As in Williams' time, obstetrical hemorrhage continues along with hypertension and infection to be one part of the infamous "triad" of maternal death causes. It also is a leading reason for admission of pregnant women to intensive care units (Chantry, 2015; Crozier, 2011; De Greve, 2016; Guntupalli, 2015). Hemorrhage was a direct cause of 11.4 percent of 5367 pregnancy-related maternal deaths from 2006 to 2013 in the United States (Creanga, 2015, 2017). Similarly, 16 percent of 1102 maternal deaths recorded in the Nationwide Inpatient Sample were caused by hemorrhage (Kuriya, 2016). In developing countries, hemorrhage's contribution is even more striking, and it is the single most important cause of maternal death worldwide (Goffman, 2016; Oladapo, 2016; Thomas, 2016). Despite these numbers, a declining maternal mortality rate from hemorrhage in the United States has been a seminal achievement. But, as discussed in Chapter 1 (Maternal Mortality), it seems unlikely that deaths from hemorrhage have reached an irreducible minimum.

GENERAL CONSIDERATIONS

Mechanisms of Normal Hemostasis

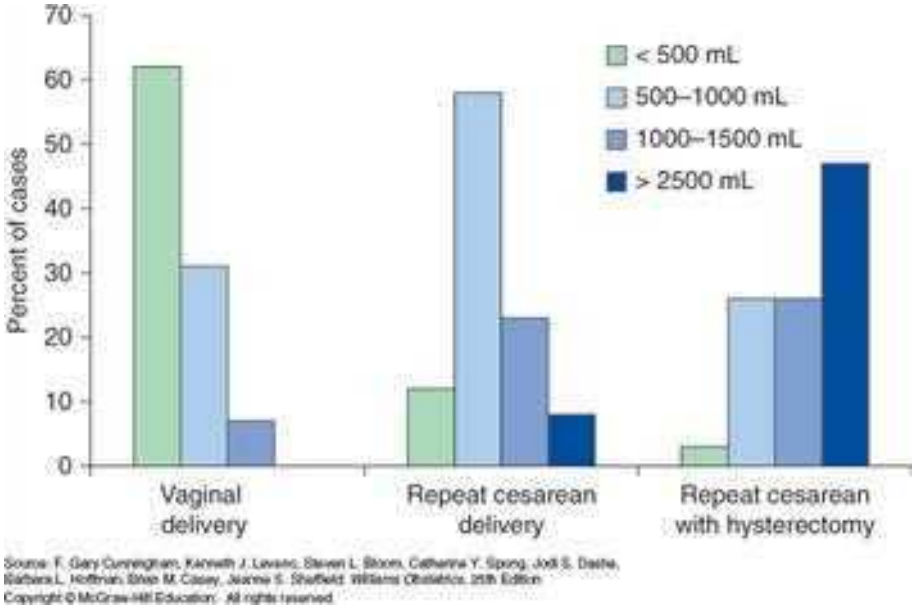
A major concept in understanding the pathophysiology and management of obstetrical hemorrhage is the mechanism by which hemostasis is achieved after normal delivery. Recall that near term an incredible amount of blood—at least 600 mL/min—flows through the intervillous space (Pates, 2010). This prodigious flow circulates through the spiral arteries, which average 120 in number. Also, recall that these vessels have no muscular layer because of their remodeling by trophoblasts, which creates a low-pressure system. With placental separation, these vessels at the implantation site are avulsed, and hemostasis is achieved first by myometrial contraction, which compresses this formidable number of large vessels. Compression is followed by clotting and obliteration of vessel lumens.

If, after delivery, the myometrium contracts vigorously, fatal hemorrhage from the placental implantation site is unlikely. *Importantly, an intact coagulation system is not necessary for postpartum hemostasis unless there are lacerations in the uterus, birth canal, or perineum.* At the same time, however, fatal postpartum hemorrhage can result from uterine atony despite normal coagulation.

Definition and Incidence

Traditionally, postpartum hemorrhage is defined as the loss of ≥500 mL of blood after completion of the third stage of labor. This is problematic because almost half of all women delivered vaginally shed that amount of blood or more when losses are carefully measured (Pritchard, 1962). These results are depicted in Figure 41-1 and show further that approximately 5 percent of women delivering vaginally lose more than 1000 mL of blood. According to the American College of Obstetricians and Gynecologists (2017d), postpartum hemorrhage is defined as cumulative blood loss >1000 mL accompanied by signs and symptoms of hypovolemia. And, almost a third of women undergoing cesarean delivery have blood loss that exceeds 1000 mL. *These studies show that estimated blood loss is commonly only approximately half the actual loss*. Because of this, estimated blood loss in excess of "average" should alert the obstetrician to possible excessive bleeding. Whether quantification of blood loss improves accuracy is controversial (Hamm, 2017; Toledo, 2007).

FIGURE 41-1
Blood loss associated with vaginal delivery, repeat cesarean delivery, and repeat cesarean delivery plus hysterectomy. (Data from Pritchard, 1962.)



The blood volume of a pregnant woman with normal pregnancy-induced hypervolemia usually rises by half, but individual increases range from 30 to 60 percent, that is, 1500 to 2000 mL for an average-sized woman (Pritchard, 1965). The equation to calculate blood volume is shown in Table 41-1. It is axiomatic that a normal pregnant woman tolerates, without any decrease in postpartum hematocrit, blood loss at delivery that approaches the volume of blood that she added during pregnancy. Thus, if blood loss is less than the pregnancy-added volume, the hematocrit remains the same acutely and during the first several days postpartum. It then rises as nonpregnant plasma volume normalizes during the next week or so. *Whenever the postpartum hematocrit is lower than one obtained on admission for delivery, blood loss can be estimated as the sum of the calculated pregnancy-added volume plus 500 mL for each 3 volume percent decline of the hematocrit.*

TABLE 41-1

Calculation of Maternal Total Blood Volume

Nonpregnant blood volume[a]: $\frac{[\text{Height (inches)} \times 50] + [\text{Weight (pounds)} \times 25]}{7} = \text{Blood volume (mL)}$
Pregnancy blood volume:
Average increase is 30 to 60 percent of calculated nonpregnant volume
Increases across gestational age and plateaus at approximately 34 weeks
Usually larger with low normal-range hematocrit (~30) and smaller with high normal-range hematocrit (~40)
Average increase is 40 to 80 percent with multifetal gestation
Average increase is less with preeclampsia—volumes vary inversely with severity
Postpartum blood volume with serious hemorrhage:
Assume acute return to nonpregnant total volume after fluid resuscitation
Pregnancy hypervolemia cannot be restored postpartum

[a]Formula arrived at by measuring blood volume and blood loss in more than 100 women using ^{51}Cr-labeled erythrocytes.

Data from Hernandez, 2012.

Excessive blood loss has been estimated by several methods. Sosa and colleagues (2009) used specially constructed drapes and reported that 10.8 percent of women had hemorrhage in excess of 500 mL with vaginal delivery, whereas 1.9 percent lost >1000 mL. Compared with the findings of Figure 41-1, these estimates likely are too low. Tita and associates (2012) used a 6-volume percent drop in the postpartum hematocrit to define clinically significant blood loss with vaginal delivery. This decline easily signifies a >1000-mL blood loss in the averaged-sized woman. They documented this amount in a fourth of women, which agrees with Figure 41-1.

Another marker used to estimate hemorrhage incidence is the transfusion rate. In the study by Tita just cited, more than 6 percent of women who delivered vaginally underwent blood transfusions. In a study of more than 66,000 women delivered at Parkland Hospital, 2.3 percent overall were given blood transfusions for hypovolemia (Hernandez, 2012). Half of these women had undergone cesarean delivery. Importantly, for those transfused, these investigators calculated blood loss to average approximately 3500 mL! Finally, Green and coworkers (2016) reported that the incidence of *massive transfusion* for postpartum hemorrhage was 23 per 100,000 births.

From the foregoing, it is apparent that significant blood loss accompanies up to a fourth of vaginal deliveries. The amounts and proportions for cesarean delivery are much greater. And, hemorrhage is underreported. For example, data from the National Hospital Discharge Summary database reported postpartum hemorrhage

incidences of only 2.0 and 2.6 percent for two epochs in the United States (Berg, 2009). Similar incidences have been reported by others (Kramer, 2013; Mehrabadi, 2013; Patterson, 2014).

Risks

Numerous clinical circumstances raise the risks for obstetrical hemorrhage. The imposing list shown in Table 41-2 illustrates that hemorrhage can manifest at any time throughout pregnancy, delivery, and the puerperium. Thus, any description of obstetrical hemorrhage should include gestational age. Contributions to maternal death from some of these causes of are shown in Figure 41-2.

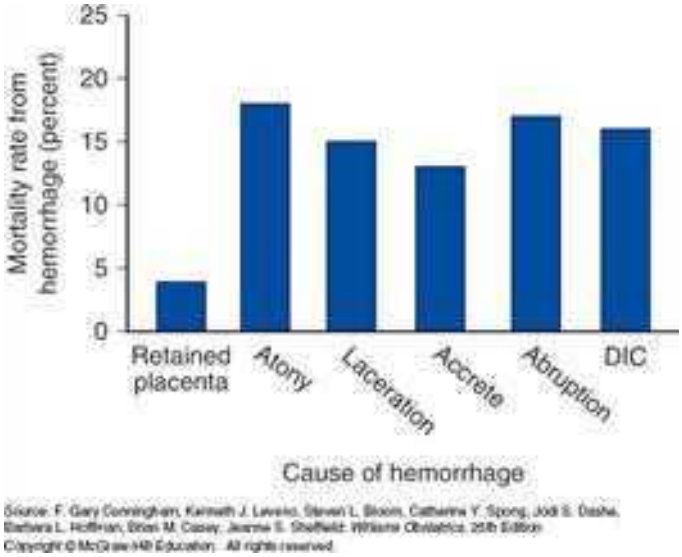
TABLE 41-2

Obstetrical Hemorrhage: Causes, Predisposing Factors, and Vulnerable Patients

Abnormal Placentation	**Uterine Atony**
Placenta previa	Uterine overdistention
Placental abruption	Large fetus
Morbidly adherent placenta	Multiple fetuses
Ectopic pregnancy	Hydramnios
Hydatidiform mole	Retained clots
Injuries to the Birth Canal	Labor induction
Episiotomy and lacerations	Anesthesia or analgesia
Forceps or vacuum delivery	Halogenated agents
Cesarean delivery or hysterectomy	Conduction analgesia with hypotension
Uterine rupture	Labor abnormalities
Previously scarred uterus	Rapid labor
High parity	Prolonged labor
Hyperstimulation	Augmented labor
Obstructed labor	Chorioamnionitis
Intrauterine manipulation	Previous uterine atony
Midforceps rotation	Parity: primiparity, high parity
Breech extraction	**Coagulation Defects—Intensify Other Causes**
Obstetrical Factors	Massive transfusions
Obesity	Placental abruption
Previous postpartum hemorrhage	Sepsis syndrome
Early preterm pregnancy	Severe preeclampsia syndrome
Sepsis syndrome	Acute fatty liver
Preeclampsia/eclampsia	Anticoagulant treatment
Vulnerable Patients	Congenital coagulopathies
Chronic renal insufficiency	Amnionic fluid embolism
Constitutionally small size	Prolonged retention of dead fetus
	Saline-induced abortion

FIGURE 41-2

Contributions to maternal death from various causes of obstetrical hemorrhage. Percentages are approximations because of different classification schemata used. DIC = disseminated intravascular coagulopathy. (Data from Al-Zirqi, 2008; Berg, 2010; Creanga, 2015; Zwart, 2008.)



Timing

Antepartum Hemorrhage

Obstetrical hemorrhage is traditionally classified as *antepartum*—such as with placenta previa or placental abruption, or as *postpartum*—commonly caused by uterine atony or genital tract lacerations. In individual women, however, these terms are nonspecific, and it is reasonable to specify the cause and gestational age as descriptors.

Bleeding during various times in gestation may give a clue to its cause. Many aspects of bleeding during the first half of pregnancy from abortion or ectopic pregnancy are covered in Chapters 18 and 19. Discussions that follow concern pregnancies with a viable-size fetus. *In these cases, rapid assessment should always consider the deleterious fetal effects of maternal hemorrhage.*

During active labor, slight vaginal bleeding is common. This “bloody show” is the consequence of effacement and dilation of the cervix, with tearing of small vessels. Uterine bleeding above the cervix, however, is concerning. It may follow some separation of a placenta previa implanted in the immediate vicinity of the cervical canal, or it may be from a placental abruption or uterine tear. In some women, especially with a placenta previa, cervical varicosities may bleed (O’Brien, 2013). Rarely, there may be velamentous insertion of the umbilical cord, and the involved placental vessels may overlie the cervix—*vasa previa.* In this case, serious fetal hemorrhage follows laceration of these vessels at the time of membrane rupture (Swank, 2016).

Near term in many women, the source of uterine bleeding is not identified, bleeding ceases, and no apparent anatomical cause is found at delivery. In most of these cases, bleeding likely originated from a slight marginal placental separation. *Despite this, any pregnancy with antepartum bleeding remains at higher risk for an adverse outcome even though bleeding has stopped and placenta previa has been excluded sonographically.*

Bleeding after midpregnancy is associated with several adverse outcomes. The Canadian Perinatal Network described 806 women with hemorrhage between 22 and 28 weeks’ gestation (Sabourin, 2012). Placental abruption (32 percent), previa (21 percent), and cervical bleeding (6.6 percent) were the most frequent causes identified. In a third, no cause was found. Of all women, 44 percent were delivered before 29 weeks’ gestation. In more than 68,000 women in Scotland, the incidence of antepartum hemorrhage after the first trimester was 11 percent (Bhandari, 2014). These women were at significantly higher risk for preterm birth, labor induction, and postpartum hemorrhage.

Postpartum Hemorrhage

In most cases, the source of postpartum hemorrhage can and should be determined. Frequent causes are uterine atony with placental site bleeding, genital tract trauma, or both. Postpartum hemorrhage is usually obvious. Important exceptions are unrecognized intrauterine and intravaginal blood accumulation and uterine rupture with intraperitoneal or retroperitoneal bleeding. Another consideration is an expanding vulvar or vaginal hematoma (Puerperal Hematomas). Initial evaluation attempts to differentiate uterine atony from genital tract lacerations. For this, risk factors are sought, the lower genital tract is examined, and uterine tone is assessed. Atony is identified by a boggy, soft uterus during bimanual examination and by expression of clots and hemorrhage during uterine massage.

Persistent bleeding despite a firm, well-contracted uterus suggests that hemorrhage most likely is from lacerations. Bright red blood further suggests arterial bleeding. *To confirm that lacerations are a source of bleeding, careful inspection of the vagina, cervix, and uterus is essential.* Sometimes bleeding may be caused by both atony and trauma, especially after forceps or vacuum-assisted vaginal delivery. Examination is easier if conduction analgesia was given. If there are no lower genital tract lacerations and the uterus is contracted, yet supracervical bleeding persists, then manual exploration of the uterus is done to exclude a uterine tear (Kaplanoglu, 2016). This also is completed routinely after internal podalic version, breech extraction, or successful vaginal birth after cesarean.

Late postpartum hemorrhage describes bleeding after the first 24 hours. Found in up to 1 percent of women, it may be serious and is discussed in Chapter 37 (American College of Obstetricians and Gynecologists, 2017d).

Blood Loss Estimation

As noted, visual estimates are notoriously inaccurate, especially with excessive bleeding. Instead of sudden massive hemorrhage, postpartum bleeding is frequently steady. If atony persists, bleeding may appear to be only moderate at any given instant but may continue until serious hypovolemia develops. Bleeding from an episiotomy or a vaginal laceration can also appear to be only minimal to moderate. But, constant seepage can lead to enormous blood loss relatively quickly. In some cases, after placental separation, blood may not escape vaginally but instead may collect within the uterine cavity, which can become distended by 1000 mL or more of blood. In others, postpartum uterine massage is applied to a roll of abdominal fat mistaken for the uterus.

All of these factors can lead to an underappreciation of the magnitude of hemorrhage over time. The effects of hemorrhage depend to a considerable degree on the maternal nonpregnant blood volume and the corresponding degree of pregnancy-induced hypervolemia. For this and other reasons, hypovolemia may not be recognized until very late. *A treacherous feature of postpartum hemorrhage is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood have been lost.* The normotensive woman initially may actually become somewhat hypertensive from catecholamine release in response to hemorrhage. And importantly, women with preeclampsia may become “normotensive” despite remarkable hypovolemia.

Some gravidas may be particularly susceptible to hemorrhage because their blood volume expansion is less than expected. This situation is most commonly encountered in small women—even those with normal pregnancy-induced hypervolemia. Women with severe preeclampsia or eclampsia are also more vulnerable to hemorrhage because they frequently do not have a normal blood volume accrual. Specifically, Zeeman and associates (2009) documented a mean increase above nonpregnant volume of only 10 percent in *eclamptic* women (Chap. 40, Blood Volume). A third example is the moderate-to-severe curtailing of pregnancy-induced volume expansion in women with chronic renal insufficiency (Chap. 53, Chronic Kidney Disease). *When excessive hemorrhage is suspected in these high-risk women, crystalloid and blood are promptly administered for suspected hypovolemia.*

UTERINE ATONY

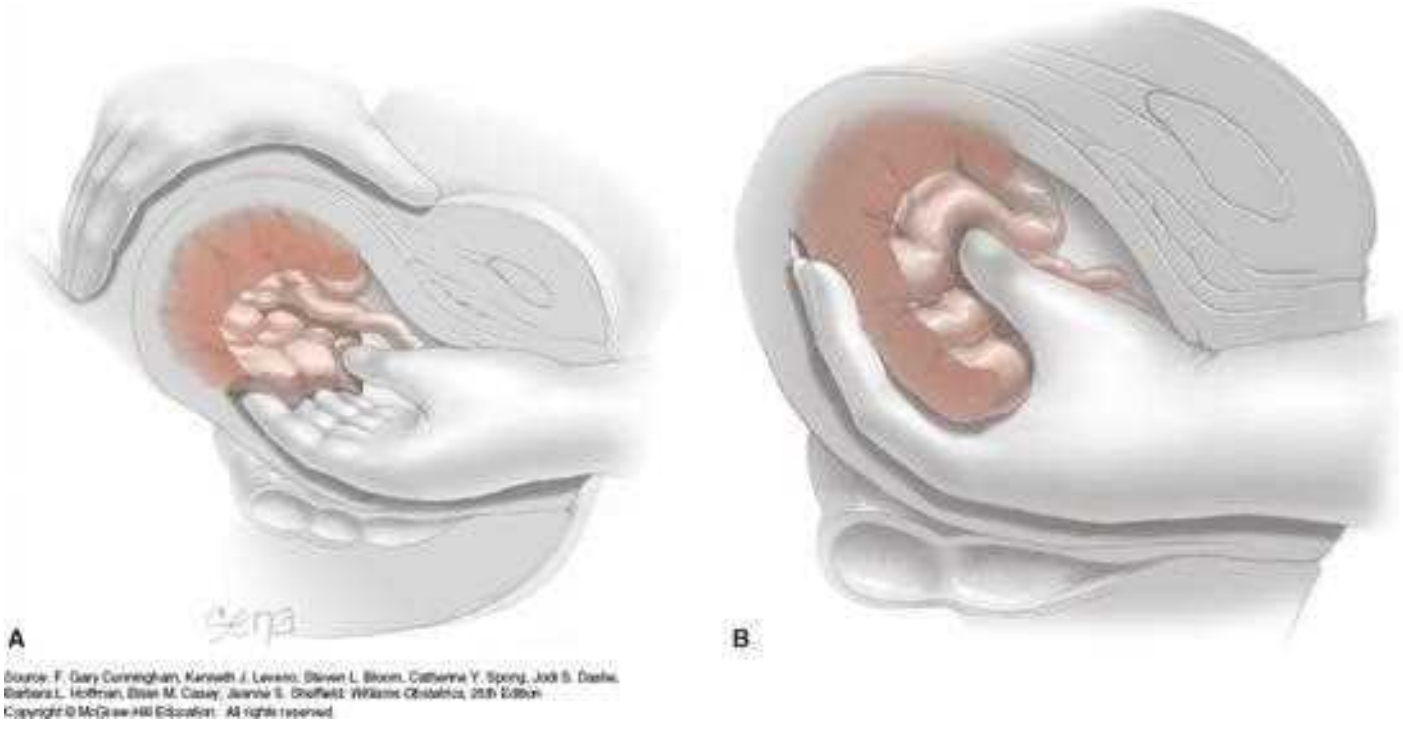
Third-Stage Labor Management

The most frequent cause of obstetrical hemorrhage is failure of the uterus to contract sufficiently after delivery and to arrest bleeding from vessels at the placental implantation site (General Considerations). That said, some bleeding is inevitable during third-stage labor as the placenta begins to separate. Blood from the implantation site may escape into the vagina immediately—the *Duncan mechanism* of placental separation, or it remains concealed behind the placenta and membranes until the placenta is delivered—the *Schultze mechanism.* After signs of placental separation, the uterus should be massaged if it is not contracted firmly, and placental descent is indicated by a slack umbilical cord. *Importantly, separation and delivery of the placenta by cord traction, especially when the uterus is atonic, may cause uterine inversion.*

If heavy bleeding persists after delivery of the newborn and while the placenta remains partially or totally attached, then manual placental removal is indicated (Cummings, 2016; Frolova, 2016). For this, adequate analgesia is mandatory, and aseptic surgical technique should be used. As illustrated in Figure 41-3, the fingertips of one hand, with fingers approximated, are insinuated between the uterine wall and placenta. A sweeping forward motion in this plane will peel the placenta off its uterine attachment. After its removal, trailing membranes are carefully teased free from the decidua using ring forceps as needed. Another method to clear membranes is to wipe out the uterine cavity with a gauze-wrapped hand. Most recommend ampicillin or cefazolin antimicrobial prophylaxis after manual removal (World Health Organization, 2015).

FIGURE 41-3

Manual removal of placenta. **A.** One hand grasps the fundus. The other hand is inserted into the uterine cavity, and the fingers are swept from side to side as they are advanced. **B.** When the placenta has become detached, it is grasped and removed.



The fundus is always palpated following placental delivery to confirm that the uterus is well contracted. If it is not firm, then vigorous fundal massage usually prevents postpartum hemorrhage from atony (Hofmeyr, 2013). Simultaneously, 20 units of oxytocin in 1000 mL of crystalloid solution will often be effective given intravenously at 10 mL/min for a dose of 200 mU/min. Higher concentrations are minimally more effective (Tita, 2012). *Oxytocin is never given as an undiluted bolus dose because serious hypotension or cardiac arrhythmias can develop.*

Risk Factors

In many women with known risks, uterine atony can at least be anticipated well in advance of delivery. In one study, however, up to half of women with atony after cesarean delivery had no risk factors (Rouse, 2006). The magnitude of risk for atony imposed by each of the factors shown in Table 41-2 varies considerably between reports. *Primiparity* and *high parity* are risk factors (Driessen, 2011). In one study, the incidence of postpartum hemorrhage rose from 0.3 percent in women of low parity to 1.9 percent with parity of four or greater. It was 2.7 percent with parity of seven or greater (Babinszki, 1999). The *overdistended uterus* is prone to hypotonia after delivery, and thus women with a large fetus, multiple fetuses, or hydramnios are at greater risk. *Labor abnormalities* predispose to atony and include hyper- or hypotonic labor. Similarly, *labor induction* or *augmentation* with either prostaglandins or oxytocin is more likely to be followed by atony (Driessen, 2011). The frequency of hemorrhage increases with prolongation of the third stage (Frolova, 2016). Finally, the woman who has had a *prior postpartum hemorrhage* is at risk for recurrence.

Evaluation and Management

With immediate postpartum hemorrhage, careful inspection is done to exclude birth canal laceration. Because bleeding can be caused by retained placental fragments, inspection of the placenta after delivery should be routine. If a defect is seen, the uterus should be manually explored and the fragment removed. Occasionally, retention of a *succenturiate lobe* may cause postpartum hemorrhage (Chap. 6, Shape and Size Variants). During examination for lacerations and causes of atony, the uterus is massaged and uterotonic agents are administered.

Uterotonic Agents

Several compounds can prompt the postpartum uterus to contract (Chap. 27, Immediate Postpartum Care). One of these is routinely selected and given to *prevent* postpartum bleeding by ensuring uterine contractions. Most of these same agents are also used to *treat* uterine atony with bleeding. Moreover, because many trials combine results from atony prophylaxis and treatment, their evaluation is problematic. For example, o*xytocin* has been used for more than 70 years, and in most cases, it is infused intravenously or given intramuscularly after placental delivery. Neither route has been shown to be superior (Dagdeviren, 2016). This or other uterotonics given prophylactically will prevent most cases of uterine atony.

To treat uterine atony, ergot alkaloids have been used for centuries. If atony persists despite oxytocin and other preventive measures, ergot derivatives can be used for second-line treatment. Ergot preparations include methylergonovine (Methergine) and ergonovine, however, only methylergonovine is currently manufactured in the United States. Given parenterally, these drugs rapidly stimulate tetanic uterine contractions and act for approximately 45 minutes (Schimmer, 2011). A common regimen is 0.2 mg of either drug given intramuscularly. Methergine can be repeated at 2- to 4-hour intervals as needed. *A caveat is that ergot agents, especially given intravenously, may cause dangerous hypertension, especially in women with preeclampsia.* Severe hypertension is also seen with concomitant use of protease inhibitors given for human immunodeficiency viral (HIV) infection. These adverse effects notwithstanding, it is speculative whether ergot derivatives offer superior therapeutic effects compared with oxytocin.

In cases of atony refractory to one agent, an agent from a different group can be added. At least two randomized studies have addressed combined ergot-oxytocin regimens. In one, ergometrine plus oxytocin was compared with ergometrine alone to prevent postpartum hemorrhage (Koen, 2016). The overall need for transfusion was significantly lower with the combination regimen. Another comparable study reaffirmed these findings (Şentürk, 2016).

During the past 40 years, other second-line agents for atony have included the E- and F-series prostaglandins. Carboprost tromethamine (Hemabate) is the 15-methyl derivative of prostaglandin $F_{2\alpha}$. It is approved for uterine atony treatment in a dose of 250 µg (0.25 mg) given intramuscularly. This dose can be repeated if necessary at 15- to 90-minute intervals up to a maximum of eight doses. Observational data indicate an 88-percent success rate (Oleen, 1990). Carboprost causes side effects in approximately 20 percent of women. These include, in descending order of frequency, diarrhea, hypertension, vomiting, fever, flushing, and tachycardia. Another pharmacological effect is pulmonary airway and vascular constriction. Thus, carboprost should not be used for asthmatic women and those with suspected amnionic fluid embolism (General Management). We have occasionally encountered severe hypertension with carboprost given to women with preeclampsia. It has also been reported to cause arterial oxygen desaturation that averaged 10 percent (Hankins, 1988). Relative contraindications to carboprost include renal, liver, and cardiac disease (American College of Obstetricians and Gynecologists, 2017d).

E-series prostaglandins can also prevent or treat atony. Dinoprostone—prostaglandin E_2—may be used off label and is given as a 20-mg suppository per rectum or per vaginum every 2 hours. It typically causes diarrhea, which is problematic for the rectal route, whereas vigorous vaginal bleeding may preclude its use per vaginum. Hypotension, which is commonly encountered with hemorrhage, is considered a contraindication by some. Intravenous prostaglandin E_2—*sulprostone*—is used in Europe, but it is not available in the United States (Schmitz, 2011).

Misoprostol—*Cytotec*—is a synthetic prostaglandin E_1 analogue that is used for prevention and treatment of atony (Abdel-Aleem, 2001; Ugwu, 2016). Most studies have addressed prevention and have conflicting conclusions. In a Cochrane review, Mousa and associates (2014) reported no added benefits for misoprostol use compared with oxytocin or ergonovine for treatment. Derman and coworkers (2006) compared a 600-µg oral dose given preventively at delivery against placebo. They found that the drug lowered the incidence of hemorrhage from 12 to 6 percent and that of severe hemorrhage from 1.2 to 0.2 percent. In another study, Gerstenfeld and Wing (2001) concluded that 400 µg misoprostol administered rectally was not superior to intravenous oxytocin given to prevent postpartum hemorrhage. From a systematic review, Villar (2002) found that oxytocin and ergot preparations administered after delivery were more effective than misoprostol for

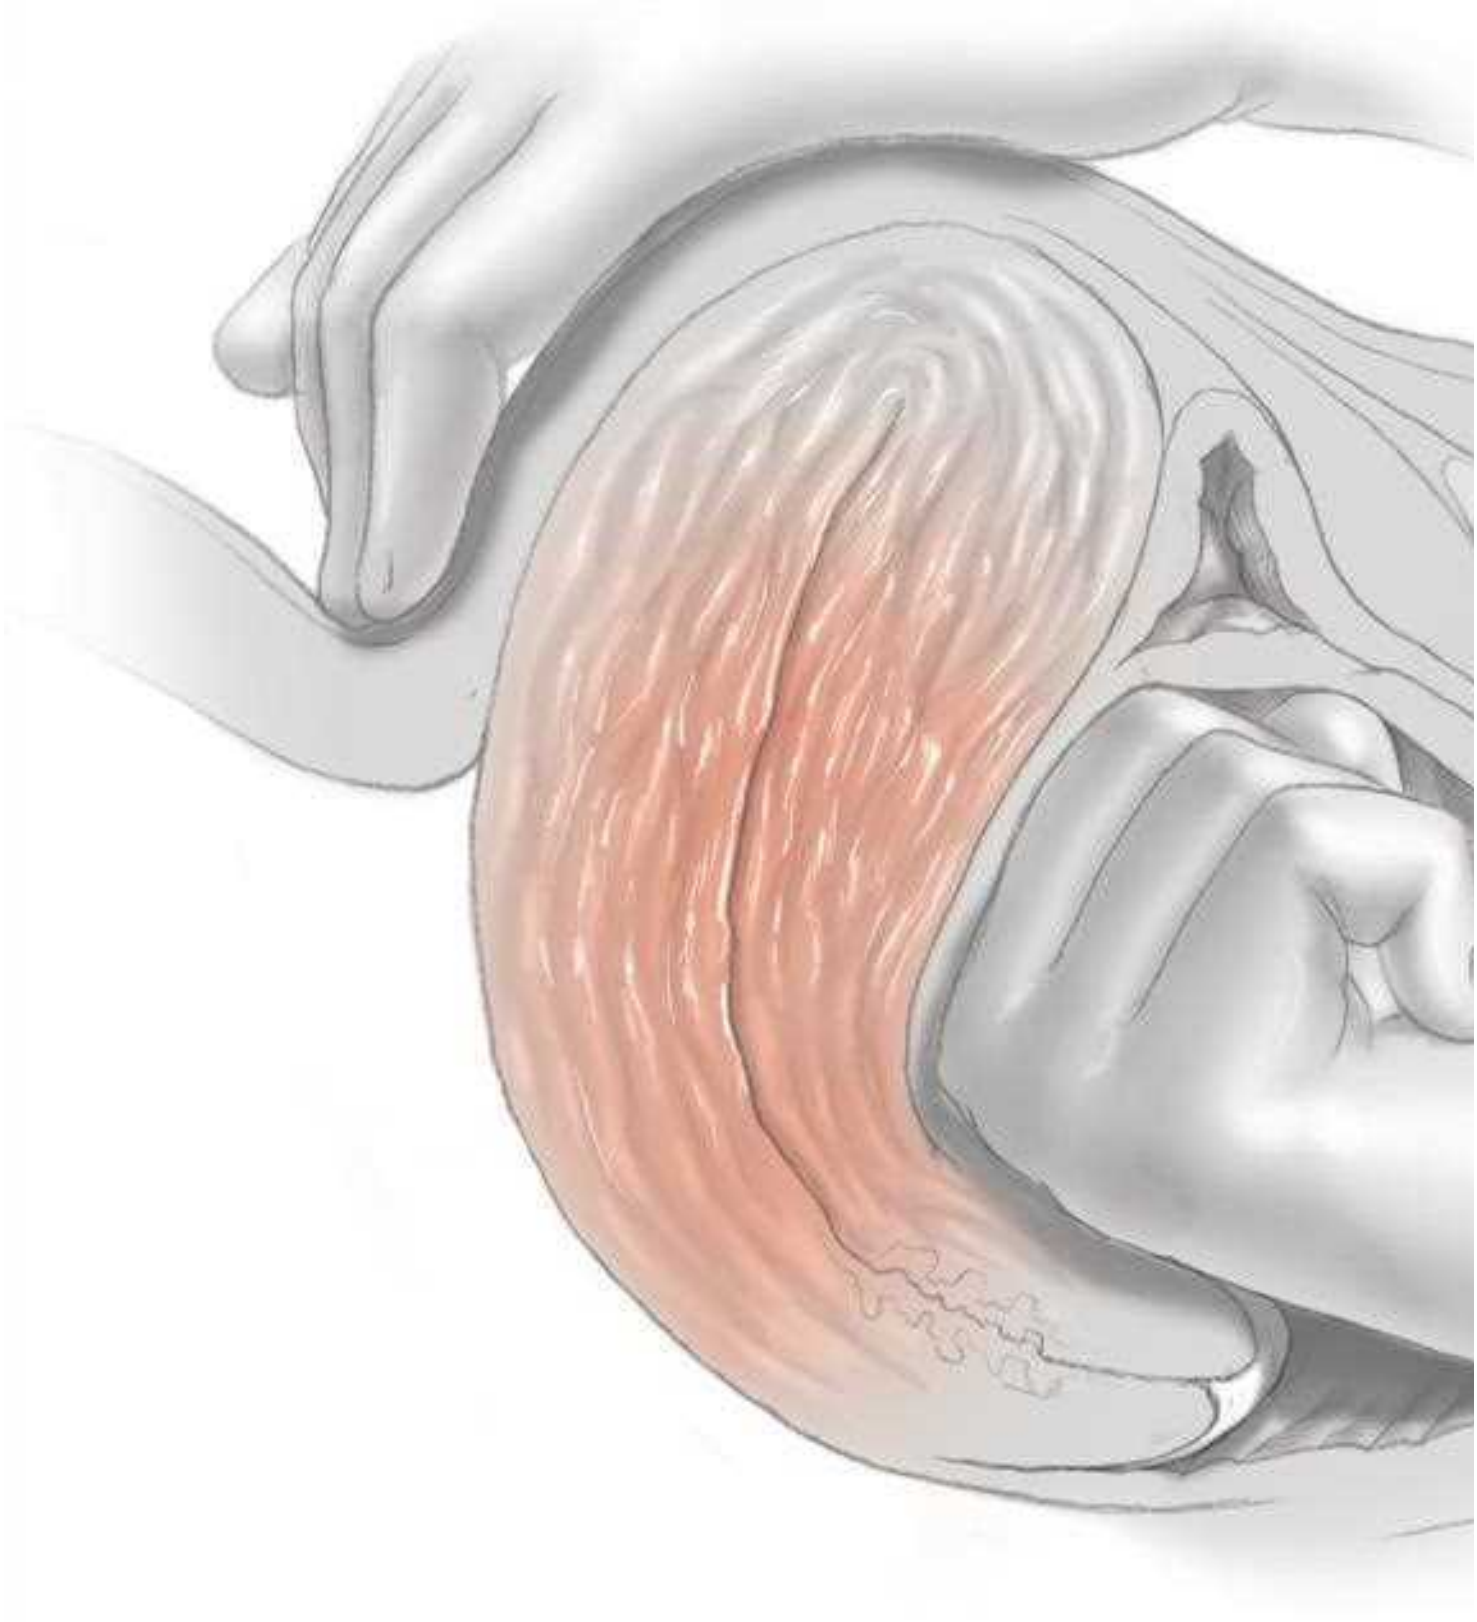
prevention of postpartum hemorrhage (Chap. 27, Immediate Postpartum Care). If misoprostol is used to treat atony, the American College of Obstetricians and Gynecologists (2017d) recommends a dose of 600 to 1000 µg rectally, orally, or sublingually.

Bleeding Unresponsive to Uterotonic Agents

If bleeding persists after initial measures for atony have been implemented, then the following management steps are performed immediately and simultaneously:

1. Begin bimanual uterine compression, which is easily done and controls most cases of continuing hemorrhage (Fig. 41-4). This technique is not simply fundal massage. The posterior uterine wall is massaged by one hand on the abdomen, while the other hand is made into a fist and placed into the vagina. This fist kneads the anterior uterine wall through the anterior vaginal wall and the uterus is also compressed between the two hands.
2. Immediately mobilize the emergent-care obstetrical team to the delivery room and call for whole blood or packed red cells.
3. Request urgent help from the anesthesia team.
4. Secure at least two large-bore intravenous catheters so that crystalloid with oxytocin can be continued simultaneously with blood products. Insert an indwelling Foley catheter for continuous urine output monitoring.
5. Begin volume resuscitation with rapid intravenous infusion of crystalloid (Hypovolemic Shock).
6. With sedation, analgesia, or anesthesia established and now with optimal exposure, once again manually explore the uterine cavity for retained placental fragments and for uterine abnormalities, including lacerations or rupture.
7. Thoroughly inspect the cervix and vagina again for lacerations that may have escaped attention.
8. If the woman is still unstable or if there is persistent hemorrhage, then blood transfusions are given (Hypovolemic Shock).

FIGURE 41-4
Bimanual compression for uterine atony. The uterus is positioned with the fist of one hand in the anterior fornix pushing against the anterior wall, which is held in place by the other hand on the abdomen. The abdominal hand is also used for uterine massage.



At this juncture, after causes other than atony have been excluded and after hypovolemia is reversed, several other measures are considered if bleeding continues. Their use depends on several factors such as parity, desire for sterilization, and experience with each method.

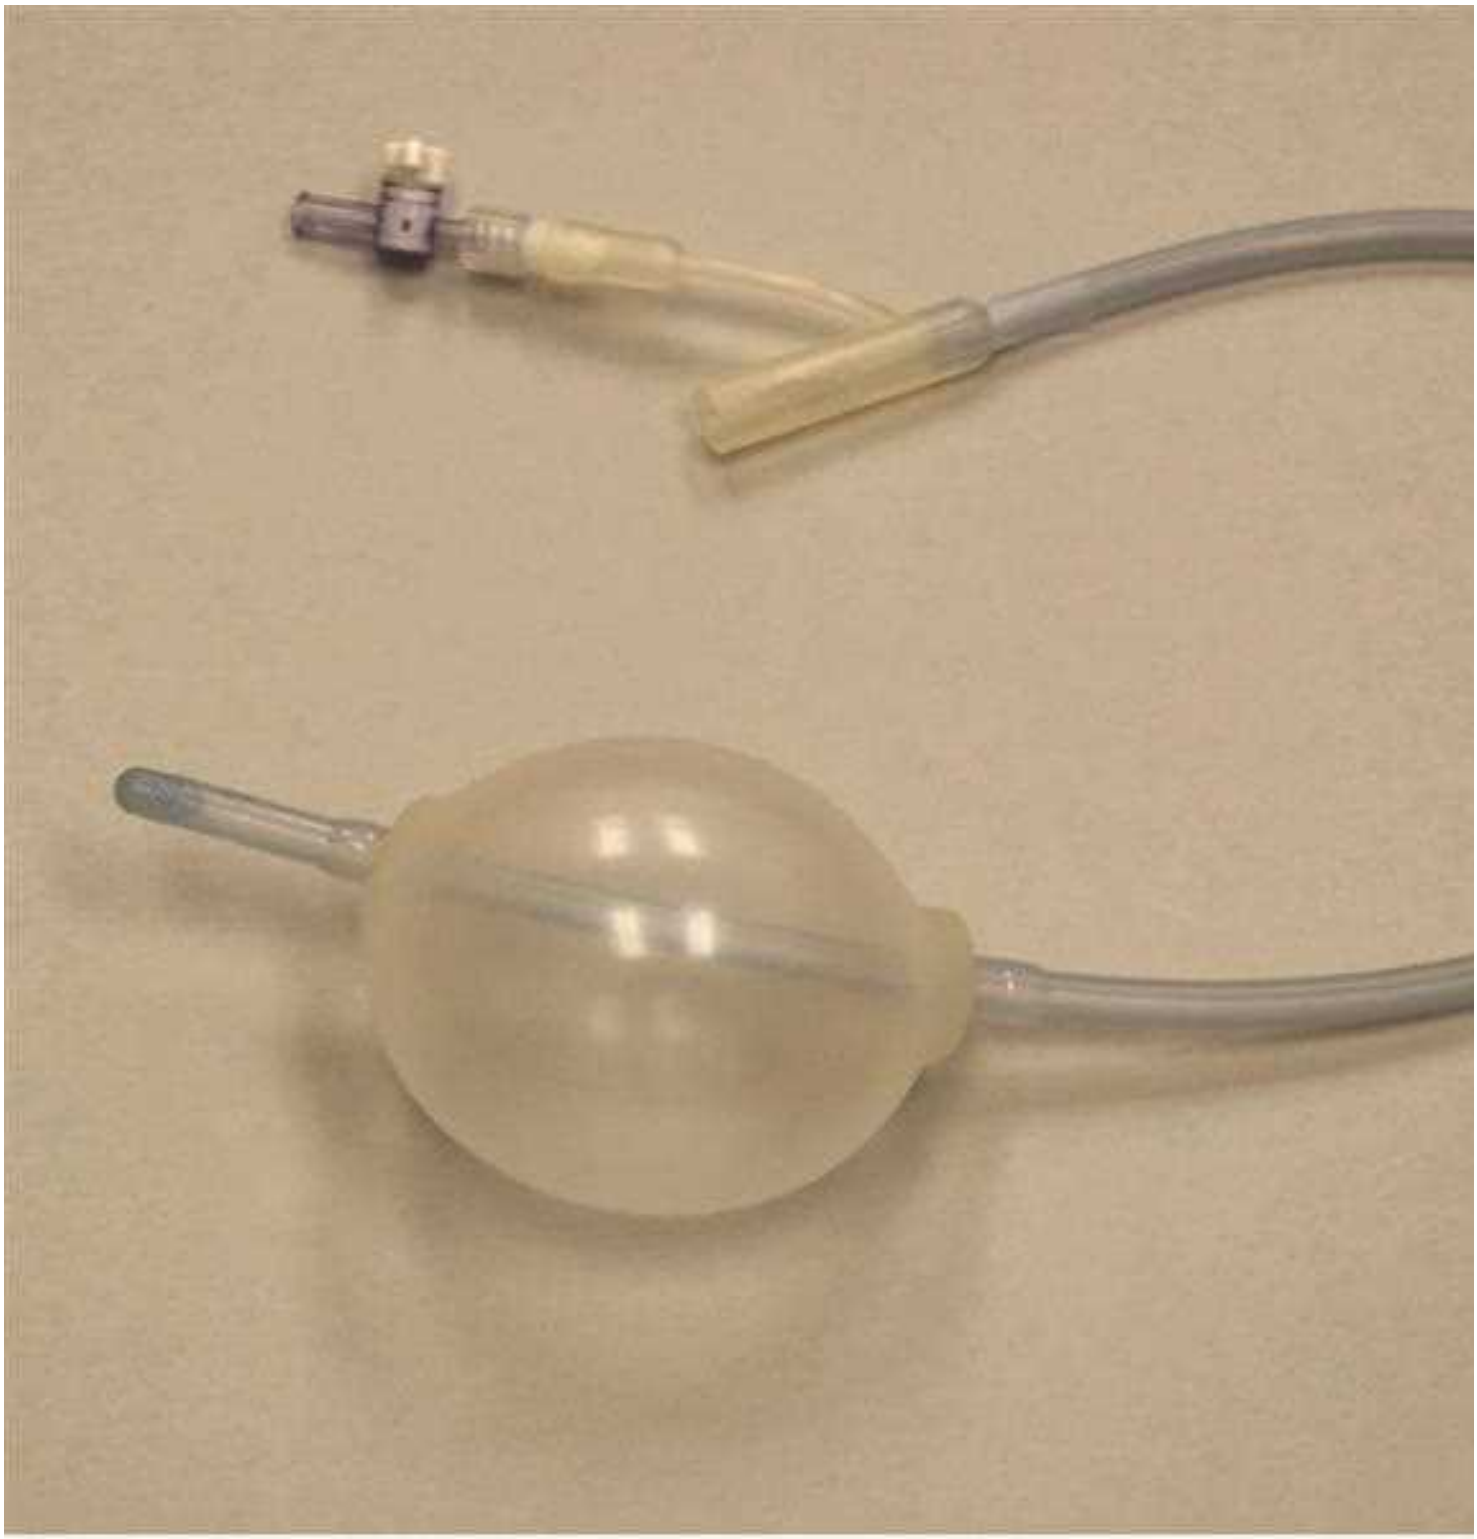
Balloon Tamponade

Uterine packing to treat refractory uterine atony fell from favor because of concerns regarding concealed bleeding and infection (Gilstrap, 2017). Newer techniques of balloon tamponade help alleviate some of these concerns (Sentilhes, 2016; Zelop, 2011). In one technique, the tip of a 24F to 30F Foley catheter with a 30-mL balloon is guided into the uterine cavity and filled with 60 to 80 mL of saline. The open tip permits continuous drainage of blood from the uterus. We have experienced balloon rupture when more than 50 mL was instilled into the balloon, thus a 34F Foley with a 60-ml balloon can be used. If bleeding subsides, the catheter is typically

removed after 12 to 24 hours. Similar devices for tamponade include Segstaken-Blakemore, Rusch, and ebb balloons and condom catheters (Antony, 2017; Georgiou, 2009).

Enthusiasm has developed for specially constructed intrauterine balloons to treat hemorrhage from uterine atony and other causes. A *Bakri Postpartum Balloon* or *BT-Cath* may be inserted and inflated to tamponade the endometrial cavity and stop bleeding (Fig. 41-5). Insertion requires two or three team members. The first performs abdominal sonography during the procedure. The second places the deflated balloon into the uterus and stabilizes it. The third member instills fluid to inflate the balloon, rapidly infusing at least 150 mL followed by further instillation over a few minutes for a total of 300 to 500 mL to arrest hemorrhage. It is reasonable to remove the balloon after approximately 12 hours (Einerson, 2017).

FIGURE 41-5
Intrauterine Bakri balloon for postpartum hemorrhage.



In prospective studies, nearly 150 women have been managed for postpartum hemorrhage with these uterine balloons (Grönvall, 2013; Kaya, 2016; Vintejoux, 2015). Perhaps a fourth of cases were caused by uterine atony. For all causes, the success rate was noted to be approximately 85 percent. Combinations of balloon tamponade and uterine compression sutures have also been described (Diemert, 2012; Yoong, 2012). Failures for all of these require various surgical methods including hysterectomy.

Surgical Procedures

These include uterine compression sutures, pelvic vessel ligation, angiographic embolization, and hysterectomy. These are discussed in Adjunctive Surgical Procedures.

UTERINE INVERSION

Puerperal inversion of the uterus is one of the classic hemorrhagic disasters encountered in obstetrics. Unless promptly recognized and managed appropriately, associated bleeding often is massive. Risk factors include alone or in combination: (1) fundal placental implantation, (2) uterine atony, (3) cord traction applied *before* placental separation, and (4) abnormally adhered placentation such as with the accrete syndromes (Morbidly Adherent Placenta).

Depending on which of these factors are contributory, the incidence and severity of uterine inversion varies. There is progressive severity of inversion as shown in Figure 41-6. The worst scenario is complete inversion with the uterus protruding from the birth canal (Fig. 41-7).

FIGURE 41-6
Progressive degrees of uterine inversion.

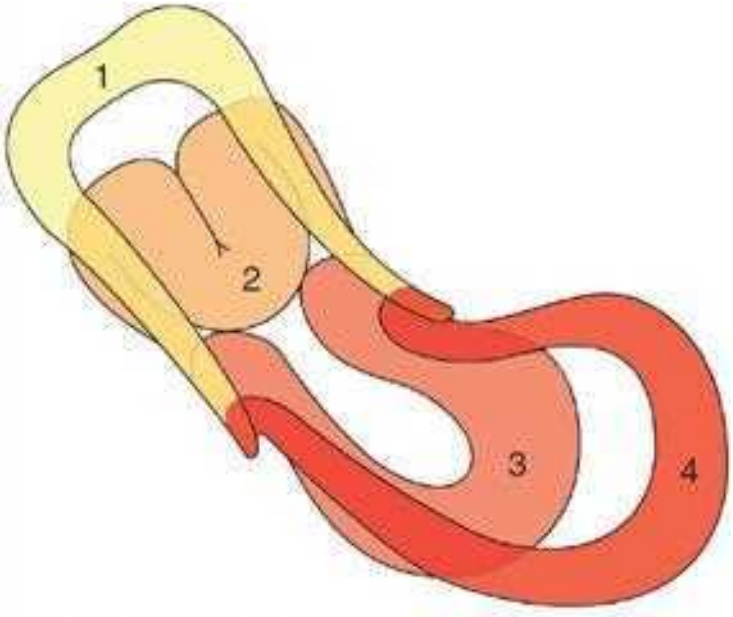


FIGURE 41-7
Maternal death during home delivery caused by exsanguination from uterine inversion and a fundally implanted placenta accreta.

The incidence of uterine inversion ranges from 1 in 2000 to 1 in 20,000 vaginal deliveries (Coad, 2017; Ogah, 2011; Rana, 2009; Witteveen, 2013). Our experiences at Parkland Hospital comport with the higher 1:2000 incidence. This is despite our policy of discouraging placental delivery by cord traction alone, and before certainty of its separation. It is unknown if *active management of third-stage labor* with cord traction applied ostensibly *after* signs of placental separation raises the likelihood of uterine inversion (Deneux-Tharaux, 2013; Gülmezoglu, 2012; Prick, 2013).

Recognition and Management

Immediate recognition of uterine inversion improves the chances of a quick resolution and good outcome (Furukawa, 2015b). If initially unrecognized, continued hemorrhage likely will prompt closer examination of the birth canal. Although complete inversion is usually evident, the partially inverted uterus can be mistaken for a uterine myoma, and sonography can aid differentiation (Pan, 2015; Smulian, 2013). Many cases are associated with immediate life-threatening hemorrhage, and a fourth require blood replacement (Coad, 2017).

Once any degree of uterine inversion is recognized, several steps must be implemented urgently and simultaneously:

1. Immediate assistance is summoned, including obstetrical and anesthesia personnel.
2. Blood is brought to the delivery suite for potential use.
3. The woman is evaluated for emergency general anesthesia. Large-bore intravenous infusion systems are secured to begin rapid crystalloid infusion to treat hypovolemia while awaiting arrival of blood products.

4. If the recently inverted uterus has not contracted and retracted completely and if the placenta has already separated, then the uterus may often be replaced simply by pushing up on the inverted fundus with the palm of the hand and fingers in the direction of the long axis of the vagina (Fig. 41-8). Some use two fingers rigidly extended to push the center of the fundus upward. *Care is taken not to apply so much pressure as to perforate the uterus with the fingertips.*

5. If the placenta is still attached, then attempts are made to reposition the uterus with the placenta in situ. Many recommend a trial of an intravenously administered tocolytic drug such as terbutaline, magnesium sulfate, or nitroglycerin for uterine relaxation and repositioning (You, 2006). If these fail to provide sufficient relaxation, then a rapidly acting halogenated inhalational agent is administered. After the uterus is replaced, the placenta is carefully manually removed.

6. If uterine repositioning fails with the placenta attached, then it is peeled off and steady pressure with the fist, palm, or fingers is applied to the inverted fundus in an attempt to push it up into and through the dilated cervix as described in Step 4.

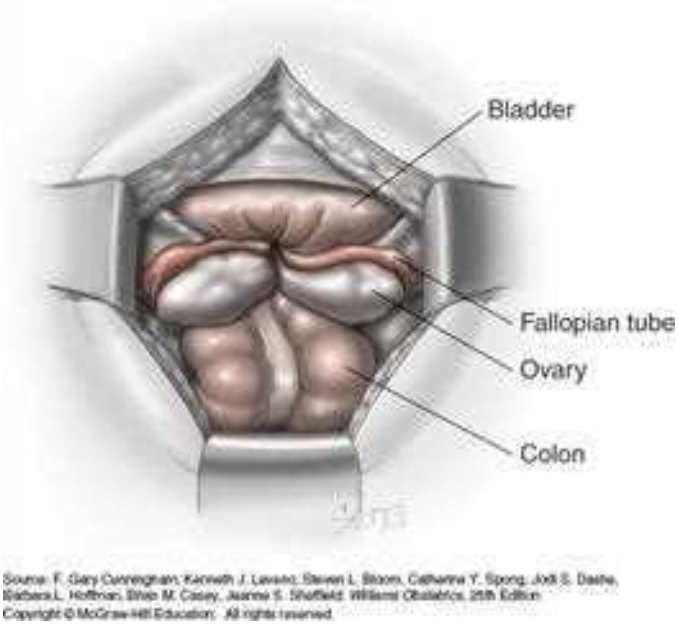
7. Once the uterus is restored to its normal configuration, tocolysis is stopped. Oxytocin is then infused, and other uterotonics may be given as described for atony (Risk Factors). Meanwhile, the operator maintains the fundus in its normal anatomical position while applying bimanual compression to control further hemorrhage until the uterus is well contracted (see Fig. 41-4). The operator continues to monitor the uterus transvaginally for evidence of subsequent inversion. A Bakri balloon has been used to maintain the repositioned uterus (Haeri, 2015; Ida, 2015).

FIGURE 41-8
Incomplete uterine inversion repositioned by using the abdominal hand for palpation of the crater-like depression while simultaneously gently pushing the inverted fundus upward.

Surgical Intervention

In most cases, the inverted uterus can be restored to its normal position by the techniques just described. Occasionally, manual replacement fails. One cause is a dense myometrial constriction ring. At this point, laparotomy is imperative. The anatomical configuration found at surgery can be confusing as shown in Figure 41-9. With agents given for tocolysis, a combined effort is made to reposition the uterus by simultaneously pushing upward from below and pulling upward from above. Application of atraumatic clamps to each round ligament and upward traction may be helpful—the *Huntington procedure*. In some cases, placing a deep traction suture in the inverted fundus or grasping it with tissue forceps may be of aid. Either or both of these may be technically difficult. If a constriction ring still prohibits repositioning, a sagittal surgical cut—*Haultain incision*—is made posteriorly through the muscular ring to release it. The exposed fundus can then be reinverted (Sangwan, 2009). After uterine replacement, tocolytics are stopped, oxytocin and other uterotonics are given, and the uterine incision is repaired. Risks of separation of this posterior hysterotomy incision during subsequent pregnancy, labor, and delivery are unknown. Further illustration and discussion is found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Zahn, 2017).

FIGURE 41-9
Surgical anatomy of a completely inverted uterus viewed from above at laparotomy.



In some cases, the uterus will again invert almost immediately after repositioning. With this problem, uterine compression sutures can be used to prevent another inversion (Matsubara, 2009; Mondal, 2012). Occasionally, chronic puerperal uterine inversion may become apparent weeks after delivery.

INJURIES TO THE BIRTH CANAL

Childbirth is invariably associated with trauma to the birth canal, which includes the uterus and cervix, vagina, and perineum. Injuries sustained during labor and delivery range from minor mucosal tears to lacerations that create life-threatening hemorrhage or hematomas.

Vulvovaginal Lacerations

According to the American College of Obstetricians and Gynecologists (2016b), up to 80 percent of women sustain some type of laceration at vaginal delivery. These may lie proximally or distally along the lower genital tract.

First, small tears of the anterior vaginal wall near the urethra are relatively common. They are often superficial with little to no bleeding, but they occasionally require sutures for hemostasis. Those large enough to require extensive repair are typically associated with short-term voiding difficulty, and an indwelling bladder catheter will obviate this.

Deeper perineal lacerations are usually accompanied by varying degrees of injury to the outer third of the vaginal vault. Some extend to involve the anal sphincter or varying depths of the vaginal walls. Repair of these perineal lacerations is detailed in Chapter 27 (Laceration and Episiotomy Repairs).

Lacerations involving the middle or upper third of the vaginal vault usually are comorbid with injuries of the perineum or cervix. These sometimes are missed unless inspection is thorough. Those that extend upward usually are longitudinal. They may follow spontaneous delivery but frequently result from injuries sustained during operative vaginal delivery. Most involve deeper underlying tissues and thus usually cause significant hemorrhage, which is controlled by suture repair. For this, effective analgesia or anesthesia, clear visualization, capable assistance, and sufficient resuscitation of hypovolemia are mandatory.

Extensive vaginal or cervical tears should prompt a careful search for evidence of retroperitoneal hemorrhage or of peritoneal perforation with hemorrhage. Also, intrauterine exploration is considered to exclude uterine tears or rupture (Conrad, 2015). If peritoneal perforation or uterine rupture is strongly suspected, laparotomy is considered (Rafi, 2010). As discussed later (Angiographic Embolization), imaging and potential embolization may be suitable for large retroperitoneal hematomas.

Cervical Lacerations

Superficial lacerations of the cervix can be seen on close inspection in more than half of all vaginal deliveries. Most of these measure <0.5 cm and seldom require repair. Deeper lacerations are less frequent, but even these may be unnoticed. Due to ascertainment bias, variable incidences are described. For example, with close inspection, the incidence of cervical lacerations in the Consortium on Safe Labor database was 1 percent in nulliparas and 0.5 percent in multiparas (Landy, 2011). But, the overall incidence in a study of more than 81,000 Israeli women was only 0.16 percent (Melamed, 2009). Such lacerations are more likely to be associated with vacuum- or forceps-assisted vaginal delivery (Fong, 2014).

Cervical lacerations are not usually problematic unless they cause hemorrhage or extend to the vagina. Rarely, the cervix may be entirely or partially avulsed from the vagina in the anterior, posterior, or lateral fornices, an injury termed co*lporrhexis*. Another rare injury is when the entire vaginal portion of the cervix is avulsed—*annular* or *circular detachment*. These injuries sometimes follow forceps deliveries performed through an incompletely dilated cervix with the blades applied over the cervix. In some women, cervical tears reach into the lower uterine segment and involve the uterine artery and its major branches. They occasionally extend into the peritoneal cavity. More severe lacerations usually manifest as external hemorrhage or as a hematoma, however, they may occasionally be unsuspected. In the Israeli study just cited, almost 11 percent of women with a cervical laceration required blood transfusions (Melamed, 2009).

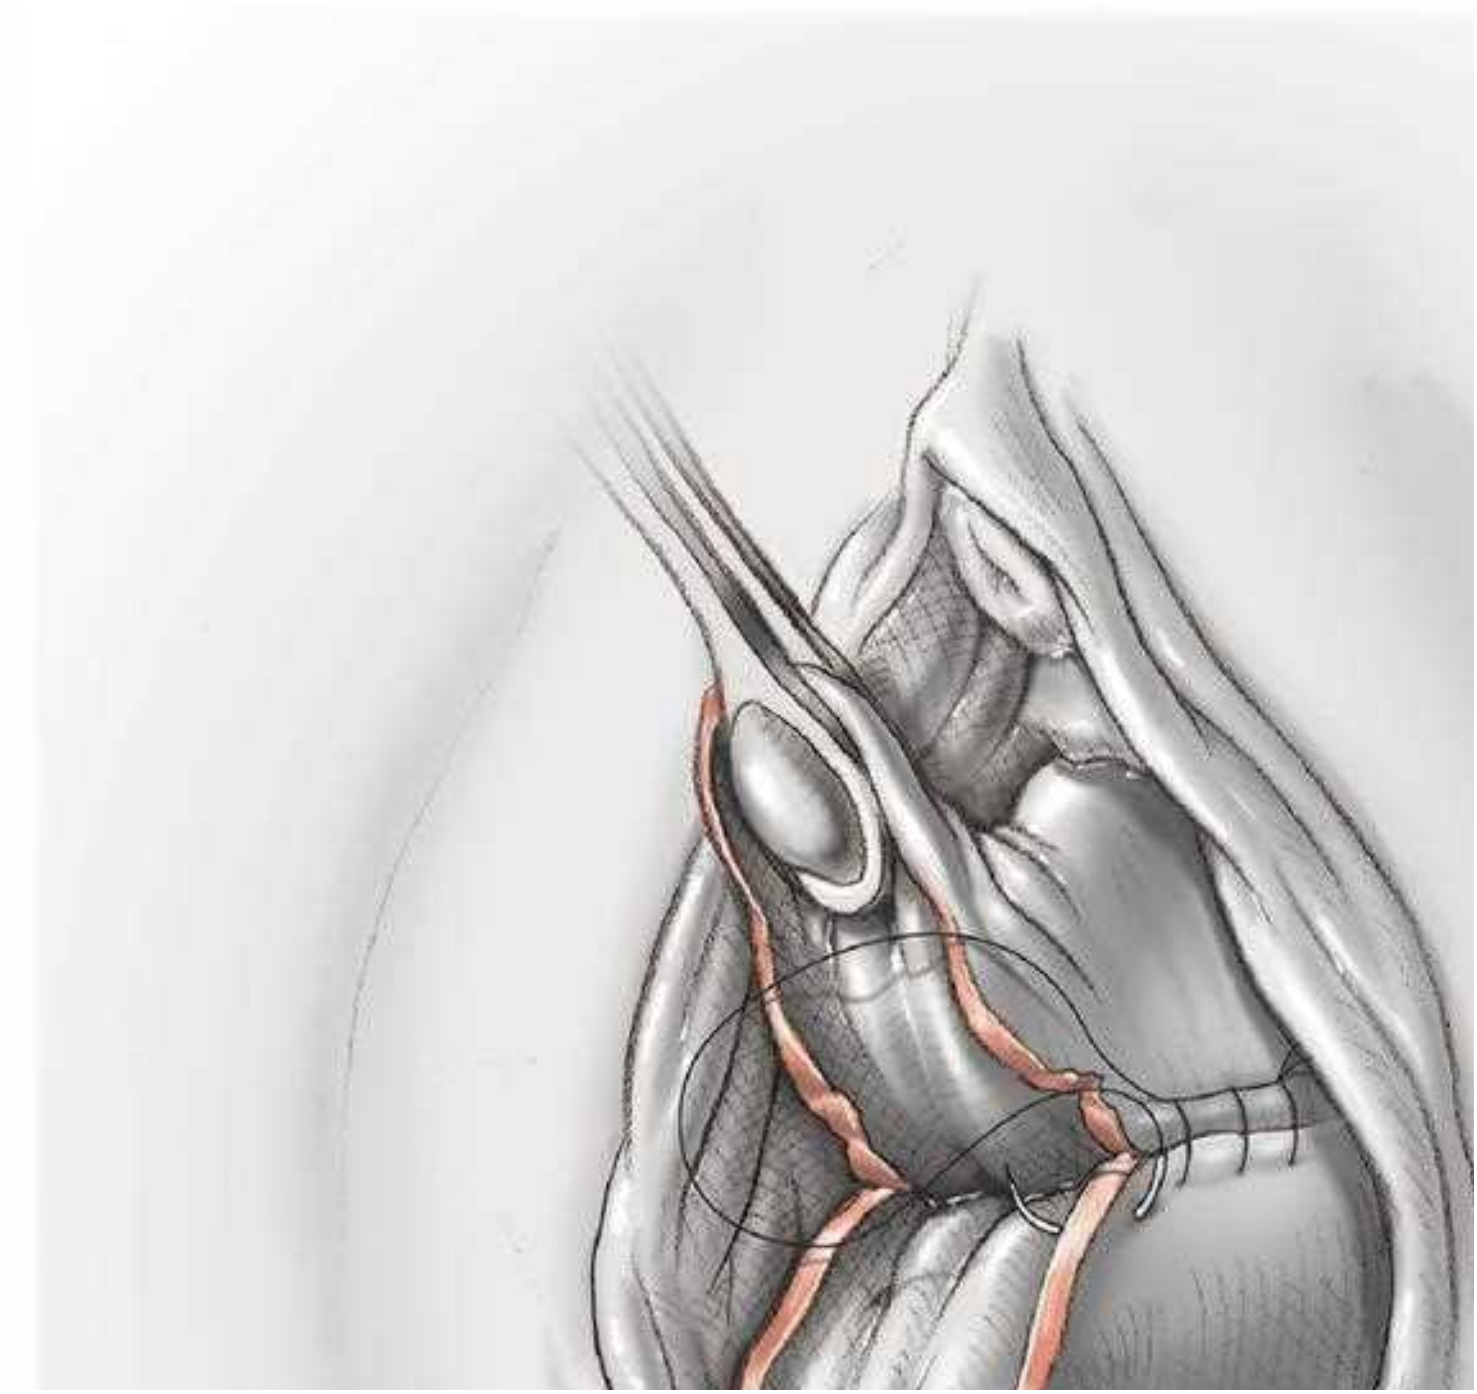
At times, the edematous anterior cervical lip is compressed between the fetal head and maternal symphysis pubis. This usually is of little consequence and resolves spontaneously. Rarely, this causes severe ischemia, and the anterior lip may undergo necrosis and subsequently separate from the rest of the cervix.

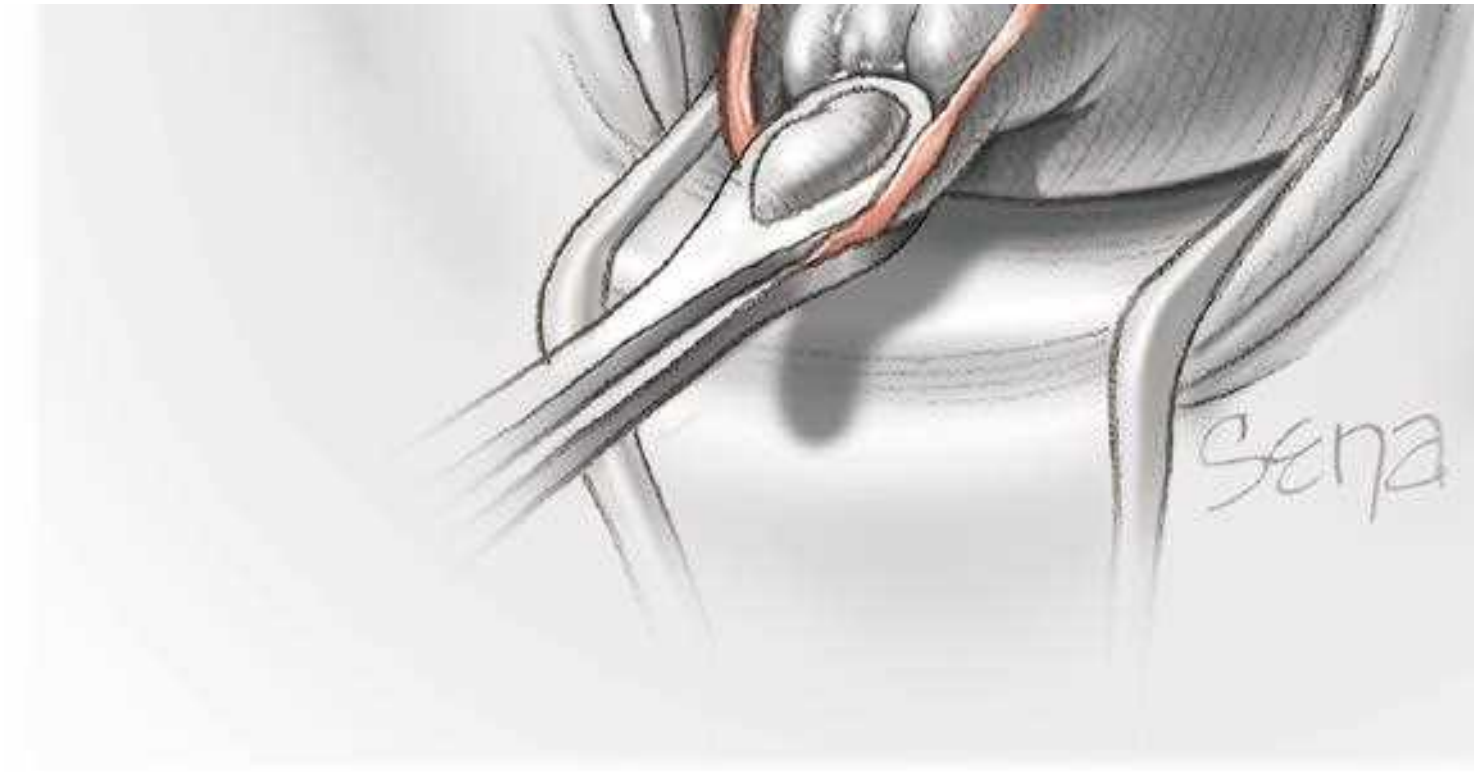
As with vulvovaginal lacerations, cervical tears can be more fully appreciated with adequate exposure, which may be best attained with transfer to an operating room. An assistant applies firm downward pressure on the uterus, while the operator exerts gentle traction on the lips of the cervix with ring forceps. A second assistant can provide even better exposure with right-angle vaginal wall retractors or Breisky vaginal retractors. Use of suction devices can also aid viewing.

In general, cervical lacerations of 1 and even 2 cm are not repaired unless they are bleeding. Such tears heal rapidly and ultimately create an irregular, sometimes stellate appearing, external cervical os that indicates previous delivery.

Deep cervical tears usually require surgical repair. When the laceration is limited to the cervix or even when it extends somewhat into the vaginal fornix, satisfactory results are obtained by suturing the cervix after bringing it into view as depicted in Figure 41-10. While cervical lacerations are repaired, any associated vaginal lacerations or an episiotomy may be tamponaded with gauze packs to arrest their bleeding. Because hemorrhage usually comes from the upper angle of the wound, the first suture using 2–0 chromic or polyglactin is placed in tissue above the angle. Subsequently, either interrupted or continuous locking sutures are serially placed outward toward the operator. If the uterus is involved and hemorrhage persists, some of the methods described later (Adjunctive Surgical Procedures) may be necessary to obtain hemostasis.

FIGURE 41-10
Repair of cervical laceration with appropriate surgical exposure. Continuous absorbable sutures are placed beginning at the upper angle of the laceration.



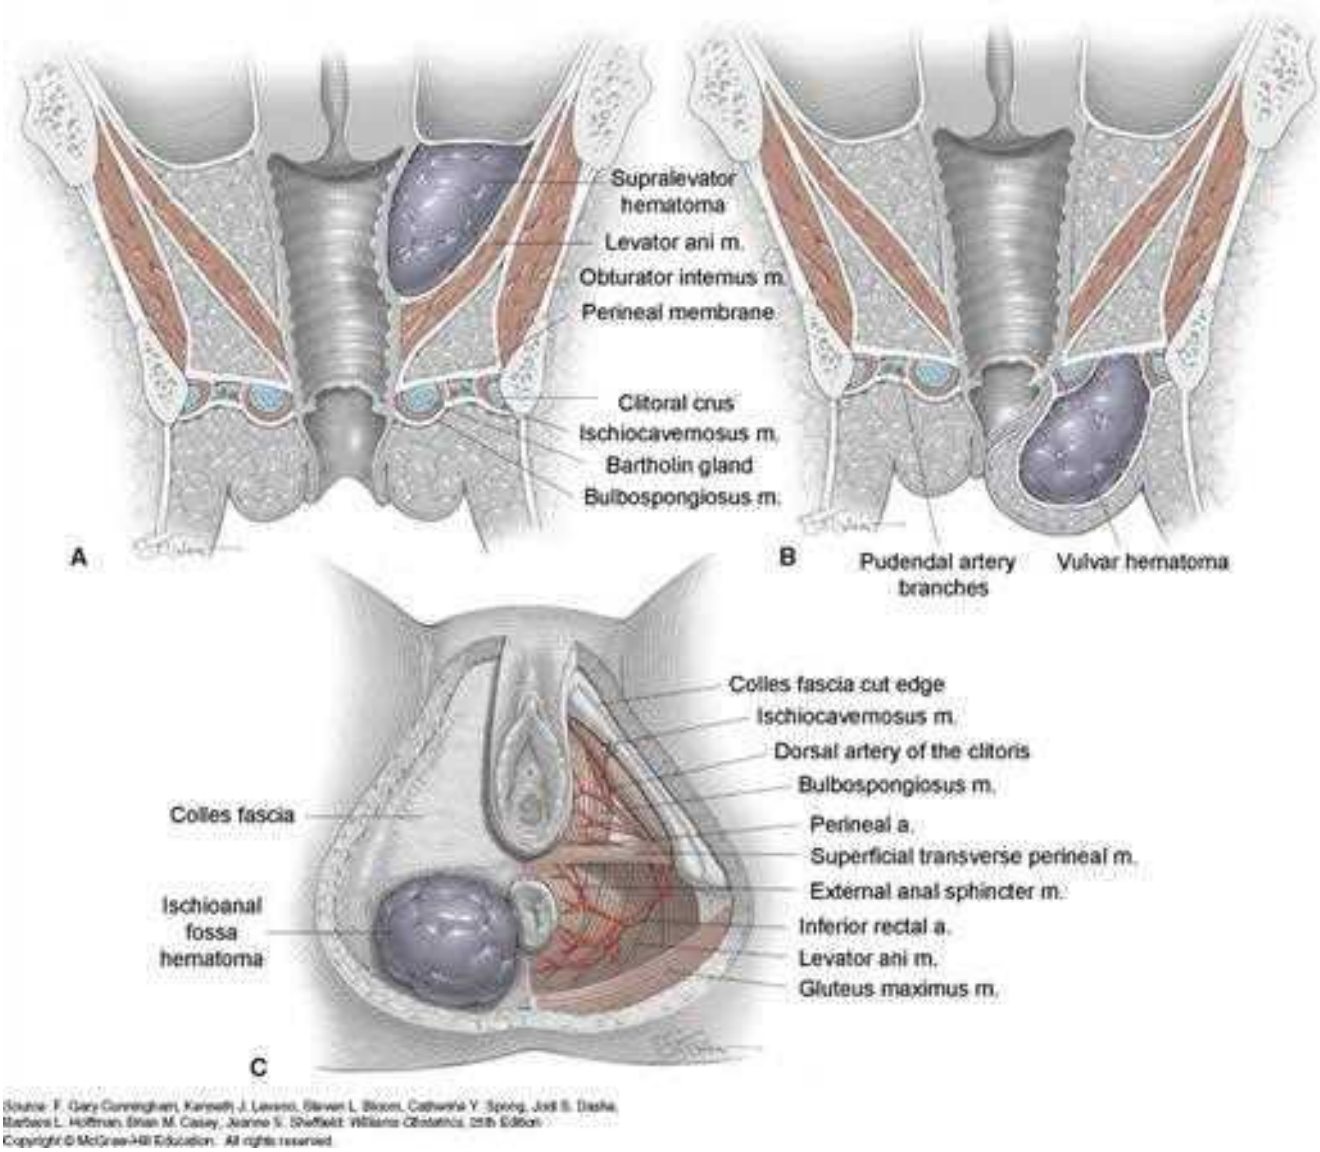


Puerperal Hematomas

Classification and Risks

Pelvic hematomas can have several anatomical manifestations following childbirth. One classification is anatomical and describes vulvar, vulvovaginal, paravaginal, and retroperitoneal hematomas. Vulvar hematomas may involve the vestibular bulb or branches of the pudendal artery, which are the inferior rectal, perineal, and clitoral arteries (Fig. 41-11). Paravaginal hematomas may involve the descending branch of the uterine artery. In some cases, a torn vessel lies above the pelvic fascia, and a supralevator hematoma develops. These can extend into the upper portion of the vaginal canal and may almost occlude its lumen. Continued bleeding may dissect retroperitoneally to form a mass palpable above the inguinal ligament. In some cases, it may even dissect up behind the ascending colon to the hepatic flexure (Rafi, 2010).

FIGURE 41-11
Schematic drawing showing types of puerperal hematomas. **A.** Coronal view showing a supralevator hematoma. **B.** Coronal view showing an anterior perineal triangle hematoma. **C.** Perineal view showing posterior perineal triangle anatomy and an ischioanal fossa hematoma. (Reproduced with permission from Cunningham FG: Genital tract lacerations and hematomas. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd edition. New York, McGraw-Hill Education, 2017a.)



Risks for puerperal hematomas include vaginal or perineal laceration, episiotomy, or an operative delivery (Iskender, 2016). Any hematoma can also develop following stretch and rupture of a blood vessel without an associated laceration (Nelson, 2012). This may be especially true with forceps delivery. Occasionally, they are associated with an underlying coagulopathy (Obstetrical Coagulopathies).

Diagnosis

Perineal, vulvar, and paravaginal hematomas can develop rapidly and frequently cause excruciating pain (Fig. 41-12). A tense, tender swelling of varying size rapidly develops, encroaches on the vaginal lumen, and causes overlying skin or epithelium to become ecchymotic. A paravaginal hematoma may escape detection initially. However, symptoms of pelvic pressure, pain, or inability to void should prompt evaluation. Others may go undetected until other measures of hypovolemia become evident. When there is a supralevator extension, the hematoma extends upward in the paravaginal space and between the leaves of the broad ligament. The hematoma may escape detection until it can be felt on abdominal palpation or until hypovolemia develops. Imaging with sonography or computed tomographic scanning may be useful (Cichowski, 2017; Kawamura, 2014; Takeda, 2014).

FIGURE 41-12
Left-sided anterior perineal triangle hematoma associated with a vaginal laceration following spontaneous delivery in a woman with consumptive coagulopathy from acute fatty liver of pregnancy.

Clinical Course and Management

Small hematomas often remained contained and show minimal expansion. In others, the tissues overlying an expanding hematoma may rupture from pressure necrosis. In some, profuse hemorrhage may follow, but in other cases, the hematoma drains in the form of large clots and old blood. In those that involve the paravaginal space and extend above the levator sling, retroperitoneal bleeding may be massive and occasionally fatal. Finally, we have encountered a few that rebled up to 2 weeks postpartum (Cunningham, 2017a).

Vulvovaginal hematomas are managed according to their size, location, duration since delivery, and expansion. If bleeding ceases, then small- to moderate-sized hematomas may be treated expectantly until absorbed. But, if pain is severe or if the hematoma continues to enlarge, surgical exploration is preferable. *Blood loss with large puerperal hematomas is nearly always considerably more than the clinical estimate.* Hypovolemia is common, and transfusions are frequently required when surgical repair is necessary.

For repair, an incision is made at the point of maximal distention, blood and clots are evacuated, and bleeding points ligated. The cavity may then be obliterated with absorbable sutures. Often, no sites of bleeding are identified. Nonetheless, the evacuated hematoma cavity is surgically closed, and the vagina is packed for 12 to 24 hours. Supralevator hematomas are more difficult to treat. Although some can be evacuated by vulvar or vaginal incisions, laparotomy or interventional embolization, described next, is a consideration if bleeding continues.

Angiographic embolization has become popular for management of some puerperal hematomas. This is especially true for supralevator or retroperitoneal hematomas. Embolization can be used primarily, or more likely secondarily, if surgical attempts at hemostasis have failed or if the hematoma is difficult to access surgically (Distefano, 2013; Lee, 2012; Poujade, 2012). The use of a Bakri balloon for a paracervical hematoma has also been described (Gizzo, 2013; Grönvall, 2013). Finally, ultrasound-guided drainage of a recurrent supralevator hematoma has been reported (Mukhopadhyay, 2015).

Uterine Rupture

Predisposing Factors

Uterine rupture frequently is catastrophic. It may be *primary*, defined as occurring in a previously intact or unscarred uterus, or may be *secondary* and associated with a preexisting incision, injury, or anomaly of the myometrium. Some of the etiologies associated with uterine rupture are presented in Table 41-3. Importantly, the contribution of each of these underlying causes has changed remarkably during the past 50 years. Specifically, before 1960, when the cesarean delivery rate was much lower and women of great parity were numerous, primary uterine rupture predominated. As the incidence of cesarean delivery rose and especially as a subsequent trial of labor in these women became prevalent through the 1990s, uterine rupture through the cesarean hysterotomy scar became the preeminent cause (Gibbins, 2015; Mone, 2016). However, concurrent with the diminished enthusiasm for a trial of labor in women with a prior cesarean delivery, incidence trends for the two types of rupture have again changed. In a study of 3942 cases of uterine rupture in more than 15 million women, approximately half were in women with a prior cesarean delivery (Yao, 2017). In 40 cases of rupture at Parkland Hospital from 2009 to 2016, 15 events (37 percent) were primary, and 25 (63 percent) were secondary (Happe, 2017).

TABLE 41-3

Some Causes of Uterine Rupture

Preexisting Uterine Injury or Anomaly	Uterine Injury or Abnormality Incurred in Current Pregnancy
Surgery involving the myometrium:	**Before delivery:**
Cesarean delivery or hysterotomy	Persistent, intense, spontaneous contractions
Previously repaired uterine rupture	Labor stimulation—oxytocin or prostaglandins
Myomectomy incision through or to the endometrium	Intraamnionic instillation—saline or prostaglandins
Deep cornual resection of interstitial fallopian tube	Perforation by internal uterine pressure catheter
Metroplasty	External trauma—sharp or blunt
Coincidental uterine trauma:	External version
Abortion with instrumentation—sharp or suction curette, sounds	Uterine overdistention—hydramnios, multifetal pregnancy
Sharp or blunt trauma—assaults, vehicular accidents, bullets, knives	**During delivery:**
Silent rupture in previous pregnancy	Internal version second twin
Congenital:	Difficult forceps delivery
Pregnancy in undeveloped uterine horn	Rapid tumultuous labor and delivery
Defective connective tissue—Marfan or Ehlers-Danlos syndrome	Breech extraction
	Fetal anomaly distending lower segment
	Vigorous uterine pressure during delivery
	Difficult manual removal of placenta
	Acquired:
	Placental accrete syndromes
	Gestational trophoblastic neoplasia
	Adenomyosis
	Sacculation of entrapped retroverted uterus

Additional risks for rupture include other previous operations or manipulations that traumatize the myometrium. Examples are uterine curettage or perforation, endometrial ablation, myomectomy, or operative hysteroscopy (Kieser, 2002; Pelosi, 1997). In a study by Porreco and colleagues (2009), seven of 21 women without a prior cesarean delivery had undergone prior uterine surgery.

In developed countries, the incidence of rupture is 1 in 4800 deliveries (Getahun, 2012). During a 40-year period in Norway, the uterine rupture rate rose significantly to about 1 in 1560 deliveries (Al-Zirqi, 2016). The frequency of primary rupture, however, approximates 1 in 10,000 to 15,000 births (Porreco, 2009). As discussed, one reason is a decreased incidence of women of great parity. Another is that excessive or inappropriate uterine stimulation with oxytocin—previously a frequent cause—has mostly disappeared. Maggio and associates (2014) found no association between the number of Montevideo units and secondary uterine rupture. In addition, in a recent analysis of three trials comparing high- versus low-dose oxytocin regimens, the rate of uterine rupture did not differ between groups (Budden, 2014). The rate of rupture is elevated with sequential induction of labor with prostaglandins and oxytocin (Al-Zirqi, 2017). At Parkland Hospital, we too have encountered primary uterine rupture in a disparate number of women in whom labor was induced with prostaglandin E_1.

Blunt abdominal trauma can precipitate uterine rupture. Although the distended pregnant uterus is surprisingly resistant, pregnant women sustaining such trauma should be watched carefully for signs of a ruptured uterus (Chap. 47, Other Blunt Trauma). In one study of 13 cases of primary uterine rupture, trauma accounted for

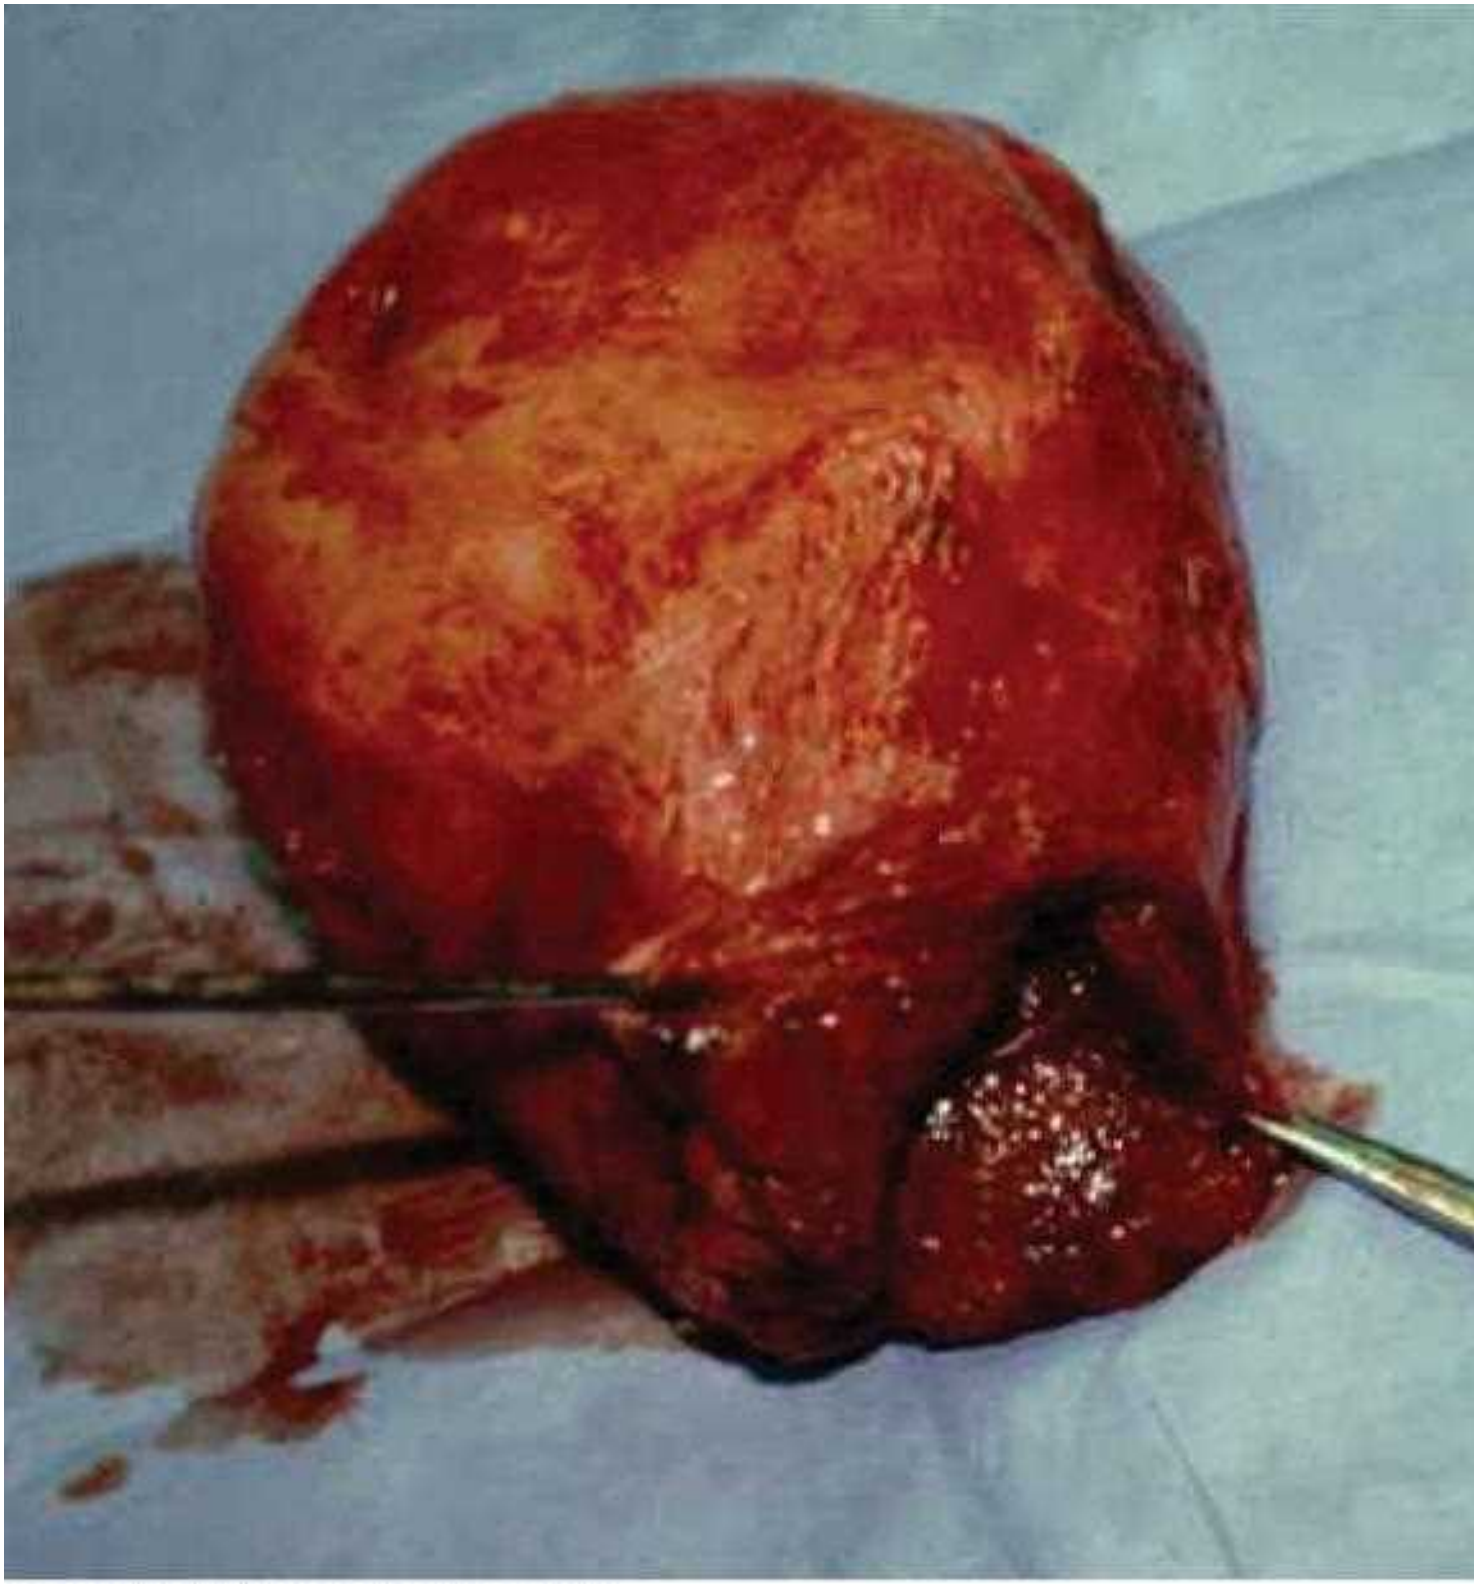
three cases (Miller, 1996). Other causes of traumatic rupture that are uncommon today are those due to internal podalic version and extraction, difficult forceps delivery, breech extraction, and unusual fetal enlargement such as with hydrocephaly.

Uncommon associations of rupture are uterine anomalies or multifetal pregnancy (Bankada, 2015; Tarney, 2013; Tola, 2014). Occasionally, focal inherent weakness in the myometrium predisposes to rupture. Examples include anatomical anomalies, leiomyomas, adenomyosis, choriocarcinoma, and connective-tissue defects such as Ehlers-Danlos syndrome (Arici, 2013; Nikolaou, 2013; Noh, 2013; Ramskill, 2014; Sun, 2016).

Pathogenesis

Rupture of the previously intact uterus during labor most often involves the thinned-out lower uterine segment. When the rent is in the immediate vicinity of the cervix, it frequently extends transversely or obliquely. When the rent forms in the portion of the uterus adjacent to the broad ligament, the tear is usually longitudinal. Although these tears develop primarily in the lower uterine segment, they can extend upward into the active segment or downward through the cervix and into the vagina (Fig. 41-13). In some cases, the bladder may also be lacerated. If the rupture is of sufficient size, the uterine contents will usually escape into the peritoneal cavity. If the presenting fetal part is firmly engaged, however, then only a portion of the fetus may be extruded from the uterus. Fetal prognosis is largely dependent on the degree of placental separation and magnitude of maternal hemorrhage and hypovolemia. In some cases, the overlying peritoneum remains intact, and this usually is accompanied by hemorrhage that extends into the broad ligament to cause a large retroperitoneal hematoma.

FIGURE 41-13
Supracervical hysterectomy specimen showing uterine rupture during spontaneous labor with a vertical tear at the left lateral edge of lower uterine segment.



Following vaginal delivery in an unscarred uterus, we and others have occasionally encountered cases of an incomplete tear on the inside of the uterus that extends vertically into the active segment and is a source of profuse hemorrhage (Conrad, 2015). These tears are usually not visible from below but are found at the time of hysterectomy for intractable bleeding despite a contracted uterus. Hemorrhage with this type of tear can be torrential, and bleeding is usually not slowed until the uterine artery pedicles are clamped bilaterally.

Management and Outcomes

The varied clinical presentations of uterine rupture and its management are discussed in detail in Chapter 31 (Uterine Scar Rupture). In the most recent maternal mortality statistics from the Centers for Disease Control and Prevention, uterine rupture accounted for almost 10 percent of deaths caused by hemorrhage (Creanga, 2015, 2017). Maternal morbidity includes hysterectomy that may be necessary to control hemorrhage. Rates of perinatal mortality and morbidity, which may include

severe neurological impairment, are also high (Gibbins, 2015; Porreco, 2009). Maternal obesity comorbid with uterine rupture is associated with increased rates of adverse neonatal outcomes (Yao, 2017).

PLACENTAL ABRUPTION

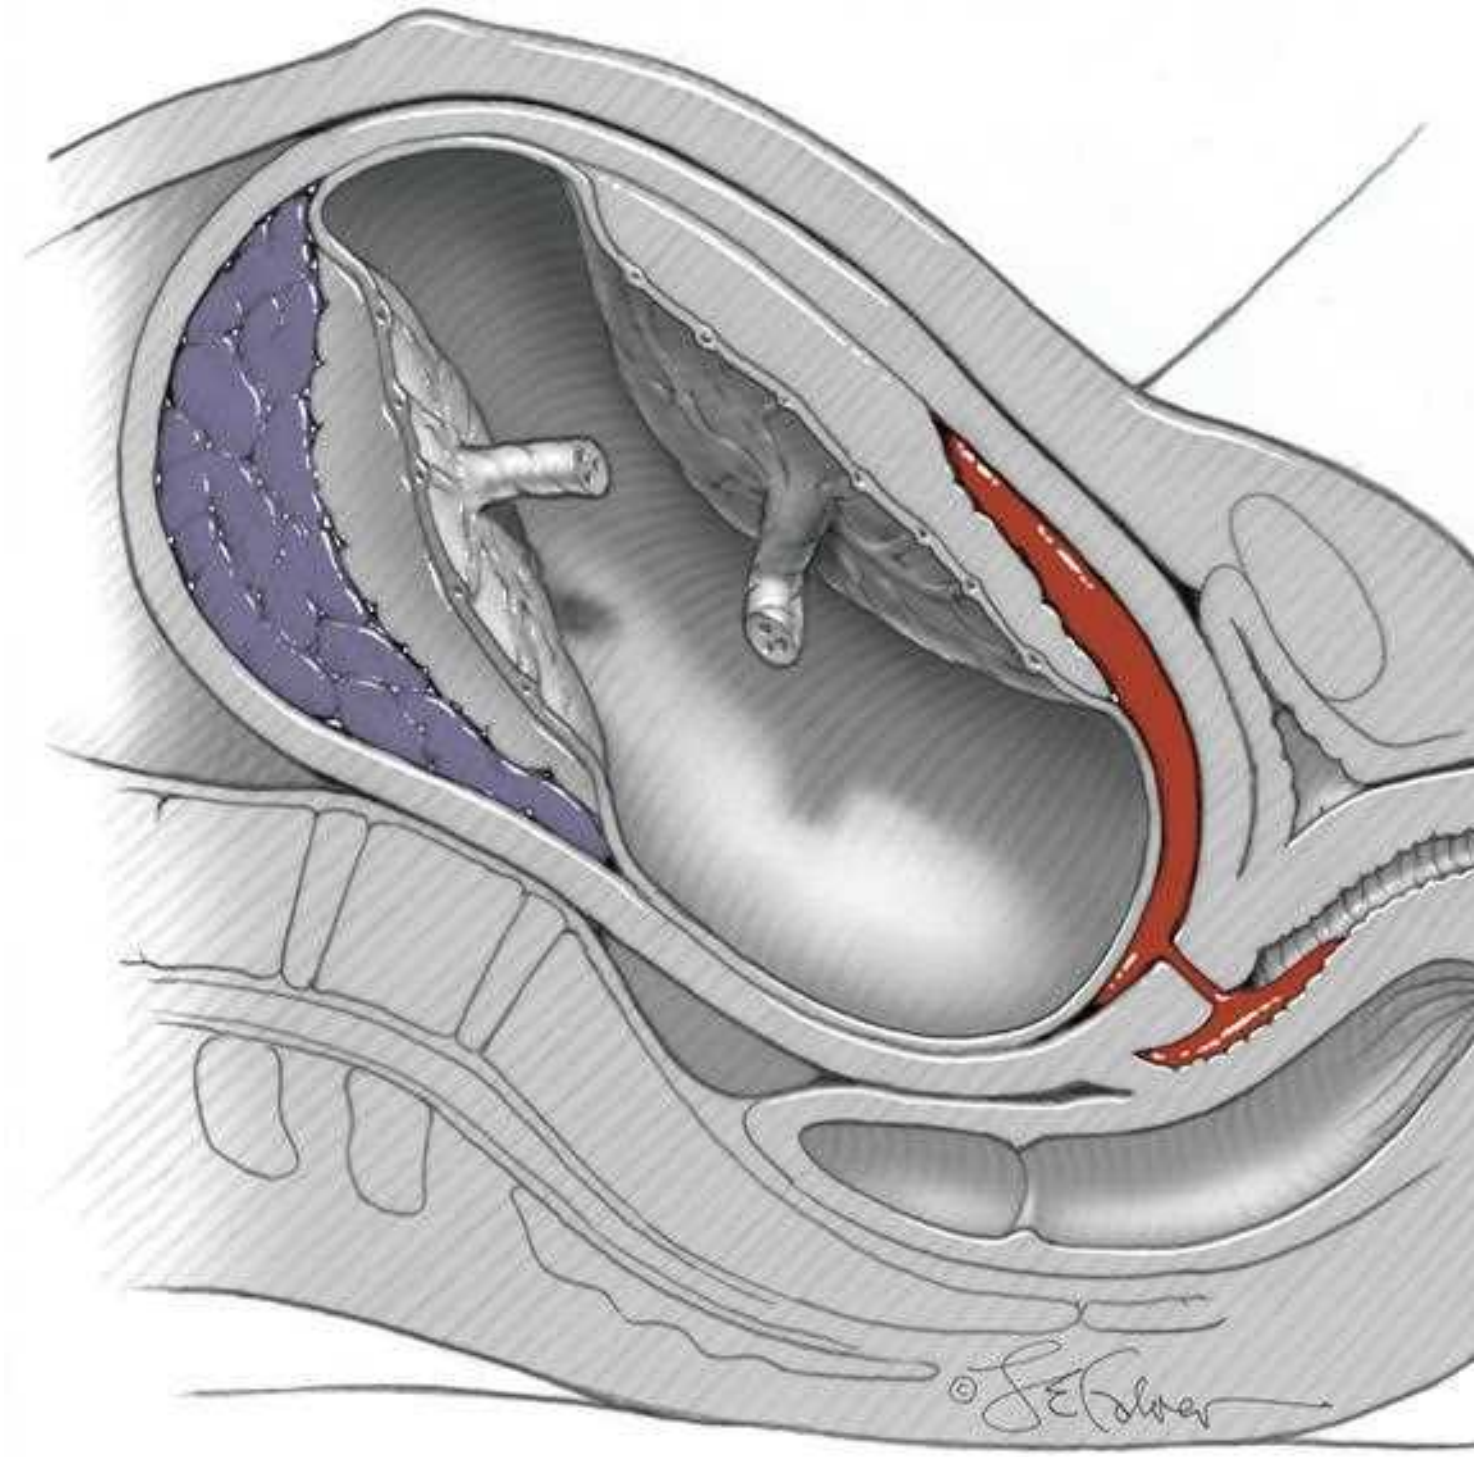
Etiopathogenesis

Separation of the placenta—either partially or totally—from its implantation site before delivery is described by the Latin term *abruptio placentae*. Literally translated, this refers to "rending asunder of the placenta," which denotes a sudden accident that is a clinical characteristic of most cases. In the purest sense, the cumbersome—and thus seldom used—term *premature separation of the normally implanted placenta* is most descriptive because it excludes separation of a placenta previa.

