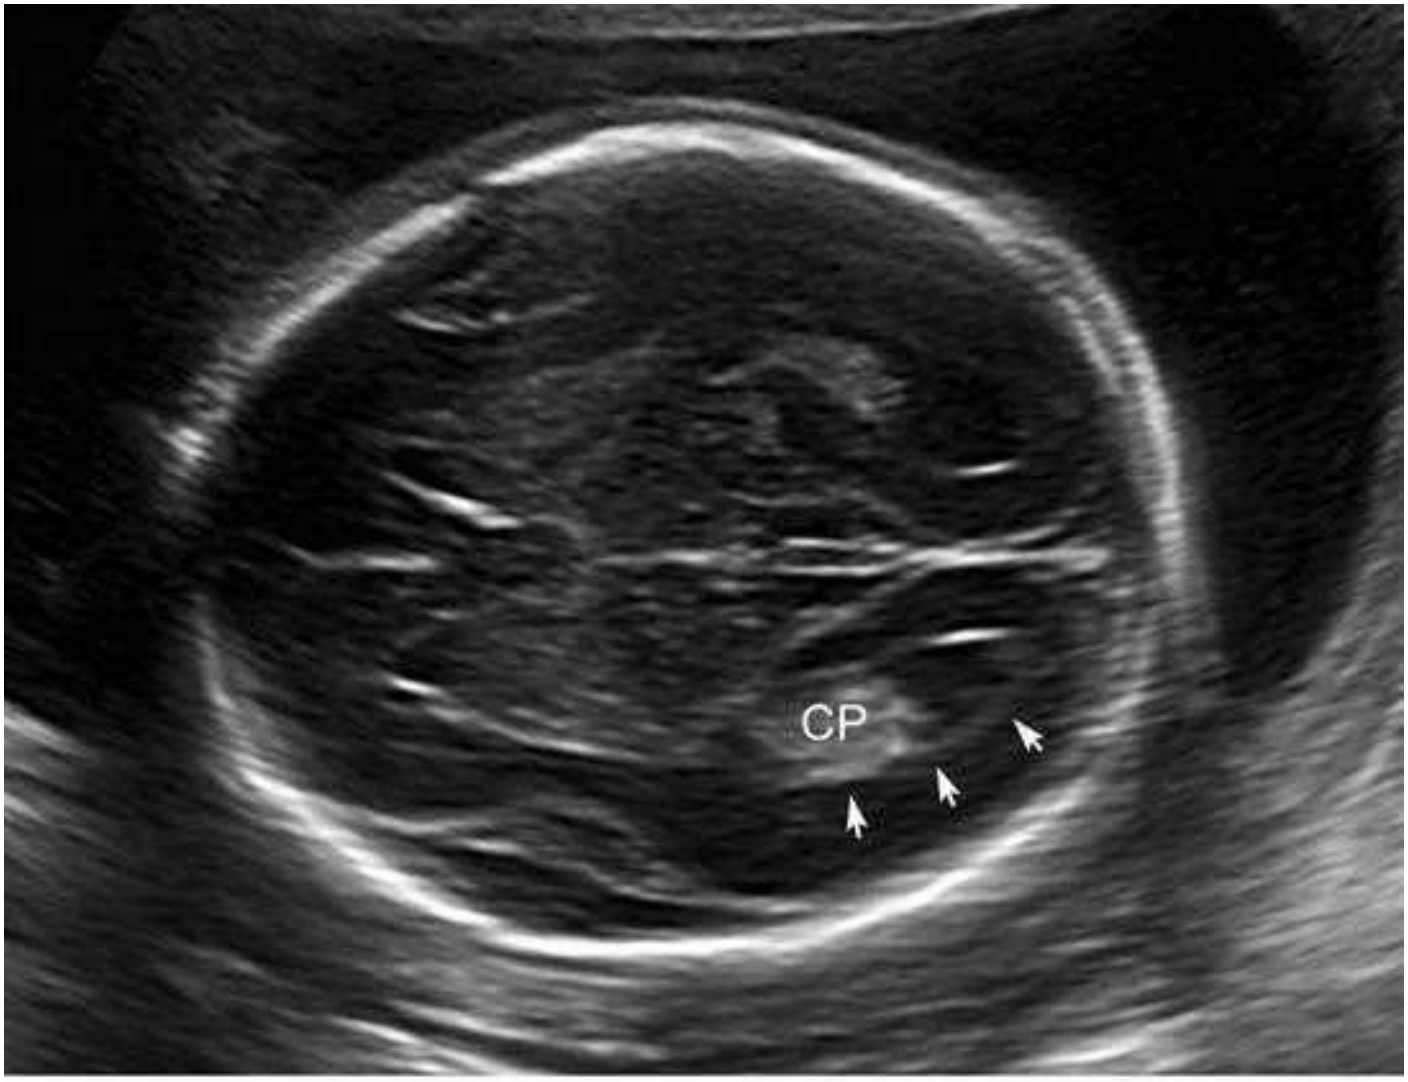


FIGURE 10-7

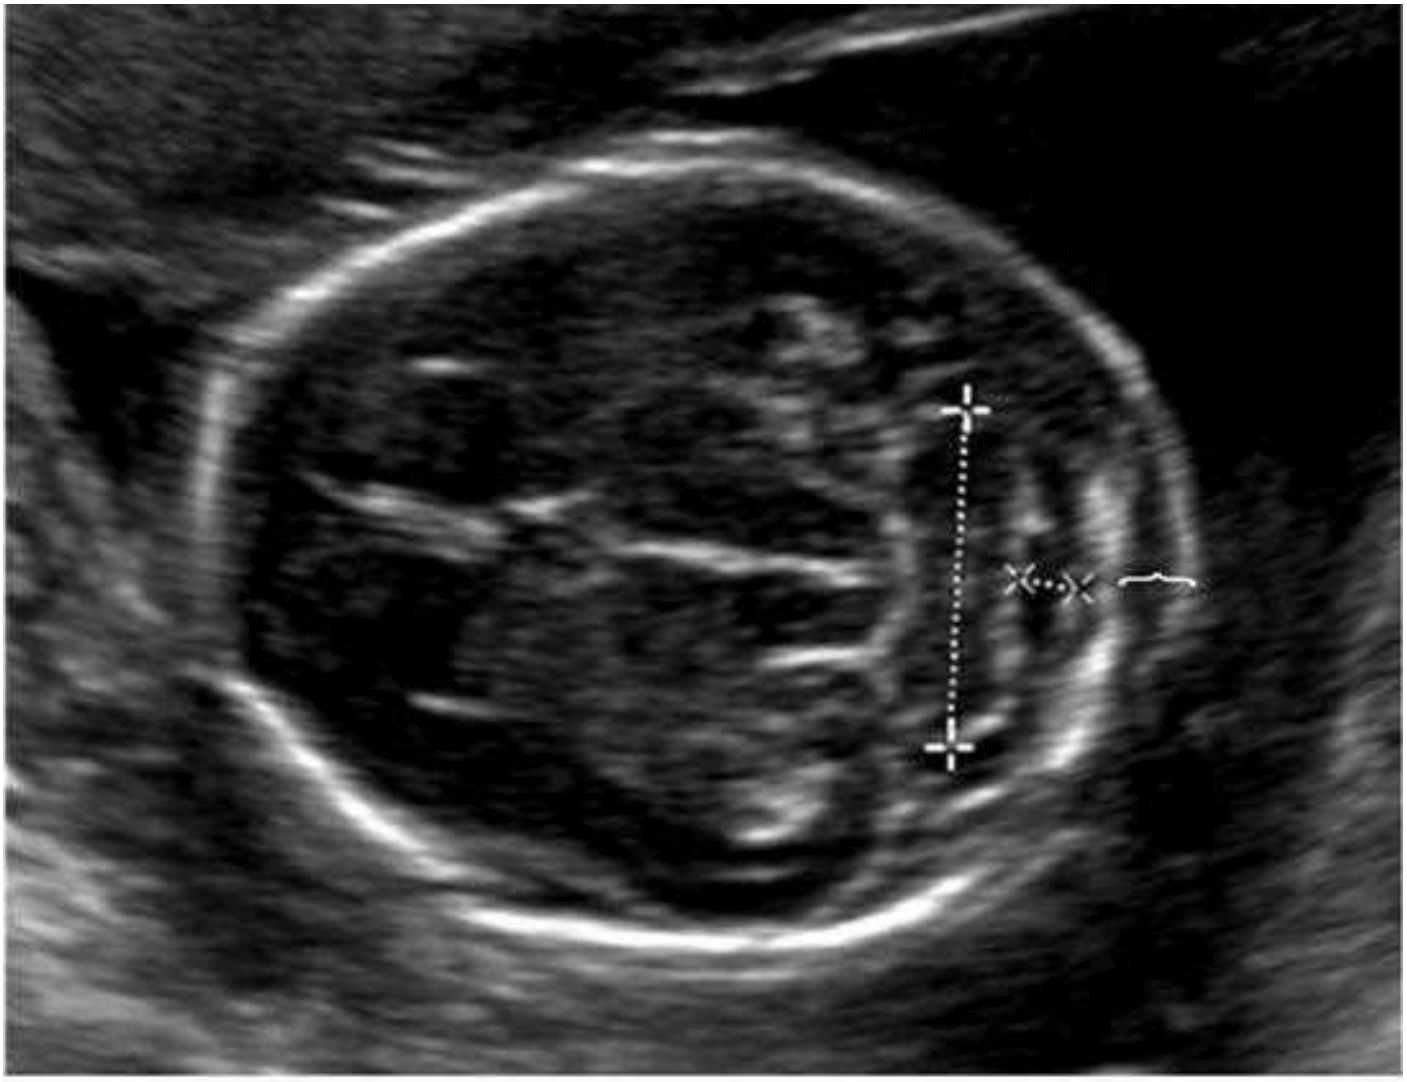
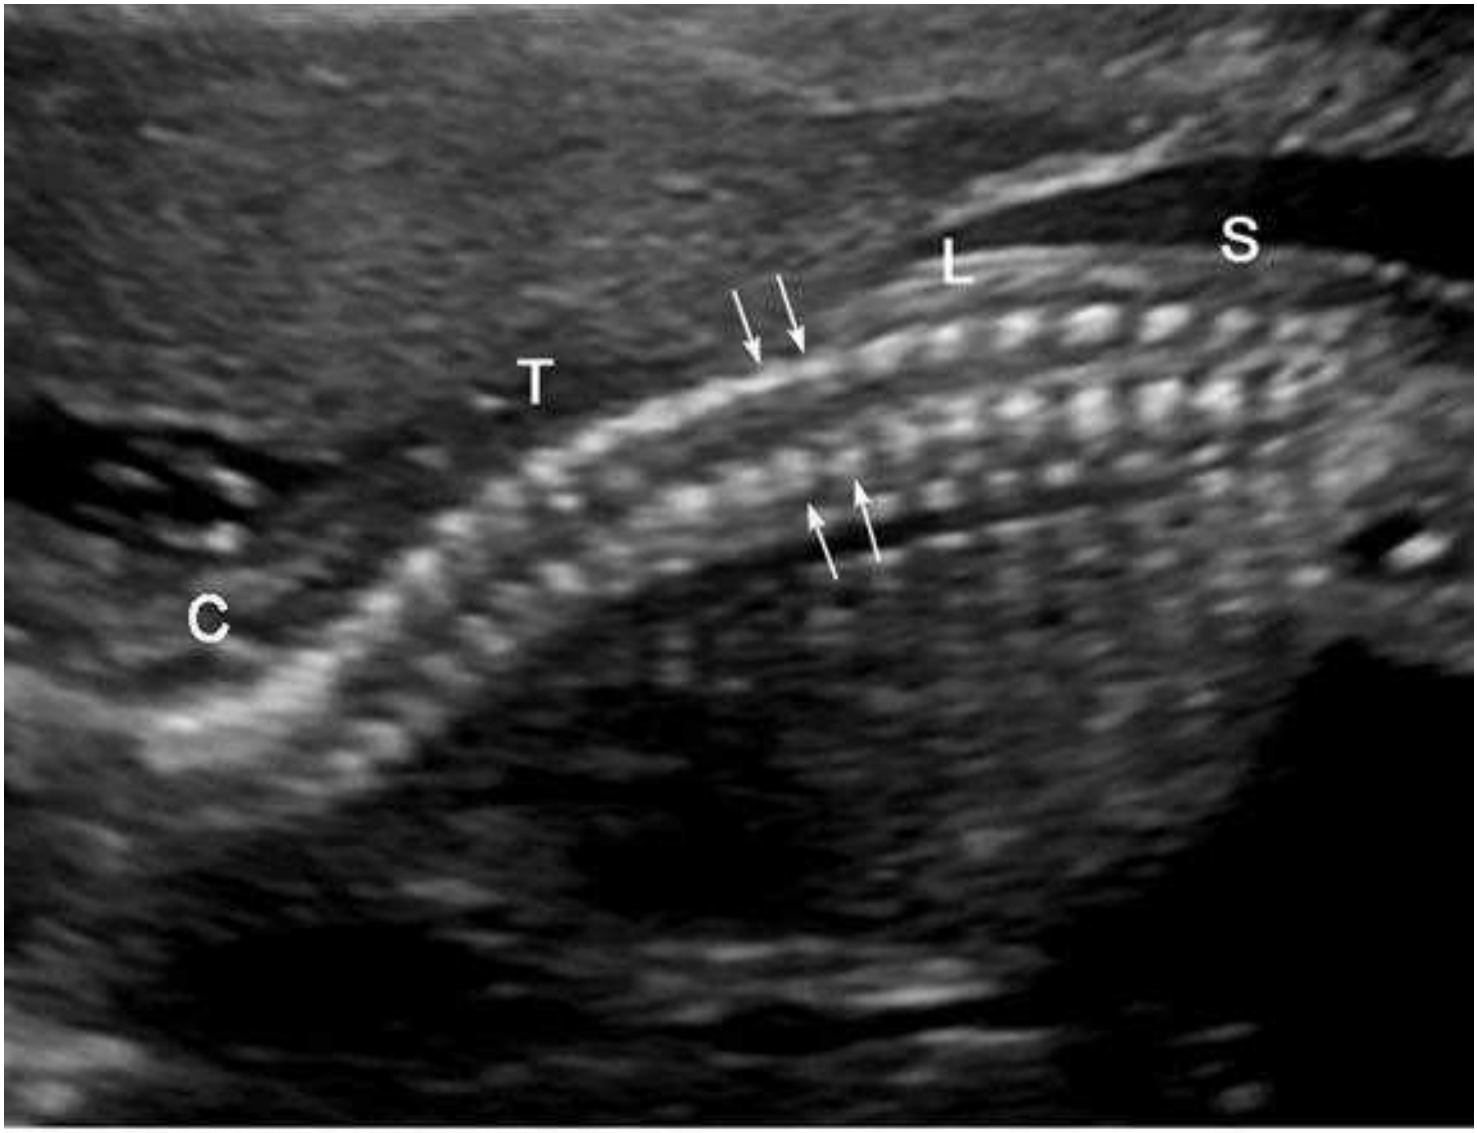
Transcerebellar view of the posterior fossa, demonstrating measurement of the cerebellum (+), cisterna magna (*x*), and nuchal fold thickness (*bracket*). Care is taken not to angle obliquely down the spine, which may artificially increase the nuchal fold measurement.



Imaging of the spine includes evaluation of the cervical, thoracic, lumbar, and sacral regions (Fig. 10-8). Representative spinal images for record keeping are often obtained in the sagittal or coronal plane, but real-time imaging of each spinal segment in the transverse plane is more sensitive for anomaly detection. Transverse images demonstrate three ossification centers. The anterior ossification center is the vertebral body, and the posterior paired ossification centers represent the junction of vertebral laminae and pedicles. Ossification of the spine proceeds in a cranial-caudal fashion, such that ossification of the upper sacrum (S_1-S_2) is not generally visible sonographically before 16 weeks' gestation, and ossification of the entire sacrum may not be visible until 21 weeks (De Biasio, 2003). Thus, detection of some spinal abnormalities can be challenging in the early second trimester.

FIGURE 10-8

Normal fetal spine. In this sagittal image of a 21-week fetus, the cervical (*C*), thoracic (*T*), lumbar (*L*), and sacral spine (*S*) are depicted. Arrows denote the parallel rows of paired posterior ossification centers—representing the junction of vertebral lamina and pedicles.



If a brain or spinal abnormality is identified, targeted sonography is indicated. The International Society of Ultrasound in Obstetrics and Gynecology (2007) has published guidelines for a "fetal neurosonogram." Fetal MR imaging may also be helpful (Fetal Anatomical Evaluation).

Neural-Tube Defects

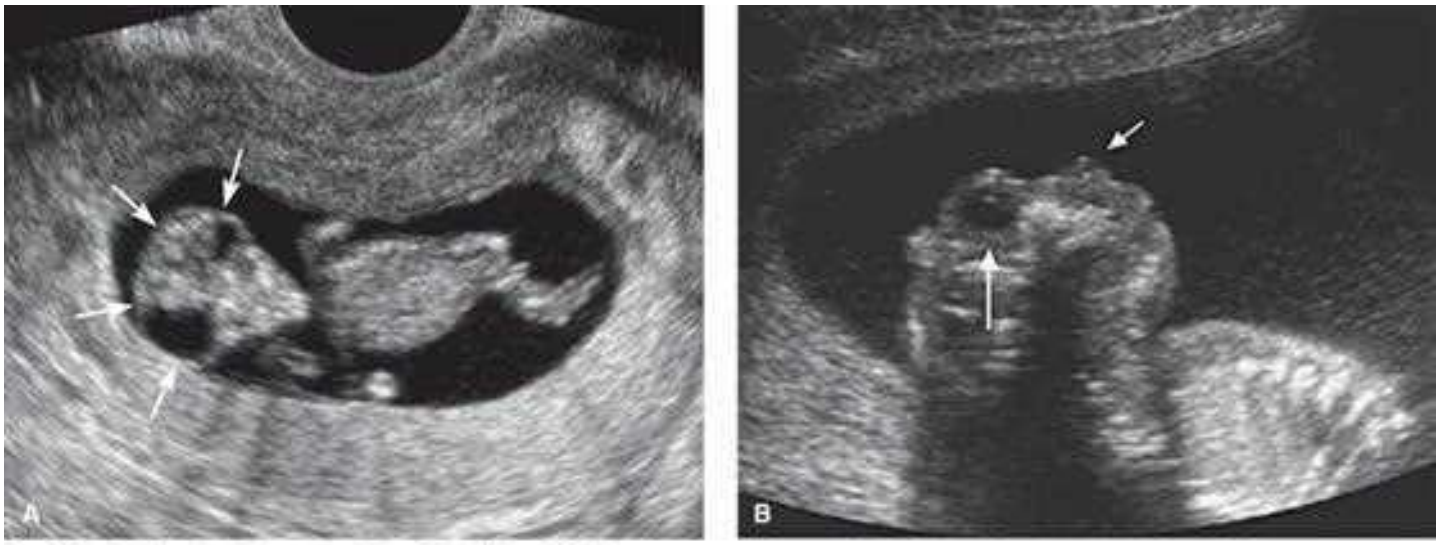
These defects include anencephaly, myelomeningocele (also called spina bifida), cephalocele, and other rare spinal fusion (or *schisis*) abnormalities. They result from incomplete closure of the neural tube by the embryonic age of 26 to 28 days. Their birth prevalence is 0.9 in 1000 in the United States and most of Europe and 1.3 in 1000 in the United Kingdom (Cragan, 2009; Dolk, 2010). Many neural-tube defects can be prevented with folic acid supplementation. When isolated, neural-tube defect inheritance is multifactorial, and the recurrence risk without periconceptional folic acid supplementation is 3 to 5 percent (Chap. 13, Genetic Tests).

Screening for neural-tube defects with maternal serum alpha-fetoprotein (MSAFP) has been offered routinely as part of prenatal care since the 1980s (Chap. 14, Maternal Serum AFP Elevation: Neural-Tube Defect Screening). Women currently have the option of neural-tube defect screening with MSAFP, sonography, or both (American College of Obstetricians and Gynecologists, 2016). Serum screening is generally performed between 15 and 20 weeks' gestation. And, if using an upper threshold of 2.5 multiples of the median (MoM), the anticipated detection rate is at least 90 percent for fetal anencephaly and 80 percent for myelomeningocele. Targeted sonography is the preferred diagnostic test, and in addition to characterizing the neural-tube defect, it may identify other abnormalities or conditions that also result in MSAFP elevation (Table 14-6).

Anencephaly is characterized by absence of the cranium and telencephalic structures above the level of the skull base and orbits (Fig. 10-9). *Acrania* is absence of the cranium with protrusion of disorganized brain tissue. Both are uniformly lethal and are generally considered together, with anencephaly as the final stage of acrania (Bronshtein, 1991). These anomalies are often diagnosed in the late first trimester, and with adequate visualization, virtually all cases may be diagnosed in the second trimester. Inability to image the BPD raises suspicion. The face often appears triangular, and sagittal images readily demonstrate absence of the ossified cranium. Hydramnios from impaired fetal swallowing is common in the third trimester.

FIGURE 10-9

Anencephaly/acrania. **A.** Acrania. This 11-week fetus has absence of the cranium, with protrusion of a disorganized mass of brain tissue that resembles a “shower cap” (*arrows*) and a characteristic triangular facial appearance. **B.** Anencephaly. This sagittal image shows the absence of forebrain and cranium above the skull base and orbit. The long white arrow points to the fetal orbit, and the short white arrow indicates the nose.



Cephalocele is the herniation of meninges through a cranial defect, typically located in the midline occipital region (Fig. 10-10). When brain tissue herniates through the skull defect, the anomaly is termed an *encephalocele.* Herniation of the cerebellum and other posterior fossa structures constitutes a *Chiari III malformation*. Associated hydrocephalus and microcephaly are common, and survivors have a high incidence of neurological deficits and intellectual disability. Cephalocele is an important feature of the autosomal recessive *Meckel-Gruber syndrome,* which includes cystic renal dysplasia and polydactyly. A cephalocele not located in the occipital midline raises suspicion for *amnionic-band sequence* (Chap. 6, Amniochorion).

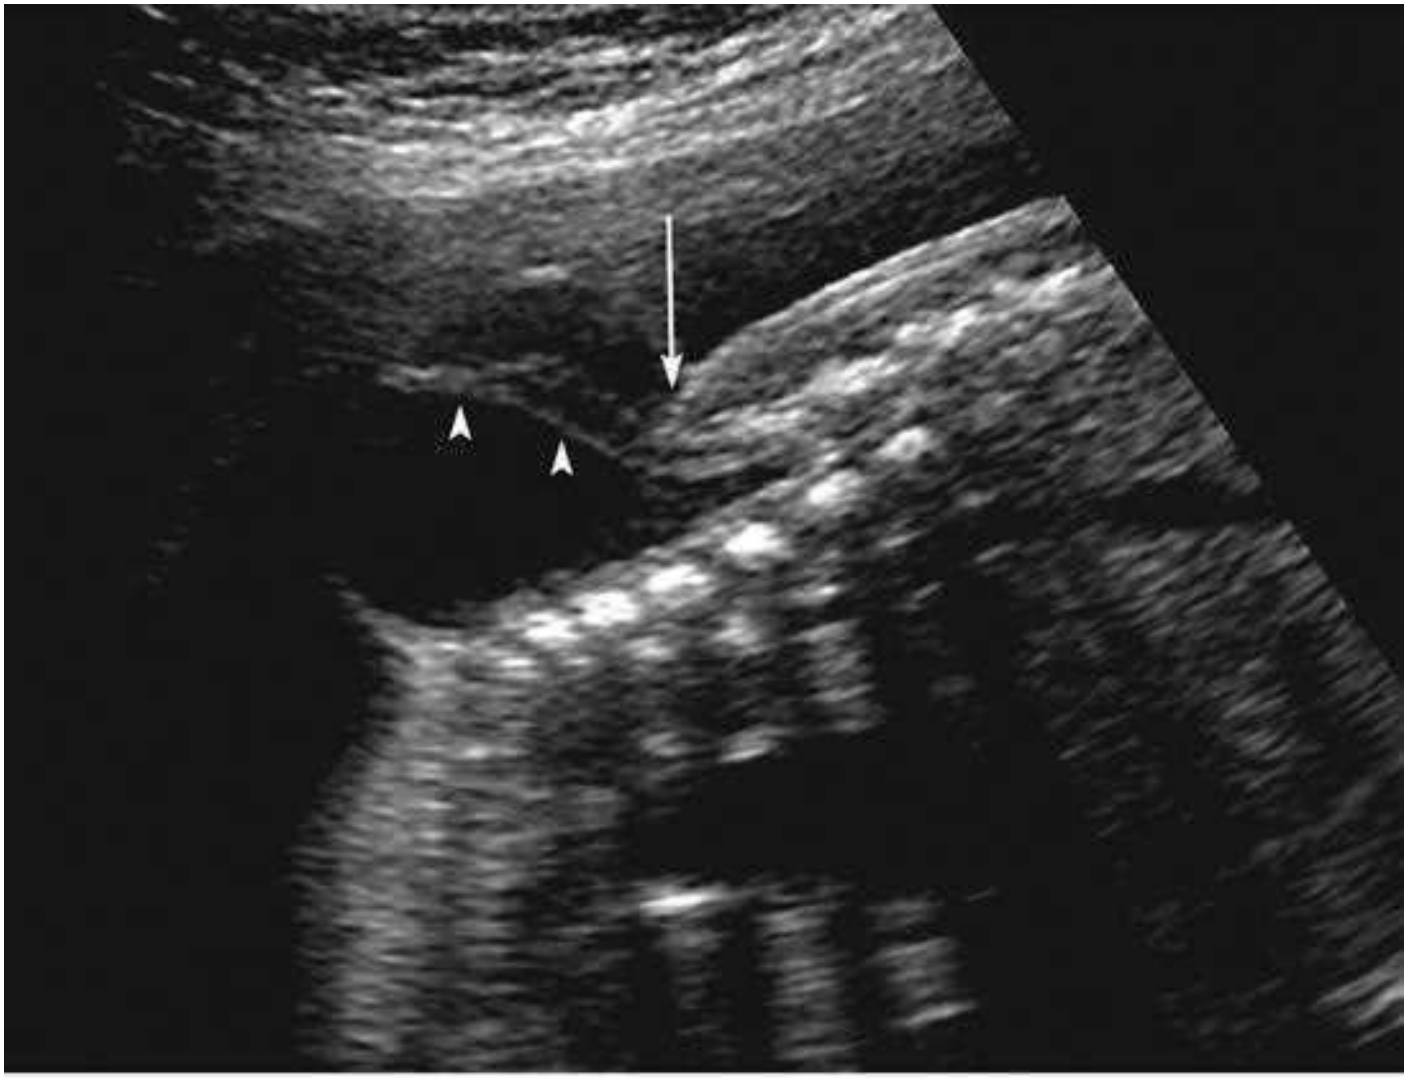
FIGURE 10-10

Encephalocele. This transverse image depicts a large defect in the occipital region of the cranium (*arrows*) through which meninges and brain tissue have herniated.

Spina bifida is a defect in the vertebrae, typically the dorsal arches, with exposure of the meninges and spinal cord. The birth prevalence approximates 1 in 2000 (Cragan, 2009; Dolk, 2010). Most cases are *open spina bifida*—the defect includes the skin and soft tissues. Herniation of a meningeal sac containing neural elements is termed a *myelomeningocele* (Fig. 10-11). When only a meningeal sac is present, the defect is a *meningocele.* Although the sac may be easier to image in the sagittal plane, transverse images more readily demonstrate separation or splaying of the lateral processes.

FIGURE 10-11

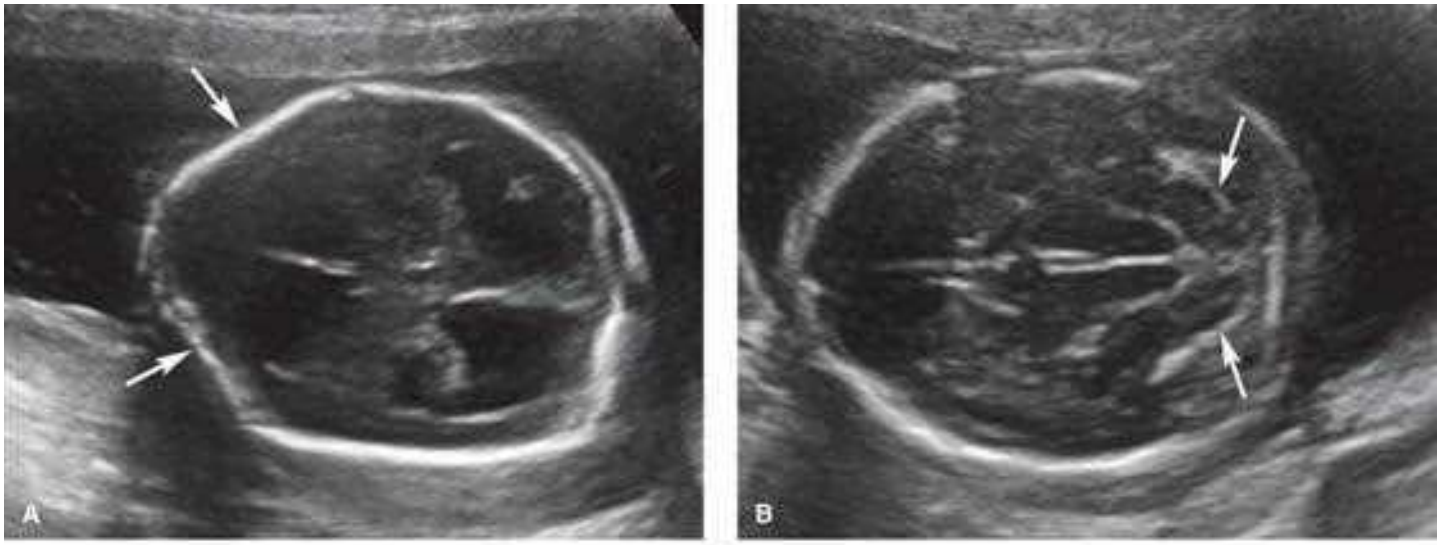
Myelomeningocele. In this sagittal image of a lumbosacral myelomeningocele, the arrowheads indicate nerve roots within the anechoic herniated sac. The overlying skin is visible above the level of the spinal defect but abruptly stops at the defect (*arrow*).



Detection of spina bifida is aided by two characteristic cranial findings (Nicolaides, 1986). Scalloping of the frontal bones is termed the *lemon sign*, and anterior curvature of the cerebellum with effacement of the cisterna magna is the *banana sign* (Fig. 10-12). These findings are manifestations of the Chiari II malformation, also called the *Arnold-Chiari malformation*. This develops when downward displacement of the spinal cord pulls a portion of the cerebellum through the foramen magnum and into the upper cervical canal. *Ventriculomegaly* is another frequent associated sonographic finding, particularly after midgestation. More than 80 percent of infants with open spina bifida require ventriculoperitoneal shunt placement. A small BPD is often present as well. Children with spina bifida require multidisciplinary care to address problems related to the defect, therapeutic shunting, and deficits in swallowing, bladder and bowel function, and ambulation. Fetal myelomeningocele surgery is discussed in Chapter 16 (Open Fetal Surgery).

FIGURE 10-12

Cranial findings in myelomeningocele. **A.** Image of a fetal head at the level of the lateral ventricles demonstrates inward bowing or scalloping of the frontal bones (*arrows*)—the lemon sign. **B.** Image of a fetal head at the level of the posterior fossa shows anterior curvature of the cerebellum (*arrows*) with effacement of the cisterna magna—the banana sign.

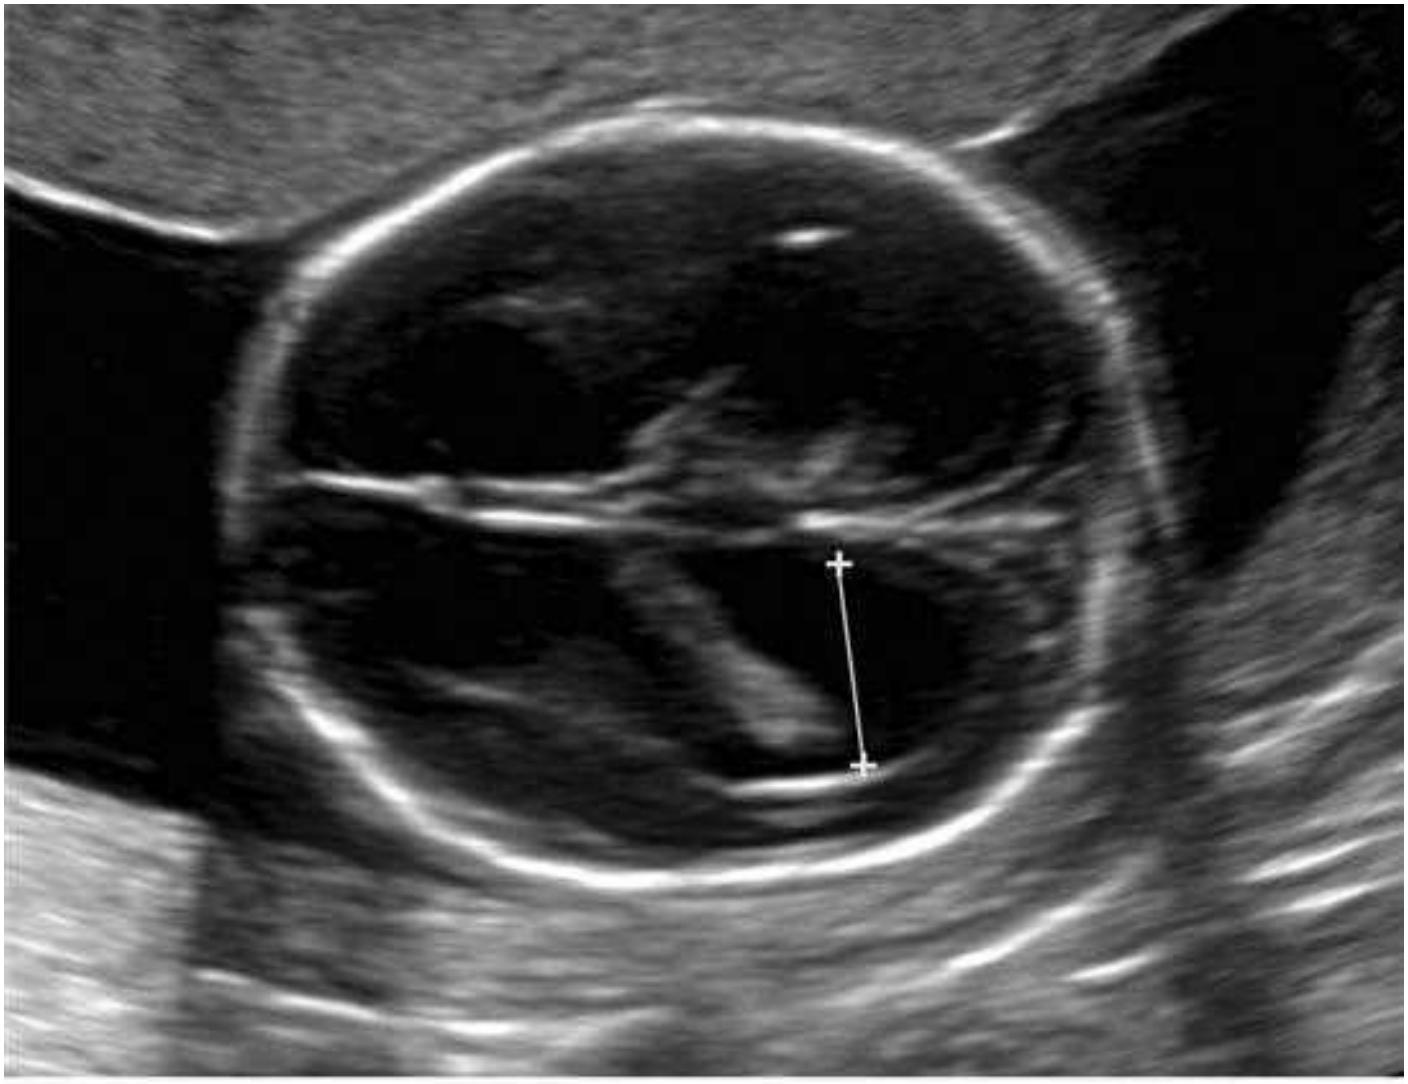


Ventriculomegaly

Characterized by distention of the cerebral ventricles by cerebrospinal fluid (CSF), this finding is a nonspecific marker of abnormal brain development (Pilu, 2011). The atrium normally measures between 5 and 10 mm from 15 weeks' gestation until term (see Fig. 10-6). Mild ventriculomegaly is diagnosed when the atrial width measures 10 to 15 mm (Fig. 10-13), and overt or severe ventriculomegaly when it exceeds 15 mm. The larger the atrium, the greater the likelihood of an abnormal outcome (Gaglioti, 2009; Joó, 2008). CSF is produced within the ventricles by the *choroid plexus*, which is composed of loose connective tissue surrounding an epithelium-lined capillary core. The choroid plexus often appears to *dangle* within the ventricle when severe ventriculomegaly is present.

FIGURE 10-13

Ventriculomegaly. In this transverse view of the cranium, the white line depicts measurement of the atrium of the lateral ventricle, which measured 12 mm, consistent with mild ventriculomegaly.



Ventriculomegaly may be caused by various genetic and environmental insults. It may be due to other central nervous system (CNS) abnormalities—such as Dandy-Walker malformation or holoprosencephaly, to an obstructive process—such as aqueductal stenosis, or to a destructive process—such as porencephaly or an intracranial teratoma. Initial evaluation includes a targeted examination of fetal anatomy, testing for congenital infections such as cytomegalovirus and toxoplasmosis, and chromosomal microarray analysis, which is described in Chapter 13 (Chromosomal Microarray Analysis). Fetal MR imaging should be considered to assess for associated abnormalities that may not be detectable sonographically.

Prognosis is generally determined by etiology, severity, and rate of progression. However, even with mild-appearing and isolated ventriculomegaly, prognosis can vary widely. In a systematic review of nearly 1500 mild-to-moderate cases, 1 to 2 percent were associated with congenital infection, 5 percent with aneuploidy, and 12 percent with neurological abnormality (Devaseelan, 2010). A neurological abnormality was significantly more common if ventriculomegaly progressed with advancing gestation.

Agenesis of the Corpus Callosum

The corpus callosum is the major fiber bundle connecting reciprocal regions of the cerebral hemispheres. With complete agenesis of the corpus callosum, a normal cavum septum pellucidum cannot be visualized sonographically. Also, the frontal horns are displaced laterally, and the atria show mild enlargement posteriorly—such that the ventricle has a characteristic “teardrop” appearance (Fig. 10-14). Callosal dysgenesis involves only the caudal portions—the body and splenium—and consequently may be more difficult to detect prenatally.

FIGURE 10-14

Agenesis of the corpus callosum. This image demonstrates a “teardrop” shaped ventricle with mild ventriculomegaly (*dotted line*) and laterally displaced frontal horns (*arrow*). A normal cavum septum pellucidum cannot be visualized.

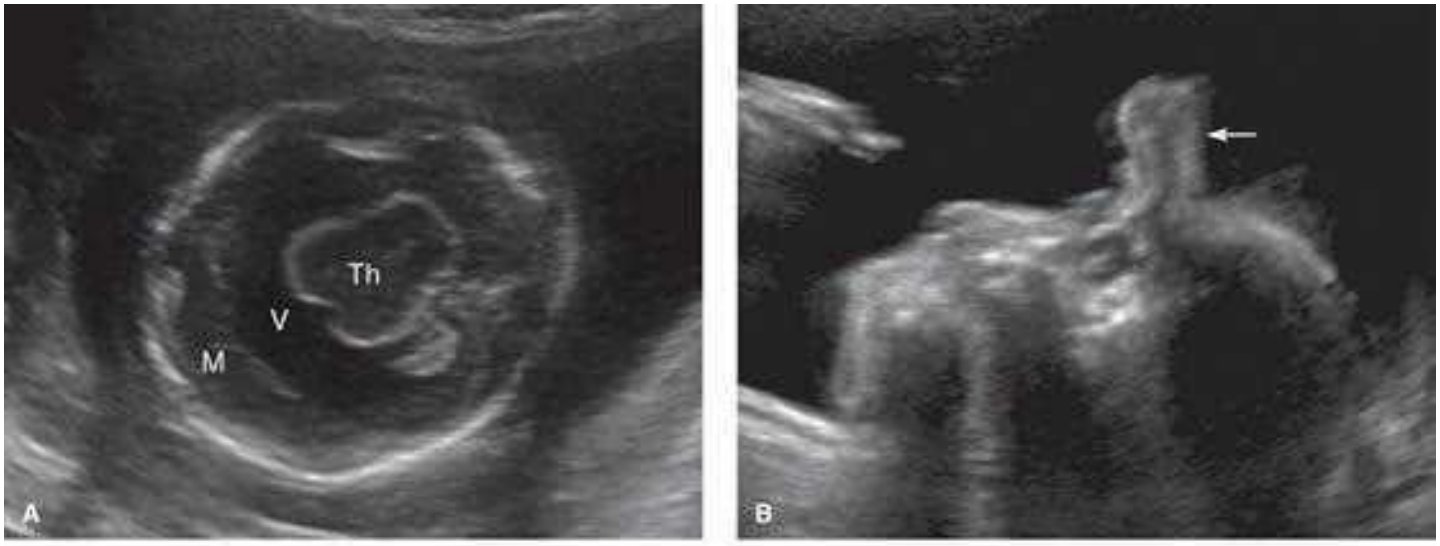
In population-based studies, agenesis of the corpus callosum has a prevalence of 1 in 5000 births (Glass, 2008; Szabo, 2011). In a review of apparently isolated cases, fetal MR imaging identified additional brain abnormalities in more than 20 percent (Sotiriadis, 2012). If the anomaly was still considered isolated following MR imaging, normal developmental outcome was reported in 75 percent of cases, but severe disability occurred in 12 percent. Agenesis of the corpus callosum is associated with other anomalies, aneuploidy, and more than 200 genetic syndromes. Thus, genetic counseling can be challenging.

Holoprosencephaly

In early normal brain development, the prosencephalon or forebrain divides as it becomes the telencephalon and diencephalon. With holoprosencephaly, the prosencephalon fails to divide completely into two separate cerebral hemispheres and underlying paired diencephalic structures. Main forms of holoprosencephaly are a continuum that contains, with decreasing severity, *alobar*, *semilobar*, and *lobar* types. In the most severe form—*alobar holoprosencephaly*—a single monoventricle, with or without a covering mantle of cortex, surrounds fused central thalami (Fig. 10-15). In *semilobar holoprosencephaly*, partial separation of the hemispheres occurs. *Lobar holoprosencephaly* is characterized by a variable degree of fusion of frontal structures and should be considered when a normal CSP cannot be seen.

FIGURE 10-15

Alobar holoprosencephaly. **A.** Transverse cranial image of a fetus with alobar holoprosencephaly, depicting fused thalami (*Th*) encircled by a monoventricle (*V*) with a covering mantle *(M)* of cortex. The midline falx is absent. (Reproduced with permission from Rafael Levy, RDMS.) **B.** In this profile view of the face, a soft tissue mass—a proboscis (*arrow*), protrudes from the region of the forehead.



Differentiation into two cerebral hemispheres is induced by prechordal mesenchyme, which is also responsible for differentiation of the midline face. Thus, holoprosencephaly may be associated with anomalies of the orbits and eyes—hypotelorism, cyclopia, or micro-ophthalmia; lips—median cleft; or nose—ethmocephaly, cebocephaly, or arhinia with proboscis (see Fig. 10-15).

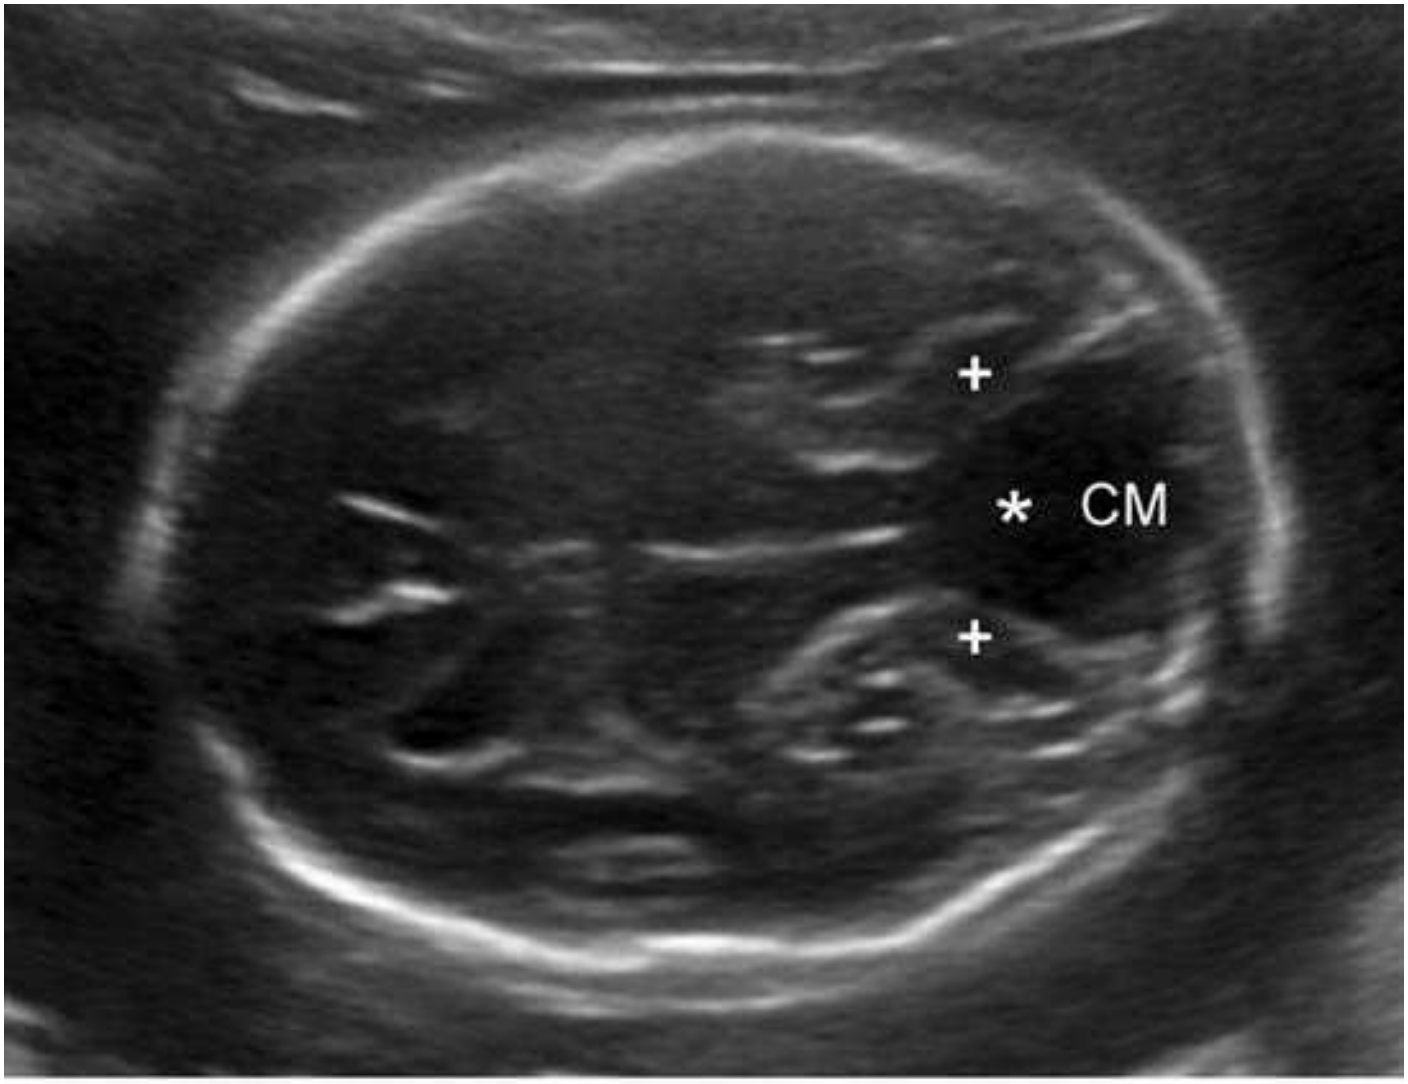
The birth prevalence of holoprosencephaly is only 1 in 10,000 to 15,000. However, the abnormality has been identified in nearly 1 in 250 early abortuses, which attests to the extremely high in-utero lethality (Orioli, 2010; Yamada, 2004). The alobar form accounts for 40 to 75 percent of cases, and 30 to 40 percent have a numerical chromosomal abnormality, particularly trisomy 13 (Orioli, 2010; Solomon, 2010). Conversely, two thirds of trisomy 13 cases are found to have holoprosencephaly. Fetal karyotype or chromosomal microarray analysis should be offered when this anomaly is identified.

Dandy-Walker Malformation—Vermian Agenesis

This posterior fossa abnormality is characterized by agenesis of the cerebellar vermis, posterior fossa enlargement, and elevation of the tentorium. Sonographically, fluid in the enlarged cisterna magna visibly communicates with the fourth ventricle through the cerebellar vermis defect, with visible separation of the cerebellar hemispheres (Fig. 10-16). The birth prevalence approximates 1 in 12,000 (Long, 2006). Associated anomalies and aneuploidy are common. These include ventriculomegaly in 30 to 40 percent, other anomalies in approximately 50 percent, and aneuploidy in 40 percent (Ecker, 2000; Long, 2006). Dandy-Walker malformation is also associated with numerous genetic and sporadic syndromes, congenital viral infections, and teratogen exposure, all of which greatly affect the prognosis. Thus, the initial evaluation mirrors that for ventriculomegaly (Ventriculomegaly).

FIGURE 10-16

Dandy-Walker malformation. This transcerebellar image demonstrates agenesis of the cerebellar vermis. The cerebellar hemispheres (+) are widely separated by a fluid collection that connects the 4th ventricle (*asterisk*) to the enlarged cisterna magna (*CM*).



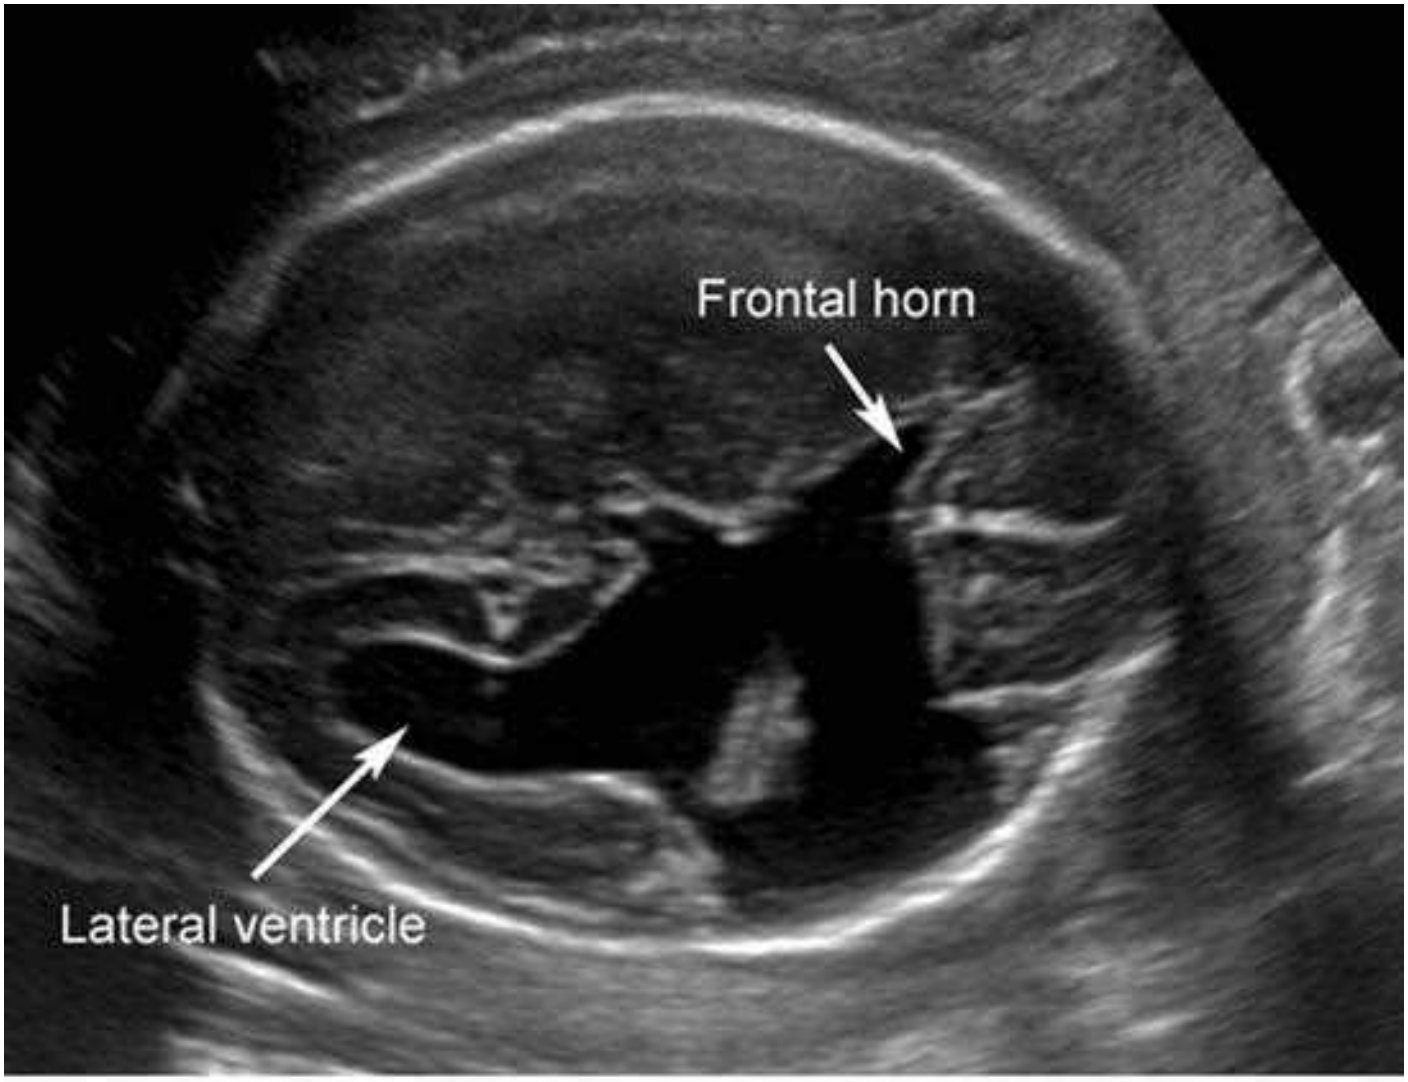
Inferior vermian agenesis, also called *Dandy-Walker variant*, is a term used when only the inferior portion of the vermis is absent. But, even when vermian agenesis appears to be partial and relatively subtle, the prevalence of associated anomalies and aneuploidy is still high, and the prognosis is often poor (Ecker, 2000; Long, 2006).

Schizencephaly and Porencephaly

Schizencephaly is a rare brain abnormality characterized by clefts in one or both cerebral hemispheres, typically involving the perisylvian fissure. The cleft is lined by heterotopic gray matter and communicates with the ventricle, extending through the cortex to the pial surface (Fig. 10-17). Schizencephaly is believed to be an abnormality of neuronal migration, which explains its typically delayed recognition until after midpregnancy (Howe, 2012). It is associated with absence of the cavum septum pellucidum, resulting in the frontal horn communication shown in the image below.

FIGURE 10-17

Schizencephaly. This transverse image of the fetal head shows a large cleft that extends from the right lateral ventricle through the cortex. Because the borders of the cleft are separate, the defect is termed *open-lipped*. (Reproduced with permission from Michael Davidson, RDMS.)



In contrast, porencephaly is a cystic space within the brain that is lined by white matter and may or may not communicate with the ventricular system. It is generally considered to be a destructive lesion and may develop following intracranial hemorrhage in the setting of neonatal alloimmune thrombocytopenia or following death of a monochorionic co-twin (Fig. 45-20). Fetal MR imaging should be considered when either of these CNS anomalies is identified.

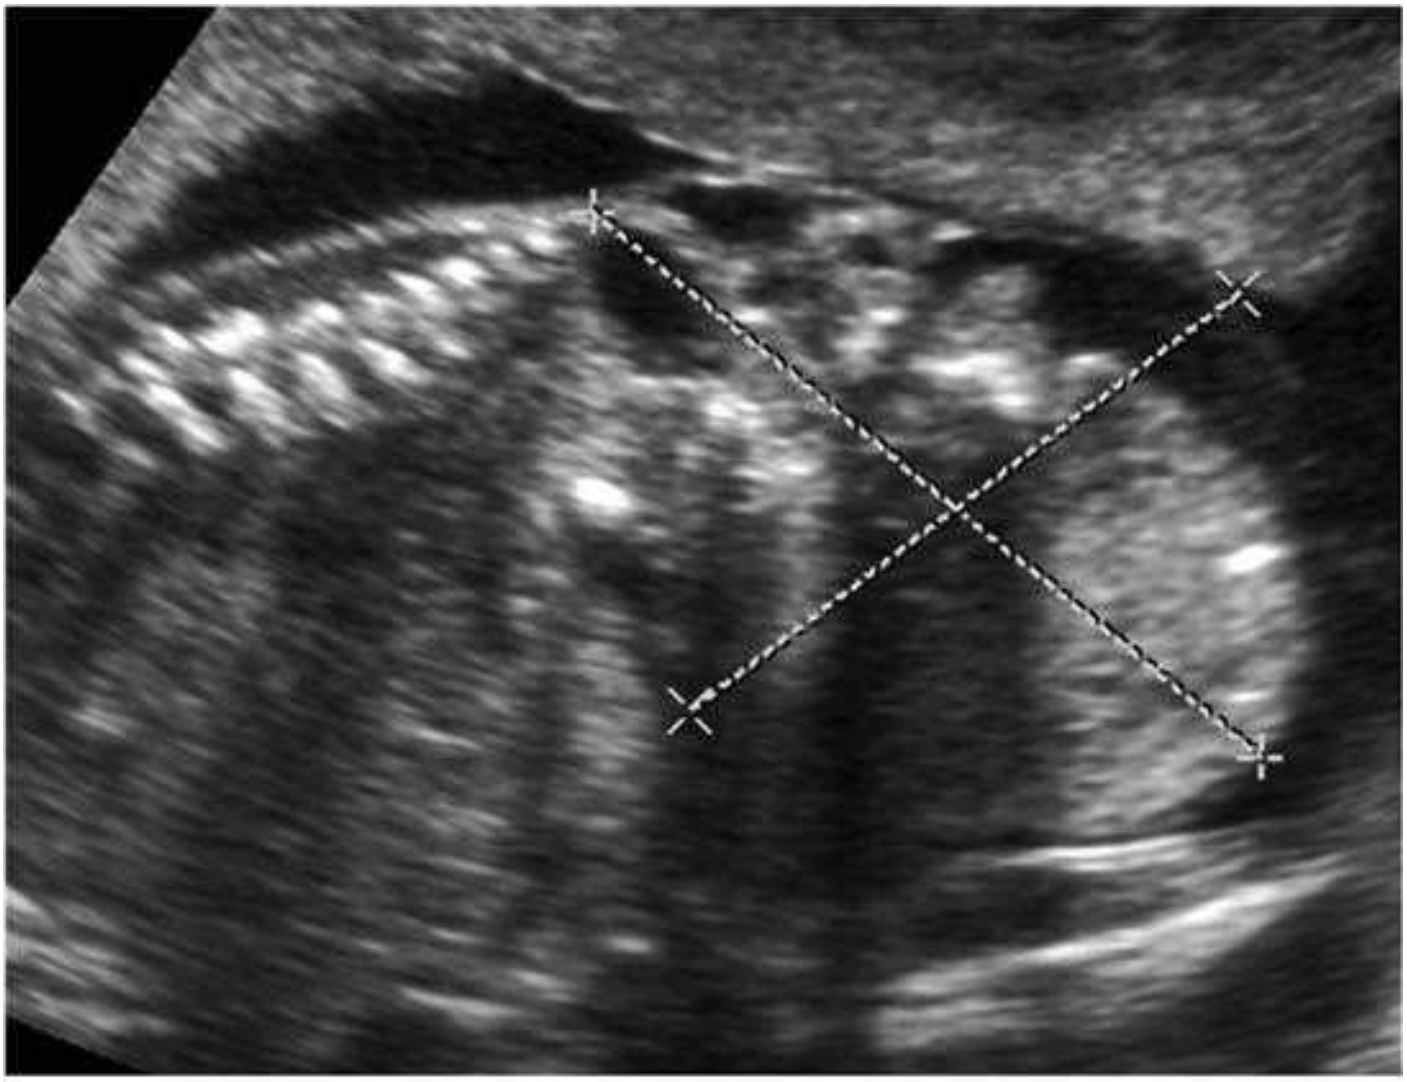
Sacrococcygeal Teratoma

This germ cell tumor is one of the most common tumors in neonates, with a birth prevalence of approximately 1 in 28,000 (Derikx, 2006; Swamy, 2008). It is thought to arise from the totipotent cells along Hensen node, anterior to the coccyx. Classification of sacrococcygeal teratoma (SCT) includes four types (Altman, 1974). Type 1 is predominantly external with a minimal presacral component; type 2 is predominantly external but with a significant intrapelvic component; type 3 is predominantly internal but with abdominal extension; and type 4 is entirely internal with no external component. The tumor histological type may be mature, immature, or malignant.

Sonographically, SCT appears as a solid and/or cystic mass that arises from the anterior sacrum and usually extends inferiorly and externally as it grows (Fig. 10-18). Solid components often have varying echogenicity, appear disorganized, and may enlarge rapidly with advancing gestation. Internal pelvic components may be more challenging to visualize, and fetal MR imaging should be considered. Hydramnios is frequent, and hydrops may develop from high-output cardiac failure, either as a consequence of tumor vascularity or secondary to bleeding within the tumor and resultant anemia. Mentioned throughout this chapter, hydrops is more fully described in Chapter 15 (Hydrops Fetalis). Fetuses with tumors >5 cm often require cesarean delivery, and classical hysterotomy may be needed (Gucciardo, 2011). As shown in Figure 16-3, fetal surgery is suitable for some SCT cases.

FIGURE 10-18

Sacrococcygeal teratoma. Sonographically, this tumor appears as a solid and/or cystic mass that arises from the anterior sacrum and tends to extend inferiorly and externally as it grows. In this image, a 7 × 6 cm inhomogeneous solid mass is visible below the normal-appearing sacrum. There is also an internal component to the tumor.



Caudal Regression Sequence—Sacral Agenesis

This rare anomaly is characterized by absence of the sacral spine and often portions of the lumbar spine. It is approximately 25 times more common in diabetic pregnancies (Garne, 2012). Sonographic findings include a spine that appears abnormally short, lacks normal lumbosacral curvature, and terminates abruptly above the level of the iliac wings. Because the sacrum does not lie between the iliac wings, they are abnormally close together and may appear "shield-like." There may also be abnormal positioning of the lower extremities and lack of normal local soft tissue development. Caudal regression should be differentiated from *sirenomelia*, which is a rare anomaly characterized by a single fused lower extremity that occupies the midline.

Face and Neck

Normal fetal lips and nose are shown in Figure 10-19. A fetal profile is not a required component of standard examination but may be helpful in identifying cases of *micrognathia*—an abnormally small jaw (Fig. 10-20). Micrognathia should be considered in the evaluation of hydramnios (Chap. 11, Hydramnios). Use of the *ex-utero intrapartum treatment (EXIT)* procedure for severe micrognathia is discussed in Chapter 16 (Ex-Utero Intrapartum Treatment).

FIGURE 10-19

Midline face. This view demonstrates the integrity of the upper lip.

FIGURE 10-20

Fetal profile. **A.** This image depicts a normal fetal profile. **B.** This fetus has severe micrognathia, which creates a severely recessed chin.

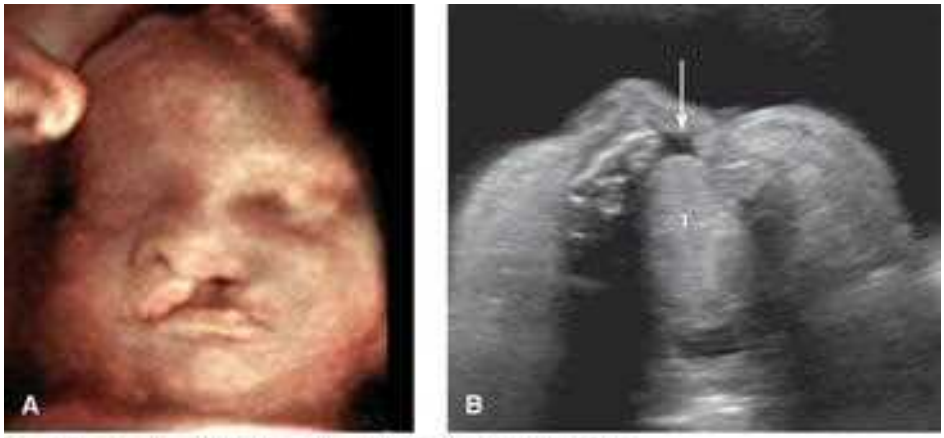
Facial Clefts

There are three main types of clefts. The first type, *cleft lip and palate*, always involves the lip, may also involve the hard palate, can be unilateral or bilateral, and has a birth prevalence that approximates 1 in 1000 (Cragan, 2009; Dolk, 2010). If isolated, the inheritance is multifactorial—with a recurrence risk of 3 to 5 percent

for one prior affected child. If a cleft is visible in the upper lip, a transverse image at the level of the alveolar ridge may demonstrate that the defect also involves the primary palate (Fig. 10-21).

FIGURE 10-21

Cleft lip/palate. **A.** This fetus has a prominent unilateral (left-sided) cleft lip. **B.** Transverse view of the palate in the same fetus demonstrates a defect in the alveolar ridge (*arrow*). The tongue (*T*) is also visible.



In one systematic review of low-risk pregnancies, cleft lip was identified sonographically in only about half of cases (Maarse, 2010). Approximately 40 percent of those detected in prenatal series are associated with other anomalies or syndromes, and aneuploidy is common (Maarse, 2011; Offerdal, 2008). The rate of associated anomalies is highest for bilateral defects that involve the palate. Using data from the Utah Birth Defect Network, Walker and associates (2001) identified aneuploidy in 1 percent with cleft lip alone, 5 percent with unilateral cleft lip and palate, and 13 percent with bilateral cleft lip and palate. It is reasonable to offer fetal chromosomal microarray analysis when a cleft is identified.

The second type of cleft is *isolated cleft palate.* It begins at the uvula, may involve the soft palate, and occasionally involves the hard palate—but does not involve the lip. The birth prevalence approximates 1 in 2000 (Dolk, 2010). Identification of isolated cleft palate has been described using specialized 2- and 3-dimensional sonography (Ramos, 2010; Wilhelm, 2010). However, it is not expected to be visualized during a standard sonographic examination (Maarse, 2011; Offerdal, 2008).

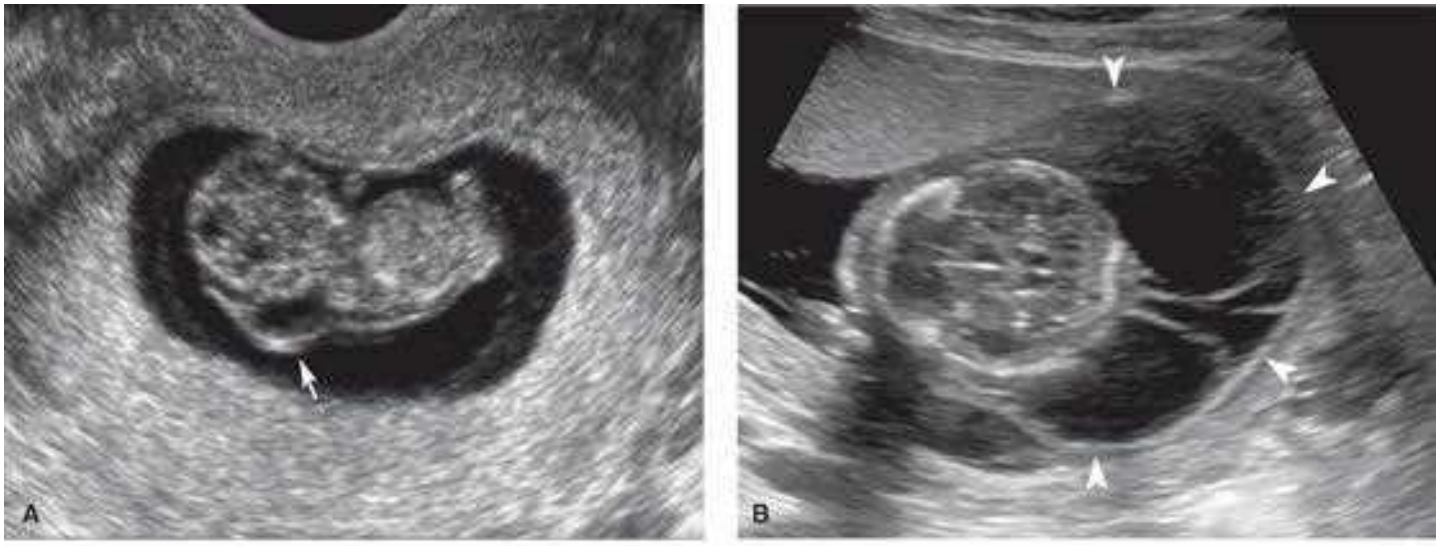
A third type of cleft is *median cleft lip,* which is found in association with several conditions. These include agenesis of the primary palate, hypotelorism, and holoprosencephaly. Median clefts may also be associated with hypertelorism and frontonasal hyperplasia, formerly called the *median cleft face syndrome*.

Cystic Hygroma

This venolymphatic malformation is characterized by fluid-filled sacs that extend from the posterior neck (Fig. 10-22). Cystic hygromas may be diagnosed as early as the first trimester and vary widely in size. They are believed to develop when lymph from the head fails to drain into the jugular vein and accumulates instead in jugular lymphatic sacs. Their birth prevalence approximates 1 in 5000. But, reflecting the high in-utero lethality of the condition, the first-trimester incidence exceeds 1 in 300 (Malone, 2005).

FIGURE 10-22

Cystic hygromas. **A.** This 9-week fetus with a cystic hygroma (*arrow*) was later found to have Noonan syndrome. **B.** Massive multiseptated hygromas (*arrowheads*) in the setting of hydrops fetalis at 15 weeks' gestation.



Up to 70 percent of cystic hygromas are associated with aneuploidy. When cystic hygromas are diagnosed in the first trimester, trisomy 21 is the most common aneuploidy, followed by 45,X and trisomy 18 (Kharrat, 2006; Malone, 2005). First-trimester fetuses with cystic hygromas are five times more likely to be aneuploid than fetuses with a thickened nuchal translucency. When cystic hygromas are diagnosed in the second trimester, approximately 75 percent of aneuploid cases are 45,X—*Turner syndrome* (Johnson, 1993; Shulman, 1992).

Even in the absence of aneuploidy, cystic hygromas confer a significantly greater risk for other anomalies, particularly cardiac anomalies that are flow-related. These include hypoplastic left heart and coarctation of the aorta. Cystic hygromas also may be part of a genetic syndrome. One is *Noonan syndrome,* an autosomal dominant disorder that shares several features with Turner syndrome, including short stature, lymphedema, high-arched palate, and often pulmonary valve stenosis.

Large cystic hygromas are usually associated with hydrops fetalis, rarely resolve, and carry a poor prognosis. Small hygromas may undergo spontaneous resolution, and provided that fetal karyotype and echocardiography results are normal, the prognosis *may* be good. The likelihood of a nonanomalous liveborn neonate with normal karyotype following identification of first-trimester hygroma is approximately 1 in 6 (Kharrat, 2006; Malone, 2005).

Thorax

The lungs appear homogeneous and surround the heart. In the four-chamber view of the heart, they comprise approximately two thirds of the area, with the heart occupying the remaining third. The thoracic circumference is measured at the skin line in a transverse plane at the level of the four-chamber view. In cases of suspected pulmonary hypoplasia secondary to a small thorax, such as with severe skeletal dysplasia, comparison with a reference table may be helpful (Appendix, Fetal Sonographic Measurements). Various abnormalities may appear sonographically as cystic or solid space-occupying lesions or as an effusion outlining the heart or lung(s). Fetal therapy for thoracic abnormalities is discussed in Chapter 16 (Percutaneous Procedures).

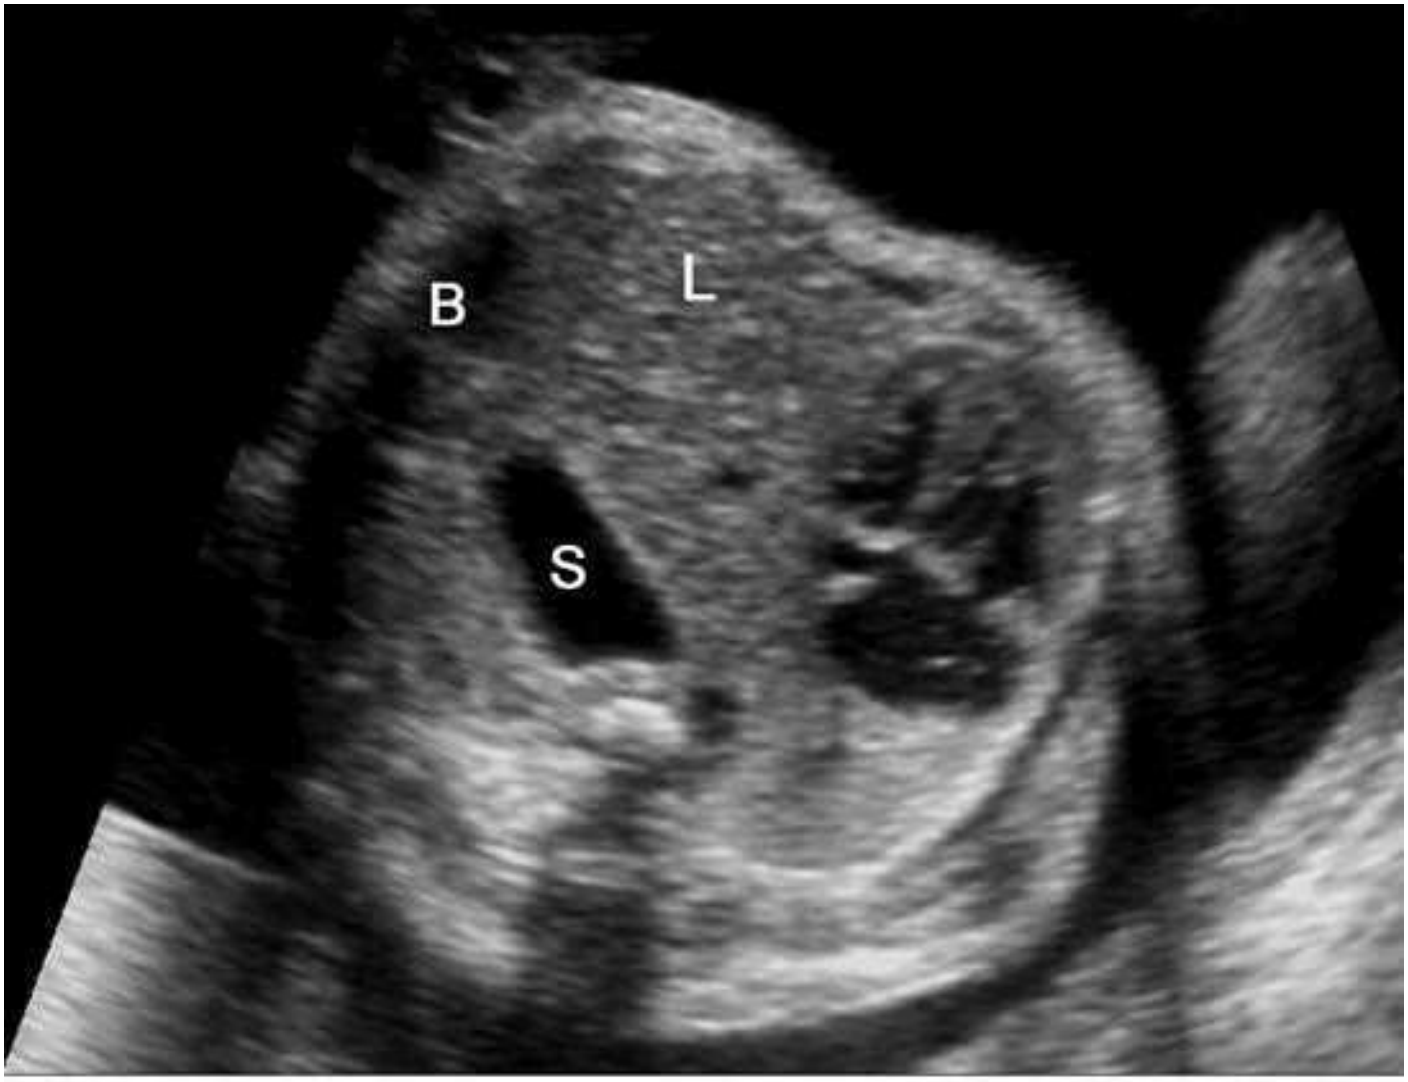
Congenital Diaphragmatic Hernia

This is a defect in the diaphragm through which abdominal organs herniate into the thorax. It is left-sided in approximately 75 percent of cases, right-sided in 20 percent, and bilateral in 5 percent (Gallot, 2007). The prevalence of congenital diaphragmatic hernia (CDH) is 1 in 3000 to 4000 births (Cragan, 2009; Dolk, 2010). Associated anomalies and aneuploidy are found in 40 percent of cases (Gallot, 2007; Stege, 2003). With suspected CDH, targeted sonography and fetal echocardiography should be performed, and fetal chromosomal microarray analysis should be offered. In population-based series, the presence of an associated abnormality reduces the overall survival rate of neonates with CDH from approximately 50 percent to about 20 percent (Colvin, 2005; Gallot, 2007). If there are no associated abnormalities, the major causes of neonatal mortality are pulmonary hypoplasia and pulmonary hypertension.

Sonographically, left-sided CDH typically shows dextroposition of the heart toward the right side of the thorax and a cardiac axis pointing toward the midline (Fig. 10-23). Associated findings include the stomach bubble or bowel peristalsis in the chest and a wedge-shaped mass—the liver—located anteriorly in the left hemithorax. Liver herniation complicates at least 50 percent of cases and is associated with a 30-percent reduction in the survival rate (Mullassery, 2010). With large lesions, impaired swallowing and mediastinal shift may result in hydramnios and hydrops, respectively.

FIGURE 10-23

Congenital diaphragmatic hernia. In this transverse view of the thorax, the heart is shifted to the far right side of the chest by a left-sided diaphragmatic hernia containing stomach (*S*), liver (*L*), and bowel (*B*).



Efforts to reduce neonatal mortality rates and need for extracorporeal membrane oxygenation (ECMO) have focused on indicators such as the sonographic lung-to-head ratio, MR imaging measurements of lung volume, and the degree of liver herniation (Jani, 2012; Oluyomi-Obi, 2016; Worley, 2009). These and fetal therapy for CDH are reviewed in Chapter 16 (Congenital Diaphragmatic Hernia).

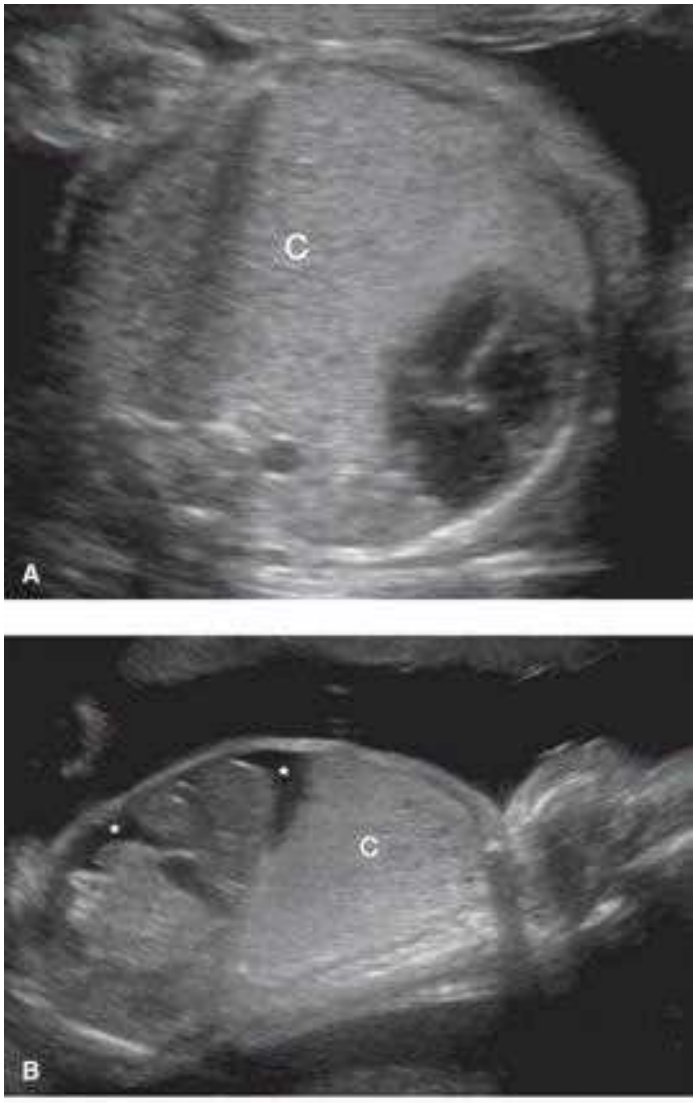
Congenital Cystic Adenomatoid Malformation

This abnormality represents a hamartomatous overgrowth of terminal bronchioles that communicates with the tracheobronchial tree. It is also called *congenital pulmonary airway malformation (CPAM),* based on an understanding that not all histopathological types are *cystic* or *adenomatoid* (Azizkhan, 2008; Stocker, 1977, 2002). The estimated prevalence is 1 in 6000 to 8000 births, and this rate is rising because of improved sonographic detection of milder cases (Burge, 2010; Duncombe, 2002).

Sonographically, congenital cystic adenomatoid malformation (CCAM) is a well-circumscribed thoracic mass that may appear solid and echogenic or may have one or multiple variably sized cysts (Fig. 10-24). It usually involves one lobe, has blood supply from the pulmonary artery, and drains into the pulmonary veins. Lesions with cysts ≥5 mm are generally termed *macrocystic*, and lesions with cysts <5 mm are termed *microcystic* (Adzick, 1985).

FIGURE 10-24

Transverse **(A)** and sagittal **(B)** images of a 26-week fetus with a very large left-sided microcystic congenital cystic adenomatoid malformation (CCAM). The mass (*C*) fills the thorax and has shifted the heart to the far right side of the chest, with development of ascites (*asterisks*). Fortunately, the mass did not continue to grow, the ascites resolved, and the neonate was delivered at term and did well following resection.



In a review of 645 CCAM cases, the overall survival rate exceeded 95 percent, and 30 percent of cases demonstrated apparent prenatal resolution. The other 5 percent of cases—typically very large lesions with associated mediastinal shift—were complicated by hydrops, and the prognosis was poor (Cavoretto, 2008). CCAMs often become less conspicuous with advancing gestation. However, a subset of CCAMs demonstrates rapid growth between 18 and 26 weeks' gestation. Corticosteroid therapy has been used for large microcystic lesions to forestall growth and potentially ameliorate hydrops (Curran, 2010; Peranteau, 2016). If a large dominant cyst is present, thoracoamnionic shunt placement may lead to hydrops resolution. Fetal therapy for CCAM is discussed in Chapter 16 (Percutaneous Procedures).

Pulmonary Sequestration

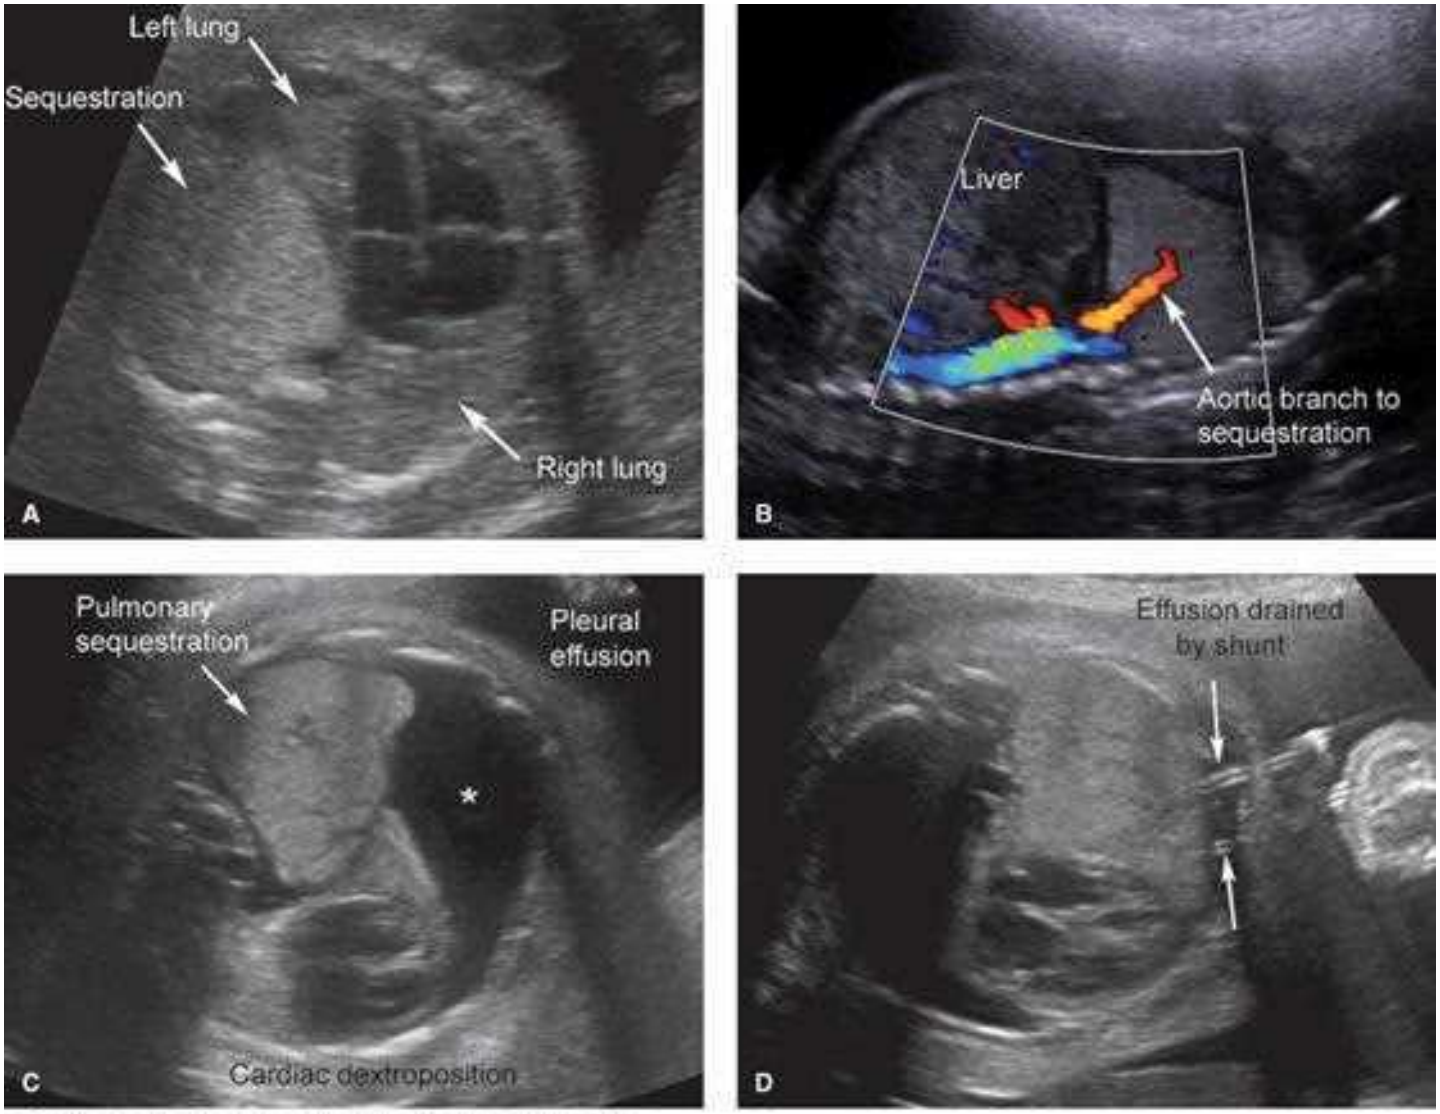
Also called a *bronchopulmonary sequestration*, this abnormality is an accessory lung bud "sequestered" from the tracheobronchial tree, that is, a mass of nonfunctioning lung tissue. Most cases diagnosed prenatally are *extralobar,* which means they are enveloped in their own pleura. Overall, however, most sequestrations present in adulthood and are *intralobar*—within the pleura of another lobe. Extralobar pulmonary sequestration is considered significantly less common than CCAM, and no precise prevalence has been reported. Lesions have a left-sided predominance and most often involve the left lower lobe. Of cases, 10 to 20 percent are located below the diaphragm, and associated anomalies have been reported in approximately 10 percent of cases (Yildirim, 2008).

Sonographically, pulmonary sequestration presents as a homogeneous, echogenic thoracic mass (Fig. 10-25A). Thus, it may resemble a microcystic CCAM. However, the blood supply is from the systemic circulation—from the aorta rather than the pulmonary artery (see Fig. 10-25B). In 5 to 10 percent with pulmonary sequestration, a large ipsilateral pleural effusion develops, and without treatment, this may result in pulmonary hypoplasia or hydrops (see Fig. 10-25C,D). Therapeutic thoracoamnionic shunting of effusions is discussed in Chapter 16 (Percutaneous Procedures). Hydrops may also result from mediastinal shift or high-output cardiac failure due to the left-to-right shunt imposed by the mass. In the absence of a pleural effusion, the reported survival rate exceeds 95 percent, and 40 percent of cases demonstrate apparent prenatal resolution (Cavoretto, 2008).

FIGURE 10-25

Pulmonary sequestration. **A.** This transverse image at the level of the 4-chamber view of the heart depicts a pulmonary sequestration involving the left lower lobe in a 25-week fetus. Mass effect leads to dextroposition of the heart to the right side of the chest. **B.** A sagittal image shows the pulmonary sequestration supplied by a branch of the abdominal aorta. **C.** Over the next 3 weeks, a large ipsilateral pleural effusion develops (*asterisk*), resulting in mediastinal shift and

dextroposition of the heart to the far right thorax. **D.** Following placement of a double-pigtail shunt through the chest wall and into the effusion, the effusion drained and the lung significantly reexpanded. Arrows points to coils of the pigtail shunt. (Reproduced with permission from Dr. Elaine Duryea.)



Congenital High Airway Obstruction Sequence

This rare anomaly usually results from laryngeal or tracheal atresia. The normal egress of lung fluid is obstructed, and the tracheobronchial tree and lungs become massively distended. Sonographically, the lungs appear brightly echogenic, the bronchi are dilated, the diaphragm is flattened or everted, and the heart is compressed (Fig. 10-26). Venous return is impaired and ascites develops, typically followed by hydrops. In one review of 118 cases, associated anomalies were identified in more than 50 percent (Sanford, 2012). Congenital high airway obstruction sequence (CHAOS) is a feature of the autosomal recessive *Fraser syndrome* and has been associated with the 22q11.2 deletion syndrome. In some cases, the obstructed airway spontaneously perforates, which potentially confers a better prognosis. The EXIT procedure has significantly improved outcome in selected cases (Chap. 16, Ex-Utero Intrapartum Treatment).

FIGURE 10-26

Congenital high airway obstruction sequence (CHAOS). The lungs appear brightly echogenic, and one is marked by an “L.” The bronchi, one of which is noted by an arrow, are dilated with fluid. Flattening and eversion of the diaphragm is common, as is ascites (*asterisks*).

Heart

Cardiac malformations are the most common class of congenital anomalies, and their overall prevalence is 8 in 1000 births (Cragan, 2009). Almost 90 percent of cardiac defects are multifactorial or polygenic in origin, another 1 to 2 percent result from a single-gene disorder or gene-deletion syndrome, and 1 to 2 percent stem from exposure to a teratogen such as isotretinoin, hydantoin, or maternal diabetes. Based on data from population-based registries, approximately 1 in 8 liveborn and stillborn neonates with a congenital heart defect has a chromosomal abnormality (Dolk, 2010; Hartman, 2011). Of chromosomal abnormalities associated with cardiac anomalies, trisomy 21 accounts for more than 50 percent of cases. Others are trisomy 18, 22q11.2 deletion, trisomy 13, and monosomy X (Hartman, 2011). Of these aneuploid fetuses, 50 to 70 percent also have extracardiac anomalies. Chromosomal microarray analysis should be offered when cardiac defects are found.

Traditionally, detection of congenital cardiac anomalies is more challenging than for anomalies of other organ systems. Routine second-trimester sonography identifies approximately 40 percent of those with major cardiac anomalies before 22 weeks' gestation, and specialized sonography may identify 80 percent (Romosan, 2009; Trivedi, 2012). For selected anomalies, prenatal detection may improve neonatal survival. This may be particularly true for *ductal-dependent* lesions—those requiring prostaglandin infusion after birth to keep the ductus arteriosus open (Franklin, 2002; Mahle, 2001; Tworetzky, 2001).

Basic Cardiac Examination

Standard cardiac assessment includes a four-chamber view, evaluation of rate and rhythm, and evaluation of the left and right ventricular outflow tracts (Figs. 10–27 and 10-28A–C). Examination of the cardiac outflow tracts aids detection of abnormalities that might not be appreciated in the four-chamber view. These include tetralogy of Fallot, transposition of the great vessels, and truncus arteriosus.

FIGURE 10-27

The four-chamber view. **A.** Diagram demonstrating measurement of the cardiac axis from the four-chamber view of the fetal heart. **B.** Sonogram of the four-chamber view at 22 weeks' gestation shows the normal symmetry of the atria and ventricles, normal position of the mitral and triscuspid valves, pulmonary veins entering the left atrium, and descending aorta (*Ao*). L = left; LA = left atrium; LV = left ventricle; R = right; RA = right atrium; RV = right ventricle.

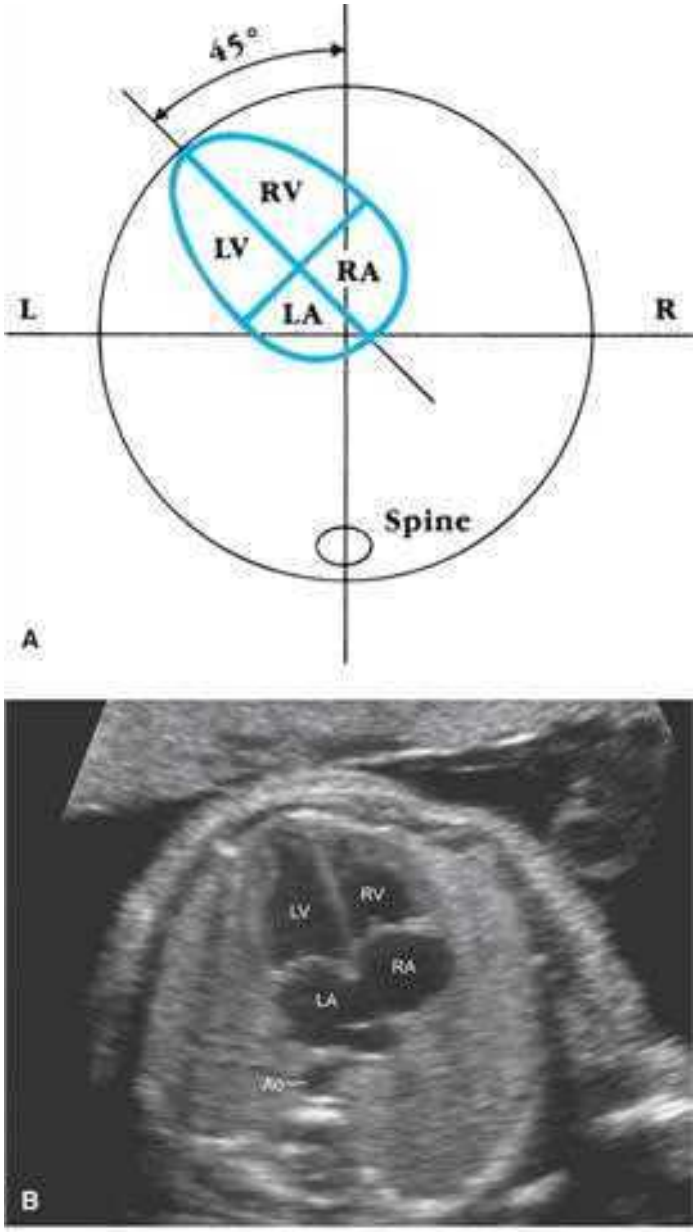


FIGURE 10-28

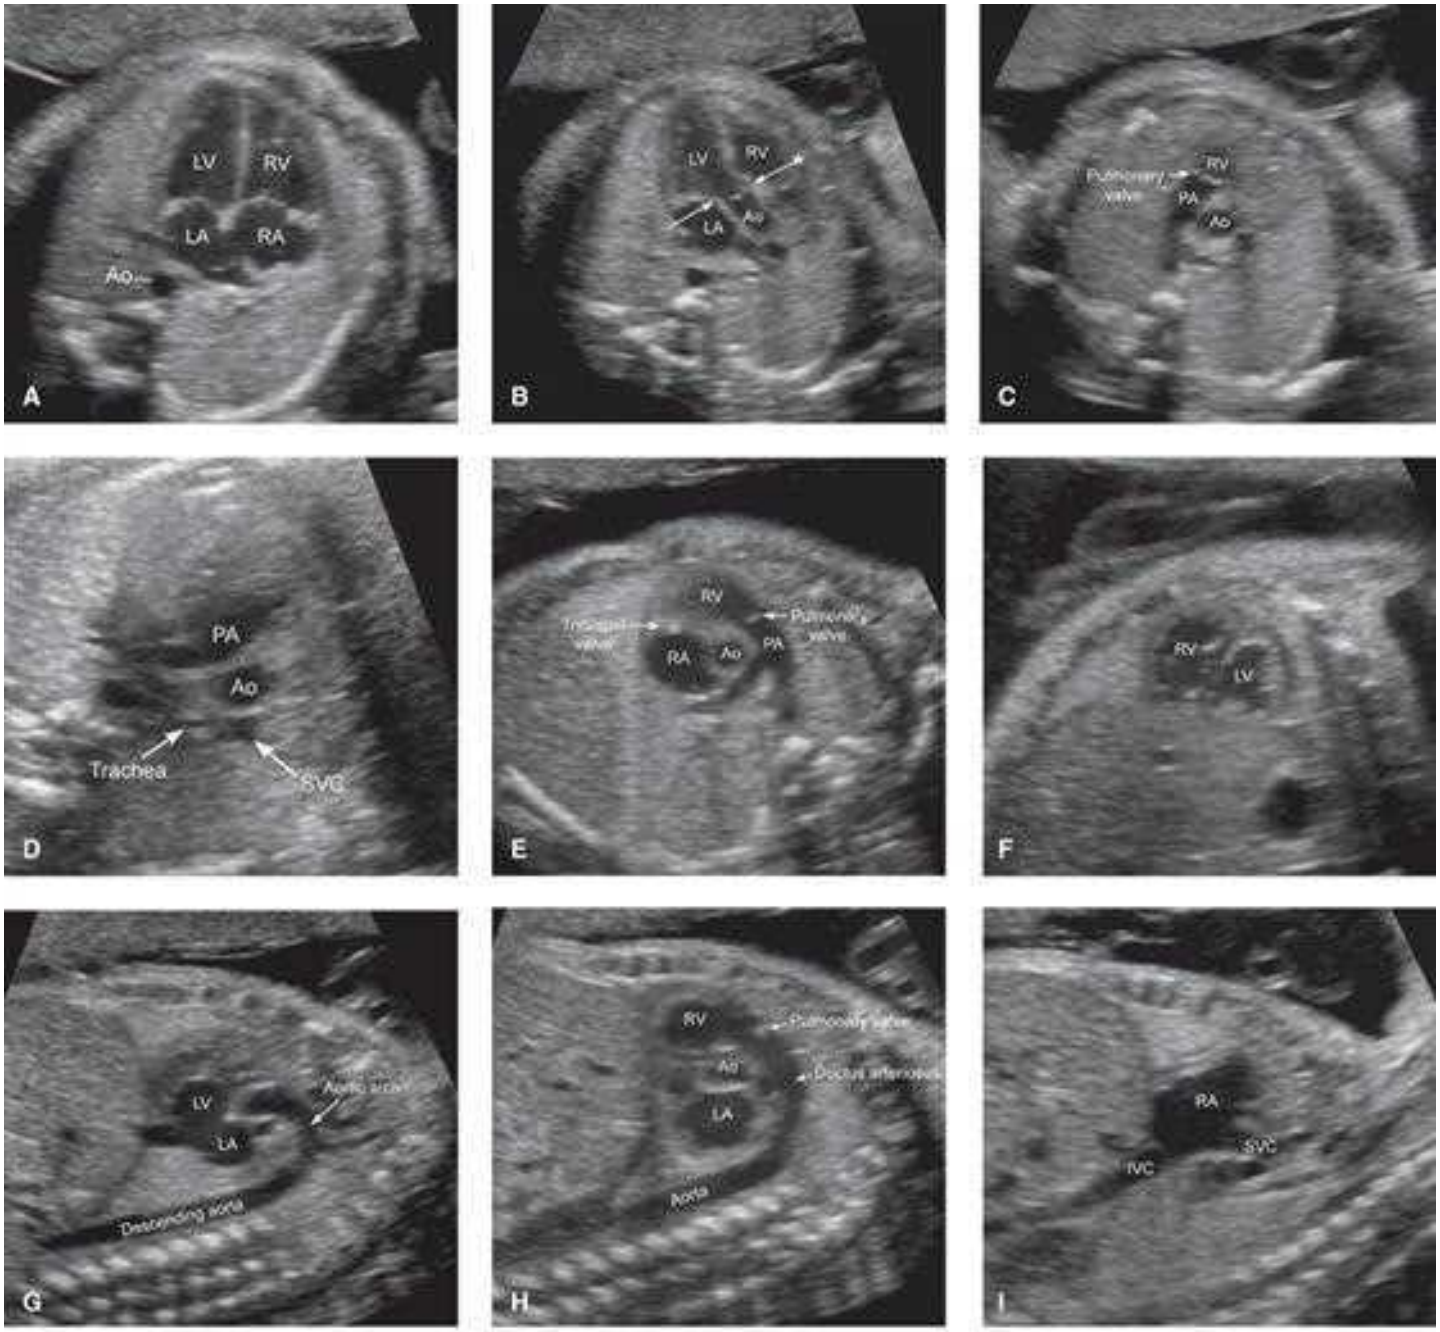
Fetal echocardiography gray-scale imaging planes. **A.** Four-chamber view. **B.** Left ventricular outflow tract view. The white arrow illustrates the mitral valve becoming the wall of the aorta. The arrow with asterisk marks the interventricular septum becoming the opposing aortic wall. **C.** Right ventricular outflow tract view. **D.** Three vessel and trachea view. **E.** High short-axis view (outflow tracts). **F.** Low short-axis view (ventricles). **G.** Aortic arch view. **H.** Ductal arch view. **I.** Superior and inferior vena cavae views. Ao = aorta; IVC = inferior vena cava; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle; SVC = superior vena cava.

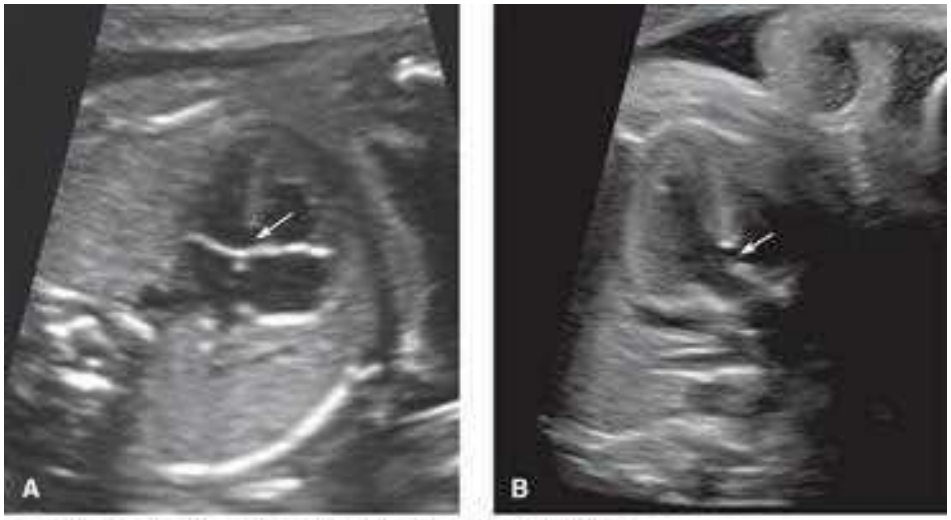


The *four-chamber view* is a transverse image of the fetal thorax at a level immediately above the diaphragm. It allows evaluation of cardiac size, position in the thorax, cardiac axis, atria and ventricles, foramen ovale, atrial septum primum, interventricular septum, and atrioventricular valves (see Fig. 10–27). The atria and ventricles should be similar in size, and the apex of the heart should form a 45-degree angle with the left anterior chest wall. Abnormalities of cardiac axis are frequently encountered with structural cardiac anomalies and occur in more than a third (Shipp, 1995).

The *left ventricular outflow tract view* is a transverse image just above the diaphragm and demonstrates that the ascending aorta arises entirely from the left ventricle. The interventricular septum is shown to be in continuity with the anterior wall of the aorta, and the mitral valve in continuity with the posterior wall of the aorta (see Fig. 10–28B). Ventricular septal defects and outflow tract abnormalities are often visible in this view (Fig. 10–29).

FIGURE 10-29

Ventricular septal defect. **A.** In this four-chamber view of a 22-week fetus, a defect (*arrow*) is noted in the superior (membranous) portion of the interventricular septum. **B.** The left-ventricular outflow tract view of the same fetus demonstrates a break (*arrow*) in continuity between the interventricular septum and the anterior wall of the aorta.



The *right ventricular outflow tract view* shows the right ventricle giving rise to the pulmonary artery (see Fig. 10–28C). Together, the left and right outflow tract views demonstrate the normal perpendicular orientation of the aorta and pulmonary artery, and the comparable size of these great arteries. Structures visible in the right ventricular outflow tract view include the right ventricle and the main pulmonary artery, which subsequently branches into the right and left pulmonary arteries. These structures are also visible in the short axis view, shown in Figure 10–28E.

Fetal Echocardiography

This is a specialized examination of fetal cardiac structure and function designed to identify and characterize abnormalities. Guidelines for its performance have been developed collaboratively by the American Institute of Ultrasound in Medicine, American College of Obstetricians and Gynecologists, Society for Maternal-Fetal Medicine, American Society of Echocardiography, and American College of Radiology. Echocardiography indications include suspected fetal cardiac anomaly, extracardiac anomaly, or chromosomal abnormality; fetal arrhythmia; hydrops; thick nuchal translucency; monochorionic twin gestation; first-degree relative to the fetus with a congenital cardiac defect; in vitro fertilization; maternal anti-Ro or anti-La antibodies; exposure to a medication associated with cardiac defects; and maternal metabolic disease associated with cardiac defects—such as pregestational diabetes or phenylketonuria (American Institute of Ultrasound in Medicine, 2013a). Components of the examination are listed in Table 10-9, and examples of nine required gray-scale imaging views are shown in Figure 10-28. Examples of selected cardiac anomalies are reviewed below.

TABLE 10-9

Components of Fetal Echocardiography

Basic imaging parameters
Evaluation of atria
Evaluation of ventricles
Evaluation of great vessels
Cardiac and visceral situs
Atrioventricular junctions
Ventriculoarterial junctions
Scanning planes, gray scale
Four-chamber view
Left ventricular outflow tract
Right ventricular outflow tract
Three-vessel and trachea view
Short-axis view, low (ventricles)
Short-axis view, high (outflow tracts)
Aortic arch
Ductal arch
Superior and inferior vena cavae
Color Doppler evaluation
Systemic veins (vena cavae and ductus venosus[a])
Pulmonary veins
Foramen ovale
Atrioventricular valves[a]
Atrial and ventricular septae
Aortic and pulmonary valves[a]
Ductus arteriosus
Aortic arch
Umbilical artery and vein (optional)[a]
Cardiac rate and rhythm assessment

[a]Pulsed-wave Doppler sonography should be used as an adjunct to evaluate these structures.

Cardiac biometry and functional assessment are optional but should be considered for suspected structural/functional abnormalities.

Adapted from the American Institute of Ultrasound in Medicine, 2013b.

Ventricular Septal Defect

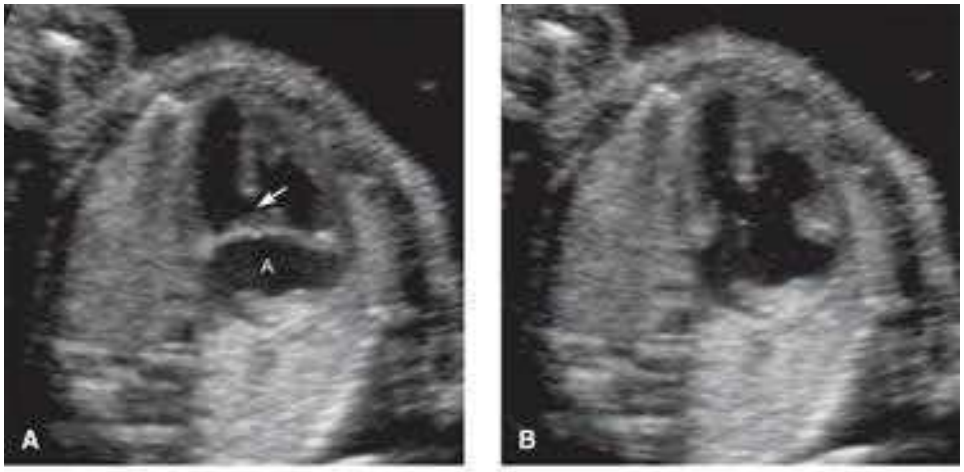
This is the most common congenital cardiac anomaly and is found in approximately 1 in 300 births (Cragan, 2009; Dolk, 2010). Even with adequate visualization, the prenatal detection rate of ventricular septal defect (VSD) is low. A defect may be appreciated in the membranous or muscular portion of the interventricular septum in the four-chamber view, and color Doppler demonstrates flow through the defect. Imaging of the left ventricular outflow tract may show discontinuity of the interventricular septum as it becomes the wall of the aorta (see Fig. 10-29). Fetal VSD is associated with other abnormalities and aneuploidy, and chromosomal microarray analysis should be offered. That said, the prognosis for an isolated defect is good. More than a third of prenatally diagnosed VSDs close in utero, and another third close in the first year of life (Axt-Fliedner, 2006; Paladini, 2002).

Endocardial Cushion Defect

This is also called an *atrioventricular (AV) septal defect* or *AV canal defect*. It has a prevalence of approximately 1 in 2500 births and is associated with trisomy 21 in more than half of cases (Christensen, 2013; Cragan, 2009; Dolk, 2010). The endocardial cushions are the crux of the heart, and defects jointly involve the atrial septum primum, interventricular septum, and medial leaflets of the mitral and tricuspid valves (Fig. 10-30). Approximately 6 percent of cases occur with heterotaxy syndromes, that is, those in which the heart and/or abdominal organs are on the incorrect side. Endocardial cushion defects associated with heterotaxy can have comorbid conduction system abnormalities resulting in third-degree AV block, which confers a poor prognosis (Chap. 16, Tachyarrhythmias).

FIGURE 10-30

Endocardial cushion defect. **A.** During ventricular systole, the lateral leaflets of the mitral and triscuspid valves come together in the midline. But the atrioventricular valve plane is abnormal, a common atrium (*A*) is observed, and there is a visible defect (*arrow*) in the interventricular septum. **B.** During diastolic filling, opening of the atrioventricular valves more clearly demonstrates the absence of their medial leaflets.

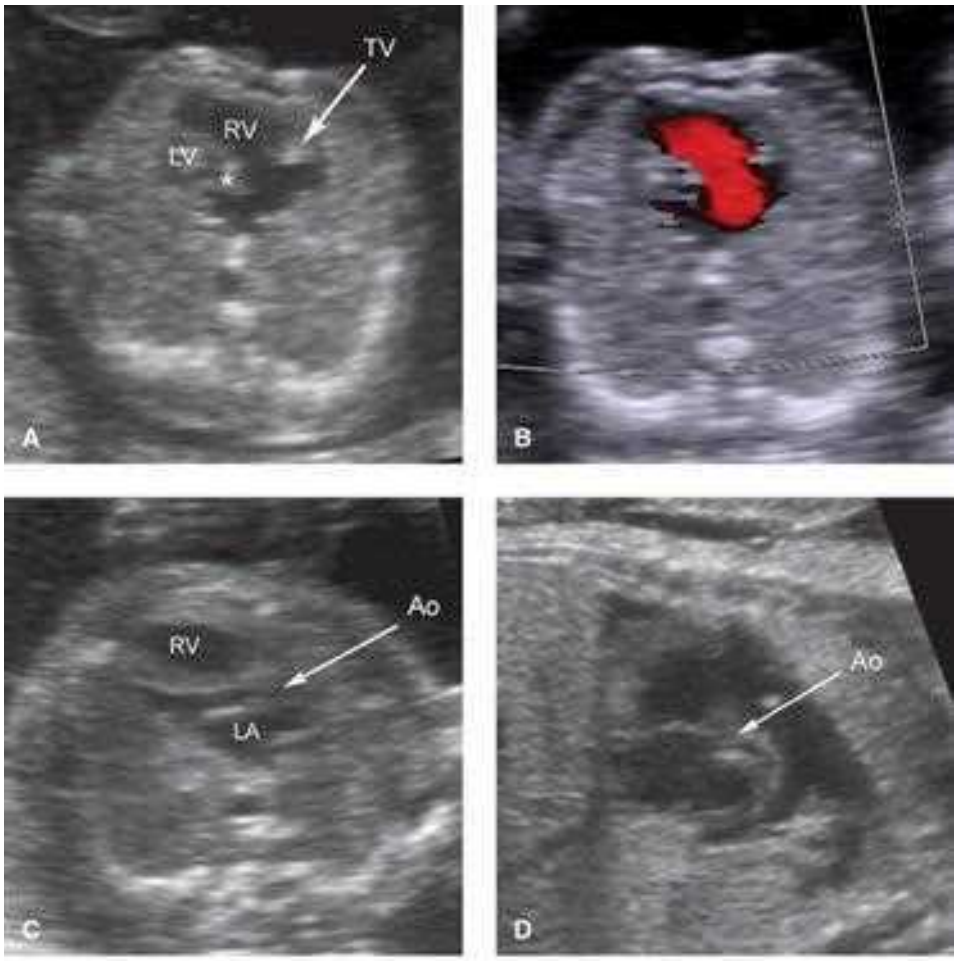


Hypoplastic Left Heart Syndrome

This anomaly is found in approximately 1 in 4000 births (Cragan, 2009; Dolk, 2010). Sonographically, the left side of the heart may appear “filled-in” or the left ventricle may be so small and attenuated that a ventricular chamber is difficult to appreciate (Fig. 10-31). There may be no visible left ventricular inflow or outflow, and reversal of flow may be documented in the aortic arch.

FIGURE 10-31

Hypoplastic left heart syndrome. **A.** In this 4-chamber view at 16 weeks, the left ventricle (*LV*) appears “filled in” and is significantly smaller than the right ventricle (*RV*). The tricuspid valve (*TV*) is open, whereas the mitral valve appears closed (*asterisk*). **B.** Color Doppler depicts flow from the right atrium to the right ventricle only, and left ventricular filling is not visible. **C.** The left ventricular outflow tract view demonstrates marked narrowing of the aorta (Ao). RV = right ventricle; LA = left atrium. **D.** The tiny circle (arrow) in this short axis view is the hypoplastic aortic root. (Reproduced with permission from Rafael Levy, RDMS.)



Although this anomaly was once considered a lethal prognosis, 70 percent of affected infants may now survive to adulthood (Feinstein, 2012). Postnatal treatment consists of a three-stage palliative repair or cardiac transplantation. Still, morbidity remains high, and developmental delays are common (Lloyd, 2017;

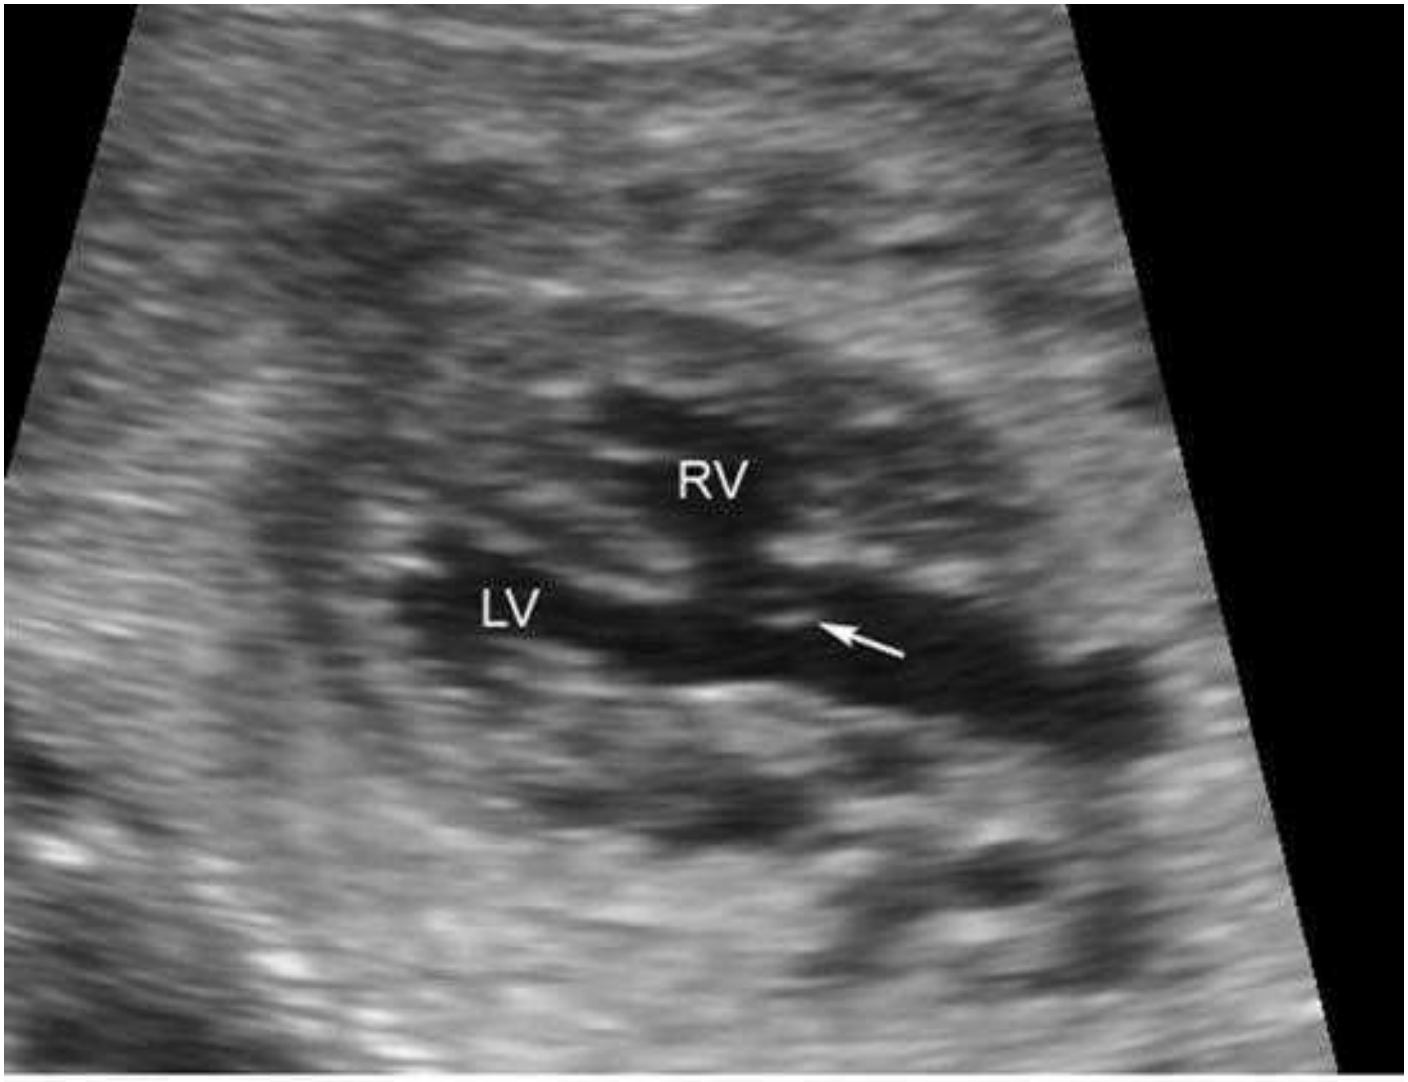
Paladini, 2017). This is a ductal-dependent lesion for which neonatal administration of prostaglandin therapy is essential. Fetal therapy for hypoplastic left heart is discussed in Chapter 16 (Radiofrequency Ablation).

Tetralogy of Fallot

This anomaly occurs in approximately 1 in 3000 births (Cragan, 2009; Dolk, 2010; Nelson, 2016). It includes a ventricular septal defect; an overriding aorta; a pulmonary valve abnormality, typically stenosis; and right ventricular hypertrophy (Fig. 10-32). The last does not present before birth. Due to the location of the ventricular septal defect, the four-chamber view may appear normal.

FIGURE 10-32

Tetralogy of Fallot. This image shows a ventricular septal defect with an overriding aorta in a fetus with tetralogy of Fallot. The arrow points to the aortic valve. The left ventricle (*LV*) and right ventricle (*RV*) are labeled.



Following postnatal repair, the 20-year survival rates exceed 95 percent (Knott-Craig, 1998). However, cases with *pulmonary atresia* have a more complicated course. There is also a variant in which the pulmonary valve is *absent.* These affected fetuses are at risk for hydrops and for tracheomalacia from compression of the trachea by an enlarged pulmonary artery.

Cardiac Rhabdomyoma

This is the most common cardiac tumor. Approximately 50 percent of cases are associated with tuberous sclerosis, an autosomal dominant disease with multiorgan system manifestations. Tuberous sclerosis is caused by mutations in the hamartin (*TSC1*) and tuberin (*TSC2*) genes.

Cardiac rhabdomyomas appear as well-circumscribed echogenic masses, usually within the ventricles or outflow tracts. They may be single or multiple; may grow in size during gestation; and occasionally, may lead to inflow or outflow obstruction. In cases without obstruction or large tumor size, the prognosis is relatively good from a cardiac standpoint, because the tumors tend to regress after the neonatal period. Because extracardiac findings of tuberous sclerosis may not be apparent with prenatal sonography, MR imaging may be considered to evaluate fetal CNS anatomy (Fetal Anatomical Evaluation).

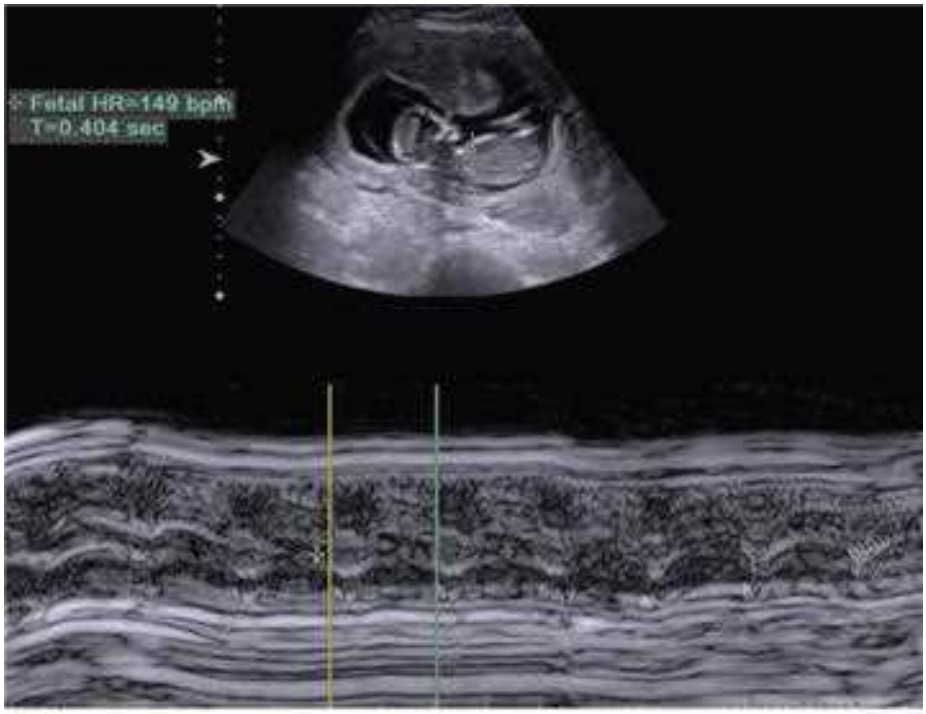
M-Mode

Motion-mode or M-mode imaging is a linear display of cardiac cycle events, with time on the x-axis and motion on the y-axis. It is often used to measure embryonic or fetal heart rate (Fig. 10-33). If an abnormality of heart rate or rhythm is identified, M-mode imaging permits separate evaluation of atrial and

ventricular waveforms. Thus, it is particularly useful for characterizing arrhythmias and their response to treatment (Chap. 16, Tachyarrhythmias). M-mode can also be used to assess ventricular function and atrial and ventricular outputs.

FIGURE 10-33

M-mode, or motion mode, is a linear display of the events of the cardiac cycle, with time on the x-axis and motion on the y-axis. M-mode is used commonly to measure the fetal heart rate, as in this 12-week fetus.

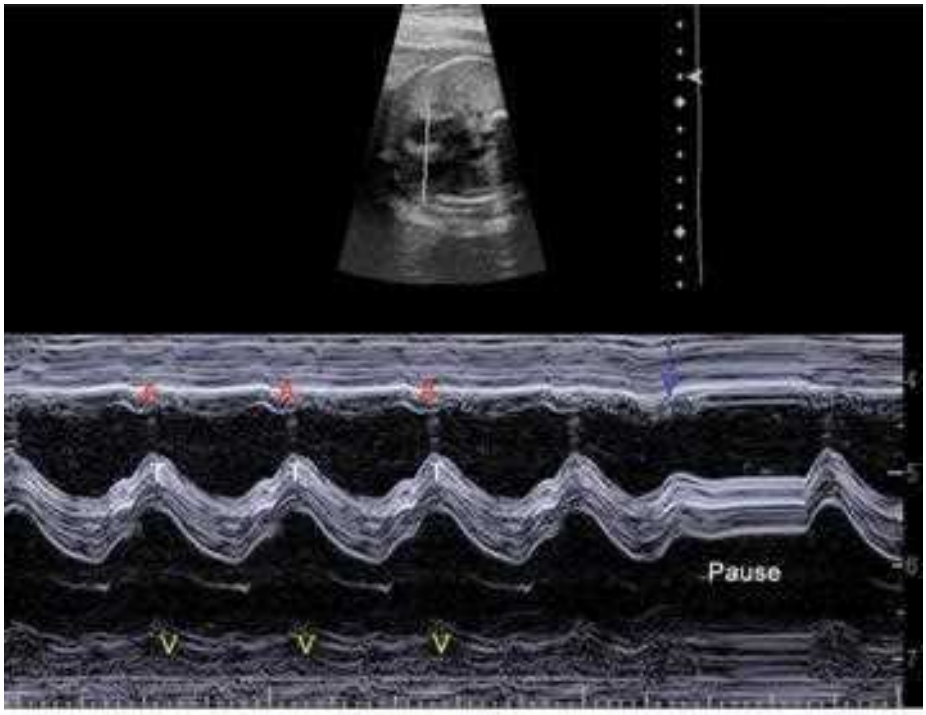


Premature Atrial Contractions

Also called atrial extrasystoles, these are the most common fetal arrhythmia and a frequent finding. They represent cardiac conduction system immaturity and typically resolve later in gestation or in the neonatal period. Premature atrial contractions (PACs) may be conducted and thus sound like an extra beat. However, they are more commonly blocked, and with handheld Doppler they sound like a dropped beat. As shown in Figure 10-34, the dropped beat may be demonstrated with M-mode evaluation as a compensatory pause that follows the premature contraction.

FIGURE 10-34

M-mode. In this image, there is normal concordance between atrial (*A*) and ventricular contractions (*V*). Movement of the tricuspid valve (*T*) is also shown. There is also a premature atrial contraction (*arrow*) and a subsequent early ventricular contraction, followed by a compensatory pause.



PACs sometimes occur with an atrial septal aneurysm but are not associated with major structural cardiac abnormalities. Older case reports describe an association with maternal caffeine consumption and with hydralazine (Lodeiro, 1989; Oei, 1989). In approximately 2 percent of cases, affected fetuses are later identified to have a *supraventricular tachycardia* (SVT) that requires urgent treatment (Copel, 2000). Accordingly, pregnancies with fetal PACs are often followed with fetal heart rate assessment as often as every 1 to 2 weeks until ectopy resolves. Treatment of fetal SVT and other arrhythmias is discussed in Chapter 16 (Tachyarrhythmias).

Abdominal Wall

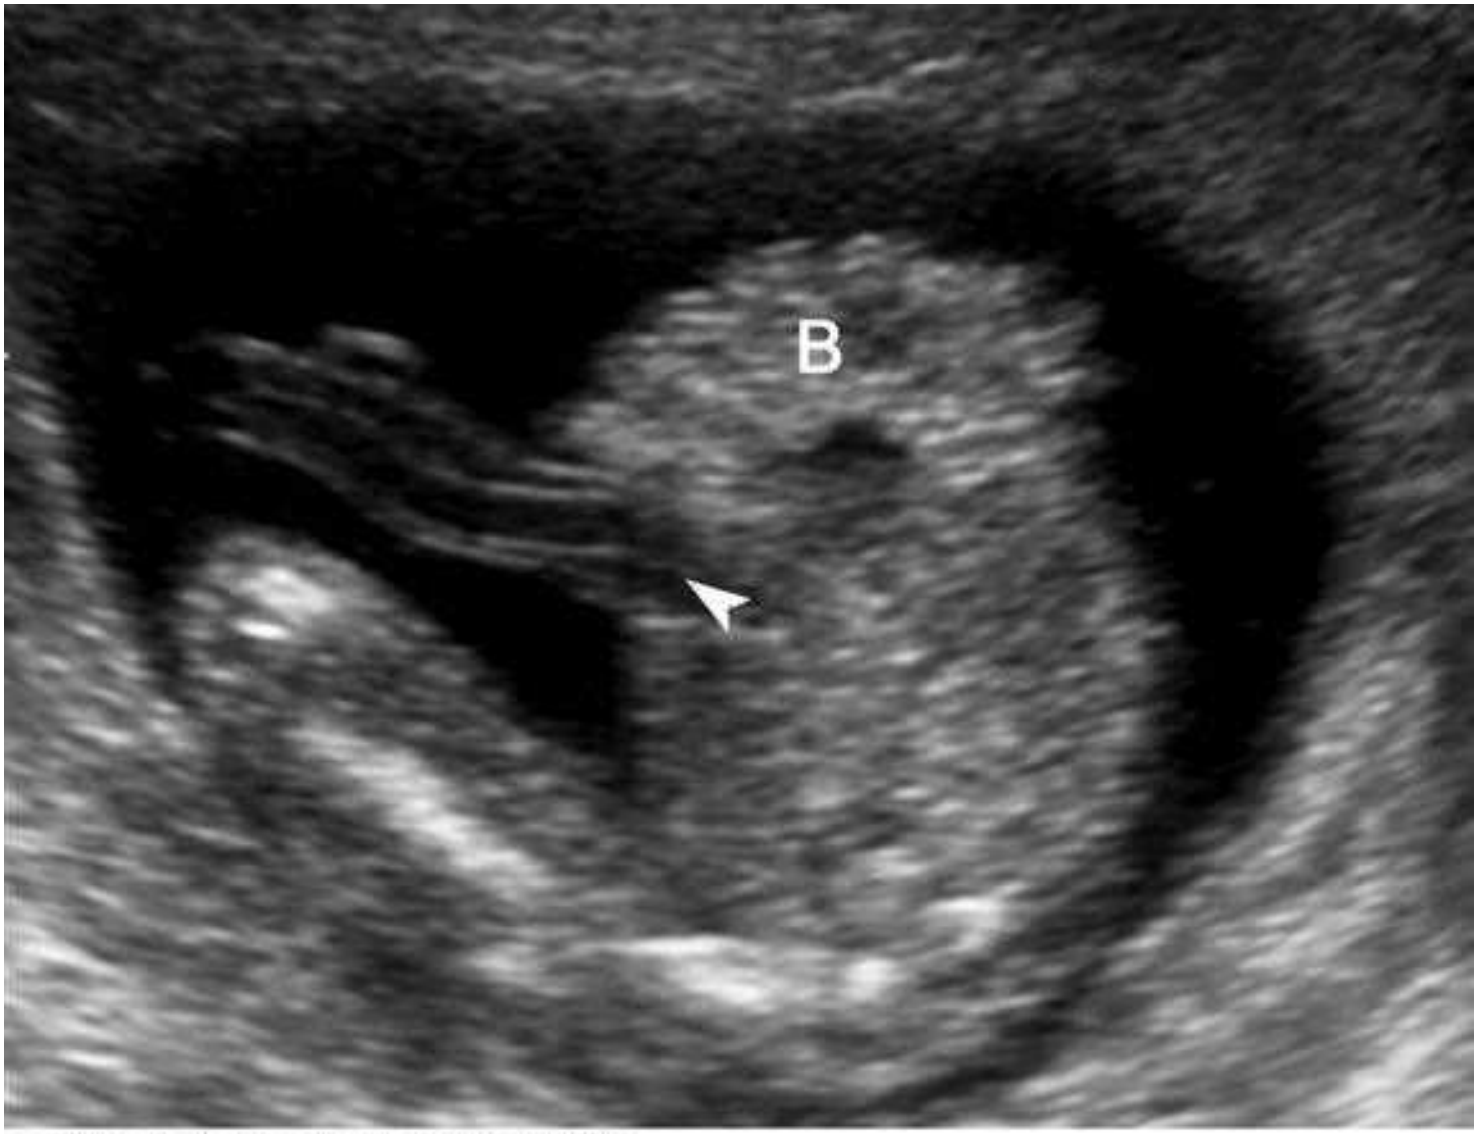
The integrity of the abdominal wall is assessed at the level of the cord insertion during the standard examination (Fig. 10-35). Ventral wall defects include gastroschisis, omphalocele, and body stalk anomaly.

FIGURE 10-35
Normal ventral wall. Transverse view of the abdomen in a second-trimester fetus with an intact anterior abdominal wall and normal cord insertion.

Gastroschisis is a full-thickness abdominal wall defect located to the right of the umbilical cord insertion. Bowel herniates through the defect into the amnionic cavity (Fig. 10-36). The prevalence is approximately 1 in 2000 births (Jones, 2016; Nelson, 2015). Gastroschisis is the one major anomaly more common in fetuses of younger mothers, and the average maternal age is 20 years (Santiago-Muñoz, 2007). Coexisting bowel abnormalities such as *jejunal atresia* are found in approximately 15 percent of cases (Nelson, 2015; Overcash, 2014). Gastroschisis is not associated with aneuploidy, and the survival rate is 90 to 95 percent (Kitchanan, 2000; Nelson, 2015; Nembhard, 2001).

FIGURE 10-36

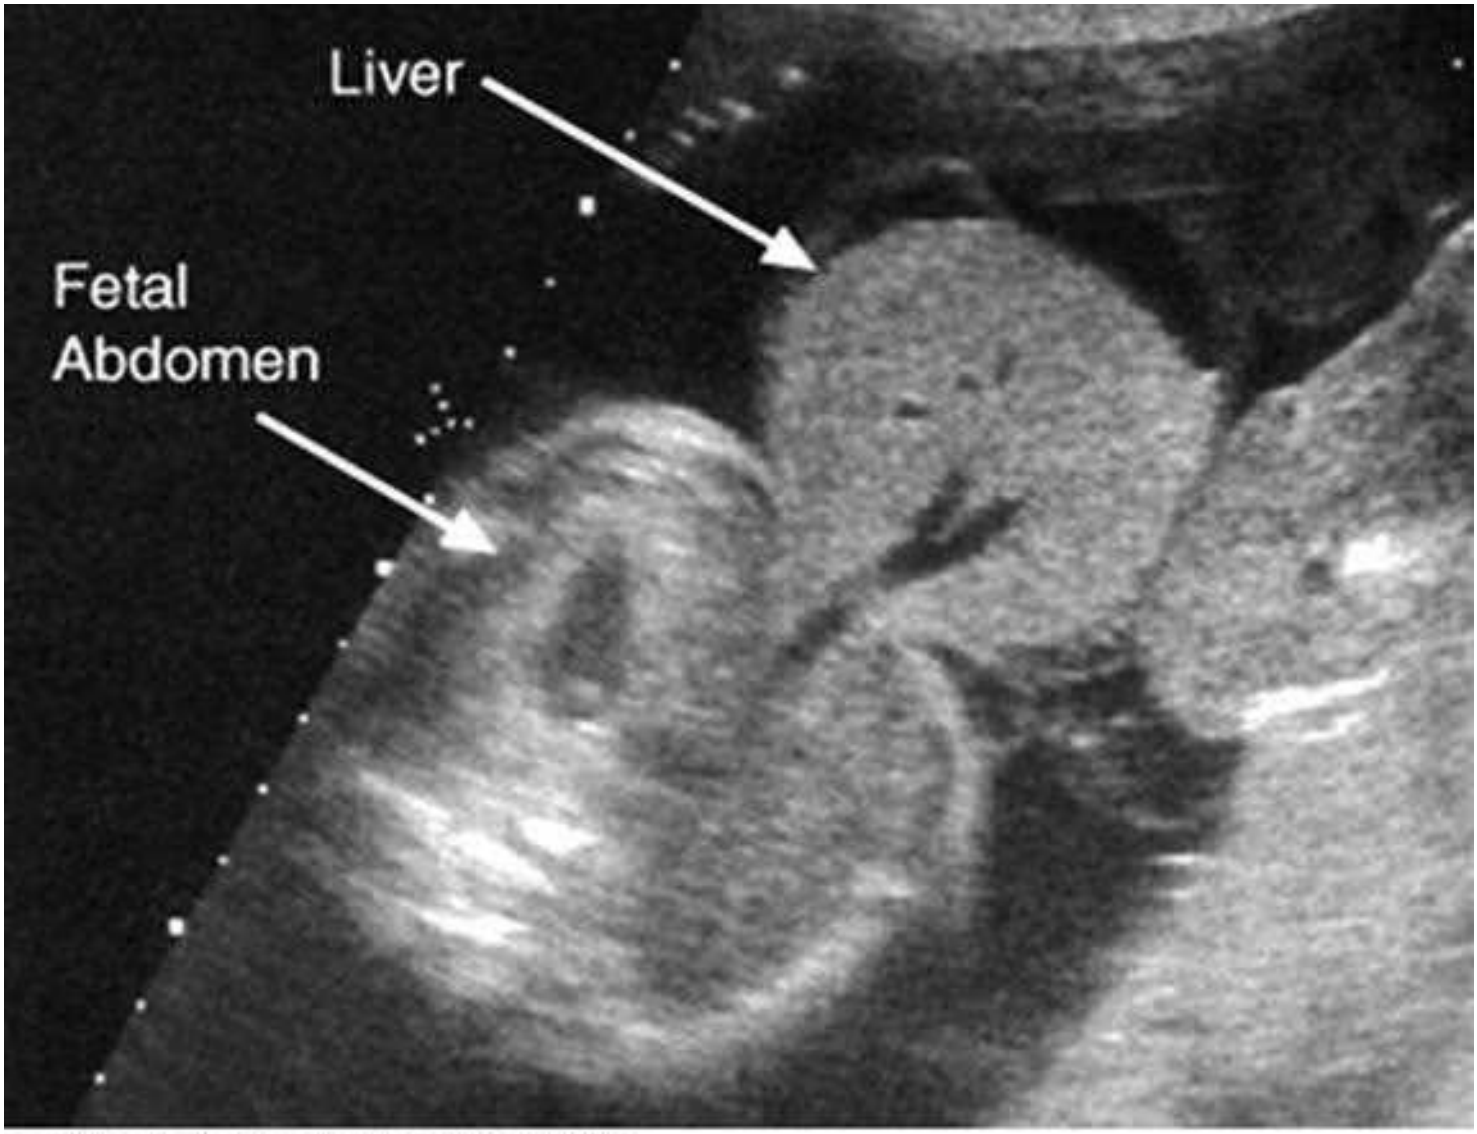
Gastroschisis. This 18-week fetus has a full-thickness ventral wall defect to the right of the cord insertion (*arrowhead*), through which multiple small bowel loops (*B*) have herniated into the amnionic cavity.



Fetal-growth restriction complicates gastroschisis in 15 to 40 percent of cases (Overcash, 2014; Santiago-Muñoz, 2007). Growth restriction does not appear to be associated with adverse outcomes such as longer hospitalization or higher mortality rate (Nelson, 2015; Overcash, 2014). However, earlier gestational age at delivery does pose a risk for adverse outcome with gastroschisis, and planned delivery at 36 to 37 weeks does not confer neonatal benefit (Al-Kaff, 2016; Overcash, 2014; South, 2013).

Omphalocele complicates 1 in 3000 to 5000 pregnancies (Canfield, 2006; Dolk, 2010). It forms when the lateral ectomesodermal folds fail to meet in the midline. This leaves the abdominal contents covered only by a two-layered sac of amnion and peritoneum into which the umbilical cord inserts (Fig. 10-37). More than half of cases are associated with other major anomalies or aneuploidy. Omphalocele also is a component of syndromes such as *Beckwith–Wiedemann, cloacal exstrophy,* and *pentalogy of Cantrell.* Smaller defects confer greater risk for aneuploidy (De Veciana, 1994). Chromosomal microarray analysis should be offered in all cases of omphalocele.

FIGURE 10-37
Omphalocele. Transverse view of the abdomen showing an omphalocele as a large abdominal wall defect with exteriorized liver covered by a thin membrane.



Body stalk anomaly, also known as *limb-body-wall complex* or *cyllosoma*, is a rare, lethal anomaly characterized by abnormal formation of the body wall. Typically, *no* abdominal wall is visible, and the abdominal organs extrude into the extraamnionic coelom. There is close approximation or fusion of the body to the placenta, and the umbilical cord is extremely short. Acute-angle scoliosis is another feature. Amnionic bands are often identified.

Gastrointestinal Tract

The stomach is visible in nearly all fetuses after 14 weeks' gestation. If the stomach is not seen during initial evaluation, the examination is repeated, and targeted sonography should be considered. Nonvisualization of the stomach may be secondary to impaired swallowing in the setting of oligohydramnios or to underlying causes such as esophageal atresia, a craniofacial anomaly, or a CNS or musculoskeletal abnormality. Fetuses with hydrops may also have impaired swallowing.

The bowel, liver, gallbladder, and spleen can be identified in many second- and third-trimester fetuses. Bowel appearance changes with fetal maturation. Occasionally, it may be bright or echogenic, which may indicate small amounts of swallowed intraamnionic blood, especially with comorbid MSAFP elevation. Bowel that appears as bright as fetal bone confers a slightly greater risk for underlying gastrointestinal malformations, for cystic fibrosis, for trisomy 21, and for congenital infection such as cytomegalovirus (Fig. 14-3).

Gastrointestinal Atresia

Bowel atresia is characterized by obstruction and proximal bowel dilation. In general, the more proximal the obstruction, the more likely it is to lead to hydramnios. At times, hydramnios from proximal small-bowel obstruction can be sufficiently severe to result in maternal respiratory compromise or preterm labor and may necessitate amnioreduction (Chap. 11, Oligohydramnios).

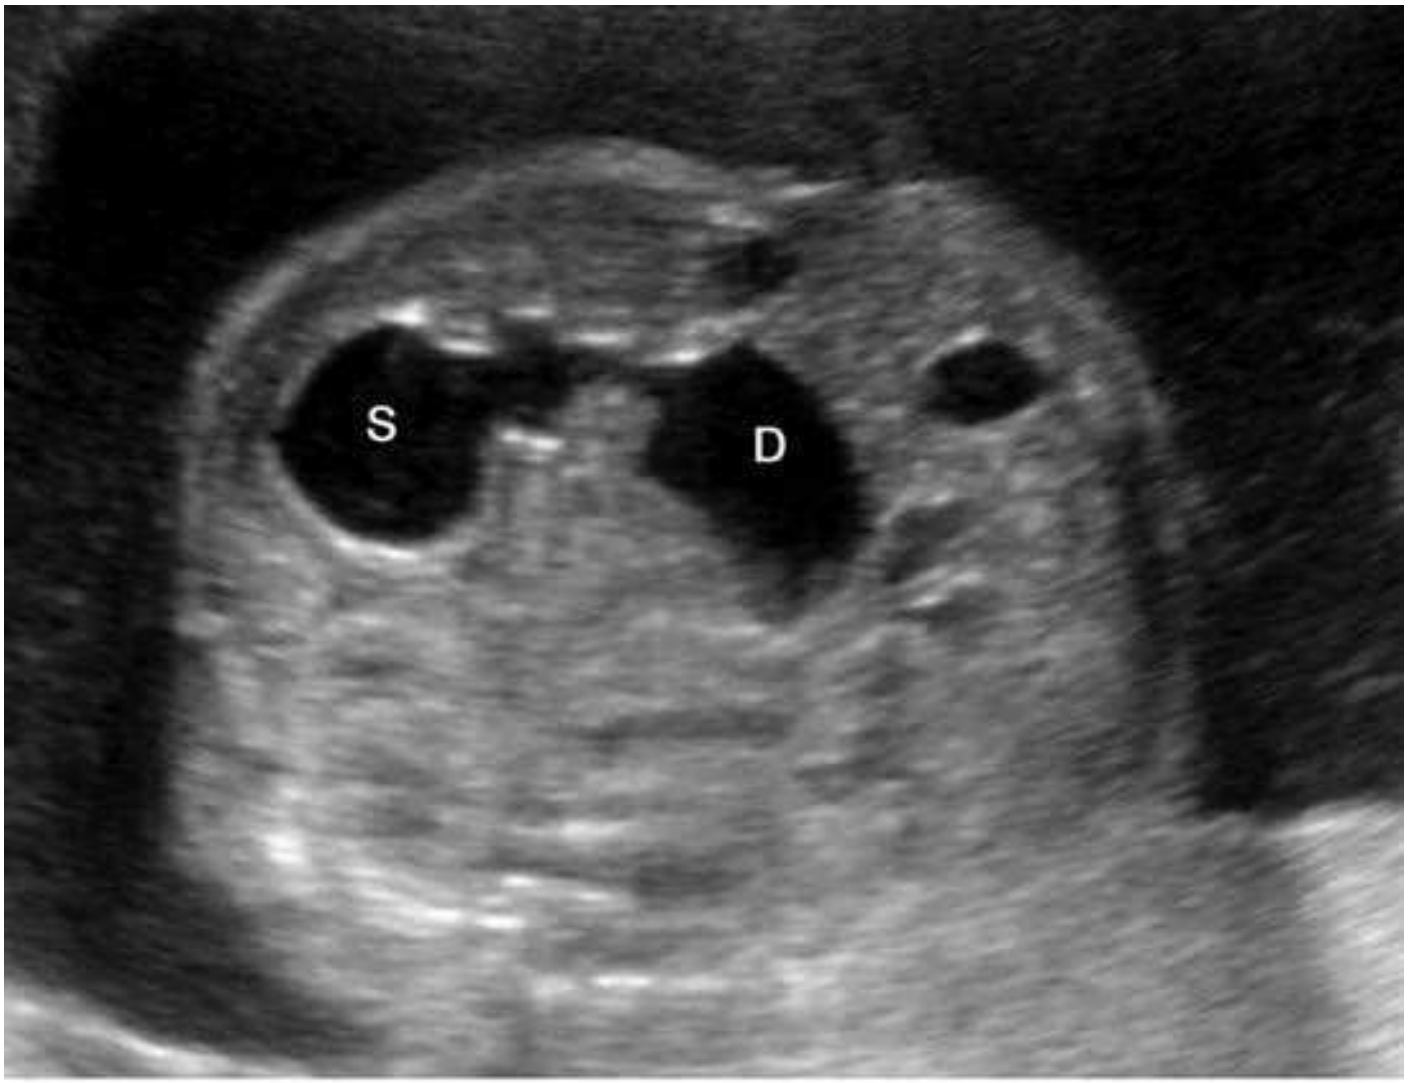
Esophageal atresia occurs in approximately 1 in 4000 births (Cragan, 2009; Pedersen, 2012). It may be suspected when the stomach cannot be visualized and hydramnios is present. That said, in up to 90 percent of cases, a concomitant *tracheoesophageal fistula* allows fluid to enter the stomach, such that prenatal detection is problematic. More than half have associated anomalies or genetic syndromes. Multiple malformations are present in 30 percent of cases, and aneuploidy such as trisomy 18 or 21, in 10 percent (Pedersen, 2012). Cardiac, urinary tract, and other gastrointestinal abnormalities are the most frequently

associated anomalies. Approximately 10 percent of cases of esophageal atresia occur as part of the VACTERL association, which is vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities (Pedersen, 2012).

Duodenal atresia is found in approximately 1 in 10,000 births (Best, 2012; Dolk, 2010). It is characterized by the sonographic *double-bubble sign,* which represents distention of the stomach and the first part of the duodenum (Fig. 10-38). This finding is usually not present before 22 to 24 weeks' gestation. Demonstrating continuity between the stomach and proximal duodenum confirms that the second "bubble" is the proximal duodenum. Approximately 30 percent of affected fetuses have an associated chromosomal abnormality or genetic syndrome, particularly trisomy 21. Of cases without a genetic abnormality, a third have associated anomalies, most commonly cardiac defects and other gastrointestinal abnormalities (Best, 2012). Obstructions in the more distal small bowel usually result in multiple dilated loops that may have enhanced peristaltic activity.

FIGURE 10-38

Duodenal atresia. The *double-bubble* sign represents distension of the stomach (*S*) and the first part of the duodenum (*D*), as seen on this axial abdominal image. Demonstrating continuity between the stomach and proximal duodenum confirms that the second "bubble" is the proximal duodenum.



Large-bowel obstructions and anal atresia are less readily diagnosed by sonography, because hydramnios is not a typical feature and the bowel may not be significantly dilated. A transverse view through the pelvis may show an enlarged rectum as an anechoic structure between the bladder and the sacrum.

Kidneys and Urinary Tract

The fetal kidneys are visible adjacent to the spine, frequently in the first trimester and routinely by 18 weeks' gestation (Fig. 10-39). The length of the kidney approximates 20 mm at 20 weeks and grows by about 1.1 mm each week thereafter (Chitty, 2003). With advancing gestation, the kidneys become relatively less echogenic, and a rim of perinephric fat aids visualization of their margins.

FIGURE 10-39

Normal fetal kidneys. The kidneys are visible adjacent to the fetal spine in this 29-week fetus. With advancing gestation, a rim of perinephric fat aids visualization of the kidney margins. A physiological amount of urine is visible in the renal pelves and is marked in one kidney by an arrow.

The fetal bladder is readily visible in the second trimester as a round, anechoic structure in the anterior midline of the pelvis. With application of Doppler, the bladder is outlined by the two superior vesical arteries as they become the umbilical arteries of the umbilical cord (Fig. 10-40 and Chap. 6, Umbilical Cord). The fetal ureters and urethra are not visible sonographically unless abnormally dilated.

FIGURE 10-40

Normal fetal bladder. The normal fetal bladder is readily visible as a round, fluid-filled structure in the anterior pelvis, outlined by the two superior vesical arteries as they become the umbilical arteries of the umbilical cord.

The placenta and membranes are the major sources of amnionic fluid early in pregnancy. However, after 18 weeks' gestation, most of the fluid is produced by the kidneys (Chap. 11, Normal Amnionic Fluid Volume). Fetal urine production rises from 5 mL/hr at 20 weeks to approximately 50 mL/hr at term (Rabinowitz, 1989). Normal amnionic fluid volume in the second half of pregnancy suggests urinary tract patency with at least one functioning kidney. But, unexplained oligohydramnios suggests a urinary tract defect or placental perfusion abnormality.

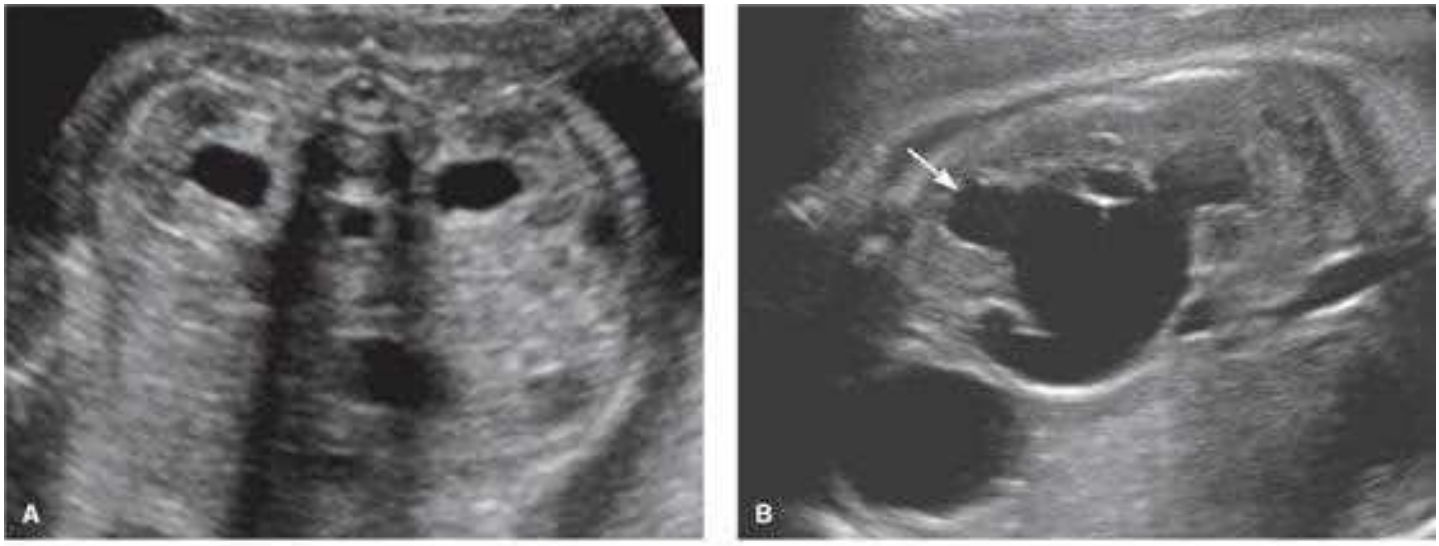
Renal Pelvis Dilatation

This finding is present in 1 to 5 percent of fetuses. It is also called urinary tract dilatation or hydronephrosis. In 40 to 90 percent of cases, it is transient or physiological and does not represent an underlying abnormality (Ismaili, 2003; Nguyen, 2010). In approximately a third of cases, a urinary tract abnormality is confirmed in the neonatal period. Of these, *ureteropelvic junction (UPJ) obstruction* and *vesicoureteral reflux (VUR)* are the most frequent.

The fetal renal pelvis is measured anterior to posterior in a transverse plane, and calipers are placed on the inner border of the fluid collection (Fig. 10-41). Although various thresholds have been defined, the pelvis is typically considered dilated if it exceeds 4 mm in the second trimester or 7 mm at approximately 32 weeks' gestation (Reddy, 2014). Typically, the second-trimester threshold is used to identify pregnancies that warrant subsequent third-trimester evaluation.

FIGURE 10-41

Renal pelvis dilatation. This common finding is identified in 1 to 5 percent of pregnancies. **A.** In this 34-week fetus with mild renal pelvis dilatation, the anterior-posterior diameter of the renal pelvis measured 7 mm in the transverse plane. **B.** Sagittal image of the kidney in a 32-week fetus with severe renal pelvis dilatation secondary to ureteropelvic junction obstruction. The arrow points to one of the rounded calyces.



The Society for Fetal Urology categorized renal pelvis dilatation based on a metaanalysis of more than 100,000 screened pregnancies (Table 10-10) (Lee, 2006; Nguyen, 2010). The degree of dilatation correlates with the likelihood of an underlying abnormality. Other suggestive findings of pathology include calyceal dilatation, cortical thinning, or dilatation elsewhere along the urinary tract. Mild pyelectasis in the second trimester is associated with a slightly greater risk for Down syndrome and is considered a soft marker for this (Fig. 14-3).

TABLE 10-10

Risk for Postnatal Urinary Abnormality According to Degree of Renal Pelvis Dilatation[a]

Dilatation	Second Trimester	Third Trimester	Postnatal Abnormality
Mild	4 to <7 mm	7 to <9 mm	12%
Moderate	7 to ≤10 mm	9 to ≤15 mm	45%
Severe	>10 mm	>15 mm	88%

[a]Society for Fetal Urology Classification.

Modified from Lee, 2006; Nguyen, 2010.

Ureteropelvic Junction Obstruction

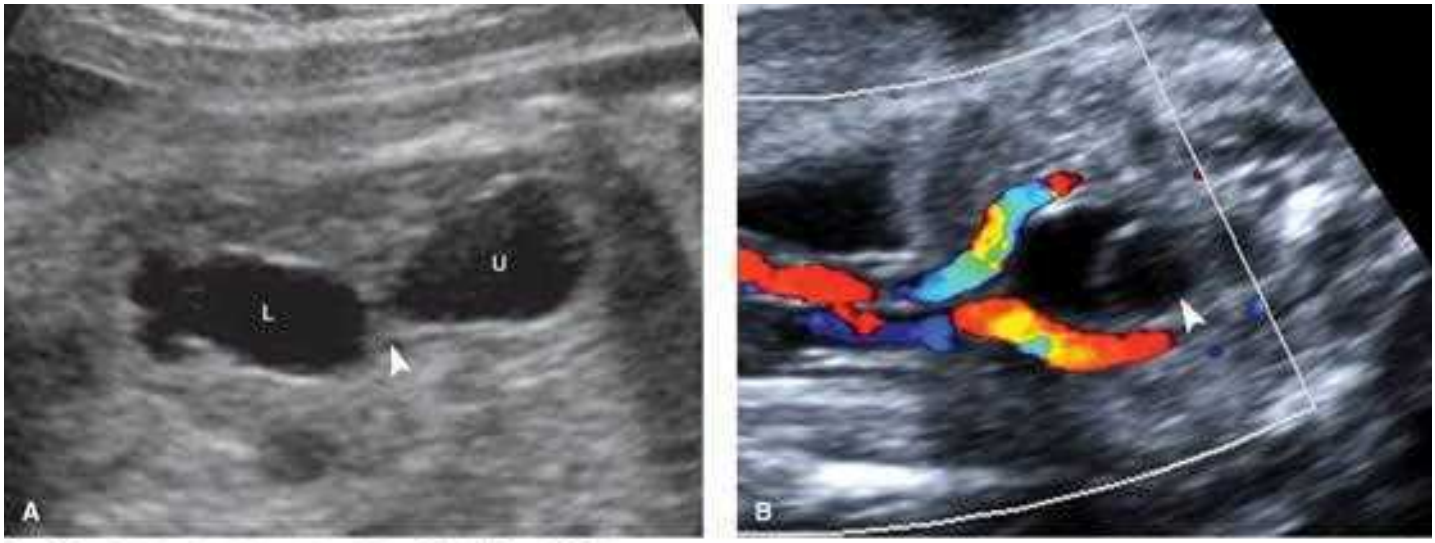
This condition is the most common abnormality associated with renal pelvis dilatation. The birth prevalence is 1 in 1000 to 2000, and males are affected three times more often than females (Williams, 2007; Woodward, 2002). Obstruction is generally functional rather than anatomical, and it is bilateral in up to a fourth of cases. The likelihood of ureteropelvic junction obstruction rises from 5 percent with mild renal pelvis dilatation to more than 50 percent with severe dilatation (Lee, 2006).

Duplicated Renal Collecting System

In this anatomical anomaly, the upper and lower poles of the kidney—called moieties—are each drained by a separate ureter (Fig. 10-42). Duplication is found in approximately 1 in 4000 pregnancies, is more common in females, and is bilateral in 15 to 20 percent of cases (James, 1998; Vergani, 1998; Whitten, 2001). Sonographically, an intervening tissue band separates two distinct renal pelves. Development of hydronephrosis or ureteral dilatation may occur due to abnormal implantation of one or both ureters within the bladder—a relationship that reflects the anatomical *Weigert-Meyer* rule. The upper pole ureter may develop obstruction from a ureterocele within the bladder, whereas the lower pole ureter has a shortened intravesical segment that predisposes to vesicoureteral reflux (see Fig. 10-42B). Thus, both moieties may become dilated from different etiologies, and both are at risk for loss of function.

FIGURE 10-42

Duplicated renal collecting system. The upper and lower moieties of the kidney are each drained by a separate ureter. **A.** Renal pelvis dilatation is visible in both the upper (*U*) and lower (*L*) pole moieties, which are separated by an intervening band of renal tissue (*arrowhead*). **B.** The bladder, encircled by the highlighted umbilical arteries, contains a ureterocele (*arrowhead*).



Renal Agenesis

The prevalence of bilateral renal agenesis is approximately 1 in 8000 births, whereas that of unilateral renal agenesis is 1 in 1000 births (Cragan, 2009; Dolk, 2010; Sheih, 1989; Wiesel, 2005). When a kidney is absent, color Doppler imaging of the descending aorta demonstrates absence of the ipsilateral renal artery (Fig. 10-43). In addition, the ipsilateral adrenal gland typically enlarges to fill the renal fossa, termed the *lying down adrenal sign* (Hoffman, 1992). As with other fetal anomalies, amniocentesis for chromosomal microarray analysis should be considered.

FIGURE 10-43

Renal agenesis. **A.** In this coronal image of the fetal abdomen, color Doppler shows the course of the abdominal aorta. The ultrasound beam is perpendicular to the aorta, demonstrating absence of the renal arteries bilaterally. **B.** This coronal image of a fetus with unilateral renal agenesis shows the adrenal gland (*arrowheads*) filling the renal fossa, termed the "lying-down" adrenal sign. The adrenal gland has a hypoechoic cortex and hyperechoic medulla.

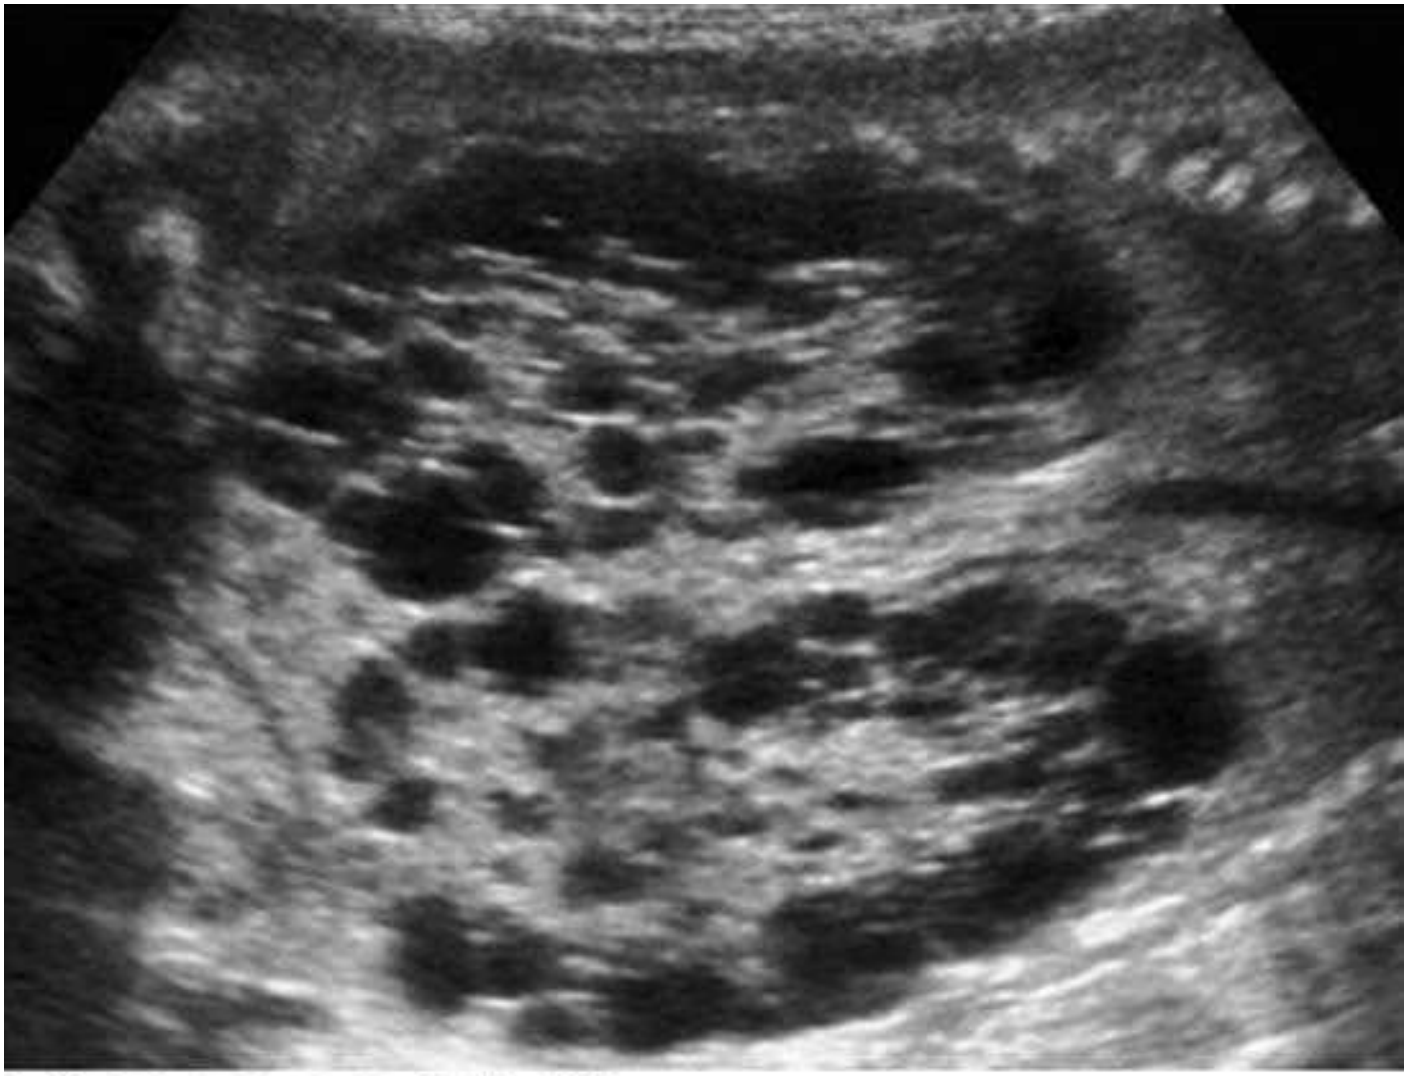
If renal agenesis is bilateral, no urine is produced, and the resulting anhydramnios leads to pulmonary hypoplasia, limb contractures, and a distinctively compressed face. When this combination results from renal agenesis, it is called *Potter syndrome,* after Dr. Edith Potter, who described it in 1946. When these abnormalities result from severely decreased amnionic fluid volume from another etiology, such as bilateral multicystic dysplastic kidney or autosomal recessive polycystic kidney disease, it is called *Potter sequence.* The prognosis for these abnormalities is extremely poor.

Multicystic Dysplastic Kidney

This severe form of renal dysplasia results in a nonfunctioning kidney. The nephrons and collecting ducts do not form normally, such that primitive ducts are surrounded by fibromuscular tissue, and the ureter is atretic (Hains, 2009). Sonographically, the kidney contains numerous smooth-walled cysts of varying size that do not communicate with the renal pelvis and are surrounded by echogenic cortex (Fig. 10-44).

FIGURE 10-44

Multicystic dysplastic kidneys. Coronal view of the fetal abdomen demonstrates markedly enlarged kidneys containing multiple cysts of varying sizes that do not communicate with a renal pelvis.



Unilateral multicystic dysplastic kidney (MCDK) has a prevalence of 1 in 4000 births. Contralateral renal abnormalities are present in 30 to 40 percent—most frequently vesicoureteral reflux or ureteropelvic junction obstruction (Schreuder, 2009). Nonrenal anomalies have been reported in 25 percent of cases, and cystic dysplasia may occur as a component of many genetic syndromes (Lazebnik, 1999; Schreuder, 2009). If MCDK is isolated and unilateral, the prognosis is generally good.

Bilateral MCDK is found in approximately 1 in 12,000 births. It is associated with severely decreased amnionic fluid volume starting early in gestation. This leads to Potter sequence and a poor prognosis (Lazebnik, 1999).

Polycystic Kidney Disease

Of the hereditary polycystic diseases, only the infantile form of *autosomal recessive polycystic kidney disease (ARPKD)* may be reliably diagnosed prenatally. ARPKD is a chronic, progressive disease of the kidneys and liver that results in cystic dilatation of the renal collecting ducts and in congenital hepatic fibrosis (Turkbey, 2009). The carrier frequency of a disease-causing mutation in the *PKHD1* gene approximates 1 in 70, and the disease prevalence is 1 in 20,000 (Zerres, 1998). The phenotypic variability of ARPKD ranges from lethal pulmonary hypoplasia at birth to presentation in late childhood or even adulthood with predominantly hepatic manifestations. Sonographically, infantile ARPKD displays abnormally large kidneys that fill and distend the fetal abdomen and have a solid, ground-glass texture. Severe oligohydramnios confers a poor prognosis.

Autosomal dominant polycystic kidney disease (ADPKD), which is far more common, usually does not manifest until adulthood (Chap. 53, Pregnancy Outcomes). Even so, some fetuses with ADPKD have mild renal enlargement and enhanced renal echogenicity in the setting of normal amnionic fluid volume. The differential diagnosis for these findings includes several genetic syndromes, aneuploidy, or normal variant.

Bladder Outlet Obstruction

Distal obstruction of the urinary tract is more frequent in male fetuses, and the most common etiology is *posterior urethral valves*. Characteristically, the bladder and proximal urethra are dilated, termed the “keyhole” sign, and the bladder wall is thick (Fig. 10-45). Oligohydramnios, particularly before midpregnancy, portends a poor prognosis because of pulmonary hypoplasia. Unfortunately, the outcome may be poor even with normal amnionic fluid volume. Evaluation includes a careful search for associated anomalies, which may occur in 40 percent of cases, and for aneuploidy, which has been reported in 5 to 8 percent (Hayden, 1988; Hobbins, 1984; Mann, 2010). If neither are present, affected male fetuses with severe oligohydramnios who have fetal urinary electrolytes

suggesting a potentially favorable prognosis may be fetal therapy candidates. Evaluation and treatment of fetal bladder outlet obstruction is discussed in Chapter 16 (Urinary Shunts).

FIGURE 10-45

Posterior urethral valve. In this 19-week fetus with severe bladder outlet obstruction, the bladder is dilated and thick-walled, with dilatation of the proximal urethra that resembles a "keyhole." Adjacent to the bladder is an enlarged kidney with evidence of cystic dysplasia, conferring a poor prognosis.

Skeletal Abnormalities

The 2015 revision of the Nosology and Classification of Genetic Skeletal Disorders includes an impressive 436 skeletal anomalies in 42 groups, characterized by genetic abnormalities, phenotypic features, or radiographic criteria (Bonafe, 2015). The two types of skeletal dysplasias are *osteochondrodysplasias*—the generalized abnormal development of bone and/or cartilage, and *dysostoses*—which are abnormalities of individual bones, for example, *polydactyly.* In addition to these *malformations*, skeletal abnormalities include *deformations*, as with some cases of clubfoot, and *disruptions* such as limb-reduction defects.

Skeletal Dysplasias

The prevalence of skeletal dysplasias approximates 3 in 10,000 births. Two groups account for more than half of all cases: the *fibroblast growth factor 3 (FGFR3) chondrodysplasia* group and the *osteogenesis imperfecta* and decreased bone density group. Each occurs in 0.8 in 10,000 births (Stevenson, 2012).

Evaluation of a pregnancy with suspected skeletal dysplasia includes a survey of every long bone, as well as the hands and feet, skull size and shape, clavicles, scapulae, thorax, and spine. Reference tables are used to determine which long bones are affected and ascertain the degree of shortening (Appendix, Fetal Sonographic Measurements). Involvement of all long bones is termed *micromelia,* whereas predominant involvement of only the proximal, intermediate, or distal long bone segments is termed *rhizomelia, mesomelia,* and *acromelia*, respectively. The degree of ossification should be noted, as should presence of bowing or fractures. Each of these may provide clues to narrow the differential diagnosis and occasionally suggest a specific skeletal dysplasia. Many, if not most, skeletal dysplasias have a genetic component, and knowledge of specific mutations has advanced dramatically (Bonafe, 2015).

Although precise characterization may elude prenatal diagnosis, it is frequently possible to determine whether a skeletal dysplasia is lethal. Lethal dysplasias show profound long bone shortening, with measurements <5th percentile, and display femur length-to-abdominal circumference ratios below 16 percent (Nelson, 2014; Rahemtullah, 1997; Ramus, 1998). Generally, other sonographic abnormalities are evident. Pulmonary hypoplasia is suggested by a thoracic circumference <80 percent of the abdominal circumference value, by a thoracic circumference <2.5th percentile, and a cardiac circumference >50 percent of the thoracic circumference value (Appendix, Fetal Sonographic Measurements). Affected pregnancies also may develop hydramnios and/or hydrops (Nelson, 2014).

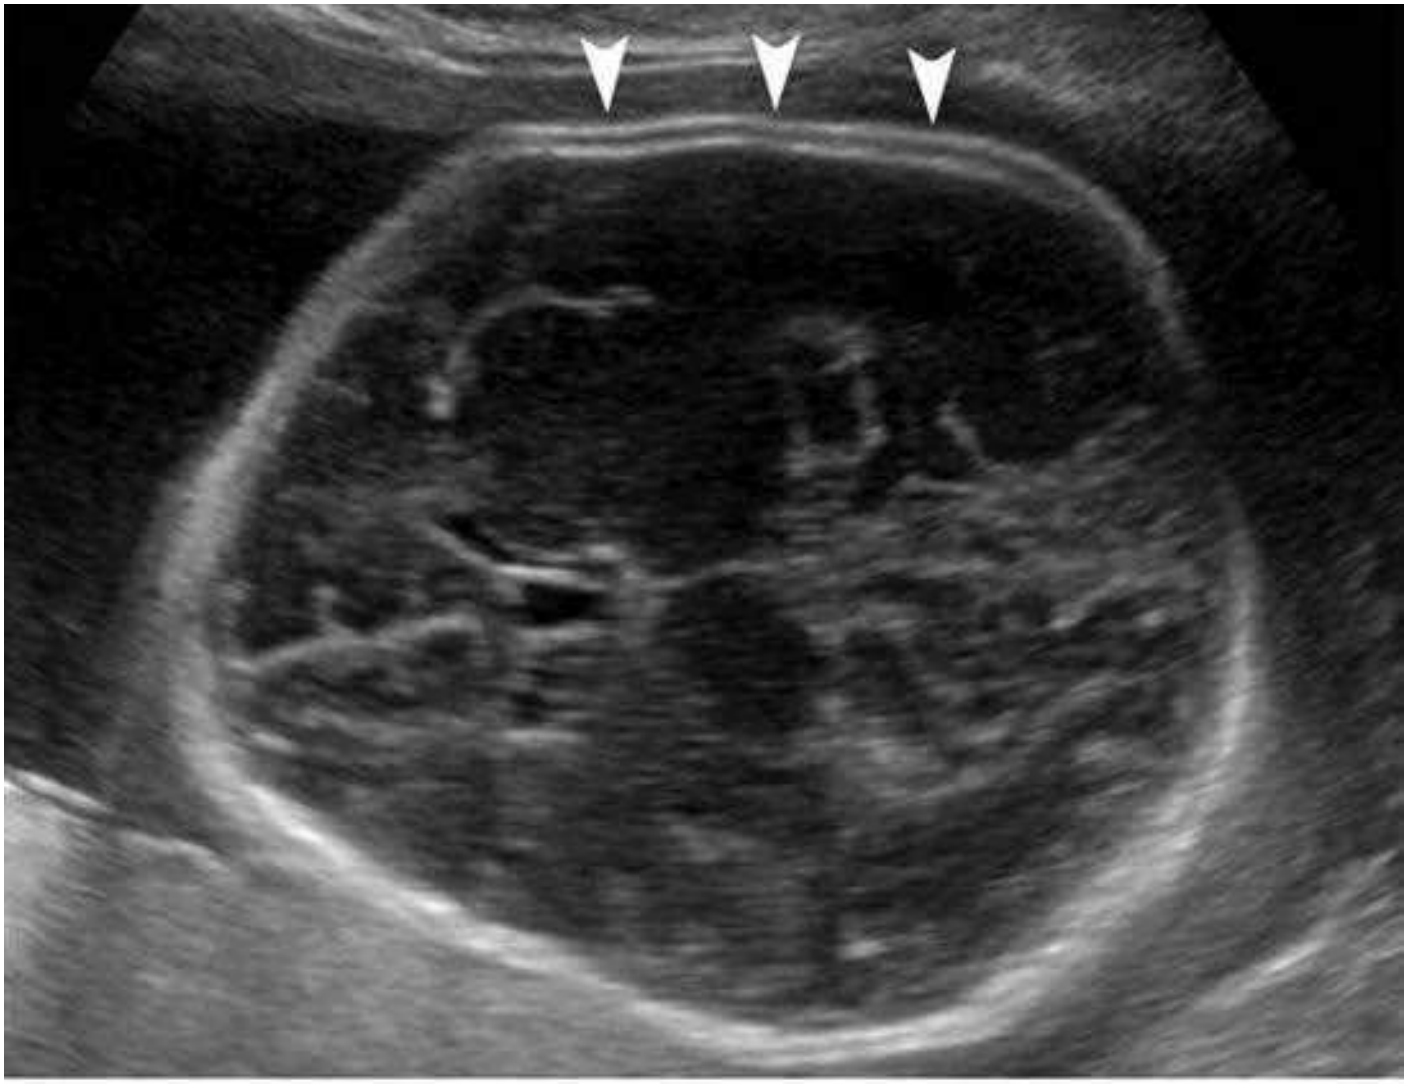
The FGFR3 chondrodysplasias include *achondroplasia* and *thanatophoric dysplasia.* Achondroplasia, also called *heterozygous achondroplasia*, is the most common nonlethal skeletal dysplasia. An impressive 98 percent of cases are due to a specific point mutation in the *FGFR3* gene. It has an autosomal dominant inheritance, and 80 percent of cases result from a new mutation. Achondroplasia is characterized by long bone shortening that is predominantly *rhizomelic*, an enlarged head with frontal bossing, depressed nasal bridge, exaggerated lumbar lordosis, and a trident configuration of the hands. Intelligence is typically normal. Sonographically, the femur and humerus measurements may not lie below the 5th percentile until the early third trimester. Thus, this condition is usually not diagnosed until late in pregnancy. In homozygotes, which represent 25 percent of the offspring of heterozygous parents, the condition is characterized by greater long bone shortening and is lethal.

The other major class of FGFR3 dysplasias, *thanatophoric dysplasia*, is the most common lethal skeletal disorder. It is characterized by severe micromelia, and affected fetuses—particularly those with type II—may develop a characteristic cloverleaf skull deformity (*Kleeblattschädel*) due to craniosynostosis. More than 99 percent of cases may be confirmed with genetic testing.

Osteogenesis imperfecta represents a group of skeletal dysplasias typified by hypomineralization. There are multiple types, and more than 90 percent of cases are characterized by a mutation in the *COL1A1* or *COL1A2* gene. Type IIa, also called the perinatal form, is lethal. It displays a profound lack of skull ossification, such that gentle pressure on the maternal abdomen from the ultrasound transducer results in visible skull deformation (Fig. 10-46). Other features include multiple in-utero fractures and ribs that appear “beaded.” Inheritance is autosomal dominant, such that all cases result from either new mutations or gonadal mosaicism (Chap. 13, Modes of Inheritance). Another skeletal dysplasia that results in severe hypomineralization is *hypophosphatasia*, which has an autosomal recessive inheritance.

FIGURE 10-46

Osteogenesis imperfecta. Type IIa, which is lethal, is characterized by such profound lack of skull ossification that gentle pressure on the maternal abdomen from the ultrasound transducer results in visible deformation (flattening) of the skull (*arrowheads*).

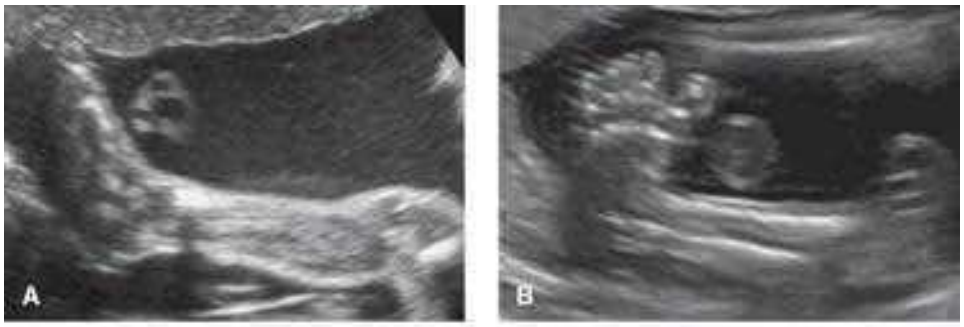


Clubfoot—Talipes Equinovarus

This disorder is notable for a deformed talus and shortened Achilles tendon. The affected foot is abnormally fixed and positioned with *equinus* (downward pointing), *varus* (inward rotation), and forefoot adduction. Most cases are considered malformations, with a multifactorial genetic component. However, an association with environmental factors and with early amniocentesis suggests that deformation also plays a role (Tredwell, 2001). Sonographically, the footprint is visible in the same plane as the tibia and fibula (Fig. 10-47).

FIGURE 10-47

Foot position. **A.** Normal fetal lower leg, demonstrating normal position of the foot. **B.** With talipes equinovarus, the foot "print" is visible in the same plane as the tibia and fibula.



The prevalence of clubfoot approximates 1 in 1000 births, and the male:female ratio is 2:1 (Carey, 2003; Pavone, 2012). Clubfoot is bilateral in approximately 50 percent of affected individuals, and associated anomalies are present in at least 50 percent of all cases (Mammen, 2004; Sharma, 2011). Frequently associated anomalies include neural-tube defects, arthrogryposis, and myotonic dystrophy and other genetic syndromes. In cases with associated anomalies, aneuploidy is

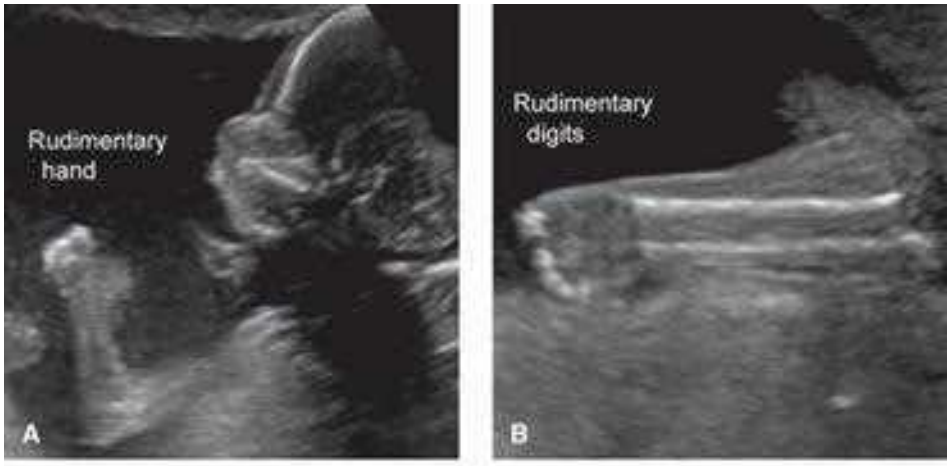
found in approximately 30 percent. In contrast, the rate is <4 percent when clubfoot appears isolated (Lauson, 2010; Sharma, 2011). Thus, a careful search for associated structural abnormalities is warranted, and chromosomal microarray analysis may be considered.

Limb-Reduction Defects

Documentation of the arms and legs is a component of the standard examination. The absence or hypoplasia of all or part of one or more extremities is a *limb-reduction defect*. The birth prevalence is 4 to 8 in 10,000 (Kucik, 2012; Stoll, 2010; Vasluian, 2013). Approximately half of these are isolated defects, up to one third occur as part of a recognized syndrome, and individuals in the remaining cases have other coexisting anomalies (Stoll, 2010; Vasluian, 2013). Upper extremities are affected more frequently than lower ones. Of categories, a terminal *transverse limb defect* lacks part or all of a distal limb to create a stump (Fig. 10-48). This is more common than a *longitudinal defect*, which is complete or partial absence of the long bone(s) on only one side of a given extremity.

FIGURE 10-48

Transverse limb-reduction defect. **A.** At 18 weeks' gestation, only a rudimentary hand was visible. **B.** By 24 weeks, the radius and ulna were normal in size and appearance, and small rudimentary digits were evident.



Absence of an entire extremity is termed *amelia. Phocomelia,* associated with thalidomide exposure, is an absence of one or more long bones with the hands or feet attached to the trunk (Chap. 12, Thalidomide and Lenalidomide). Limb-reduction defects are associated with numerous genetic syndromes, such as *Roberts syndrome*, an autosomal recessive condition characterized by *tetraphocomelia.* A *clubhand deformity*, usually from an absent radius, is associated with trisomy 18 and is also a component of the *thrombocytopenia-absent radius syndrome* (Fig. 13-5B). Limb-reduction defects may occur in the setting of a disruption such as amnionic-band sequence (Chap. 6, Amniochorion). They have also been associated with chorionic villus sampling when performed before 10 weeks' gestation (Fig. 14-6).

THREE- AND FOUR-DIMENSIONAL SONOGRAPHY

During the past two decades, three-dimensional (3-D) sonography has gone from a novelty to a standard feature of most modern ultrasound equipment (Fig. 10-49). 3-D sonography is not *routinely* used during a standard examination nor considered a required modality. However, it may be a component of specialized evaluations.

FIGURE 10-49

Fetal face. Surface rendered three-dimensional image of a normal fetal face and hand at 32 weeks.

Most 3-D scanning uses a special transducer developed for this purpose. After a region of interest is identified, a 3-D volume is acquired that can be rendered to display axial, sagittal, coronal, or oblique images. Sequential "slices" may be generated, similar to computed tomographic (CT) or MR images. Unlike two-dimensional (2-D) scanning, which appears to be in "real time," 3-D imaging is static and obtained by processing a volume of stored images. With *four-dimensional (4-D) sonography*, also known as real-time 3-D sonography, rapid reconstruction of the rendered images conveys the impression that the scanning is in real time.

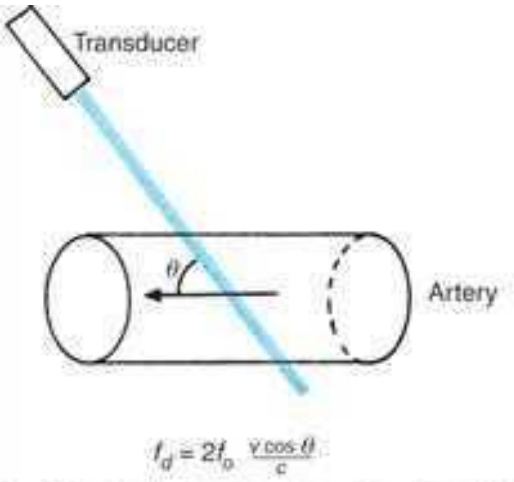
For 4-D imaging, one application known as *spatiotemporal image correlation—STIC* improves visualization of cardiac anatomy. During an automated sweep over the heart, the STIC application acquires a volume that includes thousands of 2D images captured at a rate as high as 150 frames per second (Devore, 2003). These individual images are obtained at different locations in the heart but at the same point in time. These views are subsequently arranged according to their spatial and temporal domains. This permits display of an ordered sequence of volume sets in a continuous cine loop (or video clip) of the cardiac cycle (Yeo, 2016). For example, after obtaining a volume sweep over the cardiac apex, an application such as Fetal Intelligent Navigation Echocardiography (FINE) can be applied to display videos of each of the different cardiac views shown in Fig. 10-28 (Garcia, 2016). It is hoped that such technology may eventually improve detection of fetal cardiac anomalies.

For selected anomalies, such as those of the face and skeleton, for tumors, and for some cases of neural-tube defects, 3-D sonography can add useful information (American College of Obstetricians and Gynecologists, 2016; Goncalves, 2005). That said, comparisons of 3-D and conventional 2-D sonography for the diagnosis of most congenital anomalies have not demonstrated better overall detection rates (Goncalves, 2006; Reddy, 2008). The American College of Obstetricians and Gynecologists (2016) concludes that proof of a clinical advantage of 3-D sonography for prenatal diagnosis is generally lacking.

DOPPLER

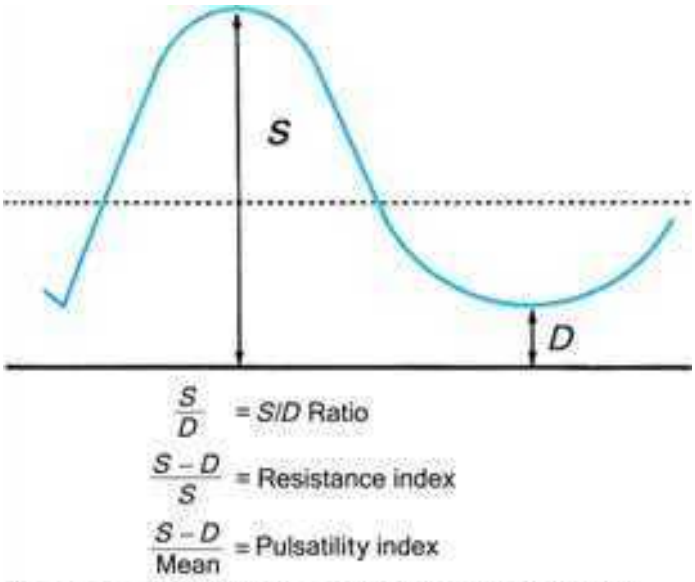
When sound waves strike a moving target, the frequency of the waves reflected back is shifted in proportion to the velocity and direction of that moving target—a phenomenon known as the *Doppler shift*. Because the magnitude and direction of the frequency shift depend on the relative motion of the moving target, Doppler can help evaluate flow within blood vessels. The Doppler equation is shown in Figure 10-50.

FIGURE 10-50
Doppler equation. Ultrasound emanating from the transducer with initial frequency f_0 strikes blood moving at velocity v. Reflected frequency f_d is dependent on angle θ between beam of sound and vessel.



An important component of the equation is the angle of insonation, abbreviated as theta (θ). This is the angle between the sound waves from the transducer and flow within the vessel. Measurement error becomes large when θ is not close to zero, in other words, when blood flow is not coming *directly* toward or away from the transducer. For this reason, ratios are often used to compare different waveform components, allowing cosine θ to cancel out of the equation. Figure 10-51 is a schematic of the Doppler waveform and describes the three ratios commonly used. The simplest is the *systolic-diastolic ratio (S/D ratio),* which compares the maximal (or peak) systolic flow with end-diastolic flow to evaluate downstream impedance to flow. Currently, two types of Doppler modalities are available for clinical use.

FIGURE 10-51
Doppler systolic–diastolic waveform indices of blood flow velocity. S represents the peak systolic flow or velocity, and D indicates the end-diastolic flow or velocity. The mean, which is the time-average mean velocity, is calculated from computer-digitized waveforms.



Continuous-wave Doppler equipment has two separate types of crystals—one transmits high-frequency sound waves, and another continuously captures signals. In M-mode imaging, continuous-wave Doppler is used to evaluate motion through time, however, it cannot image individual vessels.

Pulsed-wave Doppler uses only one crystal, which transmits the signal and then waits until the returning signal is received before transmitting another one. It allows precise targeting and visualization of the vessel of interest. Pulsed-wave Doppler can be configured to allow color-flow mapping—such that blood flowing

toward the transducer is displayed in red and that flowing away from the transducer appears in blue. Various combinations of pulsed-wave Doppler, color-flow Doppler, and real-time sonography are commercially available.

Umbilical Artery

Umbilical artery Doppler has been subjected to more rigorous assessment than any previous test of fetal health. The umbilical artery differs from other vessels in that it normally has forward flow throughout the cardiac cycle. Moreover, the amount of flow during diastole increases as gestation advances, and this reflects decreasing placental impedance. *As a result, the S/D ratio normally declines from approximately 4.0 at 20 weeks' gestation, to generally less than 3.0 after 30 weeks' and finally to 2.0 at term.* Because of downstream impedance to flow, *more* end-diastolic flow is observed at the placental cord insertion than at the fetal ventral wall. Thus, abnormalities such as absent or reversed end-diastolic flow will appear first at the fetal cord insertion site. The International Society of Ultrasound in Obstetrics and Gynecology recommends that umbilical artery Doppler measurements be made in a free loop of cord (Bhide, 2013). However, assessment close to the ventral wall insertion may optimize measurement reproducibility when flow is diminished (Berkley, 2012).

The waveform is considered abnormal if the S/D ratio is >95th percentile for gestational age. In extreme cases of growth restriction, end-diastolic flow can become absent or even reversed (Fig. 44-8). Such reversal of end-diastolic flow has been associated with greater than 70-percent obliteration of the small muscular arteries in placental tertiary stem villi (Kingdom, 1997; Morrow, 1989).

As described in Chapter 44 (Prevention), umbilical artery Doppler aids management of fetal-growth restriction and has been associated with improved outcome in these cases (American College of Obstetricians and Gynecologists, 2015). It is not recommended for complications other than growth restriction. Similarly, its use for growth-restriction screening is not advised (Berkley, 2012). Abnormal umbilical artery Doppler findings should prompt a complete fetal evaluation, if not already done, because abnormal measurements are associated with major fetal anomalies and aneuploidy (Wenstrom, 1991).

Ductus Arteriosus

Doppler evaluation of the ductus arteriosus has been used primarily to monitor fetuses exposed to indomethacin and other nonsteroidal antiinflammatory agents (NSAIDs). Indomethacin, which is used by some for tocolysis, may cause ductal constriction or closure, particularly when used in the third trimester (Huhta, 1987). The resulting increased pulmonary flow can cause reactive hypertrophy of the pulmonary arterioles and eventual development of pulmonary hypertension. In a review of 12 randomized controlled trials involving more than 200 exposed pregnancies, Koren and coworkers (2006) reported that NSAIDs raised the odds of ductal constriction 15-fold. When these agents are indicated, their duration is typically limited to less than 72 hours. And, women taking NSAIDs are closely monitored so that these can be discontinued if ductal constriction is identified. Fortunately, ductal constriction is often reversible after NSAID discontinuation.

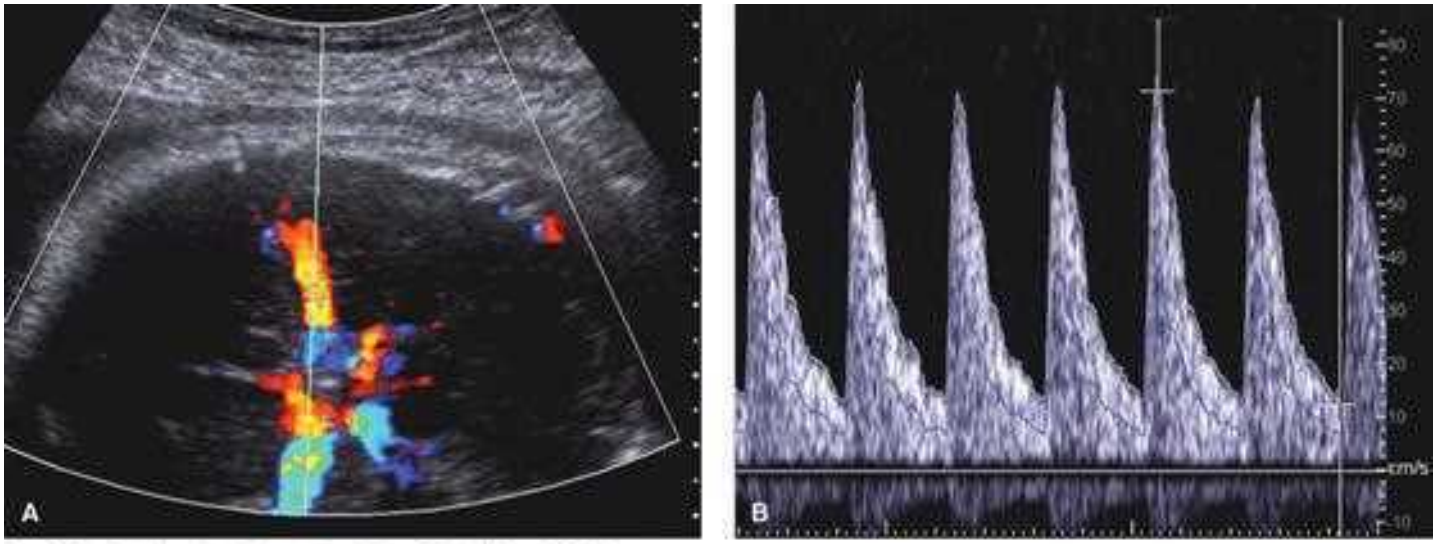
Uterine Artery

Uterine blood flow is estimated to rise from 50 mL/min early in gestation to 500 to 750 mL/min by term. The uterine artery Doppler waveform is characterized by high diastolic flow velocities and markedly turbulent flow. Greater resistance to flow and development of a *diastolic notch* are associated with later development of gestational hypertension, preeclampsia, and fetal-growth restriction. Zeeman and coworkers (2003) also found that women with chronic hypertension who had elevated uterine artery impedance at 16 to 20 weeks' gestation were at greater risk to develop superimposed preeclampsia. However, the technique, best testing interval, and defining criteria for this indication have not been standardized. As the predictive value of uterine artery Doppler testing is considered to be low, its use for screening or for clinical decision-making is not recommended in either high-risk or low-risk pregnancies (Sciscione, 2009).

Middle Cerebral Artery

Doppler interrogation of the middle cerebral artery (MCA) has been investigated and applied clinically for fetal anemia detection and fetal-growth restriction evaluation. Anatomically, the path of the MCA is such that flow often approaches the transducer "head-on," allowing for accurate determination of flow velocity (Fig. 10-52). The MCA is imaged in an axial view of the head at the base of the skull, ideally within 2 mm of the internal carotid artery origin. Velocity measurement is optimal when the insonating angle is close to zero, and no more than 30 degrees of angle correction should be used. In general, velocity assessment is not performed in other fetal vessels, because a larger insonating angle is needed and confers significant measurement error.

FIGURE 10-52
Middle cerebral artery (MCA) Doppler. **A.** Color Doppler of the circle of Willis, demonstrating the correct location to sample the MCA. **B.** The waveform demonstrates a peak systolic velocity exceeding 70 cm/sec in a 32-week fetus with severe fetal anemia secondary to Rh alloimmunization.



When fetal anemia is present, the *peak systolic velocity* is enhanced due to greater cardiac output and decreased blood viscosity (Segata, 2004). This has permitted the reliable, noninvasive detection of fetal anemia in cases of blood-group alloimmunization. Mari and colleagues (2000) demonstrated that an MCA peak systolic velocity threshold of 1.50 MoM could reliably identify fetuses with moderate or severe anemia. As discussed in Chapter 15 (Management of the Alloimmunized Pregnancy), MCA peak systolic velocity has replaced invasive testing with amniocentesis as the preferred test for fetal anemia detection (Society for Maternal-Fetal Medicine, 2015).

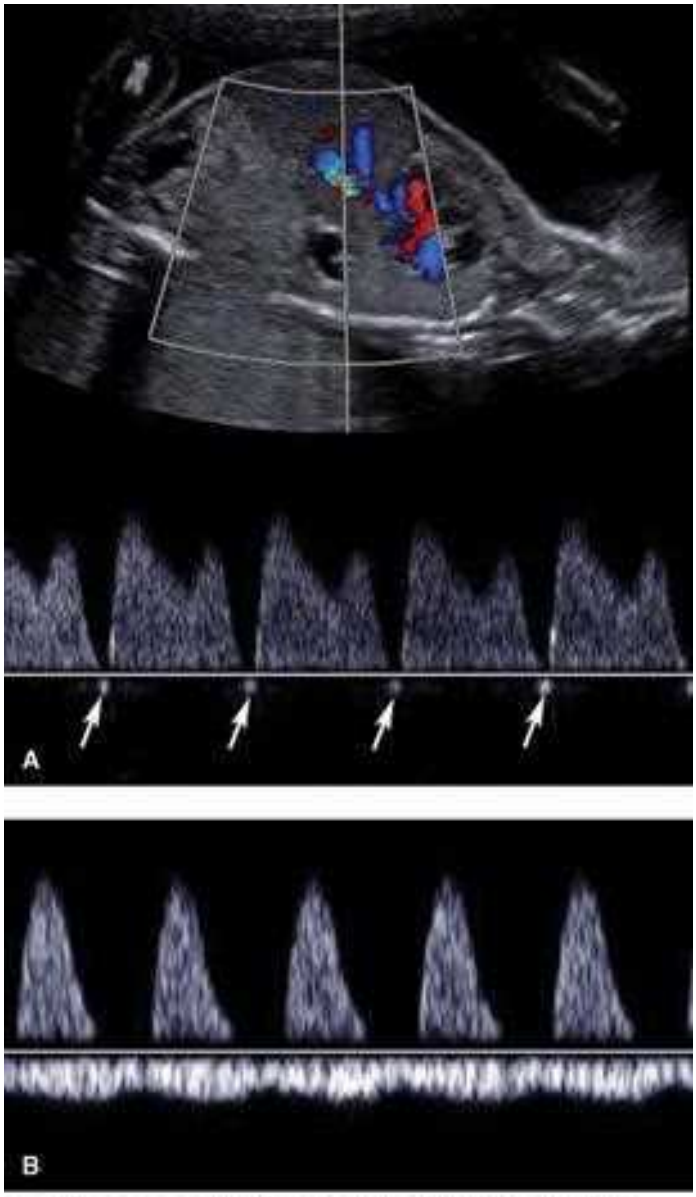
MCA Doppler has also been studied as an adjunct in evaluation of fetal-growth restriction. Fetal hypoxemia is believed to result in increased blood flow to the brain, heart, and adrenal glands, leading to greater end-diastolic flow in the MCA. This phenomenon, “brain-sparing,” is actually a misnomer, as it is not protective for the fetus but rather is associated with perinatal morbidity and mortality (Bahado-Singh, 1999; Cruz-Martinez, 2011). The utility of MCA Doppler to aid the timing of delivery is uncertain. It has *not* been evaluated in randomized trials or adopted as standard practice in the management of growth restriction (American College of Obstetricians and Gynecologists, 2015; Berkley, 2012).

Ductus Venosus

The ductus venosus is imaged as it branches from the umbilical vein at approximately the level of the diaphragm. Fetal position poses more of a challenge in imaging the ductus venosus than it does with either the umbilical artery or the middle cerebral artery. The waveform is biphasic and normally has forward flow throughout the cardiac cycle. The first peak reflects ventricular systole, and the second is ventricular diastolic filling. These are followed by a nadir during atrial contraction—termed the *a-wave*.

It is believed that Doppler findings in preterm fetuses with growth restriction show a progression in which umbilical artery Doppler abnormalities are followed by ones in the middle cerebral artery and then in the ductus venosus. However, manifestations of these abnormalities vary widely (Berkley, 2012). With severe fetal-growth restriction, cardiac dysfunction may lead to flow in the a-wave that is decreased, absent, and eventually reversed, along with pulsatile flow in the umbilical vein (Fig. 10-53).

FIGURE 10-53
Venous Doppler abnormalities. **A.** Reversal of a-wave flow in the ductus venosus. Arrows depict a-waves below the baseline. This finding may be identified with cardiac dysfunction in the setting of severe fetal-growth restriction. **B.** Pulsatile flow in the umbilical vein. The undulating umbilical venous waveform below the baseline indicates tricuspid regurgitation. Above the baseline is the umbilical artery waveform, in which there is no visible end-diastolic flow. Because the venous waveform is below the baseline in this image, it is not possible to determine whether the umbilical artery end-diastolic flow is reversed.



Ductus venosus abnormalities have potential to identify preterm growth-restricted fetuses that are at greatest risk for adverse outcomes (Baschat, 2003, 2004; Bilardo, 2004; Figueras, 2009). As noted by the Society for Maternal-Fetal Medicine, however, they have not been sufficiently evaluated in randomized trials (Berkley, 2012). In sum, Doppler assessment of vessels other than the umbilical artery has not been shown to improve perinatal outcome, and thus their role in clinical practice remains uncertain (American College of Obstetricians and Gynecologists, 2015).

MAGNETIC RESONANCE IMAGING

Image resolution with MR is often superior to that with sonography because it is not as hindered by bony interfaces, maternal obesity, oligohydramnios, or an engaged fetal head. Thus, it can serve as an adjunct to sonography in evaluating suspected fetal abnormalities. Examples include complex abnormalities of the fetal CNS, thorax, gastrointestinal system, genitourinary system, and musculoskeletal system. MR has also been used in the evaluation of maternal pelvic masses and placental invasion. MR imaging, however, is not portable, it is time-consuming, and its use is generally limited to referral centers with expertise in fetal imaging.

To guide clinical use, the American College of Radiology and Society for Pediatric Radiology (2015) have developed a practice guideline for fetal MR imaging. This document acknowledges primacy of sonography as the preferred screening modality. Moreover, it recommends that fetal MR imaging be used for problem solving to ideally contribute to prenatal diagnosis, counseling, treatment, and delivery planning. Specific indications for fetal MR imaging are listed in Table 10-11 and are discussed subsequently.

TABLE 10-11

Fetal Conditions for Which Magnetic Resonance Imaging May Be Indicated[a]

Brain and spine
Ventriculomegaly
Agenesis of the corpus callosum
Cavum septum pellucidum abnormalities
Holoprosencephaly
Posterior fossa abnormalities
Cerebral cortical malformation or migrational abnormalities
Cephalocele
Solid or cystic masses
Vascular malformations
Hydranencephaly
Infarctions
Hemorrhage
Monochorionic twin pregnancy complications
Neural-tube defects
Sacrococcygeal teratoma
Sacral agenesis (caudal regression)
Sirenomelia
Vertebral anomalies
Family history conferring a risk for brain anomaly
Skull, face, and neck
Venolymphatic malformations
Hemangiomas
Goiter
Teratomas
Facial clefts
Other abnormalities with potential airway obstruction
Thorax
Congenital cystic adenomatoid malformation
Extralobar pulmonary sequestration
Bronchogenic cyst or congenital lobar overinflation
Diaphragmatic hernia
Effusions
Mediastinal masses
Assessment for esophageal atresia
Evaluation of pulmonary hypoplasia secondary to diaphragmatic hernia, oligohydramnios, chest mass, or skeletal dysplasia
Abdomen, pelvis, and retroperitoneum
Abdominopelvic cystic mass evaluation
Tumor evaluation (sacrococcygeal teratoma, neuroblastoma, hemangioma, suprarenal or renal masses)
Complex genitourinary anomalies (bladder outlet obstruction syndromes, bladder exstrophy, cloacal exstrophy)
Assess renal anomalies with oligohydramnios
Diagnose bowel anomalies (anorectal malformations, complex obstructions)
Complications of monochorionic twins
Determine vascular anatomy prior to laser treatment
Assess morbidity after death of a monochorionic co-twin
Evaluate conjoined twins
Fetal surgery assessment
Fetal brain anatomy before and after surgical intervention
Anomalies for which fetal surgery is planned

[a]In some cases, magnetic resonance (MR) imaging is indicated only if the anomaly is suspected but cannot be adequately characterized sonographically, which is assessed on a case-by-case basis.

Data from American College of Radiology, 2015.

Safety

MR imaging uses no ionizing radiation, but theoretical concerns include the effects of fluctuating electromagnetic fields and high sound-intensity levels. The strength of the magnetic field is measured in *tesla (T),* and most imaging studies during pregnancy are performed using 1.5 T. A few preliminary studies advocate the use of 3 T for fetal imaging to potentially improve signal-to-noise ratios and thus image clarity (Victoria, 2016). For safety, all clinical examinations must adhere to the specific absorption rate, which is regulated by the Food and Drug Administration, and the ALARA principle should be followed. Thus, for routine clinical examinations, the lower field strength of 1.5 T is recommended (Prayer, 2017).

Human and tissue studies support the safety of fetal MR imaging. Repetitive exposure of human lung fibroblasts to a static 1.5-T magnetic field does not affect cellular proliferation (Wiskirchen, 1999). Fetal heart rate patterns have been evaluated before and during MR imaging, and no significant differences were observed (Vadeyar, 2000). Children exposed to MR as fetuses do not show a greater incidence of disease or disability when tested at age 9 months or 3 years (Baker, 1994; Clements, 2000).

Glover and associates (1995) attempted to mimic the sound level experienced by the fetal ear by having an adult volunteer swallow a microphone while the stomach was filled with a liter of fluid to represent the amnionic sac. Sound intensity was attenuated at least 30-dB from the body surface to the fluid-filled stomach and reduced the sound pressure from 120 dB to below 90 dB. This level is considerably less than the 135 dB experienced from vibroacoustic stimulation used in antepartum well-being assessments (Chap. 17, Acoustic Stimulation Tests). Cochlear function testing in infants exposed to 1.5-T MR imaging as fetuses showed no hearing impairment (Reeves, 2010).

The American College of Radiology (2013) concludes that based on available evidence, MR imaging has no documented deleterious effects on the developing fetus. Therefore, MR imaging can be performed in pregnancy if data are needed to care for the fetus or mother. Health-care providers who are pregnant may work in and around an MR unit, but it is recommended that they not remain in the MR scanner magnet room—known as Zone IV—while an examination is in progress.

Gadolinium-based MR contrast agents are gadolinium (Gd^{3+}) chelates. These contrast agents readily enter the fetal circulation and are excreted via fetal urination into amnionic fluid, where they may remain for an indeterminate period before being ingested and reabsorbed. The longer the gadolinium-chelate molecule remains in a protected space such as the amnionic sac, the greater the potential for dissociation of the toxic Gd^{3+} ion. Accordingly, gadolinium contrast should be avoided during pregnancy because of this potential for dissociation. Routine use of gadolinium is not recommended unless there are overwhelming potential benefits (American College of Radiology, 2013). In adults with renal disease, this contrast agent has been associated with development of nephrogenic systemic fibrosis, a potentially severe complication.

Technique

Before MR examination, all women complete a written safety questionnaire that includes information about metallic implants, pacemakers, or other metal- or iron-containing devices that may alter the study (American College of Radiology, 2013). Iron supplementation may cause artifact in the colon but does not usually affect the resolution of fetal images. In more than 4000 MR procedures performed at Parkland Hospital in pregnancy during the past 15 years, maternal anxiety secondary to claustrophobia and/or fear of MR equipment has developed in less than 1 percent of our patients. To reduce maternal anxiety in this small group, a single oral dose of diazepam, 5 to 10 mg, or lorazepam, 1 to 2 mg, may be given.

To begin an MR examination, women are placed in a supine or left lateral decubitus position. A torso coil is used in most circumstances to send and receive the radiofrequency pulses, but a body coil can be used alone to accommodate large maternal habitus. A series of three-plane localizers, or scout views, are obtained relative to the maternal coronal, sagittal, and axial planes. The gravid uterus is imaged in the maternal axial plane (7-mm slices, 0 gap) with a T2-weighted fast acquisition. Typically, these may be a single-shot fast spin echo sequence (SSFSE), half-Fourier acquisition single-shot turbo spin echo (HASTE), or rapid acquisition with relaxation enhancement (RARE), depending on the brand of machine. Next, a fast T1-weighted acquisition such as spoiled gradient echo (SPGR) is performed (7-mm thickness, 0 gap). These large-field-of-view acquisitions through the maternal abdomen and pelvis are particularly good for identifying fetal and maternal anatomy.

Orthogonal images of targeted fetal or maternal structures are then obtained. In these cases, 3- to 5-mm slice thickness, 0 gap T2-weighted acquisitions are performed in the coronal, sagittal, and axial planes. Depending on the anatomy and underlying suspected abnormality, T1-weighted images can be performed to evaluate for subacute hemorrhage, fat, or location of normal structures that appear bright on these sequences, such as liver and meconium in the colon (Brugger, 2006; Zaretsky, 2003b).

Short T1 inversion recovery (STIR) and frequency-selective fat-saturated T2-weighted images may provide differentiation in cases in which the water content of the abnormality is similar to that of the normal structure. An example is a thoracic mass compared with normal lung. Diffusion-weighted imaging may be employed to evaluate for restricted diffusion, which can be seen in ischemia, cellular tumors, or clotted blood (Brugger, 2006; Zaretsky, 2003b). Our series also includes an axial brain 3- to 5-mm T2-weighted sequence to obtain head biometry for gestational age estimation using the biparietal diameter and head circumference (Reichel, 2003).

Fetal Anatomical Evaluation

Whenever a fetal abnormality is identified, findings from the affected organ and other organ systems should be thoroughly characterized. Accordingly, a fetal anatomical survey is generally completed during each MR examination. In a recent prospective study, nearly 95 percent of the anatomical components recommended by the International Society of Ultrasound in Obstetrics and Gynecology were visible at 30 weeks' gestation (Millischer, 2013). The aorta and pulmonary artery were the most difficult to evaluate. Zaretsky and coworkers (2003a) similarly found that with the exclusion of cardiac structures, fetal anatomical evaluation was possible in 99 percent of cases.

Central Nervous System

For intracranial anomalies, very fast T2-weighted images produce excellent tissue contrast, and CSF-containing structures are hyperintense or bright. This allows exquisite detail of the posterior fossa, midline structures, and cerebral cortex. T1-weighted images are used to identify hemorrhage.

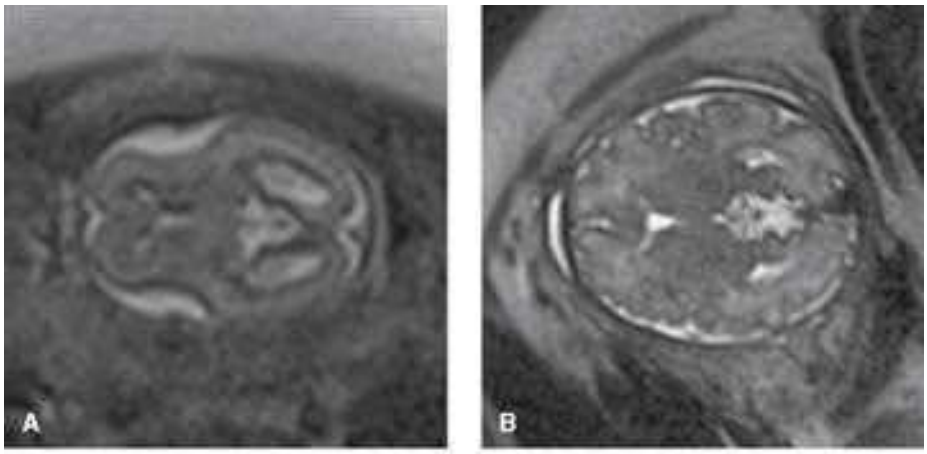
CNS biometry obtained with MR imaging is comparable with that obtained using sonography (Twickler, 2002). Nomograms have been published for multiple intracranial structures, including corpus callosum and cerebellar vermis lengths (Garel, 2004; Tilea, 2009).

MR imaging provides valuable added information for cerebral abnormalities suspected sonographically (Benacerraf, 2007; Li, 2012). In early studies, MR imaging changed the diagnosis in 40 to 50 percent of cases and affected management in 15 to 50 percent (Levine, 1999b; Simon, 2000; Twickler, 2003). Additional information is more likely to be gained when the examination is performed beyond 24 weeks' gestation. More recently, Griffiths and associates (2017) reported that MR evaluation of suspected fetal brain anomalies identified additional findings in nearly 50 percent and changed prognosis in 20 percent.

Fetuses with a cerebral abnormality may have a significant lag in cortical development. Levine and colleagues (1999a) demonstrated that MR imaging accurately portrays cerebral gyration and sulcation patterns (Fig. 10-54). Sonography permits limited evaluation of subtle migrational abnormalities, and MR imaging provides greater accuracy, particularly later in gestation.

FIGURE 10-54

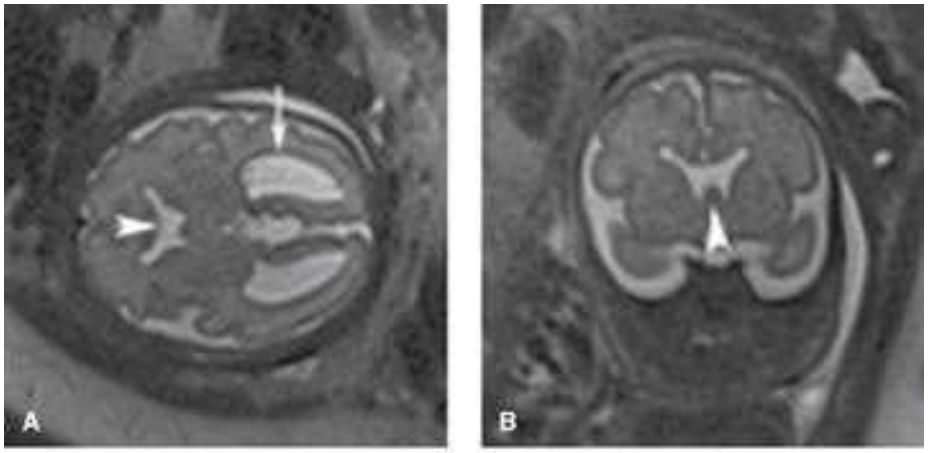
Axial images of the fetal brain at 23 weeks' gestation **(A)** and at 33 weeks **(B)** demonstrate the normal gyration and sulcation progression during fetal development. These images were obtained using a Half Fourier Acquisition Single Shot Turbo Spin Echo (HASTE) sequence because it is relatively motion insensitive.



For ventriculomegaly, fetal MR imaging is selected to help identify associated underlying CNS dysmorphology (Ventriculomegaly). In cases of septo-optic dysplasia, MR imaging may confirm absence of the septum pellucidum and display hypoplastic optic tracts (Fig. 10-55). In other fetuses, MR imaging can also assist with identifying agenesis or dysgenesis of the corpus callosum and characterizing migrational abnormalities (Benacerraf, 2007; Li, 2012; Twickler, 2003).

FIGURE 10-55

Septo-optic dysplasia. Axial **(A)** and coronal **(B)** images at 30 weeks' gestation confirm absence of the cavum septum pellucidum (*arrowheads*) in both. There is also associated mild ventriculomegaly (*arrow*).

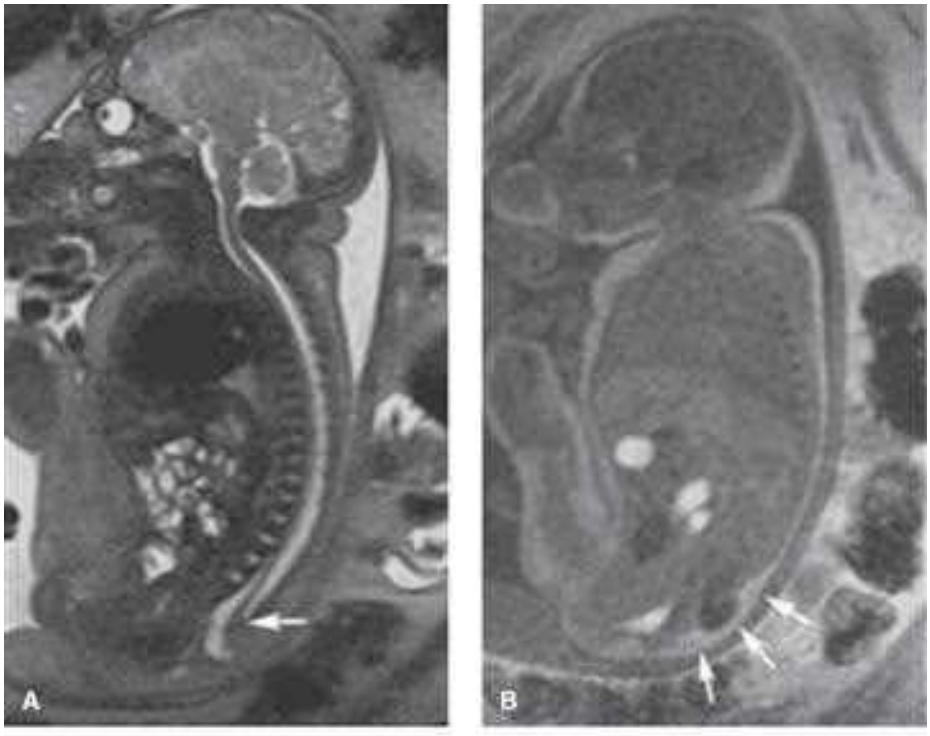


Another fetal MR imaging indication is evaluation of suspected intraventricular hemorrhage (IVH). Fetal IVH risk factors include atypical-appearing ventriculomegaly, neonatal alloimmune thrombocytopenia, and a monochorionic multifetal gestation complicated by demise of one fetus or by severe twin-twin transfusion syndrome (Hu, 2006). If hemorrhage is seen, MR imaging characteristics may indicate which structures are involved and approximately when bleeding occurred. In the setting of congenital fetal infections, MR imaging can delineate the variable degrees of neural parenchymal abnormality and subsequent maldevelopment (Soares de Oliveira-Szejnfeld, 2016).

Aside from cerebral structure, suspected spinal dysraphisms, including neural-tube defects, can also be further characterized for surgical planning. Figure 10-56 demonstrates a complex skin-covered dysraphism with associated tethering of the spinal cord. This terminal myelocystocele will benefit from early intervention following delivery.

FIGURE 10-56

Terminal myelocystocele, 36 weeks' gestation. **A.** In this sagittal T2-weighted image, the spinal cord is tethered, expanding into the terminal cyst (*arrow*). **B.** Seen in this T1-weighted image, the meningocele and terminal cyst are covered by subcutaneous fat (*arrows*) and skin.

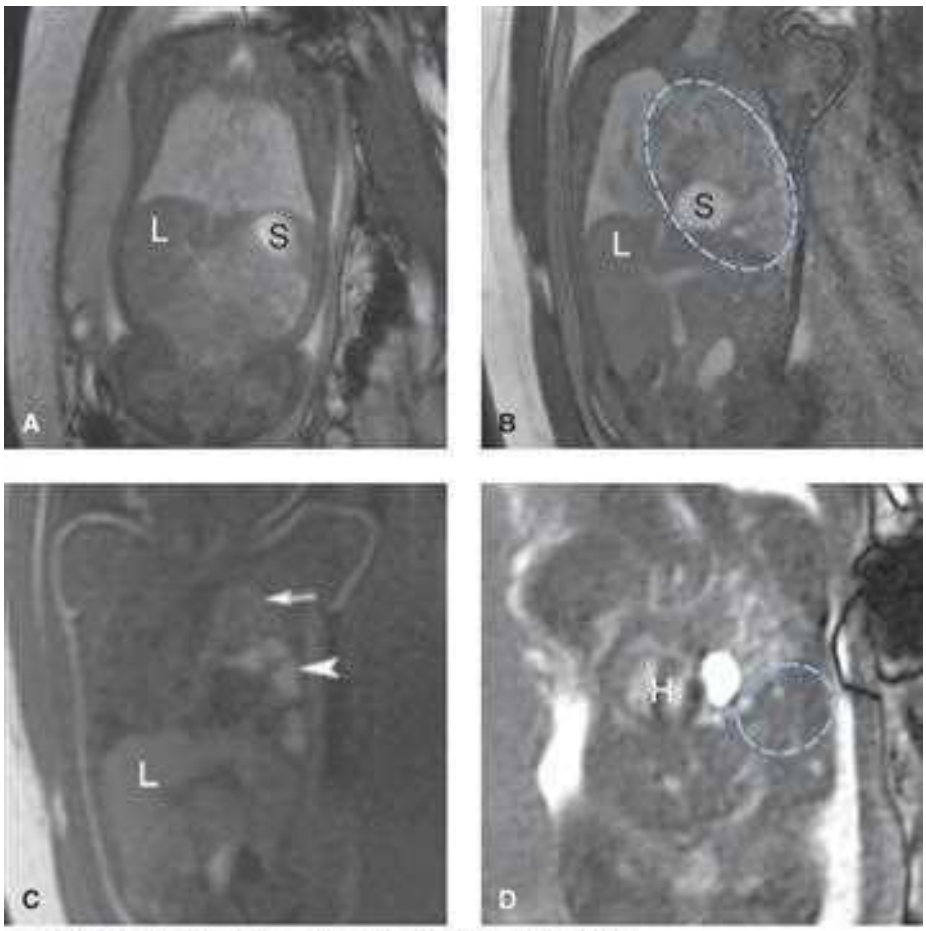


Thorax

Many thoracic abnormalities are readily seen with targeted sonography. MR imaging, however, may help delineate the location and size of space-occupying thoracic lesions and quantify remaining lung tissue volumes. MR imaging can aid in characterizing the type of congenital cystic adenomatoid malformation and in visualizing the blood supply of pulmonary sequestration (Heart). With congenital diaphragmatic hernia, MR imaging can help verify and quantify the abdominal organs within the thorax. This includes the volume of herniated liver and compressed lung tissue volumes (Fig. 10-57) (Debus, 2013; Lee, 2011; Mehollin-Ray, 2012). Also in fetuses with diaphragmatic hernia, MR imaging can assist in identifying other organ-system abnormalities, which may greatly affect fetal prognosis (Kul, 2012). MR imaging similarly is used for chest evaluation in skeletal dysplasia and to measure lung volumes in pregnancies with prolonged oligohydramnios secondary to renal disease or ruptured membranes (Messerschmidt, 2011; Zaretsky, 2005).

FIGURE 10-57

A. Coronal image of normal lungs on a balanced sequence at 29 weeks' gestation. The liver (*L*) and stomach (*S*) lie below the diaphragm. **B.** Left-sided congenital diaphragmatic hernia (CDH) (*dotted ellipse*) seen on balanced sequence at 33 weeks. **C.** The T1-weighted sequence confirms the subdiaphragmatic position of the liver and better delineates the small bowel (*arrow*) and meconium-containing colon (*arrowhead*) that have herniated into the chest. **D.** Another image of a left-sided CDH at 22 weeks demonstrates no normal lung, the heart (*H*) displaced into the right chest, and an elevated liver (*dotted ellipse*).



Abdomen

When sonographic viewing of fetal abdominal abnormalities is limited by oligohydramnios or maternal obesity, MR imaging may add value (Caire, 2003). Hawkins and coworkers (2008) found that lack of signal in a contracted fetal bladder on T2-weighted sequences was associated with lethal renal abnormalities (Fig. 10-58). Differences in signal characteristics between meconium in the fetal colon and urine in the bladder may permit definition of cystic abdominal abnormalities (Farhataziz, 2005). Given the predictable pattern of meconium accumulation within the gastrointestinal tract and high signal intensity on T1-weighted sequences, MR imaging is a complementary tool in diagnosing gastrointestinal abnormalities and complex cloacal malformations (Furey, 2016). Peritoneal calcifications related to meconium peritonitis are more readily apparent sonographically, whereas pseudocysts and resultant abnormalities of meconium migration are better delineated with MR imaging.

FIGURE 10-58

A. Sagittal short T1 inversion recovery (STIR) image through a fetus with posterior urethral valve at 23 weeks' gestation. Notice the characteristic dilation of the posterior urethra (*arrowhead*). **B.** At 31 weeks, a coronal image shows progression of severe hydronephrosis, cystic changes in the parenchyma, hydroureter, and anhydramnios. The lungs (*L*) show a decreased signal and are small. **C.** An axial balanced sequence shows a distended bladder (*B*) with thickened wall (*arrows*).

Adjunct to Fetal Therapy

As indications for fetal therapy have grown, MR imaging is used preoperatively to outline abnormalities. At some centers, before laser ablation of placental anastomoses for twin-twin transfusion syndrome, MR imaging is performed to assess the fetal brain for IVH or periventricular leukomalacia (Chap. 45, Twin-Twin Transfusion Syndrome) (Hu, 2006; Kline-Fath, 2007). Because of its precision in visualizing brain and spine findings in cases of myelomeningocele, it is often used preoperatively. For sacrococcygeal teratomas, if fetal surgery is considered, MR imaging may identify tumor extension into the fetal pelvis (Avni, 2002; Neubert, 2004; Perrone, 2017). With a fetal neck mass for which an EXIT is considered, MR imaging may help delineate the lesion extent and its effect on the oral cavity, hypopharynx, and trachea (Hirose, 2003; Lazar, 2012; Ogamo, 2005; Shiraishi, 2000). Finally, MR imaging can also calculate a jaw index when an EXIT procedure may be needed for severe micrognathia (MacArthur, 2012; Morris, 2009). Fetal therapy is discussed in Chapter 16 (Ex-Utero Intrapartum Treatment).

Placenta

The clinical importance of identifying women with placenta accreta is discussed in Chapter 41 (Morbidly Adherent Placenta). Sonography is generally used to identify placental invasion into the myometrium, however, MR evaluation is an adjunct for indeterminate cases. Findings concerning for invasion include dark intraplacental bands on T2-weighted images, focal bulging, and placental heterogeneity (Leyendecker, 2012). When used in a complementary role, MR imaging sensitivity is high for detection of placental invasion, although the depth of invasion is difficult to predict. Clinical risk factors and sonographic findings should be taken into account when interpreting MR placental images.

Emerging Concepts

Of these, MR diffusion tensor imaging and tractography may allow further understanding of neural development and more precise definition of abnormality and pathology (Kasprian, 2008; Mitter, 2015). Automatic and semiautomated extraction of quantitative data from MR imaging volumetric acquisitions of fetal brain and placenta may enable subanalyses of massive datasets not previously possible with laborious manual segmentation (Tourbier, 2017; Wang, 2016). Using multiparametric MR of the placenta in vivo will expand our understanding of function and pathology without risk to mother or fetus. Last, although echocardiography will always be paramount in fetal heart assessment, MR imaging may contribute to volumetric cardiac analysis and will further evaluation of the aorta, which is often difficult to completely examine sonographically (Lloyd, 2017).

CHAPTER 11: Amnionic Fluid

It is generally agreed that amniotic fluid represents in great part a transudation from the maternal vessels, but many authorities consider that a portion of it is derived from urinary secretion of the foetus.

—J. Whitridge Williams (1903)

INTRODUCTION

At the time Williams wrote this, the fetal kidney was thought by many to be nonfunctional. Since that time, however, much has been learned of this complex multifunctional *liquor amnii*. Amnionic fluid serves several roles during pregnancy. Fetal breathing of amnionic fluid is essential for normal lung growth, and fetal swallowing permits gastrointestinal (GI) tract development. Amnionic fluid also creates a physical space for fetal movement, which is necessary for neuromusculoskeletal maturation. It further guards against umbilical cord compression and protects the fetus from trauma. Amnionic fluid even has bacteriostatic properties. Abnormalities of volume may result from fetal or placental pathology—indicating a problem with fluid production or its circulation. These volume extremes may be associated with increased risks for adverse pregnancy outcome.

NORMAL AMNIONIC FLUID VOLUME

Amnionic fluid volume increases from approximately 30 mL at 10 weeks to 200 mL by 16 weeks and reaches 800 mL by the mid-third trimester (Brace, 1989; Magann, 1997). The fluid is approximately 98-percent water. A full-term fetus contains roughly 2800 mL of water and the placenta another 400 mL, such that the term uterus holds nearly 4 liters of water (Modena, 2004). Abnormally decreased fluid volume is termed *oligohydramnios,* whereas abnormally increased fluid volume is termed *hydramnios* or *polyhydramnios.*

Physiology

Early in pregnancy, the amnionic cavity is filled with fluid that is similar in composition to extracellular fluid. During the first half of pregnancy, transfer of water and other small molecules takes place across the amnion—*transmembranous flow;* across the fetal vessels on placental surface—*intramembranous flow*; and *transcutaneous flow*—across fetal skin. Fetal urine production begins between 8 and 11 weeks' gestation, but it does not become a major component of amnionic fluid until the second trimester, which explains why fetuses with lethal renal abnormalities may not manifest severe oligohydramnios until after 18 weeks. Water transport across the fetal skin continues until keratinization occurs at 22 to 25 weeks. This explains why extremely preterm neonates can experience significant fluid loss across their skin.

With advancing gestation, four pathways play a major role in amnionic fluid volume regulation (Table 11-1). First, fetal urination is the primary source of amnionic fluid in the second half of pregnancy. By term, fetal urine production may exceed 1 liter per day, and the entire amnionic fluid volume is recirculated on a daily basis. Fetal urine osmolality is similar to that of amnionic fluid and significantly hypotonic to that of maternal and fetal plasma. Specifically, the osmolality of maternal and fetal plasma approximates 280 mOsm/mL, whereas that of amnionic fluid is about 260 mOsm/L. The hypotonicity of amnionic fluid accounts for significant *intramembranous* fluid transfer across and into fetal vessels on the placental surface. This transfer reaches 400 mL per day and is a second regulator of fluid volume (Mann, 1996). In the setting of maternal dehydration, the resultant increase in maternal osmolality favors fluid transfer from the fetus to the mother, and then from the amnionic fluid compartment into the fetus (Moore, 2010).

TABLE 11-1

Amnionic Fluid Volume Regulation in Late Pregnancy

Pathway	Effect on Volume	Approximate Daily Volume (mL)
Fetal urination	Production	1000
Fetal swallowing	Resorption	750
Fetal lung fluid secretion	Production	350
Intramembranous flow across fetal vessels on the placental surface	Resorption	400
Transmembranous flow across amnionic membrane	Resorption	Minimal

Data from Magann, 2011; Modena, 2004; Moore, 2010.

An important third source of amnionic fluid regulation is the respiratory tract. Approximately 350 mL of lung fluid is produced daily late in gestation, and half of this is immediately swallowed. Last, fetal swallowing is the primary mechanism for amnionic fluid resorption and averages 500 to 1000 mL per day (Mann, 1996). Impaired swallowing, secondary to either a central nervous system abnormality or GI tract obstruction, can result in an impressive degree of hydramnios. The remaining pathways are transmembranous and transcutaneous flow, which together account for a far smaller proportion of fluid transport in the second half of pregnancy.

Measurement

From a practical standpoint, the actual volume of amnionic fluid is rarely measured outside of the research setting. That said, direct measurement and dye-dilution methods of fluid quantification have contributed to our understanding of normal physiology. These measurements have further been used to validate sonographic fluid assessment techniques. Dye dilution involves injecting a small quantity of a dye such as aminohippurate into the amnionic cavity under sonographic guidance and then sampling the amnionic fluid to determine the dye concentration and hence to calculate the volume.

Brace and Wolf (1989) reviewed 12 studies done through the 1960s in which amnionic fluid volume was assessed using these measurement techniques. Although fluid volume increased across gestation, they found that the mean value did not change significantly between 22 and 39 weeks—it was approximately 750 mL. There was considerable variation at each week of gestation, especially in the mid-third trimester, when the 5th percentile was 300 mL and the 95th percentile nearly 2000 mL. In contrast, Magann and colleagues (1997), using dye-dilution measurements, found that amnionic fluid volume rose with advancing gestation. Specifically, the average fluid volume was approximately 400 mL between 22 and 30 weeks, doubling thereafter to a mean of 800 mL. The volume remained at this level until 40 weeks and then declined by approximately 8 percent per week. The two reports differed in the regression methodology employed, and despite different conclusions, both identified a wide normal range, particularly in the third trimester. This normal variation is similarly observed sonographically.

Sonographic Assessment

Amnionic fluid volume evaluation is a component of every standard sonogram performed in the second or third trimester (Chap. 10, Amnionic Fluid Volume). It may be measured using either of two semi-quantitative techniques, the single deepest pocket of fluid or the amnionic fluid index (AFI), which was described by Phelan and associates (1987). Both measurements are reproducible and, in the setting of a fluid abnormality, can be followed serially over time to assess trends and to aid communication among providers. For these reasons, semiquantitative assessment of amnionic fluid is preferred to qualitative or subjective estimation (American College of Obstetricians and Gynecologists, 2016). Using either technique, a fluid pocket must be at least 1 cm in width to be considered adequate. Fetal parts or loops of umbilical cord may be visible in the pocket, but they are not included in the measurement. Color Doppler is generally used to verify that umbilical cord is not within the measurement.

Single Deepest Pocket

This is also called the largest or *maximal vertical pocket* of amnionic fluid. The ultrasound transducer is held perpendicular to the floor and parallel to the long axis of the woman. Then, while scanning in the sagittal plane, the largest vertical pocket of fluid is identified and measured. *The single deepest pocket measurement is considered normal if above 2 cm and less than 8 cm, with values below and above this range indicating oligohydramnios and hydramnios, respectively.* These thresholds are based on data from Chamberlain and associates (1984) and correspond to the 3rd and 97th percentiles. When evaluating twin pregnancies and other multifetal gestations, a single deepest pocket of amnionic fluid is assessed in each gestational sac, again using a normal range of more than 2 cm to less than 8 cm (Hernandez, 2012; Society for Maternal-Fetal Medicine, 2013). The fetal biophysical profile

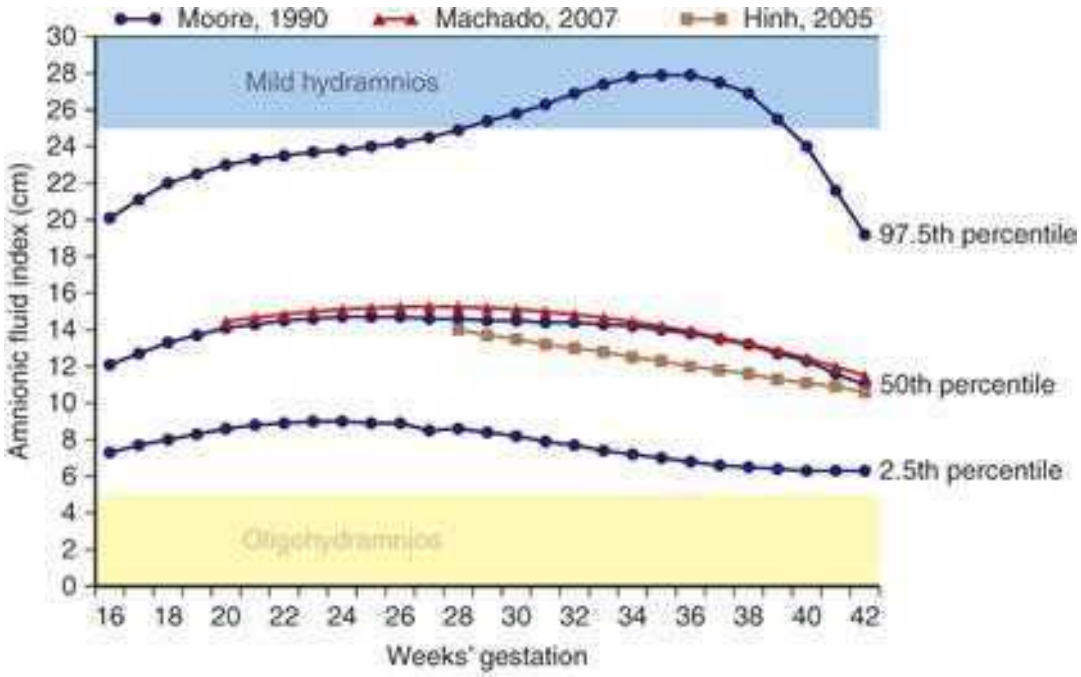
similarly uses a single deepest vertical pocket threshold of more than 2 cm to indicate normal amnionic fluid volume. This is discussed further in Chapter 17 (Acoustic Stimulation Tests).

Amnionic Fluid Index

As with the single deepest fluid pocket measurement, the ultrasound transducer is held perpendicular to the floor and parallel to the long axis of the woman. The uterus is divided into four equal quadrants—the right and left upper and lower quadrants, respectively. The AFI is the sum of the single deepest pocket from each quadrant. The intraobserver variability of the AFI approximates 1 cm, and the interobserver variability is about 2 cm. Variations are larger when fluid volumes are above the normal range (Moore, 1990; Rutherford, 1987). A useful guideline is that the AFI approximates three times the single deepest pocket of fluid (Hill, 2003).

Determination of whether the AFI is normal may be based on either a static numerical threshold or a gestational age-specific percentile reference range. The AFI is generally considered normal if greater than 5 cm and below 24 or 25 cm. Values outside these ranges indicate oligohydramnios and hydramnios, respectively. The upper threshold of 24 cm is used in consensus documents (American College of Obstetricians and Gynecologists, 2016; Reddy, 2014). The 25-cm threshold is often applied in research studies (Khan, 2017; Luo, 2017; Pri-Paz, 2012). Moore and Cayle (1990) have provided normal curves for AFI values based on a cross-sectional evaluation of nearly 800 uncomplicated pregnancies. The mean AFI was found to be between 12 and 15 cm from 16 weeks until 40 weeks' gestation. Other investigators have published nomograms with similar mean values (Hinh, 2005; Machado, 2007). Figure 11-1 depicts these AFI nomogram reference values in relation to commonly used thresholds for hydramnios and oligohydramnios.

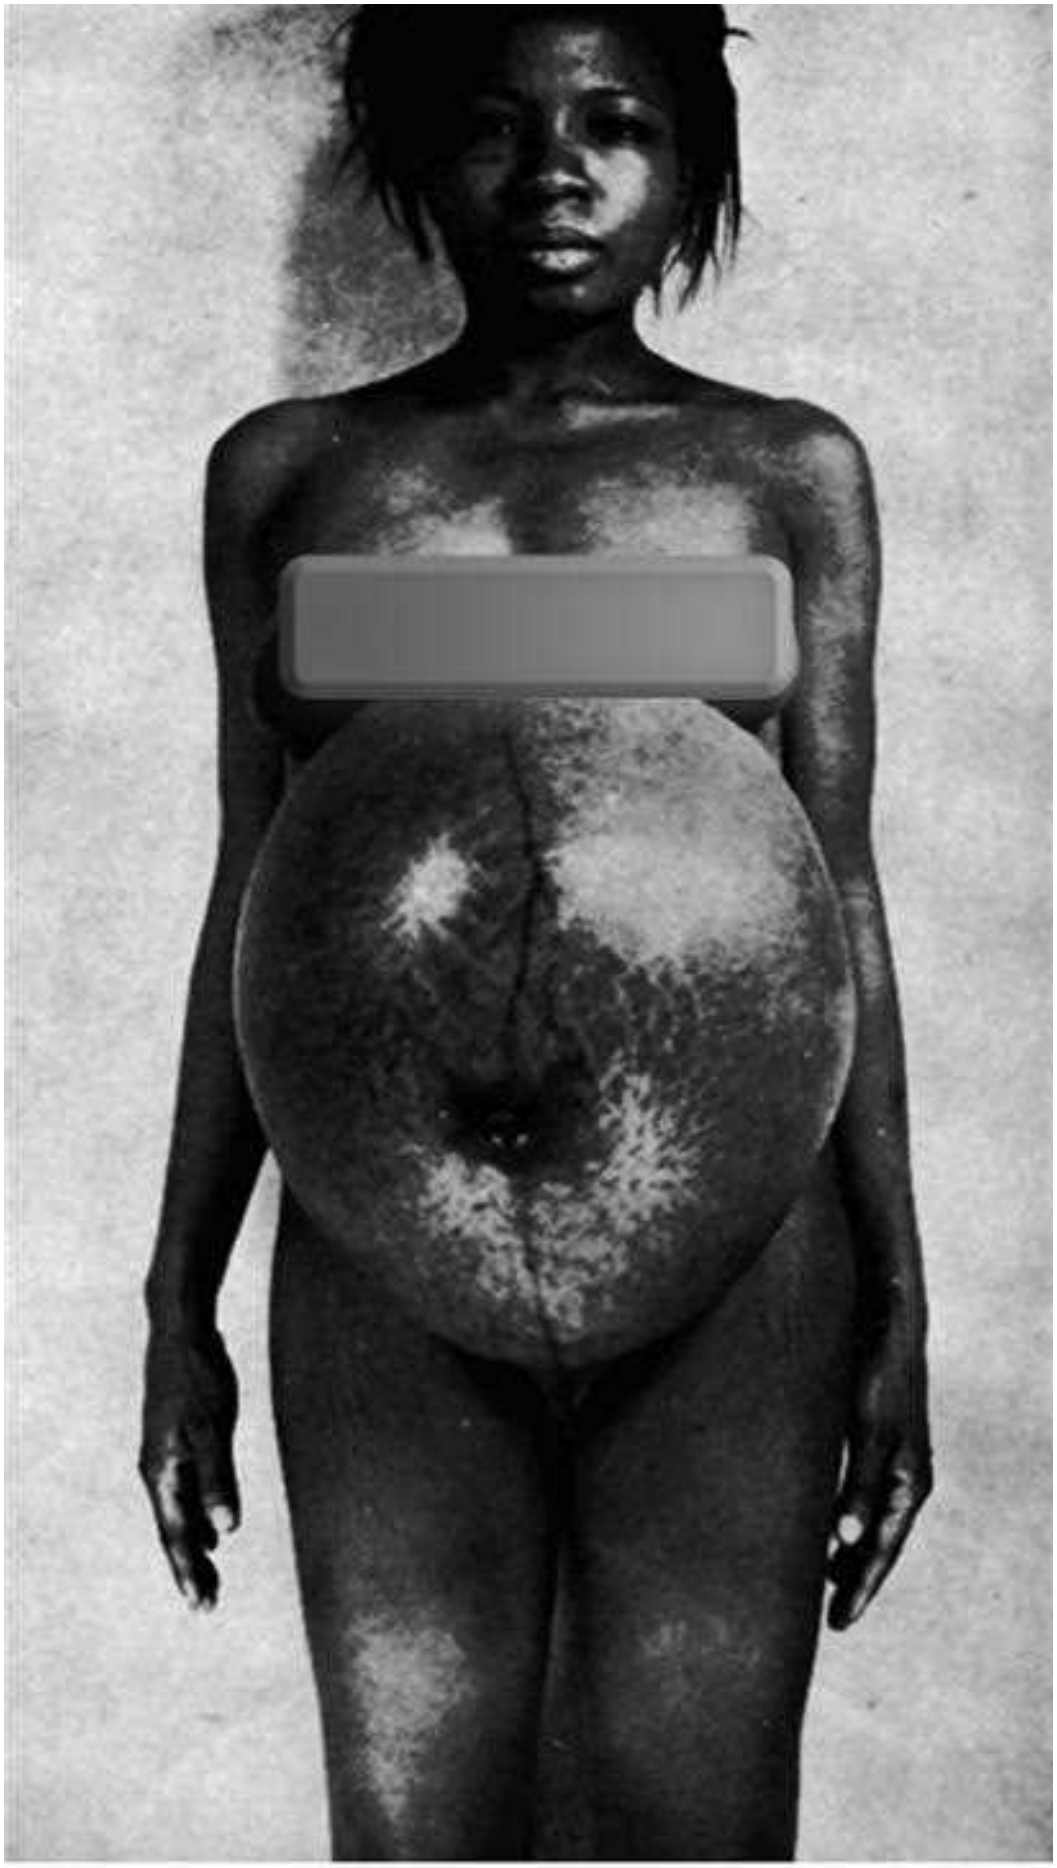
FIGURE 11-1
Amnionic fluid index (AFI) according to gestational-age-specific and threshold values. The blue curves represent the 2.5th, 50th, and 97.5th AFI percentile values, based on the nomogram by Moore (1990). Red and tan curves represent 50th percentile values for AFI from Machado (2007) and from Hinh and Ladinsky (2005), respectively. The light blue and yellow shaded bars indicate threshold values used to define hydramnios and oligohydramnios, respectively.



HYDRAMNIOS

This is an abnormally increased amnionic fluid volume, and it complicates 1 to 2 percent of singleton pregnancies (Dashe, 2002; Khan, 2017; Pri-Paz, 2012). It is more frequently noted in multifetal gestations (Hernandez, 2012). Hydramnios may be suspected if the uterine size exceeds that expected for gestational age. The uterus may feel tense, and palpating fetal small parts or auscultating fetal heart tones may be difficult. An extreme example is shown in Figure 11-2.

FIGURE 11-2
Severe hydramnios—5500 mL of amnionic fluid was measured at delivery.



Hydramnios may be further categorized according to degree. Such categorization is primarily used in research studies to stratify risks. Several groups have termed hydramnios as *mild* if the AFI is 25 to 29.9 cm; *moderate,* if 30 to 34.9 cm; and *severe,* if 35 cm or more (Lazebnik, 1999; Luo, 2016; Odibo, 2016; Pri-Paz, 2012). Mild hydramnios is the most common, comprising approximately two thirds of cases; moderate hydramnios accounts for about 20 percent; and severe hydramnios for approximately 15 percent. Using the single deepest pocket of amnionic fluid, mild hydramnios is defined as 8 to 9.9 cm, moderate as 10 to 11.9 cm, and severe hydramnios as 12 cm or more (Fig. 11-3). In general, severe hydramnios is far more likely to have an underlying etiology and to have consequences for the pregnancy than mild hydramnios, which is frequently idiopathic and benign.

FIGURE 11-3
Sonogram of severe hydramnios at 35 weeks in a pregnancy complicated by fetal aqueductal stenosis. This pocket of amnionic fluid measures >15 cm, and the amnionic fluid index measured nearly 50 cm.

Etiology

Underlying causes of hydramnios include fetal anomalies—either structural abnormalities or genetic syndromes—in approximately 15 percent, and diabetes in 15 to 20 percent (Table 11-2). Congenital infection, red blood cell alloimmunization, and placental chorioangioma are less frequent etiologies. Infections that may present with hydramnios include cytomegalovirus, toxoplasmosis, syphilis, and parvovirus. Hydramnios is often a component of *hydrops fetalis*, and several of the above causes—selected anomalies, infections, and alloimmunization—may result in a hydropic fetus and placenta. The underlying pathophysiology in such cases is complex but is frequently related to a high cardiac-output state. Severe fetal anemia is a classic example. Because the etiologies of hydramnios are so varied, hydramnios treatment also differs and is tailored in most cases to the underlying cause.

TABLE 11-2

Hydramnios: Prevalence and Associated Etiologies—Values in Percent

	Golan (1993) n = 149	Many (1995) n = 275	Biggio (1999) n = 370	Dashe (2002) n = 672	Pri-Paz (2012) n = 655
Prevalence	1	1	1	1	2
Amnionic fluid index					
Mild 25–29.9 cm	—	72	—	66	64
Moderate 30–34.9 cm		20		22	21
Severe >35 cm		8		12	15
Etiology					
Idiopathic	65	69	72	82	52
Fetal anomaly[a]	19	15[a]	8	11[a]	38[a]
Diabetes	15	18	20	7	18

[a]A significant correlation was identified between severity of hydramnios and likelihood of an anomalous infant.

Congenital Anomalies

Selected anomalies and the likely mechanism by which they cause hydramnios are shown in Table 11-3. Many of these abnormalities are depicted and discussed in Chapter 10. Because of this association, targeted sonography is indicated whenever hydramnios is identified. If a fetal abnormality is encountered concurrent with hydramnios, amniocentesis with chromosomal microarray analysis should be offered, because the aneuploidy risk is significantly elevated (Dashe, 2002; Pri-Paz, 2012).

TABLE 11-3

Selected Anomalies and Mechanism for Hydramnios

Mechanism	Anomaly Examples
Impaired swallowing (CNS)	Anencephaly
	Hydranencephaly
	Holoprosencephaly
Impaired swallowing (craniofacial)	Cleft lip/palate
	Micrognathia
Tracheal compression or obstruction	Neck venolymphatic abnormality
	CHAOS[a]
Thoracic etiology (mediastinal shift)	Diaphragmatic hernia[a]
	Cystic adenomatoid malformation[a]
	Pulmonary sequestration[a]
High-output cardiac state	Ebstein anomaly[a]
	Tetralogy of Fallot with absent pulmonary valve[a]
	Thyrotoxicosis[a]
Functional cardiac etiology	Cardiomyopathy, myocarditis[a]
Cardiac arrhythmia	Tachyarrhythmia[a]: atrial flutter, atrial fibrillation, supraventricular tachycardia
	Bradyarrhythmia[a]: heart block
GI obstruction	Esophageal atresia
	Duodenal atresia
Renal-Urinary	Ureteropelvic junction obstruction (“paradoxical hydramnios”)
	Baarter syndrome
Neurological or muscular etiology	Arthrogryposis, akinesia sequence
	Myotonic dystrophy
Neoplastic etiology	Sacrococcygeal teratoma[a]
	Mesoblastic nephroma[a]
	Placental chorioangioma[a]

[a]Poses risk for hydrops.

CHAOS = congenital high-airway obstruction sequence; GI = gastrointestinal.

Importantly, the degree of hydramnios correlates with the likelihood of an anomalous infant (Lazebnik, 1999; Pri-Paz, 2012). At Parkland Hospital, the prevalence of an anomalous neonate was approximately 8 percent with mild hydramnios, 12 percent with moderate hydramnios, and more than 30 percent with severe hydramnios (Dashe, 2002). Even if no abnormality was detected with targeted sonography, the likelihood of a major anomaly identified at birth was 1 to 2 percent if hydramnios was mild or moderate and 10 percent if hydramnios was severe. The overall reported risk that an underlying anomaly will be discovered after delivery has ranged from 9 percent in the neonatal period to 28 percent among infants followed to 1 year of age (Abele, 2012; Dorleijn, 2009). The anomaly risk is particularly high with hydramnios coexistent with fetal-growth restriction (Lazebnik, 1999).