Placental abruption is initiated by hemorrhage into the decidua basalis. The decidua then splits, leaving a thin layer adhered to the myometrium. Consequently, the process begins as a decidual hematoma and expands to cause separation and compression of the adjacent placenta. Inciting causes of many cases have been posited. The phenomenon of impaired trophoblastic invasion with subsequent atherosis is related in some cases of preeclampsia complicated by abruption (Brosens, 2011). Inflammation or infection may be contributory (Mhatre, 2016; Nath, 2007). Histological findings cannot be used to determine timing of the abruption (Chen, 2017).

Abruption likely begins with rupture of a decidual spiral artery and then an expanding retroplacental hematoma. In the early stages of placental abruption, clinical symptoms may be absent. Even with continued bleeding and placental separation, placental abruption can still be either *total* or *partial* (Fig. 41-14). With either, bleeding typically insinuates itself between the membranes and uterus, ultimately escaping through the cervix to cause *external hemorrhage*. Less often, the blood is retained between the detached placenta and the uterus, leading to *concealed hemorrhage* and delayed diagnosis. The delay translates into greater maternal and fetal hazards. Also with concealed hemorrhage, the likelihood of consumptive coagulopathy is elevated. This is because increased pressure within the intervillous space, caused by the expanding retroplacental clot, forces more placental thromboplastin into the maternal circulation (Diagnosis).

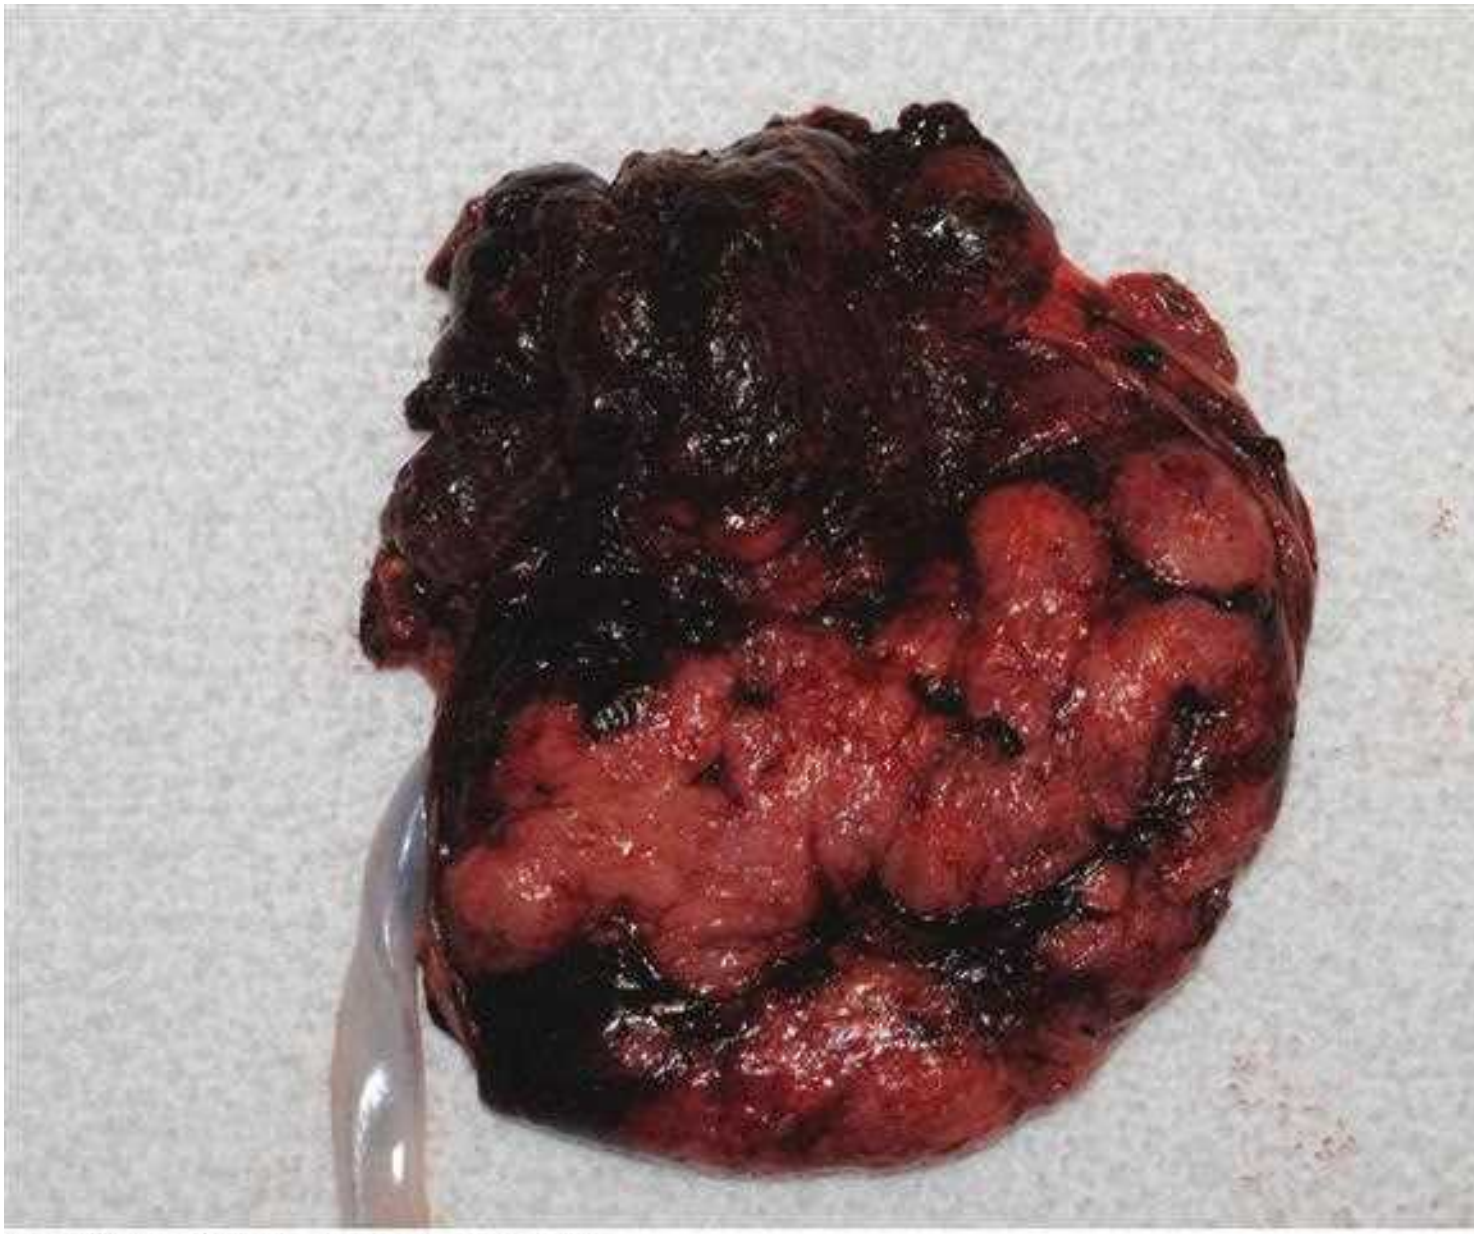
FIGURE 41-14
Schematic of placental abruption. Shown to left is a total placental abruption with concealed hemorrhage. To the right is a partial abruption with blood and clots dissecting between membranes and decidua to the internal cervical os and then externally into the vagina.



Most blood in the retroplacental hematoma in a nontraumatic placental abruption is maternal. This is because hemorrhage derives from separation within the maternal decidua, and placental villi are usually initially intact. In 78 women at Parkland Hospital with a nontraumatic placental abruption, fetal-to-maternal hemorrhage was documented in only 20 percent—and all of these had <10 mL fetal blood loss (Stettler, 1992). Atkinson and colleagues (2015) identified fetal cells in peripheral blood in only 4 percent of 68 women with a placental abruption.

When clinically suspected, an abruption is seen on a freshly delivered placenta as a circumscribed depression on the maternal surface. These usually measure a few centimeters in diameter and are covered by dark, clotted blood. Because several minutes are required for these anatomical changes to materialize, a very recently separated placenta may appear totally normal at delivery. Our experiences are like those of Benirschke and associates (2012) in that the "age" of the retroplacental clot cannot be determined exactly. In the example shown in Figure 41-15, a large dark clot is well formed, it has depressed the placental bulk, and it likely is at least several hours old.

FIGURE 41-15
Partial placental abruption with a dark adherent clot.



Defining severity of placental abruption is problematic. We have considered abruption severe when the fetus dies, however, maternal and fetal complications can be serious even with a liveborn fetus. Ananth and coworkers (2016) have defined *severe abruption* as displaying one or more of the following: (1) maternal sequelae that include disseminated intravascular coagulation, shock, transfusion, hysterectomy, renal failure, or death; (2) fetal complications such as nonreassuring fetal status, growth restriction, or death; or (3) neonatal outcomes that include death, preterm delivery, or growth restriction.

Traumatic Abruption

External trauma—usually from motor vehicle accidents or aggravated assault—can cause placental separation. The frequency of abruption originating from trauma varies. Kettel (1988) and Stafford (1988) and their associates have appropriately stressed that abruption can stem from relatively minor trauma. The clinical presentation and consequences of these abruptions differ somewhat from spontaneous cases. For example, associated fetomaternal hemorrhage, while seldom clinically significant with most spontaneous abruptions, is more common with trauma because of concomitant placental tears or "fractures" (Chap. 47, Placental Injuries). Fetal bleeding that averaged 12 mL was noted in a third of women with a traumatic abruption reported by Pearlman (1990). In eight women cared for at Parkland Hospital, we found fetal-to-maternal hemorrhage of 80 to 100 mL in three of eight cases of traumatic placental abruption (Stettler, 1992). Importantly, in some cases of trauma, a nonreassuring fetal heart rate tracing may not be accompanied by other evidence of placental separation. A sinusoidal tracing is one example. Traumatic abruption is considered in more detail in Chapter 47 (Placental Injuries).

Chronic Abruption

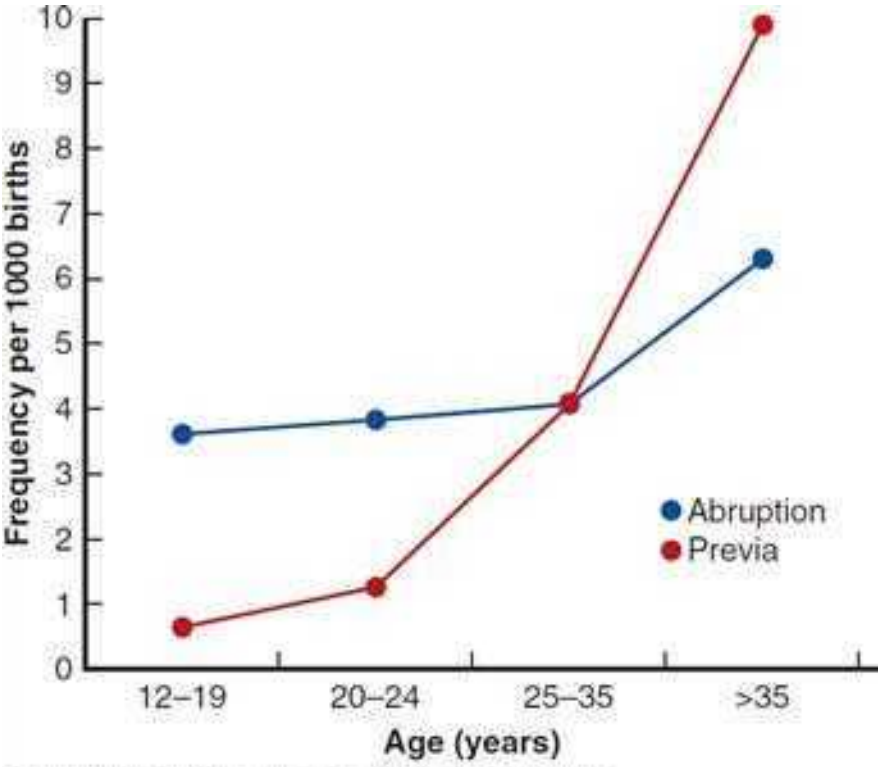
Some cases of chronic placental separation begin early in pregnancy. Dugoff and coworkers (2004) observed an association between some abnormally elevated maternal serum aneuploidy markers and subsequent abruption. Other have correlated first- and second-trimester bleeding with third-trimester placental abruption (Ananth, 2006; Weiss, 2004). In some cases of a chronic abruption, subsequent oligohydramnios develops—*chronic abruption-oligohydramnios sequence—CAOS*

(Elliott, 1998). Even later in pregnancy, hemorrhage with retroplacental hematoma formation is occasionally arrested completely without delivery. These women may have abnormally elevated serum levels of alpha-fetoprotein or placenta-specific RNAs as markers of the event (Miura, 2016; Ngai, 2012).

Frequency

The reported incidence of placental abruption varies because of different criteria used for diagnosis. That said, its frequency averages 0.5 percent or 1 in 200 deliveries. From one database of almost 28 million births from 2006 through 2012, the incidence of placental abruption was nearly 1 percent (Ananth, 2016). From a cohort of more than 1.57 million births in the Netherlands, Ruiter and coworkers (2015) found the frequency was 0.22 percent—1 in 450. In more than 250,000 deliveries at Parkland Hospital from 2000 through 2015, the incidence of placental abruption averaged 0.35 percent or 1 in 290 (Fig. 41-16).

FIGURE 41-16
Frequency of placental abruption and placenta previa by maternal age at Parkland Hospital from 2000 through 2015.

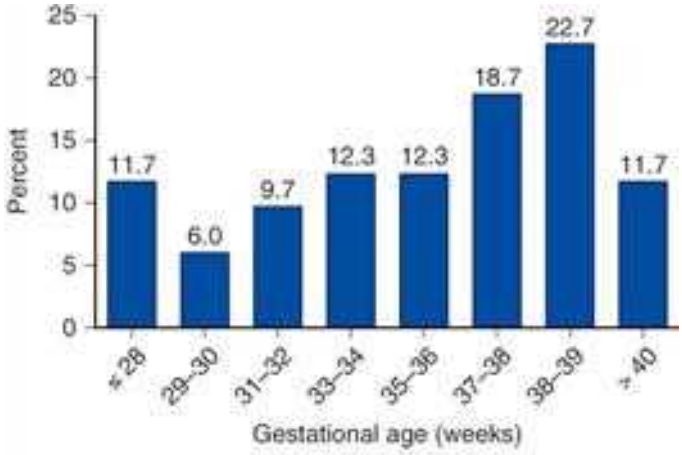


The frequency of placental abruption has *risen* in this country, and most of this increase is in black women (Ananth, 2005, 2016). At Parkland Hospital, however, the frequency of severe abruption has declined. This discrepancy may be explained in part by the variations in management of early-onset preeclampsia (Chap. 40, Preeclampsia). Specifically, with placental abruption *so extensive as to kill the fetus*, the incidence was 0.24 percent or 1 in 420 births from 1956 through 1967 (Pritchard, 1967). As the number of high-parity women giving birth declined along with improved availability of prenatal care and emergency transportation, the frequency of abruption causing fetal death dropped to 0.12 percent through 1989 in our obstetrical population. And, most recently through 2015, it declined to 0.05 percent or 1 in 2060.

Perinatal Morbidity and Mortality

Overall, perinatal outcomes are influenced by gestational age, and the frequency of placental abruption rises across the third trimester. As seen in Figure 41-17, more than half of the placental abruptions at Parkland Hospital developed at gestational ages ≥37 weeks. Perinatal mortality and morbidity, however, are more common with earlier abruptions (Furukawa, 2015a). Of other related factors, major fetal congenital anomalies have greater association with placental abruption (Riihimäki, 2013).

FIGURE 41-17
Frequency of placental abruption by gestational age at Parkland Hospital.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Although the rates of fetal death have declined, the contribution of abruption as a cause of stillbirth remains prominent because other causes have also decreased. For example, since the early 1990s, 10 to 12 percent of all third-trimester stillbirths at Parkland Hospital have been the consequence of placental abruption. Others have documented high perinatal mortality rates caused by placental abruption. Salihu and colleagues (2005) analyzed more than 15 million singleton births between 1995 and 1998. The perinatal mortality rate associated with placental abruption was 119 per 1000 births compared with 8 per 1000 for the general obstetrical population.

Neonatal deaths are common following placental abruption. At Parkland Hospital, 15 percent of liveborn neonates died. Perinatal morbidity—often severe—is also common in surviving newborns (Abdella, 1984). Studies by Matsuda and coworkers (2003, 2013) reported that 20 percent of survivors developed cerebral palsy. These observations are similar to ours from Parkland Hospital. Notably, 20 percent of liveborn neonates of women with an abruption had severe acidemia, defined by a cord arterial blood pH <7.0 or base deficit of ≥12 mmol/L. One review confirmed the associated risk for cerebral palsy (Downes, 2017). Even so, Ananth and coworkers (2017) attribute adverse neurodevelopmental outcomes to be largely attributable to preterm delivery.

Predisposing Factors

Demographic Factors

Several predisposing factors raise the risk for placental abruption, and some are listed in Table 41-4. *Advancing maternal age* is one, although data are conflicting regarding women of *great parity* (Okby, 2017; Pritchard, 1991). *Race* or ethnicity also appears to be important. In almost 366,000 deliveries at Parkland Hospital, abruption severe enough to kill the fetus was most common in black and white women—1 in 200, less so in Asian women—1 in 300, and least common in Latin-American women—1 in 350 (Pritchard, 1991). A *familial association* was found in an analysis of a Norwegian population-based registry (Rasmussen, 2009). If a woman had a severe abruption, the risk for her sister was doubled.

TABLE 41-4

Risk Factors for Placental Abruption

Risk Factor	Relative Risk
Prior abruption	10–188
Increased age and parity	1.3–2.3
Preeclampsia	2.1–4.0
Chronic hypertension	1.8–3.0
Chorioamnionitis	3.0
Preterm ruptured membranes	2.4–4.9
Multifetal gestation	2–8
Low birthweight	14.0
Hydramnios	2–8
Cigarette smoking	1.4–1.9
Single umbilical artery	3.4
Cocaine use	NA
Uterine leiomyoma	NA

NA = not available.

Data from Ananth, 1999a,b, 2004, 2007; Aviram, 2015; Gutvirtz, 2016; Morgan, 2016; Nath, 2007, 2008; Ruiter, 2015.

Pregnancy-Associated Hypertension

Some form of hypertension is the most frequent condition associated with placental abruption. This includes gestational hypertension, preeclampsia, chronic hypertension, or a combination thereof. In a report by Pritchard and colleagues (1991) that described 408 women with placental abruption and fetal demise, hypertension was apparent in half once hypovolemia was corrected. Half of these latter women—a fourth of all 408—had chronic hypertension. Looked at another way, one Maternal–Fetal Medicine Units (MFMU) Network study found that 1.5 percent of pregnant women with chronic hypertension suffered placental abruption (Sibai, 1998). As discussed in Chapter 50 (Adverse Pregnancy Effects), at Parkland Hospital, the frequency of placental abruption in treated chronically hypertensive women was almost 1 percent, which was threefold higher than the 0.3-percent baseline (Morgan, 2016).

Chronic hypertension with superimposed preeclampsia or with fetal-growth restriction confers an even greater risk (Ananth, 2007). Even so, the severity of hypertension does not necessarily correlate with abruption incidence (Morgan, 2016; Zetterstrom, 2005). The long-term effects of these associations are apparent from the significantly elevated cardiovascular mortality risk in women with prior abruption, with or without chronic hypertension (DeRoo, 2016; Pariente, 2013). Observations from the Magpie Trial Collaborative Group suggest that women with preeclampsia, with or without chronic hypertension, given magnesium sulfate may have a reduced risk for abruption (Altman, 2002).

Preterm Prematurely Ruptured Membranes

The abruption risk substantially rises when placental membranes rupture before term (American College of Obstetricians and Gynecologists, 2016a; Hackney, 2016). Major and colleagues (1995) reported that 5 percent of 756 women with ruptured membranes between 20 and 36 weeks' gestation developed an abruption. It was 17 percent with previable prematurely ruptured membranes (Kibel, 2016). The risk for abruption with preterm rupture is further increased with comorbid infection (Ananth, 2004). In these cases, inflammation and infection as well as preterm delivery may be primary causes leading to abruption (Nath, 2007, 2008).

Somewhat related, Aviram and coworkers (2015) found an eightfold higher abruption risk in pregnancies ≥34 weeks if hydramnios was comorbid. Abrupt uterine decompression during membrane rupture may be an inciting factor.

Prior Abruption

Many of the predisposing factors are chronic, and in these cases, placental abruption has a high recurrence rate. Pritchard and associates (1970) identified a recurrence rate of 12 percent—and half of these caused another fetal death. Furuhashi and colleagues (2002) reported a 22-percent recurrence rate—half recurred at a gestational age 1 to 3 weeks earlier than the first abruption. In the Dutch study mentioned previously, Ruiter and coworkers (2015) cited a recurrence risk of 5.8 percent. Looked at a second way, Tikkanen and associates (2006) found that of 114 parous women who experienced an abruption, 9 percent had a prior abruption. A third perspective is provided by a population-based study of 767,000 pregnancies reported by Rasmussen and Irgens (2009). They found a 6.5-fold higher risk for recurrence of a "mild" abruption and 11.5-fold risk for a "severe" abruption. For women who had two severe abruptions, the risk for a third was increased 50-fold.

Management of a pregnancy subsequent to an abruption is difficult because another separation may suddenly occur, even remote from term. In many of these recurrences, fetal well-being is almost always reassuring beforehand. Thus, antepartum fetal testing is usually not predictive. Because term abruptions tend to be recurrent, Ruiter and coworkers (2015) recommend labor induction at 37 weeks. Our practice at Parkland Hospital is to induce labor at 38 weeks if other complications do not develop beforehand.

Other Associations

Cigarette smoking is linked to an elevated risk for abruption (Misra, 1999; Naeye, 1980). Results of a metaanalysis of 1.6 million pregnancies included a twofold risk for abruption in smokers (Ananth, 1999b). This risk was five- to eightfold if smokers had chronic hypertension, severe preeclampsia, or both. Similar findings are reported by others (Hogberg, 2007; Kaminsky, 2007). Antepartum Vitamin C and E were reported to be protective for abruption in smokers (Abramovici, 2015).

Cocaine abuse is linked with an alarming frequency of placental abruption (Addis, 2001; Cressman, 2014). Bingol and colleagues (1987) described 50 women who abused cocaine during pregnancy—eight had a stillbirth caused by placental abruption.

Uterine leiomyomas, especially if located near the mucosal surface behind the placental implantation site, can predispose to placental abruption. This was reviewed recently by Ezzedine and Norwitz (2016).

Isolated single umbilical artery is associated with a 3.4-fold increased risk for placental abruption (Gutvirtz, 2016). Twins resulting from infertility treatments also carry greater risk (Okby, 2017). Subclinical hypothyroidism or high levels of antithyroid antibodies have been associated with a two- to threefold higher risk for abruption (Abbassi-Ghanavati, 2010; Casey, 2014; Maraka, 2016).

Women affected by some of the thrombophilias have higher associated rates of thromboembolic disorders during pregnancy. However, the link with placental abruption is less clear (American College of Obstetricians and Gynecologists, 2017a,b). Lupus anticoagulant is associated with maternal floor infarction of the placenta but is less so with typical abruptions. No convincing evidence supports a role for thrombophilias and placental abruption.

Clinical Findings and Diagnosis

Most women with a placental abruption have sudden-onset abdominal pain, vaginal bleeding, and uterine tenderness. In a prospective study, Hurd and colleagues (1983) reported that 78 percent with placental abruption had vaginal bleeding, 66 percent had uterine tenderness or back pain, and 60 percent had a nonreassuring fetal status. Other findings included frequent contractions and persistent hypertonus. In a fifth of these women, preterm labor was diagnosed, and abruption was not suspected until fetal distress or death followed.

Importantly, the signs and symptoms of placental abruption can vary considerably. In some women, external bleeding can be profuse, yet placental separation may not be so extensive as to compromise the fetus. In others, there may be no external bleeding, but the placenta is sufficiently sheared off that the fetus is dead—a concealed abruption. In one unusual case, a multiparous woman cared for at Parkland Hospital presented with a nosebleed. She had no abdominal or uterine pain, tenderness, or vaginal bleeding. Her fetus was dead, however, and her blood did not clot. The plasma fibrinogen level was 25 mg/dL. Labor was induced, and a total abruption was confirmed at delivery.

Differential Diagnosis

With severe placental abruption, the diagnosis generally is obvious. From the previous discussion, it follows that less severe, more common forms of abruption cannot always be recognized with certainty. Thus, the diagnosis is one of exclusion. Unfortunately, no laboratory tests or other diagnostic methods accurately confirm lesser degrees of placental separation. Sonography has limited use because the placenta and fresh clots may have similar imaging characteristics. Glantz and Purnell (2002) reported only 24-percent sensitivity for sonography in 149 consecutive women with a suspected placental abruption. *Importantly, negative findings with sonographic examination do not exclude placental abruption.* Conversely, magnetic resonance (MR) imaging is highly sensitive for placental abruption and should be considered if the diagnostic information would change management (Masselli, 2011).

With abruption, some degree of intravascular coagulation is almost universal. Thus, elevated serum levels of d-dimers may be suggestive, but this has not been adequately tested. Preliminary data show that serum alpha-fetoprotein levels >280 µg/L have a positive-predictive value of 97 percent (Ngai, 2012).

Thus, in the woman with vaginal bleeding and a live fetus, it is often necessary to exclude placenta previa and other causes of bleeding by clinical and sonographic evaluation. It has long been taught—perhaps with some justification—that *painful* uterine bleeding signifies placental abruption, whereas *painless* uterine bleeding is indicative of placenta previa. The differential diagnosis is usually not this straightforward, and labor accompanying previa may cause pain suggestive of placental abruption. On the other hand, pain from abruption may mimic normal labor, or it may be painless, especially with a posterior placenta. At times, the cause of the vaginal bleeding remains obscure even after delivery.

Hypovolemic Shock

Placental abruption is one of several notable obstetrical entities that may be complicated by massive and sometimes torrential hemorrhage. Hypovolemic shock is caused by maternal blood loss. In an earlier report from Parkland Hospital, Pritchard and Brekken (1967) described 141 women with abruption so severe as to kill the fetus. Blood loss in these women often amounted to at least half of their pregnant blood volume. Importantly, massive blood loss and shock can develop with a concealed abruption. Prompt treatment of hypotension with crystalloid and blood infusion is essential, and resuscitation steps are described later (Hypovolemic Shock).

Consumptive Coagulopathy

Obstetrical events—mainly placental abruption and amnionic fluid embolism—led to the initial recognition of *defibrination syndrome.* This syndrome is currently referred to as *consumptive coagulopathy* or *disseminated intravascular coagulation,* which later is described more broadly in Obstetrical Coagulopathies. The major mechanism causing procoagulant consumption is intravascular activation of clotting. Abruption is the most common cause of clinically profound consumptive coagulopathy in obstetrics—and indeed, probably in all of medicine (Cunningham, 2015).

An important consequence of intravascular coagulation is the activation of plasminogen to plasmin, which lyses fibrin microemboli to maintain microcirculatory patency. With placental abruption severe enough to kill the fetus, there are always pathological levels of fibrinogen–fibrin degradation products and D-dimers in maternal serum (Erez, 2015). Their quantification is not clinically useful. In a third of women with an abruption severe enough to kill the fetus, the plasma fibrinogen level will be <150 mg/dL. These levels are dependent on the maternal preabruption fibrinogen level, and thus higher levels are "protective" (Cunningham, 2015; Wang, 2016). Clinically significant low levels may cause troublesome surgical bleeding. Levels of several other coagulation factors are also variably decreased. In addition, thrombocytopenia, sometimes profound, may accompany severe hypofibrinogenemia initially and becomes common after repeated blood transfusions.

Consumptive coagulopathy is more likely with a concealed abruption because intrauterine pressure is higher. This forces more thromboplastin into the large veins draining the implantation site. With a partial abruption and a live fetus, severe coagulation defects are less common. Our experience has been that if serious coagulopathy develops, it is usually evident by the time abruption symptoms appear.

Couvelaire Uterus

At the time of cesarean delivery, it is not uncommon to find widespread extravasation of blood into the uterine musculature and beneath the serosa (Fig. 41-18). It is named after Couvelaire, who in the early 1900s termed it *uteroplacental apoplexy*. These myometrial hemorrhages seldom cause uterine atony, and alone they are not an indication for hysterectomy. Effusions of blood are also seen beneath the tubal serosa, between the leaves of the broad ligaments, in the substance of the ovaries, and free in the peritoneal cavity.

FIGURE 41-18
Couvelaire uterus from total placental abruption after cesarean delivery. Blood markedly infiltrates the myometrium to reach the serosa, especially at the cornua. The small serosal leiomyoma seen on the lower anterior uterine surface is an incidental finding. (Used with permission from Dr. Angela Fields Walker.)

End-Organ Injury

Acute kidney injury (AKI) is a general term describing renal dysfunction from many causes (Chap. 53, Acute Kidney Injury). Delayed or incomplete treatment of hypovolemia with severe placental abruption can be one. However, even with abruption complicated by severe disseminated intravascular coagulation, prompt and vigorous treatment of hemorrhage with blood and crystalloid solution usually prevents clinically significant renal dysfunction. The risk for renal injury with abruption is magnified when preeclampsia coexists (Alexander, 2015; Drakeley, 2002). Most cases of AKI are reversible and not so severe as to require dialysis. Generally, long-term outcomes are good (Arazi, 2015). That said, irreversible *acute cortical necrosis* encountered in pregnancy can be associated with abruption (Gopalakrishnan, 2015).

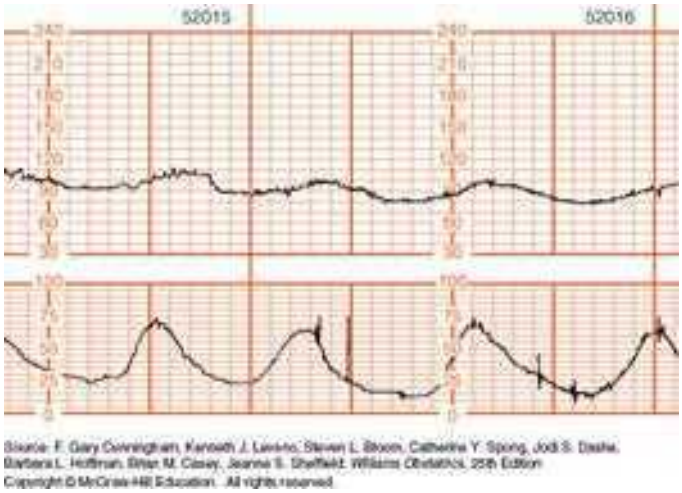
Rarely, pituitary failure—*Sheehan syndrome*—follows severe intrapartum or early postpartum hemorrhage. Described in Chapter 58 (Acromegaly), the exact pathogenesis is not well understood, especially because endocrine abnormalities are infrequent even in women who suffer catastrophic hemorrhage (Matsuwaki, 2014; Robalo, 2012).

Management

Treatment of the woman with a placental abruption varies depending on her clinical condition, gestational age, and the amount of associated hemorrhage. With a living viable-aged fetus, and with vaginal delivery not imminent, emergency cesarean delivery is chosen by most. In some women, fetal compromise will be evident as shown in Figure 41-19. When evaluating fetal status, sonographic confirmation of fetal heart activity may be necessary because sometimes an electrode applied directly to a dead fetus will provide misleading information by recording the maternal heart rate. If the fetus has died or if it is not considered sufficiently mature to live outside the uterus, then vaginal delivery is preferable. In either case, prompt and intensive resuscitation with blood plus crystalloid is begun to replace blood lost from retroplacental and external hemorrhage. These measures are lifesaving for the mother and hopefully for her fetus. If the diagnosis of abruption is uncertain and the fetus is alive and without evidence of compromise, then close observation may be warranted provided that immediate intervention is available. Colón and coworkers (2016) performed a randomized trial and found no benefits to magnesium sulfate tocolysis given to women with a preterm “nonsevere” abruption at 24 to 34 weeks’ gestation.

FIGURE 41-19

Placental abruption with fetal compromise. Lower panel: Uterine hypertonus with a baseline pressure of 20 to 25 mm Hg and frequent contractions peaking at approximately 75 mm Hg. Upper panel: The fetal heart rate demonstrates baseline bradycardia with repetitive late decelerations.



Cesarean Delivery

The compromised fetus is usually best served by cesarean delivery, and the speed of response is an important factor in perinatal outcomes. Kayani and coworkers (2003) studied this relationship in 33 singleton pregnancies with a clinically overt placental abruption and fetal bradycardia. Of the 22 neurologically intact survivors, 15 were delivered within a 20-minute decision-to-delivery interval. However, eight of 11 infants who died or developed cerebral palsy were delivered with intervals >20 minutes.

A major hazard to cesarean delivery is imposed by clinically significant consumptive coagulopathy. Preparations include plans for blood and component replacement and assessment of coagulation—especially fibrinogen levels.

Vaginal Delivery

If the fetus has died, then vaginal delivery is usually preferred. As reviewed earlier, hemostasis at the placental implantation site depends primarily on myometrial contraction and not blood coagulability. Thus, after vaginal delivery, uterotonic agents and uterine massage are used to stimulate myometrial contractions. Uterine muscle fibers compress placental site vessels and prompt hemostasis even if coagulation is defective.

In some instances, vaginal delivery may not be preferable, even with a dead fetus. One example is brisk hemorrhage that cannot be successfully managed by vigorous blood replacement. Others are the myriad obstetrical complications that prohibit vaginal delivery in general. These are listed in Table 30-1.

In some women with extensive placental abruption, labor tends to be rapid because the uterus is usually persistently hypertonic. This can magnify fetal compromise. In some cases, *baseline* intraamnionic pressures reach 50 mm Hg or higher, and with contractions, pressures may attain levels exceeding 100 mm Hg. Overall, however, first-and second-stage labor do not appear to be shortened (Downes, 2016).

Early amniotomy has long been championed in the management of placental abruption. This ostensibly achieves better spiral artery compression to diminish implantation site bleeding and reduce thromboplastin infusion into the maternal vascular system. Although evidence supporting this theory is lacking, membrane rupture may hasten delivery. However, if the fetus is small, the intact sac may be more efficient in promoting cervical dilation. If rhythmic uterine contractions are not superimposed on baseline hypertonus, then oxytocin is given in standard doses. No data indicate that oxytocin augments thromboplastin escape into the maternal circulation to worsen coagulopathy (Clark, 1995; Pritchard, 1967). In light of hypertonus associated with abruption, misoprostol may be a less favored induction agent due to its association with uterine tachysystole.

In the past, some had set arbitrary time limits to permit vaginal delivery. Instead, experiences illustrate that maternal outcome depends on the diligence with which adequate fluid and blood replacement therapy are pursued rather than on the interval to delivery. Observations from Parkland Hospital described by Pritchard and Brekken (1967) are similar to those from the University of Virginia reported by Brame and associates (1968). Specifically, women with severe abruption who were transfused during 18 hours or more before delivery had similar outcomes to those in whom delivery was accomplished sooner.

Expectant Management with a Preterm Fetus

If possible, delaying delivery may benefit an immature fetus. Bond and colleagues (1989) expectantly managed 43 women with placental abruption before 35 weeks' gestation, and 31 of them were given tocolytic therapy. The mean interval-to-delivery for all 43 was approximately 12 days. Cesarean delivery was performed in 75 percent, and there were no stillbirths. As discussed earlier, women with a very early abruption may develop *chronic abruption-oligohydramnios sequence*. In one report, Elliott and coworkers (1998) described four women with an abruption at a mean gestational age of 20 weeks who developed oligohydramnios and delivered at an average gestational age of 28 weeks. In a description of 256 women with an abruption at <28 weeks' gestation, Sabourin and colleagues (2012) reported that a mean of 1.6 weeks was gained. Of the group, 65 percent were delivered <29 weeks, and half of all women underwent emergent cesarean delivery.

Unfortunately, even continuous fetal heart rate monitoring does not guarantee universally good outcomes. For example, a normal tracing may precede sudden further separation with instant fetal compromise. In some of these, if the separation is sufficient, the fetus will die before it can be delivered. Tocolysis is advocated by some for suspected abruption if the fetus does not display compromise. Some investigators have observed that tocolysis improved outcomes in a highly selected cohort of women with preterm pregnancies (Bond, 1989; Combs, 1992; Sholl, 1987). In another study, Towers and coworkers (1999) administered magnesium sulfate, terbutaline, or both to 95 of 131 women with abruption diagnosed before 36 weeks. The perinatal mortality rate was 5 percent in both groups with or without tocolysis. Similar results were reported from a randomized trial (Colón, 2016). We are of the opinion that suspected placental abruption contraindicates use of tocolytic agents.

PLACENTA PREVIA

The Latin *previa* means *going before*—and in this sense, the placenta goes before the fetus into the birth canal. In obstetrics, placenta previa describes a placenta that is implanted somewhere in the lower uterine segment, either over or very near the internal cervical os. Because these anatomical relationships cannot always be precisely defined, and because they frequently change across pregnancy, terminology can sometimes be confusing.

Placental Migration

Beginning with the use of sonography in obstetrics, the term *placental migration* was coined to describe the apparent movement of the placenta away from the internal os (King, 1973). Obviously, the placenta does not move per se, and the mechanism of *apparent* movement is not completely understood. To begin with, *migration* is clearly a misnomer, because decidual invasion anchors chorionic villi at the cervical os.

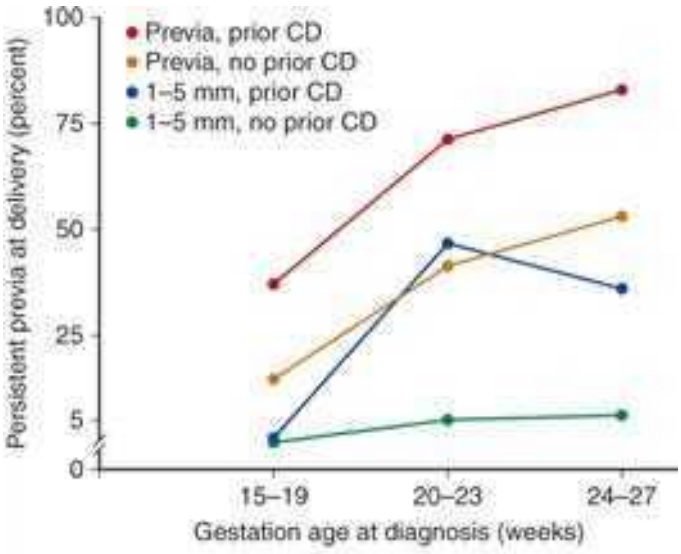
Explanations of placental migration are likely additive. First, apparent movement of the low-lying placenta relative to the internal os is related to the imprecision of two-dimensional sonography. Second, as pregnancy progresses, growth of the lower and upper uterine segments differs. With greater blood flow in the upper uterus, placental growth is more likely directed toward the fundus—*trophotropism*. Many of those placentas that "migrate" most likely never were circumferentially implanted with true villous invasion that reached the internal cervical os. *Importantly, a low-lying placenta or placenta previa is less likely to "migrate" if there is a prior cesarean delivery scar.*

The frequency of placental migration has been quantified. Sanderson and Milton (1991) studied 4300 women at midpregnancy and found that 12 percent had a low-lying placenta. Of placentas not covering the internal os, previa did not persist, and none subsequently had placental hemorrhage. Conversely, approximately 40 percent of placentas that covered the os at midpregnancy continued to do so until delivery. Thus, placentas that lie close to but not over the internal os up to the early third trimester are unlikely to persist as a previa by term (Heller, 2014; Parrott, 2015). However, other evidence from Bohrer and associates (2012) showed that a second-trimester low-lying placenta was associated with antepartum admission for hemorrhage and increased blood loss at delivery.

The likelihood that placenta previa persists after being identified sonographically at given epochs before 28 weeks' gestation is shown in Figure 41-20. For twin pregnancies, similar findings are reported until 23 weeks, after which the previa persistence rate is much higher (Kohari, 2012). Stafford and coworkers (2010), but not Trudell and colleagues (2013), found that a previa and a third-trimester cervical length <30 mm elevated the risks for hemorrhage, uterine activity, and preterm birth. Friszer and associates (2013) showed that women admitted for bleeding had a greater chance of delivery in the subsequent 7 days when the cervical length was <25 mm, although Trudell (2013) again did not confirm this.

FIGURE 41-20

Likelihood of persistence of placenta previa or low-lying placenta 1 to 5 mm from the internal os at delivery. These are shown as a function of sonographic diagnosis at three pregnancy epochs. CD = cesarean delivery. (Data from Oyelese, 2006.)



Classification

Terminology for placenta previa has evolved, and from a Fetal Imaging Workshop sponsored by the National Institutes of Health (NIH), the following classification was recommended:

Placenta previa—the internal os is covered partially or completely by placenta (Figs. 41-21 and 41-22). In the past, these were further classified as either total or partial previa.

Low-lying placenta—implantation in the lower uterine segment is such that the placental edge does not cover the internal os but lies within a 2-cm wide perimeter around the os. A previously used term, *marginal previa,* described a placenta that was at the edge of the internal os but did not overlie it (Reddy, 2014).

FIGURE 41-21
Placenta previa showing that copious hemorrhage could be anticipated with any cervical dilatation.

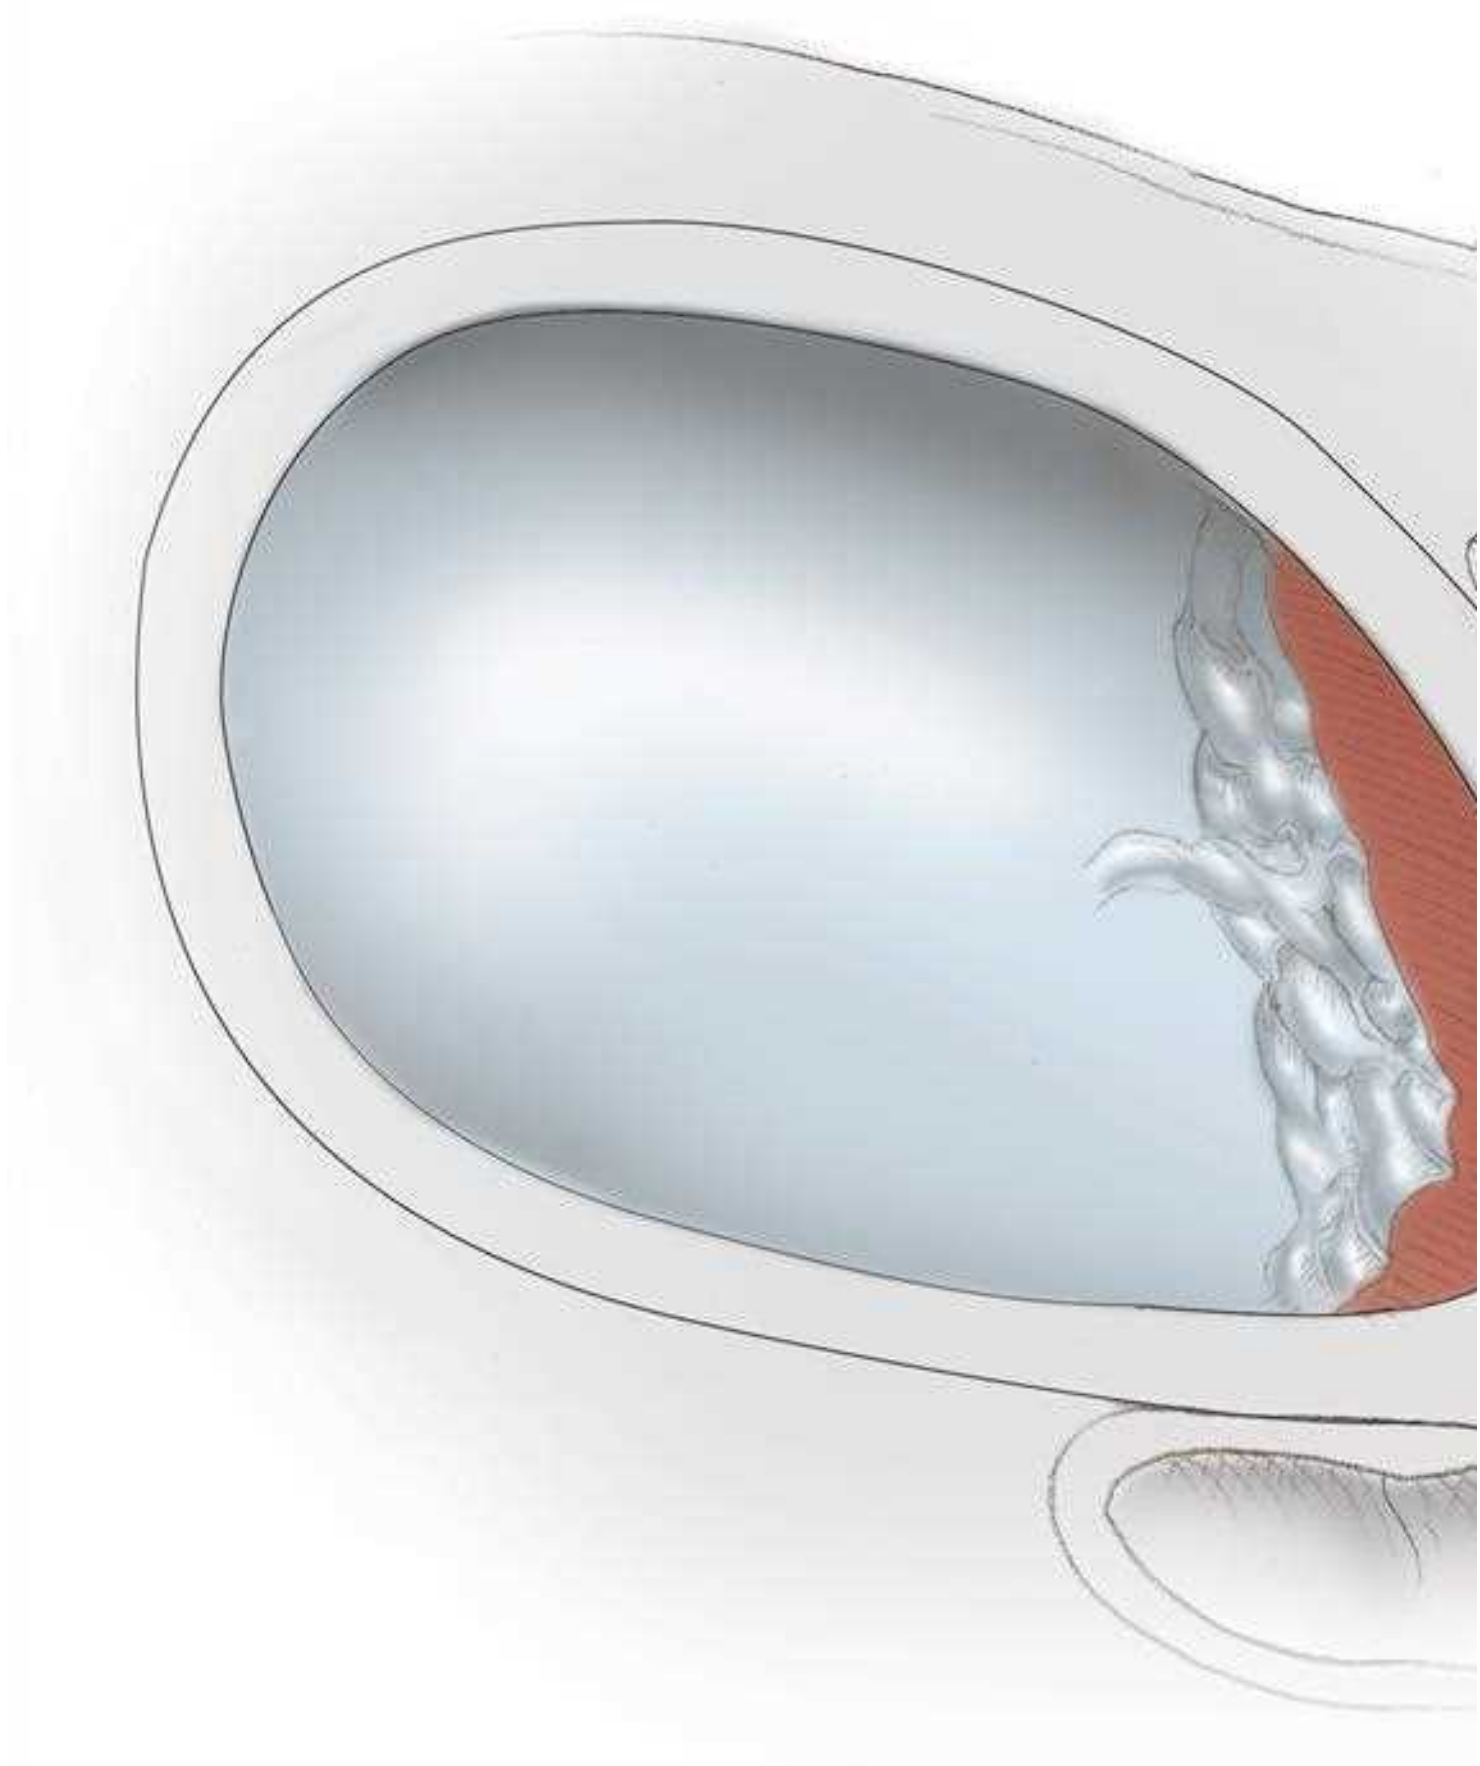


FIGURE 41-22

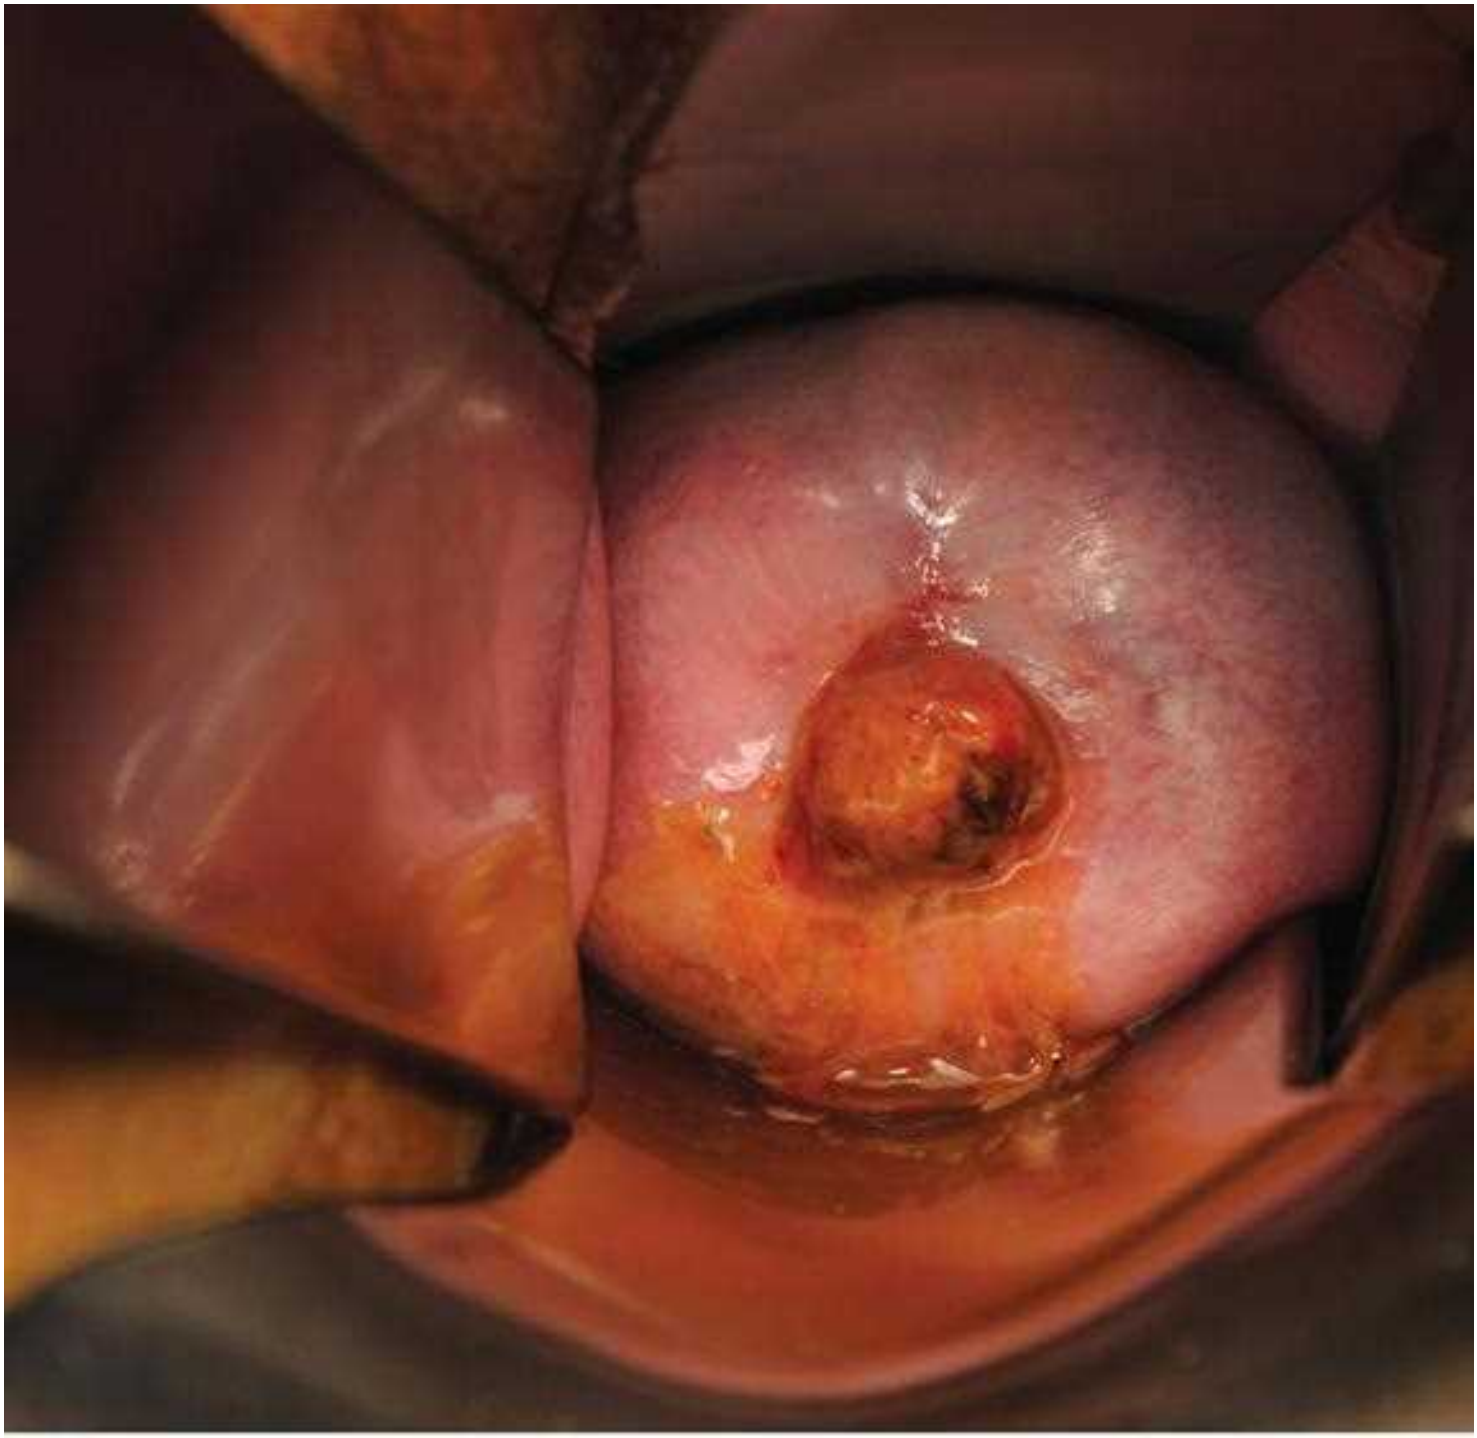
On speculum examination, placenta is visible protruding through the cervical os. (Used with permission from Dr. Maureen E. Flowers.)



Clearly, the classification of some cases of previa will depend on cervical dilation at the time of assessment (Dashe, 2013; Reddy, 2014). For example, a low-lying placenta at 2-cm dilation may become a partial placenta previa at 4-cm dilation because the cervix has opened to expose the placental edge. Conversely, a placenta previa that appears to be total before cervical dilation may become partial at 4-cm dilation because the cervical opening now extends beyond the edge of the placenta. *Digital palpation in an attempt to ascertain these changing relations between the placental edge and internal os as the cervix dilates usually causes severe hemorrhage!*

With any degree of placenta previa, a certain amount of spontaneous placental separation is inevitable during lower uterine segment remodeling and cervical dilation. Although this frequently causes bleeding, and thus technically constitutes a placental abruption, this term is usually not applied in these instances.

Somewhat but not always related is *vasa previa,* in which fetal vessels course through membranes and present at the cervical os (Catanzarite, 2016). Vasa previa was recently reviewed by the Society for Maternal-Fetal Medicine (2015) and is discussed in Chapter 6 (Remnants and Cysts).

Incidence and Associated Factors

Demographic Factors

The incidence of placenta previa has risen during past 30 years. Reported incidences average 0.3 percent or 1 case per 300 to 400 deliveries. The frequency at Parkland Hospital from 1988 through 2003 for nearly 250,000 births was 2.6 per 1000. For the 2004 to 2015 epoch, it rose to 3.8 per 1000. Similar frequencies have been reported from Austria, Finland, and Israel (Kollmann, 2016; Räisänen, 2014; Rosenberg, 2011).

Several demographic factors may contribute to this higher risk for placenta previa. First, *maternal age* raises the frequency of placenta previa (Biro, 2012; Roberts, 2012). In the First- and Second-Trimester Evaluation of Risk (FASTER) trial, which included more than 36,000 women, the frequency of previa was 0.5 percent for women <35 years compared with 1.1 percent in those ≥35 years (Cleary-Goldman, 2005). At Parkland Hospital, this incidence differed from a low rate of approximately 0.65 per 1000 births for women ≤19 years to almost 10 per 1000 births for women older than 35 (see Fig. 41-16).

Multiparity also elevates the risk for previa (Räisänen, 2014). Obviously, the effects of advancing maternal age and parity are confounding. Still, Babinszki and colleagues (1999) reported that the 2.2-percent incidence in women with parity of five or greater was significantly higher than that of women with lower parity. The interpregnancy interval does not affect this rate (Fox, 2015).

Cigarette smoking increases the relative risk of placenta previa at least twofold (Usta, 2005). It has been postulated that carbon monoxide hypoxemia causes compensatory placental hypertrophy and more surface area. Smoking may also be related to decidual vasculopathy. Last, *uterine leiomyomas* are a risk factor for previa (Jenabi, 2017).

Clinical Factors

Several clinical characteristics also raise previa risks. Foremost, women with one or more *prior cesarean deliveries* are at greater risk for subsequent placental disorders that include placenta previa, abruption, or morbidly adherent placenta (Gibbins, 2018; Klar, 2014). The cumulative risks for placenta previa that accrue with the increasing number of cesarean deliveries are extraordinary. The risk rises even further if there was a prior prelabor cesarean delivery (Downes, 2015). In one MFMU Network study of 30,132 women undergoing cesarean delivery, the incidence was 1.3 percent for those with only one prior cesarean delivery, but it was 3.4 percent if there were six or more prior cesareans (Silver, 2006). In a retrospective cohort of nearly 400,000 women who were delivered of two consecutive singletons, those with a cesarean delivery for the first pregnancy had a 1.6-fold greater risk for previa in the second pregnancy (Gurol-Urganci, 2011). These same investigators reported a 1.5-fold higher risk from six similar population-based cohort studies. The likelihood of previa is increased more than eightfold in women with parity greater than four and who have more than four prior cesarean deliveries (Gesteland, 2004; Gilliam, 2002).

Importantly, women with a prior uterine incision and placenta previa have an elevated likelihood that cesarean hysterectomy will be necessary because of an associated morbidly adherent placenta (Wei, 2014). In one study, 6 percent of women with a primary cesarean delivery for previa required a hysterectomy. This rate was 25 percent for women with a previa undergoing repeat cesarean delivery (Frederiksen, 1999).

Maternal serum alpha-fetoprotein (MSAFP) levels, if abnormally elevated for otherwise unexplained reasons during prenatal screening, raise the risk for previa and a host of other abnormalities. Moreover, women with a previa and comorbid MSAFP level ≥2.0 multiples of the median (MoM) at 16 weeks' gestation were at greater risk for late-pregnancy bleeding and preterm birth (Chap. 14, Maternal Serum AFP Elevation: Neural-Tube Defect Screening).

Last, *assisted reproductive technology (ART)* used for conception elevates previa risks. Some of this association may derive from overlapping effects. For example, older women comprise a significant portion of ART patients (Luke, 2017). In addition, multifetal gestation is a well-known risk of both in vitro fertilization and previa. However, even adjusting for these overlapping elements, ART is still associated with higher previa rates (Romundstad, 2006).

Clinical Features

Painless bleeding is the most characteristic event with placenta previa. Bleeding usually does not develop until near the end of the second trimester or later, but it can begin even before midpregnancy. And undoubtedly, some late abortions are caused by an abnormally located placenta. Bleeding from a previa usually begins without warning and without pain or contractions in a woman who has had an uneventful prenatal course. This so-called *sentinel bleed* is rarely so profuse as to prove fatal. Usually it ceases, only to recur. However, in perhaps 10 percent of women, particularly those with a placenta implanted near but not over the cervical os, there is no bleeding until labor onset. Bleeding at this time varies from slight to profuse, and it may clinically mimic placental abruption.

A specific sequence of events leads to bleeding in cases in which the placenta is located over the internal os. First, the uterine body remodels to form the lower uterine segment. With this, the internal os dilates, and some of the implanted placenta inevitably separates. Bleeding that ensues is augmented by the inherent inability of myometrial fibers in the lower uterine segment to contract and thereby constrict torn vessels. Similarly, bleeding from this lower segment implantation site also frequently continues after placental delivery. Last, there may be lacerations in the friable cervix and lower segment. These may be especially problematic following manual removal of a somewhat adhered placenta.

Morbidly adherent placentas are a frequent and serious complication associated with placenta previa. Described later (Morbidly Adherent Placenta), this abnormally firm placental attachment derives in part from poorly developed decidua that lines the lower uterine segment. Biswas and coworkers (1999) performed placental bed biopsies in 50 women with a previa and in 50 control women. Trophoblastic giant-cell infiltration of spiral arterioles—rather than endovascular trophoblast cells—was found in half of previa specimens. In contrast, only 20 percent of biopsies from normally implanted placentas had these changes. In another study of 514 cases of previa, abnormal placental attachment was identified in 7 percent (Frederiksen, 1999). As discussed, previa overlying a prior cesarean incision conveys a particularly high risk for morbidly adherent placenta.

Coagulation defects are rare complications of placenta previa, even when implantation site separation is extensive (Cunningham, 2015). Placental thromboplastin, which incites the intravascular coagulation seen with placental abruption, is presumed to readily escape through the cervical canal rather than be forced into the maternal circulation. The paucity of large myometrial veins in this area may also be protective.

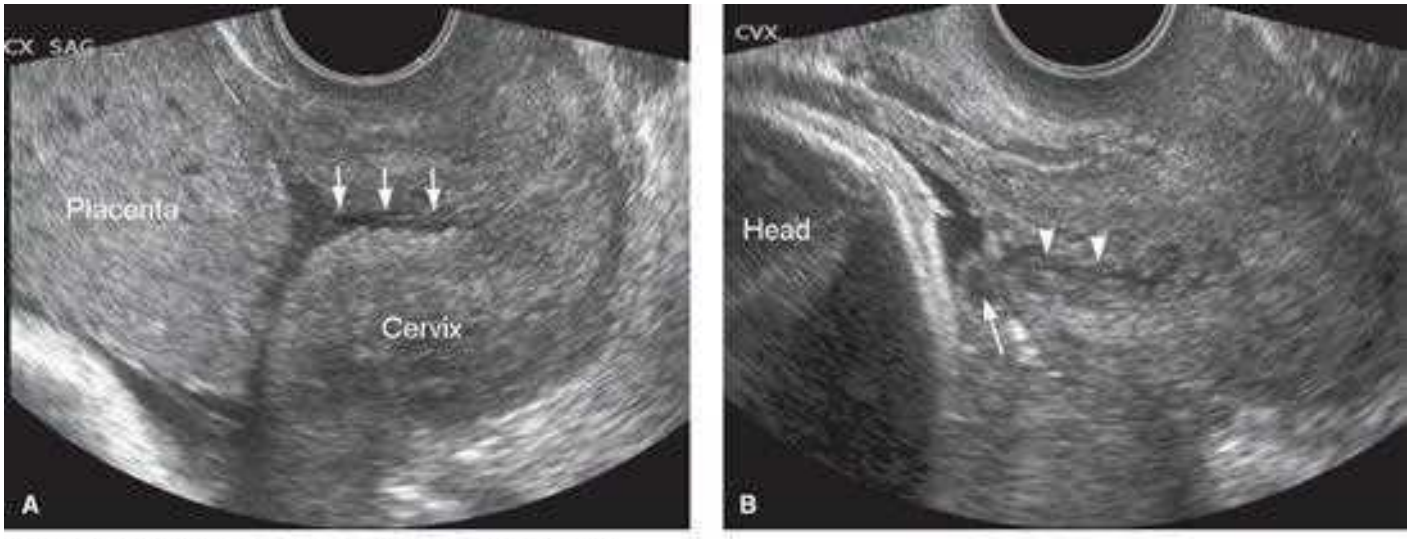
Diagnosis

Whenever there is uterine bleeding after midpregnancy, placenta previa or abruption are always considered. In the Canadian Perinatal Network study discussed earlier (Uterine Atony), placenta previa accounted for 21 percent of women admitted from 22 to 28 weeks' gestation with vaginal bleeding (Sabourin, 2012). Previa should not be excluded until sonographic evaluation has clearly proved its absence. If sonography is not readily available, diagnosis by clinical examination is done using the *double set-up* technique because it requires that a finger be passed through the cervix and the placenta palpated. A digital examination should not be performed unless delivery is planned. *A cervical digital examination is done with the woman in an operating room and with preparations for immediate cesarean delivery. Even the gentlest examination can cause torrential hemorrhage.* Fortunately, double set-up examination is rarely necessary because placental location can almost always be ascertained sonographically.

Quick and accurate localization can be accomplished using standard sonographic techniques (American Institute of Ultrasound in Medicine, 2013). This is usually done with transabdominal sonography. If the placenta clearly overlies the cervix or if it lies away from the lower uterine segment, the examination has excellent sensitivity and negative-predictive value (Olive, 2006; Quant, 2014). Obese women may have limitations of visualization of the lower uterine segment. Also, a full bladder may artificially elongate the cervix and compress the lower uterine segment to give the impression that the placenta overlies the cervix. If placental location remains in question, then transvaginal sonography is the most accurate method of assessment (Fig. 41-23). It is safe, even when there is bleeding.

FIGURE 41-23

Placenta previa. **A.** In this transvaginal image at 34 weeks' gestation, the anterior placenta completely covers the internal cervical os outlined by arrows. **B.** This transvaginal image at 34 weeks' gestation depicts a posterior placenta (*arrow*) that just reaches the level of the internal cervical os. (Reproduced with permission from Cunningham FG: Placenta previa and morbidly adherent placenta. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd edition. New York, McGraw-Hill Education, 2017b.)



Accuracy depends on the sonographic technique used. In a comprehensive study, the internal os was visualized in all cases with transvaginal sonography but in only 30 percent with transabdominal sonography (Farine, 1988). As discussed, according to the Fetal Imaging Workshop, if the placental edge is <2 cm from the internal os, but not covering it, the placenta is considered low lying (Reddy, 2014). In the absence of any other indication, sonography need not be frequently repeated simply to document placental position. At Parkland, women with a placenta previa identified at 18 to 22 weeks' gestation with a prior cesarean delivery are evaluated again at 28 weeks and those without at 32 weeks. Restriction of activity is not necessary unless a previa persists beyond 28 weeks or if clinical findings such as bleeding or contractions develop before this time. At 32 weeks' gestation, if the placental edge is still <2 cm from the os, then transvaginal sonography is repeated at 36 weeks.

Using MR imaging, several investigators have reported excellent results in visualizing placental abnormalities. That said, it is unlikely that this technique will replace sonography for routine evaluation anytime soon. However, MR imaging has proved useful for evaluation of morbidly adherent placenta (Clinical Presentation and Diagnosis).

Management

Women with a placenta previa are managed based on their individual clinical circumstances. Three prominent factors include fetal age and maturity, labor, and bleeding severity. In one study of 214 women with a previa, 43 percent had an emergency delivery, and half of these were preterm (Ruiter, 2015). But, if the fetus is immature and active bleeding subsides, close observation in an obstetrical unit is indicated. Data are sparse regarding tocolytic administration for uterine contractions. Although robust randomized trials are lacking, Bose and colleagues (2011) recommend that if tocolytics are given, they be limited to 48 hours of administration. We categorically recommend against their use in this setting.

After bleeding has ceased for approximately 2 days and the fetus is judged to be healthy, a woman can usually be discharged home with instructions for "pelvic rest." Importantly, the woman and her family must fully appreciate the possibility of recurrent bleeding and be prepared for immediate transport back to the hospital. In other cases, prolonged hospitalization may be ideal.

The frequency of emergency delivery in women with placenta previa ranges from 25 to 40 percent (Gibbins, 2018; Kassir, 2017). But, in properly selected patients, long-term inpatient care does not appear to add benefits compared with outpatient management (Neilson, 2003). In one randomized study of 53 women who had a bleeding previa at 24 to 36 weeks' gestation, maternal or fetal morbidity rates did not differ between management method (Wing, 1996). Of all study women, 60 percent had recurrent bleeding, and half eventually required expeditious cesarean delivery.

For women who are near term and who are not bleeding, plans are made for scheduled cesarean delivery. Timing balances fetal immaturity risks against antepartum hemorrhage. One NIH workshop suggested elective delivery at 36 to 37 completed weeks' gestation (Spong, 2011). The Society for Maternal-Fetal Medicine (2017) recommends delivery between 34 and 37 weeks. At Parkland Hospital, we usually perform elective cesarean delivery at 38 weeks. With a suspected morbidly adherent placenta, delivery is recommended at 34 to 35 completed weeks by the NIH workshop (Management). Our practice is to schedule delivery at 36 completed weeks.

Delivery

Practically all women with placenta previa undergo cesarean delivery. Many surgeons recommend a vertical laparotomy incision to provide rapid entry in cases with torrential bleeding or operating space if hysterectomy is required. As discussed, cesarean delivery is emergently performed in more than half because of hemorrhage, for which about a fourth require blood transfusion (Boyle, 2009; Sabourin, 2012). Although a low transverse hysterotomy is usually possible, this may cause fetal bleeding if the placenta is implanted anteriorly and the placenta is incised. In such cases, fetal delivery should be expeditious (Silver, 2015a). A vertical uterine incision may be preferable in some instances. In either case, even when the incision extends through the placenta, maternal or fetal outcomes are rarely compromised.

Following placental removal, the placenta site may bleed uncontrollably due to poorly contracted smooth muscle, which is characteristic of the lower uterine segment. If hemostasis at the placental implantation site cannot be obtained by adequate uterotonic administration and pressure, it can be oversewn with 0-chromic sutures. Cho and associates (1991) described interrupted 0-chromic sutures at 1-cm intervals to form a circle around the bleeding portion of the lower segment to control hemorrhage. Others have reported success with compression sutures that traversed and compressed the anterior and posterior uterine wall (Kayem, 2011; Penotti, 2012).

Of other methods, Bakri or Foley balloon tamponade used alone or coupled with compression sutures has been described (Albayrak, 2011; Diemert, 2012; Kumru, 2013). Law and coworkers (2010) successfully used a hemostatic gel. Other surgical options are bilateral uterine or internal iliac artery ligation, illustrated later (Adjunctive Surgical Procedures). Finally, pelvic artery embolization has also gained acceptance.

Hysterectomy

If these more conservative methods fail and bleeding is brisk, hysterectomy is necessary. Placenta previa—especially with an abnormally adherent placenta—currently is the most frequent indication for peripartum hysterectomy at Parkland Hospital and other institutions (Jakobsson, 2015; Wong, 2011). When there is no associated accrete syndrome, the reported incidence of hysterectomy is 2 percent (Gibbins, 2018).

Thus, it is not possible to accurately estimate the effect on the hysterectomy rate from previa alone without considering the associated accrete syndromes. *Again, for women whose placenta previa is implanted anteriorly at the site of a prior uterine incision, the likelihood of an associated morbidly adherent placenta and need for hysterectomy is increased.* In a study of 318 peripartum hysterectomies performed in the United Kingdom, 40 percent were done for abnormal placentation (Knight, 2007). Similar results were reported for 211 hysterectomies from the Nordic Obstetric Surveillance Study (Jakobsson, 2015). At Parkland Hospital, 44 percent of cesarean hysterectomies were done for bleeding placenta previa or for a morbidly adherent placenta (Wortman, 2015). The technique for peripartum hysterectomy is described in Chapter 30 (Peripartum Hysterectomy).

Maternal and Perinatal Outcomes

Placenta previa and coexistent accrete syndromes both contribute substantively to maternal morbidity and mortality rates. The maternal mortality ratio is increased approximately threefold for women with a placenta previa (Gibbins, 2018; Oyelese, 2006). In another report of 5367 maternal deaths in the United States from 2006 to 2013, placenta previa alone accounted for nearly 3 percent of deaths from hemorrhage (Creanga, 2015, 2017).

The report from the Consortium on Safe Labor emphasizes the ongoing perinatal morbidity with placenta previa (Lai, 2012). Preterm delivery continues to be a major cause of perinatal death (Nørgaard, 2012). In deliveries with placenta previa in the United States in 1997, the neonatal mortality rate was threefold higher than that in unaffected pregnancies and stemmed primarily from preterm delivery (Salihu, 2003). Ananth and colleagues (2003) reported a comparably elevated risk of neonatal death even for fetuses who delivered at term. This is at least partially related to the fetal anomaly rate, which is two- to threefold higher in pregnancies with placenta previa (Crane, 1999).

The association of fetal-growth restriction with placenta previa is likely minimal after controlling for gestational age. In a population-based cohort of more than 500,000 singleton births, Ananth and associates (2001) found that most low-birthweight newborns associated with placenta previa resulted from preterm birth. Harper and coworkers (2010) reported similar findings from a cohort of nearly 58,000 women. In contrast, at least two studies reported a greater risk for fetal-growth restriction (Räisänen, 2014; Weiner, 2016).

MORBIDLY ADHERENT PLACENTA

Etiopathogenesis

The term *morbidly adherent placenta* describes aberrant placentation characterized by abnormally implanted, invasive, or adhered placenta. We also refer to these disorders collectively as *accrete syndromes* and use these terms interchangeably. Derivation of accrete comes from the Latin *ac-* + *crescere*—to adhere or become attached to (Benirschke, 2012).

In the accrete syndromes, abnormal placental adherence to the myometrium stems in part from partial or total absence of the decidua basalis and imperfect development of the fibrinoid or Nitabuch layer, described in Chapter 5 (Decidual Histology). If the decidual spongy layer is lacking either partially or totally, then the physiological line of cleavage is absent, and some or all cotyledons are densely anchored. Microscopically, placental villi attach to smooth muscle fibers rather than to decidual cells. This decidual deficiency then prevents normal placental separation after delivery. The surface area of the implantation site involved and the depth of trophoblastic tissue ingrowth are variable between women, but all affected placentas can potentially cause significant hemorrhage.

Substantiated data now suggest that accrete syndromes are not solely caused by this anatomical layer deficiency (Duzyj, 2017; Tantbirojn, 2008). Indeed, the cytotrophoblasts may control decidual invasion through factors such as angiogenesis (Duzyj, 2015; Goh, 2016; Wehrum, 2011). Also, accrete syndrome tissue specimens show “hyperinvasiveness” (Pri-Paz, 2012). Myometrial fibers attached to the basal plate in an antecedent pregnancy are predictive markers for a subsequent placenta accreta (Linn, 2015; Miller, 2016). This implies an antecedent “constitutional endometrial defect” in most cases. The greater risk conveyed by previous surgical uterine trauma may be partially explained by an enhanced vulnerability to trophoblast invasion (Garmi, 2012; Gill, 2015; Jauniaux, 2017).

This association with prior trauma is reinforced by the close relationship between *cesarean-scar pregnancy (CSP)* and later development of placenta accreta in the same pregnancy. Indeed, accruing evidence suggests that CSP and accrete syndromes lie on a spectrum and that CSP is a precursor, as both share the same histopathology (Happe, 2018; Timor-Tritsch, 2014). CSP frequency has been reported to approximate 1 in 2000 pregnancies (Berhie, 2015; Rotas, 2006). Described in Chapter 19 (Cesarean Scar Pregnancy), early rupture and hemorrhage are not uncommon with CSP, and women often elect pregnancy-terminating interventions to avoid these (Michaels, 2015; Timor-Tritsch, 2015).

Classification

Variants of the morbidly adherent placenta are classified by the depth of trophoblastic growth (Figs. 41-24 and 41-25). *Placenta accreta* indicates that villi are attached to the myometrium. With *placenta increta*, villi actually invade the myometrium, and *placenta percreta* defines villi that penetrate through the myometrium and to or through the serosa (Bailit, 2015; Silver, 2015a). In clinical practice, these three variants are encountered in an approximate ratio of 80:15:5, respectively (Wong, 2008). In all three varieties, abnormal adherence may involve all lobules—*total placenta accreta*. If all or part of a single lobule is abnormally attached, it is described as a *focal placenta accreta*. Histological diagnosis cannot be made from the placenta alone, and myometrial samples are necessary for confirmation (Benirschke, 2012).

FIGURE 41-24
Morbidly adherent placentas: **A.** Placenta accreta. **B.** Placenta increta. **C.** Placenta percreta.

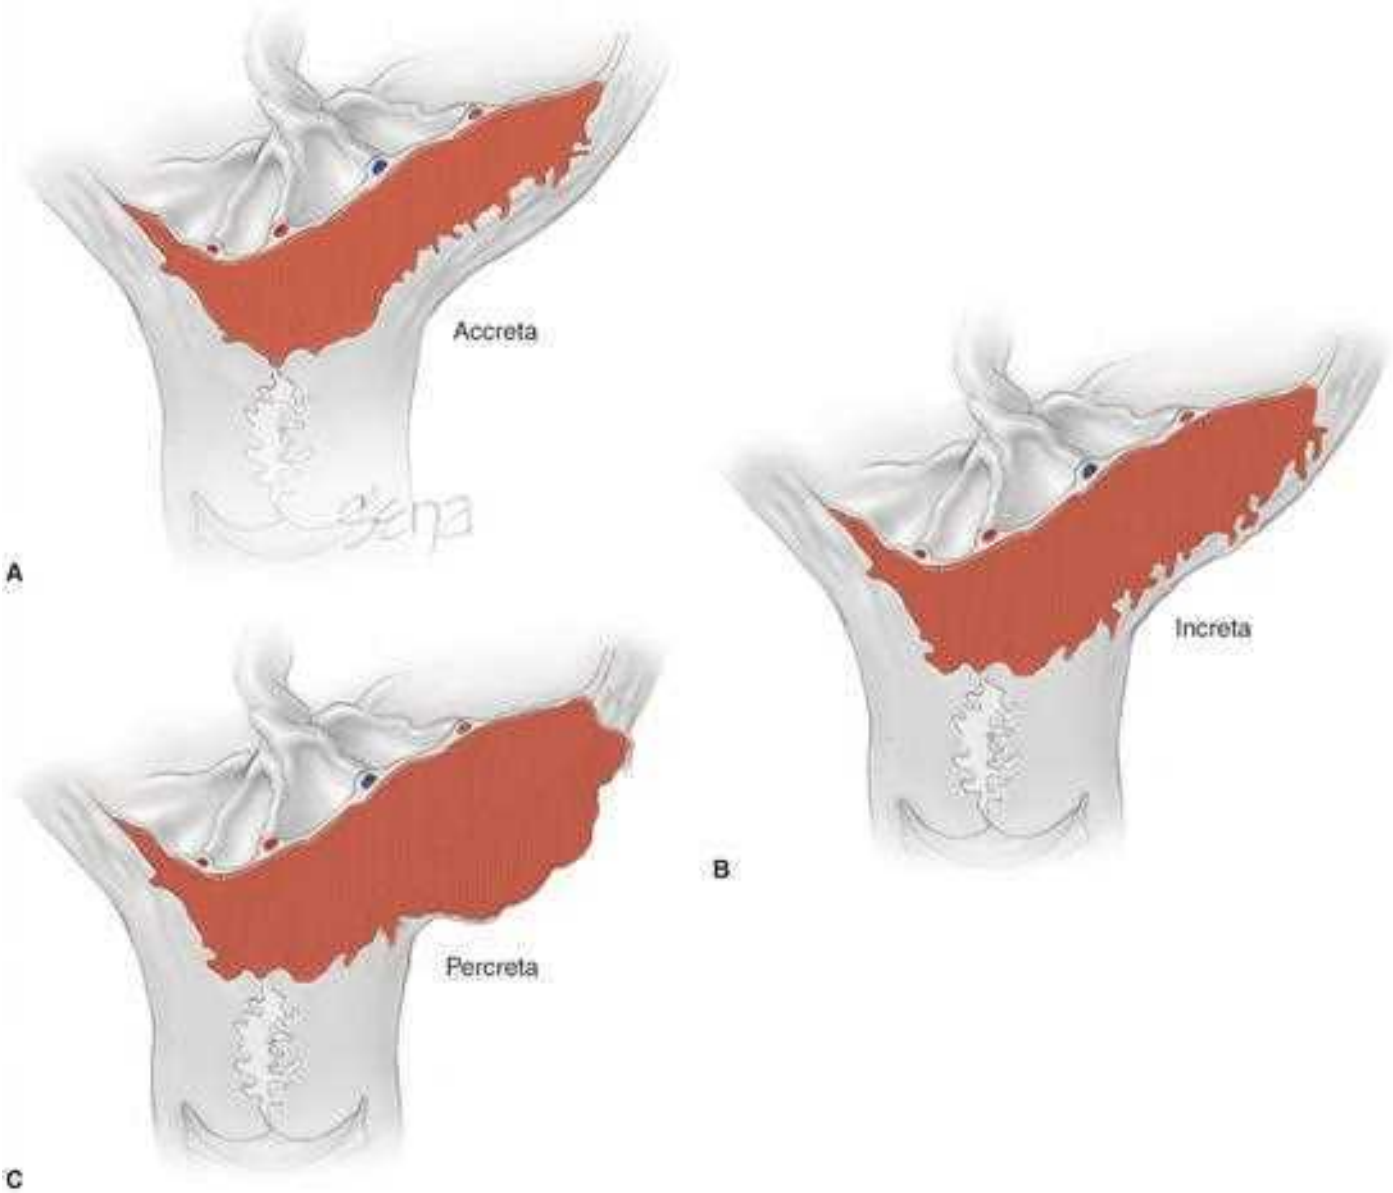


FIGURE 41-25

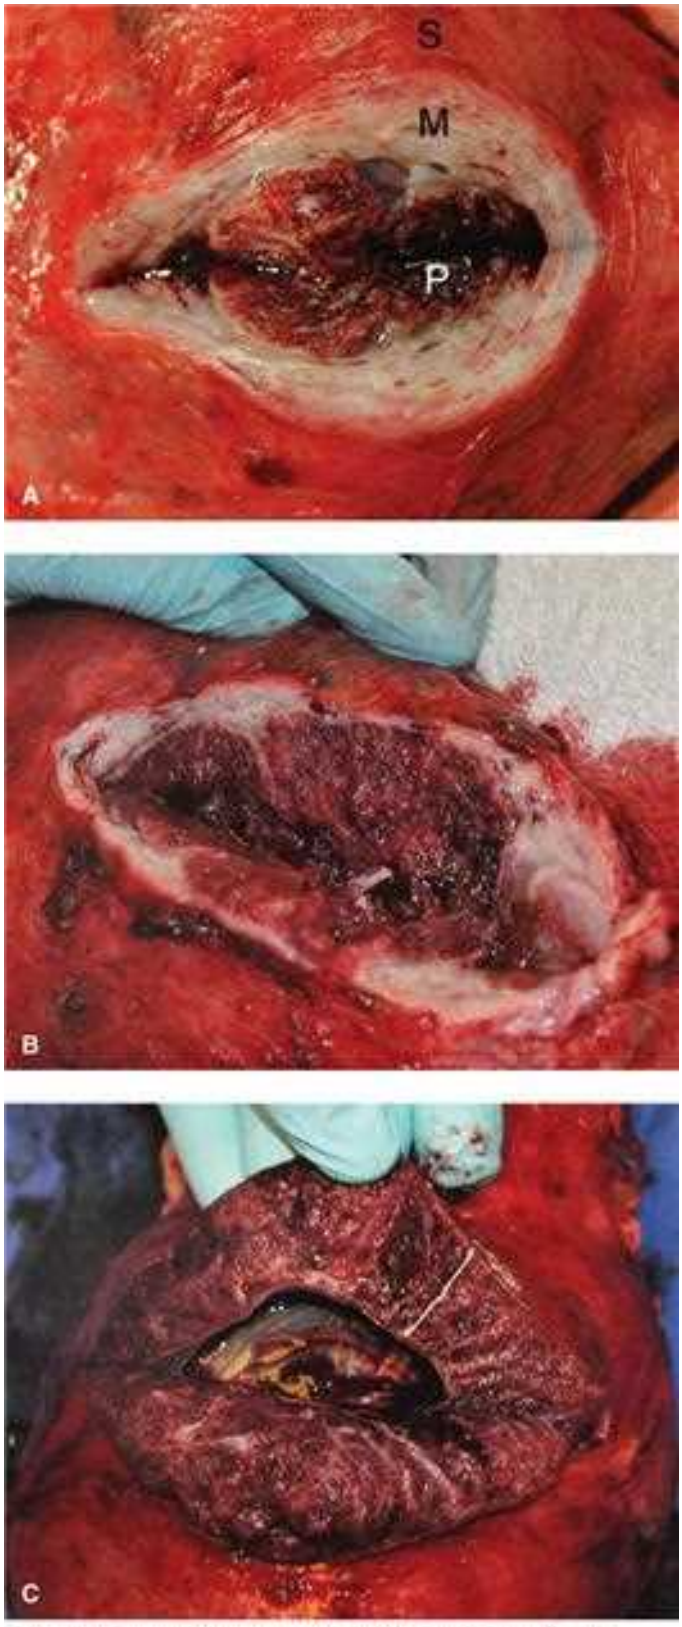
Varying degrees of myometrial invasion with the accrete syndromes. Incisions begin on the serosal surface and extend through to the placenta. **A.** In this case, the myometrium (*M*) shows minimal invasion by the placenta (*P*). S = uterine serosa. **B.** A greater degree of myometrial invasion is seen here. **C.** In this example, the placenta (*brackets*) extends to the serosal edge, held by the surgeon's hand. No myometrium remains at this site. (Reproduced with permission from Dr. C. Edward Wells in Cunningham FG: Placenta previa and morbidly adherent placenta. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd edition. New York, McGraw-Hill Education, 2017b.)



Incidence

The frequency of accrete syndromes was 1 in 20,000 births almost 100 years ago (McKeogh, 1951). As late as 1971, Hellman and Pritchard in the 14th edition of *Williams Obstetrics* described accreta to be the subject of case reports. Since then, the incidence has grown remarkably in direct relationship to the rising cesarean delivery rate. For example, incidence was 1 in 2500 births in the 1980s, but it was 1 per 731 births in the report from the MFMU Network comprising 115,502 women (Bailit, 2015). And a Canadian study of more than 570,000 births found an incidence of 1 in 700 deliveries (Mehrabadi, 2015). In the Nationwide Inpatient Sample, the prevalence of accreta was 3.7 per 1000 births—1 per 270 (Mogos, 2016).

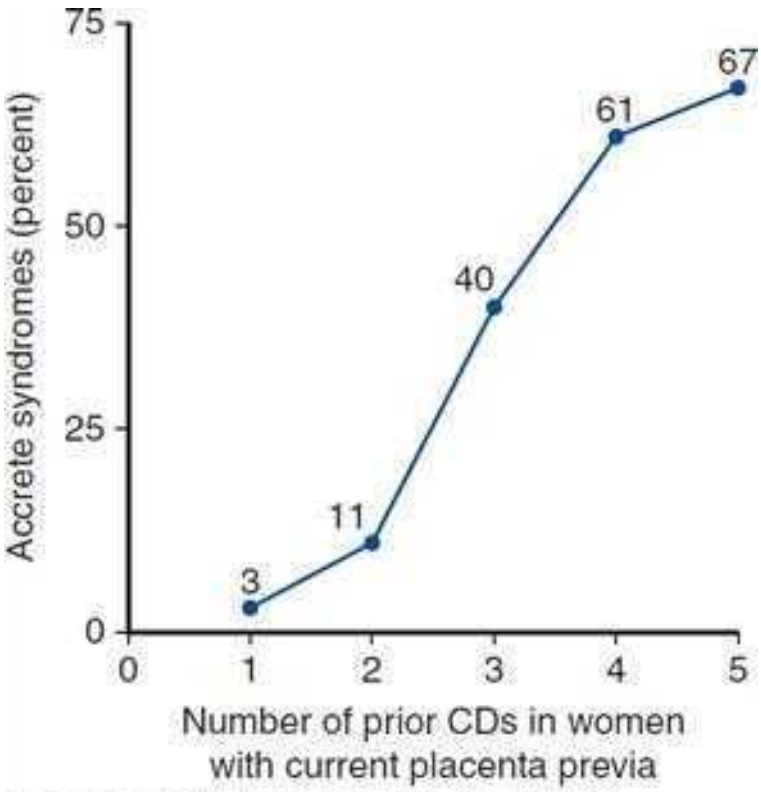
This rising frequency has made accrete syndromes one of the most formidable problems in obstetrics. In one review of 5367 pregnancy-related maternal deaths in the United States from 2006 to 2013, 13 percent were due to hemorrhage caused by accrete syndromes (Creanga, 2015, 2017). In addition, they are a leading cause of hemorrhage and emergency peripartum hysterectomy (Awan, 2011; Eller, 2011; Rossi, 2010). The American College of Obstetricians and Gynecologists (2017c) and the Society for Maternal-Fetal Medicine (2010) have taken the lead to address and optimize management.

In subsequent pregnancies following placenta accreta, recurrence risks are high. Women in whom hysterectomy is avoided have an estimated 20-percent incidence of recurrence (Cunningham, 2016; Roeca, 2017). In addition, some evidence shows that these women have greater risks for previa, uterine rupture, and hysterectomy (Eshkoli, 2013).

Risk Factors

These are similar in many aspects to those for placenta previa (Classification). That said, the two most important risk factors are an associated previa, a prior cesarean delivery, and more likely a combination of the two (Klar, 2014). A classical hysterotomy incision has a higher risk for a subsequent accrete placenta (Gyamfi-Bannerman, 2012). In fact, almost half of women with a prior cesarean delivery had myometrial fibers seen microscopically adhered to the placenta (Hardardottir, 1996; Miller, 2016). An associated previa confers an even higher risk. This is shown in Figure 41-26, and the astonishing increase in frequency of associated accrete syndromes is apparent with a concomitant previa.

FIGURE 41-26
Frequency of morbidly adherent placenta in women with 1 to 5 prior cesarean deliveries (CDs) now with a previa. (Data from Silver, 2006.)



Dysfunctional decidual formation also may follow any other type of myometrial trauma such as curettage or endometrial ablation (Benirschke, 2012; Gill, 2015). Even without a prior hysterotomy, coexisting placenta previa is additive to frequency, and in one study, 10 percent of such women with a previa had an associated accrete syndrome. A shorter cervical length with placenta accrete syndromes did not confer a greater risk for preterm delivery (Rac, 2017).

Another risk marker became apparent with widespread use of MSAFP and human chorionic gonadotropin (hCG) screening for neural-tube defects and aneuploidies. In one study of more than 9300 women screened at 14 to 22 weeks' gestation, the risk for accrete syndromes was eightfold higher with MSAFP levels >2.5 MoM, and it was increased fourfold with maternal serum free β-hCG levels >2.5 MoM (Hung, 1999).

Clinical Presentation and Diagnosis

In cases of first- and second-trimester accrete syndromes, there is usually hemorrhage that is the consequence of coexisting placenta previa. Such bleeding will typically prompt evaluation and management. In some women who do not have an associated previa, accreta may not be identified until third-stage labor when an adhered placenta is encountered. Unfortunately, imaging modalities are less than perfect to identify all of these placentas early.

Ideally, sonography is used for antepartum identification of abnormal placental ingrowth (Chantraine, 2013; Jauniaux, 2016; Reddy, 2014; Tam Tam, 2012). Happe and colleagues (2018) found that first-trimester measurement of the smallest myometrial thickness can be used to predict the necessity for peripartum hysterectomy with an accrete syndrome. Other findings include loss of the normal hypoechoic retroplacental zone between the placenta and uterus, placental vascular lacunae,

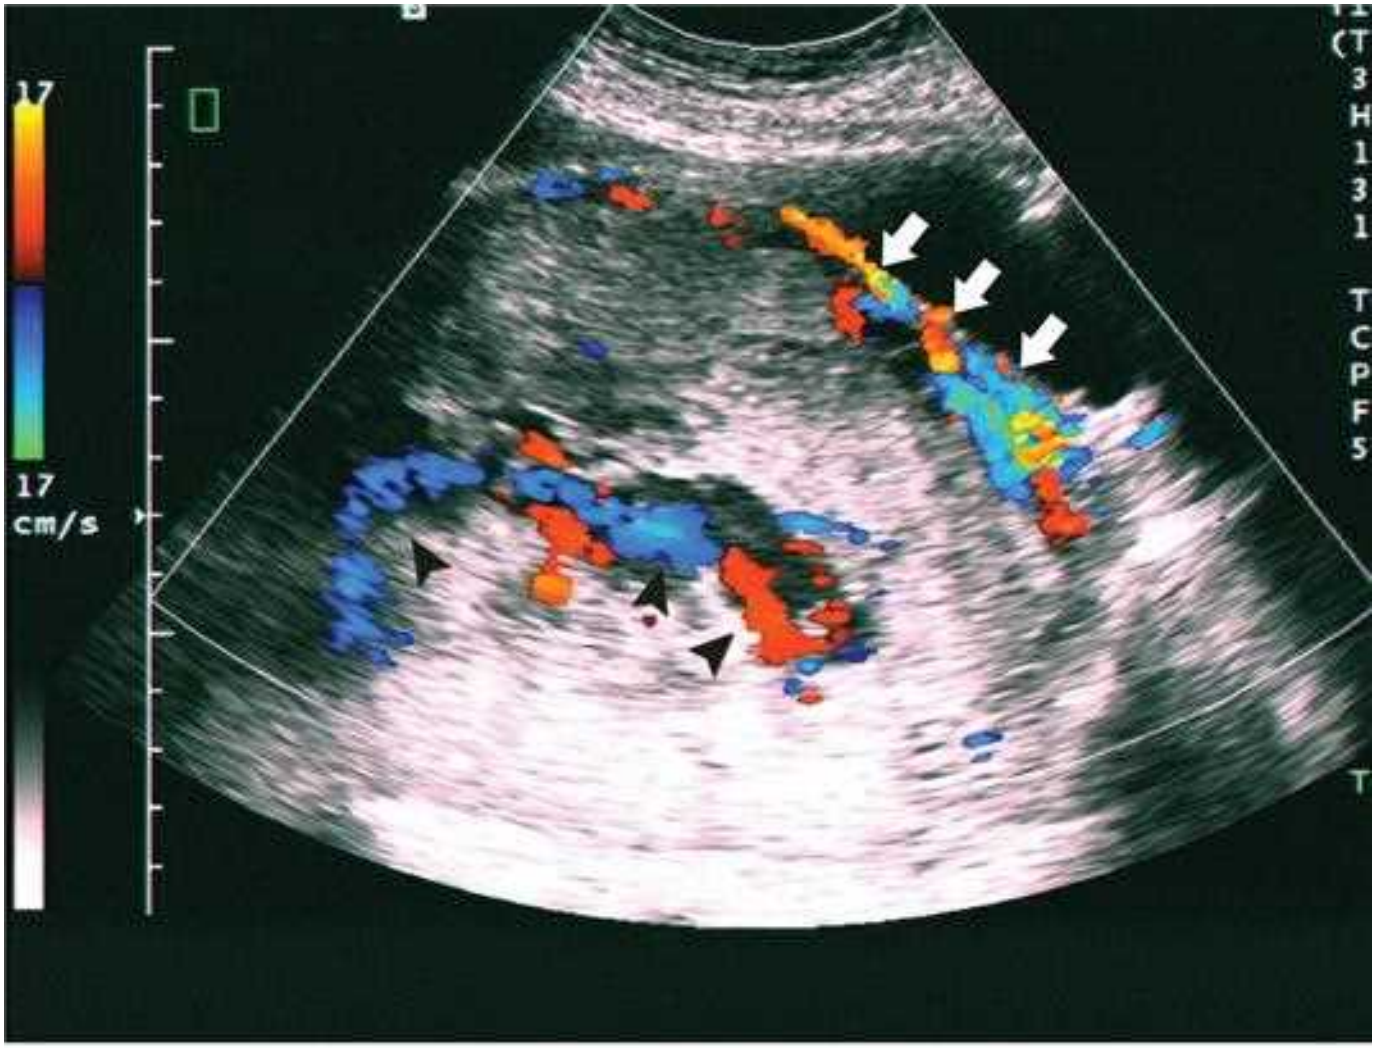
and placental bulging into the posterior bladder wall (Fig. 41-27). Using these criteria, Warshak and associates (2006) calculated the following values: sensitivity of 77 percent; specificity of 96 percent; positive-predictive value of 98 percent. Similar values are cited by the American College of Obstetricians and Gynecologists (2017c) and others (Chalubinski, 2013; Elhawary, 2013; Maher, 2013).

FIGURE 41-27
Transabdominal sonogram of placental percreta shows multiple and massive placental "lakes" or "lacunae". (Reproduced with permission from Dr. Martha Rac in Cunningham FG: Placenta previa and morbidly adherent placenta. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd edition. New York, McGraw-Hill Education, 2017b.)