Although amnionic fluid volume abnormalities are associated with fetal malformations, the converse is not usually the case. In the Spanish Collaborative Study of Congenital Malformations that included more than 27,000 anomalous infants, only 4 percent of pregnancies were complicated by hydramnios, and another 3 percent with oligohydramnios (Martinez-Frias, 1999).

Diabetes Mellitus

The amnionic fluid glucose concentration is higher in diabetic women than in those without diabetes, and the AFI may correlate with the amnionic fluid glucose concentration (Dashe, 2000; Spellacy, 1973; Weiss, 1985). Such findings support the hypothesis that maternal hyperglycemia causes fetal hyperglycemia, with resulting fetal osmotic diuresis into the amnionic fluid compartment. That said, rescreening for gestational diabetes in pregnancies with hydramnios does not appear to be beneficial, provided that the second-trimester glucose tolerance test result was normal (Frank Wolf, 2017).

Multifetal Gestation

Hydramnios is generally defined in multifetal gestations as a single deepest amnionic fluid pocket measuring 8 cm or more. It may be further characterized as moderate if the single deepest pocket is at least 10 cm and severe if this pocket is at least 12 cm. In a review of nearly 2000 twin gestations, Hernandez and colleagues (2012) identified hydramnios in 18 percent of both monochorionic and dichorionic pregnancies. As in singletons, severe hydramnios was more strongly associated with fetal abnormalities. In monochorionic gestations, hydramnios of one sac and oligohydramnios of the other are diagnostic criteria for twin-twin transfusion syndrome (TTTS), discussed in Chapter 45 (Twin-Twin Transfusion Syndrome). Isolated hydramnios of one sac also may precede the development of this syndrome (Chon, 2014). In the absence of TTTS, hydramnios does not generally raise pregnancy risks in nonanomalous twins (Hernandez, 2012).

Idiopathic Hydramnios

This accounts for up to 70 percent of cases of hydramnios and is thus identified in as many as 1 percent of pregnancies (Panting-Kemp, 1999; Pri-Paz, 2012; Wiegand, 2016). Idiopathic hydramnios is rarely identified during midtrimester sonography and is often an incidental finding later in gestation. The gestational age at sonographic detection usually lies between 32 and 35 weeks (Abele, 2012; Odibo, 2016; Wiegand, 2016). Although it is a diagnosis of exclusion, an underlying fetal abnormality may subsequently become apparent with advancing gestation, particularly if the degree of hydramnios becomes severe. In the absence of an etiology, idiopathic hydramnios is mild in approximately 80 percent of cases, and resolution is reported in more than a third of affected pregnancies (Odibo, 2016; Wiegand, 2016). Mild, idiopathic hydramnios is most commonly a benign finding, and associated pregnancy outcomes are usually good.

Complications

Unless hydramnios is severe or develops rapidly, maternal symptoms are infrequent. With chronic hydramnios, fluid accumulates gradually, and a woman may tolerate excessive abdominal distention with relatively little discomfort. Acute hydramnios, however, tends to develop earlier in pregnancy. It may result in preterm labor before 28 weeks or in symptoms that become so debilitating as to necessitate intervention.

Symptoms may arise from pressure exerted within the overdistended uterus and upon adjacent organs. When distention is excessive, such as that shown in Figure 11-2, the mother may suffer dyspnea and orthopnea to such a degree that she may be able to breathe comfortably only when upright. Edema may develop as a consequence of major venous system compression by the enlarged uterus, and it tends to be most pronounced in the lower extremities, vulva, and abdominal wall. Rarely, oliguria may result from ureteral obstruction by the enlarged uterus (Chap. 53, Lower Genital Tract Lesions). Maternal complications such as these are typically associated with severe hydramnios from an underlying etiology.

Maternal complications associated with hydramnios include placental abruption, uterine dysfunction during labor, and postpartum hemorrhage. Placental abruption is fortunately infrequent. It may result from the rapid decompression of an overdistended uterus that follows fetal-membrane rupture or therapeutic amnioreduction. With prematurely ruptured membranes, a placental abruption occasionally occurs days or weeks after amniorrhexis. Uterine dysfunction consequent to overdistention may lead to postpartum atony and, in turn, postpartum hemorrhage.

Pregnancy Outcomes

Some outcomes more common with hydramnios include birthweight >4000 g, cesarean delivery, and importantly, perinatal mortality. Pregnancies with idiopathic hydramnios are associated with birthweights exceeding 4000 g in nearly 25 percent of cases, and the likelihood appears to be greater if the hydramnios is moderate or severe (Luo, 2016; Odibo, 2016; Wiegand, 2016). A rationale for this association is that larger fetuses have higher urine output, by virtue of their increased volume of distribution, and fetal urine is the largest contributor to amnionic fluid volume. Cesarean delivery rates are also higher in pregnancies with idiopathic hydramnios, with reported rates of 35 to 55 percent (Dorleijn, 2009; Khan, 2017; Odibo, 2016).

An unresolved question is whether hydramnios alone raises the risk for perinatal mortality. Some studies have found no increase in stillbirth or neonatal death rates with idiopathic hydramnios, whereas others show a greater risk (Khan, 2017; Pilliod, 2015; Wiegand, 2016). Using birth certificate data from the state of California, Pilliod and coworkers (2015) identified hydramnios in 0.4 percent of singleton, nonanomalous pregnancies, and affected pregnancies had significantly greater stillbirth rates. At 37 weeks, the stillbirth risk was sevenfold higher in pregnancies with hydramnios. By 40 weeks, this risk was more than tenfold higher-66 per 10,000 births compared with 6 per 10,000 without hydramnios.

Risks appear to be compounded when a growth-restricted fetus is identified with hydramnios (Erez, 2005). The combination also has a recognized association with trisomy 18. When an underlying cause is identified, degree of hydramnios has been associated with likelihood of preterm delivery, small-for-gestational age newborn, and perinatal mortality (Pri-Paz, 2012). However, *idiopathic* hydramnios is generally not associated with preterm birth (Magann, 2010; Many, 1995; Panting-Kemp, 1999).

Management

As previously noted, treatment is directed to the underlying cause. Occasionally, severe hydramnios may result in early preterm labor or the development of maternal respiratory compromise. In such cases, large-volume amniocentesis—termed *amnioreduction*—may be needed. The technique is similar to that for genetic amniocentesis, described in Chapter 14 (Technique). One difference is that it is generally done with a larger needle, 18- or 20-gauge, and uses either an evacuated container bottle or a larger syringe. Approximately 1000 to 2000 mL of fluid is slowly withdrawn over 20 to 30 minutes, depending on the severity of hydramnios and gestational age. The goal is to restore amnionic fluid volume to the upper normal range. Hydramnios severe enough to necessitate amnioreduction almost invariably has an underlying cause, and subsequent amnioreduction procedures may be required as often as weekly or even semiweekly.

In a review of 138 singleton pregnancies requiring amnioreduction for hydramnios, a fetal GI malformation was identified in 20 percent, a chromosomal abnormality or genetic condition in almost 30 percent, and a neurological abnormality in 8 percent (Dickinson, 2014). In only 20 percent of cases was the hydramnios idiopathic. The initial amnioreduction procedure in this series was performed at 31 weeks' gestation, and the median gestational age at delivery was 36 weeks. Complications within 48 hours of amnioreduction included delivery in 4 percent and ruptured membranes in 1 percent. There was no instance of chorioamnionitis, placental abruption, or bradycardia requiring delivery (Dickinson, 2014).

OLIGOHYDRAMNIOS

This is an abnormally decreased amount of amnionic fluid. Oligohydramnios complicates approximately 1 to 2 percent of pregnancies (Casey, 2000; Petrozella, 2011). When no measurable pocket of amnionic fluid is identified, the term *anhydramnios* may be used. Unlike hydramnios, which is often mild and often confers a benign prognosis in the absence of an underlying etiology, oligohydramnios is always a cause for concern, as discussed in Pregnancy Outcomes.

The sonographic diagnosis of oligohydramnios is usually based on an AFI less than 5 cm or a single deepest pocket of amnionic fluid below 2 cm (American College of Obstetricians and Gynecologists, 2016). Using the Moore nomogram, an AFI threshold of 5 cm is below the 2.5th percentile throughout the second and third trimesters (see Fig. 11-1). Either criterion is considered acceptable. However, use of AFI rather than single deepest pocket will identify more pregnancies as having oligohydramnios, without evidence of improvement in pregnancy outcomes (Kehl, 2016; Nabhan, 2010). When evaluating multifetal pregnancies for TTTS, a single deepest pocket below 2 cm is used to define oligohydramnios (Society for Maternal-Fetal Medicine, 2013).

Etiology

Pregnancies complicated by oligohydramnios include those in which the amnionic fluid volume has been severely diminished since the early second trimester and those in which the fluid volume was normal until near-term or even full-term. The prognosis depends heavily on the underlying cause and thus varies. Whenever oligohydramnios is diagnosed, it becomes an important consideration in clinical management.

Early-Onset Oligohydramnios

When amnionic fluid volume is abnormally decreased from the early second trimester, it may reflect a fetal abnormality that precludes normal urination, or it may represent a placental abnormality sufficiently severe to impair perfusion. In either circumstance, the prognosis is poor. Ruptured membranes should be excluded, and targeted sonography is performed to assess for fetal and placental abnormalities.

Oligohydramnios after Midpregnancy

When amnionic fluid volume becomes abnormally decreased in the late second or in the third trimester, it is very often associated with fetal-growth restriction, with a placental abnormality, or with a maternal complication such as preeclampsia or vascular disease (Table 11-4). The underlying cause in such cases is frequently uteroplacental insufficiency, which can impair fetal growth and reduce fetal urine output. Exposure to selected medications has also been linked with oligohydramnios as discussed subsequently. Investigation of third-trimester oligohydramnios generally includes evaluation for ruptured membranes and sonography to assess fetal growth. Umbilical artery Doppler studies are recommended if growth restriction is identified (Chap. 10, Doppler). Oligohydramnios is commonly encountered in late-term and *postterm pregnancies* (Chap. 43, Placental Dysfunction). Magann and coworkers (1997) found that amnionic fluid volume decreased by approximately 8 percent per week beyond 40 weeks.

TABLE 11-4

Pregnancy Outcomes in Women Diagnosed with Oligohydramnios between 24 and 34 Weeks' Gestation

Factor	AFI ≤5 cm (n = 166)	AFI 8 to 24 cm (n = 28,185)	*p* Value
Major malformation	42 (25)	634 (2)	<.001
Stillbirth	8 (5)	133 (<1)	<.001
Gestational age at delivery[a]	35.1 ± 3.3	39.2 ± 2.0	<.001
Preterm birth, spontaneous[a]	49 (42)	1698 (6)	<.001
Preterm birth, indicated[a]	23 (20)	405 (2)	<.001
Cesarean delivery for nonreassuring fetal status[a]	10 (9)	1083 (4)	<.001
Birthweight <10th percentile[a]	61 (53)	3388 (12)	<.001
<3rd percentile[a]	43 (37)	1130 (4)	<.001
Neonatal death[a]	1 (1)	24 (<1)	<.001[b]

Data expressed as No. (%) and mean ± standard deviation.

[a]Anomalous infants excluded.

[b]This difference was no longer significant after adjustment for gestational age at delivery.

Data from Petrozella, 2011.

Congenital Anomalies

By approximately 18 weeks, the fetal kidneys are the main contributor to amnionic fluid volume. Selected renal abnormalities that lead to absent fetal urine production include bilateral *renal agenesis*, bilateral *multicystic dysplastic kidney*, unilateral renal agenesis with contralateral multicystic dysplastic kidney, and the infantile form of *autosomal recessive polycystic kidney disease*. Urinary abnormalities may also result in oligohydramnios because of fetal *bladder outlet obstruction*. Examples of this are *posterior urethral valves*, *urethral atresia* or *stenosis*, or the *megacystis microcolon intestinal hypoperistalsis syndrome*. Complex fetal genitourinary abnormalities such as *persistent cloaca* and *sirenomelia* similarly may result in a lack of amnionic fluid. Many of these renal and urinary abnormalities are discussed and depicted in Chapter 10 (Renal Pelvis Dilatation). If no amnionic fluid is visible beyond the mid-second trimester due to a genitourinary etiology, the prognosis is extremely poor unless fetal therapy is an option. Fetuses with bladder-outlet obstruction may be candidates for vesicoamnionic shunt placement (Chap. 16, Urinary Shunts).

Medication

Oligohydramnios has been associated with exposure to drugs that block the renin-angiotensin system. These include angiotensin-converting enzyme (ACE) inhibitors, angiotensin-receptor blockers, and nonsteroidal antiinflammatory drugs (NSAIDs). When taken in the second or third trimester, ACE inhibitors and angiotensin-receptor blockers may create fetal hypotension, renal hypoperfusion, and renal ischemia, with subsequent anuric renal failure (Bullo, 2012; Guron, 2000). Fetal skull bone hypoplasia and limb contractures have also been described (Schaefer, 2003). NSAIDs can be associated with

fetal ductus arteriosus constriction and with lower fetal urine production. In neonates, their use may result in acute and chronic renal insufficiency (Fanos, 2011). These agents are discussed in Chapter 12 (Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs).

Pregnancy Outcomes

Oligohydramnios is associated with adverse pregnancy outcomes. Casey and colleagues (2000) found that an AFI ≤5 cm complicated 2 percent of pregnancies undergoing sonography at Parkland Hospital after 34 weeks' gestation. Fetal malformation rates were elevated in those with oligohydramnios. Even in their absence, rates of stillbirth, growth restriction, nonreassuring heart rate pattern, and meconium aspiration syndrome were higher than in nonaffected pregnancies. Petrozella and associates (2011) similarly reported that an AFI ≤5 cm identified between 24 and 34 weeks was associated with increased risks for stillbirth, spontaneous or medically indicated preterm birth, heart rate pattern abnormalities, and growth restriction (see Table 11-4). In one metaanalysis comprising more than 10,000 pregnancies, women with oligohydramnios had a twofold greater risk for cesarean delivery for fetal distress and a fivefold higher risk for an Apgar score <7 at 5 minutes compared with pregnancies with a normal AFI (Chauhan, 1999).

As discussed, evidence suggests that if oligohydramnios is defined as an AFI ≤5 cm rather than a single deepest pocket ≤2 cm, more pregnancies will be classified as such. One review of trials encompassing more than 3200 high-risk and low-risk pregnancies compared outcomes according to which definition was used (Nabhan, 2008). Rates of cesarean delivery, neonatal intensive care unit admission, umbilical artery pH <7.1, or Apgar score <7 at 5 minutes did not differ between groups. Using AFI criteria, however, twice as many pregnancies were diagnosed with oligohydramnios. In this group, there was a doubling of the labor induction rate and a 50-percent increase in the cesarean delivery rate for fetal distress. Kehl and colleagues (2016) performed a prospective trial with more than 1000 term pregnancies in which women with oligohydramnios, defined either by an AFI <5 cm or a single deepest pocket <2 cm, were randomized to labor induction or expectant care. Significantly more pregnancies were diagnosed with oligohydramnios using the AFI criterion—10 percent compared with just 2 percent—when single deepest pocket was used. This led to a higher rate of labor induction in the AFI group, but no difference in neonatal outcomes.

Pulmonary Hypoplasia

When diminished amnionic fluid is first identified before the mid-second trimester, particularly before 20 to 22 weeks, pulmonary hypoplasia is a significant concern. The underlying etiology is a major factor in the prognosis for such pregnancies. Severe oligohydramnios secondary to a renal abnormality generally has a lethal prognosis. If a placental hematoma or chronic abruption is severe enough to result in oligohydramnios—the *chronic abruption-oligohydramnios sequence (CAOS)*—it commonly also causes growth restriction (Chap. 41, Frequency). The prognosis for this constellation is similarly poor. Oligohydramnios that results from membrane rupture in the second trimester is reviewed in Chapter 42 (Considerations with Expectant Management).

Management

Initially, an evaluation for fetal anomalies and growth is essential. In a pregnancy complicated by oligohydramnios and fetal-growth restriction, close fetal surveillance is important because of associated morbidity and mortality (Chap. 44, Management). Oligohydramnios detected before 36 weeks' gestation in the presence of normal fetal anatomy and growth is generally managed expectantly in conjunction with enhanced fetal surveillance. However, evidence of fetal or maternal compromise will override potential complications from preterm delivery. Antepartum management of oligohydramnios may include maternal hydration. In a recent review of 16 trials of pregnancies with apparent isolated oligohydramnios, oral or intravenous hydration was associated with significant improvement in the AFI. However, it was not clear whether this translated into better pregnancy outcomes (Gizzo, 2015).

Amnioinfusion, discussed in Chapter 24 (Management Options), may be used intrapartum to help resolve variable fetal heart rate decelerations. It is not considered treatment for oligohydramnios per se, although the decelerations are presumed secondary to umbilical cord compression resulting from lack of amnionic fluid. Amnioinfusion is not the standard of care for other etiologies of oligohydramnios and is not generally recommended.

"Borderline" Oligohydramnios

The term *borderline AFI* or *borderline oligohydramnios* is somewhat controversial. It usually refers to an AFI between 5 and 8 cm (Magann, 2011; Petrozella, 2011). Through the mid-third trimester, an AFI value of 8 cm is below the 5th percentile on the Moore nomogram (see Fig. 11-1). Petrozella and colleagues (2011) found that pregnancies between 24 and 34 weeks with an AFI between 5 and 8 cm were not more likely than those with an AFI above 8 cm to be complicated by maternal hypertension, stillbirth, or neonatal death. That said, higher rates of preterm delivery, cesarean delivery for a nonreassuring fetal heart rate pattern, and fetal-growth restriction were found. Wood and colleagues (2014) similarly reported a higher rate of fetal-growth restriction in pregnancies with borderline AFI. Thus, results evaluating pregnancy outcomes with borderline AFI have been mixed. Magann and associates (2011) concluded that evidence is insufficient to support fetal testing or delivery in this setting.

CHAPTER 12: Teratology, Teratogens, and Fetotoxic Agents

All infectious diseases have a tendency to bring about death of the child and its subsequent expulsion from the uterus. The fatal result is usually due to the transmission of toxins, and occasionally the specific micro-organisms from the mother to the child. Poisoning with phosphorus, lead, illuminating gas, and other substances may lead to similar results.

—J. Whitridge Williams (1903)

INTRODUCTION

Other than referring to fetal deformities that might impede vaginal delivery, little is written in the first edition of this book regarding teratogens and fetal malformations. This is despite the fact that birth defects are common, and 2 to 3 percent of all newborns have a major congenital abnormality detectable at birth (Cragan, 2009; Dolk, 2010). There are undoubtedly medications that pose significant risk to the developing embryo or fetus (Table 12-1). However, 80 percent of birth defects do not have an obvious etiology, and of those with an identified cause, nearly 95 percent of cases have chromosomal or genetic origins (Feldkamp, 2017). The Food and Drug Administration (FDA) (2005) estimates that less than 1 percent of all birth defects are caused by medications. Their remarkably small contribution to congenital abnormalities is shown in Figure 12-1.

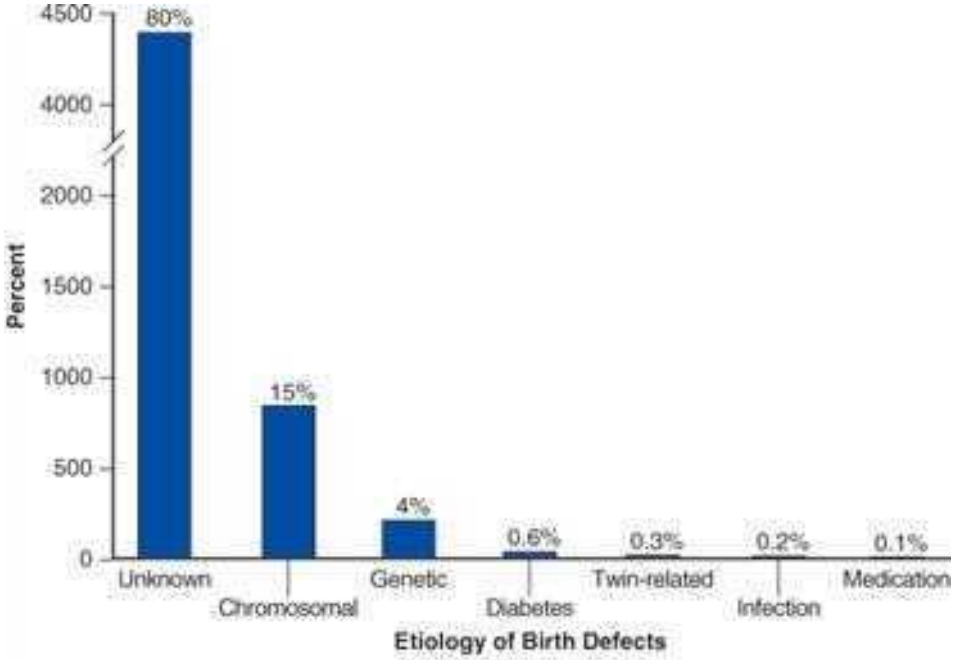
TABLE 12-1

Selected Teratogens and Fetotoxic Agents

Acitretin	
Alcohol	Lithium
Ambrisentan	Macitentan
Angiotensin-converting enzyme inhibitors	Methimazole
Angiotensin-receptor blockers	Mercury
Androgens	Methotrexate
Bexarotene	Misoprostol
Bosentan	Mycophenolate
Carbamazepine	Paroxetine
Chloramphenicol	Phenobarbital
Cocaine	Phenytoin
Corticosteroids	Radioactive iodine
Cyclophosphamide	Ribavirin
Danazol	Tamoxifen
Diethylstilbestrol (DES)	Tetracycline
Efavirenz	Thalidomide
Fluconazole	Tobacco
Isotretinoin	Toluene
Lamotrigine	Topiramate
Lead	Trastuzumab
Leflunomide	Tretinoin
Lenalidomide	Valproic acid
	Warfarin

FIGURE 12-1

Etiology of birth defects. Known and unknown causes of 5504 birth defects from a population-based review of 270,878 births.



That said, significant concern surrounds medication use in pregnancy. This is because so many pregnant women are prescribed medications and because safety data are often lacking. Investigators from the National Birth Defects Prevention Study found that women take an average of two to three medications per pregnancy and that 70 percent use medication in the first trimester (Mitchell, 2011). And, in one review of medications approved by the FDA between 2000 and 2010, the Teratogen Information System (TERIS) advisory board deemed the pregnancy risk "undetermined" for more than 95 percent of these agents (Adam, 2011).

TERATOLOGY

The study of birth defects and their etiology is termed teratology, derived from the Greek *teratos,* meaning monster. A *teratogen* may be defined as any agent that acts during embryonic or fetal development to produce a permanent alteration of form or function. Thus, a teratogen may be a medication or other chemical substance, a physical or environmental factor such as heat or radiation, a maternal metabolite as in diabetes or phenylketonuria, or an infection such as cytomegalovirus. Even obesity is considered a teratogen (Stothard, 2009; Waller, 2007).

Strictly defined, a teratogen causes only structural abnormalities. A *hadegen*—after the god Hades—is an agent that interferes with organ maturation and function, and a *trophogen* alters growth. Substances in the latter two groups typically affect development in the fetal period or after birth, when exposures are often more difficult to document. In most circumstances, the term teratogen is used to refer to all three types of agents.

Criteria for Determining Teratogenicity

The guidelines shown in Table 12-2 were proposed by Shepard (1994) as a framework for discussion and have proven useful for more than 25 years. Although each individual criterion is not required to establish teratogenicity, the following tenets must be considered (Shepard, 2002a):

TABLE 12-2

Criteria for Determining Teratogenicity

Essential Criteria: 1. Careful delineation of clinical cases, particularly if there is a specific defect or syndrome 2. Proof that exposure occurred at critical time during development (see Fig. 12-2) 3. Consistent findings by at least two epidemiological studies with: a. exclusion of bias, b. adjustment for confounding variables, c. adequate sample size (power), d. prospective ascertainment if possible, and e. relative risk (RR) of 3.0 or greater, some recommend RR of 6.0 or greater ***or*** For a rare environmental exposure associated with a rare defect, at least three reported cases. This is easiest if defect is severe
Ancillary Criteria: 4. The association is biologically plausible 5. Teratogenicity in experimental animals is important but not essential 6. The agent acts in an unaltered form in an experimental model

Data from from Shepard 1994, 2002a.

The defect has been completely characterized. This is preferably done by a geneticist or dysmorphologist because various genetic and environmental factors may produce similar anomalies. It is easiest to prove causation when a rare exposure produces a rare defect, when at least three cases with the same exposure have been identified, and when the defect is severe.

The agent must cross the placenta. Although almost all drugs cross the placenta, transport must be of sufficient quantity to directly influence embryonic or fetal development or to alter maternal or placental metabolism to exert an indirect effect. Placental transfer depends on maternal metabolism; on specific characteristics of the drug, such as protein binding and storage, molecular size, electrical charge, and lipid solubility; and on placental metabolism, such as by the cytochrome P_{450} enzyme system. In early pregnancy, the placenta also has a relatively thick membrane that slows diffusion.

Exposure must occur during a critical developmental period.

The *preimplantation period* is the 2 weeks between fertilization and implantation and is known as the “all or none” period. As the zygote undergoes cleavage, an insult damaging a large number of cells typically causes embryonic death. However, if only a few cells are injured, compensation may be possible and allow normal development (Clayton-Smith, 1996). From animal data, insults that appreciably diminish the cell number in the inner cell mass may produce a dose-dependent diminution in body length or size (Iahnaccone, 1987).

The *embryonic period* extends from the second through the eighth week postconception. It encompasses organogenesis and is thus the most crucial period with regard to structural malformations. Critical developmental periods for each organ system are illustrated in Figure 12-2.

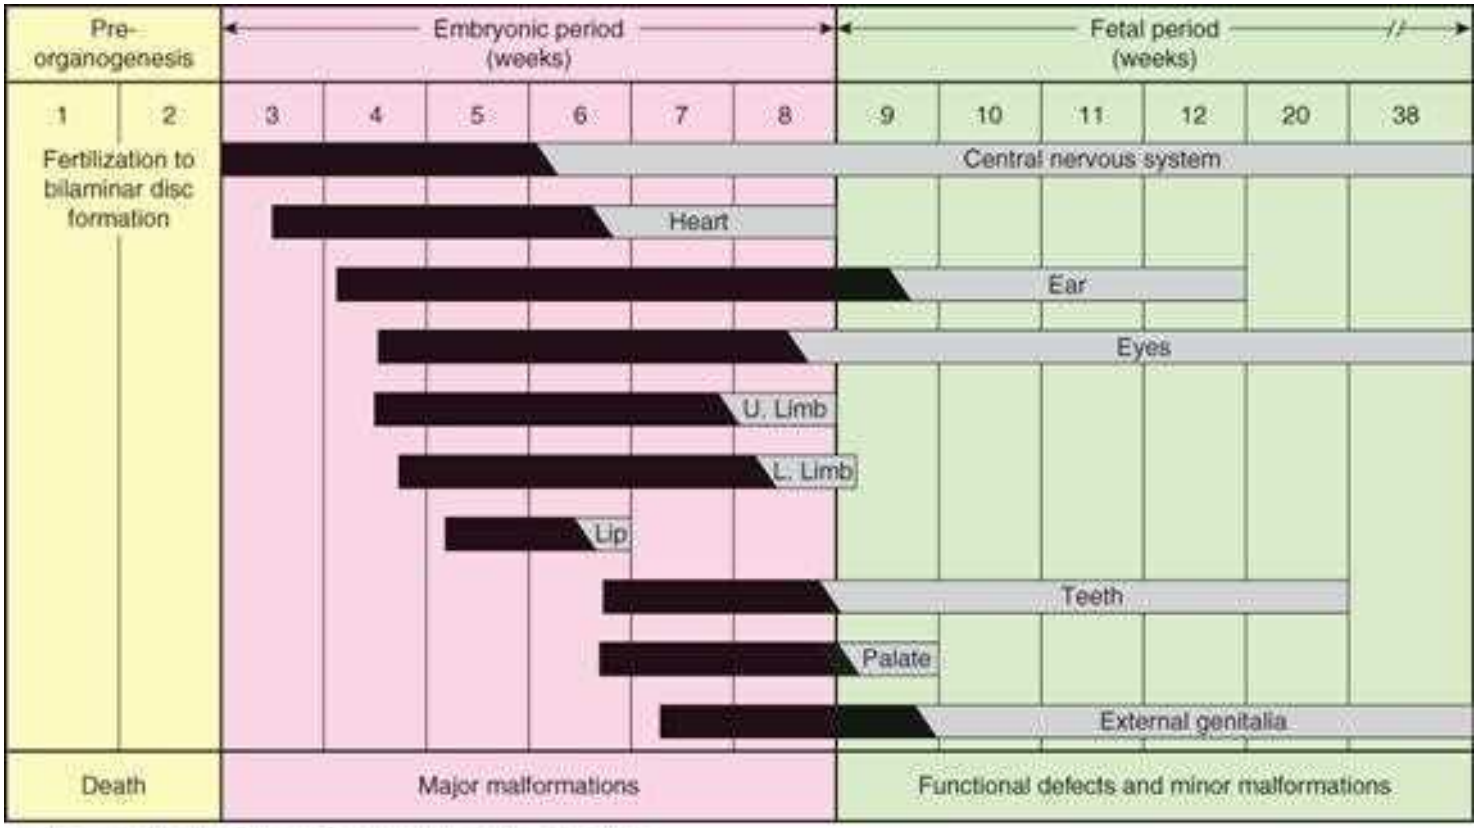
The *fetal period*, which is beyond 8 weeks postconception, is characterized by continued maturation and functional development. During this time, certain organs remain vulnerable.

A biologically plausible association is supportive. Because birth defects and medication exposures are both common, they may be temporally but not causally related.

Epidemiological findings must be consistent. Because initial evaluation of teratogen exposure is often retrospective, it may be hampered by recall bias, inadequate reporting, and incomplete assessment of the exposed population. Potential confounding factors include varying dosages, concomitant drug therapy, and comorbid maternal disease(s). Familial and environmental variables can also influence development of birth defects. Thus, an important criterion for teratogenicity is that two or more high-quality epidemiological studies report similar findings. Finally, a relative risk of *3.0 or greater* is generally considered necessary to support the hypothesis, whereas a lesser risk is interpreted with caution (Khoury, 1992).

The suspected teratogen causes a defect in animal studies. This criterion is not obligatory. In fact, the Teratology Society (2005) states that establishment of causation in teratology-related litigation requires human data.

FIGURE 12-2
Timing of organogenesis during the embryonic period. (Reproduced with permission from Salder TW: Langman’s Medical Embryology, 6th ed. Baltimore, Williams & Wilkins; 1990.)



Failure to employ these tenets and criteria has contributed to erroneous conclusions regarding the safety of some widely used drugs. The poster child for this is the medicolegal fiasco surrounding Bendectin. This antiemetic was a combination of doxylamine and pyridoxine, with or without dicyclomine, and was safe and effective for nausea and vomiting in early pregnancy. More than 30 million women used this drug worldwide, and the 3-percent congenital anomaly rate among exposed fetuses was not different from the background rate (McKeigue, 1994). Despite considerable evidence that this combination of an antihistamine and a B-vitamin is not teratogenic, Bendectin was the target of numerous lawsuits, and the financial burden of defending these forced its withdrawal from the marketplace. As a consequence, hospitalizations for hyperemesis doubled (Koren, 1998). Ironically, the combination of doxylamine and pyridoxine was subsequently remarketed under the brand name Diclegis and was approved by the FDA in 2013.

Studies in Pregnant Women

The study of medication safety—or teratogenicity—in pregnant women is fraught with complications. First, animal studies are considered necessary but insufficient. For example, thalidomide is harmless in several animal species but resulted in phocomelia in thousands of children born across Europe in the late 1950s and early 1960s. Second, medications are rarely approved by the FDA for a pregnancy-related indication. Instead, pregnant women are considered a special population and summarily excluded from medication trials. Last, drug concentration and thus embryo-fetal exposure are affected by pregnancy physiology. These include changes in volume of distribution, cardiac output, gastrointestinal absorption, hepatic metabolism, and renal clearance. In the absence of research trials, counseling is based on case reports or series, case-control studies, cohort studies, and pregnancy registry data.

Case Reports and Series

Many, if not most, major teratogens were first described by clinicians who observed a rare defect occurring after a rare exposure. This has been termed the “astute clinician model” (Carey, 2009). Congenital rubella syndrome was identified in this way by Gregg (1941), an Australian ophthalmologist whose observations challenged the view that the uterine environment was impervious to noxious agents. Other teratogens identified through case series include thalidomide and alcohol (Jones, 1973; Lenz, 1962). Shepard (2002a) recommended that establishment of teratogenicity in this way requires proven exposure at a critical time in development and probably at least three such cases, each carefully delineated. Unfortunately, teratogens are less likely to be identified if the exposure is uncommon, if the defects are relatively nonspecific, or if abnormalities develop in only a small proportion of exposed fetuses. A major limitation of case series is their lack of a control group.

Case-Control Studies

These studies begin with groups of affected infants (cases) and unaffected controls and are structured to allow retrospective assessment of prenatal exposure to particular substances. Case-control studies are an efficient way to study rare outcomes (Alwan, 2015). These permit investigators to evaluate associations and generate useful hypotheses. However, case-control studies have inherent potential for *recall bias.* Namely, parents of an affected infant are often more likely to recall exposure than those whose child is not ill. Confounding by indication is another concern, that is, the indication for the medication

may be the cause of the birth defect. And importantly, birth defect registries have statistical power to detect small differences that may not be clinically meaningful. Grimes and Schulz (2012) have cautioned that unless odds ratios in case-control studies are above three- to fourfold, the observed associations may not be correct.

The National Birth Defects Prevention Study

An excellent example of a population-based case-control study is the National Birth Defects Prevention Study (NBDPS). Funded by Congress and coordinated by the National Center on Birth Defects and Developmental Disabilities, the NBDPS took place between 1997 and 2013 across ten states with active birth defects surveillance programs. Clinical geneticists reviewed each potential case, and standardized telephone interviews were conducted with mothers whose pregnancies were affected or unaffected to obtain information regarding medication exposure and risk factors (Mitchell, 2011; Reefhuis, 2015). Live births, stillbirths, and terminated pregnancies were included and totaled approximately 32,000 cases and nearly 12,000 controls.

The NBDPS has yielded more than 200 scientific manuscripts. It identified novel—although often small—associations between individual birth defects and the following classes of medications: antibiotics, antidepressants, antiemetics, antihypertensives, asthma medications, nonsteroidal antiinflammatory drugs (NSAIDs), and opioids (Ailes, 2016; Broussard, 2011; Fisher, 2017; Hernandez, 2012; Lin, 2012; Munsie, 2011). The NBDPS also found associations between birth defects and exposures such as secondhand smoke, pesticides, and nitrogen oxide, which is a marker of traffic-related air pollution (Hoyt, 2016; Rocheleau, 2015; Stingone, 2017).

The NBDPS did have limitations related to study design. First, interviews were conducted 6 weeks to 2 years following delivery, which raised the likelihood of recall bias. For example, 25 percent of women could not remember which antibiotic they had taken (Ailes, 2016). Another weakness was that only two thirds of women agreed to participate, and there were differences in ethnicity and socioeconomic status between cases and controls. These factors potentially led to selection bias (Reefhuis, 2015). In addition, medical records were not reviewed to verify dosage, and this precluded assessment of dose-response relationships. And a major limitation was that because the NBDPS included only a small number of cases of each birth defect and analyzed them for multiple maternal exposures, it was not possible to adjust for multiple comparisons. As a result, some of the associations observed were likely due to chance (Alwan, 2015). For example, the study of antibiotics and birth defects included 43 comparisons and identified four significant associations, but chance alone predicted that two associations would be identified (Ailes, 2016). Last, the low absolute risk of an abnormality complicates counseling and prenatal management. In many instances, the risk identified by the NBDPS was as low as 1 case per 1000 exposed pregnancies.

Cohort Studies

These studies begin with cohorts of pregnant women who are exposed or unexposed to a particular medication. The percentage of infants or children affected with birth defects is examined in each cohort. Because individual birth defects are rare, cohort studies require a *very* large sample size. Medicaid datasets and private insurance claims databases are commonly used for cohort studies of teratogenicity in the United States (Ehrenstein, 2010). Inability to adjust for confounding variables—such as the indication for which the medication was needed—may be an important limitation of this study design.

Pregnancy Registries

Potentially harmful agents may be monitored by clinicians who prospectively enroll exposed pregnancies in a registry. The FDA (2017b) maintains an active list on their webpage titled Pregnancy Registries. As of 2017, this included registries for 100 individual medications and for medication groups used to treat asthma, autoimmune disease, cancer, epilepsy, human immunodeficiency virus (HIV) infection, and transplant rejection. Similar to case series, exposure registries are hampered by lack of a control group. The prevalence of an abnormality identified through a registry requires knowledge of the baseline prevalence of that anomaly in the population. Investigators typically use a birth defect registry to assess population prevalence. One example is the Metropolitan Atlanta Congenital Defects Program, which is an active surveillance program established in 1967 for fetuses and infants with birth defects.

COUNSELING FOR MEDICATION EXPOSURE

Questions regarding medication and illicit drug use should be part of routine preconceptional and prenatal care. Misinformation is common. Individuals tend to underestimate the background risk for birth defects in the general population and exaggerate potential risks associated with medication exposure. In a recent population-based study of more than 270,000 births from Utah that included 5500 fetuses and infants with major birth defects, only 4 cases were attributed to medication exposure (see Fig. 12-1) (Feldkamp, 2017). And yet, Koren and colleagues (1989) reported that a fourth of women exposed to nonteratogenic drugs thought they had a 25-percent risk for fetal anomalies. Misinformation may be amplified by inaccurate reports in the lay press. Knowledgeable counseling may allay anxiety considerably and may even avert pregnancy termination.

Several sources are available to assist providers with accurate and updated risk information. PubMed is a free tool from the National Center for Biomedical Information that aids rapid search of published research. Online databases, such as Reprotox, TERIS, and Shepard's Online Catalog of Teratogenic Agents, offer reviews of medication risks. They summarize human and animal studies of teratogenicity and fetotoxicity, address the quality of the available evidence, and provide magnitude of risk. Lactmed, a database from the National Library of Medicine, specifically deals with medication use by breastfeeding women. Its entries on specific medications describe levels in breast milk and potential effects on the infant. Finally, with recent changes to the FDA labeling requirements, discussed next, the manufacturer's prescribing information has become increasingly helpful.

The Food and Drug Administration: Letters and Labels

In 1979, the FDA developed a letter classification system in an effort to provide therapeutic guidance for prescribing medications in pregnancy. Five categories—A, B, C, D, and X—were intended to summarize available evidence from human or animal studies of embryonic–fetal risk. These letters also conveyed benefits of the given medication balanced against its potential risks. The system, shown in Table 12-3, was intended to simplify risk–benefit data.

TABLE 12-3

Food and Drug Administration Letter Categories for Drugs and Medications (1979–2015)[a]

Category A:	Studies in pregnant women have not shown an increased risk for fetal abnormalities if administered during the first (second, third, or all) trimester(s) of pregnancy, and the possibility of fetal harm appears remote.
Category B:	Animal reproduction studies have been performed and have revealed no evidence of impaired fertility or harm to the fetus.
	or
	Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus during the first trimester of pregnancy, and there is no evidence of a risk in later trimesters.
Category C:	Animal reproduction studies have shown that this medication is teratogenic (or embryocidal or has other adverse effect), and there are no adequate and well-controlled studies in pregnant women.
	or
	There are no animal reproduction studies and no adequate and well-controlled studies in humans.
Category D:	This medication can cause fetal harm when administered to a pregnant woman. If this drug is used during pregnancy or if a woman becomes pregnant while taking this medication, she should be apprised of the potential hazard to the fetus.
Category X:	This medication is contraindicated in women who are or may become pregnant. It may cause fetal harm.

[a]Medications approved after June 2015 are not assigned a letter category, whereas older medications will have letter categories phased out after this date.

Unfortunately, information regarding medication risk was very often incomplete and led to an overreliance on the definition of the letter category alone. However, a higher letter grade did not necessarily mean greater risk, and drugs in the same category often had very different risks. Very few medications—fewer than 1 percent—had demonstrated safety in human pregnancy (category A), and most had no safety data in human or animal studies (category C). Another difficulty was that the classification system did not address inadvertent exposure, a common reason for counseling. Ultimately, it is the responsibility of the clinician to interpret letter category information in the context of medication dosage and route, timing of exposure during pregnancy, other medications used, and underlying medical condition(s).

To address these deficiencies, new labeling requirements were created and went into effect in 2015. Updates to older medications will be phased in over time (Food and Drug Administration, 2014). With the new requirements, the FDA letter categories have been (or will be) removed from all prescription drug and biological product labeling. The format for providing information includes a summary of risks, clinical considerations, and available data. The pregnancy subsection has registry information, if available, as well as labor and delivery information. For each medication, a lactation subsection—formerly called "nursing mothers"—is included. There is also a section to address potential risks in females and males with reproductive potential.

Presenting Risk Information

In addition to potential embryonic and fetal risks from drug exposure, counseling should discuss the risks and/or genetic implications of the underlying condition for which the drug is given. Risks associated with not treating the condition are also described. Even the manner in which information is presented affects perception. For example, women given negative information—such as a 2-percent chance of a malformed newborn—are more likely to perceive an exaggerated risk than women given positive information—such as a 98-percent chance of an unaffected infant (Jasper, 2001). Instead of citing a higher odds ratio, it may be helpful to provide the *absolute risk* for a particular defect or the *attributable risk*, which is the difference between prevalence in exposed and unexposed individuals (Conover, 2011). The association between oral corticosteroid medications and cleft lip sounds far more concerning when presented as a tripling or 200-percent increase in risk than when described as an increase from 1 per 1000 to 3 per 1000 or as a 99.7-percent likelihood of no cleft development following exposure.

With a few notable exceptions, most commonly prescribed drugs and medications can be used with relative safety during pregnancy. Many drugs discussed in this chapter are *low-risk teratogens*, which are medications that produce defects in fewer than 10 per 1000 maternal exposures (Shepard, 2002a). Because risks conferred by low-risk teratogens are so close to the population background rate of fetal anomalies, they may not be a major factor in deciding whether to discontinue treatment for an important condition (Shepard, 2002b). *Remember that all women have an approximate 3-percent chance of having a newborn with a birth defect.* Although exposure to a confirmed teratogen may elevate this risk, the magnitude of the increase is usually only 1 or 2 percent or at most, doubled or tripled. The concept of risk versus benefit is often central to counseling. Some untreated diseases pose a more serious threat to both mother and fetus than medication exposure risks.

KNOWN AND SUSPECTED TERATOGENS

Considering the thousands of compounds available, relatively few medications and other substances are considered to be major human teratogens. The most common examples are listed in Table 12-1. With few exceptions, in every clinical situation potentially requiring therapy with a known teratogen, alternative drugs can be given with relative safety. Realizing limitations in available evidence, pregnant women should be advised to take any medication only when it is clearly needed. In general, targeted sonography is indicated if there has been exposure to any major teratogen during the embryonic period.

Alcohol

Ethanol is a potent and prevalent teratogen. It is considered the leading cause of preventable developmental disabilities worldwide (Hoyme, 2016). In the United States, 8 percent of pregnant women report drinking alcohol and between 1 and 2 percent admit to binge drinking (Centers for Disease Control and Prevention, 2012).

The fetal effects of alcohol abuse have been recognized since the 1800s. Lemoine (1968) and Jones (1973) and their coworkers are credited with describing the spectrum of alcohol-related fetal defects known as *fetal alcohol syndrome* (Table 12-4). For every child with the syndrome, many more are born with neurobehavioral deficits from alcohol exposure (American College of Obstetricians and Gynecologists, 2013). *Fetal alcohol spectrum disorder* is an umbrella term that includes five conditions attributed to prenatal alcohol damage: (1) fetal alcohol syndrome, (2) partial fetal alcohol syndrome, (3) alcohol-related birth defects, (4) alcohol-related neurodevelopmental disorder, and (5) neurobehavioral disorder associated with prenatal alcohol exposure (Williams, 2015). The birth prevalence of fetal alcohol syndrome is estimated to be as high as 1 percent in the United States (Centers for Disease Control, 2012; Guerri, 2009). But, studies of school children have identified fetal alcohol spectrum disorder in 2 to 5 percent (May, 2009, 2014).

TABLE 12-4

Criteria for Prenatal Alcohol Exposure, Fetal Alcohol Syndrome, and Alcohol-Related Birth Defects

Documented Prenatal Alcohol Exposure—one or more required

1. ≥6 drinks per week for ≥2 weeks
2. ≥3 drinks per occasion for ≥2 occasions
3. Risk identified with a validated screening questionnaire
4. Laboratory testing indicating alcohol intoxication or positive alcohol-exposure biomarker
5. Documentation of an alcohol-related legal or social problem

Fetal Alcohol Syndrome Diagnostic Criteria—all required

1. Dysmorphic facial features (≥2 required)
    a. Short palpebral fissures
    b. Thin vermilion border of the upper lip
    c. Smooth philtrum
2. Prenatal and/or postnatal growth impairment, ≤10th percentile
3. Abnormal brain growth, morphogenesis, or physiology (≥1 required)
    a. Head circumference ≤10th percentile
    b. Structural brain abnormalities
    c. Recurrent nonfebrile seizures
4. Neurobehavioral impairment (defined as >1.5 SD below mean)
    a. Child <3 years: developmental delay
    b. Child ≥3 years: global cognitive impairment, or cognitive deficit in at least 1 neurobehavioral domain, or behavioral deficit in at least 1 domain

Alcohol-Related Birth Defects

Cardiac: atrial or ventricular septal defect, aberrant great vessels, conotruncal heart defects

Skeletal: radioulnar synostosis, vertebral segmentation defects, joint contractures, scoliosis

Renal: aplastic or hypoplastic kidneys, dysplastic kidneys, horseshoe kidney, ureteral duplication

Eyes: strabismus, ptosis, retinal vascular abnormalities, optic nerve hypoplasia

Ears: conductive or neurosensory hearing loss

Data from Hoyme, 2016.

Criteria and Characteristics

Fetal alcohol syndrome has specific criteria (see Table 12-4). These include central nervous system (CNS) abnormalities, pre- or postnatal growth impairment, and a characteristic pattern of minor facial abnormalities (Fig. 12-3). Similar criteria have been established for the other conditions that make up fetal alcohol spectrum disorder (Hoyme, 2016). Prenatal alcohol exposure criteria are also available to assist with assessment.

FIGURE 12-3

Fetal alcohol syndrome. **A.** At 2½ years. **B.** At 12 years. Note persistence of short palpebral fissures, epicanthal folds, flat midface, hypoplastic philtrum, and thin upper vermilion border. (Reproduced with permission from Streissguth AP, Clarren, SK, Jones KL. Natural history of fetal alcohol syndrome: a 10-year follow-up of eleven patients, Lancet. 1985 Jul 13;2(8446):85–91.)

Alcohol-related birth defects include cardiac and renal anomalies, orthopedic problems, and abnormalities of the eyes and ears (see Table 12-4). An association has further been reported between periconceptional alcohol use and omphalocele and gastroschisis (Richardson, 2011). There are no established sonographic criteria for prenatal diagnosis of fetal alcohol syndrome. That said, in some cases, major abnormalities or growth restriction may be suggestive (Paintner, 2012).

Dose Effect

Fetal vulnerability to alcohol is modified by genetic components, nutritional status, environmental factors, coexisting maternal disease, and maternal age (Abel, 1995). The Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics have stressed that *no* amount of alcohol can be considered safe in pregnancy (Williams, 2015). Binge drinking, however, is believed to pose particularly high risk for alcohol-related birth defects and has also been linked to a higher risk for stillbirth (Centers for Disease Control, 2012; Maier, 2001; Strandberg-Larsen, 2008).

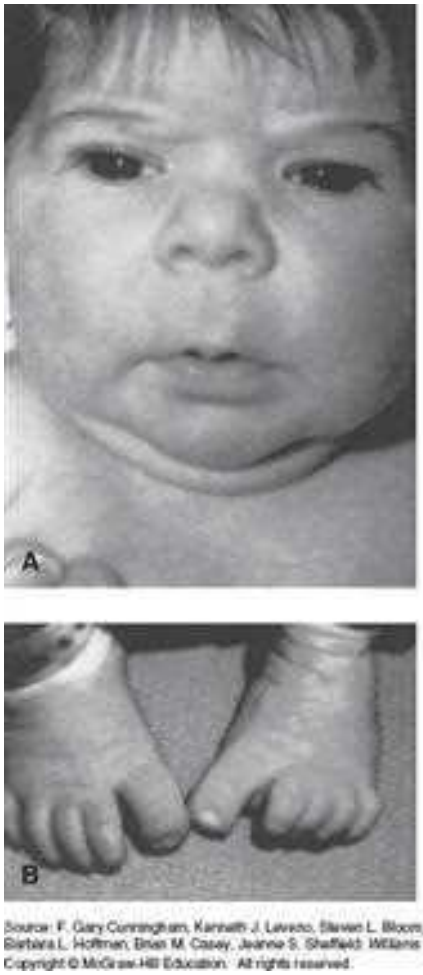
Antiepileptic Medications

Traditionally, women with epilepsy requiring treatment with medication were informed that their risk for fetal malformations was increased. More recent data suggest that the risk may not be as great as once thought, particularly for newer agents. The most frequently reported anomalies are orofacial clefts, cardiac malformations, and neural-tube defects.

Of agents in current use, valproic acid confers the greatest risk (Vajda, 2014). The North American Antiepileptic Drug (NAAED) Pregnancy Registry reported that major malformations developed in 9 percent of fetuses with first-trimester valproate exposure. This included a 4-percent risk for neural-tube defects (Hernandez-Diaz, 2012). School-aged children with in utero exposure to valproic acid have poorer cognitive development—including significantly lower intelligence quotient (IQ) scores—than children exposed to other antiepileptic drugs (Bromley, 2014; Meador, 2009).

Regarding other specific anticonvulsants, one recent metaanalysis identified higher malformation rates among exposed children compared with rates among children born to women with untreated epilepsy. Rates were twofold higher among children exposed to carbamazepine or phenytoin, threefold higher among those exposed to phenobarbital, and fourfold higher among those exposed to topiramate as monotherapy (Weston, 2016). The risk for fetal malformations is approximately doubled if multiple agents are required (Vajda, 2016). Several older anticonvulsants also produce a constellation of malformations similar to the fetal hydantoin syndrome, which is described in Figure 12-4.

FIGURE 12-4
Fetal hydantoin syndrome. **A.** Facial features including upturned nose, mild midfacial hypoplasia, and long upper lip with thin vermilion border. **B.** Distal digital hypoplasia. (Reproduced with permission from Buehler BA1, Delimont D, van Waes M, et al: Prenatal prediction of risk of the fetal hydantoin syndrome, N Engl J Med. 1990 May 31;322(22):1567–1572.)



These risks do not appear to hold for the newer agents levetiracetam and lamotrigine, although the number of reported pregnancies to date is smaller (Mølgaard-Nielsen, 2011; Weston, 2016). The Motherisk Program reviewed eight studies of levetiracetam and concluded that monotherapy was associated with a 2-percent major malformation rate, which is no different from that for the general population (Chaudhry, 2014).

Providers are encouraged to enroll pregnant women treated with antiepileptic medication in the NAAED Pregnancy Registry. Management of epilepsy in pregnancy is discussed in Chapter 60 (Preconceptional Counseling).

Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs

These medications may result in *ACE-inhibitor fetopathy*. Normal renal development depends on the fetal renin-angiotensin system. ACE-inhibitor medication may cause fetal hypotension and renal hypoperfusion, with subsequent ischemia and anuria (Guron, 2000; Pryde, 1993). Reduced perfusion can result in fetal-growth restriction and calvarium maldevelopment, and oligohydramnios may lead to pulmonary hypoplasia and limb contractures (Barr, 1991). Because angiotensin-receptor blockers have a similar mechanism of action, concerns regarding fetotoxicity have been generalized to include this entire medication class.

Concerns were also raised about ACE-inhibitor embryotoxiciy, although these have largely been disproven. In 2006, a review of 29,000 infants from the Tennessee Medicaid database identified a two- to threefold greater risk for neonatal cardiac and CNS abnormalities among the 209 that had prenatal ACE-inhibitor exposure (Cooper, 2006). Subsequent larger studies have not corroborated these observations. First, in a retrospective cohort study of more than 460,000 pregnancies, risks for birth defects were not greater with ACE inhibitors than with other antihypertensive medications (Li, 2011). Similarly, Bateman and coworkers (2017) reviewed 1.3 million pregnancies from the Medicaid Analytic eXtract and found no higher risk for any malformation with ACE-inhibitor exposure after adjusting for confounding factors such as diabetes. Thus, women with inadvertent first-trimester exposure to these medications can be reassured. However, given the many therapeutic options for treating hypertension during pregnancy, discussed in Chapter 50 (Management During Pregnancy), it is recommended that ACE inhibitors and angiotensin receptor-blocking drugs be avoided in pregnancy.

Antifungal Medications

From this class of drugs, fluconazole has been associated with a pattern of congenital malformations resembling the autosomal recessive *Antley-Bixler syndrome*. Abnormalities include oral clefts, abnormal facies, and cardiac, skull, long-bone, and joint abnormalities. Such findings have been reported only with chronic, first-trimester, high-dose treatment at doses of 400 to 800 mg daily.

Regarding low-dose treatment of vulvovaginal candidiasis, the Motherisk Program recently conducted a systematic review of pregnancies with first-trimester fluconazole exposure of 150 or 300 mg in total (Alsaad, 2015). The overall risk for birth defects was not greater, although a small increase in rates of cardiac malformations could not be excluded. A population-based cohort study from Denmark identified a threefold greater risk for tetralogy of Fallot following exposure to low-dose fluconazole (Mølgaard-Nielsen, 2013). The birth prevalence of tetralogy of Fallot rose from 3 to 10 cases per 10,000. This is a risk so low that we would not endorse specialized sonography for this indication. Notably, investigators did not identify increased risks for 14 other birth defects previously associated with exposure to high-dose azole antifungal agents (Mølgaard-Nielsen, 2013).

Antiinflammatory Agents

Nonsteroidal Antiinflammatory Drugs

This drug class includes both aspirin and traditional NSAIDs such as ibuprofen and indomethacin. They exert their effects by inhibiting prostaglandin synthesis. In a report from the NBDPS, at least 20 percent of pregnant women recall first-trimester NSAID use, particularly ibuprofen and aspirin, and such exposure is not a major risk factor for birth defects (Hernandez, 2012).

However, when taken in late pregnancy, indomethacin may cause constriction of the fetal ductus arteriosus and subsequent pulmonary hypertension. Fetal ductal constriction is more likely when the drug is taken in the third trimester for longer than 72 hours. The risk is 15-fold higher among indomethacin-exposed pregnancies (Koren, 2006). The drug also may decrease fetal urine production and amnionic fluid volume (Rasanen, 1995; van der Heijden, 1994; Walker, 1994). In one systematic review, indomethacin tocolysis was associated with neonatal morbidity (Hammers, 2015a,b). Specifically, the risk for bronchopulmonary dysplasia, severe intraventricular hemorrhage, and necrotizing enterocolitis was increased approximately 50 percent (odds ratio 1.5).

With aspirin, a low dosage of 100 mg daily or less does *not* confer a greater risk for constriction of the ductus arteriosus or for adverse infant outcomes (Di Sessa, 1994; Grab, 2000). As with other NSAIDs, however, high-dose aspirin use should be avoided, particularly in the third trimester.

Leflunomide

This is a pyrimidine-synthesis inhibitor used to treat rheumatoid arthritis but is contraindicated in pregnancy. In several animal species, it results in fetal hydrocephalus, eye anomalies, skeletal abnormalities, and embryo death when given at or below human-equivalent doses (Sanofi-Aventis, 2016). The active metabolite, teriflunomide, is detectable in plasma for up to 2 years following discontinuation of the medication. Women who become pregnant while taking leflunomide, and even those of childbearing potential who have discontinued it, are recommended to undergo an accelerated drug elimination procedure with either cholestyramine or activated charcoal (Sanofi-Aventis, 2016). Reassuringly, in a cohort of 60 women with first-trimester leflunomide exposure who completed cholestyramine washout, the rate of birth defects was not increased (Chambers, 2010).

Antimicrobial Drugs

Medications used to treat infections are among those most frequently administered during pregnancy. Over the years, experience has accrued regarding their general safety. With a few exceptions cited below, most of the commonly used antimicrobial agents are considered safe for the embryo-fetus.

Aminoglycosides

Some preterm neonates treated with gentamicin or streptomycin have developed nephrotoxicity and ototoxicity. Despite theoretical concern for potential fetal toxicity, no adverse effects have been demonstrated, and no congenital defects resulting from prenatal exposure have been identified.

Chloramphenicol

This antimicrobial is not considered teratogenic and is no longer routinely used in the United States. More than 50 years ago, a constellation of findings termed the *gray baby syndrome* was described in neonates who received the medication. Preterm newborns were unable to conjugate and excrete the drug and manifested abdominal distention, respiratory abnormalities, an ashen-gray color, and vascular collapse (Weiss, 1960). Chloramphenicol was subsequently avoided in late pregnancy due to theoretical concerns.

Nitrofurantoin

From NBDPS results, first-trimester nitrofurantoin exposure is linked to a twofold risk for cleft lip (Ailes, 2016; Crider, 2009). Considering that the birth prevalence of clefts approximates 1 case per 1000, the likelihood that a nitrofurantoin-exposed fetus would *not* have a cleft would thus be 998 per 1000. For other birth defects, initial associations with this antibiotic did not persist in the final NBDPS cohort (Ailes, 2016).

In one systematic review of nitrofurantoin exposure in pregnancy, results of cohort and case-control studies differed (Goldberg, 2015). Five cohort studies included 9275 exposed pregnancies and nearly 1.5 million unexposed pregnancies, and the review found no higher risk for any malformation. However, among three case-control studies that had nearly 40,000 cases matched with 130,000 controls, the rate of hypoplastic left heart syndrome was threefold greater (Goldberg, 2015). For context, this increase in risk would result in a birth prevalence of fewer than 1 case per 1000 exposed infants. The American College of Obstetricians and Gynecologists (2017e) has concluded that first-trimester nitrofurantoin use is appropriate if no suitable alternatives are available.

Sulfonamides

These drugs are often combined with trimethoprim and used to treat infections during pregnancy. One indication is treatment of methicillin-resistant *Staphylococcus aureus* (MRSA) infection. The NBDPS, which included 107 pregnancies with periconceptional trimethoprim-sulfamethoxazole exposure and birth defects, identified a fivefold greater risk to have offspring with esophageal atresia or diaphragmatic hernia (Ailes, 2016). Similar to findings with nitrofurantoin exposure, this degree of increase would confer a risk of approximately 1 case per 1000 exposed infants for these selected birth defects. However, these findings have not been corroborated by other reports. One review from the Medication Exposure in Pregnancy Risk Evaluation Program included more than 7500 infants with first-trimester exposure to trimethoprim-sulfamethoxazole (Hansen, 2016). Compared with either unexposed infants or those exposed to penicillins or cephalosporins, no greater risk for any congenital abnormality was identified. The American College of Obstetricians and Gynecologists (2017e) considers sulfonamides appropriate for first-trimester use if suitable alternatives are lacking.

Sulfonamides displace bilirubin from protein-binding sites. Thus, if given near the time of preterm delivery, these agents theoretically might worsen neonatal hyperbilirubinemia. However, a population-based review of more than 800,000 births from Denmark found no association between exposure to sulfamethoxazole in late pregnancy and neonatal jaundice (Klarskov, 2013).

Tetracyclines

These drugs are no longer commonly used in pregnant women. They are associated with yellowish-brown discoloration of deciduous teeth when used after 25 weeks' gestation. The risk for subsequent dental caries does not appear greater (Billings, 2004; Kutscher, 1966). In contrast, a recent systematic review of doxycycline in pregnancy identified no higher rates of either birth defects or staining of deciduous teeth (Cross, 2016).

Antineoplastic Agents

Cancer management in pregnancy includes many chemotherapeutic agents generally considered to be at least potentially toxic to the embryo, fetus, or both. For the many novel polyclonal antibody therapies designated as antineoplastics, there are few data concerning their safety. Some risks with these and with other antineoplastic agents are discussed in Chapter 63 (Cancer Therapy in Pregnancy). A few of the more common agents for which experience in pregnancy has accrued are considered next.

Cyclophosphamide

This alkylating agent inflicts a chemical insult on developing fetal tissues and leads to cell death and heritable DNA alterations in surviving cells. Pregnancy loss rates are increased, and reported malformations include skeletal abnormalities, limb defects, cleft palate, and eye abnormalities (Enns, 1999; Kirshon, 1988). Surviving infants may have growth abnormalities and developmental delays. Environmental exposure among health-care workers is associated with a higher risk for spontaneous abortion (Chap. 18, Paternal Factors).

Methotrexate

This folic-acid antagonist is a potent teratogen. It is used for cancer chemotherapy, immunosuppression of autoimmune diseases and psoriasis, nonsurgical treatment of ectopic pregnancy, and medical abortion. It is similar in action to aminopterin, which is no longer used clinically, and can cause defects known collectively as the fetal *methotrexate-aminopterin syndrome*. This includes craniosynostosis with a "clover-leaf" skull, wide nasal bridge, low-set ears, micrognathia, and limb abnormalities (Del Campo, 1999). The embryo is thought to be most vulnerable at 8 to 10 weeks postconception and at dosages of at least 10 mg/week. However, this is not universally accepted (Feldkamp, 1993).

The standard 50 mg/m^2 dose given to treat ectopic pregnancy or to induce elective abortion exceeds this threshold dose. Some reports have suggested an association with cardiac anomalies, particularly conotruncal defects, in intrauterine pregnancies inadvertently treated with methotrexate for suspected ectopic pregnancy (Dawson, 2014; Hyoun, 2012). Thus, ongoing pregnancies after treatment with methotrexate—especially if used in conjunction with misoprostol—raise serious concerns for fetal malformations (Nurmohamed, 2011).

Tamoxifen

This nonsteroidal selective estrogen-receptor modulator (SERM) is used as an adjuvant to treat breast cancer. No pattern of birth defects has been described in limited case reports and series (Braems, 2011). However, tamoxifen has been associated with malformations similar to those caused by diethylstilbestrol (DES) exposure in rodents, including vaginal adenosis. Consequently, women who become pregnant on therapy or within 2 months of its discontinuation should be apprised of the potential long-term risks of a DES-like syndrome.

Trastuzumab

This is a recombinant monoclonal antibody directed to the human epidermal growth factor receptor 2 (HER2) protein. Used to treat breast cancers that express HER2 protein, this drug has not been associated with fetal malformations. However, cases of oligohydramnios sequence resulting in pulmonary hypoplasia, renal failure, skeletal abnormalities, and neonatal deaths have been reported (Genentech, 2017). Surveillance for these complications is recommended for exposed pregnancies and for those treated at any time in the 7 months prior to conception. A trastuzumab pregnancy exposure registry

and a pregnancy pharmacovigilance program have been established to monitor pregnancy outcomes. These warnings also apply to those treated with ado-trastuzumab emtansine.

Antiviral Agents

The number of drugs used to treat viral infections has increased rapidly during the past 20 years. For most, experience in pregnant women is limited.

Ribavirin

This nucleoside analogue is a component of therapy for hepatitis C infection, discussed in Chapter 55 (Hepatitis D). Ribavirin causes birth defects in multiple animal species at doses significantly lower than those recommended for human use. Reported malformations include skull, palate, eye, skeleton, and gastrointestinal abnormalities. The drug has a half-life of 12 days and persists in extravascular compartments following therapy discontinuation. Treated women must use two forms of contraception and have monthly pregnancy tests while on therapy and for 6 months following drug discontinuation (Genentech, 2015). Ribavirin use is also contraindicated in men whose partners are pregnant.

Efavirenz

This is a nonnucleoside reverse transcriptase inhibitor used to treat HIV infection (Chap. 65, Delivery Planning). CNS and ocular abnormalities have been reported in cynomolgus monkeys treated with doses comparable to those used in humans. Several case reports also describe neural-tube defects following human exposure to efavirenz. Reassuringly, the Antiretroviral Pregnancy Registry has identified no increased birth defect rates in more than 800 pregnancies with first-trimester exposure (Bristol-Meyers Squibb, 2017b).

Endothelin-Receptor Antagonists

Bosentan, ambrisentan, and macitentan are three endothelin-receptor antagonists used to treat pulmonary arterial hypertension (Chap. 49, Cardiomyopathies). The endothelin-receptor signaling pathway is important for neural-crest development. Mice deficient in endothelin receptors develop neural-crest cell defects that include craniofacial and cardiac outflow tract abnormalities (de Raaf, 2015). Each of these three agents has been found to cause similar birth defects in multiple animal species (Actelion, 2017). No human data are available. Endothelin-receptor antagonists may be obtained only through restricted access programs, each of which has stringent requirements that include contraception and monthly pregnancy testing (Actelion, 2016, 2017; Gilead, 2015).

Sex Hormones

Some of the functions and effects of male and female hormones on the developing fetus are discussed in Chapter 3 (Sexual Differentiation). It is intuitive that exposure of female fetuses to excessive male sex hormones—and vice versa—might be detrimental.

Testosterone and Anabolic Steroids

Androgen exposure in reproductive-aged women typically stems from anabolic steroid use to accrue lean body mass and muscular strength. Exposure of a female fetus may cause varying degrees of virilization and may result in ambiguous genitalia similar to that encountered in congenital adrenal hyperplasia. Findings can include labioscrotal fusion with first-trimester exposure and phallic enlargement from later fetal exposure (Grumbach, 1960; Schardein, 1980).

Danazol

This ethinyl testosterone derivative has weak androgenic activity. It is used to treat endometriosis, immune thrombocytopenic purpura, migraine headaches, premenstrual syndrome, and fibrocystic breast disease. In a review of inadvertent exposure during early pregnancy, Brunskill (1992) reported that 40 percent of exposed female fetuses were virilized. There was a dose-related pattern of clitoromegaly, fused labia, and urogenital sinus malformation.

Diethylstilbestrol

This medication is included for historical context. From 1940 until 1971, between 2 and 10 million pregnant women were given this synthetic estrogen for ill-advised indications. It was removed from the market after Herbst and associates (1971) reported a series of eight women exposed to DES in utero who developed an otherwise rare neoplasm, vaginal clear-cell adenocarcinoma. With no relationship to drug dosage, the absolute cancer risk approximates 1 case per 1000 DES-exposed fetuses. Twofold greater rates of vaginal and cervical intraepithelial neoplasia were also described (Vessey, 1989).

DES exposure has further been associated with genital tract abnormalities in exposed fetuses of both genders. Women may have a hypoplastic, T-shaped uterine cavity; cervical collars, hoods, septa, and coxcombs; and “withered” fallopian tubes (Goldberg, 1999; Salle, 1996). Some are described and illustrated in Chapter 3 (Diethylstilbestrol Reproductive Tract Abnormalities (Class VII)). Later in life, women exposed in utero have slightly higher rates of earlier menopause and breast cancer (Hoover, 2011). Men may develop epididymal cysts, microphallus, hypospadias, cryptorchidism, and testicular hypoplasia (Klip, 2002; Stillman, 1982).

Immunosuppressant Medications

Some of the immune functions necessary for pregnancy maintenance are discussed in Chapter 5 (Amnion). Given these important interactions, immunosuppressant drugs logically might affect pregnancy.

Corticosteroids

These medications include glucocorticoids and mineralocorticoids, which have antiinflammatory and immunosuppressive actions. They are frequently used to treat serious disorders such as asthma and autoimmune disease. Corticosteroids have been associated with clefts in animal studies. In one metaanalysis of case-control studies by the Motherisk Program, systemic corticosteroid exposure was associated with a threefold increase in the rate of clefts. This is an absolute risk of 3 cases per 1000 exposed fetuses (Park-Wyllie, 2000). A 10-year prospective cohort study by the same group, however, did not identify higher risks for major malformations. Based on these findings, corticosteroids are not considered to represent a major teratogenic risk.

Unlike other corticosteroids, the active metabolite of prednisone, which is prednisolone, is inactivated by the placental enzyme 11β-hydroxysteroid dehydrogenase 2. Thus, it may not effectively reach the fetus.

Mycophenolate Mofetil

This inosine monophosphate dehydrogenase inhibitor, and a related agent, mycophenolic acid, are immunosuppressants. They are used to prevent rejection in organ-transplant recipients and to treat autoimmune disease (Chap. 59, Perinatal Mortality and Morbidity). Mycophenolate is a potent teratogen. From the National Transplantation Pregnancy Registry, of pregnancies in which mycophenolate was not discontinued until after the first trimester, birth defects complicated 30 percent, and another 30 percent spontaneously aborted (King, 2017). One prospective review by the European Network of Teratology Information Services similarly identified a spontaneous loss rate of nearly 30 percent in exposed pregnancies. More than 20 percent of liveborn infants had major anomalies (Hoeltzenbein, 2012).

Many affected infants have a pattern of defects termed *mycophenolate embryopathy.* This includes microtia, auditory canal atresia, clefts, coloboma and other eye anomalies, short fingers with hypoplastic nails, and cardiac defects (Anderka, 2009; Merlob, 2009). A Risk Evaluation and Mitigation Strategy (REMS) has been developed for mycophenolate prescribers who treat women with reproductive potential. REMS are safety strategies mandated by the FDA to help manage known risks associated with a medicine yet still allow patients to have access to the benefits of a given drug.

Radioiodine

Radioactive iodine-131 is used for treatment of thyroid cancer and thyrotoxicosis and for diagnostic thyroid scanning. It is also a component of iodine-131 tositumomab therapy, which is employed to treat a type of non-Hodgkin lymphoma. Radioiodine is contraindicated during pregnancy because it readily crosses the placenta and is then concentrated in the fetal thyroid gland by 12 weeks' gestation. It may cause severe or irreversible fetal and neonatal hypothyroidism, which can lead to decreased mental capacity and delayed skeletal maturation (Jubilant DraxImage, 2016). Pregnancy testing should be performed before administration of radioiodine-131.

Lead

Prenatal lead exposure is associated with fetal-growth abnormalities and with childhood developmental delay and behavioral abnormalities. According to the CDC (2010), no level of lead exposure is considered safe in pregnancy. Care and testing for at-risk pregnancies is discussed in Chapter 9 (Common Concerns).

Mercury

Environmental spills of methyl mercury in Minamata Bay, Japan, and rural Iraq demonstrated that the developing nervous system is particularly susceptible to this heavy metal. Prenatal exposure causes disturbances in neuronal cell division and migration. This leads to a range of defects from developmental delay to microcephaly and severe brain damage (Choi, 1978).

The principal concern for prenatal mercury exposure is the consumption of certain species of large fish (Chap. 9, Common Concerns). The FDA (2017a) advises that pregnant women and breastfeeding mothers avoid consumption of king mackerel, marlin, orange roughy, shark, swordfish, tilefish, and bigeye tuna.

Psychiatric Medications

Treatment of psychiatric illness in pregnancy, including a discussion of the risks and benefits of various psychiatric medications, is described in Chapter 61 (Psychological Adjustments to Pregnancy). Selected birth defects and adverse effects associated with specific medications are presented here.

Lithium

This medication has been associated with Ebstein anomaly, a rare cardiac abnormality that otherwise complicates only 1 per 20,000 births. Ebstein anomaly is characterized by apical displacement of the tricuspid valve, often resulting in severe tricuspid regurgitation and marked right atrial enlargement that confer significant morbidity. A report from the Lithium Baby Registry initially suggested that the risk for Ebstein anomaly was as high as 3 percent. However,

subsequent series have identified an attributable risk for Ebstein anomaly and co-occurring right-sided cardiac anomalies of only 1 to 4 per 1000 exposed pregnancies (Patorno, 2017; Yacobi, 2008). In a review of four case-control studies that included more than 200 infants with Ebstein anomaly, no cases were attributed to lithium exposure (Cohen, 1994).

Neonatal lithium toxicity stems from exposure near delivery. The manufacturer recommends that if possible, the dosage should be decreased or drug discontinued 2 to 3 days prior to delivery to reduce this risk (West-Ward, 2016). Findings typically persist for 1 to 2 weeks and may include neonatal hypothyroidism, diabetes insipidus, cardiomegaly, bradycardia, electrocardiogram abnormalities, cyanosis, and hypotonia (American College of Obstetricians and Gynecologists, 2016).

Selective Serotonin- and Norepinephrine-Reuptake Inhibitors

As a class, these medications are not considered major teratogens (American College of Obstetricians and Gynecologists, 2016). The one exception is paroxetine, which has been associated with a higher risk for cardiac anomalies, particularly atrial and ventricular septal defects. Three large databases—a Swedish national registry, a United States insurance claims database, and the Motherisk Program—each identified a 1.5- to twofold greater risk for cardiac malformations following first-trimester paroxetine exposure (Bar-Oz, 2007; Sebela, 2017). For these reasons, the American College of Obstetricians and Gynecologists (2016) recommends that paroxetine be avoided in women planning pregnancy. Fetal echocardiography should be considered for those with first-trimester paroxetine exposure.

Neonatal effects have been associated with prenatal exposure to selective serotonin-reuptake inhibitors (SSRIs) and selective norepinephrine-reuptake inhibitors (SNRIs). Approximately 25 percent of neonates exposed to SSRIs in late pregnancy manifest one or more nonspecific findings considered to represent poor neonatal adaptation (Chambers, 2006; Costei, 2002; Jordan, 2008). Collectively termed the *neonatal behavioral syndrome*, findings can include jitteriness, irritability, hyper- or hypotonia, feeding abnormalities, vomiting, hypoglycemia, thermoregulatory instability, and respiratory abnormalities. Fortunately, these neonatal behaviors are typically mild and self-limited and last approximately 2 days. Jordan and coworkers (2008) reported that affected newborns were not more likely to require a higher level of care, to experience respiratory abnormalities, or to have prolonged hospitalization. Rarely, neonates exposed to SSRIs in late pregnancy demonstrated more severe adaptation abnormalities (Ornoy, 2017).

Another concern with late-pregnancy exposure is the possible association of SSRI medications with *persistent pulmonary hypertension of the newborn (PPHN)*. The baseline incidence approximates 2 cases per 1000 term newborns. PPHN is characterized by elevated pulmonary vascular resistance with right-to-left shunting and resultant hypoxemia. Two recent population-based cohort studies—together involving more than 5 million pregnancies—identified an attributable risk of only 1 to 2 cases per 1000 births (Huybrechts, 2015; Kieler, 2012). Not only is the risk for this condition quite low, but cases associated with SSRI medication have not been severe (Ornoy, 2017).

Antipsychotic Medications

No antipsychotic medications are considered teratogenic. Exposed neonates can manifest abnormal extrapyramidal muscle movements and withdrawal symptoms that include agitation, abnormally enhanced or diminished muscle tone, tremor, sleepiness, feeding difficulty, and respiratory abnormalities. These findings are nonspecific and transient, similar to the neonatal behavioral syndrome that can follow SSRI exposure. An FDA (2011) alert cites all medications in this class. These include older drugs such as haloperidol and chlorpromazine, as well as newer medications such as aripiprazole, olanzapine, quetiapine, and risperidone.

Retinoids

These vitamin A derivatives are among the most potent human teratogens. Three retinoids available in the United States are highly teratogenic when orally administered—isotretinoin, acitretin, and bexarotene. By inhibiting neural-crest cell migration during embryogenesis, they create a pattern of cranial neural-crest defects—termed *retinoic acid embryopathy*—that involve the CNS, face, heart, and thymus (Fig. 12-5). Specific anomalies may include ventriculomegaly, maldevelopment of the facial bones or cranium, microtia or anotia, micrognathia, cleft palate, conotruncal heart defects, and thymic aplasia or hypoplasia.

FIGURE 12-5
Isotretinoin embryopathy. **A.** Bilateral microtia or anotia with stenosis of external ear canal. **B.** Flat, depressed nasal bridge and ocular hypertelorism. (Used with permission from Dr. Edward Lammer.)

Isotretinoin

13-*cis*-Retinoic acid is a vitamin A isomer that stimulates epithelial cell differentiation and is used for dermatological disorders, especially cystic nodular acne. First-trimester exposure is associated with a high rate of pregnancy loss, and up to a third of fetuses have malformations (Lammer, 1985). The iPLEDGE program is an FDA-mandated REMS for isotretinoin and is found at: www.ipledgeprogram.com. This web-based, restricted-distribution program requires participation for all patients, physicians, and pharmacies to help eliminate embryonic–fetal exposure. Although other countries have instituted similar programs, inadvertent exposure remains a global concern (Crijns, 2011).

Acitretin

This retinoid is used to treat severe psoriasis and was introduced to replace etretinate. The latter is a lipophilic retinoid with such a long half-life (120 days) that birth defects resulted more than 2 years after therapy was discontinued. Although acitretin has a short half-life, it is metabolized to etretinate, and thus remains in the body for prolonged periods (Stiefel Laboratories, 2015). To obviate exposure, the manufacturer of acitretin has developed a pregnancy risk management program. Called "Do Your P.A.R.T"—Pregnancy prevention Actively Required during and after Treatment, this program promotes a delay of conception for at least 3 years following therapy discontinuation.

Bexarotene

This retinoid is used to treat cutaneous T-cell lymphoma. When given to rats in doses comparable to those for human therapy, fetuses developed eye and ear abnormalities, cleft palate, and incomplete ossification. For a woman to receive this medication, the manufacturer requires two forms of contraception that are initiated 1 month before therapy and are continued for 1 month after bexarotene discontinuation. This is coupled with monthly pregnancy testing during treatment (Valeant Pharmaceuticals, 2015). Males who have partners who could become pregnant are advised to use condoms during sexual intercourse while taking bexarotene and for 1 month after discontinuing therapy.

Topical Retinoids

These compounds, initially used to treat acne, have become so popular for the treatment of sun damage that they are called *cosmeceuticals* (Panchaud, 2012). The most commonly used topical agents are tretinoin, isotretinoin, and adapalene. Systemic absorption is low, and this argues against plausible teratogenicity.

Isolated case reports have described malformations following topical tretinoin, and it is unknown whether this is due to variability in absorption or perhaps potential individual susceptibility (Kaplan, 2015). A prospective study by the European Network of Teratology Information Services found no higher rates of birth defects or spontaneous losses, and no case of retinoid embryopathy (Panchaud, 2012). One systematic review by the Motherisk Program included 635 pregnancies with exposure to topical retinoids. Investigators similarly identified no higher risk for congenital malformations, spontaneous abortion, stillbirth, low birthweight, or preterm delivery (Kaplan, 2015). These results may be reassuring to pregnant women with inadvertent exposure.

Notably, the manufacturer of tazarotene cautions that application over a sufficient body surface area could be comparable to oral treatment. Accordingly, its use in pregnancy is not recommended (Allergan, 2017).

Vitamin A

There are two natural forms of vitamin A. Beta-carotene, which is a precursor of provitamin A, is found in fruits and vegetables and has never been shown to cause birth defects (Oakley, 1995). Retinol is preformed vitamin A, which has been associated with cranial neural-crest defects when more than 10,000 IU per day is consumed in the first trimester (Rothman, 1995). It seems reasonable to avoid doses of preformed preparations that exceed the recommended 3000 IU daily allowance (American Academy of Pediatrics, 2017).

Thalidomide and Lenalidomide

Possibly the most notorious human teratogen, thalidomide causes malformations in 20 percent of fetuses exposed between 34 and 50 days menstrual age. The characteristic malformation is *phocomelia*—an absence of one or more long bones. As a result, hands or feet are attached to the trunk, occasionally by a small rudimentary bone. Cardiac malformations, gastrointestinal abnormalities, external ear malformations, eye anomalies, and other limb-reduction defects are also common following thalidomide exposure. The manufacturer reports that up to 40 percent of affected newborns do not survive the neonatal period (Celgene, 2017a).

Thalidomide was marketed outside the United States from 1956 to 1960, before its teratogenicity was appreciated. The ensuing disaster, with thousands of affected children, was instructive of several important teratological principles. First, the placenta is not an effective barrier to the transfer of toxic substances from mother to embryo (Dally, 1998). Second, different species show extreme variability in their susceptibility to drugs and chemicals. Namely, thalidomide produced no defects in multiple rodent species and was assumed to be safe for humans. Last, exposure timing and defect type are often closely related (Vargesson, 2015). For example, upper-limb amelia may develop with thalidomide exposure during days 24 to 30 postconception, upper-limb phocomelia with exposure during days 24 to 33, and lower-limb phocomelia with exposure during days 27 to 33.

Thalidomide was first approved in the United States in 1999 and currently is used to treat erythema leprosum nodosum and multiple myeloma (Celgene, 2017a). The FDA has mandated a web-based, restricted-distribution program for thalidomide, called THALOMID REMS, which is required before patients, physicians, and pharmacies can access the medication.

Lenalidomide is an analogue of thalidomide that is used to treat some types of myelodysplastic syndrome and multiple myeloma. It crosses the placenta in multiple animal species, and it causes thalidomide-like limb abnormalities in monkeys (Celgene, 2017b). Because of obvious teratogenicity concerns, a restricted-distribution program similar to that used for thalidomide has been developed.

Warfarin

This anticoagulant is a vitamin K antagonist with a long half-life. Because of its low molecular weight, it readily crosses the placenta and may cause embryotoxic and fetotoxic effects. Warfarin analogues, such as Coumadin, are considered contraindicated in pregnancy. An exception, as discussed in Chapter 49 (Surgically Corrected Heart Disease), is treatment of women with mechanical heart valves who are at high risk for thromboembolism (Bristol-Myers Squibb, 2017a).

Warfarin embryopathy is characterized by stippled epiphyses and nasal hypoplasia (Fig. 12-6). In one review of 63 cases attributed to warfarin exposure, 80 percent displayed characteristic findings, which include depressed nasal bridge with nasal hypoplasia and choanal atresia, along with stippled epiphyses of the femur, humerus, calcanei, and distal phalanges (Van Driel, 2002). It may result from exposure between the 6th and 9th weeks' gestation (Hall, 1980). The prevalence of the warfarin embryopathy following exposure during this critical period is estimated to be 6 percent (van Driel, 2002). One metaanalysis of cases in which the warfarin dosage was ≤5 mg/d identified embryopathy in 1 percent of exposed fetuses. This suggests that risk may be dose dependent (Hassouna, 2014).

FIGURE 12-6
Warfarin embryopathy or fetal warfarin syndrome: nasal hypoplasia and depressed nasal bridge seen in a fetal sonographic image **(A)** and in the same newborn **(B)**.

If used beyond the first trimester, warfarin may lead to hemorrhage into fetal structures, which can cause abnormal growth and deformation from scarring (Warkany, 1976). Nearly 50 percent of reported embryopathy cases also have CNS anomalies (van Driel, 2002). Abnormalities can include agenesis of the corpus callosum; cerebellar vermian agenesis, which is the Dandy-Walker malformation; microphthalmia; and optic atrophy (Hall, 1980). Affected infants are also at risk for blindness, deafness, and developmental delays.

Herbal Remedies

With various herbal remedies, associated risks are more challenging to estimate because studies are few and because these compounds are not FDA-regulated. The European Committee of Herbal Medicinal Products provides assessment reports and monographs on selected herbal substances and preparations, but safety data are generally limited (Wiesner, 2017). Animal studies have not been conducted, and thus knowledge of complications often derives from reports of acute toxicity (Hepner, 2002; Sheehan, 1998). Further, the identity, quantity, and purity of each ingredient are usually unknown. Given these uncertainties, it seems prudent to counsel pregnant women to avoid these substances. A list of selected herbal compounds and their potential effects is shown in Table 12-5.

TABLE 12-5

Pharmacological Actions and Adverse Effects of Some Herbal Medicines

Herb and Common Name	Relevant Pharmacological Effects	Concerns
Aloe (oral ingestion) Black cohosh	Smooth-muscle stimulant Smooth-muscle stimulant	May cause uterine contractions Causes uterine contractions; also has an estrogenic compound
Blue cohosh	Smooth-muscle stimulant	Causes uterine contractions; contains compounds teratogenic in multiple animal species
Echinacea: *purple coneflower root*	Activates cell-mediated immunity	Allergic reactions; decreases immunosuppressant effectiveness; possible immunosuppression with long-term use
Ephedra: *ma huang*	Direct and indirect sympathomimetic; tachycardia and hypertension	Hypertension, arrhythmias, myocardial ischemia, stroke; depletes endogenous catecholamines; life-threatening interaction with monoamine oxidase inhibitors
Evening primrose oil	Contains linoleic acids, a prostaglandin precursor	Possible complications if used for labor induction
Garlic: *ajo*	Inhibits platelet aggregation; increased fibrinolysis; antihypertensive activity	Risk of bleeding, especially when combined with other platelet aggregation inhibitors
Ginger	Cyclooxygenase inhibitor, thromboxane synthetase inhibitor	Increased risk of bleeding
Ginkgo biloba	Anticoagulant	Risk of bleeding; interferes with monoamine oxidase inhibitors
Ginseng	Lowers blood glucose; inhibition of platelet aggregation	Hypoglycemia; hypertension; risk of bleeding
Kava: *awa, intoxicating pepper, kawa*	Sedation, anxiolysis	Sedation; tolerance and withdrawal
Valerian: *all heal, garden heliotrope, vandal root*	Sedation	Sedation; hepatotoxicity, benzodiazepine-like acute withdrawal
Yohimbe		Hypertension, arrhythmias

Data from Ang-Lee, 2001; Briggs, 2015; Hall, 2012; Wiesner, 2017.

Recreational Drugs

Not uncommonly, fetuses are exposed to one or more illicit drugs. Assessment of outcomes attributable to these drugs may be confounded by factors such as poor maternal health, malnutrition, infectious disease, and polysubstance abuse. Moreover, illegal substances may contain toxic contaminants such as lead, cyanide, herbicides, and pesticides. Impurities added as diluents may independently have serious adverse perinatal effects. As noted in Known and Suspected Teratogens, alcohol is a significant teratogen. Because it is legally obtained and ubiquitous, its use also confounds the study of illicit drug teratogenicity.

Amphetamines

These sympathomimetic amines are not considered to be major teratogens. Methamphetamine enhances dopamine release and blocks its reuptake. It is prescribed to treat attention-deficit/hyperactivity disorder and narcolepsy. Methamphetamine abuse has been rising in the United States since the late 1980s (American College of Obstetricians and Gynecologists, 2017b). In utero exposure has been consistently associated with higher rates of small-for-gestational age newborns (Gorman, 2014; Smith, 2006). Hypertensive complications, placental abruption, preterm birth, and stillbirth are other associated complications (Gorman, 2014). Behavioral abnormalities have been described in both infants and school-aged children (Eze, 2016).

Cocaine

With this CNS stimulant, most adverse outcomes result from its vasoconstrictive and hypertensive effects. Serious potential maternal complications are cerebrovascular hemorrhage, myocardial damage, and placental abruption. Studies of congenital abnormalities and cocaine exposure have yielded conflicting results, but associations with cleft palate, cardiovascular abnormalities, and urinary tract anomalies have been reported (Chasnoff, 1988; Lipshultz, 1991; van Gelder, 2009). Cocaine use is also associated with fetal-growth restriction and preterm delivery. Children exposed as fetuses have risks for behavioral abnormalities and cognitive impairments (Bada, 2011; Gouin, 2011).

Opioids–Narcotics

The dramatic rise in narcotic use among non-pregnant and pregnant individuals has been aptly termed an epidemic. Opioids are not considered to be major teratogens. The NBDPS did identify a slightly greater risk for spina bifida, gastroschisis, and cardiac abnormalities with periconceptional opioid exposure (Broussard, 2011). The American College of Obstetricians and Gynecologists (2017c) stresses that this potential, small increase in birth defects with maintenance therapy should be weighed against the risks associated with uncontrolled opioid abuse. Heroin addiction is associated with adverse pregnancy outcomes from the effects of repeated narcotic withdrawal on the fetus and placenta (American College of Obstetricians and Gynecologists, 2017c). These include preterm birth, placental abruption, fetal-growth restriction, and fetal death.

Neonatal narcotic withdrawal, called the *neonatal abstinence syndrome*, may manifest in 40 to 90 percent of exposed newborns (Blinick, 1973; Creanga, 2012; Dashe, 2002; Zelson, 1973). As discussed in Chapter 33 (Neonatal Abstinence Syndrome), CNS irritability may progress to seizures if untreated and may be accompanied by tachypnea, apneic episodes, poor feeding, and failure to thrive. At-risk neonates are closely monitored using a scoring system, and those severely affected are treated with opioids (Finnegan, 1975). The proportion of exposed newborns developing neonatal abstinence syndrome has risen significantly in recent years (Creanga, 2012; Lind, 2015).

The American College of Obstetricians and Gynecologists (2017c) recommends that pregnant women with opioid-use disorder be maintained on opioid-agonist therapy to reduce the risks associated with illicit opioid abuse and associated behaviors. Treatment includes either methadone, usually through a licensed outpatient opioid treatment program, or buprenorphine, which may be given in an office-based setting by a licensed buprenorphine prescriber. A multidisciplinary treatment program is recommended to reduce the likelihood of additional opioid abuse while on maintenance therapy. The College (2017c) discourages withdrawal from methadone during pregnancy because of high relapse rates. At Parkland Hospital, pregnant opioid users who decline maintenance therapy are offered inpatient hospitalization for controlled methadone taper, with the goal of reducing the likelihood of neonatal abstinence syndrome (Dashe, 2002; Stewart, 2013).

Marijuana

This is the illicit drug most commonly used in pregnancy (American College of Obstetricians and Gynecologists, 2017a). Based on data from the National Survey on Drug Use and Health, the prevalence of marijuana use in pregnancy was nearly 4 percent in 2014 (Brown, 2017). Cannabinoids are not considered to be major teratogens, but there is concern because endogenous cannabinoids play key roles in human brain development. In one metaanalysis of nearly 8000 exposed pregnancies, adverse outcomes such as preterm birth and low birthweight were increased only in the presence of concomitant tobacco use (Conner, 2016).

Miscellaneous Drugs

Phencyclidine (PCP) or angel dust is not associated with congenital anomalies. More than half of exposed newborns, however, experience withdrawal symptoms characterized by tremors, jitteriness, and irritability. *Toluene* is a common solvent used in paints and glue. Occupational exposure is reported to have significant fetal risks (Wilkins-Haug, 1997). When abused by women in early pregnancy, it is associated with *toluene embryopathy*, which is phenotypically similar to fetal alcohol syndrome. Abnormalities include pre- and postnatal growth deficiency, microcephaly, midface hypoplasia, short palpebral fissures, and wide nasal bridge (Pearson, 1994). Up to 40 percent of exposed children have developmental delays (Arnold, 1994).

Tobacco

Cigarette smoke contains a complex mixture of nicotine, cotinine, cyanide, thiocyanate, carbon monoxide, cadmium, lead, and various hydrocarbons (Stillerman, 2008). In addition to being fetotoxic, many of these substances have vasoactive effects or reduce oxygen levels. Tobacco is not considered a major teratogen, although selected birth defects have been reported to occur with greater frequency among newborns of women who smoke. It is plausible that the vasoactive properties of tobacco smoke could produce congenital defects related to vascular disturbances. For example, the prevalence of Poland sequence, which is caused by an interruption in the vascular supply to one side of the fetal chest and ipsilateral arm, is twofold greater in smokers (Martinez-Frias, 1999). A small increased risk for cardiac anomalies has also been reported and may be dose related (Alverson, 2011; Malik, 2008; Sullivan, 2015). One study analyzing more than 6 million births found an association between maternal smoking and hydrocephaly, microcephaly, omphalocele, gastroschisis, cleft lip and palate, and hand abnormalities (Honein, 2001). Electronic nicotine delivery systems are not considered safe, as nicotine may have adverse effects on fetal brain and lung development (American College of Obstetricians and Gynecologists, 2017d).

The best-documented adverse reproductive outcome from smoking is a dose-response reduction in fetal growth. Newborns of mothers who smoke weigh on average 200 g less than newborns of nonsmokers (D'Souza, 1981). Smoking doubles the risk of low birthweight and raises the risk of fetal-growth restriction two- to threefold (Werler, 1997). Even secondhand smoke increases the risk for low birthweight (Hegaard, 2006). Women who stop smoking early in pregnancy may have neonates with normal birthweights (Cliver, 1995). Other adverse outcomes associated with cigarette smoking include preterm birth,

placenta previa, placenta abruption, spontaneous abortion, and sudden infant death syndrome (American College of Obstetricians and Gynecologists, 2017d). Risks of childhood asthma and obesity are also increased.

CHAPTER 13: Genetics

Foetal death may be due to abnormalities in the ovum itself or due to some disease on the part of the mother, and now and again of the father. The death of the foetus is frequently due to abnormalities in the development of the embryo which are inconsistent with foetal life.

—J. Whitridge Williams (1903)

INTRODUCTION

In Williams' first edition of *Obstetrics*, he rarely referenced inherited conditions that Gregor Mendel had described 50 years earlier. Fast-forward to 2017, when the science of genetics is a major obstetrical discipline.

Genetics is the study of genes, heredity, and the variation of inherited characteristics. Medical genetics deals with the etiology and pathogenesis of human diseases that are at least partially genetic in origin, along with their prediction and prevention. Thus, it is closely linked to *genomics*, which is the study of gene function and interaction. In addition to chromosomal, mendelian, and nonmendelian genetic conditions reviewed in this chapter, medical genetics includes prenatal and preimplantation genetic diagnosis, as well as newborn genetic screening, which are discussed in Chapters 14 and 32, respectively.

Genetic disease is common. Between 2 and 3 percent of newborns have a recognized structural defect. In another 3 percent of individuals, a defect is diagnosed by age 5, and another 8 to 10 percent of persons are discovered by age 18 to have one or more functional or developmental abnormalities. Advances in genomics are used increasingly to provide information regarding susceptibility to genetic diseases, and every indication suggests that this field will reshape prenatal diagnosis.

GENOMICS IN OBSTETRICS

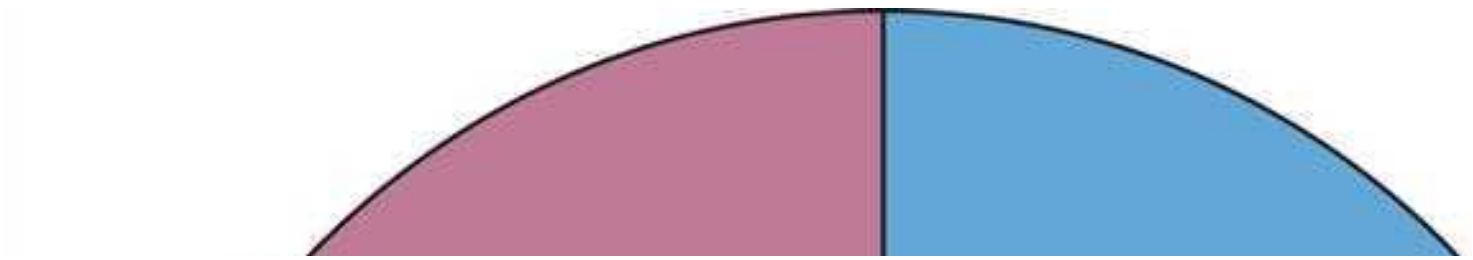
Completed in 2003, the Human Genome Project identified more than 25,000 human genes and led to rapid expansion of genomic research to better understand disease biology (McKusick, 2003). More than 99 percent of our DNA is identical. However, genetic code varies every 200 to 500 base pairs, usually as a single-nucleotide polymorphism. The human genome contains more than 80 million such genetic variants, and understanding their potential role in disease requires not only sophisticated interpretation but also integration of resources (Rehm, 2015).

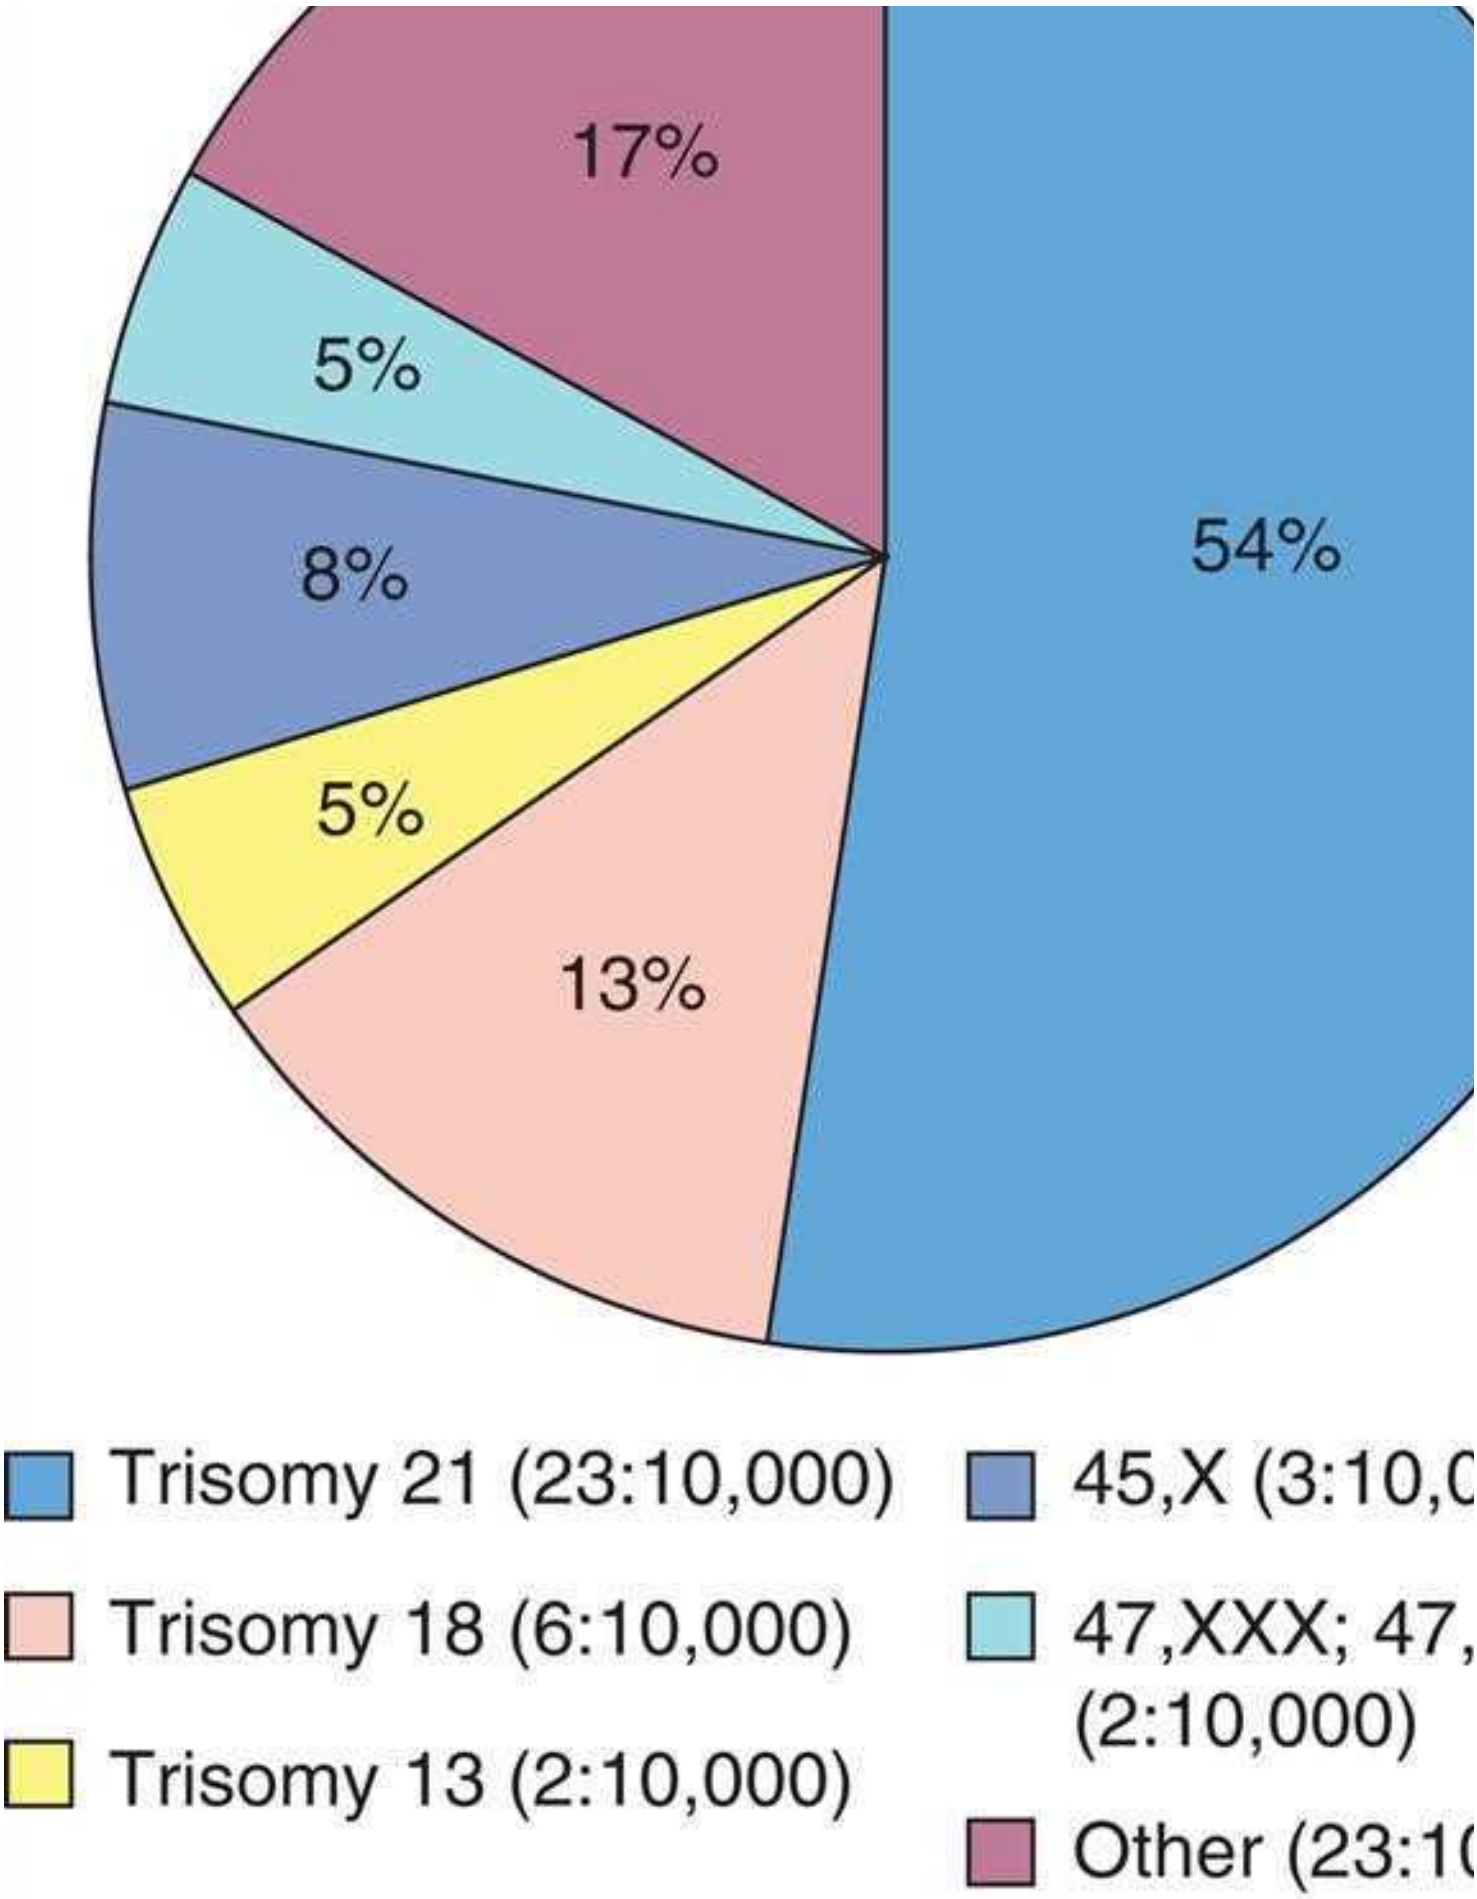
The National Center for Biotechnology Information (NCBI) maintains genetic and genomic databases that are freely accessible to clinicians and researchers. Several of these databases are particularly useful in obstetrics and maternal-fetal medicine practice. The *GeneReviews* database provides in-depth clinical information for nearly 700 genetic conditions, including diagnostic criteria, management, and genetic counseling considerations (National Center for Biotechnology Information, 2017a). The *Genetic Testing Registry (GTR)* database contains information regarding the benefits and limitations of available tests for a given disorder. It lists more than 48,000 genetic tests and instructions for specimen collection and transport to individual laboratories throughout the world (National Center for Biotechnology Information, 2017b). Another database, *Online Mendelian Inheritance in Man* (OMIM), is a comprehensive catalog of human genes and phenotypes that allows clinicians to search for syndromes based on particular traits or abnormalities. As of early 2017, OMIM included more than 15,000 genes and nearly 5000 mendelian and mitochondrial conditions with a known molecular basis (Johns Hopkins University, 2017). The National Library of Medicine (2017) has also established a database of genetic information intended for patients—one that trainees may find especially helpful—the *Genetics Home Reference (GHR)*. This database contains data on more than 2400 genetic conditions and genes, including resources for families.

CHROMOSOMAL ABNORMALITIES

Chromosomal abnormalities figure prominently in genetic disease. Aneuploidy accounts for more than 50 percent of first-trimester miscarriages, approximately 20 percent of second-trimester losses, and 6 to 8 percent of stillbirths and early-childhood deaths (Reddy, 2012; Stevenson, 2004; Wou, 2016). In the European Surveillance of Congenital Anomalies (EUROCAT) network of population-based registries, chromosomal abnormalities were identified in 0.4 percent of births (Wellesley, 2012). Of recognized pregnancies with aneuploidy, trisomy 21 composes just more than half of all cases. Trisomy 18 accounts for almost 15 percent, and trisomy 13 for 5 percent (Fig. 13-1).

FIGURE 13-1
Prevalence and relative proportion of selected chromosomal abnormalities from EUROCAT (European Surveillance of Congenital Anomalies) population-based registries that included >10,000 aneuploid live births, fetal deaths, and pregnancy terminations, 2000–2006. (Data from Wellesley, 2012.)





Standard Nomenclature

Karyotypes are described using the International System for Human Cytogenomic Nomenclature (McGowan-Jordan, 2016). Abnormalities fall into two broad categories—those of *chromosome number*, such as trisomy, and those of *chromosome structure*, such as a deletion or translocation. Each chromosome has a short arm, termed the "p" or petit arm, and a long arm, known as the "q" arm, selected because it is the next letter in the alphabet. The two arms are separated by the centromere.

When reporting a karyotype, the total number of chromosomes is listed first, corresponding to the number of centromeres. This is followed by the sex chromosomes, XX or XY, and then by a description of any structural variation. Specific abnormalities are indicated by standard abbreviations, such as del (deletion) and inv (inversion). The affected region or bands of the p or q arms are then designated, so that the reader will know the exact abnormality location and type. Examples are shown in Table 13-1.

TABLE 13-1

Examples of Karyotype Designations Using the 2016 International System for Human Cytogenetic Nomenclature

Karyotype	Description
46,XX	Normal female chromosome constitution
47,XY,+21	Male with trisomy 21
47,XX,+21/46,XX	Female who is a mosaic of trisomy 21 cells and cells with normal constitution
46,XY,del(4)(p14)	Male with terminal deletion (del) of the short arm of chromosome 4 at band p14
46,XX,dup(5)(p14p15.3)	Female with duplication (dup) of the short arm of chromosome 5 from band p14 to band p15.3
45,XY,der(13;14)(q10;q10)	Male with balanced robertsonian translocation (der) of the long arms of chromosomes 13 and 14—the karyotype now has one normal 13, one normal 14, and the translocation chromosome, reducing the normal 46 chromosome complement to 45
46,XX,t(11;22)(q23;q11.2)	Female with a balanced reciprocal translocation (t) between chromosomes 11 and 22, with breakpoints at 11q23 and 22q11.2
46,XY,inv(3)(p21q13)	Male with inversion (inv) of chromosome 3 that extends from p21 to q13—a pericentric inversion because it includes the centromere
46,X,r(X)(p22.1q27)	Female with one normal X and one ring (r) X chromosome, with the regions distal to p22.1 and q27 deleted from the ring
46,X,i(X)(q10)	Female with one normal X chromosome and an isochromosome (i) of the long arm of the other X
ish 22q11.2(HIRAx2)	FISH of metaphase cells using a probe for the HIRA locus of the 22q11.2 region, with 2 signals identified (no evidence of microdeletion)
ish del(22)(q11.2q11.2) (HIRA-)	FISH of metaphase cells using a probe for the HIRA locus of the 22q11.2 region, with only one signal identified, consistent with the microdeletion
arr[GRCh38] 18p11.32q23 (102328_79093443)x3	Microarray analysis (arr), genome build GRCh38, showing a single copy gain on chromosome 18 from band p11.32 to band q23 (essentially the entire chromosome), consistent with trisomy 18
arr[GRCh38] 4q32.2q35.1 (163146681_183022312)x1	Microarray analysis (arr), genome build GRCh38, showing a copy loss on the long arm of chromosome 4 at bands q32.2 through q35.1 (19.9 Mb)
arr[GRCh38] 15q11.2q26 (23123715_101888908)x2 hmz	SNP microarray analysis (arr), genome build GRCh 38, showing homozygosity for the entire long arm of chromosome 15

FISH = fluorescence in situ hybridization; GRCh38 = Genome Reference Consortium human build 38; HIRA = histone cell cycle regulator; SNP = single nucleotide pleomorphism.

Used with permission from Dr. Kathleen S. Wilson.

Terminology is similar for fluorescence in situ hybridization. Described in Genetic Tests, this technique is used to rapidly identify of a specific chromosome abnormality and verify suspected microdeletion or microduplication syndromes. The report begins with the designation *ish* for in situ hybridization performed on metaphase cells and *nuc ish* for hybridization performed on interphase nuclei. If no abnormality is identified, this is followed by the probe's specific chromosomal region, such as 22q11.2, and then the name of the probe and the number of signals visualized—for example, HIRAx2. If a deletion is identified, *del* is included before the chromosomal region, and the name of the probe is followed by a minus sign (HIRA-), as shown in Table 13-1. The 22q11.2 microdeletion syndrome is discussed in Abnormalities of Chromosome Structure.

A recent addition to the standard nomenclature is terminology to represent copy number variants identified by *chromosomal microarray analysis*, which is discussed in Chromosomal Microarray Analysis. *Copy number variant* is another term for a microdeletion or microduplication of DNA too small to be visualized with a standard karyotype. The array designation begins with the abbreviation *arr* and the version of the genome build to which the nucleotide designations are aligned, such as GRCh38 for Genome Reference Consortium human build 38. This is followed by the number of the chromosome on which the abnormality is identified, by the p or q arm, and by the specific bands in question. Array reports next include the affected base pair coordinates, thus conveying the exact size and location within the genome for every abnormality identified—including copy number variants of uncertain significance.

Abnormalities of Chromosome Number

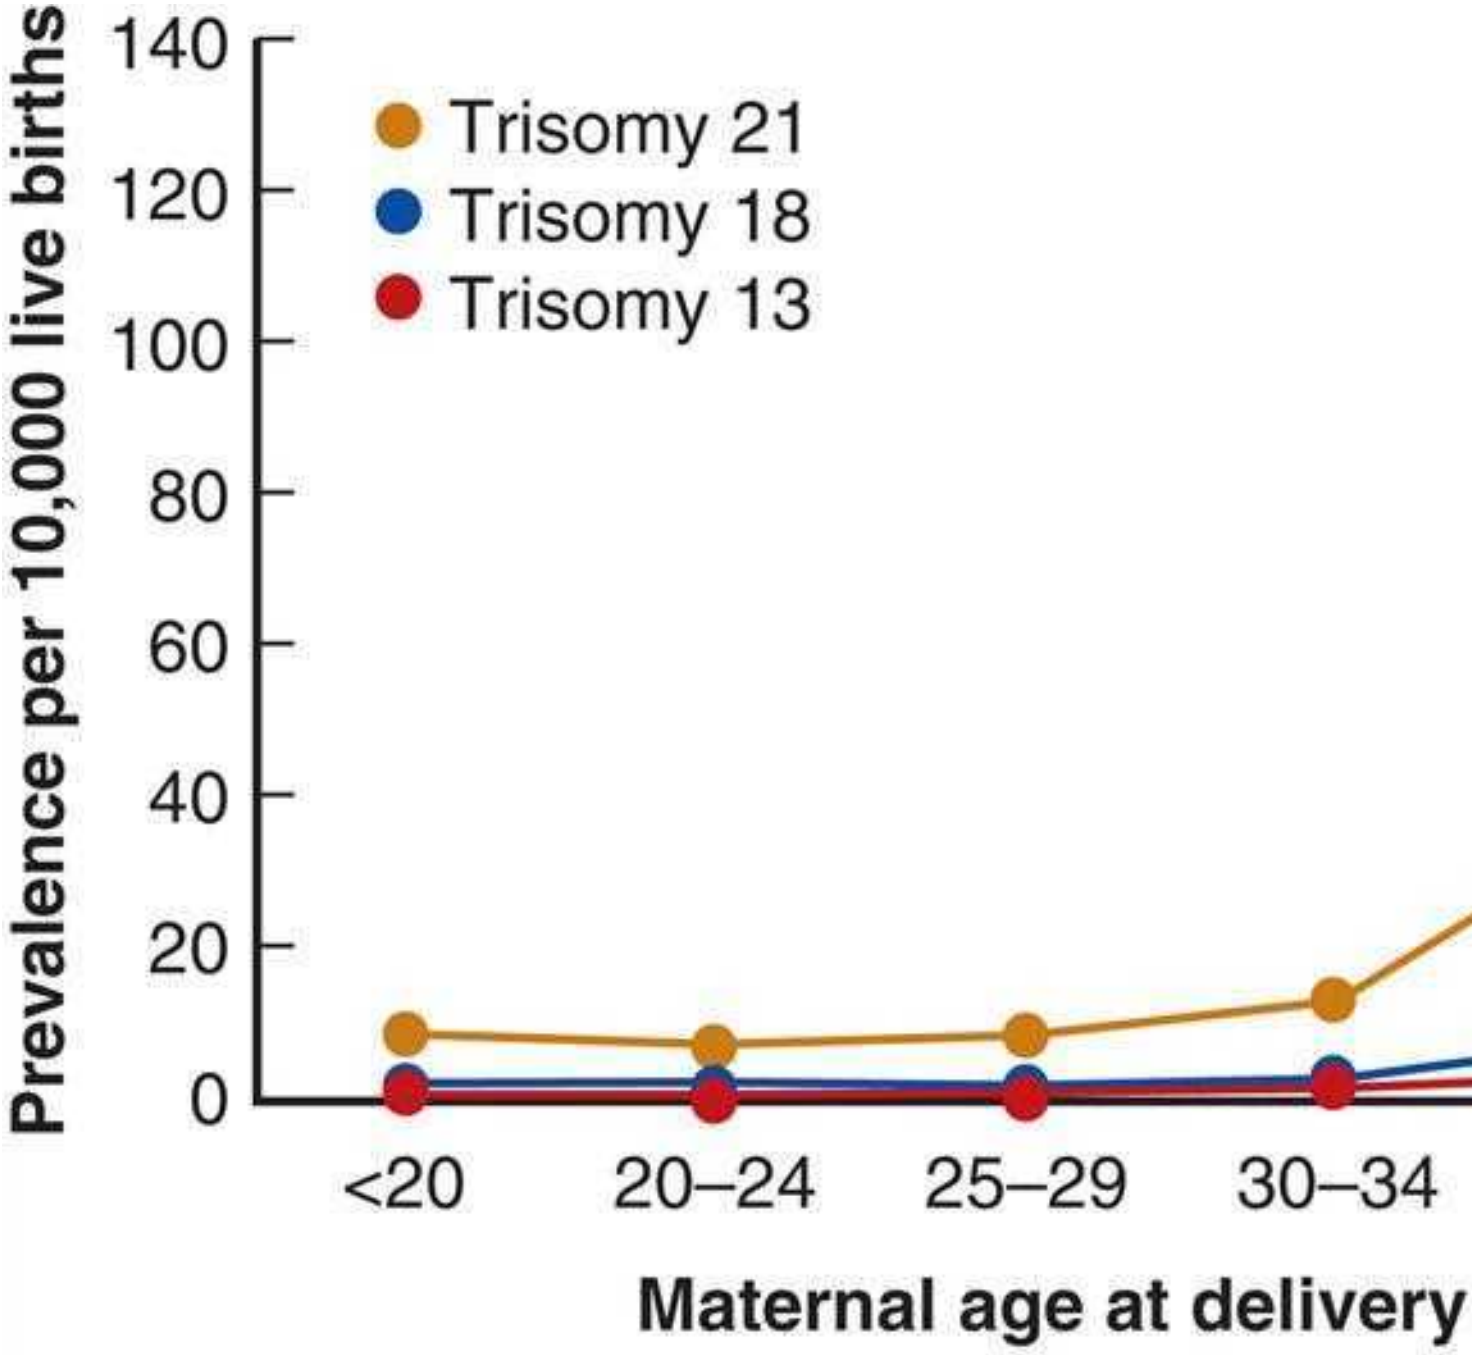
The most easily recognized chromosomal abnormalities are numerical. *Aneuploidy* is inheritance of either an extra chromosome—resulting in trisomy, or loss of a chromosome—*monosomy*. These differ from *polyploidy*, which is an abnormal number of haploid chromosome sets, such as triploidy. The estimated incidence of various numerical chromosomal abnormalities is shown in Figure 13-1.

Autosomal Trisomies

These account for approximately half of all chromosomal abnormalities. In most cases, trisomy results from nondisjunction, which is failure of normal chromosomal pairing and separation during meiosis. Nondisjunction may occur if the chromosomes: (1) fail to pair up, (2) pair up properly but separate prematurely, or (3) fail to separate.

The risk of any autosomal trisomy rises steeply with maternal age, particularly after age 35 (Fig. 13-2). Oocytes are suspended in midprophase of meiosis I from birth until ovulation, in some cases for 50 years. Following completion of meiosis at ovulation, nondisjunction results in one gamete having two copies of the affected chromosome, leading to trisomy if fertilized. The other gamete, receiving no copy of the affected chromosome, will be monosomic if fertilized. It is estimated that 10 to 20 percent of oocytes are aneuploid secondary to meiotic errors, compared with 3 to 4 percent of sperm. Although each chromosome pair is equally likely to have a segregation error, it is rare for trisomies other than 21, 18, or 13 to result in a term pregnancy, and most fetuses with trisomies 18 and 13 die before term.

FIGURE 13-2
Prevalence of autosomal trisomies according to maternal age found in population-based birth defects surveillance programs in the United States, 2006–2010, which included live births, stillbirths, and pregnancy terminations. (Data from Mai, 2013. Redrawn with permission from Dashe JS: Aneuploidy screening. Obstet Gynecol 128(1):181, 2016.)



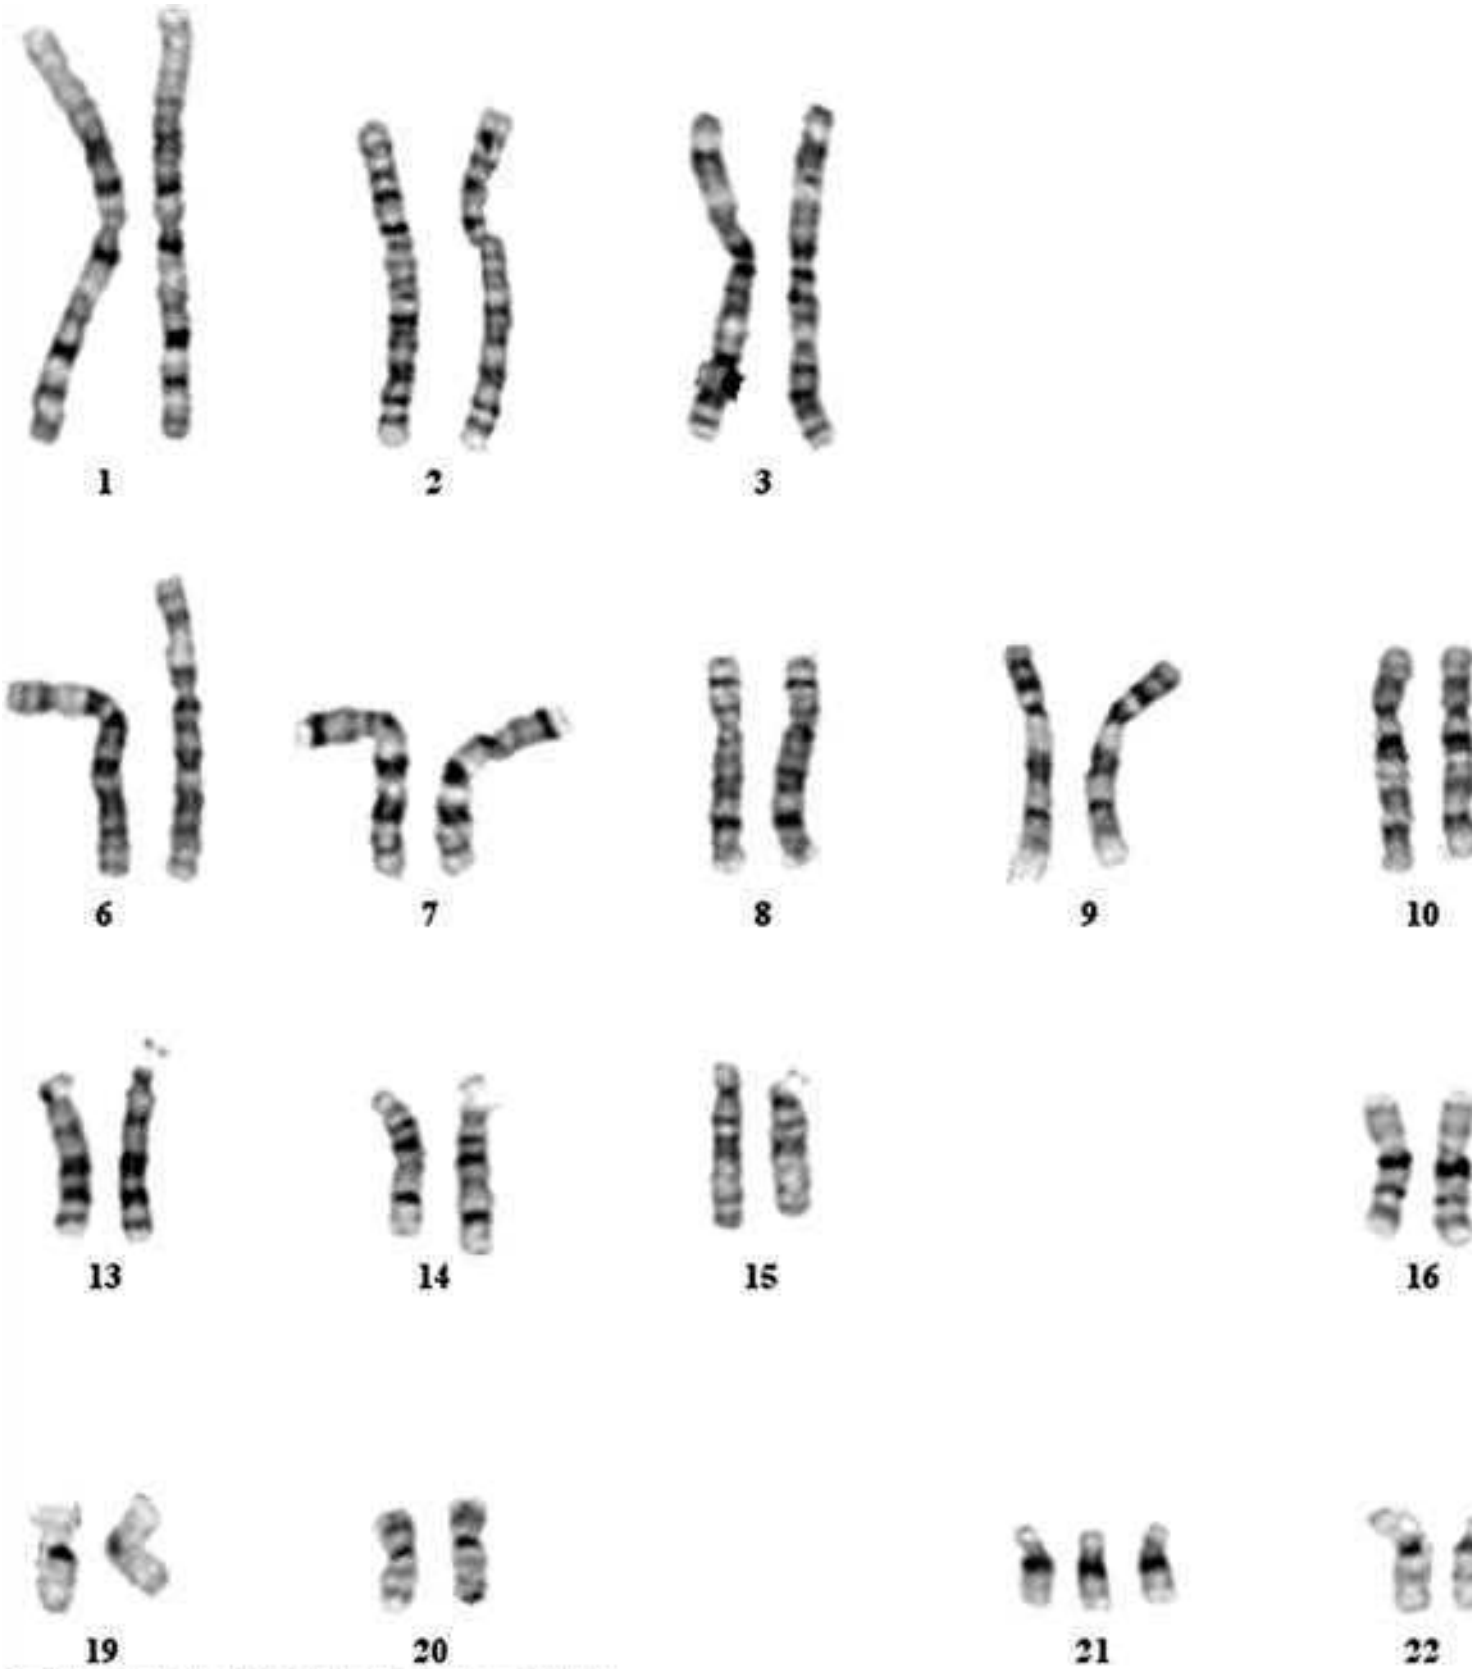
Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

After a pregnancy with an autosomal trisomy, the risk for any autosomal trisomy in a future pregnancy approximates 1 percent until the woman's age-related risk exceeds this. Accordingly, prenatal diagnosis with chorionic villus sampling or amniocentesis is offered in these subsequent pregnancies (Chap. 14, Technique). Parental chromosomal studies are not indicated unless the affected pregnancy was caused by an unbalanced translocation or other structural rearrangement.

Trisomy 21—Down Syndrome

In 1866, J. L. H. Down described a group of intellectually disabled children with distinctive physical features. Nearly 100 years later, Lejeune (1959) demonstrated that Down syndrome is caused by an autosomal trisomy (Fig. 13-3). Trisomy 21 causes 95 percent of Down syndrome cases, whereas 3 to 4 percent of cases are due to a robertsonian translocation, described later (Isochromosomes). The remaining 1 to 2 percent results from an isochromosome or from mosaicism. The nondisjunction that yields trisomy 21 occurs during meiosis I in approximately 75 percent of cases, and the remaining events are during meiosis II.