Despite these findings, some investigators report less spectacular results with sonography (Jauniaux, 2016; Primo, 2014). Bowman and colleagues (2014) described the sensitivity of sonography to be 54 percent; specificity, 88 percent; positive-predictive value, 82 percent; negative-predictive value, 65 percent; and accuracy, 65 percent. Location affects sonographic accuracy. In one study, the detection rate was 90 percent for anterior placenta accreta compared with 50 percent for posterior wall ones (Pilloni, 2016). Nageotte (2014) concluded that identification of the morbidly adherent placenta with sonography should be interpreted along with clinical and operative findings.

Better results have been reported by some using three-dimensional (3-D) sonography and power Doppler (Collins, 2015; Doyle, 2015). We too have found that the addition of Doppler color flow mapping is highly predictive of myometrial invasion (Fig. 41-28). This is suspected if the distance between the uterine serosa–bladder wall interface and the retroplacental vessels measures <1 mm and if there are large intraplacental lacunae (Rac, 2015a; Twickler, 2000). Similarly, Cali and associates (2013) reported that hypervascularity of the uterine serosa–bladder wall interface had the highest positive- and negative-predictive values for placenta percreta.

FIGURE 41-28
Transvaginal sonogram of placental invasion with a morbidly adherent placenta. Retroplacental vessels (*white arrows*) invade the myometrium and obscure the bladder–serosal interface. Abnormal intraplacental venous lakes (*black arrowheads*) are commonly seen in this setting.



MR imaging can be added to outline anatomy and to identify invasion of adjacent structures, including possible ureteral involvement (Chalubinski, 2013; Reddy, 2014). Although gadolinium is usually not added during pregnancy, this contrast may enhance images (Millischer, 2017). Lax and coworkers (2007) described three MR imaging findings that suggest accreta: uterine bulging, heterogeneous signal intensity within the placenta indicative of lacunae, and dark intraplacental bands on T2-weighted imaging. Some recommend use of MR imaging if sonography results are inconclusive or there is a posterior previa (American College of Obstetricians and Gynecologists, 2017c; Silver, 2015a).

Management

Preoperative assessment ideally begins once a possible accrete syndrome is recognized antenatally (Fitzpatrick, 2014; Sentilhes, 2013). *A major decision concerns the timing of and the ideal facility for delivery.* Considerations include appropriate surgical, anesthesia, intensive care, and blood banking capabilities. An obstetrical surgeon or gynecological oncologist and surgical, urological, and interventional radiological consultants should be available (Brennan, 2015; Shamshirsaz, 2015). The American College of Obstetricians and Gynecologists (2017c) and the Society for Maternal-Fetal Medicine (2010) recommend planned delivery in a tertiary-care facility. In some of these, specially designed teams have been assembled and are on call (Al-Khan, 2014; Erfani, 2017a; Smulian, 2017; Walker, 2013).

Silver and colleagues (2015b) have provided criteria for accreta centers of excellence. Shown in Table 41-5 are some criteria to consider transfer to a higher level-of-care facility. Women who refuse blood or its derivatives pose especially difficult management dilemmas (Barth, 2011). If possible, delivery is best scheduled for peak availability of all resources and team members. Even so, a third of cases require unscheduled delivery, and contingency plans should be ready (Pettit, 2017).

TABLE 41-5

Criteria for Consideration of Delivery in an Accrete Center of Excellence

Suspicion for morbidly adherent placenta on sonogram
Placenta previa with abnormal ultrasound appearance
Placenta previa with ≥3 prior cesarean deliveries
Prior classical cesarean delivery and anterior placentation
Prior endometrial ablation or pelvic irradiation
Inability to adequately evaluate or exclude placenta accreta
Any other reason to suspect morbidly adherent placenta

Reproduced with permission from Silver, 2015b.

Timing of Delivery

Timing balances fetal immaturity risks against serious adverse maternal consequences of emergency cesarean delivery (Stephenson, 2016). The American College of Obstetricians and Gynecologists (2017c) recommends individualization of delivery timing. It cites a decision-analysis study that justifies elective delivery without fetal lung maturity testing after 34 completed weeks (Robinson, 2010). The Society for Maternal-Fetal Medicine (2017) recommends delivery between 34 and 37 weeks. Two recent surveys found that most practitioners do not deliver these women until 36 weeks or later (Esakoff, 2012; Wright, 2013). At Parkland Hospital, we generally schedule these procedures after 36 completed weeks but are prepared also to manage them in nonelective situations (Rac, 2015b). Perlman and colleagues (2017) recommend individualization based on specific risk criteria.

In some cases, placenta accrete syndrome is not recognized until laparotomy. If there are inadequate resources to surgically manage the percreta, and if the woman is stable and not bleeding, then the fetus is not delivered, the abdominal incision is closed, and she is transferred to a tertiary-care facility.

Preoperative Prophylactic Catheterization

In cases that may involve one or both ureters, catheterization may aid in dissection or identification and repair of injury. Some, but not all, advocate preoperative ureteral catheterization (Eller, 2011; Society for Maternal-Fetal Medicine, 2010; Tam Tam, 2012).

Balloon-tipped intraarterial catheters to mitigate blood loss and thereby enhance surgical visibility have also gained supporters. Catheters are advanced preoperatively into the internal iliac arteries, and then after delivery, they are inflated to occlude pelvic blood flow (Ballas, 2012; Desai, 2012). Alternatively, the catheters can be used to deliver occluding emboli to bleeding arterial sites. Others have concluded that these procedures offer borderline efficacy and have serious risks (Salim, 2015; Sentilhes, 2009). Complications have included thromboses of the common and left iliac arteries (Bishop, 2011). At this time, the American College of Obstetricians and Gynecologists (2017c) concludes that a firm recommendation cannot be made for or against intraarterial catheter use. Similarly, there are no obvious benefits to internal artery ligation (Eller, 2011; Po, 2012).

Cesarean Delivery and Hysterectomy

Before commencing with delivery, the risk of hysterectomy to prevent exsanguination should be estimated. Some of these abnormal placentations, especially if partial, may be amenable to placental delivery with hemostatic suture placement. Confirmation of a percreta or increta almost always mandates hysterectomy. Because the scope of invasion may not be apparent before delivery of the fetus, we complete many dissection steps early. This also minimizes blood loss during potentially tedious dissection after hysterotomy. Thus, we usually attempt to create a wide bladder flap *before* making the hysterotomy incision (Cunningham, 2017b). The round ligaments are divided, and the lateral edges of the peritoneal reflection are dissected downward. If possible, these incisions are extended to encircle the entire placental implantation site that visibly occupies the prevesical space and posterior bladder wall. Following this, a classical hysterotomy or transverse fundal incision is made to avoid the placenta (Kotsuji, 2013).

After fetal delivery, the extent of placental invasion is assessed without attempts at manual placental removal. In a report from the United Kingdom, attempts for partial or total placental removal prior to hysterectomy were associated with twice as much blood loss (Fitzpatrick, 2014). Generally speaking, with obvious percreta or increta, hysterectomy is usually the best course, and the placenta is left in situ (Eller, 2011). With more extensive placental ingrowth, there may be little or no bleeding until manual placental removal is attempted. Unless there is spontaneous separation with bleeding that mandates emergency hysterectomy, the operation begins after full assessment is made. With bleeding, successful treatment depends on immediate blood replacement therapy and other measures that can include uterine or internal iliac artery ligation, balloon occlusion, or embolization.

The group at Baylor College of Medicine has described a modified radical hysterectomy for surgical management of the morbidly adherent placenta (Shamshirsaz, 2015). For a description of this technique, refer to *Cunningham and Gilstrap's Operative Obstetrics* (Yeomans, 2017). At Parkland Hospital, we have had cases in which

a traditional radical hysterectomy was necessary to excise all abnormally implanted placenta.

Conservative Management

Occasionally, it may be possible to trim the umbilical cord, repair the hysterotomy incision, leave the placenta in situ, and not pursue hysterectomy. This option may be used for women in whom abnormal placentation was not suspected before cesarean delivery and in whom uterine closure stops bleeding. After this, she can be transferred to a higher-level facility for definitive management. Another consideration is the woman with a strong desire for fertility and who has received extensive counseling.

Conservative management was reviewed by Perez-Delboy (2014) and Fox (2015) and their colleagues. In some of these cases, the placenta spontaneously resorbed between 1 and 12 months with a mean of 6 months. Numerous complications can occur and include sepsis, disseminated intravascular coagulation, pulmonary embolism, and arteriovenous malformation (Fox, 2015; Judy, 2015; Roach, 2015).

In some of these women, a subsequent hysterectomy—either planned or prompted by bleeding or infection—is performed days to weeks postpartum when blood loss might be lessened (Al-Khan, 2014; Sentilhes, 2009). In one study, only 21 percent of such women ultimately required hysterectomy (Bretelle, 2007). In other reports, however, up to 60 percent eventually required emergency hysterectomy (Clausen, 2013; Pather, 2014). Evidence that treatment with methotrexate aids resorption is lacking. Last, for women in whom the placenta is left in situ, serial serum β-hCG measurements are not informative, and serial sonographic or MR imaging is recommended (Timmermans, 2007; Worley, 2008).

At this time, we agree with the American College of Obstetricians and Gynecologists (2017c) that leaving the placenta in situ is seldom indicated. Exceptions are for temporization to permit transfer to a higher level of care.

Pregnancy Outcomes

In sum, these syndromes can have disastrous outcomes for both mother and fetus. Although the depth of placental invasion does not correspond with perinatal outcome, it is of paramount maternal significance (Seet, 2012). Shown in Table 41-6 are outcomes from reports of women from tertiary-care hospitals and in whom the diagnosis of morbidly adherent placenta was made preoperatively. Despite these advantages, a litany of complications included hemorrhage, urinary tract injury, intensive care unit admission, and secondary surgical procedures. Some of these reports chronicle outcomes in a second cohort of women in whom care was not given at a tertiary-care facility or in whom the diagnosis of percreta was not made until delivery, or both. In these cohorts, morbidity was higher, and there was one maternal death.

TABLE 41-6

Selected Maternal Outcomes in Women with a Morbidly Adherent Placenta Identified Prenatally and Delivered in Tertiary-Care Units

Outcome[a]	San Diego[b] n = 62	Utah[c] n = 60	Toronto[d] n = 33	New Jersey[e] n = 42	Houston[f] n = 107
Gestational age (wk)	33.9 ± 1.1	34 (17–41)	~32 (19–39)	~34.6 (25–40)	~33 (29–35)
Operating time (min)	194 ±1.6	NS	107 (68–334)	NS	287 (74–608)
Transfusions	~75%	70%	NS	NS	~65%
RBC (units)	4.7 ± 2.2	≥4 (30%)	3.5 (0–20)	0–11	3 (0–6)
FFP (units)	4.1 ± 2.3	NS	NS	0–6	1 (0–2.5)
Surgical outcomes					
Bladder injury	23%	37%	30%	17%	35%
Ureteral injury	8%	7%	0	NS	2%
Postoperative					
ICU admission	72%	30%	15%	21%	100%
LOS (days)	7.4 ± 1.8	3–13	2–13	4–13	2–12

OBSTETRICAL COAGULOPATHIES

The terms *consumptive coagulopathy, defibrination syndrome,* or *disseminated intravascular coagulation (DIC)* are often used interchangeably, but there is an important distinction in these terms. An event related to actual consumption of procoagulants within the intravascular tree results in a *consumptive* coagulopathy. In contrast, massive loss of procoagulants from hemorrhage results in a *dilutional* coagulopathy. Semantics aside, the clinicopathological coagulation disturbances with consumptive coagulopathy culminate in a systemic intravascular activation that completely disrupts natural hemostasis. As a result, an ineffective balance of natural anticoagulant mechanisms leads to widespread fibrin deposition that can cause multiorgan failure (Levi, 2013).

Disseminated Intravascular Coagulation in Pregnancy

Because of the many definitions and variable severity, citing an accurate incidence for consumptive coagulopathy in pregnant women is problematic, but it ranges from 0.03 to 0.35 percent (Erez, 2014; Rattray, 2012). For example, some degree of significant coagulopathy is found in virtually all cases of placental abruption and amnionic fluid embolism. Other instances in which frequently occurring but less recognized degrees of coagulation activation can be found include sepsis, thrombotic microangiopathies, acute kidney injury, acute fatty liver, severe preeclampsia, and hemolysis, elevated liver enzyme levels, low platelet count (HELLP) syndrome (Cunningham, 2015). The overall contribution of each of these obstetrical disorders also varies depending on the population studied (Erez, 2015).

When consumptive coagulopathy is severe, the likelihood of maternal and perinatal morbidity and mortality is increased. In one study of 49 cases, antecedent causes included those listed above, and 59 percent received blood transfusions, 18 percent underwent hysterectomy, 6 percent were dialyzed, and three mothers died (Rattray, 2012). The perinatal mortality rate was 30 percent. Callaghan and associates (2012) reviewed data from the Nationwide Inpatient Sample and found a rising prevalence of DIC from 1998 to 2009. And, from 2010 to 2011, DIC was the second most common severe maternal morbidity indicator (Creanga, 2014). Notably, DIC

was associated with nearly a fourth of maternal deaths during this study period. Despite these statistics, consumptive coagulopathy as the sole cause of maternal death is relatively uncommon and accounts for only 0.2 percent of pregnancy-related deaths in the United States (Creanga, 2015).

Pregnancy-Induced Coagulation Changes

During normal pregnancy, extensive changes in coagulation and fibrinolysis develop to create a procoagulant state. Some of these include appreciable increases in the plasma concentrations of factors I (fibrinogen), VII, VIII, IX, and X. A partial list of these normal values is found in the Appendix (Serum and Blood Constituents). At the same time, plasminogen levels rise considerably, but levels of plasminogen activator inhibitor-1 and 2 (PAI-1 and PAI-2) also grow. Thus, *plasmin activity* usually declines until after delivery (Hale, 2012; Hui, 2012). The mean platelet count drops by 10 percent during pregnancy, and platelet activation is enhanced (Kenny, 2015).

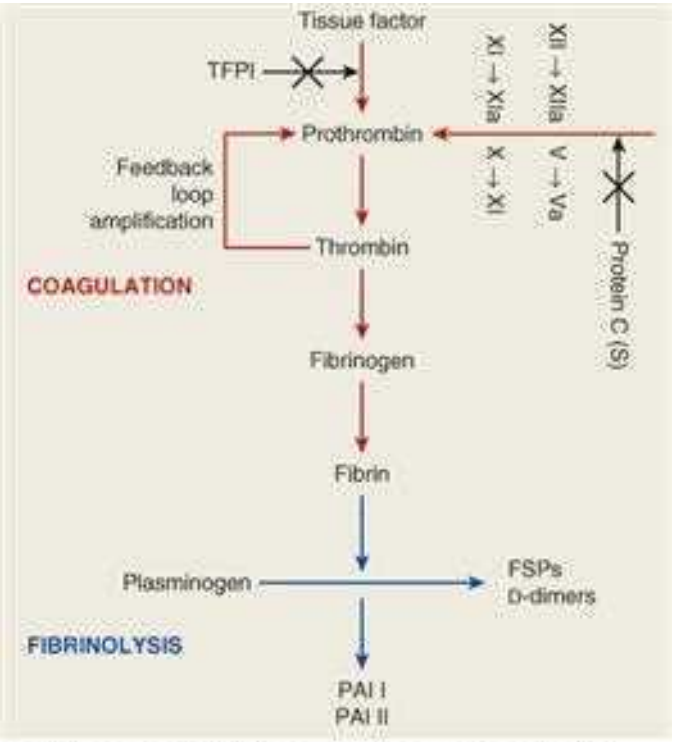
The net results of these changes include greater levels of fibrinopeptide A, β-thromboglobulin, platelet factor 4, and fibrinogen-fibrin degradation products, which includes d-dimers. Along with lower concentrations of anticoagulant protein S, hypercoagulability, and decreased fibrinolysis, there is augmented—yet compensated—intravascular coagulation that may function to maintain the uteroplacental interface.

Activation of Normal Coagulation

Instead of the "waterfall" sequential activation of clotting, a current theory proposes that tissue factor—an integral membrane glycoprotein—serves as the principal initiator of coagulation (Levi, 2010b). Coagulation then moves forward but incorporates a feedback loop. To begin, tissue factor forms complexes with factor VII/VIIa to activate factors IX and X. Tissue factor is found in highly vascularized organs such as the brain, lungs, and placenta; in amnionic fluid; and in certain other cell types (Kuczyński, 2002; Østerud, 2006; Uszyński, 2001).

Tissue factor-factor VIIa complexes ultimately generate activated factor X (Xa) to initiate clotting. Subsequently, the previously labeled "intrinsic" pathway amplifies this process. Specifically, the initial thrombin produced directly activates factor XI by providing a feedback amplification loop. This primary role of tissue factor–factor VIIa complex in coagulation and consequent amplification loop of thrombin is depicted in Figure 41-29 (Rapaport, 1995). The end result of this amplified coagulation process is fibrin formation. This is then counterbalanced by the fibrinolytic system, in which plasminogen is activated. As shown in Figure 41-29, even this process is tied initially to tissue factor. The final result is production of fibrinogen/fibrin degradation products, which include d-dimers.

FIGURE 41-29
Schematic of coagulation pathway. FSP = fibrin split products; PAI = plasminogen activator inhibitor; TFPI = tissue factor pathway inhibitor.



Activation of Pathological Coagulation

The initiation of DIC begins with the release of tissue factor by pathological entities. Tissue factor is released by subendothelial tissue and stimulated monocytes, which in turn provoke release of cytokines from the endothelium. With generalized endothelial activation, diffuse activation of coagulation follows. This pathological cycle of coagulation and fibrinolysis becomes clinically important when coagulation factors and platelets are sufficiently depleted to create consumptive coagulopathy.

Several obstetrical syndromes can trigger consumptive coagulopathy. The best known and most common is placental abruption with its significant release of thromboplastin. Another is embolization of amnionic fluid and debris into the maternal circulation. This causes activation of factor X by abundant mucin found in fetal squames. Other causes include endotoxins from gram-negative bacteria and exotoxins from gram-positive bacteria.

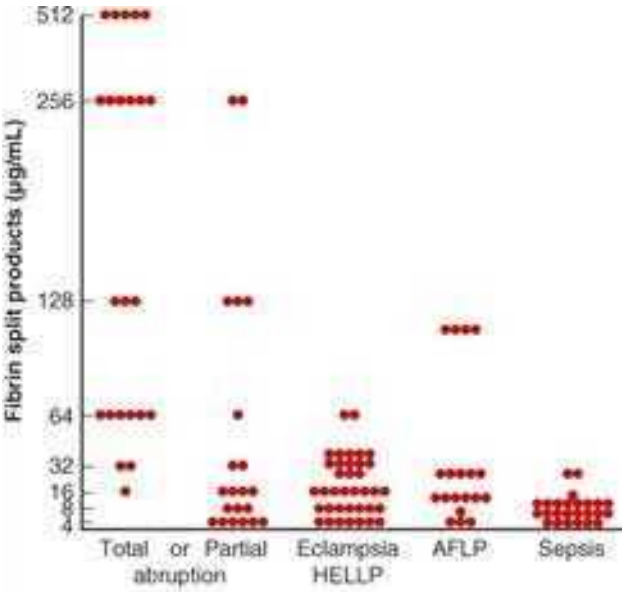
Diagnosis

Bioassay is an excellent method to detect or suspect clinically significant coagulopathy. Excessive bleeding at sites of modest trauma characterizes defective hemostasis. Examples include persistent bleeding from venipuncture sites, nicks from shaving the perineum or abdomen, trauma from bladder catheterization, and spontaneous bleeding from the gums, nose, or gastrointestinal tract. Purpura or petechiae at pressure sites such as sphygmomanometer cuffs or tourniquets suggest significant thrombocytopenia. Any surgical procedure provides the ultimate bioassay and elicits generalized oozing from abdominal wall layers, the retroperitoneal space, the episiotomy, or incisions and dissections for cesarean delivery or hysterectomy.

Of laboratory tests, fibrinogen, fibrin, and degradation product levels can be informative. In late pregnancy, plasma fibrinogen levels typically have risen to 300 to 600 mg/dL. Even with severe consumptive coagulopathy, levels may sometimes be sufficiently high to protect against clinically significant hypofibrinogenemia. For example, defibrination caused by a placental abruption might lower an initial fibrinogen level of 600 mg/dL to 250 mg/dL. Although this would indicate massive fibrinogen consumption, levels are still adequate to promote clinical coagulation—usually about 150 mg/dL. If serious *hypofibrinogenemia*—less than 50 mg/dL—is present, the clot formed from whole blood in a glass tube may initially be soft but not necessarily remarkably reduced in volume. Then, over the next half hour or so, as platelet-induced clot retraction develops, the clot becomes quite small. When many of the erythrocytes are extruded, the volume of liquid in the tube clearly exceeds that of clot.

As depicted in Figure 41-29, fibrinolysis cleaves fibrin and fibrinogen into various fibrin degradation products that are detected by several sensitive assays. There are many fragment types, and monoclonal antibodies in assay kits usually measure d-dimers specific for that assay. These values are always abnormally high with clinically significant consumptive coagulopathy. At least in obstetrical disorders, quantification has not been correlated with outcomes. Examples of the magnitude of fibrin split product elevations in various obstetrical coagulopathies is shown in Figure 41-30.

FIGURE 41-30
Quantification of fibrin-split products in various obstetrical syndromes that cause disseminated intravascular coagulation. AFLP = Acute fatty liver of pregnancy; HELLP = hemolysis, elevated liver enzyme levels, low platelet count. (Reproduced with permission from Cunningham FG, Nelson DB: Disseminated intravascular coagulation syndromes in obstetrics. Obstet Gynecol. 2015 Nov;126(5):999–1011.)



Thrombocytopenia is likely if petechiae are abundant or if clotted blood fails to retract within an hour or so. Confirmation is provided by a low platelet count. If severe preeclampsia syndrome is comorbid, there may also be *qualitative platelet dysfunction* (Chap. 40, Maternal Thrombocytopenia).

Prothrombin time (PT) and partial thromboplastin time (PTT) are standard coagulation tests. Prolongation may stem from very low fibrinogen concentrations, from appreciably reduced levels of the procoagulants needed to generate thrombin, or from large amounts of circulating fibrinogen-fibrin degradation products.

Thromboelastometry and thromboelastography are point-of-care tests used as adjuncts to conventional laboratory studies (Abdul-Kadir, 2014). Their current role may serve to guide blood product replacement, discussed later (Viscoelastic Assays).

Using many of these tests, several organizations have attempted to establish a more uniform definition of DIC. One is the International Society on Thrombosis and Haemostasis (ISTH) scoring system. The score is used *only after* a condition known to cause intravascular coagulation is identified and is calculated using a combination of laboratory tests. Composite ISTH-DIC scores <5 suggest nonovert DIC, whereas scores ≥5 are compatible with overt DIC. Other than one report of acute fatty liver of pregnancy, this scoring system has not been applied widely in obstetrics (Nelson, 2014).

General Management

To halt ongoing defibrination, prompt identification and removal of the inciting source of the coagulopathy is a priority. With surgical incisions or extensive lacerations accompanied by severe hemorrhage, rapid replacement of procoagulants is usually indicated. Vigorous restoration and maintenance of the circulation to treat hypovolemia cannot be overemphasized. Adequate perfusion restores hepatic and endothelial synthesis of procoagulants and permits prompt removal of activated coagulation factors, fibrin, and fibrin degradation products by the reticuloendothelial system.

Aside from these fundamental steps, few other agents have proven soundly effective. Although seemingly counterintuitive, unfractionated heparin had been recommended but has now been abandoned. Other examples include use of antifibrinolytic agents—either tranexamic acid or epsilon-aminocaproic acid (Amicar) (American College of Obstetricians and Gynecologists, 2017d; Pacheco, 2017). Currently, use of these two agents is not recommended because the fibrinolytic system is necessary for dissolution of widespread fibrin thromboses caused by generalized intravascular coagulation (Hunt, 2014). Discussed later (Packed Red Blood Cells), recombinant factor VIIa (rFVIIa) has been used to help control severe obstetrical hemorrhage from other causes. However, current clinical evidence is insufficient to make firm recommendations on its administration for obstetrical coagulopathies.

Specific Comorbid Conditions

Placental abruption is the most common cause of severe consumptive coagulopathy in obstetrics and is discussed more fully in Placental Abruption. Typical quantified levels of fibrin-split products with abruption are shown in Figure 41-30. With *preeclampsia, eclampsia,* and *HELLP syndrome,* endothelial activation is a hallmark and is discussed in Chapter 40 (Pathogenesis). In general, the clinical severity of preeclampsia is directly correlated with thrombocytopenia and fibrinogen-fibrin degradation products (Kenny, 2015; Levi, 2010b). As shown in Figure 41-30, intravascular coagulation is seldom severe enough to be clinically worrisome (Pritchard, 1976).

Fetal Death and Delayed Delivery

Consumptive coagulopathy associated with prolonged retention of a dead fetus is unusual today because fetal death can be easily confirmed and there are highly effective methods for labor induction. With singleton pregnancies, if the dead fetus is undelivered, most women enter spontaneous labor within 2 weeks. Gross disruption of maternal coagulation rarely develops before 4 weeks (Pritchard, 1959, 1973). After 1 month, however, almost a fourth will develop consumptive coagulopathy.

Obvious coagulation derangement occasionally develops in a multifetal pregnancy in which one fetus dies while the other survives (Chescheir, 1988; Landy, 1989). This situation is uncommon, and in one study of 22 such pregnancies, none developed a coagulopathy (Petersen, 1999). Most cases are seen in monochorionic twins with shared circulations, which are described in Chapter 45 (Monochorionic Twins and Vascular Anastomoses).

Amnionic Fluid Embolism

The classic triad of abrupt hemodynamic and respiratory compromise along with DIC underpins its diagnosis (Clark, 2016). Most reports describe a frequency of 1 in 40,000 to 1 in 50,000 (Clark, 2014; Knight, 2010; Kramer, 2012). The case-fatality rate in all of these studies ranges from 11 to 43 percent. From another perspective, amnionic fluid embolism was the cause of 5 to 15 percent of all pregnancy-related deaths in the United States and Canada (Berg, 2003, 2010; Creanga, 2015; Kramer, 2012).

Predisposing conditions are rapid labor, meconium-stained fluid, and tears into uterine and other large pelvic veins that permit an exchange of fluids between the maternal and fetal compartment (Society for Maternal-Fetal Medicine, 2016). Other commonly cited risks include older maternal age; postterm pregnancy; labor induction or augmentation; eclampsia; cesarean, forceps, or vacuum delivery; placental abruption or previa; and hydramnios (Knight, 2010, 2012; Kramer, 2012). The association of uterine hypertonus appears to be the *effect* rather than the *cause* because uterine blood flow ceases when intrauterine pressures exceed 35 to 40 mm Hg. Thus, a hypertonic contraction would be the *least* likely circumstance for amnionic fluid and other debris to enter uterine veins (Clark, 1985). For this reason, hypertonus from oxytocin is not implicated.

Diagnosis

Proposed criteria for diagnosis of amnionic fluid embolism are shown in Table 41-7. The classic example is dramatic, and a woman in the late stages of labor or immediately postpartum begins gasping for air. Seizures or cardiorespiratory arrest rapidly follows accompanied by massive hemorrhage from consumptive coagulopathy. Clinical manifestations are variable. For example, we and others have managed several women in whom otherwise uncomplicated vaginal or cesarean delivery was followed by severe acute consumptive coagulopathy without overt cardiorespiratory difficulties. In those women, consumptive coagulopathy appears to be the *forme fruste* of amnionic fluid embolism (Kramer, 2012; Porter, 1996).

TABLE 41-7

Diagnostic Criteria for Amnionic Fluid Embolism

Abrupt onset of cardiorespiratory arrest, or both hypotension and respiratory compromise.
Documentation of overt disseminated intravascular coagulation. Coagulopathy must be detected prior to loss of sufficient blood to cause dilutional or shock-related consumptive coagulopathy.
Clinical onset during labor or within 30 minutes of placental delivery.
No fever ≥38°C.

Adapted from Clark, 2016.

Because of this clinical variability, other sources of acute cardiac or respiratory failure should be considered. These include myocardial infarction, pulmonary or air embolism, high spinal blockade, eclampsia, and anaphylactic shock. In some cases, the temporal relationship of events aids diagnosis. *Unfortunately, no specific diagnostic laboratory test confirms or refutes the diagnosis of amnionic fluid embolism, and it remains a clinical diagnosis.* Importantly, women suffering from excessive blood loss and resulting coagulopathy may be misdiagnosed with amnionic fluid embolism, when the true culprit is unrecognized or underappreciated hemorrhage (Clark, 2016). In either event, a woman with cardiopulmonary compromise should receive immediate resuscitation (Society for Maternal-Fetal Medicine, 2016).

Pathophysiology

The mechanism of injury from amnionic fluid embolism has evolved. Early theories proposed that amnionic fluid and debris entered maternal circulation and obstructed pulmonary artery flow, which led to hypoxia, right heart failure, and death. However, during normal delivery, amnionic fluid commonly enters the maternal circulation through venous channels at the placental implantation site or from small lacerations. Accordingly, squames, fetal cells, and trophoblasts can often be identified in maternal peripheral blood at delivery (Clark, 1986; Lee, 1986). And, infused amnionic fluid is generally innocuous, even in large amounts (Adamsons, 1971; Stolte, 1967).

Current explanations describe disruption of the maternal-fetal interface, which allows material from the fetal compartment to enter maternal circulation. This leads to abnormal activation of proinflammatory mediator systems, similar to the systemic inflammatory response syndrome (SIRS), and causes initial, transient pulmonary vasoconstriction and hypertension. Acute right ventricular failure is then followed by hemodynamic collapse from right ventricular infarction coupled with interventricular septum displacement to the left and ultimately decreased left-sided cardiac output. This right and now left ventricular dysfunction is followed by cardiogenic pulmonary edema and systemic hypotension. Concurrently in this process, acute respiratory failure with severe hypoxemia from shunting develops. Notably, the resulting multiorgan dysfunction is an interrelated process, with both the cardiac and pulmonary systems affecting each other.

Women who survive beyond these first phases invariably have the third component of the classic triad—a consumptive coagulopathy. Similar to the coagulation process described earlier, the material from the fetal compartment containing tissue factor activates factor VII. This leads to the development of DIC (see Fig. 41-29).

In those who succumb, postmortem histopathological findings may be obvious (Fig. 41-31). However, detection of such material may require special stains, and even then, debris may not be seen. In one study, fetal elements were detected in 75 percent of autopsies and in 50 percent of specimens prepared from concentrated buffy coat aspirates taken antemortem from a pulmonary artery catheter (Clark, 1995).

Management

The initial period of systemic and pulmonary hypertension with amnionic fluid embolism is transient. Thus, immediate high-quality cardiopulmonary resuscitation and advanced cardiac life support must be initiated without delay (Society for Maternal-Fetal Medicine, 2016). These are discussed in detail in Chapter 47 (Cardiopulmonary Resuscitation).

If resuscitation is successful, hemodynamic instability is common in survivors. Both fever and hyperoxia will worsen ischemia–reperfusion injury to the brain, and thus both are avoided. A suitable goal for temperature is 36°C and for mean arterial pressure is 65 mm Hg (Society for Maternal-Fetal Medicine, 2016). Additional supportive care measures such as intubation are usually necessary. During the phase of right ventricular failure, inotropic agents such as dobutamine may improve right heart output, and later systemic hypotension should be treated with vasopressors such as norepinephrine. Excess fluid administration is discouraged due to risks of worsening dilation of an already engorged right ventricle, which may cause right-sided myocardial infarction and displacement of the interventricular septum.

Beginning either immediately after cardiopulmonary collapse or during the ensuing phases of injury, a coagulopathy develops in most cases from activation of factor VII and X. This may be exacerbated by ongoing hemorrhage. A common source of obstetrical bleeding is uterine atony. Therefore, immediate evaluation of coagulation parameters is prudent with concurrent clinical management of bleeding.

Clinical Outcomes

Most reports describe dismal outcomes with amnionic fluid embolism. This is likely influenced by underdiagnosis and reporting biases that favor the most severe cases with the highest mortality rates. Several reports are illustrative. From a California database of 1.1 million deliveries, the mortality rate with amnionic fluid embolism was 60 percent (Gilbert, 1999). In a report of 34 mothers from China, 90 percent died (Weiwen, 2000). Death can be amazingly rapid, and 12 of the 34 died within 30 minutes. The mortality rate was somewhat better in the largest study from Canada. Of 120 women with an amnionic fluid embolism, only a fourth died. Survivors commonly have profound neurological impairment. Clark (1995) observed that only 8 percent of women who lived despite cardiac arrest survived neurologically intact. Overall, prognosis appears to be more associated with disease severity and the attendant cardiac arrest than with any specific treatment modality (Clark, 2014).

As perhaps expected, perinatal outcomes are also poor and are inversely related to the maternal cardiac arrest-to-delivery interval. Even so, neonatal survival rate is 70 percent, but unfortunately, up to half of survivors suffer residual neurological impairment. In the Canadian study, 28 percent of infants were considered to be asphyxiated at birth (Kramer, 2012).

Sepsis Syndrome

Various infections that are accompanied by endo- or exotoxin release can lead to sepsis syndrome. Although a feature of this syndrome includes activation of coagulation, seldom does sepsis alone cause massive procoagulant consumption. *Escherichia coli* bacteremia is frequently seen with antepartum pyelonephritis and puerperal infections, however, accompanying consumptive coagulopathy is usually not severe. Some notable exceptions are septicemia associated with puerperal infection or septic abortion caused by exotoxins released from infecting organisms such as group A *Streptococcus pyogenes, Staphylococcus aureus*, or *Clostridium perfringens, C sordellii*, or *C novyi* (Herrera, 2016). Treatment of sepsis syndrome and septic shock is discussed in Chapter 47 (Sepsis Syndrome).

Purpura Fulminans

This severe—often lethal—form of consumptive coagulopathy is caused by microthrombi in small blood vessels leading to skin necrosis and sometimes vasculitis. Debridement of large areas of skin over the extremities and buttocks frequently requires treatment in a burn unit. Purpura fulminans usually complicates sepsis in women with heterozygous protein C deficiencies and low protein C serum levels (Levi, 2010b). Note that homozygous protein C or S deficiency results in fatal *neonatal purpura fulminans* (Chap. 52, Protein S Deficiency).

Abortion

Septic abortion—especially associated with the organisms just discussed—can incite coagulation and worsen hemorrhage, especially with midtrimester abortions. Indeed, sepsis syndrome accompanied by intravascular coagulation accounts for 25 percent of abortion-related deaths (Saraiya, 1999). In the past, especially with illegal abortions, infections with *C perfringens* were a frequent cause of intense intravascular hemolysis at Parkland Hospital (Pritchard, 1971). More recently, however, septic abortions from infection with *C sordellii* have emerged as important causes (Chap. 18, Inevitable Abortion).

Second-trimester induced abortions can stimulate intravascular coagulation even in the absence of sepsis. Ben-Ami and associates (2012) described a 1.6-percent incidence in 1249 late second-trimester pregnancies terminated by dilation and evacuation. Two thirds were done for fetal demise, which may have been contributory to coagulopathy. Another source of intense coagulation is from instillation of hypertonic solutions to effect midtrimester abortions. These are not commonly used currently for pregnancy terminations. The mechanism is thought to initiate coagulation by thromboplastin release into maternal circulation from the placenta, fetus, and decidua by the necrobiotic effect of hypertonic solutions (Burkman, 1977).

MANAGEMENT OF HEMORRHAGE

Recognition of obstetrical hemorrhage severity is crucial to its management. Visual estimation of blood loss, especially when excessive, is notoriously inaccurate, and true blood loss is often two to three times the clinical estimate. Consider also that in obstetrics, part and sometimes even all of the lost blood may be concealed. Estimation is further complicated in that peripartum hemorrhage also includes the pregnancy-induced augmented blood volume. After pregnancy hypervolemia is lost at delivery, blood loss can be estimated by calculating 500 mL loss for each 3 volume percent drop in hematocrit. The hematocrit nadir depends on the speed of resuscitation with intravenous crystalloids. *With acute blood loss, the real-time hematocrit is at its maximum whenever measured in the delivery, operating, or recovery room.*

A prudent rule is that any time blood loss is considered more than average, then the hematocrit is determined and plans are made for close observation for potential physiological deterioration. Urine output measured hourly is one of the most important "vital signs." *Unless diuretic agents are given—and these are seldom indicated with active bleeding—accurately measured urine flow reflects renal perfusion, which in turn reflects perfusion of other vital organs.* Urine flow of at least 30 mL, and preferably ≥50 mL per hour, should be maintained.

Hypovolemic Shock

Shock from hemorrhage evolves through several stages. Early in the course of massive bleeding, mean arterial pressure, stroke volume, cardiac output, central venous pressure, and pulmonary capillary wedge pressure decline. Increases in arteriovenous oxygen content difference reflect a relative rise in tissue oxygen extraction, although overall oxygen consumption falls.

Blood flow to capillary beds in various organs is controlled by arterioles. These are resistance vessels that are partially controlled by the central nervous system. However, approximately 70 percent of total blood volume is contained in venules, which are passive resistance vessels controlled by humoral factors. Catecholamine release during hemorrhage prompts greater venular tone, which provides an autotransfusion from this capacitance reservoir (Barber, 1999). This is accompanied by compensatory rises in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. In addition, cardiac output and blood volume are redistributed from the effect of selective, centrally mediated arteriolar constriction or relaxation—*autoregulation*. Thus, although perfusion to the kidneys, splanchnic beds, muscles, skin, and uterus is diminished, relatively more blood flow is diverted to the heart, brain, and adrenal glands.

When the blood volume deficit exceeds approximately 25 percent, compensatory mechanisms usually are inadequate to maintain cardiac output and blood pressure. Importantly, additional small losses of blood will now cause rapid clinical deterioration. Following an initial augmented *total oxygen extraction* by maternal tissue, maldistribution of blood flow results in *local* tissue hypoxia and metabolic acidosis. This creates a vicious cycle of vasoconstriction, organ ischemia, and cellular death.

Another important clinical effect of hemorrhage is activation of lymphocytes and monocytes, which in turn causes endothelial cell activation and platelet aggregation. These promote release of vasoactive mediators that occlude small vessels and further impair microcirculatory perfusion. Other common obstetrical syndromes—preeclampsia and sepsis—also lead to loss of capillary endothelial integrity, additional loss of intravascular volume into the extracellular space, and platelet aggregation. These then can incite DIC.

The pathophysiological events just described create important but often overlooked extracellular fluid and electrolyte shifts involved in both the genesis and successful treatment of hypovolemic shock. These include changes in the cellular transport of various ions such as sodium and water into skeletal muscle as well as potassium loss. Replacement of extracellular fluid and intravascular volume are both necessary. *Survival is enhanced in acute hemorrhagic shock if blood plus crystalloid solution is given compared with blood transfusions alone.*

Fluid Resuscitation

Whenever excessive blood loss is suspected in a pregnant woman, steps are simultaneously taken to identify the bleeding source and to begin resuscitation. If she is undelivered, restoration of blood volume is beneficial to mother and fetus, and it also prepares for emergent delivery. If she is postpartum, it is essential to immediately identify uterine atony, retained placental fragments, or genital tract lacerations. At least one and preferably more large-bore intravenous infusion systems are established promptly with rapid administration of crystalloid solutions, while blood is made available. An operating room is readied, and a surgical and anesthesia team are assembled immediately. Specific management of hemorrhage is further dependent on its etiology.

It cannot be overemphasized that treatment of serious hemorrhage demands prompt and adequate refilling of the intravascular compartment with crystalloid solutions. These rapidly equilibrate into the extravascular space, and only 20 percent of crystalloid remains intravascularly in critically ill patients after 1 hour (Zuckerbraun, 2010). *Because of this, initial fluid is infused in a volume two to three times the estimated blood loss.*

Resuscitation of hypovolemic shock with colloid versus crystalloid solutions has been debated. In a Cochrane review of resuscitation of nonpregnant critically ill patients, Perel and coworkers (2013) found equivalent benefits but concluded that colloid solutions were more expensive. Similar results were found in the Saline versus Albumin Fluid Evaluation (SAFE) randomized trial of almost 7000 nonpregnant patients (Finfer, 2004). We concur with Zuckerbraun and colleagues (2010) that acute volume resuscitation is preferably done with crystalloid and blood.

Blood Replacement

The hematocrit level or hemoglobin concentration that mandates blood transfusion is controversial. Cardiac output does not substantively drop until the hemoglobin concentration falls to approximately 7 g/dL or hematocrit of 20 volume percent. At this level, several organizations recommend consideration for red cell transfusions (Carson, 2017). Also, Military Combat Trauma Units in Iraq used a target hematocrit of 21 volume percent (Barbieri, 2007). In general, with *ongoing* obstetrical hemorrhage, we recommend rapid blood infusion when the hematocrit is <25 volume percent. This decision is dependent on whether the fetus has been delivered; surgery is imminent or ongoing operative blood loss is expected; or acute hypoxia, vascular collapse, or other factors are present.

Scant clinical data elucidate these issues. In a study from the Canadian Critical Care Trials Group, nonpregnant patients were randomly assigned to restrictive red cell transfusions to maintain hemoglobin concentration >7 g/dL or to liberal transfusions to maintain the hemoglobin level at 10 to 12 g/dL. The 30-day mortality rate was similar—19 versus 23 percent in the restrictive versus liberal groups, respectively (Hébert, 1999). Transfusion therapy in nonpregnant patients with septic shock had similar mortality rates when 7 g/dL was compared with 9 g/dL as targets for transfusions (Holst, 2014). *The number of units transfused in a given woman to reach a target hematocrit depends on her body mass and on expectations of additional blood loss.*

Blood Component Products

Contents and effects of transfusion of various blood components are shown in Table 41-8. *Compatible whole blood is ideal for treatment of hypovolemia from catastrophic hemorrhage.* It has a shelf life of 40 days, and 70 percent of the transfused red cells function for at least 24 hours following transfusion. One unit raises the hematocrit by 3 to 4 volume percent. Important for obstetrical hemorrhage, whole blood replaces many coagulation factors in obstetrics—especially fibrinogen—and its plasma treats hypovolemia. A collateral derivative is that women with severe hemorrhage are resuscitated with fewer blood donor exposures than with packed red cells and components (Shaz, 2009).

TABLE 41-8

Blood Products Commonly Transfused in Obstetrical Hemorrhage

Product	Volume per Unit	Contents per Unit	Effect on Hemorrhage
Whole blood	About 500 mL; Hct ~40 percent	RBCs, plasma, 600–700 mg fibrinogen, no platelets	Restores blood volume and fibrinogen, increases Hct 3–4 volume percent per unit
Packed RBCs	250–300 mL; Hct ~55–80 percent	RBCs, minimal fibrinogen, no platelets	Increases Hct 3–4 volume percent per unit
Fresh-frozen plasma (FFP)	About 250 mL; 30-minute thaw	Colloid, 600–700 mg fibrinogen, no platelets	Restores circulating volume and fibrinogen
Cryoprecipitate	About 15 mL, frozen	One unit ~200 mg fibrinogen, other clotting factors, no platelets	15–20 units or 3–4 g will increase baseline fibrinogen ~150 mg/dL
Platelets	About 50 mL, stored at room temperature	One unit raises platelet count about 5000/µL; single-donor apheresis bag preferable	6–10 units transfused: single-donor bag preferable to raise platelets ~30,000/µL

Hct = hematocrit; RBCs = red blood cells.

Evidence supports the preferable use of whole blood for massive hemorrhage, including our experiences at Parkland Hospital (Alexander, 2009; Hernandez, 2012). Of more than 66,000 deliveries, women with obstetrical hemorrhage treated with whole blood had significantly lower incidences of renal failure, acute respiratory distress syndrome, pulmonary edema, hypofibrinogenemia, intensive care unit admissions, and maternal death compared with those given packed red cells and component therapy. Freshly donated whole blood has also been used successfully for life-threatening massive hemorrhage at combat support hospitals (Murdock, 2014; Stubbs, 2016).

In most institutions today, however, whole blood is rarely available. Thus, most women with obstetrical hemorrhage and ongoing massive blood loss are given packed red cells and crystalloid. In these instances, no data support a 1:1 plasma: red cell transfusion ratio. As subsequently discussed, many institutions use *massive transfusion protocols* designed to anticipate all facets of massive obstetrical hemorrhage. These “recipes” commonly contain a combination of red cells, plasma, cryoprecipitate, and platelets (Cunningham, 2015; Pacheco, 2011; Shields, 2011).

Several studies have assessed plasma:red cell ratio with massive transfusion protocols used in civilian trauma units and military combat hospitals (Borgman, 2007; Gonzalez, 2007; Hardin, 2014; Johansson, 2007). Patients undergoing massive transfusion—defined as 10 or more units of blood—had much higher survival rates as the ratio of plasma to red cell units neared 1:1.4, that is, one unit of plasma given for each 1.4 units of packed red cells. By way of contrast, the highest mortality group had a ratio of 1:8. *Most of these studies found that component replacement is rarely necessary with acute replacement of 5 to 10 units of packed red cells.*

From the foregoing, when red cell replacement exceeds five units or so, evaluation of platelet count, clotting studies, and plasma fibrinogen concentration is reasonable. In the woman with obstetrical hemorrhage, the platelet count should be maintained >50,000/µL by the infusion of platelet concentrates. A fibrinogen level <150 mg/dL or a sufficiently prolonged PT or PTT in a woman with surgical bleeding is an indication for replacement. Fresh-frozen plasma is administered in doses of 10 to 15 mL/kg, or alternatively, cryoprecipitate is infused (see Table 41-8).

Dilutional Coagulopathy

A major drawback of treatment for massive hemorrhage with crystalloid solutions and packed red blood cells is depletion of platelets and clotting factors. This can lead to a *dilutional coagulopathy* that is clinically indistinguishable from DIC (Hossain, 2013).

Thrombocytopenia is the most frequent coagulation defect found with blood loss and multiple transfusions (Counts, 1979). In addition, packed red cells have only very small amounts of soluble clotting factors, and stored whole blood is deficient in platelets and in factors V, VIII, and XI. As discussed, massive replacement with red cells only and without factor replacement can also cause *hypofibrinogenemia* and prolongation of the PT and PTT. Because many causes of obstetrical hemorrhage also cause consumptive coagulopathy, the distinction between dilutional and consumptive coagulopathy can be confusing. Fortunately, treatment for both is similar.

Type and Screen versus Crossmatch

A blood type and antibody screen should be performed for any woman at significant risk for hemorrhage. Screening involves mixing maternal serum with standard reagent red cells that carry antigens to which most of the common clinically significant antibodies react. Crossmatching involves the use of actual donor erythrocytes rather than the standardized red cells. This process is efficient, and only 0.03 to 0.07 percent of patients identified as having no antibodies are subsequently found to have antibodies (Boral, 1979). *Importantly, administration of screened blood rarely results in adverse clinical sequelae.*

Packed Red Blood Cells

One unit of packed erythrocytes is derived from one unit of whole blood to have a hematocrit of 55 to 80 volume percent. One unit will increase the hematocrit by 3 to 4 volume percent.

Platelets

With surgical delivery or with lacerations, platelet transfusions are considered with ongoing obstetrical hemorrhage when the platelet count falls below 50,000/μL (Kenny, 2015). In the *nonsurgical patient*, bleeding is rarely encountered if the platelet count is 10,000/μL or higher (Murphy, 2010). The preferable source of platelets is one "bag" obtained by single-donor apheresis. This contains the equivalent of six units from six individual donors. Depending on maternal size, each single-donor apheresis six-unit bag raises the platelet count by approximately 20,000/μL (Schlicter, 2010). If these bags are not available, then individual-donor platelet units are used, and six to eight such units are generally transfused one at a time.

Importantly, the donor plasma in platelet units must be compatible with recipient erythrocytes. Further, because some red blood cells are invariably transfused along with the platelets, only units from D-negative donors should be given to D-negative recipients. If it is necessary to give these, however, adverse sequelae are unlikely (Lin, 2002).

Fresh-Frozen Plasma

This component is prepared by separating plasma from whole blood and then freezing it. Approximately 30 minutes are required for frozen plasma to thaw. It is a source of all stable and labile clotting factors, including fibrinogen. Thus, it is often used for treatment of women with consumptive or dilutional coagulopathy. *Plasma is not appropriate for use as a volume expander in the absence of specific clotting factor deficiencies.* It should be considered in a bleeding woman with a fibrinogen level <150 mg/dL or with an abnormal PT or PTT.

An alternative to frozen plasma is *liquid plasma (LQP).* This never-frozen plasma is stored at 1 to 6°C for up to 26 days, and in vitro, it appears to be superior to thawed plasma (Matijevic, 2013).

Cryoprecipitate and Fibrinogen Concentrate

Each unit of cryoprecipitate is prepared from one unit of fresh-frozen plasma. Each 10- to 15-mL unit contains at least 200 mg of fibrinogen along with factor VIII:C, factor VIII:von Willebrand factor, factor XIII, and fibronectin (American Association of Blood Banks, 2014). It is usually given as a "pool" or "bag" using an aliquot of fibrinogen concentrate taken from 8 to 120 donors. Cryoprecipitate is an ideal source of fibrinogen when levels are dangerously low and there is oozing from surgical incisions. Another alternative is virus-inactivated fibrinogen concentrate. Each gram of this raises the plasma fibrinogen level approximately 40 mg/dL (Ahmed, 2012; Kikuchi, 2013).

Recombinant Activated Factor VII

This synthetic vitamin K-dependent protein is available as *NovoSeven.* It binds to exposed tissue factor at the site of injury to generate thrombin that activates platelets and the coagulation cascade. Since its introduction, rFVIIa has been used to help control hemorrhage from surgery, trauma, and obstetrical causes (Goodnough, 2016; Murakami, 2015). Most Level I trauma centers include it in their massive transfusion protocols, and it is included in the one used at Parkland Hospital. Importantly, rFVIIa will not be effective if the plasma fibrinogen level is <50 mg/dL or the platelet count is <30,000/μL.

One major concern with rFVIIa use is arterial—and to a lesser degree venous—thrombosis. In a review of 35 randomized trials with nearly 4500 subjects, arterial thromboembolism developed in 55 percent (Levi, 2010a). A second concern is that it was found to be only marginally effective (Pacheco, 2011).

Tranexamic Acid

This antifibrinolytic drug has been used for traumatic and obstetrical hemorrhage. Tranexamic acid inhibits clot lysis to help forestall bleeding by preventing plasmin from degrading fibrin. Its use has been associated with a higher incidence of renal cortical necrosis (Frimat, 2016). The evidence supporting its use as an adjunct in obstetrical hemorrhage is limited, and its routine use for prophylaxis is not recommended American College of Obstetricians and Gynecologists, 2017d; Pacheco, 2017).

Massive Transfusion Protocols

These function to speed blood product delivery to the bedside or operating room, which permits product infusion early in the resuscitation process. The rationale is to prevent adverse effects of aggressive resuscitation solely with crystalloid and packed red blood cells. That said, it is not necessary to activate massive transfusions until at least four to five units of red cells have been given within 2 hours or so. Once activated, red cells, plasma, platelets, and fibrinogen are given by protocol in amounts shown in Table 41-9. Some protocols include rFVIIa and others include tranexamic acid.

TABLE 41-9

Parkland Hospital Obstetrical Massive Transfusion Protocol

Round No.	PRBC 5 Units	FFP 3 Units	Plts 6-pack	Cryo 1 Unit	rVIIa 2 mg
1	X	X			
2	X	X	X		X
3	X	X		X	
4	X	X	X		X
5	X	X			
6	X	X	X	X	X
7	X	X			
8	X	X	X		X

Cryo = cryoprecipitate; FFP = fresh frozen plasma; Plts = Platelets; PRBC = packet red blood cells; rVIIa = recombinant activated factor VII (NovoSeven).

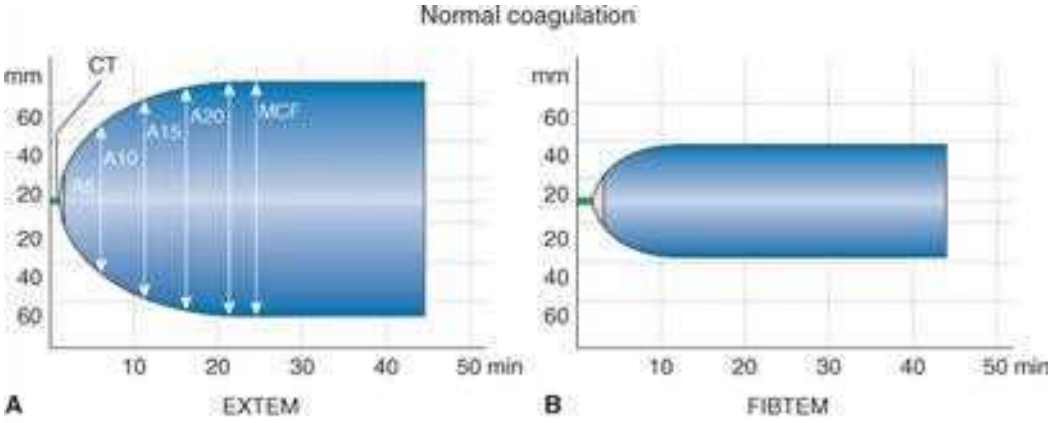
As expected, studies attesting to the superiority for survival with massive transfusion protocols are limited. Most reports describe nonpregnant trauma victims, but some observational studies address obstetrical hemorrhage (Green, 2016; Pacheco, 2016). More data with use of these protocols is needed.

Viscoelastic Assays

Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) are point-of-care tests that assess coagulation in whole blood during massive transfusions. These tests work by analyzing both clot formation and breakdown in a whole blood sample from a given patient. Testing produces a profile of coagulation dynamics, and displayed values indicate the speed and quality of clot formation (Fig. 41-32). These assays provide information regarding time to clot formation, clot strength, and fibrinolysis. Currently, they guide blood product replacement in trauma, liver transplant, and cardiac surgery patients. Studies of TEG and ROTEM techniques in pregnant women have confirmed the hypercoagulable state of pregnancy and provide reference ranges for use in this population (Butwick, 2015; de Lange, 2014; Solomon, 2012).

FIGURE 41-32

TEG/ROTEM based viscoelastic assays of coagulation profiles in a pregnant woman. **A.** EXTEM clot profile: CT = clotting time; A5–20 = clot amplified at 5, 10, 15, 20 min; MCF = maximum clot firmness. **B.** FIBTEM clot profile showing excellent fibrin-based clot quality. (Reproduced with permission from Solomon C, Collis RE, Collins PW: Haemostatic monitoring during postpartum haemorrhage and implications for management, Br J Anaesth. 2012 Dec;109(6):851–863.)



Although these point-of-care tests appear promising, they also have several limitations. For example, they cannot be used to detect disorders of primary hemostasis (Solomon, 2012). Additionally, these tests cannot diagnose coagulopathies stemming from platelet dysfunction or antiplatelet drugs. A major drawback is the risk of misinterpretation when tests are used by inadequately trained personnel. Further study is necessary before these tests are widely applied for treatment of obstetrical hemorrhage.

Topical Hemostatic Agents

Several agents can be used to control persistent surgical oozing. These were recently reviewed by Miller and colleagues (2015). Other than for cesarean hysterectomy, these are seldom used in obstetrical hemorrhage.

Cell Salvage and Autologous Transfusion

Preoperative patient phlebotomy and autologous blood storage for transfusion has been disappointing. Exceptions are women with a rare blood type or with unusual antibodies. Most have concluded that autologous transfusions are not cost effective (Etchason, 1995; Pacheco, 2011, 2013).

Intraoperative blood salvage with reinfusion is considered to be a safe intervention in obstetrical patients. As discussed in Chapter 30 (Patient Preparation), this practice may be helpful for women declining transfusion. Prior concern centered on amnionic fluid contamination and embolism (Dhariwal, 2014; Goucher, 2015; Pacheco, 2011). A recent randomized trial involving 3028 women compared routine cell salvage use against routine care, in which salvage was employed only for bleeding indications. The rate of nonautologous donor blood transfusion was reduced in the cell salvage group—2.5 versus 3.5 percent, but this was not a significant difference (Khan, 2017). Similar to prior reports, no cases of amnionic fluid embolism were reported.

Transfusion Complications

Of serious known risks, *transfusion of an incompatible blood component* may result in acute hemolysis. If severe, this can cause DIC, acute kidney injury, and death. Preventable errors responsible for most of such reactions frequently include mislabeling of a specimen or incorrectly transfusing a patient not slated for those products. The rate of such errors in the United States is estimated to be 1 in 14,000 units, but these events are likely underreported (Lerner, 2010). A transfusion reaction is characterized by fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, severe anxiety, and hemoglobinuria. Immediate supportive measures include stopping the transfusion, treating hypotension and hyperkalemia, provoking diuresis, and alkalinizing the urine.

Transfusion-related acute lung injury (TRALI) is the most common cause of transfusion-related mortality. The syndrome is characterized by severe dyspnea, hypoxia, and noncardiogenic pulmonary edema that develop within 6 hours of transfusion (Peters, 2015). TRALI is estimated to complicate at least 1 in 12,000 transfusions (Carson, 2017). Although the pathogenesis is incompletely understood, injury to the pulmonary capillaries may arise from anti-human leukocyte antigen (HLA) and neutrophil (HNA) antibodies in donor plasma (Lerner, 2010). A delayed form of TRALI has been reported to begin 6 to 72 hours following transfusion (Marik, 2008). Management is supportive and may include mechanical ventilation (Chap. 47, Clinical Course).

Bacterial infection from transfusion of a contaminated blood component is unusual because organism growth is discouraged by refrigeration. The most often implicated contaminants of red cells include *Yersinia, Pseudomonas, Serratia, Acinetobacter,* and *Escherichia* species. The more important risk is from bacterial contamination of platelets, which are stored at room temperature. Current estimates are that 1 in 1000 to 2000 platelet units are contaminated. Death from transfusion-related sepsis is 1 per 17,000 for single-donor platelets and 1 per 61,000 for apheresis-donor packs (Lerner, 2010).

Viral infection risks from transfusion have been curtailed. The risk of HIV or hepatitis C virus infection in screened blood is estimated to be 1 case per 1 to 2 million units transfused (Carson, 2017; Stramer, 2004). The risk for HIV-2 infection is less. Other viral infections include hepatitis B transmission, which is estimated to be <1 per 100,000 transfused units (Jackson, 2003). Because of its high prevalence, cytomegalovirus-infected leukocytes are often transfused. Thus, precautions are taken for immunosuppressed recipients, keeping in mind that this includes the fetus.

Also, risks for transmitting West Nile virus, human T-lymphotropic virus type I, parvovirus B19, and toxoplasmosis are slight (American Association of Blood Banks, 2013; Foroutan-Rad, 2016). Finally, Zika virus has emerged as another relevant transfusion-transmitted infection (Motta, 2016). The Food and Drug Administration (2016) revised recommendations for collection of all whole blood components to include testing for Zika virus. This practice has been affirmed by the Centers for Disease Control and Prevention (2016).

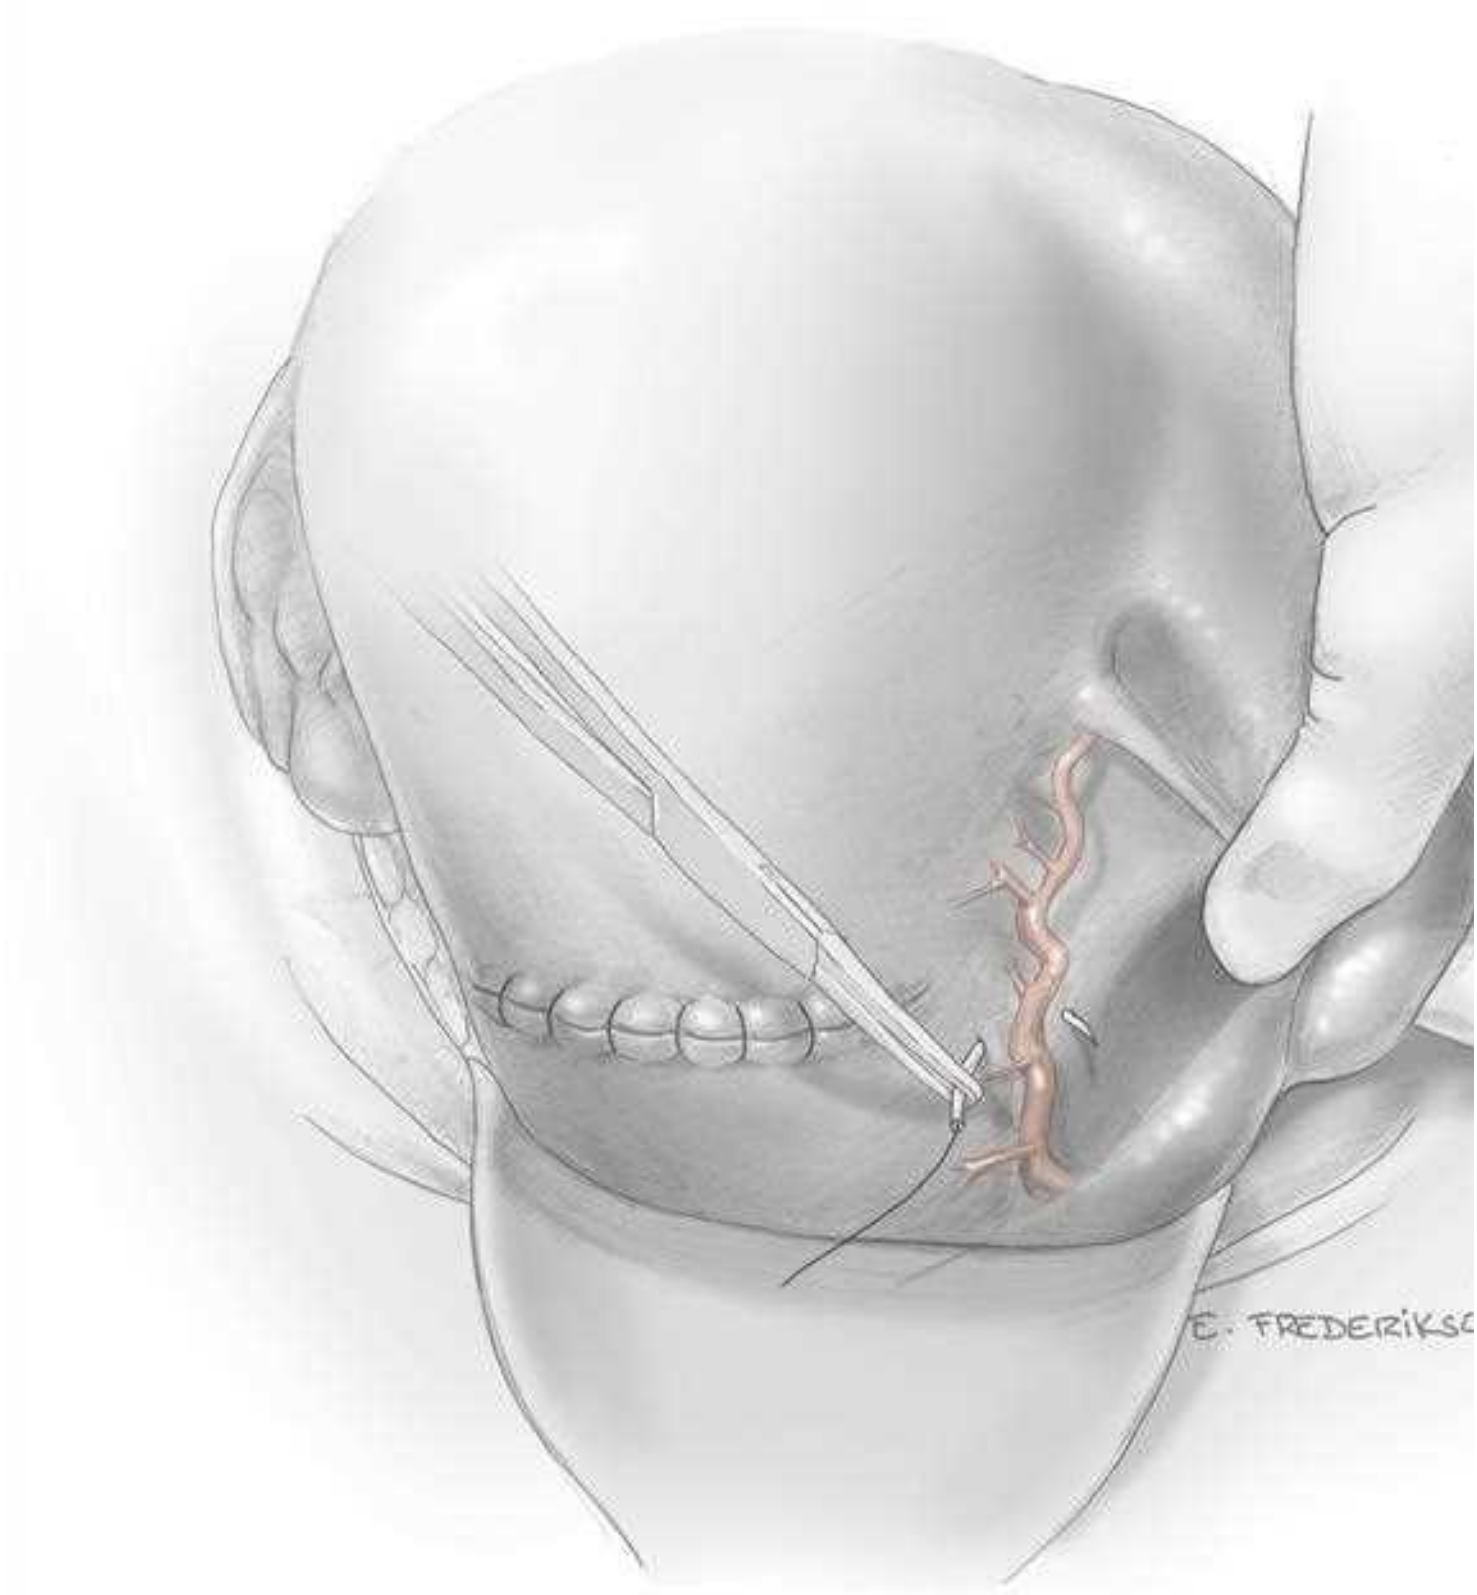
Adjunctive Surgical Procedures

Several invasive procedures can help arrest postpartum hemorrhage. A report from the Agency for Healthcare Research and Quality concluded that most studies addressing these methods are of poor quality (Likis, 2015). In one study of 6660 women with postpartum hemorrhage, 4.4 percent underwent an invasive procedure, and 1.1 percent had a hysterectomy (Kayem, 2016). The failure rate of conservative measures was 15 percent in surgical and embolization procedures.

Uterine Artery Ligation

The technique for unilateral or bilateral uterine artery ligation is used primarily for lacerations at the lateral part of a hysterotomy incision (Fig. 41-33). In our experiences, this procedure is less helpful for hemorrhage from uterine atony.

FIGURE 41-33
Uterine artery ligation. The suture goes through the lateral uterine wall anteriorly, curves around posteriorly, then re-enters anteriorly. When tied, it encompasses the uterine artery.

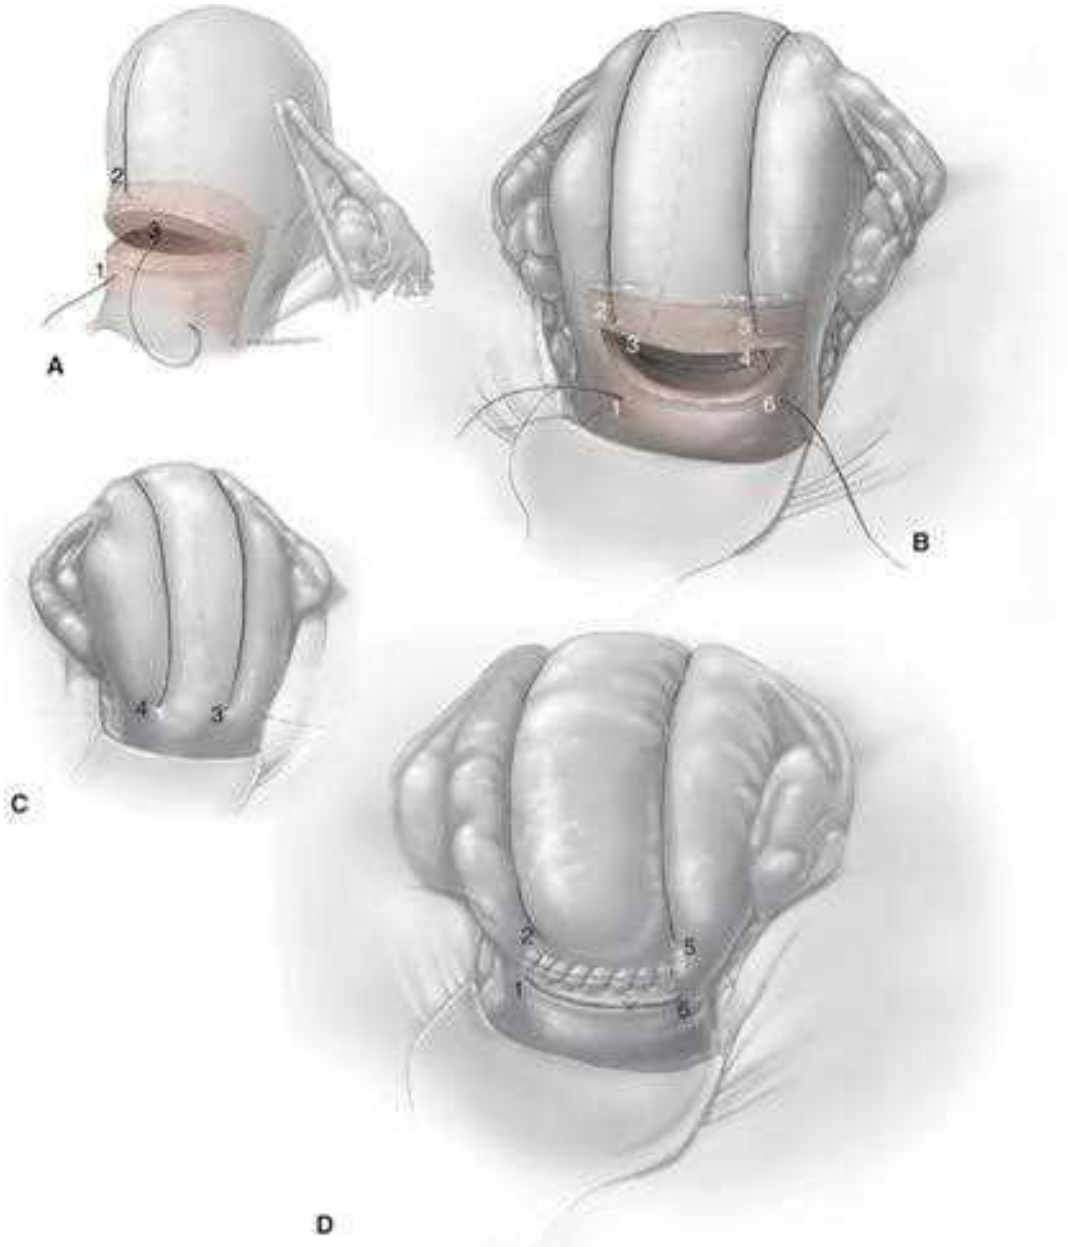


Uterine Compression Sutures

This surgical technique uses a no. 2 chromic suture to compress the anterior and posterior uterine walls together (B-Lynch, 1997). Because they give the appearance of suspenders, they are also called *braces* (Fig. 41-34). Several modifications of the B-Lynch technique have been described (Cho, 2000; Hayman, 2002; Matsubara, 2013; Nelson, 2007). Indications vary for its application, and this will affect the success rate. For example, B-Lynch (2005) cited 948 cases with only seven failures. Conversely, Kayem and associates (2011) described 211 women who had an overall failure rate of 25 percent, which did not differ between B-Lynch sutures and their modifications. In another series, the failure rate was 20 percent (Kaya, 2016). From their review, Sathe and coworkers (2016) reached similar conclusions.

FIGURE 41-34

Uterine compression suture or “brace.” The B-Lynch suture technique is illustrated from an anterior view of the uterus in Figures **A**, **B**, and **D** and a posterior view in Figure **C**. The numbers denote the sequential path of the suture and are shown in more than one figure. **Step 1.** Beginning below the incision, the needle pierces the lower uterine segment to enter the uterine cavity. **Step 2.** The needle exits the cavity above the incision. The suture then loops up and around the fundus to the posterior uterine surface. **Step 3.** The needle pierces the posterior uterine wall to reenter the uterine cavity. The suture then traverses to the opposite side within the cavity. **Step 4.** The needle exits the uterine cavity through the posterior uterine wall. From the back of the uterus, the suture loops up and around the fundus to the front of the uterus. **Step 5.** The needle pierces the myometrium above the incision to reenter the uterine cavity. **Step 6.** The needle exits below the incision and the sutures at points 1 and 6 are tied below the incision. The hysterotomy incision is then closed in the usual fashion.



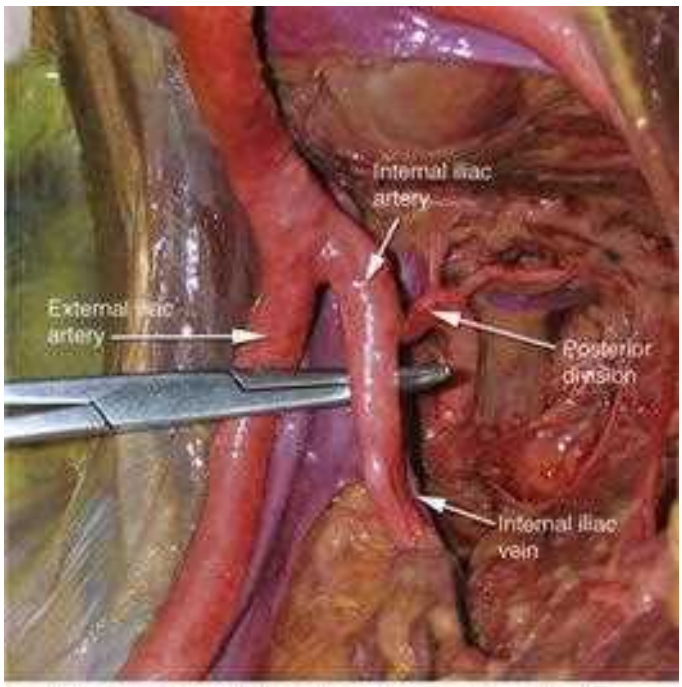
Some unique complications can rarely follow compression sutures (Matsubara, 2013). Most involve variations of uterine ischemic necrosis with peritonitis (Gottlieb, 2008; Joshi, 2004; Ochoa, 2002; Treloar, 2006). In one case, total uterine necrosis followed B-Lynch sutures that were placed in combination with bilateral ligation of uterine, uteroovarian, and round ligament arteries (Friederich, 2007). In most cases, subsequent pregnancies are uneventful if compression sutures are used (An, 2013). A few women, however, with B-Lynch or Cho sutures developed uterine wall defects (Akoury, 2008). Another long-term complication is uterine cavity synechiae (Alouini, 2011; Ibrahim, 2013; Poujade, 2011).

Internal Iliac Artery Ligation

For years, ligation of one or both internal iliac arteries has been used to reduce pelvic hemorrhage. Drawbacks are that the procedure may be technically difficult and is only successful half of the time (American College of Obstetricians and Gynecologists, 2017d). It is not particularly helpful for abating hemorrhage with postpartum atony (Clark, 1985).

For ligation, adequate exposure is obtained by opening the peritoneum over the common iliac artery and dissecting down to the bifurcation of the external and internal iliac arteries (Fig. 41-35). Branches distal to the external iliac arteries are palpated to verify pulsations at or below the inguinal area. Ligation of the internal iliac artery 5 cm distal to the common iliac bifurcation will usually avoid the posterior division branches (Bleich, 2007). The areolar sheath of the artery is incised longitudinally, and a right-angle clamp is carefully passed just beneath the artery from lateral to medial. Care must be taken not to perforate contiguous large veins, especially the internal iliac vein. Suture—usually nonabsorbable—is passed under the artery with a clamp, and the vessel is then securely ligated.

FIGURE 41-35
Ligation of the right internal iliac artery. Unembalmed cadaveric dissection shows the right-angle clamp passing underneath the anterior division of the internal iliac artery just distal to its posterior division. (Used with permission from Dr. Marlene Corton.)



The most important mechanism of action with internal iliac artery ligation is an 85-percent reduction in pulse pressure in those arteries distal to the ligation (Burchell, 1968). This converts an arterial pressure system into one with pressures approaching those in the venous circulation. This creates vessels more amenable to hemostasis via pressure and clot formation.

Even bilateral internal iliac artery ligation does not appear to interfere with subsequent reproduction. Nizard and colleagues (2003) reported follow-up in 17 women who had bilateral artery ligation. From a total of 21 pregnancies, 13 were normal, three ended with miscarriage, three were terminated, and two were ectopic.

Angiographic Embolization

This modality is now used for many causes of intractable hemorrhage when surgical access is difficult. In more than 500 women reported, embolization was 90-percent effective (Grönvall, 2014; Lee, 2012; Poujade, 2012; Zhang, 2015). After his review, Rouse (2013) concluded that embolization can be used to arrest refractory postpartum hemorrhage. Other reports have been less enthusiastic. Fertility is not impaired, and many subsequent successful pregnancies have been reported (Chauleur, 2008; Fiori, 2009; Kolomeyevskaya, 2009). *An important caveat for these procedures is that women with hemodynamic instability related to active bleeding should not be removed from the operating room.*

Complications of embolization are relatively uncommon but can be severe. Case reports detail instances of iatrogenic iliac artery rupture, uterine ischemic necrosis, and uterine infection (Grönvall, 2014; Katakam, 2009; Nakash, 2012). Finally, Al-Thunyan and coworkers (2012) described a woman with massive buttock necrosis and paraplegia following bilateral internal iliac artery embolization.

In a few instances, massive blood loss and difficult surgical dissection is anticipated. The use of balloon-tipped catheters preoperatively inserted into the iliac or uterine arteries was described earlier in management of placenta accrete syndromes (Management).

Pelvic Packing

For significant bleeding refractory to suture or topical hemostats, pelvic packing with gauze and termination of the operation may be considered. Rolls of gauze are packed to provide constant local pressure. This may serve as a temporizing step prior to interventional embolization. In other cases, packing alone may be left for 24 to 48 hours. If the patient is stable and bleeding appears to have stopped, packing is removed.

The *umbrella* or *parachute pack* uses a similar concept (Logothetopulos, 1926). Although seldom used today, it can be lifesaving if all other measures have failed, especially in low-resource areas (Dildy, 2006; Howard, 2002). The pack is constructed of a sturdy sterile plastic bag that is filled with gauze rolls that are unwound and

knotted together. Sufficient rolls are used to provide enough volume to fill the pelvis. The pack is introduced transabdominally with the stalk exiting the vagina. Mild traction is applied by tying the stalk to a 1-liter fluid bag, which is hung over the foot of the bed. The umbrella pack is removed vaginally after 24 hours.

CHAPTER 42: Preterm Birth

It is generally admitted that there exists in the medulla a centre for uterine contractions, which can be stimulated by an excess of carbon dioxide in the blood, by anaemia and the presence of various toxic substances; and it seems highly probable that the frequency of premature labour in cases of renal insufficiency and eclampsia may be due to the action of metabolic poisons upon the centre.

—J. Whitridge Williams (1903)

INTRODUCTION

In this textbook's first edition, very little was mentioned regarding preterm birth. Indeed, preterm birth was not incorporated as a stand-alone topic until the 13th edition in 1966. And, this content totaled only three sentences that cited use of isoxsuprine as a tocolytic agent. In contrast, present-day research now produces more than 3000 articles published annually. Data derive from study of animal models, translational research, clinical trials, and genetic investigations. Despite efforts, elucidating the biology of human parturition and the subsequent efforts to prevent preterm birth remain elusive (Martin, 2017).

DEFINITION OF PRETERM BIRTH

Low birthweight defines neonates who are born too small. *Preterm* or *premature birth* describes neonates who are born too early. With respect to gestational age, a newborn may be preterm, term, or postterm. With respect to size, a newborn may be normally grown and *appropriate for gestational age*; undersized, thus, *small for gestational age*; or overgrown and consequently, *large for gestational age*. Small for gestational age categorizes newborns whose birthweight is <10th percentile for gestational age. Other frequently used terms have included *fetal-growth restriction* or *intrauterine growth restriction*. The term large for gestational age describes newborns whose birthweight is >90th percentile for gestational age. The term *appropriate for gestational age* designates newborns whose weight is between the 10th and 90th percentiles.

Thus, neonates born before term can be small or large for gestational age, but still preterm by definition. *Low birthweight* refers to neonates weighing 1500 to 2500 g; *very low birthweight* are those between 1000 and 1500 g; and *extremely low birthweight* refers to those between 500 and 1000 g.

Before the 15th edition of this textbook, a *preterm* or *premature newborn* was defined by a birthweight <2500 g. With that edition, preterm neonates were considered to be those delivered before 37 completed weeks, that is, $<36^{6/7}$ weeks (Pritchard, 1976). This definition, which has now been in use for more than 40 years, was first promulgated in 1976 by the World Health Organization (WHO) and the International Federation of Gynecology and Obstetrics (FIGO). The definition derived from a statistical analysis of gestational age distribution at birth (Steer, 2005). Importantly, the denotation lacks a specific functional basis and should be clearly distinguished from the concept of *prematurity*. Prematurity represents incomplete development of various organ systems at birth. For example, the lungs are particularly affected, leading to the respiratory distress syndrome (RDS) (Chap. 34, Respiratory Distress Syndrome).

In 2013 in the United States, 23,446 infants died in their first year of life, and a third of infants died from preterm-related causes (Matthews, 2015). Gestational age at delivery and the risk of neonatal morbidity and mortality are inversely related (Frey, 2016). Namely, neonates born in the early-preterm period make up the smallest proportion of births, but these infants experience disproportionately higher rates of prematurity-related complications (Table 42-1).

TABLE 42-1

Infant Mortality Rates in the United States in 2013

	Live Births No. (%)	Infant Deaths (per 1000 births)
Total infants	3,932,181 (100)	23,446 (6)
Gestational age:		
<34 weeks	133,503 (3)	13,284 (100)
34–36 weeks	313,858 (8)	2268 (7)
<37 weeks	447,361 (11)	15,552 (35)
37–38 weeks	974,162 (25)	2933 (3)
39–41 weeks	2,291,468 (58)	4218 (2)
≥42 weeks	215,510 (5)	515 (2)

Data from Matthews, 2015.

Beginning in 2005, in recognition that neonates born between $34^{0/7}$ weeks and $36^{6/7}$ weeks experience morbidities and mortality characteristic of premature newborns, preterm births were subdivided. Those before $33^{6/7}$ weeks are labeled *early preterm,* and those occurring between 34 and 36 completed weeks are *late preterm*. Indeed, compared with births at $39^{0/7}$ weeks through $40^{6/7}$ weeks, these late-preterm infants experience morbidities that are also associated with prematurity (Spong, 2013). Recently, this concept has expanded to births $37^{0/7}$ weeks through $38^{6/7}$ weeks, which are now defined as *early term,* and those $39^{0/7}$ weeks through $40^{6/7}$ weeks, which are defined as *term*.

This revised terminology has led some to redefine a short gestation as those $<39^{0/7}$ weeks. By doing so, more than a third of live births in the United States in 2015 would be defined as having a shortened period of gestation (Martin, 2017). One implication is that only 65 percent of births in the United States occurred during the optimal 39 to 41 weeks' gestation. This emphasizes the realization that fetal maturation in humans is a continuum that is completed later in human pregnancy than previously appreciated. As a result, adverse neonatal sequelae from neonatal immaturity with elective delivery before 39 completed weeks are appreciable (Reddy, 2009; Tita, 2009).

This knowledge resulted in the development and application of the "39-week rule" to deter nonmedically indicated deliveries before 39 weeks (Spong, 2011). An unintended consequence of this health-care strategy has been a rise in stillbirth rates in the United States. One concern is that the rule may be misapplied to gestations with true medical indications for early delivery (Hill, 2017; Nicholson, 2016). Spong (2016) has emphasized the need to perform necessary obstetrical interventions when indicated.

PRETERM BIRTH RATE TRENDS

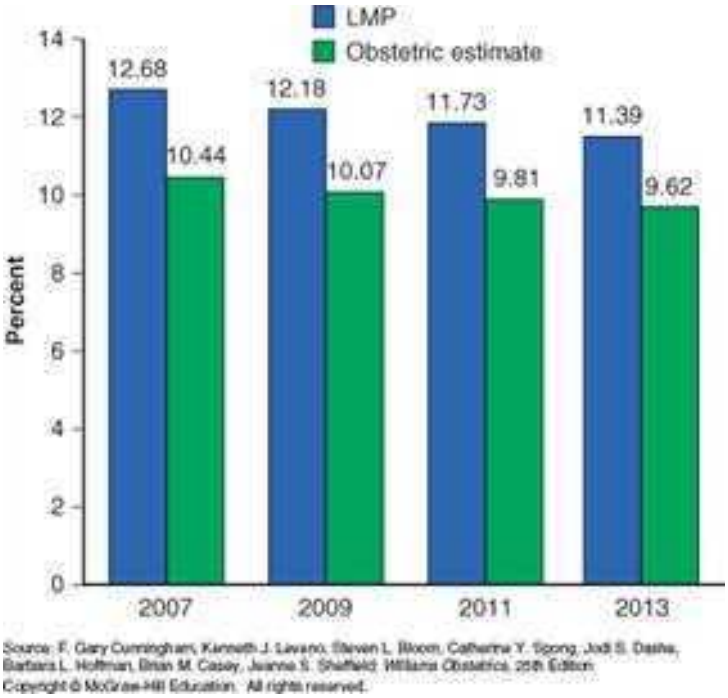
Methodology

In the United States, the preterm birth rate rose slightly from 9.57 percent in 2014 to 9.63 percent for 2015 (Martin, 2017). This marks the first rise in this percentage since 2007. Although concerning, some argue that the drop in preterm birth rates from 2007 to 2014 reflected systematic bias associated with changes in obstetrical dating (Frey, 2016).

Specifically, beginning with the 2014 data year, the National Vital Statistics Reports from the National Center for Health Statistics transitioned to a new standard for estimating newborn gestational age for birth certificate completion (Martin, 2015). The new measure—obstetrical estimate of gestational age at delivery—replaced calculations based on the date of the last normal menses (Chap. 44, Fetal Growth versus Birthweight). As shown in Figure 42-1, these measures differ and do not provide equivalent absolute numerical comparisons of preterm birth rates. For example, the 2015 obstetrical estimate-based preterm birth rate was 9.6 percent compared with the last menstrual period-based rate of 11.3 percent (Martin, 2017). *Thus, current national data are now not directly comparable to previously reported rates of preterm birth due to differing gestational age calculation methodologies.* The national data are now reported starting with year 2007, which coincides with the year that this information became available.

FIGURE 42-1

Percentage of preterm births in the United States according to method of assessment of gestational age. LMP = date of last normal menses. (Adapted with permission from Martin JA, Osterman MJ, Kirmeyer SE, et al: Measuring gestational age in vital statistics data: transitioning to the obstetric estimate. Natl Vital Stat Rep. 2015 Jun 1;64(5):1–20.)



Trend Factors

Ferré and colleagues (2016) using National Vital Statistics System data showed that the overall reduction of preterm birth before 2014 was in part due to the changes in maternal age distribution. Specifically, teen birth rates declined. This translated into a drop in preterm birth rates over the same epoch and could explain the lower infant mortality rates (Callaghan, 2017).

One disturbing aspect of preterm birth rate trends in the United States is persistent racial and ethnic disparities. Rates of preterm birth among black women are markedly elevated above those for white and Hispanic women in every year recorded (Martin, 2017). Moreover, rates of births before 32 completed weeks in black women are higher than those in white and Hispanic women combined. Some investigators attribute this disparity to socioeconomic circumstances (Collins, 2007; Leveno, 2009).

Internationally, the rates of preterm birth in the United States are also higher compared with those in other industrialized countries (Ananth, 2009; Delnord, 2017; Martin, 2017).

PRETERM NEWBORN MORBIDITY

Newborns born before 37 weeks suffer various morbidities, largely due to organ system immaturity (Table 42-2). That said, remarkable strides have been made in neonatal survival for those born preterm. This is especially true for neonates born after 28 weeks. In a study of more than 18,000 newborns weighing between 400 and 1500 g or aged between 22 and 32 weeks' gestation, survival rates were analyzed as a function of both birthweight *and* gestational age (Fanaroff, 2007). After achieving a birthweight of ≥1000 g or a gestational age of 28 weeks for females, or 30 weeks for males, survival rates reach 95 percent.

TABLE 42-2

Major Short- and Long-Term Problems in Very-Low-Birthweight Infants

Organ or System	Short-Term Problems	Long-Term Problems
Pulmonary	Respiratory distress syndrome, air leak, bronchopulmonary dysplasia, apnea of prematurity	Bronchopulmonary dysplasia, reactive airway disease, asthma
Gastrointestinal or nutritional	Hyperbilirubinemia, feeding intolerance, necrotizing enterocolitis, growth failure	Failure to thrive, short-bowel syndrome, cholestasis
Immunological	Hospital-acquired infection, immune deficiency, perinatal infection	Respiratory syncytial virus infection, bronchiolitis
Central nervous system	Intraventricular hemorrhage, periventricular leukomalacia, hydrocephalus	Cerebral palsy, hydrocephalus, cerebral atrophy, neurodevelopmental delay, hearing loss
Ophthalmological	Retinopathy of prematurity	Blindness, retinal detachment, myopia, strabismus
Cardiovascular	Hypotension, patent ductus arteriosus, pulmonary hypertension	Pulmonary hypertension, hypertension in adulthood
Renal	Water and electrolyte imbalance, acid-base disturbances	Hypertension in adulthood
Hematological	Iatrogenic anemia, need for frequent transfusions, anemia of prematurity	
Endocrinological	Hypoglycemia, transiently low thyroxine levels, cortisol deficiency	Impaired glucose regulation, increased insulin resistance

Data from Eichenwald, 2008.

Threshold of Viability

Births once considered to be “abortuses” because the fetus weighed <500 g are now classified as live births. In the United States in 2014, 5863 live births <500 g were recorded (Martin, 2017). For those newborns delivered before 33 weeks’ gestation, perinatal and neonatal care has advanced tremendously. As a result, the *threshold of viability,* which is the lower limit of fetal maturation compatible with extrauterine survival, has been reassessed. Currently, the threshold of viability lies between 20 and 26 weeks’ gestation.

Neonates born in this *periviable period* have been described as fragile and vulnerable because of their immature organ systems. Many of these are described in Chapter 34 (Retinopathy of Prematurity) and include brain injury from hypoxic-ischemic injury and sepsis. In this setting, hypoxia and sepsis start a cascade of events that lead to brain hemorrhage, to white-matter injury that causes periventricular leukomalacia, and to poor subsequent brain growth eventuating in neurodevelopmental impairment. Associated morbidities include intellectual disability, cerebral palsy, blindness, seizures, and spastic quadriparesis that can result in the need for a lifetime of medical care (Annas, 2004). Because active brain development normally occurs throughout the second and third trimesters, those born <25 weeks are believed to be especially vulnerable to brain injury.

To clarify obstetrical care of these fetuses, the Society for Maternal-Fetal Medicine, the *Eunice Kennedy Shriver* National Institute for Child Health and Human Development (NICHD), the American Academy of Pediatrics, and the American College of Obstetricians and Gynecologists convened a joint workshop in 2013 (Raju, 2014). The executive summary statement from this meeting served as the underpinnings for an Obstetric Care Consensus document from the American College of Obstetricians and Gynecologists (2017e).

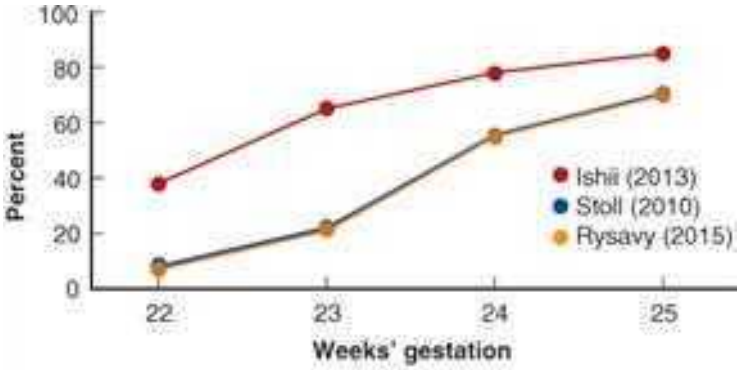
Periviable Neonatal Survival

The Obstetric Care Consensus summary provides a review of outcomes for those born in the periviable period. Delivery before 23 weeks typically results in death, and survival rates approximate only 5 percent (Fig. 42-2). Among those that live, morbidity is nearly universal. Notably, the authors highlight the wide variation in practices regarding active resuscitation and suggest that these variations may explain the differing perinatal outcomes

among different institutions. An important caveat, however, is ascertainment bias. For example, the mean survival rate is 45 percent if the denominator is all live births compared with 72 percent if the denominator is only newborns admitted to neonatal intensive care (Guillen, 2011). Another source of bias is use of multicenter datasets with considerable differences in obstetrical and early neonatal interventions, particularly at 22 and 23 weeks' gestation (Stoll, 2010).

FIGURE 42-2

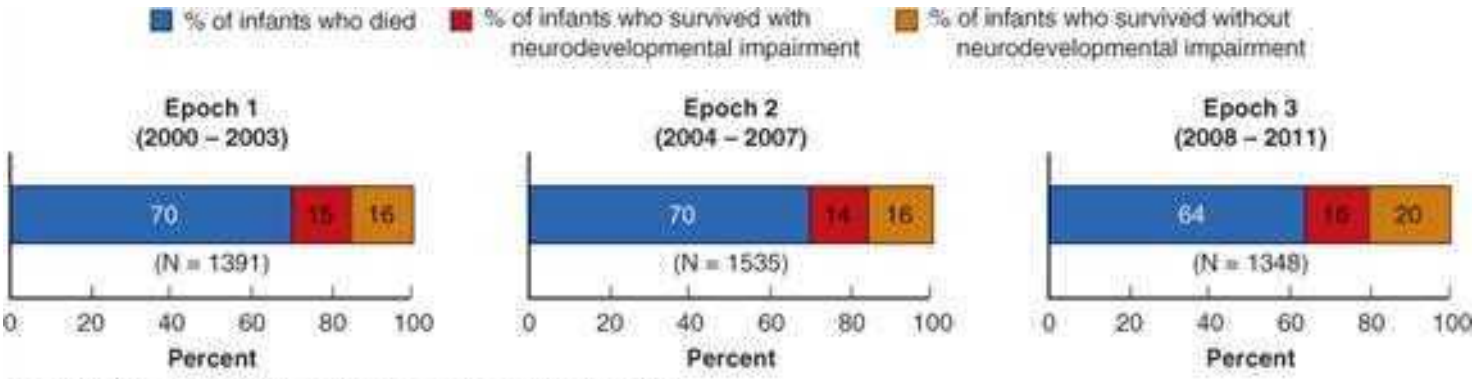
Neonatal survival rates according to condition at birth and gestational age. Ishii (2013) data curve reflects liveborn survival rates; Stoll (2010) curve reflects liveborn survival rates; Rysavy (2015) curve reflects overall survival rates.



To evaluate contemporaneous outcomes of neonates born at 22 to 24 weeks, the NICHD Neonatal Research Network reported both survival and neurodevelopmental outcomes assessed across consecutive birth-year epochs of 2000 to 2003, 2004 to 2007, and 2008 to 2011 in infants aged 18 to 22 months (Younge, 2017). The percentage of infants who survived rose significantly from 30 percent in 2000 to 2003 to 36 percent in 2008 to 2011. The percentage of infants who survived without neurodevelopmental impairment also significantly grew from 16 percent to 20 percent during the same time period (Fig. 42-3). Although rates of survival without neurodevelopmental impairment increased over time among infants born at 23 and 24 weeks, only 1 percent of infants born at 22 weeks survived without neurodevelopmental impairment (Younge, 2017).

FIGURE 42-3

Mortality and neurodevelopmental outcomes at 18 to 22 months of corrected age by birth epoch in neonates born at 22 to 24 weeks. (Data from Younge N, Goldstein RF, Bann CM, et al: Survival and neurodevelopmental outcomes among periviable infants, N Engl J Med. 2017 Feb 16;376(7):617–628.)



Somewhat similar results were published from Sweden (Serenius, 2013). This report details a national population-based prospective study of all neonates born before 27 weeks. Shown in Table 42-3 are the survival and disability rates for 707 Swedish infants born alive from 22 to 26 weeks' gestation between 2004 and 2007 in Sweden. Compared with rates in the United States, rates of survival without neurodevelopmental impairment were higher in the Swedish cohort for infants born at 24 weeks during 2004 to 2007.

TABLE 42-3

Outcomes at 2½ Years Corrected Age by Gestational Age at Birth in Sweden, 2004–2007

	Gestational Age (wk)					
Outcome	**22**	**23**	**24**	**25**	**26**	**Total**
Liveborn infants (no.)	51	101	144	205	206	707
Survived to 1 year (%)	10	53	67	82	85	70
Percent disabled[a]						
No disability	0	30	34	44	49	42

Moderate	20	30	21	17	10	16
Severe	40	21	13	10	7	11

[a]Percentage with disability at 2½ years corrected age. The overall rate of disabilities includes performance on the Bayley III assessments, mental development delay, cerebral palsy, and visual and hearing disabilities.

Data from Serenius F, Källén K, Blennow M, et al: Neurodevelopmental outcome in extremely preterm infants at 2.5 years after active perinatal care in Sweden, JAMA 2013 May 1;309(17):1810–1820.

Clinical Management

The Obstetric Care Consensus document also addresses management options based on the clinical characteristics of a given pregnancy. Nonmodifiable factors are fetal gender, weight, and plurality. Potentially modifiable antepartum and intrapartum factors include the location of delivery, intent to intervene by cesarean delivery or labor induction, and administration of antenatal corticosteroids and magnesium sulfate. Postnatal management addresses the initiation or withdrawal of intensive care after birth. Areas of general guidance were then reviewed for each week of gestation (Table 42-4).

TABLE 42-4

General Guidelines for Obstetrical Interventions for Threatened and Imminent Periviable Delivery

	<22 Weeks	22 Weeks	23 Weeks	24 Weeks+
Neonatal assessment for resuscitation	Not recommended	Consider	Consider	Recommended
Corticosteroid therapy	Not recommended	Not recommended	Consider	Recommended
Magnesium sulfate neuroprotection	Not recommended	Not recommended	Consider	Recommended
Tocolysis	Not recommended	Not recommended	Consider	Recommended
Antimicrobial therapy for PPROM	Consider	Consider	Consider	Recommended
Continuous EFM	Not recommended	Not recommended	Consider	Recommended
GBS prophylaxis	Not recommended	Not recommended	Consider	Recommended
Cesarean delivery for fetal indication	Not recommended	Not recommended	Consider	Recommended
Aggressive resuscitation	Comfort care only	Not recommended unless considered potentially viable	Consider	Recommended

EFM = electronic fetal monitoring; GBS = group B streptococcus; PPROM = preterm premature rupture of membranes.