FIGURE 13-3
Abnormal male karyotype with trisomy 21, consistent with Down syndrome (47,XY,+21). (Used with permission from Dr. Frederick Elder.)



Down syndrome is the most common nonlethal trisomy. Its approximate prevalence is 1 in 500 recognized pregnancies. However, fetal losses and pregnancy terminations yield an estimated prevalence of 13.5 in 10,000 births in the United States—1 per 740 (Mai, 2013; Parker, 2010). The fetal death rate beyond 20 weeks' gestation approximates 5 percent (Loane, 2013). Coinciding with the older maternal age distribution during the past four decades, the prevalence of Down syndrome has risen approximately 33 percent (Loane, 2013; Parker, 2010; Shin, 2009).

Notably, adult women with Down syndrome are fertile, and a third of their offspring will have Down syndrome (Scharrer, 1975). Males with Down syndrome are almost always sterile because of markedly reduced spermatogenesis.

Approximately 30 percent of second-trimester fetuses with Down syndrome have a major malformation that can be identified sonographically (Hussamy, 2017; Vintzileos, 1995). As discussed in Chapter 14 (Sonographic Screening), when both major anomalies and minor aneuploidy markers are considered, an estimated 50 to 60 percent of Down syndrome pregnancies can be detected sonographically (American College of Obstetricians and Gynecologists, 2016d). Approximately half of liveborn neonates with Down syndrome are found to have cardiac defects, particularly ventricular septal defects and endocardial cushion defects (Figs. 10-29 and 10-30) (Bergstrom, 2016; Freeman, 2008). Gastrointestinal abnormalities are identified in 12 percent and include esophageal atresia, Hirschsprung disease, and duodenal atresia (Fig. 10-38) (Bull, 2011).

Characteristic features of Down syndrome are shown in Figure 13-4. Typical findings include brachycephaly; epicanthal folds and up-slanting palpebral fissures; Brushfield spots, which are grayish spots on the periphery of the iris; a flat nasal bridge; and hypotonia. Infants often have loose skin at the nape of the neck, short fingers, a single palmar crease, hypoplasia of the middle phalanx of the fifth finger, and a prominent space or "sandal-toe gap" between the first and second toes. Some of these findings are prenatal sonographic markers for Down syndrome, reviewed in Chapter 14 (Sonographic Screening).

FIGURE 13-4

Trisomy 21—Down syndrome. **A.** Characteristic facial appearance. **B.** Redundant nuchal tissue. **C.** Single transverse palmar crease. (Used with permission from Dr. Charles P. Read and Dr. Lewis Waber.)

Health problems common in children with Down syndrome include hearing loss in 75 percent, severe optical refractive errors in 50 percent, cataracts in 15 percent, obstructive sleep apnea in 60 percent, thyroid disease in 15 percent, and a higher incidence of leukemia (Bull, 2011). The degree of mental impairment is usually mild to moderate, with an average intelligence quotient (IQ) score of 35 to 70. Social skills in affected children are often higher than predicted by their IQ scores.

Data suggest that approximately 95 percent of liveborn infants with Down syndrome survive the first year. The 10-year survival rate is at least 90 percent overall and is 99 percent if major malformations are absent (Rankin, 2012; Vendola, 2010). Several organizations offer education and support for prospective parents faced with prenatal diagnosis of Down syndrome. These include the March of Dimes, National Down Syndrome Congress (www.ndsccenter.org), and National Down Syndrome Society (www.ndss.org).

Trisomy 18—Edwards Syndrome

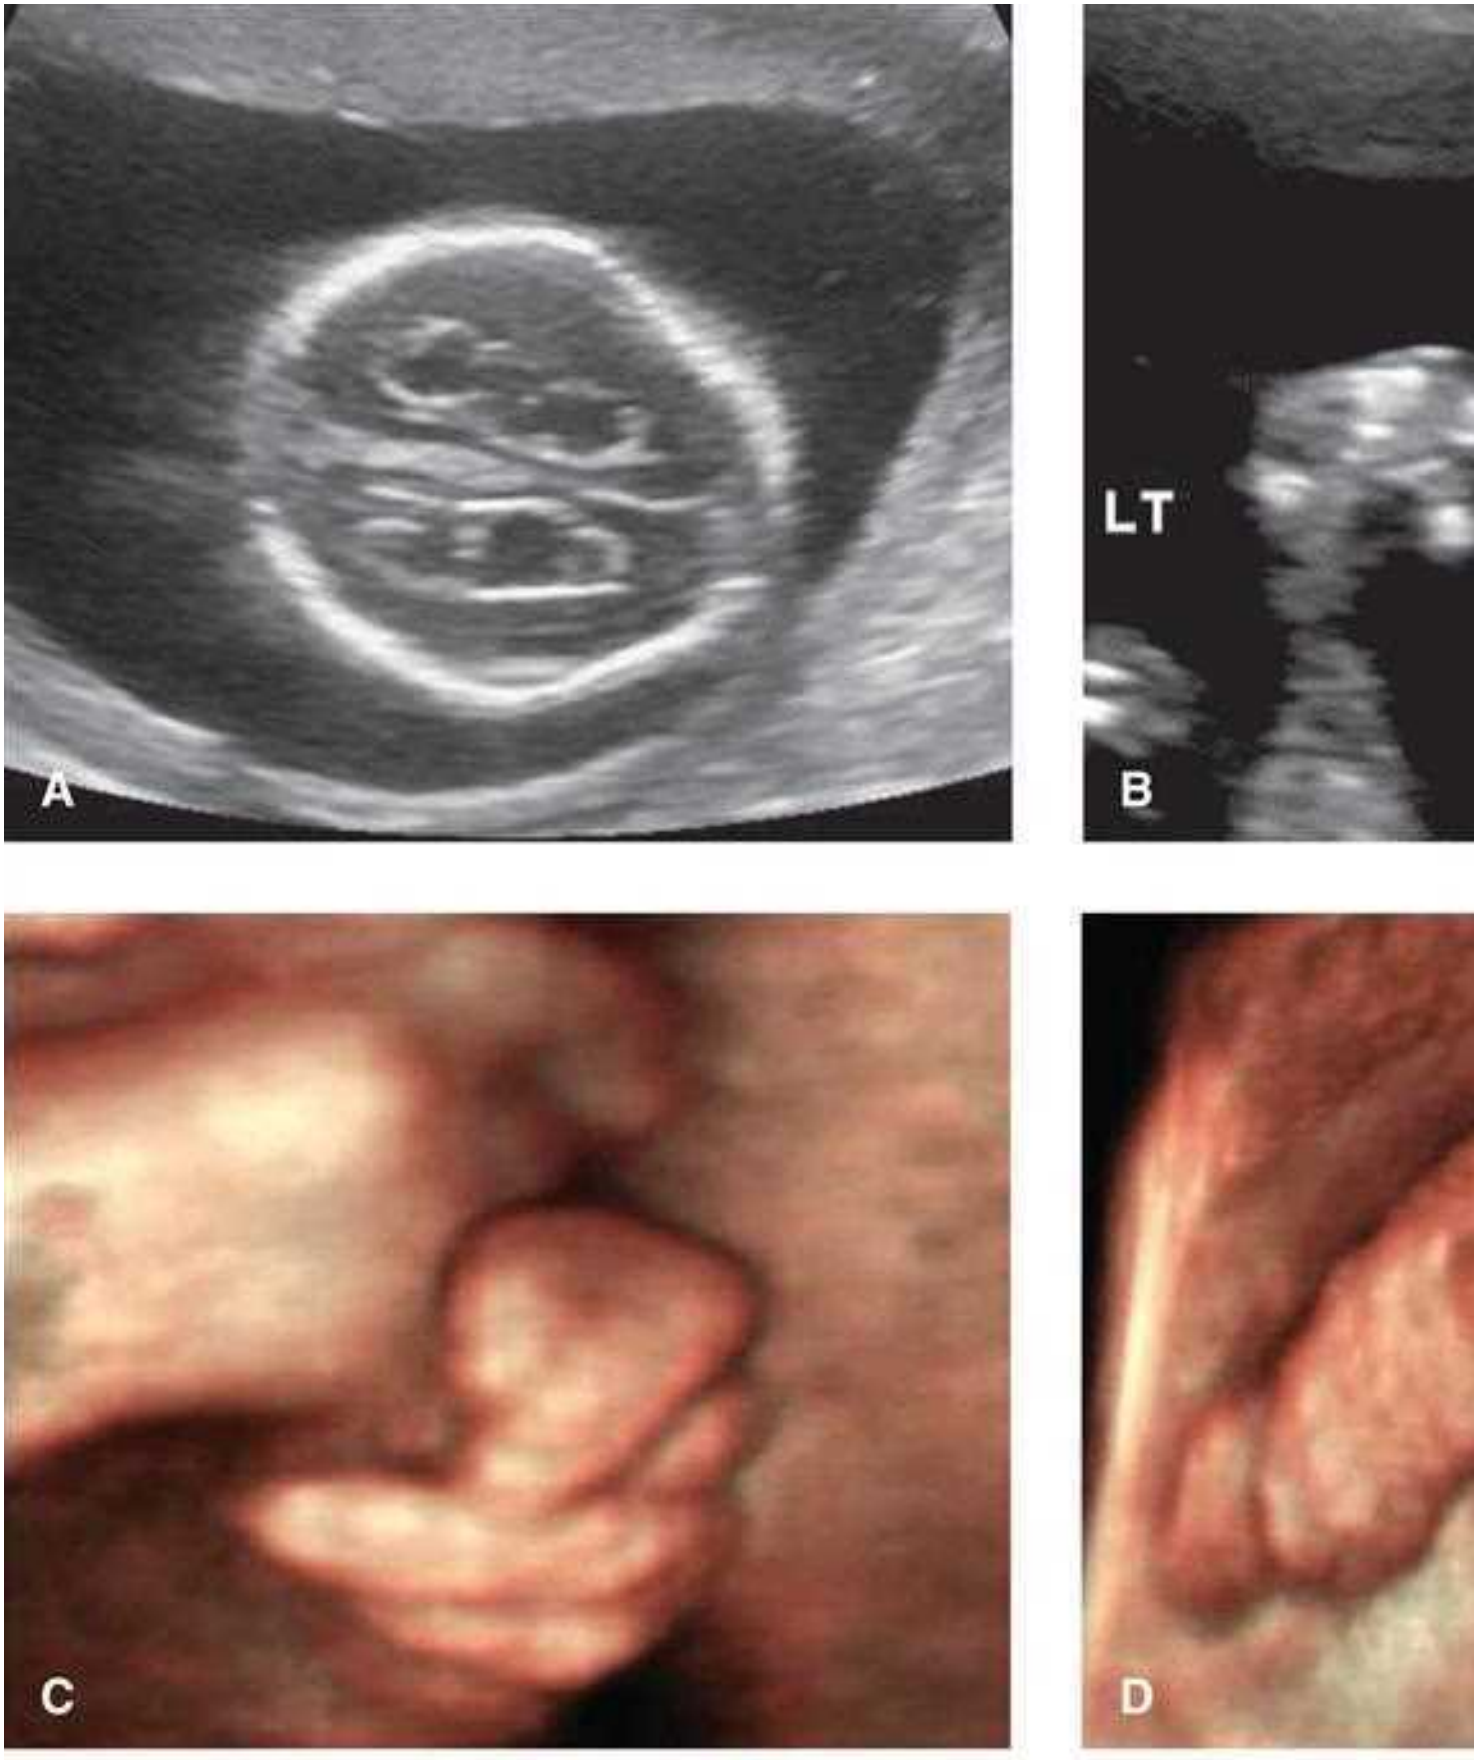
The association between this constellation of abnormalities and an autosomal trisomy was first described by Edwards (1960). In population-based series, prevalence of trisomy 18 approximates 1 in 2000 recognized pregnancies—including abortuses, stillbirths, and live births, and approximately 1 in 6600 liveborn neonates (Loane, 2013; Parker, 2010). The difference in prevalence is explained by the high in-utero lethality of the condition and the termination of many affected pregnancies. Perhaps not surprisingly, survival of liveborn neonates is likewise bleak. More than half die within the first week, and the 1-year survival rate approximates only 2 percent (Tennant, 2010; Vendola, 2010). The syndrome is three- to fourfold more common in females (Lin, 2006; Rosa, 2011). Unlike Down and Patau syndromes, which involve acrocentric chromosomes and thus may stem from a robertsonian translocation, Edwards syndrome uncommonly results from a chromosomal rearrangement.

Virtually every organ system can be affected by trisomy 18. Common major anomalies include heart defects in more than 90 percent—particularly ventricular septal defects, as well as cerebellar vermian agenesis, myelomeningocele, diaphragmatic hernia, omphalocele, imperforate anus, and renal anomalies such as horseshoe kidney (Lin, 2006; Rosa, 2011; Yeo, 2003). Sonographic images of several of these are shown in Chapter 10.

Cranial and extremity abnormalities are also frequent and include a prominent occiput, posteriorly rotated and malformed ears, micrognathia, clenched hands with overlapping digits, radial aplasia with hyperflexion of the wrists, and rockerbottom or clubbed feet (Fig. 13-5). A “strawberry-shaped” cranium is noted in approximately 40 percent of cases, abnormally wide cavum septum pellucidum in more than 90 percent, and choroid plexus cysts in up to 50 percent (Abele, 2013; Yeo, 2003). Importantly, isolated choroid plexus cysts are not associated with trisomy 18. These cysts only raise the risk for trisomy 18 if fetal structural abnormalities or an abnormal aneuploidy screening test result is also present (Reddy, 2014).

FIGURE 13-5

Trisomy 18—Edwards Syndrome. **A.** This transventricular sonographic view shows fetal choroid plexus cysts and an angulated “strawberry-shaped” skull. **B.** Radial clubhand is manifested as a single forearm bone (radius), with the hands in a fixed, hyperflexed position at right angles to the forearms. **C.** This three-dimensional (3-D) sonographic image shows the characteristic hand position of clenched fists with overlapping digits. **D.** 3-D sonographic image displays a rockerbottom foot.



Pregnancies with trisomy 18 that reach the third trimester often develop fetal-growth restriction, and the mean birthweight is <2500 g (Lin, 2006; Rosa, 2011). Because abnormal fetal heart rate tracings are common during labor, mode of delivery and management of heart rate abnormalities should be discussed in advance. In older reports, more than half of undiagnosed fetuses underwent cesarean delivery for “fetal distress” (Schneider, 1981).

Trisomy 13—Patau Syndrome

This constellation of fetal abnormalities and their association with an autosomal trisomy was first described by Patau and colleagues (1960). The prevalence of trisomy 13 approximates 1 in 12,000 live births and 1 in 5000 recognized pregnancies, which includes abortuses and stillbirths (Loane, 2013; Parker, 2010). As with trisomy 18, trisomy 13 is highly lethal, and most affected fetuses are lost or terminated.

Approximately 80 percent of pregnancies with Patau syndrome result from trisomy 13. The remainder is caused by a robertsonian translocation involving chromosome 13. The most frequent structural chromosomal rearrangement is a translocation between chromosomes 13 and 14, der(13;14)(q10;q10). This translocation is carried by approximately 1 in 1300 individuals, although the risk of an affected liveborn neonate is less than 2 percent (Nussbaum, 2007).

Trisomy 13 is associated with abnormalities of virtually every organ system. One characteristic finding is holoprosencephaly (Fig. 10-15). This is present in approximately two thirds of cases and may be accompanied by microcephaly, hypotelorism, and nasal abnormalities that range from a single nostril to a proboscis. Cardiac defects are found in up to 90 percent of fetuses with trisomy 13 (Shipp, 2002). Other abnormalities that suggest trisomy 13 include neural-tube defects—particularly cephalocele, microphthalmia, cleft lip-palate, omphalocele, cystic renal dysplasia, polydactyly, rockerbottom feet, and areas of skin aplasia (Lin, 2007). For the fetus or newborn with a cephalocele, cystic kidneys, and polydactyly, the differential diagnosis includes trisomy 13 and the autosomal-recessive Meckel-Gruber syndrome. Sonographic images of several of these are shown in Chapter 10 (Neural-Tube Defects).

Few fetuses with trisomy 13 survive until birth. Of those that do, the 1-week survival rate approximates 40 percent, and 1-year survival rate is only about 3 percent (Tennant, 2010; Vendola, 2010). Counseling regarding prenatal diagnosis and management options is similar to that described for trisomy 18.

Unlike other aneuploidies, fetal trisomy 13 confers risk to the pregnant woman. Hyperplacentosis and preeclampsia develop in up to half of pregnancies with trisomy 13 carried beyond the second trimester (Tuohy, 1992). Chromosome 13 contains the gene for soluble fms-like tyrosine kinase-1 (sFlt-1), which is an antiangiogenic protein associated with preeclampsia (Chap. 40, Endothelial Cell Injury). Investigators have documented overexpression of the sflt-1 protein by trisomic 13 placentas and in serum of women with preeclampsia (Bdolah, 2006; Silasi, 2011).

Other Trisomies

In the absence of mosaicism, discussed later (Chromosomal Mosaicism), other autosomal trisomies rarely yield a liveborn neonate. Case of live births with trisomy 9 and with trisomy 22 have been noted (Kannan, 2009; Tinkle, 2003). Trisomy 16 is the most common trisomy found with first-trimester losses and accounts for 16 percent of these losses. However, it is not identified later in gestation. Trisomy 1 has never been reported.

Monosomy

Nondisjunction creates an equal number of nullisomic and disomic gametes. As a rule, missing chromosomal material is more devastating than extra chromosomal material, and almost all monosomic conceptuses are lost before implantation. The one exception is monosomy for the X chromosome (45,X), Turner syndrome, which is discussed subsequently. Despite the strong association between maternal age and trisomy, maternal age and monosomy are not linked.

Polyploidy

This is an abnormal number of complete haploid chromosomal sets. Polyploidy accounts for approximately 20 percent of spontaneous abortions but is rare in later gestations.

Triploid pregnancies have three haploid sets—69 chromosomes. One parent must contribute two sets, and the phenotypic presentation differs according to the parent of origin. With *diandric triploidy*, also known as type I triploidy, the extra chromosomal set is paternal, resulting from fertilization of one egg by two sperm or by a single diploid—and thus abnormal—sperm. Diandric triploidy produces a partial molar pregnancy, discussed in Chapter 20 (Epidemiology and Risk Factors). Diandric triploidy accounts for most triploid conceptions, but their first-trimester loss rate is extremely high. As a result, two thirds of triploid pregnancies identified beyond the first trimester are caused instead by *digynic triploidy* (Jauniaux, 1999). With a digynic triploid pregnancy, also known as type II triploidy, the extra chromosomal set is maternal, and the egg fails to undergo the first or second meiotic division before fertilization. Digynic triploid placentas do not develop molar changes. However, the fetus usually displays asymmetrical growth restriction.

The prevalence of recognized triploid pregnancies approximates 1 in 5000 pregnancies (Zalel, 2016). Triploidy is a lethal aneuploidy, and more than 90 percent of fetuses with either the diandric or digynic form have multiple structural anomalies. These include central nervous system defects—particularly involving the posterior fossa, as well as cardiac, renal, and extremity anomalies (Jauniaux, 1999; Zalel, 2016). Counseling, prenatal diagnosis, and delivery options are similar to those for trisomies 18 and 13. The recurrence risk for a woman whose triploid fetus survived past the first trimester is 1 to 1.5 percent, and thus prenatal diagnosis is offered in future pregnancies (Gardner, 1996).

Tetraploid pregnancies have four haploid sets of chromosomes, resulting in either 92,XXXX or 92,XXYY. This suggests a postzygotic failure to complete an early cleavage division. The conceptus invariably succumbs, and the recurrence risk is minimal.

Sex Chromosome Abnormalities

45, X—Turner Syndrome

First described by Turner (1938), this syndrome later was found to be caused by monosomy X (Ford, 1959). The prevalence of Turner syndrome is approximately 1 in 2500 liveborn girls (Cragan, 2009; Dolk, 2010). The missing X chromosome is paternally derived in 80 percent of cases (Cockwell, 1991; Hassold, 1990). Screening for Turner syndrome with cell-free DNA is discussed in Chapter 14 (Cell-Free DNA Screening).

Turner syndrome is the only monosomy compatible with life, but it is also the most common aneuploidy in first-trimester losses, accounting for 20 percent. This is explained by the wide range in phenotype. Approximately 98 percent of affected conceptuses are so abnormal that they abort early in the first trimester. Of the remainder, many manifest large, septated cystic hygromas in the late first or early second trimester (Fig. 10-22). When cystic hygromas are accompanied by hydrops

fetalis, fetuses nearly always die in utero (Chap 15, Hydrops Fetalis). Less than 1 percent of pregnancies with Turner syndrome yield a liveborn neonate. And, only half of these actually have monosomy X. Approximately a fourth have mosaicism, such as 45,X/46,XX or 45,X/46,XY, and another 15 percent have isochromosome X, that is, 46,X,i(Xq)(Milunsky, 2004; Nussbaum, 2007).

Abnormalities associated with Turner syndrome include left-sided cardiac defects—such as coarctation of the aorta, hypoplastic left heart syndrome, or bicuspid aortic valve—in 30 to 50 percent; renal anomalies, particularly horseshoe kidney; and hypothyroidism. Other features are short stature, broad chest with widely spaced nipples, congenital lymphedema—puffiness over the dorsum of hands and feet, and a "webbed" posterior neck resulting from cystic hygromas. Intelligence scores are generally in the normal range, but affected individuals are at risk for difficulties with visual-spatial organization, nonverbal problem solving, and interpretation of social cues (Jones, 2006). Growth hormone is typically administered in childhood to ameliorate short stature (Kappelgaard, 2011). More than 90 percent have ovarian dysgenesis and require estrogen repletion starting just before adolescence. An exception is mosaicism involving the Y chromosome, as this confers risk for germ cell neoplasm—regardless of whether the child is phenotypically male or female. Accordingly, eventual prophylactic bilateral gonadectomy is indicated (Cools, 2011; Schorge, 2016).

47,XXX

Approximately 1 in 1000 female newborns has an additional X chromosome—47,XXX. The extra X is maternally derived in more than 90 percent of cases (Milunsky, 2004). Affected infants do not have a characteristic appearance, and in the past most children did not come to attention until school age. However, the incidence of 47,XXX is weakly associated with maternal age, and cell-free DNA screening has resulted in increased diagnoses (Table 14-5). Frequent features include tall stature, hypertelorism, epicanthal folds, kyphoscoliosis, clinodactyly, and hypotonia (Tartaglia, 2010; Wigby, 2016). More than a third are diagnosed with a learning disability, half have attention deficit disorder, and overall cognitive scores are in the low-average range. No specific pattern of malformations has been described, but genitourinary problems and seizure disorders are more common (Wigby, 2016). Pubertal development is unaffected. Primary ovarian insufficiency has been reported (Holland, 2001). Because of variable presentation and subtle abnormal findings, it is estimated that this diagnosis is ascertained clinically in only 10 percent of affected children.

Females with two or more extra X chromosomes—48,XXXX or 49,XXXXX—are likely to have physical abnormalities apparent at birth. These abnormal X complements are associated with intellectual disability. For both males and females, the IQ score is lower with each additional X chromosome.

47,XXY—Klinefelter Syndrome

This is the most common sex chromosome abnormality and found in approximately 1 in 600 male infants. The additional X chromosome is maternally or paternally derived with equal propensity (Jacobs, 1995; Lowe, 2001). The association with either advanced maternal or paternal age is weak (Milunsky, 2004).

Like 47,XXX, newborns with 47,XXY usually appear phenotypically normal and do not have a higher incidence of anomalies. As children, boys are typically taller than average and have normal prepubertal development. However, they have gonadal dysgenesis, do not undergo normal virilization, and require testosterone supplementation beginning in adolescence. They may develop gynecomastia. IQ scores usually lie in the average to low-average range, and many have delays in language development and reading (Boada, 2009; Girardin, 2011).

47,XYY

This aneuploidy occurs in approximately 1 in 1000 male newborns. As with 47,XXX and XXY individuals, affected boys tend to be tall. A third have macrocephaly, nearly two thirds demonstrate hypotonia, and tremors are also common (Bardsley, 2013). Rates of major anomalies are not elevated, although hypertelorism and clinodactyly may be identified in more than half. Pubertal development is normal, and fertility is unimpaired. Affected children carry risks for oral and written language impairments, attention deficit disorder is diagnosed in more than half, and the rate of autism spectrum disorder is also increased (Bardsley, 2013; Ross, 2009). Intelligence scores generally lie in the normal range.

Males with more than two Y chromosomes—48,XYYY—or with both additional X and Y chromosomes—48,XXYY or 49,XXXYY—are more likely to have congenital abnormalities, medical problems, and intellectual disability (Tartaglia, 2011).

Abnormalities of Chromosome Structure

Structural chromosomal abnormalities include deletions, duplications, translocations, isochromosomes, inversions, ring chromosomes, and mosaicism (see Table 13-1). Their overall birth prevalence approximates 0.3 percent (Nussbaum, 2007). Identification of a structural chromosomal abnormality raises two primary questions. First, what phenotypic abnormalities or later developmental abnormalities are associated with this finding? Second, is evaluation of parental karyotype indicated—specifically, are the parents at increased risk of carrying this abnormality? If so, what is their risk of having future affected offspring?

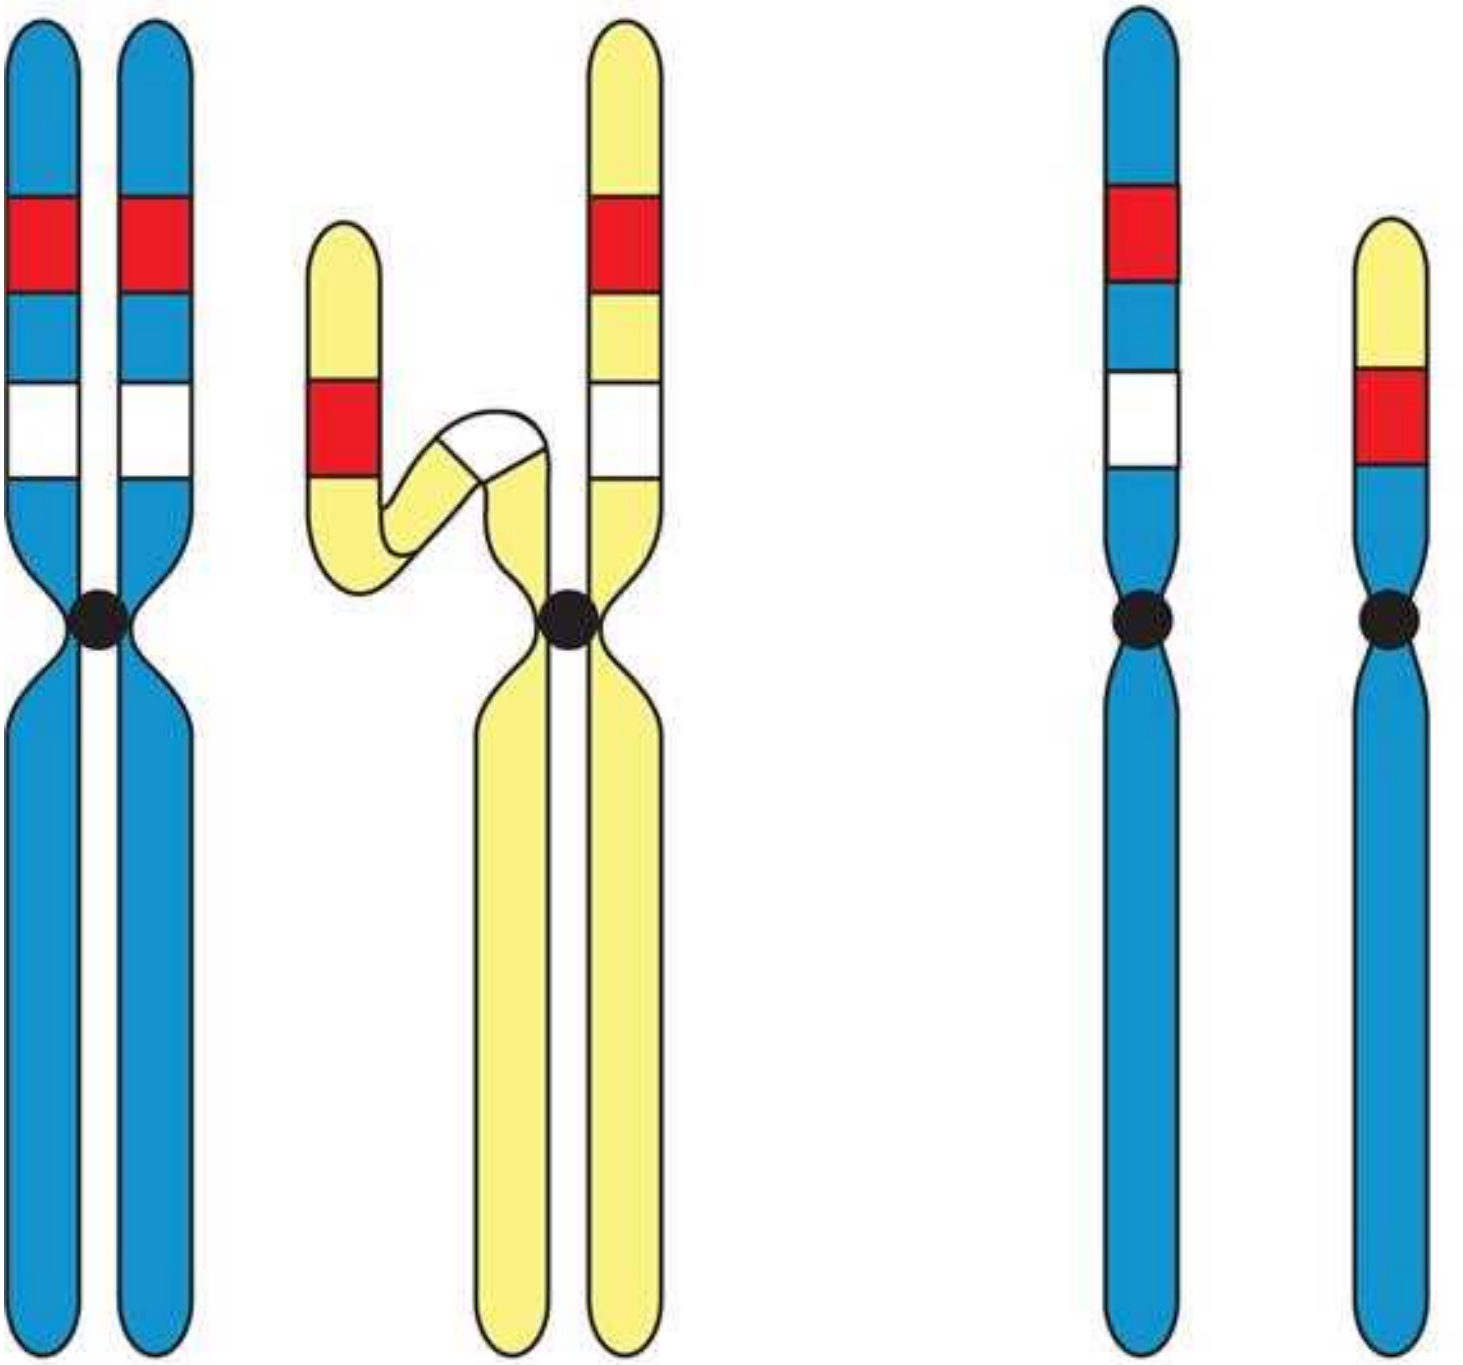
Deletions and Duplications

A chromosomal deletion indicates that a portion of a chromosome is missing, whereas a duplication means that a portion has been included twice. Most deletions and duplications occur during meiosis and result from malalignment or mismatching during the pairing of homologous chromosomes. The misaligned segment may then be deleted, or if the mismatch remains when the two chromosomes recombine, it may result in a deletion in one chromosome and duplication in the other (Fig. 13-6). When a deletion or duplication is identified in a fetus or infant, parental karyotyping should be offered, because if either parent carries a balanced translocation, the recurrence risk in subsequent pregnancies is significantly increased. Deletions involving DNA segments large enough to be seen with standard cytogenetic karyotyping are identified in approximately 1 in 7000 births (Nussbaum, 2007). Common deletions may be referred to by eponyms—for example, del 5p is called *cri du chat syndrome*.

FIGURE 13-6

A mismatch during pairing of homologous chromosomes may lead to a deletion in one chromosome and a duplication in the other. Del = deletion; Dupl = duplication.

Meiosis I



Normal Del

Microdeletions and Microduplications

These chromosomal deletions or duplications—smaller than 3 to 5 million base pairs—are too small to be detected with standard karyotyping. However, prenatal chromosomal microarray analysis (CMA), described later (Chromosomal Microarray Analysis), permits identification of syndromes associated with these microdeletion or duplications. When CMA is used, the region of DNA that is missing or duplicated is termed a *genomic copy number variant*. Despite the relatively small size, a microdeletion or duplication may involve a stretch of DNA that contains multiple genes—causing a *contiguous gene syndrome*, which can encompass serious but unrelated phenotypic abnormalities (Schmickel, 1986). In some cases, a microduplication may involve the exact DNA region that causes a recognized microdeletion syndrome (Table 13-2). When a specific microdeletion syndrome is suspected clinically, it is confirmed using either CMA or fluorescence in situ hybridization.

TABLE 13-2

Selected Microdeletion Syndromes

Syndrome	Prevalence	Location	Features
Alagille	1:70,000	20p12.2	Cholestasis (paucity of intrahepatic bile ducts), cardiac disease, skeletal disease, ocular abnormalities, dysmorphic facies
Angelman	1:12,000 to 1:20,000	15q11.2–q13 (maternal genes)	Dysmorphic facies—"happy puppet" appearance, mental retardation, ataxia, hypotonia, seizures
Cri-du-chat	1:20,000 to 1:50,000	5p15.2–15.3	Abnormal laryngeal development with "cat-like" cry, hypotonia, mental retardation
Kallmann syndrome	1:10,000 to 1:86,000	Xp22.3	Hypogonadotropic hypogonadism, anosmia
Langer-Giedion	Rare	8q23.3	Trichorhinophalangeal syndrome, dysmorphic facies, sparse hair, redundant skin, mental retardation
Miller-Dieker	Rare	17p13.3	Neuronal migration abnormalities with lissencephaly, microcephaly, dysmorphic facies
Prader-Willi	1:10,000 to 1:30,000	15q11.2–q13 (paternal genes)	Obesity, hypotonia, mental retardation, hypogonadotropic hypogonadism, small hands and feet
Retinoblastoma	1:280,000	13q14.2	Retinoblastoma, retinoma (benign neoplasm), non-retinal (second primary) tumors
Rubenstein-Taybi	1:100,000 to 1:125,000	16p13.3	Dysmorphic facies, broad thumbs/toes, mental retardation, increased tumor risk
Smith-Magenis	1:15,000 to 1:25,000	17p11.2	Dysmorphic facies, speech delay, hearing loss, sleep disturbances, self-destructive behaviors
Velocardiofacial/DiGeorge/Shprintzen	1:4,000	22q11.2	Conotruncal cardiac defects, cleft palate, velopharyngeal incompetence, thymic and parathyroid abnormalities, developmental delay
WAGR	1:500,000	11p13	Wilms tumor, aniridia, genitourinary anomalies (including ambiguous genitalia), mental retardation
Williams-Beuren	1:7500 to 1:10,000	7q11.23	Dysmorphic facies, dental malformation, mental retardation, aortic and peripheral pulmonary artery stenosis
Wolf-Hirschhorn	1:20,000 to 1:50,000	4p16.3	Dysmorphic facies, delayed growth and development, cleft lip/palate, coloboma, cardiac septal defects
X-linked ichthyosis	1:6,000	Xp22.3	Steroid sulfatase deficiency, corneal opacities

Prevalence reflects live births.

Data from National Library of Medicine, 2017; Johns Hopkins University, 2017.

22q11.2 Microdeletion Syndrome

This syndrome is also known as DiGeorge syndrome, Shprintzen syndrome, and velocardiofacial syndrome. It is the most common microdeletion, with a prevalence of 1 in 3000 to 6000 births. Although inherited in an autosomal dominant fashion, more than 90 percent of cases arise from de novo mutations. The full deletion

includes 3 million base pairs, encompasses 40 genes, may include 180 different features, and thus poses some counseling challenges (Shprintzen, 2008). Features can vary widely, even among affected family members. Previously, different constellations of features were thought to characterize the DiGeorge and Shprintzen phenotypes, but it is now accepted that they represent the same microdeletion (McDonald-McGinn, 2015).

In approximately 75 percent of affected individuals, associated abnormalities include conotruncal cardiac anomalies, such as tetralogy of Fallot, truncus arteriosus, interrupted aortic arch, and ventricular septal defects (McDonald-McGinn, 2015). Immune deficiency, such as T-cell lymphopenia, also develops in approximately 75 percent. More than 70 percent have velopharyngeal insufficiency or cleft palate. Learning disabilities, autism spectrum disorder, and intellectual disability are also common. Other manifestations include hypocalcemia, renal anomalies, esophageal dysmotility, hearing loss, behavioral disorders, and psychiatric illness—particularly schizophrenia. Short palpebral fissures, bulbous nasal tip, micrognathia, short philtrum, and small or posteriorly rotated ears are characteristic facial features.

Chromosomal Translocations

These are DNA rearrangements in which a segment of DNA breaks away from one chromosome and attaches to another. The rearranged chromosomes are called derivative (der) chromosomes. There are two types—reciprocal and robertsonian translocations.

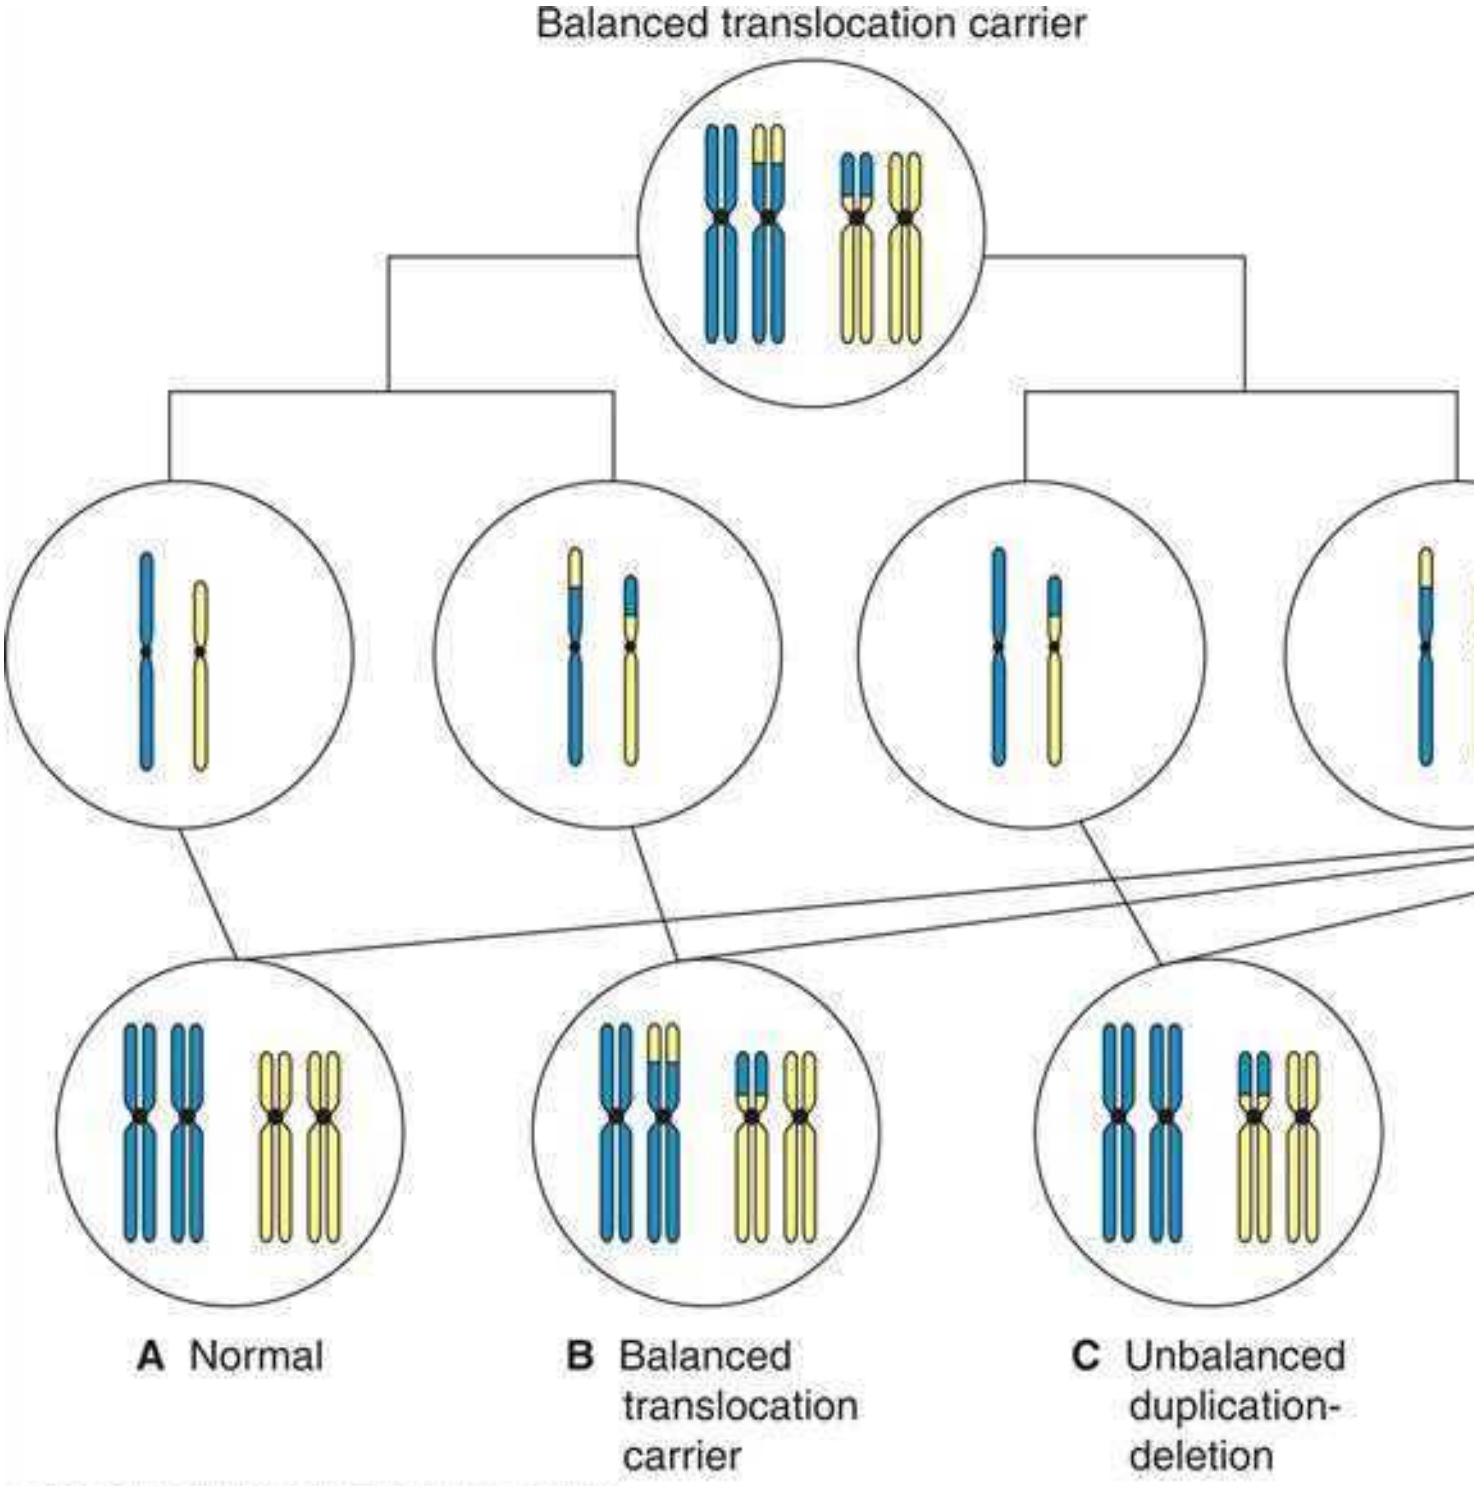
Reciprocal Translocations

A double-segment or reciprocal translocation begins when breaks occur in two different chromosomes. The broken fragments are then exchanged, so that each affected chromosome contains a fragment of the other. If no chromosomal material is gained or lost in this process, the translocation is considered balanced. The prevalence of reciprocal translocations approximates 1 in 600 births (Nussbaum, 2007). Although the balanced translocation carrier is usually normal phenotypically, repositioning of specific genes within chromosomal segments can cause abnormalities. The risk of a major structural or developmental abnormality in an apparent balanced translocation carrier is approximately 6 percent. Interestingly, using CMA technology, up to 20 percent of individuals who appear to have a balanced translocation are found instead to have missing or redundant DNA segments (Manning, 2010).

Balanced translocation carriers are at risk to produce unbalanced gametes, resulting in abnormal offspring. As shown in Figure 13-7, if an oocyte or sperm contains a translocated chromosome, fertilization results in an unbalanced translocation—monosomy for part of one affected chromosome and trisomy for part of the other. The observed risk of a specific translocation can often be estimated by a genetic counselor. In general, translocation carriers identified after the birth of an abnormal child have a 5- to 30-percent risk of producing liveborn offspring with an unbalanced translocation. Carriers identified for other reasons, for example, during an infertility evaluation, have only a 5-percent risk. This is likely because the gametes are so abnormal that conceptions are nonviable.

FIGURE 13-7

A carrier of a balanced translocation may produce offspring who are also carriers of the balanced rearrangement **(B)**, offspring with unbalanced translocations **(C, D)**, or offspring with normal chromosomal complements **(A)**.



Robertsonian Translocations

These involve only *acrocentric* chromosomes, which are chromosomes 13, 14, 15, 21, and 22. The acrocentric chromosomes have extremely short p arms. In a robertsonian translocation, the q arms of two acrocentric chromosomes fuse at one centromere to form a derivative chromosome. The other centromere and both sets of p arms are lost. Because the number of centromeres determines the chromosome count, a robertsonian translocation carrier has only 45 chromosomes. Fortunately, the p arms of the acrocentric chromosomes—the satellite regions—contain redundant copies of genes that code for ribosomal RNA. As these are present in multiple copies on other acrocentric chromosomes, their loss does not affect the translocation carrier, who is usually phenotypically normal. However, when the derivative chromosome is paired during fertilization with a haploid chromosome from the partner, resulting offspring will be trisomic for that chromosome.

Robertsonian translocations are found in 1 in 1000 individuals. The incidence of abnormal offspring approximates 15 percent if a robertsonian translocation is carried by the mother and 2 percent if carried by the father. Robertsonian translocations are not a major cause of miscarriage and are found in fewer than 5 percent of couples with recurrent pregnancy loss. When a fetus or child is found to have a translocation trisomy, both parents should be offered karyotype analysis. If neither parent is a carrier, the recurrence risk is extremely low.

Balanced robertsonian carriers have reproductive difficulties for a number of reasons. If the fused chromosomes are homologous, that is, from the same chromosome pair, the carrier can produce only unbalanced gametes. Each egg or sperm contains either both copies of the translocated chromosome, which would result in trisomy if fertilized, or no copy, which would result in monosomy. If the fused chromosomes are nonhomologous, four of the six possible gametes would be abnormal. The most common robertsonian translocation is der(13;14)(q10;q10), which accounts for up to 20 percent of cases of Patau syndrome (Trisomy 18—Edwards Syndrome).

Isochromosomes

These abnormal chromosomes are composed of either two q arms or two p arms of one chromosome fused together. Isochromosomes are thought to arise when the centromere breaks transversely instead of longitudinally during meiosis II or mitosis. They can also result from a meiotic error in a chromosome with a robertsonian translocation. An isochromosome containing the q arms of an acrocentric chromosome behaves like a homologous robertsonian translocation, and such a carrier can produce only abnormal unbalanced gametes. When an isochromosome involves nonacrocentric chromosomes, with p arms containing important genetic material, the fusion and abnormal centromere break results in two isochromosomes. One is composed of both p arms, and one is composed of both q arms. It is likely that one of these isochromosomes would be lost during cell division, resulting in the deletion of all the genes located on the lost arm. Thus, a carrier is usually phenotypically abnormal and produces abnormal gametes. The most common isochromosome involves the long arm of the X chromosome, i(Xq), which is the etiology of 15 percent of cases of Turner syndrome.

Chromosomal Inversions

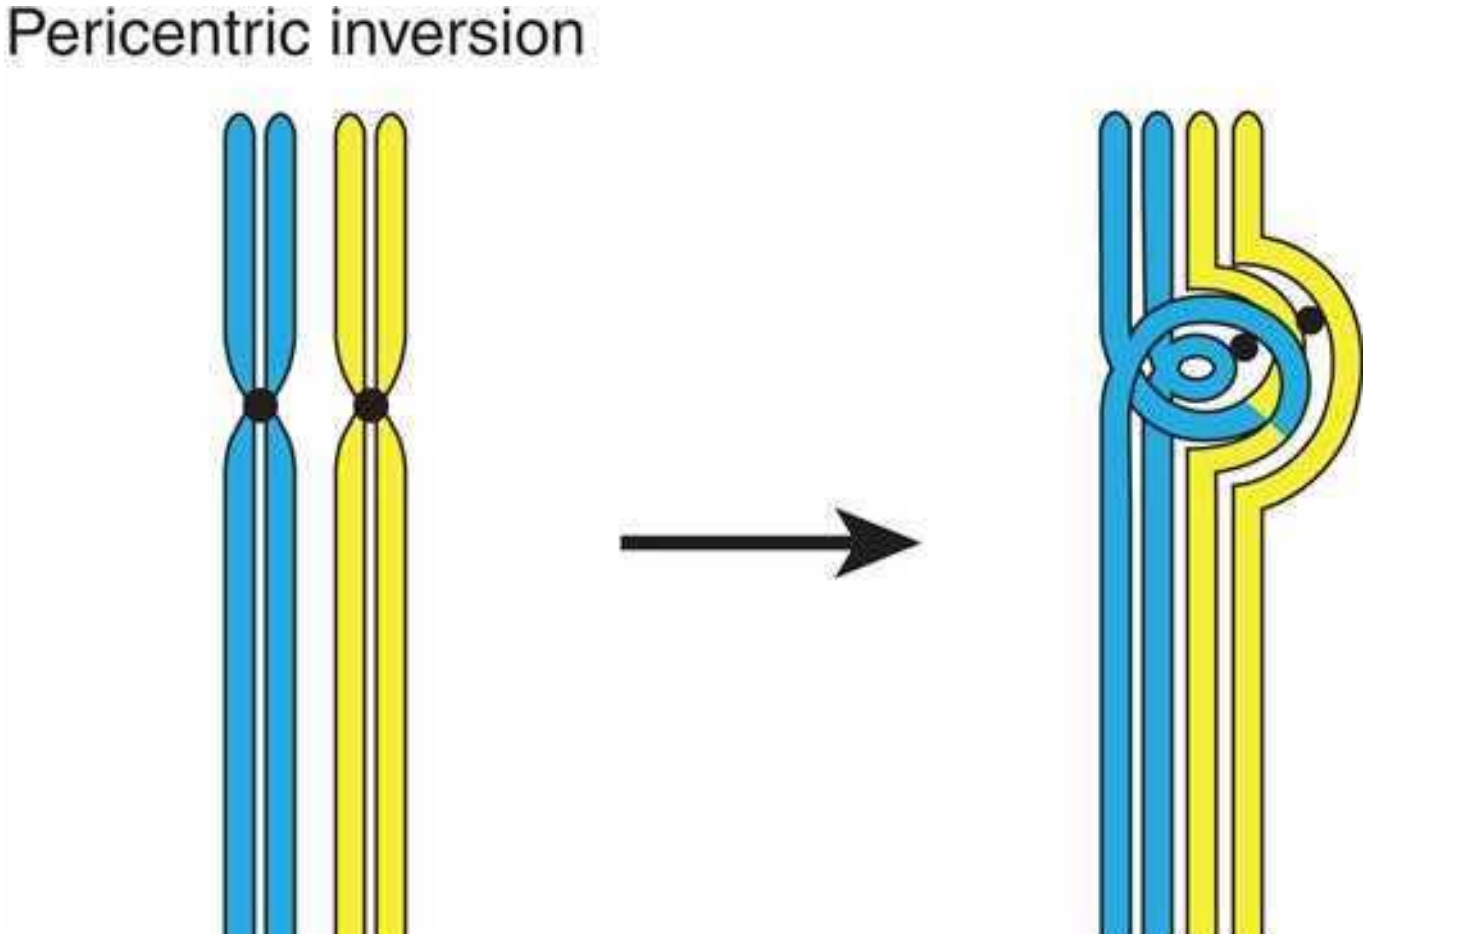
When there are two breaks in the same chromosome, and the intervening genetic material is inverted before the breaks are repaired, the result is a chromosomal inversion. Although no genetic material is lost or duplicated, the rearrangement may alter gene function. There are two types—pericentric and paracentric inversions.

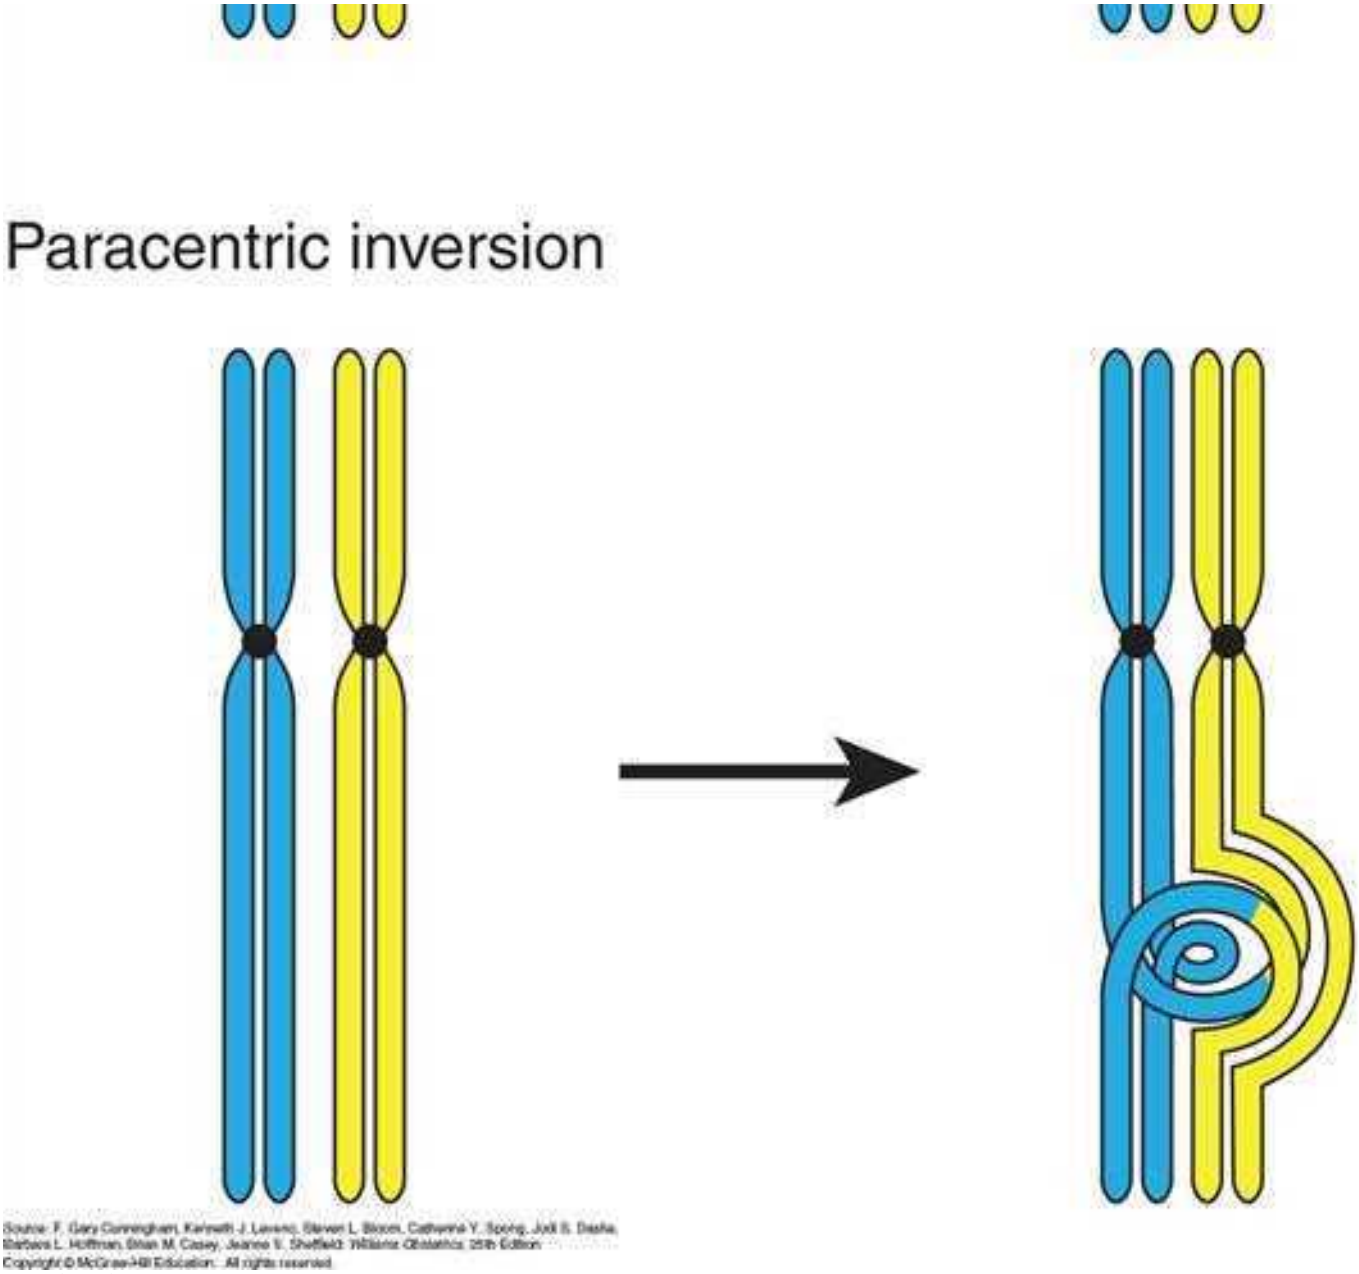
Pericentric Inversion

This results from breaks in both the p and q arms of a chromosome, such that the inverted material includes the centromere (Fig. 13-8). A pericentric inversion causes problems in chromosomal alignment during meiosis and confers significant risk for the carrier to produce abnormal gametes and abnormal offspring. In general, the observed risk of abnormal offspring in a pericentric inversion carrier is 5 to 10 percent if ascertainment was made after the birth of an abnormal child. But the risk is only 1 to 3 percent if prompted by another indication. An important exception is a pericentric inversion on chromosome 9. This is inv(9)(p11q12), which is a normal variant present in approximately 1 percent of the population.

FIGURE 13-8

Mechanism of meiosis in the setting of either pericentric inversion (one involving the centromere) or paracentric inversion (not involving the centromere). Individuals with pericentric inversions are at increased risk for producing offspring with a duplication/deletion. Those with paracentric inversions are at increased risk for early pregnancy loss.





Paracentric Inversion

If there are two breaks within one arm of a chromosome—either p or q—the inverted material does not include the centromere, and the inversion is paracentric (see Fig. 13-8). The carrier makes either normal balanced gametes or gametes that are so abnormal as to preclude fertilization. Thus, although infertility may be a problem, the risk of having an abnormal offspring is extremely low.

Ring Chromosome

If there are deletions at each end of the same chromosome, the ends may come together to form a ring chromosome. The telomere regions, which are the ends of a chromosome, contain specialized nucleoprotein complexes that stabilize the chromosome. If just the telomeres are lost, all necessary genetic material is retained, and the carrier is essentially balanced. If a deletion extends more proximally than the telomere, the carrier is likely to be phenotypically abnormal. An example of this is a ring X chromosome, which may result in Turner syndrome.

Chromosomal Mosaicism

A mosaic individual has two or more cytogenetically distinct cell lines that are derived from a single zygote. Phenotypic expression of mosaicism depends on several factors, including whether the cytogenetically abnormal cells involve the fetus, part of the fetus, just the placenta, or some combination. Of amnionic fluid cultures, mosaicism is found in approximately 0.3 percent but may not reflect the fetal chromosomal complement (Carey, 2014). When the abnormal cells are present in only a single flask of amnionic fluid, the finding is likely pseudomosaicism, caused by cell-culture artifact (Bui, 1984; Hsu, 1984). When abnormal cells involve multiple cultures, however, true mosaicism is more likely, and further testing may be warranted. A second cell line is verified in 60 to 70 percent of these fetuses (Hsu, 1984; Worton, 1984).

Confined Placental Mosaicism

With chorionic villus sampling, studies demonstrate that up to 2 percent of placentas are mosaic, with the mosaicism confined to the placenta in most of these cases (Baffero, 2012; Henderson, 1996). Amniocentesis should be offered. In a series of more than 1000 pregnancies with mosaicism found from chorionic villus sampling, subsequent amniocentesis identified true fetal mosaicism in 13 percent. Uniparental disomy, discussed later (Imprinting), was found in 2 percent, and the remainder resulted from confined placental mosaicism (Malvestiti, 2015). If mosaicism is detected for a chromosome known to contain imprinted genes—such as chromosomes 6, 7, 11, 14, or 15—testing for uniparental disomy should be considered, as there may be fetal consequences (Grati, 2014a).

Although outcomes with confined placental mosaicism are generally good, fetal-growth restriction is more common, and the stillbirth risk is also higher (Reddy, 2009). Fetal-growth restriction may stem from impaired functioning of the aneuploid placental cells (Baffero, 2012). Placental mosaicism for trisomy 16 confers a particularly poor prognosis.

Gonadal Mosaicism

Mosaicism confined to the gonads likely arises from a mitotic error in cells destined to become the gonad, resulting in a population of abnormal germ cells. Because spermatogonia and oogonia divide throughout fetal life, and spermatogonia continue to divide throughout adulthood, gonadal mosaicism may also follow a meiotic error in previously normal germ cells. Gonadal mosaicism can account for de novo diseases in the offspring of normal parents. Autosomal dominant examples are achondroplasia and osteogenesis imperfecta, and X-linked ones include Duchenne muscular dystrophy. Gonadal mosaicism also explains the 6-percent recurrence risk after the birth of a child with a disease caused by a “new” mutation.

MODES OF INHERITANCE

A monogenic or *mendelian* disorder is caused by a mutation or alteration in a single locus or gene in one or both members of a gene pair. Types of mendelian inheritance include autosomal dominant, autosomal recessive, X-linked, and Y-linked. Other monogenic inheritance patterns, described subsequently, include mitochondrial inheritance, uniparental disomy, imprinting, and trinucleotide repeat expansion—also termed anticipation. By age 25, approximately 0.4 percent of the population exhibits an abnormality attributed to a monogenic disorder, and 2 percent will have at least one such disorder during their lifetime (Table 13-3).

TABLE 13-3

Selected Monogenic (Mendelian) Disorders

Autosomal Dominant
Achondroplasia
Acute intermittent porphyria
Adult polycystic kidney disease
Antithrombin III deficiency
BRCA1 and BRCA2 breast and/or ovarian cancer
Ehlers-Danlos syndrome
Familial adenomatous polyposis
Familial hypercholesterolemia
Hereditary hemorrhagic telangiectasia
Hereditary spherocytosis
Huntington disease
Hypertrophic obstructive cardiomyopathy
Long QT syndrome
Marfan syndrome
Myotonic dystrophy
Neurofibromatosis type 1 and 2
Tuberous sclerosis
von Willebrand disease
Autosomal Recessive
α_1-Antitrypsin deficiency
Congenital adrenal hyperplasia
Cystic fibrosis
Gaucher disease
Hemochromatosis
Homocystinuria
Phenylketonuria
Sickle-cell anemia
Tay-Sachs disease
Thalassemia syndromes
Wilson disease
X-Linked
Androgen insensitivity syndrome
Chronic granulomatous disease
Color blindness
Fabry disease
Fragile X syndrome
Glucose-6-phosphate deficiency
Hemophilia A and B
Hypophosphatemic rickets
Muscular dystrophy—Duchenne and Becker
Ocular albinism type 1 and 2

Relationship between Phenotype and Genotype

When considering inheritance, it is the phenotype that is dominant or recessive, not the genotype. With a dominant disease, the normal gene may direct the production of normal protein, but the phenotype is abnormal because it is determined by protein produced by the abnormal gene. With a recessive disease, a heterozygous carrier may produce detectable levels of an abnormal gene product but have no features of the condition because the phenotype is directed by the product of the normal co-gene. For example, erythrocytes from carriers of sickle-cell anemia contain approximately 30 percent hemoglobin S, but because the other 70 percent is hemoglobin A, these cells do not usually sickle in vitro.

Heterogeneity

Genetic heterogeneity explains how different genetic mechanisms can result in the same phenotype. *Locus heterogeneity* indicates that a specific disease phenotype can be caused by mutations in different genetic loci. It also explains why some diseases appear to follow more than one type of inheritance. An example is retinitis pigmentosa, which may develop following mutations in at least 35 different genes or loci and may result in autosomal dominant, autosomal recessive, or X-linked forms.

Allelic heterogeneity describes how different mutations of the same gene may affect presentation of a particular disease. For example, although only one gene has been associated with cystic fibrosis—the *cystic fibrosis conductance transmembrane regulator* gene—more than 2000 mutations in this gene have been described and result in variable disease severity (Chaps. 14 and 51, Cystic Fibrosis and Sarcoidosis).

Phenotypic heterogeneity explains how different disease states can arise from different mutations in the same gene. As an example, mutations in the *fibroblast growth factor receptor 3 (FGFR3)* gene may result in several different skeletal disorders, including achondroplasia and thanatophoric dysplasia, both of which are discussed in Chapter 10 (Skeletal Abnormalities).

Autosomal Dominant Inheritance

If only one copy of a gene pair determines the phenotype, that gene is considered to be dominant. Carriers have a 50-percent chance of passing on the affected gene with each conception. A gene with a dominant mutation generally specifies the phenotype in preference to the normal gene. That said, not all individuals will necessarily manifest an autosomal dominant condition the same way. Factors that affect the phenotype of an autosomal dominant condition include penetrance, expressivity, and occasionally, presence of codominant genes.

Penetrance

This characteristic describes whether or not a dominant gene is expressed at all. A gene with recognizable phenotypic expression in all individuals is 100-percent penetrant, whereas penetrance is incomplete if some carriers express the gene but some do not. This may be quantitatively expressed—for example, a gene that is expressed in some way in 80 percent of individuals who have that gene is 80-percent penetrant. Importantly, incomplete penetrance explains why some autosomal dominant diseases may appear to "skip" generations.

Expressivity

Individuals with the same autosomal dominant trait may manifest the condition differently, even within the same family. Genes with variable expressivity can produce disease manifestations that range from mild to severe. Examples include neurofibromatosis, tuberous sclerosis, and adult polycystic kidney disease.

Codominant Genes

If two different alleles in a gene pair are both expressed in the phenotype, they are considered to be codominant. Blood type, for example, is determined by expression of dominant A and B red-cell antigens that can be expressed simultaneously. Another example of codominance is the group of genes responsible for hemoglobin production. An individual with one gene directing production of hemoglobin S and the other directing production of hemoglobin C will produce both S and C hemoglobin (Chap. 56, Pregnancy and Sickle-Cell Syndromes).

Advanced Paternal Age

Paternal age older than 40 is associated with increased risk for spontaneous genetic mutations, particularly single base substitutions. This may result in offspring with new autosomal dominant disorders or X-linked carrier states. In particular, advanced paternal age has been associated with mutations in the *fibroblast growth factor receptor 2 (FGFR2)* gene, which may cause craniosynostosis syndromes such as Apert, Crouzon, and Pfeiffer syndromes; mutations in the *FGFR3* gene, which may result in achondroplasia and thanatophoric dysplasia; and mutations in the *RET proto-oncogene,* which may cause multiple endocrine neoplasia syndromes (Jung, 2003; Toriello, 2008). Using whole genome sequencing, described later (Whole Genome Sequencing and Whole Exome Sequencing), Kong and associates (2012) also demonstrated that paternal age contributes to a rise in the rate of single-nucleotide polymorphisms among offspring. This rate is approximately two mutations for each year of paternal age. Because individual autosomal dominant disorders are uncommon, the actual risk for any specific condition is low, and no screening or testing is specifically recommended.

Advanced paternal age has also been associated with a slightly greater risk for fetal Down syndrome and for isolated structural abnormalities (Grewal, 2012; Toriello, 2008; Yang, 2007). It is not generally considered to pose an elevated risk for other aneuploidies, probably because the aneuploid sperm cannot fertilize an egg.

Autosomal Recessive Inheritance

Recessive diseases develop only when both gene copies are abnormal. Many enzyme deficiency diseases display autosomal recessive inheritance, and enzyme activity in the carrier is usually about half of normal. Unless carriers are screened for a specific disease, such as cystic fibrosis, they usually are recognized only after the birth of an affected child or the diagnosis of an affected family member (Chap. 14, Cystic Fibrosis). If a couple has a child with an autosomal recessive disease, the recurrence risk is 25 percent for each subsequent pregnancy. Thus, 1/4 of offspring will be homozygous normal, 2/4 will be heterozygous carriers, and 1/4 will be homozygous abnormal. In other words, three of four children will be phenotypically normal, and 2/3 of phenotypically normal siblings are actually carriers.

A heterozygous carrier of a recessive condition is only at risk to have affected children if his or her partner is heterozygous or homozygous for the disease. Genes for rare autosomal recessive conditions have low prevalence in the general population. Thus, the likelihood that a partner will be a gene carrier is small, unless there is consanguinity or the partner is a member of an at-risk group. Heterozygous carriers are usually undetectable clinically but may have biochemical test abnormalities

that can be used for carrier screening. Other recessive conditions can be identified only by molecular genetic testing (Chap. 14, Carrier Screening for Genetic Disorders).

Inborn Errors of Metabolism

Most of these autosomal recessive diseases result from absence of a crucial enzyme, leading to incomplete metabolism of proteins, lipids, or carbohydrates. The metabolic intermediates that build up are toxic to various tissues and may result in intellectual disability or other abnormalities.

Phenylketonuria

Also known as phenylalanine hydroxylase (PAH) deficiency, this autosomal recessive disease is caused by mutations in the *PAH* gene. PAH metabolizes phenylalanine to tyrosine, and homozygotes have diminished or absent enzyme activity. This leads to abnormally high levels of phenylalanine, resulting in progressive intellectual impairment, autism, seizures, motor deficits, and neuropsychological abnormalities (Blau, 2010). Because phenylalanine competitively inhibits tyrosine hydroxylase—which is essential for melanin production, affected individuals also have hair, eye, and skin hypopigmentation. More than 500 *PAH* gene mutations have been characterized, and the carrier frequency is 1 in 60, such that the disease affects approximately 1 in 15,000 newborns (American College of Obstetricians and Gynecologists, 2017c). Prompt diagnosis and restriction of dietary phenylalanine beginning early in infancy are essential to prevent neurological damage, and all states mandate newborn screening for phenylketonuria (PKU).

Phenylalanine restriction alone would result in inadequate protein consumption, and phenylalanine-free amino acid-based supplementation is required. Also, in 2007, a synthetic form of the PAH cofactor tetrahydrobiopterin (sapropterin) was approved for PKU treatment. Approximately 25 to 50 percent of affected individuals are sapropterin-responsive and may experience a significant decline in phenylalanine levels and improvement in neuropsychiatric symptoms (Vockley, 2014). Lifelong maintenance of phenylalanine concentrations in the range of 2 to 6 mg/dL (120 to 360 µmol/L) is necessary to prevent worsening neurocognitive and psychiatric problems (American College of Obstetricians and Gynecologists, 2017c). Fortunately, even those who have previously discontinued therapy may experience improved neuropsychological function with treatment.

During pregnancy, women with PKU whose phenylalanine levels remain above the recommended range are at risk to have otherwise normal (heterozygous) offspring who sustain in utero damage as a result of being exposed to toxic phenylalanine concentrations. Phenylalanine is actively transported to the fetus. Hyperphenylalaninemia raises the risk for miscarriage and for PKU embryopathy, characterized by intellectual disability, microcephaly, seizures, growth impairment, and cardiac anomalies. Among women on unrestricted diets, the risk to have a child with intellectual disability exceeds 90 percent, microcephaly occurs in more than 70 percent, and as many as 1 in 6 children have cardiac defects (Lenke, 1980). The Maternal Phenylketonuria Collaborative Study, which included 572 pregnancies followed more than 18 years, reported that maintenance of serum phenylalanine levels in the recommended range between 2 and 6 mg/dL significantly reduced the fetal abnormality risk and resulted in childhood IQ scores in the normal range (Koch, 2003; Platt, 2000). Preconceptional counseling and consultation with providers from experienced PKU centers is recommended.

Consanguinity

Two individuals are considered consanguineous if they have at least one recent ancestor in common. Although uncommon in Western countries, more than 1 billion people are estimated to live in countries in which 20 to 50 percent of marriages are consanguineous (Romeo, 2014). In medical genetics, a union is consanguineous if between second cousins or closer relatives. First-degree relatives share half of their genes, second-degree relatives share a fourth, and third-degree relatives—first cousins—share one eighth. Because of the potential for shared deleterious genes, consanguinity confers an increased risk to have offspring with otherwise rare autosomal recessive diseases or multifactorial disorders. In population-based series, first cousins are reported to have a twofold risk for congenital anomalies (Sheridan, 2013; Stoltenberg, 1997). Consanguinity also is associated with a greater rate of stillbirth (Kapurubandara, 2016). Because CMA performed using a single-nucleotide polymorphism platform may identify consanguinity, it is important that preprocedural counseling include this possibility.

Incest is defined as a sexual relationship between first-degree relatives such as parent-child or brother-sister and is universally illegal. Progeny of such unions carry the highest risk of abnormal outcomes, and older studies reported that up to 40 percent of offspring were abnormal as a result of recessive and multifactorial disorders (Baird, 1982; Freire-Maia, 1984).

X-Linked and Y-Linked Inheritance

Most X-linked diseases are recessive. Common examples include color blindness, hemophilia A and B, and Duchenne and Becker muscular dystrophy. Males with an X-linked recessive gene are usually affected by the disease it causes, because they lack a second X chromosome to express the normal dominant gene. A male with an X-linked disease cannot have affected sons because they cannot receive his X chromosome. When a woman carries a gene causing an X-linked recessive condition, each of her sons has a 50-percent risk of being affected, and each daughter has a 50-percent chance of being a carrier.

Women with an X-linked recessive gene are generally unaffected by the disease it causes. In some cases, however, the random inactivation of one X chromosome in each cell—termed lyonization—is skewed, and female carriers may have features of the condition. For example, approximately 10 percent of female carriers of hemophilia A will have factor VIII levels less than 30 percent of normal, and a similar proportion of female hemophilia B carriers have factor IX levels less than 30 percent. Levels below these thresholds confer a greater risk for abnormal bleeding when affected women give birth (Plug, 2006). Indeed, even with higher levels, carriers are reported to be at increased risk for bleeding complications (Olsson, 2014). Similarly, female carriers of Duchenne or Becker muscular dystrophy carry an elevated risk for cardiomyopathy, and periodic evaluation for cardiac dysfunction and neuromuscular disorders is recommended (American Academy of Pediatrics, 2008).

X-linked dominant disorders mainly affect females, because they tend to be lethal in males. Two examples are vitamin D-resistant rickets and incontinentia pigmenti. One exception is fragile X syndrome, which is discussed subsequently.

The prevalence of Y-linked chromosomal disorders is low. This chromosome carries genes important for sex determination and various cellular functions related to spermatogenesis and bone development. Deletion of genes on the long arm of Y results in severe spermatogenic defects, whereas genes at the tip of the short arm are critical for chromosomal pairing during meiosis and for fertility.

Mitochondrial Inheritance

Human cells contain hundreds of mitochondria, each with its own genome and associated replication system. Oocytes contain approximately 100,000 mitochondria. Sperm hold only about 100, and these are destroyed after fertilization. Each mitochondrion has multiple copies of a 16.5-kb circular DNA molecule that contains 37 genes. Mitochondrial DNA encodes peptides required for oxidative phosphorylation and encodes ribosomal and transfer RNAs.

Mitochondria are inherited exclusively from the mother. Thus, although males and females both can be affected by a mitochondrial disorder, transmission is only through the mother. When a cell replicates, mitochondrial DNA sorts randomly into each of the daughter cells, a process termed replicative segregation. A consequence of replicative segregation is that any mitochondrial mutation will be propagated randomly into the daughter cells. Because each cell holds multiple copies of mitochondrial DNA, the mitochondrion may contain only normal or only abnormal DNA, termed *homoplasmy.* Alternatively, it may contain both normal and mutated DNA, namely *heteroplasmy.* If a heteroplasmic oocyte is fertilized, the relative proportion of mutated DNA may affect whether the individual manifests a given mitochondrial disease. It is not possible to predict the potential degree of heteroplasmy among offspring, and this poses challenges for genetic counseling.

As of 2016, 33 mitochondrial diseases or conditions with known molecular basis were described in Online Mendelian Inheritance in Man (Johns Hopkins University, 2017). Examples include myoclonic epilepsy with ragged red fibers (MERRF), Leber optic atrophy, Kearns-Sayre syndrome, Leigh syndrome, several forms of mitochondrial myopathy and cardiomyopathy, and susceptibility to chloramphenicol toxicity.

DNA Triplet Repeat Expansion—Anticipation

Mendel's first law is that genes are passed unchanged from parent to progeny, and barring new mutations, this is true for many genes or traits. However, certain genes are unstable, and their size, and thus function, may be altered during parent-to-child transmission. This is manifested clinically by anticipation—a phenomenon in which disease symptoms seem to be more severe and to appear at an earlier age in each successive generation. Examples of some DNA triplet (trinucleotide) repeat diseases are shown in Table 13-4.

TABLE 13-4

Some Disorders Caused by DNA Triplet Repeat Expansion

Dentatorubral-pallidoluysian atrophy
Fragile X syndrome
Friedreich ataxia
Huntington disease
Spinal and bulbar muscular atrophy
Myotonic dystrophies
Spinocerebellar ataxias

Fragile X Syndrome

This is the most common inherited form of intellectual disability and affects approximately 1 in 3600 males and 1 in 4000 to 6000 females (American College of Obstetricians and Gynecologists, 2017a). Fragile X syndrome is caused by expansion of a repeated trinucleotide DNA segment—cytosine-guanine-guanine (CGG)—at chromosome Xq27.3. When the CGG repeat number reaches a critical size—the full mutation—the *fragile X mental retardation 1 (FMR1)* gene becomes methylated. Methylation inactivates the gene, which halts expression of FMR1 protein. This protein is most abundant in nerve cells and is essential for normal cognitive development.

Although transmission of the syndrome is X-linked, both the sex of the affected individual and the number of CGG repeats determine the degree of clinical normalcy or impairment. Intellectual disability is generally more severe in males, in whom average IQ scores are 35 to 45 (Nelson, 1995). Affected individuals may have speech and language problems and attention-deficit/hyperactivity disorder. Fragile X syndrome is also the most common known cause of autism or "autistic like" behavior. Associated phenotypic abnormalities become more prominent with age and include a narrow face with large jaw, prominent ears, connective tissue abnormalities, and macroorchidism in postpubertal males. Clinically, four groups have been described (American College of Obstetricians and Gynecologists, 2017a):

Full mutation—more than 200 repeats

Premutation—55 to 200 repeats

Intermediate—45 to 54 repeats

Unaffected—fewer than 45 repeats

Full mutations are expressed (penetrant) in all males and many females. When a full mutation is present, males typically have significant cognitive and behavioral abnormalities and phenotypic features. In females, random X-inactivation, however, results in variable expression, and the disability may be much less severe. With

rare exception, the parent of origin of repeat expansion that leads to a full mutation is female (Monaghan, 2013).

For individuals with a premutation, evaluation and counseling are more complex. A female with the fragile X premutation is at risk to have offspring with the full mutation, depending on the repeat number. The risk of a full mutation in an offspring is 5 percent or less if the CGG repeat number is <70 but exceeds 95 percent with 100 to 200 CGG repeats (Nolin, 2003). Expansion is extremely unlikely in a male premutation carrier, but all of his daughters will carry the premutation. Among women with no risk factors, approximately 1 in 250 carries a fragile X premutation, and the risk approximates 1 in 90 in those with a family history of intellectual disability (Cronister, 2008). Premutation carriers may themselves experience significant health consequences. Males with the premutation are at increased risk for the fragile X tremor ataxia syndrome (FXTAS). This syndrome is characterized by memory loss, executive function deficits, anxiety, and dementia (Monaghan, 2013). Females are at risk for FXTAS as well, although less so. They also have a 20-percent risk for fragile X-associated primary ovarian insufficiency.

The American College of Obstetricians and Gynecologists (2016c, 2017a) recommends carrier screening for women with a family history of fragile X syndrome; individuals with unexplained intellectual disability, developmental delay, or autism; and women with primary ovarian insufficiency. Prenatal diagnosis can be accomplished by amniocentesis or chorionic villus sampling. Specimens obtained by either can define the CGG repeat number, although chorionic villus sampling may not accurately determine *FMR1* gene methylation status.

Imprinting

This term describes some genes that are inherited but not expressed, depending on whether they are inherited from the mother or father. Thus, the resulting phenotype varies according to the parent of origin. Imprinting affects gene expression by epigenetic control, which modifies genetic structure using methods other than altering the underlying nucleotide sequence. For example, methyl group addition may alter gene expression and thereby affect the phenotype without changing the genotype. Importantly, the effect may be reversed in a subsequent generation, because a female who inherits an imprinted gene from her father will pass it in her oocytes with a maternal—rather than paternal—imprint, and vice versa.

Selected diseases that can involve imprinting are shown in Table 13-5. A useful example includes two very different diseases that affect the same region of DNA. First, *Prader-Willi syndrome* is characterized by obesity and hyperphagia; short stature; small hands, feet, and external genitalia; and mild mental retardation. In more than 70 percent of cases, Prader-Willi syndrome is caused by microdeletion or disruption for the paternal 15q11.2-q13. The remaining cases are due to maternal uniparental disomy or due to maternal gene imprinting with the paternal gene inactivated.

TABLE 13-5

Some Disorders That Can Involve Imprinting

Disorder	Chromosomal Region	Parental Origin
Angelman	15q11.2-q13	Maternal
Beckwith-Wiedemann	11p15.5	Paternal
Myoclonus-dystonia	7q21	Maternal
Prader-Willi	15q11.2-q13	Paternal
Pseudohypoparathyroidism	20q13.2	Variable
Russell-Silver syndrome	7p11.2	Maternal

Data from Online Mendelian Inheritance in Man (Johns Hopkins University, 2017.)

In contrast, *Angelman syndrome* includes severe intellectual disability; normal stature and weight; absent speech; seizure disorder; ataxia and jerky arm movements; and paroxysms of inappropriate laughter. In approximately 70 percent of cases, Angelman syndrome is caused by microdeletion for the maternal 15q11.2-q13. In 2 percent, the syndrome is caused by paternal uniparental disomy, and another 2 to 3 percent is due to paternal gene imprinting with the maternal genes inactivated.

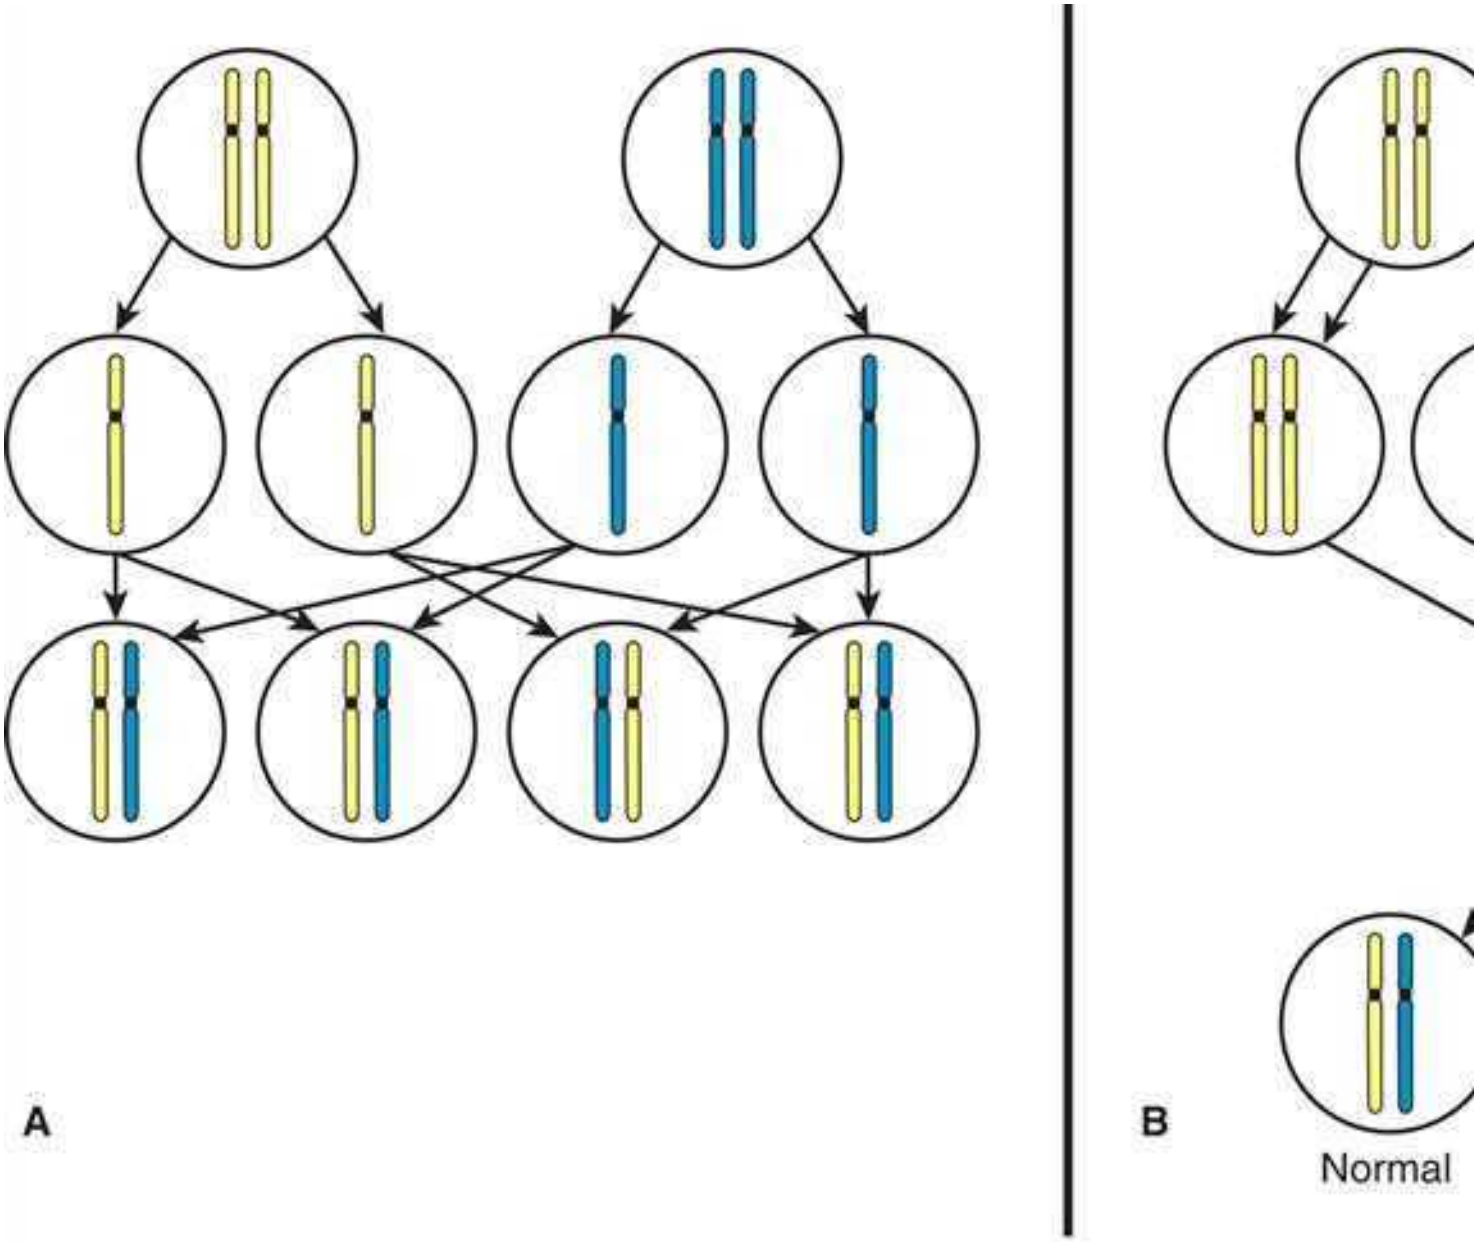
There are other examples of imprinting important to obstetrics. Complete hydatidiform mole, with a paternally derived diploid chromosomal complement, is characterized by abundant placental growth with no fetal structures (Chap. 20, Epidemiology and Risk Factors). Conversely, an ovarian teratoma, with a maternally derived diploid chromosomal complement, is characterized by the growth of various fetal but no placental tissues (Porter, 1993).

Uniparental Disomy

This occurs when both members of a chromosome pair are inherited from the same parent. Often, uniparental disomy does not have clinical consequences. Although both copies are inherited from one parent, they are not identical. However, if chromosomes 6, 7, 11, 14, or 15 are involved, offspring are at increased risk for an abnormality because of parent-of-origin differences in gene expression (Shaffer, 2001). Several genetic mechanisms may cause uniparental disomy, the most common of which is trisomic rescue, shown in Figure 13-9. After a nondisjunction event produces a trisomic conceptus, one of the three homologues may be lost. This will result in uniparental disomy for that chromosome in approximately one third of cases.

FIGURE 13-9

Mechanism of uniparental disomy arising from trisomic "rescue." **A.** In normal meiosis, one member of each pair of homologous chromosomes is inherited from each parent. **B.** If nondisjunction results in a trisomic conceptus, one homologue is sometimes lost. In a third of cases, loss of one homologue leads to uniparental disomy.



Isodisomy is the unique situation in which an individual receives two *identical* copies of one chromosome in a pair from one parent. This mechanism explains some cases of cystic fibrosis, in which only one parent is a carrier but the fetus inherits two copies of the same abnormal chromosome from that parent (Spence, 1988; Spotila, 1992). It also has been implicated in abnormal growth related to placental mosaicism.

Multifactorial Inheritance

Traits or diseases are considered to have multifactorial inheritance if they are determined by the combination of multiple genes and environmental factors (Table 13-6). Polygenic traits are determined by the combined effects of more than one gene. Most congenital and acquired conditions, as well as common traits, display multifactorial inheritance. Examples include malformations such as clefts and neural-tube defects, diseases such as diabetes and heart disease, and features or traits such as head size or height. Abnormalities that display multifactorial inheritance tend to recur in families, but not according to a mendelian pattern. If a couple has had a child with a multifactorial birth defect, their empirical risk to have another affected child is 3 to 5 percent. This risk declines exponentially with successively more distant relationships.

TABLE 13-6

Characteristics of Multifactorial Diseases

There is a genetic contribution: No mendelian pattern of inheritance No evidence of single-gene disorder
Nongenetic factors are also involved in disease causation: Lack of penetrance despite predisposing genotype Monozygotic twins may be discordant
Familial aggregation may be present: Relatives are more likely to have disease-predisposing alleles
Expression more common among close relatives: Becomes less common in less closely related relatives—fewer predisposing alleles Greater concordance in monozygotic than dizygotic twins

Adapted from Nussbaum, 2007.

Multifactorial traits that have a normal distribution in the population are termed continuously variable. A measurement that is more than two standard deviations above or below the population mean is considered abnormal. Continuously variable traits tend to be less extreme in the offspring of affected individuals, because of the statistical principle of regression to the mean.

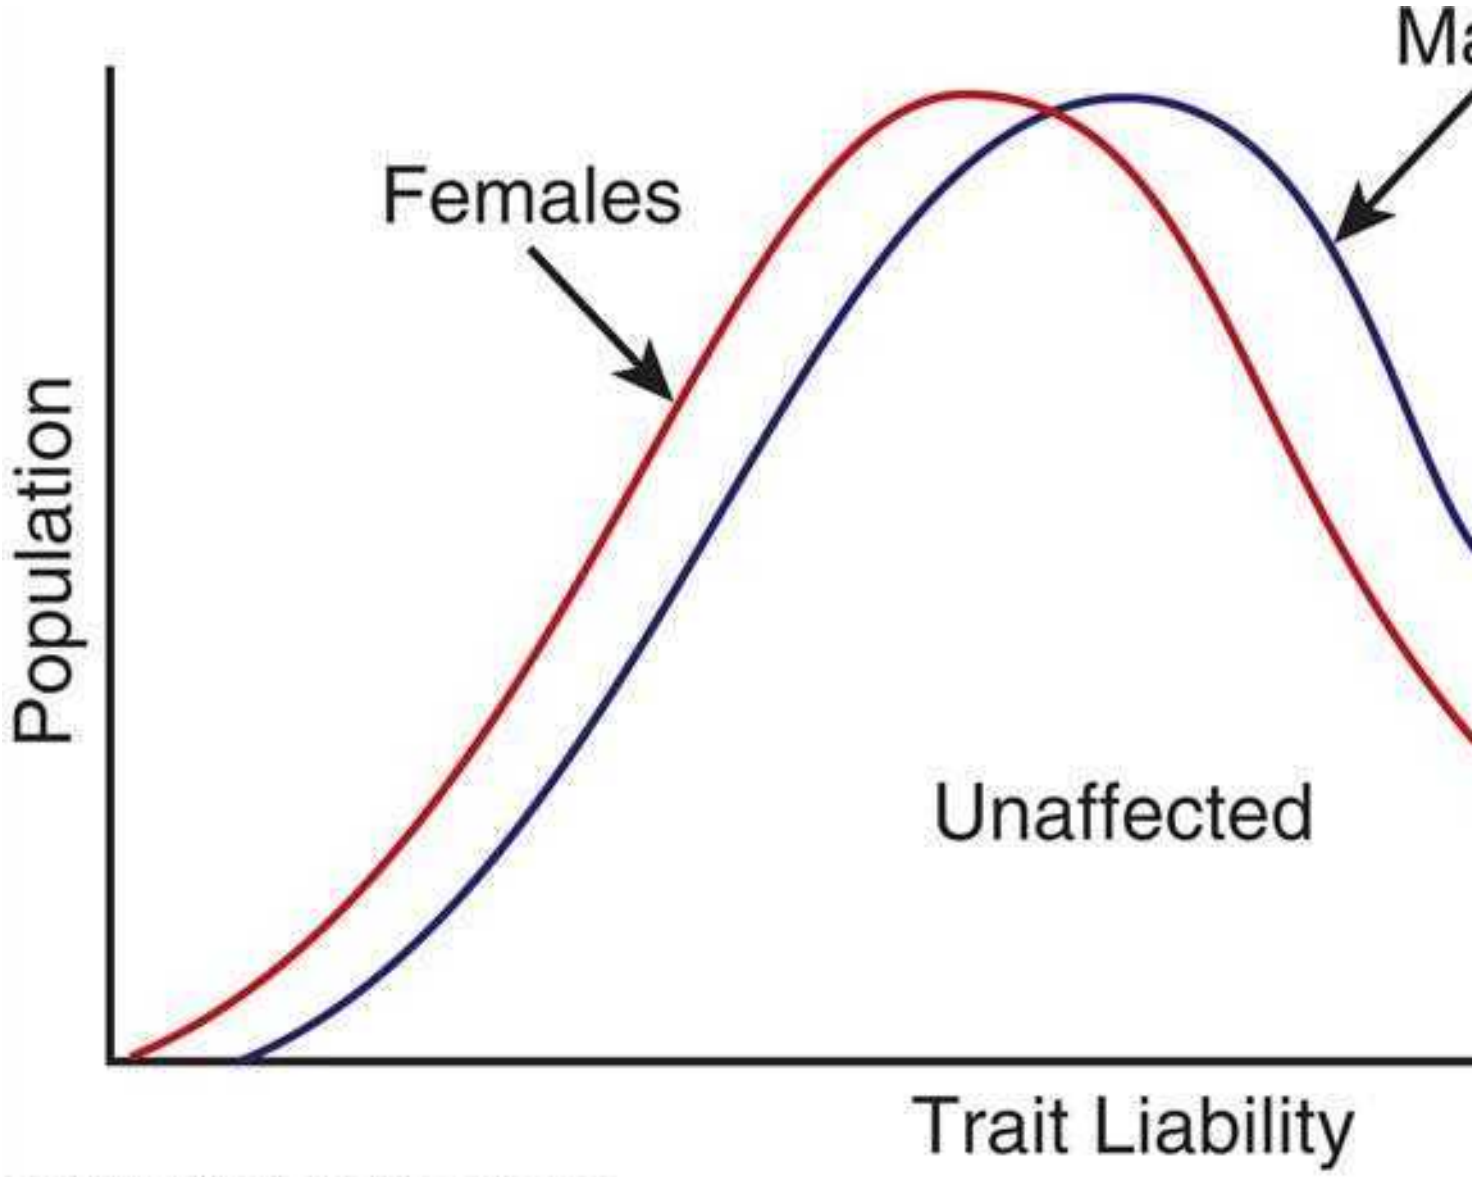
Threshold Traits

Some multifactorial traits do not appear until a threshold is exceeded. Genetic and environmental factors that create propensity or liability for the trait are themselves normally distributed, and only individuals at the extreme of the distribution exceed the threshold and exhibit the trait or defect. Phenotypic abnormality is thus an all-or-none phenomenon. Examples include cleft lip-palate and pyloric stenosis.

Certain threshold traits have a clear male or female predominance. If an individual of the less common gender has the characteristic or defect, the recurrence risk is greater in his or her offspring (Fig. 13-10). An example is pyloric stenosis, which is approximately four times more common in males (Krogh, 2012). A female with pyloric stenosis has likely inherited more predisposing genetic factors than are necessary to produce the defect in a male, and the recurrence risk for her children or siblings is thus higher than the expected 3 to 5 percent. Her male siblings or male offspring would have the highest liability because they not only will inherit more than the usual number of predisposing genes but also are the more susceptible gender.

FIGURE 13-10

Schematic example of a threshold trait, such as pyloric stenosis, which has a predilection for males. Each gender is normally distributed, but at the same threshold, more males than females will develop the condition.



The recurrence risk for threshold traits is also greater if the defect is severe. For example, the recurrence risk after the birth of a child with bilateral cleft lip and palate is approximately 8 percent, but it is only about 4 percent following a child with unilateral cleft lip alone.

Cardiac Defects

Structural cardiac anomalies are the most common birth defects, with a birth prevalence of 8 cases per 1000. More than 100 genes believed to be involved in cardiovascular morphogenesis have been identified, including those directing production of various proteins, protein receptors, and transcription factors (Olson, 2006; Weismann, 2007).

The risk of having a child with a cardiac anomaly is approximately 5 to 6 percent if the mother has the defect and 2 to 3 percent if the father has the defect (Burn, 1998). Selected left-sided lesions, including hypoplastic left heart syndrome, coarctation of the aorta, and bicuspid aortic valve, may have recurrence risks four- to sixfold higher (Lin, 1988; Lupton, 2002; Nora, 1988). Observed recurrence risks for specific cardiac malformations are listed in Table 49-4.

Neural-Tube Defects

These disorders are also classic examples of multifactorial inheritance. Development of neural-tube defects (NTDs) may be influenced by hyperthermia, hyperglycemia, teratogen exposure, ethnicity, family history, fetal gender, and various genes. Selected risks are more strongly associated with the specific defect location. Hyperthermia has been linked with anencephaly risk; pregestational diabetes with cranial and cervical-thoracic defects; and valproic acid exposure with lumbosacral defects (Becerra, 1990; Hunter, 1984; Lindhout, 1992). Sonographic features of NTDs are described in Chapter 10 (Neural-Tube Defects), their prevention with folic acid is discussed in Chapter 9 (Pragmatic Nutritional Surveillance), and fetal therapy for myelomeningocele is reviewed in Chapter 16 (Open Fetal Surgery).

More than 50 years ago, Hibbard and Smithells (1965) postulated that abnormal folate metabolism was responsible for many NTDs. For a woman with a prior affected child, the recurrence risk of 3 to 5 percent is decreased by at least 70 percent—and potentially by as much as 85 to 90 percent—with periconceptional oral folic acid supplementation at a dosage of 4 mg/d (Grosse, 2007; MRC Vitamin Study Research Group, 1991). However, most NTD cases do not occur in the setting of

maternal folic acid deficiency, and it has become clear that the gene-nutrient interactions underlying folate-responsive NTDs are complex. The NTD risk may be affected by genetic variation in folate transport or accumulation, impaired folate utilization via secondary nutrient deficiencies such as vitamin B_{12} or choline deficiency, and genetic variation in activity of folate-dependent metabolic enzymes (Beaudin, 2009).

GENETIC TESTS

All pregnant women should have the option of prenatal aneuploidy *screening* and prenatal genetic *diagnosis* (American College of Obstetricians and Gynecologists, 2016b). Aneuploidy screening may be performed with serum analyte-based screening or with a DNA-based screen, namely, cell-free DNA found in the maternal circulation. Prenatal genetic screening of the parents also aids carrier status determination in at-risk individuals (Chap. 14, Carrier Screening for Genetic Disorders).

For prenatal genetic diagnosis, the most commonly used tests are cytogenetic analysis (karyotyping), fluorescence in situ hybridization (FISH), and chromosomal microarray analysis. Testing may be performed on amnionic fluid or chorionic villi. In selected circumstances, whole genome or whole exome sequencing may be considered, but these are not recommended for routine use. To diagnose a specific disease whose genetic basis is known, DNA-based tests are often employed, typically using polymerase chain reaction (PCR) for rapid amplification of DNA sequences.

Cytogenetic Analysis

Karyotype analysis is commonly performed to test for chromosomal abnormalities. Any tissue containing dividing cells or cells that can be stimulated to divide is suitable for cytogenetic analysis. Karyotyping detects numerical abnormalities, that is, aneuploidy. It also identifies balanced or unbalanced structural rearrangements of at least 5 to 10 megabases in size. Karyotyping has diagnostic accuracy exceeding 99 percent.

The dividing cells are arrested in metaphase, and their chromosomes are stained to reveal light and dark bands. The most commonly used technique is Giemsa staining, which yields the G-bands shown in Figure 13-3. Each chromosome has a unique banding pattern that permits its identification and detection of deleted, duplicated, or rearranged segments. The accuracy of cytogenetic analysis rises with the number of bands produced. High-resolution metaphase banding routinely yields 450 to 550 visible bands per haploid chromosome set. Banding of prophase chromosomes generally yields 850 bands.

Because only dividing cells can be evaluated, the rapidity with which results are obtained correlates with the rapidity of cell growth in culture. Amnionic fluid, which contains epithelial cells, gastrointestinal mucosal cells, and amniocytes, usually yields results in 7 to 10 days. Fetal blood cells may provide results in 36 to 48 hours but are rarely needed (Chap. 14, Fetal Blood Sampling). If fetal skin fibroblasts are evaluated postmortem, stimulation of cell growth can be more difficult, and cytogenetic analysis may take 2 to 3 weeks (Chap. 35, Laboratory Evaluation).

Fluorescence In Situ Hybridization

This technique may be used for rapid identification of a specific chromosome abnormality and for verification of suspected microdeletion or duplication syndromes, such as the 22q11.2 microdeletion described earlier (Abnormalities of Chromosome Structure). Because of its 1- to 2-day turnaround time, FISH is often selected for cases in which findings may alter pregnancy management. To perform FISH, cells are fixed onto a glass slide, and fluorescent-labeled probes are hybridized to the fixed chromosomes (Figs. 13-11 and 13-12). Each probe is a DNA sequence that is complementary to a region of the chromosome or gene being investigated. If the DNA sequence is present, hybridization is detected as a bright signal visible by microscopy. The number of signals indicates the number of chromosomes or genes of that type in the cell being analyzed. Findings are probe-specific. Namely, FISH does not provide information on the entire chromosomal complement but merely the chromosomal or gene region of interest.

FIGURE 13-11
Steps in fluorescence in situ hybridization (FISH).

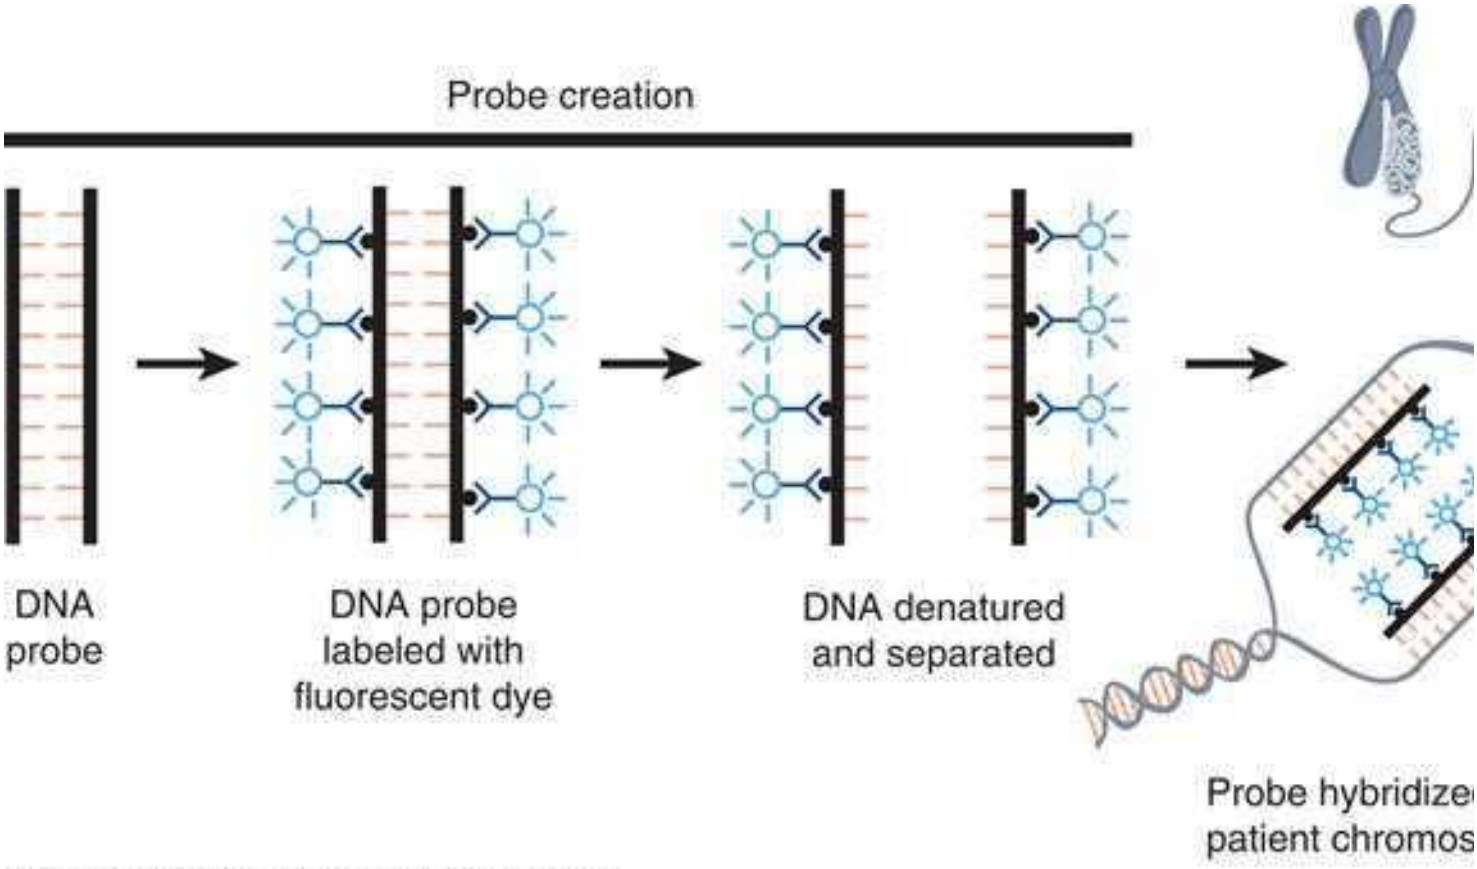


FIGURE 13-12

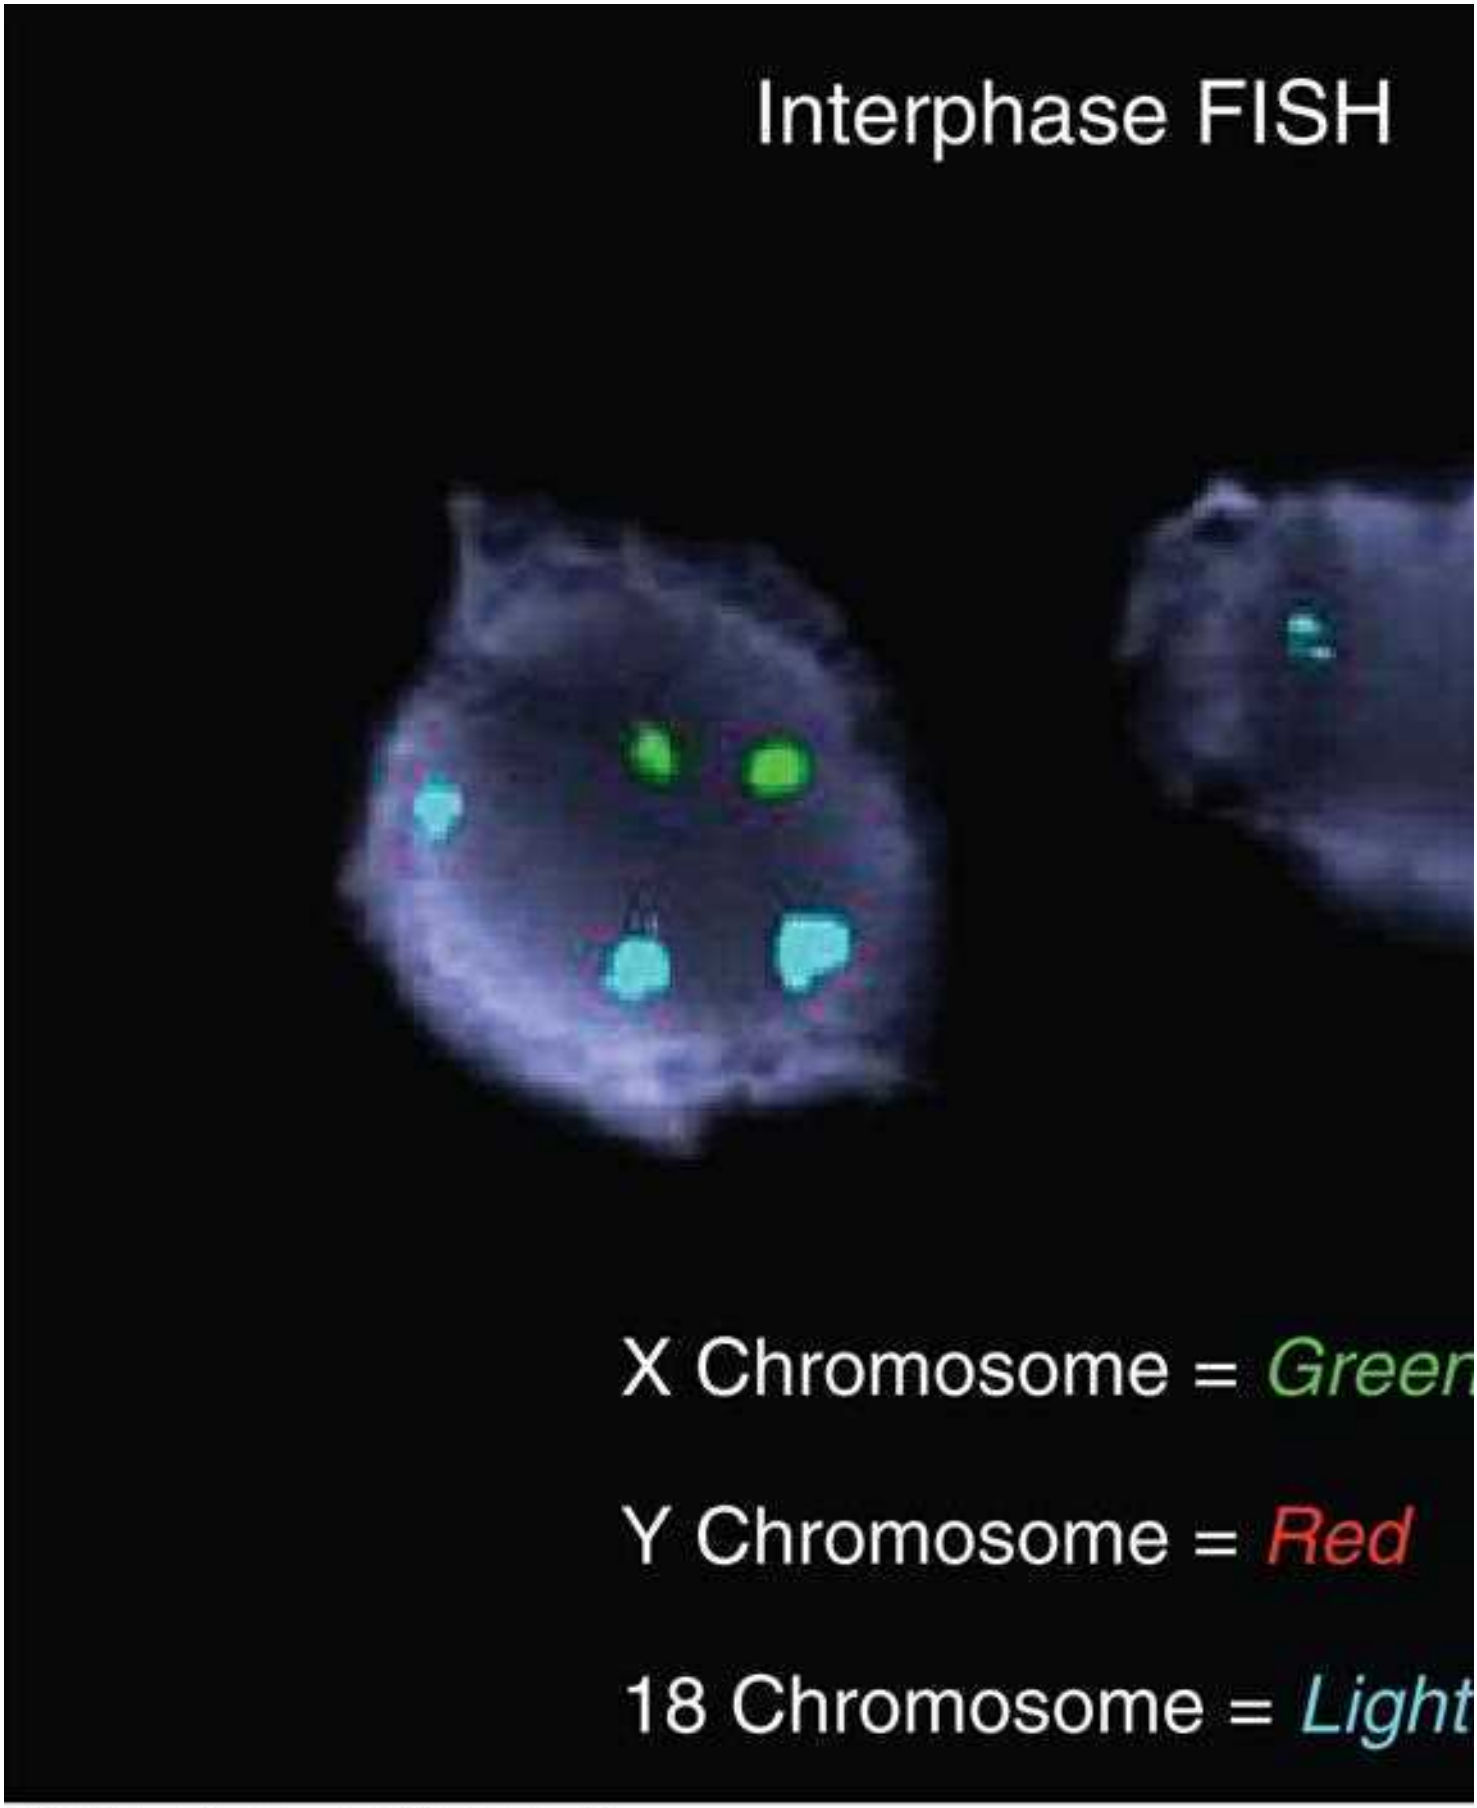
Interphase fluorescence in situ hybridization (FISH) using α-satellite probes for chromosomes 18, X, and Y. In this case, the three light blue signals, two green signals, and absence of red signals indicate that this is a female fetus with trisomy 18. (Used with permission from Dr. Frederick Elder.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

The most common prenatal application of FISH involves testing interphase chromosomes with DNA sequences specific to chromosomes 21, 18, 13, X, and Y. Figure 13-12 shows an example of interphase FISH using α-satellite probes for chromosomes 18, X, and Y to confirm trisomy 18. In a review of more than 45,000 samples, the concordance between FISH analysis and standard cytogenetic karyotyping was 99.8 percent (Tepperberg, 2001). The American College of Obstetricians and

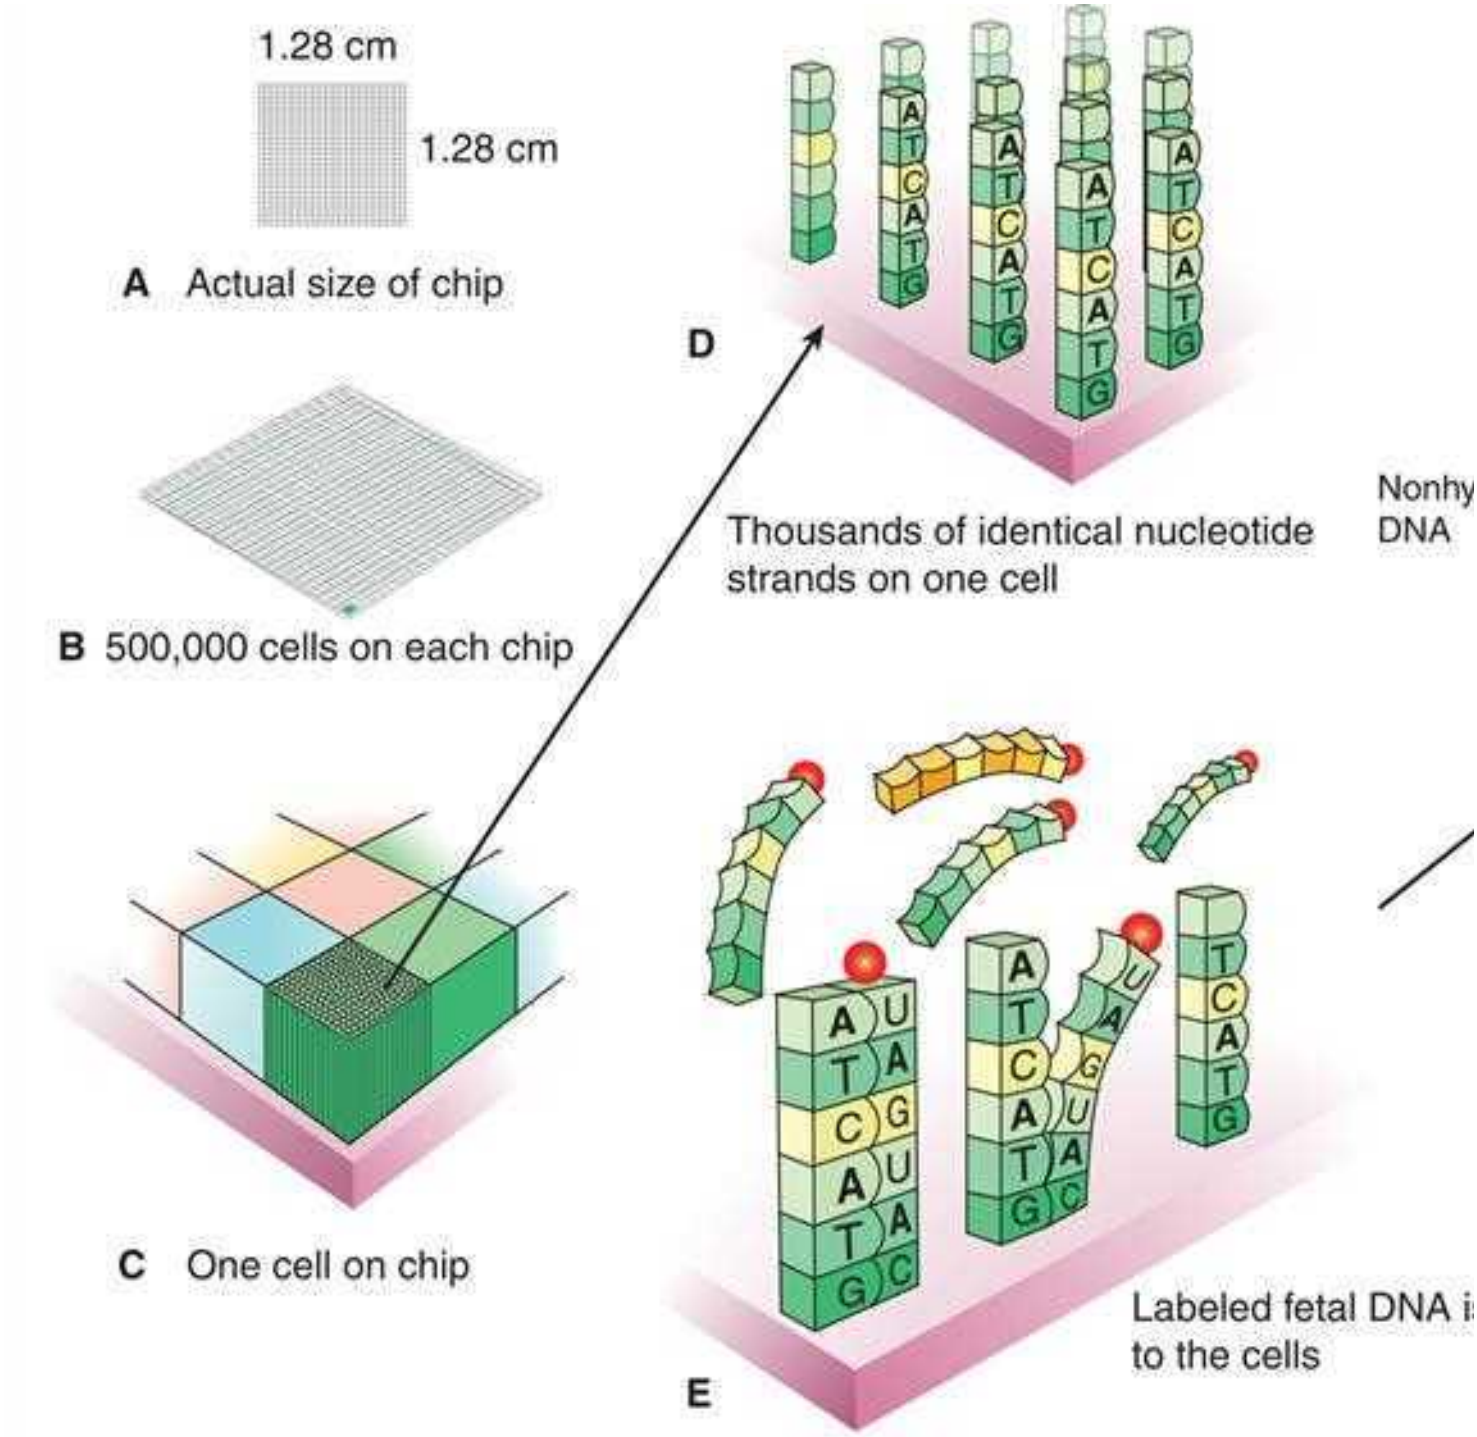
Gynecologists (2016b) recommends that clinical decision-making based on FISH incorporate clinical information consistent with the suspected diagnosis, such as an abnormal aneuploidy screening test result or sonographic finding, or incorporate a confirmatory diagnostic test such as karyotyping or CMA.

Chromosomal Microarray Analysis

This test is 100 times more sensitive than standard karyotyping and detects microduplications and microdeletions as small as 50 to 100 kilobases. Direct CMA can yield results in 3 to 5 days, whereas if cultured cells are required, results may take 10 to 14 days (American College of Obstetricians and Gynecologists, 2016b). Microarrays use either a comparative genomic hybridization (CGH) platform, a single-nucleotide polymorphism (SNP) platform, or a combination of the two. The CGH microarray platform compares test specimen DNA with a normal control sample. Shown in Figure 13-13, the CGH chip contains reference DNA fragments of known sequence—oligonucleotides. Fetal DNA from the amniocentesis or chorionic villus sampling specimen is labeled with a fluorescent dye and then hybridized to the DNA on the chip. Normal control DNA is labeled with a different probe and also hybridized to the chip. Then, the intensity of the fluorescent signals from the two samples is compared. With an SNP array, the chip contains known DNA sequence variants—single-nucleotide polymorphisms. When fetal DNA is labeled and hybridized to the chip, the fluorescent signal intensity indicates copy number variation.

FIGURE 13-13

Chromosomal microarray analysis. **A.** Actual microarray chip size. **B.** Each chip contains thousands of cells (squares). **C & D.** Each cell contains thousands of identical oligonucleotides on its surface, and each cell is unique in its nucleotide content. **E.** During genetic analysis, a mixture containing tagged fetal DNA is presented to the chip. Complementary DNA sequences bind. **F.** If a laser is shined on the chip, DNA sequences that have bound will glow. This identifies a matching sequence. (Modified with permission from Doody KJ: Treatment of the infertile couple. In Hoffman BL, Schorge JO, Schaffer JI, et al (eds): Williams Gynecology, 2nd ed. New York, McGraw-Hill, 2012.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Both types of platforms detect aneuploidy, unbalanced translocations, and microdeletions and microduplications. Neither type of array platform currently detects balanced chromosomal rearrangements. For this reason, couples with recurrent pregnancy loss should be offered karyotyping as the first-line test (Society for Maternal-Fetal Medicine, 2016). In addition, SNP arrays are able to identify triploidy and can detect *absence of heterozygosity.* The latter can occur with uniparental disomy when both copies of a chromosome are inherited from one parent. Further, absence of heterozygosity may occur when there is consanguinity, and counseling prior to performance of an SNP array should include this possibility.

Arrays may be genome-wide or may be targeted to known genetic syndromes. Genome-wide arrays are typically used in research settings, for example, to identify novel microdeletion syndromes in individuals with intellectual disability (Slavotinek, 2008). Targeted arrays are generally preferred prenatally because the likelihood of detecting a *copy number variant of uncertain clinical significance* is lower. In a systematic review, Hillman and colleagues (2013) identified copy number variants of uncertain significance in 1 to 2 percent of prenatal specimens. Not unexpectedly, this may be a source of significant distress to families, even with comprehensive pretest counseling.

Clinical Applications

In pregnancies at increased risk for autosomal trisomy based on aneuploidy screening, karyotyping or FISH plus karyotyping should be offered, and CMA should be made available (American College of Obstetricians and Gynecologists, 2016b). When the karyotype is normal, CMA has identified clinically relevant copy number variants in approximately 6.5 percent of pregnancies with fetal abnormalities and in 1 to 2 percent with no obvious fetal abnormality (Callaway, 2013). The American College of Obstetricians and Gynecologists (2016b) and the Society for Maternal-Fetal Medicine (2016) recommend that CMA be offered as a first-tier test when fetal structural abnormalities are identified, replacing fetal karyotyping in these cases. If a particular anomaly that strongly suggests a specific aneuploidy is identified, such as an endocardial cushion defect (trisomy 21) or alobar holoprosencephaly (trisomy 13), karyotyping or FISH may be offered as the initial test. It is recommended that genetic counseling include information about the benefits and limitations of both CMA and karyotyping, and that each be made available to women who elect prenatal diagnosis (Society for Maternal-Fetal Medicine, 2016). CMA may identify instances of autosomal dominant genetic disorders that have not yet manifested in an affected parent, and it may also identify instances of nonpaternity.

For stillbirth evaluation, CMA is more likely than standard karyotyping to provide a genetic diagnosis, in part because it does not require dividing cells. The Stillbirth Collaborative Research Network found that when karyotyping was uninformative, approximately 6 percent of cases had either aneuploidy or a pathogenic copy number variant identified with CMA (Reddy, 2012). Overall, CMA yields results nearly 25 percent more often than standard karyotyping alone.

Whole Genome Sequencing and Whole Exome Sequencing

Most fetuses with structural abnormalities have a normal karyotype and a normal CMA result. Whole genome sequencing (WGS) is a technique for analyzing the entire genome. Whole exome sequencing (WES) analyzes just the DNA coding regions, which account for approximately 1 percent of the genome. These next-generation sequencing tools are increasingly used in the postnatal setting to evaluate suspected genetic syndromes and intellectual disability. The American College of Medical Genetics Board of Directors (2012) states that WGS and WES may be considered for evaluation of the fetus with a likely genetic disorder in which CMA has failed to arrive at a diagnosis. The American College of Obstetricians and Gynecologists (2016a) suggests that this be in only selected circumstances, for example, with recurrent or lethal anomalies in which other approaches have been noninformative. Importantly, WGS and WES have significant limitations in their current form, including turnaround times that may be prohibitively long and a high rate of variants of uncertain significance (American College of Medical Genetics, 2012; Atwal, 2014). As a result, the clinical utility of this promising technology for prenatal cases is currently limited.

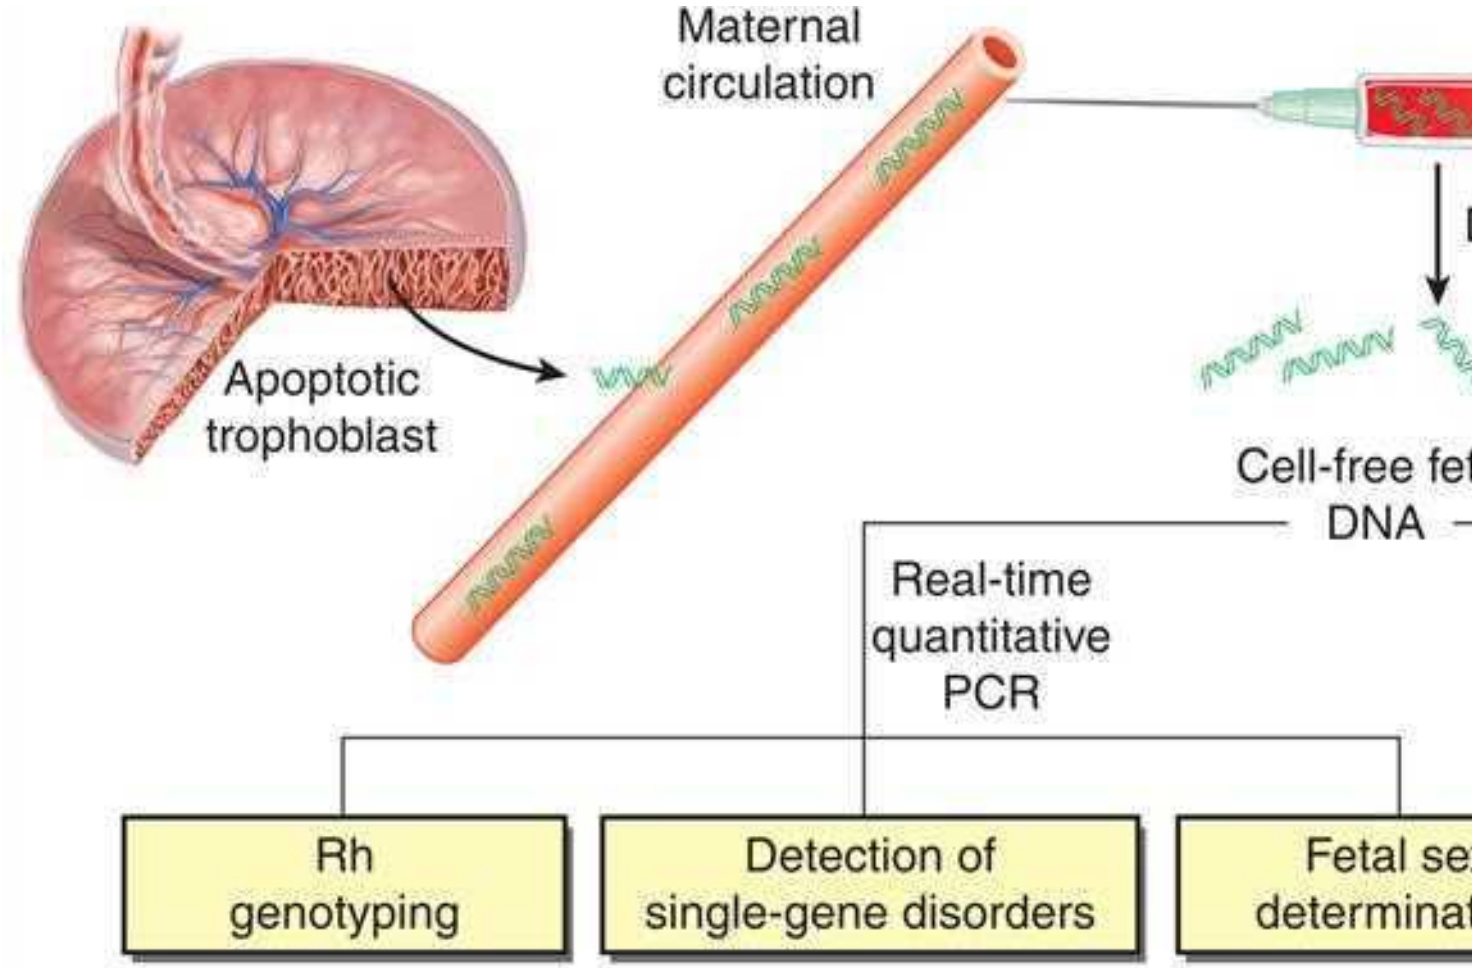
Fetal DNA in the Maternal Circulation

Fetal cells are present in maternal blood at a very low concentration, only 2 to 6 cells per milliliter (Bianchi, 2006). Sometimes, intact fetal cells may persist in the maternal circulation for decades following delivery. Persistent fetal cells may engraft in the mother and result in *microchimerism*, which has been implicated in maternal autoimmune diseases such as scleroderma, systemic lupus erythematosus, and Hashimoto thyroiditis. For prenatal diagnosis, the use of intact fetal cells from maternal blood is limited by low cell concentration, cell persistence into successive pregnancies, and difficulties in distinguishing fetal from maternal cells. In these cases, however, cell-free DNA overcomes these limitations.

Cell-Free DNA

These DNA fragments are derived from maternal cells and from apoptotic placental trophoblast cells—although DNA from the latter is often termed “fetal.” Cell-free DNA can be reliably detected in maternal blood after 9 to 10 weeks’ gestation (American College of Obstetricians and Gynecologists, 2017b). The proportion of cell-free DNA that is placental is called the fetal fraction, and it composes approximately 10 percent of the total circulating cell-free DNA in maternal plasma. Unlike intact fetal cells, cell-free DNA is cleared within minutes from maternal blood. In research settings, cell-free DNA has been used to detect numerous single-gene disorders transmitted through paternally inherited alleles. These include myotonic dystrophy, achondroplasia, Huntington disease, congenital adrenal hyperplasia, cystic fibrosis, and α-thalassemia (Wright, 2009). Clinical applications of cell-free DNA are aneuploidy screening, fetal sex determination, and Rh D genotyping (Fig. 13-14).

FIGURE 13-14
Cell-free DNA is actually derived from apoptotic trophoblast. The DNA is isolated from maternal plasma, and real-time quantitative polymerase chain reaction (PCR) may be used to target specific regions or sequences. This may be used for Rh D genotyping, detection of paternally inherited single-gene disorders, or fetal sex determination. Screening for autosomal trisomies and sex chromosomal aneuploidies is performed using whole-genome sequencing, chromosome selective or targeted sequencing, and analysis of single nucleotide polymorphisms.



Aneuploidy Screening

Several different types of assays are used to screen for fetal autosomal trisomies and sex chromosomal aneuploidies. These include whole-genome sequencing, which is also called massively parallel or shotgun sequencing; chromosome selective or targeted sequencing; and analysis of SNPs (American College of Obstetricians and Gynecologists, 2016a,b). By simultaneously sequencing millions of DNA fragments, investigators can identify whether the proportion or ratio of fragments from one chromosome is higher than expected. Sequences of fetal DNA are specific to individual chromosomes. Thus, samples from women with a Down syndrome fetus have a larger proportion of DNA sequences from chromosome 21.

The screening performance of cell-free DNA is excellent. In a metaanalysis of 37 studies of largely high-risk pregnancies, the pooled sensitivity to detect Down syndrome was 99 percent, and to identify trisomies 18 and 13, 96 and 91 percent, respectively. For each, the specificity was 99.9 percent (Gil, 2015). The false-positive rate is cumulative for each aneuploidy for which screening is performed, but it is usually below 1 percent. As a result, cell-free DNA screening is recommended as a screening option in those at greater risk for fetal autosomal trisomy (American College of Obstetricians and Gynecologists, 2017b; Society for Maternal-Fetal Medicine, 2015).

Unfortunately, cell-free DNA screens do not yield a result in 4 to 8 percent of cases. This may be due to assay failure, high assay variance, or low fetal fraction (Norton, 2012; Pergament, 2014; Quezada, 2015). Such pregnancies carry a greater risk for fetal aneuploidy. In addition, results may not reflect the fetal DNA complement but rather may indicate confined placental mosaicism, early demise of an aneuploid cotwin, maternal mosaicism, or rarely occult maternal malignancy (Bianchi, 2015; Curnow, 2015; Grati, 2014b; Wang, 2014). Recommendations for counseling are discussed in Chapter 14 (Cell-Free DNA for Secondary Screening).

Fetal Sex Determination

From the standpoint of genetic disease, fetal sex determination may be clinically useful if the fetus is at risk for an X-linked disorder. It may also be beneficial if the fetus is at risk for congenital adrenal hyperplasia because maternal corticosteroid therapy may be avoided if the fetus is male (Chap. 16, Congenital Adrenal Hyperplasia). In a metaanalysis of more than 6000 pregnancies by Devaney and associates (2011), the sensitivity of cell-free DNA testing for fetal sex determination approximated 95 percent between 7 and 12 weeks' gestation and improved to 99 percent after 20 weeks. The test specificity was 99 percent at both time periods, suggesting that cell-free fetal DNA is a reasonable alternative to invasive testing in selected cases.

Rh D Genotype Evaluation

In a predominantly white population, nearly 40 percent of fetuses of Rh D-negative women are themselves Rh D negative. Fetal Rh D genotype assessment from maternal blood can eliminate administration of anti-D immune globulin in these pregnancies, thereby reducing cost and potential risk. With Rh D alloimmunization, early identification of an Rh D-negative fetus might avoid unnecessary middle cerebral artery Doppler assessment or amniocentesis. Evaluation using cell-free DNA is done using real-time PCR to target several exons of the *RHD* gene. These are typically exons 4, 5, and 7.

Rh D-genotyping is performed routinely with cell-free DNA in Denmark and the Netherlands (Clausen, 2012; de Haas, 2016). In a population-based study of more than 25,000 Rh D-negative women screened at 27 weeks, the false-negative rate—in which Rh D-negative status was missed—was only 0.03 percent. The false-positive rate—in which Rh immune globulin would be given unnecessarily—was less than 1 percent (de Haas, 2016). Similar results were reported from the United Kingdom, although the false-negative rate was higher in the first trimester (Chitty, 2014). Investigators concluded that false-negative screening results might increase the alloimmunization risk, but by less than 1 case per million births (Chitty, 2014). Rh D alloimmunization is discussed in Chapter 15 (Red Cell Alloimmunization).

CHAPTER 14: Prenatal Diagnosis

Careful examination should ordinarily lead to a correct diagnosis of hydrocephalus in the last weeks of pregnancy. In many cases the deformity can be detected by external palpation.

—J. Whitridge Williams (1903)

INTRODUCTION

In the initial edition of Williams Obstetrics, very few fetal disorders could be identified before delivery. Now, more than 100 years later, prenatal diagnosis has become a separate field of its own. Strictly speaking, prenatal diagnosis is the science of identifying congenital abnormalities, aneuploidies, and other genetic syndromes in the fetus. It encompasses the diagnosis of structural malformations with specialized sonography; routine screening tests for aneuploidy and neural-tube defects; diagnostic tests such as karyotyping and chromosomal microarray analysis performed on chorionic villi and amniocentesis specimens; and additional screening and diagnostic tests offered to those with pregnancies at risk for specific genetic disorders. The goal of prenatal diagnosis is to provide accurate information regarding short- and long-term prognosis, recurrence risk, and potential therapy, thereby improving patient counseling and optimizing outcomes.

Management of an affected pregnancy, including whether a woman would elect pregnancy termination, may be incorporated into the discussion of screening and testing options. However, nondirective counseling is central to prenatal diagnosis. This practice provides the patient with unbiased knowledge regarding a diagnosis and preserves her autonomy (Flessel, 2011). Fetal imaging of congenital anomalies is discussed in Chapter 10, and pregnancy termination is discussed in Chapter 18.

HISTORICAL PERSPECTIVE

More than 40 years ago, Brock (1972, 1973) observed that pregnancies complicated by neural-tube defects had higher levels of alpha-fetoprotein (AFP) in maternal serum and amnionic fluid. This formed the basis for the first maternal serum screening test for a fetal condition. The beginning of widespread serum screening came in 1977, after a collaborative trial from the United Kingdom established the association between elevated maternal serum AFP levels (MSAFP) and fetal open neural-tube defects (Wald, 1977). When screening was performed at 16 to 18 weeks' gestation, detection approached 90 percent for pregnancies with fetal anencephaly and 80 percent for those with myelomeningocele (spina bifida). These sensitivities are comparable to current testing (American College of Obstetricians and Gynecologists, 2016a).

The terms *level I* and *level II* sonography were coined in this context. In the California MSAFP Screening Program of the 1980s and early 1990s, women received serum screening prior to sonography, and those with an elevated MSAFP level would undergo level I sonography to identify an incorrect gestational age, multifetal gestation, or fetal demise (Filly, 1993). A third of pregnancies with an elevated MSAFP level had one of these three etiologies. Although birth defects were occasionally detected during level I sonography, this was not the expectation. If level I sonography did not identify an etiology for the MSAFP level elevation, amniocentesis would be offered. Then, only if the amnionic fluid AFP concentration were elevated would the woman undergo level II sonography. This more detailed and comprehensive survey of fetal anatomy was performed to detect and characterize the fetal abnormality.

If the amnionic fluid AFP level was elevated, an assay for amnionic fluid acetylcholinesterase was concurrently performed. This capitalized on the tendency of acetylcholinesterase to leak directly from exposed neural tissue into the amnionic fluid. The presence of both analytes in the amnionic fluid was considered diagnostic for neural-tube defects (American College of Obstetricians and Gynecologists, 2016a).

The overall sensitivity of amniocentesis to diagnose open neural-tube defects approximates 98 percent, with a false-positive rate of 0.4 percent (Milunsky, 2004). Importantly, other fetal abnormalities are associated with elevated amnionic fluid AFP levels and positive assay results for acetylcholinesterase. These include ventral wall defects, esophageal atresia, fetal teratoma, cloacal exstrophy, and skin abnormalities such as epidermolysis bullosa. Thus, by current standards, these amnionic fluid analytes would be considered ancillary screening tests, understanding that a positive result would prompt additional fetal imaging.

With current imaging technology, most neural-tube defects are detected with sonography, and targeted sonography is the diagnostic test of choice (Dashe, 2006). Pregnant women now have the option of neural-tube defect screening with either MSAFP or sonography (American College of Obstetricians and Gynecologists, 2016c). Although level II is used as a synonym for *targeted sonography*, the former might best be removed from our lexicon. Namely, today's targeted sonography includes a much more comprehensive evaluation of fetal anatomy (Chap. 10, Fetal Anomaly Detection).

As MSAFP screening was being adopted, the designation "advanced maternal age" (AMA) became popular. A 1979 National Institutes of Health Consensus Development Conference recommended advising pregnant women who were 35 years and older about the possibility of amniocentesis for fetal karyotyping. The threshold was based on the greater risk for selected fetal chromosomal abnormalities with increasing maternal age and on the assumption that at that time, the loss rate attributable to amniocentesis was equivalent to the fetal Down syndrome risk at maternal age 35. *Notably, this is no longer the case, as discussed later* (Chorionic Villus Sampling).

Serum aneuploidy screening soon became available for women who would be younger than 35 at delivery. In 1984, Merkatz and colleagues reported that MSAFP levels were *lower* in pregnancies with trisomies 21 and 18 at 15 to 21 weeks' gestation. Maternal age was incorporated into the calculation, such that a specific risk

could be assigned (DiMaio, 1987; New England Regional Genetics Group, 1989). The MSAFP screen detected approximately 25 percent of cases of fetal trisomy 21 when the threshold ratio for a positive result was set at 1:270. This ratio reflects the approximate second-trimester risk for Down syndrome at maternal age 35. This trisomy 21 risk threshold and the associated 5-percent false-positive rate became standards that remain in use in some laboratories today.

For more than a decade after its introduction, serum aneuploidy screening was intended for women younger than 35, because it simply did not have sufficient sensitivity to be offered to women who had higher a priori risk. This is also no longer the case. And, because the prevalence of fetal aneuploidy rises sharply with maternal age, the positive-predictive value of all aneuploidy screening tests—whether analyte-based or cell-free DNA tests—is higher in women aged 35 years or older. Women 35 and older now make up more than 15 percent of deliveries in the United States (Fig. 14-1). At Parkland Hospital, this age group accounts for half of births with Down syndrome (Hussamy, 2017).

SCREENING FOR ANEUPLOIDY

Aneuploidy is the presence of one or more extra chromosomes, usually resulting in trisomy, or loss of a chromosome—monosomy. Data from population-based registries that include births, fetal deaths, and pregnancy terminations indicate an overall prevalence of 4 such abnormalities per 1000 births (Wellesley, 2012).

Aneuploidy accounts for more than 50 percent of first-trimester abortions, about 20 percent of second-trimester losses, and 6 to 8 percent of stillbirths and early-childhood deaths (Reddy, 2012; Stevenson, 2004; Wou, 2016). Of recognized pregnancies with chromosomal abnormalities, trisomy 21 composes approximately half of cases; trisomy 18 accounts for 15 percent; trisomy 13, for 5 percent; and the sex chromosomal abnormalities—45,X, 47,XXX, 47,XXY, and 47,XYY—for approximately 12 percent (Wellesley, 2012).

The risk for fetal trisomy increases with maternal age, particularly after age 35 (Fig. 13-2). When counseling, a provider includes specific maternal-age-related aneuploidy risks (Tables 14-1 and 14-2). Other important fetal aneuploidy risk factors include a numerical chromosomal abnormality or structural chromosomal rearrangement in the woman or her partner—such as balanced translocation—or a prior pregnancy with autosomal trisomy or triploidy.

42	1/23	1/33	1/13	1/22

[a]Risk applies to one or both fetuses.

Data from Meyers C, Adam R, Dungan J, et al: Aneuploidy in twin gestations: when is maternal age advanced? Obstet Gynecol. 1997 Feb;89(2):248–251.

Broadly speaking, there are two types of aneuploidy screening tests, those that are traditional or analyte-based and those that are cell-free DNA-based. All pregnant women should be offered aneuploidy screening or diagnostic testing early in pregnancy (American College of Obstetricians and Gynecologists, 2016c). Considerations prior to screening are as follows:

1. *Has the patient elected screening?* At least 20 percent of women elect not to receive aneuploidy screening, even when financial barriers are removed. Fewer than 40 percent of women with a positive screening result elect prenatal diagnosis (Dar, 2014; Kuppermann, 2014).

2. *Would the patient prefer prenatal diagnosis?* Diagnostic testing is safe and effective, and chromosomal microarray analysis provides information about genetic conditions that screening tests and karyotyping alone currently do not (American College of Obstetricians and Gynecologists, 2016b). This is discussed further in Prenatal Diagnostic Procedures and Preimplantation Testing and in Chapter 13 (Chromosomal Microarray Analysis).

3. *Is this a multifetal gestation?* All traditional (analyte-based) aneuploidy screening tests are significantly less effective in multifetal gestations, and cell-free DNA screening is not currently recommended with multifetal gestations (Cell-Free DNA for Secondary Screening).

4. *What method will be used for neural-tube defect screening?* Whenever a patient elects an aneuploidy screening test that does not include second-trimester serum analytes, screening for neural-tube defects should be performed separately, either with MSAFP assessment or with sonography (American College of Obstetricians and Gynecologists, 2016c).

5. *Does the fetus have a major anomaly?* If so, diagnostic testing is recommended rather than screening.

The American College of Obstetricians and Gynecologists (2016c) has affirmed that screening for aneuploidy should be an informed patient choice, with an underlying foundation of shared decision making that fits her clinical circumstances, values, interests, and goals. Elements of counseling prior to aneuploidy screening are listed in Table 14-3.

TABLE 14-3

Aneuploidy Screening Counseling Elements

1. **All pregnant women have 3 options: screening, diagnostic testing, and no screening or testing.**
   The purpose of a screening test is to provide information, not to dictate a course of action.
   Diagnostic testing is safe and effective and provides information that screening does not.
2. **The difference between a screening test and a diagnostic test.**
   Screening evaluates whether the pregnancy is at increased risk and estimates degree of risk.
   Detection rate, false-negative rate, and false-positive rate are provided.
   Cell-free DNA screening does not always provide a result.
   Irreversible management decisions should not be based on screening test results.
   With a positive screening result, a diagnostic test is recommended if the patient wants to know whether the fetus is affected.
3. **Basic information is provided about each condition covered by the screening test (prevalence, associated abnormalities, prognosis), and screening test limitations.**
   A benefit of diagnosis includes earlier identification of associated abnormalities.
   In case of trisomy 18 or 13, diagnosis may affect pregnancy management if complications arise such as growth restriction or nonreassuring fetal heart rate.
   With sex chromosome aneuploidies, phenotypic expression varies widely. Several are so mild they would otherwise not be diagnosed.
4. **The patient's a priori risk for fetal aneuploidy may affect her screening test options or election.**
   Age-related risk information may be found in reference tables.
   If a patient has had a prior fetus with autosomal trisomy, robertsonian translocation, or other chromosomal abnormality, additional evaluation and counseling are suggested.

Modified with permission from Dashe JS: Aneuploidy screening in pregnancy, Obstet Gynecol. 2016 Jul;128(1):181–194.

Statistical Considerations

Aneuploidy screening can be challenging because the test characteristics of each option may vary with maternal age and with whether the test is analyte-based or cell-free DNA-based.

The test sensitivity is the detection rate—that is, the proportion of aneuploid fetuses identified by the screening test. Its converse, the false-negative rate, is the percentage of cases that the test is expected to miss. A first-trimester screening test with a sensitivity of 80 percent is expected to miss 1 in 5 cases. The sensitivity of screening tests for Down syndrome has increased steadily during the past 30 years, from just 25 percent with serum AFP alone to more than 90 percent with integrated or sequential screening.

Another key characteristic is the false-positive rate, the percentage of unaffected pregnancies that will "falsely" screen positive. This approximates 5 percent for first-trimester screening, quadruple-marker screening, or integrated screening options (Baer, 2015; Kazerouni, 2011; Malone, 2005b; Norton, 2015). The converse of false-positive rate is specificity— analyte-based screens will be reassuring in approximately 95 percent of unaffected pregnancies. Although test sensitivity has improved, the false-positive rate has been held constant for many different aneuploidy screening tests (Table 14-4). Both statistics are relevant for counseling. An additional consideration is that with all analyte-based screening tests, women 35 and older have higher rates of positive results (Kazerouni, 2011; Malone, 2005b).

TABLE 14-4

Characteristics of Screening Tests for Trisomy 21 in Singletons

Screening Test	Detection Rate	False-Positive Rate	Positive-Predictive Value[a]
Quadruple screen:			
AFP, hCG, estriol, inhibin	80–82%	5%	3%
First-trimester screen:			
NT, hCG, PAPP-A	80–84%	5%	3–4%
First-trimester NT alone	64–70%	5%	
Integrated screening	94–96%	5%	5%
Sequential screening:			
Stepwise	92%	5.1%	5%
Contingent	91%	4.5%	5%
Cell-free DNA screening:			
Positive result	99%	0.1%	Table 14-5
Low fetal fraction or no result	—	4–8%	4%

[a]The positive-predictive value represents the overall population studied and cannot be applied to any individual patient.

AFP = alpha-fetoprotein; hCG = human chorionic gonadotropin; NT = nuchal translucency; PAPP-A = pregnancy-associated plasma protein A.

Data from Baer, 2015; Gil, 2015; Malone, 2005b; Norton, 2015; Pergament, 2014; Quezada, 2015; Dashe, 2016.

Importantly, neither sensitivity nor false-positive rate conveys individual risk. The statistic that patients and providers usually consider to be the test result is the positive-predictive value, which is the proportion of those with a positive screening result who actually have an aneuploid fetus. It may be expressed as a 1:X ratio or as a percentage. The positive-predictive value is directly affected by disease prevalence, so it is much higher for women aged 35 years and older than for younger women (Table 14-5). Positive-predictive values can also be reported for cohorts of pregnancies. For example, the positive-predictive value reported in a research trial is the proportion of women with positive screening results who have affected fetuses (see Table 14-4). Negative-predictive value is the proportion of those with a negative screening test result who have unaffected (euploid) fetuses. Because the prevalence of aneuploidy is so low, the negative-predictive value of all aneuploidy screening tests generally exceeds 99 percent (Gil, 2015; Norton, 2015).

TABLE 14-5

Positive-Predictive Value of Cell-Free DNA Screening for Autosomal Trisomies and Selected Sex Chromosome Abnormalities, According to Maternal Age

Maternal Age	Trisomy 21	Trisomy 18	Trisomy 13	45,X	47,XXY
20	48%	14%	6%	41%	29%
25	51%	15%	7%	41%	29%
30	61%	21%	10%	41%	29%
35	79%	39%	21%	41%	30%
40	93%	69%	50%	41%	52%
45	98%	90%	NA	41%	77%

NA = not available; NIPT = non-invasive prenatal test.

Positive-predictive values were obtained using the NIPT/Cell Free DNA Screening Predictive Value Calculator from the Perinatal Quality Foundation, 2017.

Calculations are based on prevalence at 16 weeks' gestation using sensitivities and specificities from Gil, 2015.

Traditional Aneuploidy Screening Tests

These screening tests have multiple markers or analytes and are also called conventional or traditional to differentiate them from cell-free DNA-based screening. There are three categories: first-trimester screens, second-trimester screens, and combinations of first- and second-trimester screens. If the test has a first-trimester component, it almost always includes a measurement of the sonographic nuchal translucency, which is discussed in the next section.

Each maternal serum analyte is measured as a concentration—for example, nanograms per milliliter of AFP. The concentration is converted to a multiple of the median (MoM) by adjusting for maternal age, maternal weight, and gestational age. The nuchal translucency measurement increases with crown-rump length (CRL), and thus its value is adjusted for CRL and also reported as an MoM. The AFP analyte is further adjusted for maternal race and ethnicity and for presence of diabetes, which all affect the calculation of neural-tube defect risk rather than of aneuploidy risk (Greene, 1988; Huttly, 2004). Reporting these results as an MoM of the unaffected population normalizes the distribution of analyte levels and permits comparison of results from different laboratories and populations.

The analyte-based aneuploidy screening result is based on a composite likelihood ratio, and the maternal age-related risk is multiplied by this ratio. This principle similarly applies to modification of fetal Down syndrome risk by selected sonographic markers, which are discussed later in Sonographic Screening. Each woman is provided with a specific risk for trisomy 21 and for trisomy 18—or in the first trimester, for trisomy 18 or 13 in some cases. The result is expressed as a ratio that represents the positive-predictive value.

Importantly, each screening test also has a predetermined value at which or above which it is deemed "positive" or abnormal. For second-trimester tests, this threshold has traditionally been set at the risk for fetal Down syndrome in a woman aged 35 years—approximately 1 in 270 in the second trimester (see Table 14-1). The threshold selected for a positive screen reflects the laboratory requirement but is somewhat problematic, as it may bear no relationship to patient preference. However, a positive screening result may affect whether the patient is deemed "high risk," receives formal genetic counseling, and is offered diagnostic testing with chorionic villus sampling or amniocentesis. Thus, it behooves the provider to discuss the patient's preferences prior to screening.

First-Trimester Aneuploidy Screening

Also called combined first-trimester screening, this test combines two maternal serum analytes, human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein A (PAPP-A), with the sonographic measurement of the nuchal translucency (NT). It is performed between 11 and 14 weeks' gestation. In cases of fetal Down syndrome, the first-trimester serum free β-hCG level is higher and the PAPP-A level is lower. With trisomy 18 and trisomy 13, levels of both analytes are lower (Cuckle, 2000; Malone, 2005b).

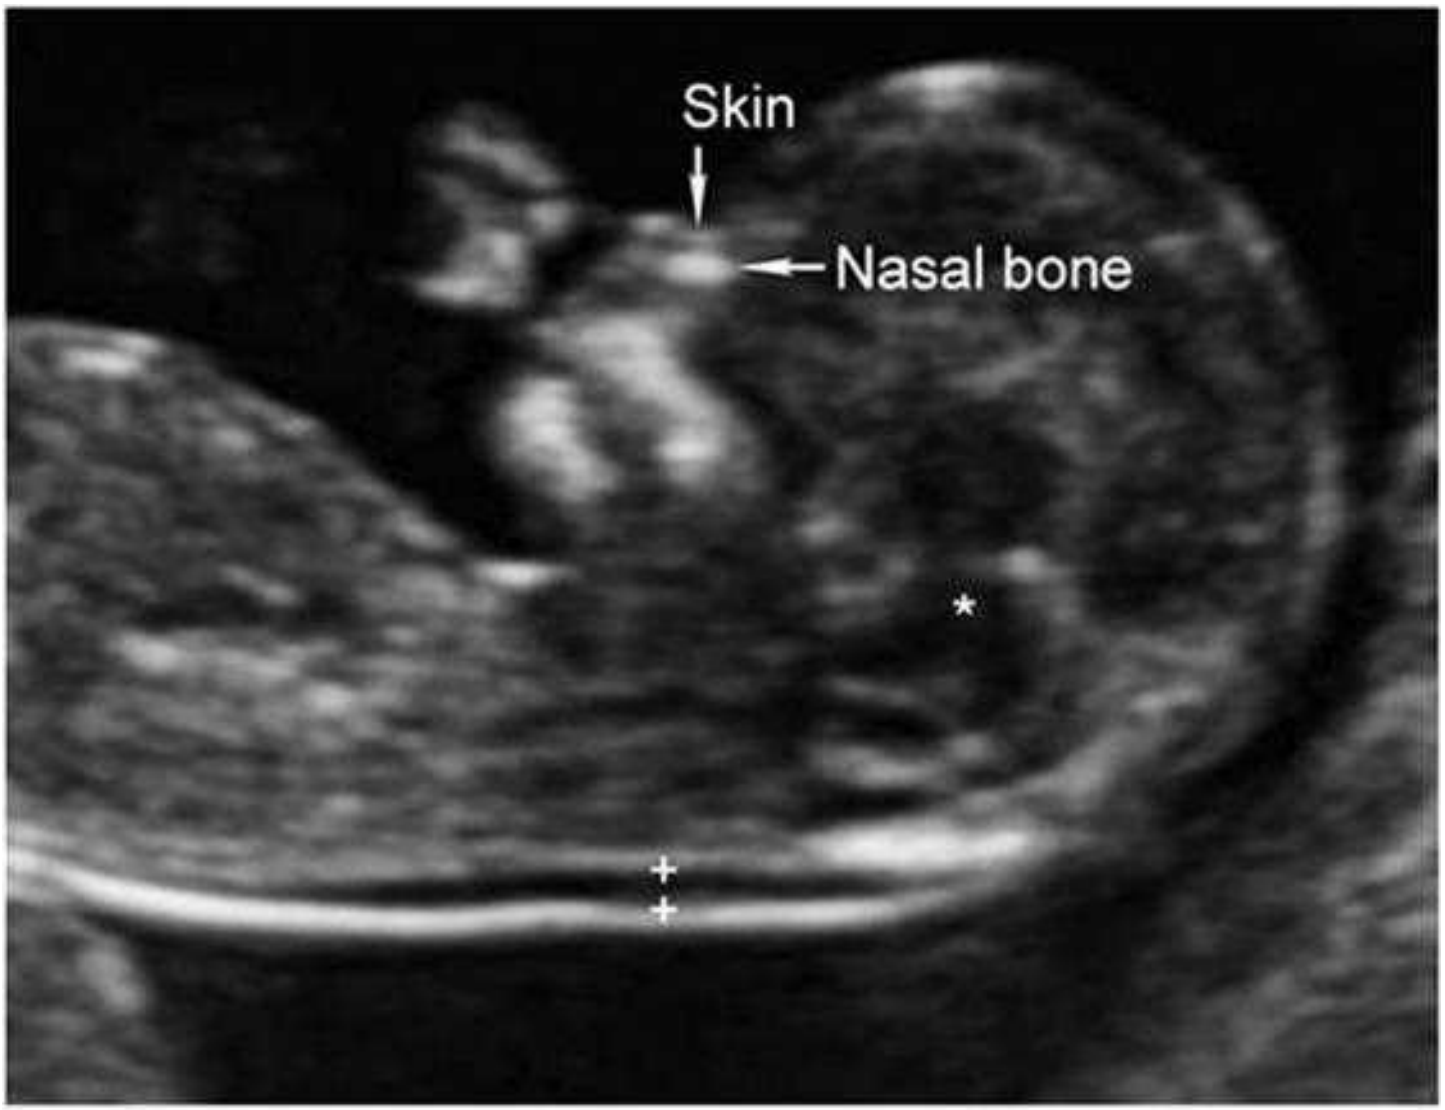
Nuchal Translucency

This is the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck (Fig. 14-2). An increased NT thickness is not a fetal abnormality but rather is a marker that confers increased risk. It is measured in the sagittal plane and is valid when the CRL value lies between 38 to 45 mm and 84 mm, with the lower limit varying according to the laboratory. Specific criteria for NT measurement are listed in Table 10-4. Whenever possible, it is helpful to differentiate increased NT from cystic hygroma, which is a venolymphatic malformation that appears as a septated hypoechoic space behind the neck, extending along the length of the back (Fig. 10-22). Cystic hygroma confers a fivefold increased aneuploidy risk when identified in the first trimester (Malone, 2005a).

FIGURE 14-2

Sagittal image of a normal, 12-week fetus demonstrating correct caliper placement (+) for nuchal translucency measurement. The fetal nasal bone and overlying skin are indicated. The nasal tip and the 3rd and 4th ventricles (*asterisk*), which are other landmarks that should be visible in the nasal bone image, are also shown. (Used

with permission from Dr. Michael Zaretsky.)



In addition to aneuploidy, an increased NT thickness is associated with other genetic syndromes and various birth defects, especially fetal cardiac anomalies (Simpson, 2007). And, if the NT measurement reaches 3 mm or more, the aneuploidy risk is unlikely to normalize using serum analyte assessment (Comstock, 2006). Because of this, if the NT measurement is at least 3 mm or exceeds the 99th percentile, the patient should receive counseling and be offered targeted sonography with fetal echocardiography. In addition, she should be offered cell-free DNA screening and prenatal diagnosis (American College of Obstetricians and Gynecologists, 2016c).

The NT must be imaged and measured with a high degree of precision for aneuploidy detection to be accurate. This has led to standardized training, certification, and ongoing quality review programs. In the United States, training, credentialing, and monitoring are available through the Nuchal Translucency Quality Review program of the Perinatal Quality Foundation and through the Fetal Medicine Foundation.

Efficacy of First-Trimester Screening

Before first-trimester screening became widely adopted, four large prospective trials were conducted, together including more than 100,000 pregnancies (Reddy, 2006). When the false-positive rate was set at 5 percent, the overall rate for trisomy 21 detection was 84 percent, comparable to quadruple-marker screening (see Table 14-4). The detection rate is approximately 5 percent higher if performed at 11 weeks' compared with 13 weeks' gestation, and slightly lower—80 to 82 percent—when cases with cystic hygroma are analyzed separately (Malone, 2005a). In a recent multicenter trial, first-trimester screening detected approximately 80 percent of fetuses with trisomy 21, 80 percent with trisomy 18, and 50 percent with trisomy 13 (Norton, 2015).

As an isolated marker, NT detects approximately two thirds of fetuses with Down syndrome, with a false-positive rate of 5 percent (Malone, 2005b). However, NT is generally used as an isolated marker only in screening for multifetal gestations, in which serum screening is less accurate or may not be available. The NT distribution is similar in twins and singletons (Cleary-Goldman, 2005). In twin pregnancies, serum free β-hCG and PAPP-A levels are approximately double the singleton values (Vink, 2012). Even with specific curves, a normal dichorionic cotwin will tend to normalize screening results, and thus, the aneuploidy detection rate is at least 15-percent lower (Bush, 2005).

Maternal age affects the performance of first-trimester aneuploidy screening. Prospective trials have demonstrated Down syndrome detection rates of 67 to 75 percent in women younger than 35 years at delivery, which are 10 percent lower than the overall detection rates in these studies (Malone, 2005b; Wapner, 2003). Among women older than 35 at delivery, Down syndrome detection reached 90 to 95 percent, albeit at a higher false-positive rate of 15 to 22 percent.

Unexplained Abnormalities of First-Trimester Analytes

There is a significant association between serum PAPP-A levels below the 5th percentile and preterm birth, growth restriction, preeclampsia, and fetal demise (Cignini, 2016; Dugoff, 2004; Jelliffe-Pawlowski, 2015). Similarly, low levels of free β-hCG have been associated with fetal demise (Goetzl, 2004). The sensitivity and positive-predictive values of isolated markers are generally too low to make them clinically useful as screening tests.

There has been renewed interest in low-dose aspirin for prevention of early preeclampsia in women identified as at risk based on mean arterial pressure, uterine artery Doppler values, and PAPP-A levels. However, these observations are preliminary (Park, 2015).

Second-Trimester Aneuploidy Screening

Currently, the only second-trimester multiple marker test widely used in the United States is the quadruple marker or “quad” screening test. It is performed from 15 to 21 weeks’ gestation, and inclusive gestational age ranges vary according to individual laboratories. Pregnancies with fetal Down syndrome are characterized by lower maternal serum AFP, higher hCG, lower unconjugated estriol, and higher dimeric inhibin levels. When the quad screen was initially described, the Down syndrome detection rate approximated 70 percent. But, by the early 2000s, the reported detection rate in two large prospective trials had improved to 81 to 83 percent, with a 5-percent screen-positive rate (Malone, 2005b; Wald, 1996, 2003). The improved detection rate is attributable, at least in part, to accurate gestational age assessment with sonography. In a review of more than 500,000 pregnancies receiving quadruple-marker screening through the statewide California Prenatal Screening Program, trisomy 21 detection was 78 percent with sonographic gestational age assessment but only 67 percent when the screen was calculated based on last menstrual period alone (Kazerouni, 2011). As with first-trimester screening, aneuploidy detection rates are lower in younger women and higher in women older than 35 years at delivery. If second-trimester serum screening is used in twin pregnancies, aneuploidy detection rates are significantly lower (Vink, 2012). With trisomy 18, the levels of the first three analytes are all decreased, and inhibin is not part of the calculation. Trisomy 18 detection is similar to that for Down syndrome, with a false-positive rate of only 0.5 percent (Benn, 1999).

Although the quadruple-marker screening test is used to screen for Down syndrome and trisomy 18, pregnancies with *other* chromosomal abnormalities may be identified as well. The California Prenatal Screening Program found that the quadruple-marker screen result was abnormal in 96 percent of those with triploidy, in 75 percent with Turner syndrome (45,X), in 44 percent with trisomy 13, and in more than 40 percent of those with other major chromosomal abnormalities (Kazerouni, 2011). Although a specific risk for these aneuploidies cannot be provided based on the test result, the information may be relevant for women considering amniocentesis.

Quadruple-marker screening offers no benefit over first-trimester screening from the standpoint of trisomy 21 or trisomy 18 detection. As a stand-alone test, it is generally used if women do not begin care until the second trimester or if first-trimester screening is not available. In 2011, women who initiated prenatal care beyond the first trimester made up nearly 25 percent of pregnancies in the United States. As subsequently discussed, combining first- and second-trimester screening yields an even greater aneuploidy detection rate.

Maternal Serum AFP Elevation: Neural-Tube Defect Screening

All pregnant women are offered screening for fetal open neural-tube defects in the second trimester, either with MSAFP screening or with sonography (American College of Obstetricians and Gynecologists, 2016c). Measurement of the MSAFP concentration between 15 and 20 weeks’ gestation has been offered as part of routine prenatal care for more than 30 years. Because AFP is the major protein in fetal serum, analogous to albumin in a child or adult, the normal concentration gradient between fetal plasma and maternal serum is on the order of 50,000:1. Defects in fetal integument, such as neural-tube and ventral-wall defects, permit AFP to leak into the amnionic fluid, resulting in dramatically increased maternal serum levels. The AFP value rises by about 15 percent per week during the screening window (Knight, 1992). The MoM is generally recalculated if the first-trimester CRL or second-trimester biparietal diameter differs from the stated gestational age by more than 1 week.

Using an MSAFP level of 2.5 MoM as the upper limit of normal, the neural-tube defect detection rate is at least 90 percent for anencephaly and 80 percent for spina bifida, with a screen-positive rate of 3 to 5 percent (American College of Obstetricians and Gynecologists, 2016a; Milunsky, 2004). Higher screening threshold values are used in twin pregnancies (Cuckle, 1990).

Virtually all cases of anencephaly and many cases of spina bifida may be detected or suspected during a standard second-trimester sonographic examination (Dashe, 2006). Most centers now use targeted sonography as the primary method to evaluate elevated MSAFP levels and as the prenatal diagnostic test of choice for neural-tube defects (Chap. 10, Neural-Tube Defects). If targeted sonography is not available and myelomeningocele cannot be excluded, amniocentesis may be considered for measurement of amnionic fluid AFP and acetylcholinesterase levels. That said, we recommend additional imaging prior to establishing the diagnosis, with the understanding that other abnormalities or conditions can result in elevation of these amnionic fluid analytes (Table 14-6). Sonographic findings characteristic of fetal neural-tube defects are reviewed in Chapter 10 (Neural-Tube Defects). Fetal surgery for myelomeningocele is discussed in Chapter 16 (Open Fetal Surgery).

TABLE 14-6

Conditions Associated with an Elevated MSAFP Concentration

Underestimated gestational age
Multifetal gestation
Fetal death
Neural-tube defect
Gastroschisis
Omphalocele
Cystic hygroma
Esophageal or intestinal obstruction
Liver necrosis
Renal anomalies—polycystic kidneys, renal agenesis, congenital nephrosis, urinary tract obstruction
Cloacal exstrophy
Osteogenesis imperfecta
Sacrococcygeal teratoma
Congenital skin abnormality
Pilonidal cyst
Chorioangioma of placenta
Placenta intervillous thrombosis
Placental abruption
Oligohydramnios
Preeclampsia
Fetal-growth restriction
Maternal hepatoma or teratoma

MSAFP = maternal serum alpha-fetoprotein.

Unexplained Abnormalities of Second-Trimester Analytes

The positive-predictive value of an elevated MSAFP value is only 2 percent. Approximately 98 percent of pregnancies with an MSAFP level exceeding 2.5 MoM have an etiology other than a neural-tube defect. Thus, counseling is indicated not only to inform the patient about the benefits and limitations of targeted sonography for the diagnosis of neural-tube defects but also to review the numerous other conditions. Some of these include fetal anomalies, placental abnormalities, and adverse outcomes associated with MSAFP level elevation (see Table 14-6). The likelihood of one of these abnormalities or of an adverse pregnancy outcome in the absence of a recognized abnormality rises in proportion to the AFP level. Adverse outcomes include fetal-growth restriction, preeclampsia, preterm birth, fetal demise, and stillbirth. More than 40 percent of pregnancies may be abnormal if the MSAFP level is greater than 7 MoM (Reichler, 1994).

Second-trimester elevation of either hCG or dimeric inhibin alpha levels also shows significant association with adverse pregnancy outcomes. The outcomes reported are similar to those associated with MSAFP level elevation. Moreover, the likelihood of adverse outcome is augmented when levels of several markers are elevated (Dugoff, 2005).

Many of these complications are assumed to result from placental damage or dysfunction. However, the sensitivity and positive-predictive values of these markers are considered too low to be useful for screening or management. No specific program of maternal or fetal surveillance has been found to favorably affect pregnancy outcomes (Dugoff, 2010). At Parkland Hospital, prenatal care for these women is not altered unless a specific complication arises. Despite the extensive list of possible adverse outcomes, it is reassuring that most women with unexplained elevation of these analytes have normal outcomes.

Low Maternal Serum Estriol Level

A maternal serum estriol level less than 0.25 MoM has been associated with two uncommon but important conditions. The first, *Smith-Lemli-Opitz syndrome*, is an autosomal recessive condition resulting from mutations in the 7-dehydrocholesterol reductase gene. It is characterized by abnormalities of the central nervous system, heart, kidney, and extremities; with ambiguous genitalia; and with fetal-growth restriction. For this reason, the Society for Maternal-Fetal Medicine has recommended that sonographic evaluation be performed if an unconjugated estriol level is <0.25 MoM (Dugoff, 2010). If abnormalities are identified, an elevated amnionic fluid 7-dehydrocholesterol level can confirm the diagnosis.

The second condition is *steroid sulfatase deficiency*, also known as *X-linked ichthyosis*. It is typically an isolated condition, but it may also occur in the setting of a contiguous gene deletion syndrome (Chap. 13, Abnormalities of Chromosome Structure). In such cases, it may be associated with Kallmann syndrome, chondrodysplasia punctata, and/or mental retardation (Langlois, 2009). If the estriol level is <0.25 MoM and the fetus appears to be male, chromosomal microarray analysis or fluorescence in situ hybridization to assess the steroid sulfatase locus on the X-chromosome may be considered.

Integrated and Sequential Screening

As shown in Table 14-4, if first-trimester screening is combined with second-trimester screening, aneuploidy detection is significantly improved. Combined screening test options require coordination between the provider and laboratory. Specifically, if a second sample is required, it is obtained during the appropriate gestational

age window, sent to the same laboratory, and linked to the first-trimester results. The first- and second-trimester components cannot be performed independently because if either component yields positive results, then providing accurate risk assessment would be problematic.

Three types of screening strategies are available:

1. *Integrated screening* combines results of first- and second-trimester tests. This includes a combined measurement of fetal NT and serum analyte levels at 11 to 14 weeks' gestation plus quadruple markers at approximately 15 to 21 weeks. An aneuploidy risk is then calculated from these seven parameters. As expected, integrated screening has the highest Down syndrome detection rate—94 to 96 percent, with a false-positive rate of 5 percent (see Table 14-4). If NT measurement is not available, then s*erum integrated screening* includes all six serum markers to calculate risk. This screening, however, is less effective, and Down syndrome detection rates are 85 to 88 percent (Malone, 2005b).

2. *Sequential screening* involves performing first-trimester screening and informing the patient of the results. This is coupled with the understanding that if the calculated risk value lies above a specified threshold, she will receive counseling and will be offered diagnostic testing. There are two testing strategies in this category:

- With *stepwise sequential screening*, women with first-trimester screen results that confer risk for Down syndrome above a particular threshold are offered invasive testing, and the remaining women receive second-trimester screening. Using data from the First- and Second-Trimester Evaluation of Risk (FaSTER) trial, when the first-trimester threshold is set at approximately 1:30, and the overall threshold is set at 1:270, stepwise sequential screening resulted in a 92-percent detection rate of Down syndrome pregnancies, with a false-positive rate of 5 percent (see Table 14-4) (Cuckle, 2008).

- With *contingent sequential screening*, women are divided into high-, moderate-, and low-risk groups. Those at highest risk for Down syndrome—for example, risk >1:30, are counseled and offered invasive testing. Women at moderate risk, between 1:30 and 1:1500, undergo second-trimester screening, whereas those at lowest risk of <1:1500 receive negative screening test results and have no further testing (Cuckle, 2008). Using this strategy, more than 75 percent of those screened are provided with reassuring results almost immediately, while still maintaining a high detection rate of about 91 percent, with a 5-percent false-positive rate (see Table 14-4). This option is also more cost effective because a second-trimester test is obviated in most patients.

In a population-based review of 450,000 pregnancies from the California Prenatal Screening Program, integrated screening detected 94 percent of trisomy 21 fetuses and 93 percent with trisomy 18 (Baer, 2015). Additionally, the screening result was abnormal in 93 percent of cases of trisomy 13, in 91 percent with triploidy, and in 80 percent with Turner syndrome. Women considering options of integrated screening and cell-free DNA screening may find this information helpful.

Cell-Free DNA Screening

This was introduced in 2011 and has completely changed the prenatal screening paradigm. The test works by identifying DNA fragments that are derived primarily from apoptotic trophoblasts, which are placental cells undergoing programmed cell death. Thus, the term cell-free *fetal* DNA is somewhat of a misnomer. Screening is not gestational-age dependent and can be performed at any time after 9 to 10 weeks' gestation. Results are available in 7 to 10 days (American College of Obstetricians and Gynecologists, 2017c). Three types of assays are currently available: whole-genome sequencing, which is also called massively parallel or shotgun sequencing; chromosome selective or targeted sequencing; and analysis of single nucleotide polymorphisms.

The screening performance of cell-free DNA is excellent. In a metaanalysis of 37 studies of largely high-risk pregnancies, the pooled sensitivity to detect Down syndrome was 99 percent, and for trisomies 18 and 13, 96 percent and 91 percent, respectively. For each of these autosomal trisomies, the specificity was 99.9 percent. Thus, most unaffected pregnancies received a normal screening result. Cell-free DNA also detects 90 percent with Turner syndrome (45,X) and 93 percent with sex chromosome aneuploidies other than 45,X (Gil, 2015). The false-positive rate is cumulative for each aneuploidy for which screening is performed, but it is usually only 0.5 to 1 percent. As a result, cell-free DNA screening is recommended as a screening option in those at increased risk for fetal autosomal trisomy (American College of Obstetricians and Gynecologists, 2017c; Society for Maternal-Fetal Medicine, 2015). This includes the following categories:

1. Women who will be 35 years or older at delivery
2. A positive first- or second-trimester analyte-based screening test
3. Sonogram with a minor aneuploidy marker
4. Prior pregnancy with autosomal trisomy
5. Known carriage (patient or partner) of a balanced robertsonian translocation involving chromosome 21 or 13.

Cell-Free DNA for Secondary Screening

If cell-free DNA screening is performed as a *secondary screen* following a positive first- or second-trimester analyte-based test result, a normal result is not quite as reassuring. The residual risk for chromosomal abnormality is estimated to be 2 percent (Norton, 2014). Compared with amniocentesis, use of cell-free DNA screening after an initial abnormal analyte-based test result is estimated to yield a 20-percent reduction in aneuploidy diagnoses. This takes into consideration false-negative diagnoses and aneuploidies not detectable with cell-free DNA screening (Davis, 2014; Norton, 2014). In addition, definitive diagnosis may be delayed, potentially affecting management. Concurrent or parallel screening is not recommended, and if an aneuploidy screening test of any type yields a negative result, additional screening is not indicated (American College of Obstetricians and Gynecologists, 2016b, 2017c).

The association between increased NT values and fetal structural and genetic abnormalities has raised questions about the role of a NT measurements following cell-free DNA screening. The College (2016b) has stated that NT measurement is not necessary at the time of cell-free DNA screening but that sonography may help to

confirm fetal number and viability and to assign gestational age. The Society for Maternal-Fetal Medicine (2015) states that after a negative cell-free DNA screening test result, the additional clinical utility of NT measurement to detect other chromosomal or structural abnormalities is unknown but appears to be limited.

Cell-Free DNA Screening in Low-Risk Pregnancies

Most studies of cell-free DNA have been conducted in high-risk pregnancies. Pragmatically, chromosomal abnormalities are individually so rare that even large studies of low-risk pregnancies contain few affected cases. Available data suggest that the high sensitivity and specificity for Down syndrome detection are preserved in low-risk pregnancies (Norton, 2015; Pergament, 2014; Zhang, 2015). Importantly, the positive-predictive value of cell-free DNA screening still depends greatly on maternal age and the specific aneuploidy in question (see Table 14-5). For a woman in her early 20s, the positive-predictive value is approximately 50 percent for fetal trisomy 21, 15 percent for trisomy 18, and <10 percent for trisomy 13. Hence, decisions for irreversible medical intervention should not be based on the results of this or other screening test alone.

Cell-Free DNA Screening Limitations

Important caveats are considered with selection of cell-free DNA aneuploidy screening. Because the cell-free DNA that is analyzed is maternal and placental, results may not reflect the fetal DNA complement but rather may indicate confined placental mosaicism, early demise of an aneuploid co- twin, maternal mosaicism, or even occult maternal malignancy (Bianchi, 2015; Curnow, 2015; Grati, 2014; Wang, 2014). In addition, if a twin pregnancy is identified sonographically, cell-free DNA screening is not currently recommended because of limited evidence regarding efficacy.

Another limitation is that cell-free DNA testing does not yield a result in approximately 4 to 8 percent of screened pregnancies, due to assay failure, high assay variance, or low fetal fraction (Norton, 2012; Pergament, 2014; Quezada, 2015). Most cell-free DNA is maternal. The fetal fraction is the proportion derived from the placenta and generally is about 10 percent of the total. A low fetal fraction is usually defined as <4 percent of the total and confers significantly higher risk for fetal aneuploidy (Ashoor, 2013; Norton, 2015; Pergament, 2014). Women with a low fetal fraction or “no-call” results have fetal aneuploidy rates as high as 4 percent, a percentage comparable to the average predictive value conferred by a positive first-trimester screening test result (see Table 14-4). The fetal fraction is not related to maternal age or analyte-based screening test results. However, it is lower earlier in pregnancy and appears to be reduced in women of greater weight (Ashoor, 2013).

Because of the increased risk for fetal aneuploidy in cases not generating a cell-free DNA screening result (no-call result), genetic counseling is indicated, and amniocentesis should be offered. If the patient elects repeat screening, the risk for screen failure may exceed 40 percent (Dar, 2014; Quezada, 2015). Targeted sonography is recommended but is not a substitute for amniocentesis, because it is unclear what the residual risk would be with normal sonogram findings. (American College of Obstetricians and Gynecologists, 2016b, 2017c). Pretest counseling should include the possibility of a low fetal fraction or no-call result and its clinical significance.

Comparison with Analyte-Based Screening

Cell-free DNA screening has obvious advantages, but it is not simply a “better” test—because no screening test is superior for all test characteristics (American College of Obstetricians and Gynecologists, 2016c). Compared with analyte-based tests, benefits of cell-free DNA screening in women 35 years and older include the lower likelihood of a false-positive result, its higher positive-predictive value, and the fact that isolated minor aneuploidy markers are generally not a concern (Sonographic Screening).

But, analyte-based tests are frequently positive with a large range of chromosomal abnormalities, whereas cell-free DNA screens are specific for individual aneuploidies (Baer, 2015; Kazerouni, 2011). Women younger than 35 are at lower risk for the specific autosomal trisomies for which cell-free DNA screening is typically performed. Thus, if the goal is to select a screening test that will identify the highest proportion of fetuses with any chromosomal abnormality, the yield may be comparable or even slightly higher with integrated or sequential screening than with current cell-free DNA screening (Baer, 2015; Norton, 2014).

Sonographic Screening

Sonography can augment aneuploidy screening by providing accurate gestational age assessment, by detecting multifetal gestations, and by identifying major structural abnormalities and minor sonographic markers. As shown in Table 14-7, with rare exceptions, the aneuploidy risk associated with any major abnormality is high enough to warrant offering prenatal diagnosis. Generally, chromosomal microarray analysis is recommended as the first-line test. Importantly, a fetus with one abnormality may have others that are less likely to be detected sonographically but that greatly affect the prognosis. Aneuploidy screening—including cell-free DNA—is not recommended if a major abnormality has been identified. The fetal risk cannot be normalized with a normal screening result, not merely because screening results can be falsely negative, but also because major anomalies confer risk for genetic syndromes not identified through screening tests.

TABLE 14-7

Aneuploidy Risk Associated with Selected Major Fetal Anomalies

Abnormality	Birth Prevalence	Aneuploidy Risk (%)	Common Aneuploidies[a]
Cystic hygroma	1/5000	50–70	45,X; 21; 18; 13; triploidy
Nonimmune hydrops	1/1500–4000	10–20	21, 18, 13, 45X, triploidy
Ventriculomegaly	1/1000–2000	5–25	13, 18, 21, triploidy
Holoprosencephaly	1/10,000–15,000	30–40	13, 18, 22, triploidy
Dandy-Walker malformation	1/12,000	40	18, 13, 21, triploidy
Cleft lip/palate	1/1000	5–15	18, 13
Cardiac defects	5–8/1000	10–30	21; 18; 13; 45,X; 22q11.2 microdeletion
Diaphragmatic hernia	1/3000–4000	5–15	18, 13, 21
Esophageal atresia	1/4000	10	18, 21
Duodenal atresia	1/10,000	30	21
Gastroschisis	1/2000–4000	No increase	
Omphalocele	1/4000	30–50	18, 13, 21, triploidy
Clubfoot	1/1000	5–30	18, 13

[a]Numbers indicate autosomal trisomies except where indicated. For example, 45,X indicates Turner syndrome.

Data from Best, 2012; Canfield, 2006; Colvin, 2005; Cragan, 2009; Dolk, 2010; Ecker, 2000; Gallot, 2007; Long, 2006; Orioli, 2010; Pedersen, 2012; Sharma, 2011; Solomon, 2010; Walker, 2001.

If a major abnormality is identified, targeted sonography is indicated. Sonography is not an alternative to prenatal diagnosis, but the aneuploidy risk is further increased if additional findings are identified. An earlier study reported that only 25 to 30 percent of second-trimester fetuses with Down syndrome had a major malformation that could be identified sonographically (Vintzileos, 1995). When both major anomalies and minor aneuploidy markers are considered, it is estimated that 50 to 60 percent of Down syndrome pregnancies can be detected sonographically (American College of Obstetricians and Gynecologists, 2016c). Fortunately, most fetuses with aneuploidy that is likely to be lethal in utero—such as trisomy 18 and 13 and triploidy—usually have sonographic abnormalities that can be seen by the second trimester.

Second-Trimester Markers—"Soft Signs"

For three decades, investigators have recognized that the sonographic detection of aneuploidy, particularly Down syndrome, may be improved by minor markers that are collectively referred to as "soft signs." Minor markers are normal variants rather than fetal abnormalities, and in the absence of aneuploidy or an associated abnormality, they do not significantly affect prognosis. They are present in at least 10 percent of unaffected pregnancies (Bromley, 2002; Nyberg, 2003). Examples of these sonographic findings are listed in Table 14-8 and depicted in Figure 14-3. Findings are generally useful from 15 to 20 or 22 weeks' gestation. Six of these markers have been the focus of sonographic studies, in which likelihood ratios have been derived that allow a numerical aneuploidy risk to be calculated (Table 14-9). The risk rises steeply with the number of markers identified. Alternatively, absence of a minor marker has been used to reduce the calculated risk (Agathokleous, 2013). This should be done systematically, following a protocol that specifies the markers included in a model, the definition for what constitutes a finding, and positive- and negative-likelihood ratios (Reddy, 2014).

TABLE 14-8

Second-Trimester Sonographic Markers or "Soft Signs" Associated with Fetal Trisomy 21[a]

Aberrant right subclavian artery
Brachycephaly or shortened frontal lobe
Clinodactyly (hypoplasia of the 5th digit middle phalanx)
Echogenic bowel
Flat facies
Echogenic intracardiac focus
Nasal bone absence or hypoplasia
Nuchal fold thickening
Renal pelvis dilation (mild)
"Sandal gap" between first and second toes
Shortened ear length
Single transverse palmar crease
Single umbilical artery
Short femur
Short humerus
Widened iliac angle

[a]Listed alphabetically.

TABLE 14-9

Likelihood Ratios and False-Positive Rates for Isolated Second-Trimester Markers Used in Down Syndrome Screening Protocols

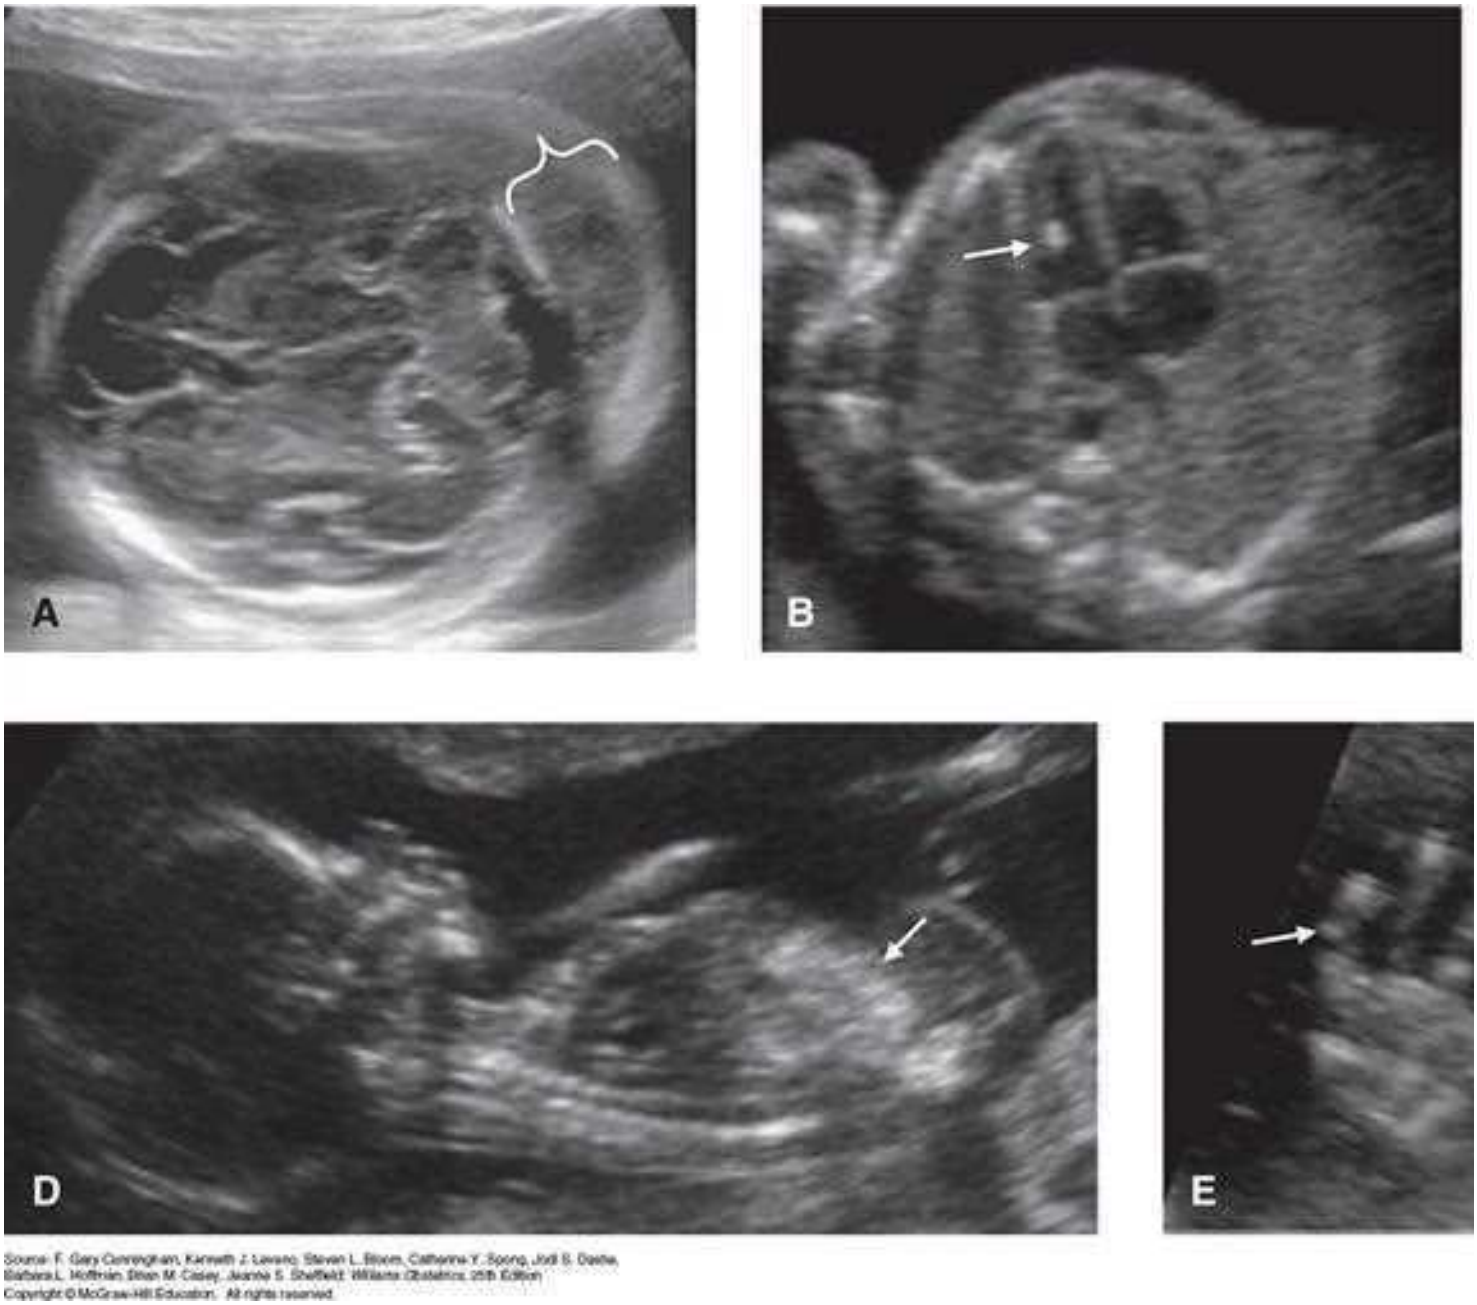
Sonographic Marker	Likelihood Ratio	Prevalence in Unaffected Fetuses (%)
Nuchal skinfold thickening	11–17	0.5
Renal pelvis dilation	1.5–1.9	2.0–2.2
Echogenic intracardiac focus	1.4–2.8	3.8–3.9[a]
Echogenic bowel	6.1–6.7	0.5–0.7
Short femur	1.2–2.7	3.7–3.9
Short humerus	5.1–7.5	0.4
Any one marker	1.9–2.0	10.0–11.3
Two markers	6.2–9.7	1.6–2.0
Three or more	80–115	0.1–0.3

[a]Higher in Asian individuals.

Data from Bromley, 2002; Nyberg, 2001; Smith-Bindman, 2001.

FIGURE 14-3

Minor sonographic markers that are associated with increased risk for fetal Down syndrome. **A.** Nuchal skinfold thickening (*bracket*). **B.** Echogenic intracardiac focus (*arrow*). **C.** Mild renal pelvis dilatation (pyelectasis) (*arrows*). **D.** Echogenic bowel (*arrow*). **E.** Clinodactyly—hypoplasia of the 5th finger middle phalanx creates an inward curvature (*arrow*). **F.** "Sandal-gap" (*arrow*).



The *nuchal skinfold* is measured in the transcerebellar view of the fetal head, from the outer edge of the skull to the outer border of the skin (see Fig. 14-3A). A measurement ≥6 mm is typically considered abnormal (Benacerraf, 1985). This finding is present in approximately 1 per 200 pregnancies and confers a more than tenfold risk for Down syndrome (Bromley, 2002; Nyberg, 2001; Smith-Bindman, 2001).

An *echogenic intracardiac focus* is a focal papillary muscle calcification that is neither a structural nor functional cardiac abnormality. It is usually left-sided (see Fig. 14-3B). Such a focus is present in approximately 4 percent of fetuses, but it may be found in up to 30 percent of Asian individuals (Shipp, 2000). As an isolated finding, this approximately doubles the risk for fetal Down syndrome (see Table 14-9). Bilateral echogenic foci are associated with trisomy 13 (Nyberg, 2001).

Mild *renal pelvis dilatation* is usually transient or physiological and does not represent an underlying abnormality (Chap. 10, Renal Pelvis Dilatation). The renal pelves are measured in a transverse image of the kidneys, anterior-to-posterior, with calipers placed at the inner borders of the fluid collection (see Fig. 14-3C). A measurement ≥4 mm is found in about 2 percent of fetuses and approximately doubles the risk for Down syndrome. The degree of pelvic dilatation beyond 4 mm correlates with the likelihood of an underlying renal abnormality, and additional evaluation is generally performed at approximately 32 weeks.

Echogenic fetal bowel is defined as bowel that appears as bright as fetal bone (see Fig. 14-3D). It is identified in approximately 0.5 percent of pregnancies and most commonly represents small amounts of swallowed blood, frequently in the setting of maternal serum AFP level elevation. Although typically associated with normal outcomes, it raises the risk for Down syndrome approximately sixfold. Echogenic bowel has also been associated with fetal cytomegalovirus infection and cystic fibrosis—representing inspissated meconium in the latter.

The femur and humerus are slightly shorter in Down syndrome fetuses. The femur is considered “short” for Down syndrome screening if it measures below the 2.5th percentile or is shortened to ≤90 percent of that expected based on the measured biparietal diameter (American College of Obstetricians and Gynecologists, 2016c; Benacerraf, 1987). As an isolated finding in an otherwise low-risk pregnancy, it is generally not considered to pose great enough risk to warrant counseling

modification. Similarly, a humerus shortened to ≤89 percent of that expected, based on a given biparietal diameter, has also been associated with an elevated risk for Down syndrome.

If an isolated minor marker is identified in a woman who has not yet received aneuploidy screening, screening should be offered, and a minor marker is considered an indication to offer cell-free DNA screening (American College of Obstetricians and Gynecologists, 2016c). If cell-free DNA screening has already been performed, the association between isolated minor markers and aneuploidy risk is no longer considered relevant (Reddy, 2014). And, if the cell-free DNA screening result is negative, the fetal aneuploidy risk is not modified by the marker. Conversely, if a cell-free DNA screening result is positive, the absence of minor markers is not considered reassuring.

First-Trimester Sonographic Findings

Unlike second-trimester soft signs, which may be readily visible during standard sonography, first-trimester findings associated with aneuploidy require specialized training. The fetal NT measurement has gained widespread use for aneuploidy screening. Other first-trimester sonographic findings are not routinely used in the United States but may be available in specialized centers. The Perinatal Quality Foundation's Nuchal Translucency Quality Review Program offers an education program in first-trimester nasal bone assessment (see Fig. 14-2). The Fetal Medicine Foundation also provides online instruction and certification in first-trimester assessment of nasal bone, ductus venosus flow, and tricuspid flow.

Other benefits of first-trimester sonography in women who elect aneuploidy screening include accurate assessment of gestational age and early detection of multifetal gestation or fetal demise. As discussed in Chapter 10 (Second- and Third-Trimester Sonography), first-trimester sonography may identify selected major anomalies associated with aneuploidy, such as cystic hygroma.

CARRIER SCREENING FOR GENETIC DISORDERS

Three types of carrier screening may be offered: ethnicity-based screening, panethnic screening (performed regardless of ethnicity), and expanded carrier screening —which is a type of panethnic screening performed for a larger number of conditions, potentially 100 or more. The goal of screening is to provide individuals with meaningful information to guide pregnancy planning according to their values (American College of Obstetricians and Gynecologists, 2017a). Each type of screening has benefits, risks, and limitations. For example, so many disorders are included in expanded carrier screening panels that more than 50 percent of those screened may be identified to be carriers for at least 1 condition. This can cause anxiety for families and may pose challenges if genetic counseling resources are limited. Recognizing that each type of screening is an acceptable strategy, it is recommended that obstetrical providers develop a standard approach to offer one of these three types of carrier screening to pregnant women and couples considering pregnancy (American College of Obstetricians and Gynecologists, 2017a). All carrier screening is optional and should be an informed choice.

Couples with a personal or family history of a heritable genetic disorder should be offered genetic counseling. They are provided an estimated risk of having an affected newborn and given information concerning benefits and limitations of available prenatal testing options. Prenatal diagnosis may be available if the disease-causing mutation or mutations are known. The publicly funded Genetic Testing Registry website contains detailed information regarding more than 10,000 genetic conditions and 48,000 genetic tests (www.ncbi.nlm.nih.gov/gtr/). That said, many genetic disorders are characterized by a high degree of penetrance but variable expressivity. Thus, prediction of phenotype may not be possible, even when family members are affected. Common examples include neurofibromatosis, tuberous sclerosis, and Marfan syndrome. There are also conditions for which risk may be refined by detection of associated sonographic abnormalities or by gender determination if X-linked.

Ethnicity-based carrier screening is offered for certain autosomal recessive disorders that are found in greater frequency in specific racial or ethnic groups (Table 14-10). The *founder effect* occurs when an otherwise rare gene is found with greater frequency in a certain population and can be traced back to a single family member or small group of ancestors. This phenomenon may develop when generations of individuals procreate only within their own groups because of religious or ethnic prohibitions or geographical isolation. Because it is becoming increasingly difficult to assign a single ethnicity, a panethnic screening panel is another option.

TABLE 14-10

Autosomal Recessive Diseases Found with Increased Frequency in Certain Ethnic Groups

Disease	Heritage of Groups at Increased Risk
Sickle hemoglobinopathies	African, Mediterranean, Middle Eastern, Indian
α-Thalassemia	African, Mediterranean, Middle Eastern, West Indian, Southeast Asian
β-Thalassemia	African, Mediterranean, Middle Eastern, Indian, Southeast Asian
Inborn errors of metabolism:	Ashkenazi Jewish
Tay-Sachs disease Canavan disease Familial dysautonomia Bloom syndrome Familial hyperinsulinism Fanconi anemia Gaucher disease Glycogen storage disease type I Joubert syndrome Maple syrup urine disease Mucolipidosis type IV Niemann-Pick disease Usher syndrome	Tay-Sachs is also more common in groups with French-Canadian and Cajun heritage

The American College of Obstetricians and Gynecologists (2017a) has developed the following criteria for expanded carrier screening panels:

1. Conditions included in the panel should have a carrier frequency of at least 1:100, which correlates with a population frequency, at minimum, of 1:40,000.
2. Conditions should have a well-defined phenotype, detrimental effect on quality of life, cognitive or physical impairment, early onset, or require surgical or medical intervention.
3. Conditions primarily associated with disease of adult onset are not recommended for inclusion.
4. If an individual is at increased risk for a specific condition, such as Tay-Sachs disease or β-thalassemia, the provider should consider that the test included in the panel may not be the most sensitive one for that condition.

Cystic Fibrosis

This disorder is caused by a mutation in the *cystic fibrosis conductance transmembrane regulator (CFTR)* gene, which is located on the long arm of chromosome 7 and encodes a chloride-channel protein. Although the most common CFTR gene mutation associated with classic cystic fibrosis (CF) is the Δ*F508* mutation, more than 2000 mutations have been identified (Cystic Fibrosis Mutation Database, 2016). CF may develop from either *homozygosity* or *compound heterozygosity* for mutations in the CFTR gene. In other words, one mutation must be present in each copy of the gene, but they need not be the same mutation. As expected, this results in a tremendous range of clinical disease severity. Median survival is approximately 37 years, but approximately 15 percent have milder disease and can survive for decades longer. Care for the pregnant woman with CF is discussed in Chapter 51 (Pathophysiology).

The American College of Obstetricians and Gynecologists (2017a,b) recommends that all patients who are considering pregnancy or who are already pregnant should be offered carrier screening for CF, regardless of ethnicity.

The current recommended screening panel contains 23 panethnic CF gene mutations, selected because they are present in at least 0.1 percent of patients with classic CF (American College of Obstetricians and Gynecologists, 2017b). The CF carrier frequency approximates 1 in 25 in non-Hispanic white Americans and those of Ashkenazi Jewish descent, who are from Eastern Europe. Thus, the incidence of CF in a child born to a non-Hispanic white couple approximates $¼ \times {}^{1}/_{25} \times {}^{1}/_{25}$, or 1:2500. As shown in Table 14-11, both CF incidence and the sensitivity of the screening test are lower for other ethnicities.

TABLE 14-11

Cystic Fibrosis Detection and Carrier Rates before and after Testing

Racial or Ethnic Group	Detection (%)	Carrier Risk before Test	Carrier Risk after Negative Test
Ashkenazi Jewish	94.0	1/24	1 in 384
Caucasian	88.3	1/25	1 in 206
Hispanic American	71.7	1/58	1 in 203
African American	64.5	1/61	1 in 171
Asian American	48.9	1/94	1 in 183

Data from American College of Medical Genetics, 2006.

Although a negative screening test result does not preclude the possibility of carrying a less-common mutation, it reduces the risk substantively from the background rate. If both parents are carriers, chorionic villus sampling or amniocentesis can help determine whether the fetus has inherited one or both of the parental mutations. Counseling following identification of two disease-causing mutations is challenging, because phenotype prediction is reasonably accurate only for pancreatic disease, and then only for well-characterized mutations. Prognosis is most heavily affected by the degree of pulmonary disease, which varies considerably even among individuals with the most common genotype associated with classic disease, that is, those homozygous for the Δ*F508* mutation. This likely reflects the effect of genetic modifiers on protein function, which may further vary depending on the CFTR mutation and on exposure and susceptibility to environmental factors (Cutting, 2005; Drumm, 2005).

Spinal Muscular Atrophy

This autosomal recessive disorder results in spinal cord motor neuron degeneration that leads to skeletal muscle atrophy and generalized weakness. There is currently no effective treatment. The prevalence of spinal muscular atrophy (SMA) is 1 in 6,000 to 10,000 live births. Types I, II, III, and IV are caused by mutations in the *survival motor neuron (SMN1)* gene, which is located on the long arm of chromosome 5 (5q13.2) and encodes the SMN protein. Types I and II account for 80 percent of cases and are both lethal (American College of Obstetricians and Gynecologists, 2017b). SMA type I, known as Werdnig-Hoffmann, is the most severe. Disease onset is within the first 6 months, and affected children die of respiratory failure by age 2 years. Type II generally has onset before age 2 years, and the age at death can range from 2 years to the third decade of life. Type III also presents before age 2 years, with disease severity that is milder and more variable. Type IV does not present until adulthood.

The American College of Obstetricians and Gynecologists (2017b) recommends that carrier screening for SMA be offered to all women who are considering pregnancy or are currently pregnant. The SMA carrier frequency approximates 1:35 in those of non-Hispanic white (caucasian) ethnicity, 1:41 in Ashkenazi Jews, 1:53 in Asians, 1:66 in African Americans, and 1:117 in those of Hispanic white ethnicity (Hendrickson, 2009). Carrier detection rates range from 90 to 95 percent for each race/ethnicity except African Americans, in whom it just exceeds 70 percent. Approximately 2 percent of individuals with *SMN1* mutations are not identified with carrier screening. In addition, although there is usually one copy of the *SMN1* gene on each chromosome, approximately 3 to 4 percent of individuals have two copies of this gene on one chromosome and no copies on the other. These individuals are carriers for the disease. African Americans are more likely to have this genetic variation, which explains the lower sensitivity of screening in this group. The American College of Obstetricians and Gynecologists (2017b) recommends that prior to screening for SMA, providers counsel about its potential spectrum of severity, carrier frequency, and its detection rate. Posttest counseling should include the residual risk after a negative screening result, which differs according to the patient's ethnicity and also according to the number of *SMN1* copies detected. Most unaffected individuals have two copies, but a small percentage has three copies and is at even lower risk. If the patient or her partner has a family history of SMA, or if carrier screening is positive, genetic counseling is recommended.

Sickle Hemoglobinopathies

These include sickle-cell anemia, sickle-cell hemoglobin C disease, and sickle-cell β-thalassemia. Their pathophysiology and inheritance are discussed in detail in Chapter 56 (Polycythemias).

African and African-American patients are at increased risk to carry hemoglobin S and other hemoglobinopathies and should be offered preconceptional or prenatal screening. Of African Americans, 1 in 12 has sickle-cell trait, 1 in 40 carries hemoglobin C, and 1 in 40 carries the trait for β-thalassemia. Hemoglobin S is also more common among individuals of Mediterranean, Middle Eastern, and Asian Indian descent (Davies, 2000). The American College of Obstetricians and Gynecologists (2015) recommends that patients of African descent be offered hemoglobin electrophoresis. If a couple is at risk to have a child with a sickle hemoglobinopathy, genetic counseling should be offered. Prenatal diagnosis can be performed with either chorionic villus sampling or amniocentesis.

Thalassemias

These syndromes are the most common single-gene disorders worldwide, and up to 200 million people carry a gene for one of these hemoglobinopathies (Chap. 56, Thalassemia Syndromes). Some individuals with thalassemia have microcytic anemia secondary to decreased synthesis of either α- or β-hemoglobin chains. In

general, *deletions* of α-globin chains cause α-thalassemia, whereas *mutations* in β-globin chains cause β-thalassemia. Less commonly, an α-globin chain mutation also causes α-thalassemia.

Alpha-Thalassemia

The number of α-globin genes that are deleted may range from one to all four. If two α-globin genes are deleted, both may be deleted from the same chromosome—*cis* configuration (αα/––), or one may be deleted from each chromosome—*trans* configuration (α–/α–). Alpha-thalassemia trait is common among individuals of African, Mediterranean, Middle Eastern, West Indian, and Southeast Asian descent and results in mild anemia. The *cis* configuration is more prevalent among Southeast Asians, whereas those of African descent are more likely to inherit the *trans* configuration. Clinically, when both parents carry *cis* deletions, offspring are at risk for an absence of α-hemoglobin, called Hb Barts disease. This typically leads to hydrops and fetal loss as discussed in Chapter 15 (Hydrops Fetalis).

Detection of α-thalassemia or α-thalassemia trait is based on molecular genetic testing and is not detectable using hemoglobin electrophoresis. Because of this, routine carrier screening is not offered. If there is microcytic anemia in the absence of iron deficiency and the hemoglobin electrophoresis is normal, then testing for α-thalassemia can be considered, particularly among individuals of Southeast Asian descent (American College of Obstetricians and Gynecologists, 2015).

Beta-Thalassemia

Mutations in β-globin genes may cause reduced or absent production of β-globin chains. If the mutation affects one gene, it results in β-thalassemia minor. If both copies are affected, the result is either β-thalassemia major—termed Cooley anemia—or β-thalassemia intermedia. Because of reduced production of hemoglobin A among carriers, electrophoresis demonstrates elevated levels of hemoglobins that do not contain β-chains. These include hemoglobins F and A_2.

β-Thalassemia minor is more common among individuals of African, Mediterranean, and Southeast Asian descent. The American College of Obstetricians and Gynecologists (2015) recommends that they be offered carrier screening with hemoglobin electrophoresis, particularly if found to have microcytic anemia in the absence of iron deficiency. Hemoglobin A_2 levels exceeding 3.5 percent confirm the diagnosis. Other ethnicities at increased risk include those of Middle Eastern, West Indian, and Hispanic descent.

Tay-Sachs Disease

This autosomal recessive lysosomal-storage disease is characterized by absence of the hexosaminidase A enzyme. This leads to accumulation of GM2 gangliosides in the central nervous system, progressive neurodegeneration, and death in early childhood. Affected individuals have almost complete absence of the enzyme, whereas carriers are asymptomatic but have less than 55-percent hexosaminidase A activity. The carrier frequency of Tay-Sachs disease in Jewish individuals of Eastern European (Ashkenazi) descent approximates 1 in 30, but it is much lower, only about 1 in 300, in the general population. Other groups at greater risk for Tay-Sachs disease include those of French-Canadian and Cajun descent. An international Tay-Sachs carrier-screening campaign was initiated in the 1970s and met with unprecedented success in the Ashkenazi Jewish population. The incidence of Tay-Sachs disease subsequently declined more than 90 percent (Kaback, 1993). Most cases of Tay-Sachs disease now occur in non-Jewish individuals.

The American College of Obstetricians and Gynecologists (2017b) has the following screening recommendations for Tay-Sachs disease:

1. Screening should be offered before pregnancy if both members of a couple are of Ashkenazi Jewish, French-Canadian, or Cajun descent, or if there is a family history of Tay-Sachs disease.
2. When only one member of the couple is of one of the above ethnicities, the high-risk partner may be screened first, and if found to be a carrier, the other partner also should be offered screening. If there is a family history of Tay-Sachs disease, an expanded carrier screening panel may not be the best approach unless the familial mutation is included in the panel.
3. Molecular testing (DNA-based mutation analysis) is highly effective in Ashkenazi Jewish individuals and other high-risk groups, but the detection rate in low-risk groups is more limited.
4. Biochemical analysis of the hexosaminidase A serum level has a sensitivity of 98 percent and is the test that should be performed in individuals from low-risk ethnicities. *Leukocyte testing* must be used if the woman is already pregnant or taking oral contraceptives.
5. If both partners are found to be carriers of Tay-Sachs disease, genetic counseling and prenatal diagnosis should be offered. Hexosaminidase activity may be measured from chorionic villus sampling or amniocentesis specimens.

Other Recessive Diseases in Ashkenazi Jewish Individuals

The carrier rate among individuals of Eastern European (Ashkenazi) Jewish descent approximates 1 in 30 for Tay-Sachs disease, 1 in 40 for Canavan disease, and 1 in 32 for familial dysautonomia. Fortunately, the detection rate of screening tests for each is at least 98 percent in this population. Because of their relatively high prevalence and consistently severe and predictable phenotype, the American College of Obstetricians and Gynecologists (2017b) recommends that carrier screening for these three conditions be offered to Ashkenazi Jewish individuals, either before conception or during early pregnancy. This is in addition to carrier screening for cystic fibrosis and spinal muscular atrophy, which are offered to all women who are considering pregnancy or who are currently pregnant. Further, there are several other autosomal recessive conditions for which the College recommends that screening be considered (American College of Obstetricians and Gynecologists, 2017b). As of 2017, these include Bloom syndrome, familial hyperinsulinism, Fanconi anemia, Gaucher disease, glycogen storage disease type I (von Gierke disease), Joubert syndrome, maple syrup urine disease, mucolipidosis type IV, Niemann-Pick disease, and Usher syndrome. Gaucher disease differs from the other conditions listed in

that it is has a wide range in phenotype—from childhood illness to absence of symptoms throughout life. Also, effective treatment is available in the form of enzyme therapy.

PRENATAL DIAGNOSTIC PROCEDURES AND PREIMPLANTATION TESTING

Diagnostic procedures used in prenatal diagnosis include amniocentesis, chorionic villus sampling (CVS), and rarely fetal blood sampling. These enable characterization of an increasingly large number of genetic abnormalities before birth. Karyotype analysis has a diagnostic accuracy of more than 99 percent for aneuploidy and chromosomal abnormalities larger than 5 to 10 megabases. In the setting of a fetal structural abnormality, chromosomal microarray analysis (CMA) is recommended as the first-line genetic test performed, as it may detect clinically significant chromosomal abnormalities in approximately 6 percent of fetuses with normal standard karyotype (Callaway, 2013; de Wit, 2014). An exception would be if the structural abnormality strongly suggests a particular karyotype—such as endocardial cushion defect with trisomy 21 or holoprosencephaly with trisomy 13. In such cases, karyotyping with or without fluorescence in-situ hybridization (FISH) may be offered as the initial test (American College of Obstetricians and Gynecologists, 2016b). Among those without evidence of a fetal structural abnormality and with a normal karyotype, CMA has detected additional chromosomal abnormalities (pathogenic copy number variants) in approximately 1 percent. It is therefore made available whenever a prenatal diagnostic procedure is performed (American College of Obstetricians and Gynecologists, 2016b; Callaway, 2013). Types of CMA platforms and their benefits and limitations are reviewed in Chapter 13 (Chromosomal Microarray Analysis).

Ironically, improvements in aneuploidy screening tests, in particular the widespread use of cell-free DNA screening, have resulted in a dramatic drop in the number of prenatal diagnostic procedures. Larion and colleagues (2014) reported a 70-percent decline in CVS procedures and a nearly 50-percent drop in amniocentesis procedures following introduction of cell-free DNA screening in 2012. This further amplified the decrease in amniocentesis procedures that began following adoption of first-trimester screening (Warsof, 2015). In addition, because so many disorders can be diagnosed from amnionic fluid specimens, fetal blood sampling is now rarely, if ever, indicated for genetic diagnoses.

Amniocentesis

This is the most common prenatal diagnostic procedure. Transabdominal withdrawal of amnionic fluid is generally done between 15 and 20 weeks but may be performed at any point later in gestation. Indications include diagnosis of fetal genetic disorders, congenital infections, and alloimmunization, as well as assessment of fetal lung maturity. The most common types of prenatal diagnostic tests are CMA to assess copy-number gains or losses, karyotype analysis to test for aneuploidy, and FISH to identify gain or loss of specific chromosomes or chromosome regions (Chap. 13, Genetic Tests). Because amniocytes must be cultured before fetal karyotype can be assessed, the time needed for karyotyping is 7 to 10 days. In contrast, FISH studies are usually completed within 24 to 48 hours. CMA can often be performed directly on uncultured amniocytes with a turnaround time of only 3 to 5 days, and if amniocyte culture is required, turnaround time is 10 to 14 days (American College of Obstetricians and Gynecologists, 2016b).

Technique

Amniocentesis is performed using aseptic technique, with a 20- or 22-gauge spinal needle and ultrasound guidance (Fig. 14-4). A standard spinal needle is 9 cm long, and depending on patient habitus, a longer needle may be required. Measurement of the sonographic distance from skin to amnionic fluid pocket may aid needle selection. Sonography is used to identify a pocket of amnionic fluid that is close to the midline, being cognizant of uterine size and shape. The needle is inserted perpendicular to the skin and guided into the deepest portion of the fluid pocket, avoiding fetal parts and umbilical cord. Efforts are made to puncture the chorioamnion rather than to push or "tent" it away from the uterine wall. The amnion usually fuses with the adjacent chorion by 16 weeks' gestation, and the procedure is generally deferred until after chorioamnion fusion has occurred. Discomfort from the procedure is considered minor, and local anesthetic has not been found to be beneficial (Mujezinovic, 2011).

FIGURE 14-4

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Following the procedure, the color and clarity of the fluid are documented. Amnionic fluid should be clear and colorless or pale yellow. Blood-tinged fluid is more frequent if there is transplacental passage of the needle. However, it generally clears with continued aspiration. The placenta implants along the anterior uterine wall in approximately half of pregnancies. In these cases, the placenta will be traversed by the needle approximately 60 percent of the time (Bombard, 1995). Needle

passage through the placenta is avoided when possible, although fortunately this has not been associated with greater pregnancy loss rates (Marthin, 1997). Dark brown or greenish fluid may represent a past episode of intraamnionic bleeding.

The volume of fluid generally needed for commonly performed analyses is shown in Table 14-12. Because the initial 1 to 2 mL of fluid aspirate may be contaminated with maternal cells, it is generally discarded. Approximately 20 to 30 mL of fluid is then collected for either fetal CMA or karyotyping before removing the needle. Sonography is used to observe the uterine puncture site for bleeding, and fetal cardiac motion is documented at the procedure's end. If the patient is Rh D-negative and unsensitized, anti-D immune globulin is administered following the procedure (Chap. 15, Prevention of Anti-D Alloimmunization).

TABLE 14-12

Selected Tests Performed on Amnionic Fluid and Typical Volume of Fluid Required

Test	Volume (mL)[a]
Fetal karyotype	20
Chromosomal microarray analysis	20
FISH[b]	10
Alpha-fetoprotein	2
PCR tests for cytomegalovirus, toxoplasmosis, or parvovirus	1–2 each test
Cytomegalovirus culture	2–3
Delta OD 450 (bilirubin analysis)	2–3
Genotype studies (alloimmunization)	20
Fetal lung maturity tests	10

[a]The volume of fluid needed for each test may vary according to individual laboratory specifications.

[b]Fluorescence in-situ hybridization (FISH) is typically performed for chromosomes 21, 18, 13, X, and Y.

PCR = polymerase chain reaction.

Multifetal Pregnancy

When performing the procedure in a diamnionic twin gestation, careful attention is paid to the location of each sac and the dividing membrane. Until recently, a small quantity of dilute indigo carmine dye was often injected before removing the needle from the first sac, with return of clear amnionic fluid anticipated following needle placement into the second sac. Because of widespread shortages of indigo carmine dye, most experienced providers offer amniocentesis in multifetal gestations when indicated, without dye injection. Methylene blue dye is contraindicated because it has been associated with jejunal atresia and neonatal methemoglobinemia (Cowett, 1976; van der Pol, 1992).

Complications

The procedure-related loss rate following midtrimester amniocentesis has decreased with improvements in imaging technology. Based on single-center studies and metaanalysis data, the amniocentesis procedure-related loss rate approximates 0.1 to 0.3 percent when performed by an experienced provider—about 1 per 500 procedures (Akolekar, 2015; American College of Obstetricians and Gynecologists, 2016b; Odibo, 2008). The loss rate may be doubled in women with class 3 obesity, which is a body mass index (BMI) >40 kg/m^2 (Harper, 2012). In twin pregnancies, Cahill and coworkers (2009) reported a loss rate of 1.8 percent attributable to amniocentesis.

The amniocentesis indication can influence loss rates, which can be greater with some fetal abnormalities, aneuploidies, and conditions such as hydrops. And, some losses are due to abnormal placental implantation or abruption, uterine abnormalities, or infection. Wenstrom and colleagues (1990) analyzed 66 fetal deaths following nearly 12,000 procedures and found that 12 percent were associated with preexisting intrauterine infection.

Other complications of amniocentesis include amnionic fluid leakage or transient vaginal spotting in 1 to 2 percent. Following leakage of amnionic fluid, which generally occurs within 48 hours of the procedure, fetal survival exceeds 90 percent (Borgida, 2000). Needle injuries to the fetus are rare. Amnionic fluid culture is successful in more than 99 percent of cases, although cells are less likely to grow if the fetus is abnormal (Persutte, 1995).

Early Amniocentesis

This describes amniocentesis performed between 11 and 14 weeks' gestation. The technique is the same as for traditional amniocentesis, but sac puncture may be more challenging due to lack of membrane fusion to the uterine wall. Less fluid is typically withdrawn—approximately 1 mL for each gestational week (Shulman,

1994; Sundberg, 1997).

Early amniocentesis is associated with significantly higher rates of procedure-related complications than other fetal procedures. These include development of talipes equinovarus (clubfoot), amnionic fluid leakage, and fetal loss (Canadian Early and Mid-Trimester Amniocentesis Trial, 1998; Philip, 2004). Given these risks, the American College of Obstetricians and Gynecologists (2016b) recommends that early amniocentesis not be performed.

Chorionic Villus Sampling

Biopsy of chorionic villi is typically performed between 10 and 13 weeks' gestation. As with amniocentesis, the specimen is generally sent for karyotyping or CMA. The primary advantage of villus biopsy is that results are available earlier in pregnancy, permitting more time for decision-making and safer pregnancy termination, if desired. Very few analyses specifically require either amnionic fluid or placental tissue.

Technique

Chorionic villi may be obtained transcervically or transabdominally, using aseptic technique. Both approaches are considered equally safe and effective (American College of Obstetricians and Gynecologists, 2016b). Transcervical CVS is performed using a specifically designed catheter made from flexible polyethylene that contains a blunt-tipped, malleable stylet. Transabdominal sampling is performed using an 18- or 20-gauge spinal needle. With either technique, transabdominal sonography is used to guide the catheter or needle into the early placenta—*chorion frondosum*, followed by aspiration of villi into a syringe containing tissue culture media (Fig. 14-5).

FIGURE 14-5

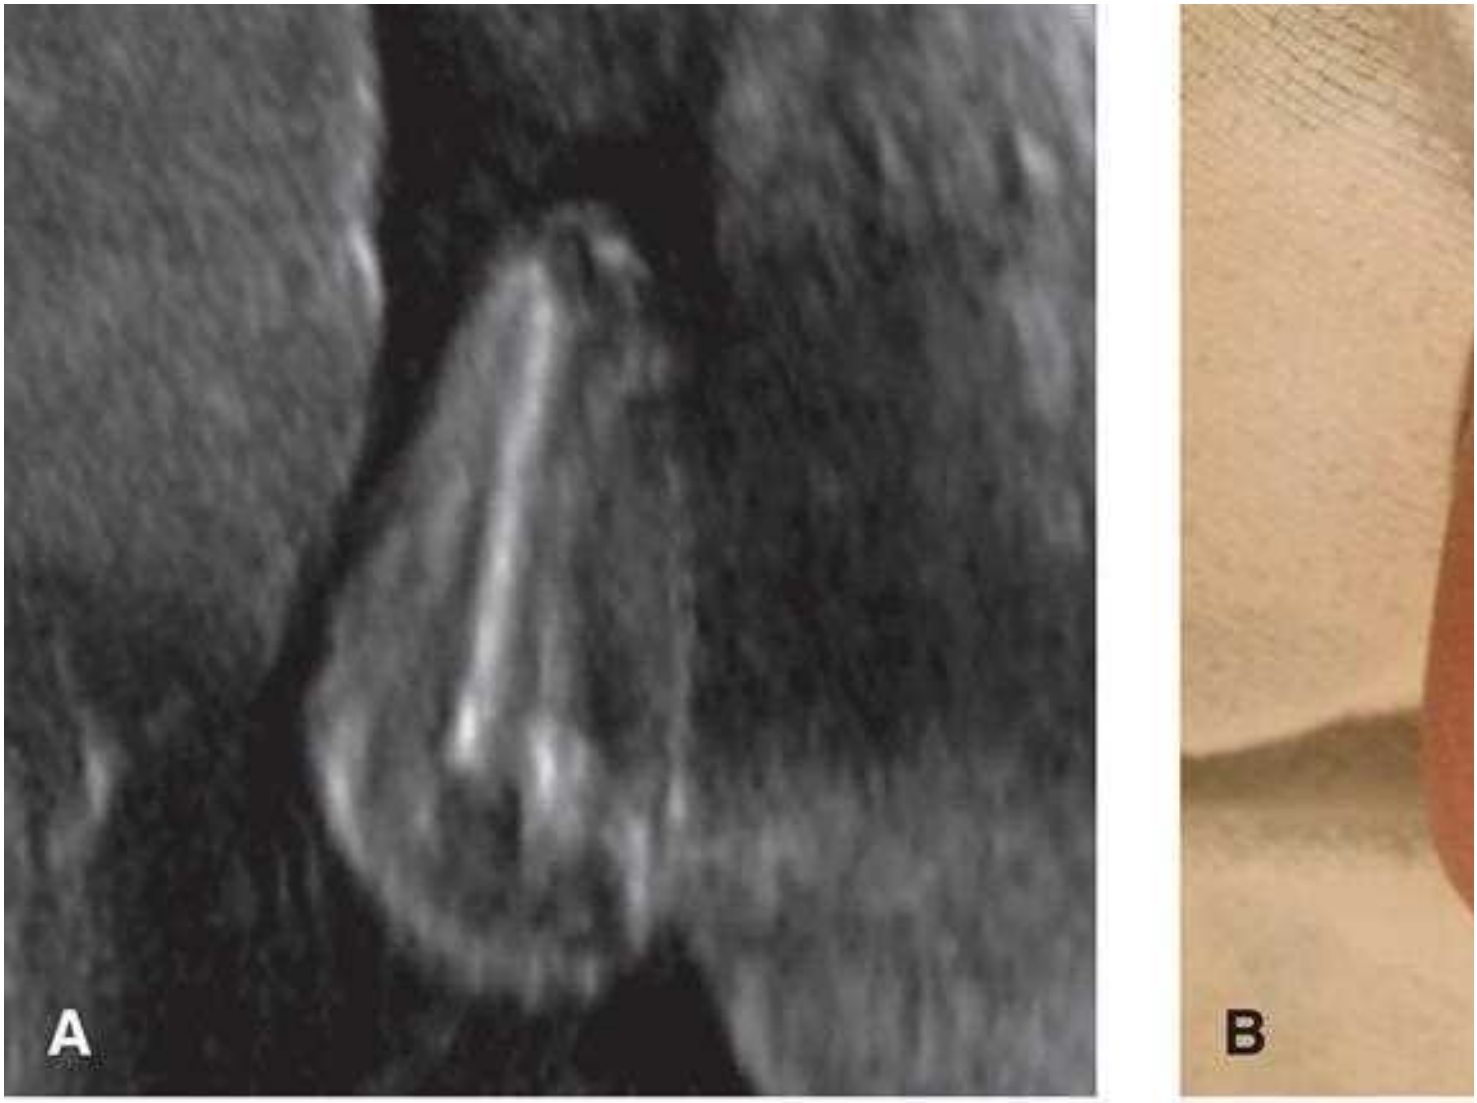
Relative contraindications include vaginal bleeding or spotting, active genital tract infection, extreme uterine ante- or retroflexion, or body habitus precluding adequate visualization. If the patient is Rh D-negative and unsensitized, anti-D immune globulin is administered following the procedure.

Complications

The *overall* loss rate following CVS is higher than that following midtrimester amniocentesis. This is because of background spontaneous losses, that is, losses that would have occurred between the first and second trimester in the absence of a fetal procedure. The procedure-related fetal loss rate is comparable with that of amniocentesis. Caughey and colleagues (2006) found that the overall loss rate following CVS was approximately 2 percent compared with less than 1 percent following amniocentesis. However, the adjusted procedure-related loss rate approximated 1 per 400 for either procedure. The indication for CVS will also affect the loss rate. For example, fetuses with increased NT thickness have a greater likelihood of demise. Finally, there is a learning curve associated with safe performance of CVS (Silver, 1990; Wijnberger, 2003).

An early problem with CVS was its association with *limb-reduction defects* and *oromandibular limb hypogenesis,* shown in Figure 14-6 (Firth, 1991, 1994; Hsieh, 1995). These were subsequently found to be associated with procedures performed at 7 weeks' gestation (Holmes, 1993). When performed at ≥10 weeks' gestation, the incidence of limb defects does not exceed the background population rate of about 1 per 1000 (Evans, 2005; Kuliev, 1996).

FIGURE 14-6
Oromandibular limb hypogenesis is characterized by transverse limb deficiency and absence or hypoplasia of the tongue or mandible. This is hypothesized to result from vascular disruption with subsequent loss of tissue. **A.** Sonogram obtained at 25 weeks' gestation demonstrates a fetal limb reduction defect involving the right hand. **B.** Photograph of the right extremity of the same newborn. Chorionic villus sampling was not performed in this pregnancy. (Used with permission from Dr. Jamie Morgan.)



Vaginal spotting is not uncommon following transcervical sampling, but it is self-limited and not associated with pregnancy loss. The incidence of infection is less than 0.5 percent (American College of Obstetricians and Gynecologists, 2016c).

A limitation of CVS is that chromosomal mosaicism is identified in up to 2 percent of specimens (Malvestiti, 2015). In most cases, the mosaicism reflects confined placental mosaicism rather than a true second cell line within the fetus. This is discussed in Chapter 13 (Chromosomal Mosaicism). Amniocentesis should be offered, and if the result is normal, the mosaicism is usually presumed to be confined to the placenta. Confined placental mosaicism has been associated with growth-restricted newborns (Baffero, 2012).

Fetal Blood Sampling

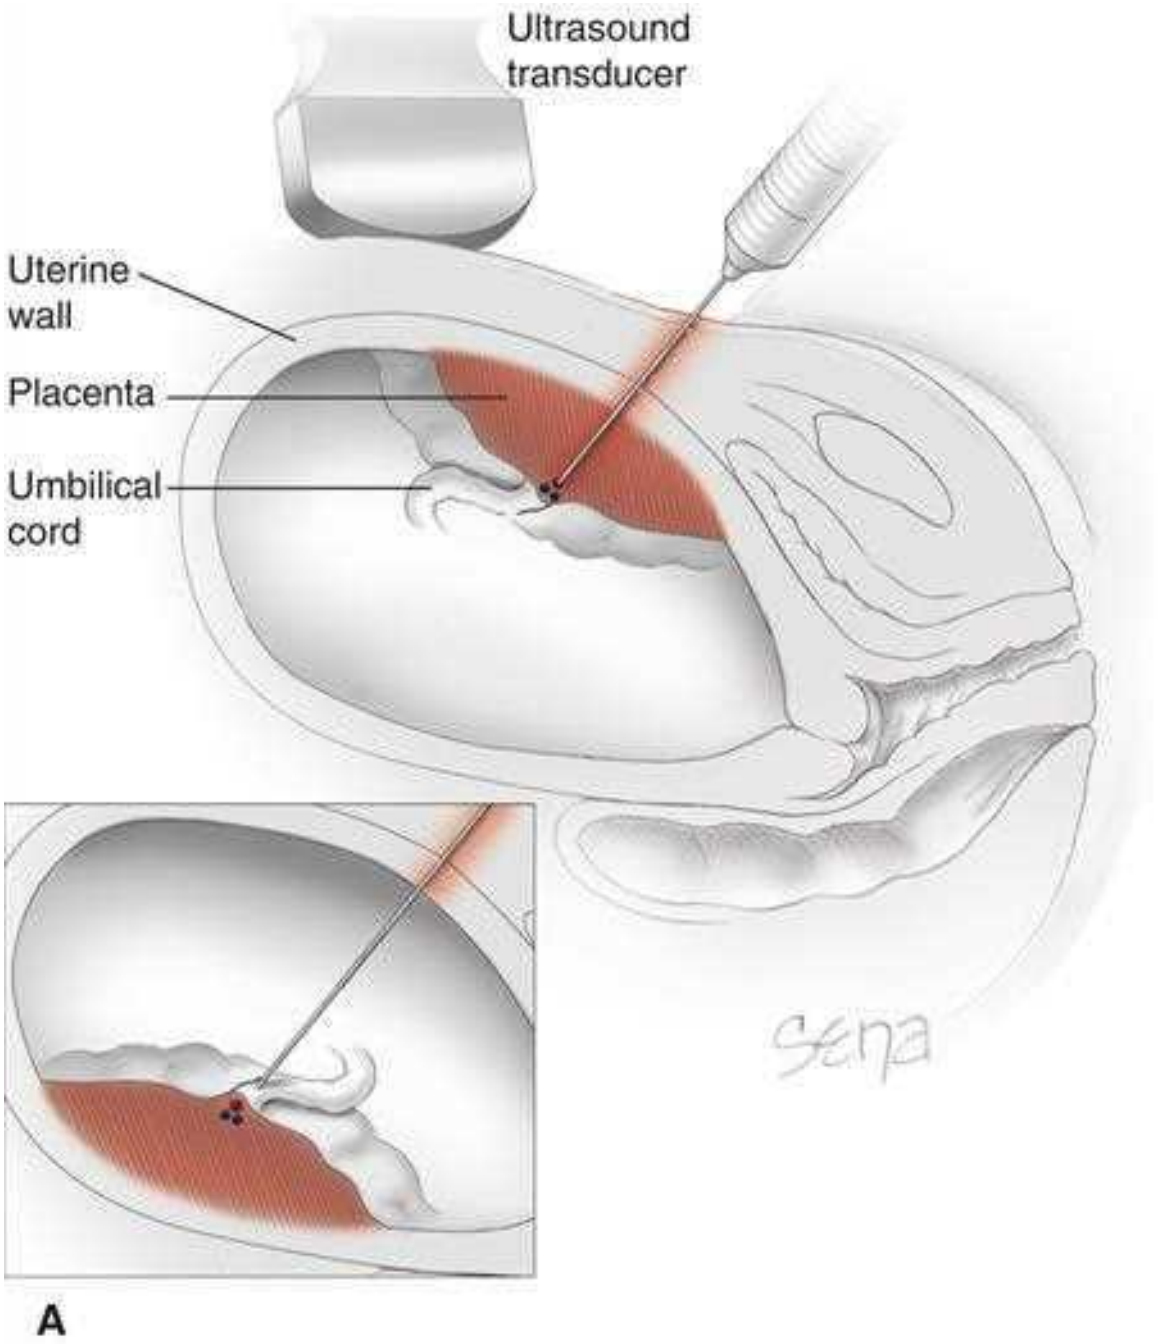
This procedure is also called cordocentesis or percutaneous umbilical blood sampling (PUBS). It was initially described for fetal transfusion of red blood cells in the setting of anemia from alloimmunization, and fetal anemia assessment remains the most common indication (Chap. 16, Surgical Therapy). Fetal blood sampling is also performed for assessment and treatment of platelet alloimmunization and for fetal karyotype determination, particularly in cases of mosaicism identified following amniocentesis or CVS. Fetal blood karyotyping can be accomplished within 24 to 48 hours. Thus, it is significantly quicker than the 7- to 10-day turnaround time with amniocentesis or CVS. Although fetal blood *can* be analyzed for virtually any test performed on neonatal blood, improvements in tests available with amniocentesis and CVS have eliminated the need for fetal venipuncture in most cases (Society for Maternal-Fetal Medicine, 2013).

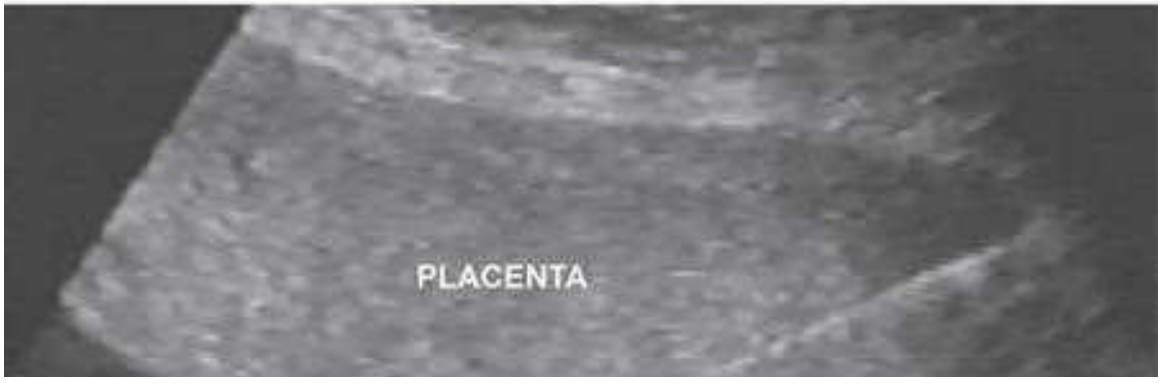
Technique

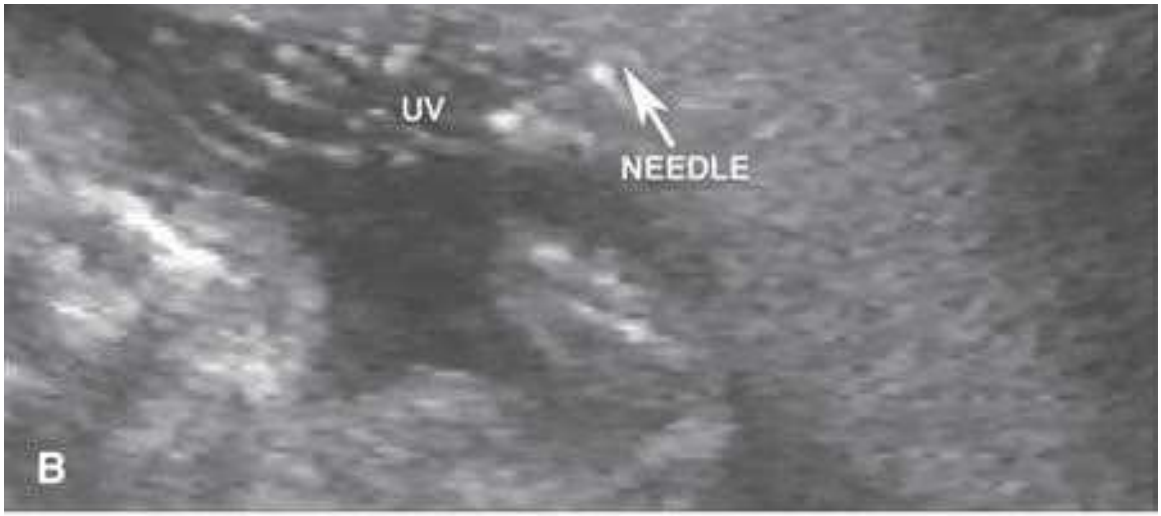
Under direct sonographic guidance, using aseptic technique, the operator introduces a 22- or 23-gauge spinal needle into the umbilical vein, and blood is slowly withdrawn into a heparinized syringe (Fig. 14-7). Adequate visualization of the needle is essential. As with amniocentesis, a longer needle may be required depending on patient habitus. Fetal blood sampling is often performed near the placental cord insertion site, where it may be easier to enter the cord if the placenta lies anteriorly. Alternatively, a free loop of cord may be punctured. Because fetal blood sampling requires more time than other fetal procedures, a local anesthetic may be administered. Prophylactic antibiotics are used at some centers, although no trials support this policy. Arterial puncture is avoided, because it may result in vasospasm and fetal bradycardia. After the needle is removed, fetal cardiac motion is documented, and the site is observed for bleeding.

FIGURE 14-7

Fetal blood sampling. **A.** Access to the umbilical vein varies depending on placental location and cord position. With an anterior placenta, the needle may traverse the placenta. Inset: With posterior placentation, the needle passes through amnionic fluid before penetrating the umbilical vein. Alternatively, a free loop of cord may be accessed. **B.** Sonogram shows an anterior placenta with transplacental needle passage into the umbilical vein (UV). (Reproduced with permission from Mastrobattista JM, Espinoza J: Invasive prenatal diagnostic procedures. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)







Complications

The procedure-related fetal loss rate following fetal blood sampling approximates 1.4 percent (Ghidini, 1993; Tongsong, 2001). The actual loss rate varies according to the procedure indication and the fetal status. Other complications may include cord vessel bleeding in 20 to 30 percent of cases, fetal-maternal bleeding in approximately 40 percent of cases in which the placenta is traversed, and fetal bradycardia in 5 to 10 percent (Boupaijit, 2012; Society for Maternal-Fetal Medicine, 2013). Most complications are transitory, with complete recovery, but some result in fetal loss.

In one series of more than 2000 procedures comparing fetal blood sampling near the placental cord insertion site with puncture of a free loop, rates of procedure success, pregnancy loss, visible bleeding from the cord, and fetal bradycardia did not differ. Time to complete the procedure was significantly shorter if the cord was sampled at the placental insertion site than in a free loop—5 versus 7 minutes. However, sampling at the insertion site had a higher rate of maternal blood contamination (Tangshewinsirikul, 2011).

Preimplantation Genetic Testing

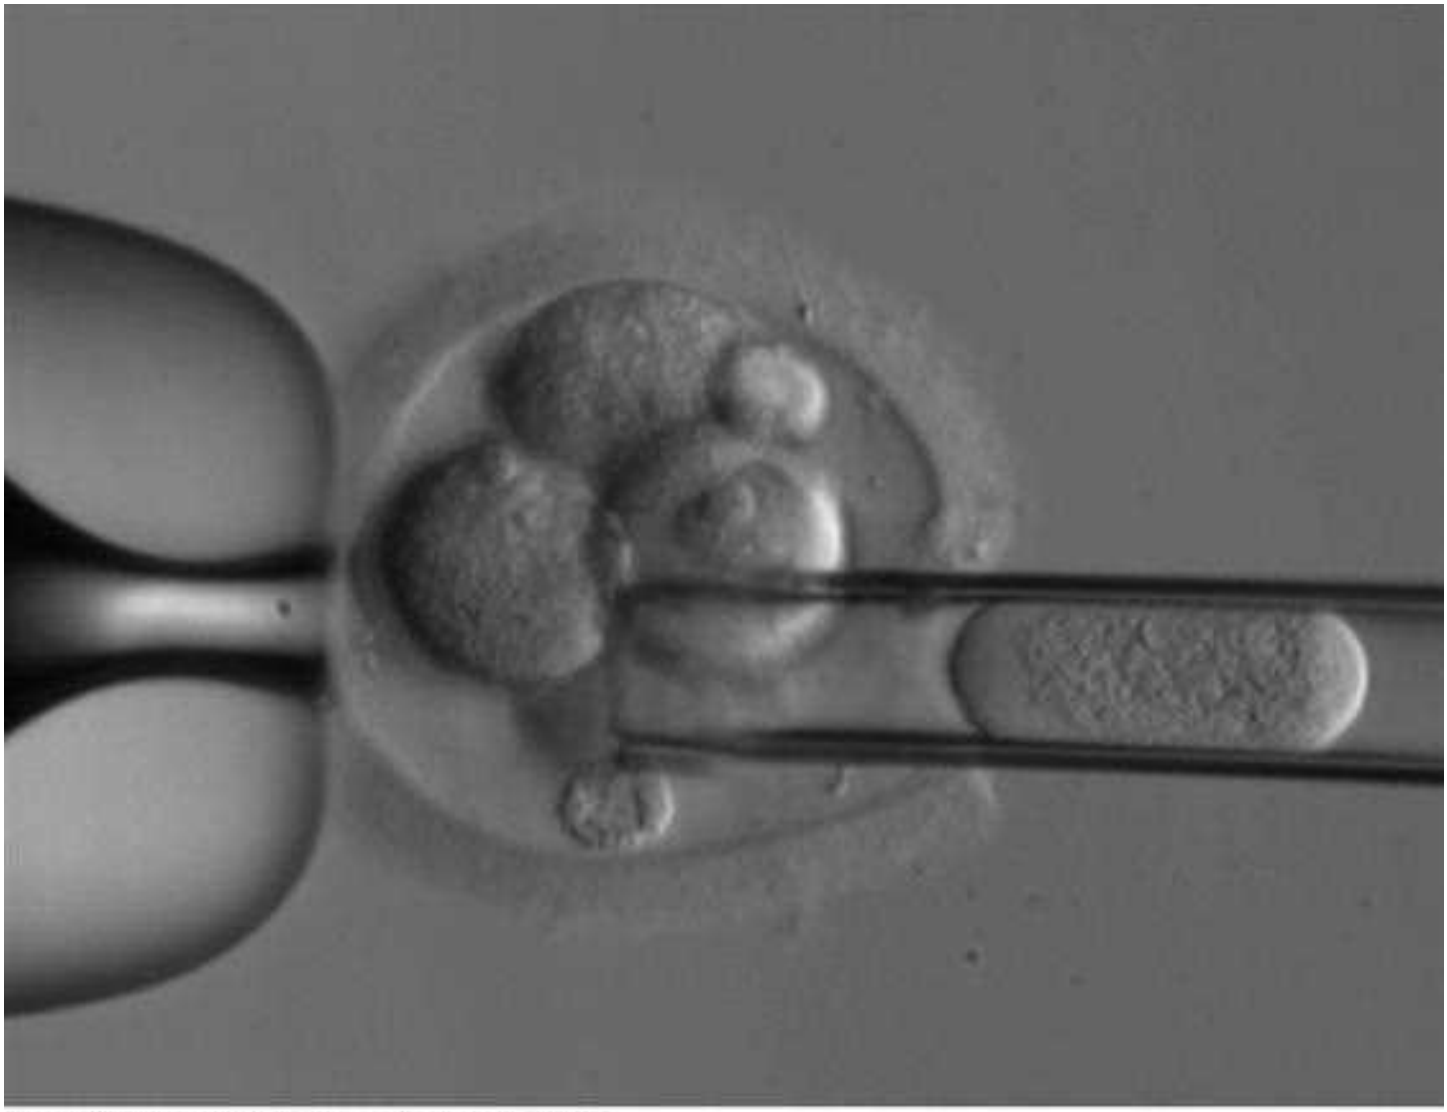
For couples undergoing in vitro fertilization (IVF), genetic testing performed on oocytes or embryos before implantation may provide valuable information regarding the chromosomal complement and single-gene disorders. There are two separate categories of testing—*preimplantation genetic diagnosis (PGD)* and *preimplantation genetic screening (PGS)*—each with different indications. Comprehensive genetic counseling is required before consideration of these procedures. There are three techniques that are used for both categories:

1. *Polar body analysis* is a technique used to infer whether a developing oocyte is affected by a maternally inherited genetic disorder. The first and second polar bodies are normally extruded from the developing oocyte following meiosis I and II, and their sampling should not affect fetal development. However, two separate micromanipulation procedures are required, and genetic abnormalities of paternal origin are not detected. This technique has been used to diagnose 146 mendelian disorders, and the reported accuracy exceeds 99 percent (Kuliev, 2011).

2. *Blastomere biopsy* is done at the 6- to 8-cell (cleavage) stage when an embryo is 3 days old. This allows both maternal and paternal genomes to be evaluated. One cell is typically removed through a hole made in the zona pellucida (Fig. 14-8). A limitation of using this technique for aneuploidy assessment is that because of mitotic nondisjunction, mosaicism of the blastomeres may not reflect the chromosomal complement of the developing embryo (American Society for Reproductive Medicine, 2008). In addition, the implantation rate of normal embryos is slightly lower following this technique.

3. *Trophectoderm biopsy* involves removal of 5 to 7 cells from a 5- to 6-day blastocyst. An advantage is that because the trophectoderm cells give rise to the trophoblast—the placenta—no cells are removed from the developing embryo. Disadvantageously, because the procedure is performed later in development, if genetic analysis cannot be performed rapidly, then cryopreservation and embryo transfer during a later IVF cycle may be required.

FIGURE 14-8
Blastomere biopsy. After a blastomere is selected, it is then drawn into the pipette. (Reproduced with permission from Doody KJ: Treatment of the infertile couple. Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Preimplantation Genetic Diagnosis

A genetic abnormality—rather than infertility—may be a reason for a couple to elect IVF. With a known carrier(s) of a specific genetic disease or a balanced chromosomal rearrangement, PGD may be performed to determine if an oocyte or embryo has the defect. Only embryos without the abnormality would be implanted.

This procedure has numerous applications. It is used to diagnose single-gene disorders such as cystic fibrosis, β-thalassemia, and hemophilia; to determine gender in X-linked diseases; to identify mutations such as *BRCA-1* that do not cause disease but confer significantly greater later cancer risk; and to match human leukocyte antigens for umbilical cord stem cell transplantation for a sibling (de Wert, 2007; Fragouli, 2007; Grewal, 2004; Rund, 2005; Xu, 2004).

Because typically only one or two cells are available for analysis and because rapid completion time is essential, this procedure is technically challenging. Risks include failure to amplify the genetic region of interest, selection of a cell that does not contain a nucleus, and maternal cell contamination. Infrequently, affected embryos thought to be normal are implanted, and unaffected embryos are misdiagnosed as abnormal and discarded. Because of this, the American Society for Reproductive Medicine (2008) encourages further prenatal diagnostic testing—either CVS or amniocentesis—to confirm PGD results.

Preimplantation Genetic Screening

This term is used for aneuploidy screening that is performed on oocytes or embryos before IVF transfer. Such screening is used with couples who are not known to have or carry a genetic abnormality. Although PGS has obvious theoretical advantages, it has faced challenges in practice.

Mosaicism is common in cleavage-stage embryo blastomeres. However, it may not be clinically significant because it often does not reflect the actual embryonic chromosomal complement. In addition, among women 35 years or older, pregnancy rates following PGS with FISH are significantly lower than rates observed following IVF without PGS (Mastenbroek, 2007, 2011). Because the number of chromosome pairs per cell nucleus that can be evaluated with FISH is limited, more recent efforts have focused on the use of chromosomal comprehensive screening with CMA (Dahdouh, 2015).

CHAPTER 15: Fetal Disorders

General dropsy of the foetus is a rare condition in which the foetus and placenta are markedly oedematous. As the result of infiltration with serum the former may attain immense proportions and the latter may be increased to three or four times its normal size. Although a good deal has been written on the subject, no satisfactory explanation of the anomaly has as yet been arrived at.

—J. Whitridge Williams (1903)

INTRODUCTION

Little was written of fetal disorders in the first edition of this textbook. General dropsy described above is today known as *hydrops fetalis* (Hydrops Fetalis). Hydrops is perhaps the quintessential fetal disorder, as it can be a manifestation of severe illness from a wide variety of etiologies. Fetal disorders may be acquired—such as alloimmunization, they may be genetic—congenital adrenal hyperplasia or α4-thalassemia, or they may be sporadic developmental abnormalities—like many structural malformations. In this chapter, fetal anemia and thrombocytopenia as well as immune and nonimmune fetal hydrops are reviewed. Fetal structural malformations are reviewed in Chapter 10, genetic abnormalities in Chapters 13 and 14, and conditions amenable to medical and surgical fetal therapies in Chapter 16. Because congenital infections arise as a result of maternal infection or colonization, they are considered in Chapters 64 and 65.

FETAL ANEMIA

Of the many causes of fetal anemia, one of the most frequent is red cell alloimmunization, which results from transplacental passage of maternal antibodies that destroy fetal red cells. Alloimmunization leads to overproduction of immature fetal and neonatal red cells—*erythroblastosis fetalis*—a condition now referred to as *hemolytic disease of the fetus and newborn (HDFN).*

In addition, several congenital infections are also associated with fetal anemia, particularly parvovirus B19, discussed in Chapter 64 (Respiratory Viruses). In Southeast Asian populations, α4-thalassemia is a common cause of severe anemia and nonimmune hydrops. Fetomaternal hemorrhage occasionally creates severe fetal anemia and is discussed in Fetomaternal Hemorrhage. Rare causes of anemia include red cell production disorders—such as Blackfan-Diamond anemia and Fanconi anemia; red cell enzymopathies—glucose-6-phosphate dehydrogenase deficiency and pyruvate kinase deficiency; red cell structural abnormalities—hereditary spherocytosis and elliptocytosis; and myeloproliferative disorders—leukemias. Anemia may be identified through fetal blood sampling, described in Chapter 14 (Fetal Blood Sampling), or by Doppler evaluation of the fetal middle cerebral artery (MCA) peak systolic velocity, described in Management of the Alloimmunized Pregnancy.