Data from the American College of Obstetricians and Gynecologists, 2017e; Raju, 2014.

Mode of delivery represents another dilemma because cesarean delivery at the threshold of viability is controversial. For example, if the fetus-neonate is perceived to be too immature for aggressive support, then cesarean delivery for common indications such as breech presentation or nonreassuring fetal heart rate patterns might be preempted. Moreover, observational studies have failed to document a benefit of cesarean delivery for the sole indication of periviability (Alfirevic, 2013).

In a study of 2906 singletons between $24^{0/7}$ and $31^{6/7}$ weeks eligible for attempted vaginal birth, 84 percent of cephalic presenting fetuses were delivered vaginally (Reddy, 2012). Neonatal mortality rates did not differ compared with those associated with planned cesarean delivery. For *breech* presentations, however, relative risk for mortality was threefold higher with attempted vaginal delivery. In another study, Werner and colleagues (2013) analyzed 20,231 newborns delivered at 24 to 34 weeks. Cesarean delivery did not protect against poor outcomes such as neonatal death, intraventricular hemorrhage, seizures, respiratory distress, and subdural hemorrhage. From these findings, the Obstetric Care Consensus proposes that cesarean delivery be *considered* for fetal indications at $23^{0/7}$ to $24^{6/7}$ weeks. However, before 22 weeks, this route is reserved only for maternal indications.

It is difficult to summarize the current practices of obstetrical care in the management of the periviable pregnancy given its rapid evolution. For example, since January 2016, the American College of Obstetricians and Gynecologists has penned three iterations of its Practice Bulletin "Management of Preterm Labor," and three versions of the "Obstetric Care Consensus" document have been published since November 2015. In this uncertain environment, individualized, patient-centered care with a multidisciplinary team remain as bedrock for the clinician.

While we do not have the answers, we describe our strategies from Parkland Hospital as one approach to management. Our policies were developed in conjunction with the Division of Neonatal Medicine. Importantly, the decision not to perform cesarean delivery does not necessarily imply that care for the fetus is discounted. Neonatologists are consulted before delivery, and a trilateral discussion of survival and morbidity rates ensues with the woman and her family. A neonatologist attends each delivery and determines subsequent management.

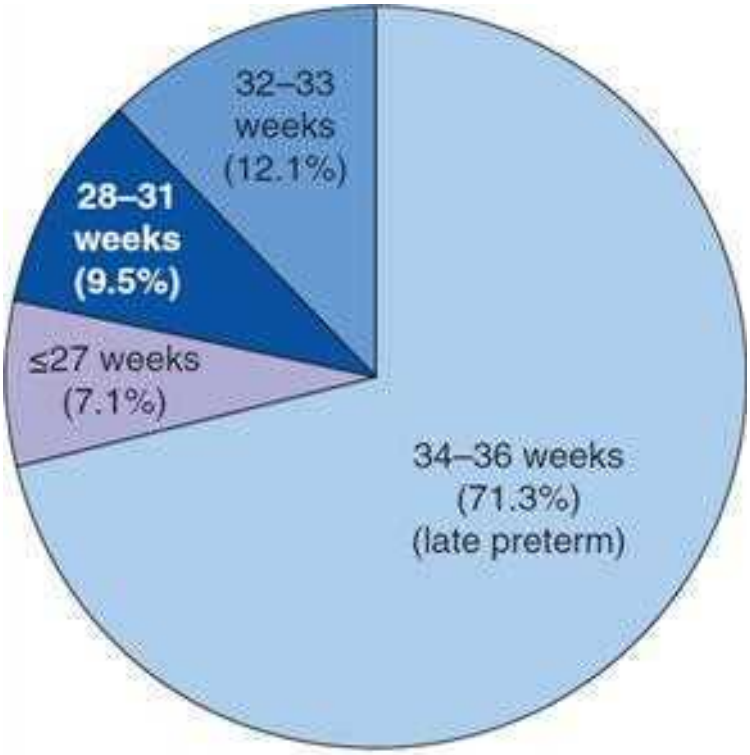
In our institution, traditional fetal indications for cesarean delivery are practiced in women at $25^{0/7}$ weeks or beyond. Cesarean delivery is not offered for fetal indications before $24^{0/7}$ weeks. At $24^{0/7}$ weeks, cesarean delivery is not offered unless fetal weight is estimated at 750 g or greater. Aggressive obstetrical management is practiced in cases of growth restriction, wherein gestational age is used to guide management rather than fetal size.

Late-Preterm Birth

Neonates born between 34 and 36 weeks account for more than 70 percent of all preterm births (Fig. 42-4). This group has been the fastest rising proportion of singleton preterm births in the United States (Raju, 2006). Nationally, the late-preterm birth rate rose from 6.82 percent to 6.87 percent from 2014 to 2015 (Martin, 2017).

FIGURE 42-4

Distribution of preterm births by gestational age in the United States in 2015. (Data from Martin JA, Hamilton BE, Osterman MJ: Births: final data for 2015. Natl Vital Stat Rep 66(1):1, 2017.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield, Williams Obstetrics, 25th Edition

To estimate the risks associated with late-preterm births, investigators analyzed neonatal mortality and morbidity rates at 34, 35, and 36 weeks compared with those of births at term between 1988 and 2005 at Parkland Hospital (McIntire, 2008). Approximately 3 percent of all births during the study period were between 24 and 32 weeks, and 9 percent were during the late-preterm weeks. Thus, and similar to the national rates, late-preterm births accounted for three fourths of all preterm births. Approximately 80 percent of these resulted from idiopathic spontaneous preterm labor or prematurely ruptured membranes (Fig. 42-5). Other obstetrical complications were implicated in the remaining 20 percent of cases. Rates of morbidity and mortality were greater in these late-preterm newborns compared with rates in term ones (Table 42-5 and Fig. 42-6). Similarly, Tomashek (2017) also reported higher neonatal mortality rates for late-preterm newborns. Rates of adverse neurodevelopment outcomes are also increased in these late-preterm infants (Petrini, 2009).

TABLE 42-5

Neonatal Morbidity Rates at Parkland Hospital in Live Births Delivered Late Preterm Compared with 39 Weeks

	Preterm Births			Term Births

Taken together, these findings suggest that a health-care focus on prematurity should include these late-preterm births. Moreover, approximately 80 percent of affected women begin labor spontaneously—similar to births before 34 weeks—and attempts to interrupt preterm labor have been insufficient (Institute of Medicine, 2007). Because of this, a national strategy aimed at prevention of late-preterm births is unlikely to provide discernible benefit without new developments in the prevention and management of preterm labor. In the meantime, the American College of Obstetricians and Gynecologists (2017c) emphasizes that *intentional* late-preterm delivery should occur only if an accepted maternal or fetal indication for delivery exists.

CAUSES OF PRETERM BIRTH

Four direct causes for preterm births in the United States include: (1) spontaneous unexplained preterm labor with intact membranes, (2) idiopathic preterm premature rupture of membranes (PPROM), (3) delivery for maternal or fetal indications, and (4) twins and higher-order multifetal births. Of

all preterm births, 30 to 35 percent are indicated, 40 to 45 percent are due to spontaneous preterm labor, and 30 to 35 percent follow preterm membrane rupture (Goldenberg, 2008). Indeed, much of the increase in the singleton preterm birth rate in the United States is explained by rising numbers of indicated preterm births (Ananth, 2005). Last, more than one of every two twins and more than nine of every ten triplets are born preterm or with low birthweight in the United States (Chap. 45, Unique Fetal Complications) (Martin, 2017).

Reasons for preterm birth have multiple, often interacting, antecedents and contributing factors (Esplin, 2016). This is particularly true for PPROM and spontaneous preterm labor.

Analogous to other complex disease processes, multiple coexistent genetic alterations and environmental factors may lead to preterm birth (Esplin, 2005; Velez, 2008; Ward, 2008). For example, inherited mutations in genes regulating collagen assembly may predispose to cervical insufficiency or prematurely ruptured membranes (Anum, 2009; Wang, 2006; Warren, 2007). And, whole blood gene expression and proteonomic biomarkers are now being used to help identify predictors of preterm birth (Cantonwine, 2016; Heng, 2016).

Spontaneous Preterm Labor

For both clinical and research purposes, pregnancies with spontaneous preterm labor yet intact fetal membranes must be distinguished from those complicated by preterm prematurely ruptured membranes. Even so, those with spontaneous preterm labor do not constitute a homogeneous group. Among the more common associated findings are multifetal pregnancy, intrauterine infection, bleeding, placental infarction, premature cervical dilation, cervical insufficiency, hydramnios, uterine fundal abnormalities, and fetal anomalies. Severe maternal illness from infections, autoimmune diseases, and gestational hypertension also raises preterm labor risks.

Despite their diversity, these processes culminate in a common end point—premature cervical dilation and effacement and premature activation of uterine contractions. Importantly, the actual process of preterm labor should be considered a final step stemming from progressive or acute changes that could be initiated days or even weeks before labor onset. Indeed, many forms of spontaneous preterm labor that result from premature initiation of phase 2 of parturition may be viewed in this light (Chap. 21, Phase 2: Preparation for Labor). Although the end result in preterm birth is the same as at term with cervical ripening and myometrial activation, recent studies in animal models support the idea that preterm birth is not always an acceleration of the normal process. Diverse pathways to instigate parturition exist and are dependent on the etiology of preterm birth. Four major causes include uterine distention, maternal–fetal stress, premature cervical changes, and infection.

Uterine Distention

Multifetal pregnancy and hydramnios are well-recognized risks for preterm birth. Early uterine distention likely acts to initiate expression of contraction-associated proteins (CAPs) in the myometrium. The CAP genes that are influenced by stretch include those coding for gap-junction proteins such as connexin 43, for oxytocin receptors, and for prostaglandin synthase (Korita, 2002; Lyall, 2002; Sooranna, 2004). More recent reports suggest that levels of gastrin-releasing peptides (GRPs) are increased with stretch to promote myometrial contractility. GRP antagonists can inhibit uterine contractility (Tattershell, 2012). Also, a stretch-induced potassium channel—TREK-1—is upregulated during gestation and downregulated in labor. This suggests a potential role in uterine relaxation during pregnancy (Buxton, 2010).

Excessive uterine stretch also leads to early activation of the placental–fetal endocrine cascade shown in Figure 21-10. The resultant early rise in maternal corticotropin-releasing hormone and estrogen levels can further enhance the expression of myometrial CAP genes (Warren, 1990; Wolfe, 1988). Finally, the influence of uterine stretch should be considered with regard to the cervix. Prematurely increased stretch and endocrine activity may initiate events that shift the timing of uterine activation, including premature cervical ripening.

Maternal–Fetal Stress

Stress is defined as a condition or adverse circumstance that disturbs the normal physiological or psychological functioning of an individual. Examples of stressors are nutrient restriction, obesity, infection, and diabetes. Psychological duress can include racial discrimination, childhood stress, depression, or posttraumatic stress syndrome (Gillespie, 2017; Goldstein, 2017; Shaw, 2017). A quantitative measure of “stress” is difficult. Yet, considerable evidence shows a correlation between some degree of maternal stress and adverse birth outcomes that include stillbirth, preterm birth, and abnormal fetal development (Hobel, 2003; Ruiz, 2003). Factors that activate this cascade likely are broad and influence the stress response.

One potential mechanism for stress-induced preterm birth is premature activation of the placental–adrenal endocrine axis. One trigger may be elevations in cortisol from maternal psychological stress (Lockwood, 1999; Petraglia, 2010; Wadhwa, 2001). Activation of this axis yields rising maternal serum levels of placental-derived corticotropin-releasing hormone (CRH). This raises adult and fetal adrenal steroid hormone production and promotes early loss of uterine quiescence (Fig. 21-10).

If preterm delivery is associated with early activation of the fetal adrenal–placental endocrine axis, maternal estrogen levels would likely be prematurely elevated. Indeed, an early rise in serum estriol concentrations is noted in women with subsequent preterm labor (Heine, 2000; McGregor, 1995). Physiologically, this premature rise in estrogen levels may alter myometrial quiescence and accelerate cervical ripening.

Another mechanism by which stress may translate to preterm birth is premature cellular senescence. As part of normal physiology, aging of fetal and decidual cells precipitates the release of uterotonic signals for uterine activation at term (Menon, 2014a). Animal studies supported by correlative studies in women demonstrate that accelerated senescence of the decidua results in preterm birth (Cha, 2013; Hirota, 2010). In addition, premature cellular senescence may contribute to PPROM (Menon, 2016).

Cervical Dysfunction

In most cases, premature cervical remodeling precedes premature labor onset. In some instances, cervical dysfunction of either the epithelia or stromal extracellular matrix is the underlying cause. For example, an intact cervical epithelial barrier is critical to prevent ascending infection. Disruption of this barrier, such as that in mice lacking the glycosaminoglycan hyaluronan, predisposes mice to ascending infection and preterm birth (Akgul, 2014). Interestingly, the enhanced risk of preterm birth from group B streptococcal colonization may be in part due to the bacteria's ability to secrete hyaluronidase. This enzyme degrades hyaluronic acid in the cervicovaginal epithelia to aid bacterial ascension (Vornhagen, 2017).

Second, the mechanical competence of the cervix can be reduced. For example, genetic mutations in components of collagen and elastic fibers or proteins required for their assembly are risk factors for cervical insufficiency, PPROM, and preterm birth (Anum, 2009; Nallasamy, 2017; Pyeritz, 2000).

Infection

A patent female reproductive tract, although essential for conception and delivery, is theoretically problematic during phase 1 of parturition. Bacteria can gain access to intrauterine tissues through: (1) transplacental transfer of maternal systemic infection, (2) retrograde flow of infection into the peritoneal cavity via the fallopian tubes, or (3) ascending infection with bacteria from the vagina and cervix. Because the lower pole of the fetal membrane–decidual junction is contiguous with the cervical canal orifice, this anatomical arrangement provides a passageway for microorganisms. Ascending infection is considered to be the most common entry route. Ascending microorganisms colonize the cervix, decidua, and possibly the membranes, where they then may enter the amnionic sac.

Intraamnionic infection as a primary cause of preterm labor in pregnancies with intact membranes accounts for 25 to 40 percent of preterm births (Goncalves, 2002; Iams, 1987). In some instances, histological evidence of inflammation is found in the fetal membranes, decidua, or umbilical cord. Other cases are deemed "subclinical." Current data suggest that microbial invasion of the reproductive tract is sufficient to induce infection-mediated preterm birth. Affected women are more likely to develop clinical chorioamnionitis and PPROM compared with women with sterile cultures. Moreover, their neonates are also more likely to have perinatal complications that include RDS, intraventricular hemorrhage, and necrotizing enterocolitis (Hitti, 2001). Although the clinical course is more severe when intraamnionic infection is obvious, inflammation in the absence of detectable intraamnionic microorganisms—termed *sterile intraamnionic inflammation*—is also a risk factor for an inflammatory response, described in the next section (Lee, 2007, 2008; Romero, 2014). In sum, the earlier the onset of preterm labor, the greater the likelihood of underlying infection (Goldenberg, 2000; Goncalves, 2002; Watts, 1992).

The incidence of culture-positive amnionic fluid collected by amniocentesis during spontaneous term labor is similar to that with preterm labor (Gomez, 1994; Romero, 1993). It has been suggested that at term, amnionic fluid is infiltrated by bacteria as a consequence of labor, whereas in preterm pregnancies, bacteria represent an inciting cause of labor. Thus, fetal infection, as defined by bacteria detected within the amnionic fluid, has both differing etiologies and consequences.

Despite these observations, considerable data associate chorioamnionitis with preterm labor (Goldenberg, 2002; Üstün, 2001). With chorioamnionitis, microbes may invade maternal tissue only and not amnionic fluid. Despite this, endotoxins can stimulate amnionic cells to secrete cytokines that enter amnionic fluid. This scenario may serve to explain the apparently contradictory observations concerning an association between amnionic fluid cytokines and preterm labor in cases in which microbes are not detected in the amnionic fluid.

Inflammatory Responses

Inflammatory responses drive the pathogenesis of infection-induced preterm labor. Lipopolysaccharide (LPS) or other toxins elaborated by bacteria are recognized by pattern-recognition receptors such as *toll-like receptors* (Janssens, 2003). These receptors are present on mononuclear phagocytes, decidual cells, cervical epithelia, and trophoblasts (Chuang, 2000; Gonzalez, 2007; Holmlund, 2002). Loss of specific toll-like receptors results in delayed parturition in mouse models (Montalbano, 2013). Instead, activation of toll-like receptors induces a signaling cascade that activates production of chemokines such as interleukin 8 (IL-8) and cytokines such as IL-1β. Activation also recruits immune cells into the reproductive tract. Cytokines are produced by immune cells and by cells within the cervix, decidua, membranes, or fetus itself.

LPS-induced production of IL-1β in turn promotes a series of responses that include: (1) increased synthesis of others, that is, IL-6, IL-8, and tumor-necrosis factor alpha (TNF-α); (2) proliferation, activation, and migration of leukocytes; (3) modifications in extracellular matrix proteins; and (4) mitogenic and cytotoxic effects such as fever and acute-phase response (El-Bastawissi, 2000). Also, in many tissues, including myometrium, decidua, and amnion, IL-1β promotes prostaglandin formation that induces cervical ripening and loss of myometrial quiescence (Casey, 1990; Challis, 2002; Keelan, 2003). The importance of prostaglandins to infection-mediated preterm birth is supported by the observation that prostaglandin inhibitors can reduce the rate of LPS-induced preterm birth in both the mouse and nonhuman primate (Gravett, 2007; Timmons, 2014). Inhibition of

cyclooxygenase-2 prevents inflammation-mediated preterm labor in the mouse. And, immunomodulators plus antibiotics delay preterm delivery after experimental intraamnionic infection in a nonhuman primate model.

Proteases such as matrix metalloproteinases (MMPs) are also induced by IL-1β and function to break down extracellular matrix components such as collagen or elastic fibers. This disrupts the structural integrity of fetal membranes and the cervix. Current evidence from animal and human studies suggests that many aspects of infection-mediated preterm birth differ from pathways that regulate term parturition (Hamilton, 2012; Holt, 2011; Shynlova, 2013a,b; Timmons, 2014).

Origin of Cytokines

Uterine cytokines are likely important for preterm labor. For example, it appears that cytokines produced in maternal decidua and myometrium will have effects on that side, whereas cytokines produced in the membranes or in cells within the amnionic fluid will not be transferred to maternal tissues. The transfer of cytokines such as IL-1β from decidua across the membranes into amnionic fluid, however, appears to be severely limited. Additionally, the human myometrium expresses chemokine receptors that decline during labor (Hua, 2013).

The requirement of leukocytes for initiation of term labor in women remains inconclusive. In general, resident and invading leukocytes produce the bulk of cytokines in cases of inflammation resulting from infection. Indeed, with infection, leukocytes—mainly neutrophils, macrophages, and T lymphocytes—infiltrate the cervix, lower uterine segment, fundus, and membranes at the time of labor. Invading leukocytes and certain parenchymal cells produce cytokines and appear to be the primary source of myometrial cytokines (Young, 2002). By contrast, in the decidua, both stromal cells and leukocytes likely contribute. In the cervix, glandular and surface epithelial cells appear to produce cytokines.

The presence of cytokines in amnionic fluid and their association with preterm labor is well documented. But, their exact cellular origin—with or without recoverable microorganisms—is not well defined. Amnionic fluid cytokines are most likely secreted by mononuclear phagocytes or neutrophils activated and recruited into the amnionic fluid. Thus, the amount of amnionic fluid IL-1β would be determined by the number of leukocytes recruited, their activational status, or the effect of amnionic fluid constituents on their IL-1β secretion rate.

Vaginal Microbiota

Factors that predispose to ascending infection and then preterm birth are a key focus of ongoing basic research. Mucosal immunity and barrier function of the cervicovaginal epithelia, the microbiota composition in the vaginal tract, and their interplay are a major topic (Smith, 2017). From animal studies, mucosal immunity of the lower reproductive tract can be disrupted by viral infection with a subsequent enhanced susceptibility to ascending bacterial infection (Racicot, 2013, 2017). Along with the ability of the cervicovaginal epithelia to respond to environmental insults, the composition of the microbe ecosystem in the vaginal tract may also determine susceptibility to ascending infection.

New technologies based on genomic analysis have shown that the nonpregnant vaginal tract hosts a complex microbial community (Gajer, 2012; White, 2011). Also described in Chapter 65 (Vaginitis), these community state types can differ widely among women who are all healthy. And, the vaginal microbiome changes during normal pregnancy (Aagaard, 2012; Stout, 2017). Namely, the diversity and richness of microbe populations are reduced during pregnancy and become more stable. Compared with nonpregnant controls, *Lactobacillus* species show an enhanced dominance. Some but not all studies report an increased population of certain microbes—for example, *Gardnerella vaginalis* and *Ureaplasma urealyticum*—in women with preterm birth (Donders, 2009; Nelson, 2014). However, differences in populations of pregnant women studied, in definitions of preterm birth, and in data analysis may complicate interpretation of these data.

Some specific microorganisms are detected more frequently than others in amnionic fluid of women with preterm labor (Gerber, 2003; Hillier, 1988; Yoon, 1998). These include *G vaginalis, Fusobacterium* species*, Mycoplasma hominis*, and *U urealyticum.* Their identification was interpreted by some as presumptive evidence that specific microorganisms are more commonly involved as pathogens in the induction of preterm labor. Another interpretation, however, is that given direct access to the membranes after cervical dilation, selected microorganisms, such as fusobacteria, are more capable of burrowing through these exposed tissues and will do so. Fusobacteria are found in the vaginal fluid of only 9 percent of women but in 28 percent of positive amnionic fluid cultures from pregnancies with preterm labor and intact membranes (Chaim, 1992).

Preterm Premature Rupture of Membranes

This term defines spontaneous rupture of the fetal membranes before 37 completed weeks and before labor onset (American College of Obstetricians and Gynecologists, 2016d). Such rupture likely has various causes, but intrauterine infection, oxidative stress-induced DNA damage, and premature cellular senescence are major predisposing events (Dutta, 2016; Gomez, 1997; Mercer, 2003). Associated risk factors include lower socioeconomic status, body mass index <19.8, nutritional deficiencies, and cigarette smoking. Women with PPROM carry an enhanced risk for recurrence during a subsequent pregnancy (Bloom, 2001). Despite these known risk factors, none is identified in most cases of preterm rupture.

Molecular Changes

Increased apoptosis or necroptosis of membrane cellular components and greater levels of specific proteases in membranes and amnionic fluid are related to PPROM. Most tensile strength of the membranes is provided by the amnionic extracellular matrix and interstitial amnionic collagens that

are produced in mesenchymal cells (Casey, 1996). Thus, collagen degradation has been a focus of research. The MMP family is involved with normal tissue remodeling and particularly with collagen degradation. Some members are found in higher concentrations in amnionic fluid from pregnancies with PPROM (Maymon, 2000; Park, 2003; Romero, 2002). MMP activity is in part regulated by tissue inhibitors of matrix metalloproteinases—TIMPs. Several of these inhibitors are found in lower concentrations in amnionic fluid from women with ruptured membranes. Elevated MMP levels found at a time when protease inhibitor expression declines further supports that their expression alters amnionic tensile strength.

Studies of amniochorion explants show greater MMP expression following treatment with certain cytokines (Fortunato, 1999a,b, 2002). With membrane rupture, thrombin activity rises, which activates MMPs and prostaglandin synthesis. Studies by Mogami (2013) provide a mechanism by which bacterial endotoxin or TNF-α elicits release of fetal fibronectin (fFN) by amnion epithelial cells. The fFN then binds toll-like receptor 4 in the amnion mesenchymal cells to activate signaling cascades. These result in augmented prostaglandin E (PGE_2) synthesis and elevated activity of MMPs.

Higher prostaglandin levels promote cervical ripening and uterine contractions. Greater MMP concentrations allow collagen breakdown in the fetal membranes resulting in premature rupture.

In pregnancies with PPROM, the amnion exhibits a higher degree of cell death and more apoptosis markers than that in term amnion (Arechavaleta-Velasco, 2002; Fortunato, 2003). In vitro studies indicate that apoptosis is likely regulated by bacterial endotoxin, IL-1β, and TNF-α. In addition, oxidative stress initiated by events other than infection can induce DNA damage, premature senescence, and subsequent inflammation and proteolysis that leads to PPROM (Menon, 2014a,b). Last, there are proteins involved in the synthesis of mature cross-linked collagen or matrix proteins that bind collagen and thereby promote tensile strength. These proteins are altered in membranes with premature rupture (Wang, 2006).

Infection

Several studies have investigated the incidence of infection-induced PPROM. Bacterial cultures of amnionic fluid support a role for infection in a significant proportion. One review of 18 studies and almost 1500 women with PPROM found that bacteria were isolated from amnionic fluid in a third of cases (Goncalves, 2002). Accordingly, some have given antimicrobial treatment to women in spontaneous preterm labor with intact membranes, however, results have been disappointing as discussed later in Antimicrobials (Kenyon, 2008b).

The inflammatory response that leads to membrane weakening and mediators of this process are currently areas of research. One goal is to identify early risk markers for PPROM.

Multifetal Pregnancy

Twins and higher-order multifetal births account for approximately 3 percent of neonates born in the United States (Martin, 2017). Preterm delivery continues to be the major cause of the excessive perinatal morbidity and mortality with multifetal pregnancies. The effects of uterine stretch discussed in Causes of Preterm Birth are obvious. Many of these interrelationships are discussed in Chapter 45 (Preterm Birth).

CONTRIBUTING FACTORS

Pregnancy Factors

Several genetic and environmental factors affect the frequency of preterm labor. Of these, threatened abortion in early pregnancy is associated with higher rates of later adverse outcomes. Weiss (2004) reported outcomes with vaginal bleeding at 6 to 13 weeks' gestation in nearly 14,000 women. Both light and heavy bleeding were associated with subsequent preterm labor, placental abruption, and pregnancy loss before 24 weeks.

Birth defects in the fetus may also predispose to preterm birth. In a secondary analysis of data from the First- and Second-Trimester Evaluation of Risk (FASTER) Trial, birth defects were associated with preterm birth and low birthweight neonates (Dolan, 2007).

Lifestyle Factors

Cigarette smoking, inadequate maternal weight gain, and illicit drug use affect the incidence and outcome of low-birthweight neonates (Chap. 44, Accelerated Lung Maturation). Extremes of maternal weight—both underweight and obese mothers—have an enhanced risk of preterm birth (Cnattingius, 2013; Girsen, 2016). Other maternal factors implicated include young or advanced maternal age, poverty, short stature, and vitamin C deficiency (Casanueva, 2005; Gielchinsky, 2002; Kramer, 1995; Leveno, 2009; Meis, 1995).

As discussed in Causes of Preterm Birth, psychological factors such as depression, anxiety, and chronic stress are associated with preterm birth (Hoffman, 2016; Venkatesh, 2016). In one review of more than 50 studies, Donovan and coworkers (2016) found a significant link between low birthweight and preterm birth in women injured by physical abuse (Chap. 47, Trauma).

Studies of work and physical activity related to preterm birth have yielded conflicting results (Goldenberg, 2008). Some evidence suggests that working long hours and hard physical labor are probably linked to a higher risk of preterm birth (Luke, 1995). However, aerobic exercise in normal-

weight women with uncomplicated singleton pregnancies appears to be safe and not associated with preterm birth (American College of Obstetricians and Gynecologists, 2017d; Di Mascio, 2016). One metaanalysis of physical activity found that leisure-time physical activity was associated with a reduced risk of preterm birth (Aune, 2017).

Genetic Factors

The recurrent, familial, and racial nature of preterm birth suggests that genetics may play a causal role. Accumulating literature on genetic variants buttresses this concept (Gibson, 2007; Hampton, 2006; Macones, 2004; Velez, 2009). Several such studies have also implicated immunoregulatory genes in potentiating chorioamnionitis in cases of preterm delivery due to infection (Varner, 2005).

Periodontal Disease

Gum inflammation is a chronic anaerobic inflammation that affects as many as 50 percent of pregnant women in the United States (Goepfert, 2004). Vergnes and Sixou (2007) performed a metaanalysis of 17 studies and concluded that periodontal disease was significantly associated with preterm birth. To better study this relationship, Michalowicz (2006) randomly assigned 813 pregnant women between 13 and 17 weeks' gestation who had periodontal disease to treatment during pregnancy or postpartum. Treatment during pregnancy improved periodontal disease and was safe. However, treatment failed to significantly alter preterm birth rates. This position was reaffirmed by a joint workshop of the European Federation of Periodontology and the American Academy of Periodontology (Sanz, 2013).

Interval between Pregnancies

The intervals between pregnancies are linked with adverse perinatal outcomes. In a metaanalysis, intervals <18 months and >59 months were associated with greater risks for both preterm birth and small-for-gestational age newborns (Conde-Agudelo, 2006). The causal effect of short interpregnancy intervals, however, has been questioned (Ball, 2014).

Prior Preterm Birth

The most important risk factor for preterm labor is a prior preterm delivery. Data from nearly 16,000 women delivered at Parkland Hospital are instructive. Namely, the recurrent preterm delivery risk for women with a preterm first delivery was threefold greater than that of women whose first neonate was born at term. More than a third of women whose first two newborns were preterm subsequently delivered a third preterm newborn. Most—70 percent—of the recurrent births in this study occurred within 2 weeks of the gestational age of the prior preterm delivery. The causes of prior preterm delivery also recurred. Although women with prior preterm births are clearly at risk for recurrence, they represented only 10 percent of the total preterm births in this study. Expressed another way, 90 percent of the preterm births at Parkland Hospital could not be predicted based on a history of preterm birth. Laughon and associates (2014) confirmed the importance of prior *spontaneous* preterm birth. Notably, these investigators also found that prior *indicated* preterm birth was strongly associated with subsequent spontaneous preterm birth. Variations in the definition of spontaneous and indicated used may explain this association.

Ultimately, risk of recurrent preterm birth is influenced by three factors: the frequency of prior preterm deliveries, severity as measured by gestational age, and the order in which the prior preterm delivery occurred (McManemy, 2007). That is, an individual woman's risk for recurrent preterm birth is influenced by her past number and sequence of preterm and term births. For example, a risk of recurrent preterm birth for a gravida 3 para 2 woman with a prior preterm birth followed by a term birth differs from a woman with a prior term birth followed by preterm birth. Thus, the influence of reproductive history has a profound prognostic significance for risk of recurrence. Moreover, this may also influence the supposed benefit attributed to various interventions described later.

Infection

Antibiotic Prophylaxis

As discussed in Cervical Dysfunction, a link between some cases of preterm birth and infection seems irrefutable (Goldenberg, 2008). In several studies, antimicrobial treatment has been given to prevent preterm labor thought to be due to microbial invasion. These strategies especially targeted *Mycoplasma* species. Morency and colleagues (2007) performed a metaanalysis of 61 articles and suggested that antimicrobials given in the second trimester may prevent subsequent preterm birth. Andrews and associates (2006) reported results of a randomized trial in which they gave a course of azithromycin plus metronidazole every 4 months to 241 nonpregnant women whose last pregnancy resulted in spontaneous delivery before 34 weeks. Approximately 80 percent of the women with subsequent pregnancies had received study drug within 6 months of their subsequent conception. Such interconceptional antimicrobial treatment did not reduce the rate of recurrent preterm birth. Using a subgroup analysis of these same women, Tita and coworkers (2007) concluded that such use of antimicrobials may be harmful. In another randomized study, 2661 women received placebo or metronidazole plus erythromycin between 20 and 24 weeks' gestation followed by ampicillin plus metronidazole during labor

(Goldenberg, 2006). This antimicrobial regimen did not reduce the rate of preterm birth or that of histological chorioamnionitis. At this time, antibiotic prophylaxis to prevent preterm birth is not recommended in women with preterm labor and intact membranes (Flenady, 2013).

Bacterial Vaginosis

In this condition, normal, hydrogen peroxide-producing, lactobacillus-predominant vaginal flora is replaced with anaerobes (Hillier, 1995; Nugent, 1991). Its diagnosis and management are discussed in Chapter 65 (Vaginitis). Using Gram staining, relative concentrations of the bacterial morphotypes characteristic of bacterial vaginosis are determined and graded by the *Nugent score* or assessed clinically with *Amsel criteria*.

Bacterial vaginosis has been associated with spontaneous abortion, preterm labor, PPROM, chorioamnionitis, and amnionic fluid infection (Hillier, 1995; Kurki, 1992; Leitich, 2003a,b). Environmental factors appear to be important in bacterial vaginosis development. Exposure to chronic stress, ethnic differences, and frequent or recent douching are associated with higher rates of the condition (Culhane, 2002; Ness, 2002). A gene-environment interaction has also been described (Macones, 2004). Women with bacterial vaginosis and a susceptible TNF-α genotype had a ninefold increased incidence of preterm birth.

From all of these studies, adverse vaginal flora seems associated with spontaneous preterm birth. Unfortunately, to date, screening and treatment have not prevented preterm birth. These are discussed further in Chapter 65 (Trichomoniasis). Indeed, microbial resistance or antimicrobial-induced change in the vaginal flora results from regimens intended to eliminate bacterial vaginosis (Beigi, 2004; Carey, 2005).

DIAGNOSIS

Symptoms

Early differentiation between true and false labor is difficult—especially before demonstrable cervical effacement and dilation. Uterine activity alone can be misleading because of *Braxton Hicks contractions*. These irregular, nonrhythmical contractions can cause considerable confusion in the diagnosis of true labor. Not infrequently, women who deliver before term have uterine activity that is attributed to Braxton Hicks contractions that prompt an incorrect diagnosis of false labor. Accordingly, the American College of Obstetricians and Gynecologists (2016b) defines preterm labor to be regular contractions before 37 weeks that are associated with cervical change.

In addition to contractions, pelvic pressure, menstrual-like cramps, watery vaginal discharge, and lower back pain have been empirically associated with impending preterm birth. Such complaints are thought by some to be common in normal pregnancy and are therefore often minimized by patients and obstetrical care providers.

The importance of these symptoms as a harbinger of labor has been emphasized by some but not all investigators (Iams, 1990; Kragt, 1990). Iams and coworkers (1994) found that the signs and symptoms signaling preterm labor, including uterine contractions, appeared only within 24 hours of preterm labor.

Chao (2011) prospectively studied 843 women with a singleton fetus who presented to Parkland Hospital with preterm labor symptoms between $24^{0/7}$ and $33^{6/7}$ weeks, intact membranes, and cervical dilation <2 cm. Those whose cervix remained <2 cm were sent home with a diagnosis of false preterm labor. When analyzed against the general obstetrical population, women sent home had a similar rate of birth before 34 weeks—2 versus 1 percent. However, these women did have significantly higher rates of birth between 34 and 36 weeks—5 percent compared with 2 percent. Women with cervical dilation of 1 cm at discharge were significantly more likely to deliver before 34 weeks compared with women without cervical dilation—5 percent versus 1 percent. Importantly, almost 90 percent of the 1-cm group delivered within 21 days of the initial presentation.

Cervical Change

Researchers have evaluated asymptomatic cervical changes that may predict preterm labor. Asymptomatic cervical dilation after midpregnancy is suspected to be a risk factor for preterm delivery, although some clinicians consider it to be a normal anatomical variant. Moreover, study results have suggested that parity alone is not sufficient to explain cervical dilation discovered early in the third trimester.

Cook (1996) longitudinally evaluated cervical status with transvaginal sonography between 18 and 30 weeks in nulliparas and multiparas who all subsequently gave birth at term. Cervical length and diameter were identical in both groups throughout these critical weeks. In a study from Parkland Hospital, routine digital cervical examinations were performed between 26 and 30 weeks in 185 asymptomatic women. Approximately 25 percent of women whose cervix was dilated 2 or 3 cm delivered before 34 weeks (Leveno, 1986a). Other investigators have verified cervical dilation as a predictor of increased preterm delivery risk (Copper, 1995).

Although women with dilation and effacement in the third trimester are at greater risk for preterm birth, detection does not necessarily improve pregnancy outcome. Buekens and associates (1994) randomly assigned 2719 women to undergo routine cervical examinations at each prenatal visit

and compared them with 2721 women in whom serial examinations were not performed. Knowledge of antenatal cervical dilation did not affect any pregnancy outcome related to preterm birth or the frequency of interventions for preterm labor. The investigators also reported that cervical examinations were not related to PPROM. Thus, it seems that prenatal cervical examinations in asymptomatic women are neither beneficial nor harmful.

Ambulatory Uterine Monitoring

An external tocodynamometer belted around the abdomen and connected to an electronic waist recorder allows a woman to ambulate while uterine activity is recorded. Results are transmitted via telephone daily. Women are educated concerning signs and symptoms of preterm labor, and clinicians are kept apprised of their progress. The 1985 approval of this monitor by the Food and Drug Administration (FDA) prompted its widespread clinical use. Subsequently, it was proven that the use of this expensive and time-consuming system does not reduce preterm birth rates (Collaborative Home Uterine Monitoring Study Group, 1995; Iams, 2002; Urquhart, 2017). Despite improvements in technology with the internet and cellular telephones, use of such monitoring is discouraged (American College of Obstetricians and Gynecologists, 2016c).

Fetal Fibronectin

This glycoprotein is produced in 20 different molecular forms by various cell types, including hepatocytes, fibroblasts, endothelial cells, and fetal amnion cells. Present in high concentrations in maternal blood and amnionic fluid, fFN is thought to function in intercellular adhesion during implantation and in maintenance of placental adherence to uterine decidua (Leeson, 1996). Detected in cervicovaginal secretions in women who have normal pregnancies with intact membranes at term, fFN appears to reflect stromal remodeling of the cervix before labor.

Lockwood (1991) reported that fFN detection in cervicovaginal secretions before membrane rupture was a possible marker for impending preterm labor. Qualitative and quantitative fFN levels are measured using enzyme-linked immunosorbent assays, and values exceeding 50 ng/mL are considered positive. Sample contamination by amnionic fluid and maternal blood should be avoided. Interventional studies based on the use of fFN screening in asymptomatic women have not demonstrated improved perinatal outcomes (Andrews, 2003; Esplin, 2017; Grobman, 2004). The American College of Obstetricians and Gynecologists (2016c) does not recommend screening with fFN tests. Its use in conjunction with cervical length measurement is discussed next.

Cervical Length Measurement

Progressively shorter cervical canals assessed sonographically are associated with increased rates of preterm birth (Iams, 1996). The technique to measure cervical length with sonography is described in Chapter 10 (Cervical Length Assessment). When performed by trained operators, cervical length analysis using transvaginal sonography is safe, highly reproducible, and more sensitive than transabdominal sonographic screening (American College of Obstetricians and Gynecologists, 2016c). The Society for Maternal-Fetal Medicine (2016b) has provided guidance for the performance of proper cervical length measurement. The Society recommends that sonographers and practitioners obtain specific training in the acquisition and interpretation of cervical length imaging through accreditation programs.

Transvaginal cervical sonography is not affected by maternal obesity, cervix position, or shadowing from the fetal presenting part. Because of the inability to easily distinguish the lower uterine segment from the cervix in early gestation, transvaginal cervical length assessment is typically performed after 16 weeks' gestation. Such interrogation is currently limited to singleton gestations and not recommended for multifetal gestations outside of research trials (American College of Obstetricians and Gynecologists, 2016c).

Indications for cervical length measurement are somewhat controversial. For those women with a history of prior spontaneous preterm birth, the Society for Maternal-Fetal Medicine (2016b) recommends transvaginal cervical length screening. But, the American College of Obstetricians and Gynecologists (2016c) only recommends *consideration* of screening for this indication. In women with singleton pregnancies but without a history of prior preterm birth, the Society for Maternal-Fetal Medicine (2016b) views cervical length screening as reasonable yet acknowledges that this remains an area of debate.

A first concern with screening surrounds the efficacy of interventions to improve perinatal outcomes once cervical length screening has isolated at-risk gravidas. Of interventions, cervical cerclage and administration of vaginal progesterone have both been evaluated. Vaginal progesterone for this indication is discussed in Progesterone Use without Prior Preterm Birth. For prophylactic cerclage in women with prior preterm births and shortened cervices, many studies have failed to show superior primary outcomes. But, piecemeal subgroup analyses from the trials have been subsequently used as the basis for recommendations in current practice guidelines regarding cervical length assessment and consideration for cerclage placement. A second concern is the accuracy and utility of the screening test, especially in low-risk women, who represent most of the population with preterm birth (Interval between Pregnancies).

To address this issue in low-risk women, Esplin and colleagues (2017) prospectively studied 9410 nulliparas with singleton pregnancies. Universal screening of sonographically measured cervical length and quantitative measurement of vaginal fFN levels were evaluated as predictors of women

who would spontaneously deliver before 37 weeks. These measures had poor predictive performance as a screening test. In fact, all screening modalities had relative low sensitivity and low positive-predictive values. Based on these findings, routine use of these screening tests in this low-risk population is not recommended. Bloom and Leveno (2017) subsequently critiqued the use of transvaginal cervical length screening in low-risk women and the promulgation of consensus guidelines. As described in Chapter 1 (Repeal and Replace), they highlighted the staggering costs encumbering the health-care system in the United States as a result of such strategies.

PRETERM BIRTH PREVENTION

Cervical Cerclage

Prevention of preterm birth remains an elusive goal. Still, recent reports suggest that prevention in selected populations may be achievable.

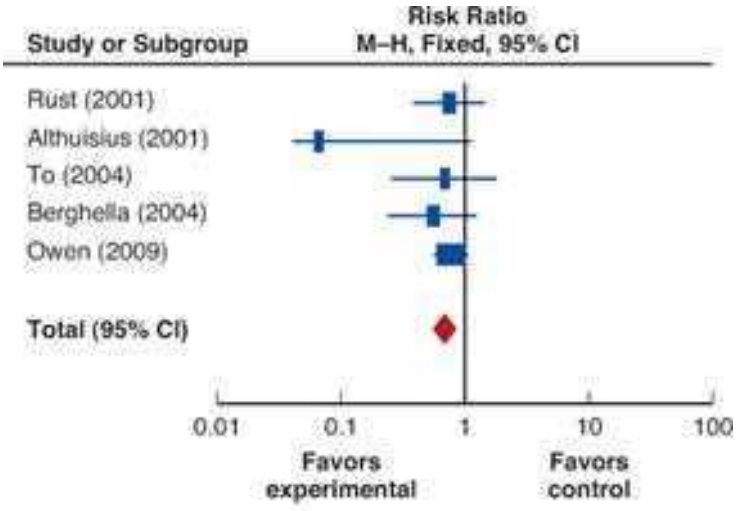
Of options, cerclage placement may be used to prevent preterm birth in at least three circumstances. First, the procedure may benefit women who have a history of recurrent midtrimester losses and who are diagnosed with cervical insufficiency. A second instance is the woman identified during sonographic examination to have a short cervix. The third indication is a "rescue" cerclage, done emergently when cervical incompetence is recognized in women with threatened preterm labor.

As is the case for virtually all obstetrical conditions, an accurate history is critical for management decisions. For recurrent abortion from cervical incompetence, historical clues are outlined in Chapter 18 (Management). For women with a short cervix incidentally detected by sonography, the benefit of cerclage placement appears directly related to whether the woman has a history of prior preterm birth. In those without a prior preterm birth, cerclage for a sonographically detected short cervix alone offers no advantage. To and associates (2004) screened 47,123 women and randomly assigned the 253 women with cervices <15 mm, with or without a history of preterm birth, to cerclage or no cerclage. The frequency of preterm delivery before 33 weeks did not differ significantly. In contrast, women with a sonographically diagnosed short cervix and a history of preterm birth may benefit. Owen and colleagues (2009) randomly assigned 302 women with prior preterm birth and with a short cervix—defined as length <25 mm—to cerclage or no procedure. The primary study outcome was not supported by the intervention. However, women with a cervical length <15 mm delivered before 35 weeks significantly less often following cerclage compared with women with no cerclage—30 versus 65 percent. This study suggested that recurrent preterm birth could be prevented in a subset of women with asymptomatic singleton gestations with both previous preterm birth and short cervical length.

These findings prompted a reassessment by Berghella and coworkers (2011), who performed a metaanalysis using individual patient data (Fig. 42-7). The primary outcomes from the included trials did not support cerclage placement. However, these investigators concluded that cerclage significantly prevented preterm birth and improved composite perinatal mortality and morbidity in women with prior spontaneous preterm birth, singleton gestation, and cervical length <25 mm.

FIGURE 42-7

Cerclage versus no cerclage for prevention of recurrent preterm birth in women with a cervical length <25 mm. Forest plot analysis of composite perinatal mortality and morbidity. CI = confidence index. (Adapted with permission from Berghella V, Rafael TJ, Szychowski JM, et al: Cerclage for short cervix on ultrasonography in women with singleton gestations and previous preterm birth: a meta-analysis, Obstet Gynecol 117(3):663, 2011.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

One caveat in the interpretation of this cerclage data is the influence of obstetrical history. For example, all of the trials comprising the metaanalysis included preterm birth as early as 16 to 17 weeks' gestation. Defining these early second trimester losses as preterm births, rather than cervical

incompetence, is problematic. Thus, it is difficult to distinguish whether these women were treated in the context of cervical incompetence or of preterm labor at 16 weeks. Nonetheless, based on these findings, the American College of Obstetricians and Gynecologists (2016c) concluded that in women with a singleton pregnancy, prior spontaneous preterm birth before 34 weeks, cervical length <25 mm, and gestational age <24 weeks, cerclage placement may be considered.

Prophylaxis with Progestogen Compounds

In most mammals, *progesterone withdrawal* is considered to be a parturition-triggering event. During human parturition, however, maternal, fetal, and amnionic fluid progesterone levels remain elevated. It has been proposed that human parturition involves functional progesterone withdrawal mediated by decreased activity of progesterone receptors (Chap. 21, Sex Steroid Hormone Role). It follows conceptually that the administration of progesterone may block preterm labor. This hypothesis has stimulated several studies of both 17-alpha hydroxyprogesterone caproate (17-OHP-C) and vaginally administered progesterone in women with varying risks for preterm birth.

At present, the reported benefits of either of these progestogen therapies are limited to women with singleton pregnancies. Progesterone prophylaxis specifically in multifetal gestations has not lowered preterm birth rates (Caritis, 2009; Rouse, 2007). Accordingly, both the American College of Obstetricians and Gynecologists (2016c) and the Society for Maternal-Fetal Medicine (2017a) approve the use of progestogen therapy for prevention of preterm birth in select women with singleton pregnancies. Criteria are a history of prior preterm birth or no prior preterm birth but a sonographically identified short cervix.

Prior Preterm Birth and Progestogen Compounds

17-OHP-C is a synthetic progestogen, and the first and only drug approved by the FDA for prevention of recurrent preterm birth. The approval in 2011 was supported by a study by the Maternal-Fetal Medicine Units (MFMU) Network (Meis, 2003). In this trial, 463 women with a prior preterm birth were randomly assigned to receive weekly intramuscular injections of inert oil or 17-OHP-C from 16 through 36 weeks' gestation. They reported a significantly reduced recurrence of preterm birth in 36 percent of women receiving 17-OHP-C compared with 55 percent of those given placebo.

This MFMU study has been challenged because of the unexpectedly high preterm delivery rate in the placebo arm (Romero, 2013). One explanation for this high rate in the placebo group was asymmetry in the risks of recurrence. Indeed, 41 percent of the control group had ≥2 prior preterm births compared with only 28 percent in the 17-OHP-C group. Another concern was that the injection dosage of 17-OHP-C, which was 250 mg weekly, was empirically chosen (Caritis, 2014). Only later reports described the pharmacokinetics of 17-OHP-C (Caritis, 2012). Nonetheless, the Society for Maternal-Fetal Medicine (2017a) recently reaffirmed the use of 17-OHP-C, rather than vaginal progesterone, for prevention of recurrent preterm birth.

Metabolism

Sharma and associates (2008) reported that the metabolism of 17-OHP-C was predominantly mediated by the CYP3A enzymatic system. Thus, other agents that induce or inhibit this enzymatic system as well as hepatic impairment may alter drug levels. They also showed that 17-OHP-C is not converted after administration to the primary progesterone metabolite, 17α-hydroxyprogesterone. The relative binding affinity of 17-OHP-C to progesterone receptors approximates only 30 percent of that by progesterone (Attardi, 2007). Because synthetic 17-OHP-C is not converted to a naturally occurring progestogen and is not superior to progesterone in eliciting a hormonal response via the classic steroid-receptor mediated pathway, alternative pathways are now being considered to explain its efficacy (Manuck, 2011).

Caritis and colleagues (2012) examined 61 women receiving 17-OHP-C therapy and found that the half-life was relatively long (median 16.2 days). Pharmacokinetic parameters were affected by maternal body habitus and varied widely between subjects. In addition, 17-OHP-C crossed the placental barrier and was detectible in cord plasma 44 days after the last maternal injection (Caritis, 2012). Despite this, evidence to date suggests that 17-OHP-C is safe for the fetus. No abnormalities, including abnormal genitalia, were found in a 48-month follow-up study of infants exposed in the 2003 MFMU Network trial (Northen, 2007).

Pricing Concerns

There are special concerns involving 17-OHP-C and subsequent price-gouging claims (Cohen, 2011; Romero, 2013). In 2011, the FDA gave temporary approval to KV Pharmaceutical to market 17-OHP-C under the brand name *Makena*. Because regulations prohibited compounding, there was no competitor for this relatively inexpensive drug, and *Makena* was priced at $1500 per injection. This caused widespread concern because the cumulative cost of *Makena* would be more than $30,000 per pregnancy.

Use of 17-OHP-C at Parkland Hospital

A program for implementation of 17-OHP-C was incorporated at Parkland Hospital in 2012. Given the concerns above, a local compounding pharmacy provided 250-mg, single-dose vials of 17-OHP-C in sesame oil at a cost of $25 per dose. Nelson and colleagues (2017) recently reported their findings

from this program in a prospective study of 430 women given compounded 17-OHP-C. Use of 17-OHP-C was ineffective for prevention of recurrent preterm birth at 35 weeks or less compared with a historical cohort from Parkland. As shown in Table 42-6, 17-OHP-C did not significantly reduce the rates of recurrent preterm birth regardless of prior preterm birth number or sequence. Moreover, plasma concentrations of 17-OHP-C were not different at 24 weeks or 32 weeks between women delivered ≤35 weeks and those delivered later. Interestingly, levels were consistent with those previously reported using castor oil as a vehicle (Caritis, 2014). Last, the gestational age interval at which preterm birth recurred did not differ after use of 17-OHP-C. A side effect of 17-OHP-C was a significant increase in the rate of gestational diabetes. Taken together, 17-OHP-C use was ineffective to prevent recurrent preterm birth and was associated with a significant side effect.

TABLE 42-6

Prior Obstetrical History of 430 Women with Births ≤35 weeks and Recurrence Rates After 17-OHP-C at Parkland Hospital

	No 17-OHP-C	17-OHP-C Treated			
Prior Birth <35 Weeks	Historical Cohort		Recurrence		
	Recurrence Rate[a]	No.	No.	Rate	*p* value[b]
Overall	16.8%	430	106	25%	1.0
Para 1	18%	141	44	31%	1.0
Para 2:					
Both ≤35 weeks	43%	48	20	42%	0.49
Only 2nd birth ≤35 weeks	17%	52	11	21%	0.84
Only 1st birth ≤35 weeks	11%	39	2	5%	0.18
Para 3+:					
All ≤35 weeks	45%	27	12	44%	0.56
Other sequences of ≤35 weeks	12%	123	17	14%	0.78

From the foregoing studies, evidence to support the use of 17-OHP-C to prevent recurrent preterm birth is problematic (Young, 2017). The mechanism of action remains unknown, and the pharmacological properties have yet to be established. Evidence of clinical effectiveness has yet to be replicated. A condition of the FDA approval for 17-OHP-C was that a confirmatory multicenter, double-blind randomized controlled trial be conducted with a preferred primary end point of delivery <35 weeks. This international trial—PROLONG—is currently underway with scheduled completion in 2018 and with an estimated enrollment of 1707 participants (PROLONG, 2014).

Progesterone Use without Prior Preterm Birth

Three randomized trials are at the center of whether progestogen therapy should be used in women without prior preterm births. These trials, shown in Table 42-7, hinge on sonographically determined cervical length. In the first trial, Fonseca and colleagues (2007) randomly assigned 250 women with short cervices measuring ≤15 mm identified during routine prenatal care. Women were given nightly 200-mg micronized progesterone vaginal capsules or placebo from 24 to 34 weeks' gestation. Spontaneous delivery <34 weeks was significantly reduced by progesterone therapy. Importantly, this trial included not only nulliparas but also those with twins or prior preterm birth.

TABLE 42-7

Randomized Trials of Progestogen Compounds Given Prophylactically to Prevent Preterm Labor

Investigator	Women Randomized	Cervical Length[a]	Progestogen Compound	Progestogen vs Placebo
Fonseca (2007)	n = 250; 5% nulliparous, 10% twins, 15% prior PTB; 8 hospitals: UK, Greece, Brazil, Chile	<15 mm	Progesterone, 200-mg vaginal capsules daily	Delivery <34 weeks: 19% vs 34%, $p = .02$
Hassan (2011)	n = 465; singletons only; 55% nulliparous; 13% prior PTB; 44 hospitals in 10 countries	10–20 mm	Progesterone, 90-mg vaginal gel daily	Delivery <33 weeks: 9% vs 16%, $p = .02$
Grobman (2012)	n = 657; singletons only; nulliparous only; 14 centers across US	<30 mm	17-OHP-C, 250 mg IM weekly	Delivery <37 weeks: 25% vs 24%, p = NS

[a]Determined sonographically.

17-OHP-C = 17-hydroxyprogesterone caproate; IM = intramuscularly; NS = nonsignificant; PTB = preterm birth; UK = United Kingdom; US = United States.

In the second trial, Hassan and coworkers (2011) randomly assigned 465 women with a short cervix—10 to 20 mm—to vaginal progesterone gel, 90 mg daily, or placebo. This trial also included nulliparas and women with prior preterm births.

From these studies, the FDA rejected progesterone gel for use because the results did not meet the level of statistical significance required to show efficacy in the subjects recruited in the United States. According to Likis and colleagues (2012), the heterogeneity of these first two studies that included women with varied indications for progestogen treatment, combined with the fact that outcomes were not reported by risk factors such as nulliparity, made it impossible to interpret the efficacy of progesterone for specific indications.

The third study randomly assigned administration of 17-OHP-C intramuscular injection or placebo between 16 and $22^{3/7}$ weeks to nulliparas with a singleton gestation and a cervical length <30 mm detected sonographically (Table 42-8) (Grobman, 2012). Treatment with 17-OHP-C given weekly did not reduce the frequency of preterm birth before 37 weeks. Regardless of cervical length, 17-OHP-C was ineffective.

TABLE 42-8

Comparison of 17-OHP-C versus Placebo to Prevent Preterm Birth at <37 and <34 Weeks

Variable	17-OHP-C N = 327	Placebo N = 330	RR (95% CI)	*p* value[a]
Preterm birth <37 wk:				
Cervical length, mm				.59
<10	5/9 (56)	10/16 (63)	0.89 (0.4–1.78)	
10–20	19/50 (38)	18/40 (45)	0.84 (0.52–1.38)	
>20	58/268 (21)	52/274 (19)	1.4 (0.82–1.52)	
Preterm birth <34 wk:

CI = confidence interval; RR = relative risk; 17-OHP-C = 17-hydroxyprogesterone caproate.

Data from Grobman, 2012.

Thus, vaginal progesterone, but not 17-OHP-C, appears to benefit women with a sonographically measured short cervix. Romero and Stanczyk (2013) provided a review to explain the conflicting evidence and argued that naturally occurring progesterone, which is used in the vaginal preparations, is not the same as synthetic 17-OHP-C. Likewise, Furcron and coworkers (2015) found that 17-OHP-C did not have local antiinflammatory effects at the maternal-fetal interface or cervix. Further, 17-OHP-C did not protect against endotoxin-induced preterm birth.

From all these studies, the American College of Obstetricians and Gynecologists (2016c) concluded that universal cervical length screening in women without a prior preterm birth is not mandatory. However, this screening strategy could be considered in the context of treatment with vaginal progesterone.

The OPPTIMUM Study

This study of 1228 high-risk women with singleton pregnancies is the largest to date for vaginal progesterone prophylaxis (Norman, 2016). This randomized trial of vaginal progesterone, 200 mg daily from 22–24 weeks to 34 weeks of gestation, was termed the OPPTIMUM study—*dOes Progesterone Prophylaxis To prevent preterm labor IMprove oUtcoMe?* High-risk women were defined as those with a prior spontaneous birth ≤34 weeks or with a cervical length ≤25 mm or a positive fFN test result combined with other clinical risk factors for preterm birth.

The primary outcomes of OPPTIMUM were unique in that both immediate obstetrical and childhood outcomes were examined. These were fetal death or birth <34 weeks; a composite of death, brain injury, or bronchopulmonary dysplasia; and a standardized cognitive score at 2 years of age. Contrary to earlier reports, vaginal progesterone was not associated with a lower risk of preterm birth or composite neonatal adverse outcomes. In children at 2 years of age, vaginal progesterone also had no long-term benefit or harm.

Thus, evidence is conflicting as to the efficacy of progestogens across the spectrum of the various specific indications. Some have attempted to resolve these issues through systematic review and metaanalysis (Prior, 2017; Romero, 2016, 2017). As outlined in this entire section, virtually all evidence supporting use of progestogens for a specific indication can be challenged in some way. We agree with the conclusions from the OPPTIMUM

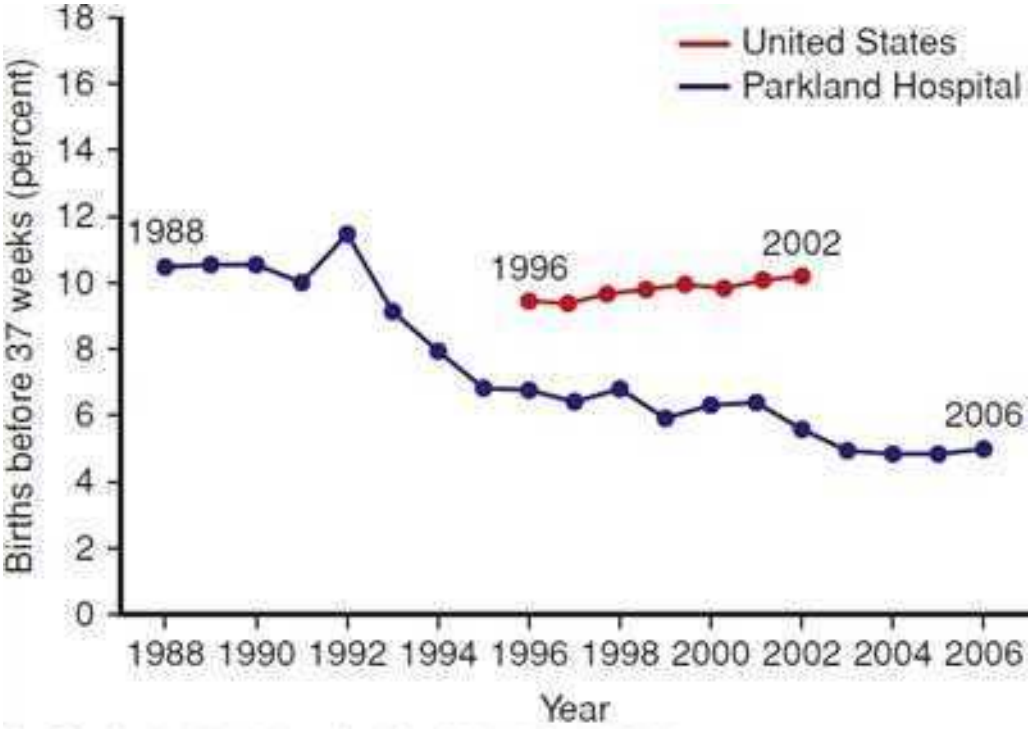
trial (Norman, 2016) that the results of recent studies should prompt a major review of progesterone use for preterm birth prophylaxis, a search to identify specific women who might specifically benefit, and a redoubling of efforts to find alternative strategies to prevent preterm birth in women at risk.

Geographic-Based Public Health-Care Programs

A well-organized prenatal system lowers the preterm birth rate in high-risk indigent populations (Creasy, 1980). One example is the Parkland Hospital prenatal clinic system (Leveno, 2009). As shown in Figure 42-8, the declining preterm birth rate between 1988 and 2006 coincided with a substantial rise in prenatal care attendance. In the early 1990s, a concerted effort was made to improve access to prenatal care by creating seamless care that began with antenatal enrollment and extended through delivery and the puerperium. Prenatal clinics were placed strategically throughout Dallas County to provide convenient access for our patients. Prenatal protocols are used by nurse practitioners at all clinic sites to guarantee homogeneous care. Women with high-risk pregnancy complications are referred to our hospital-based central clinic system. Here, Maternal-Fetal Medicine clinics operate each weekday and are staffed by residents and midwives and supervised by fellows and faculty.

FIGURE 42-8

Percentage of births before 37 weeks' gestation at Parkland Hospital from 1988 to 2006 compared with that in the United States from 1996 to 2002. Analysis in both cohorts was limited to singleton liveborn infants ≥500 g who received prenatal care. (Reproduced with permission from with permission from Leveno KJ, McIntire DD, Bloom SL, et al: Decreased preterm births in an inner-city public hospital, Obstet Gynecol. 2009 Mar;113(3):578–584.)



Thus, prenatal care is considered one component of a comprehensive and orchestrated public health-care system that is community-based. We believe that the drop in preterm births experienced at our inner-city hospital is at least partially attributable to a geographically based public health-care program specifically targeting minority populations of pregnant women. A similar obstetrical care system for indigent women at the University of Alabama at Birmingham has also produced salutary results (Tita, 2011).

MANAGEMENT OF PRETERM PREMATURE RUPTURE OF MEMBRANES

Methods used to diagnose ruptured membranes are detailed in Chapter 22 (Identification of Labor). A history of vaginal leakage of fluid, either as a continuous stream or a gush, should prompt a speculum examination to visualize gross vaginal pooling of amnionic fluid, clear fluid from the cervical canal, or both. Confirmation of PPROM is usually accompanied by sonographic examination to assess amnionic fluid volume, to identify the presenting part, and if not previously determined, to estimate gestational age. Once PPROM is identified, the general scheme shown in Table 42-9 can guide management.

TABLE 42-9

Management of Preterm Premature Rupture of Membranes

Gestational Age	Management
34 weeks or more	Plan delivery: labor induction unless contraindicated Group B streptococcal prophylaxis[a] Single corticosteroid course may be considered up to $36^{6/7}$ weeks[b]
32 weeks to 33 completed weeks	Expectant management Group B streptococcal prophylaxis[a] Single corticosteroid course[c] Antimicrobials to prolong latency
24 weeks to 31 completed weeks	Expectant management Group B streptococcal prophylaxis[a] Single corticosteroid course[c] Tocolytics: no consensus Antimicrobials to prolong latency Magnesium sulfate for neuroprotection may be considered[d]
<24 weeks	Expectant management or induction of labor[e] Group B streptococcal prophylaxis is not recommended[f] Single corticosteroid course may be considered[e,f] Tocolytics: no consensus[e,f] Antimicrobials: may be considered[e,g]

[a]Figure 64-7 outlines group B streptococcal prophylaxis for preterm gestations.

[b]May be considered between $34^{0/7}$ and $36^{6/7}$ weeks in those who have not received a previous course of antenatal corticosteroids.

[c]Repeat, or rescue, course of corticosteroids with preterm rupture of membranes is controversial.

[d]Magnesium sulfate for neuroprotection in accordance with one of the larger studies.

[e]See Periviable Neonatal Survival (Periviable Neonatal Survival) to aid patient counseling and decision making.

[f]Intervention not recommended before viability but may be considered as early as $23^{0/7}$ weeks of gestation.

[g]May be considered as early as $20^{0/7}$ weeks of gestation.

Data from American College of Obstetricians and Gynecologists 2016a, d, 2017a, e.

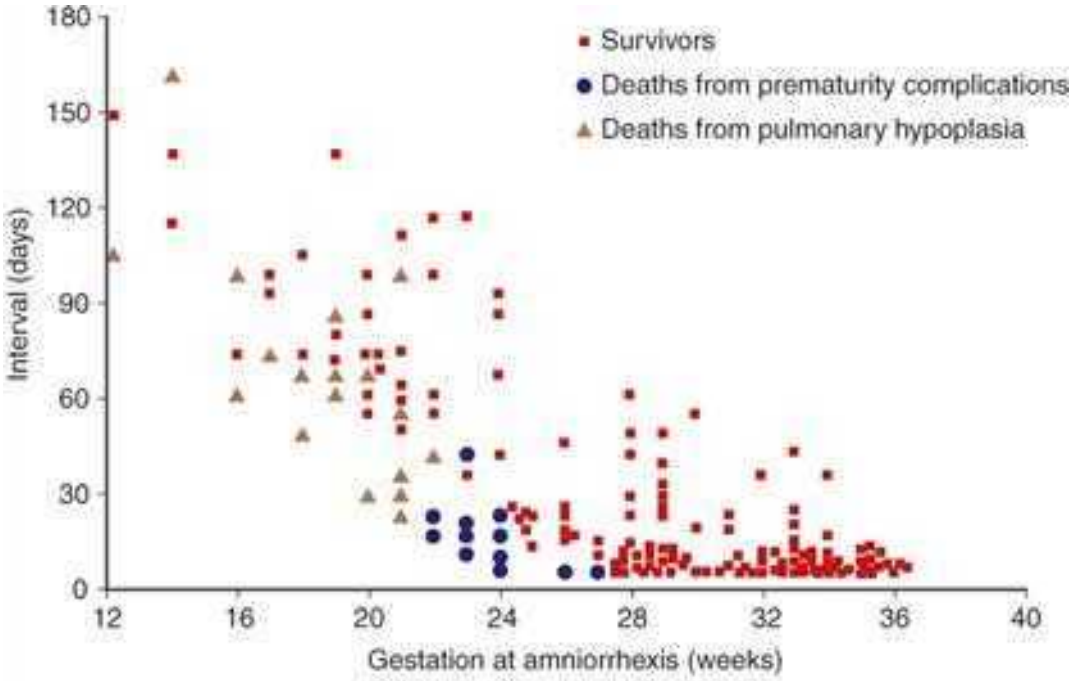
Natural History

Cox and associates (1988) described pregnancy outcomes of 298 consecutive women who gave birth following spontaneously ruptured membranes between 24 and 34 weeks' gestation at Parkland Hospital. Although this complication was identified in only 1.7 percent of pregnancies, it contributed to 20 percent of all perinatal deaths. By the time they presented, 76 percent of the women were already in labor, and 5 percent were delivered for other complications. Thus, only 19 percent initially were permitted expectant management. Ultimately, delivery was delayed 48 hours or more after membrane rupture in only 7 percent of the total study cohort. There was benefit noted from delayed delivery, however, as none of the neonates died in this group. This contrasted with a neonatal death rate of 80 per 1000 in preterm newborns delivered within 48 hours of membrane rupture. Nelson and colleagues later (1994) reported similar results.

The time from PPROM to delivery is inversely proportional to the gestational age when rupture occurs (Carroll, 1995). As shown in Figure 42-9, very few days are gained when membranes ruptured during the third trimester compared with midpregnancy.

FIGURE 42-9

Relationship of time between preterm membrane rupture and delivery in 172 singleton pregnancies. (Reproduced with permission from Carroll SG, Blott M, Nicolaides KH: Preterm prelabor amniorrhexis: Outcome of live births, Obstet Gynecol 1995 Jul;86(1):18–25.)



Hospitalization

Most clinicians hospitalize women with ruptured membranes. Concerns regarding the costs of lengthy hospitalizations are usually moot, because most women enter labor within a week or less after membrane rupture. Carlan and coworkers (1993) randomly assigned 67 women with ruptured membranes to home or hospital management. No benefits were found for hospitalization, and maternal hospital stays were reduced by 50 percent in those sent home—14 versus 7 days. Importantly, the investigators emphasized that this study was too small to conclude that home management was safe in regard to umbilical cord prolapse.

Intentional Delivery

Before the mid-1970s, labor was usually induced in women with preterm ruptured membranes because of fear of sepsis. Maternal infection risk and fetal prematurity risk vary according to the gestational age at membrane rupture, and management decisions hinge on this balance. With regard to periviable pregnancy, Morales (1993b) expectantly managed 94 singleton pregnancies with ruptured membranes before 25 weeks. The average time gained was 11 days. Although 41 percent of infants survived to age 1 year, only 27 percent of the original cohort were neurologically normal. Similar results were reported by Farooqi (1998) and Winn (2000) and their colleagues. Management of these early pregnancies is discussed in Late-Preterm Birth.

For PPROM in general, two randomized trials in the 1990s compared labor induction with expectant management (Cox, 1995; Mercer, 1993). In both of these studies, the balance of risk and benefit was difficult to ascertain, as neither immediate delivery nor expectant management were proven to be superior for neonatal outcomes. Lieman and associates (2005) found that neonatal outcomes did not improve with expectant management beyond 33 weeks. McElrath and coworkers (2003) found that prolonged latency after membrane rupture was not associated with a greater incidence of fetal neurological damage. An important correlate is that infection—specifically chorioamnionitis—is recognized as a risk factor for development of neonatal neurological injury (Gaudet, 2001; Wu, 2000).

Bond and colleagues (2017) recently compared planned early birth with expectant management for women with PPROM before 37 weeks' gestation. They evaluated 12 randomized trials totaling 3617 women and 3628 newborns. No clinically important differences in the incidence of neonatal sepsis between women who immediately delivered and those managed expectantly were identified. Although the incidence of chorioamnionitis was lower, neonates of women randomized to early birth were more likely to be born at an earlier gestational age and encountered attendant perinatal sequelae.

The authors concluded that in women with rupture of membranes before 37 weeks' gestation without contraindications to continuing the pregnancy, a policy of expectant management with careful monitoring was associated with better outcomes for both the mother and newborn.

The American College of Obstetricians and Gynecologists (2016d) has recognized the controversies of immediate delivery compared with expectant management. Clearly, gestational age is an important consideration. At $24^{0/7}$ to $33^{6/7}$ weeks, expectant management in the absence of nonreassuring fetal status, clinical chorioamnionitis, or placental abruption is recommended. At $34^{0/7}$ weeks of gestation or greater, delivery is still recommended by the College for all women with ruptured membranes. Our current practices at Parkland Hospital are consistent with these recommendations.

Considerations with Expectant Management

Several scenarios during expectant management merit consideration. One is performance of digital cervical examination. Alexander and colleagues (2000) analyzed findings in women with PPROM expectantly managed between 24 and 32 weeks' gestation. They compared those who had one or two digital cervical examinations with women who were not examined. Those who were examined had a rupture-to-delivery interval of 3 days compared with 5 days in those not examined. This difference did not worsen maternal or neonatal outcomes.

Rupture of membranes following second-trimester amniocentesis is uncommon (Chap. 14, Chorionic Villus Sampling). Compared with women with spontaneous rupture during the second trimester, Borgida and associates (2000) found that pregnancies complicated by PPROM after genetic amniocentesis resulted in significantly better perinatal outcomes. The perinatal survival rate was 91 percent. After counseling, affected women are typically managed expectantly as outpatients with serial surveillance of amnionic fluid volume (American College of Obstetricians and Gynecologists, 2016d). In the series cited above, the mean time to documentation of a normal amnionic fluid volume after amniocentesis approximated 2 weeks.

Tocolysis has been used in few studies. In women with ruptured membranes and lack of labor, prophylactic tocolysis does not improve neonatal outcomes but is associated with greater rates of chorioamnionitis (Mackeen, 2014). Similarly, therapeutic tocolysis—for those with ruptured membranes and labor—has also not provided significant perinatal benefit (Garite, 1987).

There is uncertainty regarding PPROM in the woman who has undergone cervical cerclage. McElrath and associates (2002) studied 114 women with a cerclage in place who later had ruptured membranes before 34 weeks. They were compared with 288 controls. Pregnancy outcomes were equivalent in both groups. Cerclage retention for more than 24 hours after preterm rupture of membranes may be associated with pregnancy prolongation, however, there is risk of intrauterine infection and its consequences (Giraldo-Isaza, 2011; Laskin, 2012). As discussed in Chapter 18 (Induced Abortion), such management is controversial.

With PPROM in general, the volume of amnionic fluid remaining after rupture appears to have prognostic importance in pregnancies before 26 weeks. Hadi and colleagues (1994) described 178 pregnancies with ruptured membranes between 20 and 25 weeks. Almost 40 percent developed oligohydramnios, defined by the absence of fluid pockets measuring 2 cm or more. Virtually all women with oligohydramnios delivered before 25 weeks, whereas 85 percent with adequate amnionic fluid volume were delivered in the third trimester. Carroll and coworkers (1995) observed no cases of pulmonary hypoplasia in fetuses born after membrane rupture at 24 weeks or beyond. This suggests that 23 weeks or less is the threshold for development of lung hypoplasia (Chap. 7, Respiratory System). Further, when contemplating early expectant management, consideration is also given to oligohydramnios and resultant limb compression deformities (Chap. 11, Management).

Other risk factors have also been evaluated. First, in neonates born to women with active herpetic lesions who were expectantly managed, the infectious morbidity risk appeared to be outweighed by risks associated with preterm delivery (Major, 2003). Second, Lewis and associates (2007) found that expectant management of women with PPROM and noncephalic presentation was associated with a higher rate of umbilical cord prolapse, especially before 26 weeks.

Clinical Chorioamnionitis

As discussed, infection is a major concern with membrane rupture. While some cases remain subclinical, if chorioamnionitis is diagnosed, prompt efforts to effect delivery, preferably vaginally, are initiated. Because maternal leukocytosis alone is not a consistent finding, *fever is the only reliable indicator for the diagnosis of chorioamnionitis*. Institutional practices and protocols vary in defining the temperature threshold. Traditionally, a temperature ≥38°C (100.4°F) accompanying ruptured membranes has implied infection. At Parkland Hospital, we still adhere to this criterion.

In 2015, a workshop sponsored by the NICHD was convened and suggested renaming this condition "intraamnionic infection and inflammation" (Higgins, 2016). The merits and clinical utility of this novel "triple I" terminology have been questioned (Barth, 2016). Nonetheless, the American College of Obstetricians and Gynecologists (2017b) recently revised both the definitions and temperature thresholds for intraamnionic infection. Using these new definitions, the diagnosis of suspected intraamniotic infection is made when the maternal temperature is ≥39.0°C or when the maternal temperature is 38.0 to 38.9°C and one additional clinical risk factor is present. Suggested factors include low parity, multiple digital examinations, use of internal uterine and fetal monitors, meconium-stained amnionic fluid, and the presence of certain genital tract pathogens.

Examples are group B streptococcus and sexually transmitted agents. Isolated maternal fever is defined as any maternal temperature between 38.0°C and 38.9°C with no additional risk factors present, and with or without persistent temperature elevation.

With chorioamnionitis, fetal and neonatal morbidity are substantively increased. Alexander and colleagues (1998) studied 1367 very-low-birthweight neonates delivered at Parkland Hospital. Approximately 7 percent were born to women with overt chorioamnionitis, and their outcomes were compared with similar newborns without clinical infection. Those in the infected group had higher incidences of sepsis, RDS, early-onset seizures, intraventricular hemorrhage, and periventricular leukomalacia. The investigators concluded that these very-low-birthweight newborns were vulnerable to neurological injury attributable to chorioamnionitis. Yoon and colleagues (2000) found that intraamnionic infection in preterm neonates was related to increased rates of cerebral palsy. Petrova and associates (2001) studied more than 11 million singleton live births in the United States from 1995 to 1997. During labor, 1.6 percent of all women had fever, and this was a strong predictor of infection-related death in both term and preterm neonates.

Antimicrobial Therapy

The proposed microbial pathogenesis for spontaneous preterm labor or ruptured membranes has prompted investigators to give various antimicrobials to forestall delivery. Mercer and associates (1995) reviewed 13 randomized trials performed before 35 weeks. Their metaanalysis indicated that only three of 10 outcomes were *possibly* benefited: (1) fewer women developed chorioamnionitis, (2) fewer newborns developed sepsis, and (3) pregnancy was more often prolonged 7 days in women given antimicrobials. Rates of neonatal survival, necrotizing enterocolitis, RDS, or intracranial hemorrhage, however, were unaffected.

To further address this issue, the MFMU Network designed a trial to study expectant management combined with placebo or with a 7-day antibiotic regimen. Treatment included intravenous ampicillin plus erythromycin every 6 hours for 48 hours, which was followed by oral amoxicillin plus erythromycin, every 8 hours for 5 days. The women had membrane rupture between 24 and 32 weeks' gestation. Neither tocolytics nor corticosteroids were given. Antimicrobial-treated women had significantly fewer newborns with RDS, necrotizing enterocolitis, and composite adverse outcomes (Mercer, 1997). The latency period was also significantly longer. Specifically, 50 percent of women given an antimicrobial regimen remained undelivered after 7 days of treatment compared with only 25 percent of those given placebo. Also, a significantly greater number of treated pregnancies were undelivered at 14 and 21 days. Cervicovaginal group B streptococcal colonization did not alter these results.

Other studies have examined the efficacy of shorter treatment lengths and different antimicrobial combinations. Three-day treatments compared with 7-day regimens using either ampicillin or ampicillin-sulbactam appear equally effective in regard to perinatal outcomes (Lewis, 2003; Segel, 2003). Similarly, erythromycin compared with placebo offered a range of significant neonatal benefits. The amoxicillin-clavulanate regimen was not recommended, however, because of its association with an increased incidence of neonatal necrotizing enterocolitis (Kenyon, 2004).

Some predicted that prolonged antimicrobial therapy in such pregnancies might have unwanted consequences (Carroll, 1996; Mercer, 1999). Stoll and associates (2002) studied 4337 neonates weighing from 400 to 1500 g and born from 1998 to 2000. Their outcomes were compared with those of 7606 neonates of similar birthweight born from 1991 to 1993 and prior to the practice of antibiotic prophylaxis. The overall rate of early-onset sepsis did not change between these two epochs. But, the rate of group B streptococcal sepsis dropped from 5.9 per 1000 births in the 1991 to 1993 group to 1.7 per 1000 births in the 1998 to 2000 group. Comparing these same epochs, the rate of *Escherichia coli* sepsis, however, rose from 3.2 to 6.8 per 1000 births. Almost 85 percent of coliform isolates from the more recent cohort were resistant to ampicillin. Neonates with early-onset sepsis were more likely to die, especially if they were infected with coliforms. Long term, Kenyon and coworkers (2008a) found that antimicrobials given for women with PPROM had no effect on the health of children at age 7 years.

Corticosteroids to Accelerate Fetal Lung Maturity

The use of antenatal corticosteroids in the setting of PPROM was once considered controversial as the magnitude of the benefits was not as great as when the membranes were intact. A single course of corticosteroids, however, is now recommended for pregnant women with ruptured membranes between $24^{0/7}$ and $34^{0/7}$ weeks' gestation (American College of Obstetricians and Gynecologists, 2017a). As with periviability (Late-Preterm Birth), a single course of corticosteroids as early as $23^{0/7}$ weeks in those who are at risk for preterm delivery within 7 days may be considered (American College of Obstetricians and Gynecologists, 2017e). A similar controversy is found at the other end of the gestational age spectrum, wherein corticosteroid administration in the late-preterm period is also under consideration (Corticosteroids for Fetal Lung Maturation).

Membrane Repair

Tissue sealants are used for various purposes in medicine, including achieving surgical hemostasis. As discussed in Chap. 18 (Inevitable Abortion), there are limited reports of sealants in the repair of fetal membranes. Crowley and coworkers (2016) recently reviewed the available evidence and concluded that data are currently insufficient to evaluate sealing procedures for ruptured membranes. At Parkland Hospital, we do not currently use these agents for this indication.

MANAGEMENT OF PRETERM LABOR WITH INTACT MEMBRANES

Women with signs and symptoms of preterm labor with intact membranes are managed similarly to those with PPROM. If possible, delivery before 34 weeks' gestation is delayed. Drugs used to abate or suppress preterm uterine contractions are subsequently discussed.

Amniocentesis to Detect Infection

Several tests have been used to diagnose intraamnionic infection (Andrews, 1995; Romero, 1993; Yoon, 1996). Although such infection can be confirmed with a positive test result, there is little utility for routine amniocentesis (American College of Obstetricians and Gynecologists (2017b).

Corticosteroids for Fetal Lung Maturation

Because glucocorticosteroids were found to accelerate lung maturation in preterm sheep fetuses, Liggins and Howie (1972) evaluated them to treat women. Corticosteroid therapy was effective in lowering the incidence of RDS and neonatal mortality rates if birth was delayed for at least 24 hours after *initiation* of betamethasone. Infants exposed to corticosteroids in these early studies have now been followed to age 31 years with no ill effects detected. In 1995, a National Institutes of Health (NIH) Consensus Development Conference panel recommended corticosteroids for fetal lung maturation in threatened preterm birth. In a subsequent meeting, another NIH Conference (2000) concluded that data were insufficient to assess corticosteroid effectiveness in pregnancies complicated by hypertension, diabetes, multifetal gestation, fetal-growth restriction, or fetal hydrops. It was concluded, however, that it was reasonable to administer corticosteroids to these women.

A recent metaanalysis by Roberts and associates (2017) of 30 studies totaling 7774 women and 8158 infants quantified the benefit of a single course of corticosteroids. Treatment was associated with lower rates of perinatal death, neonatal death, RDS, intraventricular hemorrhage, necrotizing enterocolitis, need for mechanical ventilation, and systemic infection in the first 48 hours of life. No obvious benefits were gained for chronic lung disease, death in childhood, or neurodevelopmental delay in childhood. Therapy was not associated with chorioamnionitis. Parenthetically, corticosteroids given prophylactically to women at risk of preterm birth in low- and middle-income countries actually *increase* perinatal mortality rates (Althabe, 2015).

A single course of corticosteroids is currently recommended by the American College of Obstetricians and Gynecologists (2017a) for women between 24 and 34 weeks who are at risk for delivery within 7 days. This recommendation for premature twins has been challenged (Viteri, 2016). Boundaries of gestational age for corticosteroid administration are also now being explored. For pregnancies at 23 weeks and at risk of delivery within 7 days, a single course of corticosteroids may be considered (Late-Preterm Birth). Administration of corticosteroids during the periviable period is linked to a family's decision regarding resuscitation and should be considered in that context (American College of Obstetricians and Gynecologists, 2017e).

Betamethasone and dexamethasone appear to be equivalent for fetal lung maturation (Murphy, 2007). These two drugs are comparable in reducing rates of major neonatal morbidities in preterm newborns (Elimian, 2007). A treatment course may be two 12-mg doses of betamethasone, and each dose is given intramuscularly 24 hours apart. With dexamethasone, 6-mg doses are given intramuscularly every 12 hours for four doses. Because treatment for less than 24 hours may be beneficial and reduce neonatal morbidity and mortality rates, a first dose of antenatal corticosteroids is administered regardless of the ability to complete additional doses before delivery (American College of Obstetricians and Gynecologists, 2017a).

Women at Risk for Late-Preterm Delivery

The MFMU Network conducted a randomized trial to assess whether administration of antenatal betamethasone to women who were likely to deliver in the late-preterm period would decrease respiratory and other neonatal complications (Gyamfi-Bannerman, 2016). Even though only 60 percent of the study cohort of 2831 women received both injections, the rate of respiratory complications measured as a composite outcome was lower with corticosteroid use compared with placebo—11.6 versus 14.4 percent. Because of these findings, *consideration* for administration of a single course of betamethasone for women between $34^{0/7}$ and $36^{6/7}$ weeks has been recommended by both the American College of Obstetricians and Gynecologists (2017a) and the Society for Maternal-Fetal Medicine (2016a).

Adoption of this practice has not been universal. Both short- and long-term neonatal safety are concerns (Crowther, 2016; Kamath-Rayne, 2016). Specifically, in the newborns receiving betamethasone, rates of hypoglycemia were significantly greater (Gyamfi-Bannerman, 2016). Neonatal hypoglycemia is particularly worrisome for possible adverse long-term consequences that include developmental delay (Kerstjens, 2012). Another caveat is that the largest effects of betamethasone included a reduction in transient tachypnea of the newborn—a self-limited condition with little clinical significance (Kamath-Rayne, 2016). Specifically, the rates of transient tachypnea of the newborn were 6.7 and 9.9 percent in those given betamethasone and placebo, respectively. These rates are three- to fourfold higher than those reported by the Consortium on Safe Labor (2010), which was a retrospective, observational study that abstracted detailed labor and delivery information from 19 hospitals across the United States on 233,844 deliveries. Because of these issues, we do not provide corticosteroids beyond 34 weeks at Parkland Hospital at this time.

Repeated Courses

Single versus additional courses of intramuscular corticosteroids for lung maturation has been the topic of two major trials. Although both found repeated courses to be beneficial in reducing neonatal respiratory morbidity rates, the long-term consequences were much different. In one randomized study by Crowther and associates (2007), all women at risk for preterm birth were given a primary course of betamethasone. Women were then given serial weekly doses of 11.4 mg of betamethasone for persistent risk or were given placebo. These investigators found no adverse effects in the infants followed to age 2 years. Wapner and coworkers (2007) studied infants born to 495 women who were randomly assigned to receive a single corticosteroid course that contained two doses or assigned to repeated courses that were given weekly. A nonsignificant rise in the cerebral palsy rate was identified in infants exposed to repeated courses. The doubled betamethasone dose in this study was worrisome because some experimental evidence supports the view that adverse effects are dose dependent (Bruschettini, 2006). Stiles (2007) summarized these two studies as "early gain, long-term questions." We agree, and at Parkland Hospital, we follow the recommendation by the American College of Obstetricians and Gynecologists (2017a) for single-course therapy.

Rescue Therapy

This refers to administration of a second corticosteroid dose when delivery becomes imminent and more than 7 days have elapsed since the initial dose. In one randomized trial, 326 women received placebo or a single 12-mg dose of betamethasone (Peltoniemi, 2007). Paradoxically, the rescue dose of betamethasone increased the risk of RDS. In another randomized study of 437 women with gestations <33 weeks, Garite and associates (2009) reported significantly lower rates of respiratory complications and neonatal composite morbidity with rescue corticosteroids versus placebo. Rates of perinatal mortality and other morbidities, however, did not differ. Last, McEvoy and colleagues (2010) found that treated infants had improved respiratory compliance.

Garite and coworkers (2009) randomly assigned 437 women with singletons or twins <33 weeks' gestation and with intact membranes to one rescue course of either betamethasone or dexamethasone or placebo. These women had all previously completed a single course of corticosteroids before 30 weeks' gestation and at least 14 days before the rescue course. RDS developed in 41 percent of the newborns given rescue corticosteroids compared with 62 percent of those randomized to placebo. Rates of other morbidities attributable to prematurity did not differ. In a metaanalysis, Crowther and colleagues (2011) concluded that a single course of corticosteroids should be considered in women whose prior course was administered at least 7 days previously and who were <34 weeks' gestation. The American College of Obstetricians and Gynecologists (2017a) has taken the position that a single rescue course of antenatal corticosteroids *be considered* in women before 34 weeks whose prior course was administered at least 7 days previously. Effects of rescue therapy beyond 34 weeks are currently unknown. At Parkland Hospital, we currently do not provide additional courses of corticosteroids beyond the initial single-course therapy.

Magnesium Sulfate for Neuroprotection

Very-low-birthweight neonates whose mothers were treated with magnesium sulfate for preterm labor or preeclampsia were found to have a reduced incidence of cerebral palsy at 3 years (Grether, 2000; Nelson, 1995). Because of this, randomized trials were designed to investigate this hypothesis. In one trial, 1063 women at risk of delivery before 30 weeks were given magnesium sulfate or placebo (Crowther, 2003). Magnesium exposure improved some perinatal outcomes. Namely, rates of both neonatal death and cerebral palsy were lower in the magnesium-treated group—but this study was not sufficiently powered. The multicenter French trial reported by Marret and associates (2008) had similar problems.

More convincing evidence for magnesium neuroprotection came from the MFMU Network study—*Beneficial Effects of Antenatal Magnesium Sulfate—BEAM—Study* (Rouse, 2008). This was a placebo-controlled trial in 2241 women at imminent risk for preterm birth between 24 and 31 weeks. Women randomized to magnesium sulfate were given a 6-g bolus over 20 to 30 minutes followed by a maintenance infusion of 2 g per hour. Magnesium sulfate was actually infusing at the time of delivery in approximately half of the treated women. A 2-year follow-up was available for 96 percent of the children. Results are shown in Table 42-10. This trial can be interpreted differently depending on statistical methodologies employed. Some interpret these findings to mean that magnesium infusion prevents cerebral palsy regardless of the gestational age at which therapy is given. Those with a differing view conclude that this trial only supports use of magnesium sulfate for prevention of cerebral palsy before 28 weeks.

TABLE 42-10

Magnesium Sulfate for the Prevention of Cerebral Palsy[a]

	Treatment		
Perinatal Outcome[a]	**Magnesium Sulfate No. (%)**	**Placebo No. (%)**	**Relative Risk (95% CI)**
Infants with 2-year follow-up	1041 (100)	1095 (100)	—
Fetal or infant death	99 (9.5)	93 (8.5)	1.12 (0.85–1.47)
Moderate or severe cerebral palsy:			
Overall	20/1041 (1.9)	3/1095 (3.4)	0.55 (0.32–0.95)
<28–31 weeks[b]	12/442 (2.7)	30/496 (6)	0.45 (0.23–0.87)
≥24–27 weeks[b]	8/599 (1.3)	8/599 (1.3)	1.00 (0.38–2.65)

[b]Weeks' gestation at randomization.

CI = confidence index.

Data from Rouse, 2008.

Subsequent to these studies, Doyle and associates (2009) reviewed five randomized trials to assess neuroprotective effects. A total of 6145 infants were studied, and these reviewers concluded that magnesium exposure compared with no exposure significantly lowered risks for cerebral palsy. Rates of other neonatal morbidity did not differ significantly. It was calculated that treatment given to 63 women would prevent one case of cerebral palsy.

Controversy surrounding magnesium efficacy for neuroprotection prompted a debate at the 2011 annual meeting of the Society for Maternal-Fetal Medicine. Rouse (2011) spoke for the benefits of magnesium sulfate, whereas Sibai (2011) challenged that the reported benefits were false positive due to random statistical error in the metaanalysis by Doyle (2009). Another peculiarity is the apparent lack of dose-response for efficacy (McPherson, 2014). Because none of the individual studies found a benefit from magnesium sulfate for fetal neuroprotection, the American College of Obstetricians and Gynecologists (2016a) concluded that those electing prophylaxis should develop specific guidelines. To guide such therapy, the American College of Obstetricians and Gynecologists (2012) issued a *Patient Safety Checklist* for use of magnesium sulfate for neuroprotection. For those with PPROM, prophylaxis may similarly be considered. At Parkland Hospital, we provide magnesium sulfate for neuroprotection with threatened preterm delivery from $24^{0/7}$ to $27^{6/7}$ weeks.

Antimicrobials

Results have been disappointing in studies of antimicrobials given to arrest preterm labor. From one Cochrane metaanalysis, antimicrobial prophylaxis given to women with intact membranes did not reduce preterm birth rates or affect other clinically important short-term outcomes (Flenady, 2013). However, rates of short- and longer-term harm were higher for children of mothers exposed to antibiotics. Kenyon (2001) reported the ORACLE Collaborative Group study of 6295 women with spontaneous preterm labor and intact membranes, but without evidence of infection. Women were randomly assigned to receive antimicrobial or placebo therapy. The primary outcomes of neonatal death, chronic lung disease, and major cerebral abnormality were similar in both groups. In a follow-up of the ORACLE II trial, fetal exposure to antimicrobials in this clinical setting was associated with an increased cerebral palsy rate at age 7 years compared with that in children without fetal exposure (Kenyon, 2008b). Importantly, antimicrobial use described here is distinct from that given for group B streptococcal prophylaxis (Chap. 64, Methicillin-Resistant Staphylococcus aureus).

Bed Rest

This is one of the most often prescribed interventions during pregnancy, yet one of the least studied. One systematic review concluded that evidence neither supported nor refuted bed rest for prevention of preterm birth (Sosa, 2004). Goulet and coworkers (2001) randomly assigned 250 Canadian women to either home care or hospitalization after treatment of an acute episode of preterm labor and found no benefits. There have, however, been reports of possible harm. Kovacevich and associates (2000) reported that bed rest for 3 days or more increased thromboembolic complications to 16 per 1000 women compared with only 1 per 1000 with normal ambulation. Promislow and colleagues (2004) observed significant bone loss in pregnant women prescribed outpatient bed rest. More recently, Grobman and associates (2013) noted that women with activity restriction were nearly 2.5 times more likely to have a preterm birth before 34 weeks. This finding, however, may reflect ascertainment bias. That is, women with restricted activity may have been assigned to bed rest because they were viewed to be at more imminent risk of preterm delivery. McCall and coworkers (2013) summarized the literature on bed rest, and they found insufficient evidence to support its use. The American College of Obstetricians and Gynecologists (2017d) suggests that, although frequently prescribed, bed rest is only rarely indicated, and ambulation should be considered in most cases.

Cervical Pessaries

Silicone rings, such as the *Arabin pessary*, are being used to support the cervix in women with a sonographically short cervix. For 385 Spanish women with a cervical length ≤25 mm, Goya and associates (2012) provided a silicone pessary or expectant management. Newborns spontaneous delivered before 34 weeks' gestation in 6 percent of women in the pessary group compared with 27 percent in the expectant management group. Another trial randomly assigned almost 100 women with a cervix <25 mm at 20 to 24 weeks to silicone pessaries or expectant management (Hui, 2013). The pessary did not lower the rate of delivery <34 weeks. Similar findings were reported by Nicolaides and colleagues (2016). The Society for Maternal-Fetal Medicine (2017b) recently recognized the conflicting published reports and lack of an FDA-approved pessary for the indication of preterm birth prevention. They currently recommend pessary prophylaxis only within research protocols.

Emergency or Rescue Cerclage

Some evidence supports the concept that cervical incompetence and preterm labor lie along a spectrum leading to preterm delivery. Consequently, investigators have evaluated cerclage placement after preterm labor begins to manifest clinically. Althuisius and colleagues (2003) randomly assigned 23 women with cervical incompetence before 27 weeks to bed rest, with or without emergency McDonald cerclage. Delivery delay was significantly greater in the cerclage group compared with those assigned to bed rest—54 versus 24 days, respectively. Terkildsen and coworkers (2003) studied 116 women who underwent second-trimester emergency cerclage. Nulliparity, membranes extending beyond the external cervical os, and cerclage before 22 weeks were associated with a significantly decreased chance of significant pregnancy continuation. For women facing a poor pregnancy prognosis due to cervical dilation at midgestation, it seems reasonable to offer emergency or rescue cerclage with appropriate counseling. However, it is unclear if such interventions truly confer a benefit or merely increase the risk of membrane rupture and infection (Hawkins, 2017).

Tocolysis to Treat Preterm Labor

Although several drugs and other interventions have been used to prevent or inhibit preterm labor, none is completely effective. The American College of Obstetricians and Gynecologists (2016b) has concluded that tocolytic agents do not markedly prolong gestation but may delay delivery in some women for up to 48 hours. This may allow transport to an obstetrical center with higher-level neonatal care and permit time for a course of corticosteroid therapy. Although delivery may be delayed to administer corticosteroids, treatment has not improved perinatal outcome rates (Gyetvai, 1999).

Beta-adrenergic agonists, magnesium sulfate, calcium-channel blockers, or indomethacin are the recommended tocolytic agents for this short-term use. The gestational age range for tocolytic use is debatable. But, because corticosteroids are not generally used after 34 weeks, and because the perinatal outcomes in preterm neonates are generally good after this time, most do not recommend use of tocolytics after 33 weeks' gestation (Goldenberg, 2002).

In many women, tocolytics stop contractions temporarily but rarely prevent preterm birth. The College (2016b) notes that maintenance therapy with tocolytics is ineffective for preventing preterm birth. Importantly, no trial has ever convincingly shown reductions in rates of any important adverse outcome by a tocolytic drug compared with placebo (Walker, 2016). Maintenance tocolysis after acute therapy is not recommended.

β-Adrenergic Receptor Agonists

Several compounds react with β-adrenergic receptors to reduce intracellular ionized calcium levels and prevent activation of myometrial contractile proteins (Chap. 21, G-Protein–Coupled Receptors). Of β-mimetic drugs in the United States, ritodrine and terbutaline have been used in obstetrics, but only ritodrine is approved for preterm labor by the FDA.

Ritodrine was voluntarily withdrawn from the United States market in 2003, but a discussion of ritodrine is included here to present issues with β-mimetic drug use. In one early trial, neonates whose mothers were treated with ritodrine for threatened preterm labor had lower rates of preterm

birth and its complications (Merkatz, 1980). In a randomized trial at Parkland Hospital, intravenous ritodrine delayed delivery for 24 hours but without other benefits (Leveno, 1986b). Additional studies confirmed a delivery delay up to 48 hours (Canadian Preterm Labor Investigators Group, 1992).

β-Agonist drug infusion has resulted in serious and even fatal maternal side effects. Pulmonary edema is a special concern, and its contribution to morbidity is discussed in Chapter 47 (Acute Pulmonary Edema). In one early study, tocolysis was the third most common cause of acute respiratory distress and death in pregnant women during a 14-year period in Mississippi (Perry, 1998). The cause of pulmonary edema is multifactorial. Risk factors include tocolytic therapy with β-agonist drugs, multifetal gestation, concurrent corticosteroid therapy, tocolysis for more than 24 hours, and intravenous infusion of large volumes of crystalloid. β-Agonist agents cause retention of sodium and water, and with time—usually 24 to 48 hours—these can cause volume overload (Hankins, 1988). The drugs have been implicated in increased capillary permeability, cardiac rhythm disturbances, and myocardial ischemia.

Terbutaline is commonly used in the United States to forestall preterm labor. Like ritodrine, it may cause pulmonary edema (Angel, 1988). Low-dose terbutaline can be administered long-term by subcutaneous pump (Lam, 1988; Perry, 1995). But, randomized trials have shown no benefit for terbutaline pump therapy (Guinn, 1998; Wenstrom, 1997). Oral terbutaline given to prevent preterm delivery is also ineffective (How, 1995; Parilla, 1993). In one trial, 203 women with arrested preterm labor at 24 to 34 weeks' gestation were randomly assigned to receive 5-mg terbutaline tablets or placebo every 4 hours (Lewis, 1996). Of outcomes, delivery rates at 1 week, median latency duration, mean gestational age at delivery, and incidence of preterm labor relapse were similar in both groups. Because of reports of serious maternal side effects, the FDA (2011) issued a warning regarding the use of terbutaline to treat preterm labor. The American College of Obstetricians and Gynecologists (2016b) recommends only short-term inpatient use of terbutaline as a tocolytic or as acute therapy of uterine tachysystole. Subcutaneous dosages of 0.25 mg are commonly used for the latter indication. Terbutaline, used as a tocolytic prior to external cephalic version, is discussed in Chapter 28 (Tocolysis).

Magnesium Sulfate

Ionic magnesium in a sufficiently high concentration can alter myometrial contractility. Its role is presumably that of a calcium antagonist, and when given in pharmacological doses, it may inhibit labor. Intravenous magnesium sulfate, given as a 4-g loading dose and followed by a continuous infusion of 2 g/hr, usually arrests labor (Steer, 1977). Like β-mimetic agents, magnesium treatment can cause pulmonary edema (Samol, 2005). However, this has not been our experience at Parkland Hospital in the treatment of tens of thousands of preeclamptic women with intravenous magnesium sulfate. Pharmacology and toxicology of magnesium are considered in more detail in Chapter 40 (Pharmacology and Toxicology).