Progressive fetal anemia from any cause leads to heart failure, hydrops fetalis, and ultimately death. Fortunately, the prevalence and the course of this otherwise devastating disorder have been dramatically changed by prevention and treatment. Prevention of D alloimmunization is with *anti-D immune globulin*. Identification and treatment of fetal anemia is with MCA Doppler studies and intrauterine transfusions, respectively. Severely anemic fetuses transfused in utero have survival rates exceeding 90 percent, and even in cases of hydrops fetalis, survival rates approach 80 percent (Lindenberg, 2013; Zwiers, 2017).

Red Cell Alloimmunization

Currently, 33 different blood group systems and 339 red cell antigens are recognized by the International Society of Blood Transfusion (Storry, 2014). Although some of these are immunologically and genetically important, many are so rare as to be of little clinical significance. Any individual who lacks a specific red cell antigen may produce an antibody when exposed to that antigen. Such antibodies can prove harmful to that individual if she receives an incompatible blood transfusion. Accordingly, blood banks routinely screen for erythrocyte antigens. These antibodies may also be harmful to a mother's fetus during pregnancy. As noted, maternal antibodies formed against fetal erythrocyte antigens may cross the placenta to cause fetal red cell lysis and anemia.

Typically, a fetus inherits at least one red cell antigen from the father that is lacking in the mother. Thus, the mother may become sensitized if enough fetal erythrocytes reach her circulation to elicit an immune response. Even so, alloimmunization is uncommon for the following reasons: (1) low prevalence of incompatible red cell antigens; (2) insufficient transplacental passage of fetal antigens or maternal antibodies; (3) maternal-fetal ABO incompatibility, which leads to rapid clearance of fetal erythrocytes before they elicit an immune response; (4) variable antigenicity; and (5) variable maternal immune response to the antigen.

In population-based screening studies, the prevalence of red cell alloimmunization in pregnancy approximates 1 percent (Bollason, 2017; Koelewijn, 2008). Most cases of severe fetal anemia requiring antenatal transfusion are attributable to anti-D, anti-Kell, anti-c, or anti-E alloimmunization (de Haas, 2015).

Alloimmunization Detection

At the first prenatal visit, a blood type and antibody screen are routinely assessed, and unbound antibodies in maternal serum are detected by the *indirect Coombs test* (Chap. 9, Definitions). When the result is positive, the specific antibodies are identified, their immunoglobulin subtype is determined as either immunoglobulin G (IgG) or M (IgM), and the titer is quantified. Only IgG antibodies are a concern because IgM antibodies do not cross the placenta. Selected antibodies and their potential to cause fetal hemolytic anemia are listed in Table 15-1. The critical titer is the level at which significant fetal anemia could potentially develop. This may be

different for each antibody, is determined individually by each laboratory, and usually ranges between 1:8 and 1:32. If the critical titer for anti-D antibodies is 1:16, a titer ≥1:16 indicates the possibility of severe hemolytic disease. An important exception is Kell sensitization, which is discussed in Alloimmunization to Minor Antigens.

TABLE 15-1

Selected Red Cell Antigens and Their Relationship to Fetal Hemolytic Disease

Blood Group System	Antigens	Fetal Hemolysis Potential
CDE (Rh)	D, c	Severe disease risk
	E, Be^a, Ce, Cw, Cx, ce, Dw, Evans, e, G, Goa7, Hr, Hro, JAL, HOFM, LOCR, Riv, Rh29, Rh32, Rh42, Rh46, STEM, Tar	Severe disease infrequent, mild disease risk
Kell	K	Severe disease risk
	k, Kp^a, Kp^b, K11, K22 Ku, Js^a, Js^b, Ula	Severe disease infrequent, mild disease risk
Duffy	Fy^a	Severe disease infrequent, mild disease risk
	Fy^b	Not associated with fetal hemolytic disease
Kidd	Jk^a	Severe disease infrequent, mild disease risk
	Jk^b, Jk^3	Mild disease possible
MNS	M, N, S, s, U, Mt^a, Ena, Far, Hil, Hut, Mi^a, Mit, Mut, Mur, Mv, sD, Vw	Severe disease infrequent, mild disease risk
Colton	Co^a, Co^3	Severe disease infrequent, mild disease risk
Diego	Di^a, Di^b, Wr^a, Wr^b	Severe disease infrequent, mild disease risk
Dombrock	Do^a, Gy^a, Hy, Jo^a	Mild disease possible
Gerbich	Ge^2, Ge^3, Ge^4, Ls^a	Mild disease possible
Scianna	Sc2	Mild disease possible
I	I, i	Not associated with fetal hemolytic disease
Lewis	Le^a, Le^b	Not associated with fetal hemolytic disease

From de Haas, 2015; Moise, 2008; Weinstein, 1982.

CDE (Rh) Blood Group Incompatibility

The CDE system includes five red cell proteins or antigens: C, c, D, E, and e. There is no “d” antigen, and D-negativity is defined as the absence of the D antigen. Although most people are D positive or negative, more than 200 D antigen variants exist (Daniels, 2013). Rh was formerly termed *rhesus* because of a misconception that red cells from rhesus monkeys expressed human blood group antigen. In transfusion medicine, “rhesus” is no longer used (Sandler, 2017).

CDE antigens are clinically important. D-negative individuals may become sensitized after a single exposure to as little as 0.1 mL of fetal erythrocytes (Bowman, 1988). The two responsible genes—*RHD* and *RHCE*—are located on the short arm of chromosome 1 and are inherited together, independent of other blood group genes. The incidence of antigen positivity varies according to racial and ethnic origin. Nearly 85 percent of non-Hispanic white Americans are D-positive. The

incidence approximates 90 percent for Native Americans, 93 percent for African Americans and Hispanic Americans, and at least 99 percent for Asian individuals (Garratty, 2004).

The prevalence of D alloimmunization complicating pregnancy ranges from 0.5 to 0.9 percent (Koelewijn, 2008; Martin, 2005). Without anti-D immune globulin prophylaxis, a D-negative woman delivered of a D-positive, *ABO-compatible* newborn has a 16-percent likelihood of developing alloimmunization. Two percent will become sensitized by the time of delivery, 7 percent by 6 months postpartum, and the remaining 7 percent will be "sensibilized"—producing detectable antibodies only in a subsequent pregnancy (Bowman, 1985). If there is *ABO incompatibility*, the D alloimmunization risk approximates 2 percent without prophylaxis (Bowman, 2006). The reason for the differing rates relative to ABO blood type results from erythrocyte destruction of ABO-incompatible cells, which thereby limits sensitizing opportunities. D sensitization also may occur following first-trimester pregnancy complications, prenatal diagnostic procedures, and maternal trauma (Table 15-2).

TABLE 15-2

Causes of Fetomaternal Hemorrhage Associated with Red Cell Antigen Alloimmunization[a]

Pregnancy Loss
Ectopic pregnancy
Spontaneous abortion
Elective abortion
Fetal death (any trimester)
Procedures
Chorionic villus sampling
Amniocentesis
Fetal blood sampling
Evacuation of molar pregnancy
Other
Delivery
Abdominal trauma
Placental abruption
Unexplained vaginal bleeding during pregnancy
Manual placental removal
External cephalic version

[a]For each of the above, anti-D immune globulin is recommended.

Expanded from American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017; American College of Obstetricians and Gynecologists, 2017.

The C, c, E, and e antigens have lower immunogenicity than the D antigen but can cause hemolytic disease. Sensitization to E, c, and C antigens complicates approximately 0.3 percent of pregnancies in screening studies and accounts for about 30 percent of red cell alloimmunization cases (Howard, 1998; Koelewijn, 2008). Anti-E alloimmunization is the most common, but the need for fetal or neonatal transfusions is greater with anti-c alloimmunization than with anti-E or anti-C (de Haas, 2015; Hackney, 2004; Koelewijn, 2008).

The Grandmother Effect

In virtually all pregnancies, small amounts of maternal blood enter the fetal circulation. Real-time polymerase chain reaction (PCR) has been used to identify maternal D-positive DNA in peripheral blood from preterm and full-term D-negative newborns (Lazar, 2006). Thus, it is possible for a D-negative female fetus exposed to maternal D-positive red cells to develop sensitization. When such an individual reaches adulthood, she may produce anti-D antibodies even before or early in her first pregnancy. This mechanism is called the *grandmother effect or theory* because the fetus in the current pregnancy is jeopardized by maternal antibodies that were initially provoked by his or her *grandmother's* erythrocytes.

Alloimmunization to Minor Antigens

Because routine administration of anti-D immunoglobulin prevents anti-D alloimmunization, proportionately more cases of hemolytic disease are caused by red cell antigens other than D (American College of Obstetricians and Gynecologists, 2016; Koelewijn, 2008). These are also known as minor antigens. Kell antigens are among the most frequent. Other antigens with potential to cause severe alloimmunization include Duffy group A—Fy^a, MNS, and Kidd—Jk^a (de Hass, 2015; Moise, 2008). Most cases of sensitization to minor antigens result from incompatible blood transfusions. However, if an IgG red cell antibody is detected and there is any doubt as to its significance, the clinician should err on the side of caution, and the pregnancy should be evaluated for hemolytic disease.

Only a few blood group antigens pose *no* fetal risk. Lewis antibodies—Le^a and Le^b, as well as I antibodies, are cold agglutinins. They are predominantly IgM and are not expressed on fetal red cells (American College of Obstetricians and Gynecologists, 2016). Another antibody that does not cause fetal hemolysis is Duffy group B—Fy^b.

Kell Alloimmunization

Approximately 90 percent of non-Hispanic white Americans and up to 98 percent of African Americans are Kell negative. Kell type is not routinely determined. Transfusion history is important, as nearly 90 percent of Kell sensitization cases result from transfusion with Kell-positive blood.

Kell sensitization may develop more rapidly and may be more severe than with sensitization to D and other blood group antigens. This is because Kell antibodies attach to erythrocyte precursors in the fetal bone marrow, thereby impairing the normal hemopoietic response to anemia. With fewer erythrocytes produced, there is less hemolysis, and severe anemia may not be predicted by the maternal Kell antibody titer. One option is to use a lower critical titer—1:8—for Kell sensitization (Moise, 2012). The American College of Obstetricians and Gynecologists (2016) has recommended that antibody titers not be used to monitor Kell-sensitized pregnancies.

ABO Blood Group Incompatibility

Incompatibility for the major blood group antigens A and B is the most common cause of hemolytic disease in newborns, but it does not cause appreciable hemolysis in the fetus. Approximately 20 percent of newborns have ABO blood group incompatibility, yet only 5 percent are affected clinically. And in such cases, the resulting anemia is typically mild.

The condition differs from CDE incompatibility in several respects. First, ABO incompatibility is often seen in firstborn neonates, whereas sensitization to other blood group antigens is not. This is because most group O women have developed anti-A and anti-B isoagglutinins before pregnancy from exposure to bacteria displaying similar antigens. Second, ABO alloimmunization rarely becomes more severe in successive pregnancies. Last, ABO incompatibility is considered a pediatric disease—rarely of obstetrical concern. This is because most anti-A and anti-B antibodies are IgM and do not cross the placenta. Fetal red cells also have fewer A and B antigenic sites than adult cells and are thus less immunogenic.

Consequently, fetal surveillance and early delivery are not indicated in pregnancies with prior ABO incompatibility. Careful neonatal observation is essential, however, because hyperbilirubinemia may require treatment with phototherapy or occasionally transfusion (Chap. 33, Polycythemia and Hyperviscosity).

Management of the Alloimmunized Pregnancy

An estimated 25 to 30 percent of fetuses from D-alloimmunized pregnancies will have mild-to-moderate hemolytic anemia. And without treatment, up to 25 percent will develop hydrops (Tannirandorn, 1990). If alloimmunization is detected and the titer is below the critical value, the titer is generally repeated every 4 weeks for the duration of the pregnancy (American College of Obstetricians and Gynecologists, 2016). Importantly, if a prior pregnancy was complicated by alloimmunization, serial titer assessment is not indicated, and the pregnancy is assumed to be at risk regardless of titer. Management of such pregnancies is discussed subsequently. In any pregnancy in which an antibody titer has reached a critical value, there is no benefit to repeating it. The pregnancy is at risk even if the titer drops, and further evaluation is still required.

Determining Fetal Risk

Up to 40 percent of D-negative pregnant women carry a D-negative fetus. The presence of anti-D antibodies reflects maternal sensitization but does not indicate whether the fetus is D-positive. If a woman became sensitized in a prior pregnancy, her antibody titer might rise to high levels during the current pregnancy even if the current fetus is D-negative, due to an *amnestic response.* In a non-Hispanic white couple in which the woman is D-negative, there is an 85-percent chance that the man is D-positive. But, in 60 percent of these cases, he will be heterozygous at the D-locus. And, if he is heterozygous, then half of his children will be at risk for hemolytic disease. Transfusion history is relevant. Alloimmunization to a red cell antigen other than D may have occurred following a blood transfusion in the past, and if that antigen is not present on paternal erythrocytes, the pregnancy is not at risk.

Initial evaluation of alloimmunization begins with determining the paternal erythrocyte antigen status. *Provided that paternity is certain*, if the father is negative for the red cell antigen to which the mother is sensitized, the pregnancy is not at risk. In a D-alloimmunized pregnancy in which the father is D-positive, it is helpful to determine paternal zygosity for the D antigen using DNA-based analysis. If the father is heterozygous—or if paternity is not known—the woman should be offered assessment of fetal genotype. Traditionally, this was done with amniocentesis and PCR testing of uncultured amniocytes, which has a positive-predictive value of 100 percent and negative-predictive value of approximately 97 percent (American College of Obstetricians and Gynecologists, 2016; Van den Veyver, 1996). Fetal testing for other antigens—such as E/e, C/c, Duffy, Kell, Kidd, and M/N—is also available with this method. Chorionic villus sampling is not recommended because of greater risk for fetomaternal hemorrhage and subsequent worsening of alloimmunization.

Noninvasive fetal D genotyping has been performed using cell-free DNA (cfDNA) from maternal plasma (Chap. 13, Fetal DNA in the Maternal Circulation). The reported sensitivity exceeds 99 percent, the specificity exceeds 95 percent, and positive- or negative-predictive values are similarly very high (de Haas, 2016; Johnson, 2017; Moise, 2016; Vivanti, 2016). Fetal D genotyping with cfDNA is routinely used in parts of Europe. There are two potential indications in D-negative pregnant women: (1) in women *with* D alloimmunization, testing can identify fetuses that are also D-negative and do not require anemia surveillance, and (2) in women *without* D alloimmunization, anti-D immune globulin might be withheld if the fetus is D negative. In the case of the latter, the American College of Obstetricians and Gynecologists (2017) does not recommend routine cfDNA screening in D-negative pregnancies until it becomes cost-effective.

Management of the alloimmunized pregnancy is individualized and may consist of maternal antibody titer surveillance, sonographic monitoring of the fetal MCA peak systolic velocity, amnionic fluid bilirubin studies, or fetal blood sampling. Accurate pregnancy dating is critical. The gestational age at which fetal anemia developed in prior pregnancies is important because anemia tends to occur earlier and be sequentially more severe.

Middle Cerebral Artery Doppler Velocimetry

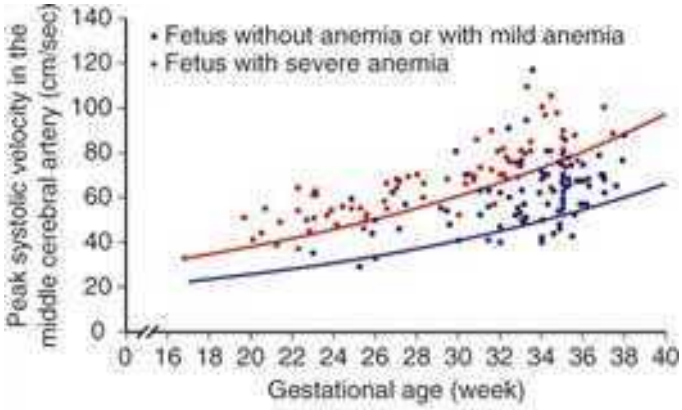
Serial measurement of the peak systolic velocity of the fetal MCA is the recommended test for detection of fetal anemia (Society for Maternal–Fetal Medicine, 2015a). The anemic fetus shunts blood preferentially to the brain to maintain adequate oxygenation. The velocity rises because of increased cardiac output and decreased

blood viscosity. The technique is discussed in Chapter 10 (Ductus Arteriosus) and requires training and experience (American College of Obstetricians and Gynecologists, 2016).

In a landmark study, Mari and coworkers (2000) measured the MCA peak systolic velocity serially in 111 fetuses at risk for anemia and in 265 normal control fetuses. The threshold value of 1.5 multiples of the median (MoM) for gestational age correctly identified all fetuses with moderate or severe anemia. This provided a sensitivity of 100 percent, with a false-positive rate of 12 percent.

The MCA peak systolic velocity is followed serially, and values are plotted on a curve like the one shown in Figure 15-1. If the velocity is between 1.0 and 1.5 MoM and the slope is rising—such that the value is approaching 1.5 MoM—surveillance is generally increased to weekly Doppler interrogation. If the MCA peak systolic velocity exceeds 1.5 MoM and the gestational age is younger than 34 or 35 weeks, fetal blood sampling should be considered and followed by fetal transfusion if needed (Society for Maternal–Fetal Medicine, 2015a). The false-positive rate of MCA peak systolic velocity increases significantly beyond 34 weeks, due to the normal augmentation in cardiac output that develops at this gestational age (Moise, 2008; Zimmerman, 2002).

FIGURE 15-1
Doppler measurements of the peak systolic velocity in the middle cerebral artery (MCA) in 165 fetuses at risk for severe anemia. The blue line indicates the median peak systolic velocity in normal pregnancies, and the red line shows 1.5 multiples of the median. (Reproduced with permission from Oepkes D, Seaward PG, Vandenbussche et al: Doppler ultrasonography versus amniocentesis to predict fetal anemia, N Engl J Med. 2006 Jul 13;355(2):156–164.)



Amniotic Fluid Spectral Analysis

This test is included for historical interest. More than 50 years ago, Liley (1961) demonstrated the utility of amnionic fluid spectral analysis to measure bilirubin concentration and to thereby estimate hemolysis severity. Amnionic fluid bilirubin concentration was measured by a spectrophotometer and was represented as the change in optical density absorbance at 450 nm—ΔOD_{450}. The likelihood of fetal anemia was determined by plotting the ΔOD_{450} value on a graph that was divided into zones. These zones roughly correlated with fetal hemoglobin concentration, and thus with anemia severity. The original Liley graph was valid from 27 to 42 weeks' gestation and was subsequently modified by Queenan (1993) to include gestational ages as early as 14 weeks. However, the amnionic fluid bilirubin level is normally high in midpregnancy, limiting the reliability of this technique.

Middle cerebral artery velocimetry is more accurate than ΔOD_{450} assessment and does not confer risks for increased alloimmunization associated with amniocentesis. It has replaced ΔOD_{450} assessment for this purpose.

Fetal Blood Transfusion

If there is evidence of severe fetal anemia, because of either elevated MCA peak systolic velocity or development of fetal hydrops, management is strongly influenced by gestational age. Fetal blood sampling and intrauterine transfusion are generally performed prior to 34 to 35 weeks (Society for Maternal-Fetal Medicine, 2015a). Intravascular transfusion into the umbilical vein under sonographic guidance is the preferred method of fetal transfusion. Transfusion into the fetal peritoneal cavity may be necessary with severe, early-onset hemolytic disease in the early second trimester, a time when the umbilical vein is too narrow to readily permit needle entry. With hydrops, although peritoneal absorption is impaired, some prefer to transfuse into both the fetal peritoneal cavity and the umbilical vein.

Transfusion is generally recommended only if the fetal hematocrit is <30 percent (Society for Maternal-Fetal Medicine, 2015a). Once hydrops has developed, the hematocrit is generally 15 percent or lower. The red cells transfused are type O, D-negative, cytomegalovirus-negative, packed to a hematocrit of approximately 80 percent to prevent volume overload, irradiated to prevent fetal graft-versus-host reaction, and leukocyte-poor. The fetal–placental volume allows rapid infusion of a relatively large quantity of blood. Before transfusion, a paralytic agent such as vecuronium may be given to the fetus to minimize movement. In a nonhydropic fetus, the target hematocrit is generally 40 to 50 percent. The volume transfused may be estimated by multiplying the estimated fetal weight in grams by 0.02 for each 10-percent rise in hematocrit needed (Giannina, 1998). In the severely anemic fetus at 18 to 24 weeks' gestation, less blood is transfused initially, and another transfusion may be planned for approximately 2 days later. Subsequent transfusions usually take place every 2 to 4 weeks, depending on the hematocrit.

The MCA peak systolic velocity threshold for severe anemia is higher following an initial transfusion—1.70 MoM rather than 1.50 MoM (Society for Maternal-Fetal Medicine, 2015a). It is hypothesized that the change in threshold compensates for the contribution of donor cells in the initial transfusion, because donor cells (from adults) have a smaller mean corpuscular volume. Alternately, the timing of subsequent transfusions is based on anemia severity and posttransfusion hematocrit.

Following transfusion, the fetal hematocrit generally drops by approximately 1 percent per day. A more rapid initial decline may be encountered in the setting of fetal hydrops.

Outcomes

Procedure-related complications have declined significantly at experienced centers in recent years, with overall survival rates exceeding 95 percent (Zwiers, 2017). Complications include fetal death in approximately 2 percent, need for emergent cesarean delivery in 1 percent, and infection and preterm rupture of membranes in 0.3 percent each, respectively. The stillbirth rate exceeds 15 percent if transfusion is required before 20 weeks (Lindenberg, 2013; Zwiers, 2017). Considering that fetal transfusion is potentially lifesaving in severely compromised fetuses, these risks should not dissuade therapy.

Van Kamp (2001) reported that if hydrops had developed, the survival rate approached 75 to 80 percent. However, of the nearly two thirds with resolution of hydrops following transfusion, more than 95 percent survived. The survival rate was <40 percent if hydrops persisted.

Lindenberg (2012) reviewed long-term outcomes following intrauterine transfusion in a cohort of more than 450 alloimmunized pregnancies. Alloimmunization was secondary to anti-D in 80 percent, anti-Kell in 12 percent, and anti-c in 5 percent. Approximately a fourth of affected fetuses had hydrops, and more than half also required exchange transfusion in the neonatal period. Among nearly 300 children aged 2 to 17 years who participated in neurodevelopmental testing, fewer than 5 percent had severe impairments. These included severe developmental delay in 3 percent, cerebral palsy in 2 percent, and deafness in 1 percent.

Prevention of Anti-D Alloimmunization

Anti-D immune globulin is one of the success stories of modern obstetrics. It has been used for nearly five decades to prevent D alloimmunization. In countries without access to anti-D immune globulin, up to 10 percent of D-negative pregnancies are complicated by hemolytic disease of the fetus and newborn (Zipursky, 2015). With immunoprophylaxis, however, the alloimmunization risk is reduced to <0.2 percent. Despite long-standing and widespread use, its mechanism of action is not completely understood.

As many as 90 percent of alloimmunization cases occur from fetomaternal hemorrhage at delivery. Routine postpartum administration of anti-D immune globulin to at-risk pregnancies within 72 hours of delivery lowers the alloimmunization rate by 90 percent (Bowman, 1985). Additionally, provision of anti-D immune globulin at 28 weeks' gestation reduces the third-trimester alloimmunization rate from approximately 2 percent to 0.1 percent (Bowman, 1988). *Whenever there is doubt whether to give anti–D immunoglobulin, it should be given.* If not needed, it will not cause harm, but failure to provide it when needed can have severe consequences.

Current preparations of anti-D immune globulin are derived from human plasma donated by individuals with high-titer anti-D immunoglobulin D antibodies. Formulations prepared by cold ethanol fractionation and ultrafiltration must be administered intramuscularly because they contain plasma proteins that could result in anaphylaxis if given intravenously. However, formulations prepared using ion exchange chromatography may be administered either intramuscularly or intravenously. This is important for treatment of significant fetomaternal hemorrhage, which is discussed subsequently. Both preparation methods effectively remove viral particles, including hepatitis and human immunodeficiency viruses. Depending on the preparation, the half-life of anti-D immune globulin ranges from 16 to 24 days, which is why it is given both in the third trimester and following delivery. The standard intramuscular dose of anti-D immune globulin—300 µg or 1500 IU—will protect the average-sized mother from a fetal hemorrhage of up to 30 mL of fetal whole blood or 15 mL of fetal red cells.

In the United States, anti-D immune globulin is given prophylactically to all D-negative, unsensitized women at approximately 28 weeks' gestation, and a second dose is given after delivery if the newborn is D-positive (American College of Obstetricians and Gynecologists, 2017). Before the 28-week dose of anti-D immune globulin, repeat antibody screening is recommended to identify individuals who have become alloimmunized (American Academy of Pediatrics, 2017). Following delivery, anti-D immune globulin should be given within 72 hours. Recognizing that 40 percent of neonates born to D-negative women are also D negative, administration of immune globulin is recommended only after the newborn is confirmed to be D positive (American College of Obstetricians and Gynecologists, 2017). If immune globulin is inadvertently not administered following delivery, it should be given as soon as the omission is recognized, because there may be some protection up to 28 days postpartum (Bowman, 2006). Anti-D immune globulin is also administered after pregnancy-related events that could result in fetomaternal hemorrhage (see Table 15-2).

Anti-D immune globulin may produce a weakly positive—1:1 to 1:4—indirect Coombs titer in the mother. This is harmless and should not be confused with development of alloimmunization. Additionally, as the body mass index increases above 27 to 40 kg/m^2, serum antibody levels decrease by 30 to 60 percent and may be less protective (MacKenzie, 2006; Woelfer, 2004). D-negative women who receive other types of blood products—including platelet transfusions and plasmapheresis—are also at risk of becoming sensitized, and this can be prevented with anti-D immune globulin. Rarely, a small amount of antibody crosses the placenta and results in a weakly positive direct Coombs test in cord and infant blood. Despite this, passive immunization does not cause significant fetal or neonatal hemolysis.

It is estimated that in 2 to 3 per 1000 pregnancies, the volume of fetomaternal hemorrhage exceeds 30 mL of whole blood (American College of Obstetricians and Gynecologists, 2017). A single dose of anti-D immune globulin would be insufficient in such situations. If additional anti-D immune globulin is considered only for women with risk factors such as those shown in Table 15-2, then *half* of those who require additional immune globulin may be missed. For this reason, all D-negative women should be screened at delivery, typically with a rosette test, followed by quantitative testing if indicated (American College of Obstetricians and Gynecologists, 2017).

The rosette test is a qualitative test that identifies whether fetal D-positive cells are present in the circulation of a D-negative woman. A sample of maternal blood is mixed with anti-D antibodies that coat any D-positive fetal cells present in the sample. Indicator red cells bearing the D-antigen are then added, and rosettes form around the fetal cells as the indicator cells attach to them by the antibodies. Thus, if rosettes are visualized, there are fetal D-positive cells in that sample. In the

setting of D incompatibility, or any time a large fetomaternal hemorrhage is suspected—regardless of antigen status, a Kleihauer-Betke test or flow cytometry test are used. These are discussed in Fetal Thrombocytopenia.

The dosage of anti-D immune globulin is calculated from the estimated volume of the fetal-to-maternal hemorrhage, as described in Fetal Thrombocytopenia. One 300-µg dose is given for each 15 mL of fetal red cells or 30 mL of fetal whole blood to be neutralized. If using an intramuscular preparation of anti-D immune globulin, no more than five doses may be given in a 24-hour period. If using an intravenous preparation, two ampules—totaling 600 µg—may be given every 8 hours. To determine if the administered dose was adequate, the indirect Coombs test may be performed. A positive result indicates that there is excess anti–D immunoglobulin in maternal serum, thus demonstrating that the dose was sufficient. Alternatively, a rosette test may be performed to assess whether circulating fetal cells remain.

Serological Weak D Phenotypes

Formerly called D^u, these are the most common antigenic D variants in the United States and Europe. Serological weak D phenotypes have been further refined into two general categories using molecular analysis—RHD genotyping. Molecular weak D phenotypes carry reduced numbers of intact D antigens on the red cell surface. Those designated partial D types have protein deletions associated with abnormal D antigens that lack epitopes (Sandler, 2017). When this distinction is known, it can have clinical consequences in terms of sensitization risk and need for anti-D immune globulin.

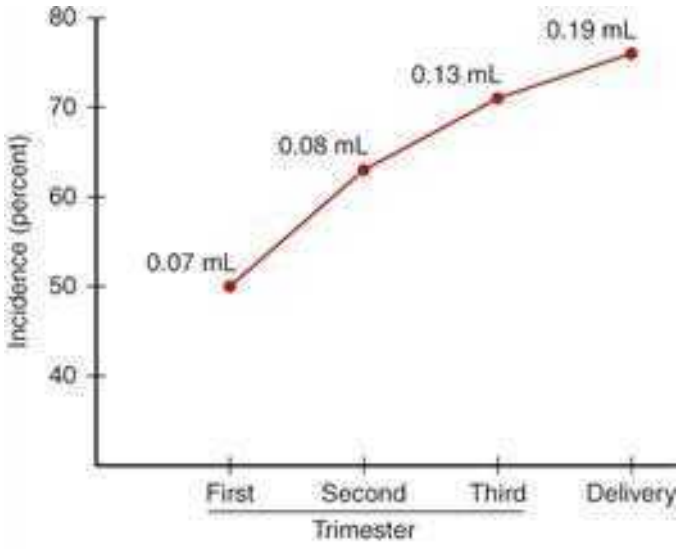
Traditionally, serological weak D individuals have been considered to be D-positive or -negative depending on the clinical situation. For the purposes of blood donation, they are categorized as D-positive, whereas transfusion recipients with weak D are considered D-negative. In pregnancy, weak D has also been considered D-negative, so that individuals receive immune globulin and avoid potential sensitization (American College of Obstetricians and Gynecologists, 2017; Sandler, 2015).

Many non-Hispanic white Americans who test positive for weak D have weak D phenotypes 1, 2, or 3. Individuals with these phenotypes may be managed as though they are D-positive. Because they are not at risk for alloimmunization, anti-D immune globulin is not needed (Sandler 2015, 2017). In contrast, individuals with partial D antigens may be at risk for D-sensitization and do require immune globulin. Molecular RHD genotyping has been suggested for pregnant women with weak D phenotype, but cost-benefit analysis of this strategy is presently lacking (American College of Obstetricians and Gynecologists, 2017). *If molecular genetic testing has not been performed in those with serologic weak D phenotype, D immunoprophylaxis should be administered to those with weak D phenotype.*

FETOMATERNAL HEMORRHAGE

A small amount of fetomaternal bleeding likely occurs in all pregnancies, and in two thirds, this may be sufficient to provoke an antigen-antibody reaction. As shown in Figure 15-2, the incidence increases with advancing gestation and the volume of fetal blood in the maternal circulation. Fortunately, a large blood loss—true fetomaternal hemorrhage—is rare. In one series of more than 30,000 pregnancies, fetomaternal hemorrhage ≥150 mL occurred in 1 per 2800 births (de Almeida, 1994). The prevalence of fetomaternal hemorrhage of at least 30 mL—the volume of fetal blood covered by a standard 300-µg dose of anti-D immune globulin—is estimated to be 3 per 1000 pregnancies (Wylie, 2010).

FIGURE 15-2
Incidence of fetal-to-maternal hemorrhage during pregnancy. The numbers at each data point represent total volume of fetal blood estimated to have been transferred into the maternal circulation. (Data from Choavaratana, 1997.)



Selected causes of fetomaternal hemorrhage are shown in Table 15-2. It also may occur with placenta previa, placental chorioangioma, or vasa previa (Giacoia 1997; Rubod, 2007). In each of these circumstances, however, fetomaternal hemorrhage is extremely uncommon if not rare. And, in more than 80 percent of cases, no cause is identified. With significant hemorrhage, the most common presenting complaint is decreased fetal movement (Bellussi, 2017; Wylie, 2010). A sinusoidal fetal heart rate pattern is infrequently seen but warrants immediate evaluation (Chap. 24, Periodic Fetal Heart Rate Changes). Sonography may demonstrate elevated MCA peak systolic velocity, and indeed this is reported to be the most accurate predictor (Bellusi, 2017; Wylie, 2010). Hydrops is an ominous finding. If fetomaternal hemorrhage is suspected, an elevated MCA peak systolic velocity or sonographic evidence of hydrops prompts consideration of urgent fetal transfusion or delivery.

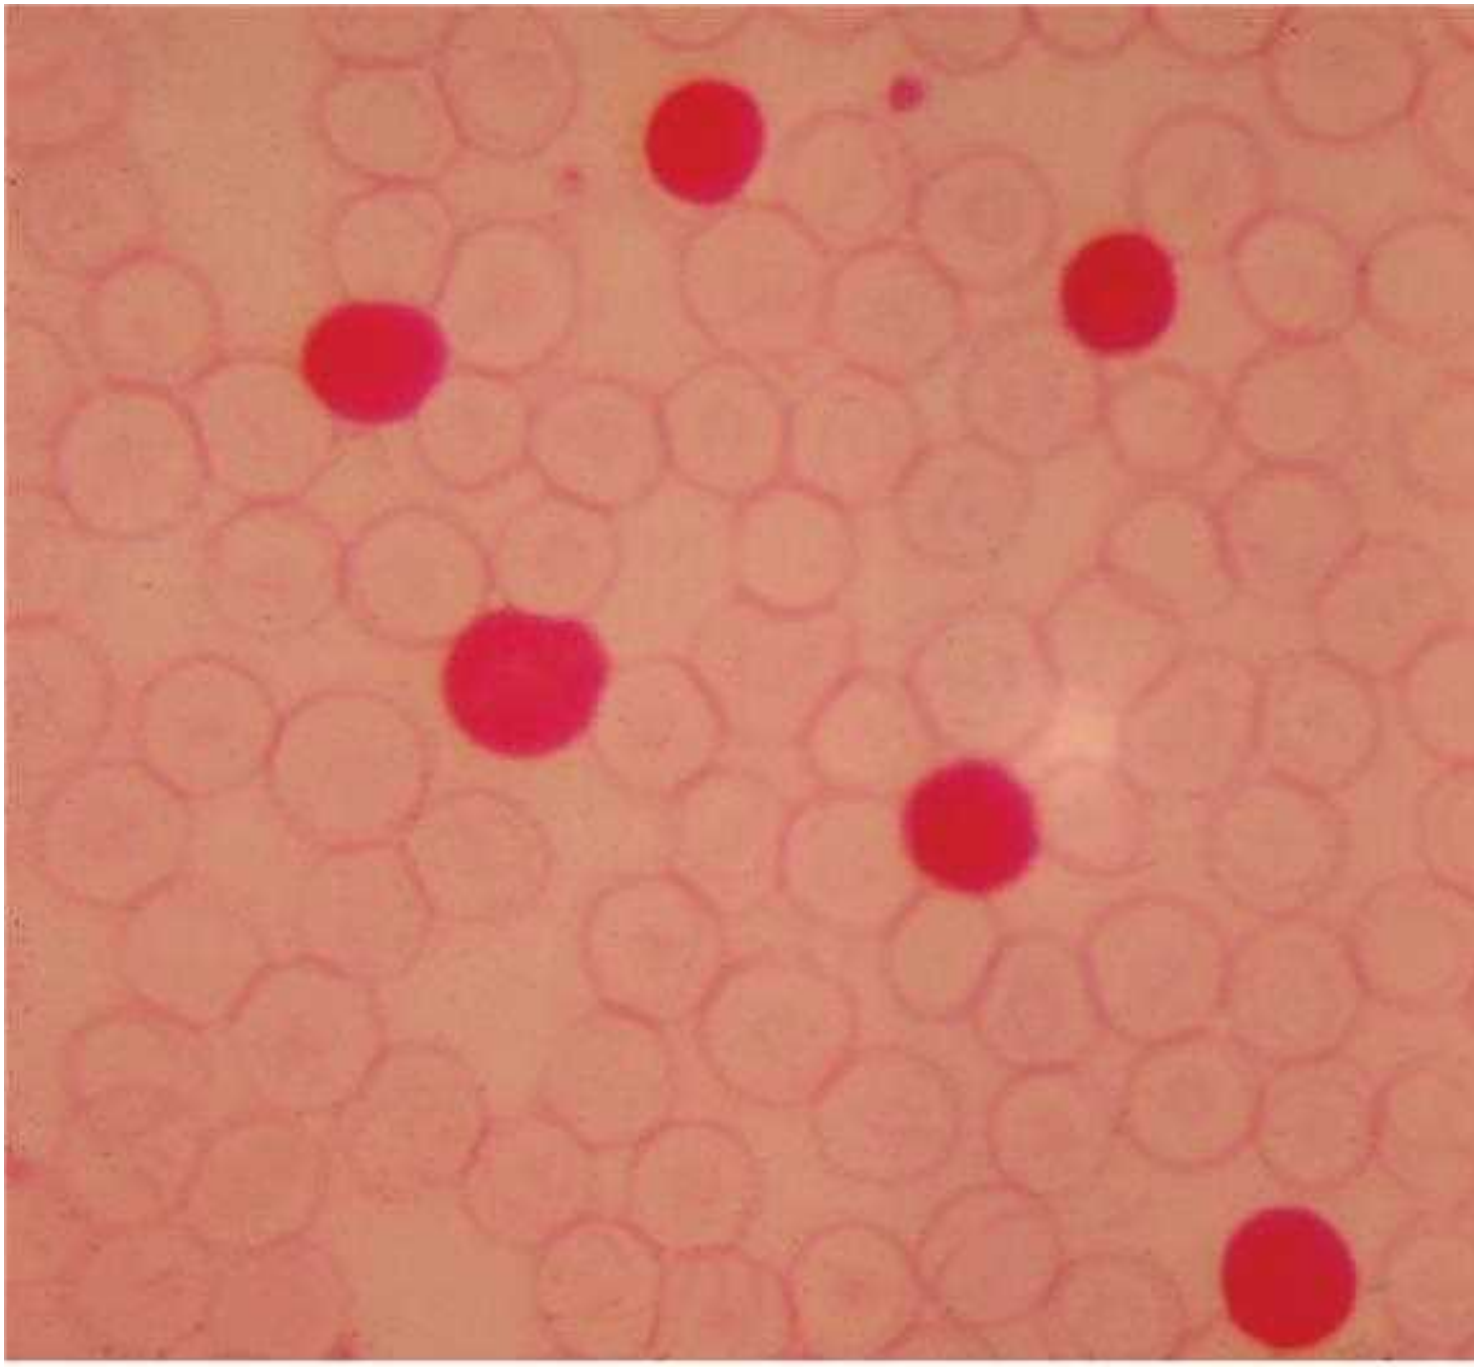
One limitation of quantitative tests for fetal cells in the maternal circulation is that they do not provide information regarding hemorrhage timing or chronicity (Wylie, 2010). In general, anemia developing gradually or chronically, as in alloimmunization, is better tolerated by the fetus than acute anemia. Chronic anemia may not produce fetal heart rate abnormalities until the fetus is moribund. In contrast, significant acute hemorrhage is poorly tolerated by the fetus and may cause profound fetal neurological impairment from cerebral hypoperfusion, ischemia, and infarction. In some cases, fetomaternal hemorrhage is identified during stillbirth evaluation (Chap. 35, Risk Factors).

Laboratory Tests

Once fetomaternal hemorrhage is recognized, the volume of fetal blood loss should be estimated. The volume is essential to calculate the appropriate dose of anti D-immune globulin if the woman is D-negative, and it may influence obstetrical management.

The most commonly used quantitative test for fetal red cells in the maternal circulation is the acid elution or *Kleihauer-Betke (KB) test* (Kleihauer, 1957). Fetal erythrocytes contain hemoglobin F, which is more resistant to acid elution than hemoglobin A. After exposure to acid, only fetal hemoglobin remains, such that after staining, the fetal erythrocytes appear red and adult erythrocytes appear as “ghosts” (Fig. 15-3). The fetal cells are then counted and expressed as a percentage of adult cells. The KB test is labor intensive. Importantly, there are two scenarios in which it may not be accurate: (1) maternal hemoglobinopathies such as β-thalassemia in which the fetal hemoglobin level is elevated and (2) pregnancies at or near term, when the fetus has already started to produce hemoglobin A.

FIGURE 15-3
Kleihauer-Betke test demonstrating massive fetal-to-maternal hemorrhage. After acid-elution treatment, fetal red cells rich in hemoglobin F stain darkly, whereas maternal red cells with only very small amounts of hemoglobin F stain lightly.



Hemorrhage Quantification

The volume of fetomaternal hemorrhage is calculated from the KB test result using the following formula:

$$\text{Fetal blood volume} = \frac{\text{MBV} \times \text{maternal Hct} \times \text{\% fetal cells in KB}}{\text{newborn Hct}}$$

One method is to estimate the maternal blood volume (MBV) as 5000 mL for a normal-size, normotensive women at term. Thus, for 1.7-percent positive KB-stained cells in a woman of average size with a hematocrit of 35 percent and whose fetus has a hematocrit of 50 percent:

$$\text{Fetal blood volume} = \frac{5000 \times 0.35 \times 0.017}{0.5} = 60 \text{ mL}$$

The fetal-placental blood volume at term approximates 125 mL/kg. For a 3000-g fetus, that would equate to 375 mL. Thus, this fetus lost approximately 15 percent (60 ÷ 375 mL) of the fetal-placental volume. Because the hematocrit is 50 percent in a term fetus, this 60 mL of whole blood represents 30 mL of red cells lost into the maternal circulation. This loss should be well tolerated hemodynamically but would require two 300-µg doses of anti-D immunoglobulin to prevent alloimmunization. A more precise method to estimate the maternal blood volume includes a calculation based on the maternal height, weight, and anticipated physiological maternal blood volume accrual (Table 41-1).

Fetomaternal hemorrhage can also be quantified using flow cytometry, which uses monoclonal antibodies to hemoglobin F or to the D antigen, followed by quantification of fluorescence (Chambers, 2012; Welsh, 2016). Flow cytometry is an automated test that can analyze a greater number of cells than the KB test. Further, it is unaffected by maternal levels of fetal hemoglobin or by fetal levels of hemoglobin A. Flow cytometry has been reported to be more sensitive and accurate than the KB test, however, it uses specialized technology not routinely available in many hospitals (Chambers, 2012; Corcoran, 2014; Fernandes, 2007).

FETAL THROMBOCYTOPENIA

Alloimmune Thrombocytopenia

This condition is also referred to as *neonatal alloimmune thrombocytopenia (NAIT)* or *fetal and neonatal alloimmune thrombocytopenia (FNAIT).* Alloimmune thrombocytopenia (AIT) is the most common cause of severe thrombocytopenia among term newborns, with a frequency of 1 to 2 per 1000 births (Kamphuis, 2010; Pacheco, 2013; Risson, 2012). FNAIT is caused by maternal alloimmunization to paternally inherited fetal platelet antigens. The resulting maternal antiplatelet antibodies cross the placenta in a manner similar to red cell alloimmunization (Red Cell Alloimmunization). Unlike *immune thrombocytopenia*, the maternal platelet count is normal with FNAIT. And, unlike anti-D alloimmunization, severe sequelae may affect the *initial* at-risk pregnancy.

Maternal platelet alloimmunization is most often against human platelet antigen-1a (HPA-1a). It accounts for 80 to 90 percent of cases and is associated with the greatest severity (Bussel, 1997; Knight, 2011; Tiller, 2013). This is followed in order of frequency by HPA-5b, HPA-1b, and HPA-3a. Alloimmunization to other antigens accounts for only 1 percent of reported cases.

Approximately 85 percent of non-Hispanic white individuals are HPA-1a positive. Two percent are homozygous for HPA-1b and thus at risk for alloimmunization. Importantly, however, only 10 percent of homozygous HPA-1b mothers who carry an HPA-1a fetus will produce anti-platelet antibodies. Approximately a third of affected fetuses or neonates will develop severe thrombocytopenia, and 10 to 20 percent of those with severe thrombocytopenia sustain an intracranial hemorrhage (ICH) (Kamphuis, 2010). As a result, population-based screening studies have identified FNAIT-associated ICH in 1 per 25,000 to 60,000 pregnancies (Kamphuis, 2010; Knight, 2011).

FNAIT may present in various ways. In some cases, neonatal thrombocytopenia may be an incidental finding or the newborn may manifest petechiae. In the other extreme, a fetus or neonate may develop devastating ICH—often before birth. Of 600 pregnancies with FNAIT identified through a large international registry, fetal or neonatal ICH complicated 7 percent of cases (Tiller, 2013). Hemorrhage affected the first-born child in 60 percent and occurred before 28 weeks' gestation in half. A third of affected children died soon after birth, and 50 percent of survivors had severe neurological disabilities. Bussel and coworkers (1997) evaluated fetal platelet counts before therapy in 107 fetuses with FNAIT. Thrombocytopenia severity was predicted by a prior sibling with perinatal ICH, and 98 percent of cases were identified this way. The initial platelet count was <20,000/μL in 50 percent. In cases in which the platelet count was initially >80,000/μL, they noted that it dropped by more than 10,000/μL each week in the absence of therapy.

Diagnosis and Management

Alloimmune thrombocytopenia is typically diagnosed following delivery of a neonate with severe and unexplained thrombocytopenia to a woman whose platelet count is normal. Rarely, the diagnosis is ascertained after identifying fetal ICH. The condition recurs in 70 to 90 percent of subsequent pregnancies, is often severe, and usually develops earlier with each successive pregnancy. Traditionally, fetal blood sampling was performed to detect fetal thrombocytopenia and to tailor therapy, with transfusion of platelets if the fetal platelet count was <50,000/μL. Because of procedure-related complications, however, experts recommend abandoning routine fetal platelet sampling in favor of empirical treatment with intravenous immune globulin (IVIG) and prednisone (Berkowitz, 2006; Pacheco, 2011).

Therapy is stratified according to whether a prior affected pregnancy was complicated by perinatal ICH, and if so, at what gestational age (Table 15-3). Pioneering work by Bussel (1996) and Berkowitz (2006) and their colleagues demonstrated the efficacy of such treatment. In one series of 50 pregnancies with fetal thrombocytopenia secondary to FNAIT, IVIG raised the platelet count by approximately 50,000/μL, and no fetus developed ICH (Bussel, 1996). Among pregnancies at particularly high risk—based on a platelet count <20,000/μL or sibling with FNAIT-associated ICH—the addition of corticosteroids to IVIG increased the platelet count in 80 percent of cases (Berkowitz, 2006). Cesarean delivery has been recommended at or near term. A *noninstrumental* vaginal delivery is generally considered only if fetal blood sampling has demonstrated a platelet count >100,000/μL (Pacheco, 2011).

TABLE 15-3

Fetal-Neonatal Alloimmune Thrombocytopenia (FNAIT) Treatment Recommendations

Risk Group	Criteria	Suggested Management
1	Prior fetus or newborn with ICH, but no maternal anti-HPA antibody identified	Maternal anti-HPA antibody screening and cross-matching with paternal platelets at 12, 24, and 32 weeks' gestation; no treatment for negative test results
2	Prior fetus or newborn with thrombocytopenia and maternal anti-HPA antibody, but no ICH	Beginning at 20 wks: IVIG 1g/kg/wk and prednisone 0.5 mg/kg/d ***or*** IVIG 2 g/kg/wk Beginning at 32 weeks: IVIG 2 g/kg/wk and prednisone 0.5 mg/kg/d. Continue until delivery
3	Prior fetus with 3rd-trimester ICH or prior newborn with ICH, and maternal anti-HPA antibody	Beginning at 12 wks: IVIG 1 g/kg/wk Beginning at 20 wks: either increase IVIG to 2 g/kg/wk ***or*** add prednisone 0.5 mg/kg/d Beginning at 28 wks: IVIG 2 g/kg/wk ***and*** prednisone 0.5 mg/kg/d. Continue until delivery
4	Prior fetus with ICH before the 3rd trimester and maternal anti-HPA antibody	Beginning at 12 wks: IVIG 2 g/kg/wk Beginning at 20 wks: add prednisone 1 mg/kg/d Continue both until delivery

HPA = human platelet antigen; ICH = intracerebral hemorrhage; IVIG = intravenous immunoglobulin G.

Data from Pacheco, 2011.

Additional considerations include risks and costs associated with therapy. Side effects of IVIG may include fever, headache, nausea/vomiting, myalgia, and rash. Maternal hemolysis also has been described (Rink, 2013). Costs for IVIG may exceed $70 per gram or nearly $10,000 for each weekly 2-g/kg infusion for an average-size pregnant woman (Pacheco, 2011).

Immune Thrombocytopenia

Also known as immune or idiopathic thrombocytopenic purpura (ITP), this autoimmune disorder is characterized by antiplatelet IgG antibodies that attack platelet glycoproteins. In pregnancy, these antibodies may cross the placenta and cause fetal thrombocytopenia. Maternal ITP is discussed in Chapter 56 (Platelet Disorders). Fetal thrombocytopenia is usually mild. However, neonatal platelet levels may fall rapidly after birth, with a nadir at 48 to 72 hours of life. Neither the maternal platelet count, identification of antiplatelet antibodies, nor treatment with corticosteroids effectively predicts fetal or neonatal platelet counts (Hachisuga, 2014). Importantly, fetal platelet counts are usually adequate to allow vaginal delivery without an increased risk of ICH. In a recent review of more than 400 pregnancies with ITP, there was no case of fetal or neonatal ICH and no infant with any central nervous system abnormality (Wyszynski, 2016). Fetal bleeding complications are considered rare, and fetal blood sampling is not recommended (Neunert, 2011). Delivery mode is based on standard obstetrical indications.

HYDROPS FETALIS

This term refers to excessive accumulation of serous fluid. Strictly defined, *hydrops fetalis* is edema of the fetus. Traditionally, the diagnosis was made after delivery of a massively edematous neonate, often stillborn (Fig. 15-4). With sonography, hydrops has become a prenatal diagnosis. It is defined as two or more fetal effusions—pleural, pericardial, or ascites—or one effusion plus anasarca. As hydrops progresses in severity, edema is invariably a component, and is usually accompanied by placentomegaly and hydramnios. Clinically significant edema is defined sonographically as skin thickness >5 mm, and placentomegaly if the placenta thickness is at least 4 cm in the second trimester or 6 cm in the third trimester (Bellini, 2009; Society for Maternal–Fetal Medicine, 2015b). Hydrops may result from a wide range of conditions with varying pathophysiologies, each with the potential to make the fetus severely ill. It is divided into two categories. If found in association with red cell alloimmunization, it is termed *immune*, otherwise, it is *nonimmune.*

FIGURE 15-4
Hydropic, macerated stillborn infant and characteristically large placenta. The etiology was B19 parvovirus infection. (Used with permission from Dr. April Bleich.)

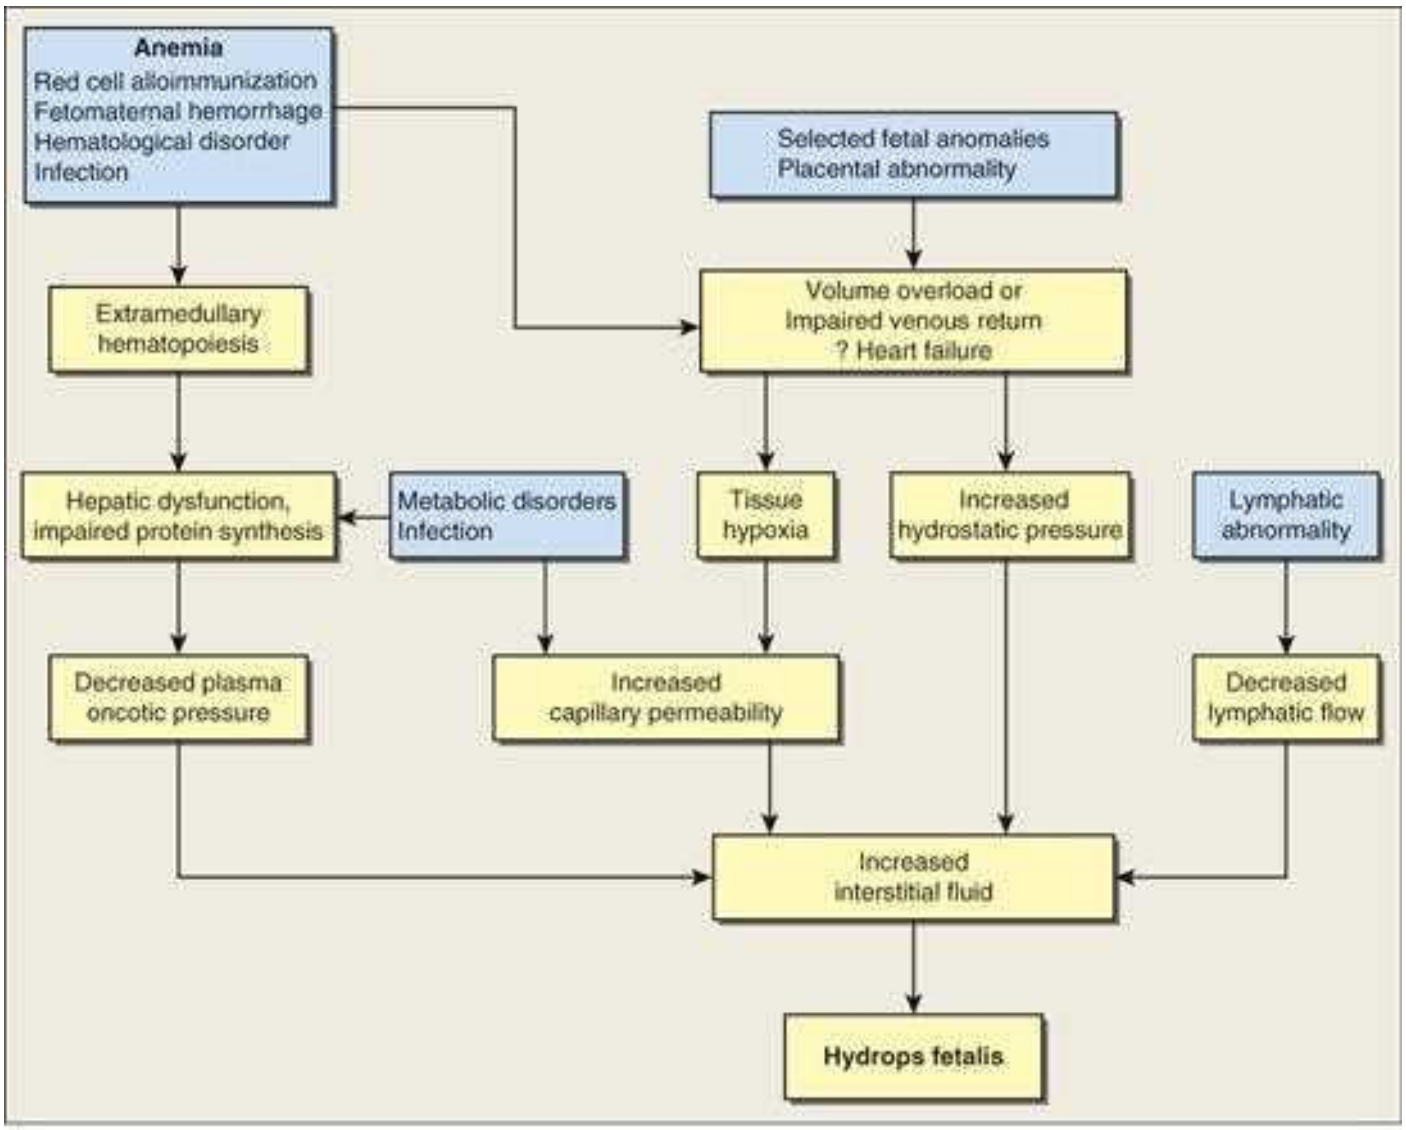
Immune Hydrops

The incidence of immune hydrops has dramatically declined with the advent of anti-D immune globulin, MCA Doppler studies for detection of severe anemia, and prompt fetal transfusion when needed (Fetal Blood Transfusion). However, fewer than 10 percent of hydrops cases are caused by red cell alloimmunization (Bellini, 2012; Santolaya, 1992).

The pathophysiology underlying hydrops remains unknown. Immune hydrops is postulated to share several physiological abnormalities with nonimmune hydrops. As shown in Figure 15-5, these include decreased colloid oncotic pressure, increased hydrostatic (or central venous) pressure, and enhanced vascular permeability. Immune hydrops results from transplacental passage of maternal antibodies that destroy fetal red cells. The resultant anemia stimulates marrow erythroid hyperplasia and extramedullary hematopoiesis in the spleen and liver. The latter likely causes portal hypertension and impaired hepatic protein synthesis, which lowers plasma oncotic pressure (Nicolaides, 1985). Fetal anemia also may raise central venous pressure (Weiner, 1989). Finally, tissue hypoxia from anemia may increase capillary permeability, such that fluid collects in the fetal thorax, abdominal cavity, and/or subcutaneous tissue.

FIGURE 15-5

Proposed pathogenesis of immune and nonimmune hydrops fetalis. (Adapted from Bellini, 2009; Lockwood, 2009.)



The degree of anemia in immune hydrops is typically severe. In a series of 70 pregnancies with fetal anemia from red cell alloimmunization, Mari and coworkers (2000) found that all those with immune hydrops had hemoglobin values *<5 g/dL*. As discussed in Fetal Blood Transfusion, immune hydrops is treated with fetal blood transfusions.

Nonimmune Hydrops

At least 90 percent of cases of hydrops are nonimmune (Bellini, 2012; Santolaya, 1992). The prevalence estimate is 1 per 1500 second-trimester pregnancies (Heinonen, 2000). The number of specific disorders that can lead to nonimmune hydrops is extensive. Etiologies and the proportion of births within each hydrops category from a review of more than 6700 affected pregnancies are summarized in Table 15-4. A cause is identified in at least 60 percent prenatally and in more than 80 percent postnatally (Bellini, 2009; Santo, 2011). Currently, approximately 20 percent of cases remain idiopathic (Bellini, 2015). As shown in Figure 15-5, several different pathophysiological processes are proposed to account for the final common pathway of hydrops fetalis.

TABLE 15-4

Categories and Etiologies of Nonimmune Hydrops Fetalis

Category	Percent[a]
Cardiovascular Structural defects: Ebstein anomaly, Fallot tetralogy with absent pulmonary valve, hypoplastic left or right heart, premature closure of ductus arteriosus, arteriovenous malformation (vein of Galen aneurysm) Cardiomyopathies Tachyarrhythmias Bradycardia, as may occur in heterotaxy syndrome with endocardial cushion defect or with anti-Ro/La antibodies	21
Chromosomal Turner syndrome (45,X), triploidy, trisomies 21, 18, and 13	13
Hematological Hemoglobinopathies, such as α4-thalassemia Erythrocyte enzyme and membrane disorders Erythrocyte aplasia/dyserythropoiesis Decreased erythrocyte production (myeloproliferative disorders) Fetomaternal hemorrhage	10
Lymphatic Abnormalities Cystic hygroma, systemic lymphangiectasis, pulmonary lymphangiectasis	8
Infections Parvovirus B19, syphilis, cytomegalovirus, toxoplasmosis, rubella, enterovirus, varicella, herpes simplex, coxsackievirus, listeriosis, leptospirosis, Chagas disease, Lyme disease	7
Syndromic Arthrogryposis multiplex congenita, lethal multiple pterygium, congenital lymphedema, myotonic dystrophy type I, Neu-Laxova, Noonan, and Pena-Shokeir syndromes	5
Thoracic Abnormalities Cystic adenomatoid malformation Pulmonary sequestration Diaphragmatic hernia Hydro/chylothorax Congenital high airway obstruction sequence (CHAOS) Mediastinal tumors Skeletal dysplasia with very small thorax	5
Gastrointestinal Meconium peritonitis, gastrointestinal tract obstruction	1
Kidney and Urinary Tract Kidney malformations Bladder outlet obstructions Congenital (Finnish) nephrosis, Bartter syndrome, mesoblastic nephroma	2
Placental, Twin, and Cord Abnormalities Placental chorioangioma, twin-twin transfusion syndrome, twin reversed arterial perfusion sequence, twin anemia polycythemia sequence, cord vessel thrombosis	5

[a]Percentages reflect the proportion within each category from a systematic review of 6775 pregnancies with nonimmune hydrops.

Modified from Bellini, 2015.

Importantly, the etiology of nonimmune hydrops varies according to when in gestation it is identified. Of those diagnosed prenatally, aneuploidy accounts for approximately 20 percent, cardiovascular abnormalities for 15 percent, and infections for 14 percent—the most common of these being parvovirus B19 (Santo, 2011). Overall, only 40 percent of pregnancies with nonimmune hydrops result in a liveborn neonate, and of these, the neonatal survival rate is only about 50 percent. Sohan and colleagues (2001) reviewed 87 pregnancies with hydrops and found that 45 percent of those diagnosed before 24 weeks' gestation had a chromosomal abnormality. The most frequent aneuploidy was 45,X—*Turner syndrome*, and in such cases, the survival rate was <5 percent (Chap. 13, Polyploidy). If hydrops is detected in the first trimester, the aneuploidy risk is nearly 50 percent, and most have cystic hygromas (Fig. 10-22).

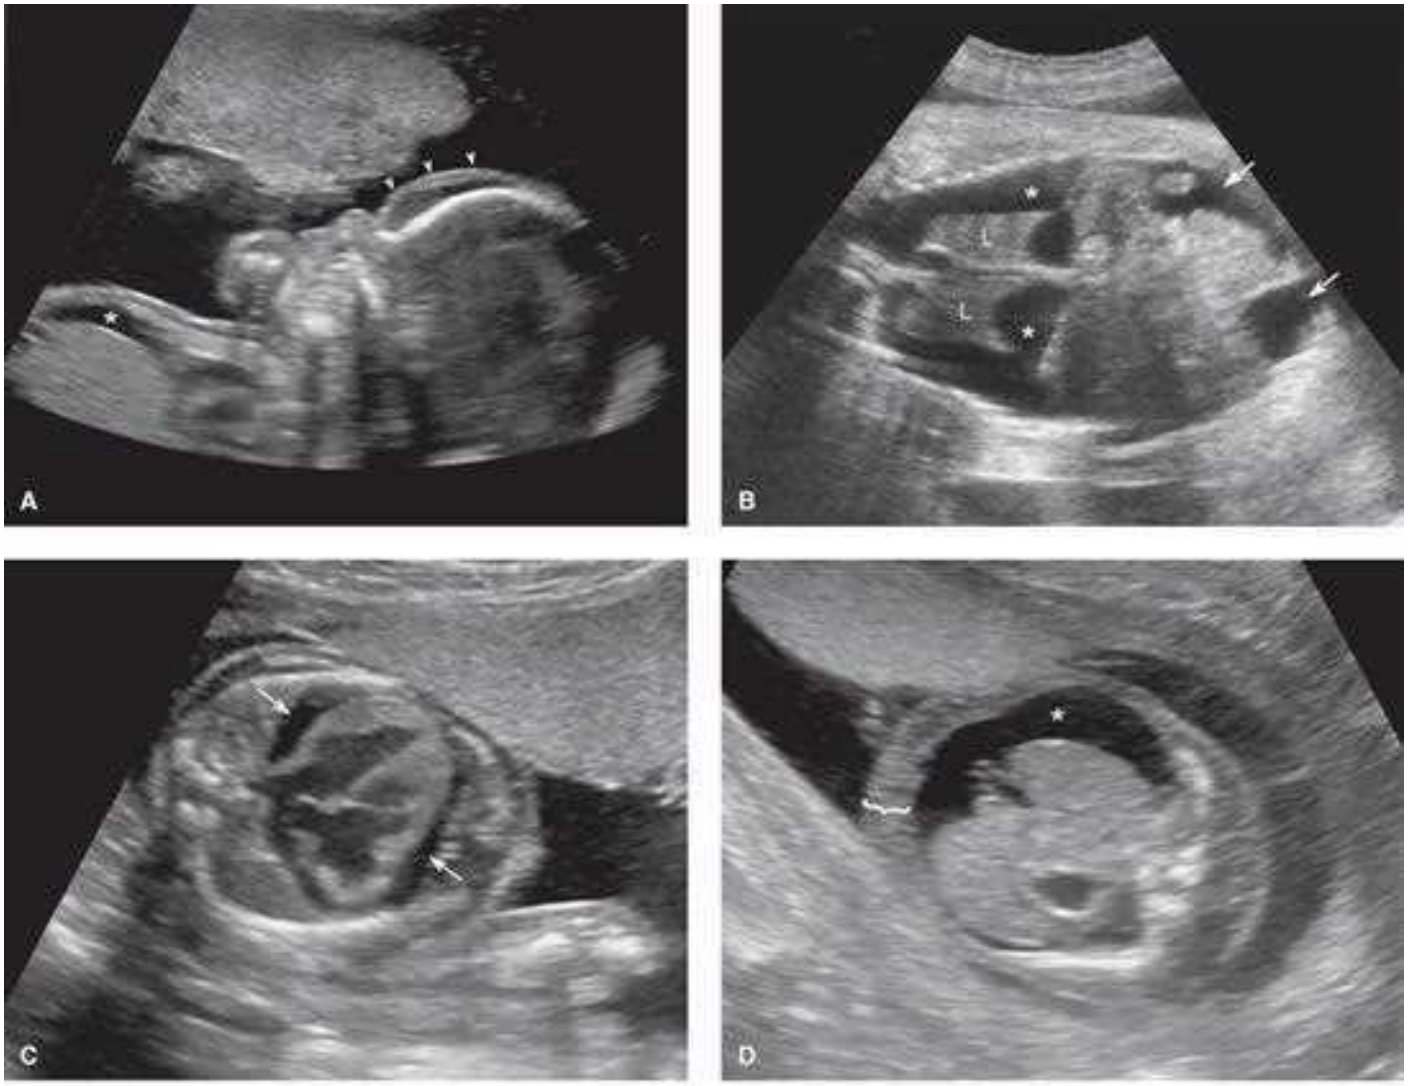
Although the prognosis of nonimmune hydrops is guarded, it is heavily dependent on etiology. In large series from Thailand and Southern China, α4-thalassemia is the predominant cause of nonimmune hydrops, accounting for 30 to 50 percent of cases and conferring an extremely poor prognosis (Liao, 2007; Ratanasiri, 2009; Suwanrath-Kengpol, 2005). In contrast, treatable etiologies such as parvovirus, chylothorax, and tachyarrhythmias, which each comprise about 10 percent of cases, can result in survival in two thirds of cases with fetal therapy (Sohan, 2001).

Diagnostic Evaluation

Hydrops is readily detected sonographically. As noted, two effusions or one effusion plus anasarca are required for diagnosis. Edema may be particularly prominent around the scalp, or equally obvious around the trunk and extremities. Effusions are visible as fluid outlining the lungs, heart, or abdominal viscera (Fig. 15-6).

FIGURE 15-6

Hydropic features. **A.** This profile of a 23-week fetus with nonimmune hydrops secondary to B19 parvovirus infection depicts scalp edema (*arrowheads*) and ascites (*). **B.** This 34-week fetus had hydrops secondary to an arteriovenous malformation in the brain, known as a vein of Galen aneurysm. In this coronal image, prominent pleural effusions (*) outline the lungs (L). Fetal ascites is also present (*arrows*), as is anasarca. **C.** This axial (transverse) image depicts a pericardial effusion (*arrows*) in a 23-week fetus with hydrops from B19 parvovirus infection. The degree of cardiomegaly is impressive, and the ventricular hypertrophy raises concern for myocarditis, which can accompany parvovirus infection. **D.** This axial (transverse) image depicts fetal ascites (*) in a 15-week fetus with hydrops secondary to large cystic hygromas. Anasarca is also seen (*bracket*).



In many cases, targeted sonographic and laboratory evaluation will identify the underlying cause of fetal hydrops. These include cases due to fetal anemia, arrhythmia, structural abnormality, aneuploidy, placental abnormality, or complications of monochorionic twinning. Depending on the circumstances, initial evaluation includes the following:

1. Indirect Coombs test for alloimmunization
2. Targeted sonographic fetal and placental examination, including:
   - A detailed anatomical survey to assess for the structural abnormalities listed in Table 15-4
   - MCA Doppler peak systolic velocity to assess for fetal anemia
   - Fetal echocardiography with M-mode evaluation
3. Amniocentesis for fetal karyotype and for parvovirus B19, cytomegalovirus, and toxoplasmosis testing as discussed in Chapter 64. Consideration of chromosomal microarray analysis if fetal anomalies are present
4. Kleihauer-Betke test for fetomaternal hemorrhage if anemia is suspected, depending on findings and test results
5. Consideration of testing for alpha-thalassemia and/or inborn errors of metabolism.

Isolated Effusion or Edema

Although one effusion or anasarca alone is not diagnostic for hydrops, the above evaluation should be considered if these are encountered, as hydrops may develop. For example, an isolated pericardial effusion may be the initial finding in fetal parvovirus B19 infection (Chap. 64, West Nile Virus). An isolated pleural effusion may represent a chylothorax, which is amenable to prenatal diagnosis, and for which fetal therapy may be lifesaving if hydrops develops (Chap. 16, Percutaneous Procedures). Isolated ascites also may be the initial finding in fetal parvovirus B19 infection, or it may result from a gastrointestinal abnormality such as meconium peritonitis. Finally, isolated edema, particularly involving the upper torso or the dorsum of the hands and feet, may be found in Turner or Noonan syndrome or may represent congenital lymphedema syndrome (Chap. 13, Polyploidy).

Mirror Syndrome

An association between fetal hydrops and development of maternal edema in which the fetus *mirrors* the mother is attributed to Ballantyne. He called the condition *triple edema* because the fetus, mother, and placenta all became edematous. The etiology of the hydrops is not related to development of mirror syndrome. It has been associated with hydrops from D alloimmunization, twin-twin transfusion syndrome, placental chorioangioma, and with fetal cystic hygroma, Ebstein anomaly, sacrococcygeal teratoma, chylothorax, bladder outlet obstruction, supraventricular tachycardia, vein of Galen aneurysm, and various congenital infections (Braun, 2010).

In a review of more than 50 cases of mirror syndrome, Braun (2010) found that approximately 90 percent of women had edema, 60 percent had hypertension, 40 percent had proteinuria, 20 percent had liver enzyme elevation, and nearly 15 percent had headache and visual disturbances. Based on these findings, it is reasonable to consider mirror syndrome a form of severe preeclampsia (Espinoza, 2006; Midgley, 2000). Others, however, have suggested that it is a separate disease process with hemodilution rather than hemoconcentration (Carbillon, 1997; Livingston, 2007).

Some reports describe the same imbalance of angiogenic and antiangiogenic factors that is observed with preeclampsia, and this suggests a common pathophysiology (Espinoza, 2006; Goa, 2013; Llurba, 2012). These findings, which include elevated concentrations of soluble fms-like tyrosine kinase-1 (sFlt-1), decreased placental growth factor (PlGF) levels, and elevation of soluble vascular endothelial growth factor receptor-1 (sVEGFR-1) concentrations, are discussed further Chapter 40 (Endothelial Cell Injury).

In most cases with mirror syndrome, prompt delivery is indicated and followed by resolution of maternal edema and other findings (Braun, 2010). However, in isolated cases of fetal anemia, supraventricular tachycardia, hydrothorax, and bladder outlet obstruction, successful fetal treatment resulted in resolution of both fetal hydrops and maternal mirror syndrome (Goa, 2013; Livingston, 2007; Llurba, 2012; Midgley, 2000). Normalization of the angiogenic imbalance has also been described following fetal transfusion for parvovirus B19 infection. Fetal therapy for these conditions is reviewed in Chapter 16. Given the parallels to severe preeclampsia, delaying delivery to effect fetal therapy should be considered only with caution. If the maternal condition deteriorates, delivery is recommended.

CHAPTER 16: Fetal Therapy

Minor grades of hydramnios rarely require active treatment. On the other hand, when the abdomen is immensely distended and respiration is seriously hampered, the termination of pregnancy is urgently indicated. In such cases, the symptoms can be promptly relieved by perforating the membranes through the cervix, after which the amniotic fluid drains off and labour pains set in.

—J. Whitridge Williams (1903)

INTRODUCTION

The concept of fetal therapy—even amniocentesis—was not considered by Williams in his first edition. Aside from a few destructive procedures to aid vaginal delivery, any type of fetal treatment is not mentioned as even a remote possibility. Again, fast forward to this 25th edition, when interventions developed during the past three decades have dramatically altered the course of selected fetal anomalies and conditions. Reviewed in this chapter are fetal disorders amenable to treatment with either maternal medication or surgical procedures. The management of fetal anemia and thrombocytopenia is reviewed in Chapter 15, and treatment of some fetal infections is discussed in Chapters 64 and 65.

MEDICAL THERAPY

Fetal pharmacotherapy uses medications administered to the mother and then transported transplacentally to the fetus. As described here, it can be used to treat an array of serious conditions.

Arrhythmias

Fetal cardiac rhythm disturbances may be broadly categorized as *tachyarrhythmias,* heart rates >180 beats per minute (bpm); *bradyarrhythmia,* heart rate <110 bpm; and ectopy, typically premature atrial contractions. If these are identified, fetal M-mode sonography is performed to measure the atrial and ventricular rates and to clarify the relationship between atrial and ventricular beats, thereby diagnosing the type of rhythm disturbance.

Premature Atrial Contractions

This is by far the most common arrhythmia and is identified in 1 to 2 percent of pregnancies (Hahurij, 2011; Strasburger, 2010). Generally a benign finding, premature atrial contractions represent immaturity of the cardiac conduction system, and they typically resolve later in gestation or in the neonatal period. If the premature atrial contraction is conducted, it sounds like an extra beat when auscultated with handheld Doppler or fetoscope. However, premature atrial contractions are more commonly blocked and sound like dropped beats.

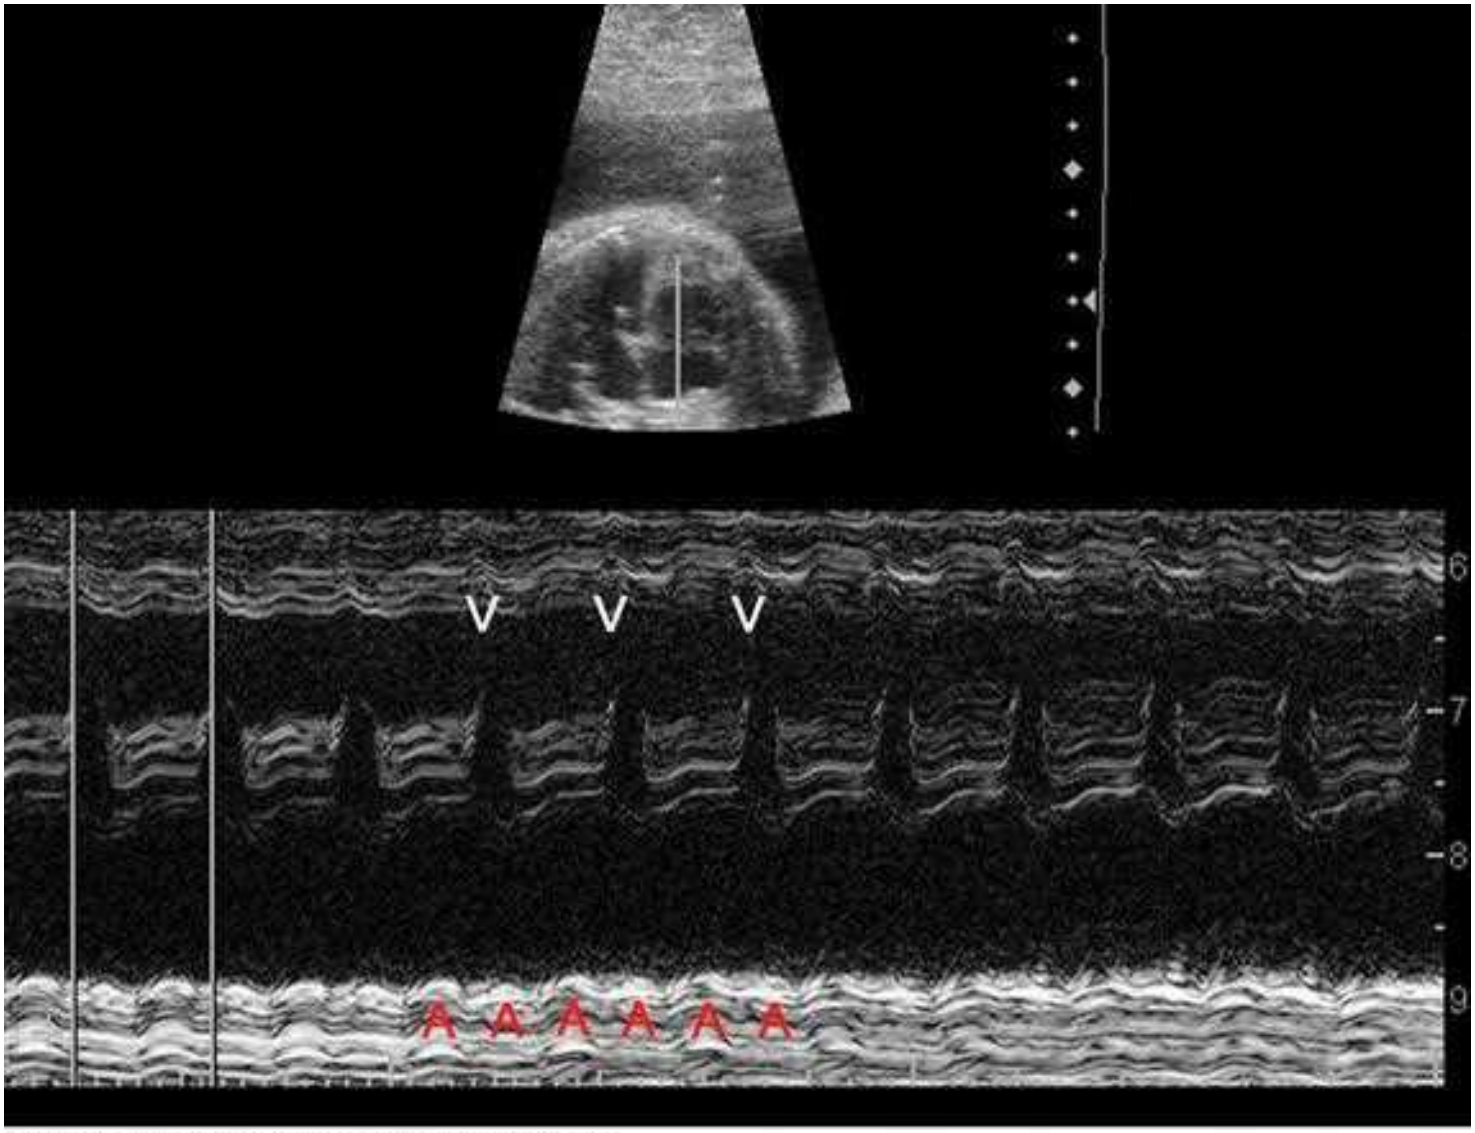
In general, premature atrial contractions are not associated with major structural cardiac abnormalities, although they sometimes occur with an atrial septal aneurysm. As shown in Figure 10-34, M-mode evaluation demonstrates that the dropped beat is a compensatory pause following the premature atrial contraction. They may occur as frequently as every other beat, known as *blocked atrial bigeminy*. This results in an auscultated fetal ventricular rate as low as 60 to 80 bpm. Unlike other causes of bradycardia, atrial bigeminy is benign and does not require treatment (Strasburger, 2010).

Approximately 2 percent of fetuses with premature atrial contractions are later found to have a *supraventricular tachycardia* (Copel, 2000; Srinivasan, 2008). Given the importance of identifying and treating supraventricular tachyarrhythmias, a fetus with premature atrial contractions is often monitored with heart rate assessment every 1 to 2 weeks until the ectopy resolves. This requires neither sonography nor fetal echocardiography, as the rate and rhythm may be easily ascertained with handheld Doppler.

Tachyarrhythmias

The two most common tachyarrhythmias are *supraventricular tachycardia* (SVT) and *atrial flutter.* SVT is characterized by an abrupt increase in the fetal heart rate to 180 to 300 bpm with 1:1 atrioventricular concordance. The typical range is 200 to 240 bpm. SVT may develop secondary to an ectopic focus or to an accessory atrioventricular pathway leading to a reentrant tachycardia. Atrial flutter is characterized by a much higher atrial rate, generally 300 to 500 bpm, with varying degrees of atrioventricular block. As a result, the ventricular rate in a fetus with atrial flutter may range from below normal to approximately 250 bpm (Fig. 16-1). In contrast, fetal *sinus tachycardia* typically presents with a gradual heart rate rise to a rate that is only slightly above normal. With this, readily discernible causes may be maternal fever or hyperthyroidism, or rarely, fetal anemia or infection.

FIGURE 16-1
Atrial flutter. In this M-mode image at 28 weeks' gestation, calipers mark the ventricular rate, which is approximately 225 bpm. There are two atrial beats (*A*) for each ventricular beat (*V*), such that the atrial rate is approximately 450 bpm with 2:1 atrioventricular block.



If a fetal tachyarrhythmia is identified, it is important to determine whether it is *sustained*—defined as present for at least 50 percent of the time. It may be necessary to monitor the fetal heart rate for 12 to 24 hours upon initial detection, and then periodically to reassess (Srinivasan, 2008). Unsustained or intermittent tachyarrhythmias generally do not require treatment, provided that fetal surveillance is reassuring.

Sustained fetal tachyarrhythmia with ventricular rates exceeding 200 bpm impairs ventricular filling to a degree that the risk for hydrops is significant. With atrial flutter, lack of coordinated atrioventricular contractions may further compound this risk. Maternal administration of antiarrhythmic agents that cross the placenta may convert the rhythm to normal or lower the baseline heart rate to forestall heart failure. Therapy may require dosages at the upper end of the therapeutic adult range. Thus, a maternal electrocardiogram is obtained before and during therapy.

Antiarrhythmic medications most commonly used include digoxin, sotalol (Betapace), flecainide (Tambocor), and procainamide (Pronestyl). Their selection depends on the type of tachyarrhythmia as well as provider familiarity and experience with the drug. Traditionally, digoxin has been the initial preferred treatment, although it may poorly transfer to the fetus after hydrops has developed. Many centers now use flecainide or sotalol as first-line therapy (Jaeggi, 2011; Shah, 2012). In many cases, additional agents are needed, particularly if hydrops has developed. SVT is generally more likely than atrial flutter to convert to a normal rhythm. With either arrhythmia, however, the overall neonatal survival rate now exceeds 90 percent (Ekman-Joelsson, 2015; Jaeggi, 2011; van der Heijden, 2013).

Bradyarrhythmia

The most common etiology of pronounced fetal bradycardia is *congenital heart block*. Approximately 50 percent of cases occur in the setting of a structural cardiac abnormality involving the conduction system. These include *heterotaxy*, in particular *left-atrial isomerism*; *endocardial cushion defect*; and less commonly *corrected transposition of the great vessels* (Srinivasan, 2008). The prognosis of heart block secondary to a structural cardiac anomaly is extremely poor, and fetal loss rates exceed 80 percent (Glatz, 2008; Strasburger, 2010).

In a structurally normal heart, 85 percent of atrioventricular block cases develop secondary to transplacental passage of maternal anti-SSA/Ro or anti-SSB/La antibodies (Buyon, 2009). Many of these women have, or subsequently develop, systemic lupus erythematosus or other connective tissue disease (Chap. 59, Perinatal Mortality and Morbidity). The risk of third-degree heart block with these antibodies is small—only about 2 percent. But, the risk may reach 20 percent if a

prior infant has been affected. Immune-mediated congenital heart block confers a mortality rate of 20 to 30 percent, requires permanent pacing in two thirds of surviving children, and also poses a risk for cardiomyopathy (Buyon, 2009). If associated with effusions, bradyarrhythmias, or endocardial fibroelastosis, neonatal status may progressively worsen after birth (Cuneo, 2007).

Initial research efforts focused on maternal corticosteroid therapy to potentially reverse fetal heart block or forestall it. Friedman and colleagues (2008, 2009) conducted a prospective multicenter trial of pregnancies with anti-SSA/Ro antibodies—the PR Interval and Dexamethasone (PRIDE) study. Weekly sonographic surveillance was performed, and heart block was treated with maternal oral dexamethasone 4 mg daily. Unfortunately, progression from second- to third-degree block was not prevented with maternal dexamethasone therapy, and third-degree atrioventricular block was *irreversible*. In rare cases, there was a potential benefit in reversing first-degree atrioventricular block. However, first-degree block did not generally progress even without treatment. In a subsequent review of 156 pregnancies with isolated second- or third-degree fetal heart block, dexamethasone therapy similarly did not affect disease progression, need for pacemaker in the neonatal period, or overall survival rates (Izmirly, 2016). Thus, dexamethasone use cannot be recommended for this indication.

More recent efforts have turned to potential therapy with hydroxychloroquine (Plaquenil), a mainstay of treatment for systemic lupus erythematosus (Chap. 59, Perinatal Mortality and Morbidity). In a multicenter review of more than 250 pregnancies in women whose prior pregnancies had been complicated by neonatal lupus, recurrence of congenital heart block was significantly lower if the woman had been treated with hydroxychloroquine during pregnancy (Izmirly, 2012). Research in this area is ongoing.

Maternal terbutaline has also been given to increase the fetal heart rate in cases with sustained bradycardia of any cause in which the fetal heart rate is below 55 bpm. Reversal of hydrops with this therapy has been reported (Cuneo, 2007, 2010).

Congenital Adrenal Hyperplasia

Several autosomal recessive enzyme deficiencies cause impaired fetal synthesis of cortisol from cholesterol by the adrenal cortex. This results in congenital adrenal hyperplasia (CAH). CAH is the most common etiology of androgen excess in females with 46,XX disorders of sex development, formerly female pseudohermaphroditism (Chap. 3, Bladder and Perineal Abnormalities). Lack of cortisol stimulates adrenocorticotrophic hormone (ACTH) secretion by the anterior pituitary, and the resulting androstenedione and testosterone overproduction leads to virilization of female fetuses. Sequelae may include formation of labioscrotal folds, persistence of a urogenital sinus, or even creation of a penile urethra and scrotal sac.

More than 90 percent of CAH cases are caused by 21-hydroxylase deficiency, which is found in classic and nonclassic forms. The incidence of classic CAH approximates 1:15000 births overall and is higher in selected populations. For example, it has been reported in approximately 1:300 Yupik Eskimos (Nimkarn, 2010). Among those with classic CAH, 75 percent are at risk for *salt-wasting adrenal crises* and require postnatal treatment with mineralocorticoids and glucocorticoids to prevent hyponatremia, dehydration, hypotension, and cardiovascular collapse. The remaining 25 percent with classic CAH have the *simple virilizing type* and also require glucocorticoid supplementation. As discussed in Chapter 32 (Routine Newborn Care), all states mandate newborn screening for CAH.

The efficacy of maternal dexamethasone treatment to suppress fetal androgen overproduction and either obviate or ameliorate virilization of female fetuses has been recognized for more than 30 years (David, 1984; New, 2012). Prenatal corticosteroid therapy is considered successful in 80 to 85 percent of cases (Miller, 2013; Speiser, 2010). The alternative is consideration of postnatal genitoplasty, a complex and somewhat controversial surgical procedure (Braga, 2009).

The typical preventive regimen is oral dexamethasone given to the mother at a dosage of 20 µg/kg/d—up to 1.5 mg per day, divided in three doses. The critical period for external genitalia development is 7 to 12 weeks' gestation, and treatment to prevent virilization should be initiated by 9 weeks—*before it is known whether the fetus is at risk.* Because this is an autosomal recessive condition, affected females make up only 1 in 8 at-risk conceptions.

Typically, carrier parents are identified after the birth of an affected child. Molecular genetic testing is clinically available, initially using sequence analysis of the *CYP21A2* gene, which encodes the 21-hydroxylase enzyme (Nimkarn, 2016). If this is uninformative, gene-targeted deletion/duplication analysis is performed, and additional testing such as whole exome sequencing may be considered (Chap. 13, Whole Genome Sequencing and Whole Exome Sequencing).

A goal of prenatal diagnosis is to limit dexamethasone exposure in males and in unaffected females. Prenatal diagnosis with molecular genetic testing may be performed on chorionic villi—at 10 to 12 weeks' gestation—or on amniocytes after 15 weeks. Cell-free DNA testing of maternal serum has potential to replace invasive tests such as chorionic villus sampling and amniocentesis for CAH (Chap. 13, Fetal DNA in the Maternal Circulation). Determination of fetal gender using cell-free fetal DNA has at least 95-percent sensitivity when performed at or beyond 7 weeks' gestation (Devaney, 2011). In the research setting, cell-free DNA testing using hybridization probes flanking the *CYP21A2* gene can be effective as early as $5^{6/7}$ weeks' gestation (New, 2014).

Maternal treatment with dexamethasone has become a topic of significant controversy. The Endocrine Society recommends that treatment be given only in the context of research protocols (Miller, 2013; Speiser, 2010). It should be noted that if therapy is initiated shortly before 9 weeks, the dose of dexamethasone used is not considered to have significant teratogenic potential because organogenesis of major organs has already taken place (McCullough, 2010). Ongoing concerns, however, focus on the potential effects of either excess *endogenous* androgens or excess *exogenous* dexamethasone on the developing brain. Although maternal dexamethasone has been used for many years to prevent virilization of female fetuses with CAH, long-term safety data are relatively limited.

Congenital Cystic Adenomatoid Malformation

Sonographically, this malformation is a well-circumscribed lung mass that may appear solid and echogenic or may have one or multiple variably sized cysts (Fig. 10-24). Lesions with cysts ≥5 mm are termed macrocystic, whereas microcystic lesions have smaller cysts or appear solid (Adzick, 1985). Also called congenital pulmonary airway malformation (CPAM), it represents a hamartomatous overgrowth of terminal bronchioles. Therapy for macrocystic congenital cystic adenomatoid malformation (CCAM) is discussed later (Percutaneous Procedures).

Occasionally, a microcystic CCAM may demonstrate rapid growth, generally between 18 and 26 weeks' gestation. The mass may become so large that it causes mediastinal shift, which may compromise cardiac output and venous return, resulting in hydrops (Cavoretto, 2008). A CCAM-volume ratio (CVR) has been used to quantify size and risk for hydrops in these severe cases (Crombleholme, 2002). This ratio is an estimate of the CCAM volume (length × width × height × 0.52) divided by the head circumference. In a series of 40 pregnancies with microcystic CCAM, the mean CVR was 0.5 at 20 weeks' gestation, peaking in size at 1.0 at 26 weeks, followed by a pronounced decline prior to delivery (Macardle, 2016). A third of fetuses had no increase in mass size. In the absence of a dominant cyst, a CVR exceeding 1.6 is associated with a hydrops risk as high as 60 percent. However, CCAM growth resulting in hydrops develops in fewer than 2 percent of cases if the initial CVR is below 1.6 (Ehrenberg-Buchner, 2013; Peranteau, 2016). Importantly, a CVR in the range of 1.6 indicates that the mass essentially fills the thorax, and thus it is not unexpected that ascites or hydrops may develop.

If the CVR exceeds 1.6 or if signs of hydrops develop, corticosteroid treatment has been used in an effort to improve outcome. Regimens include dexamethasone—6.25 mg every 12 hours for four doses, or betamethasone—12.5 mg intramuscularly every 24 hours for two doses. Following a single course of corticosteroids, hydrops resolved in approximately 80 percent of cases, and 90 percent of treated fetuses survived (Loh, 2012; Peranteau, 2016). Recently, multiple courses of steroids—generally two—have been advocated for fetuses with large CCAM lesions and with persistent or worsening hydrops or ascites despite a single course of medication (Derderian, 2015; Peranteau, 2016).

Thyroid Disease

Identification of fetal thyroid disease is rare and usually prompted by sonographic detection of a fetal goiter. If a goiter is found, determination of fetal hyper- or hypothyroidism is essential, and thyroid hormone levels may be measured in amnionic fluid or fetal blood. Traditionally, fetal blood sampling, described in Chapter 14 (Fetal Blood Sampling), is preferred to amniocentesis for guiding treatment, although data are limited (Abuhamad, 1995; Ribault, 2009). Goals of therapy are correction of the physiological abnormality and diminished goiter size. The goiter may compress the trachea and esophagus to such a degree that severe hydramnios or neonatal airway compromise may develop. Hyperextension of the fetal neck by a goiter can create labor dystocia.

Fetal Thyrotoxicosis

Untreated fetal thyrotoxicosis may present with goiter, tachycardia, growth restriction, hydramnios, accelerated bone maturation, and even heart failure and hydrops (Huel, 2009; Peleg, 2002). The cause is usually maternal Graves disease with transplacental passage of IgG thyroid-stimulating immunoglobulins. Fetal blood sampling may confirm the diagnosis (Duncombe, 2001; Heckel, 1997; Srisupundit, 2008). Confirmed fetal thyrotoxicosis is followed by maternal antithyroid treatment. During this, if the mother develops hypothyroidism, she is given supplemental levothyroxine (Hui, 2011).

Fetal Hypothyroidism

In a woman receiving medication for Graves disease, transplacental passage of methimazole or propylthiouracil may cause *fetal hypothyroidism* (Bliddal, 2011a). Other potential causes of fetal hypothyroidism resulting in goiter include transplacental passage of thyroid peroxidase antibodies, fetal thyroid dyshormonogenesis, and maternal overconsumption of iodine supplements (Agrawal, 2002; Overcash, 2016).

Goitrous hypothyroidism may lead to hydramnios, neck hyperextension, and delayed bone maturation. If the mother is receiving antithyroid medication, discontinuation is generally recommended, along with intraamnionic levothyroxine injection. Numerous case reports describe intraamnionic levothyroxine treatment. However, optimal dosage and frequency have not been established, and reported dosages range from 50 to 800 µg every 1 to 4 weeks (Abuhamad, 1995; Bliddal, 2011b; Ribault, 2009).

SURGICAL THERAPY

Also called *maternal-fetal surgery*, these procedures are offered for selected congenital abnormalities in which the likelihood of fetal deterioration is so great that delaying treatment until after delivery would risk fetal death or substantially greater postnatal morbidity. Open fetal surgery is a highly specialized intervention performed at relatively few centers in the United States and for only a few fetal conditions. Criteria for consideration of fetal surgery are listed in Table 16-1. In many cases, data regarding the safety and efficacy of these procedures are limited. The Agency for Healthcare Research and Quality stresses that when considering fetal surgery, the overriding concern must be maternal and fetal safety. Accomplishing the fetal goals of the procedure is secondary (Walsh, 2011).

TABLE 16-1

Guiding Principles for Fetal Surgical Procedures

Accurate prenatal diagnosis for the defect is available, with staging if applicable
The defect appears isolated, with no evidence of other abnormality or underlying genetic syndrome that would significantly worsen survival or quality of life
The defect results in a high likelihood of death or irreversible organ destruction, and postnatal therapy is inadequate
The procedure is technically feasible, and a multidisciplinary team is in agreement regarding the treatment plan
Maternal risks from the procedure are well documented and considered acceptable
There is comprehensive parental counseling
It is recommended that there be an animal model for the defect and procedure

Modified from Deprest, 2010; Harrison, 1982; Vrecenak, 2013; Walsh, 2011.

Some abnormalities amenable to fetal surgical treatment, antepartum or intrapartum, are shown in Table 16-2. An overview of these procedures, their indications, and complications is provided here to assist with initial patient evaluation and counseling. Additional content is also found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition.

TABLE 16-2

Selected Fetal Abnormalities Amenable to Fetal Surgery

Open Fetal Surgery
Myelomeningocele
Congenital cystic adenomatoid malformation (CCAM)
Extralobar pulmonary sequestration
Sacrococcygeal teratoma
Fetoscopic Surgery
Twin-twin transfusion: laser of placental anastomoses
Diaphragmatic hernia: fetal endoscopic tracheal occlusion (FETO)
Posterior urethral valves: cystoscopic laser
Congenital high airway obstruction: vocal cord laser
Amnionic band release
Percutaneous Procedures
Shunt therapy
Posterior-urethral valves/bladder outlet obstruction
Pleural effusion: chylothorax or sequestration
Dominant cyst in CCAM
Radiofrequency ablation
Twin-reversed arterial perfusion (TRAP) sequence
Monochorionic twins with severe anomaly in 1 twin
Chorioangioma
Fetal intracardiac catheter procedures
Aortic or pulmonic valvuloplasty for stenosis
Atrial septostomy for hypoplastic left heart with restrictive atrial septum
Ex-Utero Intrapartum Treatment (EXIT) Procedures
Congenital diaphragmatic hernia after FETO
Congenital high airway obstruction sequence (CHAOS)
Severe micrognathia
Tumors involving neck or airway
EXIT-to-resection: resection of fetal thoracic or mediastinal mass
EXIT-to-extracorporeal membrane oxygenation (ECMO): congenital diaphragmatic hernia

Open Fetal Surgery

These procedures require extensive preoperative counseling and multidisciplinary care. The mother must undergo general endotracheal anesthesia to suppress both uterine contractions and fetal responses. Using intraoperative sonographic guidance to avoid the placental edge, a low-transverse hysterotomy incision is made with a stapling device that seals the edges for hemostasis. To replace amnionic fluid losses, warmed fluid is continuously infused into the uterus thorough a rapid infusion device. The fetus is gently manipulated to permit pulse oximetry monitoring and to establish venous access, in case fluids or blood are emergently needed. The surgical procedure is then performed. After completion, the hysterotomy is closed and tocolysis begun. Tocolysis typically includes intravenous magnesium sulfate for 24 hours, oral indomethacin for 48 hours, and, at some centers, oral nifedipine until delivery (Wu, 2009). Prophylactic antibiotics are also administered and generally continued for 24 hours following the procedure. Cesarean delivery is needed later in gestation and for all future deliveries.

Risks

Morbidities associated with fetal surgery are well characterized. In a review of 87 open procedures, Golombeck and coworkers (2006) reported the following morbidities: pulmonary edema—28 percent, placental abruption—9 percent, blood transfusion—13 percent, premature rupture of membranes—52 percent, and preterm delivery—33 percent. Wilson and associates (2010) reviewed subsequent pregnancy outcomes following open fetal surgery and reported that 14 percent of women experienced uterine rupture and 14 percent had uterine dehiscence. Morbidities identified in the recent *Management of Myelomeningocele Study (MOMS)* are shown in Table 16-3 (Adzick, 2011). Other potential risks include maternal sepsis and fetal death during or following the procedure, particularly if hydrops is present.

TABLE 16-3

Benefits and Risks of Fetal Myelomeningocele Surgery versus Postnatal Repair

	Fetal Surgery (n = 78)	Postnatal Surgery (n = 80)	*p* value
Benefits (Primary Outcomes)			
Perinatal death or shunt by 12 months[a]	68%	98%	<0.001
Shunt placement by 12 months	40%	82%	<0.001
Composite developmental score[a,b]	149 ± 58	123 ± 57	0.007
Hindbrain herniation (any)	64%	96%	<0.001
Brainstem kinking (any)	20%	48%	<0.001
Independent walking (30 months)	42%	21%	0.01
Risks			
Maternal pulmonary edema	6%	0	0.03
Placental abruption	6%	0	0.03
Maternal transfusion at delivery	9%	1%	0.03
Oligohydramnios	21%	4%	0.001
Gestational age at delivery	34 ± 3	37 ± 1	<0.001
Preterm birth			
<37 weeks	79%	15%	<0.001
<35 weeks	46%	5%	
<30 weeks	13%	0	

[a]Each primary outcome had two components. The perinatal death components of the primary outcomes as well as the Bayley Mental Development Index at 30 months did not differ between the two study cohorts.

[b]Score derived from Bayley Mental Development Index and difference between functional and anatomical level of lesion (30 months).

Data from Adzick, 2011.

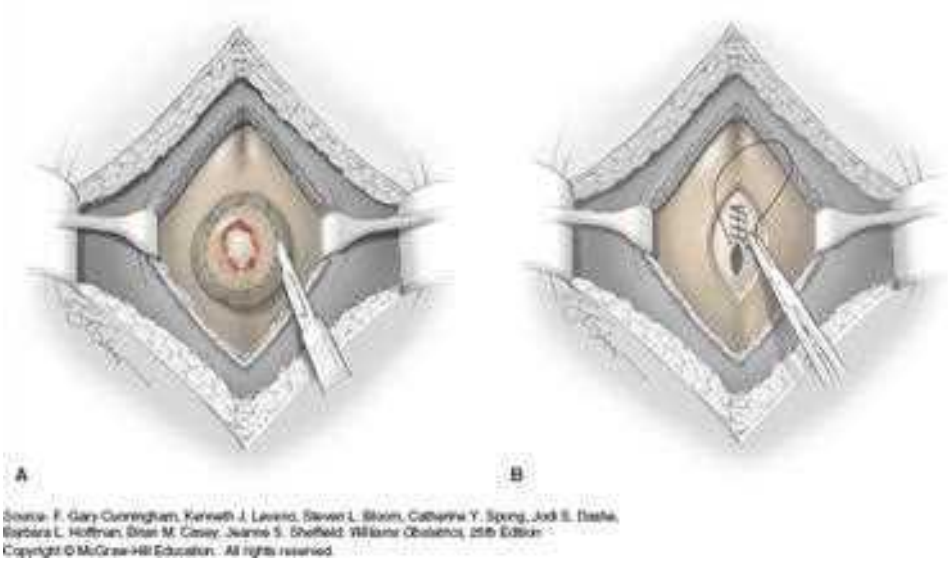
Myelomeningocele Surgery

Even with postnatal repair, children with myelomeningocele generally have varying degrees of paralysis, bladder and bowel dysfunction, developmental delays, and brainstem dysfunction from the Arnold-Chiari II malformation (Chap. 10, Ventriculomegaly). Damage is postulated to result from abnormal embryonic neurulation and from ongoing exposure of neural elements to amnionic fluid (Adzick, 2010; Meuli, 1995, 1997). Fetal myelomeningocele meets the criteria listed in Table 16-1 and is the first nonlethal birth defect for which fetal surgery has been offered (Fig. 16-2).

FIGURE 16-2

Fetal myelomeningocele surgery. **A.** With the edges of both the laparotomy and hysterotomy incisions retracted, the skin around the defect is incised. Subsequently, the neural placode is sharply dissected from the arachnoid membrane. **B.** The dural membrane is reflected to the midline to cover the neural placode and is

reapproximated using suture. In some cases a patch is needed (not shown). The fetal skin incision is subsequently sutured. Last, hysterotomy and laparotomy are then closed. (Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



In preliminary reports, infants following antepartum defect repair were more likely to have reversal of the Arnold-Chiari II malformation and were less likely to require ventriculoperitoneal shunt placement (Bruner, 1999; Sutton, 1999). Spurred by this, the randomized, multicenter MOMS trial was conducted (Adzick, 2011). Criteria for trial participation included: (1) a singleton fetus at 19.0 to 25.9 weeks' gestation; (2) an upper myelomeningocele boundary between T1 and S1 confirmed by fetal magnetic resonance (MR) imaging; (3) evidence of hindbrain herniation; and (4) a normal karyotype and no evidence of a fetal anomaly unrelated to the myelomeningocele. Women at risk for preterm birth or placental abruption, those with a contraindication to fetal surgery, and women with body mass index >35 kg/m^2 were excluded.

The MOMS findings demonstrated improved early childhood outcomes in the prenatal surgery cohort (see Table 16-3). Children who had undergone prenatal surgery were twice as likely to walk independently by 30 months. They had significantly less hindbrain herniation and were only half as likely to undergo ventriculoperitoneal shunting by the age of 1 year. A primary outcome was a composite score that was derived from the Bayley Mental Development Index and from the difference between the functional and anatomical level of the lesion at 30 months. This primary outcome was also significantly better in the prenatal surgery group.

When counseling prospective families, however, results are placed in perspective. For example, despite improvements in the proportion with independent ambulation, *most* children who received fetal surgery were not able to ambulate independently, and nearly 30 percent were not able to ambulate at all. Prenatal surgery did not confer improvements in fetal or neonatal death rates or in the Bayley Mental Development Index score at age 30 months. And, as shown in Table 16-3, surgery was associated with a small but significant risk for placental abruption and maternal pulmonary edema. Moreover, nearly half were delivered before 34 weeks, which significantly increased the risk for respiratory distress syndrome (Adzick, 2011). Long-term surveillance data have only recently become available for children who underwent fetal myelomeningocele repair prior to the MOMS trial. At a median follow-up of 10 years, these children have higher rates of behavioral problems and adverse executive functioning compared with population norms (Danzer, 2016).

Since publication of the MOMS findings, fetal myelomeningocele surgery rates have grown. Expansion of centers offering this procedure has raised concerns about the importance of training and ongoing experience, adherence to the MOMS research criteria, and need for a registry to ensure that future efforts have similar success rates (Cohen, 2014; Vrecenak, 2013).

Thoracic Masses

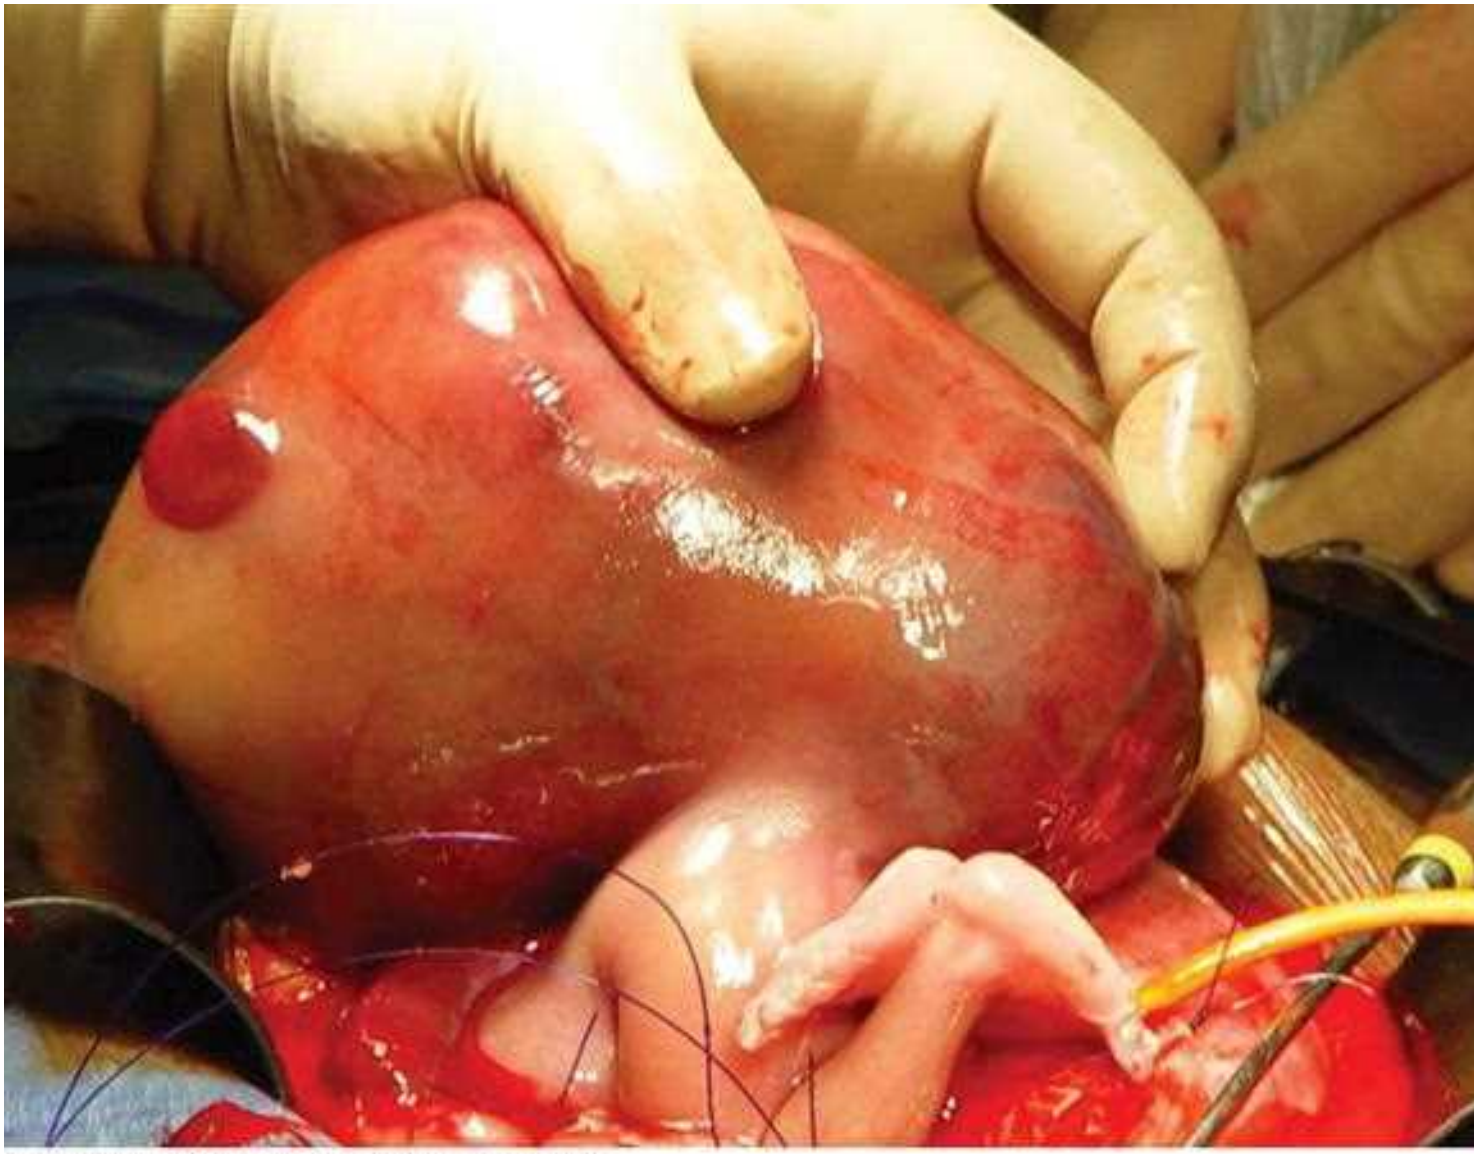
In the past, if hydrops developed in a fetus with a large pulmonary sequestration or cystic adenomatoid malformation without a dominant cyst, open fetal surgery with lobectomy was the only treatment available other than preterm delivery. Most thoracic masses are small and have a benign prognosis, and larger masses are generally treated with corticosteroids (Surgical Therapy). Fetal surgery is generally reserved for cases prior to 32 weeks in which hydrops is developing, and in selected cases, the survival rate following open lobectomy approximates 60 percent (Vrecenak, 2013). Use of the ex-utero intrapartum treatment procedure in the treatment of fetal lung masses at delivery is discussed later in Ex-Utero Intrapartum Treatment.

Sacrococcygeal Teratoma

This germ cell tumor has a prevalence of approximately 1 per 28,000 births (Derikx, 2006; Swamy, 2008). Sonographically, a sacrococcygeal teratoma (SCT) is a solid and/or cystic mass that arises from the anterior sacrum (Fig. 16-3). Fetal MR imaging can aid evaluation of the extent of the internal tumor component. The mass may grow rapidly, usually extending inferiorly and externally (Fig. 10-18). Hydramnios is common, and hydrops may develop from high-output cardiac failure, either as a consequence of tumor vascularity or secondary to bleeding within the tumor and resultant anemia. *Mirror syndrome*—maternal preeclampsia developing along with fetal hydrops—may occur in this setting (Chap. 15, Mirror Syndrome).

FIGURE 16-3

Fetal surgery for sacrococcygeal teratoma resection. Following laparotomy and hysterotomy, the caudal portion of the fetus has been delivered onto the surgical field. The tumor is held by the surgeon's hand. (Used with permission from Dr. Timothy M. Crombleholme.)



The perinatal mortality rate for cases of SCT diagnosed prenatally approximates 40 percent (Hedrick, 2004; Shue, 2013). Poor prognostic factors include a solid component comprising more than 50 percent of the tumor mass and a tumor volume-to-fetal weight ratio (tumor volume divided by estimated fetal weight) exceeding 12 percent prior to 24 weeks' gestation (Akinkuotu, 2015). Fetal loss rates approach 100 percent if hydrops or placentomegaly develop (Vrecenak, 2013). The group at the Children's Hospital of Philadelphia recommends consideration of open fetal surgery for SCT only in cases in which the tumor is completely external (Type I) and in which high cardiac output with early hydrops has developed in the second trimester (Vrecenak, 2013). For excision, hysterotomy is performed, and the external component is resected. The coccyx and any deep tumor are left in place for postnatal removal. Because tumor debulking interrupts the pathological vascular steal, normal fetal physiology may be restored.

Fetoscopic Surgery

As with open fetal surgeries, these procedures are performed at highly specialized centers, and some are considered investigational. To accomplish them, fiberoptic endoscopes only 1 to 2 mm in diameter are used to penetrate the maternal abdominal wall, the uterine wall, and membranes. Instruments such as lasers fit through 3- to 5-mm cannulas that surround the endoscope. Morbidities are generally lower than with open fetal surgery, but they still may be formidable, particularly if maternal laparotomy is required for access (Golombeck, 2006). Examples of some conditions treated by fetoscopy are listed in Table 16-2.

Twin-Twin Transfusion Syndrome

Indications and Technique

As discussed in Chapter 45 (Diagnosis), fetoscopic laser ablation of placental anastomoses is the preferred management for severe twin-twin transfusion syndrome (TTTS). It is generally performed between 16 and 26 weeks' gestation for monochorionic-diamnionic twin pregnancies with stage II to stage IV TTTS. These categories of the Quintero Staging System are described in Chapter 45 (Diagnosis) (Quintero, 1999; Society for Maternal-Fetal Medicine, 2013).

For the procedure, a fetoscope is used to view the vascular equator that separates the placental cotyledons supplying each twin (Fig. 16-4). Arteriovenous anastomoses along the placental surface of the vascular equator are photocoagulated using a 600-µm diameter diode laser or a 400-µm neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (Fig. 16-5). The procedure is typically performed under epidural or local analgesia. At the end, amnioreduction is performed to decrease the single deepest pocket of amnionic fluid to below 5 cm, and antibiotics are injected into the amnionic cavity.

FIGURE 16-4

Selective laser photocoagulation for twin-twin transfusion syndrome. The fetoscope is inserted into the recipient-twin sac and positioned over the vascular equator, which lies in between the two placental cord insertion sites. Arteriovenous anastomoses along the placental surface are individually photocoagulated using the laser. (Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)

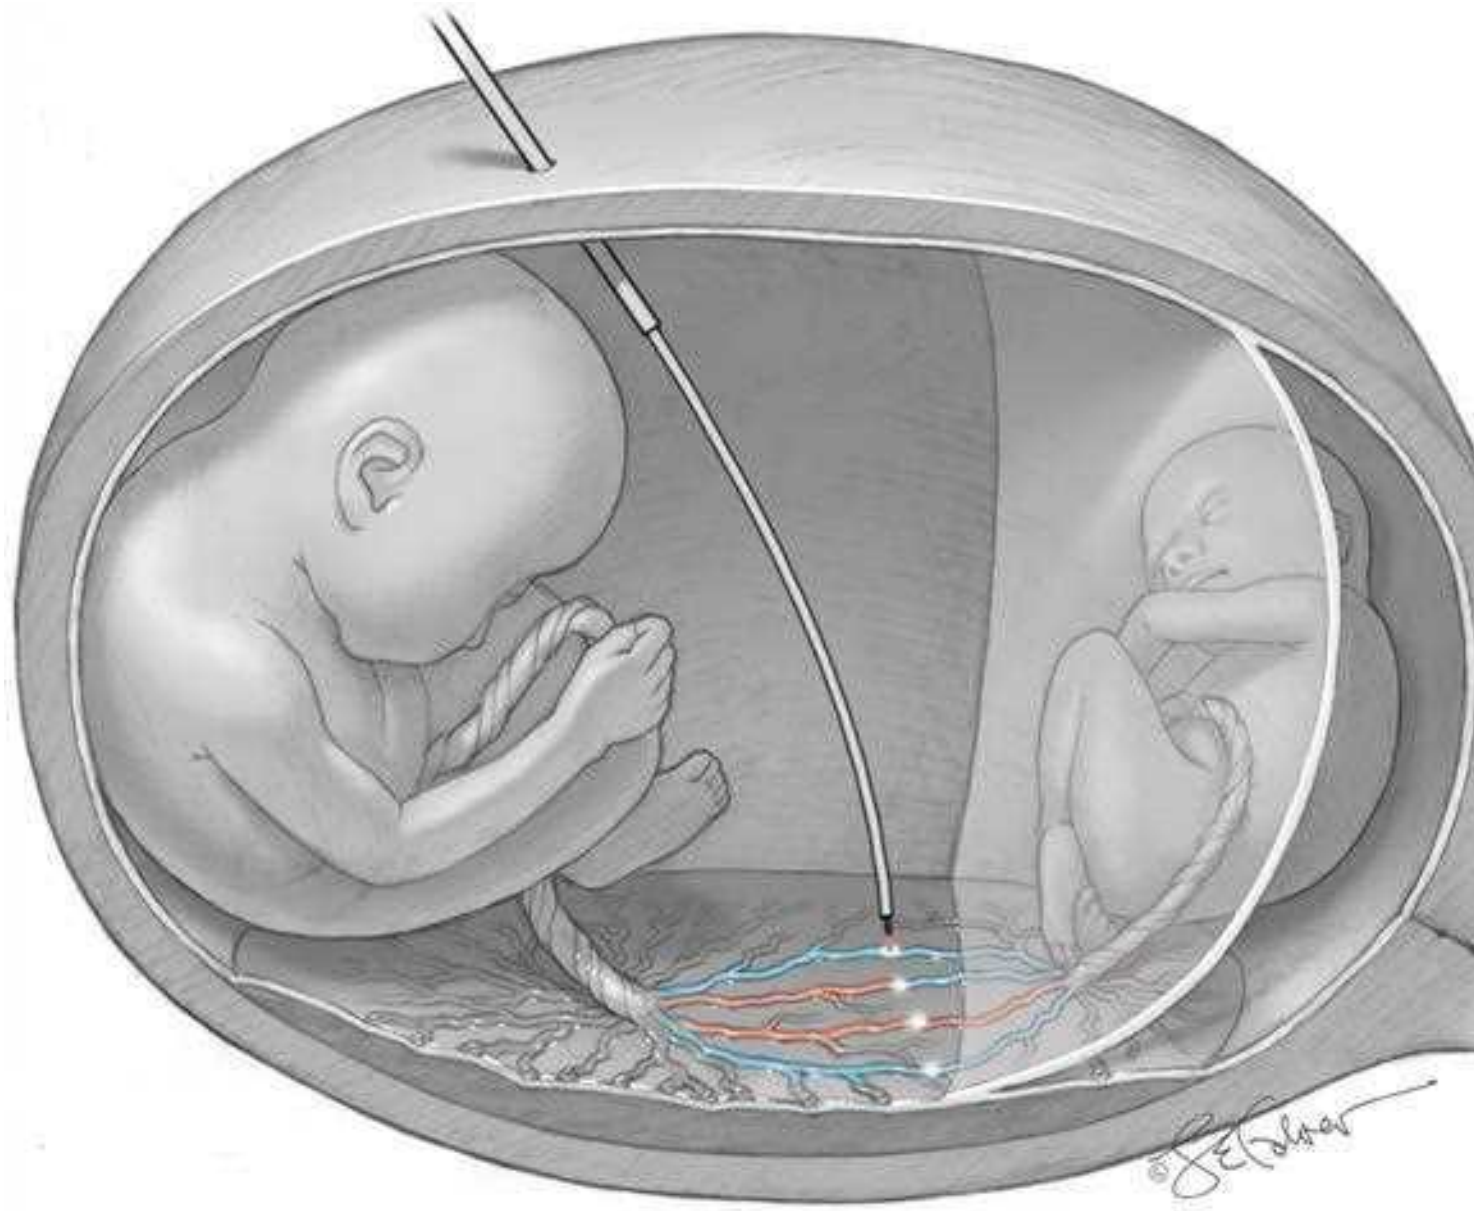


FIGURE 16-5

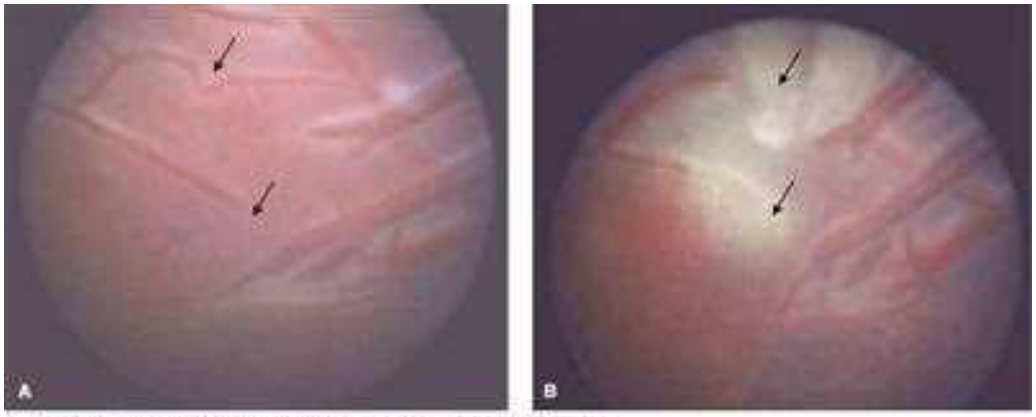
Fetoscopic photograph of laser photocoagulation for twin-twin transfusion syndrome. **A.** Vascular anastomoses (*arrows*) are shown before photocoagulation is performed. **B.** The ablation sites appear as blanched yellow-white areas (*arrows*). (Used with permission from Dr. Timothy M. Crombleholme.)



With *selective laser photocoagulation,* anastomoses crossing between the twins along the vascular equator are individually coagulated (Ville, 1995). Unfortunately, residual anastomoses remain in up to a third of cases and may lead to TTTS recurrence or to the development of twin-anemia polycythemia sequence (TAPS). The latter is a feto-fetal transfusion characterized by large differences in hemoglobin concentrations between a pair of monochorionic twins. To address these complications, the *Solomon technique* was developed. With this, after selective photocoagulation, the laser is used to coagulate the entire vascular equator, from one edge of the placenta to the other (Slaghekke, 2014a). The Solomon technique lowers the proportion of pregnancies with recurrent TTTS and TAPS in multiple trials. Also, placental dye-injection studies confirm a significant reduction in the number of residual anastomoses (Ruano, 2013; Slaghekke, 2014b).

Complications

Families should have reasonable expectations of procedural success and potential complications. Without treatment, the perinatal mortality rate for severe TTTS is 70 to 100 percent. Following laser therapy, the anticipated perinatal mortality rate approximates 30 to 50 percent, with a 5- to 20-percent risk for long-term neurological handicap (Society for Maternal-Fetal Medicine, 2013). Cystic periventricular leukomalacia and grade III to IV interventricular hemorrhage are identified neonatally in up to 10 percent of laser-treated cases (Lopriore, 2006).

Procedure-related complications include preterm prematurely ruptured membranes in up to 25 percent, placental abruption in 8 percent, vascular laceration in 3 percent, amnionic band syndrome resulting from laser laceration of the membranes in 3 percent, and TAPS in 16 percent with photocoagulation and 3 percent with the Solomon modification (Habli, 2009; Robyr, 2006; Slaghekke, 2014b). Finally, most laser-treated TTTS pregnancies deliver before 34 weeks.

Congenital Diaphragmatic Hernia

The prevalence of congenital diaphragmatic hernia (CDH) is approximately 1 in 3000 to 4000 births, and the overall survival rate is 50 to 60 percent. Associated anomalies occur in 40 percent of cases and confer a considerably lower survival rate. The main causes of mortality among those with isolated CDH are pulmonary hypoplasia and pulmonary hypertension. And, the major risk factor is liver herniation, which complicates at least half of cases and is associated with a 30-percent reduction in the survival rate (Mullassery, 2010, Oluyomi-Obi, 2017).

Because of maternal and fetal risks associated with fetal surgical intervention, efforts have focused on identifying those least likely to survive with postnatal therapy alone. Fetuses with associated anomalies are typically excluded, as are those without liver herniation. Prediction is further hampered because of improvements in neonatal care for newborns with CDH. These include permissive hypercapnia, “gentle ventilation” to avoid barotrauma, and delayed surgery.

Lung-to-Head Ratio

This sonographic ratio was developed to improve prediction of survival in fetuses with isolated left-sided CDH diagnosed before 25 weeks’ gestation (Metkus, 1996). The lung-to-head ratio (LHR) is a measurement of the right lung area, taken at the level of the four-chamber view of the heart, divided by the head circumference (Fig. 10-23). Investigators found that the survival rate was 100 percent if the LHR was >1.35, and there were no survivors if it was <0.6. Nearly three fourths of pregnancies had values between 0.6 and 1.35, and prediction was difficult in this large group because the overall survival rate approximated 60 percent (Metkus, 1996).

As of 2017, trials underway have selected a threshold LHR of <1.0 or an observed-to-expected LHR <25 percent for study inclusion. An observed LHR is obtained sonographically from the affected fetus, whereas the expected LHR is an established reference value from normal fetuses (Peralta, 2005). In a recent metaanalysis, the odds ratio for survival with an LHR <1.0 was only 0.14 (Oluyomi-Obi, 2017). Similarly, with an observed-to-expected LHR <25 percent, survival rates ranged from 13 to 30 percent. In contrast, an observed-to-expected LHR >35 percent was associated with survival rates ranging from 65 to 88 percent.

Magnetic Resonance Imaging

This has been used to estimate the total volume of lung tissue, both ipsilateral and contralateral to the diaphragmatic hernia, which may then be compared with a gestational age-matched reference. Mayer and coworkers (2011) performed a metaanalysis of 19 studies involving more than 600 pregnancies in which isolated CDH was evaluated with fetal MR imaging. Factors significantly associated with neonatal survival included the side of the defect, total fetal lung volume, observed-to-expected lung volume, and fetal liver position.