Only two randomized studies have evaluated tocolysis with magnesium sulfate. Cotton and colleagues (1984) compared magnesium sulfate, ritodrine, and placebo in 54 women with preterm labor. They identified few differences in outcomes. Cox and coworkers (1990) randomly assigned 156 women to receive magnesium sulfate or infusions of normal saline. Magnesium-treated women and their neonates had identical outcomes compared with those given placebo. Because of these findings, this method of tocolysis was abandoned at Parkland Hospital. Similarly, Crowther and associates (2014) reviewed magnesium sulfate as a tocolytic agent and concluded it was ineffective and potentially harmful. Last, the FDA (2013) has warned against prolonged use of magnesium sulfate given to arrest preterm labor because of bone thinning and fractures in fetuses exposed for more than 5 to 7 days. This was attributed to low calcium levels in the fetus.

Prostaglandin Inhibitors

These compounds are intimately involved in contractions of normal labor (Chap. 21, Uterotonins in Parturition Phase 3). Antagonists act by inhibiting prostaglandin synthesis or by blocking their action on target organs. A group of enzymes collectively termed *prostaglandin synthase* is responsible for the conversion of free arachidonic acid to prostaglandins. Several drugs block this system, including acetylsalicylate and indomethacin.

Indomethacin, a nonselective cyclooxygenase inhibitor, was first used as a tocolytic in one study of 50 women (Zuckerman, 1974). Studies that followed reported the efficacy of indomethacin in halting contractions and delaying preterm birth (Muench, 2003; Niebyl, 1980). Morales and coworkers (1989, 1993a), however, compared indomethacin with either ritodrine or magnesium sulfate and found no difference in their efficacy to forestall preterm delivery. Berghella and associates (2006) reviewed four trials of indomethacin given to women with a sonographically determined short cervix and found such therapy to be ineffective.

Indomethacin is administered orally or rectally. Most studies have limited indomethacin use to 24 to 48 hours because of concerns for oligohydramnios, which can develop with therapeutic doses. If amnionic fluid is monitored, oligohydramnios can be detected early, and it is reversible with drug discontinuation.

In a study of neonates born before 30 weeks, Norton and coworkers (1993) identified necrotizing enterocolitis in 30 percent of 37 indomethacin-exposed newborns compared with 8 percent of 37 control newborns. Higher incidences of intraventricular hemorrhage and patent ductus arteriosus were also documented in the indomethacin group. Several investigators have challenged the association between indomethacin exposure and necrotizing enterocolitis (Muench, 2001; Parilla, 2000). Similarly, Gardner (1996) and Abbasi (2003) and their colleagues found no link between indomethacin use and intraventricular hemorrhage, patent ductus arteriosus, sepsis, necrotizing enterocolitis, or neonatal death. Two metaanalyses

of the effects of antenatal indomethacin on neonatal outcomes had conflicting findings (Amin, 2007; Loe, 2005). Reinebrant and colleagues (2015) in a review of 20 studies reported no clear benefit from cyclooxygenase inhibitors, including indomethacin, compared with placebo or any other tocolytic agent.

Nitric Oxide Donors

These potent smooth-muscle relaxants affect the vasculature, gut, and uterus. In randomized clinical trials, nitroglycerin administered orally, transdermally, or intravenously was ineffective or showed no superiority over other tocolytics. In addition, maternal hypotension was a common side effect (Bisits, 2004; El-Sayed, 1999; Lees, 1999).

Calcium-Channel Blockers

Discussed in Chapter 21 (Actin-Myosin Interactions), myometrial activity is directly related to cytoplasmic free calcium, and reduced calcium concentrations inhibit contractions. Calcium-channel blockers act to inhibit, by various mechanisms, calcium entry through cell membrane channels. Although they were developed to treat hypertension, their ability to arrest preterm labor has been evaluated.

From study results, calcium-channel blockers, especially nifedipine, are safer and more effective tocolytic agents than β-agonist drugs (King, 2003; Papatsonis, 1997). Lyell and colleagues (2007) randomized 192 women at 24 to 33 weeks' gestation to either magnesium sulfate or nifedipine and found no substantial differences in efficacy or adverse effects. In another randomized study, 145 women with preterm labor between 24 and 33 weeks received nifedipine or atosiban. Neither proved superior to delay delivery, and neonatal morbidity was equivalent (Salim, 2012).

Flenady and coworkers (2014b) reviewed 38 trials of calcium- channel blockers (mainly nifedipine) for preterm labor. These investigators suggested that calcium-channel blockers have benefits compared with placebo or no treatment. But, this conclusion stemmed from a trial with unclear risk of selection bias and a three-arm study of 84 women that was not blinded (Ara, 2008; Zhang, 2002). We are currently performing a randomized, double-blind, placebo-controlled trial of nifedipine for acute tocolysis of preterm labor at Parkland Hospital.

Importantly, the combination of nifedipine with magnesium for tocolysis is potentially dangerous. Ben-Ami (1994) and Kurtzman (1993) and their coworkers reported that nifedipine enhances the neuromuscular blocking effects of magnesium, which can interfere with pulmonary and cardiac function. In one small study of 54 women with preterm labor who received either magnesium sulfate plus nifedipine or no tocolytic, neither benefit nor harm was found (How, 2006).

Atosiban

This nonapeptide oxytocin analogue is an oxytocin-receptor antagonist (ORA). Goodwin and colleagues (1995) described its pharmacokinetics in pregnant women. In randomized clinical trials, atosiban failed to improve relevant neonatal outcomes and was linked with significant neonatal morbidity (Moutquin, 2000; Romero, 2000). The FDA has denied approval of atosiban because of concerns regarding efficacy and fetal–newborn safety. Further, in 2014, a metaanalysis did not demonstrate superiority of ORAs (largely atosiban) as a tocolytic compared with placebo, β-mimetic drugs, or calcium-channel blockers in terms of pregnancy prolongation or neonatal outcomes. But, ORAs were associated with fewer maternal adverse effects (Flenady, 2014a). Recently, van Vliet and coworkers (2016) conducted a randomized trial comparing nifedipine with atosiban in 510 women with threatened preterm birth. Using a composite of adverse perinatal outcomes, no differences were reported between the two study groups.

Labor

Whether preterm labor is induced or spontaneous, abnormalities of fetal heart rate and uterine contractions are sought. We prefer continuous electronic monitoring. Fetal tachycardia, especially with ruptured membranes, is suggestive of sepsis. Some evidence supports that intrapartum acidemia may intensify some of the neonatal complications usually attributed to preterm delivery. For example, Morgan and associates (2017) found that metabolic acidemia significantly raised the risks related to prematurity in neonates delivered prior to 34 weeks' gestation. Low and colleagues (1995) observed that intrapartum acidosis—umbilical artery blood pH <7.0—had an important role in neonatal complications (Chap. 33, Neonatal Encephalopathy). Group B streptococcal infections are common and dangerous in the preterm neonate, and antimicrobial prophylaxis should be provided (Chap. 64, Methicillin-Resistant Staphylococcus aureus).

Delivery

In the absence of a relaxed vaginal outlet, an episiotomy for delivery may be necessary once the fetal head reaches the perineum. Perinatal outcome data do not support routine episiotomy or forceps delivery to protect the "fragile" preterm fetal head. Staff proficient in resuscitative techniques commensurate with the gestational age and fully oriented to any specific problems should be present at delivery. Principles of resuscitation described in Chapter 32 (Resuscitation Protocol) are applicable. The importance of specialized personnel and facilities for preterm newborn care is underscored by the improved survival rates of these neonates when delivered in tertiary-care centers.

Prevention of Intracranial Hemorrhage

Preterm newborns frequently have intracranial germinal matrix bleeding that can extend to more serious intraventricular hemorrhage (Chap. 34, Retinopathy of Prematurity). It was hypothesized that cesarean delivery to obviate trauma from labor and vaginal delivery might prevent these complications. This has not been validated by subsequent studies. Malloy (1991) analyzed 1765 newborns with birthweights <1500 g and found that cesarean delivery did not lower the risk of mortality or intracranial hemorrhage. Anderson and colleagues (1988), however, made an interesting observation regarding the role of cesarean delivery in intracranial hemorrhage prevention. These hemorrhages correlated with exposure to active-phase labor. However, they emphasized that avoidance of active-phase labor is impossible in most preterm births because decisions for delivery route are not required until active labor is firmly established.

CHAPTER 43: Postterm Pregnancy

It must be admitted that the duration of pregnancy not infrequently exceeds 280 days from the last menstrual period, and that when it lasts much longer large children are developed, which are frequently delivered only after great difficulty. Thus, whenever the menstrual history of the patient indicates that she has passed much beyond the tenth and is approaching the eleventh lunar month, we should consider the propriety of the induction of labour, provided that examination shows the child is larger than usual.

—J. Whitridge Williams (1903)

INTRODUCTION

The above passage from Williams shows that pregnancies exceeding the expected normal length were problematic more than 100 years ago. These postterm pregnancies remain so today.

The adjectives *postterm, prolonged, postdates*, and *postmature* are often loosely used interchangeably to describe pregnancies that have exceeded a duration considered to be the upper limit of normal. We eschew use of the term *postdates* because the real issue in many postterm pregnancies is "post-*what* dates?" *Postmature* is reserved for the relatively uncommon specific clinical fetal syndrome in which the newborn has recognizable features indicating a pathologically prolonged pregnancy. Therefore, *postterm* or *prolonged pregnancy* is our preferred expression for an extended pregnancy.

The international definition of prolonged pregnancy, endorsed by the American College of Obstetricians and Gynecologists (2016b,d) is one that exceeds $42^{0/7}$ weeks, namely, 294 days or more from the first day of the last menstrual period. Importantly, this is 42 "completed weeks," as pregnancies between 41 weeks 1 day and 41 weeks 6 days, although in the 42nd week, do not complete 42 weeks until the seventh day has elapsed. The method that we use widely in this book is to divide the 42nd week into 7 days, that is, $42^{0/7}$ through $42^{6/7}$ weeks.

ESTIMATED GESTATIONAL AGE

The current definition of postterm pregnancy assumes that the last menses was followed by ovulation 2 weeks later. That said, some pregnancies may not actually be postterm. Instead, the calculation may reflect an error in gestational age estimation because of faulty menstrual date recall or delayed ovulation. Thus, the two categories of pregnancies that reach 42 completed weeks are those truly 40 weeks past conception and those of less-advanced gestation but with inaccurately estimated gestational age. Even with exactly recalled menstrual dates, there still is imprecision, and the American College of Obstetricians and Gynecologists (2016d, 2017b) considers first-trimester sonography to be the most accurate method to establish or confirm gestational age. Several clinical studies support this practice (Bennett, 2004; Blondel, 2002; Joseph, 2007).

INCIDENCE

Of the 3.93 million neonates born in the United States during 2015, 0.4 percent were delivered at 42 weeks or later (Martin, 2017). In the past, the proportion was much higher. This trend suggests earlier intervention, however, the added accuracy from earlier sonographic dating of gestational age is another factor.

To identify potential predisposing factors for postterm pregnancy, Olesen and associates (2006) analyzed various characteristics in the Danish Birth Cohort. Only prepregnancy body mass index (BMI) ≥25 and nulliparity were significantly associated with prolonged pregnancy. Mission (2015) and Arrowsmith (2011) and their coworkers also reported similar associations. In nulliparas, those whose cervical length at midpregnancy is longer, that is, in the third or fourth quartile, are twice as likely to deliver after 42 weeks (van der Ven, 2016).

The tendency for some mothers to have repeated postterm births suggests that some prolonged pregnancies are biologically determined. Oberg and colleagues (2013) reported that when mother and daughter had a prolonged pregnancy, the risk for the daughter to have a subsequent postterm pregnancy was significantly increased. Laursen and associates (2004) found that maternal, but not paternal, genes influenced prolonged pregnancy. As discussed in Chapter 5 (Placental Estriol Synthesis), rare fetal-placental factors that predispose to postterm pregnancy include anencephaly, adrenal hypoplasia, and X-linked placental sulfatase deficiency (Ayyavoo, 2014; MacDonald, 1965).

PERINATAL MORTALITY AND MORBIDITY

Rates of stillbirth, neonatal death, and infant morbidity all rise after the expected due date has passed. This is best seen when perinatal mortality rates are analyzed from times before widespread intervention for postterm pregnancies. In two large Swedish studies shown in Figure 43-1, after reaching a nadir at 39 to 40 weeks, the perinatal mortality rate rose as pregnancy duration exceeded 41 weeks. This trend is also reported for the United States (Cheng, 2008; MacDorman, 2009). As shown in Table 43-1, the major cause of death in these studies includes gestational hypertension, prolonged labor with cephalopelvic disproportion, birth injuries, and hypoxic-ischemic encephalopathy. Similar outcomes were reported by Olesen and colleagues (2003) in 78,022 women with postterm pregnancies delivered before routine labor induction was adopted in Denmark. Moster and associates (2010) found higher rates of cerebral palsy in postterm births, and Yang and coworkers (2010) reported lower intelligence quotient (IQ) scores at age 6.5 years in children born ≥42 weeks' gestation. Conversely, autism was not associated with postterm birth (Gardener, 2011).

TABLE 43-1

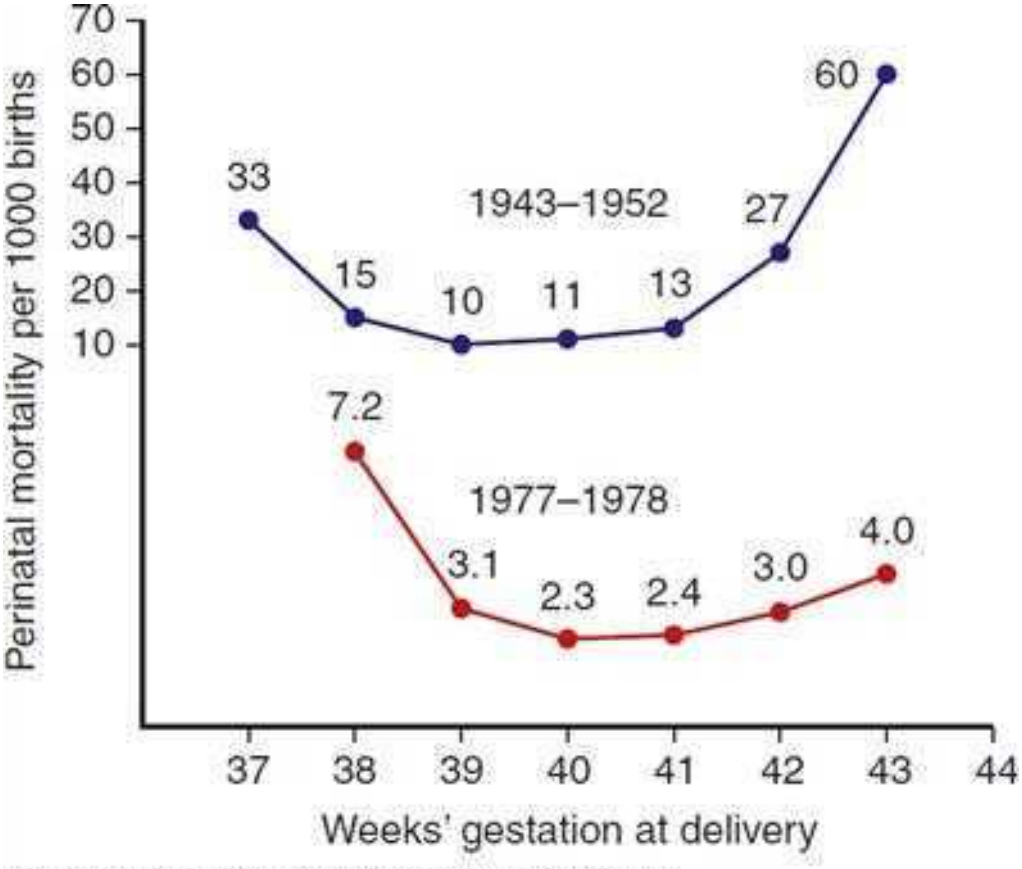
Adverse Maternal and Perinatal Outcomes Associated with Postterm Pregnancy

Maternal	Perinatal
Fetal macrosomia	Stillbirth
Oligohydramnios	Postmaturity syndrome
Preeclampsia	NICU admission
Cesarean delivery	Meconium aspiration
Dystocia	Neonatal convulsions
Fetal jeopardy	Hypoxic-ischemic encephalopathy
Shoulder dystocia	Birth injuries
Postpartum hemorrhage	Childhood obesity
Perineal lacerations	

NICU = neonatal intensive care unit.

FIGURE 43-1

Perinatal mortality rates in late pregnancy according to gestational age of all births in Sweden during 1943–1952 compared with those during 1977–1978. The partially compressed scale is used for convenience in depiction. (Adapted from Bakketeig, 1991; Lindell, 1956.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Alexander and colleagues (2000a) reviewed 56,317 consecutive singleton pregnancies delivered at ≥40 weeks between 1988 and 1998 at Parkland Hospital. Labor was induced in 35 percent of pregnancies completing 42 weeks. The rate of cesarean delivery for dystocia and fetal distress was significantly greater at 42 weeks compared with earlier deliveries. More newborns of postterm pregnancies were admitted to intensive care units. Importantly, the incidence of neonatal seizures and deaths was doubled at 42 weeks. Smith (2001) has challenged analyses such as these because the population at risk for perinatal mortality in a given week consists of all ongoing pregnancies rather than just the births in a given week. He calculated perinatal mortality rates calculated using only births in a given week of gestation from 37 to 43 completed weeks compared with the cumulative probability—the perinatal index—of death when all ongoing pregnancies are included in the denominator. Using this computation, delivery at 38 weeks had the lowest risk index for perinatal death.

PATHOPHYSIOLOGY

Postmaturity Syndrome

The postmature newborn is unique, and features include wrinkled, patchy, peeling skin; a long, thin body suggesting wasting; and advanced maturity in that the infant is open-eyed, unusually alert, and appears old and worried (Fig. 43-2). Skin wrinkling can be particularly prominent on the palms and soles. The nails are typically long. Most postmature neonates are not technically growth restricted because their birthweight seldom falls below the 10th percentile for gestational age (Chap. 44, Fetal-Growth Restriction). On the other hand, severe growth restriction—which logically must have preceded completion of 42 weeks—may be present.

FIGURE 43-2
Postmaturity syndrome. Neonate delivered at 43 weeks' gestation with thick, viscous meconium coating the desquamating skin. Note the long, thin appearance and wrinkling of the hands.

The incidence of postmaturity syndrome in newborns at 41, 42, or 43 weeks, respectively, has not been conclusively determined. From data, the syndrome complicates 10 to 20 percent of pregnancies at 42 completed weeks (American College of Obstetricians and Gynecologists, 2016d). Associated oligohydramnios substantially raises the likelihood of postmaturity. Trimmer and associates (1990) reported that 88 percent of fetuses were postmature if there was oligohydramnios defined by a sonographic maximal vertical amnionic fluid pocket that measured ≤1 cm at 42 weeks.

Placental Dysfunction

Many believe that postterm pregnancy is an abnormal state. Redman and Staff (2015) posit that limited placental capacity, which is characterized by dysfunctional syncytiotrophoblast, explains the greater risks of the postmaturity syndrome.

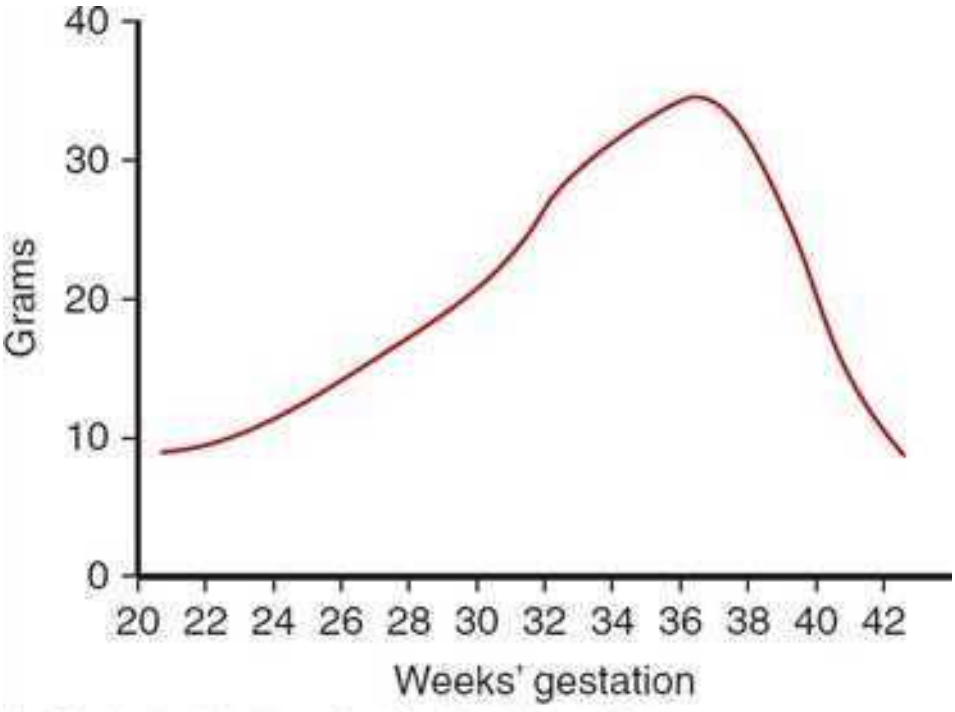
Clifford (1954) proposed that the associated skin changes were due to loss of the protective effects of vernix caseosa. He also attributed the postmaturity syndrome to placental senescence, although he did not find placental degeneration histologically. Still, the concept that postmaturity stems from placental insufficiency has persisted despite an absence of morphological or significant quantitative findings (Larsen, 1995; Redman, 2015; Rushton, 1991). There are findings that the rate of placental apoptosis—programmed cell death—is significantly greater at 41 to 42 completed weeks compared with that at 36 to 39 weeks (Smith, 1999). Several proapoptotic genes such as *kisspeptin* are upregulated in postterm placental explants compared with the same genes in term placental explants (Torricelli, 2012). The clinical significance of such apoptosis is currently unclear.

Jazayeri and coworkers (1998) investigated cord blood erythropoietin levels in 124 appropriately grown newborns delivered from 37 to 43 weeks. The only known stimulator of erythropoietin is decreased partial oxygen pressure. Thus, they sought to assess whether fetal oxygenation was compromised due to placental aging in postterm pregnancies. All women had an uncomplicated labor and delivery. These investigators found that cord blood erythropoietin levels were significantly higher in pregnancies reaching 41 weeks or more. Although Apgar scores and acid-base studies were normal, these researchers concluded that fetal oxygenation was decreased in some postterm gestations.

Another scenario is that the postterm fetus may continue to gain weight and thus be unusually large at birth. This at least suggests that placental function is not severely compromised. Indeed, continued fetal growth is the norm—albeit at a slower rate beginning at 37 completed weeks (Fig. 43-3). Nahum and colleagues (1995) confirmed that fetal growth continues until at least 42 weeks. However, Link and associates (2007) showed that umbilical blood flow did not increase concomitantly.

FIGURE 43-3

Mean daily fetal growth during previous week of gestation. (Redrawn from Hendricks CH: Patterns of fetal and placental growth: the second half of pregnancy. Obstet Gynecol 24:357, 1964.)



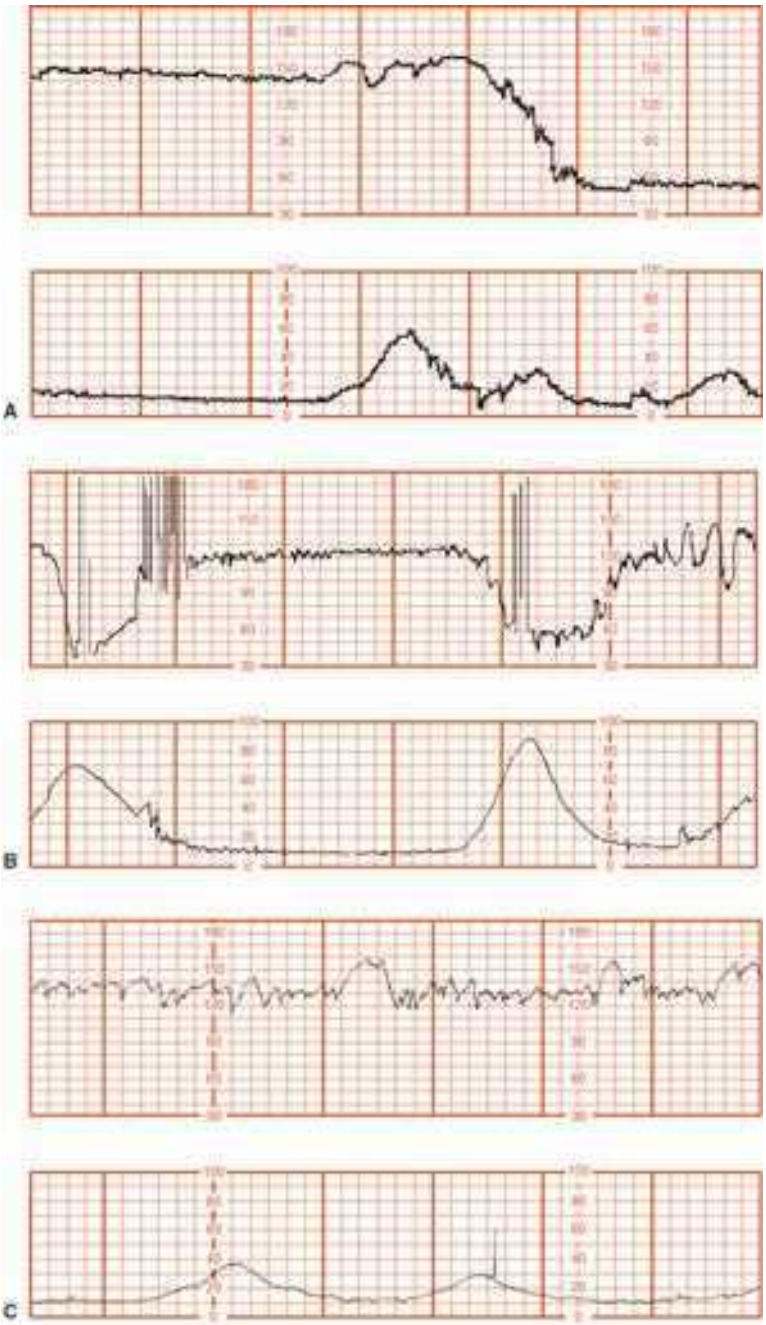
Fetal Distress and Oligohydramnios

The principal reasons for increased risks to postterm fetuses were described by Leveno and associates (1984). Both antepartum fetal jeopardy and intrapartum fetal distress were found to be the consequence of cord compression associated with oligohydramnios. In their analysis of 727 postterm pregnancies, intrapartum fetal distress detected with electronic monitoring was not associated with late decelerations characteristic of uteroplacental insufficiency. Instead, one or more prolonged decelerations such as shown in Figure 43-4 preceded three fourths of emergency cesarean deliveries for nonreassuring fetal heart rate tracings. In all but two cases, there were also variable decelerations. Another common fetal heart rate pattern, although not ominous by itself, was the saltatory baseline. As described in Chapter 24 (Prolonged Deceleration), these findings are consistent with cord occlusion as the proximate cause of the nonreassuring tracings. Other correlates included oligohydramnios and viscous meconium. Schaffer and

colleagues (2005) implicated a nuchal cord in abnormal intrapartum fetal heart rate patterns, meconium, and compromised newborn condition in prolonged pregnancies.

FIGURE 43-4

A. Prolonged fetal heart rate deceleration before emergency cesarean delivery in a postterm pregnancy with oligohydramnios. **B.** Severe—less than 70 bpm for 60 seconds or longer—variable decelerations in a postterm pregnancy with oligohydramnios. **C.** Saltatory baseline fetal heart rate showing oscillations exceeding 20 bpm and associated with oligohydramnios in a postterm pregnancy. (Reproduced with permission from Leveno KJ, Quirk JG, Cunningham FG, et al: Prolonged pregnancy, I. Observations concerning the causes of fetal distress, Am J Obstet Gynecol. 1984 Nov 1;150(5 Pt 1):465–473.)



The volume of amnionic fluid normally continues to decline after 38 weeks and may become problematic. Moreover, meconium release into an already reduced amnionic fluid volume results in thick, viscous meconium that may cause *meconium aspiration syndrome* (Chap. 33, Neonatal Encephalopathy and Cerebral Palsy).

Trimmer and coworkers (1990) sonographically measured hourly fetal urine production using sequential bladder volume measurements in 38 postterm pregnancies. Diminished urine production was found to be associated with oligohydramnios. They hypothesized that decreased fetal urine flow was likely the result of preexisting oligohydramnios that limited fetal swallowing. Oz and associates (2002), using Doppler waveforms, concluded

that fetal renal blood flow is reduced in those postterm pregnancies complicated by oligohydramnios. As a possible cause, again, the study by Link and associates (2007) showed that umbilical blood flow did not increase past term.

Fetal-Growth Restriction

In the late 1990s, the clinical significance of fetal-growth restriction in the otherwise uncomplicated pregnancy became more fully appreciated. Divon (1998) and Clausson (1999) and their coworkers analyzed births between 1991 and 1995 in the National Swedish Medical Birth Registry. Stillbirths were more common among growth-restricted newborns who were delivered after 42 weeks. Indeed, a third of postterm stillborn neonates were growth restricted. During this time in Sweden, labor induction and antenatal fetal testing usually commenced at 42 weeks. In a study from Parkland Hospital, Alexander and colleagues (2000d) analyzed outcomes for 355 neonates from pregnancies ≥42 weeks and whose birthweights were <3rd percentile. They compared these with outcomes of 14,520 similarly aged newborns above the 3rd percentile and found that morbidity and mortality rates were significantly increased in the growth-restricted neonates. Notably, a fourth of all stillbirths associated with prolonged pregnancy were in this comparatively small number of growth-restricted fetuses.

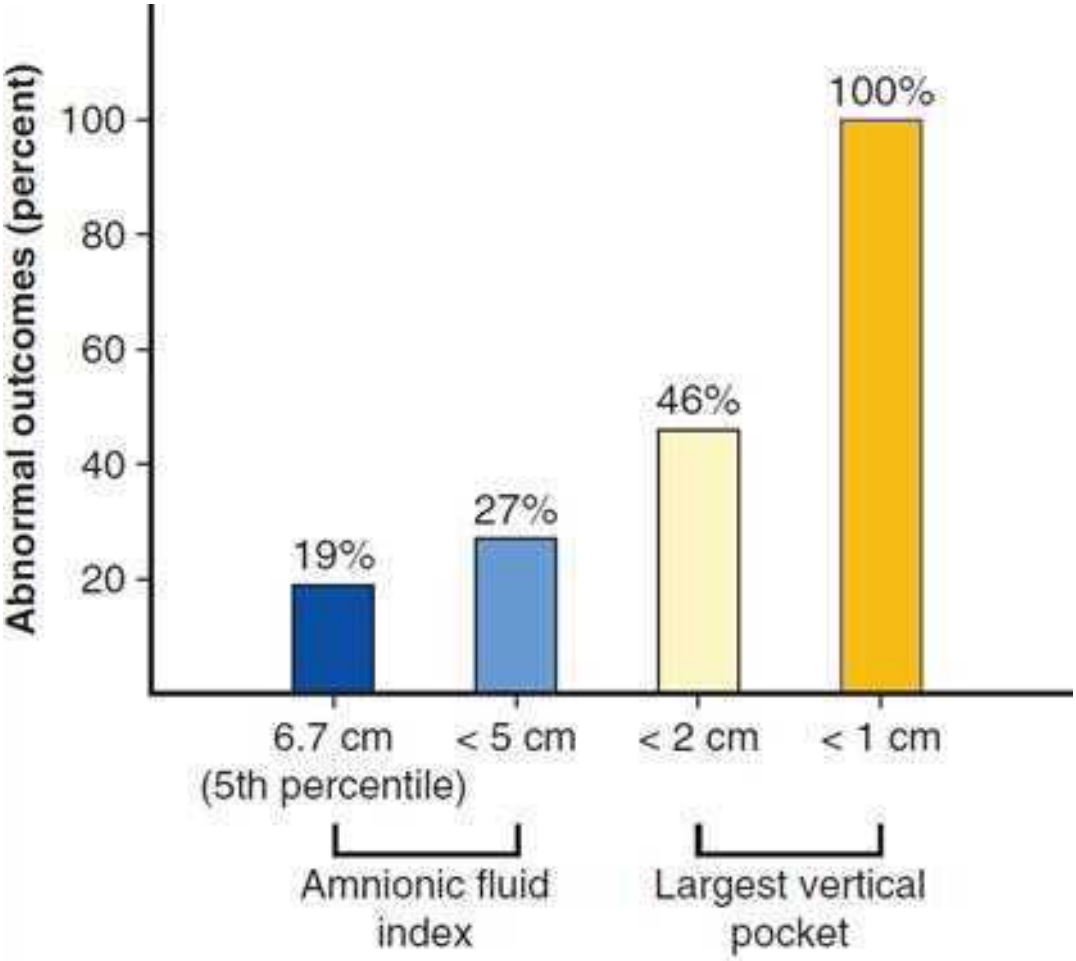
COMPLICATIONS

In the event of a medical or other obstetrical complication, it is generally not recommended that a pregnancy be allowed to continue past 42 weeks. Indeed, in many such instances, *earlier* delivery is indicated. Common examples include gestational hypertensive disorders, prior cesarean delivery, and diabetes. Other clinically important factors include amnionic fluid volume and potential fetal macrosomia.

Oligohydramnios

Most clinical studies support the view that diminished amnionic fluid determined by various sonographic methods identifies a postterm fetus with increased risks. Indeed, decreased amnionic fluid in any pregnancy signifies increased fetal risk (Chap. 11, Pregnancy Outcomes). Unfortunately, lack of an exact method to define “decreased amnionic fluid” has limited investigators, and many different criteria for sonographic diagnosis have been proposed. Fischer and colleagues (1993) attempted to determine which criteria were most predictive of normal versus abnormal outcomes in postterm pregnancies. As shown in Figure 43-5, the smaller the amnionic fluid pocket, the greater the likelihood that there was clinically significant oligohydramnios. Importantly, normal amnionic fluid volume did not preclude abnormal outcomes. Alfirevic and coworkers (1997) randomly assigned 500 women with postterm pregnancies to assessment using either the amnionic fluid index (AFI) or the deepest vertical pocket described in Chapter 11 (Measurement). They concluded that the AFI overestimated the number of abnormal outcomes in postterm pregnancies.

FIGURE 43-5
Comparison of the prognostic value of various sonographic estimates of amnionic fluid volume in prolonged pregnancies. Abnormal outcomes include cesarean or operative vaginal delivery for fetal jeopardy, 5-minute Apgar score ≤6, umbilical arterial blood pH <7.1, or admission to the neonatal intensive care unit. (Redrawn from Fischer RL, McDonnell M, Bianculli KW, et al: Amniotic fluid volume estimation in the postdate pregnancy: a comparison of techniques. Obstet Gynecol 81:698, 1993.)



Regardless of the criteria used to diagnose oligohydramnios in postterm pregnancies, most investigators have found a higher incidence of some measure of "fetal distress" during labor. Thus, oligohydramnios by most definitions is a clinically meaningful finding. Conversely, reassurance of continued fetal well-being in the presence of "normal" amnionic fluid volume is tenuous. This may be related to how quickly pathological oligohydramnios develops. Although such cases are unusual, Clement and coworkers (1987) described six postterm pregnancies in which amnionic fluid volume diminished abruptly over 24 hours, and in one of these, the fetus died.

Macrosomia

The velocity of fetal weight gain peaks at approximately 37 weeks (see Fig. 43-3). Although growth velocity slows at that time, most fetuses continue to gain weight. For example, the percentage of fetuses born in 2009 whose birthweight exceeded 4000 g was 8.2 percent at 37 to 41 weeks and increased to 11.0 percent at 42 weeks or more (Martin, 2011). According to Duryea and associates (2014), the 95th percentile at 42 weeks is 4475 g. Even so, in some studies, brachial plexus injury was not related to postterm gestation (Walsh, 2011). Intuitively, it seems that both maternal and fetal morbidity associated with macrosomia would be mitigated with timely induction to preempt further growth. This, however, does not appear to be the case. The American College of Obstetricians and Gynecologists (2016c) has concluded that current evidence does not support such a practice in women at term with suspected fetal macrosomia. Moreover, the College concluded that in the absence of diabetes, vaginal delivery is not contraindicated for women with an estimated fetal weight up to 5000 g (Chap. 27, Shoulder Dystocia). Obvious problems with all such recommendations are substantive variations in fetal weight estimation.

ANTEPARTUM MANAGEMENT

Although some intervention is indicated for prolonged pregnancies, the method and timing of this are not unanimous. The decision focuses on whether labor induction is warranted or if expectant management with fetal surveillance is best. In a survey done more than 10 years ago, Cleary-Goldman and associates (2006) reported that 73 percent of members of the American College of Obstetricians and Gynecologists routinely induced women at 41 weeks. Most of the remainder performed twice weekly fetal testing until 42 weeks.

Induction Factors

Although all obstetricians know what an “unfavorable cervix” is, the term unfortunately defies precise objective definition. Thus, investigators have used differing criteria for studies of prolonged pregnancies. Harris and coworkers (1983) defined an unfavorable cervix by a Bishop score <7 and reported this in 92 percent of women at 42 weeks (Chap. 26, Preinduction Cervical Ripening). Hannah and colleagues (1992) found that 40 percent of 3407 women with a 41-week pregnancy had an “undilated cervix.” In a study of 800 women undergoing induction for postterm pregnancy at Parkland Hospital, Alexander and associates (2000b) reported that women in whom there was no cervical dilation had a twofold higher cesarean delivery rate for “dystocia.” Yang and coworkers (2004) found that cervical length ≤3 cm measured with transvaginal sonography was predictive of successful induction. In a similar study, Vankayalapati and associates (2008) found that cervical length ≤25 mm was predictive of spontaneous labor or successful induction.

Several investigators have evaluated prostaglandin E_2 (PGE_2) and E_1 (PGE_1) for induction in women with an unfavorable cervix and prolonged pregnancies. A study by the Maternal–Fetal Medicine Units Network (1994) found that PGE_2 gel was not more effective than placebo. Alexander and associates (2000c) treated 393 women with a postterm pregnancy with PGE_2, regardless of cervical “favorability,” and reported that almost half of the 84 women with cervical dilatation of 2 to 4 cm entered labor with PGE_2 use alone. In another study, mifepristone was reported to increase uterine activity without uterotonic agents in women beyond 41 weeks (Fasset, 2008). Prostaglandins and other agents used for cervical ripening are discussed in Chapter 26 (Pharmacological Techniques).

Sweeping or stripping of the membranes to induce labor and thereby prevent postterm pregnancy was studied in 15 randomized trials during the 1990s. Boulvain and coworkers (2005) performed a metaanalysis of these and found that membrane stripping at 38 to 40 weeks lowered the frequency of postterm pregnancy. Although maternal and neonatal infection rates were not increased, this practice did not modify the cesarean delivery rate. Since then, randomized trials by Wong (2002), Kashanian (2006), Hill (2008), and their coworkers found that sweeping membranes did not reduce the need to induce labor. Drawbacks of membrane stripping included pain, vaginal bleeding, and irregular contractions without labor.

The station of the fetal head within the pelvis is another predictor of successful postterm pregnancy induction. Shin and colleagues (2004) studied 484 nulliparas who underwent induction after 41 weeks. The cesarean delivery rate was directly related to station. The rate was 6 percent if the vertex before induction was at −1 station; 20 percent at −2 station; 43 percent at −3 station; and 77 percent at −4 station.

Induction versus Fetal Testing

Because of the marginal benefits from induction with an unfavorable cervix, as just discussed, some clinicians prefer instead to implement a strategy of fetal testing beginning at 41 completed weeks. For example, in a Canadian study, 3407 women were randomly assigned at 41 or more weeks to induction or to fetal testing (Hannah, 1992). In the surveillance group, evaluation included: (1) counting fetal movements during a 2-hour period each day, (2) nonstress testing three times weekly, and (3) amnionic fluid volume assessment two to three times weekly, with pockets <3 cm considered abnormal. Labor induction resulted in a small but significant reduction in the cesarean delivery rate compared with fetal testing—21 versus 24 percent, respectively. This difference was due to fewer procedures for fetal distress. There were only two stillbirths in the fetal testing group.

The Maternal–Fetal Medicine Network performed a randomized trial of induction versus fetal testing beginning at 41 weeks (Gardner, 1996). Fetal surveillance included nonstress testing and sonographic estimation of amnionic fluid volume performed twice weekly in 175 women. Perinatal outcomes were compared with those of 265 women also at 41 weeks randomly assigned to induction with or without cervical ripening. There were no perinatal deaths, and the cesarean delivery rate was not different between management groups. The results of this study could be used to support the validity of either management scheme.

In an analysis of 22 trials, Gulmezoglu and colleagues (2012) found that induction after 41 weeks rather than surveillance was associated with significantly fewer perinatal deaths and meconium aspiration syndrome cases and a lower cesarean delivery rate. In a review of two metaanalyses and a randomized study, similar conclusions were reached (Mozurkewich, 2009).

In most studies, labor induction at $42^{0/7}$ weeks has a higher cesarean delivery rate compared with spontaneous labor. From Parkland Hospital, Alexander and coworkers (2001) evaluated pregnancy outcomes in 638 such women in whom labor was induced and compared them with outcomes of 687 women with postterm pregnancies who had spontaneous labor. Cesarean delivery rates were significantly increased—19 versus 14 percent—in the induced group because of failure to progress. When these investigators corrected for risk factors, however, they concluded that intrinsic maternal factors, rather than the induction itself, led to the higher rate. These factors included nulliparity, an unfavorable cervix, and epidural analgesia.

A large study from Denmark by Zizzo and associates (2017) is also instructive. In 2011, the Danish national guidelines were changed from labor induction at $42^{0/7}$ weeks with no fetal surveillance to labor induction at $41^{2/7}$ to $41^{6/7}$ weeks with fetal surveillance beginning at $41^{0/7}$ weeks. They compared two 3-year epochs—one before and one after 2011—and the results are shown in Table 43-2. The rate of pregnancies that progressed past $42^{0/7}$ weeks decreased from 2.85 to 0.62 percent. Concurrently, as expected, the induction rate rose significantly, and this was accompanied by a drop in the perinatal mortality rate—22 to 13 per 1000 births. The cesarean delivery rate was not changed. A similar before-and-after observational study reported that induction at ≥42 weeks was associated with a significantly lower cesarean delivery rate—15 versus 19.4 percent (Bleicher, 2017).

TABLE 43-2

National Death Cohort Study of 102,167 Pregnancies that Reached $41^{0/7}$ Weeks' Gestation

Factor	2008–2010[a]	2012–2014	*p* value
EGA >$42^{0/7}$	2.85%	0.62%	
Stillbirths	9/1000	5/1000	0.018
Neonatal deaths	13/1000	8/1000	.033
Cesarean delivery	15%	15%	NS
Vacuum delivery	11.3%	10.2%	<0.001
Induction	28%	43%	<0.001

[a]National guidelines changed between epochs as described in text.

NS = not significant.

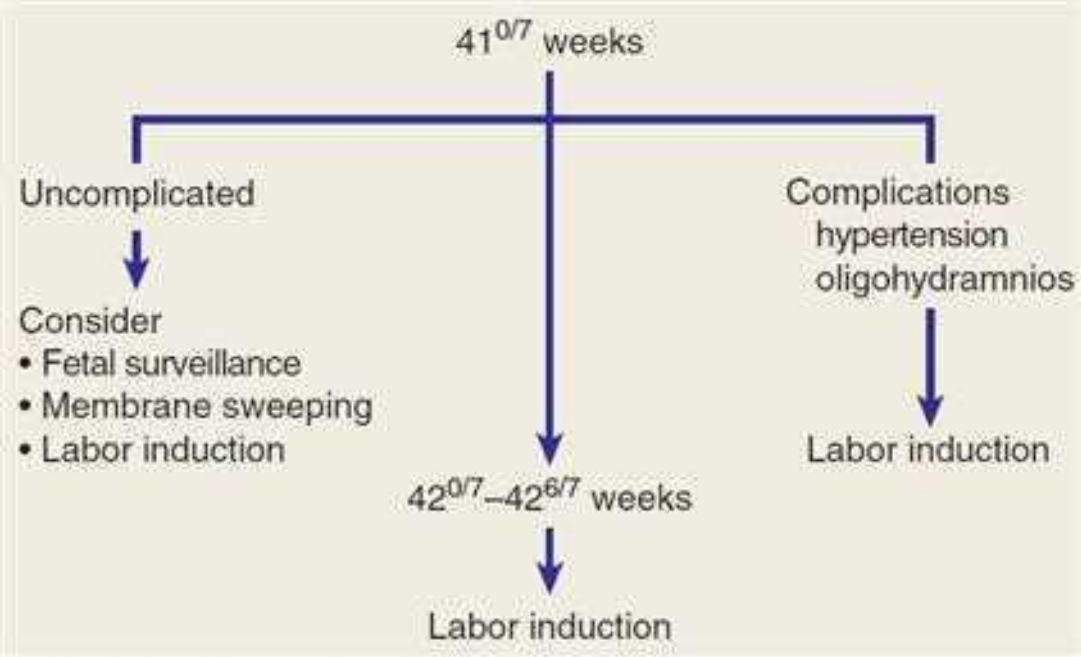
Data from Zizzo, 2017.

From the foregoing, evidence to substantiate intervention—whether induction or fetal testing—commencing at 41 versus 42 weeks is limited. Most evidence used to justify intervention at 41 weeks is from the randomized Canadian and American investigations cited earlier. No randomized studies have specifically assessed intervention at 41 weeks versus an identical intervention used at 42 weeks. A large Swedish multicenter randomized trial of more than 10,000 women at $41^{0/7}$ weeks has been designed to address the question (Elden, 2016).

Management Strategies

The American College of Obstetricians and Gynecologists (2016a) defines postterm pregnancies as having completed 42 weeks, namely, beyond $42^{0/7}$ weeks. There is insufficient evidence to mandate a management strategy between 40 and 42 completed weeks. Thus, although not considered mandatory, initiation of fetal surveillance at 41 weeks is a reasonable option. After completing 42 weeks, recommendations are for labor induction as summarized in Figure 43-6.

FIGURE 43-6
Algorithm for management of postterm pregnancy. (Summarized from American College of Obstetricians and Gynecologists, 2016d.)



When gestational age is uncertain, the American College of Obstetricians and Gynecologists (2017b) recommends delivery at 41 weeks' gestation using the best clinical estimate of gestational age. The College also recommends against amniocentesis for fetal lung maturity.

At Parkland Hospital, based on results from the trials just discussed, we consider 41-week pregnancies without other complications to be normal. Thus, no interventions are practiced solely based on fetal age until 42 completed weeks. With complications such as hypertension, decreased fetal movement, or oligohydramnios, labor induction is carried out. It is our view that large, randomized trials should be performed before otherwise uncomplicated 41-week gestations are routinely considered pathologically prolonged. In women in whom a *certain* gestational age is known, labor is induced at the completion of 42 weeks. Almost 90 percent of such women are induced successfully or enter labor within 2 days of induction. For those who do not deliver with the first induction, a second induction is performed within 3 days. Almost all women are delivered using this management plan, but in the unusual few who are not delivered, management decisions involve a third—or even more—induction versus cesarean delivery. Women classified as having *uncertain* postterm pregnancies are managed with weekly nonstress fetal testing and assessment of amnionic fluid volume. Women with an AFI ≤5 cm or with reports of diminished fetal movement undergo labor induction.

INTRAPARTUM MANAGEMENT

Labor is a particularly dangerous time for the postterm fetus. Therefore, women whose pregnancies are known or suspected to be postterm ideally come to the hospital as soon as they suspect labor. While being evaluated for active labor, we recommend that fetal heart rate and uterine contractions be monitored electronically for variations consistent with fetal compromise.

During labor, the decision to perform amniotomy is problematic. Further reduction in fluid volume following amniotomy can enhance the possibility of cord compression. Conversely, after membrane rupture, a scalp electrode and an intrauterine pressure catheter can be placed. These usually provide more precise data concerning fetal heart rate and uterine contractions. Amniotomy also aids identification of thick meconium.

Thick meconium in the amnionic fluid is particularly worrisome. The viscosity probably signifies the lack of liquid and thus oligohydramnios. Aspiration of thick meconium may cause severe pulmonary dysfunction and neonatal death (Chap. 33, Neonatal Encephalopathy and Cerebral Palsy). Because of this, amnioinfusion during labor has been proposed as a way of diluting meconium to lower the incidence of aspiration syndrome (Wenstrom, 1989). As discussed in Chapter 24 (Management Options), the benefits of amnioinfusion remain controversial. In a large randomized trial by Fraser and colleagues (2005), amnioinfusion did not reduce the risk of meconium aspiration syndrome or perinatal death. According to the American College of Obstetricians and Gynecologists (2016a), amnioinfusion does not prevent meconium aspiration, however, it remains a reasonable treatment approach for repetitive variable decelerations.

The likelihood of a successful vaginal delivery is reduced appreciably for the nullipara who is in early labor with thick, meconium-stained amnionic fluid. Therefore, if the woman is remote from delivery, strong consideration should be given to prompt cesarean delivery, especially when cephalopelvic disproportion is suspected or either hypotonic or hypertonic dysfunctional labor is evident. Some practitioners choose to avoid oxytocin use in these cases.

Until recently, it was taught—including at Parkland Hospital —that aspiration of meconium could be minimized but not eliminated by suctioning the pharynx as soon as the head was delivered. According to the American Heart Association guidelines, this in no longer recommended (Wyckoff, 2015). The American College of Obstetricians and Gynecologists (2017a) does not recommend routine intrapartum suctioning. Alternatively, if the depressed newborn has meconium-stained fluid, then intubation is carried out.

CHAPTER 44: Fetal-Growth Disorders

> *When infants are of large size and abundant, they may mechanically throw out of function so great a portion of the placenta as seriously to interfere with the nutrition of the foetus, and sometimes cause its death. Excessive development of the foetus can usually be traced to prolongation of pregnancy, large size of one or both parents, advancing age, or multiparity of the mother.*
>
> —J. Whitridge Williams (1903)

INTRODUCTION

The concept of excessive or impaired fetal growth was not considered in detail by Williams in his first edition. Abnormally diminished fetal growth was attributed to placental lesions and fetal infections. Conversely, a large fetus was of obvious concern because of associated dystocia. Currently, fetal-growth disorders at both ends of the spectrum are major problems in obstetrics.

Nearly 20 percent of the almost 4 million neonates born in the United States are at the low and high extremes of fetal growth. In 2015, 8.1 percent of newborns weighed <2500 g at birth, whereas 8.0 percent weighed >4000 g. And, although almost 70 percent of low-birthweight neonates are born preterm, the balance of low-birthweight newborns accounted for approximately 3 percent of term births in 2015 (Martin, 2017). Between 1990 and 2006, the proportion of newborns with birthweights <2500 g grew by more than 20 percent when the rate peaked at 8.3 percent (Martin, 2012). This trend toward smaller babies has slowed since the mid- to late-2000s and might partly be explained by the concurrent movement toward fewer deliveries prior to 39 weeks' gestation (Richards, 2016). In contrast, between 1990 and 2006, the incidence of birthweights >4000 g declined approximately 30 percent to a nadir of 7.6 percent in 2010 (Martin, 2012). This trend away from the upper extreme is difficult to explain because it coincides with the epidemic prevalence of obesity, a known cause of macrosomia (Morisaki, 2013).

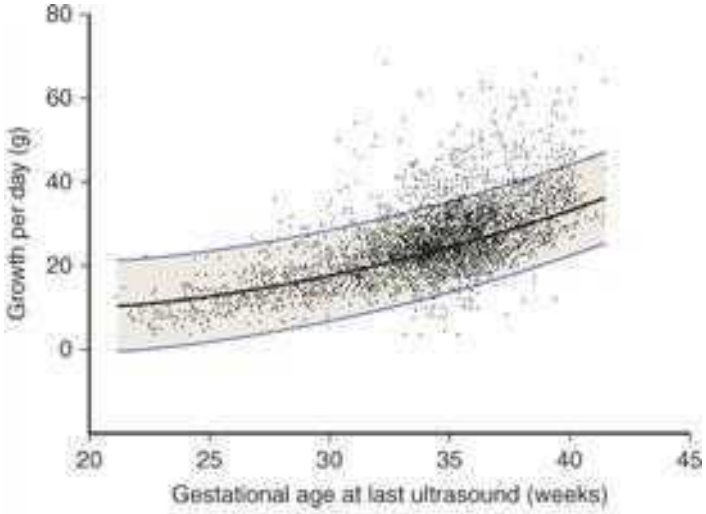
FETAL GROWTH

Pathophysiology

Human fetal growth is characterized by sequential patterns of tissue and organ growth, differentiation, and maturation. However, the "obstetrical dilemma" postulates a conflict between the need to walk upright—requiring a narrow pelvis—and the need to think—requiring a large brain, and thus a large head. Some speculate that evolutionary pressures restrict growth late in pregnancy (Mitteroecker, 2016). Thus, the ability to *growth restrict* may be adaptive rather than pathological.

Fetal growth has been divided into three phases. The initial phase of hyperplasia occurs in the first 16 weeks and is characterized by a rapid increase in cell number. The second phase, which extends up to 32 weeks' gestation, includes both cellular hyperplasia and hypertrophy. After 32 weeks, fetal mass accrues by cellular hypertrophy, and it is during this phase that most fetal fat and glycogen are accumulated. The corresponding fetal-growth rates during these three phases are 5 g/d at 15 weeks' gestation, 15 to 20 g/d at 24 weeks', and 30 to 35 g/d at 34 weeks' (Williams, 1982). As shown in Figure 44-1, the velocity of fetal growth varies considerably.

FIGURE 44-1
Increments in fetal weight gain in grams per day from 24 to 42 weeks' gestation. The black line represents the mean and the outer blue lines depict ±2 standard deviations. (Data from pregnancies managed at Parkland Hospital.)



Fetal development is determined by maternal provision of substrate and placental transfer of these, whereas fetal growth potential is governed by the genome. The precise cellular and molecular mechanisms by which normal fetal growth ensues are incompletely understood. That said, considerable evidence support an important role for insulin and insulin-like growth factors (IGFs) in regulation of fetal growth and weight gain (Luo, 2012). These growth factors are produced by virtually all fetal organs and are potent stimulators of cell division and differentiation.

Other hormones implicated in fetal growth have been identified, particularly hormones derived from adipose tissue. These hormones are known broadly as *adipokines* and include leptin, the protein product of the *obesity gene*. Fetal leptin concentrations rise during gestation, and they correlate both with birthweight and with neonatal fat mass (Briffa, 2015; Logan, 2017; Simpson, 2017). Other adipokines possibly involved include adiponectin, ghrelin, follistatin, resistin, visfatin, vaspin, omentin-1, apelin, and chemerin.

Fetal growth is also dependent on an adequate supply of nutrients. As discussed in Chapter 7 (Glucose and Fetal Growth), both excessive and diminished maternal glucose availability affect fetal growth. Reduced maternal glucose levels may result in a lower birthweight. Still, growth-restricted neonates do not typically show pathologically low glucose concentrations in cord blood (Pardi, 2006). Fetal-growth restriction in response to glucose deprivation generally results only after long-term severe maternal caloric deprivation (Lechtig, 1975).

Conversely, excessive glycemia produces macrosomia. Varying levels of glucose affect fetal growth via insulin and its associated IGFs. The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) Study Cooperative Research Group (2008) found that elevated cord C-peptide levels, which reflect fetal hyperinsulinemia, are associated with greater birthweight. This relationship was noted even in women with maternal glucose levels below the threshold for diabetes. Overgrowth does occur in the fetuses of euglycemic women. Its etiology is thus likely more complicated than merely dysregulated glucose metabolism (Catalano, 2011). Genetic factors, including genomic imprinting and epigenetic modifications via gene methylation, are also important and emphasize the potential role of inheritance (Begemann, 2015; Nawathe, 2016).

Excessive transfer of lipids may also lead to fetal overgrowth (Higa, 2013). Free or nonesterified fatty acids in maternal plasma may be transferred to the fetus via facilitated diffusion or after liberation of fatty acids from triglycerides by trophoblastic lipases (Gil-Sánchez, 2012). Generally speaking, lipolytic activity is augmented in pregnancy, and fatty acid levels are increased in nonobese women during the third trimester (Diderholm, 2005). Independent of prepregnancy body mass index (BMI), higher free fatty acid levels during the latter half of pregnancy correlate with birthweight (Crume, 2015). Other studies have correlated maternal triglyceride levels with birthweight (Di Cianni, 2005; Vrijkotte, 2011). Greater intake of certain fatty acids, particularly omega-3, is also associated with greater birthweight (Calabuig-Navarro, 2016).

Placental fatty acid metabolism and transfer may be dysregulated in fetal-growth restriction and in maternal conditions associated with fetal overgrowth. For example, levels of endothelial lipase are reduced with deficient fetal growth, and this enzyme is overexpressed in placentas of women with diabetes (Gauster, 2007, 2011). Others have reported that diabetes and obesity are associated with altered placental lipid-transport gene expression (Radaelli, 2009). Obesity is also linked with greater expression of fatty acid binding/transport proteins within the trophoblast (Myatt, 2016; Scifres, 2011). The end result of these alterations is an abnormal accumulation of lipids that can result in pathological placental inflammation and dysfunction (Calabuig-Navarro, 2016; Myatt, 2016; Yang, 2016).

Amino acids undergo active transport, which explains the normally higher fetal concentrations compared with maternal levels. In growth restriction, this pattern is reversed. One possible mechanism is altered transport of these amino acids. Remember, amino acids that reach the fetus must first cross the microvillus membrane at the maternal interface. Amino acids then traverse the trophoblastic cell, and finally cross the basal membrane into fetal blood (Chap. 5, Placenta and Chorion). In human placentas, fetal growth correlates with peroxisome proliferator activator receptor gamma (PPAR-γ) activity, which governs placental regulation of L-type amino acid (LAT) receptors 1 and 2 (Chen, 2015b). Additional modulation is from rapamycin complex (mTORC) 1 and 2 receptors (Rosario, 2013). Placental mTORC activity is reduced in fetal-growth restriction. Others have shown that increasing birthweight and maternal BMI are linked to expression and activity of particular amino-acid transporters at the microvillus membrane (Jansson, 2013).

Normal Birthweight

Normative data for fetal growth based on birthweight vary with ethnicity and geographic region. Accordingly, researchers have developed fetal-growth curves using various populations and geographic locations throughout the United States (Brenner, 1976; Ott, 1993; Overpeck, 1999; Williams, 1975). Because these curves are based on specific ethnic or regional groups, they do not represent the entire population.

To address this, birthweights such as those shown in Table 44-1 are derived nationwide in the United States. Shown in Figure 44-2 are growth curves from more than 3.2 million mothers with singleton liveborn neonates in the United States during 1991 and 2011 (Duryea, 2014). These current curves plot birthweight against a gestational age based on an *obstetrical estimate*, formed in part by sonography. These curves are thought to be more accurate and reflect more precise pregnancy dating. Older curves used gestational age derived from a last menstrual period. Comparing birthweights from 1991 to data from 2011, the more recent growth curves indicate that the earlier assessments overestimated birthweights in the case of preterm birth. In particular, the 50th percentile for fetal growth that previously corresponded to 31 to 32 weeks' gestation now corresponds to 33 to 34 weeks' when improved obstetrical dating is used.

TABLE 44-1

2011 Gestational Age Birthweight (g) Percentiles for 3,252,011 Singleton Live Births in the United States

	Percentile				
Age (wk)	**5th**	**10th**	**50th**	**90th**	**95th**
24	539	567	680	850	988
25	540	584	765	938	997
26	580	637	872	1080	1180

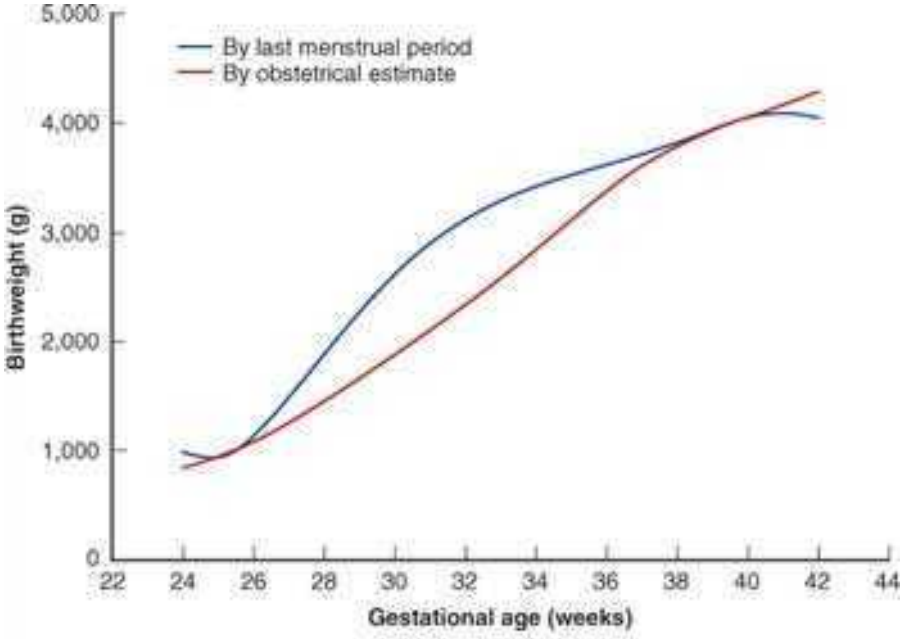
FIGURE 44-2

Fetal-growth curves for births in the United States in 2011. Curves vary depending on whether gestational age was calculated from the last menstrual period or from an improved obstetrical estimate, derived in part using sonography. (Modified with permission from Duryea EL, Hawkins JS, McIntire DD, et al: A revised birth weight reference for the United States. Obstet Gynecol. 2014 Jul;124(1):16–22.)



The curves by Alexander (1996) and Duryea (2014) and their associates are most accurately termed a *population reference*, rather than a *standard*. A population reference incorporates pregnancies of varying risks, along with the resulting outcomes, both normal and abnormal. In contrast, a *standard* incorporates normal pregnancies with normal outcomes. Because population references include preterm births, which are more likely to be growth restricted, it has been argued that the associated birthweight data overestimate deficient fetal growth (Mayer, 2013; Zhang, 2010).

One recent project sought to define regional standards in eight countries and was based on data from optimal maternal health and socioeconomic conditions. Growth trajectories from the International Fetal and Newborn Growth Consortium for the 21st Century—INTERGROWTH 21 were similar in these eight: China, India, Kenya, Brazil, Oman, Italy, the United Kingdom, and the United States (Villar, 2014). However, an international standard based on the healthiest women is of questionable value (Hanson, 2015).

Fetal Growth versus Birthweight

Most of what is known regarding normal and abnormal human fetal growth is actually based on birthweights that are assembled as references for fetal growth at particular gestational ages. This is problematic, however, because birthweight does not define the *rate* of fetal growth. Indeed, such birthweight curves reveal compromised growth only at the extreme of impaired growth. Thus, they cannot be used to identify the fetus that fails to achieve an expected size but whose birthweight is above the 10th percentile. For example, a fetus with a birthweight in the 40th percentile may not have achieved its genomic growth potential for a birthweight in the 80th percentile.

The rate or *velocity* of fetal growth can be estimated by serial sonographic anthropometry. For example, Milovanovic (2012) demonstrated that the growth rate of intrinsically small-for-gestational-age (SGA) newborns (those below the 10th percentile) approximates that of appropriate-for-gestational-age neonates. However, diminished growth velocity may be linked to perinatal morbidity and adverse postnatal metabolic changes that are independent of birthweight. Recently, Sovio and colleageus (2015) demonstrated that growth velocity of the abdominal circumference in the lowest decile distinguishes SGA newborns who suffer increased morbidity. Conversely, an excessive fetal-growth velocity, particularly of the abdominal circumference—which may be correlated with increased hepatic blood flow—is associated with an overgrown neonate (American College of Obstetricians and Gynecologists, 2016a).

Several conditions or disorders can adversely affect the normal growth of a fetus. It is important clinically to distinguish between fetal-growth restriction and constitutional low birthweight.

FETAL-GROWTH RESTRICTION

Definition

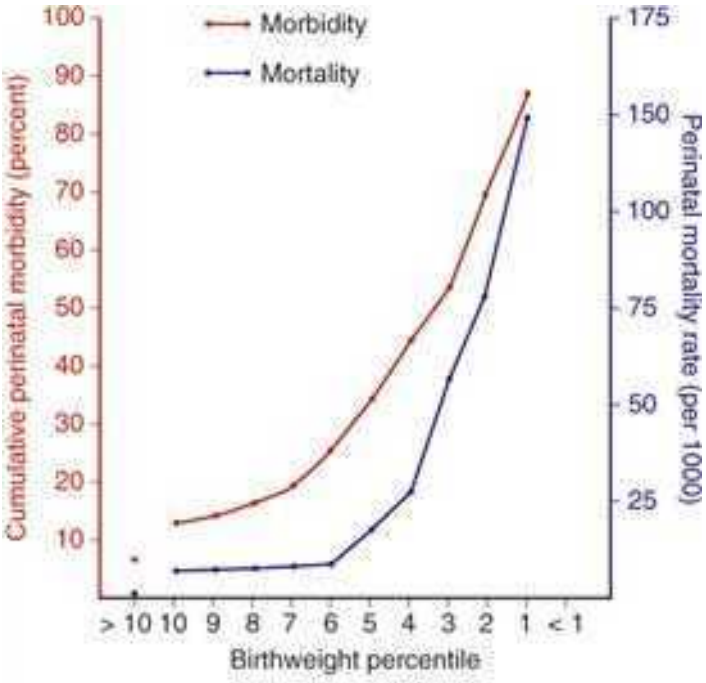
Lubchenco and coworkers (1963) published detailed comparisons of gestational ages with birthweights to derive norms for expected fetal size at a given gestational week. Battaglia and Lubchenco (1967) then classified *small-for-gestational-age* neonates as those whose weights were below the 10th percentile for their gestational age. Low-birthweight newborns who are small for gestational age are often designated as having *fetal-growth restriction.* Such infants were shown to be at increased risk for neonatal death. For example, the mortality rate of SGA neonates born at 38 weeks was 1 percent compared with 0.2 percent in those with appropriate birthweights.

Importantly, many neonates with birthweights <10th percentile are not pathologically growth restricted, but instead are small simply because of normal biological factors. As many as 70 percent of such SGA infants have normal outcomes and are thought to be appropriately grown when maternal ethnic group, parity, weight, and height are considered (Unterscheider, 2015). These small but normal infants also do not show evidence of the postnatal metabolic derangements commonly associated with deficient fetal growth. Moreover, intrinsically SGA newborns remain significantly smaller during surveillance to 2 years compared with appropriate-for-gestational age neonates, but they do not show differences in measures of metabolic risk (Milovanovic, 2012).

Because of these disparities, other classifications have been developed. Usher and McLean (1969) suggested that fetal growth standards should be based on mean weights-for-age, with normal limits defined by ±2 standard deviations. This definition would limit SGA infants to 3 percent of births instead of 10 percent. In a population-based analysis of 122,754 births at Parkland Hospital, McIntire and colleagues (1999) showed this definition to be clinically meaningful. Also, as shown in Figure 44-3, most adverse outcomes are in newborns smaller than the 3rd percentile. The importance of this cut-off has been independently confirmed in a prospective study by Unterscheider and colleagues (2013a).

FIGURE 44-3

Relationship between birthweight percentile and perinatal mortality and morbidity rates in 1560 small-for-gestational-age fetuses. A progressive increase in both mortality and morbidity rates is observed as birthweight percentile decreases.. (Data from Manning, 1995.)



More recently, individual or customized fetal-growth potential is proposed to replace a population-based threshold. In this model, a fetus that deviates from its individual optimal size at a given gestational age is considered either overgrown or growth restricted (Chiossi, 2017). Such optimal projections are based on maternal race or ethnicity. But, the superiority of customized growth curves has not been established (Chiossi, 2017; Costantine, 2013; Grobman, 2013; Zhang, 2011).

Symmetrical versus Asymmetrical Growth Restriction

Campbell and Thoms (1977) described the use of the sonographically determined *head-to-abdomen circumference ratio* (*HC/AC*) to differentiate growth-restricted fetuses. Those who were *symmetrical* were proportionately small, and those who were *asymmetrical* had disproportionately lagging abdominal growth compared with head growth. The onset or etiology of a particular fetal insult is hypothetically linked to either type of growth restriction. In the instance of *symmetrical growth restriction*, an early insult could result in a relative decrease in cell number and size. For example, early global insults such as those from chemical exposure, viral infection, or cellular maldevelopment with aneuploidy may cause a proportionate reduction of both head and body size. *Asymmetrical growth restriction* might follow a later pregnancy insult such as placental insufficiency from hypertension. In this variation, resultant diminished glucose transfer and hepatic storage would primarily affect cell size and not number. Thereby, fetal abdominal circumference—which reflects liver size—would be reduced.

Brain Sparing

Such somatic growth restriction is proposed to result from preferential shunting of oxygen and nutrients to the brain. This allows normal brain and head growth, that is—*brain sparing*. Accordingly, the ratio of brain weight to liver weight during the last 12 weeks—usually about 3 to 1—may be increased to 5 to 1 or more in severely growth-restricted infants. Because of brain-sparing effects, asymmetrical fetuses were thought to be preferentially protected from the full effects of growth restriction.

Considerable evidence has since accrued that fetal growth patterns are much more complex. For example, fetuses with aneuploidy typically have disproportionately large head sizes and thus are *asymmetrically* growth restricted, which is contrary to contemporaneous thinking (Nicolaides, 1991). Moreover, most preterm neonates with growth restriction due to preeclampsia and associated uteroplacental insufficiency are found to have more symmetrical growth impairment—again, a departure from accepted principles (Salafia, 1995).

More evidence of the complexity of growth patterns was presented by Dashe and associates (2000). These investigators analyzed 8722 consecutive liveborn singletons who had undergone sonographic examination within 4 weeks of delivery. Although only 20 percent of growth-restricted fetuses demonstrated sonographic head-to-abdomen asymmetry, these fetuses were at greater risk for intrapartum and neonatal complications. Symmetrically growth-restricted fetuses were not at increased risk for adverse outcomes compared with those appropriately grown. These investigators concluded that asymmetrical fetal-growth restriction represented significantly disordered growth, whereas symmetrical growth restriction more likely represented normal, genetically determined small stature.

Other data further challenge the concept of brain sparing. Roza and associates (2008) found that fetuses with circulatory redistribution—*brain sparing*—had a higher incidence of later behavioral problems. In another study, evidence of brain sparing was found in half of 62 growth-restricted fetuses with birthweights <10th percentile and who showed abnormal middle cerebral artery Doppler flow studies (Figueras, 2011). Compared with controls, these neonates had significantly lower neurobehavioral scores in multiple areas, suggesting profound brain injury. Zhu and coworkers (2016) prospectively compared late-onset growth restriction in 14 fetuses with that in 26 non-growth-restricted fetuses using magnetic resonance imaging to analyze hemodynamic flow. Despite the concept of brain sparing, growth-restricted infants had significantly smaller brains than controls. The complex effects of such insults—with respect to timing and severity—on brain structure, connectivity, and neurobehavioral outcomes have been recently reviewed by Miller and colleagues (2016).

Placental Abnormalities

Fetal-growth restriction is one of the "major obstetrical syndromes" associated with defects in early placentation (Brosens, 2015). Rogers and coworkers (1999) concluded that implantation-site disorders may be both a cause and consequence of hypoperfusion at the placental site. This comports with the association of certain placental angiogenic factors with pregnancy hypertensive disorders (Chap. 40, Endothelial Cell Injury). Thus, it may be that placentas from pregnancies complicated by hypertension elaborate these angiogenic factors in response to placental-site hypoperfusion, whereas pregnancies complicated by fetal-growth restriction without hypertension do not (Jeyabalan, 2008).

Mechanisms leading to abnormal trophoblastic invasion are likely multifactorial, and both vascular and immunological etiologies have been proposed. For example, *atrial natriuretic peptide converting enzyme*, also known as *corin*, plays a critical role in trophoblastic invasion and remodeling of the uterine spiral arteries (Cui, 2012). These processes are impaired in corin-deficient mice, which also develop evidence of preeclampsia. Moreover, mutations in the gene for corin have been reported in women with preeclampsia (Chen, 2015a).

Several immunological abnormalities are associated with fetal-growth restriction. This raises the prospect of maternal rejection of the "paternal semiallograft." Rudzinski and colleagues (2013) studied C4d, a component of complement that is associated with humoral rejection of transplanted tissues. They found this to be highly associated with chronic villitis—88 percent of cases versus only 5 percent of controls—and with reduced placental weight. In a study of 10,204 placentas, chronic villitis was associated with placental hypoperfusion, fetal acidemia, and fetal-growth restriction and its sequelae (Greer, 2012). Kim and coworkers (2015) extensively reviewed chronic inflammatory placental lesions and their association with fetal-growth restriction, preeclampsia, and preterm birth.

Perinatal Morbidity and Mortality

Several short-term and long-term adverse sequelae are linked with fetal-growth restriction. First, perinatal morbidity and mortality rates are substantive (see Fig. 44-3). Rates of stillbirth and adverse neonatal outcomes that include birth asphyxia, meconium aspiration, hypoglycemia, and hypothermia are all increased, as is the prevalence of abnormal neurological development. This is true for both term and preterm growth-restricted newborns. In one analysis of nearly 3000 newborns born before 27 weeks' gestation, those weighing <10th percentile had a nearly fourfold higher risk of neonatal death or neurodevelopmental impairment and a 2.6-fold increased risk of cerebral palsy compared with non-SGA neonates (De Jesus, 2013). In another analysis of more than 91,000 uncomplicated pregnancies, newborns with weights <5th percentile had a higher risk of low 5-minute Apgar score, respiratory distress, necrotizing enterocolitis, and neonatal sepsis than appropriate-weight neonates. The risks of stillbirth and neonatal death were sixfold and fourfold higher, respectively (Mendez-Figueroa, 2016).

The most severely growth-impaired newborns also have the worst outcomes. In one study of more that 44,561 neonates, only 14 percent of those weighing <1st percentile at birth survived to discharge (Griffin, 2015). For those infants who survive, the risks of adverse neurodevelopmental outcomes are substantial, especially for growth-impaired fetuses with either brain sparing or a major birth defect (Meher, 2015; Nelson, 2015b). Poor motor, cognitive, language and attention, and behavioral outcomes in growth-restricted newborns unfortunately persist into early childhood and adolescence (Baschat, 2014; Levine, 2015; Rogne, 2015).

Long-Term Sequelae

Fetal Undergrowth

Barker (1992) hypothesized that *adult* mortality and morbidity are related to fetal and infant health. This includes both under- and overgrowth. In the context of fetal-growth restriction, numerous reports describe a relationship between suboptimal fetal nutrition and an increased risk of subsequent adult hypertension, atherosclerosis, type 2 diabetes, and metabolic derangement (Burton, 2016; Jornayvaz, 2016). The degree to which low birthweight mediates adult disease is controversial, as weight gain in early life also appears important (Breij, 2014; Kerkhof, 2012; McCloskey, 2016).

Mounting evidence suggests that fetal-growth restriction may affect organ development, particularly that of the heart. Individuals with low birthweight demonstrate cardiac structural changes and dysfunction persisting through childhood, adolescence, and adulthood. In one study, 80 infants who were born SGA before 34 weeks' gestation were compared at 6 months with 80 normally grown children (Cruz-Lemini, 2016). The heart in the SGA children had a more globular ventricle that resulted in systolic and diastolic dysfunction. In another study, echocardiography in 418 adolescents showed that low birthweight was associated with a thicker left ventricular posterior wall (Hietalampi, 2012). In their review, Cohen and colleagues (2016) concluded, however, that these findings have unclear long-term significance.

Deficient fetal growth is also associated with postnatal structural and functional renal changes. In a review by Luyckx and Brenner (2015), birthweight abnormalities were evaluated for linkage with disordered nephrogenesis, renal dysfunction, chronic kidney disease, and hypertension. Both low and high birthweight, as well as maternal obesity and gestational diabetes, affect in-utero development of the kidney and its health into adulthood. However, other variables that include childhood nutrition, acute kidney injury, excessive childhood weight gain, and obesity also worsen long-term renal function.

Fetal Overgrowth

Particularly in women with diabetes and elevated cord blood levels of IGF-1, fetal overgrowth is associated with greater neonatal fat mass and morphological heart changes. Pedersen (1954) first proposed that hyperglycemia leads to fetal hyperinsulinemia and fetal overgrowth. This has been extended to organ dysmorphia, for example, increased interventricular septal thickness in neonates of mothers with gestational diabetes (Aman, 2011; Garcia-Flores, 2011). The cardiopulmonary vasculature is also adversely affected by diabetes in pregnancy. In 3277 cases of persistent pulmonary hypertension of the newborn (PPHN), maternal obesity, diabetes, and both deficient and excessive fetal growth were independent risk factors (Steurer, 2017). Long-term consequences of fetal overgrowth from obesity and diabetes are discussed in Chapters 48 (Antepartum Management) and 57 (Types of Diabetes).

Accelerated Lung Maturation

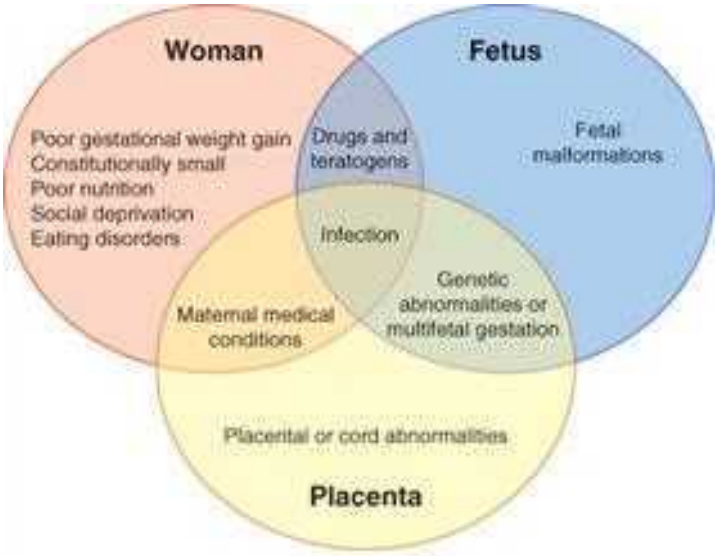
Numerous reports have described accelerated fetal pulmonary maturation in complicated pregnancies associated with growth restriction (Perelman, 1985). One possible explanation is that the fetus responds to a stressed environment by augmenting adrenal glucocorticoid secretion, which leads to accelerated fetal lung maturation (Laatikainen, 1988). Although this concept pervades modern perinatal thinking, evidence to support it is negligible.

To examine this hypothesis, Owen and associates (1990) analyzed perinatal outcomes in 178 women delivered because of hypertension. They compared these with outcomes in newborns of 159 women delivered because of spontaneous preterm labor or ruptured membranes. They concluded that a "stressed" pregnancy did not confer an appreciable survival advantage. Similar findings were described by Friedman and colleagues (1995) in women with severe preeclampsia. Two studies from Parkland Hospital also substantiate that the preterm infant accrues no apparent advantages from fetal-growth restriction (McIntire, 1999; Tyson, 1995).

Risk Factors and Etiologies

Risk factors for impaired fetal growth include potential abnormalities in the mother, fetus, and placenta. These three "compartments" are depicted in Figure 44-4. Some of these factors are known causes of fetal-growth restriction and may affect more than one compartment. For instance, cytomegalovirus infections can affect the fetus directly. In contrast, bacterial infections such as tuberculosis may have significant maternal effects that lead to poor fetal growth. Similarly, malaria, a protozoal infection, is a recognized cause of fetal-growth restriction (Briand, 2016). Importantly, many causes of diminished fetal growth are prospectively considered risk factors, because impaired fetal growth is not consistent in all affected women.

FIGURE 44-4
Risk factors and causes of impaired fetal growth centering on the mother, her fetus, and the placenta.



Constitutionally Small Mothers

It is axiomatic that small women typically have smaller newborns. As discussed subsequently, both prepregnancy weight and gestational weight gain modulate this risk. Durie and colleagues (2011) showed that the risk of delivering an SGA neonate was highest among underweight women who gained less weight than recommended by the Institute of Medicine (Chap. 9, Severe Undernutrition). Also, both maternal and paternal size influences birthweight. In a Swedish study of 137,538 term births, it was estimated that the maternal and paternal birthweights explained 6 and 3 percent of variance in birthweight, respectively (Mattsson, 2013).

Gestational Weight Gain and Nutrition

In the study by Durie (2011) cited above, gestational weight gain during the second and third trimesters that was less than that recommended by the Institute of Medicine was associated with SGA neonates in women of all weight categories except class II or III obesity. Conversely, excessive gestational weight gain was associated with an overgrown newborn in all weight categories (Blackwell, 2016).

As perhaps expected, eating disorders are linked with significantly higher risks for low birthweight and preterm birth (Micali, 2016). Marked weight gain restriction after midpregnancy should not be encouraged even in obese women (Chap. 48, Antepartum Management). Even so, it appears that food restriction to <1500 kcal/d adversely affects fetal growth minimally (Lechtig, 1975). The best documented effect of famine on fetal growth was in the *Hunger Winter* of 1944 in Holland. For 6 months, the German occupation army restricted dietary intake to 500 kcal/d for civilians, including pregnant women. This resulted in an average birthweight decline of only 250 g (Stein, 1975).

It is unclear whether undernourished women may benefit from micronutrient supplementation. In one study, almost 32,000 Indonesian women were randomly assigned to receive micronutrient supplementation or only iron and folate tablets (Prado, 2012). Offspring of those receiving the supplement had lower risks of early infant mortality and low birthweight and had improved childhood motor and cognitive abilities. Conversely, Liu and coworkers (2013) randomly assigned 18,775 nulliparas to folic acid alone; folic acid and iron; or folic acid, iron, and 13 other micronutrients. Folic acid and iron, with or without the additional micronutrients, resulted in a 30-percent reduction in risk of third-trimester anemia. But, supplementation did not affect other maternal or neonatal outcomes. A Cochrane database review of 19 trials involving 138,538 women concluded that supplementation of iron and folic acid improved birth outcomes, including lower risks of low birthweight and SGA (Haider, 2017). The importance of antenatal vitamins and trace metals is further discussed in Chapter 9 (Minerals).

Exercise in pregnancy may be beneficial for optimal fetal growth. One metaanalysis of 28 studies involving 5322 women concluded that exercise reduces the risk of fetal overgrowth without raising the risk of poor growth (Wiebe, 2015). Another metaanalysis concluded that aerobic exercise did not result in low-birthweight neonates (Di Mascio, 2016).

Social Issues

The effect of social deprivation on birthweight is interconnected with lifestyle factors such as smoking, alcohol or other substance abuse, and poor nutrition. With appropriate modifying interventions, women with psychosocial factors were significantly less likely to deliver a low-birthweight infant and also had fewer preterm births and other pregnancy complications (Coker, 2012).

Women who are immigrants may be at particular risk for poor fetal growth. In one study of 56,443 singleton pregnancies in Rotterdam, social deprivation was associated with adverse perinatal outcomes that included SGA newborns (Poeran, 2013). That said, a similar linkage was not found in socially deprived

women of non-Western origin. The effect of immigration, however, is complex and dependent on the population studied (Howell, 2017; Sanchez-Vaznaugh, 2016).

Vascular and Renal Disease

Especially when complicated by superimposed preeclampsia, chronic vascular disease commonly causes growth restriction (Chap. 50, Management During Pregnancy). In a study of more than 2000 women, vascular disease as evidenced by abnormal uterine artery Doppler velocimetry early in pregnancy was associated with higher rates of preeclampsia, SGA neonates, and delivery before 34 weeks (Groom, 2009). Using Washington state birth certificate data, Leary and colleagues (2012) found that maternal ischemic heart disease was linked to SGA infants in 25 percent of 186 births. Roos-Hesselink and coworkers (2013) described similar pregnancy outcomes in 25 women with ischemic heart disease.

Chronic renal insufficiency is frequently associated with underlying hypertension and vascular disease. Nephropathies are commonly accompanied by restricted fetal growth (Cunningham, 1990; Feng, 2015; Saliem, 2016). These relationships are considered further in Chapter 53 (Chronic Kidney Disease).

Pregestational Diabetes

Fetal-growth restriction in the newborns of women with diabetes may be related to congenital malformations or may follow substrate deprivation from advanced maternal vascular disease (Chap. 57, Preterm Delivery). Also, the likelihood of restricted growth increases with worsening White classification, particularly nephropathy (Klemetti, 2016). That said, the prevalence of serious vascular disease associated with diabetes in pregnancy is low, and the primary effect of overt diabetes, especially type 1, is fetal *overgrowth*. For example, in a prospective study of 682 consecutive pregnancies complicated by diabetes, women with type 1 diabetes were significantly more likely than women with type 2 diabetes to have a neonate weighing above the 90th and 97.7th percentiles (Murphy, 2011). Additionally, women with type 1 diabetes were significantly less likely to deliver an SGA newborn. In a recent study of 375 term singleton pregnancies complicated by type 1 diabetes, the risk of fetal overgrowth correlated with rising third-trimester glycemic values (Cyganek, 2017). Nearly a fourth of neonates were macrosomic. And, third-trimester hemoglobin A1c and fasting glucose values were independent predictors for the risk of macrosomia.

Chronic Hypoxia

Conditions associated with chronic uteroplacental hypoxia include preeclampsia, chronic hypertension, asthma, maternal cyanotic heart disease, smoking, and high altitude. When exposed to a chronically hypoxic environment, some fetuses have significantly reduced birthweight. In more than 1.8 million births in Austria, the birthweight declined 150 g for each 1000-meter rise in altitude (Waldhoer, 2015). In 63,620 Peruvian live births, the mean birthweight was significantly decreased at higher compared with lower altitudes—3065 g ± 475 g versus 3280 g ± 525 g (Gonzales, 2009). In this study, the rate of birthweights <2500 g was 6.2 percent at low altitudes, and it was 9.2 percent at high altitudes. In contrast, the rate of birthweights >4000 g was 6.3 percent at low altitudes and 1.6 percent at high altitudes.

Anemia

In most cases, maternal anemia does not restrict fetal growth. Exceptions include sickle-cell disease and some other inherited anemias (Desai, 2017; Thame, 2016). Importantly, curtailed maternal blood-volume expansion is linked to fetal-growth restriction (de Haas, 2017; Stott, 2017). This is further discussed in Chapter 40 (Blood Volume).

Antiphospholipid Syndrome

Adverse obstetrical outcomes including fetal-growth restriction have been associated with three species of antiphospholipid antibodies: *anticardiolipin antibodies, lupus anticoagulant,* and *anti-β2 glycoprotein-I antibodies.* Mechanistically, a “two-hit” hypothesis suggests that initial endothelial damage is then followed by intervillous placental thrombosis. More specifically, oxidative damage to certain membrane proteins such as β2 glycoprotein-I is followed by antiphospholipid antibody binding, which leads to immune complex formation and ultimately to thrombosis (Giannakopoulos, 2013). This syndrome is considered in detail in Chapters 52 (Acquired Thrombophilias) and 59 (Antiphospholipid Syndrome). Pregnancy outcomes in women with these antibodies may be poor and include fetal-growth restriction and fetal demise (Cervera, 2015). The primary autoantibody that predicts obstetrical antiphospholipid syndrome appears to be lupus anticoagulant (Yelnik, 2016).

Infertility

It is controversial whether pregnancies in women with prior infertility with or without treatment have an increased risk of SGA newborns (Zhu, 2007). Dickey and colleagues (2016) compared birthweight curves for singletons conceived by in vitro fertilization to the birthweight curves of Duryea (2014), described in Fetal Growth versus Birthweight. They found no reduction in fetal growth. Kondapalli and Perales-Puchalt (2013) reviewed possible links between low birthweight and infertility with its various interventions and concluded that any association remains unexplained for singletons.

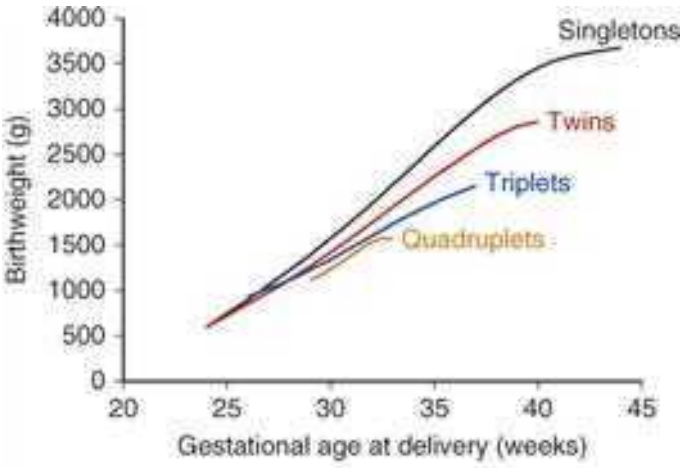
Placental, Cord, and Uterine Abnormalities

Several placental abnormalities may cause poor fetal growth. These are discussed further throughout Chapter 6 and include chronic placental abruption, extensive infarction, chorioangioma, velamentous cord insertion, placenta previa, and umbilical artery thrombosis. Growth failure in these cases is presumed secondary to uteroplacental insufficiency. Abnormal placental implantation leading to endothelial dysfunction may also limit fetal growth (Brosens, 2015). This pathology is implicated in pregnancies complicated by preeclampsia (Chap. 40, Etiology). If the placenta is implanted outside the uterus, the fetus is usually growth restricted (Chap. 19, Abdominal Pregnancy). Finally, some uterine malformations have been linked to impaired fetal growth (Chap. 3, Unicornuate Uterus (Class II)).

Multifetal Gestation

Pregnancy with two or more fetuses is more likely to be complicated by diminished growth of one or more fetuses compared with that of normal singletons. This is illustrated in Figure 44-5 and discussed in Chapter 45 (Low Birthweight).

FIGURE 44-5
Birthweight and gestational age relationships in multifetal gestations without malformations delivered at Parkland Hospital.



Drugs with Teratogenic and Fetal Effects

Several drugs and chemicals are capable of limiting fetal growth. Some are teratogenic and affect the fetus before organogenesis is complete. Some exert—or continue to exert—fetal effects after embryogenesis ends at 8 weeks. Many of these are considered in detail in Chapter 12, and examples include anticonvulsants and antineoplastic agents. Cigarette smoking, opiates and related drugs, alcohol, and cocaine may also cause growth restriction, either primarily or by decreasing maternal food intake. The link with caffeine use and fetal-growth restriction remains speculative (American College of Obstetricians and Gynecologists, 2016b). In contrast, Cyganek and colleagues (2014) studied growth restriction in pregnancies complicated by renal and liver transplants and concluded that common immunosuppressive drugs—prednisone, azathioprine, cyclosporine A, and tacrolimus—did not significantly affect fetal-growth rates.

Maternal and Fetal Infections

Viral, bacterial, protozoan, and spirochetal infections have been implicated in up to 5 percent of fetal-growth restriction cases and are discussed throughout Chapters 64 and 65. The best known of these are *rubella* and *cytomegalovirus infection*. Both promote calcifications in the fetus that are associated with cell death, and infection earlier in pregnancy correlates with worse outcomes. Toda and colleagues (2015) described a Vietnamese epidemic in which 39 percent of 292 term newborns with congenital rubella syndrome were low birthweight. In one study of 238 primary cytomegalovirus infections, no severe cases were observed when infection occurred after 14 weeks' gestation (Picone, 2013). These investigators later identified sonographic findings in 30 of 69 cases of congenital infection, and growth restriction was noted in 30 percent of these 30 cases (Picone, 2014).

Tuberculosis and *syphilis* have also both been associated with poor fetal growth. Both extrapulmonary and pulmonary tuberculosis are linked with low birthweight (Chap. 51, Tuberculosis). Sobhy (2017) analyzed 13 studies that included a total of 3384 women with active tuberculosis. The odds ratio was 1.7 for low birthweight. The etiology is uncertain, however, the adverse effects on maternal health, compounded by effects of poor nutrition and poverty, are important (Jana, 2012). Congenital syphilis is more common, and paradoxically, the placenta is almost always larger and heavier due to edema and perivascular inflammation (Chap. 65, Diagnosis). Congenital syphilis is strongly linked with preterm birth and thus low-birthweight newborns (Sheffield, 2002).

Toxoplasma gondii can also cause congenital infection, and Paquet and Yudin (2013) describe its classic association with fetal-growth restriction. Capobiango (2014) described 31 Brazilian pregnancies complicated by congenital toxoplasmosis. Only 13 percent were treated antepartum for toxoplasmosis, and low

birthweight complicated nearly 40 percent of all the pregnancies. *Congenital malaria* also causes low birthweight and poor fetal growth. Briand and colleagues (2016) emphasize the importance of prophylaxis early in pregnancy for women at risk.

Congenital Malformations

In a study of more than 13,000 fetuses with major structural anomalies, 22 percent had accompanying growth restriction (Khoury, 1988). In one study of 111 pregnancies complicated by fetal gastroschisis, a third had birthweights <10th percentile (Nelson, 2015a). As a general rule, the more severe the malformation, the more likely it is that the fetus will be SGA. This is especially evident in fetuses with chromosomal abnormalities or those with serious cardiovascular malformations.

Chromosomal Aneuploidies

Depending on which chromosome is redundant, fetuses with autosomal trisomies may display poor fetal growth. For example, in *trisomy 21*, fetal-growth restriction is generally mild. By contrast, fetal growth in *trisomy 18* is virtually always significantly limited. The crown-rump length in fetuses with trisomy 18 and 13, unlike that with trisomy 21, is typically shorter than expected (Bahado-Singh, 1997; Schemmer, 1997). By the second trimester, long-bone measurements usually are below the 3rd percentile. In one group of 174 children with trisomy 13, the mean birthweight with trisomy 13 was 2500 g, and in 254 children with trisomy 18, it was 1800 g (Nelson, 2016).

Poor fetal growth also complicates Turner syndrome, and the severity correlates with increasing haploinsufficiency of the short arm of the X chromosome (Fiot, 2016). In contrast, poor growth is not characteristic of an increased number of X chromosomes (Ottesen, 2010; Wigby, 2016). As discussed in Chapter 13 (Chromosomal Mosaicism), aneuploidic patches in the placenta—*confined placental mosaicism (CPM)*—is a recognized cause of fetal-growth restriction. Evidence suggests that aneuploidy affecting both the cytotrophoblast and mesenchymal core of the placenta, which is type 3 CPM, is associated with fetal-growth restriction (Toutain, 2010).

First-trimester prenatal programs that screen for fetal aneuploidy may incidentally identify pregnancies at risk for fetal-growth restriction unrelated to karyotype. In their analysis of 8012 women, the risk for growth restriction was higher in eukaryotic fetuses with extremely low free β-human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein-A (PAPP-A) levels (Krantz, 2004). From her review, Dugoff (2010) concluded that a low PAPP-A level is strongly associated with poor fetal growth, but studies of free β-hCG are conflicting.

Second-trimester analytes, including elevated alpha-fetoprotein and inhibin A levels and low unconjugated serum estriol concentrations, are significantly associated with birthweight below the 5th percentile. An even greater risk of poor growth is linked with certain combinations of these analytes. Still, these markers are poor screening tools for complications such as fetal-growth restriction due to low sensitivity and positive-predictive values (Dugoff, 2010). Nuchal translucency is also not predictive of fetal-growth restriction. The role of all these markers in aneuploidy screening is discussed in Chapter 14 (Traditional Aneuploidy Screening Tests).

Fetal-Growth Restriction Recognition

Identification of the inappropriately growing fetus remains a challenge. *Early* establishment of gestational age, ascertainment of maternal weight gain, and careful measurement of uterine fundal growth throughout pregnancy will identify many cases of abnormal fetal growth in low-risk women. Risk factors, including a *prior growth-restricted fetus*, raise the recurrence risk to nearly 20 percent (American College of Obstetricians and Gynecologists, 2015). In women with risk factors, serial sonographic evaluation is considered. Although examination frequency varies depending on indications, an initial early dating examination followed by an examination at 32 to 34 weeks, or when otherwise clinically indicated, will identify many growth-restricted fetuses. Even so, *definitive diagnosis* frequently cannot be made until delivery.

Uterine Fundal Height

According to one systematic review, insufficient evidence supports the utility of fundal height measurement to detect fetal-growth restriction (Robert Peter, 2015). Nonetheless, carefully performed serial fundal height measurements are recommended as a simple, safe, inexpensive, and reasonably accurate *screening* method to detect growth-restricted fetuses. As a screening tool, its principal drawback is imprecision. Haragan and coworkers (2015) reported sensitivities of 71 and 43 percent for detecting excessive or deficient fetal growth. Specificities were 85 and 66 percent, respectively.

The method used by most for fundal height measurement is described in Chapter 9 (Subsequent Prenatal Visits). Between 18 and 30 weeks' gestation, the uterine fundal height in centimeters coincides within 2 weeks of gestational age. Thus, if the measurement is more than 2 to 3 cm from the expected height, inappropriate fetal growth is suspected and sonography is considered.

Sonographic Measurement

One supporting point for routine sonographic evaluation of all pregnancies is the opportunity to diagnose growth restriction. Typically, such routine screening incorporates an early initial sonographic examination—usually at 16 to 20 weeks' gestation. Increasingly, a first-trimester examination is added to establish gestational age and identify anomalies. Some then recommend repeat sonographic evaluation at 32 to 34 weeks to evaluate fetal growth.

First-trimester sonography has limited accuracy to predict SGA newborns. For example, Crovetto and associates (2017) reported detection rates of 35 and 42 percent with false-positive rates of 5 and 10 percent, respectively. From nearly 9000 screened pregnancies, Tuuli and colleagues (2011) concluded that second-trimester sonography is superior to first-trimester scans for predicting SGA neonates. At Parkland Hospital, we provide midpregnancy sonographic screening examination of all pregnancies. Additional sonographic evaluations of fetal growth are performed as clinically indicated.

With sonography, the most common method for identifying poor fetal growth is estimation of weight using multiple fetal biometrical measurements. Combining head, abdomen, and femur dimensions provides optimum accuracy, whereas little incremental improvement is gained by adding other biometrical measurements (Platz, 2008). Of the dimensions, femur length measurement is technically the easiest and the most reproducible. Biparietal diameter and head circumference measurements are dependent on the plane of section and may also be affected by deformative pressures on the skull. Last, abdominal circumference measurements are more variable. However, these are most frequently abnormal with fetal-growth restriction because soft tissue predominates in this dimension (Fig. 44-6). Shown in Figure 44-7 is an example of a severely growth-restricted newborn.

FIGURE 44-6

Correlation of sonographic fetal weight estimation using abdominal circumference (AC) and actual birthweight. (Data from pregnancies managed at Parkland Hospital.

Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Some studies have reported a significant predictive value for small abdominal circumference with respect to lagging fetal growth. One study screened nearly 4000 pregnancies using either clinically indicated or universal sonography in the third trimester (Sovio, 2015). Universal sonography raised the rate of detection of SGA from 20 percent to 57 percent. Importantly, however, the neonatal morbidity rate was increased only if the abdominal circumference growth velocity was in the lowest decile.

Sonographic estimates of fetal weight and actual weight may be discordant by 20 percent or more, leading to both false-positive and false-negative findings. Dashe and associates (2000) studied 8400 live births at Parkland Hospital in which fetal sonographic evaluation had been performed within 4 weeks of delivery. They reported that 30 percent of growth-restricted fetuses were not detected. In a study of 2586 women with low-risk pregnancies randomly assigned to sonography at 32 or 36 weeks' gestation, sensitivity to identify grow restriction was improved at the later gestational age (Roma, 2015). Still, nearly 40 percent of cases of growth restriction defined as birthweight <3rd percentile were missed. A Cochrane database analysis of 13 trials with 34,980 women concluded that routine late pregnancy ultrasound for a low-risk or an unselected population is not associated with maternal or fetal benefit (Bricker, 2015).

Amnionic Fluid Volume Measurement

An association between pathological fetal-growth restriction and oligohydramnios has long been recognized. Petrozella and associates (2011) reported that decreased amnionic fluid volume between 24 and 34 weeks' gestation was significantly associated with malformations. In the absence of malformations, a birthweight <3rd percentile was seen in 37 percent of pregnancies with oligohydramnios, in 21 percent with borderline amnionic fluid volume, but in only 4 percent with normal volumes. Also, from a recent metaanalysis of 15 studies involving more than 35,000 pregnancies, high-risk pregnancies with oligohydramnios were more likely to be complicated by low birthweight compared with low-risk pregnancies with oligohydramnios (Rabie, 2017). Hypoxia and diminished renal blood flow are proposed explanations for oligohydramnios.

Doppler Velocimetry

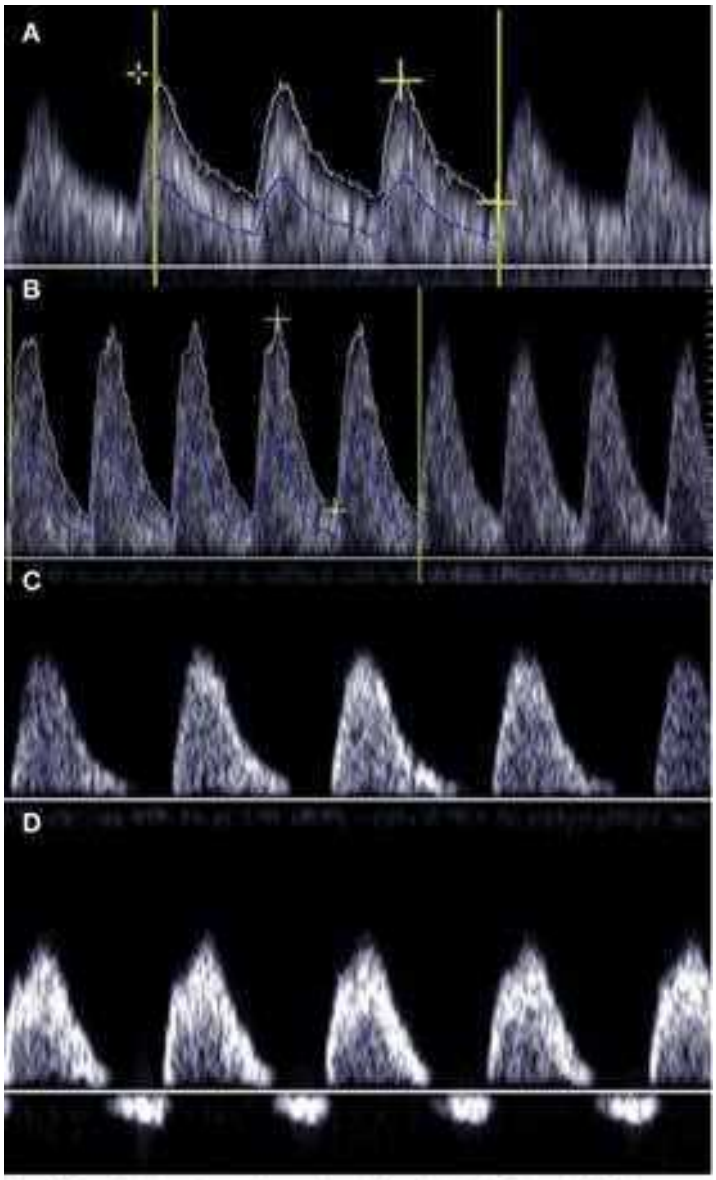
With this technique, early changes in placenta-based growth restriction are detected in peripheral vessels such as the umbilical and middle cerebral arteries. Late changes are characterized by reversal of umbilical artery flow and by abnormal flow in the ductus venosus and fetal aortic and pulmonary outflow tracts.

Of these, abnormal umbilical artery Doppler velocimetry findings—characterized by absent or reversed end-diastolic flow—are uniquely linked with fetal-growth restriction (Chap. 10, Doppler). These abnormalities highlight early versus severe growth restriction and represent the transition from fetal

adaptation to failure. Thus, persistently absent or reversed end-diastolic flow, such as that shown in Figure 44-8, has long been correlated with hypoxia, acidosis, and fetal death. In one prospective sonographic examination of 1116 fetuses with estimated fetal weights <10th percentile, only 1.3 percent of fetuses with normal umbilical artery Doppler studies had adverse outcomes compared with 11.5 percent of those with Doppler abnormalities (O'Dwyer, 2014). Unterscheider and associates (2013a) reported that abnormal umbilical artery Doppler velocimetry combined with an estimated fetal weight <3rd percentile is most strongly associated with poor obstetrical outcome.

FIGURE 44-8

Doppler velocity waveforms. **A.** Normal waveform with normal S/D ratio. **B.** Increased impedance to flow with abnormally elevated S/D ratio. **C.** Absent end-diastolic flow. **D.** Reversed end-diastolic flow.



Because of these findings, umbilical artery Doppler velocimetry is considered standard in the evaluation and management of the growth-restricted fetus. The American College of Obstetricians and Gynecologists (2015) has concluded that umbilical-artery Doppler velocimetry improves clinical outcomes. It is recommended in the management of fetal-growth restriction as an adjunct to standard surveillance techniques such as nonstress testing and biophysical profile.

Other Doppler assessments are still investigational. Interrogation of the ductus venosus was evaluated in a series of 604 fetuses <33 weeks' gestation who had an abdominal circumference <5th percentile (Baschat, 2007). Ductus venosus Doppler parameters were the primary cardiovascular factor in predicting neonatal outcome. These late changes are felt to reflect myocardial deterioration and acidemia, which are major contributors to adverse perinatal and neurological outcome. In another study of 46 growth-restricted fetuses, Doppler flow abnormalities of the aortic valve isthmus preceded those in the ductus venosus by 1 week (Figueras, 2009). In their evaluation of several fetal vessels, Turan and associates (2008) described the sequence of changes characteristic of mild placental dysfunction, progressive placental dysfunction, and severe, early-onset placental dysfunction. However, Unterscheider and colleagues (2013b) questioned whether a predictable progression of Doppler indices actually exists in fetal-growth restriction.

Prevention

Fetal-growth restriction prevention ideally begins before conception. Maternal medical conditions, medications, and nutrition are optimized, and smoking cessation is critical. Other risk factors are tailored to the maternal condition, such as antimalarial prophylaxis for women living in endemic areas and correction of nutritional deficiencies. Of note, treatment of mild-to-moderate hypertension does not reduce the incidence of growth-restricted newborns (Chap. 50, Antihypertensive Treatment in Pregnancy).

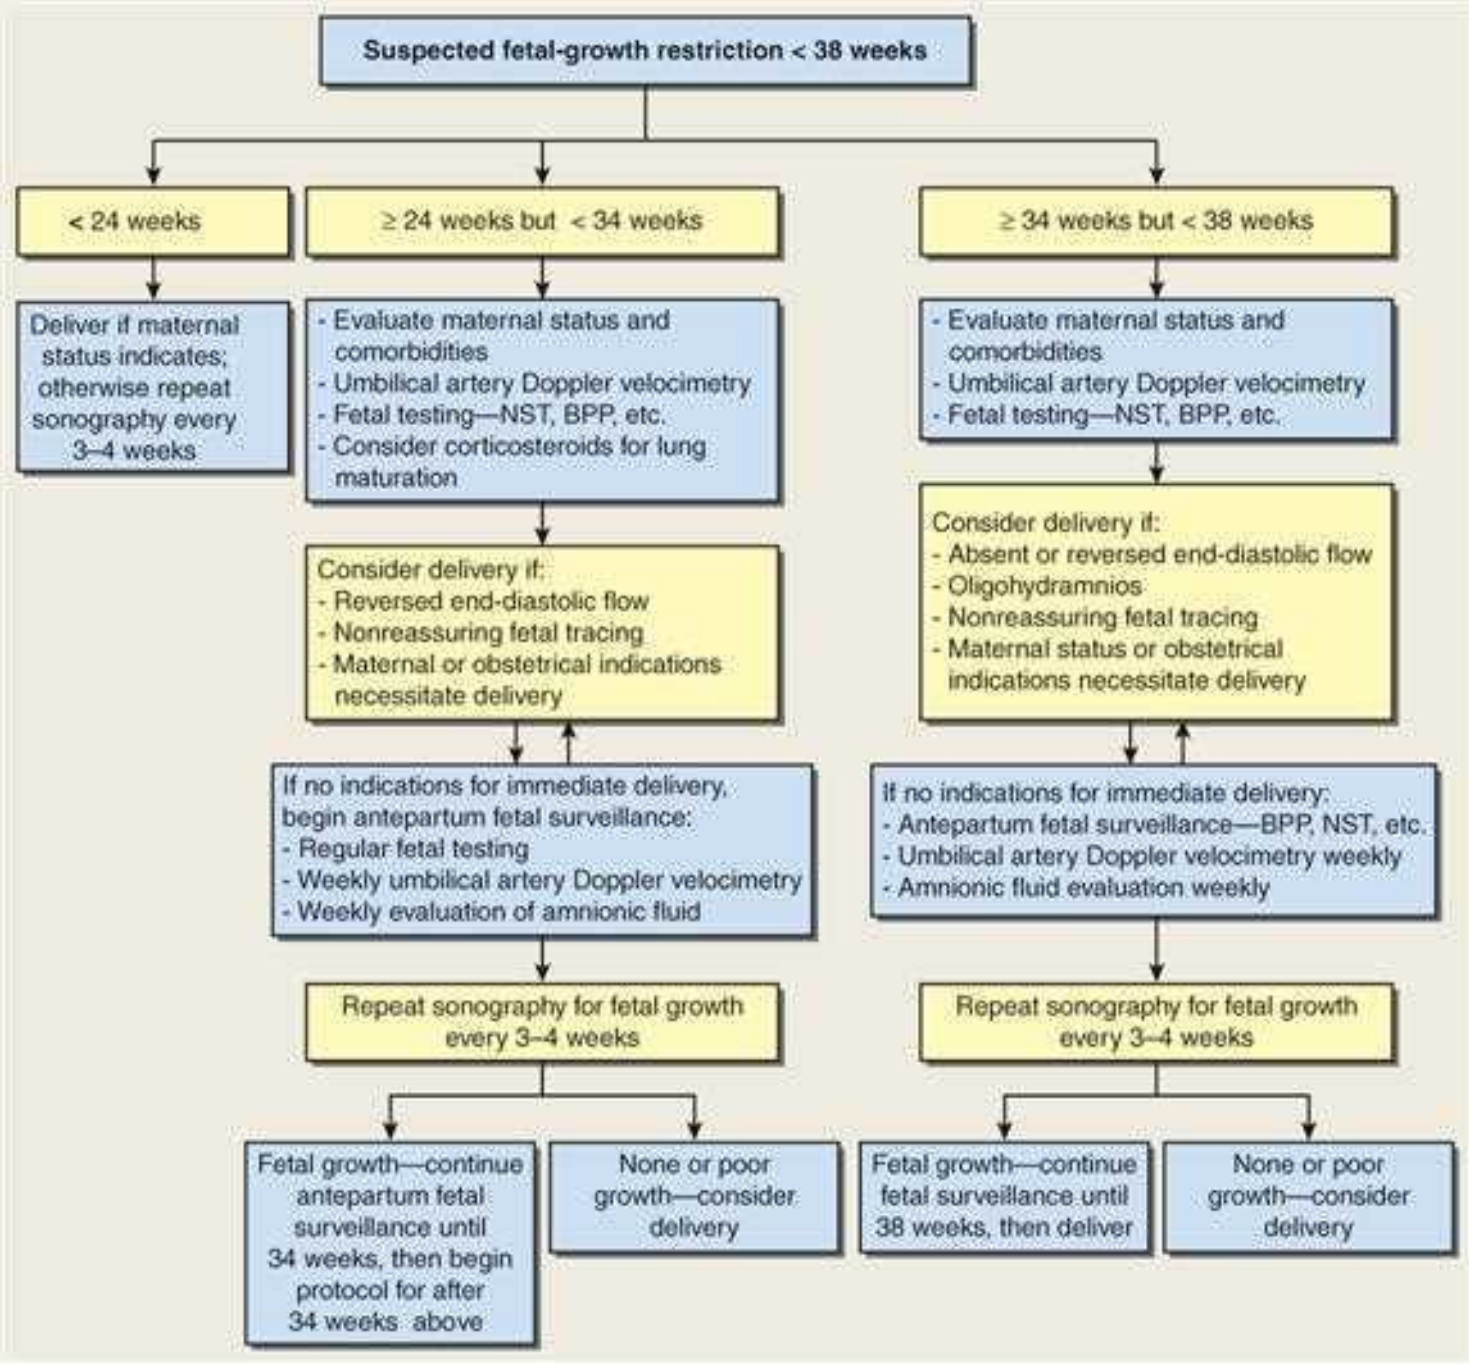
Accurate dating is essential during early pregnancy. Serial sonographic evaluations are typically used, but the best interval between assessments has not been clearly established. Given that a prior SGA newborn is associated with other adverse outcomes in a subsequent pregnancy, particularly stillbirth and preterm birth, surveillance during a subsequent pregnancy may be beneficial (Mendez-Figueroa, 2016; Spong, 2012). The American College of Obstetricians and Gynecologists (2015) notes that if growth is normal during a pregnancy following a prior pregnancy complicated by fetal-growth restriction, then Doppler velocimetry and fetal surveillance are not indicated. A recent metaanalysis of 45 trials involving 20,909 women reported that low-dose aspirin initiated prior to 16 weeks' gestation was associated with a significantly lower risk of fetal-growth restriction (Roberge, 2017). Moreover, they described a dose-response effect. The American College of Obstetricians and Gynecologists (2015) has not endorsed prophylaxis with low-dose aspirin for women with a prior growth-restricted fetus.

Management

If fetal-growth restriction is suspected, then efforts are made to confirm the diagnosis, assess fetal condition, and search for possible causes. Early-onset growth restriction is especially problematic. In pregnancies in which fetal anomalies are suspected, patient counseling and prenatal diagnostic testing are indicated (American College of Obstetricians and Gynecologists, 2015).

One management algorithm is shown in Figure 44-9. In pregnancies with suspected fetal-growth restriction, antepartum fetal surveillance includes periodic Doppler velocimetry of the umbilical arteries in addition to more frequent fetal testing. At Parkland Hospital, for women whose fetus measures ≤3rd percentile and has reached a viable age, we encourage hospitalization on our High-Risk Pregnancy Unit. Daily fetal heart rate tracings, weekly Doppler velocimetry, and sonographic assessment of fetal growth every 3 to 4 weeks are initiated. Other modalities of Doppler velocimetry, such as middle cerebral arteries or ductus venosus assessment, are considered experimental. The American College of Obstetricians and Gynecologists (2015) recommends that antenatal corticosteroids for pulmonary maturation be given to pregnancies complicated by fetal-growth restriction and at risk for birth before 34 weeks' gestation.

FIGURE 44-9
Algorithm for management of fetal-growth restriction at Parkland Hospital. BPP = biophysical profile; NST = nonstress test.



The timing of delivery is crucial, and the risks of fetal death versus the hazards of preterm birth must be considered. Several multicenter studies address these problems, but unfortunately, none have elucidated the optimal timing of delivery. For the preterm fetus, the only randomized trial of delivery timing is the Growth Restriction Intervention Trial (GRIT) (Thornton, 2004). This trial involved 548 women between 24 and 36 weeks' gestation with clinical uncertainty regarding delivery timing. Women were randomly assigned to immediate delivery or to delayed delivery until the situation worsened. The primary outcome was perinatal death or disability after reaching age 2 years. Mortality rates did not differ through 2 years of age. Moreover, children aged 6 to 13 years did not show clinically significant differences between the two groups (Walker, 2011).

In the Trial of Randomized Umbilical and Fetal Flow in Europe (TRUFFLE), ductus venosus Doppler evaluation was compared with fetal heart rate monitoring. There were 310 pregnancies between 26 and 32 weeks' gestation with fetuses displaying an abdominal circumference <10th percentile and an umbilical artery pulsatility index >95th percentile (Lees, 2015). Delivery timing was determined by the results of three differing antenatal fetal assessment arms that were: short-term fetal heart rate variability, early ductus venosus Doppler velocimetry changes, or late ductus changes. The proportion of children with neuroimpairment at 2 years of age was not different among the groups. Of note, only 32 percent of the newborns overall were delivered according to this randomization. Safety net criteria and other maternal/fetal indications prompted these protocol deviations (Visser, 2016). In a post-hoc analysis, these authors concluded that before 32 weeks, delaying delivery until ductus venosus Doppler or fetal heat rate abnormalities occur is likely safe and possibly benefits long-term outcome (Ganzevoort, 2017).

The Disproportionate Intrauterine Growth Intervention Trial at Term (DIGITAT) study examined the delivery timing of growth-restricted fetuses who were 36 weeks' gestation or older. In these 321 women who were randomized to induction or to expectant management, composite neonatal morbidity did not differ, except that neonatal admissions were lower after 38 weeks in a secondary analysis (Boers, 2010, 2012). Another secondary analysis of DIGITAT did not identify a clear subgroup that benefited from labor induction (Tajik, 2014). Other secondary analyses included assessment of neurodevelopmental and behavioral outcomes at age 2, and these also were similar between the randomized groups (Van Wyk, 2012).

Management of the Near-Term Fetus

As shown in Figure 44-9, delivery of a suspected growth-restricted fetus with normal umbilical artery Doppler velocimetry, normal amnionic fluid volume, and reassuring fetal heart rate testing can likely be deferred until 38 weeks' gestation. Said another way, uncertainty regarding the diagnosis should preclude intervention until fetal lung maturity is assured. Expectant management can be guided using antepartum fetal surveillance techniques described in Chapter 17. Most clinicians, however, recommend delivery at 34 weeks or beyond if there is clinically significant oligohydramnios. Consensus statements by the Society for Maternal-Fetal Medicine (Spong, 2011) and the American College of Obstetricians and Gynecologists (2017a) are similar. These recommend delivery between 34 and 37 weeks when there are comorbid conditions such as oligohydramnios. With a reassuring fetal heart rate pattern, vaginal delivery is planned. Notably, some of these fetuses do not tolerate labor.

Management of the Fetus Remote from Term

If growth restriction is identified in an anatomically normal fetus before 34 weeks, and amnionic fluid volume and fetal surveillance findings are normal, observation is recommended. Screening for toxoplasmosis, cytomegalovirus infection, rubella, herpes, and other infections is recommended by some. However, we and others have not found this to be productive (Yamamoto, 2013).

As long as interval fetal growth and fetal surveillance test results are normal, pregnancy is allowed to continue until fetal lung maturity is reached (see Fig. 44-9). Reassessment of fetal growth is typically made no sooner than 3 to 4 weeks. Weekly assessment of umbilical artery Doppler velocimetry and amnionic fluid volume is combined with periodic nonstress testing, although the optimal frequency has not been determined. As mentioned, we hospitalize these women in our High-Risk Pregnancy Unit and monitor their fetuses daily. If interval growth, amnionic fluid volume, and umbilical artery Doppler velocimetry are normal, then the mother is discharged home and seen intermittently for outpatient surveillance.

With growth restriction remote from term, no specific treatment ameliorates the condition. For example, evidence does not support diminished activity or bed rest to accelerate growth or improve outcomes. Despite this, many clinicians intuitively advise a program of modified rest. Nutrient supplementation, attempts at plasma volume expansion, oxygen therapy, antihypertensive drugs, heparin, and aspirin are all ineffective (American College of Obstetricians and Gynecologists, 2015).

In most cases diagnosed before term, neither a precise etiology nor a specific therapy is apparent. Management decisions hinge on assessment of the relative risks of fetal death during expectant management versus the risks from preterm delivery. Although reassuring fetal testing may allow observation with continued maturation, long-term neurological outcome is a concern (Baschat, 2014; Lees, 2015; Thornton, 2004). Baschat and associates (2009) showed that neurodevelopmental outcome at 2 years in growth-restricted fetuses was best predicted by birthweight and gestational age. Doppler abnormalities are generally not associated with poor childhood cognitive developmental scores among low-birthweight fetuses delivered in the third trimester (Llurba, 2013). These findings emphasize that adverse neurodevelopmental outcomes cannot always be predicted.

Labor and Delivery

Fetal-growth restriction is commonly the result of placental insufficiency due to faulty maternal perfusion, reduction of functional placenta, or both. If present, these conditions are likely aggravated by labor. Equally important, diminished amnionic fluid volume raises the likelihood of cord compression during labor. For these and other reasons, the frequency of cesarean delivery is increased. Accordingly, a woman with a suspected growth-restricted fetus should undergo "high-risk" intrapartum monitoring (Chap. 24, Intrapartum Surveillance of Uterine Activity).

The risk of neonatal hypoxia or meconium aspiration is also greater. Thus, care for the newborn should be provided immediately by an attendant who can skillfully clear the airway and ventilate a neonate as needed (Chap. 32, Resuscitation Protocol). The severely growth-restricted newborn is particularly susceptible to hypothermia and may also develop other metabolic derangements such as hypoglycemia, polycythemia, and hyperviscosity. In addition, low-birthweight newborns are at higher risk for motor and other neurological disabilities. Risk is greatest at the lowest extremes of birthweight (Baschat, 2009, 2014; Llurba, 2013).

FETAL OVERGROWTH

The term *macrosomia* is used rather imprecisely to describe a very large fetus or newborn. Although there is general agreement among obstetricians that neonates weighing <4000 g are not excessively large, a similar consensus has not been reached for the definition of macrosomia. Newborn weight rarely exceeds 11 pounds (5000 g), and excessively large infants are a curiosity. The largest newborn cited in the *Guinness Book of World Records* was a 23-lb 12-oz (10,800 g) infant boy born in 1879 to a Canadian woman (Barnes, 1957).

In the United States in 2015, of more than 4 million births, 6.9 percent weighed 4000 to 4499 g; 1 percent weighed 4500 to 4999 g; and 0.1 percent were born weighing 5000 g or more (Martin, 2017). To be sure, the incidence of excessively large infants grew during the 20th century. According to Williams (1903), at the beginning of the 20th century, the incidence of birthweight >5000 g was 1 to 2 per 10,000 births. This compares with 16 per 10,000 births at Parkland Hospital from 1988 through 2008 and with 11 per 10,000 in the United States in 2010. The influence of increasing maternal obesity rates is overwhelming, and its association with diabetes is well known. Of Parkland mothers with newborns weighing >5000 g, more than 15 percent were diabetic.

Definition

Several terms currently describe pathological fetal overgrowth. The most common of these—*macrosomia*—is defined by birthweights that exceed certain percentiles for a given population. Another commonly used scheme is to define macrosomia by an empirical birthweight threshold.

Birthweight Distribution

Macrosomia is frequently defined based on mathematical distributions of birthweight. Those newborns exceeding the 90th percentile for a given gestational week are usually used as the threshold for macrosomia or large-for-gestational age (LGA) birthweight. For example, the 90th percentile at 39 weeks is 4000 g. If, however, birthweights that are 2 standard deviations above the mean are used, then thresholds lie at the 97th percentile. Thus, substantially larger newborns are considered macrosomic compared with those at the 90th percentile. Specifically, the birthweight threshold at 39 weeks to be macrosomic would be approximately 4500 g for the 97th percentile rather than 4000 g for the 90th percentile.

Empirical Birthweight

Newborn weight exceeding 4000 g (8 lb 13 oz) is also a frequently used threshold to define macrosomia. Others use 4250 g or even 4500 g (10 lb). As shown in Table 44-2, birthweights ≥4500 g are uncommon. During a 30-year period at Parkland Hospital, during which there were more than 350,000 singleton births, only 1.4 percent of newborns weighed 4500 g or more. We are of the view that the upper limit of fetal growth, above which growth can be deemed abnormal, is likely two standard deviations above the mean, representing perhaps 3 percent of births. At 40 weeks, such a threshold would correspond to approximately 4500 g. The American College of Obstetricians and Gynecologists (2016a) concludes that the term *macrosomia* was an appropriate appellation for newborns who weigh 4500 g or more at birth.

TABLE 44-2

Birthweight Distribution of 354,509 Liveborn Infants at Parkland Hospital between 1988 and 2012

Birthweight (g)	Births		Maternal Diabetes	
	No.	%	No.	%
500–3999	322,074	90.9	13,365	4
4000–4249	19,106	5.4	1043	5
4250–4499	8391	2.4	573	7
4500–4649	3221	0.9	284	9
4750–4999	1146	0.3	134	12
5000–5249	385	0.1	57	15
5250–5499	127	0.04	31	24
5500 or more	59	0.02	14	24
Total	354,509		15,501	

Risk Factors

Some factors associated with fetal overgrowth are listed in Table 44-3. Many are interrelated and thus likely are additive. For example, advancing age is usually related to multiparity and diabetes, and obesity is related to diabetes. In one study, the incidence of macrosomia exceeded 24 percent in China among obese women, and macrosomia rates were also significantly higher (approximately 2.5-fold) for prolonged pregnancy and gestational diabetes (Wang, 2017). Of these, maternal diabetes is an important risk factor for fetal overgrowth (Chap. 57, Preterm Delivery). As shown in Table 44-2, the incidence

of maternal diabetes grows as birthweights >4000 g rise. It should be emphasized, however, that maternal diabetes is associated with only a small percentage of the total number of such large newborns.

Racial and ethnic factors

Maternal and Perinatal Morbidity

The adverse consequences of excessive fetal growth are considerable. Neonates with a birthweight of at least 4000 g have cesarean delivery rates >50 percent. This is particularly true with maternal obesity or diabetes or with birthweights >5000 g (Cordero, 2015; Crosby, 2017; Gaudet, 2014; Hehir, 2015). One study found a higher risk for traumatic neonatal morbidity in LGA neonates compared with normal-weight ones (Chauhan, 2017). Rates of shoulder dystocia vary greatly and can reach nearly 30 percent for macrosomic neonates when maternal diabetes is comorbid (Cordero, 2015). In general obstetrical populations that include diabetic mothers, dystocia rates are at least 5 percent for neonates with birthweights ≥5000 g (Crosby, 2017; Hehir, 2015). Rates of postpartum hemorrhage, perineal laceration, and maternal infection, which are related complications, are also higher in mothers delivering overgrown newborns. Maternal and neonatal outcomes by birthweight for large babies >4000 g delivered at Parkland Hospital are shown in Table 44-4.

TABLE 44-4

Maternal and Fetal Outcomes for 208,090 Pregnancies Delivered at Parkland Hospital from 1998 through 2012

Outcome[a]	<4000 g n = 187,119	4000–4499 g n = 17,750	4500–4999 g n = 2849	≥5000 g n = 372	*p* value
Cesarean total	46,577 (25)	5,362 (30)	1204 (42)	224 (60)	<0.001
Scheduled	12,564 (7)	1,481 (8)	316 (11)	65 (17)	<0.001

Diagnosis

Because current methods fail to accurately estimate excessive fetal size, macrosomia cannot be definitively diagnosed until delivery. Inaccuracy in clinical estimates of fetal weight by physical examination is often attributable, at least in part, to maternal obesity. Numerous attempts have been made to improve the accuracy of sonographic fetal-weight estimation. Several formulas have been proposed to calculate fetal weight using measurements of the head, femur, and abdomen. Estimates provided by these computations are reasonably accurate for predicting the weight of small, preterm fetuses but are less valid in predicting the weight of large fetuses. In one study of 248 LGA and 655 non-LGA newborns from pregnancies complicated by diabetes, only 23 percent of women diagnosed with an LGA fetus before delivery actually delivered an LGA infant (Scifres, 2015). This resulted in a more than threefold rise in the cesarean delivery rate for suspected LGA birthweights.

From the foregoing, it is apparent that sonographic estimation of fetal weight is unreliable, and its routine use to identify macrosomia is not recommended. Indeed, the American College of Obstetricians and Gynecologists (2016a) concludes that clinical fetal weight estimates are just as accurate as sonographic ones.

Management

Several interventions have been proposed to interdict fetal overgrowth. Some include prophylactic labor induction for poorly defined indications such as "impending macrosomia," or elective cesarean delivery to avoid difficult delivery and shoulder dystocia. For women with diabetes in pregnancy, insulin therapy and close attention to good glycemic control reduces birthweight. However, this has not consistently translated into reduced cesarean delivery rates. Furthermore, as noted above, erroneous diagnosis of fetal overgrowth among women with diabetes raises cesarean delivery rates (Scifres, 2015). Also previously mentioned, fetal overgrowth irrespective of the diagnosis of diabetes mellitus is strongly associated with maternal obesity and excessive gestational weight gain (Durie, 2011; Durst, 2016; Harper, 2015). Dietary intervention to limit fetal overgrowth by curbing gestational weight gain, for example, is an active area of research. Currently recommended weight gains for pregnancy according to maternal BMI are described in Chapter 9 (Nutritional Counseling).

"Prophylactic" Labor Induction

Some clinicians induce labor when fetal macrosomia is suspected in nondiabetic women. This approach is suggested to obviate further fetal growth and thereby reduce potential delivery complications. Such prophylactic induction should theoretically reduce the risk of shoulder dystocia and cesarean delivery. In one systematic review of 11 studies of expectant management versus labor induction for suspected macrosomia, labor induction increased cesarean delivery rates without improving perinatal outcomes (Sanchez-Ramos, 2002). In contrast, Magro-Malosso and colleagues (2017) performed a metaanalysis of four randomized trials involving 1190 women and concluded that labor induction at 38 or more weeks for suspected macrosomia significantly reduces the frequency of fetal overgrowth and fractures. In one of these studies, 822 women with suspected LGA fetuses were randomly assigned either to early term delivery ($37^{0/7}$ to $38^{6/7}$ weeks) or to expectant management (Boulvain, 2015). There was a higher rate of vaginal delivery that was marginally significant and a lower composite measure of morbidity. These authors cautioned that any benefits should be balanced with the risks of early-term labor induction and delivery. Namely, a review of early-term births indicates that elective delivery before 39 weeks' gestation does not improve maternal outcomes and is associated with worse neonatal outcomes (Tita, 2016). We agree with the American College of Obstetricians and Gynecologists (2016a, 2017a,b) that current evidence does not support a policy for early labor induction or delivery before 39 weeks' gestation. It remains unclear whether delivery or induction for suspected macrosomia at term is better than expectant management.

Elective Cesarean Delivery

With the delivery of macrosomic infants, shoulder dystocia and its attendant risks described in Chapter 27 (Shoulder Dystocia) are major concerns. That said, the American College of Obstetricians and Gynecologists (2017b) concluded that fewer than 10 percent of all shoulder dystocia cases result in a persistent brachial plexus injury, and 4 percent of these injuries still follow cesarean delivery.

For prevention, planned cesarean delivery on the basis of suspected macrosomia to prevent brachial plexopathy is an unreasonable strategy in the *general population* (Chauhan, 2005). Ecker and coworkers (1997) analyzed 80 cases of brachial plexus injury in 77,616 consecutive infants born at Brigham and Women's Hospital. They concluded that an excessive number of otherwise unnecessary cesarean deliveries would be needed to prevent a single brachial plexus injury in neonates born to women without diabetes. Rouse and colleagues (1996) echoed these sentiments in their analysis of nondiabetic mothers.

Conversely, planned cesarean delivery may be a reasonable strategy for *diabetic* women with an estimated fetal weight >4250 or >4500 g. Conway and Langer (1998) described a protocol of routine cesarean delivery for sonographic estimates of ≥4250 g in diabetic women. This management significantly lowered the shoulder dystocia rate from 2.4 to 1.1 percent.

In summary, we agree with the College that elective delivery for the fetus that is suspected to be overgrown is inadvisable, particularly before 39 weeks' gestation. Finally, we also conclude that elective cesarean delivery is not indicated when estimated fetal weight is <5000 g among women without diabetes and <4500 g among women with diabetes (American College of Obstetricians and Gynecologists, 2016a, 2017b).

CHAPTER 45: Multifetal Pregnancy

In single-ovum twins, there is always a certain area of the placenta in which there is anastomosis between vascular systems which is never present in the fused placenta of double-ovum twins. Thus, if at an early period the heart of one embryo is considerably stronger than that of the other, a gradually increasing area of the communicating portion of the placenta is monopolized by the former, so that its heart increases rapidly in size, whilst that of the latter receives less blood and eventually atrophies.

—J. Whitridge Williams (1903)

INTRODUCTION

In Williams' time, a great deal concerning the embryological and morphological development of multifetal pregnancies was unknown. These pregnancies may result from two or more fertilization events, from a single fertilization followed by a splitting of the zygote, or from a combination of both. Multifetal gestations were problematic during those times and remain so today for both the mother and her fetuses. For example, in this country, approximately a fourth of very-low-birthweight neonates—those born weighing <1500 g—are from multifetal gestations (Martin, 2017).

Fueled largely by infertility therapy, both the rate and the number of twins and higher-order multifetal births grew dramatically during the 1980s and 1990s in the United States. National data from Martin and coworkers (2017) presented here is informative. The twinning rate rose 76 percent from 18.9 per 1000 live births in 1980 to 33.2 in 2009. During the same time, the number of higher-order multifetal births peaked in 1998 at a rate of 1.9 per 1000 total births. Since then, however, evolving infertility management has lowered rates of higher-order multifetal births—especially among non-Hispanic white women. For example, the rate of triplets or more declined by more than 50 percent from 1998 to 2015 in this demographic group. And, in 2015, the overall multifetal birth rate was 34.5 per 1000, with twins representing nearly 97 percent of these births.

These rates of multifetal pregnancies have a direct effect on the rates of preterm birth and its comorbidities. In addition, the risks for congenital malformation and its consequences are greater with multifetal gestations. Importantly, this increased risk applies to *each* fetus and is not simply the result of more fetuses. In sum, in 2013 in the United States, multifetal births accounted for 3 percent of all live births but for 15 percent of all infant deaths. Moreover, the risk of infant death rose proportionally with the number of fetuses in the pregnancy (Matthews, 2015). Specifically, the infant mortality rate for twins was more than four times the rate for single births. In the same year, the infant mortality rate for triplets was nearly 12 times the rate for singletons, and for quadruplets, it was a staggering 26 times that for singletons! From Parkland Hospital, a comparison of singleton and twin outcomes is shown in Table 45-1. These risks are magnified further with higher-order births.

TABLE 45-1

Selected Outcomes in Singleton and Twin Pregnancies Delivered at Parkland Hospital from 1988 through 2016

Outcome	Singletons (No.)	Twins (No.)
Pregnancies	202,306	2412
Births[a]	202,306	4824
Stillbirths	1011 (5.0)	114 (23.6)
Neonatal deaths	590 (2.9)	92 (19.5)
Perinatal deaths	1601 (7.9)	206 (42.7)
Very low birthweight (<1500 g)	1927 (9.6)	507 (107.6)

[a]Birth data are represented as number (per 1000).

[b]Denominator for neonatal deaths and very low birthweight is liveborn infants.

Data from Dr. Don McIntire.

The mother may also experience higher obstetrical morbidity and mortality rates. These rates also rise with the number of fetuses (Mhyre, 2012; Young, 2012). In one study of more than 44,000 multifetal pregnancies, the risks for preeclampsia, postpartum hemorrhage, and maternal death were twofold higher than these rates in singleton gestations (Walker, 2004). The risk for peripartum hysterectomy is also greater. Francois and associates (2005) reported this to be threefold for twins and

24-fold for triplets or quadruplets. Last, compared with women with a singleton pregnancy, these mothers are at increased risk for depression as well as parental divorce (Choi, 2009; Jenna, 2011).

MECHANISMS OF MULTIFETAL GESTATIONS

Twin fetuses usually result from fertilization of two separate ova, which yields *dizygotic* or *fraternal twins*. Less often, twins arise from a single fertilized ovum that then divides to create *monozygotic* or *identical twins*. Either or both processes may be involved in the formation of higher numbers. Quadruplets, for example, may arise from as few as one to as many as four ova. These traditional models of twinning discussed in the next sections have been taught for more than 50 years and remain the widely accepted theory. More recently, Herranz (2015) offered a provocative alternative hypothesis, which posits that monozygotic twinning occurs with splitting at the postzygotic two-cell stage. Notably, data are not robust in support of either the traditional or the newly proposed model (Denker, 2015).

Dizygotic versus Monozygotic Twinning

Dizygotic twins are not in a strict sense true twins because they result from the maturation and fertilization of two ova during a single ovulatory cycle. Moreover, from a genetic perspective, dizygotic twins are like any other pair of siblings.

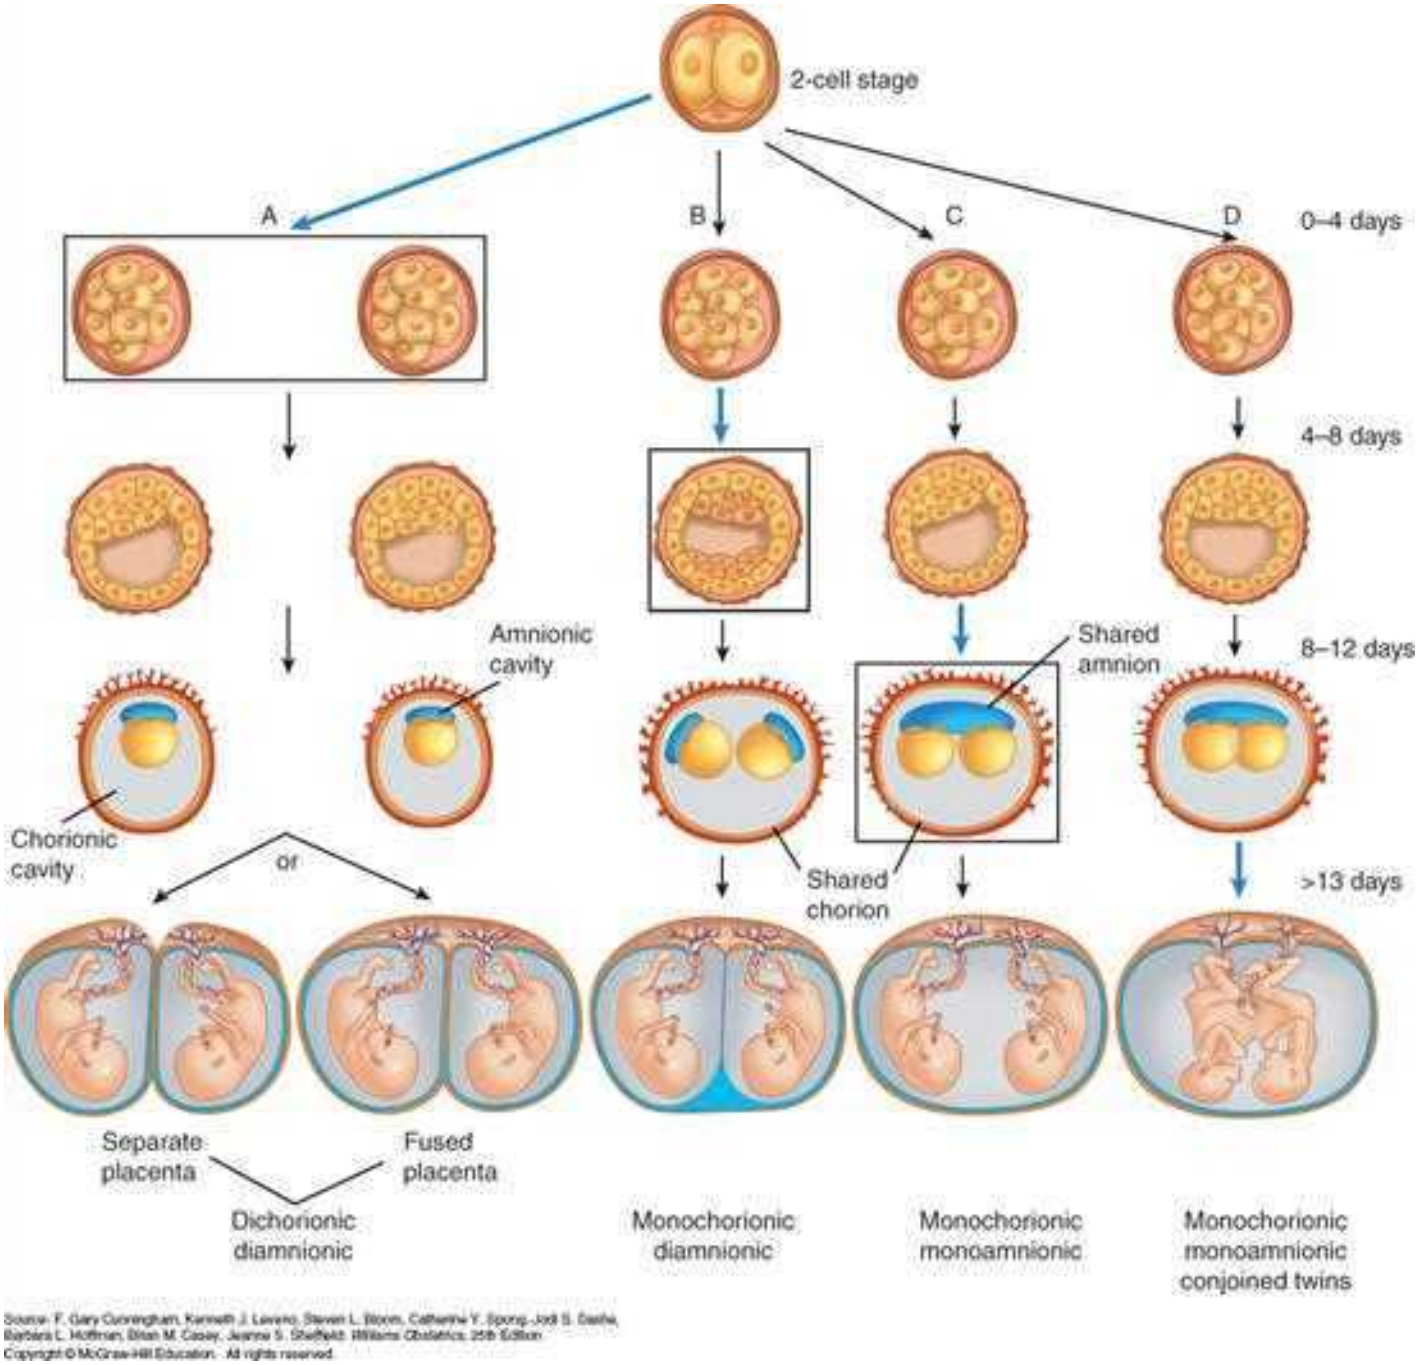
On the other hand, monozygotic or identical twins, although they have virtually the same genetic heritage, are usually not identical. Namely, the division of one fertilized zygote into two does not necessarily result in equal sharing of protoplasmic material. Monozygotic twins may actually be discordant for genetic mutations because of a postzygotic mutation, or may have the same genetic disease but with marked variability in expression. In female fetuses, skewed lyonization can produce differential expression of X-linked traits or diseases. Further, the process of monozygotic twinning is in a sense a teratogenic event, and monozygotic twins have a higher incidence of often discordant malformations (Glinianaia, 2008). For example, in one study of 926 monozygotic twins, the prevalence of congenital heart defects was 12-fold greater than the general population rate, but 68 percent of affected infants had a normal sibling (Pettit, 2013). From any of these mechanisms, dizygotic twins of the same sex may appear more nearly identical at birth than monozygotic twins.

Genesis of Monozygotic Twins

The developmental mechanisms underlying monozygotic twinning are poorly understood. The incidence of monozygotic twins is increased two- to fivefold in pregnancies conceived using assisted reproductive technology (ART). The predisposition to splitting may stem from specimen handling, growth media, or sperm DNA microinjection or may arise from intrinsic abnormalities associated with infertility (McNamara, 2016).

The outcome of the monozygotic twinning process depends on when division occurs. If zygotes divide within the first 72 hours after fertilization, two embryos, two amnions, and two chorions develop, and a diamnionic, dichorionic twin pregnancy evolves (Fig. 45-1). Two distinct placentas or a single, fused placenta may develop. If division occurs between the fourth and eighth day, a diamnionic, monochorionic twin pregnancy results. By approximately 8 days after fertilization, the chorion and the amnion have already differentiated, and division results in two embryos within a common amnionic sac, that is, a monoamnionic, monochorionic twin pregnancy. Conjoined twins result if twinning is initiated later.

FIGURE 45-1
Mechanism of monozygotic twinning. Black boxing and blue arrows in columns A, B, and C indicates timing of division. **A.** At 0 to 4 days postfertilization, an early conceptus may divide into two. Division at this early stage creates two chorions and two amnions (dichorionic, diamnionic). Placentas may be separate or fused. **B.** Division between 4 to 8 days leads to formation of a blastocyst with two separate embryoblasts (inner cell masses). Each embryoblast will form its own amnion within a shared chorion (monochorionic, diamnionic). **C.** Between 8 and 12 days, the amnion and amnionic cavity form above the germinal disc. Embryonic division leads to two embryos with a shared amnion and shared chorion (monochorionic, monoamnionic). **D.** Differing theories explain conjoined twin development. One describes an incomplete splitting of one embryo into two. The other describes fusion of a portion of one embryo from a monozygotic pair onto the other.



It has long been accepted that monochorionicity incontrovertibly indicated monozygosity. Rarely, however, monochorionic twins may in fact be dizygotic (Hackmon, 2009). Mechanisms for this are speculative, but in one review of 14 cases, nearly all had been conceived after ART procedures (Ekelund, 2008). McNamara and colleagues (2016) offer an excellent review of the mechanisms and evidence for both typical and atypical twinning.

Superfetation and Superfecundation

In *superfetation*, an interval as long as or longer than a menstrual cycle intervenes between fertilizations. Superfetation requires ovulation and fertilization during the course of an established pregnancy, which is theoretically possible until the uterine cavity is obliterated by fusion of the decidua capsularis to the decidua parietalis. Although known to occur in mares, superfetation is not known to occur spontaneously in humans. Lantieri and associates (2010) reported a case after ovarian hyperstimulation and intrauterine insemination in the presence of an undiagnosed tubal pregnancy. Most authorities believe that alleged cases of human superfetation result from markedly unequal growth and development of twin fetuses with the same gestational age.

Superfecundation refers to fertilization of two ova within the same menstrual cycle but not at the same coitus, nor necessarily by sperm from the same male. An instance of superfecundation or heteropaternity, documented by Harris (1982), is demonstrated in Figure 45-2. The mother was delivered of a black neonate whose blood type was A and a white neonate whose blood type was O. The blood type of the mother and her husband was O. More recent cases have been reported in the setting of paternity lawsuits (Girela, 1997). Given that superfecundation may also occur with ART, women should be advised to consider avoiding intercourse after embryo transfer (McNamara, 2016; Peigné, 2011).

FIGURE 45-2
An example of dizygotic twin boys as the consequence of superfecundation.

Factors Affecting Twinning

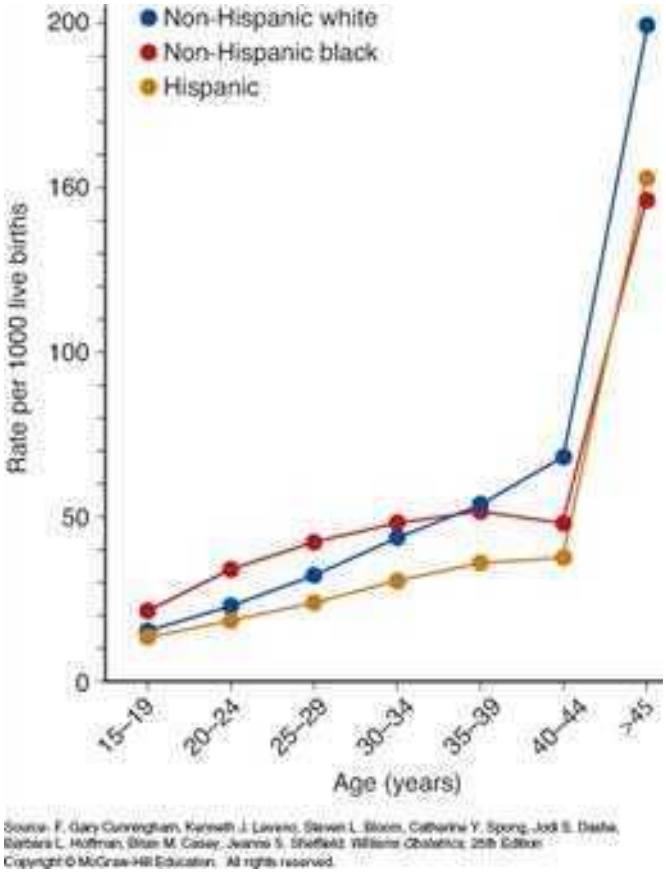
Dizygotic twinning is much more common than monozygotic splitting of a single oocyte, and its incidence is influenced by race, heredity, maternal age, parity, and, especially, fertility treatment. By contrast, the frequency of monozygotic twin births is relatively constant worldwide—approximately 1 set per 250 births, and this incidence is generally independent of demographic factors. One exception is that rates of zygotic splitting are increased following ART (Aston, 2008).

Demographics

Among different races and ethnic groups, the frequency of multifetal births varies significantly. In one analysis of more than 8 million births in the United States between 2004 and 2008, the rate of twinning was 3.5 percent in black women and 3 percent in whites (Abel, 2012). Hispanic, Asian, and Native American women had comparatively lower rates than white women. In one rural community in Nigeria, twinning occurred once in every 20 births (Knox, 1960)! These marked differences in twinning frequency may be the consequence of racial variations in levels of follicle-stimulating hormone—FSH (Nylander, 1973).

Maternal age is another important risk factor for multifetal pregnancies (Fig. 45-3). Dizygotic twinning frequency rises almost fourfold between the ages of 15 and 37 years (Painter, 2010). As such, there is a paradox of declining fertility but increasing twinning rates with advancing maternal age (Beemsterboer, 2006). Another explanation for the dramatic rise in twinning with advancing maternal age may be a higher use of ART in older women (Ananth, 2012). Paternal age has also been linked to twinning frequency, but its effect is felt to be small (Abel, 2012). Although twin pregnancy is associated with greater risks for most adverse perinatal outcomes, McLennan and associates (2017) did not find advanced maternal age to be an additional risk factor for fetal and infant death. From this population-based study of the United States, they concluded that women in their 30s may be counseled that their age is not a major additional risk factor for adverse obstetric outcomes in the setting of twin pregnancy.

FIGURE 45-3
Multifetal birth rates in the United States according to maternal age and race, 2015. (Data from Martin, 2017.)



Increasing parity independently raises the incidence of twinning in all populations studied. During a 30-year period, Antsaklis and coworkers (2013) noted a progressively increasing positive correlation between multiparity and twinning. However, they cautioned that greater use of ART may be partially contributory. In a two-year study from Nigeria, where such technology is not commonly available, Olusanya (2012) calculated the effects of multiparity compared with primiparity. They found an eightfold rise in multifetal gestation rates when parity was ≤4, and a 20-fold rise when parity was ≥5.

Heredity

As a determinant of twinning, the family history of the mother supersedes that of the father. One study of 4000 genealogical records showed that women who themselves were a dizygotic twin gave birth to twins at a rate of 1 set per 58 births (White, 1964). Women who were not a twin, but whose husbands were a dizygotic twin, gave birth to twins at a rate of 1 set per 116 pregnancies. Painter and associates (2010) performed genome-wide linkage analyses on more than 500 families of mothers of dizygotic twins and identified four potential linkage peaks. The highest peak was on the long arm of chromosome 6, and other suggestive peaks were on chromosomes 7, 9, and 16. That said, the contribution of these variants to the overall incidence of twinning is likely small (Hoekstra, 2008).

Nutrition

In animals, the litter size number grows in proportion to nutritional sufficiency. Evidence from various sources indicates that this occurs in humans as well. Nylander (1971) showed an increasing gradient in the twinning rate related to greater nutritional status as reflected by maternal size. Taller, heavier women had a twinning rate 25 to 30 percent greater than short, nutritionally deprived women. Likewise, Reddy and associates (2005) found an association of maternal weight and dizygotic twinning in the United States, in the absence of fertility drugs. Indeed, the influence of maternal weight as a factor for twinning will continue to rise in importance as the percentage of obese women in the United States continues to grow.

Evidence acquired during and after World War II suggested that twinning correlated more with nutrition than with body size. Widespread undernourishment in Europe during those years was associated with a marked fall in the dizygotic twinning rate (Bulmer, 1959). Several investigators have reported a greater prevalence of twinning among women who have taken supplementary folic acid (Ericson, 2001; Haggarty, 2006). Conversely, in a systematic review, Muggli and Halliday (2007) were unable to demonstrate a significant association. Analysis of twinning rate in Texas after folic acid fortification of cereal-grain products also failed to demonstrate an independent increase in twinning rates (Waller, 2003).

Pituitary Gonadotropin

The common factor linking race, age, weight, and fertility to multifetal gestation may be FSH levels (Benirschke, 1973). This theory is supported by the fact that greater fecundity and a higher rate of dizygotic twinning have been reported in women who conceive within 1 month after stopping oral contraceptives, but not during subsequent months (Rothman, 1977). This may be due to the sudden release of pituitary gonadotropin in amounts greater than usual during the first spontaneous cycle after stopping hormonal contraception. Indeed, the paradox of declining fertility but increasing twinning with advancing maternal age can be explained by an exaggerated pituitary release of FSH in response to decreased negative feedback from impending ovarian failure (Beemsterboer, 2006).

Infertility Therapy

Ovulation induction with FSH plus human chorionic gonadotropin (hCG) or clomiphene citrate remarkably enhances the likelihood of multiple concurrent ovulations. In their review of this practice, McClamrock and coworkers (2012) reported rates of twins and higher-order multifetal pregnancies as high as 28.6 percent and 9.3 percent, respectively. Rates this high remain a major concern. Two ongoing multicenter trials—Assessment of Multiple Gestations from Ovarian Stimulation (AMIGOS) and Pregnancy in Polycystic Ovary Syndrome II (PPCOSII)—are designed to provide guidance on achieving maximum pregnancy rates while minimizing multifetal gestation rates (Diamond, 2015; Legro, 2014).

In general with in vitro fertilization (IVF), the greater the number of embryos that are transferred, the greater the risk of twins and other multifetal gestations. In 2014, ART contributed to 1.6 percent of all newborns in the United States and to 18.3 percent of all neonates in multifetal gestations (Sunderam, 2017). The American Society for Reproductive Medicine (2017) recently revised their age-related guidelines regarding the number of cleavage-stage embryos or blastocysts to transfer during IVF. This effort aims to reduce the incidence of higher-order multifetal pregnancies. Based on these new recommendations, women younger than 35 years are encouraged to receive a single-embryo transfer, regardless of embryo stage. These practices have effectively lowered multifetal rates, and the rate of triplet or higher-order multifetal pregnancy has declined every year since 2009 (Kulkarni, 2013; Martin, 2017).

Sex Ratios in Multifetal Pregnancies

In humans, as the number of fetuses per pregnancy rises, the percentage of male conceptuses declines. Strandskov and coworkers (1946) found the percentage of males in 31 million singleton births in the United States was 51.6 percent. For twins, it was 50.9 percent; for triplets, 49.5 percent; and for quadruplets, 46.5 percent. Swedish birth data spanning 135 years reveals the number of males per 100 female newborns was 106 among singletons, 103 among twins, and 99 among triplets (Fellman, 2010). Females predominate even more in twins from late twinning events. For example, 68 percent of thoracopagus conjoined twins are female (Mutchinick, 2011). Two explanations have been offered. First, beginning in utero and extending throughout the life cycle, mortality rates are lower in females. Second, female zygotes have a greater tendency to divide.

Determining Zygosity

Twins of opposite sex are almost always dizygotic. In rare instances, due to somatic mutations or chromosome aberrations, the karyotype or phenotype of a monozygotic twin gestation can be different (Turpin, 1961). Most reported cases describe postzygotic loss of the Y chromosome in one 46,XY twin resulting in a phenotypically female twin with Turner syndrome (45,X). Zech and coworkers (2008) found a rare case of a 47,XXY zygote that underwent postzygotic loss of the X chromosome in some cells and loss of the Y chromosome in other cells. The phenotype of the resultant twins was one male and one female. Karyotype analyses revealed both to be 46,XX/46,XY genetic mosaics.

Determining Chorionicity

The risk for twin-specific complications varies in relation to both zygosity and chorionicity—the number of chorions. Shown in Table 45-2, the latter is the more important determinant. Specifically, perinatal mortality and neurological injury rates are greater in monochorionic diamnionic twins compared with dichorionic diamnionic pairs (Hack, 2008; Lee, 2008). In one retrospective analysis of more than 2000 twins, the risk of fetal demise in one or both monochorionic twin(s) was twice that in dichorionic multifetal gestations (McPherson, 2012). Moreover, the prospective risk of antepartum stillbirth is higher for monochorionic than for dichorionic twins at all preterm gestational ages. The highest risk is before 28 weeks' gestation (Glinianaia, 2011). In contrast, chorionicity differences do not significantly affect maternal outcomes (Carter, 2015).

TABLE 45-2

Overview of the Incidence of Twin Pregnancy Zygosity and Corresponding Twin-Specific Complications

	Rates of Twin-Specific Complications in Percent				
Type of Twinning	**Twins**	**Fetal-Growth Restriction**	**Preterm Delivery[a]**	**Placental Vascular Anastomosis**	**Perinatal Mortality**
Dizygotic	80	25	40	0	10–12
Monozygotic	20	40	50		15–18
Diamnionic/dichorionic	6–7	30	40	0	18–20
Diamnionic/monochorionic	13–14	50	60	100	30–40
Monoamnionic/monochorionic	<1	40	60–70	80–90	58–60
Conjoined	0.002 to 0.008	—	70–80	100	70–90

[a]Delivery before 37 weeks.

Data from Manning, 1995.

Sonographic Determination

This has become an integral tool to assist in multifetal pregnancy management. Indeed, the diagnosis and evaluation of a multifetal gestation is now considered a recognized indication for first-trimester sonography (Reddy, 2014). In addition, the North American Fetal Therapy Network (NAFTNet)—a consortium of 30 medical institutions in the United States and Canada—have provided recommendations for determination of chorionicity using sonography (Emery, 2015).

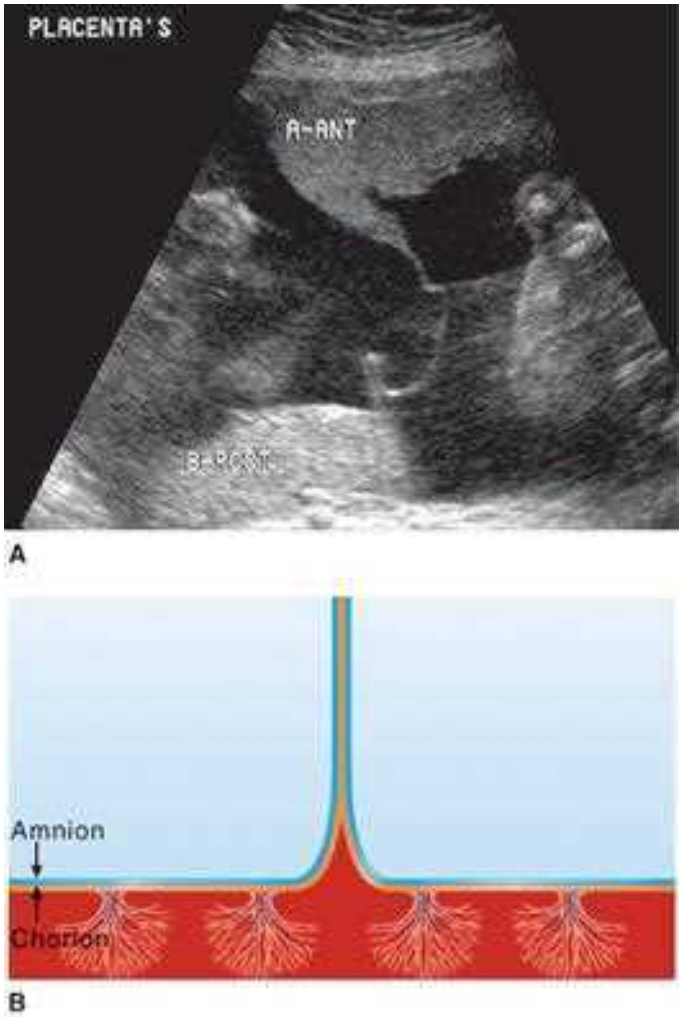
Sonographic features used to evaluate chorionicity vary according to gestational age. Accuracy is greatest in the first trimester and diminishes as gestational age advances. Namely, chorionicity can be determined sonographically with 98-percent accuracy in the first trimester but may be incorrect in up to 10 percent of second-trimester examinations (Emery, 2015; Lee, 2006). Moreover, for sonographic evaluations between 15 and 20 weeks' gestation, the odds of chorionicity misclassification rise by approximately 10 percent for each week of advancing gestational age in pregnancies compared with those completed before 14 weeks (Blumenfeld, 2014). Overall, chorionicity can be correctly determined with sonography before 24 weeks in approximately 95 percent of cases (Lee, 2006).

Early in the first trimester, the number of chorions equates to the number of gestational sacs. A thick band of chorion separating two gestational sacs signals a dichorionic pregnancy, whereas monochorionic twins have a single gestational sac. If the gestation is monochorionic diamnionic, it may be difficult to visualize the thin intervening amnion before 8 weeks' gestation (Emery, 2015). If the intervening membrane is difficult to visualize, the number of yolk sacs *usually* correlates with the number of amnions. However, the number of yolk sacs as a predictor of amnionicity may not always be accurate (Shen, 2006). Although uncommonly seen early, cord entanglement identifies a monoamnionic gestation. When chorionicity is uncertain, additional later sonographic examinations are performed.

After 10 to 14 weeks' gestation, sonographic assessment of chorionicity may be determined using four features. These are the number of placental masses, thickness of the membrane dividing the sacs, presence of an intervening membrane, and fetal gender (Emery, 2015). First, two separate placentas suggest dichorionicity. The converse is not necessarily true, such as cases with a single fused placental mass. Second, identification of a thick dividing membrane—generally ≥2 mm—supports a presumed diagnosis of dichorionicity. In a dichorionic pregnancy, this visualized membrane is composed of a total of four layers—two amnion and two chorion. Also, the *twin peak sign*—also called *lambda* or *delta sign*—is seen by examining the point of origin of the dividing membrane on the placental surface. The peak appears as a triangular projection of placental tissue extending a short distance between the layers of the dividing membrane (Fig. 45-4).

FIGURE 45-4

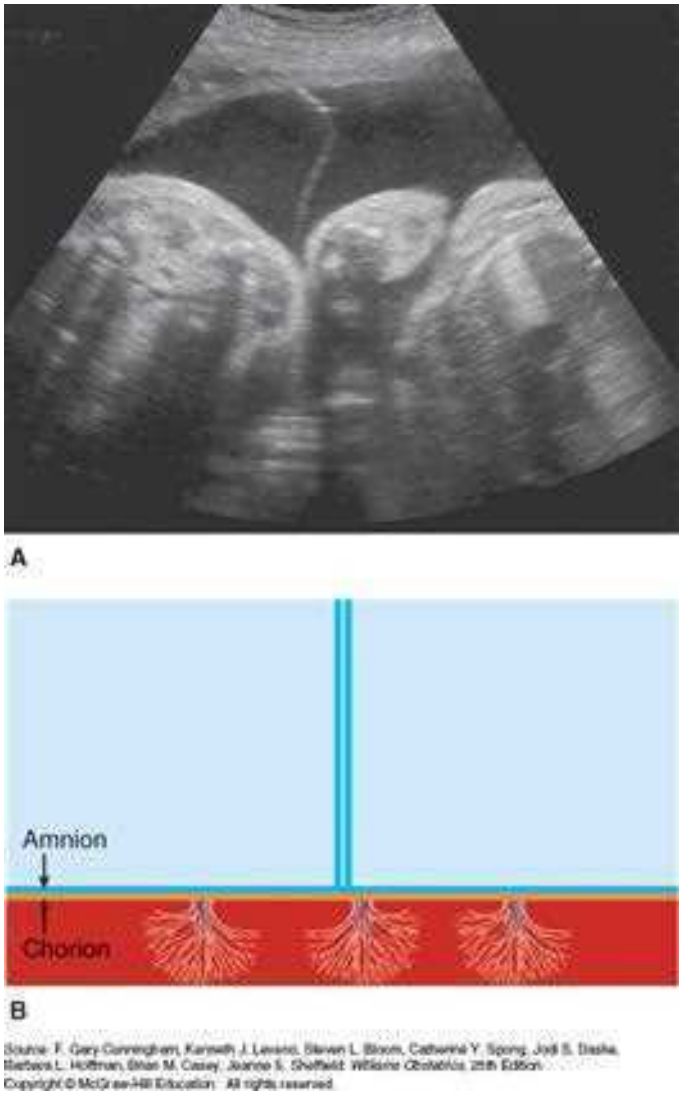
A. Sonographic image of the "twin-peak" sign, also termed the "lambda sign," in a 24-week gestation. At the top of this sonogram, tissue from the anterior placenta is seen extending downward between the amnion layers. This sign confirms dichorionic twinning. **B.** The "twin-peak" sign is seen at the bottom of this schematic diagram. The triangular portion of placenta insinuates between the amniochorion layers.



In contrast, monochorionic pregnancies have a dividing membrane that is so thin (generally <2 mm) that it may not be seen until the second trimester. The relationship between the membranes and placenta without apparent extension of placenta between the dividing membranes is called the *T sign* (Fig. 45-5). Evaluation of the dividing membrane can establish chorionicity in more than 99 percent of pregnancies in the first trimester (Miller, 2012). Lack of a dividing membrane signals a monochorionic monoamnionic gestation.

FIGURE 45-5

A. Sonographic image of the "T" sign in a monochorionic diamnionic gestation at 30 weeks. **B.** Schematic diagram of the "T" sign. Twins are separated only by a membrane created by the juxtaposed amnion of each twin. A "T" is formed at the point at which amnions meet the placenta.



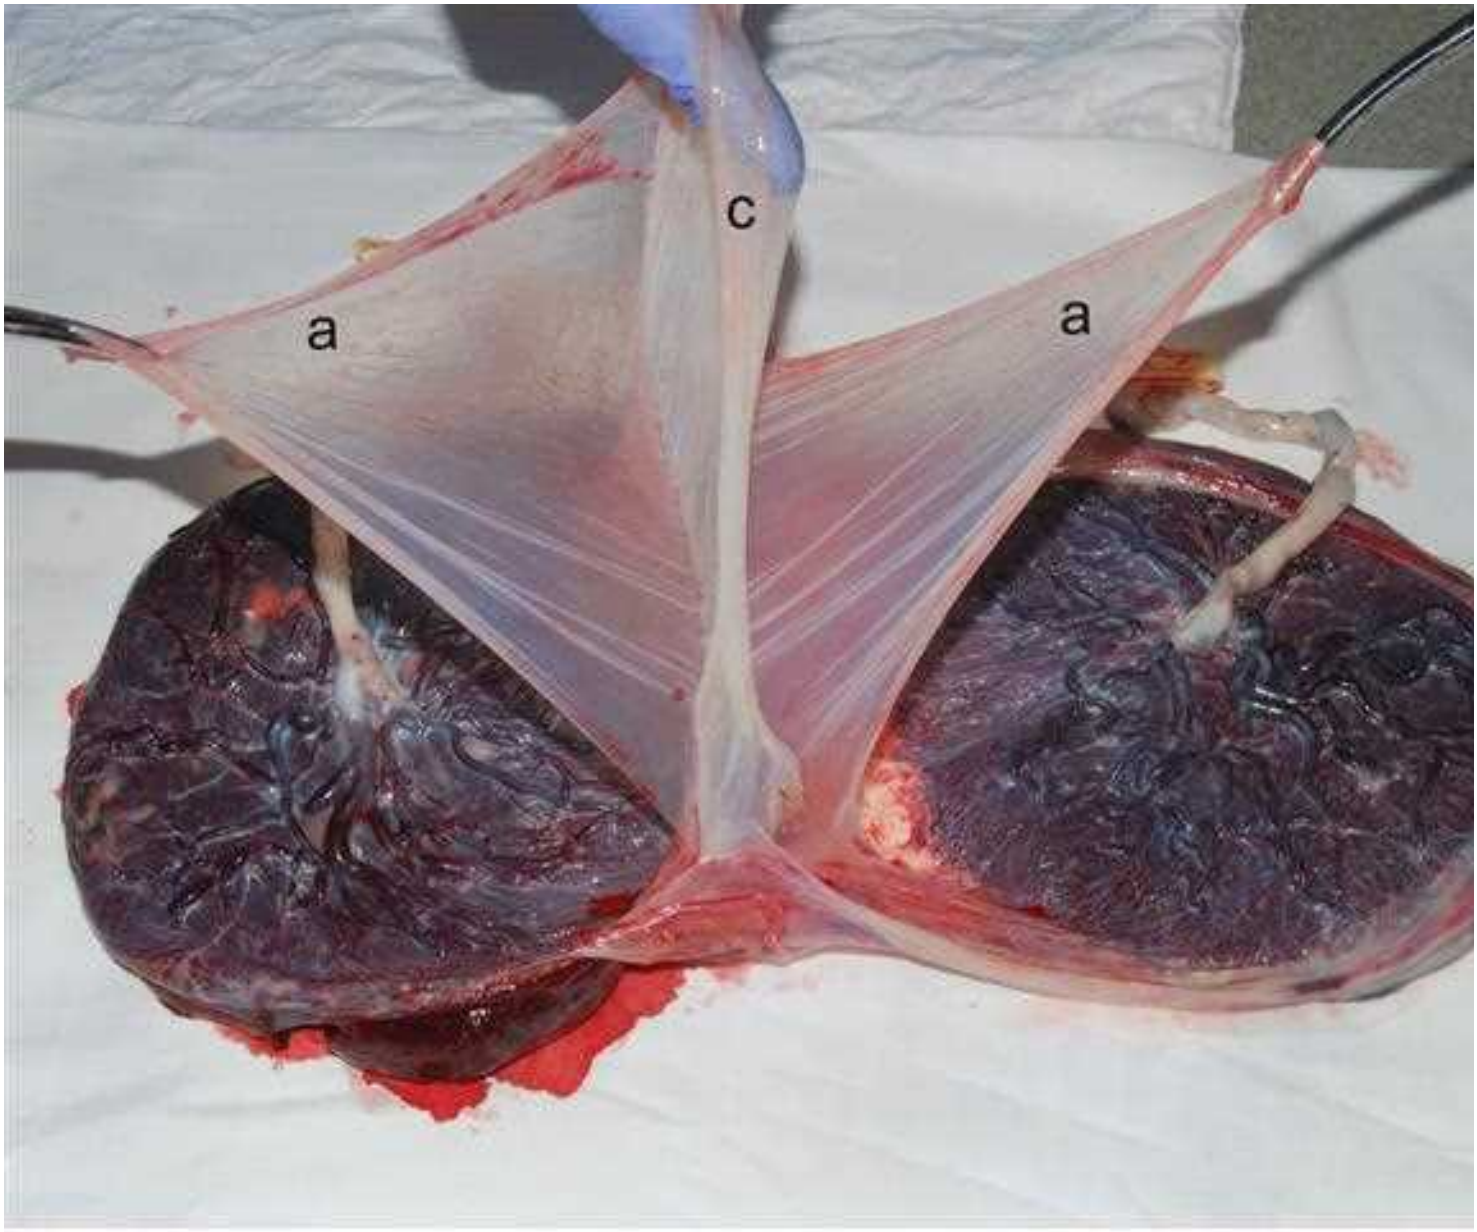
Last, twins with differing gender indicates a dichorionic (and dizygotic) gestation (Emery, 2015). A rare exception to this scenario would be a heterokaryotypic monochorionic gestation, described earlier (Sex Ratios in Multifetal Pregnancies). If both twins are the same gender, additional measures are necessary.

Placental Examination

A carefully performed visual examination of the placenta and membranes after delivery serves to establish zygosity and chorionicity promptly in approximately two thirds of cases. The following systematic examination is recommended. As the first neonate is delivered, one clamp is placed on a portion of its cord. Cord blood is generally not collected until after delivery of the other twin. As the second neonate is delivered, two clamps are placed on that cord, and so on as necessary. Alternatively, in higher-order deliveries, color-tagged clamps can be simpler. Until the delivery of the last fetus, each cord segment must remain clamped to prevent fetal hypovolemia and anemia caused by blood leaving the placenta via anastomoses and then through an unclamped cord. At this time, evidence is insufficient to recommend for or against delayed umbilical cord clamping in multifetal gestations (American College of Obstetricians and Gynecologists, 2017a). At Parkland Hospital, we currently do not perform delayed cord clamping in these pregnancies.

The placenta is carefully delivered to preserve the attachment of the amnion and chorion. With one common amnionic sac or with juxtaposed amnions not separated by chorion, the fetuses are monozygotic (see Fig. 45-1). If adjacent amnions are separated by chorion, the fetuses could be either dizygotic or monozygotic, but dizygosity is more common (Fig. 45-6). If the neonates are of the same sex, blood typing of cord blood samples may be helpful. Different blood types confirm dizygosity, although demonstrating the same blood type in each fetus does not confirm monozygosity. For definitive diagnosis, more complicated techniques such as DNA fingerprinting can be used. However, these tests are generally not performed at birth unless medical indications dictate a need.

FIGURE 45-6
Dichorionic diamnionic twin placenta. The membrane partition that separated twin fetuses is elevated and consists of chorion (***c***) between two amnions (***a***).



DIAGNOSIS OF MULTIFETAL GESTATION

Clinical Evaluation

During physical examination, accurate fundal height measurement, described in Chapter 9 (Subsequent Prenatal Visits), is essential. With multifetal pregnancies, uterine size is typically larger during the second trimester than expected for a singleton. Rouse and associates (1993) reported fundal heights in 336 well-dated twin pregnancies. Between 20 and 30 weeks' gestation, fundal heights averaged approximately 5 cm greater than expected for singletons of the same fetal age.

Diagnosing twins by palpation of fetal parts before the third trimester is difficult. Even late in pregnancy, this may be challenging, especially if one twin overlies the other, if the woman is obese, or if there is hydramnios. Palpating two fetal heads, often in different uterine quadrants, strongly supports a twin diagnosis. Late in the first trimester, two fetal heartbeats may be differentiated with Doppler ultrasonic equipment if their rates are clearly distinct from each other and from that of the mother.

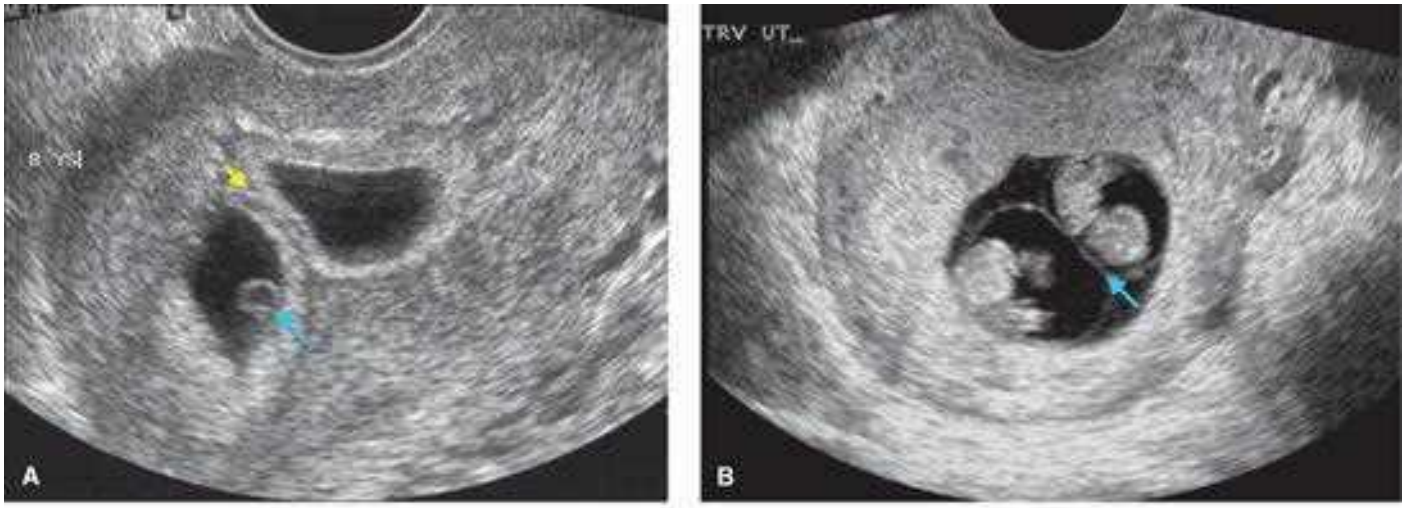
Overall, however, using clinical criteria alone to diagnose multifetal gestations is unreliable. For example, in the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial, for 37 percent of women who did not have a screening ultrasound examination, their twin pregnancies were not diagnosed until 26 weeks' gestation. And, in 13 percent of unscanned women, their multifetal gestations were only diagnosed during their admission for delivery (American College of Obstetricians and Gynecologists, 2016; LeFevre, 1993).

Sonography

Sonographic examination should detect practically all sets of twins. And, given the increased frequency of sonographic examinations during the first trimester, early detection of a twin pregnancy is common. Sonography can also be used to determine fetal number, estimated gestational age, chorionicity, and amnionicity. With careful examination, separate gestational sacs, if present, can be identified early in twin pregnancy (Fig. 45-7). Subsequently, each fetal head should be seen in two perpendicular planes so as not to mistake a cross section of the fetal trunk for a second fetal head. Ideally, two fetal heads or two abdomens should be seen in the same image plane to avoid scanning the same fetus twice and interpreting it as twins.

FIGURE 45-7

Sonograms of first-trimester twins. **A.** Dichorionic diamnionic twin pregnancy at 6 weeks' gestation. Note the thick dividing chorion (*yellow arrow*). One of the yolk sacs is indicated (*blue arrow*). **B.** Monochorionic diamnionic twin pregnancy at 8 weeks' gestation. Note the thin amnion encircling each embryo, resulting in a thin dividing membrane (*blue arrow*).



Higher-order multifetal gestations are more challenging to evaluate. Even in the first trimester, it can be difficult to identify the actual number of fetuses and their position. This determination is especially important if pregnancy reduction or selective termination is considered (Selective Reduction or Termination).

Other Diagnostic Aids

Abdominal radiography can be used if fetal number in a higher-order multifetal gestation is uncertain. However, radiographs generally have limited utility and may lead to an incorrect diagnosis if fetuses move during the exposure or if exposure time is inadequate. Additionally, fetal skeletons before 18 weeks' gestation are insufficiently radiopaque and may be poorly seen.

Although not typically used to diagnose multifetal pregnancy, magnetic resonance (MR) imaging may help delineate complications in monochorionic twins (Hu, 2006). In one review of 17 complicated twin gestations evaluated by both sonographic and MR imaging, the latter provided a more detailed assessment of twin pathology (Bekiesinska-Figatowska, 2013). This was particularly helpful in cases of conjoined twins.

No biochemical test reliably identifies multifetal gestations. Serum and urine levels of β-hCG and maternal serum levels of alpha-fetoprotein (MSAFP) are generally higher with twins compared with those in singletons. However, levels may vary considerably and overlap with those of singletons.

MATERNAL PHYSIOLOGICAL ADAPTATIONS

The various physiological burdens of pregnancy and the likelihood of serious maternal complications are typically greater with multifetal gestations than with a singleton pregnancy. This is considered, especially when counseling a woman whose health is compromised and in whom a multifetal gestation is recognized early. Similar consideration is given to the woman who is not pregnant but is considering infertility treatment.

Beginning in the first trimester, and temporarily associated with higher serum β-hCG levels, women with a multifetal gestation often have nausea and vomiting in excess of that with a singleton pregnancy. In women carrying more than one fetus, blood volume expansion is greater and averages 50 to 60 percent compared with 40 to 50 percent in those with a singleton (Pritchard, 1965). This augmented hypervolemia teleologically offsets blood loss with vaginal delivery of twins, which is twice that with a single fetus. Although red cell mass also accrues, it does so proportionately less in twin pregnancies. Combined with greater iron and folate requirements, this predisposes to anemia.

Women carrying twins also have a typical pattern of arterial blood pressure change. MacDonald-Wallis and coworkers (2012) analyzed serial blood pressures in more than 13,000 singleton and twin pregnancies. As early as 8 weeks' gestation, the diastolic blood pressure in women with twins was lower than that with singleton pregnancies but generally rose by a greater degree at term. An earlier study demonstrated that this rise was at least 15 mm Hg in 95 percent of women with twins compared with only 54 percent of women with a singleton (Campbell, 1986).

Hypervolemia along with decreased vascular resistance has an impressive effect on cardiac function. In one study of 119 women with a twin pregnancy, cardiac output rose another 20 percent above that in women with a singleton pregnancy (Kametas, 2003). Similarly, Kuleva and coworkers (2011) using serial

echocardiography found a greater increase in cardiac output in 20 women with uncomplicated twin pregnancies. Both studies found the augmented cardiac output was predominantly due to greater stroke volume rather than higher heart rate. Vascular resistance was significantly lower in twin gestations throughout pregnancy compared with singleton ones. In a study of 30 uncomplicated twin pregnancies, this same group of investigators using echocardiography later identified progressive diastolic dysfunction from the first to third trimester. The dysfunction subsequently normalized after delivery (Ghi, 2015).

Uterine growth in a multifetal gestation is substantively greater than in a singleton pregnancy. The uterus and its nonfetal contents may achieve a volume of 10 L or more and weigh in excess of 20 pounds. Especially with monozygotic twins, excessive amounts of amnionic fluid may rapidly accumulate. In these circumstances, maternal abdominal viscera and lungs can be appreciably compressed and displaced by the expanding uterus. As a result, the size and weight of the large uterus may preclude more than a sedentary existence for these women.

If hydramnios develops, maternal renal function can become seriously impaired, most likely as the consequence of obstructive uropathy (Quigley, 1977). With severe hydramnios, therapeutic amniocentesis may provide relief for the mother, may improve obstructive uropathy, and possibly may lower the preterm delivery risk that follows preterm labor or prematurely ruptured membranes. Unfortunately, hydramnios is often characterized by acute onset remote from term and by rapid reaccumulation despite amniocentesis.

PREGNANCY COMPLICATIONS

Spontaneous Abortion

Miscarriage is more likely with multifetal gestation. In one 16-year study, the spontaneous abortion rate per live birth in singleton pregnancies was 0.9 percent compared with 7.3 percent in multifetal ones (Joó, 2012). Also, twins achieved through ART are at greater risk for abortion compared with those conceived spontaneously (Szymusik, 2012).

In some cases, one fetus may be spontaneously lost rather than the entire gestation. As a result, the incidence of twins in the first trimester is much greater than the incidence of twins at birth. It has been estimated that 1 in *80 births* are multifetal, whereas 1 in *8 pregnancies* begin multifetal but are spontaneously reduced (Corsello, 2010). Sonography studies in the first trimester have shown that one twin is spontaneously reduced or "vanishes" before the second trimester in up to 10 to 40 percent of all twin pregnancies (Brady, 2013). The incidence is higher following ART conception. Also, monochorionic twins have a significantly greater risk of spontaneous reduction than dichorionic twins (Sperling, 2006). Undoubtedly, some threatened abortions are the result of death and resorption of one embryo from an unrecognized twin gestation.

Dickey and associates (2002) described spontaneous reduction in 709 multifetal pregnancies. Before 12 weeks, one or more embryos died in 36 percent of twin pregnancies, in 53 percent of triplet pregnancies, and in 65 percent of quadruplet pregnancies. Interestingly, ultimate pregnancy duration and birthweight were inversely related to the initial gestational sac number regardless of the final number of fetuses at delivery. This effect was most pronounced in twins who started as quadruplets. Chasen and coworkers (2006) reported that spontaneous reduction of an IVF twin pregnancy to a singleton pregnancy was associated with perinatal outcomes intermediate between those for IVF singleton and IVF twin pregnancies that did not undergo spontaneous reduction. Evidence for adverse immediate and long-term effects of twin spontaneous reduction on the remaining pregnancy is conflicting (McNamara, 2016).

Notably, spontaneous reduction of a twin gestation may affect prenatal screening results. In one study of ART-conceived gestations, Gjerris and colleagues (2009) compared 56 twin pregnancies with a single early demise and 897 singleton gestations. They found no differences in first-trimester serum marker concentrations as long as the embryonic loss was identified before 9 weeks' gestation. If diagnosed after 9 weeks, the serum markers were higher and less precise in gestations with an early demise of one twin than in the singleton gestations. With a vanishing twin, first-trimester maternal serum levels of the pregnancy associated plasma protein-A (PAPP-A) can be elevated. Second-trimester MSAFP and dimeric inhibin A levels can also be higher (Huang, 2015). This phenomenon may also affect noninvasive prenatal testing using cell-free DNA (cfDNA). In one report, this effect was thought to be responsible for 15 percent of the false-positive results from quantitative counting methods (Futch, 2013). The recent development of single nucleotide polymorphism technology for cfDNA testing appears to hold promise in better identifying these cases (Curnow, 2015). Regardless, the diagnosis of a spontaneously reduced abortus is ideally excluded to help avoid confusion with results from aneuploidy and neural-tube defect screening.

Congenital Malformations

As noted earlier, the incidence of congenital malformations is appreciably higher in multifetal gestations compared with that in singleton pregnancies. In one survey-based study, the congenital malformation rate was 406 per 10,000 twins compared with 238 per 10,000 singletons (Glinianaia, 2008). The malformation rate in monochorionic twins was almost twice that of dichorionic twin gestations. This increase has been attributed to the higher incidence of structural defects in monozygotic twins. Indeed, one large population-based study between 1998 and 2010 found that twins had a 73-percent greater risk of congenital heart disease than singletons. The risk was substantially higher among monochorionic twins (Best, 2015). But, from a 30-year European registry of multifetal births, structural anomaly rates rose steadily from 2.16 percent in 1987 to 3.26 percent in 2007 (Boyle, 2013). Yet, during this time, the proportion of dizygotic twins grew by 30 percent, whereas the proportion of monozygotic twins remained stable. This higher risk of congenital malformations in dizygotic twins over time correlated with increased availability of ART. An increase in rates of birth defects related to ART has been reported repeatedly (Boulet, 2016; Talauliker, 2012).

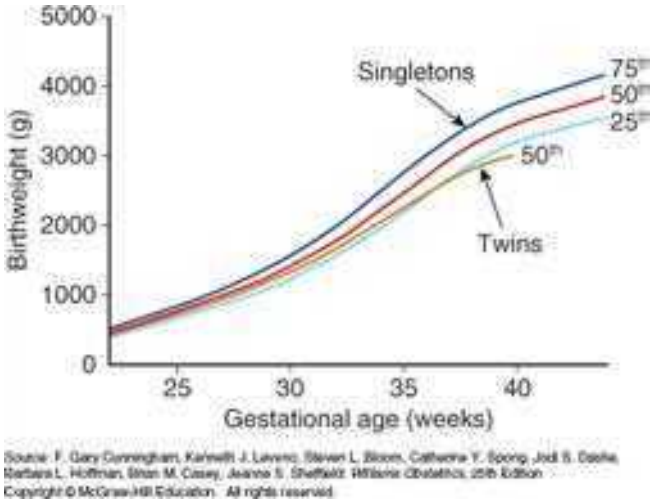
Low Birthweight

Multifetal gestations are more likely to be low birthweight than singleton pregnancies due to restricted fetal growth and preterm delivery. From 1988 to 2012 at Parkland Hospital, data were collected from 357,205 singleton neonates without malformations and from 3714 normal twins who were both liveborn. Birthweights in

twins closely paralleled those of singletons until 28 to 30 weeks' gestation. Thereafter, twin birthweights progressively lagged (Fig. 45-8). Beginning at 35 to 36 weeks' gestation, twin birthweights clearly diverge from those of singletons.

FIGURE 45-8

Birthweight percentiles (25th to 75th) for 357,205 singleton neonates compared with the 50th birthweight percentile for 3714 twins, Parkland Hospital 1988—2012. Infants with major malformations, pregnancies complicated by stillbirth, and twin gestations with >25 percent discordance were also excluded. (Data from Dr. Don McIntire.)



In general, the degree of growth restriction increases with fetal number. The caveat is that this assessment is based on growth curves established for singletons. Several authorities argue that fetal growth in twins is different from that of singleton pregnancies. And thus, abnormal growth should be diagnosed only when fetal size is less than expected for *multifetal gestation*. Accordingly, twin and triplet growth curves have been developed (Kim, 2010; Odibo, 2013; Vora, 2006). At Parkland, we use the standards of birthweight in twin gestations stratified by placental chorionicity for identification of suspected fetal-growth restriction (Ananth, 1998).

The degree of growth restriction in monozygotic twins is likely to be greater than that in dizygotic pairs (Fig. 45-9). With monochorionic embryos, allocation of blastomeres may not be equal, vascular anastomoses within the placenta may cause unequal distribution of nutrients and oxygen, and discordant structural anomalies resulting from the twinning event itself may affect growth. For example, the quintuplets shown in Figure 45-10 represent three dizygotic and two monozygotic fetuses. When delivered at 31 weeks, the three neonates from separate ova weighed 1420, 1530, and 1440 g, whereas the two derived from the same ovum weighed 990 and 860 g.

FIGURE 45-9

Marked growth discordance in monochorionic twins. (Used with permission from Dr. Laura Greer.)

FIGURE 45-10

Davis quintuplets at 3 weeks following delivery. The first, second, and fourth newborns from the left each arose from separate ova, whereas the third and fifth neonates are from the same ovum.

In the third trimester, the larger fetal mass leads to accelerated placental maturation and relative placental insufficiency. In dizygotic pregnancies, marked size discordancy usually results from unequal placentation, with one placental site receiving more perfusion than the other. Size differences may also reflect different genetic fetal-growth potentials. Discordancy can also result from fetal malformations, genetic syndromes, infection, or umbilical cord abnormalities such as velamentous insertion, marginal insertion, or vasa previa (Chap. 44, Accelerated Lung Maturation).

Hypertension

Pregnancy-related hypertensive disorders are more likely to develop with multifetal gestations. The exact incidence attributable to twin pregnancy is difficult to determine because these gestations are more likely to deliver preterm and before preeclampsia usually develops. Also, women with twin pregnancies are often older and multiparous, qualities associated with lower rates of preeclampsia (Francisco, 2017). The incidence of pregnancy-related hypertension in women with twins is 20 percent at Parkland Hospital. In their analysis of 513 twin pregnancies, Fox and coworkers (2014) identified 15 percent of parturients with preeclampsia. Another study compared 257 women with twins and gestational diabetes against 277 nondiabetic women carrying twins. These researchers found a twofold greater risk of preeclampsia in women diagnosed with gestational diabetes (Gonzalez, 2012). Conversely, no specific zygosity confers a greater rate of hypertensive disorder in twin pregnancies (Lučovnik, 2016). Finally, from the National Center for Health Statistics, Luke and associates (2008) analyzed 316,696 twin, 12,193 triplet, and 778 quadruplet pregnancies. These investigators noted that the risk for pregnancy-associated hypertension was significantly increased for triplets and quadruplets (11 and 12 percent, respectively) compared with that for twins (8 percent).

These data suggest that fetal number and placental mass are involved in preeclampsia pathogenesis. Women with twin pregnancies have levels of antiangiogenic soluble fms-like tyrosine kinase-1 (sFlt-1) that are twice that of singletons. Levels are seemingly related to greater placental mass rather than primary placental pathology (Bdolah, 2008; Maynard, 2008). Rana and coworkers (2012) measured antiangiogenic sFlt-1 and proangiogenic placental growth factor (PlGF) in 79 women with twins referred for evaluation of preeclampsia. In the 58 women identified with either gestational hypertension or preeclampsia, there was an incremental rise in sFlt-1 concentrations, decline in PlGF levels, and increase in sFlt-1/PlGF ratios compared with normotensive twin pregnancies. With multifetal gestation, hypertension not only develops more often but also tends to develop earlier and be more severe. In the analysis of angiogenic factors mentioned above, more than half of affected women presented before 34 weeks, and their sFlt-1/PlGF ratio rise was more striking (Rana, 2012). This relationship is discussed in Chapter 40 (Endothelial Cell Injury).

Preterm Birth

The duration of gestation shortens with accruing fetal number. More than five of every 10 twins and nine of 10 triplets born in the United States in 2015 were delivered preterm (Martin, 2017). Prematurity is sixfold and tenfold greater in twins and triplets, respectively (Giuffre, 2012). One review showed that approximately 60 percent of preterm births in twins are indicated, about a third result from spontaneous labor, and 10 percent follow prematurely ruptured membranes (Chauhan, 2010). In another analysis of almost 300,000 live births, the proportion of preterm birth associated with premature membrane rupture rose with gestational plurality from 13 percent with singletons to 20 percent with triplets or more (Pakrashi, 2013).

Although the causes of preterm delivery in twins and singletons may be different, neonatal outcome is generally the same at similar gestational ages (Kilpatrick, 1996; Ray, 2009; Salem, 2017). However, outcomes for preterm twins who are markedly discordant may not be comparable with those for singletons because whatever caused the discordance may have long-lasting effects (Yinon, 2005).

Long-Term Infant Development

Historically, twins have been considered cognitively delayed compared with singletons (Record, 1970; Ronalds, 2005). However, in cohort studies evaluating normal-birthweight term newborns, cognitive outcomes between twins and singletons are similar (Lorenz, 2012). Christensen and associates (2006) found similar national standardized test scores in the ninth grade in 3411 twins and 7796 singletons born between 1986 and 1988.

In contrast, among normal-birthweight neonates, the cerebral palsy risk is higher among twins and higher-order multiples. For example, the cerebral palsy rate has been reported to be 2.3 per 1000 in singletons, 12.6 per 1000 in twins, and 44.8 per 1000 in triplets (Giuffre, 2012). Greater risks of fetal-growth restriction, congenital anomalies, twin-twin transfusion syndrome, and fetal demise of a cotwin are suggested contributors to these differences (Lorenz, 2012).

UNIQUE FETAL COMPLICATIONS

Several unique complications arise in multifetal pregnancies. These are described in twins but can be found in higher-order multifetal gestations. Most fetal complications due to the twinning process itself are seen with monozygotic twins. Their pathogenesis is best understood after reviewing the possibilities shown in Figure 45-1.

Monoamnionic Twins

Only about 1 percent of all monozygotic twin gestations will share an amnionic sac, and approximately 1 in 20 monochorionic twin gestations are monoamnionic (Hall, 2003; Lewi, 2013). Diamnionic twins can become monoamnionic if the dividing membrane spontaneous or iatrogenically ruptures. Their morbidity and mortality rates then mirror those of monoamnionic twins.

Historical mortality rates in monoamnionic twins were reported to be as high as 70 percent. Contemporary outcomes are improved, yet the demise rate after viability remains elevated (Post, 2015). Of those fetuses alive before 16 weeks' gestation, less than half survive until the neonatal period. Fetal abnormalities and spontaneous miscarriage contribute to most losses (Prefumo, 2015). After 20 weeks, the perinatal mortality rate for monoamnionic twin pregnancies approximates 15 percent (Shub, 2015). A high fetal death rate is attributable to preterm birth, congenital anomalies, twin-twin transfusion syndrome, or cord entanglement.

Congenital anomaly rates in monoamnionic twins reach 18 to 28 percent (Post, 2015). Since concordance of anomalies is found in only approximately one quarter of cases, the finding of normal anatomy in one twin does not negate the need for a thorough evaluation in the second. Also, because of the higher risk of cardiac anomalies, fetal echocardiography is indicated in these pregnancies. Of note, monoamnionic twins are by definition monozygotic and thus presumed to be genetically identical. Consequently, either both or none of the fetuses have chromosomal abnormalities except in rare cases of discordance (Zwijnenburg, 2010). Indeed, the risk for Down syndrome in each fetus of the monozygotic pair is similar to or lower than the risk in maternal age-matched singletons (Sparks, 2016). The standard methods for Down syndrome screening in these pregnancies can be applied (Chap. 14, Traditional Aneuploidy Screening Tests).

The rate of twin-twin transfusion syndrome in monoamnionic twins is lower than the rate reported in monochorionic diamnionic pregnancies. This may be due to the near universal presence in monoamnionic twins of arterioarterial anastomoses, which are presumed to be protective (Hack, 2009b; Post, 2015). Nonetheless, twin-twin transfusion syndrome surveillance is recommended and described in Diagnosis.

Umbilical cords frequently entangle (Fig. 45-11). Morbid cord entanglement appears to occur early, and monoamnionic pregnancies that have successfully reached 30 to 32 weeks' gestation are at reduced risk. In one Dutch series, the incidence of intrauterine demise dropped from 15 percent after 20 weeks to 4 percent at gestational ages >32 weeks (Hack, 2009a). Although color-flow Doppler sonography is used to diagnose entanglement (Fig. 45-12), factors that lead to pathological umbilical vessel constriction are unknown. A consequence is that fetal death from cord entanglement is unpredictable. Unfortunately, monitoring for this is relatively ineffective. In one study, after analysis of more than 10,000 hours of fetal tracing from 17 sets of monoamnionic twins, Quinn and colleagues (2011) concluded that monitoring was physically possible in only 50 percent of cases. An abnormal fetal heart rate tracing prompted delivery in only six cases.

FIGURE 45-11

Monozygotic twins in a single amnionic sac. The smaller fetus apparently died first, and the second subsequently succumbed when umbilical cords entwined.