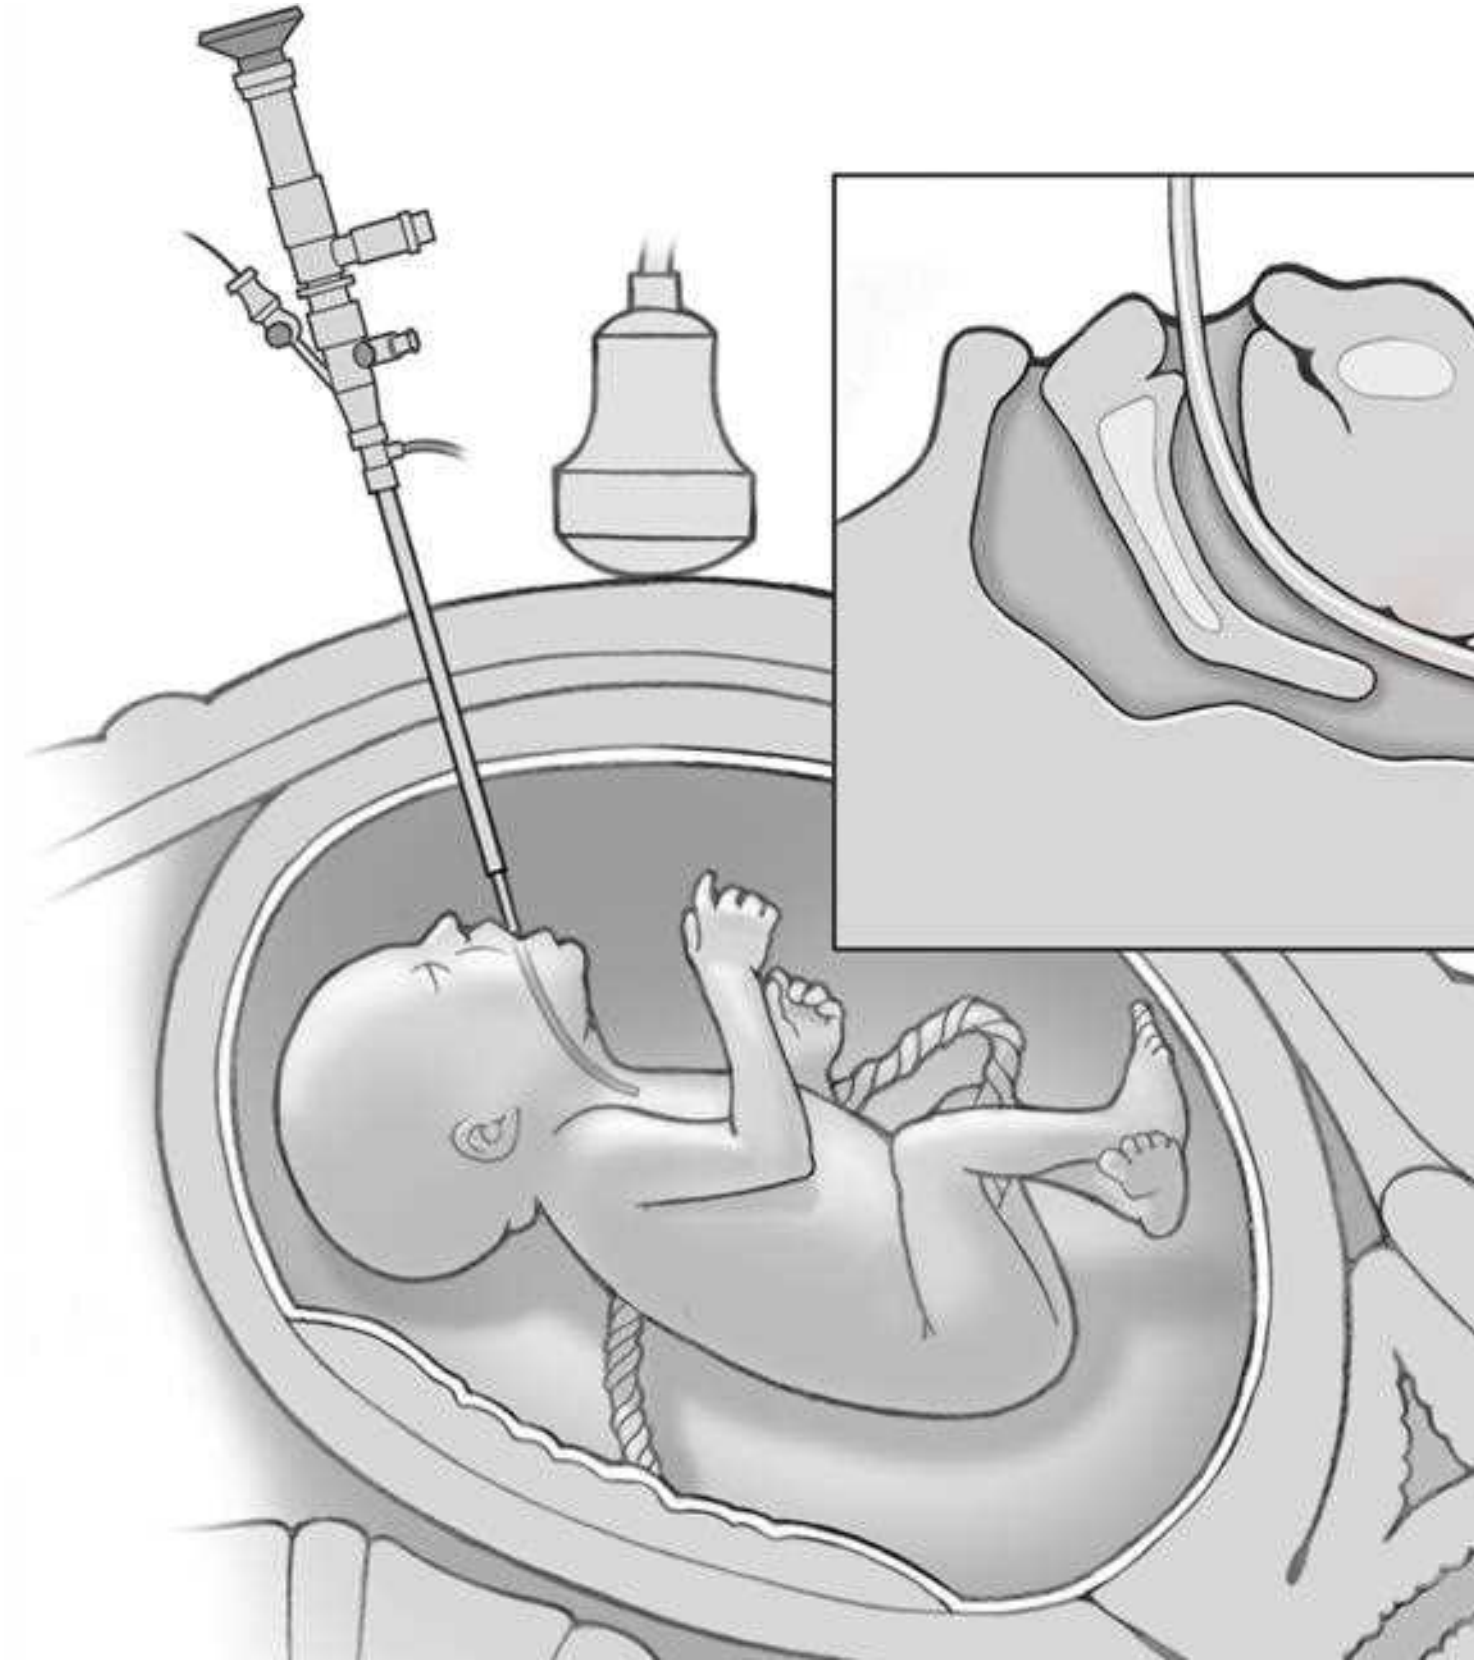
Fetal MR imaging has also been used to quantify the volume of herniated liver (Fig. 10-57). Two reasons underlie the rationale for assessing liver volume. First, liver herniation is perhaps the strongest predictor of outcome in fetuses with isolated CDH. Second, liver volume might be a more reliable predictor because lungs are inherently more compressible than liver. Indeed, these MR parameters—lung volumes and degree of liver herniation—correlate well with postnatal survival rates and may be more useful predictors than sonographic parameters (Bebbington, 2014; Ruano, 2014; Worley, 2009).

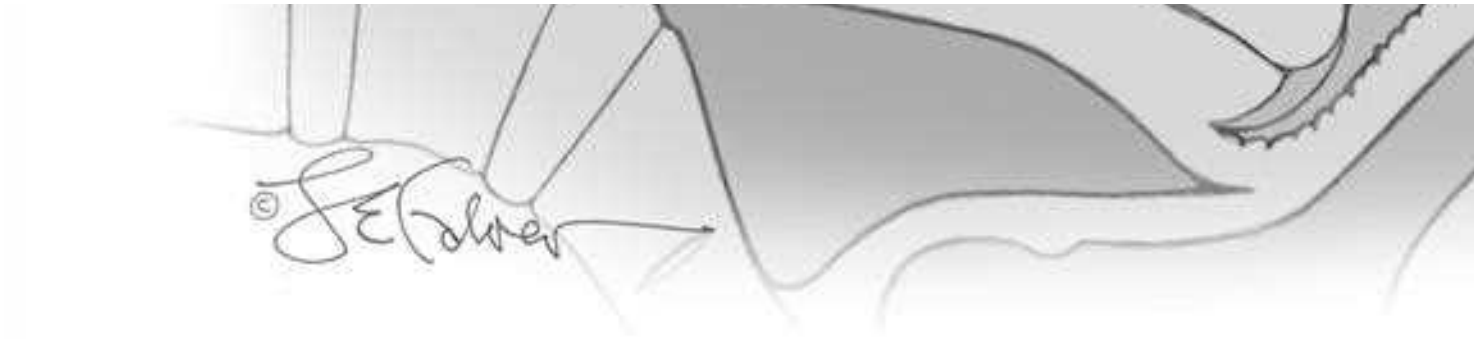
Tracheal Occlusion

Early attempts to treat severe diaphragmatic herniation used open fetal surgery to reposition the liver into the abdomen, which unfortunately kinked the umbilical vein and led to fetal demise (Harrison, 1993). Knowledge that lungs normally produce fluid and that fetuses with upper airway obstruction develop hyperplastic lungs formed the rationale for tracheal occlusion. The idea was to "plug the lung until it grows" (Hedrick, 1994). Initial efforts focused on occluding the trachea with an external clip (Harrison, 1993). Subsequently, a detachable silicone balloon was placed within the trachea endoscopically (Fig. 16-6).

FIGURE 16-6

Fetoscopic tracheal occlusion (FETO). The endoscope enters the fetal oropharynx and advances down the trachea. Inset: The balloon is inflated to occlude the trachea, and then the endoscope is removed. (Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)





The balloon technique—termed *fetal endoscopic tracheal occlusion (FETO)*—uses a 3-mm operating sheath and fetoscopes as small as 1 mm (Deprest, 2011; Ruano, 2012). The procedure is generally performed between 27 and 30 weeks' gestation, with the goal of removing the balloon at approximately 34 weeks, either through a second fetoscopic procedure or by ultrasound-guided puncture (Jiménez, 2017). If these are unsuccessful, the balloon is removed during an ex-utero intrapartum treatment procedure at delivery (Ex-Utero Intrapartum Treatment).

In 2003, a randomized trial of the FETO procedure in pregnancies with isolated CDH, liver herniation, and LHR <1.4 did not identify a benefit from fetal therapy (Harrison, 2003). Survival rates 90 days after birth were unexpectedly high in both groups and approximated 75 percent. Following this study, however, enthusiasm for the technique continued, particularly outside the United States. Using a lower LHR threshold of 1.0 in addition to liver herniation as prerequisites for inclusion, significantly higher postnatal survival rates have been reported. Rates improved from <25 percent with postnatal therapy to approximately 50 percent with FETO (Jani, 2009; Ruano, 2012). In a recent metaanalysis of five trials that included 211 pregnancies, those treated with FETO were 13 times more likely to survive (Al-Maary, 2016). At present, FETO is available in the United States only in research trials.

Endoscopic Myelomeningocele Repair

After publication of the MOMS findings, research efforts focused on whether maternal morbidities associated with open fetal myelomeningocele repair might be mitigated if the procedure was accomplished endoscopically. Araujo Junior and associates (2016) conducted a systematic review that included 456 open cases and 84 endoscopic surgeries. The endoscopic procedures were generally performed by inserting instruments through the maternal abdominal wall and then through the uterine wall, with partial carbon dioxide insufflation of the uterus. The rate of maternal myometrial dehiscence or attenuation was only 1 percent following endoscopy compared with 26 percent following open procedures. However, endoscopy was associated with significantly increased rates of preterm delivery before 34 weeks—80 versus 45 percent, and of perinatal mortality—14 versus 5 percent.

Belfort and colleagues (2017) recently described their outcomes in 22 pregnancies with fetal myelomeningocele using a technique in which the maternal abdomen was opened, the uterus exteriorized, and the procedure then performed endoscopically using warmed carbon dioxide insufflation. In contrast with earlier endoscopic reports, most treated pregnancies were delivered at term, with no perinatal losses. Further, the proportion of infants requiring hydrocephalus treatment prior to 1 year of age—approximately 40 percent—was similar to that with open fetal surgery in the MOMS trial (Adzick, 2011; Belfort, 2017). Research efforts in this area will undoubtedly continue.

Percutaneous Procedures

Sonographic guidance can be used to permit therapy with a shunt, radiofrequency ablation needle, or angioplasty catheter. With these procedures, desired instruments cross the maternal abdominal wall, uterine wall, and membranes to reach the amnionic cavity and fetus. Risks include maternal infection, preterm labor or prematurely ruptured membranes, and fetal injury or loss.

Thoracic Shunts

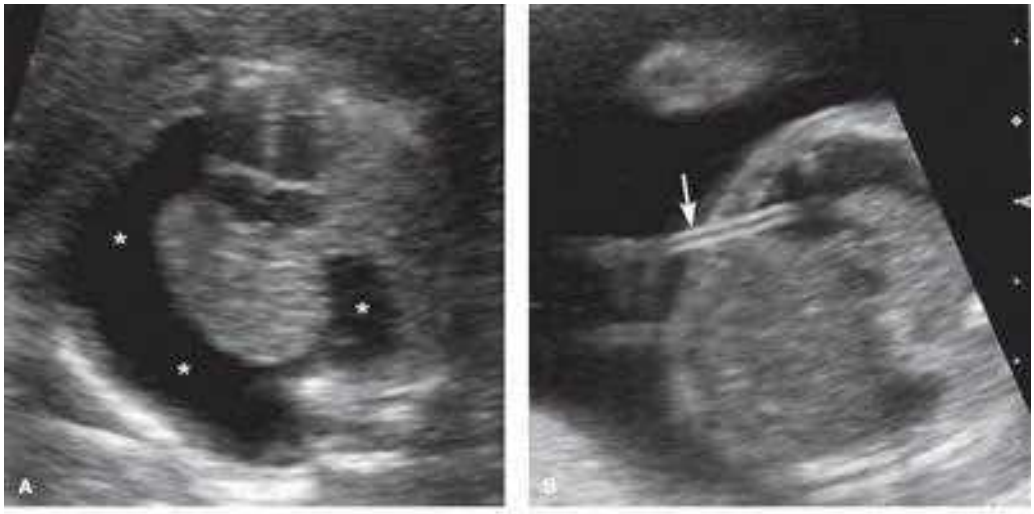
A shunt placed from the fetal pleural cavity into the amnionic cavity may be used to drain pleural fluid (Fig. 16-7). A large effusion may cause a significant mediastinal shift, resulting in pulmonary hypoplasia or in heart failure and hydrops. The most common etiology of a primary effusion is *chylothorax*—caused by lymphatic obstruction. Pleural effusions may also form secondary to congenital viral infection or aneuploidy, or they may be associated with a malformation such as *pulmonary sequestration.* Yinon and associates (2010) reported aneuploidy in approximately 5 percent and associated anomalies in 10 percent of cases.

Typically, the effusion is first drained using a 22-gauge needle with sonographic guidance. Tests for aneuploidy and infection are performed, as well as a cell count. A pleural-fluid cell count with greater than 80-percent lymphocytes, in the absence of infection, is diagnostic of chylothorax. If the fluid reaccumulates, a trocar and cannula may be inserted through the fetal chest wall, and a double-pigtail shunt may be placed to drain the effusion. If the effusion is right-sided, the shunt is placed in the lower third of the chest to permit maximum expansion of the lung. If left-sided, the shunt is placed along the upper axillary line to allow the heart to return to normal position (Mann, 2010). The overall survival rate is 70 percent, and that for hydropic fetuses approximates 50 percent (Mann, 2010; Yinon, 2010). Shunt displacement into the amnionic cavity is not uncommon. If the shunt remains in place, it must be clamped immediately upon delivery of the newborn to avoid pneumothorax.

FIGURE 16-7

Thoracoamnionic shunt placement. **A.** A large, right-sided fetal pleural effusion (*asterisks*) and ascites were identified at 18 weeks' gestation. The effusion was drained but rapidly reaccumulated. The xanthochromic fluid contained 95-percent lymphocytes, consistent with chylothorax. **B.** A double-pigtail shunt (*arrow*) was

inserted under ultrasound guidance. Following shunt placement, the effusion and ascites resolved.



Shunts can also drain a dominant cyst in fetuses with macrocystic *congenital cystic adenomatoid malformation*. However, cysts rarely are large enough to pose a risk for hydrops or pulmonary hypoplasia. Shunt placement may improve survival to 90 percent in the absence of hydrops and to more than 75 percent with hydrops (Litwinska, 2017).

Urinary Shunts

Vesicoamnionic shunts are used in selected fetuses with severe bladder-outlet obstruction in which diminished amnionic fluid portends a grim prognosis (Fig. 16-8). Distal obstruction of the urinary tract occurs more often in male fetuses. The most common etiology is *posterior urethral valves,* followed by *urethral atresia* and by *prune belly syndrome*, which is also called *Eagle-Barrett syndrome*. Sonographic findings include dilation of the bladder and proximal urethra, termed the “keyhole” sign, along with bladder wall thickening (Fig. 10-45). Associated oligohydramnios before midpregnancy leads to pulmonary hypoplasia. Unfortunately, postnatal renal function may be poor even when amnionic fluid volume is normal.

Evaluation includes a careful search for concurrent anomalies, which may coexist in 40 percent of cases, and for aneuploidy, which has been reported in 5 to 8 percent of cases (Hayden, 1988; Hobbins, 1984; Mann, 2010). Fetal urine sampled at vesicocentesis may be used to perform genetic studies. As with other structural fetal abnormalities, chromosomal microarray analysis is recommended. Because visualization may be limited due to lack of amnionic fluid, counseling should include the increased likelihood that associated anomalies may be missed sonographically.

Potential candidates are fetuses without other severe anomalies or genetic syndromes and without sonographic features that confer poor prognosis, for example, renal cortical cysts. Therapy is generally offered only if the fetus is male, because in females, the underlying anomaly tends to be even more severe. Serial bladder drainage—vesicocentesis—performed under sonographic guidance at approximately 48-hour intervals is used to evaluate fetal urine electrolyte and protein content. Fetal urine is normally hypotonic due to tubular resorption of sodium and chloride, whereas isotonic urine in the setting of obstruction suggests renal tubular damage. Serial assessment permits classification of the renal prognosis as good or poor and helps guide candidate selection (Table 16-4).

TABLE 16-4

Fetal Urinary Analyte Values with Bladder Outlet Obstruction

Analyte	Good Prognosis	Poor Prognosis
Sodium	<90 mmol/L	>100 mmol/L
Chloride	<80 mmol/L	>90 mmol/L
Calcium	<7 mg/dL	>8 mg/dL
Osmolality	<180 mmol/L	>200 mmol/L
β_2-Microglobulin	<6 mg/L	>10 mg/L
Total protein	<20 mg/dL	>40 mg/dL

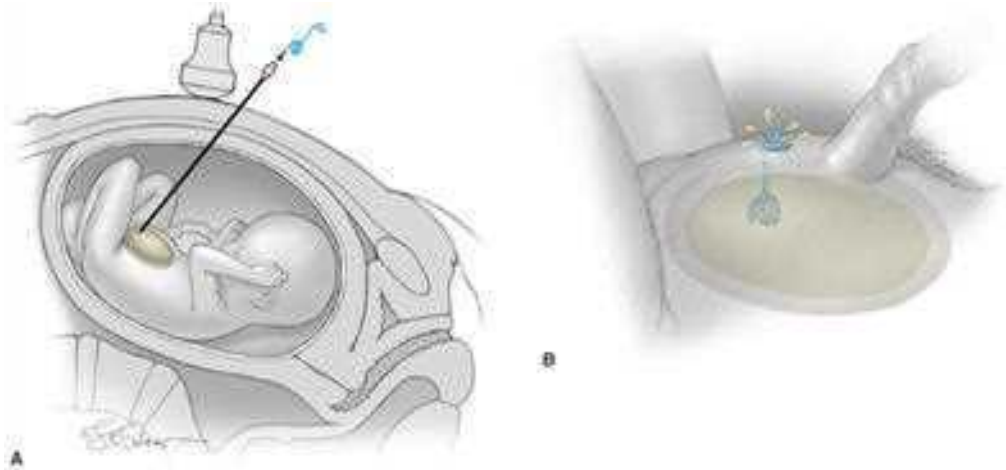
Good or poor prognosis is based on values from serial vesicocentesis performed between 18 and 22 weeks' gestation, using the last specimen obtained.

Data from Mann, 2010.

Shunt placement allows urine to drain from the bladder into the amnionic cavity. When successful, this often prevents pulmonary hypoplasia, however, renal function is not reliably preserved. Before shunting, amnioinfusion of warmed lactated Ringer solution is generally performed to aid catheter placement. Amnioinfusion also aids sonographic evaluation of fetal anatomy. A small trocar and cannula are then inserted into the fetal bladder under sonographic guidance. The shunt is placed as low as possible within the bladder to avoid dislodgement after bladder decompression. A double-pigtail catheter is used. The distal end lies within the fetal bladder, and the proximal end drains into the amnionic cavity.

FIGURE 16-8

Vesicoamnionic shunt placement. **A.** After amnioinfusion is performed, a trocar is inserted into the distended fetal bladder under sonographic guidance. The pigtail catheter is threaded into the trocar. **B.** The double-pigtail shunt has been deployed down the trocar, and the trocar has been removed. The distal end of the shunt is coiled within the fetal bladder, and the proximal end is draining into the amnionic cavity. (Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw-Hill Education, 2017.)



Complications include displacement of the shunt out of the fetal bladder in up to 40 percent of cases, urinary ascites in about 20 percent, and development of gastroschisis in 10 percent (Freedman, 2000; Mann, 2010). Preterm delivery is common, and neonatal survival rates range from 50 to 90 percent (Biard, 2005; Walsh, 2011). A third of surviving children have required dialysis or renal transplantation, and almost half have respiratory problems (Biard, 2005). In one randomized trial, vesicoamnionic shunt placement was compared with conservative management in 31 cases (Morris, 2013). Those receiving shunts had higher survival rates. However, only two children had normal renal function at age 2 years.

Radiofrequency Ablation

With this procedure, high-frequency alternating current is used to coagulate and desiccate tissue. Radiofrequency ablation (RFA) has become a favored modality for treatment of *twin-reversed arterial perfusion (TRAP) sequence,* also known as *acardiac twin* (Chap. 45, Twin Anemia–Polycythemia Sequence). Without treatment, the mortality rate for the normal or pump twin in severe TRAP sequence exceeds 50 percent. The procedure is also used for selective termination with other monochorionic twin complications (Bebbington, 2012).

Under sonographic guidance, a 17- to 19-gauge RFA needle is directed into the base of the umbilical cord of the acardiac twin and inserted into its abdomen. After a 2-cm area of coagulation is achieved, color Doppler sonography is applied to verify absent flow into the acardius. In several centers, survival rates for the normal twin following RFA have significantly improved (Lee, 2007; Livingston, 2007). RFA was performed at approximately 20 weeks' gestation in 98 pregnancies with TRAP sequence reported by the North American Fetal Therapy Network (NAFTNet). The median gestational age at delivery was 37 weeks, and the neonatal survival rate was 80 percent. The major complication was prematurely ruptured membranes and preterm birth. Twelve percent were delivered at approximately 26 weeks (Lee, 2013).

RFA has generally been offered for TRAP sequence when the volume of the acardiac twin is large. In the NAFTNet series cited above, the median size of the acardius relative to the pump twin was 90 percent (Lee, 2013). Considering procedure-related risks, expectant management with close fetal surveillance is instead considered if the estimated weight of the acardius is below 50 percent of the pump twin (Jelin, 2010). Finally, acardiac twins are more likely to complicate monoamnionic gestations. In one recent series, pump twin survival following RFA was 88 percent in monochorionic diamnionic pregnancies but only 67 percent in monoamnionic pregnancies (Sugibayashi, 2016).

Fetal Intracardiac Catheter Procedures

Selected fetal cardiac lesions may worsen during gestation, further complicating or even obviating options for postnatal repair. Severe narrowing of a cardiac outflow tract may result in progressive myocardial damage in utero, and a goal of fetal intervention is to permit muscle growth and preserve ventricular function (Walsh, 2011). These innovative procedures include *aortic valvuloplasty* for critical aortic stenosis; *atrial septostomy* for hypoplastic left heart syndrome with intact interatrial septum; and *pulmonary valvuloplasty* for pulmonary atresia with intact interventricular septum.

Fetal aortic valvuloplasty is the most commonly performed cardiac procedure, accounting for 75 percent of cases reported by the International Fetal Cardiac Intervention Registry (Moon-Grady, 2015). It is offered for selected cases of critical aortic stenosis in which the left ventricle is either normal sized or dilated. The goal is to prevent progression to hypoplastic left heart and to permit postnatal biventricular repair (McElhinney, 2009). Under sonographic guidance, an 18-gauge cannula is inserted through uterus and fetal chest wall and into the left ventricle. Although the procedure is ideally performed percutaneously—through the maternal abdominal wall—laparotomy may be needed if the fetal position is unfavorable. The cannula tip is positioned in front of the stenotic aortic valve, and a 2.5- to 4.5-mm balloon catheter is then guided into the aortic annulus and inflated. Fetal bradycardia requiring treatment complicates a third of cases, and hemopericardium requiring drainage affects approximately 20 percent (Moon-Grady, 2015).

From the first 100 cases at Boston Children's Hospital, 85 children survived, 38 of whom achieved biventricular circulation (Freud, 2014). Despite these successes, the mortality rate and risk for neurodevelopmental impairment in childhood appear to be similar to cases treated with postnatal repair (Laraja, 2017; Moon-Grady, 2015).

Fetal atrial septostomy, also using a percutaneous balloon catheter, is offered in select cases of hypoplastic left heart with an intact or highly restrictive interatrial septum. This condition has a postnatal mortality rate of nearly 80 percent (Glantz, 2007). In an effort to ensure patency, atrial septal stent placement has also been performed. Of 37 cases of atrial septostomy, survival to hospital discharge was almost 50 percent (Moon-Grady, 2015).

Fetal pulmonary valvuloplasty has been offered in cases of pulmonary atresia with intact interventricular septum to prevent development of hypoplastic right heart syndrome. Although success is achieved in approximately two thirds of cases, it is not yet clear whether outcomes are improved compared with standard postnatal repair (Arzt, 2011; McElhinney, 2010).

Ex-Utero Intrapartum Treatment

This procedure allows the fetus to remain perfused by the placenta after being partially delivered, so that lifesaving treatment can be performed before completing the delivery. The technique was first developed to obtain an airway with fetal tumors involving the oropharynx and neck (Catalano, 1992; Kelly, 1990; Langer, 1992). An ex-utero intrapartum treatment (EXIT) procedure is performed by a multidisciplinary team, which may include an obstetrician, maternal-fetal medicine specialist, pediatric surgeon(s), pediatric otolaryngologist, pediatric cardiologist, anesthesiologists for the mother and fetus, and neonatologists, as well as specially trained nursing personnel. Components of the procedure are shown in Table 16-5.

TABLE 16-5

Components of the Ex-Utero Intrapartum Treatment (EXIT) Procedure

Comprehensive preoperative evaluation: specialized sonography, fetal echocardiography, magnetic resonance imaging, fetal karyotype if possible
Uterine relaxation with deep general anesthesia and tocolysis
Intraoperative sonography to confirm placental margin and fetal position and to visualize vessels at uterine entry
Placement of stay-sutures followed by use of uterine stapling device to decrease uterine entry bleeding
Maintenance of uterine volume during the procedure via continuous amnioinfusion of warmed physiological solution to help prevent placental separation
Delivery of the fetal head, neck, and upper torso to permit access as needed
Fetal injection of intramuscular vecuronium, fentanyl, and atropine
Fetal peripheral intravenous access, pulse oximeter, and cardiac ultrasound
Following procedure, umbilical lines placed prior to cord clamping
Uterotonic agents administered as needed

Data from Moldenhauer, 2013.

Selected indications are listed in Table 16-2. EXIT is the preferred procedure for intrapartum management of large venolymphatic malformations of the neck such as the one shown in Figure 16-9. At the Children's Hospital of Philadelphia, criteria for EXIT with a cervical venolymphatic malformation include compression, deviation, or obstruction of the airway by the mass, and also involvement of the floor of the mouth (Laje, 2015). In a review of 112 pregnancies with fetal cervical venolymphatic malformations, only about 10 percent met these criteria. Other indications for EXIT include severe *micrognathia* and *congenital high airway obstruction sequence (CHAOS)*, which are discussed in Chapter 10 (Figs. 10-20 and 10-26). Criteria for an EXIT procedure for micrognathia include a fetal jaw measurement below the 5th percentile along with indirect evidence of obstruction, such as hydramnios, an absent stomach bubble, or glossoptosis (Morris, 2009b). Case selection for EXIT procedures is generally based on fetal MR imaging findings (Chap. 10, Adjunct to Fetal Therapy).

FIGURE 16-9

Ex-utero intrapartum treatment (EXIT) procedure for a venolymphatic malformation. **A.** Upon delivery of the head, placental circulation was maintained and an airway was established over the course of 20 minutes by a team of pediatric subspecialists that included a surgeon, anesthesiologist, and otolaryngologist. **B.** Following a controlled intubation, the fetus was ready for delivery and transfer to the neonatal intensive care unit team. (Used with permission from Drs. Stacey Thomas and Patricia Santiago-Muñoz.)

In some cases, an EXIT procedure has been used as a bridge to other procedures. For example, resection of large thoracic masses may be accomplished by fetal thoracotomy performed with intact placental circulation. In a series of 16 fetuses with CCAM volume ratios >1.6 or hydrops, all of whom had mediastinal compression, Cass and colleagues (2013) reported that nine infants undergoing *EXIT-to-resection* survived. In contrast, there were no survivors with urgent postnatal surgery alone. Similarly, Moldenhauer (2013) reported that 20 of 22 newborns treated with EXIT-to-resection for lung masses survived. The EXIT procedure has also been used as a bridge to extracorporeal membrane oxygenation—*EXIT-to-ECMO*—in pregnancies with severe congenital diaphragmatic hernia. However, it has not been found to clearly confer survival benefit in such cases (Morris, 2009a; Shieh, 2017; Stoffan, 2012).

Counseling prior to an EXIT procedure includes procedure-related risks such as hemorrhage from placental abruption or uterine atony, need for cesarean delivery in future pregnancies, higher risk for subsequent uterine rupture or dehiscence, possible need for hysterectomy, and fetal death or permanent neonatal disability. Compared with cesarean delivery, the EXIT procedure is associated with greater blood loss, a higher incidence of wound complications, and a longer operating time—approximately 40 minutes longer depending on the procedure (Noah, 2002).

CHAPTER 17: Fetal Assessment

> *The rate of the foetal heart is subject to considerable variations, which affords us a fairly reliable means of judging as to the well-being of the child. As a general rule, its life should be considered in danger when the heart-beats fall below 100 or exceed 160.*
>
> —J. Whitridge Williams (1903)

INTRODUCTION

More than 100 years ago, the approach to fetal assessment was rather primitive. Since that time, and especially since the 1970s, technology to evaluate the health of the fetus has advanced remarkably. Techniques employed today to forecast fetal well-being focus on fetal biophysical findings that include heart rate, movement, breathing, and amnionic fluid production. These findings aid antepartum fetal surveillance to prevent fetal death and avoid unnecessary interventions, which are stated goals of the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2017).

Most fetuses will be healthy, and usually a negative—that is, normal—antepartum test result is highly reassuring, because fetal deaths within 1 week of a normal test are rare. Indeed, negative-predictive values—a true negative test—for most of the tests described are 99.8 percent or higher. In contrast, estimates of the positive-predictive values—a true positive test—for abnormal test results are low and range between 10 and 40 percent. Importantly, fetal surveillance is primarily based on circumstantial evidence. No definitive randomized clinical trials have been conducted for obvious ethical reasons (American College of Obstetricians and Gynecologists, 2016).

FETAL MOVEMENTS

Physiology

Passive unstimulated fetal activity commences as early as 7 weeks' gestation and becomes more sophisticated and coordinated by the end of pregnancy (Sajapala, 2017; Vindla, 1995). Indeed, beyond 8 menstrual weeks, fetal body movements are never absent for periods exceeding 13 minutes (DeVries, 1985). Between 20 and 30 weeks' gestation, general body movements become organized, and the fetus starts to show rest-activity cycles (Sorokin, 1982). Fetal movement maturation continues until approximately 36 weeks, when behavioral states are established in most normal fetuses. Nijhuis and colleagues (1982) described four fetal behavioral states:

State 1F is a quiescent state—quiet sleep—with a narrow oscillatory bandwidth of the fetal heart rate.

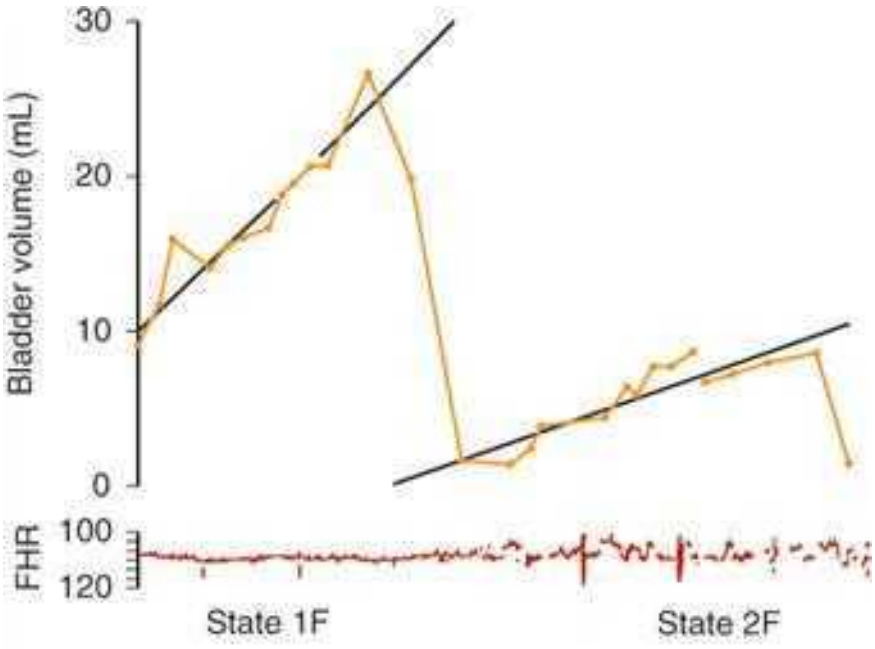
State 2F includes frequent gross body movements, continuous eye movements, and wider oscillation of the fetal heart rate. This state is analogous to rapid eye movement (REM) or active sleep in the neonate.

State 3F includes continuous eye movements in the absence of body movements and no heart rate accelerations. The existence of this state is disputed (Pillai, 1990a).

State 4F is one of vigorous body movement with continuous eye movements and heart rate accelerations. This state corresponds to the awake state in newborns.

Fetuses spend most of their time in states 1F and 2F. For example, at 38 weeks, 75 percent of time is spent in these two states. These behavioral states—particularly 1F and 2F, which correspond to quiet sleep and active sleep—have been used to develop an increasingly sophisticated understanding of fetal behavior. In a study of fetal urine production, bladder volumes increased during state 1F quiet sleep (Fig. 17-1). During state 2F, the fetal heart rate baseline bandwidth increased appreciably, and bladder volume was significantly diminished due to decreased urine production and infrequent fetal voiding. These phenomena were interpreted to represent reduced renal blood flow during active sleep.

FIGURE 17-1
Fetal bladder volume measurements together with fetal heart rate (FHR) variation recorded in relation to 1F or 2F behavior states. State 1F fetal heart rate has a narrow bandwidth consistent with quiet sleep. State 2F heart rate shows wide oscillation of the baseline consistent with active sleep. (Modified with permission from Oosterhof H, vd Stege JG, Lander M, et al: Urine production rate is related to behavioural states in the near term human fetus, Br J Obstet Gynaecol. 1993 Oct;100(10):920–922.)



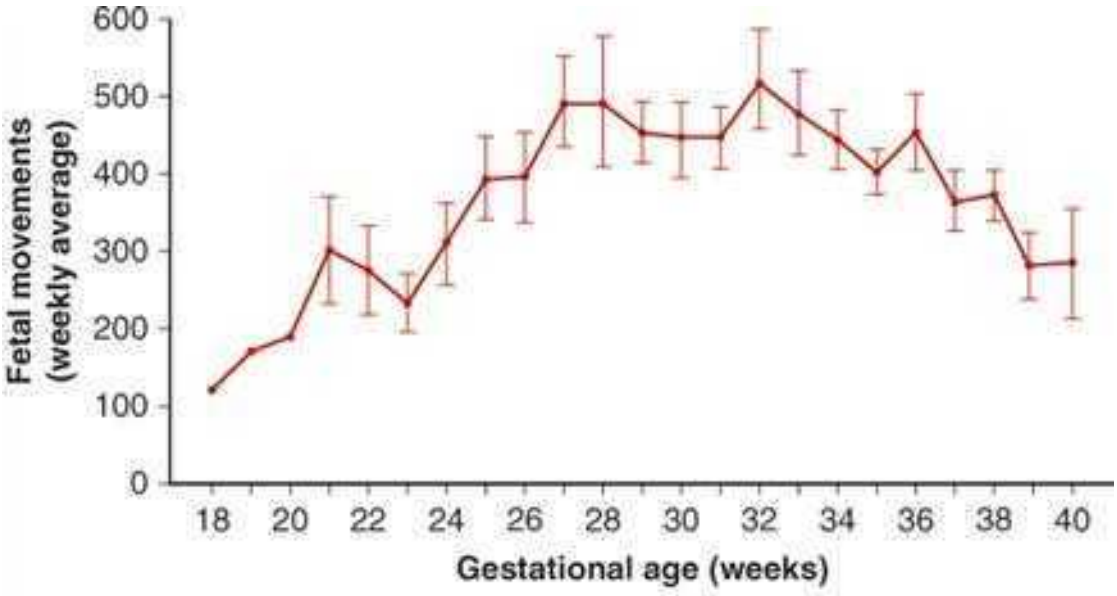
An important determinant of fetal activity appears to be sleep-awake cycles, which are independent of maternal ones. Fetal sleep cyclicity varies from approximately 20 minutes to as much as 75 minutes. In one study, the mean length of the quiet or inactive state for term fetuses was 23 minutes (Timor-Tritsch, 1978). Patrick and associates (1982) measured gross fetal body movements with real-time sonography for 24-hour periods in 31 normal pregnancies and found the longest period of inactivity to be 75 minutes. *Amnionic fluid volume* is another important determinant of fetal activity. Sherer and colleagues (1996) assessed the number of fetal movements in 465 pregnancies during biophysical profile testing in relation to amnionic fluid volume. They observed decreased fetal activity with diminished amnionic volumes and suggested that a restricted uterine space might physically limit fetal movements.

Sadovsky and coworkers (1979b) classified fetal movements into three categories according to both maternal perceptions and independent recordings using piezoelectric sensors. Weak, strong, and rolling movements were described, and their relative contributions to total weekly movements throughout the last half of pregnancy were quantified. As pregnancy advances, the rate of weak movements decreases, more vigorous movements increase for several weeks, and then rates of these subside at term. Presumably, declining amnionic fluid and space account for diminished activity at term. Figure 17-2

shows fetal movements during the last half of gestation in 127 pregnancies with normal outcomes. The mean number of weekly movements calculated from 12-hour daily recording periods rose from approximately 200 at 20 weeks' gestation to a maximum of 575 movements at 32 weeks. Fetal movements then declined to an average of 282 at 40 weeks. Normal weekly maternal counts of fetal movements ranged between 50 and 950. Count showed large daily variations, with included counts as low as 4 to 10 per 12-hour period in normal pregnancies.

FIGURE 17-2

Graph depicts averages of fetal movements counted during 12-hour periods (mean ± SEM). (Data from Sadovsky, 1979a.)



Clinical Application

Diminished fetal activity may be a harbinger of impending fetal death (Sadovsky, 1973). To quantify fetal movement, clinical methods include use of a uterine contraction tocodynamometer, visualization with sonography, and maternal subjective perceptions.

Most, but not all, investigators report excellent correlation between maternally perceived fetal motion and movements documented by instrumentation. For example, Rayburn (1980) found that 80 percent of all movements observed during sonographic monitoring were perceived by the mother. In contrast, Johnson and colleagues (1992) reported that beyond 36 weeks, mothers perceived only 16 percent of fetal body movements. Fetal motions lasting more than 20 seconds were more likely to be identified than shorter episodes. Although several fetal-movement counting protocols have been used, neither the optimal number of movements nor the ideal duration for counting them has been defined. For example, in one method, perception of 10 fetal movements in up to 2 hours is considered normal (Moore, 1989). Commonly, women may present in the third trimester complaining of subjectively reduced fetal movement. Harrington and associates (1998) reported that 7 percent of nearly 6800 women presented with a complaint of decreased fetal movement. Fetal heart rate monitoring tests were employed if sonographic scans for fetal growth or Doppler velocimetry were abnormal. Pregnancy outcomes for women who complained of decreased fetal movement were not significantly different from those for women without this complaint. Scala and colleagues (2015) reported that 6 percent of women at term reported decreased fetal movements at 36 weeks or more. Women with two or more episodes of reduced fetal movements had greater risks of growth-restricted newborns and abnormal Doppler uterine artery flow studies. However, stillbirth rates were not increased. Measurement of the myocardial performance index did not improve accuracy (Ho, 2017).

Grant and coworkers (1989) performed an unparalleled investigation of maternally perceived fetal movements and pregnancy outcome. More than 68,000 pregnancies were randomly assigned between 28 and 32 weeks' gestation. Women in the fetal movement arm of the study were instructed by specially employed midwives to record the time needed to feel 10 movements each day. This required an average of 2.7 hours each day. Women in the control group were informally asked about movements during prenatal visits. Reports of decreased fetal motion were evaluated with tests of fetal well-being. Antepartum death rates for otherwise normal singleton fetuses were similar in the two study groups. Despite the counting policy, most stillborn fetuses were dead by the time the mothers reported for medical attention. Importantly, rather than concluding that maternal perceptions of fetal activity were meaningless, these investigators concluded that informal maternal perceptions were as valuable as formally recorded fetal movement.

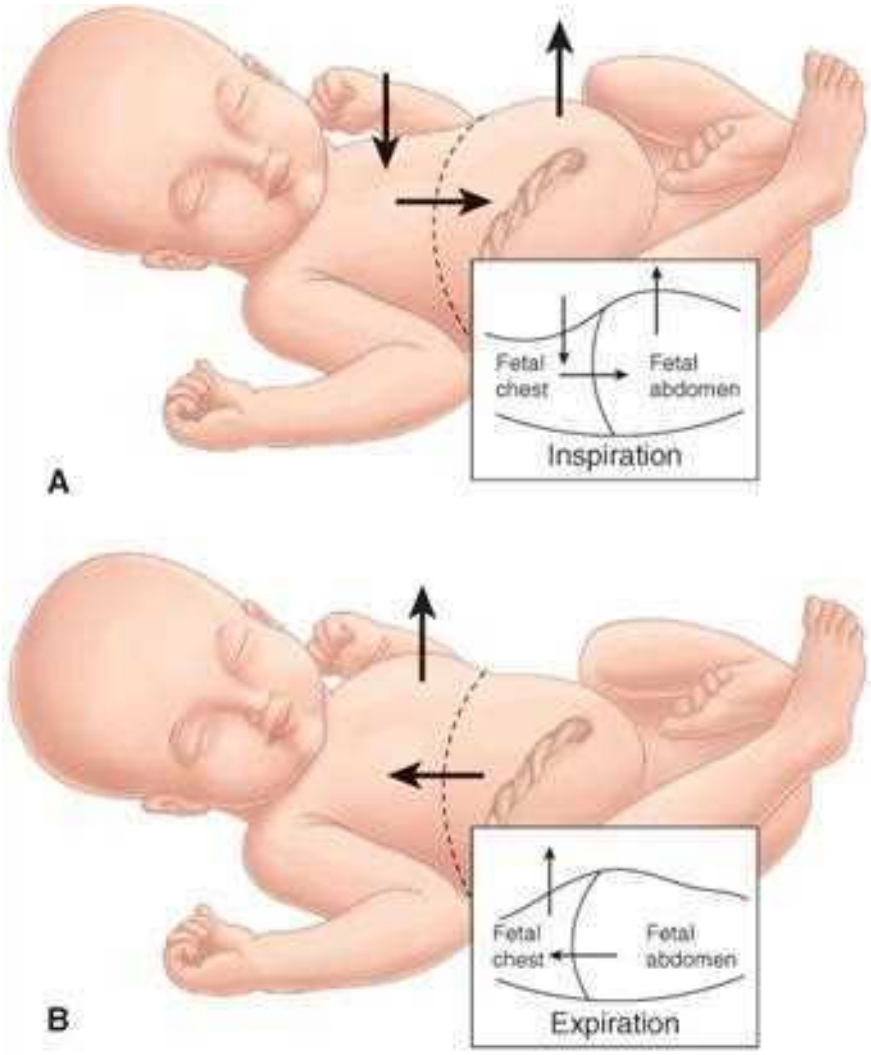
Saastad and associates (2011) reported a total of 1076 women who were randomly assigned to standardized fetal movement counting from gestational week 28 versus no counting. Growth-restricted fetuses were identified before birth significantly more often when fetal movement counting was used. The rate of 1-minute Apgar scores ≤3 was significant reduced (0.4 versus 2.3 percent) when counting was used. Also, Warrander and coworkers (2012) described placental pathology in pregnancies complicated by diminished fetal movements. Decreased movement was associated with various placental abnormalities including infarction.

FETAL BREATHING

After decades of uncertainty as to whether the fetus normally breathes, Dawes and coworkers (1972) showed small inward and outward flows of tracheal fluid in fetal sheep, indicating thoracic movement. These chest wall movements differed from those following birth in that they were discontinuous. Another interesting feature of fetal respiration was *paradoxical chest wall movement* (Fig. 17-3). In the newborn or adult, the opposite occurs. One interpretation of the paradoxical respiratory motion might be coughing to clear amnionic fluid debris. Although the physiological basis for the breathing reflex is not completely understood, such exchange of amnionic fluid appears to be essential for normal lung development (Chap. 7, Respiratory System). Dawes (1974) identified two types of respiratory movements. The first are *gasps* or *sighs,* which occurred at a frequency of 1 to 4 per minute. The second, *irregular bursts of breathing,* occurred at rates up to 240 cycles per minute. These latter rapid respiratory movements were associated with rapid eye movement. Badalian and associates (1993) studied the maturation of normal fetal breathing using color flow and spectral Doppler analysis of nasal fluid flow as an index of lung function. They suggested that fetal respiratory rate declined in conjunction with increased respiratory volume at 33 to 36 weeks and coincidental with lung maturation.

FIGURE 17-3

Paradoxical chest movement with fetal respiration. During inspiration **(A)**, the chest wall paradoxically *collapses* and the abdomen protrudes, whereas during expiration **(B)**, the chest wall *expands*. (Adapted from Johnson, 1988.)

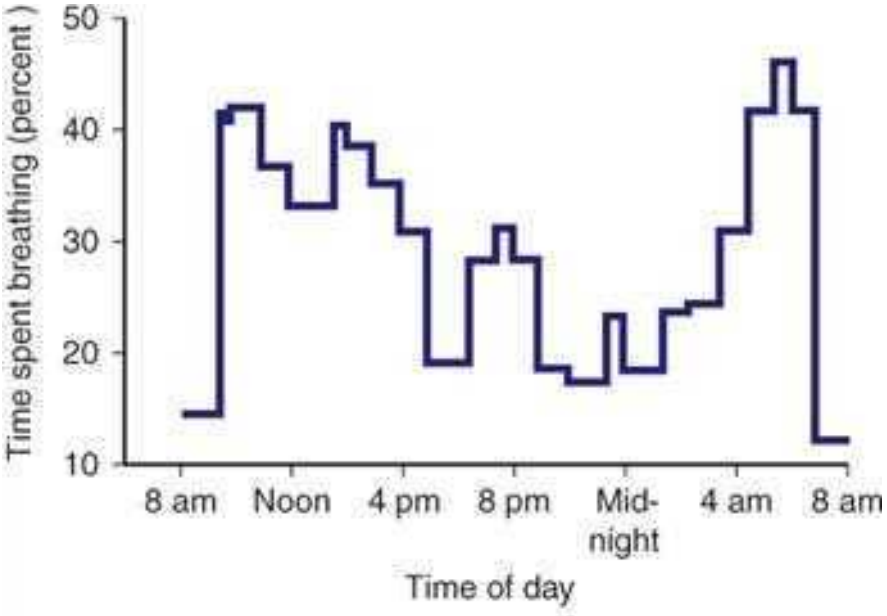


Many investigators have examined fetal breathing movements using sonography to determine whether chest wall movements might reflect fetal health. Several variables in addition to hypoxia were found to affect fetal respiratory movements. These included hypoglycemia, sound stimuli, cigarette smoking, amniocentesis, impending preterm labor, gestational age, the fetal heart rate itself, and labor—during which it is normal for respiration to cease.

Because fetal breathing movements are episodic, interpretation of fetal health when respirations are absent may be tenuous. Patrick and associates (1980) performed continuous 24-hour observation using sonography to characterize fetal breathing patterns during the last 10 weeks of pregnancy. A total of 1224 hours of fetal observation in 51 pregnancies were collected, and Figure 17-4 displays the percentages of time spent breathing near term. Clearly, there is diurnal variation, because breathing substantively diminishes during the night. In addition, breathing activity increases somewhat following maternal meals. Total absence of breathing was observed in some of these normal fetuses for up to 122 minutes, indicating that fetal evaluation to diagnose absent respiratory motion may require long periods of observation.

FIGURE 17-4

The percentage of time spent breathing by 11 fetuses at 38 to 39 weeks. There is a significant increase in fetal breathing activity after breakfast. Breathing activity diminished during the day and reached its minimum between 20:00 and 24:00 hours. There was a significant increase in the percentage of time spent breathing between 04:00 and 07:00 hours, when mothers were asleep. (Adapted with permission from Patrick J, Campbell K, Carmichael L, et al: Patterns of human fetal breathing during the last 10 weeks of pregnancy, Obstet Gynecol. 1980 Jul;56(1):24–30.)



The potential for breathing activity to be an important marker of fetal health is unfulfilled because of the multiplicity of factors that normally affect breathing. Most clinical applications have included assessment of other fetal biophysical indices, such as heart rate. As discussed subsequently, fetal breathing has become a component of the *biophysical profile.*

CONTRACTION STRESS TESTING

As amnionic fluid pressure rises with uterine contractions, myometrial pressure exceeds collapsing pressure for vessels coursing through uterine muscle. This ultimately lowers blood flow to the intervillous space. Brief periods of impaired oxygen exchange result, and if uteroplacental pathology is present, these elicit late fetal heart rate decelerations (Chap. 24, Late Deceleration). Contractions also may produce a pattern of variable decelerations as a result of cord compression, suggesting oligohydramnios, which is often a concomitant of placental insufficiency.

Ray and colleagues (1972) used this concept in 66 complicated pregnancies and developed the *oxytocin challenge test,* which was later called the *contraction stress test.* Intravenous oxytocin is used to stimulate contractions, and the criterion for a positive test result, that is, an abnormal result, is uniform repetitive late fetal heart rate decelerations. These reflected the uterine contraction waveform and had an onset at or beyond the contraction acme. Such late decelerations could be the result of uteroplacental insufficiency. In their study, the tests were generally repeated on a weekly basis, and the investigators concluded that negative contraction stress test results, that is, normal results, forecasted fetal health. A major disadvantage is that the average contraction stress test requires 90 minutes to complete.

To perform the test, the fetal heart rate and uterine contractions are recorded simultaneously with an external monitor. If at least three spontaneous contractions of 40 seconds or longer are present in 10 minutes, no uterine stimulation is necessary (American College of Obstetricians and Gynecologists, 2016). Contractions are induced with either oxytocin or nipple stimulation if there are fewer than three in 10 minutes. For oxytocin use, a dilute intravenous infusion is initiated at a rate of 0.5 mU/min and doubled every 20 minutes until a satisfactory contraction pattern is established (Freeman, 1975). The results of the contraction stress test are interpreted according to the criteria shown in Table 17-1.

Nipple stimulation to induce uterine contractions is usually successful for contraction stress testing (Huddleston, 1984). One method involves a woman rubbing one nipple through her clothing for 2 minutes or until a contraction begins. This 2-minute nipple stimulation ideally will induce a pattern of three contractions per 10 minutes. If not, after a 5-minute interval, she is instructed to retry nipple stimulation to achieve the desired pattern. If this is unsuccessful, then dilute oxytocin may be used.

Advantages include reduced cost and shortened testing times. Some have reported unpredictable uterine hyperstimulation and fetal distress, whereas others did not find excessive activity to be harmful (Frager, 1987; Schellpfeffer, 1985).

TABLE 17-1

Criteria for Interpretation of the Contraction Stress Test

Negative: no late or significant variable decelerations
Positive: late decelerations following 50% or more of contractions (even if the contraction frequency is fewer than three in 10 minutes)
Equivocal-suspicious: intermittent late decelerations or significant variable decelerations
Equivocal-hyperstimulatory: fetal heart rate decelerations that occur in the presence of contractions more frequent than every 2 minutes or lasting longer than 90 seconds
Unsatisfactory: fewer than three contractions in 10 minutes or an uninterpretable tracing

NONSTRESS TESTS

Freeman (1975) and Lee and colleagues (1975) introduced the *nonstress test* to describe fetal heart rate acceleration in response to fetal movement as a sign of fetal health. This test involved the use of Doppler-detected fetal heart rate acceleration coincident with fetal movements perceived by the mother. By the end of the 1970s, the nonstress test had become the primary method of testing fetal health. The nonstress test was easier to perform, and normal results were used to further discriminate false-positive contraction stress tests. Simplistically, the nonstress test is primarily a test of *fetal condition,* and it differs from the contraction stress test, which is considered a test of *uteroplacental function.* Currently, nonstress testing is the most widely used primary testing method for assessment of fetal well-being. It has also been incorporated into the biophysical profile testing system, subsequently discussed.

Fetal Heart Rate Acceleration

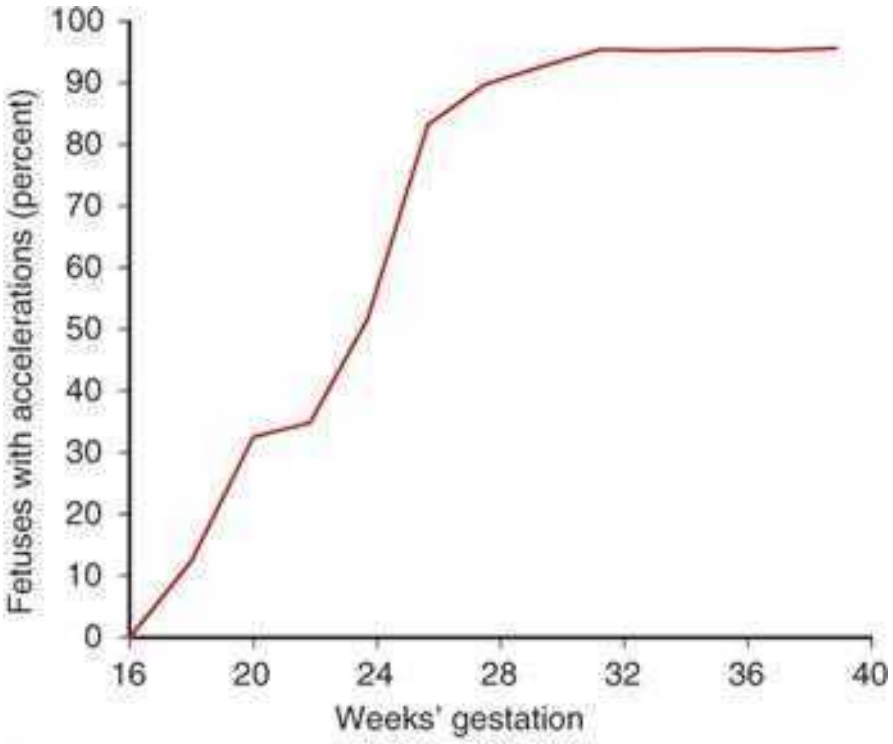
Autonomic influences are mediated by sympathetic or parasympathetic impulses from brainstem centers to normally raise or slow the fetal heart rate. *Beat-to-beat variability* is also under the control of the autonomic nervous system (Matsuura, 1996). Consequently, pathological loss of fetal heart rate acceleration may be seen in conjunction with significantly decreased beat-to-beat variability (Chap. 24, Cardiac Arrhythmia). Loss of such reactivity, however, is most commonly associated with sleep cycles. It also may be caused by central depression from medications or cigarette smoking (Jansson, 2005).

The nonstress test is based on the hypothesis that the heart rate of a fetus that is not acidemic as a result of hypoxia or neurological depression will temporarily accelerate in response to fetal movement. Fetal movements during testing are identified by maternal perception and recorded. As hypoxia develops, these fetal heart rate accelerations diminish (Smith, 1988).

Gestational age influences acceleration or reactivity of the fetal heart rate. Pillai and James (1990b) studied the development of fetal heart rate acceleration patterns during normal pregnancy. The percentage of body movements that is accompanied by accelerations and the amplitude of these accelerations both increase with gestational age (Fig. 17-5). Guinn and colleagues (1998) studied nonstress test results between 25 and 28 weeks' gestation in 188 normal fetuses. Only 70 percent of these normal fetuses demonstrated the required 15 beats per minute (bpm) or more of heart rate acceleration. Lesser degrees of acceleration, that is, 10 bpm, occurred in 90 percent of the fetuses.

FIGURE 17-5

Percentage of fetuses with at least one acceleration of 15 bpm sustained for 15 seconds concurrent with fetal movement. (Redrawn from Pillai M, James D: The development of fetal heart rate patterns during normal pregnancy, Obstet Gynecol. 1990 Nov;76(5 Pt 1):812–816.)



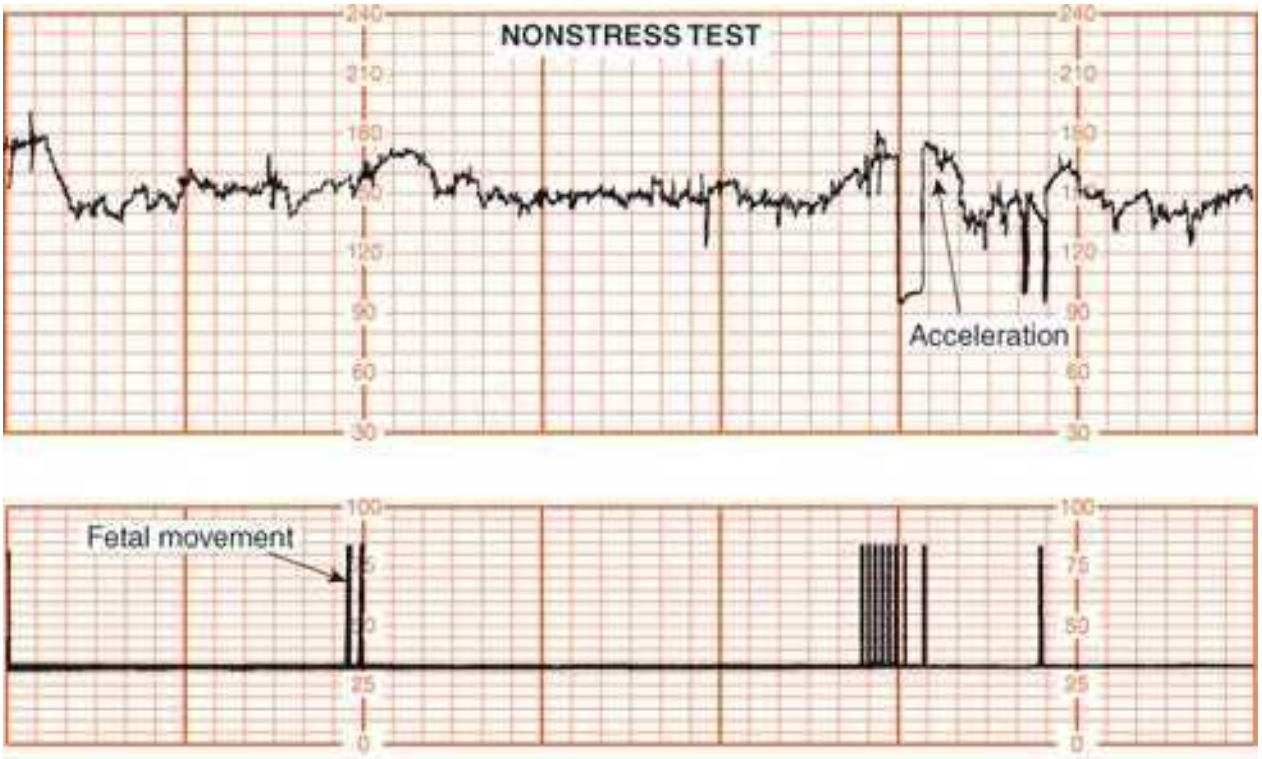
The National Institute of Child Health and Human Development Fetal Monitoring Workshop defined normal acceleration based on gestational age (Macones, 2008). In fetuses at or beyond 32 weeks' gestation, the acceleration acme is 15 bpm or more above the baseline rate, and the acceleration lasts 15 seconds or longer but less than 2 minutes. Before 32 weeks, normal accelerations are defined as having an acme that is 10 bpm or more above baseline for 10 seconds or longer. Cousins and associates (2012) compared the Workshop criteria recommended before 32 weeks, that is, 10 bpm/10 seconds, with standard 15 bpm/15 seconds criteria in a randomized trial of 143 women. They found no differences in perinatal outcomes.

Normal Nonstress Tests

Criteria to define normal nonstress test results differ. They vary regarding the number, amplitude, and duration of accelerations and the test duration. The definition recommended by the American College of Obstetricians and Gynecologists (2016) requires two or more accelerations peaking at 15 bpm or more above baseline, each lasting 15 seconds or more, and all occurring within 20 minutes of beginning the test (Fig. 17-6). It is also recommended that accelerations with or without fetal movements be accepted, and that a 40-minute or longer tracing—to account for fetal sleep cycles—should be performed before concluding that fetal reactivity is insufficient. Miller and coworkers (1996b) reviewed outcomes in fetuses with nonstress tests considered as nonreactive because there was only one acceleration. They concluded that one acceleration was just as reliable as two in predicting healthy fetal status.

FIGURE 17-6

Reactive nonstress test. In the upper panel, notice the increase of fetal heart rate by more than 15 beats/min for longer than 15 seconds following fetal movements, which are indicated by the vertical marks (*lower panel*).



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

Although a normal number and amplitude of accelerations seems to reflect fetal well-being, their absence does not invariably predict fetal compromise. Indeed, some investigators have reported 90-percent or higher false-positive rates (Devoe, 1986). Because healthy fetuses may not move for periods of up to 75 minutes, some have considered that a longer duration of nonstress testing might increase the positive-predictive value of an abnormal, that is, nonreactive, test (Brown, 1981). In this scheme, either the test became reactive during a period up to 80 minutes or the test remained nonreactive for 120 minutes, which indicated that the fetus was very ill.

Not only do definitions of normal nonstress test results differ, but the reproducibility of interpretations is problematic (Hage, 1985). Thus, although nonstress testing is popular, the reliability of test interpretation needs improvement.

Abnormal Nonstress Tests

Based on the foregoing, an abnormal nonstress test is not always ominous and can be seen with a sleeping fetus. Also, an abnormal test can revert to normal as the fetal condition changes, such as the example shown in Figure 17-7. Importantly, a normal nonstress test can become abnormal if the fetal condition deteriorates.

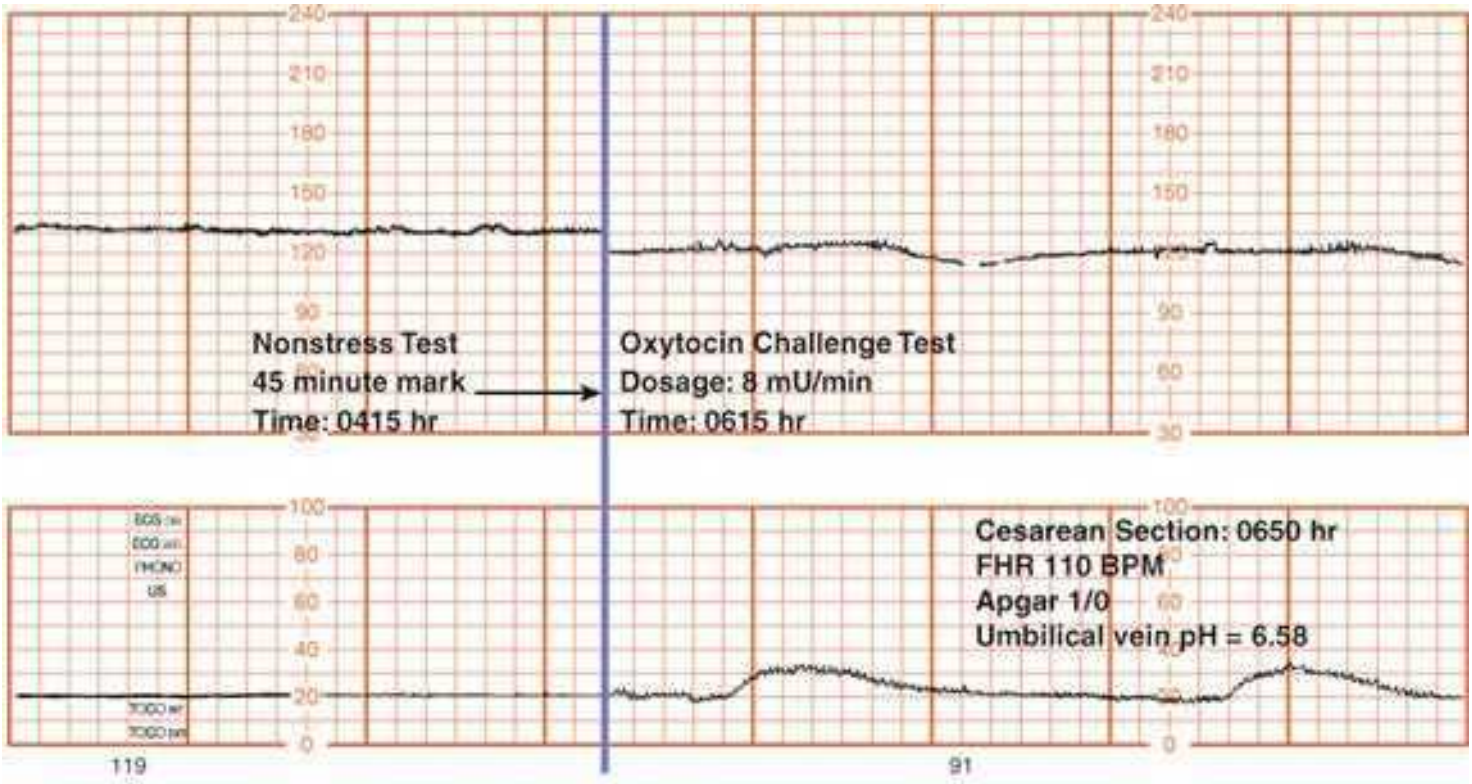
FIGURE 17-7
Two antepartum fetal heart rate (FHR) tracings in a 28-week pregnant woman with diabetic ketoacidosis. **A.** FHR tracing (*upper panel*) and accompanying contraction tracing (*second panel*). Tracing, obtained during maternal and fetal acidemia, shows absence of accelerations, diminished variability, and late decelerations with weak spontaneous contractions. **B.** Fetal heart rate tracing shows return of normal accelerations and variability of the fetal heart rate following correction of maternal acidemia.

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

There are abnormal patterns that reliably forecast severe fetal jeopardy (Fig. 17-8). Devoe and coworkers (1985) concluded that nonstress tests that were nonreactive for 90 minutes were almost invariably—93 percent—associated with significant perinatal pathology. Hammacher and coworkers (1968) described tracings with what they termed a *silent oscillatory pattern* that he considered dangerous. This pattern consisted of a fetal heart rate baseline that oscillated less than 5 bpm and presumably indicated absent acceleration and beat-to-beat variability.

FIGURE 17-8

Nonreactive nonstress test (*left side of tracing*) followed by contraction stress test showing mild, late decelerations (*right side of tracing*). Cesarean delivery was performed, and the severely acidemic fetus could not be resuscitated.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: *Williams Obstetrics*, 25th Edition

Visser and associates (1980) described a *terminal cardiotocogram,* which included: (1) baseline oscillation of less than 5 bpm, (2) absent accelerations, and (3) late decelerations with spontaneous uterine contractions. These results were similar to experiences from Parkland Hospital in which absence of accelerations during an 80-minute recording period in 27 fetuses was associated consistently with evidence of uteroplacental pathology (Leveno, 1983). The latter included fetal-growth restriction in 75 percent, oligohydramnios in 80 percent, fetal acidemia in 40 percent, meconium in 30 percent, and placental infarction in 93 percent.

Interval between Testing

Set originally rather arbitrarily at 7 days, the interval between tests appears to have been shortened as experience evolved with nonstress testing. According to the American College of Obstetricians and Gynecologists (2016), more frequent testing is advocated by some investigators for women with postterm pregnancy, multifetal gestation, pregestational diabetes, fetal-growth restriction, or pregnancy hypertension. In these circumstances, some investigators perform twice-weekly tests, with additional testing completed for maternal or fetal deterioration regardless of the time elapsed since the last test. Others perform nonstress tests daily or even more frequently, such as with severe preeclampsia remote from term.

Decelerations During Nonstress Testing

Fetal movements commonly produce heart rate decelerations. Timor-Tritsch and associates (1978) reported this during nonstress testing in half to two thirds of tracings, depending on the vigor of the fetal motion. This high incidence of decelerations inevitably makes interpretation of their significance problematic. Indeed, Meis and coworkers (1986) reported that variable fetal heart rate decelerations during nonstress tests were not a sign of fetal compromise. The American College of Obstetricians and Gynecologists (2016) has concluded that variable decelerations, if nonrepetitive and brief—less than 30 seconds—do not indicate fetal compromise or the need for obstetrical intervention. In contrast, repetitive variable decelerations—at least three in 20 minutes—even if mild, have been associated with a greater risk of cesarean delivery for

fetal distress. Decelerations lasting 1 minute or longer have been reported to have an even worse prognosis (Bourgeois, 1984; Druzin, 1981; Pazos, 1982).

Hoskins and associates (1991) attempted to refine interpretation of testing that shows variable decelerations by adding sonographic estimation of amnionic fluid volume. The incidence of cesarean delivery for intrapartum fetal distress progressively rose concurrently with the severity of variable decelerations and decline of amnionic fluid volume. Severe variable decelerations during a nonstress test plus an amnionic fluid index (AFI) ≤5 cm resulted in a 75-percent cesarean delivery rate. Fetal distress in labor, however, also frequently developed in those pregnancies with variable decelerations but with normal amounts of amnionic fluid. Similar results were reported by Grubb and Paul (1992).

False-Normal Nonstress Tests

Smith and associates (1987) performed a detailed analysis of the causes of fetal death within 7 days of normal nonstress tests. The most common indication for testing was postterm pregnancy. The mean interval between testing and death was 4 days, with a range of 1 to 7 days. The single most common autopsy finding was meconium aspiration, often associated with some type of umbilical cord abnormality. They concluded that an acute asphyxial insult had provoked fetal gasping. They also concluded that nonstress testing was inadequate to preclude such an acute asphyxial event and that other biophysical characteristics might be beneficial. Importantly, assessment of amnionic fluid volume was considered valuable. Other ascribed frequent causes of fetal death included intrauterine infection, abnormal cord position, malformations, and placental abruption.

ACOUSTIC STIMULATION TESTS

Loud external sounds have been used to startle the fetus and thereby provoke heart rate acceleration—an *acoustic stimulation nonstress test*. A commercially available acoustic stimulator is positioned on the maternal abdomen, and a stimulus of 1 to 2 seconds is applied (Eller, 1995). This may be repeated up to three times for up to 3 seconds (American College of Obstetricians and Gynecologists, 2016). A positive response is defined as the rapid appearance of a qualifying acceleration following stimulation (Devoe, 2008). In a randomized trial of 113 women undergoing nonstress testing, vibroacoustic stimulation shortened the average time of testing from 24 to 15 minutes (Perez-Delboy, 2002). Similar results were reported by Turitz and coworkers (2012). Laventhal and colleagues (2003) reported that fetal tachyarrhythmia could be provoked with vibroacoustic stimulation.

BIOPHYSICAL PROFILE

Manning and colleagues (1980) proposed the combined use of five fetal biophysical variables as a more accurate means of assessing fetal health than a single element. Typically, these tests require 30 to 60 minutes of examiner time. Shown in Table 17-2 are the five fetal biophysical components assessed: (1) heart rate acceleration, (2) breathing, (3) movements, (4) tone, and (5) amnionic fluid volume. Normal variables were assigned a score of 2 each, and abnormal variables were given a score of 0. Thus, the highest score possible for a normal fetus is 10. Maternal medications such as narcotics and sedatives can significantly lower the score (Kopecky, 2000). Ozkaya and associates (2012) found that biophysical test scores were higher if a test was performed in late evening—20:00 to 22:00 hours—compared with 08:00 to 10:00 hours.

TABLE 17-2

Components and Scores for the Biophysical Profile

Component	Score 2	Score 0
Nonstress test[a]	≥2 accelerations of ≥15 beats/min for ≥15 sec within 20–40 min	0 or 1 acceleration within 20–40 min
Fetal breathing	≥1 episode of rhythmic breathing lasting ≥30 sec within 30 min	<30 sec of breathing within 30 min
Fetal movement	≥3 discrete body or limb movements within 30 min	<3 discrete movements
Fetal tone	≥1 episode of extremity extension and subsequent return to flexion	0 extension/flexion events
Amnionic fluid volume[b]	A pocket of amnionic fluid that measures at least 2 cm in two planes perpendicular to each other (2 × 2 cm pocket)	Largest single vertical pocket ≤2 cm

[a]May be omitted if all four sonographic components are normal.

[b]Further evaluation warranted, regardless of biophysical composite score, if largest vertical amnionic fluid pocket ≤2 cm.

Manning and colleagues (1987) tested more than 19,000 pregnancies using the biophysical profile interpretation and management shown in Table 17-3. More than 97 percent of the pregnancies tested had normal test results. They reported a false-normal test rate—defined by an antepartum death of a structurally normal fetus—of approximately 1 per 1000. The most common identifiable causes of fetal death after a normal biophysical profile include fetomaternal hemorrhage, umbilical cord accidents, and placental abruption (Dayal, 1999).

TABLE 17-3

Interpretation of Biophysical Profile Score

Biophysical Profile Score	Interpretation	Recommended Management
10	Normal, nonasphyxiated fetus	No fetal indication for intervention; repeat test weekly except in diabetic patients and postterm pregnancy (twice weekly)
8/10 (Normal AFV)	Normal, nonasphyxiated fetus	No fetal indication for intervention; repeat testing per protocol
8/8 (NST not done)		
8/10 (Decreased AFV)	Chronic fetal asphyxia suspected	Deliver
6	Possible fetal asphyxia	If amnionic fluid volume abnormal, deliver
		If normal fluid at >36 weeks with favorable cervix, deliver
		If repeat test ≤6, deliver
		If repeat test >6, observe and repeat per protocol
4	Probable fetal asphyxia	Repeat testing same day; if biophysical profile score ≤6, deliver
0 to 2	Almost certain fetal asphyxia	Deliver

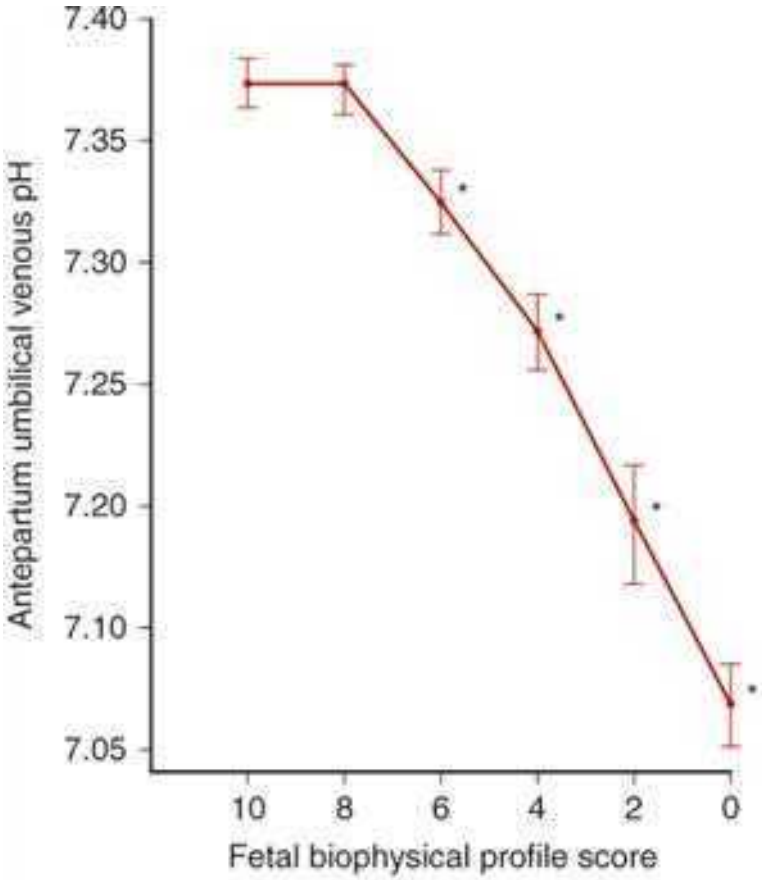
AFV = amnionic fluid volume; NST = nonstress test.

Reproduced with permission from Manning FA, Morrison I, Harman CR, et al: Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. II. An analysis of false-negative fetal deaths, Am J Obstet Gynecol. 1987 Oct;157(4 Pt 1):880–884.

Manning and coworkers (1993) published a remarkable description of 493 fetuses in which biophysical scores were performed immediately before measurement of umbilical venous blood pH values obtained via antepartum cordocentesis. Approximately 20 percent of tested fetuses had growth restriction, and the remainder had alloimmune hemolytic anemia. As shown in Figure 17-9, a biophysical score of 0 was almost invariably associated with significant fetal acidemia, whereas a normal score of 8 or 10 was associated with normal pH. An equivocal test result—a score of 6—was a poor predictor of abnormal outcome. As the abnormal score dropped from 2 or 4 down to 0, this decline was a more accurate predictor of abnormal fetal outcome. Thus overall, these scores provide poor sensitivity to predict cord blood pH.

FIGURE 17-9

Mean umbilical vein pH (±2 SD) obtained by cordocentesis in relation to fetal biophysical profile score category. (Data from Manning, 1993.)



Similar studies have substantiated these findings. Salvesen and associates (1993) concluded that the biophysical profile was of limited value in the prediction of fetal pH. Weiner and coworkers (1996) assessed 135 overtly growth-restricted fetuses and came to a similar conclusion. Kaur and colleagues (2008) performed daily biophysical profiles to ascertain the optimal delivery time in 48 growth-restricted preterm fetuses that weighed less than 1000 g. Despite scores of 8 in 27 fetuses and 6 in 13, there were six deaths and 21 acidemic fetuses. Lalor and associates (2008) performed a Cochrane review and concluded that there is insufficient evidence to support the use of the biophysical profile as a fetal well-being test in high-risk pregnancies.

Modified Biophysical Profile

Because the biophysical profile is labor intensive and requires a person trained in sonography, Clark and coworkers (1989) used an abbreviated biophysical profile as a first-line screening test in 2628 singleton pregnancies. Specifically, a vibroacoustic nonstress test was performed twice weekly and combined with AFI determination for which ≤5 cm was considered abnormal (Chap. 11, Oligohydramnios). This abbreviated biophysical profile required approximately 10 minutes to perform, and they concluded that it was a superb antepartum surveillance method because there were no unexpected fetal deaths.

Nageotte and colleagues (1994) also combined biweekly nonstress tests with the AFI and considered measures ≤5 cm to be abnormal. They performed 17,429 modified biophysical profiles in 2774 women and concluded that such testing was an excellent fetal surveillance tool. Miller and associates (1996a) reported results with more than 54,000 modified biophysical

profiles performed in 15,400 high-risk pregnancies. They described a false-negative rate of 0.8 per 1000 and a false-positive rate of 1.5 percent.

The American College of Obstetricians and Gynecologists (2016) has concluded that the modified biophysical profile test is as predictive of fetal well-being as other approaches to biophysical fetal surveillance.

AMNIONIC FLUID VOLUME

The importance of amnionic fluid volume estimation is indicated by its inclusion into virtually all schemes in which fetal health is assessed (Frøen, 2008). This is based on the rationale that diminished uteroplacental perfusion may lead to lower fetal renal blood flow, decreased urine production, and ultimately, oligohydramnios (Chap. 11, Pregnancy Outcomes). The American College of Obstetricians and Gynecologists (2016) concludes that data available from randomized trials indicate that the use of the deepest vertical pocket measurement, as opposed to the AFI, to diagnose oligohydramnios is associated with a reduction in unnecessary interventions without an increase in adverse perinatal outcomes (Nabhan, 2008; Reddy, 2014).

DOPPLER VELOCIMETRY

Blood flow velocity measured by Doppler ultrasound reflects downstream impedance (Chap. 10, Doppler). For growth-restricted fetuses, several fetal vascular circuits including the umbilical artery, middle cerebral artery, and ductus venosus have been evaluated as diagnostic tools for fetal well-being (Chap. 44, Prevention). Maternal uterine artery Doppler velocimetry has also been assessed as a modality to predict placental dysfunction, with the goal to balance stillbirth against the risks of preterm delivery (Ghidini, 2007). Even the effects of sildenafil in pregnant sheep have been evaluated using Doppler velocimetry (Alanne, 2017). The rationale is that sildenafil would improve placental blood flow in the presence of placental insufficiency. This proved untrue, as sildenafil was associated with detrimental effects on fetal cardiovascular dynamics.

Doppler Blood Flow Velocity

Waveforms were first studied in the umbilical arteries late in pregnancy, and abnormal waveforms correlated with placental villous hypovascularity. Of the small placental arterial channels, 60 to 70 percent need to be obliterated before the umbilical artery Doppler waveform becomes abnormal. Such extensive placental vascular pathology has a major effect on fetal circulation. According to Trudinger (2007), because more than 40 percent of the combined fetal ventricular output is directed to the placenta, obliteration of placental vascular channel increases afterload and leads to fetal hypoxemia. This in turn leads to ventricular dilation and redistribution of middle cerebral artery blood flow. Ultimately, pressure rises in the ductus venosus due to afterload in the right side of the fetal heart (Baschat, 2004). Clinically, abnormal Doppler waveforms in the ductus venosus are a late finding in the progression of fetal deterioration due to chronic hypoxemia.

Umbilical Artery Velocimetry

The umbilical artery systolic-diastolic (S/D) ratio is considered abnormal if it is >95th percentile for gestational age or if diastolic flow is either absent or reversed (Chap. 10, Doppler). Absent or reversed end-diastolic flow signifies greater impedance to umbilical artery blood flow (Fig. 44-8). It is reported to result from poorly vascularized placental villi and is seen in extreme cases of fetal-growth restriction (Todros, 1999). According to Zelop and colleagues (1996), the perinatal mortality rate for absent end-diastolic flow was about 10 percent, and for reversed end-diastolic flow, it approximated 33 percent.

Spinillo and associates (2005) studied neurodevelopmental outcome at 2 years of age in 266 growth-restricted fetuses delivered between 24 and 35 weeks' gestation. Of infants who had shown absent or reversed umbilical artery flow, 8 percent had evidence of cerebral palsy compared with 1 percent of those in whom Doppler flow had been normal.

Doppler ultrasound of the umbilical artery has been subjected to more extensive assessment with randomized controlled trials than has any previous test of fetal health. Williams and colleagues (2003) randomized 1360 high-risk women to either nonstress testing or Doppler velocimetry. They found a significantly higher incidence of cesarean delivery for fetal distress in the nonstress test group compared with that for those tested with Doppler velocimetry—8.7 versus 4.6 percent, respectively. One interpretation of this finding is that the nonstress test more frequently identified fetuses in jeopardy. Conversely, Gonzalez and associates (2007) found that abnormal umbilical artery Doppler findings in a cohort of growth-restricted fetuses were the best predictors of perinatal outcomes.

The utility of umbilical artery Doppler velocimetry was reviewed by the American College of Obstetricians and Gynecologists (2016). They concluded that no benefit has been demonstrated other than in pregnancies with suspected fetal-growth restriction. Similarly, velocimetry has not proved valuable as a screening test for fetal compromise in the general obstetrical population.

Various other fetal-maternal Doppler indices have been studied, including the fetal middle cerebral artery and ductus venosus and the uterine arteries. The American College of Obstetricians and Gynecologists (2016) concluded that Doppler investigations of other blood vessels besides the umbilical artery have not been shown to improve perinatal outcome.

Middle Cerebral Artery

As discussed, at this time, Doppler velocimetry interrogation of the middle cerebral artery (MCA) to detect fetal compromise is not recommended. Still, the technology has received particular attention because of observations that the hypoxic fetus attempts *brain sparing* by reducing cerebrovascular impedance and thus increasing blood flow. Such brain sparing in growth-restricted fetuses has been documented to undergo reversal (Konje, 2001). Investigators reported that 8 of 17 fetuses with this reversal died. Ott and coworkers (1998) randomized 665 women undergoing modified biophysical profile evaluation to either the profile alone or combined with middle cerebral and umbilical artery velocity flow assessment. Pregnancy outcomes between these two study groups did not differ significantly.

Middle cerebral artery Doppler velocimetry has proven valuable to detect severe fetal anemia in 165 fetuses with d-antigen alloimmunization. Oepkes and colleagues (2006) prospectively compared serial amniocentesis for measurement of bilirubin levels with Doppler measurement of peak systolic velocity in the middle cerebral artery. These investigators concluded that Doppler could safely replace amniocentesis in the management of alloimmunized pregnancies. And as discussed in Chapter 15 (Management of the Alloimmunized Pregnancy), this technique has been reported to be useful for detection and management of fetal anemia of any cause (Moise, 2008).

Ductus Venosus

Doppler ultrasound has also been used to assess the fetal venous circulation. Bilardo and colleagues (2004) prospectively studied umbilical artery and ductus venosus Doppler velocimetry in 70 growth-restricted fetuses at 26 to 33 weeks' gestation. They concluded that ductus venosus velocimetry was the best predictor of perinatal outcome. Importantly, negative or reversed flow in the ductus venosus was a late finding because these fetuses had already sustained irreversible multiorgan damage due to hypoxemia. Also, gestational age at delivery was a major determinant of perinatal outcome independent of ductus venosus flow. Specifically, 36 percent of growth-restricted fetuses delivered between 26 and 29 weeks' gestation succumbed compared with only 5 percent delivered from 30 to 33 weeks.

Baschat and coworkers (2007) studied 604 growth-restricted fetuses using umbilical artery, middle cerebral artery, and ductus venosus Doppler velocimetry and reached similar conclusions. Specifically, absent or reversed flow in the ductus venosus was associated with profound generalized fetal metabolic collapse. They too reported that gestational age was a powerful cofactor in ultimate perinatal outcome for growth-restricted fetuses delivered before 30 weeks. Put another way, by the time severely abnormal flow is seen in the ductus venosus, it is too late because the fetus is already near death. Conversely, earlier delivery puts the fetus at risk for death due to preterm delivery. Ghidini (2007) concluded that these reports do not support routine use of ductus venosus Doppler in the monitoring of growth-restricted fetuses and recommended further study.

Uterine Artery

Vascular resistance in the uterine circulation normally decreases in the first half of pregnancy due to invasion of maternal uterine vessels by trophoblastic tissue (Chap. 5, Endometrial Cycle). This process can be detected using Doppler flow velocimetry, and uterine artery Doppler may be most helpful in assessing pregnancies at high risk of uteroplacental insufficiency (Abramowicz, 2008). Persistence or development of high-resistance patterns has been linked to various pregnancy complications (Lees, 2001; Yu, 2005). In a study of 30,519 unselected British women, Smith and colleagues (2007) assessed uterine artery velocimetry at 22 to 24 weeks' gestation. The risk of fetal death before 32 weeks, when associated with abruption, preeclampsia, or fetal-growth restriction, was significantly linked to high-resistance flow. This has led to suggestions for continued research of uterine artery Doppler velocimetry as a screening tool to detect pregnancies at risk for stillbirth (Reddy, 2008). Sciscione and Hayes (2009) reviewed the use of uterine artery Doppler flow studies in obstetrical practice. Because standards for the study technique and criteria for an abnormal test are lacking, they noted that uterine artery Doppler studies should not be considered standard practice in either low- or high-risk populations.

ANTENATAL TESTING SUMMARY

Antenatal forecasts of fetal health have clearly been the focus of intense interest, and several themes emerge. First, despite a continuous evolution of testing options, the precision or efficacy of any given method is limited. Second, the wide range of normal biological fetal variation makes interpretation of test results challenging. Last, despite the invention of increasingly complex testing methods, abnormal results are seldom reliable, prompting many clinicians to use antenatal testing to forecast fetal *wellness* rather than *illness.*

Platt and coworkers (1987) reviewed the efficacy of antenatal testing between 1971 and 1985 at Los Angeles County Hospital. During this 15-year period, more than 200,000 pregnancies were managed, and nearly 17,000 of these women underwent antepartum testing of various types. Fetal surveillance rose from <1 percent of pregnancies in the early 1970s to 15 percent in the mid-1980s. These authors concluded that such testing was clearly beneficial because the fetal death rate was significantly less in the tested high-risk pregnancies compared with the rate in those not tested. The study, however, did not consider other innovations incorporated into practice during those 15 years. Preliminary results from Ghana suggest that nonstress testing may be beneficial in low-resource countries (Lawrence, 2016). In an observational study of 316 pregnancies complicated by gestational hypertension, women undergoing nonstress testing had a nonsignificant decreased risk for stillbirth compared with those not tested—3.6 versus 9.2 percent, respectively.

The benefits of antenatal fetal testing have not been sufficiently evaluated in randomized controlled trials according to Thacker and Berkelman (1986). This was concluded after reviewing 600 reports, which included only four randomized trials that were not powered to permit detection of important benefits. From their review, Enkin and colleagues (2000) concluded that "despite their widespread use, most tests of fetal well-being should be considered of experimental value only rather than validated clinical tools."

Another important and unanswered question is whether antepartum fetal surveillance identifies fetal asphyxia early enough to prevent brain damage. Manning and coworkers (1998) studied the incidence of cerebral palsy in 26,290 high-risk pregnancies managed with serial biophysical profile testing. These outcomes were compared with those of 58,657 low-risk pregnancies in which antepartum testing was not performed. The rate of cerebral palsy was 1.3 per 1000 in tested pregnancies compared with 4.7 per 1000 in untested women. Todd and coworkers (1992) attempted to correlate cognitive development in infants up to age 2 years following either abnormal umbilical artery Doppler velocimetry or nonstress test results. Only abnormal nonstress tests were associated with marginally poorer cognitive outcomes. These investigators concluded that by the time fetal compromise is diagnosed with antenatal testing, fetal damage has already been sustained. Low and associates (2003) reached a similar conclusion.

According to the American College of Obstetricians and Gynecologists (2016), a *normal* antepartum fetal test result is highly reassuring that a stillbirth will not occur within 1 week. This conclusion was reached after an analysis of reports of stillbirth rates associated with the various antepartum fetal heart rate tests (Table 17-4). Note that these results are corrected to remove lethal anomalies and unpredictable catastrophes such as placental abruption or cord accidents. The most important consideration in deciding when to begin antepartum testing is the prognosis for neonatal survival.

The severity of maternal disease is another. In general, with most high-risk pregnancies, testing begins by 32 to 34 weeks' gestation. Pregnancies with severe complications might require testing as early as 26 to 28 weeks. The frequency for repeating tests has been arbitrarily set at 7 days, but more frequent testing is often done.

TABLE 17-4

Stillbirth Rates within 1 Week of a Normal Antepartum Fetal Surveillance Test

Antepartum Fetal Test	Stillbirth[a] Rate/1000	Number
Nonstress test	1.9	5861
Contraction stress test	0.3	12,656
Biophysical profile	0.8	44,828
Modified biophysical profile	0.8	54,617

[a]Corrected for lethal anomalies and unpredictable causes of fetal death such as abruption or cord accident.

CHAPTER 18: Abortion

In the early months of pregnancy spontaneous expulsion of the ovum is nearly always preceded by the death of the foetus. For this reason the consideration of the aetiology of abortion practically resolves itself into determining the cause of foetal death. In the later months, on the other hand, the foetus is frequently born alive, and other factors must be looked for to explain its expulsion.

—J. Whitridge Williams (1903)

INTRODUCTION

In early pregnancy, miscarriage is a common event. Most early losses stem from genetic abnormalities or yet unidentified reasons. Thus, the opportunity for prevention is currently small. Women with later miscarriage or with recurrent miscarriage more likely have a repetitive cause that may be modified. In contrast to these spontaneous losses, pregnancy termination may be elected. For both induced abortion and miscarriage, management has evolved to include surgical or medical options, and providers should have an understanding of these techniques and their potential complications.

NOMENCLATURE

Abortion is defined as the spontaneous or induced termination of pregnancy before fetal viability. It thus is appropriate that miscarriage and abortion are terms used interchangeably. However, popular use of *abortion* by laypersons implies intended pregnancy termination, and many prefer *miscarriage* for spontaneous loss. In contrast, *induced abortion* describes surgical or medical termination of a live fetus that has not reached viability.

Terms used to define fetal viability and thus an abortus vary among authoritative organizations. The National Center for Health Statistics, the Centers for Disease Control and Prevention, and the World Health Organization all define *abortion* as pregnancy termination or loss before 20 weeks' gestation or with a fetus delivered weighing <500 g. These criteria, however, are somewhat contradictory because the mean birthweight of a 20-week fetus is 320 g, whereas 500 g is the mean for 22 to 23 weeks (Moore, 1977). Further confusion may derive from criteria set by state laws that define abortion even more widely.

Technological developments have added to current abortion terminology. For example, precise measurement of serum human chorionic gonadotropin (hCG) concentrations can identify extremely early pregnancies. Also, transvaginal sonography allows greater inspection of failed pregnancies, but recommendations vary as to terms for: (1) early conceptions in which no products are seen sonographically, (2) pregnancies that display a gestational sac but no embryo, and (3) those in which a dead embryo is seen (Kolte, 2015; Silver, 2011). Further, incongruity exists for the term *early pregnancy loss* itself. Currently, the American College of Obstetricians and Gynecologists (2017c) defines this as a nonviable, intrauterine pregnancy (IUP) with either an empty gestational sac or a gestational sac containing an embryo or fetus without fetal heart activity within the first $12^{6/7}$ weeks of gestation. Of other clinical terms, *spontaneous abortion* includes threatened, inevitable, incomplete, complete, and missed abortion. Septic abortion is used to further classify any of these that are complicated further by infection. *Recurrent pregnancy loss* is variably defined but is meant to identify women with repetitive miscarriage.

Other definitions help distinguish intrauterine from ectopic gestations. The term *pregnancy of unknown location (PUL)* describes a pregnancy identified by hCG testing but without a confirmed sonographic location. In this context, five categories are proposed for early pregnancies: definite ectopic pregnancy, probable ectopic, PUL, probable IUP, and definite IUP (Barnhart, 2011). Diagnostic and management options for ectopic gestation are described in Chapter 19 (Multimodality Diagnosis).

FIRST-TRIMESTER SPONTANEOUS ABORTION

Pathogenesis

More than 80 percent of spontaneous abortions occur within the first 12 weeks of gestation. With first-trimester losses, demise of the embryo or fetus nearly always precedes spontaneous expulsion. Death is usually accompanied by hemorrhage into the decidua basalis. This is followed by adjacent tissue necrosis that stimulates uterine contractions and expulsion. An intact gestational sac is usually filled with fluid. An *anembryonic miscarriage* contains no identifiable embryonic elements. Less accurately, the term blighted ovum may be used (Silver, 2011). The others are *embryonic miscarriages*, which often display a developmental abnormality of the embryo, fetus, yolk sac, and, at times, the placenta. In contrast, in later pregnancy losses, the fetus usually does not die before expulsion, and other sources for abortion are sought.

Incidence

Rates for miscarriage vary according to the study population. In pregnancies aged 5 to 20 weeks' gestation, the incidence ranges from 11 to 22 percent and is higher in earlier weeks (Ammon Avalos, 2012). To evaluate rates starting at conception, Wilcox and colleagues (1988) studied 221 healthy women trying to conceive through 707 menstrual cycles and found a miscarriage rate of 31 percent. This study found that two thirds of these losses are early and *clinically silent*. Currently, certain factors are known to influence *clinically apparent* miscarriage. However, it is unknown if these same factors also affect clinically silent pregnancy loss.

Fetal Factors

Of all miscarriages, approximately half are *euploid abortions,* that is, carrying a normal chromosomal complement. The other half has a chromosomal abnormality. Initially determined by tissue karyotyping, this percentage appears to persist even when implementing newer cytogenetic techniques (Jenderny, 2014). Notably, the American College of Obstetricians and Gynecologists (2016d) does not recommend routine use of chromosomal microarray testing of first-trimester fetal tissues. However, these organizations, and the American Society for Reproductive Medicine (2012), recognize its value if cytogenetic analysis alters future care.

Both abortion and chromosomal anomaly rates decline with advancing gestational age (Ammon Avalos, 2012; Eiben, 1990). Kajii and associates (1980) noted that 75 percent of chromosomally abnormal abortions occurred by 8 weeks' gestation. Of chromosomal abnormalities, 95 percent are caused by maternal gametogenesis errors, and 5 percent by paternal errors (Jacobs, 1980). Most common abnormalities are trisomy, found in 50 to 60 percent; monosomy X, in 9 to 13 percent; and triploidy, in 11 to 12 percent (Eiben, 1980; Jenderny, 2014).

Trisomies typically result from isolated nondisjunction, rates of which rise with maternal age (Boué, 1975). Trisomies of chromosomes 13, 16, 18, 21, and 22 are most common. In contrast, balanced structural chromosomal rearrangements may originate from either parent and are found in 2 to 4 percent of couples with recurrent pregnancy loss.

Monosomy X (45,X) is the single most frequent specific chromosomal abnormality. This is *Turner syndrome*, which usually results in abortion, but liveborn females are described in Chapter 13 (Polyploidy). Conversely, *autosomal monosomy* is rare and incompatible with life.

Triploidy is often associated with hydropic or molar placental degeneration (Chap. 20, Epidemiology and Risk Factors). The fetus within a partial hydatidiform mole frequently aborts early, and the few carried longer are all grossly deformed. Advanced maternal and paternal ages do not increase the incidence of triploidy. *Tetraploid* fetuses most often abort early in gestation, and they are rarely liveborn.

Maternal Factors

In chromosomally normal pregnancy losses, maternal influences play a role. The causes of euploid abortions are poorly understood, but various medical disorders, environmental conditions, and developmental abnormalities have been implicated.

Euploid pregnancies abort later than aneuploid ones. Specifically, the rate of euploid abortion peaks at approximately 13 weeks (Kajii, 1980). In addition, the incidence of euploid abortion rises dramatically after maternal age exceeds 35 years (Stein, 1980).

Infections

Some common viruses, bacteria, and parasites that invade the normal human can infect the fetoplacental unit by blood-borne transmission. Others may infect locally through genitourinary infection or colonization. However, despite the numerous infections acquired in pregnancy and discussed in Chapters 64 and 65, these uncommonly cause early abortion.

Medical Disorders

Some disorders are possibly linked with higher rates of early pregnancy loss and are discussed in their respective chapters. Prominent risks are associated with poorly controlled diabetes mellitus, obesity, thyroid disease, and systemic lupus erythematosus. In these and others, inflammatory mediators may be an underlying theme (Kalagiri, 2016; Sjaarda, 2017). Although thrombophilias were initially linked to various pregnancy outcomes, most putative associations have been refuted (American College of Obstetricians and Gynecologists (2017e).

Cancer

Therapeutic doses of radiation are undeniably abortifacient. Doses that cause abortion are not precisely known, but suggested parameters are found in Chapter 46 (X-Ray Dosimetry). Similarly, the effects of chemotherapy exposure in causing abortion are not well defined (Chap. 12, Antimicrobial Drugs). Particularly worrisome are women with an ongoing pregnancy after early exposure to methotrexate, described later (Medical Abortion). Of cancer survivors, those who were treated with abdominopelvic radiotherapy or chemotherapy may later be at greater risk for miscarriage, as discussed in Chapter 63 (Reproductive Tract Neoplasms).

Surgical Procedures

The risk of miscarriage caused by surgery is not well studied. But, as discussed in Chapter 46 (Medications and Surgeries), *uncomplicated* surgical procedures performed during early pregnancy are unlikely to increase the abortion risk (Mazze, 1989). Of indications, ovarian tumors can generally be resected without inciting miscarriage. An important exception involves early removal of the corpus luteum or the ovary in which it resides. If performed before 10 weeks' gestation, supplemental progesterone should be given, and supplementation is enumerated in Chapter 63 (Diagnosis).

Trauma seldom causes first-trimester miscarriage, and although Parkland Hospital is a busy trauma center, this is an infrequent association. Major trauma—especially abdominal—can cause fetal loss, but is more likely as pregnancy advances (Chap. 47, Trauma).

Nutrition

Sole deficiency of one nutrient or moderate deficiency of all does not appear to increase risks for abortion. Even in extreme cases—for example, hyperemesis gravidarum—abortion is rare. Dietary quality may play a role, as miscarriage risk may be reduced in women who consume a diet rich in fruits, vegetables, whole grains, vegetable oils, and fish (Gaskins, 2015). With regard to maternal weight, underweight is not associated with a greater miscarriage risk (Balsells, 2016). However, as noted in Chapter 48 (Pregnancy and Obesity), obesity does raise pregnancy loss rates.

Social and Behavioral Factors

Lifestyle choices reputed to be associated with a higher miscarriage risk are most often related to chronic and especially heavy use of *legal* substances. The most commonly used is alcohol, with its potent teratogenic effects discussed in Chapter 12 (Known and Suspected Teratogens). That said, an increased miscarriage risk is only seen with regular or heavy use (Avalos, 2014; Feodor Nilsson, 2014).

Approximately 10 percent of pregnant women admit to cigarette smoking (Centers for Disease Control and Prevention, 2016). It seems intuitive that cigarettes could cause early pregnancy loss (Pineles, 2014). Adverse effects of illicit drugs are discussed in Chapter 12 (Tobacco).

Excessive caffeine consumption—not well defined—has been associated with a higher abortion risk. Reports link heavy intake of approximately five cups of coffee per day—about 500 mg of caffeine—with a slightly greater abortion risk (Cnattingius, 2000; Klebanoff, 1999). Studies of "moderate" intake—less than 200 mg daily—did not indicate increased risk (Savitz, 2008; Weng, 2008). In contrast, in one prospective cohort of more than 5100 gravidas, caffeine was linked to miscarriage but not in a dose-response relationship (Hahn, 2015). Currently, the American College of Obstetricians and Gynecologists (2016e) has concluded that moderate consumption likely is not a major abortion risk and that any associated risk with higher intake is unsettled.

Occupational and Environmental Factors

Environmental toxins suggested to have a possible link to miscarriage include bisphenol A, phthalates, polychlorinated biphenyls, and dichlorodiphenyltrichloroethane (DDT) (Krieg, 2016). Even fewer studies implicate occupational exposures. In a follow-up of the Nurses Health Study II, Lawson and associates (2012) reported slightly increased miscarriage risks in nurses exposed to sterilizing agents, x-rays, and antineoplastic drugs. Also, a higher miscarriage risk was found for dental assistants exposed to more than 3 hours of nitrous oxide daily if there was no gas-scavenging equipment (Boivin, 1997).

Paternal Factors

Increasing paternal age is significantly associated with an greater risk for abortion (de La Rochebrochard, 2003). In the Jerusalem Perinatal Study, this risk was lowest before age 25 years, after which it progressively increased at 5-year intervals (Kleinhaus, 2006). The etiology of this association is not well studied, but chromosomal abnormalities in spermatozoa likely play a role (Sartorius, 2010).

Spontaneous Abortion Clinical Classification

Threatened Abortion

This diagnosis is presumed when bloody vaginal discharge or bleeding appears through a closed cervical os during the first 20 weeks. This bleeding in early pregnancy must be differentiated from that with implantation, which some women have at the time of their expected menses. Aside from this, almost one fourth of women develop bleeding during early gestation that may persist for days or weeks. It may be accompanied by suprapubic discomfort, mild cramps, pelvic pressure, or persistent low backache. Of symptoms, bleeding is by far the most predictive risk factor for pregnancy loss.

Even if miscarriage does not follow threatened abortion, rates of later adverse pregnancy outcomes are increased as shown in Table 18-1. Of these, highest risks are for preterm delivery. Weiss and coworkers (2004) noted greater risks for adverse outcomes in later pregnancy if early bleeding was heavy rather than light. Compared with those without bleeding, women with first-trimester bleeding in an initial pregnancy have higher recurrence rates in their second (Lykke, 2010).

TABLE 18-1

Adverse Outcomes That Are Increased in Women with Threatened Abortion

Maternal	Perinatal
Placenta previa	Preterm ruptured membranes
Placental abruption	Preterm birth
Manual removal of placenta	Low-birthweight infant
Cesarean delivery	Fetal-growth restriction
	Fetal and neonatal death

From Lykke, 2010; Saraswat, 2010; Weiss, 2004; Wijesiriwardana, 2006.

Every woman with an early pregnancy, vaginal bleeding, and pain should be evaluated. The primary goal is prompt diagnosis of ectopic pregnancy, and serial quantitative serum β-hCG levels and transvaginal sonography are integral tools. Because these are not 100-percent accurate to confirm early embryo death or location, repeat evaluations are often necessary. With a robust uterine pregnancy, serum β-hCG levels should rise at least 53 to 66 percent every 48 hours (Barnhart, 2004c; Kadar, 1982). Although a less-used marker, serum progesterone concentrations <5 ng/mL suggest a dying pregnancy. Values >20 ng/mL support the diagnosis of a healthy one (Daily, 1994).

Transvaginal sonography is used to locate the pregnancy and determine viability. If this cannot be done, then a *PUL* is diagnosed, and serial surveillance is implemented for clinically stable women. The gestational sac—an anechoic fluid collection that represents the exocoelomic cavity—may be seen by 4.5 weeks (Fig. 9-3). At this same time, β-hCG levels generally measure 1500 to 2000 mIU/mL (Barnhart, 1994; Timor-Tritsch, 1988). Connolly and colleagues (2013) observed that this value could be as low as 390 mIU/mL. However, they also noted that a threshold as high as 3500 mIU/mL may be needed to identify the gestational sac in some cases that ultimately yield a viable singleton IUP.

Another caveat is that a gestational sac may appear similar to other intrauterine fluid accumulations—the so-called pseudogestational sac (Fig. 19-4). This pseudosac may be blood derived from a bleeding ectopic pregnancy and is easier to exclude once a yolk sac is seen. Typically, the yolk sac is visible by 5.5 weeks and with a mean gestational-sac diameter of 10 mm. Thus, the diagnosis of an IUP should be made cautiously if the yolk sac is not yet seen (American College of Obstetricians and Gynecologists, 2016h).

For management of threatened abortion, observation is the norm. Acetaminophen-based analgesia will help relieve discomfort from cramping. Bed rest is often recommended but does not improve outcomes. The hematocrit and blood type is determined. If anemia or hypovolemia is significant, then pregnancy evacuation is generally indicated. In cases in which there is a live fetus, some instead may choose transfusion and further observation.

Incomplete Abortion

During abortion, bleeding follows partial or complete placental separation and dilation of the cervical os. Before 10 weeks' gestation, the fetus and the placenta are frequently expelled together, but later, they deliver separately. Thus, tissue may remain entirely within the uterus or partially extrude through the cervix. Products lying loosely within the cervical canal can be easily extracted with ring forceps. In contrast, with incomplete expulsion, three management options include curettage, expectant management, or misoprostol (Cytotec), which is prostaglandin E_1 (PGE_1) (Kim, 2017). The last two are deferred in clinically unstable women or those with uterine infection.

Each option has its own risks and benefits. With all three, infection and need for transfusion are uncommon. However, misoprostol and expectant care are associated with unpredictable bleeding, and some women will undergo unscheduled curettage. Expectant management of spontaneous incomplete abortion has failure rates that approximate 25 percent in randomized trials (Nadarajah, 2014; Nielsen, 1999; Trinder, 2006). Some observational studies have shown failure rates of 10 to 15 percent (Blohm, 2003; Casikar, 2012; Luise, 2002). Medical therapy carries failure rates of 5 to 30 percent (Dao, 2007; Shochet, 2012; Trinder, 2006). In many studies for this, an oral misoprostol dose of 600 µg has been used (American College of Obstetricians and Gynecologists, 2009). Alternatively, an 800-µg vaginal or a 400-µg oral or sublingual misoprostol dose is suitable. Last, curettage usually results in a quick resolution that is 95- to 100-percent successful. However, it is invasive and not necessary for all women.

Complete Abortion

At times, complete expulsion of the entire pregnancy may ensue, and the cervical os subsequently closes. A history of heavy bleeding, cramping, and passage of tissue is typical. Patients are encouraged to bring in passed tissue, in which a complete gestation should be discerned from blood clots or a decidual cast. The latter is a layer of endometrium in the shape of the uterine cavity that when sloughed can appear as a collapsed sac (Fig. 19-2).

If an expelled complete gestational sac is not identified, transvaginal sonography is performed to differentiate a complete abortion from threatened abortion or ectopic pregnancy. Characteristic findings of a complete abortion include a minimally thickened endometrium without a gestational sac. However, this does not guarantee a recent uterine pregnancy. Condous and associates (2005) described 152 women with heavy bleeding, an empty uterus with endometrial thickness <15 mm, and a diagnosis of completed miscarriage. Six percent were subsequently found to have an ectopic pregnancy. Thus, a complete abortion cannot be surely diagnosed unless: (1) true products of conception are seen grossly or (2) unless sonography confidently documents first an intrauterine pregnancy and then later an empty cavity. In unclear settings, serial serum hCG level measurements aid clarification. With complete abortion, these levels drop quickly (Table 18-2).

TABLE 18-2

Percentage Decline of Initial Serum β-hCG Levels Following Complete Spontaneous Abortion

	Percentage Decline[a]		
Initial hCG (mIU/mL)	**by day 2 Expected % (Minimum %)**	**by day 4 Expected % (Minimum %)**	**by day 7 Expected % (Minimum %)**
50	68 (12)	78 (26)	88 (34)
100	68 (16)	80 (35)	90 (47)
300	70 (22)	83 (45)	93 (62)
500	71 (24)	84 (50)	94 (68)
1000	72 (28)	86 (55)	95 (74)
2000	74 (31)	88 (60)	96 (79)
3000	74 (33)	88 (63)	96 (81)
4000	75 (34)	89 (64)	97 (83)
5000	75 (35)	89 (66)	97 (84)

[a]The percentage decline is given as the expected decline. The minimum expected decline in parentheses is the 95th percentile value. Declines less than this minimum may reflect retained either intrauterine or extrauterine trophoblast.

Data from Barnhart, 2004a; Chung, 2006.

Missed Abortion

This describes dead products of conception that have been retained for days or weeks in the uterus with a closed cervical os. Diagnosis is imperative prior to intervention and avoids interruption of a potentially live IUP. Transvaginal sonography is the primary tool.

At 5 to 6 weeks' gestation, a 1- to 2-mm embryo adjacent to the yolk sac can be seen (Daya, 1993). As listed in Table 18-3, absence of an embryo in a sac with a mean sac diameter (MSD) ≥25 mm signifies a dead fetus (Fig. 18-1). Fetal cardiac activity can typically be detected at 6 to 6.5 weeks with a crown-rump length (CRL) of 1 to 5 mm and an MSD of 13 to 18 mm (Goldstein, 1992; Levi, 1990). A threshold CRL ≥7 mm with absent cardiac activity is also used to diagnose nonviability (Doubilet, 2013). Preisler and associates (2015) implemented the guidelines in Table 18-3 and confirmed these CRL and MSD thresholds. However, for cases in which a gestational sac had no embryo or yolk sac and measured <12 mm, they recommended that to diagnose nonviability after 2 weeks, in addition to the lack of an embryo with a heartbeat, the MSD should have failed to double.

TABLE 18-3

Guidelines for Early Pregnancy Loss Diagnosis[a]

Sonographic Findings
CRL ≥ 7 mm and no heartbeat MSD ≥ 25 mm and no embryo An initial US scan shows a gestational sac with yolk sac, and after ≥ 11 days no embryo with a heartbeat is seen An initial US scan shows a gestational sac without a yolk sac, and after ≥ 2 weeks no embryo with a heartbeat is seen
Modalities Transvaginal preferable to transabdominal US M-mode imaging used to document and measure heartbeat Doppler US not used to evaluate a normal early embryo

[a]From the Society of Radiologists in Ultrasound ; American College of Radiology.

FIGURE 18-1

Transvaginal sonogram displays a large anechoic sac consistent with an anembryonic gestation. Calipers measure uterine length and anteroposterior thickness in a sagittal plane.

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

During scanning, because of theoretical temperature elevation in tissues exposed to pulsed Doppler beam, this modality is applied only when needed for additional diagnostic purposes. M-mode should be used to document cardiac activity and measure the rate (Lane, 2013). Finding of an IUP and cardiac activity lowers subsequent miscarriage rates (Siddiqi, 1988).

In addition to the diagnostic parameters of Table 18-3, other softer sonographic markers may portend early pregnancy failure. Values for yolk sac diameters (measured inner-to-inner ring) for each gestational week in normal pregnancy have been established. Yolk sac diameters ≥6 mm in pregnancies <10 weeks' gestation are suspicious for pregnancy failure (Berdahl, 2010; Lindsay, 1992). The fetal heart rate in the first trimester rises from 110 to 130 beats per minute (bpm) at 6 weeks' gestation to 160 to 170 bpm at 8 weeks (Achiron, 1991; Rauch, 2009). A slower heart rate is unfavorable, especially those <85 bpm (Laboda, 1989; Stefos, 1998). Even with cardiac activity, fetuses with a small MSD may presage embryonic loss. Specifically, a difference <5 mm between the MSD and CRL values raises concern (Bromley, 1991; Dickey, 1992). Last, subchorionic hematoma, that is, blood collected between the chorion and uterine wall, often accompanies threatened miscarriage. Studies are contradictory as to its association with ultimate pregnancy loss (Pedersen, 1990; Stabile, 1989; Tuuli, 2011). Bennett and associates (1996) noted that miscarriage risk correlated with larger hematoma size, older maternal age, and bleeding at a gestational age ≤8 weeks.

With rapid confirmation of embryonic or fetal death, surgical or medical evacuation or expectant observation is an option. As with induced abortion, nonsurgical options balance their noninvasiveness against heavier procedural bleeding, longer completion times, and lower success rates. Of options, expectant care underperforms medical or surgical options, and failure rates range from 15 to 50 percent (Luise, 2002; Trinder, 2006; Zhang, 2005). Also, weeks may pass between pregnancy failure diagnosis and actual spontaneous miscarriage.

Alternatively, misoprostol can be given to hasten uterine evacuation. A single 800-µg dose vaginally is a common standard (American College of Obstetricians and Gynecologists, 2016c). It may be repeated in 1 to 2 days, and one large trial reported that 22 percent of women required a second dose (Zhang, 2005). Overall, failure rates range from 15 to 40 percent (Petersen, 2014; Trinder, 2006). Unlike induced abortion, adding mifepristone does not add value (Stockheim, 2006). Contraindications mirror those listed in the section describing induced abortion (Medical Abortion).

Confirmation of completion may include a history of heavy bleeding, cramping, and tissue passage followed by ebbing flow; a sonographically thin endometrial thickness; and rapidly dropping serum hCG levels. That said, there is no consensus on an endometrial thickness threshold that mandates additional intervention.

Inevitable Abortion

Preterm premature rupture of membranes (PPROM) at a previable gestational age complicates 0.5 percent of pregnancies (Hunter, 2012). Rupture may be spontaneous or may follow an invasive procedure such as amniocentesis or fetal surgery. Risks for spontaneous rupture at a previable gestation are prior PPROM, prior second-trimester delivery, and tobacco use (Kilpatrick, 2006).

A gush of vaginal fluid that is seen pooling during sterile speculum examination confirms the diagnosis. In suspect cases, amnionic fluid will fern on a microscope slide or will have a pH >7, or oligohydramnios will be seen on sonography (Sugibayashi, 2013). Also, amnionic fluid proteins placental alpha microglobulin-1 and insulin growth factor binding protein-1, described in Chapter 22 (Identification of Labor), can be assayed (Doret, 2013).

In iatrogenic cases, defects are typically higher in the uterus and tend to self seal. Also, an occlusive plug—termed an amniopatch—can be created by intraamnionic instillation of autologous platelets and cryoprecipitate. Considered investigational, it is used to seal some surgical leaks (Richter, 2013).

Spontaneous rupture in the first trimester is nearly always followed by either uterine contractions or infection, and termination is typical. In some second-trimester cases not associated with pain, fever, or bleeding, fluid may have collected previously between the amnion and chorion. If this is documented, then diminished activity with observation is reasonable. After 48 hours, if no additional amnionic fluid has escaped and if there is no bleeding, cramping, or fever, then a woman may resume ambulation and pelvic rest at home.

However, more typically with second-trimester spontaneous PPROM at a previable age, 40 to 50 percent of women will deliver within the first week, and 70 to 80 percent will do so after 2 to 5 weeks (American College of Obstetricians and Gynecologists, 2016f). Average latency is 2 weeks (Hunter, 2012; Kibel, 2016). Significant maternal complications attend previable PPROM and include chorioamnionitis, endometritis, sepsis, placental abruption, and retained placenta (Waters, 2009). With bleeding, cramping, or fever, abortion is considered inevitable, and the uterus is evacuated.

Without these complications, expectant management is an option in the well-counseled patient (American College of Obstetricians and Gynecologists, 2017f). Many will choose termination due to the just-described maternal risks and tenuous neonatal outcomes. In contemporary cohorts with PPROM at <24 weeks' gestation, only approximately 20 percent of fetuses survive until hospital discharge (Esteves, 2016; Everest, 2008; Muris, 2007). Of surviving infants, 50 to 80 percent suffer long-term sequelae (Miyazaki, 2012; Pristauz, 2008). Further stratification of outcomes by gestational age is described in Chapter 42 (Periviable Neonatal Survival). Overall, prognosis is improved if previable PPROM occurred at a later gestation, latency is longer, and oligohydramnios is absent. Neonatal mortality predominantly stems from pulmonary dysfunction, which has higher rates when oligohydramnios persists (Winn, 2000). Fetal deformations may also result from scant amnionic fluid. Amnioinfusion has been investigated but is currently investigational (Roberts, 2014).

If expectant care is elected, management is described in Chapter 42 (Late-Preterm Birth). Antibiotics are considered and given for 7 days to extend latency. Other topics include lung-maturing corticosteroids, magnesium sulfate neuroprophylaxis, group B streptococcus antibiotic prophylaxis, tocolytics, and neonatal resuscitation efforts. After initial hospitalization, the patient may be discharged home, with instruction for careful surveillance for complications until viability, at which time readmission is usual (American College of Obstetricians and Gynecologists, 2016f). In subsequent pregnancies, the risk for recurrent preterm birth is great, and in one cohort study, the rate neared 50 percent (Monson, 2016).

Septic Abortion

With abortion legalization, horrific infections and maternal deaths associated previously with criminal septic abortions are now rare. Still, with spontaneous or induced abortion, organisms may invade myometrial tissues and extend to cause parametritis, peritonitis, and septicemia. Most bacteria causing septic abortion are part of the normal vaginal flora. Particularly worrisome are severe necrotizing infections and toxic shock syndrome caused by group A streptococcus—*S pyogenes* (Daif, 2009).

Rare but severe infections with otherwise low-virulence organisms can complicate medical or spontaneous abortions. Deaths have been reported from toxic shock syndrome due to *Clostridium perfringens* (Centers for Disease Control and Prevention, 2005). Similar infections are caused by *Clostridium sordellii* and have clinical manifestations that begin within a few days after an abortion. Women may be afebrile when first seen with severe endothelial injury, capillary leakage, hemoconcentration, hypotension, and a profound leukocytosis. Maternal deaths from these clostridial species approximate 0.58 per 100,000 medical abortions (Meites, 2010).

Management of clinical infection includes prompt administration of broad-spectrum antibiotics as discussed in Chapter 37 (Pathogenesis and Clinical Course). If there are retained products, then suction curettage is also performed. Most women respond to this treatment within 1 to 2 days and are discharged when afebrile. Follow-up oral antibiotic treatment is likely unnecessary (Savaris, 2011). In a very few women, severe sepsis syndrome develops, and intensive supportive care is essential. Although rare, clinical decline in the patient and widespread peritonitis despite curettage should raise concerns. Imaging that shows free air or air within the uterine wall typically prompts laparotomy (Eschenbach, 2015). If the uterus is necrotic, hysterectomy is indicated.

Anti-D Immunoglobulin

With spontaneous miscarriage, 2 percent of Rh D-negative women will become alloimmunized if not provided passive isoimmunization. With an induced abortion, this rate may reach 5 percent. The American College of Obstetricians and Gynecologists (2017g) recommends anti-Rho (D) immunoglobulin given as 300 µg intramuscularly (IM) for all gestational ages. Doses may also be graduated, with 50 µg given IM for pregnancies ≤12 weeks and 300 µg for ≥13 weeks. This is administered immediately following surgical evacuation. For planned medical or expectant management, the injection is given within 72 hours of pregnancy failure diagnosis.

With threatened abortion, immunoglobulin prophylaxis is controversial because of sparse evidence-based data (Hannafin, 2006). That said, it is reasonable to administer anti-D immunoglobulin for a threatened abortion and a live fetus, and this is our practice.

RECURRENT MISCARRIAGE

Affecting approximately 1 percent of fertile couples, recurrent pregnancy loss (RPL) is classically defined as three or more consecutive pregnancy losses <20 weeks' gestation or with a fetal weight <500 g. Mindful of this threshold, data from two large studies showed the risk for a subsequent miscarriage to be similar whether following two or three prior pregnancy losses (Bhattacharya, 2010; Brigham, 1999). And, the American Society for Reproductive Medicine (2013) now defines RPL as two or more failed pregnancies confirmed by sonographic or histopathological examination. *Primary RPL* refers to multiple losses in a woman who has never delivered a liveborn, and *secondary RPL* refers to multiple pregnancy losses in a patient with a prior live birth. Remarkably, the chances for a successful pregnancy are >50 percent even after five losses (Table 18-4).

TABLE 18-4

Predicted Success Rate of Subsequent Pregnancy According to Age and Number of Previous Miscarriages

No. of Previous Miscarriages at Age (yrs)	2	3	4	5
	Predicted Success of Subsequent Pregnancy (%)			
20	92	90	88	85
25	89	86	82	79
30	84	80	76	71
35	77	73	68	62
40+	69	64	58	52

Evaluation for RPL addresses the major etiologies, described next (American Society for Reproductive Medicine, 2012). Treatment considerations reach beyond the scope of this book, and interested readers are referred to Chapter 6 in *Williams Gynecology,* 3rd edition (Halvorson, 2016).

Etiology

Three widely accepted causes of RPL are parental chromosomal abnormalities, antiphospholipid antibody syndrome, and structural uterine abnormalities. First-trimester losses in RPL have a significantly lower incidence of genetic abnormalities than sporadic miscarriage (Stephenson, 2002; Sullivan, 2004).

The timing of recurrent loss can offer clues, and in some women, each miscarriage may occur near the same gestational age (Heuser, 2010). Genetic factors usually result in early embryonic losses, whereas autoimmune or uterine anatomical abnormalities more likely cause second-trimester losses (Schust, 2002). Approximately 40 to 50 percent of women have idiopathic RPL (Li, 2002; Stephenson, 1996).

Parental Chromosomal Abnormalities

Although these account for only 2 to 4 percent of RPL cases, karyotyping of both parents is considered by many to be essential. Of abnormalities, reciprocal translocations are most common and followed by robertsonian translocations (Fan, 2016). Their genesis and reproductive sequelae are discussed in Chapter 13 (Chromosomal Translocations).

After thorough genetic counseling, couples with an abnormal karyotype can be offered in vitro fertilization (IVF) followed by preimplantation genetic diagnosis (American Society for Reproductive Medicine, 2012; Society for Assisted Reproductive Technology, 2008). This technique is described in Chapter 14 (Preimplantation Genetic Testing). However, in couples with RPL who are *chromosomally normal,* PGD is not currently recommended.

Anatomical Factors

Several genital tract abnormalities have been implicated in RPL and other adverse pregnancy outcomes (Reichman, 2010). According to Devi Wold and colleagues (2006), 15 percent of women with three or more consecutive miscarriages will be found to have a congenital or acquired uterine anomaly.

Of acquired abnormalities, uterine synechiae—*Asherman syndrome*—usually result from destruction of large areas of endometrium. This can follow uterine curettage, hysteroscopic surgeries, or uterine compression sutures (Conforti, 2013; Rathat, 2011). Characteristic multiple filling defects are seen with hysterosalpingography or saline-infusion sonography. Treatment is hysteroscopic adhesiolysis. In many, this lowers miscarriage rates and improves live birth rates (Yu, 2008).

Uterine leiomyomas are common and may cause miscarriage, especially if located near the placental implantation site. That said, data indicating them to be a significant cause of RPL are not convincing (Saravelos, 2011). Uterine cavity distortion is apparently not requisite for bad outcomes (Sunkara, 2010). But in women undergoing IVF, pregnancy outcomes are adversely affected by submucous but not subserosal or intramural leiomyomas (Jun, 2001; Ramzy, 1998). As discussed in Chapter 63 (Ovary), most agree that excision of submucosal leiomyomas in women with RPL can be considered.

Congenital genital tract anomalies often originate from abnormal müllerian duct formation. These have an overall incidence of approximately 1 in 200 women (Nahum, 1998). Depending on their anatomy, some may raise risks for early miscarriage, whereas others may cause midtrimester abortion or preterm delivery. Unicornuate, bicornuate, and septate uteri are associated with all three types of loss (Reichman, 2010). A fuller discussion of these anatomical abnormalities and their reproductive effects is found in Chapter 3 (Bladder and Perineal Abnormalities).

Immunological Factors

Miscarriages are more common in women with systemic lupus erythematosus (Clowse, 2008). Many of these women, as well as some without lupus, carry *antiphospholipid antibodies*, a family of autoantibodies that bind to phospholipid-binding plasma proteins (Erkan, 2011). Women with RPL have a higher frequency of these antibodies compared with normal controls (Branch, 2010). As shown in Table 18-5, the *antiphospholipid antibody syndrome (APS)* is defined by these antibodies in combination with various forms of reproductive loss and substantively increased risks for venous thromboembolism (American College of Obstetricians and Gynecologists, 2017b,i). Mechanisms that cause pregnancy loss are discussed along with treatment in Chapter 59 (Pregnancy and Antiphospholipid Antibodies).

TABLE 18-5

Clinical and Laboratory Criteria for Diagnosis of Antiphospholipid Antibody Syndrome[a]

Clinical Criteria Obstetric: One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks, ***or*** Severe preeclampsia or placental insufficiency necessitating delivery before 34 weeks, ***or*** Three or more unexplained consecutive spontaneous abortions before 10 weeks Vascular: One or more episodes of arterial, venous, or small vessel thrombosis in any tissue or organ
Laboratory Criteria[b] Presence of lupus anticoagulant according to guidelines of the International Society on Thrombosis and Hemostasis, ***or*** Medium or high serum levels of IgG or IgM anticardiolipin antibodies, ***or*** Anti-β2 glycoprotein-I IgG or IgM antibody

[a]At least one clinical and one laboratory criteria must be present for diagnosis.

[b]These tests must be positive on two or more occasions at least 12 weeks apart.

IgG = immunoglobulin G; IgM = immunoglobulin M.

Modified from Branch, 2010; Erkan, 2011; Miyakis, 2006.