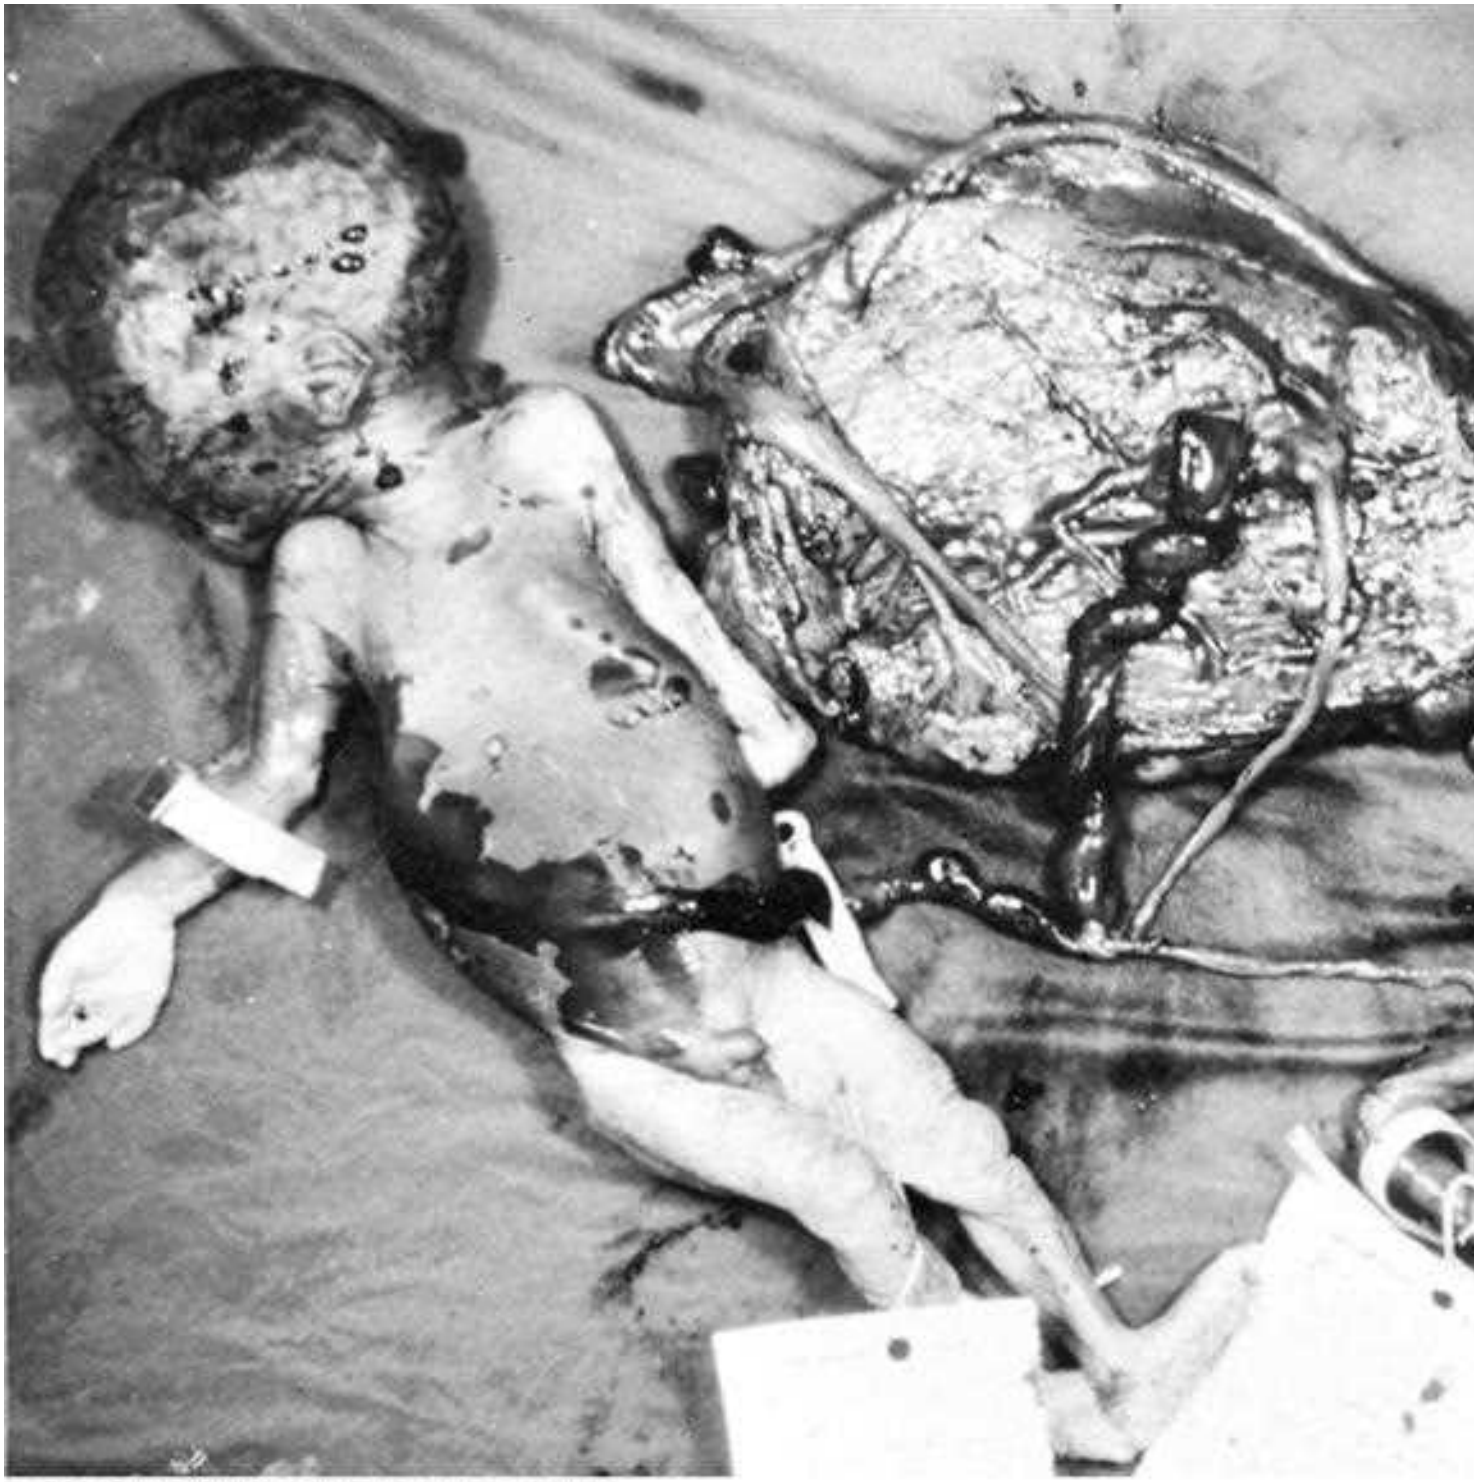


FIGURE 45-12

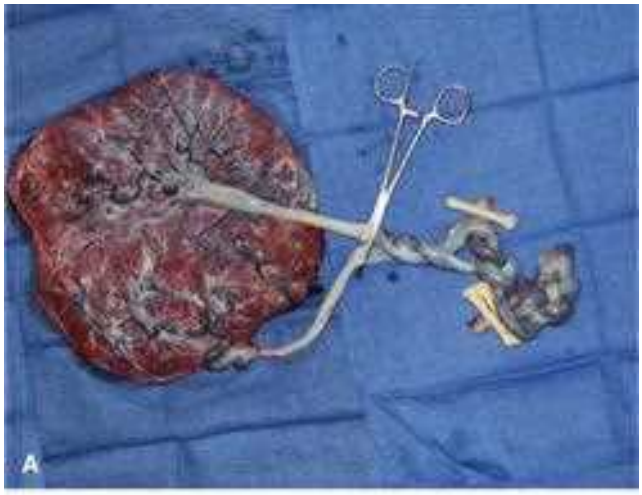
Monochorionic monoamnionic cord entanglement. **A.** Despite marked knotting of the cords, vigorous twins were delivered by cesarean. **B.** Preoperative sonogram of this pregnancy shows entwined cords. **C.** This finding is accentuated with application of color Doppler. (Used with permission from Dr. Julie Lo.)



One proposed management scheme is based on a study by Heyborne and coworkers (2005), who reported no stillbirths in 43 twin pregnancies of women admitted at 26 to 27 weeks' gestation for daily fetal surveillance. However, in 44 women managed as outpatients and admitted only for obstetrical indications, there were 13 stillbirths. Because of this report, women with monoamnionic twins are recommended to undergo 1 hour of daily fetal heart rate monitoring, either as an outpatient or inpatient, beginning at 26 to 28 weeks' gestation. With initial testing, a course of betamethasone is given to promote pulmonary maturation (Chap. 42, Corticosteroids for Fetal Lung Maturation). If fetal testing remains reassuring and no other intervening indications arise, cesarean delivery is performed at 32 to 34 weeks. A second course of betamethasone can be given before this (American College of Obstetricians and Gynecologists, 2016). This management scheme is used at Parkland Hospital and resulted in the successful 34-week delivery of the twins depicted in Figure 45-12.

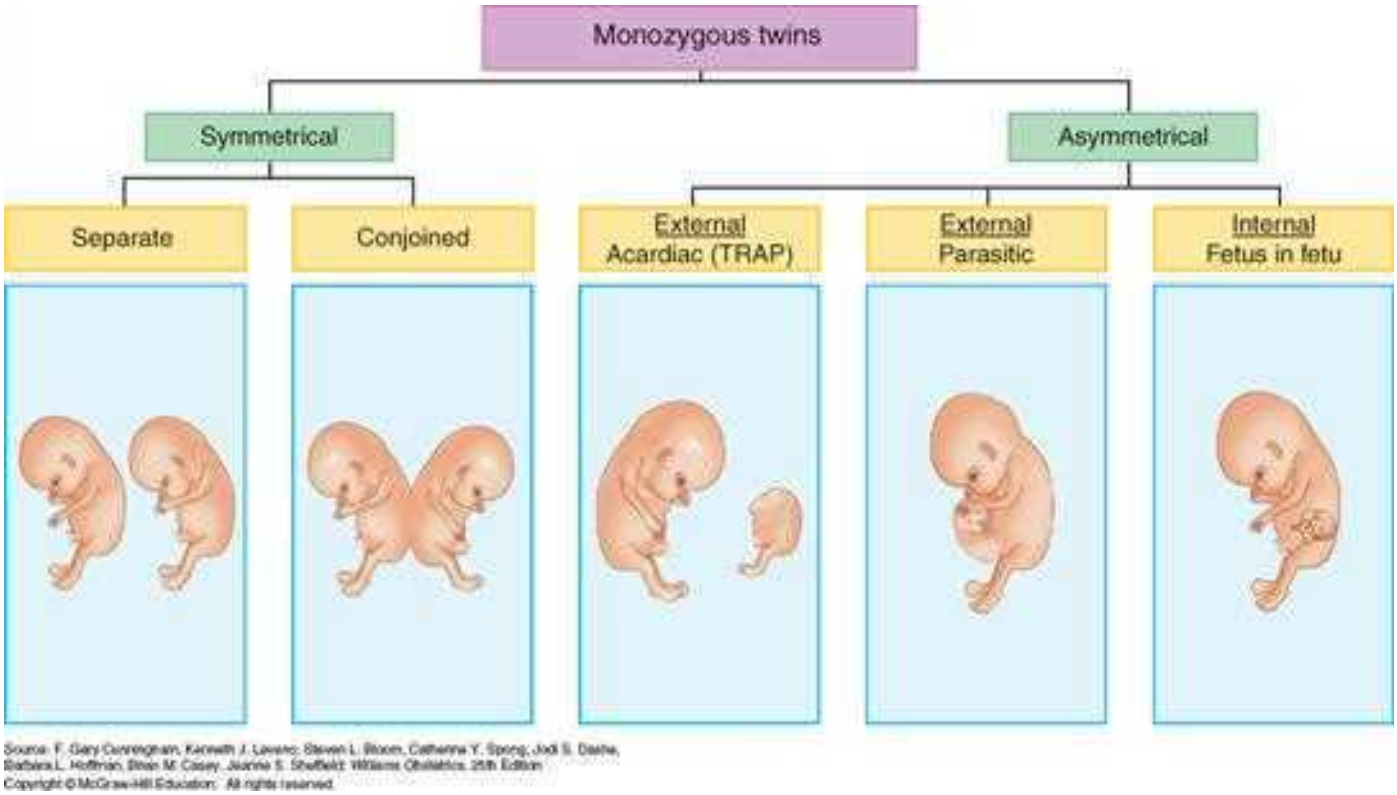
Unique and Aberrant Twinning

Of monoamnionic twins just described, one interesting subset derives from embryonic splitting on postfertilization day 9. These "mirror image twins" are genetically identical but have mirror image features such as handedness and hair whorls (Post, 2015).

More seriously, several aberrations in monozygotic twinning result in a spectrum of fetal malformations. These are traditionally ascribed to incomplete splitting of an embryo into two separate twins. However, it is possible that they may result from early secondary fusion of two separate embryos. These separated embryos are either symmetrical or asymmetrical, and the spectrum of anomalies is shown in Figure 45-13.

FIGURE 45-13

Possible outcomes of monozygotic twinning. The asymmetrical category contains twinning types in which one twin complement is substantially smaller and incompletely formed.

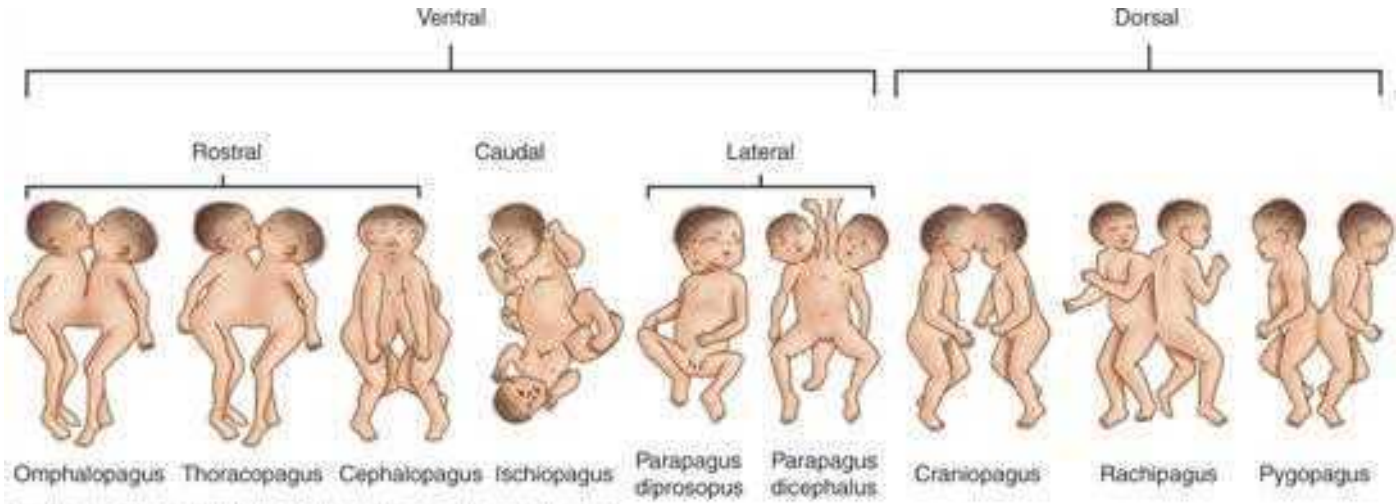


Conjoined Twins

In the United States, united or conjoined twins have been referred to as *Siamese twins*–after Chang and Eng Bunker of Siam (Thailand), who were displayed worldwide by P. T. Barnum. Joining of the twins may begin at either pole and produce characteristic forms depending on which body parts are joined or shared (Fig. 45-14). Of these, thoracopagus is the most common (Mutchinick, 2011). The frequency of conjoined twins is not well established. In Singapore, Tan and coworkers (1971) identified seven cases of conjoined twins among more than 400,000 deliveries—an incidence of 1 in 60,000.

FIGURE 45-14

Types of conjoined twins. (Modified with permission from Spencer R: Theoretical and analytical embryology of conjoined twins: part I: embryogenesis, Clin Anat. 2000;13(1):36–53.)



Conjoined twins can frequently be identified using sonography at midpregnancy (McHugh, 2006). This provides an opportunity for parents to decide whether to continue the pregnancy. As shown in Figure 45-15, identification of cases during the first trimester is also possible. During sonographic interrogation, fetal poles are closely associated and do not change relative position from one another. A targeted examination, including a careful evaluation of the organs involved, is necessary before counseling can be provided. As shown in Figure 45-16, MR imaging is a valuable adjunct to clarify shared organs. Compared with sonography, MR imaging can provide superior views, especially in later pregnancy when amnionic fluid is diminished and fetal crowding is greater (Hibbeln, 2012).

FIGURE 45-15
Sonogram of a conjoined twin pregnancy at 13 weeks' gestation. These thoracoomphalopagus twins have two heads but a shared chest and abdomen.

FIGURE 45-16
Magnetic resonance imaging of conjoined twins. This T2-weighted HASTE sagittal image demonstrates fusion from the level of the xiphoid process to just below the level of the umbilicus, that is, omphalopagus twins. Below the fused liver (*L*), there is a midline cystic mass (*arrow*) within the tissue connecting the twins. An omphalomesenteric cyst was favored given the location within the shared tissue. (Used with permission from Dr. April Bailey.)

Surgical separation of an almost completely joined twin pair may be successful if essential organs are not shared (O'Brien, 2015; Tannuri, 2013). Conjoined twins may have discordant structural anomalies that further complicate decisions about whether to continue the pregnancy. Consultation with a pediatric surgeon often assists parental decision making. A recent series in *Seminars in Pediatric Surgery* with a preface by Spitz (2015) provide an excellent reference regarding postnatal management.

Viable conjoined twins should be delivered by cesarean. For the purpose of pregnancy termination, however, vaginal delivery is possible because the union is most often pliable (Fig. 45-17). Still, dystocia is common, and if the fetuses are mature, vaginal delivery may be traumatic to the uterus or cervix.

FIGURE 45-17
Conjoined twins aborted at 17 weeks' gestation. (Used with permission from Dr. Jonathan Willms.)

External Parasitic Twins

This is a grossly defective fetus or merely fetal parts, attached externally to a relatively normal twin. A parasitic twin usually consists of externally attached supernumerary limbs, often with some viscera. Classically, however, a functional heart or brain is absent. Attachment mirrors those sites described earlier for conjoined twins (see Fig. 45-14). Parasites are believed to result from demise of the defective twin. Its surviving tissue attaches to and receives vascularity from the normal cotwin (Spencer, 2001). In one large epidemiological study, parasitic twins accounted for 4 percent of all conjoined twins and occurred more frequently in male fetuses (Mutchinick, 2011).

Fetus-in-Fetu

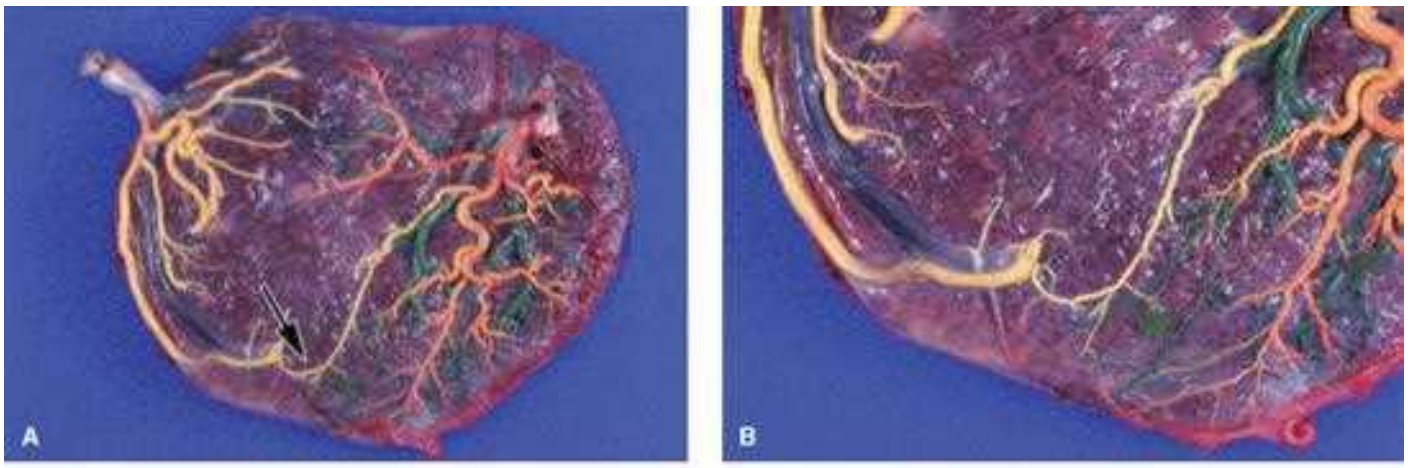
Early in development, one embryo may be enfolded within its twin. Normal development of this rare parasitic twin usually arrests in the first trimester. As a result, normal spatial arrangement of and presence of many organs is lost. Classically, vertebral or axial bones are found in the fetiform mass, whereas a heart and brain are absent. These masses are believed to represent a monozygotic, monochorionic diamnionic twin gestation and are typically supported by large parasitic vessels to the host (McNamara, 2016; Spencer, 2000). Malignant degeneration is rare (Kaufman, 2007).

Monochorionic Twins and Vascular Anastomoses

All monochorionic placentas likely share some anastomotic connections. And, with rare exceptions, anastomoses between twins are unique to monochorionic twin placentas. However, the number, size, and direction of these seemingly haphazard connections vary markedly (Fig. 45-18). In one analysis of more than 200 monochorionic placentas, the median number of anastomoses was 8, with an interquartile range of 4 to 14 (Zhao, 2013).

FIGURE 45-18

Shared placenta from pregnancy complicated by twin-twin transfusion syndrome. The following color code was applied for injection. Left twin: yellow = artery, blue = vein; right twin: red = artery, green = vein. **A.** Part of the arterial network of the right twin is filled with yellow dye, due to the presence of a small artery-to-artery anastomosis (*arrow*). **B.** Close-up of the lower portion of the placenta displays the yellow dye-filled anastomosis. (Reproduced with permission from De Paepe ME, DeKoninck P, Friedman RM: Vascular distribution patterns inmonochorionic twin placentas, Placenta. 2005 Jul;26(6):471–475.)



Artery-to-artery anastomoses are most frequent and are identified on the chorionic surface of the placenta in up to 75 percent of monochorionic twin placentas. Vein-to-vein and artery-to-vein communications are each found in approximately half. One vessel may have several connections, sometimes to both arteries and veins. In contrast to these superficial vascular connections on the surface of the chorion, deep artery-to-vein communications can extend through the capillary bed of a given villus (Fig. 45-19). These deep arteriovenous anastomoses create a common villous compartment or “third circulation” that has been identified in approximately half of monochorionic twin placentas.

FIGURE 45-19

Anastomoses between twins may be artery-to-vein (AV), artery-to-artery (AA), or vein-to-vein (VV). Schematic representation of an AV anastomosis in twin-twin transfusion syndrome that forms a “common villous district” or “third circulation” deep within the villous tissue. Blood from a donor twin may be transferred to a recipient twin through this shared circulation. This transfer leads to a growth-restricted discordant donor twin with markedly reduced amnionic fluid, causing it to be “stuck.”

Whether these anastomoses are dangerous to either twin depends on the degree to which they are hemodynamically balanced. In those with significant pressure or flow gradients, a shunt will develop between fetuses. This chronic fetofetal transfusion may result in several clinical syndromes that include *twin-twin transfusion syndrome (TTTS), twin anemia polycythemia sequence (TAPS),* and *acardiac twinning*.

Twin-Twin Transfusion Syndrome

In this syndrome, blood is transfused from a donor twin to its recipient sibling such that the donor may eventually become anemic and its growth may be restricted. In contrast, the recipient becomes polycythemic and may develop circulatory overload manifest as hydrops. Classically, the donor twin is pale, and its recipient sibling is plethoric. Similarly, one portion of the placenta often appears pale compared with the remainder. The recipient neonate may also have circulatory overload from heart failure and severe hypervolemia and hyperviscosity. Occlusive thrombosis is another concern. Finally, polycythemia in the recipient twin may lead to severe hyperbilirubinemia and kernicterus (Chap. 33, Polycythemia and Hyperviscosity). The prevalence of TTTS approximates 1 to 3 cases per 10,000 births (Society for Maternal-Fetal Medicine, 2013).

Chronic TTTS results from unidirectional flow through deep arteriovenous anastomoses. Deoxygenated blood from a *donor* placental artery is pumped into a cotyledon shared by the recipient (see Fig. 45-19). Once oxygen exchange is completed in the chorionic villus, the oxygenated blood leaves the cotyledon via a placental vein of the *recipient* twin. Unless compensated—typically through superficial arterioarterial anastomoses—this unidirectional flow leads to an imbalance in blood volumes (Lewi, 2013). Clinically important TTTS frequently is chronic and results from significant vascular volume differences between the twins. Even so, the pathogenesis is more complex than a net transfer of red blood cells from one twin to another. Indeed, in most monochorionic twin pregnancies with the syndrome, hemoglobin concentrations between the donor and recipient twin do not differ (Lewi, 2013).

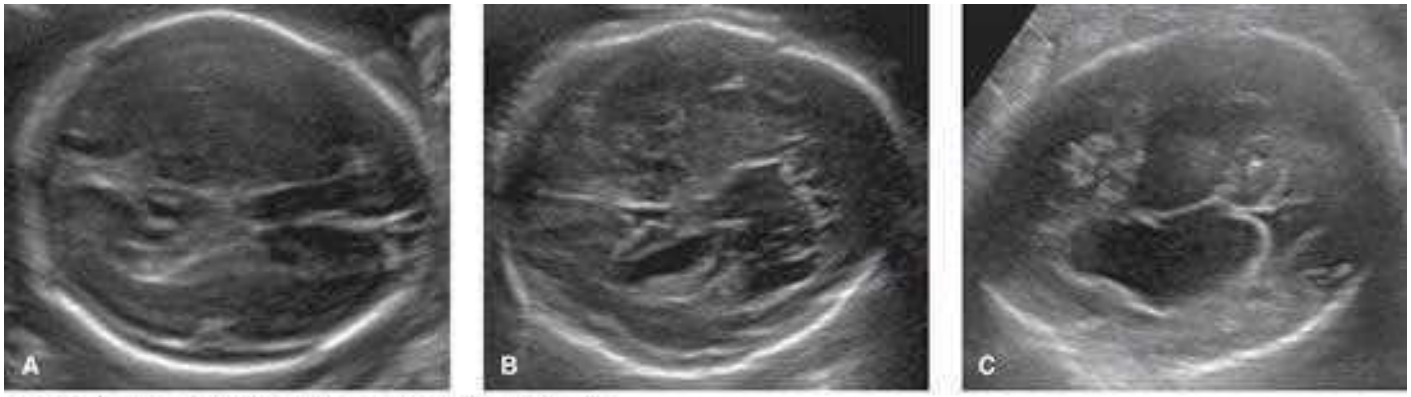
TTTS typically presents in midpregnancy when the donor fetus becomes oliguric from decreased renal perfusion (Society for Maternal-Fetal Medicine, 2013). This fetus develops oligohydramnios, and the recipient fetus develops severe hydramnios, presumably due to increased urine production. Virtual absence of amnionic fluid in the donor sac prevents fetal motion, giving rise to the descriptive term *stuck twin* or *polyhydramnios-oligohydramnios syndrome—"poly-oli."* This amnionic fluid imbalance is associated with growth restriction, contractures, and pulmonary hypoplasia in the donor twin, and premature rupture of the membranes and heart failure in the recipient.

Fetal Brain Damage

Cerebral palsy, microcephaly, porencephaly, and multicystic encephalomalacia are serious complications associated with placental vascular anastomoses in multifetal gestation. The exact pathogenesis of neurological damage is not fully understood but is likely caused by ischemic necrosis leading to cavitary brain lesions (Fig. 45-20). In the donor twin, ischemia results from hypotension, anemia, or both. In the recipient, ischemia develops from blood pressure instability and episodes of profound hypotension (Lopriore, 2011). Cerebral lesions may also be due to postnatal injury associated with preterm delivery (Chap. 34, Retinopathy of Prematurity). In one review of 315 liveborn fetuses from pregnancies with TTTS, cerebral abnormalities were found in 8 percent (Quarello, 2007).

FIGURE 45-20

These serial sonograms depict an interventricular hemorrhage with parenchymal extension and eventual porencephaly that developed following cotwin demise in a monochorionic pregnancy. From left to right, these images were obtained 1 week, 5 weeks, and 8 weeks following demise of the cotwin.



If one twin of an affected pregnancy dies, cerebral pathology in the survivor probably results from acute hypotension. A less likely cause is emboli of thromboplastic material originating from the dead fetus. Fusi and coworkers (1990, 1991) observed that with the death of one twin, acute twin-twin anastomotic transfusion from the high-pressure vessels of the living twin to the low-resistance vessels of the dead twin leads rapidly to hypovolemia and ischemic antenatal brain damage in the survivor. In one review of 343 twin pregnancies complicated by single fetal demise, the risk of neurodevelopmental morbidity in monochorionic twins was 26 percent compared with 2 percent in dichorionic twins (Hillman, 2011). This morbidity was related to the gestational age at the death of the cotwin. If the death occurred between 28 and 33 weeks' gestation, monochorionic twins had an almost eightfold risk of neurodevelopmental morbidity compared with dichorionic twins of the same gestational age. With fetal death after 34 weeks, the likelihood dramatically decreased—odds ratio 1.48.

The acuity of hypotension following the death of one twin with TTTS makes successful intervention for the survivor nearly impossible. Even with delivery immediately after a cotwin demise is recognized, the hypotension that occurs at the moment of death has likely already caused irreversible brain damage (Langer, 1997; Wada, 1998). As such, immediate delivery is not considered beneficial in the absence of another indication.

Diagnosis

The criteria used to diagnose and classify varying severities of TTTS have dramatically changed. Previously, weight discordancy and hemoglobin differences in monochorionic twins were calculated. However, in many cases, these are late findings. According to the Society for Maternal-Fetal Medicine (2013), TTTS is diagnosed based on two sonographic criteria. First, a monochorionic diamnionic pregnancy is identified. Second, hydramnios defined by a largest vertical pocket >8 cm in one sac and oligohydramnios defined by a largest vertical pocket <2 cm in the other twin is found. Only 15 percent of pregnancies complicated by lesser degrees of fluid imbalance progress to TTTS (Huber, 2006). Although growth discordance or growth restriction may be found with TTTS, these per se are not considered diagnostic criteria.

Organizations that include the American College of Obstetricians and Gynecologists (2016), Society for Maternal–Fetal Medicine (2013), and North American Fetal Therapy Network (Emery, 2015) recommend sonography surveillance of pregnancies at risk for TTTS. To aid earlier identification of amnionic fluid abnormalities and other complications of monochorionic twins, these examinations begin at approximately 16 weeks' gestation, and subsequent studies are considered every 2 weeks. Once identified, TTTS is typically classified by the Quintero (1999) staging system (Fig. 45-21):

FIGURE 45-21

A. Sonogram of stage I TTTS at 19 weeks' gestation. Oligohydramnios in the donor twin sac causes the membrane to essentially wrap around the "stuck twin" and suspend it from the anterior uterine wall. **B.** In this same pregnancy, hydramnios is seen in the recipient twin sac. The measured pocket exceeds 10 cm. **C.** Stage II TTTS in a donor twin at 17 weeks' gestation. Color Doppler highlights the arteries that outline the fetal bladder, which contains no urine.

Stage I—discordant amnionic fluid volumes as described in the earlier paragraph, but urine is still visible sonographically within the bladder of the donor twin

Stage II—criteria of stage I, but urine is not visible within the donor bladder

Stage III—criteria of stage II and abnormal Doppler studies of the umbilical artery, ductus venosus, or umbilical vein

Stage IV—ascites or frank hydrops in either twin

Stage V—demise of either fetus.

In addition to these criteria, evidence suggests that cardiac function of the recipient twin correlates with fetal outcome (Crombleholme, 2007). Although fetal echocardiographic findings are not part of the Quintero staging system, many centers routinely perform fetal echocardiography for TTTS. Theoretically, earlier diagnosis of cardiomyopathy in the recipient twin may identify pregnancies that would benefit from early intervention. One system for evaluating cardiac function—the *myocardial performance index (MPI)* or *Tei index*—is a Doppler index of ventricular function calculated for each ventricle (Michelfelder, 2007). Although scoring systems that include assessment of cardiac function have been developed, their usefulness to predict outcomes remains controversial (Society for Maternal-Fetal Medicine, 2013).

Management and Prognosis

The prognosis for multifetal gestations complicated by TTTS is related to Quintero stage and gestational age at presentation. More than three fourths of stage I cases have been reported to remain stable or regress without intervention. Conversely, outcomes in those identified at stage III or higher are much worse, and the perinatal loss rate is 70 to 100 percent without intervention (Society for Maternal-Fetal Medicine, 2013). At Parkland Hospital, among expectantly managed pregnancies with TTTS, most had early disease at diagnosis, and 50 percent of stage I cases progressed (Duryea, 2016).

Several therapies are available for TTTS and include amnioreduction, laser ablation of vascular placental anastomoses, selective feticide, and septostomy. Described further in Chapter 11 (Oligohydramnios), amnioreduction describes needle drainage of excess amnionic fluid. Septostomy is intentionally creating a hole in the dividing amnionic membrane but has largely been abandoned as treatment (Society for Maternal-Fetal Medicine, 2013). Comparative data from randomized trials for some of these other techniques are discussed below.

The Eurofetus trial included 142 women with severe TTTS diagnosed before 26 weeks. Participants were randomly assigned to laser ablation of vascular anastomoses or to serial amnioreduction (Senat, 2004). A higher survival rate to age 6 months for at least one twin was found in pregnancies undergoing laser ablation–76 versus 51 percent, respectively. Moreover, analyses of randomized studies confirm better neonatal outcomes with laser therapy compared with selective amnioreduction (Roberts, 2008; Rossi, 2008, 2009). In contrast, Crombleholme and associates (2007), in a randomized trial of 42 women, found equivalent rates of 30-day survival of one or both twins treated with either amnioreduction or selective fetoscopic laser ablation–75 versus 65 percent, respectively. Furthermore, evaluation of twins from the Eurofetus trial through 6 years of age did not demonstrate an additional survival benefit beyond 6 months or improved neurological outcomes in those treated with laser (Salomon, 2010). At this time, laser ablation of anastomoses is preferred for severe TTTS (stages II–IV). Optimal therapy for stage I disease is controversial.

After laser therapy, close ongoing surveillance is necessary. Robyr and colleagues (2006) reported that a fourth of 101 pregnancies treated with laser required additional invasive therapy because of either recurrent TTTS, or middle cerebral artery (MCA) Doppler evidence of anemia or polycythemia. Recently, in a comparison of selective laser ablation of individual anastomoses versus ablation of the entire surface of the chorionic plate along the vascular equator, Baschat and coworkers (2013) found that equatorial photocoagulation reduced the likelihood of recurrence.

Selective fetal reduction has generally been considered if severe amnionic fluid and growth disturbances develop before 20 weeks. In such cases, both fetuses typically will die without intervention. Any substance injected into one twin may affect the other twin because of shared circulations. Thus, for the fetus chosen for reduction, feticidal techniques include methods that occlude the umbilical vein or umbilical cord of using radiofrequency ablation, fetoscopic ligation, or coagulation with laser, monopolar, or bipolar energy (Challis, 1999; Chang, 2009; Parra-Cordero, 2016). Even after these procedures, however, the risks to the remaining fetus are still appreciable (Rossi, 2009). This topic is further discussed in Selective Reduction or Termination.

Twin Anemia–Polycythemia Sequence

This form of chronic fetofetal transfusion, referred to as TAPS, is characterized by significant hemoglobin differences between donor and recipient twins. However, TAPS lacks the discrepancies in amnionic fluid volumes typical of TTTS (Slaghekke, 2010). It is diagnosed antenatally by MCA peak systolic velocity (PSV) >1.5 multiples of the median (MoM) in the donor and <1.0 MoM in the recipient twin (Society for Maternal-Fetal Medicine, 2013). The spontaneous form of TAPS reportedly complicates 3 to 5 percent of monochorionic pregnancies, and it occurs in up to 13 percent of pregnancies after laser photocoagulation of the placenta. *Spontaneous* TAPS usually occurs after 26 weeks' gestation, and *iatrogenic* TAPS develops within 5 weeks of a procedure (Lewi, 2013). Although a staging system has been proposed by Slaghekke and colleagues (2010), further studies are necessary to better elucidate the natural history of TAPS and its management. In brief, evidence of fetal compromise or greater differences in MCA PSV between twins raise the stage.

Twin Reversed-Arterial-Perfusion Sequence

Also known as an *acardiac twin*, this is a rare but serious complication of monochorionic multifetal gestation. An estimated incidence is 1 case in 35,000 births. In the classic twin reversed-arterial-perfusion (TRAP) sequence, there is a normally formed donor twin that shows features of heart failure and a recipient twin that lacks a heart (acardius) and other structures. In one theory, the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt (Fig. 45-22). Within the single, shared placenta, arterial perfusion pressure of the donor twin exceeds that in the recipient twin, who thus receives reverse blood flow containing deoxygenated arterial blood from its cotwin (Lewi, 2013). This "used" arterial blood reaches the recipient twin through its umbilical arteries and preferentially goes to its iliac vessels. Thus, only the lower body is perfused, and therefore disrupted growth and development of the upper body results. In these cases, failed head growth is called *acardius acephalus*; a partially developed head with identifiable limbs is called *acardius myelacephalus*; and failure of any recognizable structure to form is *acardius amorphous,* which is shown in Figure 45-23 (Faye-Petersen, 2006). Because of this vascular connection, the normal donor

twin must not only support its own circulation but also pump blood through the underdeveloped acardiac recipient. This may lead to cardiomegaly and high-output heart failure in the normal twin (Fox, 2007).

FIGURE 45-22

Twin reversed-arterial-perfusion sequence. In the TRAP sequence, there is usually a normally formed donor twin that has features of heart failure, and a recipient twin that lacks a heart. It has been hypothesized that the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt. Within the single, shared placenta, perfusion pressure of the donor twin overpowers that in the recipient twin, who thus receives reverse blood flow from its twin sibling. The "used" arterial blood that reaches the recipient twin preferentially goes to its iliac vessels and thus perfuses only the lower body. This disrupts growth and development of the upper body.

FIGURE 45-23

Photograph of an acardiac twin weighing 475 grams. The underdeveloped head is indicated by the black arrow, and its details are shown in the inset. A yellow clamp is seen on its umbilical cord. Its viable donor cotwin was delivered vaginally at 36 weeks and weighed 2325 grams. (Used with permission from Dr. Michael D. Hnat.)

In the past, the mortality rate among the pump twins exceeded 50 percent. This stemmed largely from complications of prematurity or from a prolonged high-output state leading to cardiac failure (Dashe, 2001). Risk appears to be directly related to size of the acardiac twin. One sonographic method to estimate acardiac twin size uses the volume of an ellipse: length × width × height ×π/6. When the acardiac twin volume is <50 percent of that of the pump twin, expectant management may be reasonable given the inherent risks of fetal intervention (Chap. 15, Radiofrequency Ablation)(Jelin, 2010). When the volume of the acardiac twin is large, however,

treatment has generally been offered. Radiofrequency ablation (RFA) is the preferred modality of therapy, and contemporary reports now suggest improved perinatal outcomes. The North American Fetal Therapy Network reviewed their experiences with 98 cases from 1998 to 2008 in which RFA of the umbilical cord was performed (Lee, 2013). Median gestational age at delivery was 37 weeks, and 80 percent of neonates survived (Lee, 2013). The average gestational age at the time of the RFA was 20 weeks, and the estimated acardius-to-pump twin volume on average was 90 percent. Major complications were prematurely ruptured membranes and preterm birth.

Interestingly, TRAP sequences can also occur within monoamnionic pregnancies. The perinatal outcomes of such pregnancies appear to be worse than that of monochorionic diamnionic cases. Sugibayashi and associates (2016) in a review of 40 cases recently reported that pump twin survival following RFA was 88 percent in monochorionic diamnionic pregnancies but only 67 percent in monoamnionic pregnancies.

Hydatidiform Mole with Coexisting Normal Fetus

This unique gestation contains one normal fetus, and its cotwin is a complete molar pregnancy. Reported prevalence rates range from 1 in 22,000 to 1 in 100,000 pregnancies (Dolapcioglu, 2009). It must be differentiated from a partial molar pregnancy, in which an anomalous singleton fetus—usually triploid—is accompanied by molar tissue (Fig. 20-4). At times, a twin pregnancy may occur with a normal twin in one sac and a partial mole in the other sac (McNamara, 2016).

Diagnosis is usually made in the first half of pregnancy. Sonographically, a normal-appearing twin is accompanied by its cotwin, which is a large placenta containing multiple small anechoic cysts (Fig. 20-4). Often, these pregnancies are terminated, but pregnancy continuation is increasingly adopted. First, the pregnancy prognosis is not as poor as previously thought, and live birth rates range between 20 and 40 percent (Dolapcioglu, 2009; McNamara, 2016). Second, the risk of persistent trophoblastic disease is similar whether the pregnancy is terminated or not (Massardier, 2009; Sebire, 2002). That said, given the limited number of cases, robust data for firm recommendations are lacking. Importantly, complications of expectant management include vaginal bleeding, hyperemesis gravidarum, thyrotoxicosis, and early-onset preeclampsia (McNamara, 2016). Many of these complications result in preterm birth with its attendant adverse perinatal sequelae as well as perinatal loss. Logically, close surveillance is needed for those continuing the pregnancy.

DISCORDANT GROWTH OF TWIN FETUSES

Fetal size inequality develops in approximately 15 percent of twin gestations and may reflect pathological growth restriction in one fetus (Lewi, 2013; Miller, 2012). Generally, as the weight difference within a twin pair rises, the perinatal mortality rate increases proportionately. If it develops, restricted growth of one twin fetus, often termed *selective fetal-growth restriction*, usually develops late in the second and early third trimester. Earlier discordancy indicates higher risk for fetal demise in the smaller twin. Specifically, when discordant growth is identified before 20 weeks, fetal death occurs in approximately 20 percent of the growth-restricted fetuses (Lewi, 2013).

Etiopathogenesis

The cause of birthweight inequality in twin fetuses is often unclear, but the etiology in monochorionic twins likely differs from that in dichorionic twins. Because the single placenta is not always equally shared in monochorionic twins, these twins have greater rates of discordant growth outside of TTTS than dichorionic twins. Discordancy in monochorionic twins is usually attributed to placental vascular anastomoses that cause hemodynamic imbalance between the twins. Reduced pressure and perfusion of the donor twin can cause diminished placental and fetal growth. Even so, unequal placental sharing is probably the most important determinant of discordant growth in monochorionic twins (Lewi, 2013). Occasionally, monochorionic twins are discordant in size because they are discordant for structural anomalies.

Discordancy in dichorionic twins may result from various factors. Dizygotic fetuses may have different genetic growth potential, especially if they are of opposite genders. Second, because the placentas are separate and require more implantation space, one placenta might have a suboptimal implantation site. Bagchi and associates (2006) observed that the incidence of severe discordancy is twice as great in triplets as it is in twins. This finding lends credence to the view that in utero crowding is a factor in multifetal growth restriction. Placental pathology may play a role as well. In one study of 668 twin placentas, a strong relationship between histological placental abnormalities and birthweight discordancy was observed in dichorionic, but not monochorionic, twin pregnancies (Kent, 2012).

Diagnosis

Size discordancy between twins can be determined sonographically. That said, differences in crown-rump length are not reliable predictors for birthweight discordance (Miller, 2012). Thus, most begin surveillance for discordancy after the first trimester. One common method uses sonographic fetal biometry to compute an estimated weight for each twin (Chap. 10, Gestational Age Assessment). The weight of the smaller twin is then compared with that of the larger twin. Thus, percent discordancy is calculated as the weight of the larger twin minus the weight of the smaller twin, then divided by the weight of the larger twin. Alternatively, given that abdominal circumference (AC) reflects fetal nutrition, some use the sonographic AC value of each twin.

With these methods, some diagnose selective fetal-growth restriction if the AC measurements differ more than 20 mm or if the estimated fetal weight difference is 20 percent or more. That said, several different weight disparities between twins have been used to define discordancy. Accumulated data suggest that weight discordancy greater than 25 to 30 percent most accurately predicts an adverse perinatal outcome. At Parkland, Hollier and coworkers (1999) retrospectively evaluated 1370 delivered twin pairs and stratified twin weight discordancy in 5-percent increments within a range of 15 to 40 percent. They found that the incidence of respiratory distress syndrome, intraventricular hemorrhage, seizures, periventricular leukomalacia, sepsis, and necrotizing enterocolitis rose directly with the degree of weight discordancy. Rates of these conditions grew substantially if discordancy exceeded 25 percent. The relative risk of fetal death increased significantly to 5.6 if discordancy was more than 30 percent and rose to 18.9 if it was greater than 40 percent.

Management

Serial Sonography

Sonographic monitoring of twin growth has become a mainstay in management. Monochorionic twins are generally monitored more frequently. This is because their risk of death is higher—3.6 percent versus 1.1 percent—and the risk of neurological damage in the surviving twin is substantial compared with those risks in dichorionic twins (Hillman, 2011; Lee, 2008). Thorson and colleagues (2011) retrospectively analyzed 108 monochorionic twin pregnancies and found that a sonographic evaluation interval >2 weeks was associated with a higher Quintero stage at the time of TTTS diagnosis. These findings have led some to recommend serial sonographic examination every 2 weeks in monochorionic twins (Simpson, 2013; Society for Maternal-Fetal Medicine, 2013). However, there have been no randomized trials of the optimal frequency of sonographic surveillance in monochorionic twin pregnancies. At Parkland Hospital, monochorionic twins undergo sonographic evaluation to assess interval growth every 4 weeks. In addition, a specific ultrasound examination to search for TTTS is completed at each intervening 2-week mark between these sonograms.

For dichorionic pregnancies, a recent report suggests that sonographic evaluation every 2 weeks would identify more abnormalities prompting delivery (Corcoran, 2015). It has yet to be determined if this practice would improve perinatal outcomes. At our institution, dichorionic twins are sonographically evaluated every 6 weeks.

Fetal Surveillance

Depending on the degree of discordancy and the gestational age, fetal surveillance may be indicated, especially if one or both fetuses exhibit restricted growth. Nonstress testing, biophysical profile, and umbilical artery Doppler assessment have all been recommended in the management of twins. However, none has been assessed in appropriately sized prospective trials (Miller, 2012).

If discordancy is identified in a monochorionic twin pregnancy, umbilical artery Doppler studies in the smaller fetus may help guide management (Gratacós, 2007). Namely, investigators have correlated umbilical artery Doppler results with placental findings and with the degree of selective fetal-growth restriction to predict fetal outcome (Gratacós, 2012). These correlations have yielded categories of selective fetal-growth restriction. Type I is characterized by positive end-diastolic flow, a smaller degree of weight discordance, and a relatively benign clinical course. Type II displays persistently absent end-diastolic flow in the smaller twin and carries a high risk of deterioration and demise. Type III is intermittently absent or reversed end-diastolic flow. Because of large artery-to-artery anastomoses associated with the placentas in this category, type III is associated with a lower risk of deterioration than type II. In all evaluated cases, unequally shared placenta was noted to some degree.

With uncomplicated dichorionic multifetal gestations, use of antepartum surveillance has not improved perinatal outcomes. In sum, the American College of Obstetricians and Gynecologists (2016) recommends that antepartum testing be performed in multifetal gestations for indications similar to those for singleton fetuses (Chap. 17, Fetal Movements).

At Parkland, all women with twin discordancy ≥25 percent undergo daily monitoring as an inpatient. Data are limited to establish the optimal timing of delivery of twins for size discordancy alone. For those at advanced gestational ages, delivery can be pursued.

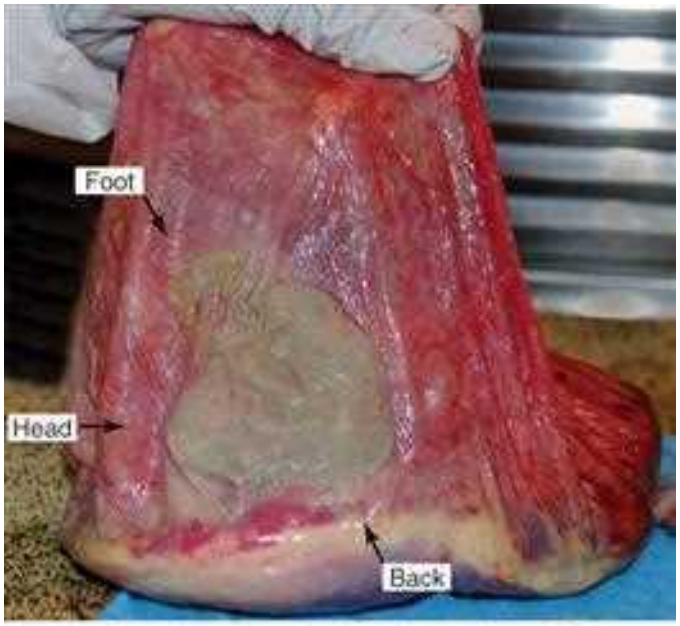
FETAL DEMISE

Death of One Fetus

At any time during multifetal pregnancy, one or more fetuses may die, either simultaneously or sequentially. Causes and incidence of fetal death are related to zygosity, chorionicity, and growth concordance.

In some pregnancies, one fetus dies remote from term, but pregnancy continues with one or more live fetuses. When this occurs early in pregnancy, it may manifest as a vanishing twin, discussed in Pregnancy Complications. In a slightly more advanced gestation, fetal death may go undetected until delivery. In this case, delivery of a normal newborn is followed by expulsion of a dead fetus that is barely identifiable. It may be compressed appreciably–*fetus compressus,* or it may be flattened remarkably through desiccation—*fetus papyraceus* (Fig. 45-24).

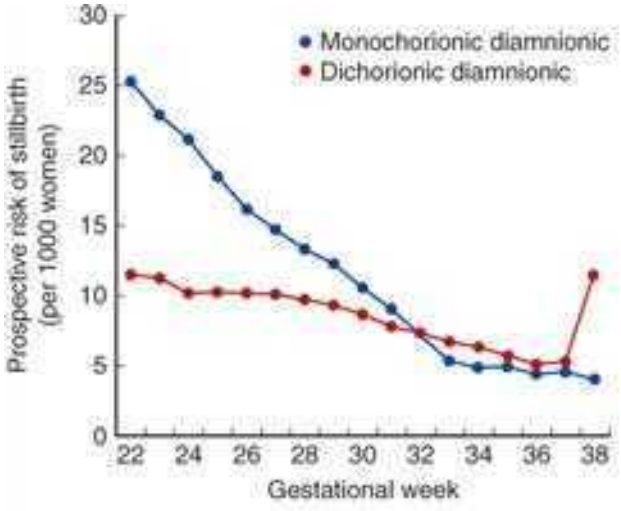
FIGURE 45-24
This fetus papyraceus is a tan ovoid mass compressed against the fetal membranes. Anatomical parts can be identified as marked. Demise of this twin had been noted during sonographic examination performed at 17 weeks' gestation. Its viable cotwin delivered at 40 weeks. (Used with permission from Dr. Michael V. Zaretsky.)



As shown in Figure 45-25, the risk of stillbirth is related to gestational age in all twins but is much higher for monochorionic twin pregnancies before 32 weeks' gestation. In a review of 9822 twin pregnancies, Morikawa and associates (2012) reported that 2.5 percent of monochorionic diamnionic twins greater than 22 weeks had a death of one or both twins. This compared with 1.2 percent of dichorionic twins. In this same review, women with monochorionic diamnionic twins who lost one twin were 16 times more likely to experience death of the cotwin than women with dichorionic twins who lost one twin. Other investigations have found similar trends (Danon, 2013; Hillman, 2011; Mahony, 2011).

FIGURE 45-25

Prospective risk of stillbirth among women who reached a given gestational week (per 1000 women). (Reproduced with permission from Morikawa M, Yamada T, Yamada T, et al: Prospective risk of stillbirth: monochorionic diamniotic twins vs dichorionic twins, J Perinat Med. 2012 Jan 10;40(3):245–249.)



Other factors that affect the prognosis for the surviving twin include gestational age at the time of the demise and duration between the demise and delivery of the surviving twin. With a vanishing twin, the risk of death after the first trimester is not increased for the survivor. However, when a fetus dies in the second trimester or later, the effect of gestational age at the time of death and the mortality risk to the cotwin are less clear. In an analysis by Hillman and colleagues (2011), cotwin demise rates were unaffected regardless of whether the first death occurred at 13 to 27 weeks' gestation or at 28 to 34 weeks. In cases with the death of one twin after the first trimester, however, the odds of spontaneous and iatrogenic preterm delivery of the remaining living twin were increased (Hillman, 2011). Preterm birth was five times more likely in monochorionic twin gestations complicated by demise of one twin between 28 and 33 weeks' gestation. If the fetus died after 34 weeks, preterm delivery rates were similar.

The neurological prognosis for a surviving cotwin depends almost exclusively on chorionicity. In their comprehensive review, Ong and coworkers (2006) found an 18-percent rate of neurological abnormality in twins with monochorionic placentation compared with only 1 percent in those with dichorionic placentation. In another review, in twin pregnancies complicated by a single fetal demise before 34 weeks, a fivefold higher risk of neurodevelopmental morbidity was identified in monochorionic twins compared with dichorionic twins. If the one fetus died after 34 weeks, the likelihood of neurological deficits was essentially the same between monochorionic and dichorionic twin pregnancies (Hillman, 2011).

Later in gestation, the death of one of multiple fetuses could theoretically trigger coagulation defects in the mother. Only a few cases of maternal coagulopathy after a single fetal death in a twin pregnancy have been reported. This is probably because the surviving twin is usually delivered within a few weeks of the demise (Eddib, 2006). That said, we have observed transient, spontaneously corrected consumptive coagulopathy in multifetal gestations in which one fetus died and was retained in utero along with its surviving twin. The plasma fibrinogen concentration initially decreased but then increased spontaneously, and the level of serum fibrinogen-fibrin degradation products increased initially but then returned to normal levels. At delivery, the portions of the placenta that supplied the living fetus appeared normal. In contrast, the part that had once provided for the dead fetus was the site of massive fibrin deposition.

Management

Decisions should be based on gestational age, the cause of death, and the risk to the surviving fetus. First-trimester losses require no additional surveillance for this specific indication. If the loss occurs after the first trimester, the risk of death or damage to the survivor is largely limited to monochorionic twin gestations. Morbidity in the monochorionic twin survivor is almost always due to vascular anastomoses, which often cause the demise of one twin followed by sudden hypotension in the other (Twin-Twin Transfusion Syndrome). For this reason, if one fetus of a monochorionic twin gestation dies after the first trimester but before viability, pregnancy termination can be considered (Blickstein, 2013). Occasionally, death of one but not all fetuses results from a maternal complication such as diabetic ketoacidosis or severe preeclampsia with abruption. Pregnancy management is based on the diagnosis and the status of both the mother and surviving fetus. If the death of one dichorionic twin is due to a discordant congenital anomaly in the first trimester, it should not affect the surviving twin.

Single fetal death during the late second and early third trimesters presents the greatest risk to the surviving twin. Although the risks of subsequent death or neurological damage to the survivor are comparatively higher for monochorionic twins at this gestational age, the risk of preterm birth is equally increased in mono- and dichorionic twins (Ong, 2006). Delivery generally occurs within 3 weeks of diagnosis of fetal demise, thus antenatal corticosteroids for survivor lung maturity should be considered (Blickstein, 2013). Regardless, unless the intrauterine environment is hostile, the goal is to prolong the preterm pregnancy.

Timing of elective delivery after conservative management of a late second- or early third-trimester single fetal death is debatable. Dichorionic twins can probably be safely delivered at term. Monochorionic twin gestations are more difficult to manage and are often delivered between 34 and 37 weeks' gestation (Blickstein, 2013). In cases of single fetal death at term, especially when the etiology is unclear, most opt for delivery instead of expectant management. The American College of Obstetricians and Gynecologists (2016) also endorse an individualized approach to such cases.

Impending Death of One Fetus

During antepartum surveillance tests of well-being, abnormal results in one twin, but not the other, pose a particular dilemma. Delivery may be the best option for the compromised fetus yet may result in death from immaturity of the cotwin. If fetal lung maturity is confirmed, salvage of both the healthy fetus and its jeopardized sibling is possible. Unfortunately, ideal management if twins are immature is problematic but should be based on the chances of intact survival for both fetuses. Often the compromised fetus is severely growth restricted or anomalous. Thus, performing amniocentesis for fetal chromosomal analysis in women of advanced maternal age carrying twin pregnancies is advantageous, even for those who would continue their pregnancies regardless of the diagnosis. Chromosomal abnormality identification in one fetus allows rational decisions regarding interventions.

PRENATAL CARE

With prenatal management of multifetal pregnancy, primary goals aim to prevent or interdict complications as they develop. A major imperative is to prevent preterm delivery of markedly immature neonates. At Parkland Hospital, women with multifetal gestations are seen every 2 weeks beginning at 22 weeks' gestation. A digital cervical examination is performed at each visit to screen for cervical shortening or dilation. Identification of other unique complications discussed earlier may also lead to interventions including admission or early delivery.

Diet

Along with more frequent prenatal visits, the maternal diet should provide additional requirements for calories, protein, minerals, vitamins, and essential fatty acids. The Institute of Medicine (2009) recommends a 37- to 54-lb weight gain for women with twins and a normal BMI. In their review, Goodnight and Newman (2009) endorse supplementation of micronutrients such as calcium, magnesium, zinc, and vitamins C, D, and E. This is based on upper intake levels from the Food and Nutrition Board of the Institute of Medicine. The daily recommended augmented caloric intake for women with twins is 40 to 45 kcal/kg/d. Diets contain 20 percent protein, 40 percent carbohydrate, and 40 percent fat divided into three meals and three snacks daily.

Sonography

As noted earlier (Fetal Demise), serial sonographic examinations are usually performed throughout the third trimester to search for abnormal fetal growth and assess amnionic fluid volume. Associated oligohydramnios may indicate uteroplacental pathology and should prompt further evaluation of fetal well-being. That said, quantifying amnionic fluid volume in multifetal gestation is sometimes difficult. Some measure the deepest vertical pocket in each sac or assess the fluid subjectively. Magann and coworkers (2000) compared subjective assessment and several objective methods of assessing amnionic fluid volume in 23 sets of twins. They found all methods to be equally poor in predicting abnormal volumes in diamnionic twins. At Parkland Hospital, the single deepest vertical pocket is measured in each sac. A measurement <2 cm is considered oligohydramnios, and a measurement >8 cm is considered hydramnios (Duryea, 2017; Hernandez, 2012).

Antepartum Fetal Surveillance

Of surveillance methods, the nonstress test or biophysical profile is often selected for twin or higher-order multifetal gestations. Because of the complex complications associated with these gestations and the potential technical difficulties in differentiating fetuses during antepartum testing, the usefulness of these methods appears limited. According to DeVoe (2008), the few exclusive studies of nonstress testing in twins suggest that the method performs the same as in singleton pregnancies.

Elliott and Finberg (1995) used the biophysical profile as the primary method for monitoring higher-order multifetal gestations. They reported that four of 24 monitored pregnancies had a poor outcome despite reassuring biophysical profile scores. Although biophysical testing is commonly performed in multifetal gestations, there are insufficient data to determine its efficacy (DeVoe, 2008).

Similar findings have been reported with the addition of umbilical artery Doppler velocimetry in twins with concordant growth. For example, when umbilical artery Doppler velocimetry was added to management compared with fetal testing based on fetal-growth parameters alone in the absence of growth discordance, perinatal outcomes were not improved (Giles, 2003). Likewise, Hack and associates (2008) investigated the utility of umbilical artery Doppler velocimetry in 67 uncomplicated monochorionic twin gestations and did not find differences in mortality rates using pulsatility indices of the umbilical artery.

All testing schemes have high false-positive rates in singletons, and data suggest that testing in multifetal gestations performs no better. In cases of abnormal testing in one twin and normal results in another, iatrogenic preterm delivery remains a major concern. Options are similar to those described in the management of impending fetal death (Prenatal Care).

PRETERM BIRTH

Preterm labor is common in multifetal pregnancies and may complicate up to 50 percent of twin, 75 percent of triplet, and 90 percent of quadruplet pregnancies (Elliott, 2007). Similar to singleton preterm labor, intraamnionic infection is documented in approximately one third of twin pregnancy cases (Oh, 2017).

In twins, the proportion of preterm births varies widely from 40 to 70 percent (Giuffre, 2012). For example, black women have disparately higher risks for preterm delivery (Grant, 2017).

Prediction of Preterm Birth

A major goal of multifetal prenatal care is accurate prediction of women likely to experience preterm delivery. Within the past decade, cervical length has been shown to be a potent predictor of preterm labor and delivery. To and associates (2006) sonographically measured cervical length in 1163 twin pregnancies at 22 to 24 weeks' gestation. Rates of preterm delivery before 32 weeks were 66 percent in those with cervical lengths of 10 mm; 24 percent for lengths of 20 mm; and only 1 percent for 40 mm. In one review, Conde-Agudelo and coworkers (2010) concluded that a cervical length <20 mm was most accurate for predicting birth before 34 weeks, with a specificity of 97 percent and positive likelihood ratio of 9.0. Kindinger and colleagues (2016) noted that prediction depended on both cervical length and gestational age at ascertainment. One study compared serial cervical length measurements with a single midgestation measurement. These authors found that multiple assessments were more accurate to determine the risk of preterm twin birth in asymptomatic women (Melamed, 2016a). In another study, a change in cervical length ≥0.2 cm identified pregnancies at risk for delivery before 35 weeks (Moroz, 2017). Interestingly, a closed internal os by digital examination was found to be as predictive of postponed delivery as was the combination of a normal sonographically measured cervical length and negative fetal fibronectin test result (McMahon, 2002). Unfortunately, cervical length assessment in twin pregnancies has not been associated with improved outcomes (Gordon, 2016).

Prevention of Preterm Birth

Several schemes have been evaluated to prevent preterm labor and delivery. In recent years, some have been shown to decrease the risk of preterm delivery, but only in subgroups of singleton pregnancies. In general, most have been disappointingly ineffective for both singleton and multifetal pregnancies (American College of Obstetricians and Gynecologists, 2016).

Bed Rest

The bulk of evidence suggests that routine hospitalization does not prolong multifetal pregnancy. In one metaanalysis, the practice did not reduce the risk of preterm birth or perinatal mortality (Crowther, 2010). At Parkland Hospital, elective hospitalization was compared with outpatient management, and no advantages were found (Andrews, 1991). Importantly, however, almost half of women managed as outpatients required admission for specific indications such as hypertension or threatened preterm delivery.

Limited physical activity, early work leave, more frequent health-care visits and sonographic examinations, and structured maternal education regarding preterm delivery risks have been advocated to reduce preterm birth rates in women with multiple fetuses. However, little evidence suggests that these measures substantially change outcome.

Prophylactic Tocolysis

This has not been studied extensively in multifetal pregnancies. In one review of prophylactic oral beta-mimetic therapy that included 374 twin pregnancies, treatment did not reduce the rate of twins delivering before 37 or before 34 weeks' gestation (Yamasmit, 2015). In light of the Food and Drug Administration warning against the use of oral terbutaline because of maternal side effects, the prophylactic use of beta-mimetic drugs in multifetal gestations seems unwarranted.

Intramuscular Progesterone Therapy

Although somewhat effective in reducing recurrent preterm birth in women with a singleton pregnancy, weekly injections of 17 alpha-hydroxyprogesterone caproate (17-OHP-C) are not effective for multifetal gestations (Caritis, 2009; Rouse, 2007). These results were corroborated in a randomized trial of 240 twin pregnancies (Combs, 2011). Moreover, women carrying twins and having a cervical length <36 mm (25th percentile) did not benefit despite their greater risk for preterm birth (Durnwald, 2010). Senat and colleagues (2013) assigned 165 asymptomatic women with twins and a cervical length <25 mm to 17-OHP-C and also found no reduction in delivery rate before 37 weeks. Last, in an evaluation of plasma drug concentrations, higher concentrations of 17-OHP-C were associated with *earlier* gestational age at delivery (Caritis, 2012). The authors concluded that 17-OHP-C may adversely lower the gestational age at delivery in women with twin gestations. In sum, administration of intramuscular 17-OHP-C to women with twin pregnancies, even to those with a shortened cervix, does not lower the preterm birth risk.

Vaginal Progesterone Therapy

Micronized progesterone administered vaginally to women with twins to prevent preterm birth has provided conflicting results. Cetingoz and coworkers (2011) gave 100 mg of micronized progesterone intravaginally daily from 24 to 34 weeks' gestation. This practice reduced rates of delivery before 37 weeks from 79 to 51 percent in 67 women with twins. In contrast, several studies have failed to demonstrate any preterm birth rate reduction in women receiving various formulations of vaginal progesterone. In the Prevention of Preterm Delivery in Twin Gestations (PREDICT) trial, 677 women with twins were randomly assigned to receive prophylactic, 200-mg progesterone pessaries or placebo pessaries (Rode, 2011). Progesterone failed to reduce delivery rates before 34 weeks. In a subgroup analysis that included only women with a short cervix or a history of prior preterm birth, also no benefit was found (Klein, 2011). Norman and colleagues (2009) also noted no lower rates of delivery before 34 weeks with progesterone gel treatment.

Romero and colleagues (2017) performed a metaanalysis of individual patient data for 303 women with twin gestation and a short cervix randomized to receive either vaginal progesterone or no treatment. They reported a significantly reduced risk of preterm birth before 30 weeks' gestation and improved composite perinatal outcomes in the treated women. Currently at Parkland Hospital, management of women with multifetal gestations does not typically include progesterone in any formulation.

The Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) is currently enrolling patients into a randomized, placebo-controlled trial to further evaluate the use of micronized vaginal progesterone or the Arabin pessary, describe subsequently (PROSPECT, 2015). The primary outcome is delivery prior to 35 weeks or fetal loss.

Cervical Cerclage

Prophylactic cerclage does not improve perinatal outcome in women with multifetal pregnancies. Studies have included women who were not specially selected but also those who were selected because of a shortened cervix that was identified sonographically (Houlihan, 2016; Newman, 2002; Rebarber, 2005). Indeed, in the latter group, cerclage may actually worsen outcomes (Berghella, 2005; Roman, 2013).

Rescue cerclage in women with a second-trimester twin gestation and a dilated cervix may be beneficial. Roman and coworkers (2016) reported a retrospective cohort study in which women undergoing rescue cerclage had significantly better neonatal outcomes than those without cerclage.

Pessary

A vaginal pessary that encircles and theoretically compresses the cervix, alters the inclination of the cervical canal, and relieves direct pressure on the internal cervical os has been proposed as an alternative to cerclage. One of the most popular is the silicone Arabin pessary. In a study of its use in women with a short cervix between 18 and 22 weeks' gestation, a subgroup analysis of 23 women with twins showed a significant reduction in the delivery rate before 32 weeks compared with the rate in 23 control pregnancies (Arabin, 2003). In another randomized trial, women treated with a cervical pessary had significantly fewer births before 34 weeks (Goya, 2016).

Other studies have been less favorable. In the randomized Pessaries in Multiple Pregnancy as a Prevention of Preterm Birth (ProTWIN) trial, 813 unselected women with twins received either the Arabin pessary between 12 and 20 weeks or no treatment (Liem, 2013). The pessary failed to reduce preterm birth overall but did decrease delivery rates before 32 weeks—29 versus 14 percent—in a subset of women with a cervical length <38 mm. Similar results were reported from a randomized multicenter trial with a total of 1180 twin pregnancies (Nicolaides, 2016). A smaller randomized study using a *Bioteque cup pessary* showed no difference in outcomes (Berghella, 2017). At this time, pessary use is not recommended by the American College of Obstetricians and Gynecologists (2016). As noted above, results from the ongoing PROSPECT trial are anticipated to provide more data.

Treatment of Preterm Labor

Although many advocate their use, therapy with tocolytic agents to forestall preterm labor in multifetal pregnancy does not result in measurably improved neonatal outcomes (Chauhan, 2010; Gyetvai, 1999). Another caveat is that tocolytic therapy in women with a multifetal pregnancy entails higher risks than in singleton pregnancy. This stems in part from augmented pregnancy-induced hypervolemia, which raises cardiac demands and increases the susceptibility to iatrogenic pulmonary edema (Chap. 47, Acute Pulmonary Edema). Gabriel and colleagues (1994) compared outcomes of 26 twin and six triplet pregnancies with those of 51 singletons—all treated with a beta-mimetic drug for preterm labor. Women with a multifetal gestation had significantly more cardiovascular complications—43 versus 4 percent—including three gravidas with pulmonary edema. In a retrospective analysis, Derbent and coworkers (2011) evaluated nifedipine tocolysis in 58 singleton and 32 twin pregnancies. These authors reported higher incidences of side effects such as maternal tachycardia in women with twins—19 versus 9 percent.

Glucocorticoids for Lung Maturation

Administration of corticosteroids to stimulate fetal lung maturation has not been well studied in multifetal gestation. However, these drugs logically should be as beneficial for multiples as they are for singletons (Roberts, 2006). In a large retrospective study evaluating betamethasone therapy efficacy in preterm twin versus preterm singleton pregnancies, no differences in neonatal morbidity between the two groups were identified (Melamed, 2016b). Gyamfi and associates (2010) evaluated betamethasone concentrations in women receiving weekly antenatal corticosteroids and found no differences in levels between twins and singletons. Conversely, another study found lower cord/maternal ratios of dexamethasone in twin versus singleton pregnancies (Kim, 2017). These treatments are discussed in Chapter 42 (Corticosteroids for Fetal Lung Maturation). At this time, guidelines for the use of these agents do not differ from those for singleton gestations (American College of Obstetricians and Gynecologists, 2016).

Preterm Premature Membrane Rupture

The frequency of preterm premature rupture of membranes (PPROM) rises with increasing plurality. In a population-based study of more than 290,000 live births, the proportion of preterm birth complicated by premature rupture was 13.2 percent in singletons (Pakrashi, 2013). This rate compared with rates of 17, 20, 20, and 100 percent in twins, triplets, quadruplets, and even higher-order multiples, respectively. Multifetal gestations with PPROM are managed expectantly similar to singleton pregnancies (Chap. 42, Intentional Delivery). Ehsanipoor and colleagues (2012) compared outcomes of 41 twin and 82 singleton pregnancies, both with ruptured membranes between 24 and 32 weeks. They found the median number of days to subsequent delivery was overall shorter for twins—3.6 days compared with 6.2 days for singletons. This latency difference was significant in pregnancies after 30 weeks—1.7 days and 6.9 days. Importantly, latency beyond 7 days approximated 40 percent in both groups.

Delayed Delivery of Second Twin

Infrequently, after preterm birth of the presenting fetus, it may be advantageous for undelivered fetus(es) to remain in utero. Trivedi and Gillett (1998) reviewed 45 case reports of asynchronous birth in multifetal gestations. Although reported outcomes may reflect bias, pregnancies with a surviving retained twin or triplet continued for an average of 49 days. No advantage was gained by management with tocolytics, prophylactic antimicrobials, or cerclage. In their 10-year experience, Roman and associates (2010) reported a median latency of 16 days in 13 twin and five triplet pregnancies with delivery of the first fetus between 20 and 25 weeks' gestation. Survival of the firstborn neonate was 16 percent. Although 54 percent of the retained fetuses survived, only 37 percent of survivors did so without major morbidity. Livingston and coworkers (2004) described 14 pregnancies in which an active attempt was made to delay delivery of 19 fetuses after delivery of the first neonate. Only one fetus survived without major sequelae, and one mother developed sepsis syndrome with shock. Arabin and van Eyck (2009) reported better outcomes in a few of the 93 twin and 34 triplet pregnancies that qualified for delayed delivery in their center during a 17-year period.

If asynchronous birth is attempted, there must be careful evaluation for infection, abruption, and congenital anomalies. The mother must be thoroughly counseled, particularly regarding the potential for serious, life-threatening infection. The range of gestational age in which the benefits outweigh the risks for delayed delivery is likely narrow. Avoidance of delivery from 23 to 26 weeks would seem most beneficial. In our experience, good candidates for delayed delivery are rare.

LABOR AND DELIVERY

Preparations

A litany of complications may be encountered during labor and delivery of multiple fetuses. In addition to preterm birth, rates of uterine contractile dysfunction, abnormal fetal presentation, umbilical cord prolapse, placenta previa, placental abruption, emergent operative delivery, and postpartum hemorrhage from uterine atony are higher. All of these must be anticipated, and thus certain precautions and special arrangements are prudent. These should include the following.

1. An appropriately trained obstetrical attendant should remain with the mother throughout labor. Continuous electronic monitoring is preferable. If membranes are ruptured and the cervix dilated, the presenting fetus is monitored internally.
2. An intravenous infusion system capable of delivering fluid rapidly is established. In the absence of hemorrhage, lactated Ringer or an aqueous dextrose solution is infused at a rate of 60 to 125 mL/hr.
3. Blood for transfusion is readily available if needed.
4. An obstetrician skilled in intrauterine identification of fetal parts and in intrauterine manipulation of a fetus should be present.
5. A sonography machine is readily available to evaluate the presentation and position of the fetuses during labor and to image the remaining fetus(es) after delivery of the first.
6. An anesthesia team is immediately available in the event that emergent cesarean delivery is necessary or that intrauterine manipulation is required for vaginal delivery.
7. For each fetus, at least one attendant who is skilled in resuscitation and care of newborns and who has been appropriately informed of the case should be immediately available.
8. The delivery area should provide adequate space for the nursing, obstetrical, anesthesia, and pediatric team members to work effectively. Equipment must be on site to provide emergent anesthesia, operative intervention, and maternal and neonatal resuscitation.

Timing of Delivery

Several factors affect this timing and include gestational age, fetal growth, lung maturity, and presence of maternal complications. As measured by determination of the lecithin-sphingomyelin ratio, pulmonary maturation is usually synchronous in twins (Leveno, 1984). Moreover, although this ratio usually does not exceed 2.0 until 36 weeks in singleton pregnancies, it often exceeds this value by approximately 32 weeks in multifetal pregnancies. Similar increased values of surfactant have been noted in twins after 31 weeks' gestation (McElrath, 2000). In a comparison of respiratory morbidity in 100 twins and 241 singleton newborns delivered by cesarean before labor, Ghi and associates (2013) found less neonatal respiratory morbidity in twins, especially those delivered <37 weeks' gestation. In some cases, however, pulmonary function may be markedly different, and the smallest, most stressed twin fetus is typically more mature.

At the other end of the spectrum, Bennett and Dunn (1969) suggested that a twin pregnancy of 40 weeks or more should be considered postterm. Twin stillborn neonates delivered at 40 weeks or beyond commonly had features similar to those of postmature singletons (Chap. 43, Incidence). From an analysis of almost 300,000 twin births, at and beyond 39 weeks, the risk of subsequent stillbirth was greater than the risk of neonatal mortality (Kahn, 2003).

From their guidelines, the American College of Obstetricians and Gynecologists (2016) recommends delivery at 38 weeks for uncomplicated dichorionic twin pregnancies. Women with uncomplicated monochorionic diamnionic twin pregnancies can undergo delivery between 34 and $37^{6/7}$ weeks. And, for women with monoamnionic twin pregnancies, delivery is recommended at 32 to 34 weeks. At Parkland Hospital, we generally follow these recommendations but do not routinely deliver monochorionic diamnionic twin pregnancies before 37 weeks unless another obstetrical indication develops.

Evaluation of Fetal Presentation

In addition to the standard preparations for the conduct of labor and delivery discussed in Chapter 22, there are special considerations for women with a multifetal pregnancy. First, the positions and presentations of fetuses are best confirmed sonographically. Although any possible combination of positions may be encountered, those most common at admission for delivery are cephalic-cephalic, cephalic-breech, and cephalic-transverse. At Parkland Hospital between 2008 and 2013, 71 percent of twin pregnancies had a cephalic presentation of the first fetus at the time of admission to labor and delivery. Importantly, with perhaps the exception of cephalic–cephalic presentations, these are all unstable before and during labor and delivery. Accordingly, compound, face, brow, and footling breech presentations are relatively common, and even more so if fetuses are small, amnionic fluid is excessive, or maternal parity is high. Cord prolapse is also frequent in these circumstances.

After this initial evaluation, if active labor is confirmed, then a decision is made to attempt vaginal delivery or to proceed with cesarean delivery. The latter is usually chosen because of fetal presentations. In general, cephalic presentation of the first fetus in a laboring woman with twins may be considered for vaginal delivery (American College of Obstetricians and Gynecologists, 2016). The proportion of women undergoing an attempted vaginal delivery varies greatly depending on the skills of the delivering physician (de Castro, 2016; Easter, 2017; Schmitz, 2017). Still, the cesarean delivery rate is high. For example, of the 547 women with the first twin presenting cephalic who were admitted to Parkland Hospital during 5 years, only 32 percent were delivered spontaneously. And, the overall cesarean delivery rate in twin pregnancies during those years was 77 percent. Notably, 5 percent of cesareans performed were for emergent delivery of the second twin following vaginal delivery of the first twin. The desire to avoid this obstetrical dilemma has contributed to the rising cesarean delivery rate in twin pregnancies across the United States (Antsaklis, 2013).

Labor Induction or Stimulation

After a comparison of 891 twins with more than 100,000 singleton pregnancies included in the Consortium of Safe Labor, Leftwich and colleagues (2013) concluded that active labor progressed more slowly in both nulliparas and multiparas with twins. Provided women with twins meet all criteria for oxytocin administration, it may be used as described in Chapter 26 (Oxytocin). Wolfe and associates (2013) evaluated the success of labor induction and concluded that oxytocin alone or in combination with cervical ripening can safely be used in twin gestations. Taylor and coworkers (2012) reported similar results. Conversely, Razavi and colleagues (2017) found that maternal morbidity was increased with labor induction. In an analysis of twin births in the United States, induction rates of twin pregnancies have decreased from a maximum of 13.8 percent in 1999 to 9.9 percent in 2008 (Lee, 2011). Generally, at Parkland Hospital we do not induce or augment labor in women with a multifetal gestation. In suitable candidates with a strong desire for vaginal birth, amniotomy induction has been one option.

Analgesia and Anesthesia

During labor and delivery of multiple fetuses, decisions regarding analgesia and anesthesia may be complicated by problems imposed by preterm labor, preeclampsia, desultory labor, need for intrauterine manipulation, and postpartum uterine atony and hemorrhage.

Labor epidural analgesia is ideal because it provides excellent pain relief and can be rapidly extended cephalad if internal podalic version or cesarean delivery is required. If general anesthesia becomes necessary for intrauterine manipulation, uterine relaxation can be accomplished rapidly with one of the halogenated inhalation agents discussed in Chapter 25 (Inhalational Anesthetics). Some clinicians use intravenous or sublingual nitroglycerin or intravenous terbutaline to achieve uterine relaxation yet avoid the risks associated with general anesthetics. These agents are usually best administered by the anesthesia team.

Delivery Route

Regardless of fetal presentation during labor, obstetricians must be ready to deal with any change of fetal position during delivery. This is especially true following delivery of the first twin. Importantly, related to delivery method, second twins at term have worse composite neonatal outcomes compared with outcomes of their cotwin regardless of delivery method (Muleba, 2005; Smith, 2007; Thorngren-Jerneck, 2001).

Cephalic-Cephalic Presentation

If the first twin presents cephalic, delivery can usually be accomplished spontaneously or with forceps. According to D'Alton (2010), there is general consensus that a trial of labor is reasonable in women with cephalic-cephalic twins. From their review, Hogle and associates (2003) found that planned cesarean delivery does not improve neonatal outcome when both twins are cephalic. The randomized trial by Barrett and coworkers (2013) affirms this conclusion.

Cephalic-Noncephalic Presentation

The optimal delivery route for cephalic–noncephalic twin pairs remains controversial. Patient selection is crucial, and options include cesarean delivery of both twins, or less commonly, vaginal delivery with intrapartum external cephalic version of the second twin. Longer intertwin delivery time has been shown in some studies to be associated with poorer second twin outcome (Edris, 2006; Stein, 2008). Thus, breech extraction may be preferable to version. Least desirable, vaginal delivery of the first but cesarean delivery of the second twin may be required due to intrapartum complications such as umbilical cord prolapse, placental abruption, contracting cervix, or fetal distress. Most but not all studies report the worst composite fetal outcomes for this scenario (Alexander, 2008; Rossi, 2011; Wen, 2004).

Several reports attest to the safety of vaginal delivery of second noncephalic twins whose birthweight is >1500g. A French multicenter study of 5915 twin pregnancies illustrates this (Schmitz, 2017). Of these, 25 percent had a planned cesarean delivery. The other 75 percent with a first twin cephalic and gestational age >32 weeks had a planned trial of vaginal delivery, which was successful in 80 percent. Interestingly, perinatal mortality and morbidity rates were significantly higher in the planned cesarean delivery group delivered <37 weeks—5.2 versus 3.0 percent, respectively. Fox and colleagues (2014) reported outcomes in 287 diamnionic twin pregnancies, of which 130 underwent a planned vaginal delivery. Only 15 percent of the planned vaginal delivery group underwent a cesarean delivery. Perinatal outcomes were similar in both groups. These two studies included only those fetuses with estimated weights >1500 g. Notably, comparable or even better fetal outcomes with vaginal delivery have been reported with neonates weighing <1500 g compared with those weighing >1500 g (Caukwell, 2002; Davidson, 1992).

Other investigators advocate cesarean delivery for both members of a cephalic-noncephalic twin pair (Armson, 2006; Hoffmann, 2012). Yang and coworkers (2005a,b) studied 15,185 cephalic-noncephalic twin pairs. The risks of asphyxia-related neonatal deaths and morbidity were higher in the group in which both twins were delivered vaginally compared with the group in which both twins underwent cesarean delivery.

To add insight into the clinical complexities just discussed, a randomized trial was designed by the Twin Birth Study Collaborative Group from Canada. The study results described by Barrett and associates (2013) included 2804 women carrying a presumed diamnionic twin pregnancy with the first fetus presenting cephalic. Women were randomly assigned between 32 and 38 weeks' gestation to planned cesarean or vaginal delivery. The time from randomization to delivery—12.4 versus 13.3 days, the mean gestational age at delivery—36.7 versus 36.8 weeks, and use of regional analgesia—92 versus 87 percent, were similar in both groups. Salient maternal and perinatal outcomes are shown in Table 45-3. No significant differences in outcomes were noted between the two groups of women. Although risks to mother or fetuses with planned vaginal delivery in these circumstances were not increased, Greene (2013) posited that this trial would have only modest effects on the cesarean delivery rate of women with twins.

TABLE 45-3

Maternal and Perinatal Outcomes of Women with a Twin Pregnancy Randomized to Planned Cesarean versus Vaginal Delivery

Outcome	Planned Cesarean Delivery	Planned Vaginal Delivery	*p* value
Maternal (No.)	1393	1393	
Cesarean delivery	89.9%	39.6%	
Before labor	53.8%	14.1%	
Serious morbidity	7.3%	8.5%	0.29
Death (No.)	1	1	
Hemorrhage	6.0%	7.8%	
Blood transfusion	4.7%	5.4%	
Thromboembolism	0.4%	0.1%	
Perinatal (No.)	2783	2782	
Primary composite outcome	2.2%	1.9%	0.49
Perinatal mortality	9 per 1000	6 per 1000	
Serious morbidity	1.3%	1.3%	
Possible encephalopathy[a]	0.5%	0.4%	
Intubation	1.0%	0.6%	

[a]Includes coma; stupor; hyperalert, drowsy or lethargic; or ≥2 seizures.

Data from Barrett, 2013.

Breech Presentation of First Twin

Problems with the first twin presenting as a breech are similar to those encountered with a singleton breech fetus. Thus, major difficulties may develop in the following settings. First, the fetus may be large, and the aftercoming head is larger than the birth canal. Second, the fetal body can be small, and delivery of the extremities and trunk through an inadequately effaced and dilated cervix causes the relatively larger head to become trapped above the cervix. This is more likely when there is significant disproportion between the head and body. Examples are preterm or growth-restricted fetuses or those with macrocephaly from hydrocephaly. Last, umbilical cord prolapse is an ever-present risk.

If these problems are anticipated or identified, cesarean delivery is often preferred with a viable-sized fetus. But even without these problems, many obstetricians perform cesarean delivery if the first twin presents as breech. This is despite data that support the safety of vaginal delivery. Specifically, Blickstein and associates (2000) reported experiences from 13 European centers with 613 twin pairs and the first twin presenting breech. Vaginal delivery was attempted in 373 of these cases and was successful in 64 percent. Cesarean delivery of the second twin was done in 2.4 percent. There was no difference in the rate of 5-minute Apgar scores <7 or of mortality in breech-presenting first twins who weighed at least 1500 g. Details of techniques for delivery of a breech presentation are described in Chapter 28 (Partial Breech Extraction).

Twin fetuses may become locked together during delivery if the first presents breech and the second cephalic. As the breech of the first twin descends through the birth canal, the chin locks between the neck and chin of the second cephalic-presenting cotwin. This phenomenon is rare, and Cohen and coworkers (1965) described it only once in 817 twin gestations. Cesarean delivery should be considered when the potential for locking is identified.

Vaginal Delivery of the Second Twin

Following delivery of the first twin, the presenting part of the second twin, its size, and its relationship to the birth canal should be quickly and carefully ascertained by combined abdominal, vaginal, and at times, intrauterine examination. Sonography is a valuable aid. If the fetal head or the breech is fixed in the birth canal, moderate fundal pressure is applied and membranes are ruptured. Immediately afterward, digital examination of the cervix is repeated to exclude cord prolapse. Labor is allowed to resume. If contractions do not begin within approximately 10 minutes, dilute oxytocin may be used to stimulate contractions.

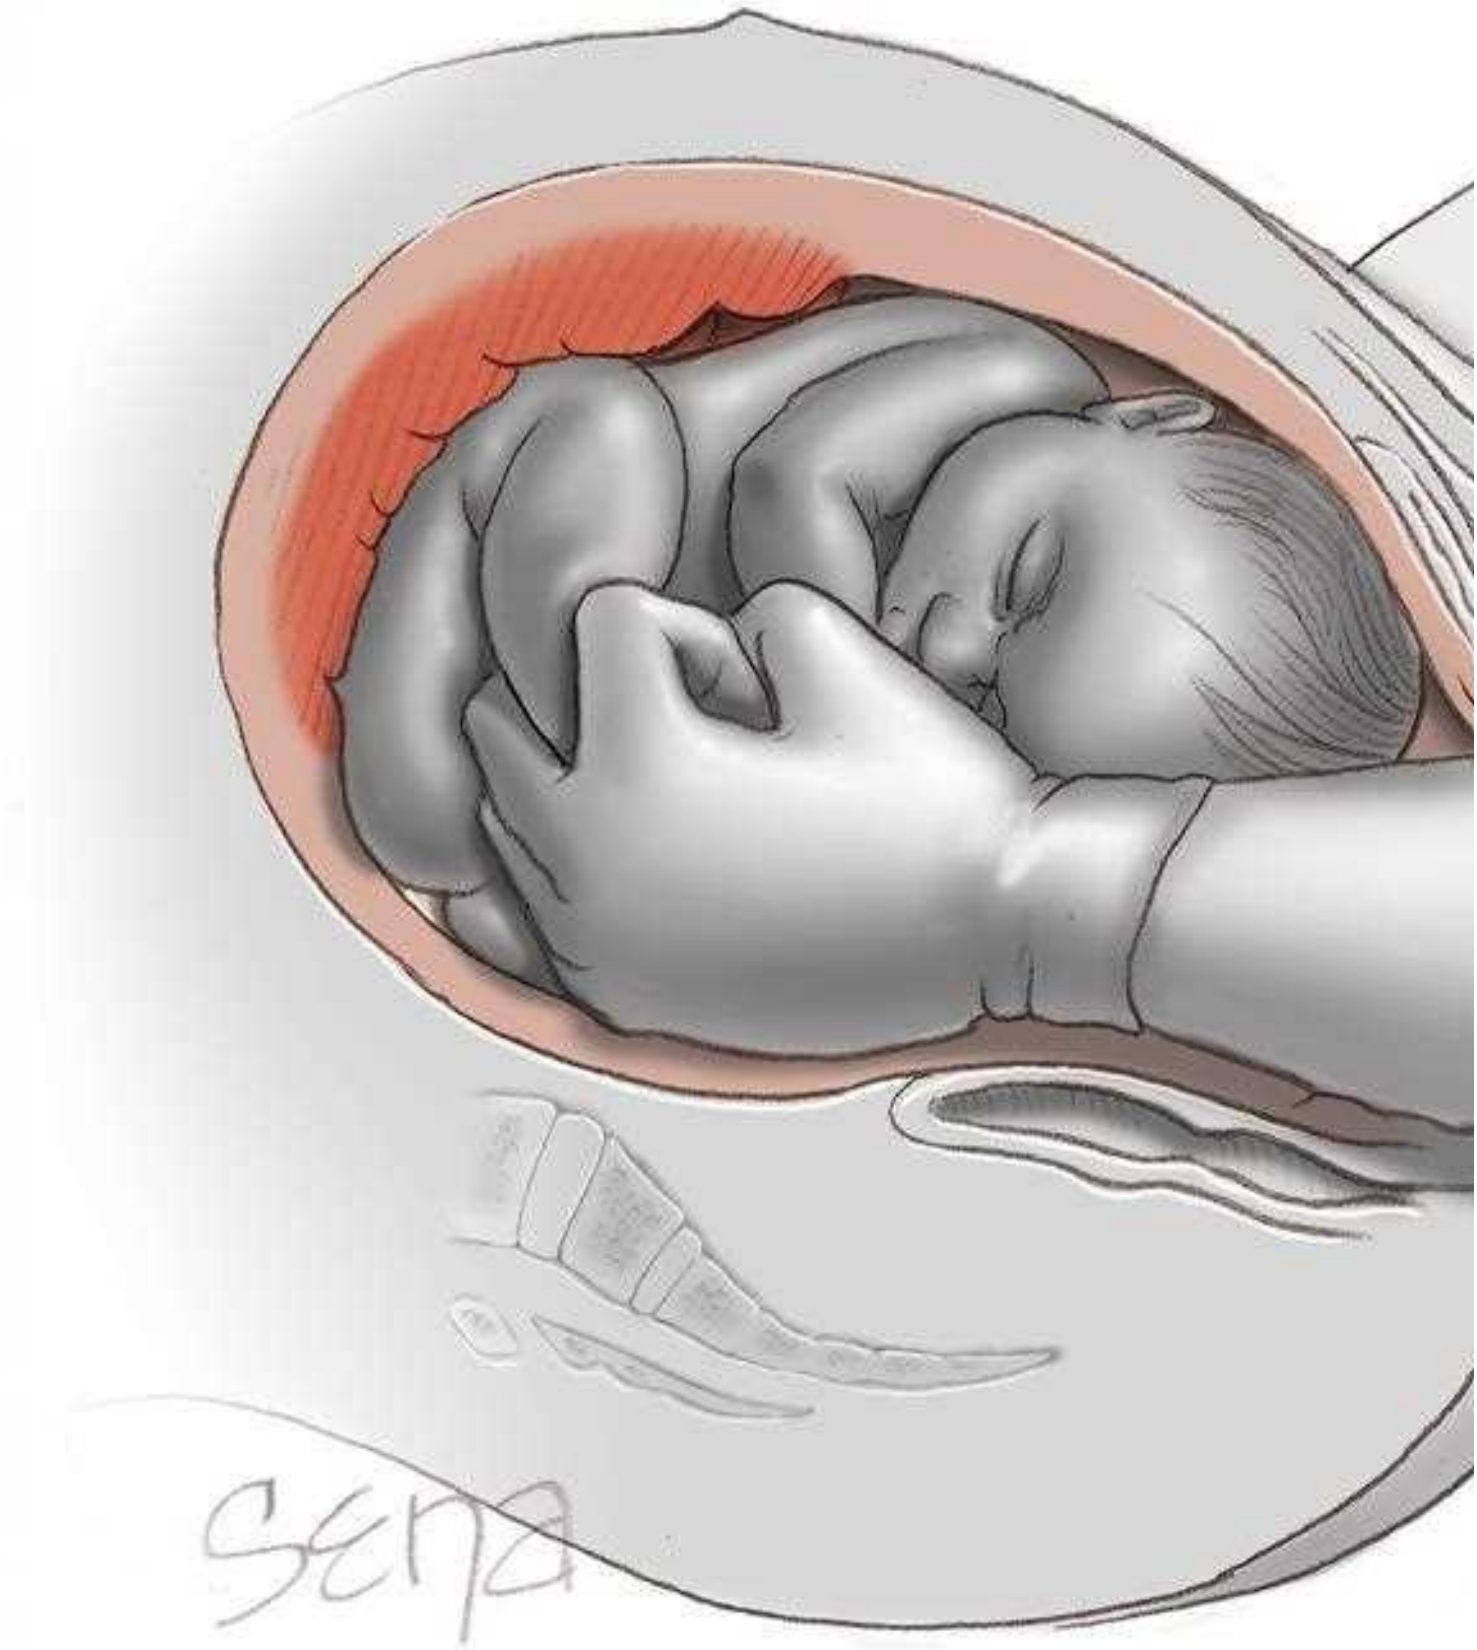
In the past, the safest interval between delivery of the first and second twins was frequently cited as <30 minutes. Rayburn and colleagues (1984) and others have shown that if continuous fetal monitoring is used, a good outcome is usually achieved even if this interval is longer. A direct correlation between worsening umbilical cord blood gas values and increasing time between delivery of first and second twins has been shown (Leung, 2002; Stein, 2008). From review of 239 twin gestations, Gourheux and associates (2007) determined that mean umbilical arterial pH was significantly lower after the delivery interval exceeded 15 minutes. In a study of more than 175,000 twin pairs, Cheng and colleagues (2017) reached similar conclusions for maternal and perinatal morbidity.

If the occiput or breech presents immediately over the pelvic inlet, but is not fixed in the birth canal, the presenting part can often be guided into the pelvis by one hand in the vagina, while a second hand on the uterine fundus exerts moderate pressure caudally. A presenting shoulder may be gently converted into a cephalic presentation. Alternatively, with abdominal manipulation, an assistant can guide the presenting part into the pelvis. Sonography can aid guidance and allow heart rate monitoring. Intrapartum external version of a noncephalic second twin has also been described.

If the occiput or breech is not over the pelvic inlet and cannot be so positioned by gentle pressure or if appreciable uterine bleeding develops, delivery of the second twin can be problematic. To obtain a favorable outcome, an obstetrician skilled in intrauterine fetal manipulation and anesthesia personnel skilled in providing anesthesia to effectively relax the uterus for vaginal delivery of a noncephalic second twin are essential (American College of Obstetricians and Gynecologists, 2016). To take maximum advantage of the dilated cervix before the uterus contracts and the cervix retracts, delay should be avoided. Prompt cesarean delivery of the second fetus is preferred if no one present is skilled in the performance of internal podalic version or if anesthesia that will provide effective uterine relaxation is not immediately available.

With internal podalic version, a fetus is turned to a breech presentation using the hand placed into the uterus (Fig. 45-26). The obstetrician grasps the fetal feet to then effect delivery by breech extraction (Chap. 28, Total Breech Extraction). As mentioned earlier, Fox and associates (2010) described a strict protocol for management of the delivery of the second twin, which included internal podalic version. They reported that none of the 110 women who delivered the first twin vaginally underwent a cesarean delivery for the second twin. Chauhan and coworkers (1995) compared outcomes of 23 second twins delivered by internal podalic version and breech extraction with those of 21 who underwent external cephalic version. Breech extraction was considered superior to external version because less fetal distress developed. Additional information and illustrations of this procedure are found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Yeomans, 2017).

FIGURE 45-26
Internal podalic version. Upward pressure on the head by an abdominal hand is applied as downward traction is exerted on the feet.



Vaginal Birth after Cesarean Delivery

Any attempt to deliver twins vaginally in a woman who has previously undergone one or more cesarean deliveries should be carefully considered. Some studies support the safety of attempting a vaginal birth after cesarean delivery (VBAC) for selected women with twins (Cahill, 2005; Ford, 2006; Varner, 2005). According to the American College of Obstetricians and Gynecologists (2017c), no evidence currently suggests an increased risk of uterine rupture, and women with twins and one

previous cesarean delivery with a low transverse incision may be considered candidates for trial of labor. At Parkland Hospital, we recommend repeat cesarean delivery.

Cesarean Delivery for Multifetal Gestation

Several unusual intraoperative problems can arise during cesarean delivery of twins or higher-order multiples. Supine hypotension is common, and thus gravidas are positioned in a left lateral tilt to deflect uterine weight off the aorta (Chap. 4, Renin, Angiotensin II, and Plasma Volume). A low transverse hysterotomy is preferable if the incision can be made large enough to allow atraumatic delivery of both fetuses. Piper forceps can be used if the second twin is presenting breech (Fig. 28-11). In some cases, a vertical hysterotomy beginning as low as possible in the lower uterine segment may be advantageous. For example, if a fetus is transverse with its back down and the arms are inadvertently delivered first, it is much easier and safer to extend a vertical uterine incision upward than to extend a transverse incision laterally or to make a "T" incision vertically.

Triplet or Higher-Order Gestation

Fetal heart rate monitoring during labor with triplet pregnancies is challenging. A scalp electrode can be attached to the presenting fetus, but it is difficult to ensure that the other two fetuses are each being monitored separately. With vaginal delivery, the first neonate is usually born with little or no manipulation. Subsequent fetuses, however, are delivered according to the presenting part. This often requires complicated obstetrical maneuvers such as total breech extraction with or without internal podalic version or even cesarean delivery. Associated with malposition of fetuses is an increased incidence of cord prolapse. Moreover, reduced placental perfusion and hemorrhage from separating placentas are more likely during delivery.

For all these reasons, many clinicians believe that pregnancies complicated by three or more fetuses should undergo cesarean delivery (American College of Obstetricians and Gynecologists, 2016). Vaginal delivery is reserved for those circumstances in which survival is not expected because fetuses are markedly immature or maternal complications make cesarean delivery hazardous to the mother. Others believe that vaginal delivery is safe under certain circumstances. Grobman and associates (1998) and Alran and coworkers (2004) reported vaginal delivery completion rates of 88 and 84 percent, respectively, in women carrying triplets who underwent a trial of labor. Neonatal outcomes did not differ from those of a matched group of triplet pregnancies undergoing elective cesarean delivery. Conversely, in one review of more than 7000 triplet pregnancies, vaginal delivery was associated with a higher perinatal mortality rate (Vintzeleos, 2005). Lappen and coworkers (2016) reported similar results from the database of the Consortium on Safe Labor. They recommended prelabor cesarean delivery for triplets. Importantly, the overall cesarean delivery rate among triplets was 95 percent.

SELECTIVE REDUCTION OR TERMINATION

In some cases of higher-order multifetal gestation, reduction of the fetal number to two or three improves survival of the remaining fetuses. Selective reduction implies early pregnancy intervention, whereas selective termination is performed later. The procedure should be performed by an operator skilled and experienced in sonographically guided procedures.

Selective Reduction

Reduction of a selected fetus or fetuses in a multichorionic multifetal gestation may be chosen as a therapeutic intervention to enhance survival of the remaining fetuses (American College of Obstetricians and Gynecologists, 2017b). One metaanalysis of nonrandomized prospective studies indicates that pregnancy reduction to twins compared with expectant management is associated with lower rates of maternal complications, preterm birth, and neonatal death (Dodd, 2004, 2012).

Pregnancy reduction can be performed transcervically, transvaginally, or transabdominally, but the transabdominal route is usually easiest. Transabdominal fetal reductions are typically performed between 10 and 13 weeks' gestation. This gestational age is chosen because most spontaneous abortions have already occurred, the remaining fetuses are large enough to be evaluated sonographically, the amount of devitalized fetal tissue remaining after the procedure is small, and the risk of aborting the entire pregnancy as a result of the procedure is low. The smallest fetuses and any anomalous fetuses are chosen for reduction. Potassium chloride is then injected under sonographic guidance into the heart or thorax of each selected fetus. Care is used to avoid entry or traverse the sacs of fetuses selected for retention.