Regarding alloimmunity, one provocative theory suggests that normal pregnancy requires formation of blocking factors that avert maternal rejection of foreign fetal antigens that are paternally derived (Chap. 5, Fetal–Maternal Interface). Factors that prevent this tolerance may underlie RPL (Berger, 2010). However, proposed therapies using paternal or third-party leukocyte immunization or intravenous immunoglobulin (IVIG) have not proved beneficial in women with idiopathic RPL (Christiansen, 2015; Stephenson, 2010).

Endocrine Factors

According to Arredondo and Noble (2006), 8 to 12 percent of recurrent miscarriages are caused by endocrine factors. Studies to evaluate these have been inconsistent and generally underpowered. Two examples, both controversial, are progesterone deficiency caused by a *luteal-phase defect* and *polycystic ovarian syndrome* (Bukulmez, 2004; Cocksedge, 2008).

In contrast, the well-known abortifacient action of uncontrolled diabetes mellitus is detailed in Chapter 57 (Impact on Pregnancy). Optimal periconceptional glycemic control will mitigate many of these losses.

Likewise, the effects of overt hypothyroidism and severe iodine deficiency on early pregnancy failure are well known and discussed in Chapter 58 (Subclinical Hypothyroidism). Correction with supplementation reverses these actions. Also, the influence of subclinical hypothyroidism and antithyroid antibodies are sporadic, and thus any effects on recurrent miscarriage rates have been debated (Garber, 2012). That said, two metaanalyses reported convincingly positive associations between these antibodies and a greater risk for sporadic and recurrent miscarriages (Chen, 2011; Thangaratinam, 2011). One ongoing randomized trial regarding potential benefits of treatment will help guide future management (Vissenberg, 2015).

MIDTRIMESTER ABORTION

Incidence and Etiology

The timespan that defines a midtrimester fetal loss extends from the end of the first trimester until the fetus weighs <500 g or gestational age reaches 20 weeks. Less than in the first trimester, the spontaneous loss rate in the second ranges from 1.5 to 3 percent and, after 16 weeks, is only 1 percent (Simpson, 2007; Wyatt, 2005). Unlike earlier miscarriages that frequently are caused by chromosomal aneuploidies, these later fetal losses are due to a multitude of causes (Table 18-6). One frequently overlooked factor is that many second-trimester abortions are medically induced because of fetal abnormalities detected by prenatal screening programs for chromosome aneuploidy and structural defects.

TABLE 18-6

Management

Midtrimester abortions are classified similarly to first-trimester miscarriages (Paternal Factors). Management is similar in many regards to that used for second-trimester induced abortion, described later (Second-Trimester Abortion Methods). One exception is cervical cerclage, which may be employed for cervical insufficiency.

Cervical Insufficiency

Also known as incompetent cervix, this is a discrete obstetrical entity characterized classically by painless cervical dilatation in the second trimester. It can be followed by prolapse and ballooning of membranes into the vagina, and ultimately, expulsion of an immature fetus. This sequence often repeats in

future pregnancies.

Although the cause of insufficiency is obscure, previous cervical trauma has been implicated. One Norwegian cohort study of more than 15,000 women with prior cervical conization found a fourfold risk of pregnancy loss before 24 weeks' gestation (Albrechtsen, 2008). However, cerclage is not beneficial for women solely with this risk and without a preterm birth history (Zeisler, 1997). Of other surgeries, dilation and evacuation carries a 5-percent risk of cervical injury, but neither it nor dilation and extraction raises the likelihood of cervical insufficiency (Chasen, 2005). In other instances, abnormal cervical development, including that following in utero exposure to diethylstilbestrol (DES), may play a role (Hoover, 2011). Last, cervical ripening changes, such as altered hyaluronan or collagen content, discussed in Chapter 21 (Cervical Ripening), may be contributory (Eglinton, 2011; Sundtoft, 2017).

Surgical Indications

For women with an unequivocal history of second-trimester painless delivery, prophylactic cerclage placement is an option and reinforces a weak cervix by an encircling suture. However, some women have a history and clinical findings that make it difficult to verify—*classic* cervical insufficiency. In one randomized trial of almost 1300 women with an atypical history, cerclage was found to be only marginally beneficial—13 versus 17 percent—to prolong pregnancy past 33 weeks (MacNaughton, 1993). It seems likely that many of these women instead had preterm labor.

In addition to history, the physical finding of early dilation of the internal cervical os may be an indicator of insufficiency. In a systematic review, cerclages that were placed based on this finding provided superior perinatal outcomes compared with expectant management (Ehsanipoor, 2015).

Transvaginal sonography is yet another tool, and cervical length and the presence of *funneling* are sought. The latter is ballooning of the membranes into a dilated internal os, but with a closed external os. In women with these findings, early randomized trials were inconclusive in proving the clinical value of cerclage to prevent preterm birth (Rust, 2001; To, 2004). A multicenter randomized trial of 302 high-risk women with cervical length <25 mm reported that cerclage prevented birth before viability but not birth before 34 weeks (Owen, 2009). Subsequently, however, Berghella and coworkers (2011) included five trials in a metaanalysis and showed that cerclage for these high-risk women significantly reduced preterm birth before 24, 28, 32, 35, and 37 weeks.

Cervical length screening is now recommended by both the American College of Obstetricians and Gynecologists (2016b) and the Society for Maternal-Fetal Medicine (2015) for women with prior preterm birth. Between 16 and 24 weeks' gestation, sonographic cervical measurement is completed every 2 weeks. If an initial or subsequent cervical length is 25 to 29 mm, then a weekly interval is considered. If the cervical length measures <25 mm, cerclage is offered to this group of women. Notably, for women *without* a history of preterm birth but with a short cervix incidentally identified sonographically, progesterone therapy is offered instead of cerclage.

With twin gestations, one retrospective analysis found no improved outcomes in women with a cervical length <25 mm (Stoval, 2013). The College (2016b) does not recommend the use of cerclage in twin pregnancies.

Presurgical Preparation

Contraindications to cerclage usually include bleeding, contractions, or ruptured membranes, which substantially raises the likelihood of failure. Thus, prophylactic cerclage before dilatation is preferable. Surgery between 12 and 14 weeks' gestation allows this early intervention yet avoids surgery in a woman with a first-trimester pregnancy destined for spontaneous loss.

Preoperatively, screening for aneuploidy and obvious malformation is completed. Cervical secretions are tested for gonorrhea and chlamydial infection. These and obvious cervical infections are treated.

At times, the cervix instead is found to be dilated, effaced, or both, and an emergent *rescue cerclage* is performed. However, there is debate as to how late this should be performed. The conundrum is that the more advanced the pregnancy, the greater the risk that surgical intervention will stimulate preterm labor or membrane rupture. At Parkland Hospital, cerclage procedures are generally not done once supposed fetal viability is reached after 23 to 24 weeks. Others, however, recommend placement later than this (Caruso, 2000; Terkildsen, 2003).

When outcomes of cerclage are evaluated, women with similar clinical presentations are ideally compared. For example, in the study of elective cerclage by Owen and associates (2009), approximately a third of women delivered before 35 weeks, and complications were few. By contrast, in a 10-year review of 75 women undergoing rescue cerclage procedures, Chasen and Silverman (1998) reported that only half were delivered after 36 weeks. Importantly, only 44 percent of those with bulging membranes at the time of cerclage reached 28 weeks. Terkildsen and associates (2003) had similar experiences. Caruso and coworkers (2000) described rescue cerclage done in 23 women with a dilated cervix and protruding membranes from 17 to 27 weeks' gestation. There were 11 liveborn neonates, and these researchers concluded that success was unpredictable. Our experiences at Parkland Hospital are that rescue cerclages have a high failure rate, and women are counseled accordingly.

If the clinical indication for cerclage is questionable, a woman may instead be observed. Most undergo cervical examinations weekly or every 2 weeks to assess effacement and dilatation. Unfortunately, rapid effacement and dilation can develop despite such precautions (Witter, 1984).

Vaginal Cerclage

Of the two vaginal cerclage operations, most use the simpler procedure developed by McDonald (1963) and shown in Figure 18-2. The more complicated operation is a modification of the procedure described by Shirodkar (1955) and shown in Figure 18-3. When either technique is performed prophylactically, women with a classic history of cervical incompetence have excellent outcomes (Caspi, 1990; Kuhn, 1977). For either vaginal or abdominal cerclage, there is insufficient evidence to recommend perioperative antibiotic prophylaxis (American College of Obstetricians and

Gynecologist, 2016b,i). Thomason and coworkers (1982) found that perioperative tocolytics failed to arrest most labor. Regional analgesia is suitable and preferred. After this, the woman is placed in standard dorsal lithotomy position. The vagina and perineum are surgically prepared, and the bladder is drained. Some operators do not use potentially irritating antiseptic solution on the exposed amnionic membranes and instead use warm saline (Pelosi, 1990). Although steps are described subsequently, a thorough and illustrated review of cerclage technique is provided by Hawkins (2017).

FIGURE 18-2

McDonald cerclage procedure for incompetent cervix. **A.** Start of the cerclage procedure with a no. 2 monofilament suture being placed in the body of the cervix very near the level of the internal os. **B.** Continuation of suture placement in the body of the cervix so as to encircle the os. **C.** Encirclement completed. **D.** The suture is tightened around the cervical canal sufficiently to reduce the diameter of the canal to 5 to 10 mm, and then the suture is tied. The effect of the suture placement on the cervical canal is apparent. A second suture placed somewhat higher may be of value if the first is not in close proximity to the internal os.

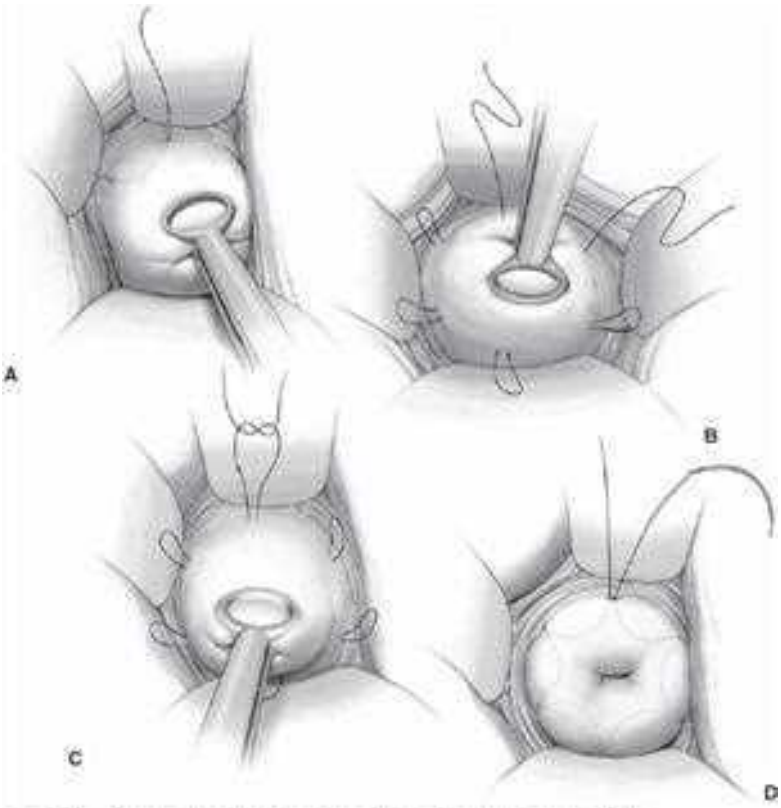

FIGURE 18-3

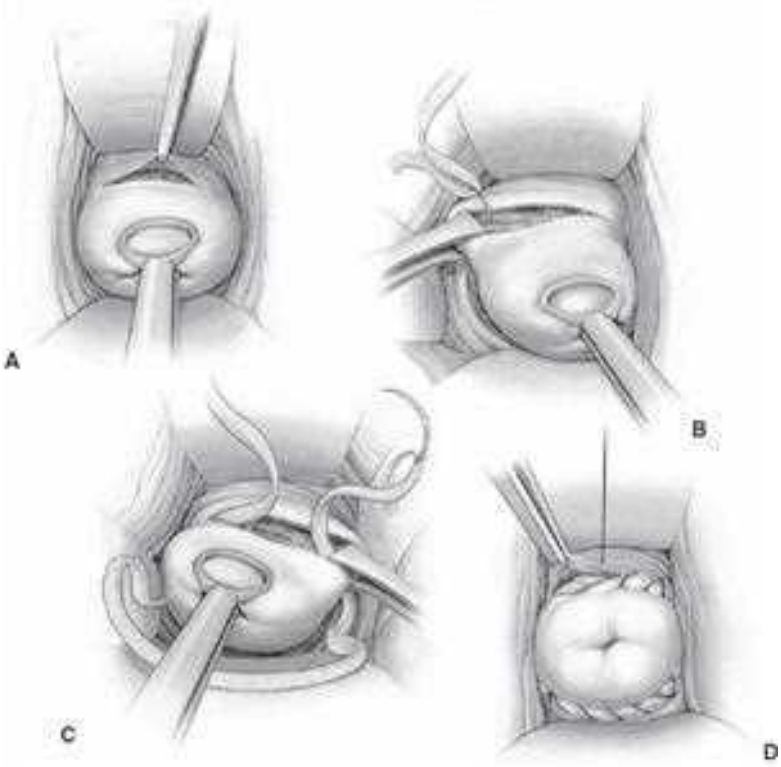
Modified Shirodkar cerclage for incompetent cervix. **A.** A transverse incision is made in the mucosa overlying the anterior cervix, and the bladder is pushed cephalad. **B.** A 5-mm Mersilene tape on a swaged-on or Mayo needle is passed anterior to posterior. **C.** The tape is then directed posterior to anterior on the other side of the cervix. Allis clamps are placed so as to bunch the cervical tissue. This diminishes the distance that the needle must travel submucosally and aids tape placement. **D.** The tape is snugly tied anteriorly, after ensuring that all slack has been taken up. The cervical mucosa is then closed with continuous stitches of chromic suture.



For suturing, options include a no. 1 or 2 nylon or polypropylene monofilament suture or 5-mm Mersilene tape. During placement, the suture is placed as high as possible and into the dense cervical stroma. Two cerclage sutures do not appear more effective than one (Giraldo-Isaza, 2013).

Rescue cerclage with a thinned dilated cervix is more difficult and risks tissue tearing and membrane puncture. Replacement of the prolapsed amnionic sac back into the uterus will usually aid suturing (Locatelli, 1999). Options include steep Trendelenburg or filling the bladder with 600 mL of saline through an indwelling Foley catheter. However, these steps may carry the cervix cephalad and away from the operating field. Membrane reduction can also be achieved by pressure from a wide moist swab or by placing a Foley catheter through the cervix and inflating the 30-mL balloon to deflect the amnionic sac cephalad. The balloon is then deflated gradually as the cerclage suture is tightened around the catheter tubing, which is then removed. Simultaneous outward traction created by ring forceps placed on the cervical edges may be helpful. In some women with bulging membranes, transabdominal amnionic fluid aspiration to decompress the sac may be considered. If this is done, bacterial cultures of the fluid should be obtained.

For uncomplicated pregnancies without labor, the cerclage is usually cut and removed at 37 weeks' gestation. This balances the risk of preterm birth against that of cervical laceration from a cerclage in place with labor contractions. Transvaginally placed cerclages are typically removed even with cesarean delivery to avoid rare long-term foreign-body complications (Hawkins, 2014). With scheduled cesarean delivery, the cerclage may be removed at 37 weeks or deferred until the time of regional analgesia and delivery. Again, the risk of labor ensuing before delivery must be considered. During extraction, particularly with a Shirodkar cerclage or a cerclage using Mersilene tape, analgesia helps ensure patient comfort and adequate visualization.

Transabdominal Cerclage

At times, suture placed at the uterine isthmus can be used and left until completion of childbearing. Because of significantly greater risks of bleeding and complications during placement, this approach is reserved for selected instances of severe cervical anatomical defects or prior transvaginal cerclage failure.

Placement of a cervicoisthmic cerclage was originally described using laparotomy, but several reports additionally detail laparoscopic or robotically assisted cervicoisthmic cerclages. Steps are summarized in Figure 18-4. Tulandi and coworkers (2014) evaluated 16 studies involving 678 pregnancies. Placement before pregnancy and during pregnancy was similar, whether performed laparoscopically or by laparotomy.

FIGURE 18-4

Transabdominal cervicoisthmic cerclage. Following incision and sharp dissection in the vesicouterine space, the bladder is mobilized caudally. At the level of the internal os, a window is made in free space medial to the uterine vessels. This avoids vessel compression by the tightened cerclage. Care is also taken to avoid the ureter, which is lateral and posterior. The suture is passed anterior to posterior or vice versa. In this case, the knot is tied anteriorly, and the vesicouterine peritoneum is closed with absorbable suture in a running fashion. Zaveri and associates (2002) reviewed 14 observational studies in which a prior transvaginal cerclage had failed to prevent preterm delivery. The risk of perinatal death or delivery before 24 weeks' gestation was only slightly lower following transabdominal cerclage compared with the risk following repeat transvaginal cerclage—6 versus 13 percent, respectively. Importantly, 3 percent of women who underwent transabdominal cerclage had serious operative complications, whereas there were none in the transvaginal group. Whittle and coworkers (2009) described 31 women in whom transabdominal cervicoisthmic cerclage was done laparoscopically between 10 and 16 weeks. The procedure was converted to laparotomy in 25 percent, and there were four failures due to chorioamnionitis. Overall, fetal survival rate approximated 80 percent.

Complications

Principal among these are membrane rupture, preterm labor, hemorrhage, infection, or combinations thereof. All are uncommon with prophylactic cerclage. In the multicenter study by Owen and colleagues (2009), of 138 procedures, there was one instance each of ruptured membranes and bleeding. In the trial by MacNaughton and associates (1993), membrane rupture complicated only 1 of more than 600 procedures done before 19 weeks. In our view, clinical infection mandates immediate removal of the suture with labor induced or augmented. Similarly, with imminent abortion or delivery, the suture should be removed at once because uterine contractions can tear through the uterus or cervix.

Following cerclage, if subsequent cervical thinning is detected by sonographic assessment, then some consider a reinforcement cerclage. In one retrospective study, however, reinforcing cerclage sutures placed later did not significantly prolong pregnancy (Contag, 2016).

Membrane rupture during suture placement or within the first 48 hours following surgery is considered by some to be an indication for cerclage removal because of the likelihood of serious fetal or maternal infection (Kuhn, 1977). That said, the range of management options includes observation, removal of the cerclage and observation, or removal of the cerclage and labor induction (O'Connor, 1999).

INDUCED ABORTION

The term *induced abortion* is defined as the medical or surgical termination of pregnancy before the time of fetal viability. Definitions used to evaluate these statistically include: (1) *abortion ratio*—the number of abortions per 1000 live births, and (2) *abortion rate*—the number of abortions per 1000 women aged 15 to 44 years. Overall, abortions most likely are underreported in the United States because clinics inconsistently list medically induced abortions. For example, the Guttmacher Institute found that 926,000 procedures were performed in 2014 (Jones, 2017). But for 2013, only about 664,400 elective abortions were reported to the Centers for Disease Control and Prevention (Jatlaoui, 2016). Of these, 66 percent were pregnancies aged ≤8 weeks' gestation, and 92 percent of abortions were completed before ≤13 weeks. The abortion ratio was 200 per 1000 live births, and the abortion rate was 12.5 per 1000 women.

Classification

Therapeutic abortion refers to termination of pregnancy for medical indications. Inclusive medical and surgical disorders are diverse and discussed throughout this text. In cases of rape or incest, many consider termination. The most frequent indication currently is to prevent birth of a fetus with a significant anatomical, metabolic, or mental deformity.

The term *elective abortion* or *voluntary abortion* describes the interruption of pregnancy before viability at the request of the woman, but not for medical reasons. Most abortions done today are elective, and thus, it is one of the most frequently performed medical procedures.

Abortion in the United States

Legal Influence

The legality of elective abortion was established by the United States Supreme Court in the case of *Roe v. Wade.* The Court defined the extent to which states might regulate abortion and ruled that first-trimester procedures must be left to the medical judgment of the physician. After this, the state could regulate abortion procedures in ways reasonably related to maternal health. Finally, subsequent to viability, the state could promote its interest in the potential of human life and regulate and even proscribe abortion, except for preservation of the life or health of the mother.

Other legislation soon followed. The 1976 Hyde Amendment forbids use of federal funds to provide abortion services except in case of rape, incest, or life-threatening circumstances. The Supreme Court in 1992 reviewed *Planned Parenthood v. Casey* and upheld the fundamental right to abortion, but established that regulations before viability are constitutional as long as they do not impose an "undue burden" on the woman. Subsequently, many states introduced counseling requirements, waiting periods, parental consent for minors, facility requirements, and funding restrictions. Such limits are often called targeted regulation of abortion providers (TRAP) laws. One major choice-limiting decision was the 2007 Supreme Court decision that reviewed *Gonzales v. Carhart* and upheld the 2003 Partial-Birth Abortion Ban Act. This was problematic because there is no medically approved definition of partial-birth abortion according to the American College of Obstetricians and Gynecologists (2014a). In 2016, some TRAP laws were dialed back by the Supreme Court ruling in the case of *Whole Woman's Health v. Hellerstedt*. With this, the justices noted that abortion laws must confer health safety benefits that outweigh burdens on access.

Provider Availability

The American College of Obstetricians and Gynecologists (2014a, 2017d) supports the legal right of women to obtain an abortion prior to fetal viability and advocates for improved access. The College also (2017a) supports abortion training, and the Accreditation Council for Graduate Medical Education mandates that obstetrics and gynecology residency education must include access to experience with induced abortion. The Kenneth J. Ryan Residency Training Program was established in 1999 to work with residency programs to improve abortion and contraceptive training. Moreover, postresidency training in these techniques is available in formal 2-year Family Planning fellowships.

Other residency programs are less codified, but teach residents technical aspects through their management of early spontaneous abortions and pregnancy interruption for fetal death, severe fetal anomalies, and life-threatening medical or surgical disorders.

The College (2016g) respects the need and responsibility of health-care providers to determine their individual positions on induced abortion. It also advocates for counseling and timely referral if providers have individual beliefs that preclude pregnancy termination. Three basic choices available to a woman considering an abortion are: (1) continued pregnancy with its risks and parental responsibilities; (2) continued pregnancy with arranged adoption; or (3) termination of pregnancy with its risks. Knowledgeable and compassionate counseling should objectively describe and provide information regarding these choices to permit informed decision-making (Templeton, 2011).

FIRST-TRIMESTER ABORTION METHODS

Pregnancy termination can be performed either medically or surgically by several methods. In the absence of serious maternal medical disorders, abortion procedures do not require hospitalization (Guiahi, 2012). However, outpatient surgical facilities should have the ability to provide emergency resuscitation and immediate transfer to a hospital (American College of Obstetricians and Gynecologists, 2014b).

Surgical Abortion

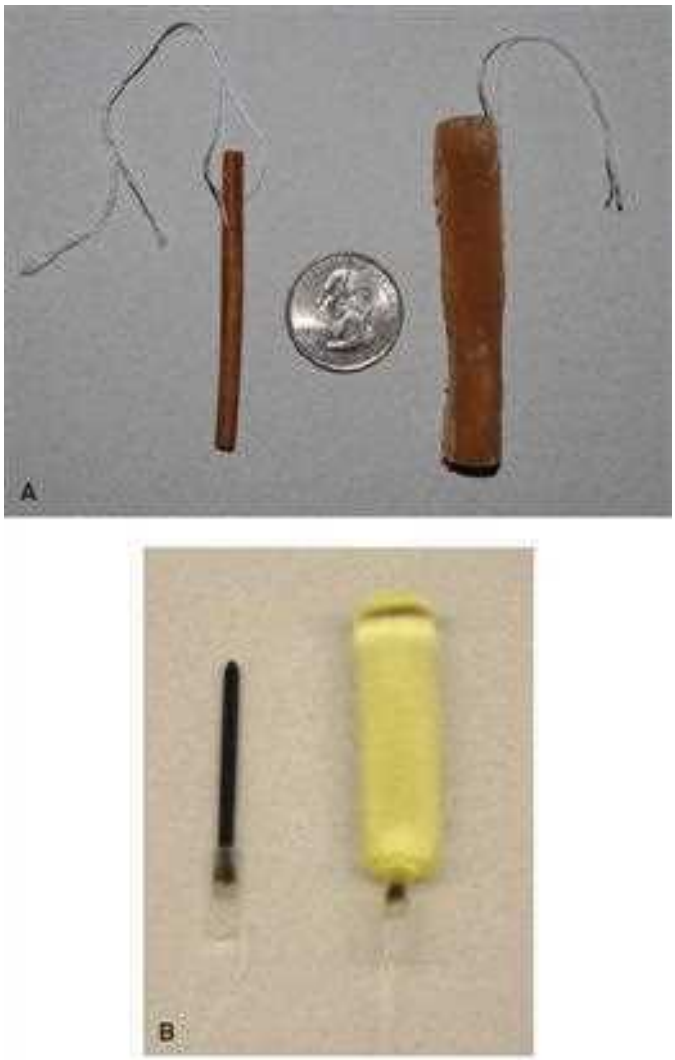
Preoperative Preparation

Surgical evacuation is performed transvaginally through an appropriately dilated cervix. For this, preoperative cervical ripening is favored by many and is typically associated with less manual intraoperative cervical dilation, a technically easier procedure, less pain, and shorter operative times (Kapp, 2010; Webber, 2015). On balance, cervical preparation adds a surgical delay and potential side effects. In a selective approach, some recommend cervical priming for first-trimester suction curettage only for those at greater risk of complications from intraoperative cervical dilation, such as those with cervical stenosis and adolescents (Allen, 2016). Of note, surgical steps presented here apply to both induced abortion and miscarriage, discussed earlier (First-Trimester Spontaneous Abortion).

For ripening, hygroscopic dilators, also called osmotic dilators, are devices that draw water from surrounding tissues and expand to gradually dilate the endocervical canal. One type is derived from various species of *Laminaria* algae that are harvested from the ocean floor (Fig. 18-5). These come in different diameters, which allow the number of inserted devices, also called tents, to be customized to a given cervix. Another device is *Dilapan-S,* which is composed of an acrylic-based gel. Each type expands to an ultimate diameter three to four times that of its dry state. However, Dilapan-S achieves this in 4 to 6 hours, which is faster than the 12 to 24 hours needed for laminaria (Fox, 2014).

FIGURE 18-5

Hygroscopic dilators. With each type, the dry unit (*left*) expands exponentially when exposed to water (*right*) as in the endocervical canal. **A.** Laminaria. **B.** Dilapan-S.



With hygroscopic dilators, shallow insertion yields insufficient internal os dilation or tent expulsion, but deep placement risks dislodgement into the uterine cavity (Fig. 18-6). Accordingly, the numbers of sponges and dilators inserted are carefully counted and recorded in the patient's chart. Once tents

are inserted, several gauze sponges at the external os help prevent spontaneous tent expulsion. Patients can ambulate, void, or stool without limitation.

FIGURE 18-6
Insertion of laminaria before dilatation and curettage. **A.** Laminaria immediately after being appropriately placed with its upper end just through the internal os. **B.** Several hours later the laminaria is now swollen, and the cervix is dilated and softened. **C.** Laminaria inserted too far through the internal os; the laminaria may rupture the membranes.

Schneider and associates (1991) described 21 cases in which women who had a hygroscopic dilator placed changed their minds. Of 17 women who chose to continue their pregnancy, there were 14 term deliveries, two preterm deliveries, and one miscarriage 2 weeks later. None suffered infection-related morbidity, including three untreated women with cervical cultures positive for *Chlamydia trachomatis*. In similar circumstances with four second-trimester terminations, Siedhoff and Cremer (2009) described two preterm and two term deliveries.

Instead of hygroscopic dilators, misoprostol is often used for cervical ripening. The typical dose is 400 µg administered sublingually, buccally, or placed into the posterior vaginal fornix 3 to 4 hours prior to surgery. Instead, oral administration proves less effective and may take longer (Allen, 2016). Another effective cervical-ripening agent is the antiprogestin mifepristone, 200 mg given orally 24 to 48 hours before surgery (Ashok, 2000). Its cost and greater delay to the procedure, however, typically favor misoprostol use instead.

In comparing hygroscopic dilators and misoprostol for ripening, randomized studies show equal or slightly greater dilation with hygroscopic dilators. Other surgical parameters do not vary significantly (Bartz, 2013; Burnett, 2005; MacIsaac, 1999). Hygroscopic dilators extend procedure time and can be uncomfortable, whereas misoprostol introduces fever, bleeding, and gastrointestinal side effects.

If not done as part of early prenatal care, hemoglobin level and Rh status are assessed. Screening for gonorrhea, for syphilis, and for human immunodeficiency virus, hepatitis B, and chlamydial infections is also completed. Obvious cervical infections are treated and resolved before elective procedures. To prevent postabortal infection after a first- or second-trimester surgical evacuation, prophylactic doxycycline, 100 mg orally 1 hour before and then 200 mg orally after, is provided (Achilles, 2011; American College of Obstetricians and Gynecologists, 2016a). Prophylaxis specifically for infective endocarditis prevention in those with valvular heart disease is not required in the absence of active infection (Nishimura, 2017). No recommendations specifically address venous thromboembolism prophylaxis for suction curettage in low-risk gravidas. At our hospital, we encourage early ambulation.

Vacuum Aspiration

Also called *suction dilation and curettage* or *suction curettage*, vacuum aspiration is a transcervical approach to surgical abortion. The cervix is first dilated and then products of conception are evacuated. For this, a rigid cannula is attached either to an electric-powered vacuum source or to a handheld 60-mL syringe for its vacuum source. These are *electric vacuum aspiration (EVA)* or *manual vacuum aspiration (MVA)*, respectively. *Sharp dilation and curettage (D & C)* in which contents are mechanically scraped out *solely* by a sharp curette is currently not recommended for pregnancy evacuation due to greater blood loss, pain, and procedural time (National Abortion Federation, 2016; World Health Organization, 2012). Importantly, this practice is distinguished from brief sharp curettage following initial aspiration. In one survey, this combination is employed by nearly 50 percent of abortion providers (O'Connell, 2009).

After bimanual examination is performed to determine uterine size and orientation, a speculum is inserted, and the cervix is swabbed with povidone-iodine or equivalent solution. The anterior cervical lip is grasped with a toothed tenaculum. The cervix, vagina, and uterus are richly supplied by nerves of Frankenhäuser plexus, which lies within connective tissue lateral to the uterosacral and cardinal ligaments. Thus, vacuum aspiration at minimum requires intravenously or orally administered sedatives or analgesics, and some add a paracervical or intracervical blockade with lidocaine (Allen, 2009; Renner, 2012). For local blocks, 5 mL of 1- or 2-percent lidocaine is most effective if placed immediately lateral to the insertion of the uterosacral ligaments into the uterus at 4 and 8 o'clock. An intracervical block with 5-mL aliquots of 1-percent lidocaine injected at 12, 3, 6, and 9 o'clock was reported to be equally effective (Mankowski, 2009). Alternatively, general or regional anesthesia may be elected.

Uterine sounding measures the depth and inclination of the cavity before other instrument insertion. If required, the cervix is further dilated with Hegar, Hank, or Pratt dilators until a suction cannula of the appropriate diameter can be inserted. The degree of required cervical dilation roughly approximates gestational age. Hegar sizes reflect their diameter in millimeters. Pratt and Hank dilators are sized in French units, which can be converted to millimeters by dividing the French number by three.

With dilation, the fourth and fifth fingers of the hand introducing the dilator should rest on the perineum and buttocks as the instrument is pushed through the internal os (Fig. 18-7). This technique minimizes forceful expansion and provides a safeguard against uterine perforation.

FIGURE 18-7
Dilatation of cervix with a Hegar dilator. Note that the fourth and fifth fingers rest against the perineum and buttocks, lateral to the vagina. This maneuver is an important safety measure because if the cervix relaxes abruptly, these fingers prevent a sudden and uncontrolled thrust of the dilator, a common cause of uterine perforation.

Following dilation, for most first-trimester aspiration procedures, an 8- to 12-mm Karman cannula is appropriate. Small cannulas carry the risk of leaving retained intrauterine tissue postoperatively, whereas large cannulas risk cervical injury and more discomfort. To begin, the cannula is slowly moved toward the fundus until resistance is met. Suction is then activated. The cannula is gradually pulled back toward the os and is slowly turned circumferentially to cover the entire surface of the uterine cavity (Fig. 18-8). This is repeated until no more tissue is aspirated. A gentle sharp curettage can

follow to remove any remaining tissue fragments (Fig. 18-9). Strong and consistent evidence supports high efficacy, safety, and patient acceptability for both MVA and EVA (Lichtenberg, 2013).

FIGURE 18-8

A suction curette has been placed through the cervix into the uterus. The figure shows the rotary motion used to aspirate the contents. (Reproduced with permission from: Hoffman BL, Corton MM: Surgeries for benign gynecologic disorders. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)

FIGURE 18-9

A sharp curette is advanced into the uterine cavity while the instrument is held with the thumb and forefinger as shown in Figure 18-7. In the movement of the curette, only the strength of these two fingers should be used. (Reproduced with permission from: Hoffman BL, Corton MM: Surgeries for benign gynecologic disorders. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)

For abortion done at ≤6 weeks' gestation, a distinct drawback is that the pregnancy may be small and missed by the curette. To identify placenta, the aspirated contents are rinsed in a strainer to remove blood, and then placed in a clear plastic container with saline and examined with back lighting (MacIsaac, 2000). Placental tissue macroscopically appears soft, fluffy, and feathery. A magnifying lens, colposcope, or microscope can augment visualization. With gestations ≤7 weeks, the failed abortion rate approximates 2 percent (Kaunitz, 1985; Paul, 2002). Thus, if products are not clearly identified, serial serum hCG levels can be informative (Dean, 2015).

Abortion Complications

In women undergoing abortion, complication rates rise with gestational age. Of these, uterine perforation and lower-genital-tract laceration are uncommon but potentially serious. In one systematic review of first-trimester abortion, the uterine perforation rate was ≤1 percent, as was the cervical or vaginal laceration rate (White, 2015). Perforation is usually recognized when the instrument passes without resistance deep into the pelvis. Risk factors include operator inexperience, prior cervical surgery or anomaly, adolescence, multiparity, and advanced gestational age (Allen, 2016; Grimes, 1984). If the uterine perforation is small and fundal, as when produced by a uterine sound or narrow dilator, observation of vital signs and for uterine bleeding is usually sufficient.

If a suction cannula or sharp curette passes into the peritoneal cavity, considerable intraabdominal damage can ensue. In these cases, laparotomy or laparoscopy to thoroughly examine the abdominal contents is often the safest course. Uterine perforation is not a contraindication to completing the curettage under direct guidance during laparoscopy or laparotomy (Owen, 2017).

Following curettage, uterine synechiae may form, and the risk of synechiae increases with the number of procedures. Most cases are mild and of unclear reproductive significance (Hooker, 2014). However, of Asherman syndrome cases, one series found that two thirds were linked to first-trimester curettage (Schenker, 1982).

Other first-trimester abortion complications are hemorrhage, incomplete removal of products, and postoperative infections, and these are germane to both surgical and medical abortion techniques. Hemorrhage with abortion is variably defined. One supported by the Society for Family Planning is bleeding that prompts a clinical response or bleeding in excess of 500 mL (Kerns, 2013). For first-trimester surgical abortions, hemorrhage complicates ≤1 percent (White, 2015). Atony, abnormal placentation, and coagulopathy are frequent sources, whereas surgical trauma is a rare cause. With medical abortion, bleeding is more common. In one study of more than 42,000 Finnish women undergoing pregnancy termination with pregnancies less 63 days, hemorrhage complicated 15 percent of medical abortion but only 2 percent of surgical cases (Niinimäki, 2009).

Infection is another risk. One review of surgical abortion found a cumulative rate of 0.5 percent in those given prophylaxis compared with 2.6 percent in those given placebo (Achilles, 2011). In another review of nearly 46,000 first-trimester abortions, the postoperative infection rate was <0.3 percent for either surgical or medical methods (Upadhyay, 2015).

Incomplete abortion may require reevacuation. For medical abortion, this neared 5 percent in one systematic review (Raymond, 2013). Reaspiration rates following surgical abortion are typically <2 percent (Ireland, 2015; Niinimaki, 2009).

In sum, first-trimester surgical abortion offers higher efficacy rates (96 to 100 percent) than medical abortion (83 to 98 percent). Medical abortion also carries a greater cumulative risk of complications, although differences are small (Lichtenberg, 2013). These are balanced against the greater privacy of medical abortion and the more invasive steps of curettage.

Medical Abortion

Agents Used

In appropriately selected women, outpatient medical abortion is an acceptable option for pregnancies with a menstrual age <63 days (American College of Obstetricians and Gynecologists (2016c). Although suitable at later gestational ages, success rates are lower.

Among legally induced abortions performed at ≤8 weeks' gestation, one third are completed medically in the United States (Jatlaoui, 2016). Three medications are used alone or in combination: mifepristone, methotrexate, and misoprostol. Of these, mifepristone augments uterine contractility by reversing progesterone-induced myometrial quiescence, whereas misoprostol directly stimulates the myometrium. Both also ripen the cervix (Mahajan,

1997; Tang, 2007). Methotrexate acts on trophoblast and halts implantation. It is used less frequently now due to current availability of the more effective mifepristone.

Contraindications to medical abortion have evolved from exclusion criteria that were used in initial clinical trials. Cautions include current intrauterine device; severe anemia, coagulopathy, or anticoagulant use; long-term systemic corticosteroid therapy; chronic adrenal failure; inherited porphyria; severe liver, renal, pulmonary, or cardiovascular disease; or uncontrolled hypertension (Guiahi, 2012). Of note, misoprostol is suitable for early pregnancy failure in those with prior uterine surgery (Chen, 2008).

Methotrexate and misoprostol are both teratogens. Thus there must be a commitment to completing the abortion once these drugs are given (Auffret, 2016; Hyoun, 2012; Kozma, 2011). With mifepristone, for women who choose to continue their pregnancies after exposure, the ongoing pregnancy rate ranges from 10 to 46 percent (Grossman, 2015). The associated major malformation rate was 5 percent in one series of 46 exposed pregnancies (Bernard, 2013).

Administration

Several dosing schemes are effective, and some are shown in Table 18-7. Because of its greater efficacy, mifepristone/misoprostol combinations are favored. Presently, for gestations up to 63 days, the most widely accepted regimen is mifepristone, 200 mg given orally on day 0 and followed in 24 to 48 hours by misoprostol 800 µg, administered by a vaginal, buccal, or sublingual route (American College of Obstetricians and Gynecologists, 2016c). Another earlier regimen used a 600-mg oral mifepristone dose followed in 48 hours by a 400-µg oral misoprostol dose (Spitz, 1998). If desired, mifepristone and misoprostol may be self-administered at home (Chong, 2015). At Planned Parenthood clinics, for first-trimester medical abortion, doxycycline 100 mg is taken orally daily for 7 days and begins with abortifacient administration (Fjerstad, 2009). The woman is then discharged home and appointed to return in 1 to 2 weeks.

TABLE 18-7

Various Regimens for Medical Termination of Pregnancy

First Trimester
Mifepristone/Misoprostol [a]Mifepristone, 200–600 mg orally; followed in 24–48 hr by: [b]Misoprostol, 200–600 µg orally *or* 400–800 µg vaginally, buccally, or sublingually
Misoprostol Alone [c]800 µg vaginally or sublingually every 3 hr for 3 doses
Methotrexate/Misoprostol [d]Methotrexate, 50 mg/m^2 BSA intramuscularly or orally; followed in 3–7 days by: [e]Misoprostol, 800 µg vaginally. Repeat if needed 1 week after methotrexate initially given
Second Trimester
Mifepristone/Misoprostol Mifepristone, 200 mg orally; followed in 24–48 hr by: Misoprostol, 400 µg vaginally or buccally every 3 hr up to 5 doses
Misoprostol Alone Misoprostol, 600–800 µg vaginally; followed by 400 µg vaginally or buccally every 3 hr up to 5 doses
Dinoprostone 20 mg vaginal suppository every 4 hr
Concentrated Oxytocin 50 units oxytocin in 500 mL of normal saline infused during 3 hr; then 1-hr diuresis (no oxytocin); then escalate sequentially in a similar fashion through 150, 200, 250, and finally 300 units oxytocin each in 500 mL normal saline

[a]Doses of 200 versus 600 mg similarly effective.

[b]Oral route may be less effective and have more nausea and diarrhea. Sublingual route has more side effects than vaginal route.

[c]Intervals 3–12 hours given vaginally; 3–4 hours given sublingually.

[d]Efficacy similar for routes of administration.

[e]Similar efficacy when given on day 3 versus day 5.

BSA = body surface area.

Pymar, 2001; Raghavan, 2009; Schaff, 2000; Shannon, 2006; von Hertzen, 2003, 2007, 2009, 2010; Winikoff, 2008.

Symptoms following misoprostol are common within 3 hours and include vomiting, diarrhea, fever, and chills. Bleeding and cramping with medical termination typically is significantly worse than with menses. Thus, adequate analgesia, usually including a narcotic, is provided. If bleeding soaks two or more pads per hour for at least 2 hours, the woman is instructed to contact her provider to determine whether she needs to be seen.

At the follow-up appointment, routine postabortal sonographic examination is typically unnecessary (Clark, 2010). Instead, assessment of the clinical course along with bimanual pelvic examination is recommended. If sonography is indicated due to concern for failed abortion or for bleeding, unnecessary surgery can be avoided if scans are interpreted appropriately. Specifically, if no gestational sac is seen and there is no heavy bleeding, then intervention is unnecessary. This is true even when, as is common, the uterus contains sonographically evident debris (Paul, 2000). Measurements <15 mm and <30 mm have been used as thresholds to signal evacuation success (Nielsen, 1999; Zhang, 2005). Another study reported that a multilayered sonographic pattern indicated a successful abortion (Tzeng, 2013). Last, hCG values may be informative. Compared with preprocedural levels, Barnhart and coworkers (2004b) found declines of 88 percent at day 3 and 82 percent at day 8 following misoprostol administration correlated with a 95-percent rate of successful abortion completion.

SECOND-TRIMESTER ABORTION METHODS

In the second trimester, fetal anomaly or death, maternal health complications, inevitable abortion, or desired termination may be indications for uterine evacuation. As in the first trimester, available options are medical or surgical. But, in the second trimester, *dilation and evacuation (D & E)* rather than suction D & C is dictated because of fetal size and bony structure.

Of options, D & E is a common means of second-trimester induced abortion in the United States. Of legally obtained abortions in 2013, 9 percent were performed by D & E at gestational ages >13 weeks (Jatlaoui, 2016). Many of the surgical and medical steps for second-trimester abortion mirror those in the first trimester, and differences are emphasized here.

Dilation and Evacuation

Preparation

With D & E, wide mechanical cervical dilation precedes evacuation of fetal parts. The degree needed rises with fetal gestational age, and inadequate dilatation risks cervical trauma, uterine perforation, or tissue retention (Peterson, 1983). Thus, presurgical cervical preparation is advised, and main options include hygroscopic dilators or misoprostol.

With laminaria, overnight preparation offers optimal cervical dilation (Fox, 2014). Uncommonly, laminaria may fail to adequately dilate the cervix, and serial laminaria insertion with an increasing number of tents over several days is one option (Stubblefield, 1982). Supplementing laminaria with misoprostol or mifepristone is another choice (Ben-Ami, 2015).

Dilapan-S is also suitable for cervical preparation. It may be preferable for same-day procedures as this device achieves its maximal effect in 4 to 6 hours (Newmann, 2014).

Misoprostol can be used instead of hydroscopic dilators for cervical preparation. The typical dose is 400 µg given vaginally or buccally 3 to 4 hours prior to D & E. Randomized trials vary regarding the ability of misoprostol to achieve results equal to that with hydroscopic dilators (Bartz, 2013; Goldberg, 2005; Sagiv, 2015). Misoprostol *added* to laminaria offers small increases in dilation but also greater side effects (Edelman, 2006).

Fewer studies have evaluated mifepristone for cervical ripening. In one, mifepristone alone provided less dilation than hydroscopic dilators (Borgatta, 2012). In another trial, mifepristone added 48 hours before misoprostol created greater cervical dilation compared with misoprostol alone (Carbonell, 2007). Last, Goldberg and associates (2015) compared hygroscopic dilation with or without added mifepristone. They found no differences for gestations <19 weeks, but the combination aided procedures for later ages.

In sum, hygroscopic dilators are consistently effective for cervical preparation before D & E. For those desiring same-day procedures, Dilapan-S alone or misoprostol alone may offer advantages. Layering agents may be most helpful for later gestations or for an inadequate response from initial hygroscopic dilators alone. Yet, layering adds cost and potential side effects (Shaw, 2016).

With elective abortion, some choose to induce fetal demise prior to D & E to avert a live birth or to avoid violating the Partial Birth Abortion Ban Act, cited later (Diedrich, 2010). For this, an intracardiac potassium chloride injection or a 1-mg intraamnionic or intrafetal digoxin injection is frequently used prior to cervical ripening (Sfakianaki, 2014; White, 2016).

Technique

During D & E, sonography can be used as an adjunct in all cases or selectively in more challenging ones. Perioperative antibiotic prophylaxis mirrors that for first-trimester procedures (Vacuum Aspiration). To reduce postprocedure bleeding, vasopressin, 2 to 4 units in 20 mL of saline or anesthetic, can be injected intracervically or as part of a paracervical block (Kerns, 2013; Schulz, 1985). Once adequate cervical dilation is achieved, the initial surgical step drains amnionic fluid with an 11- to 16-mm suction cannula or with amniotomy and gravity. This reduces the risk of amnionic fluid embolism and brings the fetus into the lower uterine segment for removal (Owen, 2017; Prager, 2009).

For pregnancies beyond 16 weeks, the fetus is extracted, usually in parts, using Sopher forceps or other destructive instruments. With complete removal of the fetus, a large-bore vacuum curette is used to remove the placenta and remaining tissue.

Major complications are infrequent with D & E, and rates range from 0.2 to 2 percent in large series (Cates, 1982; Lederle, 2015; Peterson, 1983). These include uterine perforation, cervical laceration, uterine bleeding, and postabortal infection. Rare complications include disseminated intravascular coagulopathy or amnionic fluid embolism (Ray, 2004; York, 2012).

Abnormal Placentation

Placenta previa or the accrete syndromes can raise D & E risks. Once diagnosed, *placenta accreta* typically prompts hysterectomy (Matsuzaki, 2015). For *placenta previa,* D & E is preferred to quickly evacuate the placenta, but the ability to transfuse blood products and perform possible hysterectomy must be present (American College of Obstetricians and Gynecologists, 2017h; Perriera, 2017). Medical induction may be elected, but the risk for transfusion is greater than with D & E (Nakayama, 2007; Ruano, 2004). Data are few, but predelivery uterine artery embolization may lower bleeding risks (Pei, 2017).

Prior *cesarean delivery* is not a contraindication for D & E and may be preferred over prostaglandins for those with multiple prior hysterotomies (Ben-Ami, 2009; Schneider, 1994). During medical abortion, the uterine rupture rate is 0.4 percent with one prior cesarean delivery (Berghella, 2009). From fewer data, the rate may reach 2.5 percent with two or more prior cesarean deliveries (Andrikopoulou, 2016). If a medical agent is elected in those with prior cesarean hysterotomy, misoprostol is an option. Prostaglandin E^2 (PGE^2) appears to pose similar risk (le Roux, 2001; Reichman, 2007).

Other Surgical Options

Of these, *dilation and extraction (D & X)* is similar to D & E except that a suction cannula is used to evacuate the intracranial contents after delivery of the fetal body through the dilated cervix. This aids extraction and minimizes uterine or cervical injury from large instruments or fetal bones. D & X is also called an *intact D & E*. In political parlance, this procedure has been termed *partial birth abortion*.

In some women with second-trimester pregnancies who desire sterilization, hysterotomy with tubal ligation is reasonable. If there is significant uterine disease, then hysterectomy may provide ideal treatment. In some cases of a failed second-trimester medical induction, either of these may be considered.

Medical Abortion

Principal among noninvasive methods is a mifepristone plus misoprostol regimen or misoprostol alone (see Table 18-7). Of these two options, the combined regimen yields a shorter termination duration (Kapp, 2007; Ngoc, 2011). Hygroscopic dilators may speed the time to delivery with this combined regimen (Mazouni, 2009; Vincienne, 2017). In selecting misoprostol routes, oral administration leads to a longer time to delivery compared with vaginal or sublingual routes (Dickinson, 2014). Prophylactic antibiotics are not typically given, and infection surveillance during labor is instead applied (Achilles, 2011).

Another induction agent, PGE_2, shows similar efficacy and side effects compared with misoprostol (Jain, 1994; Jansen, 2008). Simultaneous administration of an antiemetic such as metoclopramide (Reglan), an antipyretic such as acetaminophen, and an antidiarrheal such as diphenoxylate/atropine (Lomotil) will help prevent or treat symptoms. Dinoprostone (Prostin) is an available PGE_2 in the United States. However, its greater cost and poor pharmacologic stability at room temperature may make it less attractive than misoprostol.

Of other agents, high-dose intravenous oxytocin in saline will result in second-trimester abortion in 80 to 90 percent of cases (see Table 18-7). However, by comparison, misoprostol leads to higher successful induction rates and faster delivery times (Alavi, 2013).

Rarely used, ethacridine lactate is an organic antiseptic that activates myometrial mast cells to release prostaglandins (Olund, 1980). Placed extraovularly, that is, extraamnionically, it is associated with longer times to delivery and greater complication rates compared with misoprostol (Boza, 2008).

Fetal and Placental Evaluation

For second-trimester gestations, D & E or medical induction is suitable clinically and psychologically. Thus, patient input and clinical indication guide selection (Burgoine, 2005; Kerns, 2012). Once delivered, viewing and holding the fetus may or may not be desired by the patient (Sloan, 2008).

Evaluation of a stillborn fetus is described in Chapter 35 (Risk Factors). One component is autopsy, which can also be valuable for second-trimester losses or terminations due to anomaly. For example, in a study of 486 women of all ages with second-trimester miscarriage, fetal malformations were identified in 13 percent (Joo, 2009). In another, a third of otherwise normal fetuses had associated chorioamnionitis that was judged to have preceded labor (Allanson, 2010). Indeed, according to Srinivas and associates (2008), 95 percent of placentas in midtrimester miscarriages are abnormal. Other abnormalities are vascular thromboses and infarctions.

With either surgical or medical abortion, subsequent autopsy can yield information, but fragmented D & E specimens may provide less information than intact fetuses (Gawron, 2013; Lal, 2014). Karyotyping can be performed on samples from either method (Bernick, 1998).

CONSEQUENCES OF ELECTIVE ABORTION

Legally induced abortion in the United States has a low associated mortality rate, and from 2008 to 2012, the rate was <1 death per 100,000 procedures (Jatlaoui, 2016). Early abortions are safer. For example, Zane and coworkers (2015) found a mortality rate of 0.3 deaths per 100,000 procedures at ≤8 weeks' gestation; a rate of 2.5 at 14 to 17 weeks; and 6.7 at ≥18 weeks. As emphasized by Raymond and Grimes (2012), mortality rates are 14-fold greater for pregnancies that are continued.

Data relating abortion to overall maternal health and to subsequent pregnancy outcome are limited. From studies, there is no evidence for excessive mental disorders (Biggs, 2017; Munk-Olsen, 2011). There are few data regarding subsequent reproductive health, although the rates of infertility or ectopic pregnancy are not increased. Exceptions may stem from postabortal infections, especially those caused by *C trachomatis*. Of subsequent adverse pregnancy outcomes, several studies note an approximate 1.5-fold greater incidence of preterm delivery following surgical evacuation (Lemmers, 2016; Makhlouf, 2014; Saccone, 2016). This risk accrues with the number of terminations (Hardy, 2013; Klemetti, 2012). Subsequent pregnancy outcomes are similar regardless of whether a prior induced abortion was completed medically or surgically (Männistö, 2013; Virk, 2007).

After medical or surgical management of an early pregnancy termination or loss, ovulation may resume as early as 8 days, but the average time is 3 weeks (Lahteenmaki, 1978; Stoddard, 2011). Thus, unless another pregnancy is imminently desired, effective contraception is initiated to help lower the unintended pregnancy rate, which was 45 percent in 2011 in the United States (Finer, 2016). In suitable candidates described in Chapter 38 (Progestin Implants), an intrauterine device can be inserted after the procedure or medical abortion is completed (Bednarek, 2011; Korjamo, 2017). Alternatively, any of the various forms of hormonal contraception can be initiated at this time (Curtis, 2016).

For women who desire another pregnancy, conception need not be delayed. Specifically, Wong and colleagues (2015) found similar live-birth rates in groups conceiving within 3 months of first-trimester pregnancy loss compared with groups with later conception. Others have found similarly reassuring results using an interval-to-conception threshold of 6 months (Kangatharan, 2017; Love, 2010).

CHAPTER 19: Ectopic Pregnancy

As soon as an unruptured extra-uterine pregnancy is positively diagnosed, its immediate removal by laparotomy is urgently indicated, since rupture may occur at any time and the patient die from haemorrhage before operative aid can be obtained.

—J. Whitridge Williams (1903)

INTRODUCTION

Following fertilization and fallopian tube transit, the blastocyst normally implants in the endometrial lining of the uterine cavity. Implantation elsewhere is considered ectopic and accounts for 0.5 to 1.5 percent of all first-trimester pregnancies in the United States (Hoover, 2011; Stulberg, 2014). This small proportion disparately accounts for 3 percent of all pregnancy-related deaths (Creanga, 2017). Fortunately, urine and serum beta-human chorionic gonadotropin (β-hCG) assays and transvaginal sonography allow earlier diagnosis. As a result, both maternal survival rates and conservation of reproductive capacity are improved.

TUBAL PREGNANCY

Classification

Nearly 95 percent of ectopic pregnancies are implanted in the various segments of the fallopian tube. These segments are shown in Chapter 2 (Fig. 2-14). The ampulla (70 percent) is the most frequent site, followed by isthmic (12 percent), fimbrial (11 percent), and interstitial tubal pregnancies (2 percent) (Bouyer, 2002). The remaining 5 percent of nontubal ectopic pregnancies implant in the ovary, peritoneal cavity, cervix, or prior cesarean scar. Occasionally, a multifetal pregnancy contains one conceptus with normal uterine implantation that coexists with one implanted ectopically. The natural incidence of these *heterotopic pregnancies* approximates 1 per 30,000 pregnancies (Reece, 1983). However, with assisted reproductive technologies (ART), their incidence is 9 in 10,000 pregnancies (Perkins, 2015). Rarely, twin tubal pregnancy with both embryos in the same tube or with one in each tube has been reported (Eze, 2012; Goswami, 2015).

Regardless of location, D-negative women with an ectopic pregnancy who are not sensitized to D-antigen are given IgG anti-D immunoglobulin (American College of Obstetricians and Gynecologists, 2017). In first-trimester pregnancies, a 50-μg or 300-μg dose is appropriate, whereas a standard 300-μg dose is used for later gestations (Chap. 15, Prevention of Anti-D Alloimmunization).

Risks

Abnormal fallopian tube anatomy underlies many cases of tubal ectopic pregnancy. Surgeries for a prior tubal pregnancy, for fertility restoration, or for sterilization confer the highest risk. After one previous ectopic pregnancy, the chance of another is increased fivefold (Bhattacharya, 2012). Prior sexually transmitted disease or other tubal infection, which can distort normal tubal anatomy, is another factor. Specifically, one episode of salpingitis can be followed by a subsequent ectopic pregnancy in up to 9 percent of women (Westrom, 1992). Peritubal adhesions subsequent to salpingitis, appendicitis, or endometriosis can also increase chances. *Salpingitis isthmica nodosa*, which is a condition in which epithelium-lined diverticula extend into a hypertrophied muscularis layer, is another (Bolaji, 2015). Finally, congenital fallopian tube anomalies, especially those secondary to in utero diethylstilbestrol exposure, can predispose (Hoover, 2011).

Infertility, as well as the use of ART to overcome it, is linked to substantively increased risks for ectopic pregnancy (Clayton, 2006). With ART, the ectopic pregnancy rate in the United States between 2001 and 2011 was 1.6 percent (Perkins, 2015). And “atypical” implantations—cornual, abdominal, cervical, ovarian, and heterotopic pregnancy—are more frequent. Smoking is another known association, although the underlying mechanism is unclear (Hyland, 2015). Last, with any form of contraception, the absolute number of ectopic pregnancies is decreased because pregnancy occurs less often. However, with some contraceptive method failures, the relative number of ectopic pregnancies is increased. Examples include tubal sterilization, copper and progestin-releasing intrauterine devices (IUDs), and progestin-only contraceptives (Chap. 38).

Evolution and Potential Outcomes

With tubal pregnancy, because the fallopian tube lacks a submucosal layer, the fertilized ovum promptly burrows through the epithelium. The zygote comes to lie near or within the muscularis, which is invaded by rapidly proliferating trophoblast. The embryo or fetus in an ectopic pregnancy is often absent or stunted.

Outcomes of ectopic pregnancy include tubal rupture, tubal abortion, or pregnancy failure with resolution. With rupture, the invading expanding conceptus and associated hemorrhage can tear rents in the fallopian tube (Fig. 19-1). Tubal ectopic pregnancies usually burst spontaneously but may occasionally rupture following coitus or bimanual examination.

FIGURE 19-1
Ruptured ampullary early tubal pregnancy. (Used with permission from Dr. Togas Tulandi.)

Alternatively, the pregnancy may pass out the distal fallopian tube. Tubal abortion frequency depends in part on the initial implantation site, and distal implantations are favored. Subsequently, hemorrhage may cease and symptoms eventually disappear. But bleeding can persist as long as products remain in the tube. Blood slowly trickles from the tubal fimbria into the peritoneal cavity and typically pools in the rectouterine cul-de-sac. If the fimbriated extremity is occluded, the fallopian tube may gradually become distended by blood, forming a hematosalpinx. Uncommonly, an aborted fetus will implant on a peritoneal surface and become an abdominal pregnancy, which is discussed in Abdominal Pregnancy.

Last, an unknown number of ectopic pregnancies spontaneously fail and are reabsorbed. This may be documented now more regularly with the advent of sensitive β-hCG assays.

Distinctions between “acute” ectopic pregnancy just described and “chronic” ectopic pregnancy can be drawn. The more common acute ectopic pregnancies are those with a high serum β-hCG level and rapid growth, leading to a timely diagnosis. These carry a higher risk of tubal rupture (Barnhart, 2003c). With chronic ectopic pregnancy, abnormal trophoblast dies early, and thus negative or low, static serum β-hCG levels are found (Brennan, 2000). Chronic ectopic pregnancies typically rupture late, if at all, but commonly form a complex pelvic mass, which often is the reason prompting diagnostic surgery (Cole, 1982; Uğur, 1996).

Clinical Manifestations

Earlier patient presentation and more precise diagnostic technology typically allow identification before rupture. In these cases, symptoms and signs of ectopic pregnancy are often subtle or even absent. The woman does not suspect tubal pregnancy and assumes that she has a normal early pregnancy or is having a miscarriage.

With later diagnosis, the classic triad is delayed menstruation, pain, and vaginal bleeding or spotting. With tubal rupture, lower abdominal and pelvic pain is usually severe and frequently described as sharp, stabbing, or tearing. Abdominal palpation elicits tenderness. Bimanual pelvic examination, especially cervical motion,

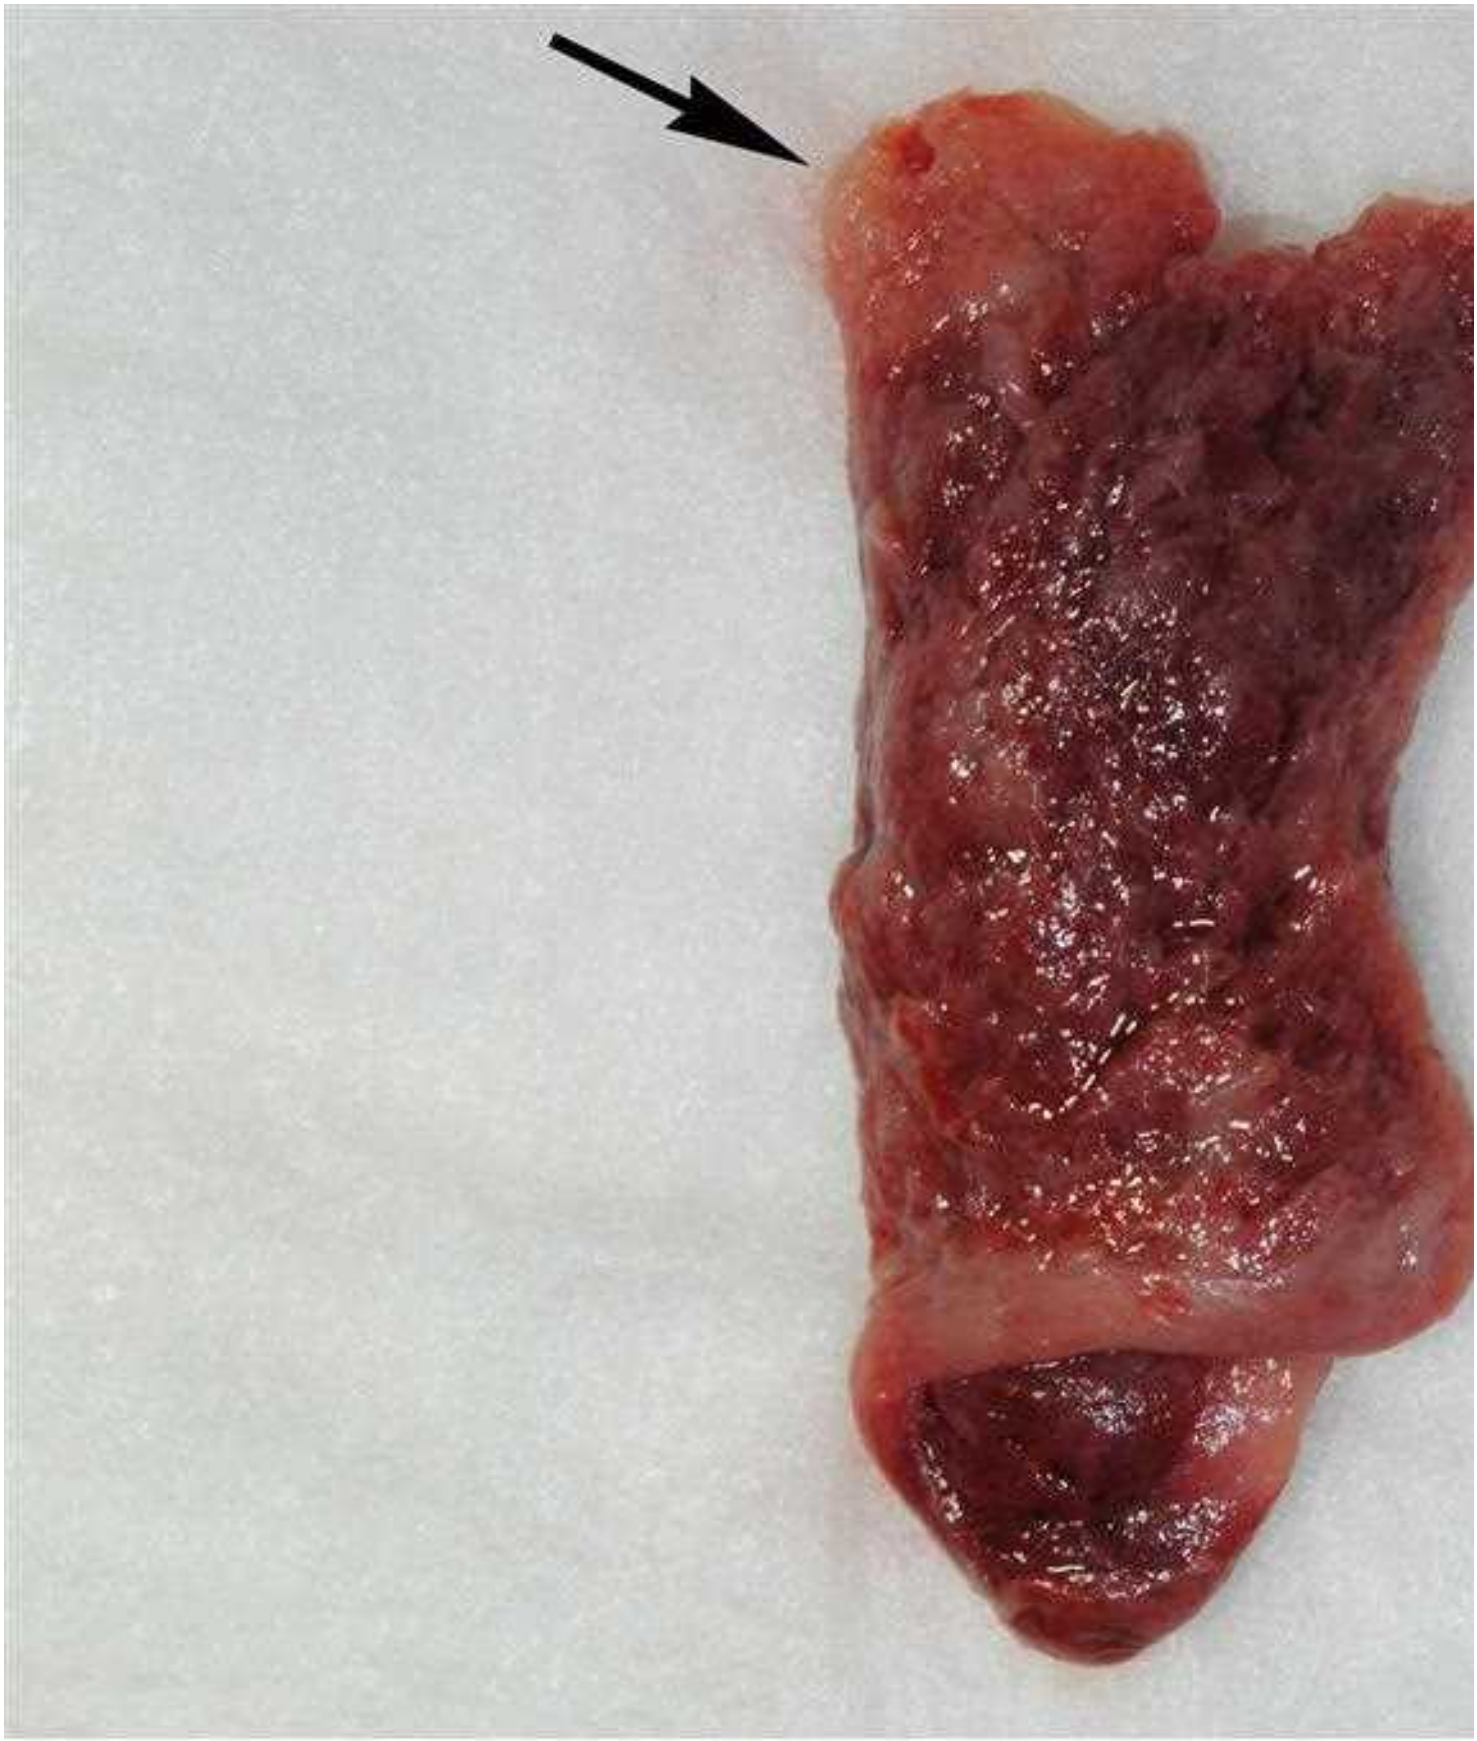
causes exquisite pain. The posterior vaginal fornix may bulge from blood in the rectouterine cul-de-sac, or a tender, boggy mass may be felt beside the uterus. The uterus can also be slightly enlarged due to hormonal stimulation. Symptoms of diaphragmatic irritation, characterized by neck or shoulder pain, especially on inspiration, develop in perhaps half of women with sizable hemoperitoneum.

Some degree of vaginal spotting or bleeding is reported by 60 to 80 percent of women with tubal pregnancy. Although profuse vaginal bleeding suggests an incomplete abortion, such bleeding occasionally is seen with tubal gestations. Moreover, tubal pregnancy can lead to significant intraabdominal hemorrhage. Responses to moderate bleeding include no change in vital signs, a slight rise in blood pressure, or a vasovagal response with bradycardia and hypotension. Blood pressure will fall and pulse will rise only if bleeding continues and hypovolemia becomes significant. Vasomotor disturbances develop, ranging from vertigo to syncope.

Even after substantive hemorrhage, hemoglobin or hematocrit readings may at first show only a slight reduction. Hence, after an acute hemorrhage, a trending decline in hemoglobin or hematocrit levels over several hours is a more valuable index of blood loss than is the initial level. In approximately half of women with a ruptured ectopic pregnancy, varying degrees of leukocytosis up to 30,000/μL may be documented.

Decidua is endometrium that is hormonally prepared for pregnancy, and the degree to which the endometrium is converted with ectopic pregnancy is variable. Thus, in addition to bleeding, women with ectopic tubal pregnancy may pass a *decidual cast.* This is the entire sloughed endometrium that takes the form of the endometrial cavity (Fig. 19-2). Importantly, decidual sloughing may also occur with uterine abortion. Thus, tissue is carefully evaluated visually by the provider and then histologically for evidence of a conceptus. If no clear gestational sac is seen or if no villi are identified histologically within the cast, then the possibility of ectopic pregnancy must still be considered.

FIGURE 19-2
This decidual cast was passed by a patient with a tubal ectopic pregnancy. The cast mirrors the shape of the endometrial cavity, and each arrow marks the portion of decidua that lined the cornua.



Multimodality Diagnosis

The differential diagnosis for abdominal pain coexistent with pregnancy is extensive. Pain may derive from uterine conditions such as miscarriage, infection, degenerating or enlarging leiomyomas, or round-ligament pain. Adnexal disease may include ectopic pregnancy; hemorrhagic, ruptured, or torsed ovarian masses;

salpingitis; or tuboovarian abscess. Last, appendicitis, cystitis, renal stone, and gastroenteritis are more common nongynecological sources of lower abdominal pain in early pregnancy.

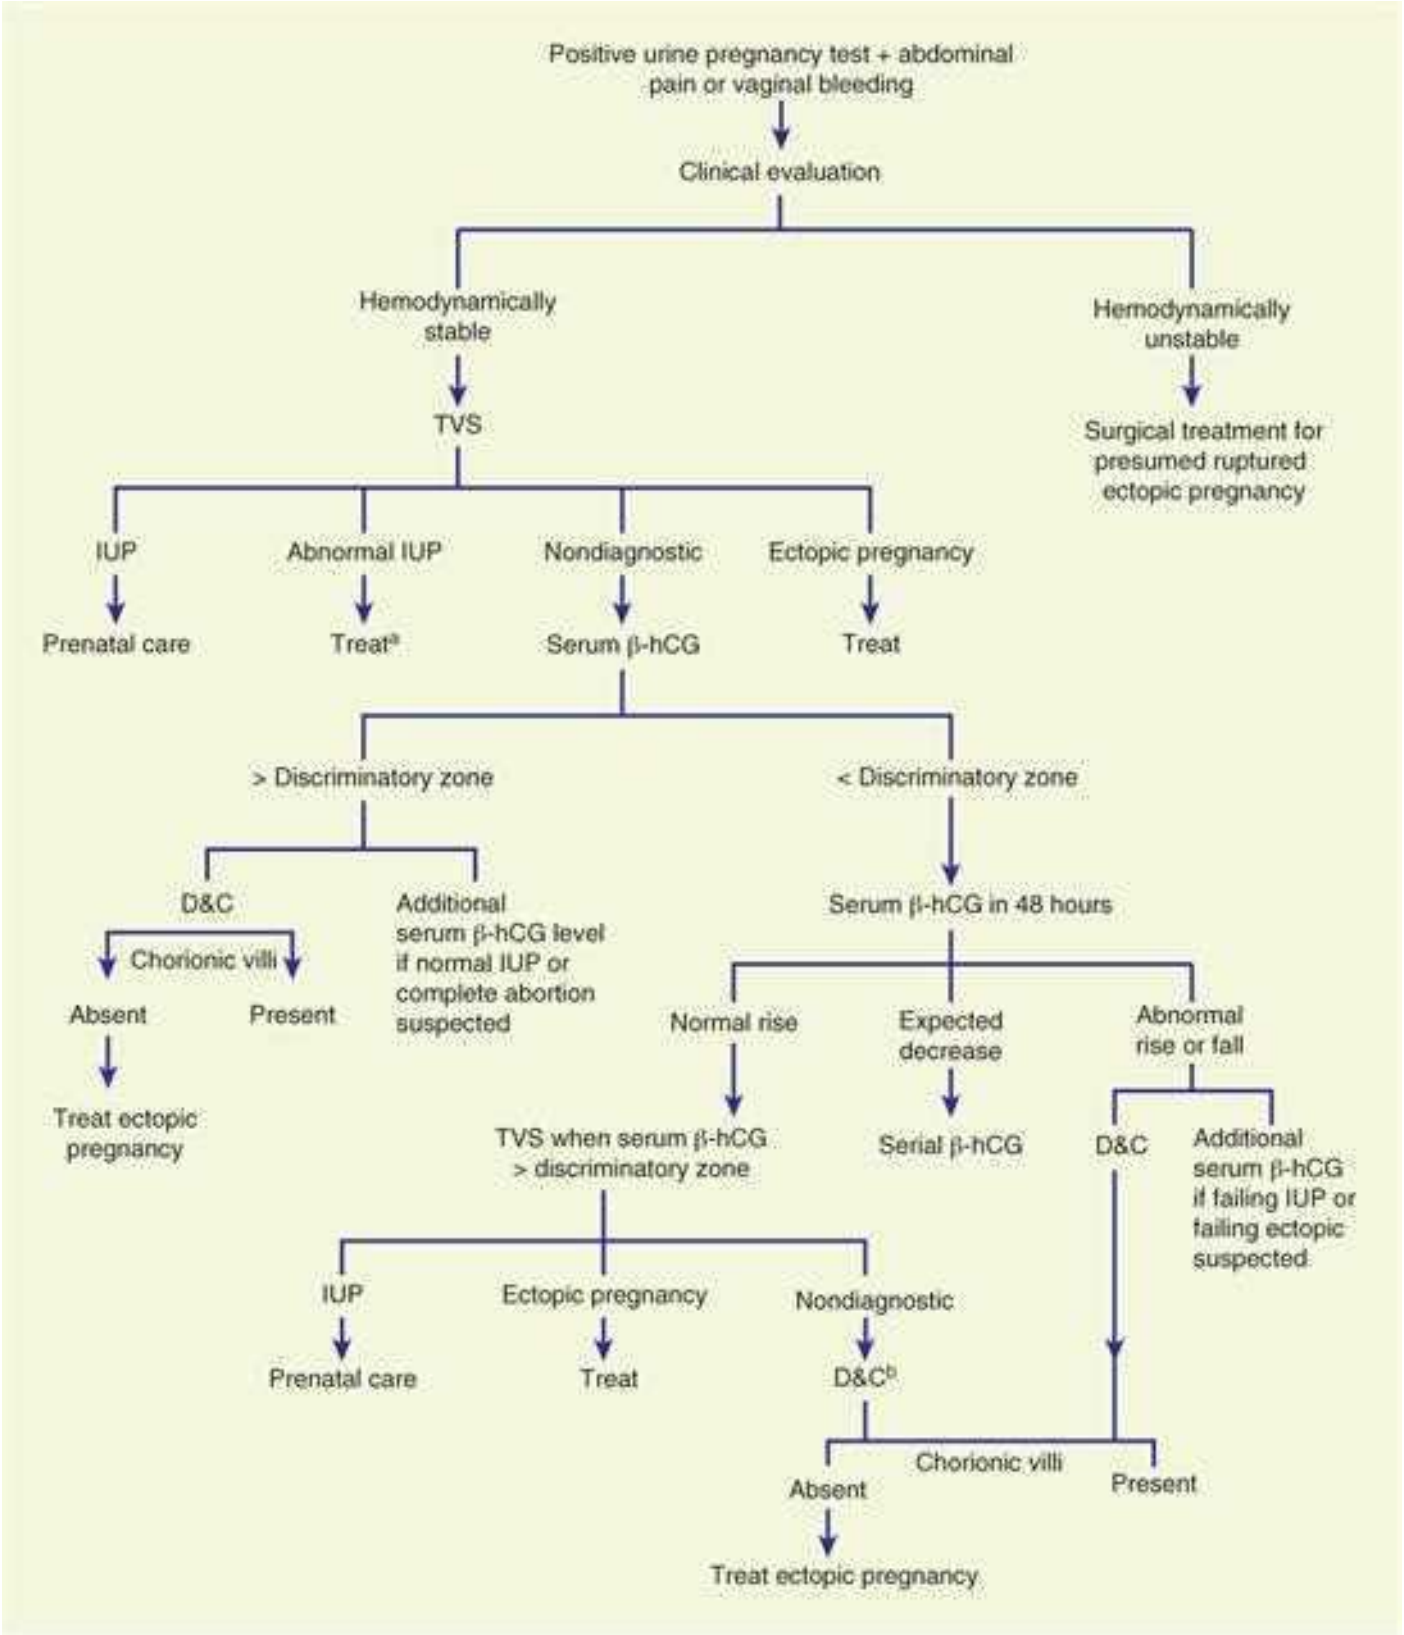
Several algorithms have been proposed to identify ectopic pregnancy. Most include these key components: physical findings, transvaginal sonography (TVS), serum β-hCG level measurement—both the initial and the subsequent pattern of rise or decline, and diagnostic surgery, which includes dilation and curettage (D&C), laparoscopy, and occasionally, laparotomy (Fig. 19-3). Algorithm use applies only to hemodynamically stable women, and those with presumed rupture undergo prompt surgical therapy. For a suspected unruptured ectopic pregnancy, all diagnostic strategies involve trade-offs. Strategies that maximize detection of ectopic pregnancy may result in termination of a normal intrauterine pregnancy (IUP). Conversely, those that reduce the potential for normal pregnancy interruption will delay ectopic pregnancy diagnosis. Patient desires for the index pregnancy are also discussed and may influence these trade-offs.

FIGURE 19-3
One suggested algorithm for evaluation of a woman with a suspected ectopic pregnancy.

[a]Expectant management, D&C, or medical regimens are suitable options.

[b]May consider repeat β-hCG level if normal IUP suspected.

β-hCG = beta human chorionic gonadotropin; D&C = dilatation and curettage; IUP = intrauterine pregnancy; TVS = transvaginal sonography.



Beta-Human Chorionic Gonadotropin

Rapid and accurate determination of pregnancy is essential to identify an ectopic pregnancy. Current pregnancy tests use enzyme-linked immunosorbent assays (ELISAs) for the beta subunit of hCG. With these assays, lower limits of detection are 20 to 25 mIU/mL for urine and ≤5 mIU/mL for serum (Greene, 2015).

With bleeding or pain and a positive pregnancy test result, an initial TVS is typically performed to identify gestation location. If a yolk sac, embryo, or fetus is identified within the uterus or the adnexa, then a diagnosis can be made. In many cases, however, TVS is nondiagnostic, and tubal pregnancy is still a possibility. In

these cases in which neither intrauterine nor extrauterine pregnancy is identified, the term *pregnancy of unknown location (PUL)* is used until additional clinical information allows determination of pregnancy location.

Levels above the Discriminatory Zone

Several investigators have described discriminatory β-hCG levels above which failure to visualize a uterine pregnancy indicates that the pregnancy either is not alive or is ectopic (Barnhart, 1994). Some institutions set their discriminatory threshold at ≥1500 mIU/mL, whereas others use ≥2000 mIU/mL. Connolly and associates (2013) suggested an even higher threshold. They noted that with live uterine pregnancies, a gestational sac was seen 99 percent of the time with a discriminatory level of >3510 mIU/mL.

If the initial β-hCG level exceeds the set discriminatory level and no evidence for an IUP is seen with TVS, then ectopic pregnancy is a concern. The diagnosis is narrowed in most cases to a failing IUP, a recent complete abortion, or an ectopic pregnancy. Early multifetal gestation also remains a possibility. Without clear evidence for ectopic pregnancy, serial β-hCG level assessment is reasonable, and a level is checked 48 hours later. This averts unnecessary methotrexate administration and avoids harming an early normal multifetal pregnancy. With greater concern for an ectopic gestation, D&C is another option to distinguish an ectopic from a failing IUP. Importantly, patient factors greatly influence these decisions.

Levels below the Discriminatory Zone

If the initial β-hCG level is below the set discriminatory value, pregnancy location is often not technically discernible with TVS. With these PULs, serial β-hCG level assays are done to identify patterns that indicate either a growing or failing IUP. Levels that rise or fall outside these expected parameters increase the concern for ectopic pregnancy. Thus, appropriately selected women with a possible ectopic pregnancy, but whose initial β-hCG level is below the discriminatory threshold, are seen 2 days later for further evaluation. Trends in levels aid diagnosis.

With early normal progressing IUPs, Barnhart and coworkers (2004b) reported a 53-percent 48-hour minimum rise with a 24-hour minimum rise of 24 percent. Seeber and associates (2006) found an even more conservative minimal 35-percent 48-hour rise in normal IUPs. With multifetal gestation, this same anticipated rate of rise is expected (Chung, 2006). Despite these guidelines, Silva and colleagues (2006) caution that a third of women with an ectopic pregnancy will have a 53-percent rise at 48 hours. They further reported that no single pattern characterizes ectopic pregnancy and that approximately half of ectopic pregnancies will show decreasing β-hCG levels, whereas the other half will have increasing levels. Also, despite a declining β-hCG level, a resolving ectopic pregnancy may rupture.

With a failing IUP, patterned rates of β-hCG level decline can also be anticipated. Following spontaneous abortion, rates decline by 21 to 35 percent at 48 hours and 68 to 84 percent at 7 days. Of note, these ranges reflect that β-hCG percentages drop faster if the initial β-hCG level is higher (Barnhart, 2004a). With resolving PULs, Butts and coworkers (2013) found greater rates of decline that ranged from 35 to 50 percent at 48 hours and 66 to 87 percent at 7 days for starting hCG values between 250 and 5000 mIU/mL.

In pregnancies without these expected rises or falls in β-hCG levels, distinction between a nonliving IUP and an ectopic pregnancy may be aided by additional β-hCG levels (Zee, 2014). Again delay is balanced against the risk from rupture. D&C is an option and provides a quicker diagnosis balanced against normal pregnancy interruption. Before curettage, a second TVS examination may be indicated and may display new informative findings.

Serum Progesterone

A single serum progesterone measurement may clarify the diagnosis in a few cases (Stovall, 1989, 1992). A value exceeding 25 ng/mL excludes ectopic pregnancy with 92-percent sensitivity (Lipscomb, 1999a; Pisarska, 1998). Conversely, values <5 ng/mL are found in only 0.3 percent of normal progressing IUPs (Mol, 1998; Verhaegen, 2012). Thus, values <5 ng/mL suggest either a nonliving IUP or an ectopic pregnancy. Because in most ectopic pregnancies, progesterone levels range between 10 and 25 ng/mL, the clinical utility of this practice is limited. One caveat is that pregnancy achieved with assisted reproductive technology may be associated with higher than usual progesterone levels (Perkins, 2000).

Transvaginal Sonography

Endometrial Findings

In a woman in whom ectopic pregnancy is suspected, TVS is performed to look for findings indicative of uterine or ectopic pregnancy. During endometrial cavity evaluation, an intrauterine gestational sac is usually visible between 4½ and 5 weeks. The yolk sac appears between 5 and 6 weeks, and a fetal pole with cardiac activity is first detected at 5½ to 6 weeks (Fig. 9-3). With transabdominal sonography, these structures are visualized slightly later.

In contrast, with ectopic pregnancy, a trilaminar endometrial pattern can be diagnostic (Fig. 19-4). Its specificity is 94 percent, but with a sensitivity of only 38 percent (Hammoud, 2005). In addition, Moschos and Twickler (2008b) determined in women with a pregnancy of unknown location at presentation that no normal IUPs had a stripe thickness <8 mm.

FIGURE 19–4

Transvaginal sonography of a pseudogestational sac within the endometrial cavity. Its cavity-conforming shape and central location are characteristic of these anechoic fluid collections. Distal to this fluid, the endometrial stripe has a trilaminar pattern, which is a common finding with ectopic pregnancy. (Reproduced with permission from Gala RB: Ectopic pregnancy. In Hoffman BL, Schorge JO, Bradshaw KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education; 2016. Photo contributor: Dr. Elysia Moschos.)

Anechoic fluid collections, which might normally suggest an early intrauterine gestational sac, may also be seen with ectopic pregnancy. These include pseudogestational sac and decidual cyst. First, a pseudosac is a fluid collection between the endometrial layers and conforms to the cavity shape (see Fig. 19-4). If a pseudosac is noted, the risk of ectopic pregnancy is increased (Hill, 1990; Nyberg, 1987). Second, a decidual cyst is identified as an anechoic area lying within the endometrium but remote from the canal and often at the endometrial-myometrial border. Ackerman and colleagues (1993b) suggested that this finding represents early decidual breakdown and precedes decidual cast formation.

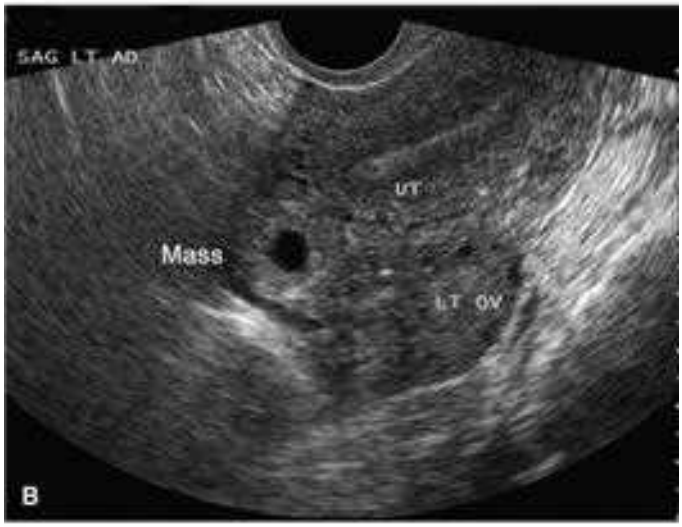
These two findings contrast with the intradecidual sign seen with uterine pregnancies. With this, an early gestational sac is seen as an anechoic sac eccentrically located within one of the endometrial stripe layers (Dashefsky, 1988). The American College of Obstetricians and Gynecologists (2016) advises caution in diagnosing an IUP in the absence of a definite yolk sac or embryo.

Adnexal Findings

The sonographic diagnosis of ectopic pregnancy rests on visualization of an adnexal mass separate from the ovary (Fig. 19-5). If fallopian tubes and ovaries are visualized and an extrauterine yolk sac, embryo, or fetus is identified, then an ectopic pregnancy is confirmed. In other cases, a hyperechoic halo or tubal ring surrounding an anechoic sac is seen (Nadim, 2017). Alternatively, an inhomogeneous adnexal mass is usually caused by hemorrhage within the ectopic sac. Overall, approximately 60 percent of ectopic pregnancies are seen as an inhomogeneous mass adjacent to the ovary; 20 percent appear as a hyperechoic ring; and 13 percent have an obvious gestational sac with a fetal pole (Condous, 2005). Importantly, not all adnexal masses represent an ectopic pregnancy, and integration of sonographic findings with other clinical information is necessary.

FIGURE 19-5

Various transvaginal sonographic findings with ectopic tubal pregnancies. For sonographic diagnosis, an ectopic mass should be seen in the adnexa separate from the ovary and may be seen as: **(A)** a yolk sac (shown here) and/or fetal pole with or without cardiac activity within an extrauterine sac, **(B)** an empty extrauterine sac with a hyperechoic ring, or **(C)** an inhomogeneous adnexal mass. In this last image, color Doppler shows a classic “ring of fire,” which reflects increased vascularity typical of ectopic pregnancies. LT OV = left ovary; SAG LT AD = sagittal left adnexa; UT = uterus.



Placental blood flow within the periphery of the complex adnexal mass—the *ring of fire*—can be seen with transvaginal color Doppler imaging. Although this can aid diagnosis, this finding can also be seen with a corpus luteum cyst, and differentiation can be challenging.

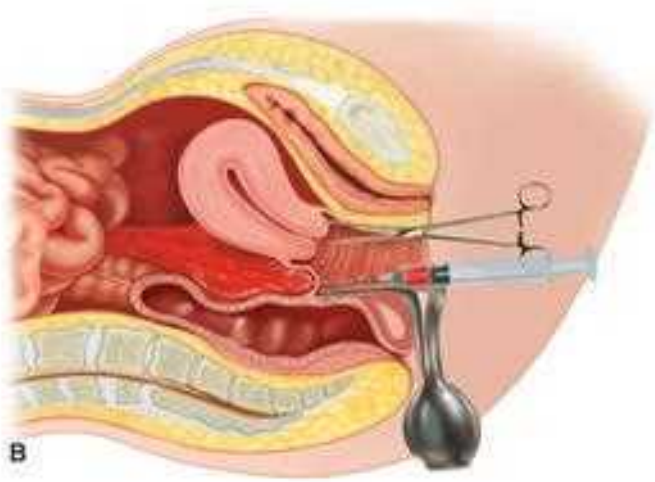
Hemoperitoneum

In affected women, blood in the peritoneal cavity is most often identified using sonography, but assessment can also be made by culdocentesis (Fig. 19-6). Sonographically, anechoic or hypoechoic fluid initially collects in the dependent retrouterine cul-de-sac, and then additionally surrounds the uterus as it fills the pelvis. As much as 50 mL of blood can be seen in the cul-de-sac using TVS, and transabdominal imaging then is used to assess the hemoperitoneum extent. Importantly, however, a small amount of peritoneal fluid is physiologically normal. With significant intraabdominal hemorrhage, blood will track up the pericolic gutters to fill Morison pouch near the liver. Free fluid in this pouch typically is not seen until accumulated volumes reach 400 to 700 mL (Branney, 1995; Rodgerson,

2001; Rose, 2004). Diagnostically, peritoneal fluid in conjunction with an adnexal mass is highly predictive of ectopic pregnancy (Nyberg, 1991). Ascites from ovarian or other cancer is a notable mimic.

FIGURE 19-6

Techniques to identify hemoperitoneum. **A.** Transvaginal sonography of an anechoic fluid collection (*arrow*) in the retrouterine cul-de-sac. **B.** Culdocentesis: with a 16- to 18-gauge spinal needle attached to a syringe, the cul-de-sac is entered through the posterior vaginal fornix as upward traction is applied to the cervix with a tenaculum. (B, Reproduced with permission from Gala RB: Ectopic pregnancy. In Hoffman BL, Schorge JO, Bradshaw KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education, 2016.)



Culdocentesis is a simple technique used commonly in the past. The cervix is pulled outward and upward toward the symphysis with a tenaculum, and a long 18-gauge needle is inserted through the posterior vaginal fornix into the retrouterine cul-de-sac. If present, fluid can be aspirated. However, a failure to do so is interpreted only as unsatisfactory entry into the cul-de-sac. Fluid containing fragments of old clots or bloody fluid that does not clot suggests hemoperitoneum. In contrast, if the blood sample clots, it may have been obtained from an adjacent blood vessel or from a briskly bleeding ectopic pregnancy. Several studies have challenged its usefulness, and culdocentesis has been largely replaced by TVS (Glezerman, 1992; Vermesh, 1990).

Endometrial Sampling

Several endometrial changes accompany ectopic pregnancy, and all lack coexistent trophoblast. Decidual reaction is found in 42 percent of samples, secretory endometrium in 22 percent, and proliferative endometrium in 12 percent (Lopez, 1994). Some recommend that the absence of trophoblastic tissue be confirmed by D&C before methotrexate treatment is given (Chung, 2011; Shaunik, 2011). Investigators found that the presumptive diagnosis of ectopic pregnancy is inaccurate in nearly 40 percent of cases without histological exclusion of a spontaneous pregnancy loss. Nevertheless, the risks of D&C are weighed against the limited maternal risks of methotrexate.

Endometrial biopsy with a Pipelle catheter was studied as an alternative to D&C and found inferior (Barnhart, 2003b; Ries, 2000). By comparison, frozen section of curettage fragments to identify products of conception is accurate in more than 90 percent of cases (Barak, 2005; Li, 2014b).

Laparoscopy

Direct visualization of the fallopian tubes and pelvis by laparoscopy offers a reliable diagnosis in most cases of suspected ectopic pregnancy. This also permits a ready transition to definitive operative therapy, which is discussed in Surgical Management.

Medical Management

Regimen Options

Medical therapy traditionally involves the antimetabolite methotrexate (MTX). This drug is a folic acid antagonist. It tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolate, which is the active form of folic acid. As a result, de novo purine and pyrimidine synthesis is halted, which leads to arrested DNA, RNA, and protein synthesis. Thus, MTX is highly effective against rapidly proliferating tissue such as trophoblast. Overall, ectopic tubal pregnancy resolution rates approximate 90 percent with its use. The drawbacks, however, are that bone marrow, gastrointestinal mucosa, and respiratory epithelium can also be harmed. It is directly toxic to hepatocytes and is renally excreted. MTX is also a potent teratogen, and MTX embryopathy is notable for craniofacial and skeletal abnormalities and fetal-growth restriction (Nurmohamed, 2011). In addition, MTX is excreted into breast milk and may accumulate in neonatal tissues and interfere with neonatal cellular metabolism (American Academy of Pediatrics, 2001; Briggs, 2015). Based on all these findings, a list of contraindications and pretherapy laboratory testing is found in Table 19-1.

TABLE 19-1

Medical Treatment Protocols for Ectopic Pregnancy

	Single Dose	Multidose
Dosing	One dose; repeat if necessary	Up to four doses of both drugs until serum β-hCG declines by 15%
Medication dosage Methotrexate Leucovorin	 50 mg/m^2 BSA (day 1) NA	 1 mg/kg, days 1, 3, 5, and 7 0.1 mg/kg days 2, 4, 6, and 8
Serum β-hCG level	Days 1 (baseline), 4, and 7	Days 1 (baseline), 3, 5, and 7
Indication for additional dose	If serum β-hCG level does not decline by 15% from day 4 to day 7 Less than 15% decline during weekly surveillance	If serum β-hCG level declines <15%, give additional dose; repeat serum β-hCG in 48 hours and compare with previous value; maximum four doses
Surveillance	Once 15% decline achieved, then weekly serum β-hCG levels until undetectable	
Methotrexate Contraindications		
Sensitivity to MTX Tubal rupture Breastfeeding	Intrauterine pregnancy Peptic ulcer disease Active pulmonary disease	

BSA = body surface area; β-hCG =β-human chorionic gonadotropin; MTX = methotrexate; NA = not applicable.

Data from American Society for Reproductive Medicine, 2013.

Of precautions, MTX is bound primarily to albumin, and its displacement by other medications such as phenytoin, tetracyclines, salicylates, and sulfonamides can increase MTX serum drug levels. Moreover, renal clearance of MTX may be impaired by nonsteroidal antiinflammatory drugs including aspirin, probenecid, or penicillins (Stika, 2012). Last, vitamins containing folic acid may lower MTX efficacy.

For ease and efficacy, intramuscular MTX administration is used most often for ectopic pregnancy medical resolution, and single-dose and multidose MTX protocols are available (see Table 19-1). As noted, MTX can lead to bone marrow depression. This toxicity can be blunted by early administration of leucovorin, which is *folinic acid* and has activity equivalent to folic acid. Thus, leucovorin, which is given within the multidose protocol, allows for some purine and pyrimidine synthesis to buffer side effects.

In comparing these two protocols, trade-offs are recognized. For example, single-dose therapy offers simplicity, less expense, and less intensive posttherapy monitoring and does not require leucovorin rescue. However, some but not all studies report a higher success rate for the multidose regimen (Alleyassin, 2006; Barnhart, 2003a; Lipscomb, 2005). At our institution, we use single-dose MTX.

Patient Selection

The best candidate for medical therapy is the woman who is asymptomatic, motivated, and compliant. With medical therapy, some classic predictors of success include a low initial serum β-hCG level, small ectopic pregnancy size, and absent fetal cardiac activity. Of these, initial serum β-hCG level is the single best prognostic indicator of successful treatment with single-dose MTX. Specifically, reported failure rates are 1.5 percent if the initial serum β-hCG concentration is <1000 mIU/mL; 5.6 percent at 1000 to 2000 mIU/mL; 3.8 percent at 2000 to 5000 mIU/mL; and 14.3 percent when levels range between 5000 and 10,000 mIU/mL (Menon, 2007). Interestingly, the initial serum β-hCG value is not a valid indicator of the number of doses needed for successful resolution (Nowak-Markwitz, 2009).

Many early trials also used “large size” as an exclusion criterion, although these data are less precise. Lipscomb and colleagues (1998) reported a 93-percent success rate with single-dose MTX when the ectopic mass was <3.5 cm. This compared with success rates between 87 and 90 percent when the mass was >3.5 cm. Last, failure rates rise if cardiac activity is seen, with an 87-percent success rate in such cases.

Treatment Side Effects

These regimens are associated with minimal laboratory changes and symptoms, although occasional toxicity may be severe. Kooi and Kock (1992) reviewed 16 studies and reported that adverse effects resolved by 3 to 4 days after MTX was discontinued. The most common were liver involvement—12 percent; stomatitis— 6 percent; and gastroenteritis—1 percent. One woman had bone marrow depression. Fortunately, MTX treatment does not diminish ovarian reserve (Boots, 2016; Uyar, 2013). Moreover, conceptions within the first 6 months after MTX treatment for this indication are not associated with elevated rates of miscarriage or fetal malformations and growth restriction (Svirsky, 2009).

Importantly, 65 to 75 percent of women initially given MTX will have increasing pain beginning several days after therapy. Thought to reflect separation of the ectopic pregnancy from the tubal wall, this "separation pain" generally is mild and relieved by analgesics. In a series of 258 MTX-treated women by Lipscomb and colleagues (1999b), 20 percent had pain that merited evaluation in a clinic or emergency room. Ultimately, 10 of these 53 underwent surgical exploration. Said another way, 20 percent of women given single-dose MTX will have significant pain, and about 20 percent of these will require laparoscopy.

Monitoring Therapy Efficacy

As shown in Table 19-1, monitoring single-dose therapy calls for serum β-hCG determinations at days 4 and 7 following initial injection on day 1. After single-dose MTX, mean serum β-hCG levels may rise or fall during the first 4 days and then gradually decline. If the level fails to drop more than 15 percent between days 4 and 7, then a second dose of MTX is required. This is necessary in 15 to 20 percent of women treated with single-dose therapy (Cohen, 2014a; Kirk, 2007).

With multidose MTX, levels are measured at 48-hour intervals until they fall more than 15 percent. Up to four doses may be given to one patient if required (Stovall, 1991).

Once appropriately dropping levels are achieved in either regimen, serum β-hCG determinations are then measured weekly until undetectable. Outpatient monitoring is preferred, but if patient safety or compliance is questioned, the woman is hospitalized during initial surveillance. Lipscomb and colleagues (1998) used single-dose MTX to successfully treat 287 women and reported that the average time to resolution—defined as a serum β-hCG level <15 mIU/mL, was 34 days. Importantly, the longest time was 109 days.

Failure is judged when the β-hCG level plateaus or rises or the tube ruptures. Importantly, tubal rupture can occur even with declining β-hCG levels. Lipscomb and associates (1998) described a 14-day mean time to rupture, but one woman had tubal rupture 32 days after single-dose MTX.

From one metaanalysis, the overall success rate for treatment with MTX is 89 percent. The success for the multidose regiment is 92.7 percent, whereas that for single-dose is 88.1 percent (Barnhart, 2003a). Despite this difference, the single dose is more frequently used because of its simplicity and convenience.

Surgical Management

Studies have compared laparotomy with laparoscopic surgery for ectopic pregnancy (Lundorff, 1991; Murphy, 1992; Vermesh, 1989). Overall, tubal patency and number of subsequent uterine pregnancies do not differ between these routes. Thus, laparoscopy is the preferred surgical treatment for ectopic pregnancy unless a woman is hemodynamically unstable. As experience has accrued, cases previously managed by laparotomy—for example, ruptured tubal pregnancies with hemoperitoneum—can safely be managed laparoscopically by those with suitable expertise (Cohen, 2013; Sagiv, 2001). That said, the lowered venous return and cardiac output associated with the pneumoperitoneum of laparoscopy must be factored into the decision to select minimally invasive surgery for hypovolemic women.

Before surgery, future fertility desires are discussed. In women desiring permanent sterilization, the unaffected tube can be ligated or removed concurrently with salpingectomy for the affected fallopian tube.

Two procedures—salpingostomy or salpingectomy—are options. Two multicenter, randomized controlled trials have compared laparoscopic outcomes between the two procedures in women with a normal contralateral fallopian tube. The European Surgery in Ectopic Pregnancy (ESEP) study randomized 231 women to salpingectomy and 215 to salpingostomy. After surgery, subsequent rates of ongoing pregnancy by natural conception did not differ significantly between groups—56 versus 61 percent, respectively (Mol, 2014). Again, in the DEMETER trial, the subsequent 2-year rate for achieving a uterine pregnancy did not differ between groups—64 versus 70 percent, respectively (Fernandez, 2013). In women with an abnormal-appearing contralateral tube, salpingostomy is a conservative option for fertility preservation.

Salpingostomy

This procedure is typically used to remove a small unruptured pregnancy. A 10- to 15-mm linear incision is made on the antimesenteric border of the fallopian tube over the pregnancy. The products usually will extrude from the incision. These can be carefully removed or flushed out using high-pressure irrigation that more thoroughly removes the trophoblastic tissue (Al-Sunaidi, 2007). Small bleeding sites are controlled with needlepoint electrocoagulation, and the incision is left unsutured to heal by secondary intention. Serum β-hCG levels are used to monitor response to both medical and surgical therapy. After linear salpingostomy, serum β-hCG levels decline rapidly over days and then more gradually, with a mean resolution time of approximately 20 days.

Seldom performed today, salpingotomy is essentially the same procedure except that the incision is closed with delayed-absorbable suture. According to Tulandi and Guralnick (1991), prognosis does not differ with or without suturing, and laparoscopic suturing adds surgical time.

Salpingectomy

Tubal resection may be used for both ruptured and unruptured ectopic pregnancies. To minimize the rare recurrence of pregnancy in the tubal stump, complete excision of the fallopian tube is advised. With one laparoscopic technique, the affected fallopian tube is lifted and held with atraumatic grasping forceps (Thompson, 2016). One of several suitable bipolar grasping devices is placed across the fallopian tube at the uterotubal junction. Once desiccated, the tube is cut. The bipolar device is then advanced across the most proximal portion of mesosalpinx. Similarly, current is applied, and the desiccated tissue cut. This process moves serially from the proximal mesosalpinx to its distal extent under the tubal ampulla. Alternatively, an endoscopic suture loop can be used to encircle and ligate the knuckle of involved fallopian tube and its underlying vascular supply within the mesosalpinx. Two consecutive suture loops are placed, and the tube distal to these ligatures is then cut free with scissors. Salpingectomy during laparotomy is shown in Chapter 39 (Nonpuerperal Tubal Sterilization).

Most tubal ectopic pregnancies are small and pliant. Accordingly, they can be held firmly by grasping forceps and drawn up into one of the accessory site cannulas. Larger tubal ectopic pregnancies may be placed in an endoscopic sac to prevent fragmentation as they are removed through the laparoscopic port site. Importantly, to remove all trophoblastic tissue, the pelvis and abdomen should be irrigated and suctioned free of blood and tissue debris. Slow and systematic movement of the patient from Trendelenburg to reverse Trendelenburg positioning during irrigation can also assist in dislodging stray tissue and fluid. These should be suctioned and removed from the peritoneal cavity.

Persistent Trophoblast

After surgery, β-hCG levels usually fall quickly and approximate 10 percent of preoperative values by day 12 (Hajenius, 1995; Vermesh, 1988). Persistent trophoblast is rare following salpingectomy, but complicates 5 to 15 percent of salpingostomies (Kayatas, 2014; Pouly, 1986; Seifer, 1993). Rates are lower for laparotomy versus laparoscopic procedures (Hajenius, 1995). Other risk factors are debatable but may include greater serum β-hCG levels and smaller ectopic size (Rabischong, 2010; Seifer, 1997). Bleeding caused by retained trophoblast is the most serious complication.

Incomplete removal of trophoblast can be identified by stable or rising β-hCG levels. Monitoring approaches are not codified. One scheme measures serum β-hCG levels on postoperative day 1, and values dropping <50 percent of the preoperative value reflect risk for persistent trophoblast (Spandorfer, 1997). Another measures weekly levels (Mol, 2008). With stable or increasing β-hCG levels, additional surgical or medical therapy is necessary. Without evidence for tubal rupture, standard therapy for this is single-dose MTX, 50 mg/m^2 × body surface area (BSA). Rupture and bleeding require surgical intervention.

Medical versus Surgical Therapy

Several randomized trials have compared methotrexate treatment with laparoscopic surgery. One multicenter trial compared a multidose MTX protocol with laparoscopic salpingostomy and found no differences for tubal preservation and primary treatment success (Hajenius, 1997). In this same study group, however, health-related quality-of-life factors such as pain, posttherapy depression, and decreased perception of health were significantly impaired after systemic MTX compared with laparoscopic salpingostomy (Nieuwkerk, 1998). In their randomized controlled trial, Fernandez and coworkers (2013) compared multidose medical therapy against salpingostomy and found that medical and conservative surgery provided similar 2-year rates of attaining a uterine pregnancy.

Evidence is conflicting when single-dose MTX is compared with surgical intervention. In two separate studies, single-dose MTX was overall less successful in resolving pregnancy than laparoscopic salpingostomy, although tubal patency and subsequent uterine pregnancy rates were similar between both groups (Fernandez, 1998; Sowter, 2001). Women treated with MTX had significantly better physical functioning immediately following therapy, but there were no differences in psychological functioning. Krag Moeller and associates (2009) reported the results from their randomized trial that had a median surveillance period of 8.6 years during which future pregnancy rates were evaluated. Ectopic-resolution success rates were not significantly different between those managed surgically and those treated with MTX. Moreover, cumulative spontaneous uterine pregnancy rates were not different between the MTX group (73 percent) and the surgical group (62 percent).

Based on these studies, we conclude that women who are hemodynamically stable and in whom there is a small tubal diameter, no fetal cardiac activity, and serum β-hCG concentrations <5000 mIU/mL have similar outcomes with medical or surgical management. Despite lower success rates with medical therapy for women with larger tubal size, higher serum β-hCG levels, and fetal cardiac activity, medical management can be offered to the motivated woman who understands the risks.

Expectant Management

In select cases, it is reasonable to observe very early tubal pregnancies that are associated with stable or falling serum β-hCG levels. Mavrelos and coworkers (2013) noted that almost one third of 333 tubal ectopic pregnancies measuring <3 cm and with β-hCG levels <1500 mIU/mL resolved without intervention. Cohen and associates (2014b) similarly followed 674 women with declining β-hCG levels to successful resolution. These findings have been supported by smaller randomized trials (Jurkovic, 2017; van Mello, 2013).

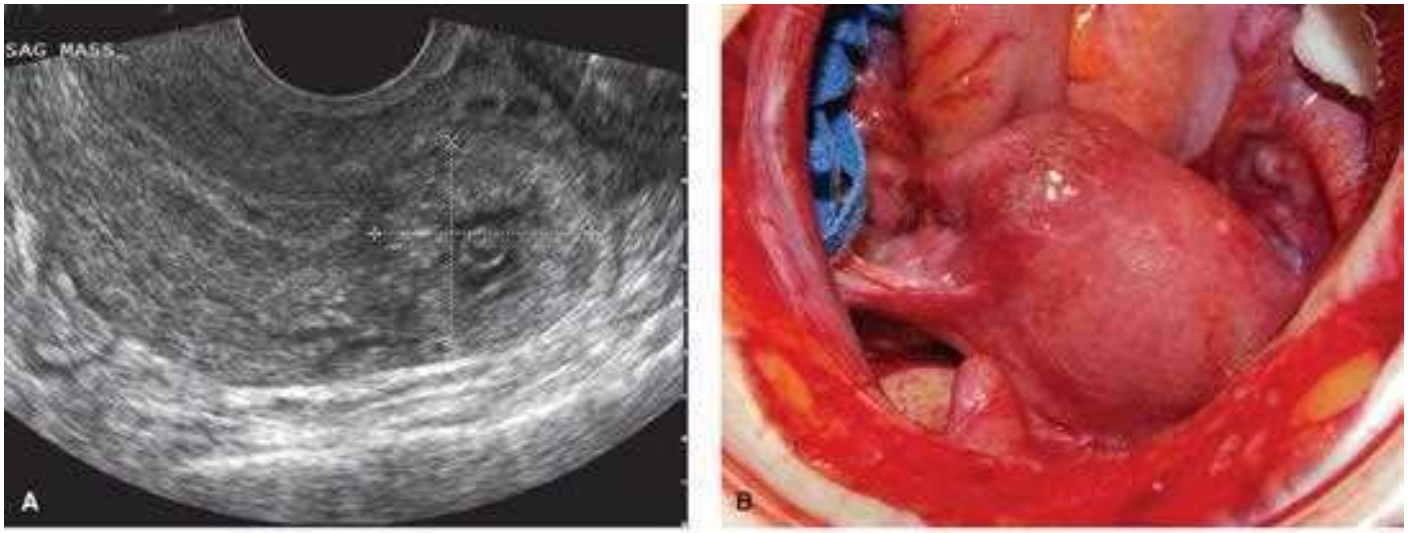
With expectant management, subsequent rates of tubal patency and intrauterine pregnancy are comparable with surgical or medical management. That said, compared with the established safety of medical and surgical therapy, the prolonged surveillance and risks of tubal rupture support the practice of expectant therapy only in appropriately selected and counseled women.

INTERSTITIAL PREGNANCY

Diagnosis

An interstitial pregnancy is one that implants within the proximal tubal segment that lies within the muscular uterine wall (Fig. 19-7). Incorrectly, they may be called cornual pregnancies, but this term describes a conception that develops in the rudimentary horn of a uterus with a müllerian anomaly (Moawad, 2010). Risk factors are similar to others discussed for tubal ectopic pregnancy, although previous ipsilateral salpingectomy is a specific risk factor for interstitial pregnancy (Lau, 1999). Undiagnosed interstitial pregnancies usually rupture following 8 to 16 weeks of amenorrhea, which is later than for more distal pregnancies. This is due to greater distensibility of the myometrium covering the interstitial fallopian tube segment. Because of the proximity of these pregnancies to the uterine and ovarian arteries, hemorrhage can be severe and associated with mortality rates as high as 2.5 percent (Tulandi, 2004).

FIGURE 19-7
Interstitial ectopic pregnancy. **A.** This parasagittal view using transvaginal sonography shows an empty uterine cavity and a mass that is cephalad and lateral to the uterine fundus (*calipers*). **B.** Intraoperative photograph during laparotomy and before cornual resection of the same ectopic pregnancy. In this frontal view, the bulging right-sided interstitial ectopic pregnancy is lateral to the round ligament insertion and medial to the isthmic portion of the fallopian tube. (Used with permission from Drs. David Rogers and Elaine Duryea.)



With transvaginal sonography and serum β-hCG assays, interstitial pregnancy can now be diagnosed early in many cases, but diagnosis can be challenging. These pregnancies sonographically can appear similar to an eccentrically implanted uterine pregnancy, especially in a uterus with a müllerian anomaly. Criteria that may aid differentiation include: an empty uterus, a gestational sac seen separate from the endometrium and >1 cm away from the most lateral edge of the uterine cavity, and a thin, <5-mm myometrial mantle surrounding the sac (Timor-Tritsch, 1992). Moreover, an echogenic line, known as the "interstitial line sign," extending from the gestational sac to the endometrial cavity most likely represents the interstitial portion of the fallopian tube and is highly sensitive and specific (Ackerman, 1993a). In unclear cases, three-dimensional (3-D) sonography, magnetic resonance (MR) imaging, or diagnostic laparoscopy can help clarify anatomy (Parker, 2012; Tanaka, 2014). Laparoscopically, an enlarged protuberance is found lying outside the round ligament and coexistent with a normal distal fallopian tube and ovary.

Management

Surgical management with either cornual resection or cornuostomy may be performed via laparotomy or laparoscopy, depending on patient hemodynamic stability and surgeon expertise (Hoffman, 2016; Zuo, 2012). With either approach, intraoperative intramyometrial vasopressin injection may limit surgical blood loss, and β-hCG levels should be monitored postoperatively to exclude remnant trophoblast. Cornual resection removes the gestational sac and surrounding cornual myometrium by means of a wedge excision (Fig. 19-8). Alternatively, cornuostomy involves incision of the cornua and suction or instrument extraction of the pregnancy. Both instances require myometrial closure.

FIGURE 19-8
During cornual resection, the pregnancy, surrounding myometrium, and ipsilateral fallopian tube are excised en bloc. The incision is angled inward as it is deepened. This creates a wedge shape into the myometrium, which is then closed in layers with delayed-absorbable suture. The serosa is closed with subcuticular style suturing. New York, McGraw-Hill Education, 2016.)

With early diagnosis, medical management may be considered. But because of the low incidence, consensus regarding methotrexate regimens is lacking. In their small series, Jermy and associates (2004) reported a 94-percent success with systemic MTX using a dose of 50 mg/m^2 × BSA. Others have described direct MTX injection into the gestational sac (Framarino-dei-Malatesta, 2014). Importantly, because these women typically have higher initial serum β-hCG levels, longer surveillance is usually needed.

The risk of uterine rupture with subsequent pregnancies following either medical or surgical management is unclear. Thus, careful observation of these women during pregnancy, along with strong consideration of elective cesarean delivery, is warranted.

Distinct from interstitial pregnancy, the term *angular pregnancy* describes implantation within the endometrial cavity but at one cornu and medial to the uterotubal junction and round ligament. An angular pregnancy displaces the round ligament upward and outward, whereas an interstitial tubal pregnancy does not shift it (Arleo, 2014). This distinction is important because angular pregnancies can sometimes be carried to term but with increased risk of abnormal placentation and its consequences (Jansen, 1981).

CESAREAN SCAR PREGNANCY

Diagnosis

This term describes implantation within the myometrium of a prior cesarean delivery scar. Its incidence approximates 1 in 2000 normal pregnancies and has increased along with the cesarean delivery rate (Ash, 2007; Rotas, 2006). The pathogenesis of cesarean scar pregnancy (CSP) has been likened to that for placenta accreta and carries similar risk for serious hemorrhage (Timor-Tritsch, 2014a,b). It is unknown if the incidence increases with multiple cesarean deliveries or if it is affected by either one- or two-layer uterine incision closure during cesarean.

Women with CSP usually present early, and pain and bleeding are common. Still, up to 40 percent of women are asymptomatic, and the diagnosis is made during routine sonographic examination (Rotas, 2006). Sonographically, differentiating between a cervicoisthmic intrauterine pregnancy and CSP can be difficult (Moschos, 2008a; Timor-Tritsch, 2016). According to Godin (1997), four sonographic criteria should be satisfied for the diagnosis and are described in Figure 19-9. Although TVS is the typical first-line imaging tool, MR imaging is useful when sonography is inconclusive (Huang, 2014; Osborn, 2012).

FIGURE 19-9

Cesarean scar pregnancy. **A.** Transvaginal sonogram of a uterus with a cesarean scar pregnancy (CSP) in a sagittal plane. An empty uterine cavity is identified by a bright hyperechoic endometrial stripe (*long, white arrow*). An empty cervical canal is similarly identified (*short, white arrow*). Last, an intrauterine mass is seen in the anterior part of the uterine isthmus (*red arrows*). Myometrium between the bladder and gestational sac is absent or thinned (1 to 3 mm). Photo contributor: Dr. Elysia Moschos.) **B.** Hysterectomy specimen containing a cesarean scar pregnancy. **C.** This same hysterectomy specimen is transversely sectioned at the level of the uterine isthmus and through the gestational sac. The uterine body lies to the left, and the cervix is on the right. A metal probe is placed through the endocervical canal to show the eccentric development of this gestation. Only a thin layer of myometrium overlies this pregnancy, which pushes anteriorly through the uterine wall. (Reproduced with permission from Gala RB: Ectopic pregnancy. In Hoffman BL, Schorge JO, Bradshaw KD, et al: Williams Gynecology, 3rd ed. New York, McGraw-Hill Education; 2016. Photo contributors: Drs. Sunil Balgobin, Manisha Sharma, and Rebecca Stone.)

Management

Treatment standards are lacking, and several options are available. Expected management is an option, and live birth rates were 57 percent in one review (Maheux-Lacroix, 2017). However, hemorrhage, placenta accreta, and uterine rupture are risks. Thus, hysterectomy is an acceptable initial choice in those desiring sterilization. It is sometimes necessary with heavy uncontrolled bleeding. Fertility-preserving options include systemic or locally injected methotrexate, either alone or combined with conservative surgery (Birch Petersen, 2016; Cheung, 2015). Surgical procedures include visually guided suction curettage, hysteroscopic removal, or isthmic excision done abdominally or vaginally. These are completed solely or with adjunctive MTX (Jurkovic, 2016; Li, 2014a; Wang, 2014; Yang, 2009). Often uterine artery embolization (UAE) is used preoperatively to minimize hemorrhage risk (Zhang, 2012; Zhuang, 2009). Foley balloon catheter placement can be another option for procedure-associated bleeding (Timor-Tritsch, 2015a).

Following conservative treatment, subsequent pregnancies have good outcomes, but placenta accreta and recurrent CSP are risks (Gao, 2016; Wang, 2015). Uterine arteriovenous malformations are a potential long-term complication (Timor-Tritsch, 2015b).

CERVICAL PREGNANCY

Diagnosis

This rare ectopic pregnancy is defined by cervical glands noted histologically opposite the placental attachment site and by all or part of the placenta found below the entrance of the uterine vessels or below the peritoneal reflection on the anterior uterus. In a typical case, the endocervix is eroded by trophoblast, and the pregnancy develops in the fibrous cervical wall. Predisposing risks include ART and prior uterine curettage (Ginsburg, 1994; Jeng, 2007).

Painless vaginal bleeding is reported by 90 percent of women with a cervical pregnancy—a third of these have massive hemorrhage (Ushakov, 1997). As pregnancy progresses, a distended, thin-walled cervix with a partially dilated external os may be evident. Above the cervical mass, a slightly enlarged uterine fundus can be felt. Identification of cervical pregnancy is based on speculum examination, palpation, and TVS. Sonographic findings typical of cervical pregnancy are shown and described in Figure 19-10. MR imaging and 3-D sonography have also been used to confirm the diagnosis (Jung, 2001; Sherer, 2008).

FIGURE 19-10

Cervical pregnancy. Transvaginal sonographic findings may include: (1) an hourglass uterine shape and ballooned cervical canal; (2) gestational tissue at the level of the cervix (*black arrow*); (3) absent intrauterine gestational tissue (*white arrows*); and (4) a portion of the endocervical canal seen interposed between the gestation and the endometrial canal. (Used with permission from Dr. Elysia Moschos.)

Management

Cervical pregnancy may be treated medically or surgically. Conservative management strives to minimize hemorrhage, resolve the pregnancy, and preserve fertility. In many centers, including ours, methotrexate has become the first-line therapy in stable women, and administration follows protocols listed in Table 19-1 (Verma, 2011; Zakaria, 2011). The drug has also been injected directly into the gestational sac, alone or with systemic doses (Jeng, 2007; Murji, 2015). Others describe MTX infusion combined with uterine artery embolization—"chemoembolization" (Xiaolin, 2010).

With MTX regimens, resolution and uterine preservation are achieved for gestations <12 weeks in 91 percent of cases (Kung, 1997). In selecting appropriate candidates, Hung and colleagues (1996) noted higher risks of systemic MTX treatment failure in those with a gestational age >9 weeks, β-hCG levels >10,000 mIU/mL, crown-rump length >10 mm, and fetal cardiac activity. For this reason, many induce fetal death with intracardiac or intrathoracic injection of potassium chloride. With a single-dose intramuscular protocol, an MTX dose between 50 and 75 mg/m^2 × BSA is typical. To resolve fetal cardiac activity, a sonographically guided fetal intracardiac injection of 2 mL (2 mEq/mL) potassium chloride solution can be given (Verma, 2009). Song and associates (2009) described management of 50 cases and observed that sonographic resolution lagged far behind serum β-hCG regression.

As an adjunct to medical or surgical therapy, uterine artery embolization has been described either as a response to bleeding or as a preprocedural preventive tool (Hirakawa, 2009; Zakaria, 2011). Also, in the event of hemorrhage, a 26F Foley catheter with a 30-mL balloon can be placed intracervically and inflated to effect

hemostasis by vessel tamponade and to monitor uterine drainage. The balloon remains inflated for 24 to 48 hours and is gradually decompressed over a few days (Ushakov, 1997).

Although conservative management is feasible for many women with cervical pregnancies, suction curettage or hysterectomy may be selected. Moreover, hysterectomy may be required with bleeding uncontrolled by conservative methods. Because of the close proximity of the ureters to the ballooned cervix, urinary tract injury rates are a concern during hysterectomy.

If cervical curettage is planned, intraoperative bleeding may be lessened by preoperative UAE, by intracervical vasopressin injection, or by a cerclage placed at the internal cervical os to compress feeding vessels (Chen, 2015; Fylstra, 2014; Wang, 2011). Also, cervical branches of the uterine artery can effectively be ligated with vaginal placement of hemostatic cervical sutures on the lateral aspects of the cervix at 3 and 9 o'clock (Bianchi, 2011). Following curettage, a Foley balloon can be placed to tamponade bleeding and is managed as described earlier. Suction curettage may be especially favored in rare cases of a heterotopic pregnancy composed of a cervical and a desired uterine pregnancy (Tsakos, 2015).

ABDOMINAL PREGNANCY

Diagnosis

These rare ectopic pregnancies are defined as an implantation in the peritoneal cavity exclusive of tubal, ovarian, or intraligamentous implantations. Although a zygote can traverse the tube and implant primarily in the peritoneal cavity, most abdominal pregnancies are thought to follow early tubal rupture or abortion with reimplantation. In cases of advanced extrauterine pregnancy, it is not unusual for the placenta to be still at least partially attached to the uterus or adnexa.

Diagnosis may be difficult. First, symptoms may be absent or vague. Laboratory tests are typically uninformative, although maternal serum alpha-fetoprotein levels can be elevated. Clinically, abnormal fetal positions may be palpated, or the cervix is displaced (Zeck, 2007). Sonographically, the diagnosis is often missed (Costa, 1991). Oligohydramnios is common but nonspecific. Other clues include a fetus seen separate from the uterus or eccentrically positioned within the pelvis; lack of myometrium between the fetus and the maternal anterior abdominal wall or bladder; extrauterine placental tissue; or bowel loops surrounding the gestational sac (Allibone, 1981; Chukus, 2015). If additional anatomical information is needed, MR imaging can help confirm the diagnosis and provide maximal information concerning placental implantation (Bertrand, 2009; Mittal, 2012).

Management

Treatment of an abdominal pregnancy depends on the gestational age at diagnosis. Conservative management carries a maternal risk for sudden and dangerous hemorrhage. Moreover, Stevens (1993) reported fetal malformations and deformations in 20 percent. Thus, we believe that termination generally is indicated when the diagnosis is made. Certainly, before 24 weeks, conservative treatment rarely is justified. Despite this, some have described waiting until fetal viability with close surveillance (Kim, 2013; Marcellin, 2014).

Once placental implantation has been assessed, several options to control intraoperative hemorrhage mimic those used for placenta accrete syndrome (Chap. 41, Adjunctive Surgical Procedures). The principal surgical objectives involve delivery of the fetus and careful assessment of placental implantation without provoking hemorrhage. Unnecessary exploration is avoided because the anatomy is commonly distorted and surrounding areas are extremely vascular. Importantly, placental removal may precipitate torrential hemorrhage because the normal hemostatic mechanism of myometrial contraction to constrict hypertrophied blood vessels is lacking. If it is obvious that the placenta can be safely removed or if there is already hemorrhage from its implantation site, then removal begins immediately. When possible, blood vessels supplying the placenta should be ligated first.

Some advocate leaving the placenta in place as the lesser of two evils. It decreases the chance of immediate life-threatening hemorrhage, but at the expense of long-term sequelae. If left in the abdominal cavity, the placenta commonly becomes infected, with subsequent formation of abscesses, adhesions, intestinal or ureteral obstruction, and wound dehiscence (Bergstrom, 1998; Martin, 1988). In many of these cases, surgical removal becomes inevitable. If the placenta is left, its involution may be monitored using sonography and serum β-hCG levels (France, 1980; Martin, 1990). Color Doppler sonography can be used to assess changes in blood flow. In some cases, and usually depending on its size, placental function rapidly declines, and the placenta is resorbed. But placental resorption may take years (Roberts, 2005; Valenzano, 2003).

If the placenta is left in place, postoperative methotrexate use is controversial. It has been recommended to hasten involution but has been reported to cause accelerated placental destruction with accumulation of necrotic tissue and infection with abscess formation (Rahman, 1982). It is difficult to envision a supporting role for the use of an antimetabolite for a senescent organ (Worley, 2008).

OVARIAN PREGNANCY

Ectopic implantation of the fertilized egg in the ovary is rare and is diagnosed if four clinical criteria are met. These were outlined by Spiegelberg (1878): (1) the ipsilateral tube is intact and distinct from the ovary; (2) the ectopic pregnancy occupies the ovary; (3) the ectopic pregnancy is connected by the uteroovarian ligament to the uterus; and (4) ovarian tissue can be demonstrated histologically amid the placental tissue. Risk factors are similar to those for tubal pregnancies, but ART or IUD failure seems to be disproportionately associated (Zhu, 2014). Presenting complaints and findings mirror those for tubal ectopic pregnancy. Although the ovary can accommodate the expanding pregnancy more easily than the fallopian tube, rupture at an early stage is the usual consequence (Melcer, 2016).

Transvaginal sonography use has resulted in a more frequent diagnosis of unruptured ovarian pregnancies. Sonographically, an internal anechoic area is surrounded by a wide echogenic ring, which in turn is surrounded by ovarian cortex (Comstock, 2005). In their review of 49 cases, Choi and associates (2011) noted that the

diagnosis may not be made until surgery, as many cases are presumed tubal ectopic pregnancy. Moreover, at surgery, an early ovarian pregnancy may be considered to be a hemorrhagic corpus luteum.

Evidence-based management accrues mainly from case reports (Hassan, 2012; Scutiero, 2012). Classically, management for ovarian pregnancies has been surgical. Small lesions can be managed by ovarian wedge resection or cystectomy, whereas larger lesions require oophorectomy (Elwell, 2015; Melcer, 2015). With conservative surgery, β-hCG levels should be monitored to exclude remnant trophoblast.

OTHER ECTOPIC SITES

Pregnancy implanted toward the mesosalpinx may rupture into a space formed between the broad ligament leaves and become an intraligamentous or broad ligament pregnancy. Rents in prior cesarean scars serve as another conduit (Rudra, 2013). These are rare, and information accrues from case reports. Clinical findings and management mirror those for abdominal pregnancy. Although laparotomy is required in most instances, a few case reports describe laparoscopic excision of early small pregnancies (Apantaku, 2006; Cormio, 2006).

Ectopic placental implantations in less expected sites have been described in case reports and include the omentum, liver, and retroperitoneum, among others (Brouard, 2015; Liang, 2014; Watrowski, 2015). Also, intramural uterine implantations at sites other than a cesarean scar have been noted in women with prior uterine surgeries, ART, or adenomyosis (Memtsa, 2013; Wu, 2013). Although laparotomy is preferred by many for these ectopic sites, laparoscopic excision by those with suitable skills is gaining acceptance.