Evans and associates (2005) analyzed more than 1000 pregnancies from 1995 to 1998. The pregnancy loss rate varied from a low of 4.5 percent for triplets that were reduced to twins. The loss rate rose with each addition to the starting number of fetuses and peaked at 15 percent for six or more fetuses. Operator skill and experience are believed responsible for the low and declining rates of pregnancy loss.

Selective Termination

With the identification of multiple fetuses discordant for structural or genetic abnormalities, three options are available: abortion of all fetuses, selective termination of the abnormal fetus, or pregnancy continuation. Because anomalies are typically not discovered until the second trimester, selective termination is performed later in gestation than selective reduction and entails greater risk. This procedure is therefore usually not performed unless the anomaly is severe but not lethal. In some cases, termination is considered because the abnormal fetus may jeopardize the normal one.

Prerequisites to selective termination include a precise diagnosis for the anomalous fetus and absolute certainty of fetal location. Unless a special procedure such as umbilical cord interruption is used, selective termination should be performed only in multichorionic multifetal gestations to avoid damaging the surviving fetuses (Lewi, 2006). Roman and coworkers (2010) compared 40 cases of bipolar umbilical cord coagulation with 20 cases of radiofrequency ablation for treatment of complicated monochorionic multifetal gestations at midpregnancy. They found similar survival rates of 87 and 88 percent, and a median gestational age >36 weeks

at delivery in both. Prefumo and colleagues (2013) reported their preliminary experience with microwave ablation of the umbilical cord for selective termination in two monochorionic twin pregnancies. One pregnancy aborted within 7 days, and the other resulted in a term singleton delivered at 39 weeks' gestation.

Evans and coworkers (1999) have provided the most comprehensive results to date on second-trimester selective termination for fetal abnormalities. A total of 402 cases were analyzed from eight centers worldwide. Included were 345 twin, 39 triplet, and 18 quadruplet pregnancies. Selective termination using potassium chloride resulted in delivery of a viable neonate or neonates in more than 90 percent of cases, with a mean age of 35.7 weeks at delivery. The entire pregnancy was lost in 7 percent of pregnancies reduced to singletons and in 13 percent of those reduced to twins. The gestational age at the time of the procedure did not appear to affect the pregnancy loss rate.

Before selective termination or reduction, a discussion should include the morbidity and mortality rates expected if the pregnancy is continued; the morbidity and mortality rates expected with surviving twins or triplets; and the risks of the procedure itself (American College of Obstetricians and Gynecologists, 2017b). Specific risks of selective termination or reduction are: (1) abortion of the remaining fetuses; (2) abortion or retention of the wrong fetus(es); (3) damage without death to a fetus; (4) preterm labor; (5) discordant or growth-restricted fetuses; and (6) maternal complications. The last includes potential infection, hemorrhage, or disseminated intravascular coagulopathy because of retained products of conception. The final decision to continue the pregnancy without intervention, to terminate the entire pregnancy, or to elect selective termination is solely the patient's (Chervenak, 2013).

CHAPTER 46: General Considerations and Maternal Evaluation

As a rule, all diseases which subject the organism to a considerable strain are much more serious when occurring in a pregnant woman.

—J. Whitridge Williams (1903)

INTRODUCTION

As reviewed by Williams in 1903, pregnant women are susceptible to any medical and surgical disorder that can affect childbearing-aged women. Some of these, especially those that are chronic, more often precede pregnancy. But, they can acutely complicate an otherwise normal pregnancy. Of estimates, one managed-care population had an overall antenatal hospitalization rate of 10.1 per 100 deliveries (Gazmararian, 2002). Approximately one third was for nonobstetrical conditions that included renal, pulmonary, and infectious diseases. In another study from the 2002 Nationwide Inpatient Sample, the injury hospitalization rate was 4.1 women per 1000 deliveries (Kuo, 2007). Last, approximately 1 in every 635 pregnant women will undergo a nonobstetrical surgical procedure (Corneille, 2010; Kizer, 2011).

Obstetricians should have a working knowledge of the wide-ranging medical disorders common to childbearing-aged women. Many of these are within the purview of the general obstetrician. Other disorders, however, will warrant consultation, and still others require a multidisciplinary team. The latter may include maternal-fetal medicine specialists, hospitalists, internists and medical subspecialists, surgeons, anesthesiologists, and numerous other disciplines (Levine, 2016). The American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2014, 2017b) has redefined aspects of maternal care and proposed required levels of specialized care.

It should be axiomatic that a woman must never be penalized because she is pregnant. To ensure this, several questions should be addressed:

What management would be recommended if the woman were not pregnant?

If the proposed management is different because the woman is pregnant, can this be justified?

What are the risks versus benefits to the mother and her fetus, and are they counter to each other?

Can an individualized management plan be devised that balances benefits versus risks of any alterations?

Such an approach allows individualized care for women with most medical and surgical disorders complicating pregnancy.

MATERNAL PHYSIOLOGY AND LABORATORY VALUES

Pregnancy induces physiological changes in virtually all organ systems. In turn, results of numerous laboratory tests are altered, and some values would, in the nonpregnant woman, be considered abnormal. Conversely, some may appear to be within a normal range but are decidedly abnormal for the gravida. These changes may amplify or obfuscate evaluation of coexisting conditions. The wide range of pregnancy effects on normal physiology and laboratory values are discussed in the chapters that follow in this section and are listed in the Appendix (Serum and Blood Constituents).

MEDICATIONS AND SURGERIES

Pregnancy Outcomes

Fortunately, most medications needed to treat frequently encountered illnesses complicating pregnancy can be given with relative safety. That said, notable exceptions are considered in Chapter 12 and throughout this text.

Regarding surgery, the risk of an adverse pregnancy outcome is not appreciably increased in most women who undergo an uncomplicated operative procedure. With complications, however, risks likely are increased. For example, perforative appendicitis with feculent peritonitis has significant maternal and perinatal morbidity and mortality rates even if surgical and anesthetic techniques are flawless. Conversely, procedure-related complications may adversely affect outcomes. For example, a woman who has uncomplicated removal of an inflamed appendix may suffer aspiration of acidic gastric contents during tracheal intubation or extubation. Still, compared with nonpregnant women undergoing similar procedures, pregnant women do not appear to have excessive complications (Silvestri, 2011). In a study of the American College of Surgeons' National Surgical Quality Improvement Program, outcomes in pregnant women were compared with matched nonpregnant controls (Moore, 2015). The investigators reported similar outcomes in the two cohorts, each with 2539 patients. In a smaller study, however, women undergoing nonobstetrical surgery after 23 weeks' gestation had a high rate of subsequent preterm delivery (Baldwin, 2015).

The most extensive data regarding anesthetic and surgical risks for the gravida and her fetus are from the Swedish Birth Registry and described by Mazze and Källén (1989). The effects on pregnancy outcomes of 5405 nonobstetrical surgical procedures performed in 720,000 pregnant women from 1973 to 1981 were analyzed. For approximately half of these procedures, general anesthesia was used and commonly involved nitrous oxide supplemented by another inhalation agent or

intravenous medications. These procedures were performed in 41 percent of women in the first trimester, 35 percent in the second, and 24 percent in the third. Overall, 25 percent were abdominal operations, and 20 percent were gynecological or urological procedures. Laparoscopy was the most frequently performed operation, and appendectomy was the most common second-trimester procedure.

Perinatal Morbidity

Excessive perinatal morbidity associated with nonobstetrical surgery is attributable in many cases to the disease itself rather than to adverse effects of surgery and anesthesia. The Swedish Birth Registry again provides valuable data (Table 46-1). Importantly, the incidences of congenital malformations or of stillbirths were not significantly different from those of nonexposed control newborns. However, incidences of low birthweight, preterm birth, and neonatal death in infants born to women who had undergone surgery were significantly greater. Increased neonatal death rates were largely due to preterm birth. In two other studies, the preterm delivery rate in women undergoing nonobstetrical surgery was also elevated (Baldwin, 2015; Hong, 2006).

TABLE 46-1

Birth Outcomes in 5405 Pregnant Women Undergoing Nonobstetrical Surgery

Outcome	Rate	*p* value[a]
Major malformation	1.9%	NS
Stillbirth	7 per 1000	NS
Neonatal death by 7 days	10.5 per 1000	<0.05
Preterm <37 wk	7.5%	<0.05
Birthweight <1500 g	1.2%	<0.05
Birthweight <2500 g	6.6%	<0.05

[a]Compared with 720,000 pregnancies in women without surgery.

NS = not significant.

Data from Mazze, 1989.

Rates of fetal abnormalities with maternal surgery in early pregnancy do not appear increased. Källén and Mazze (1990) scrutinized 572 operations performed at 4 to 5 weeks' gestation and reported a nonsignificant relationship with elevated neural-tube defect rates. In a similar study from a Hungarian database, Czeizel and colleagues (1998) found no evidence that anesthetic agents were teratogenic.

LAPAROSCOPIC SURGERY

Laparoscopy has become the most common first-trimester procedure used for diagnosis and management of several surgical disorders. In 2017, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) updated its recommendations concerning laparoscopy use in pregnant women (Table 46-2).

TABLE 46-2

Some Guidelines from the Society of American Gastrointestinal Endoscopic Surgeons (SAGES) for Laparoscopic Surgery in Pregnant Women

Indications—same as for nonpregnant women
Adnexal mass excision
Investigation of acute abdominal processes
Appendectomy, cholecystectomy, nephrectomy, adrenalectomy, splenectomy
Technique
Position: lateral recumbent
Entry: open technique, careful Veress needle, or optical trocar; fundal height may alter insertion site selection
Trocars: direct visualization for placement; fundal height may alter insertion site selection
CO_2 insufflation pressures: 10–15 mm Hg
Monitoring: capnography intraoperatively, FHR assessment pre- and postoperatively
Perioperative pneumatic compression devices and early postoperative ambulation

CO_2 = carbon dioxide; FHR = fetal heart rate.

Data from Pearl, 2017.

Information regarding surgical approach selection in pregnancy comes from the American College of Surgeons database (Silvestri, 2011). During the 5-year period ending in 2009, almost 1300 pregnant women were studied who had undergone either appendectomy or cholecystectomy. Open appendectomy was performed in 36 percent of 857 gravidas compared with only 17 percent of those not pregnant. Of those undergoing cholecystectomy, an open procedure was used in 10 percent of 436 pregnant women compared with 5 percent of nonpregnant women. No randomized trials compare laparoscopic with open surgery, however, most reviews report equally satisfactory outcomes (Bunyavejchevin, 2013; Cox, 2015; Fatum, 2001). The most frequently performed procedures were cholecystectomy, adnexal surgery, and appendectomy. For adnexal mass surgery in pregnancy, laparoscopy is preferred, and several studies confirm its relative safety (Daykan, 2016; Hoover, 2011; Webb, 2015). At first, 26 to 28 weeks became the upper gestational-age limit recommended, but as experience has accrued, many now describe laparoscopic surgery performed in the third trimester (Kizer, 2011). In one report of 59 gravidas undergoing laparoscopic cholecystectomy or appendectomy, a third were >26 weeks' gestation (Rollins, 2004). No serious adverse sequelae are linked to these procedures. In addition, laparoscopic splenectomy, adrenalectomy, and nephrectomy have also been described in pregnant women (Asizare, 2014; Dong, 2014; Gernsheimer, 2007; Miller, 2012; Stroup, 2007).

Hemodynamic Effects

Abdominal insufflation for laparoscopy causes hemodynamic changes that are summarized in Table 46-3. Reedy and associates (1995) studied baboons at the human equivalent of 22 to 26 weeks' gestation. No substantive physiological changes were found with insufflation pressures of 10 mm Hg, but 20 mm Hg caused significant maternal cardiovascular and respiratory changes after 20 minutes. These included increased respiratory rate, respiratory acidosis, diminished cardiac output, and increased pulmonary artery and capillary wedge pressures.

TABLE 46-3

Physiological Effects of CO_2 Insufflation of the Peritoneal Cavity

System	Effects[a]	Mechanisms	Possible Maternal-Fetal Effects
Respiratory	Increased PCO_2; decreased pH	CO_2 absorption	Hypercarbia, acidosis
Cardiovascular	Increased: heart rate; systemic vascular resistance; pulmonary, central venous, and mean arterial pressures	Hypercarbia and increased intraabdominal pressure	Uteroplacental hypoperfusion— possible fetal hypoxia, acidosis, and hypoperfusion[b]
	Decreased cardiac output	Decreased venous return	
Blood flow	Decreased splanchnic flow with hypoperfusion of liver, kidneys, and gastrointestinal organs	Increased intraabdominal pressure	As above
	Decreased venous return from lower extremities	Increased intraabdominal pressure	As above
	Increased cerebral blood flow	Hypercarbia possibly from shunting due to splanchnic tamponade	Increased CSF pressure[b]

[a]Effects intensified when insufflation pressure >20 mm Hg in baboons (Reedy, 1995).

[b]Data primarily from animal studies.

CO_2 =carbon dioxide; CSF = cerebrospinal fluid; PCO_2 = partial pressure of CO_2.

Data from O'Rourke, 2006; Reynolds, 2003.

In women, cardiorespiratory changes are generally not severe if insufflation pressures are kept below 15 mm Hg. With noninvasive hemodynamic monitoring in women at midpregnancy, the cardiac index decreased 26 percent by 5 minutes of insufflation and 21 percent by 15 minutes (Steinbrook, 2001). Despite this, mean arterial pressures, systemic vascular resistance, and heart rate did not change significantly.

Obesity

Laparoscopic surgery frequently is ideal for the obese woman (Sisodia, 2015). However, some outcomes may be adversely affected in obese gravidas compared with normal-weight patients. Of these, higher conversion rates to laparotomy, longer operating times, and longer hospitalizations have been reported. Also, adequate ventilation is more difficult, and greater pneumoperitoneal pressures are needed to create suitable operating space. There is anatomical distortion of the abdominal wall with displaced landmarks. Finally, the risk of developing hernias at port sites is greater.

Perinatal Outcomes

Because precise effects of laparoscopy in the human fetus are unknown, animal studies are informative. In early studies of pregnant ewes, various investigators reported that uteroplacental blood flow declines when intraperitoneal insufflation pressure exceeded 15 mm Hg (Barnard, 1995; Hunter, 1995). This was the result of decreased perfusion pressure and increased placental vessel resistance (see Table 46-3). The previously cited baboon studies by Reedy and coworkers (1995) produced similar findings.

Perinatal outcomes in women are limited to observational studies. Reedy and colleagues (1997) used the updated Swedish Birth Registry database to analyze a 20-year period with more than 2 million deliveries. Of 2181 laparoscopic procedures, most were performed during the first trimester. Perinatal outcomes for these women were compared with those of all women in the database and those undergoing open surgical procedures. These investigators confirmed the earlier findings of an increased risk of low birthweight, preterm delivery, and fetal-growth restriction. Differences were not found, however, in outcomes of women undergoing laparoscopy versus laparotomy. An observational study of 262 women undergoing surgery for an adnexal mass noted similar findings (Koo, 2012).

Technique

The following description is an overview of laparoscopic techniques in pregnancy. For a detailed description refer to Chapter 15 in *Cunningham and Gilstrap's Operative Obstetrics, 3rd edition* (Kho, 2016).

Preparation for laparoscopy differs little from that used for laparotomy. Bowel cleansing is not needed but may aid visualization and manipulations by emptying the large intestine. Nasogastric or orogastric decompression reduces the risk of stomach trocar puncture and aspiration. Aortocaval compression is avoided by a left-lateral tilt. Positioning of the lower extremities in boot-type stirrups maintains access to the vagina for fetal sonographic assessment or *manual* uterine displacement. Intrauterine manipulators are logically avoided.

Most reports describe the use of general anesthesia after tracheal intubation with monitoring of end-tidal carbon dioxide— $EtCO_2$ (Hong, 2006; Ribic-Pucelj, 2007). With controlled ventilation, $EtCO_2$ is maintained at 30 to 35 mm Hg.

Beyond the first trimester, technical modifications of standard pelvic laparoscopic entry are required to avoid uterine puncture or laceration (Fig. 46-1). Many recommend open entry techniques to avoid perforations of the uterus, pelvic vessels, and adnexa (Kizer, 2011; Koo, 2012). The abdomen is incised at or above the umbilicus, and the peritoneal cavity entered under direct visualization (Fig. 46-2). At this point, the cannula is then connected to the insufflation system, and a 12-mm Hg pneumoperitoneum is created. The initial insufflation should be conducted slowly to allow for prompt assessment and reversal of any untoward pressure-related effects. Gas leakage around the cannula is managed by tightening the surrounding skin with a towel clamp. Insertion of secondary trocars into the abdomen is most safely performed under direct laparoscopic viewing. Single-port surgery has also been described (Dursun, 2013).

FIGURE 46-1

(From Kho KA: Diagnostic and operative laparoscopy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics 3rd ed, New York McGraw-Hill Education, 2017.)

In more advanced pregnancies, direct entry through a left upper quadrant port in the midclavicular line, 2 cm beneath the costal margin, may better avoid the fundus (Donkervoort, 2011; Stepp, 2004). Known as *Palmer point*, this entry site is also used in gynecological laparoscopy because visceroparietal adhesions infrequently form here (Vilos, 2007).

Gasless laparoscopy is a less commonly selected alternative approach that uses a rod with intraabdominal fan-blade-shaped retractors. When opened, these allow the abdominal wall to be lifted upward. It avoids the typical laparoscopic cardiovascular changes because the pneumoperitoneum is created by retraction rather than insufflation (Phupong, 2007).

Complications

Risks inherent to any abdominal endoscopic procedure are probably increased slightly during pregnancy. The obvious unique complication is perforation of the pregnant uterus with either a trocar or Veress needle (Azevedo, 2009; Kizer, 2011; Mala, 2014). That said, reported complications are infrequent (Fatum, 2001; Koo, 2012). One Cochrane database review noted a need for randomized trials to deduce comparative benefits and risks of laparoscopy versus laparotomy during pregnancy (Bunyavejchevin, 2013). Pragmatically, this seems unfeasible, and common sense should dictate the approach.

RADIOGRAPHY

Imaging modalities are used as adjuncts for diagnosis and therapy during pregnancy. Options include sonography, radiography, and magnetic resonance (MR) imaging. Of these, radiography is the most problematic. Inevitably, some radiographic procedures are performed before recognition of early pregnancy, usually because of trauma or serious illness. Fortunately, most diagnostic radiographic procedures are associated with minimal fetal risks. As with drugs and medications, however, these procedures may lead to litigation if pregnancy outcome is adverse. And, x-ray exposure may lead to a needless therapeutic abortion because of patient or physician anxiety.

Since 2007, the American College of Radiology (ACR) has addressed the growing concern of radiation dose in all fields of medicine (Amis, 2007). Some of its goals were to limit exposure through radiation safety practices and promote lifelong accumulated records of exposures in any given patient. Task Force recommendations included additional considerations for special radiosensitive populations, such as children and pregnant and potentially pregnant women. At our institutions, special recommendations are made for gravidas. Radiation exposure values and duration are recorded and monitored in high-exposure areas such as computed tomography (CT) and fluoroscopy.

Ionizing Radiation

The term *radiation* literally refers to energy transmission and thus is often applied not only to x-rays, but also to microwaves, ultrasound, diathermy, and radio waves. Of these, x-rays and gamma rays have short wavelengths with very high energy and are ionizing radiation forms. The other four energy forms have rather long wavelengths and low energy (Brent, 1999b, 2009).

Ionizing radiation refers to waves or particles-*photons*-of significant energy that can change the structure of molecules such as those in DNA or that can create free radical or ions capable of secondarily damaging tissue (Hall, 1991; National Research Council, 1990). Methods of measuring the effects of x-rays are summarized in Table 46-4. The standard terms used are *exposure* (in air), *dose* (to tissue), and *relative effective dose* (to tissue). In the range of energies for diagnostic x-rays, the dose is now expressed in grays (Gy), and the relative effective dose is expressed in sieverts (Sv). These can be used interchangeably. For consistency, all doses discussed subsequently are expressed in contemporaneously used units of gray (1 Gy = 100 rad) or sievert (1 Sv = 100 rem). To convert, 1 Sv = 100 rem = 100 rad.

TABLE 46-4

Some Measures of Ionizing Radiation

Exposure	Number of ions produced by x-rays per kg of air Unit: roentgen (R)
Dose	Amount of energy deposited per kg of tissue Modern unit: gray (Gy) (1 Gy = 100 rad) Traditional unit: rad
Relative effective dose	Amount of energy deposited per kg of tissue normalized for biological effectiveness Modern unit: sievert (Sv) (1 Sv = 100 rem) Traditional unit: rem

As noted, the biological effects of x-rays are caused by an electrochemical reaction that can damage tissue. According to Brent (1999a, 2009), x- and gamma-radiation at high doses can create two types of biological effects and reproductive risks in the fetus. These are *deterministic effects* and *stochastic effects*, which are both described in the next sections.

Deterministic Effects

One potential harmful effect of radiation exposure is deterministic, which may result in abortion, growth restriction, congenital malformations, microcephaly, or mental retardation. These deterministic effects are threshold effects, and the threshold level is the *NOAEL—No Observed Adverse Effect Level* (Brent, 2009). Although controversial, the NOAEL concept supports that there is no risk below a threshold dose (0.05 Gy or 5 rad). It also suggests that the threshold for gross fetal malformations is more likely to be 0.2 Gy (20 rad).

The harmful deterministic effects of ionizing radiation have been extensively studied for cell damage with resultant disordered embryogenesis. These have been assessed in animal models, as well as in Japanese atomic bomb survivors and the Oxford Survey of Childhood Cancers (Sorahan, 1995). Additional sources have confirmed prior observations and provided more information (Groen, 2012). One is a 2003 International Commission on Radiological Protection publication that describes biological fetal effects from prenatal irradiation. Another is the Biological Effects of Ionizing Radiation—BEIR VII Phase 2 report of the National Research Council (2006), which discusses health risks from exposure to low levels of ionizing radiation.

Animal Studies

In the mouse model, the lethality risk is highest during the preimplantation period—up to 10 days postconception (Kanter, 2014). This is likely due to blastomere destruction caused by chromosomal damage (Hall, 1991). During organogenesis, high-dose radiation—1 Gy or 100 rad—is more likely to cause malformations and growth restriction and less likely to have lethal effects in the mouse. Studies of brain development suggest effects on neuronal development and a window of cortical sensitivity in early and midfetal periods. That said, acute low-dose ionizing radiation appears to have no deleterious effects (Howell, 2013).

Human Data

Data on adverse human effects of high-dose ionizing radiation mostly derive from the atomic bomb survivors of Hiroshima and Nagasaki (Greskovich, 2000; Otake, 1987). The International Commission on Radiological Protection (2003) confirmed initial studies showing that the increased risk of severe mental retardation was greatest between 8 and 15 weeks' gestation. There may be a lower-threshold dose of 0.3 Gy (30 rad), which is a range similar to the window of cortical sensitivity in the mouse model discussed earlier. The mean decrease in intelligence quotient (IQ) scores was 25 points per Gy or 100 rad. There appears to be linear dose response, but it is not clear whether there is a threshold dose. Most estimates err on the conservative side by assuming a linear nonthreshold hypothesis. In a study of fetuses exposed to low radiation doses, Choi and colleagues (2012) did not find an increased risk for congenital anomalies.

Finally, an increased risk of mental retardation in humans <8 weeks' or >25 weeks' gestation has not been documented, even with doses exceeding 0.5 Gy or 50 rad (International Commission on Radiological Protection, 2003). Reports have described high-dose radiation used to treat women for malignancy, menorrhagia, and uterine myomas. Dekaban (1968) described 22 infants with microcephaly, mental retardation, or both following exposure in the first half of pregnancy to an estimated 2.5 Gy or 250 rad.

Summary of Fetal Radiation Exposure

From 8 to 15 weeks, the fetus is most susceptible to radiation-induced mental retardation. It has not been resolved whether this is a threshold or nonthreshold linear function of dose. The Committee on Biological Effects (1990) estimates the risk of severe mental retardation to be as low as 4 percent for 0.1 Gy (10 rad) and as high as 60 percent for 1.5 Gy (150 rad). But recall that these doses are 2 to 100 times higher than those considered maximal from diagnostic radiation. Importantly, cumulative doses from multiple procedures may reach the harmful range, especially at 8 to 15 weeks' gestation. At 16 to 25 weeks, the risk is less. And again, there is no proven risk before 8 weeks or after 25 weeks. Importantly, embryofetal risks from low-dose diagnostic radiation appear to be minimal. Current evidence suggests that risks for malformations, growth restriction, or abortion are not increased from a radiation dose of less than 0.05 Gy (5 rad). Indeed, Brent (2009) concluded that gross congenital malformations would not be increased with exposure to less than 0.2 Gy (20 rad). Because diagnostic x-rays seldom exceed 0.1 Gy (10 rad), Strzelczyk and associates (2007) concluded that these procedures are unlikely to cause deterministic effects. As emphasized by Groen and coworkers (2012), 0.1 Gy is the radiation equivalent to that from more than 1000 chest x-rays!

Stochastic Effects

These effects refer to random, presumably unpredictable oncogenic or mutagenic effects of radiation exposure. Stochastic effects concern associations between fetal diagnostic radiation exposure and increased risk of childhood cancers or genetic diseases. According to Doll and Wakeford (1997), as well as the National Research Council (2006) BEIR VII Phase 2 report, excess cancers can result from in utero exposure to doses as low as 0.01 Sv or 1 rad. Stated another way by Hurwitz and colleagues (2006), the estimated risk of childhood cancer following fetal exposure to 0.03 Gy or 3 rad doubles the background risk of 1 in 600 to that of 2 in 600.

In one report, in utero radiation exposure was determined for 10 solid cancers in adults from age 17 to 45 years. There was a dose-response relationship as previously noted at the 0.1 Sv or 10 rem threshold. These cancers likely are associated with a complex series of interactions between DNA and ionizing radiation. They also make it more problematic to predict cancer risk from low-dose radiation of less than 0.1 Sv or 10 rem. Importantly, below doses of 0.1 to 0.2 Sv, there is no convincing evidence of a carcinogenic effect (Brent, 2009, 2014; Preston, 2008; Strzelczyk, 2007).

X-Ray Dosimetry

Estimates of dose to the uterus and embryo for various frequently used radiographic examinations are summarized in Table 46-5. Imaging of maternal body parts farthest from the uterus results in a very small dose of radiation scatter to the embryo or fetus. The size of the woman, radiographic technique, and equipment performance are other variables (Wagner, 1997). Thus, data in the table serve only as guidelines. When the radiation dose for a specific individual is required, a medical physicist should be consulted. Brent (2009) recommends consulting the Health Physics Society website (www.hps.org) to view some examples of questions and answers posed by patients exposed to radiation.

TABLE 46-5

Dose to the Uterus for Common Radiologic Procedures

Study	View	Dose[a] per View (mGy)	No. Films[b]	Dose (mGy)
Skull[c]	AP, PA, Lat	<0.0001	4.1	<0.0005
Chest	AP, PA[c], Lat[d]	<0.0001–0.0008	1.5	0.0002–0.0007
Mammogram[d]	CC, Lat	<0.0003–0.0005	4.0	0.0007–0.002
Lumbosacral spine[e]	AP, Lat	1.14–2.2	3.4	1.76–3.6
Abdomen[e]	AP		1.0	0.8–1.63

Therapeutic Radiation

The Radiation Therapy Committee Task Group of the American Association of Physics in Medicine (Stovall, 1995) emphasizes careful individualization of radiotherapy for the pregnant woman (Chap. 63, Cancer Therapy in Pregnancy). For example, in some cases, shielding of the fetus and other safeguards can be employed (Fenig, 2001; Nuyttens, 2002). In other instances, the fetus will be exposed to dangerous radiation doses, and a carefully designed plan must be improvised (Prado, 2000). Examples include models that estimate the fetal dose given during maternal brain radiotherapy or tangential breast irradiation (Mazonakis, 1999, 2003). The harmful effects of radiotherapy on future fertility and pregnancy outcomes were reviewed by Wo and Viswanathan (2009) and others and are detailed in Chapter 63 (Reproductive Tract Neoplasms).

Diagnostic Radiation

Radiographs

To estimate fetal risk, approximate x-ray dosimetry must be known. According to the American College of Radiology, no single diagnostic procedure results in a radiation dose significant enough to threaten embryo-fetal well-being (Hall, 1991).

For standard radiographs, dosimetry is presented in Table 46-5. In pregnancy, the AP-view chest radiograph is the most commonly used study, and fetal exposure is exceptionally small—0.0007 Gy or 70 mrad. With one abdominal radiograph, because the embryo or fetus is directly in the x-ray beam, the dose is higher—0.001 Gy or 100 mrad. The standard intravenous pyelogram may exceed 0.005 Gy or 500 mrad because of several exposures. The one-shot pyelogram described in Chapter 53 (Nephrolithiasis) is useful when urolithiasis or other causes of obstruction are unproven by sonography but still suspected. Most "trauma series," such as radiographs of an extremity, skull, or rib series, deliver low doses because of the fetal distance from the target area (Shakerian, 2015).

Fluoroscopy and Angiography

Dosimetry calculations are much more difficult with these procedures because of variations in the number of radiographs obtained, total fluoroscopy time, and fluoroscopy time in which the fetus is in the radiation field. As shown in Table 46-6, the range is variable. The Food and Drug Administration (FDA) limits the exposure rate for conventional fluoroscopy such as barium studies, however, special-purpose systems such as angiography units have the potential for much higher exposure.

TABLE 46-6

Estimated X-Ray Doses to the Uterus/Embryo from Common Fluoroscopic Procedures

Procedure	Dose to Uterus (mGy)	Fluoroscopic Exposure in Seconds (SD)
Cerebral angiography[a]	<0.1	—
Cardiac angiography[b,c]	0.65	223 (± 118)
Single-vessel PTCA[b,c]	0.60	1023 (± 952)
Double-vessel PTCA[b,c]	0.90	1186 (± 593)
Upper gastrointestinal series[d]	0.56	136
Barium swallow[b,e]	0.06	192
Barium enema[b,f,g]	20–40	289–311

[f] Assumes embryo in radiation field for entire examination.

[g] Bednarek, 1983.

PTCA = percutaneous transluminal coronary angioplasty; SD = standard deviation.

Angiography and vascular embolization may occasionally be necessary for trauma and for serious maternal disorders, especially renal disease (Wortman, 2013). As before, a greater distance from the embryo or fetus lowers the exposure and risk.

Computed Tomography

These x-ray images are usually performed by obtaining a spiral of 360-degree images that are postprocessed in multiple planes. Of these, the axial image remains the most commonly obtained. Multidetector CT (MDCT) images are now standard for common clinical indications. The most recent detectors have 16 or 64 channels, and multidetector protocols may result in increased dosimetry compared with traditional CT imaging. Several imaging parameters have an effect on exposure (Brenner, 2007). These include pitch, kilovoltage, tube current, collimation, number of slices, tube rotation, and total acquisition time. If a study is performed with and without contrast, the dose is doubled because twice as many images are obtained. Fetal exposure is also dependent on factors such as maternal size as well as fetal size and position. And as with plain radiography, the closer the target area is to the fetus, the greater the delivered dose.

Cranial CT scanning is the most commonly performed study in gravidas. It is used for neurological disorders as discussed in Chapter 60 (Central Nervous System Imaging) and with eclampsia as noted in Chapter 40 (Uteroplacental Perfusion). Nonenhanced CT scanning is commonly used to detect acute hemorrhage within the epidural, subdural, or subarachnoid spaces (Fig. 46-3). Because of the distance from the fetus, radiation dosage is negligible (Goldberg-Stein, 2012).

FIGURE 46-3

A 37-year-old with intrapartum eclampsia at term. An image from a noncontrast computed tomography head study demonstrates a large left-sided frontoparietal temporal intraparenchymal hematoma (*H*) with intraventricular extension (*arrowheads*). The midline (*arrow*) is shifted to the right due to mass effect from the hematoma. (From Kho KA: Diagnostic and operative laparoscopy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics 3rd ed, New York McGraw-Hill Education, 2017.)

Abdominal procedures are more problematic. Hurwitz and associates (2006) employed a 16-channel multidetector scanner to calculate fetal exposure at 0 and 3 months' gestation using a phantom model. Calculations were made for three commonly requested procedures in pregnant women (Table 46-7). The pulmonary embolism protocol has the same dosimetry exposure as the ventilation-perfusion (V/Q) lung scan discussed in Radiographic Contrast Agents. Because of the pitch used, the appendicitis protocol has the highest radiation exposure, however, it is very useful clinically when MR imaging is not available. Using a similar protocol in 67 women with suspected appendicitis, Lazarus and coworkers (2007) reported sensitivity of 92 percent, specificity of 99 percent, and a negative-predictive value of 99 percent. Here, dosimetry was markedly decreased compared with standard appendiceal imaging because of a different pitch. This is discussed further in Chapter 54 (Colonic Pseudo-obstruction). Last, for suspected urolithiasis, the multidetector-scan protocol is used if sonography is nondiagnostic. Using a similar protocol, White and colleagues (2007) identified urolithiasis in 13 of 20 women at an average of 26.5 weeks. Finally, as shown in Figure 46-4, abdominal tomography is performed if indicated in the pregnant woman with severe trauma (Matzon, 2015; Shakerian, 2015).

TABLE 46-7

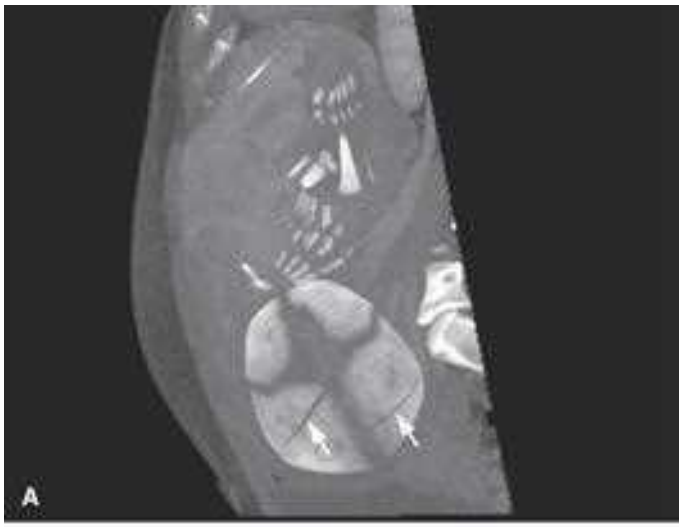
Estimated Radiation Dosimetry with 16-Channel Multidetector Computed-Tomographic (MDCT) Imaging Protocols

	Dosimetry (mGy)	
Protocol	**Preimplantation**	**3 Months' Gestation**
Pulmonary embolism	0.20–0.47	0.61–0.66
Renal stone	8–12	4–7
Appendix	15–17	20–40

Data from Hurwitz, 2006.

FIGURE 46-4

This woman in her third trimester was involved in a high-speed motor vehicle accident. **A.** Maximum intensity projection acquired for maternal indications readily identifies fetal skull fractures (*arrows*). **B.** 3-D reformatted CT image in a bone algorithm demonstrates the fetal skeleton from data acquired during the maternal examination. Again, the arrow marks one fracture site. (Reproduced with permission from Bailey AA, Twickler DM: Perioperative imaging. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics 3rd ed, New York, McGraw-Hill Education, 2017. Photo contributor: Dr. Travis Browning.)



Most experience with chest CT scanning is with suspected pulmonary embolism. The most recent recommendations for its use in pregnancy from the Prospective Investigation of Pulmonary Embolism Diagnosis—PIOPED—II investigators were summarized by Stein and associates (2007). They found that pulmonary scintigraphy—the V/Q scan—was recommended at that time for pregnant women by 70 percent of radiologists and chest CT angiography by 30 percent. Indeed, scintigraphy is still recommended by the American Thoracic Society for gravidas with a normal chest x-ray (Leung, 2012). That said, most agree that multidetector-CT angiography

has improved accuracy because of increasingly faster acquisition times (Brown, 2014). Others have reported a higher use rate for CT angiography and emphasize that dosimetry is similar to that with V/Q scintigraphy (Brenner, 2007; Greer, 2015; Hurwitz, 2006). Controversies on this topic continue, recognizing that fetal radiation doses are lower with CT angiography compared with the V/Q scan, but maternal chest radiation doses are substantially higher with CT scanning (van Mens, 2017). We prefer MDCT scanning initially for suspected pulmonary embolism (Chap. 52, Superficial Venous Thrombophlebitis).

CT pelvimetry is used by some before attempting breech vaginal delivery (Chap. 28, Delivery Complications). The fetal dose approaches 0.015 Gy or 1.5 rad, but use of a low-exposure technique may reduce this to 0.0025 Gy or 0.25 rad.

Radiographic Contrast Agents

These can be given intravenously or taken orally. Intravenous contrast agents are considered category B by the FDA. The types of intravenous contrast employed for imaging today are iodinated and low osmolality, thus, they cross the placenta to the fetus. With water-soluble iodinated contrast, no cases of neonatal hypothyroidism or other adverse effects have been documented (American College of Radiology, 2015). Oral contrast preparations, typically containing iodine or barium, have minimal systemic absorption and are unlikely to affect the fetus.

Nuclear Medicine Studies

These studies are performed by “tagging” a radioactive element to a carrier that can be injected, inhaled, or swallowed. For example, the radioisotope technetium-99m may be tagged to red blood cells, sulfur colloid, or pertechnetate. The method used to tag the agent determines fetal radiation exposure. The amount of placental transfer is obviously important, but so is renal clearance because of fetal proximity to the maternal bladder. Measurement of radioactive technetium is based on its decay, and the units used are the curie (Ci) or the becquerel (Bq). Dosimetry is usually expressed in millicuries (mCi). The effective tissue dose is expressed in sievert units (Sv) with conversion as discussed in Table 46-4: 1 Sv = 100 rem = 100 rad.

Depending on the physical and biochemical properties of a radioisotope, an average fetal exposure can be calculated (Wagner, 1997; Zanzonico, 2000). Commonly used radiopharmaceuticals and estimated absorbed fetal doses are given in Table 46-8. The radionuclide dose should be kept as low as possible (Adelstein, 1999; Zanotti-Fregonara, 2017). Exposures vary with gestational age and are greatest earlier in pregnancy for most radiopharmaceuticals. One exception is the later effect of iodine-131 on the fetal thyroid (Wagner, 1997).

TABLE 46-8

Radiopharmaceuticals Used in Nuclear Medicine Studies

Study	Estimated Activity Administered per Examination (mCi)[a]	Weeks' Gestation[b]	Dose to Uterus/Embryo (mSv)[c]
Brain	20 mCi ^{99m}Tc DTPA	<12	8.8
		12	7[c]
Hepatobiliary	5 mCi ^{99m}Tc sulfur colloid	12	0.45
	5 mCi ^{99m}Tc HIDA		1.5
Bone	20 mCi ^{99m}Tc phosphate	<12	4.6
Pulmonary			
Perfusion	3 mCi ^{99m}Tc-macroaggregated albumin	Any	0.45–0.57 (combined)
Ventilation	10 mCi ^{133}Xe gas		
Renal	20 mCi ^{99m}Tc DTPA	<12	8.8

[a]mCi = millicuries. To convert to mrad, multiply by 100.

[b]Exposures are generally greater prior to 12 weeks compared with increasing gestational ages.

[c]Some measurements account for placental transfer.

[d]The uptake and exposure of ^{131}I increases with gestational age.

DPTA = diethylenetriaminepentaacetic acid; Ga = gallium; HIDA = hepatobiliary iminodiacetic acid; I = iodine; mCi = millicurie; mSv = millisievert; Tc = technetium; TcO_4 = pertechnetate; Tl = thallium.

Data from Adelstein, 1999; Schwartz, 2003; Stather, 2002; Wagner, 1997; Zanzonico, 2000.

Discussed earlier, some still use the ventilation-perfusion lung scan for suspected pulmonary embolism. It is also used if CT angiography is nondiagnostic. Perfusion is measured with injected ^{99}Tc-macroaggregated albumin, and ventilation is measured with inhaled xenon-127 or xenon-133. Fetal exposure with either is negligible (Chan, 2002; Mountford, 1997).

Thyroid scanning with iodine-123 or iodine-131 seldom is indicated in pregnancy. With trace diagnostic doses used, however, fetal risk is minimal. Importantly, therapeutic radioiodine in doses to treat Graves disease or thyroid cancer may cause fetal thyroid ablation and cretinism.

The sentinel lymphoscintigram, which uses ^{99m}Tc-sulfur colloid to detect the axillary lymph node most likely to have metastases from breast cancer, is a commonly used preoperative study in nonpregnant women (Newman, 2007; Spanheimer, 2009; Wang, 2007). As shown in Table 46-8, the calculated dose is approximately 0.014 mSv or 1.4 mrad, which should not preclude its use during pregnancy.

SONOGRAPHY

Of all of the major advances in obstetrics, the development of sonography for study of the fetus and mother certainly is one of the greater achievements. The technique has become virtually indispensable in everyday practice. Its wide-ranging clinical uses are further discussed in Chapter 10 and in most other sections of this book.

MAGNETIC RESONANCE IMAGING

Magnetic resonance technology does not use ionizing radiation, and its application is cited throughout this book. Advantages include high soft-tissue contrast, ability to characterize tissue, and acquisition of images in any plane—particularly axial, sagittal, and coronal. An entire section in Chapter 10 (Magnetic Resonance Imaging) is devoted to mechanisms that generate MR images.

Safety

The most recent update of the expert panel on MR safety of the American College of Radiology was summarized by Kanal and colleagues (2013). The panel concluded that no harmful human effects are reported from MR imaging. Similar conclusions were reached by the Canadian Task Force on Preventive Health Care (Patenaude, 2014).

Early studies found differences in blastocyst formation of early murine embryos exposed to MR imaging with 1.5 T (T = tesla) (Chew, 2001). When operated within standardized limits, maternal and fetal imaging can be safely performed at clinical magnet strengths—3 T and below. MR imaging can be used, regardless of trimester: (1) if the information cannot be obtained with another nonionizing modality, namely sonography, (2) if the results of the study will guide maternal or fetal management during pregnancy, and (3) if the imaging cannot be delayed until the woman is no longer pregnant. The decision to use a magnetic field strength >1.5 T may be made for specific maternal indications. Early work also suggests imaging at 3 T can improve fetal assessment (Victoria, 2016). A magnetic field strength up to 4 T appears safe in animals (Magin, 2000). Vadeyar and associates (2000) reported no demonstrable fetal heart rate pattern changes during MR imaging of gravidas. Studies evaluating children exposed in utero have shown no deleterious effects (Clements, 2000; Kok, 2004; Reeves, 2010).

Contraindications to MR imaging include internal cardiac pacemakers, neurostimulators, implanted defibrillators and infusion pumps, cochlear implants, shrapnel or other metal in biologically sensitive areas, some intracranial aneurysm clips, and any metallic foreign body in the eye. Of more than 51,000 nonpregnant patients scheduled for MR imaging, Dewey and colleagues (2007) found that only 0.4 percent had an absolute contraindication to the procedure.

Contrast Agents

Elemental *gadolinium chelates* are used to create paramagnetic contrast. These cross the placenta and are found in the fetus, placenta, and amnionic fluid (Oh, 2015). In doses approximately 10 times the human dose, a gadolinium-based contrast agent caused slight developmental delay in rabbit fetuses. De Santis and associates described 26 women given a gadolinium derivative in the first trimester without adverse fetal effects (Kanal, 2013). According to Briggs and colleagues (2015), the American College of Obstetricians and Gynecologists (2017a), and the American College of Radiology (2015), routine use of gadolinium is not recommended unless there are potential benefits that outweigh fetal risks. This recommendation stems from a possible dissociation of the toxic gadolinium ion from its ligand in amnionic fluid and potential prolonged exposure of the fetus.

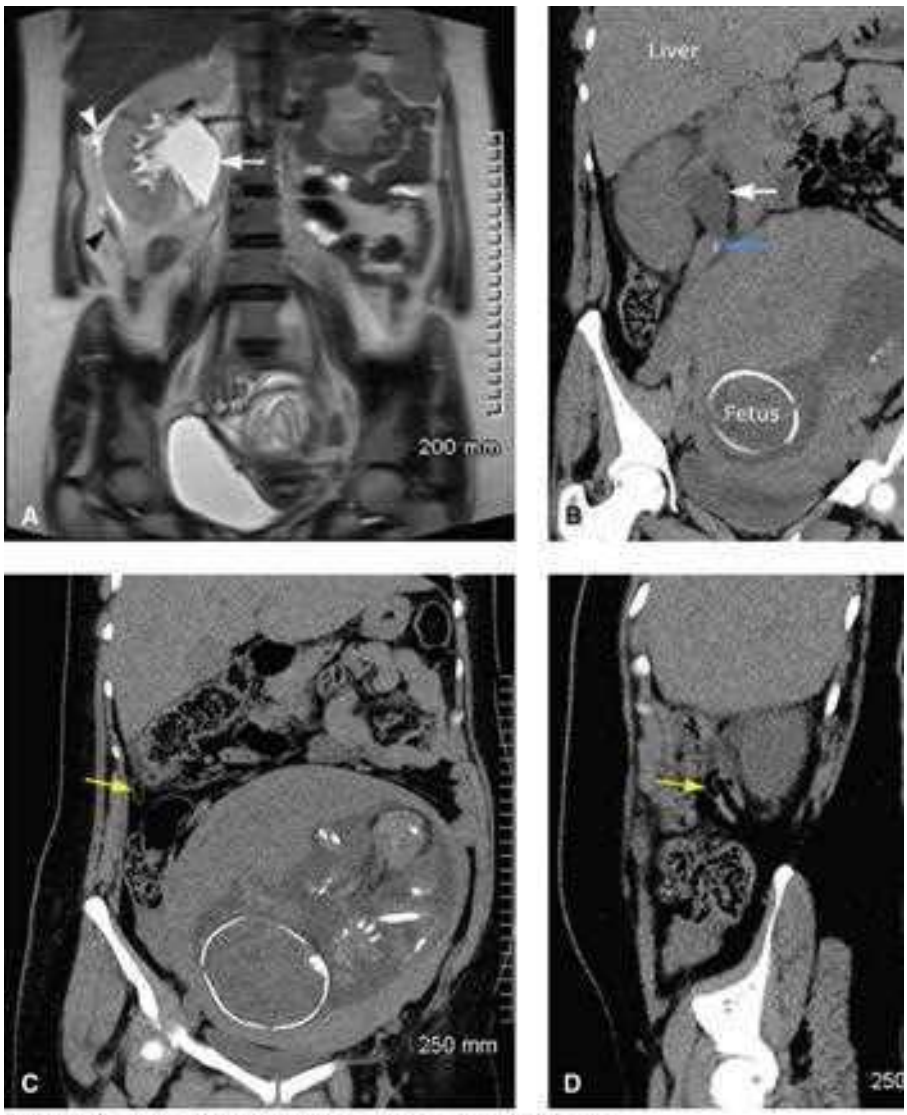
Maternal Indications

In some cases, MR imaging may be complementary to CT, and in others, MR imaging is preferable. Maternal central nervous system abnormalities, such as brain tumors or spinal trauma, are more clearly seen with MR imaging. As discussed in Chapter 40 (Cerebrovascular Pathophysiology), MR imaging has provided valuable insights into the pathophysiology of preeclampsia (Twickler, 2007; Zeeman, 2003, 2014). It is invaluable in the diagnosis of neurological emergencies (Edlow, 2013).

To evaluate the maternal abdomen and retroperitoneal space, MR imaging is a superb technique. It is chosen by many to determine the degree and extent of placenta accreta and its variants (Chap. 41, Clinical Presentation and Diagnosis). It has been employed for detection and localization of adrenal tumors, renal lesions, gastrointestinal lesions, and pelvic masses in pregnancy. For evaluating neoplasms of the chest, abdomen, and pelvis in pregnancy, it has particular value (Boyd, 2012; Tica, 2013). MR urography has been used successfully for renal urolithiasis (Mullins, 2012). As discussed in Chapter 37 (Parametrial Phlegmon), CT and MR imaging are useful for evaluation of puerperal infections, but MR imaging provides better visualization of the bladder flap area following cesarean delivery (Brown, 1999; Twickler, 1997). MR imaging now includes evaluation of right lower quadrant pain in pregnancy, specifically appendicitis (Fig. 46-5) (Baron, 2012; Dewhurst, 2013; Furey, 2014; Pedrosa, 2009; Tsai, 2017). Investigators have also found other disorders of the gastrointestinal tract to be easily diagnosed with MR imaging (Chap. 54, Upper Gastrointestinal Tract Disorders). Finally, cardiac MR imaging has shown promise in investigating normal physiology, complex defects, and cardiomyopathies (Kramer, 2015; Nelson, 2015; Stewart, 2016).

FIGURE 46-5

Multipara at 29 weeks' gestation with suspected appendicitis. **A.** Coronal T2-weighted magnetic resonance image demonstrates severe hydronephrosis (*arrow*) and perinephric fluid (*white arrowhead*) suggesting caliceal rupture. The normal appendix is seen laterally (*black arrowhead*). **B.** Coronal computed tomography (CT) better defines the source of obstruction as an 8-mm radiopaque stone at the ureteropelvic junction (*blue arrow*) and distal to the hydronephrosis (*white arrow*). **C** and **D.** In the same woman, more anterior coronal and sagittal CT images show the expected displacement of a noninflamed appendix (*yellow arrow*) into the upper abdomen with advancing gestation.



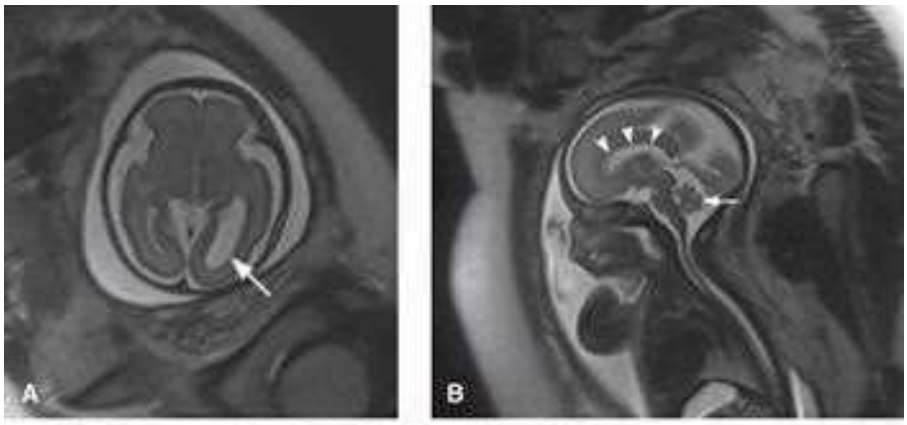
Fetal Indications

Fetal MR imaging provides a complement to sonography (Laifer-Narin, 2007; Sandrasegaran, 2006). According to Zaretsky and associates (2003a), MR imaging can be used to image almost all elements of the standard fetal anatomical survey. The most frequent fetal indications for MR imaging are evaluation of complex abnormalities of the brain, chest, and genitourinary system (Williams, 2017). Reichel (2003), Twickler (2002), and others have validated its use for fetal central nervous system anomalies and biometry (Fig. 46-6). Caire and coworkers (2003) reported its merits for fetal genitourinary anomalies. Hawkins and colleagues (2008) described MR imaging in 21 fetuses with renal anomalies and oligohydramnios. Zaretsky and associates (2003b) noted that fetal-weight estimation was more accurate using MR imaging than with sonography. Fetal movement is less problematic with faster acquisitions. Morphology is primarily assessed with fast T2-

weighted sequences such as *HASTE—Half-Fourier Acquisition Single Shot Turbo Spin Echo*, or *SSFSE—Single Shot Fast Spin Echo*. Fetal indications and findings of MR imaging are discussed more extensively in Chapter 10 (Fetal Anatomical Evaluation) and throughout this book.

FIGURE 46-6

Nullipara at 27 weeks' gestation. **A.** Axial T2-weighted MR image demonstrates mild fetal unilateral ventriculomegaly involving the left lateral ventricle (*arrow*). **B.** Sagittal T2-weighted MR image demonstrates normal development of the corpus callosum (*arrowheads*) and vermis (*arrow*).



IMAGING DURING PREGNANCY

The American College of Obstetricians and Gynecologists (2017a) has reviewed the effects of radiographic, sonographic, and magnetic-resonance exposure during pregnancy. Its suggested guidelines are shown in Table 46-9.

TABLE 46-9

Guidelines for Diagnostic Imaging During Pregnancy and Lactation

Sonography and magnetic resonance (MR) imaging are not associated with fetal risk and are preferred options for imaging in pregnancy
In general, radiation exposure during radiography, computed tomography (CT), or nuclear medicine imaging delivers a dose much lower than that associated with fetal harm. If needed to supplement sonography or MR imaging or if more readily available, these should not be withheld
With MR imaging, gadolinium contrast use should be restricted unless it significantly improves diagnostic accuracy to benefit fetal or maternal outcome
Breastfeeding should not be interrupted after gadolinium administration

Data from American College of Obstetricians and Gynecologists, 2017a.

CHAPTER 47: Critical Care and Trauma

The pregnant women is exposed to the same possibility of injury as at other times, the prognosis not being naturally altered except that abortion frequently occurs.

—J. Whitridge Williams (1903)

INTRODUCTION

These observations made more than a century ago are less applicable today to critically ill pregnant women because of current intensive care capabilities. For example, severe medical, surgical, and obstetrical disorders complicating pregnancy are frequently managed by a multidisciplinary team for optimal care. It is axiomatic that obstetricians and other members of the health-care team must have a working knowledge of the unique considerations for pregnant women. Some of those discussed in Chapter 46 include pregnancy-induced physiological changes, alterations in normal laboratory values, and consideration for the second patient—the fetus. Because these critically ill women are usually young and in good health, their prognosis is generally better than that of many other patients admitted to intensive care units (ICUs) (Gaffney, 2014).

OBSTETRICAL INTENSIVE CARE

In the United States each year, 1 to 3 percent of pregnant women require critical care services, and the risk of death during such admissions ranges from 2 to 11 percent (American College of Obstetricians and Gynecologists, 2017b). Those with pregnancy-associated complications—especially hemorrhage and hypertension—have the greatest need for intensive care (Chantry, 2015; Gaffney, 2014; Guntupalli, 2015a,b). That said, many antepartum admissions are for nonobstetrical reasons, and these include diabetes, pneumonia or asthma, heart disease, chronic hypertension, pyelonephritis, and thyrotoxicosis (Guntupalli, 2015b; Zeeman, 2006). Additionally, intrapartum and postpartum critical care for hypertensive disorders, hemorrhage, sepsis, or cardiopulmonary complications is often required. In instances of life-threatening hemorrhage, surgical procedures may be necessary, and close proximity to a delivery-operating room is paramount. For women who are undelivered, fetal well-being is also better served by this close proximity, especially because many are delivered preterm (Kilpatrick, 2016).

Organization of Critical Care

The concept and development of critical care for all aspects of medicine and surgery began in the 1960s. The National Institutes of Health held a Consensus Conference (1983) and the Society of Critical Care Medicine (1988, 1999) subsequently established guidelines for ICUs. Especially pertinent to obstetrics, these costly units prompted the evolution of a step-down *intermediate care unit*. These latter units were designed for patients who did not require intensive care, but who needed a higher level of care than that provided on a general ward. The American College of Critical Care Medicine and the Society of Critical Care Medicine (1998) have published guidelines for these units (Table 47-1).

TABLE 47-1

Guidelines for Conditions That Could Qualify for Intermediate Care

Cardiac: evaluation for possible infarction, stable infarction, stable arrhythmias, mild-to-moderate congestive heart failure, hypertensive urgency without end-organ damage
Pulmonary: stable patients for weaning and chronic ventilation, patients with potential for respiratory failure who are otherwise stable
Neurological: stable central nervous system, neuromuscular, or neurosurgical conditions that require close monitoring
Drug overdose: hemodynamically stable
Gastrointestinal: stable bleeding, liver failure with stable vital signs
Endocrine: diabetic ketoacidosis, thyrotoxicosis that requires frequent monitoring
Surgical: postoperative from major procedures or complications that require close monitoring
Miscellaneous: early sepsis, patients who require closely titrated intravenous fluids, pregnant women with severe preeclampsia or other medical problems

Data from Nasraway, 1998.

Obstetrical Critical Care

Although the evolution of critical care for obstetrical patients has generally followed developments just described, there are no specific guidelines. Most hospitals employ a blend of these concepts, and in general, units can be divided into three types.

First, in most hospitals, severely ill women are transferred to medical or surgical ICUs that are operated by specialists often certified in critical care medicine. Admissions or transfers to these units are situation-specific and based on the acuity of care needed and on the ability of the facility to provide it. For example, pregnant women who require ventilatory support, invasive monitoring, or pharmacological support of circulation are typically transferred to an ICU (Chantry, 2015). Another example is the neurological ICU (Sheth, 2012). In an earlier review of more than 25 tertiary-care referral institutions, approximately 0.5 percent of obstetrical patients were transferred to these types of ICUs (Zeeman, 2006).

A second type is the obstetrical intermediate care unit, sometimes referred to as a high-dependency care unit (HDU). One example is found at Parkland Hospital. Located within the labor and delivery unit, it has designated rooms staffed by experienced personnel. The two-tiered system incorporates the guidelines for intermediate and intensive care. Care is provided by maternal-fetal medicine specialists and nurses with experience in critical care obstetrics. As needed, this team is expanded to include other obstetricians and anesthesiologists, hospitalists, gynecological oncologists, pulmonologists, cardiologists, surgeons, and other medical and surgical subspecialists (Stevens, 2015). Many tertiary-care centers have developed similar intermediate care units and use selected triage to ICUs. Guidelines for such transfers must follow the federal Emergency Medical Treatment and Labor Act (EMTALA) guidelines. According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017), the minimal monitoring required for a critically ill patient during transport includes continuous pulse oximetry, electrocardiography, and regular assessment of vital signs. They must have secure venous access, and those who are mechanically ventilated must have endotracheal tube position confirmed and secured. Left uterine displacement and supplemental oxygen is applied routinely during transport of antepartum patients. Continuous fetal heart rate or tocodynamic monitoring is individualized.

Last, obstetrical ICUs are full-care ICUs but are operated by obstetrical and anesthesia personnel in the labor and delivery unit. Only a few obstetrical services have these capabilities (Zeeman, 2003, 2006).

For smaller hospitals, transfer to a medical or surgical ICU is usually preferable, and sometimes transfer to another hospital is necessary. As discussed, indications for admission to these types of critical care units vary, however, patient mix for these units is similar (Table 47-2). The American College of Obstetricians and Gynecologists (2017b) has summarized critical obstetrical care implementation depending on hospital size and technical facilities.

TABLE 47-2

Comparison of Acuity of Patient Mix for Obstetrical Critical Care Shown in Percent

Factor	Intermediate Care Unit (n = 483)[a]	Medical-Surgical ICU (n = 813)[b]
Stage		
Antepartum	20	23
Postpartum	80	77
Indication[c]		
Hypertension	45	40
Hemorrhage	18	21
Cardiopulmonary	12	16
Sepsis	5	8
Pregnancy-Related Mortality	0.2	2

[c]Columns of indications do not total 100 percent because some diagnoses are not listed.

Pulmonary Artery Catheter

Data obtained during pregnancy with pulmonary artery catheterization (PAC) have contributed immensely to the understanding of normal pregnancy hemodynamics and pathophysiology of common obstetrical conditions. These include preeclampsia-eclampsia, acute respiratory distress syndrome, and amniotic-fluid embolism (Clark, 1988, 1995, 1997; Cunningham, 1986, 1987; Hankins, 1984, 1985). Also, because of these studies, most have concluded that such monitoring is seldom necessary (American College of Obstetricians and Gynecologists, 2013; Gidwani, 2013; Magder, 2015).

In nonobstetrical patients, randomized trials of nearly 5000 subjects have shown no benefits with PAC (Harvey, 2005; National Heart, Lung, and Blood Institute, 2006; Sandham, 2003). According to a Cochrane Database review, no randomized trials have used PAC for preeclampsia management (Li, 2012). The overall mechanisms, benefits, and risks were recently reviewed by Magder (2015).

Hemodynamic Changes in Pregnancy

Formulas for deriving some hemodynamic parameters are shown in Table 47-3. These measurements can be indexed for body size by dividing by body surface area (BSA). Normal values for nonpregnant adults are used, but with the caveat that these may not necessarily reflect changes induced by the more "passive" uteroplacental perfusion.

TABLE 47-3

Formulas for Deriving Various Cardiopulmonary Parameters

Mean arterial pressure (MAP) (mm Hg) = [SBP + 2 (DBP)] ÷ 3
Cardiac output (CO) (L/min) = heart rate × stroke volume
Stroke volume (SV) (mL/beat) = CO/HR
Stroke index (SI) (mL/beat/m^2) = stroke volume/BSA
Cardiac index (CI) (L/min/m^2) = CO/BSA
Systemic vascular resistance (SVR) (dynes × sec × cm^{-5}) = [(MAP − CVP)/CO] × 80
Pulmonary vascular resistance (PVR) (dynes × sec × cm^{-5}) = [(MPAP − PCWP)/CO] × 80

BSA = body surface area (m^2); CVP = central venous pressure (mm Hg); DBP = diastolic blood pressure; HR = heart rate (beats/min); MAP = mean systemic arterial pressure (mm Hg); MPAP = mean pulmonary artery pressure (mm Hg); PCWP = pulmonary capillary wedge pressure (mm Hg); SBP = systolic blood pressure.

In a landmark investigation, Clark and colleagues (1989) used PAC to obtain cardiovascular measurements in healthy pregnant women and again in these same women when nonpregnant (Chap. 4, Hemodynamic Function in Late Pregnancy). Because increased blood volume and cardiac output are compensated by decreased vascular resistance and increased pulse rate, ventricular performance remains within the normal range at term.

Cardiac complications are a common indication for ICU admission of pregnant women (Guntupalli, 2015b). Evaluation of cardiac function is frequently performed using echocardiography. This technology is indispensable in interrogating cardiac anatomy and especially right-ventricular function (Krishnan, 2015; Thiele, 2015). It is considered in more detail in Chapter 49 (Peripartum Management Considerations), and some normal values are listed in the Appendix (Maternal Echocardiographic Measurements). A working knowledge of cardiovascular physiology in pregnancy is paramount to understanding the pathophysiology of gestational complications discussed later in this chapter and throughout the book.

ACUTE PULMONARY EDEMA

The incidence of pulmonary edema complicating pregnancy averages 1 in 500 deliveries at tertiary referral centers. The two general causes are: (1) *cardiogenic,* namely, hydrostatic edema caused by high pulmonary capillary hydraulic pressures, and (2) *noncardiogenic,* that is, permeability edema caused by capillary endothelial and alveolar epithelial damage. In pregnancy, noncardiogenic pulmonary edema is more common. Taken in toto, studies in gravidas indicate that more than half who develop pulmonary edema have some degree of sepsis syndrome in conjunction with tocolysis, severe preeclampsia, or obstetrical hemorrhage combined with vigorous fluid therapy (O'Dwyer, 2014; Thornton, 2011).

Although cardiogenic pulmonary edema is less frequent, common precipitating causes include resuscitation for hemorrhage and vigorous treatment of preterm labor. In one study, the causes in 51 women with pulmonary edema were cardiac failure, tocolytic therapy, iatrogenic fluid overload, and preeclampsia (Sciscione, 2003). In another study, more than half of cases were associated with preeclampsia, and the other three causes had equal distribution (Hough, 2007). In still another study of 53 cases, 83 percent were caused by hypertensive disorders, 11 percent cardiac, and 6 percent sepsis (O'Dwyer, 2015). Although used less commonly today, tocolytic therapy with β-mimetic drugs at one time was the cause of up to 40 percent of pulmonary edema cases (DiFederico, 1998; Gandhi, 2014; Jenkins, 2003).

Noncardiogenic Permeability Edema

Endothelial activation is the common denominator that is associated with preeclampsia, sepsis syndrome, and acute hemorrhage—or frequently combinations thereof—and they are the most common predisposing factors to pulmonary edema (Table 47-4). As discussed, these clinical scenarios are often associated with corticosteroids given to induce fetal lung maturation along with vigorous fluid replacement and tocolytic therapy (Thornton, 2011). Parenteral β-agonists are indisputably linked to pulmonary edema. Studies have also associated magnesium sulfate given for preeclampsia (Gandhi, 2014; Wilson, 2014; Xiao, 2014). Combined therapy is also causative. In one study of nearly 800 women given magnesium sulfate for preterm labor, 8 percent developed pulmonary edema, and half of this affected group had also received terbutaline (Samol, 2005).

TABLE 47-4

Some Causes and Associated Factors for Pulmonary Edema in Pregnancy

Noncardiogenic permeability edema: endothelial activation with capillary-alveolar leakage
Preeclampsia syndrome
Acute hemorrhage
Sepsis syndrome: pyelonephritis, metritis
Tocolytic therapy: β-mimetics, $MgSO_4$
Aspiration pneumonitis
Vigorous intravenous fluid therapy
Pancreatitis
Cardiogenic pulmonary edema: myocardial failure with hydrostatic edema from excessive pulmonary capillary pressure
Hypertensive cardiomyopathy
Obesity—adipositas cordis
Left-sided valvular disease
Vigorous intravenous fluid therapy
Pulmonary hypertension

Cardiogenic Hydrostatic Edema

Ventricular failure causing pulmonary edema in pregnancy is usually associated with some form of gestational hypertension. Although it can be due to congenital or acquired anatomical defects, diastolic dysfunction is frequently from chronic hypertension, obesity, or both (Jessup, 2003; Kenchaiah, 2002). In these women, acute systolic hypertension exacerbates diastolic dysfunction and causes pulmonary edema (Dennis, 2012; Gandhi, 2001). Of note, concentric and eccentric hypertrophy is two- to threefold more common in black women compared with white women (Drazner, 2005). In a case-control study of 28 gravidas with preeclampsia and pulmonary edema, half of them were undelivered (Gandhi, 2014).

In women with an underlying cardiomyopathy, heart failure is commonly precipitated by preeclampsia, hypertension, hemorrhage and anemia, and puerperal sepsis (Cunningham, 1986; Sibai, 1987). In many of these, when echocardiography is done later, systolic function is normal as measured by ejection fraction, but evidence for diastolic dysfunction can often be found (Aurigemma, 2004). The use of *brain natriuretic peptide (BNP)* has not been evaluated extensively in pregnancy (Seror, 2014). This neurohormone is secreted from ventricle myocytes and fibroblasts with distention seen in heart failure. In nonpregnant patients, values <100 pg/mL have an excellent negative-predictive value, and levels >500 pg/mL have an excellent positive-predictive value. It is problematic that levels frequently are 100 to 500 pg/mL, and thus nondiagnostic (Ware, 2005). Values for N-terminal BNP and atrial natriuretic peptide (ANP) are both elevated with preeclampsia (Szabo, 2014; Tihtonen, 2007). This is discussed in greater detail in Chapter 4 (Renin, Angiotensin II, and Plasma Volume), and normal values for pregnancy are given in the Appendix (Serum and Blood Constituents).

Management

Acute pulmonary edema requires emergency care. Furosemide is given in 20- to 40-mg intravenous doses along with therapy to control severe hypertension. Further treatment depends on whether a woman is ante- or postpartum. A live fetus prohibits the use of cardioactive drugs that might rapidly lower peripheral resistance and in turn severely diminish uteroplacental circulation. The cause of cardiogenic failure is determined by echocardiography, which will help direct further therapy. Acute pulmonary edema is not, per se, an indication for emergency cesarean delivery.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute lung injury that causes a form of severe permeability pulmonary edema and respiratory failure is termed acute respiratory distress syndrome (ARDS). This is a pathophysiological continuum from mild pulmonary insufficiency to dependence on high inspired oxygen concentrations and mechanical ventilation. Uniform criteria for its diagnosis are lacking, and thus the incidence is variably reported for pregnancy. In one survey of the Nationwide Inpatient Sample, 2808 pregnant women with ARDS were identified (Rush, 2017). The incidence ranged from 36 to 60 cases per 100,000 births, and the maternal mortality rate was 9 percent. In its

most extreme form, requiring ventilatory support, the associated mortality rate is 45 percent. This rate can be as high as 90 percent if caused or complicated by sepsis (Phua, 2009). Although gravidas are younger and usually healthier than the overall population, they still have mortality rates of 25 to 40 percent (Catanzarite, 2001; Cole, 2005). Finally, if ARDS develops antepartum, the perinatal mortality rate is correspondingly high.

Definitions

Most investigators define ARDS as radiographically documented pulmonary infiltrates, a ratio of arterial oxygen tension to the fraction of inspired oxygen (Pao_2:Fio_2) <200, and no evidence of heart failure (Mallampalli, 2010; Thompson, 2017). Revised by international consensus, the *Berlin Definition* was described by the ARDS Definition Task Force (2012) and includes categories of mild, moderate and severe. To date, for most interventional studies, a working diagnosis of *acute lung injury* is made when the Pao_2:Fio_2 ratio is <300 and is coupled with dyspnea, tachypnea, oxygen desaturation, and radiographic pulmonary infiltrates (Wheeler, 2007).

Etiopathogenesis

ARDS is a pathophysiological description that begins with an acute lung injury from various causes (Table 47-5). In pregnant women, sepsis and diffuse infectious pneumonia are the two most common single-agent ARDS causes. Pyelonephritis, puerperal pelvic infection, and chorioamnionitis are the most frequent causes of sepsis. As discussed in Acute Pulmonary Edema, severe preeclampsia and obstetrical hemorrhage are also commonly associated with permeability edema. Importantly, more than half of pregnant women with ARDS have some combination of sepsis, hemorrhage, shock, and fluid overload. The contribution of *transfusion-related acute lung injury (TRALI)* is unclear (Chap. 41, Topical Hemostatic Agents).

TABLE 47-5

Some Causes of Acute Lung Injury and Respiratory Failure in Pregnant Women

Pneumonia: bacterial, viral, aspiration
Sepsis syndrome: chorioamnionitis, pyelonephritis, puerperal infection, septic abortion
Hemorrhage: shock, massive transfusion, transfusion-related acute lung injury (TRALI)
Preeclampsia syndrome
Tocolytic therapy
Embolism: amnionic fluid, trophoblastic disease, air, fat
Connective-tissue disease
Substance abuse
Irritant inhalation and burns
Pancreatitis
Drug overdose
Fetal surgery
Trauma
Sickle-cell disease
Miliary tuberculosis
Cerebral hemorrhage

Data from Cole, 2005; Duarte, 2014; Golombeck, 2006; Lapinsky, 2015; Martin, 2006; Sheffield, 2005; Sibai, 2014; Snyder, 2013; Zeeman, 2003, 2006.

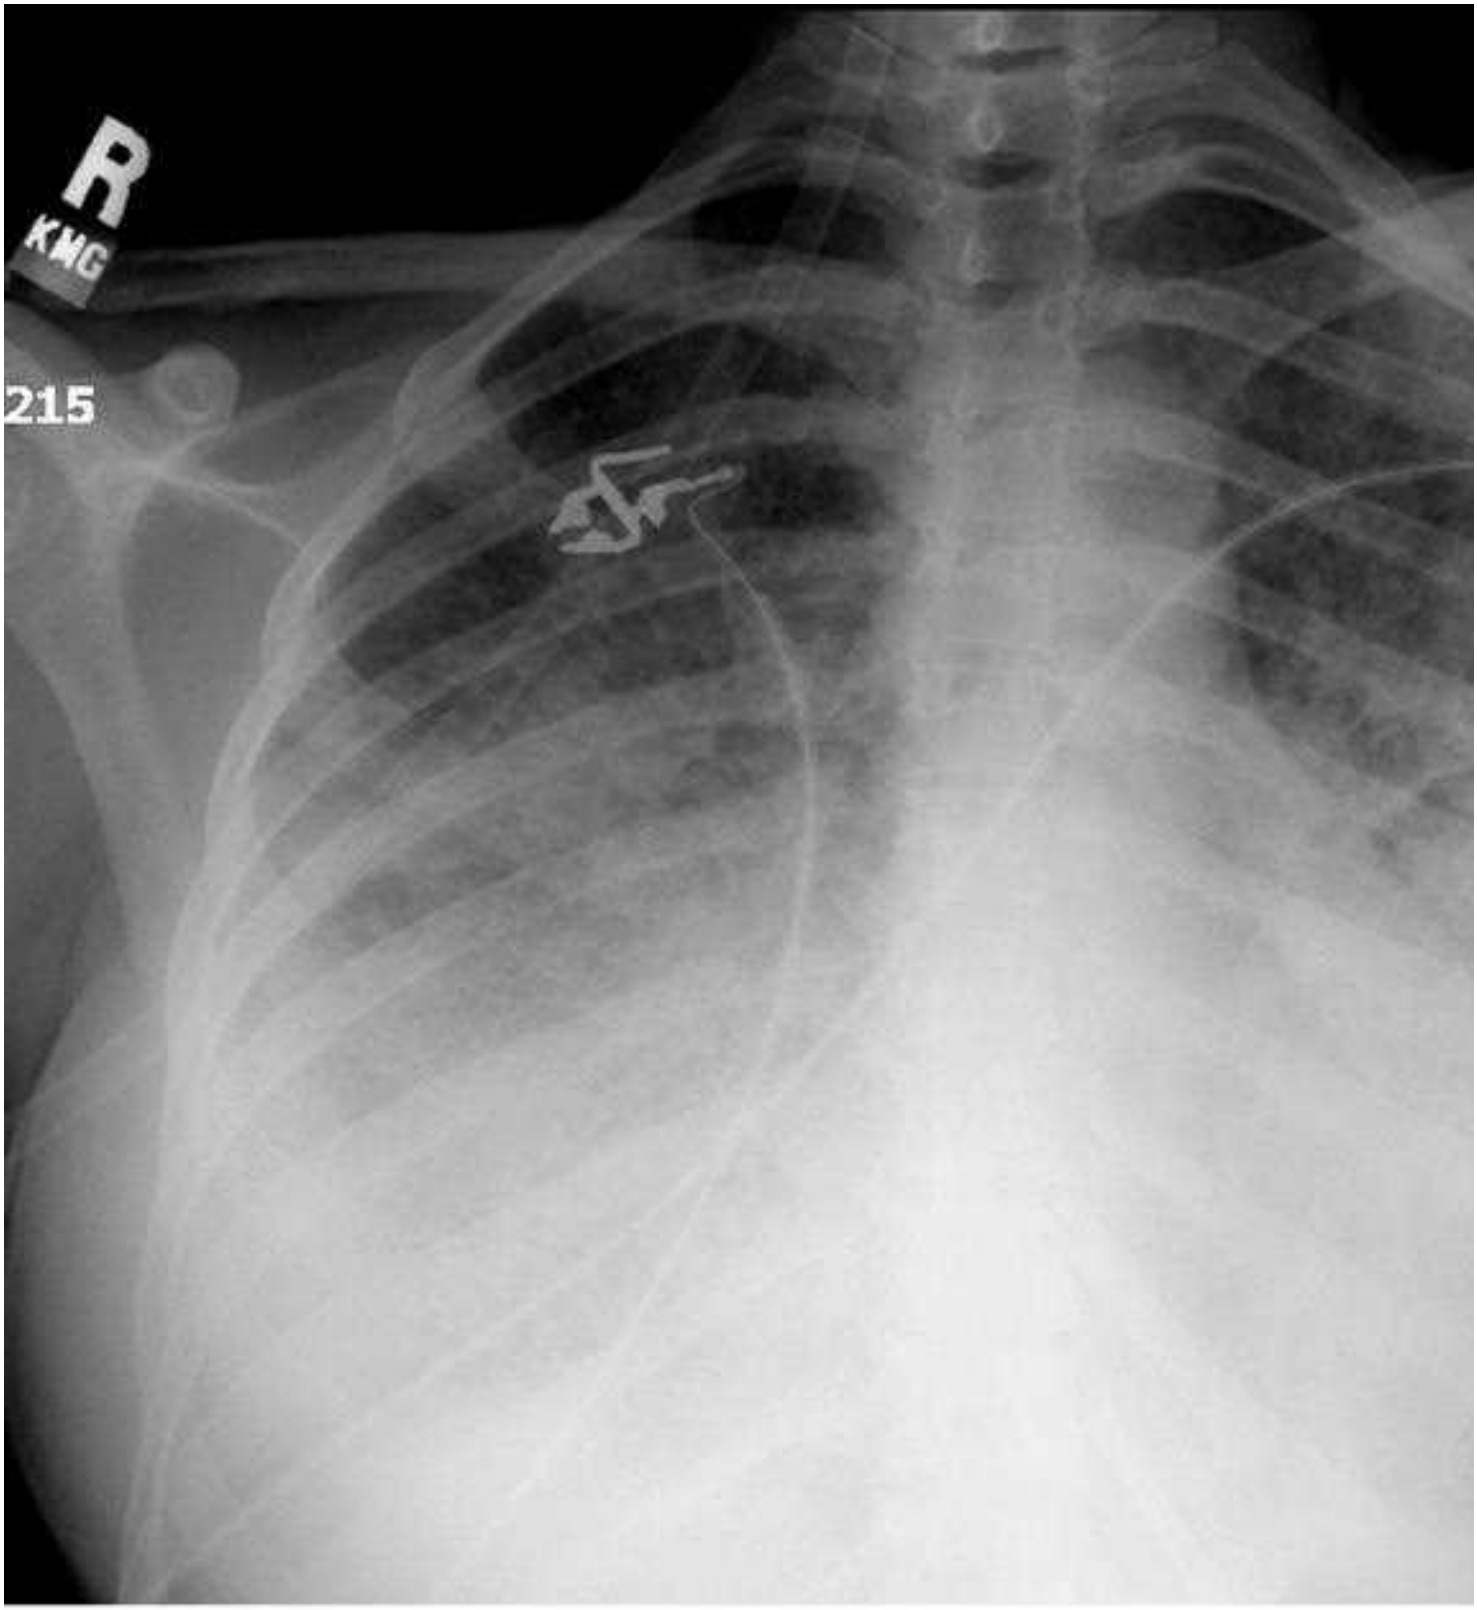
Endothelial injury in the lung capillaries releases cytokines that recruit neutrophils to the inflammation site. Here, they elaborate more cytokines to worsen tissue injury. There are three stages of ARDS development. First, the *exudative phase* follows widespread injury to microvascular endothelium, including the pulmonary vasculature, and there is also alveolar epithelial injury. These result in increased pulmonary capillary permeability, surfactant loss or inactivation, diminished lung volume, and vascular shunting with resultant arterial hypoxemia. Next, the *fibroproliferative phase* usually begins 3 to 4 days later and lasts up to day 21. Last, the *fibrotic phase* results from healing, and despite this, the long-term prognosis for pulmonary function is surprisingly good (Herridge, 2003; Levy, 2015).

Clinical Course

With pulmonary injury, the clinical condition depends largely on the insult magnitude, the ability to compensate for it, and the disease stage. For example, soon after the initial injury, physical findings are absent except perhaps hyperventilation. And at first, arterial oxygenation usually is adequate. Pregnancy-induced mild metabolic alkalosis may be accentuated by hyperventilation. With worsening, clinical and radiological evidence for pulmonary edema, decreased lung compliance, and increased intrapulmonary blood shunting become apparent. Progressive alveolar and interstitial edema develop with extravasation of inflammatory cells and erythrocytes.

Ideally, pulmonary injury is identified at this early stage, and specific therapy is directed at the underlying insult. Further progression to acute respiratory failure is characterized by marked dyspnea, tachypnea, and hypoxemia. Additional lung volume loss results in worsening of pulmonary compliance and increased shunting. Diffuse abnormalities are heard by auscultation, and a chest radiograph characteristically demonstrates bilateral lung involvement (Fig. 47-1). At this phase, the injury ordinarily would be lethal in the absence of ventilatory support. When shunting exceeds 30 percent, severe refractory hypoxemia develops along with metabolic and respiratory acidosis that can result in myocardial irritability, dysfunction, and cardiac arrest.

FIGURE 47-1
Anteroposterior chest radiograph of a second-trimester pregnant woman with marked bilateral parenchymal and pleural opacification secondary to acute respiratory distress syndrome (ARDS) due to pyelonephritis.



Management

Reduced ARDS mortality rates have resulted from advances in care of the critically ill (Levy, 2015). This requires close attention to: (1) recognizing and treating underlying medical and surgical disorders, (2) minimizing procedures and their complications, (3) administering prophylaxis against venous thromboembolism, gastrointestinal bleeding, aspiration, and central venous catheter infection, (4) promptly diagnosing nosocomial infections, and (5) providing adequate nutrition.

In cases of severe acute lung injury, providing adequate oxygenation of peripheral tissues is balanced against maneuvers that further aggravate lung injury. At least intuitively, increasing oxygen delivery should produce a corresponding increase in tissue uptake, but this is difficult to measure. Support of systemic perfusion with

intravenous crystalloid and blood is imperative. As discussed earlier, the trial conducted by the National Heart, Lung, and Blood Institute (2006) showed that pulmonary artery catheter use did not improve outcomes. Because sepsis is commonplace in lung injury, vigorous antimicrobial therapy is given for infection, and any necrotic tissues are debrided. Oxygen delivery can be greatly improved by correction of anemia. Specifically, each gram of hemoglobin carries 1.25 mL of oxygen when 90-percent saturated. By comparison, increasing the arterial Po_2 from 100 to 200 mm Hg results in the transport of only 0.1 mL of additional oxygen for each 100 mL of blood.

Reasonable goals in caring for the woman with severe lung injury are to attain a Pao_2 of 60 mm Hg or 90-percent oxygen saturation using an inspired oxygen content <50 percent and positive end-expiratory pressures <15 mm Hg. With regard to the pregnancy, it remains controversial whether delivery of the fetus improves maternal oxygenation (Mallampalli, 2010). In a study of 29 women undergoing mechanical ventilation, 10 were delivered while intubated (Lapinsky, 2015). This was associated with a modest improvement in respiratory function in perhaps half, but no factors were identified that predicted a better outcome.

Mechanical Ventilation

Noninvasive ventilation, that is, positive pressure ventilation by face mask, may be effective in some women in early stages of pulmonary insufficiency (Duarte, 2014). Early intubation is preferred in the gravida if respiratory failure is more likely than not, and especially if it appears imminent. Many successful formulas for mechanical ventilation are employed, and initially a tidal volume ≤6 mL/kg is optimal (Levy, 2015; Schwaiberger, 2016). High-frequency oscillation ventilation (HFOV) is controversial in ARDS (Ferguson, 2013; Slutsky, 2013). Adjustments are made to obtain a Pao_2>60 mm Hg or a hemoglobin oxygen saturation ≥90 percent and a $Paco_2$ of 35 to 45 mm Hg. Lower levels for Pao_2 are avoided, because placental perfusion may be impaired (Levinson, 1974).

For women who require ventilation for any length of time, the maternal mortality rate is 10 to 20 percent. In a study of 51 such women, almost half had severe preeclampsia, and most required intubation postpartum. Eleven were delivered while being ventilated, and another six were discharged undelivered (Jenkins, 2003). There were two maternal deaths, including a woman who died as a complication of tocolytic treatment. In three other reports, maternal mortality rates ranged from 10 to 25 percent (Chen, 2003; Lapinsky, 2015; Schneider, 2003). In most cases, delivery did not improve maternal outcome.

Positive End-Expiratory Pressure

With severe lung injury and high intrapulmonary shunt fractions, it may not be possible to provide adequate oxygenation with usual ventilatory pressures, even with 100-percent oxygen. Positive end-expiratory pressure is usually successful in decreasing the shunt by recruiting collapsed alveoli. At low levels of 5 to 15 mm Hg, positive pressure can typically be used safely. At higher levels, impaired right-sided venous return can result in decreased cardiac output, lowered uteroplacental perfusion, alveolar overdistention, falling compliance, and barotrauma (Schwaiberger, 2016; Slutsky, 2013).

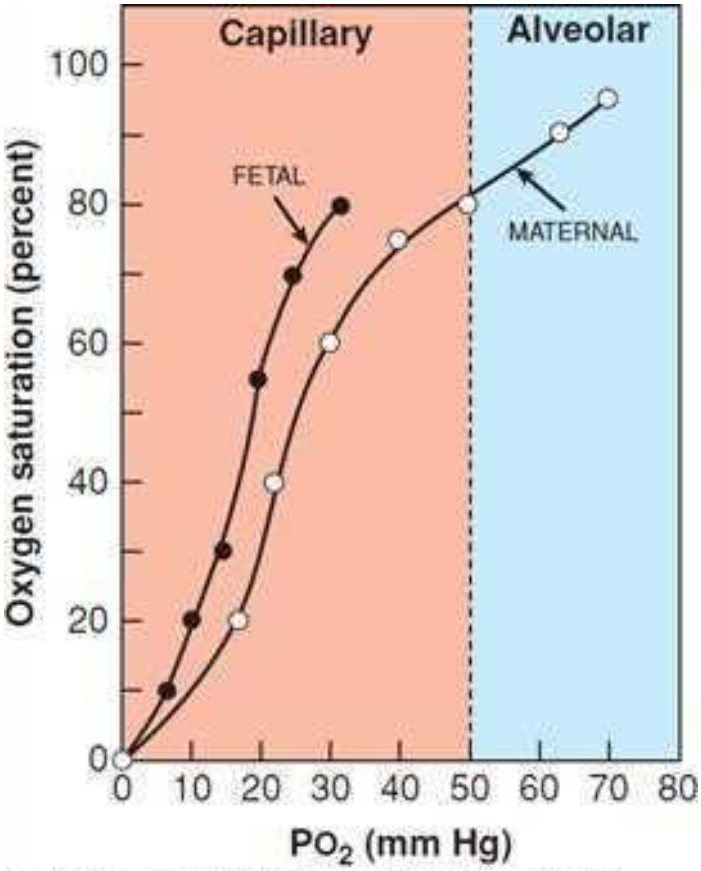
Extracorporeal Membrane Oxygenation

As discussed in Chapter 33 (Neonatal Encephalopathy and Cerebral Palsy), extracorporeal membrane oxygenation (ECMO) has been successfully used for neonatal meconium aspiration syndrome. Preliminary observation suggests that it may be useful in adults with ARDS (Brodie, 2011; Levy, 2015; Peek, 2009). ECMO use has been reported in pregnant women. In one study, 12 patients with influenza-induced lung failure were treated with ECMO, and of four maternal deaths, three were due to anticoagulation-related hemorrhage (Nair, 2011). In another study, the duration of support in four survivors was 2 to 28 days (Cunningham, 2006). In a review of 29 treated gravidas, 80 percent of cases were due to ARDS, and the maternal and perinatal mortality rate was 28 percent (Anselmi, 2015). Technical aspects of ECMO were reviewed by Brodie and Bacchetta (2011).

Fetal Oxygenation

The propensity of the hemoglobin molecule to release oxygen is described by the *oxyhemoglobin dissociation curve* (Fig. 47-2). For clinical purposes, the curve can be divided into an upper oxygen association curve representing the alveolar-capillary environment and a lower oxygen dissociation portion representing the tissue-capillary environment. Shifts of the curve have their greatest effect at the steep portion because they affect oxygen delivery. A rightward shift is associated with decreased hemoglobin affinity for oxygen and hence increased tissue-capillary oxygen interchange. Rightward shifts are produced by hypercapnia, metabolic acidosis, fever, and increased 2,3-diphosphoglycerate levels. During pregnancy, the erythrocyte concentration of 2,3-diphosphoglycerate is increased by approximately 30 percent. This favors oxygen delivery to both the fetus and maternal peripheral tissues.

FIGURE 47-2
Oxyhemoglobin dissociation curve. With higher oxygen tension (Pao_2) in the pulmonary alveoli, adult hemoglobin is maximally saturated compared with that at the lower oxygen tension in the tissue capillaries. Note that at any given oxygen tension, fetal hemoglobin carries more oxygen than adult hemoglobin, as indicated by percent saturation.



Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin. As seen in Figure 47-2, its curve is positioned to the left of the adult curve. To achieve 50-percent hemoglobin saturation, the Pa_{O_2} must be 27 mm Hg in the mother compared with only 19 mm Hg in the fetus. Under normal physiological conditions, the fetus is constantly on the dissociation, or tissue, portion of the curve. Even with severe maternal lung disease and very low Pa_{O_2} levels, oxygen displacement to fetal tissues is favored. Another example of this comes from pregnant women who live at high altitudes. Here, despite a maternal Pa_{O_2} of only 60 mm Hg, the fetal Pa_{O_2} is equivalent to that of fetuses at sea level (Subrevilla, 1971).

Intravenous Fluids

Although mortality outcomes are similar, conservative rather than liberal fluid management is associated with fewer days of mechanical ventilation (Wiedemann, 2006). Some pregnancy-induced physiological changes predispose to a greater risk of permeability edema from vigorous fluid therapy. Colloid oncotic pressure (COP) is determined by serum albumin concentration, and 1 g/dL exerts approximately 6 mm Hg pressure. As discussed in Chapter 4 (Gastrointestinal Tract), serum albumin concentrations normally drop in pregnancy. This results in a decline in oncotic pressure from 28 mm Hg in the nonpregnant woman to 23 mm Hg at term and to 17 mm Hg in the puerperium (Benedetti, 1979; Dennis, 2012). With preeclampsia, endothelial activation with leakage causes extravascular albumin loss and lowered serum albumin levels. As a result in these cases, oncotic pressure averages only 16 mm Hg antepartum and 14 mm Hg postpartum (Zinaman, 1985). These changes have a significant clinical effect on the *colloid oncotic pressure/wedge pressure gradient.* Normally, this gradient exceeds 8 mm Hg. However, when it is 4 mm Hg or less, the risk for pulmonary edema rises. No benefits are gained by albumin rather than crystalloid infusions in these women (Uhlig, 2014). These associations were reviewed by Dennis and Solnordal (2012).

Long-Term Outcomes

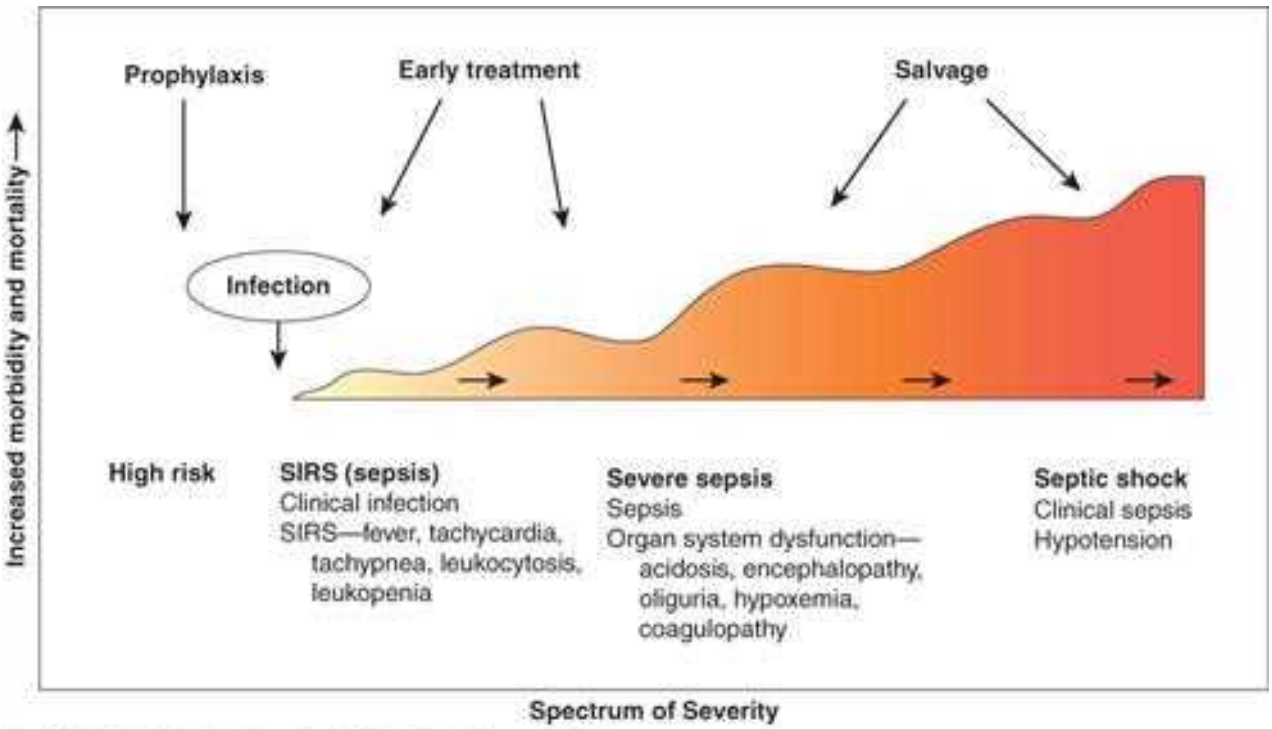
No long-term follow-up studies address gravidas who recover from ARDS. In nonpregnant subjects, risks for impaired global cognitive function at 3 and 12 months are significant (Pandharipande, 2013). Data from nonpregnant patients indicate a 1- to 2-year hiatus before basic normal activity is restored in all. In a 5-year follow-up study, Herridge and associates (2011) reported normal lung function but significant exercise limitation, physical and psychological sequelae, decreased physical quality of life, and increased use of health-care services.

SEPSIS SYNDROME

This syndrome is induced by a systemic inflammatory response to bacteria or viruses or their by-products such as endotoxins or exotoxins. The severity of the syndrome is a continuum or spectrum (Fig. 47-3). According to the Centers for Disease Control and Prevention (CDC), sepsis caused 6.2 percent of pregnancy-related deaths in the United States from 2011 to 2013 (Creanga, 2017). It was also a significant cause of maternal mortality in Michigan and the United Kingdom (Bauer, 2015; Mohamed-Ahmed, 2015; Nair, 2015).

FIGURE 47-3

The sepsis syndrome begins with a systemic inflammatory response syndrome (SIRS) in response to infection that may progress to septic shock.



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Infections that most commonly cause sepsis syndrome in obstetrics are pyelonephritis (Chap. 53, Cystitis and Urethritis), chorioamnionitis and puerperal sepsis (Chap. 37, Uterine Infection), septic abortion (Chap. 18, Inevitable Abortion), and necrotizing fasciitis (Chap. 37, Necrotizing Fasciitis). With severe sepsis, the mortality rate in nonpregnant patients is 20 to 35 percent and is 40 to 60 percent with septic shock (Angus, 2013; Munford, 2015). With shock, the mortality rate in pregnancy has been reported to be 30 percent (Mabie, 1997; Snyder, 2013). That said, the maternal mortality risk from sepsis is significantly underestimated (Bauer, 2015; Chebbo, 2016; Mohamed-Ahmed, 2015).

Etiopathogenesis

Most of what is known concerning sepsis pathogenesis comes from study of lipopolysaccharide—LPS or endotoxin (Munford, 2015). The lipid A moiety is bound by mononuclear blood cells, becomes internalized, and stimulates release of mediators and a series of complex downstream perturbations. Clinical aspects of the sepsis syndrome are manifest when cytokines are released that have endocrine, paracrine, and autocrine actions (Angus, 2013; Singer, 2016).

Although the sepsis syndrome in obstetrics may be caused by several pathogens, most cases represent a small group. For example, pyelonephritis complicating pregnancy caused by *Escherichia coli* and *Klebsiella* species commonly is associated with bacteremia and sepsis syndrome (Cunningham, 1987; Snyder, 2013). And although pelvic infections are usually polymicrobial, bacteria that cause severe sepsis syndrome are frequently endotoxin-producing Enterobacteriaceae, most commonly *E coli* (Eschenbach, 2015). Other pelvic pathogens are aerobic and anaerobic streptococci, *Bacteroides* species, and *Clostridium* species. Some strains of group A β-hemolytic streptococci and *Staphylococcus aureus*—including community-acquired methicillin-resistant strains (CA-MRSA)—produce a superantigen that activates T cells to rapidly cause all features of the sepsis syndrome—*toxic shock syndrome* (Moellering, 2011; Soper, 2011). This is discussed further in Chapter 37 (Breast Infections).

Potent bacterial *exotoxins* can also cause severe sepsis syndrome. Examples include exotoxins from *Clostridium perfringens* or *sordellii,* toxic-shock-syndrome toxin-1 (TSST-1) from *S aureus,* and toxic shock-like exotoxin from group A β-hemolytic streptococci (Daif, 2009; Soper, 2011). These last exotoxins cause rapid and extensive tissue necrosis and gangrene, especially of the postpartum uterus, and may cause profound cardiovascular collapse and maternal death (Nathan, 1993; Sugiyama, 2010). In a review discussed subsequently, the maternal mortality rate from these infections was 58 percent (Yamada, 2010).

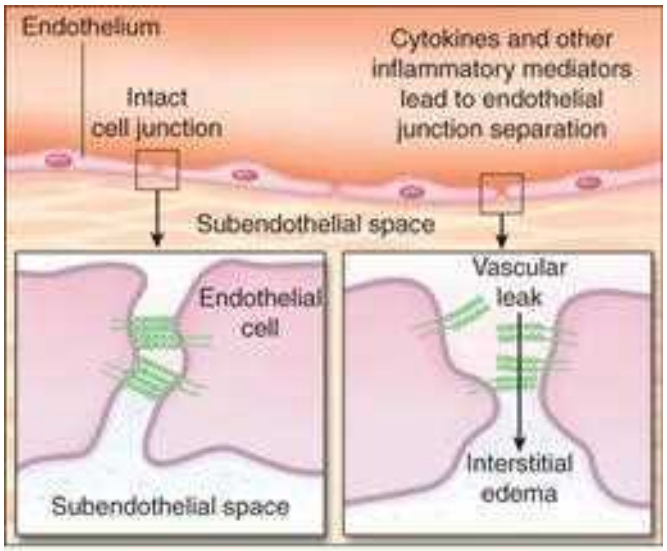
Thus, the sepsis syndrome begins with an inflammatory response that is directed against microbial endotoxins and exotoxins (Angus, 2013). CD4 T cells and leukocytes are stimulated to produce proinflammatory compounds that include tumor necrosis factor-α (TNF-α), several interleukins, other cytokines, proteases, oxidants, and bradykinin that result in a "cytokine storm" (Russell, 2006). Many other cellular reactions then follow that include stimulation of pro- and antiinflammatory compounds, procoagulant activity, gene activation, receptor regulation, and immune suppression (Filbin, 2009; Moellering, 2011). It is also likely that interleukin-6 (IL-6) mediates myocardial suppression (Pathan, 2004).

The pathophysiological response to this cascade is selective vasodilation with maldistribution of blood flow. Leukocyte and platelet aggregation cause capillary plugging. Worsening endothelial injury causes profound permeability, capillary leakage, and interstitial fluid accumulation (Fig. 47-4). Depending on the degree of injury and inflammatory response, a pathophysiological and clinical continuum evolves as depicted in Figure 47-3. The clinical syndrome begins with subtle signs of sepsis from infection and terminates with *septic shock,* which is defined by hypotension unresponsive to intravenous hydration. In its early stages, clinical shock

results primarily from decreased systemic vascular resistance that is not compensated fully by increased cardiac output. Hypoperfusion results in lactic acidosis, decreased tissue oxygen extraction, and end-organ dysfunction that includes acute lung and kidney injury.

FIGURE 47-4

Endothelial permeability. The normal interendothelial interface is shown in the left inset. Cytokines and other inflammatory mediators disassemble the cellular junctions, resulting in microvascular leaks (*right*).



Clinical Manifestations

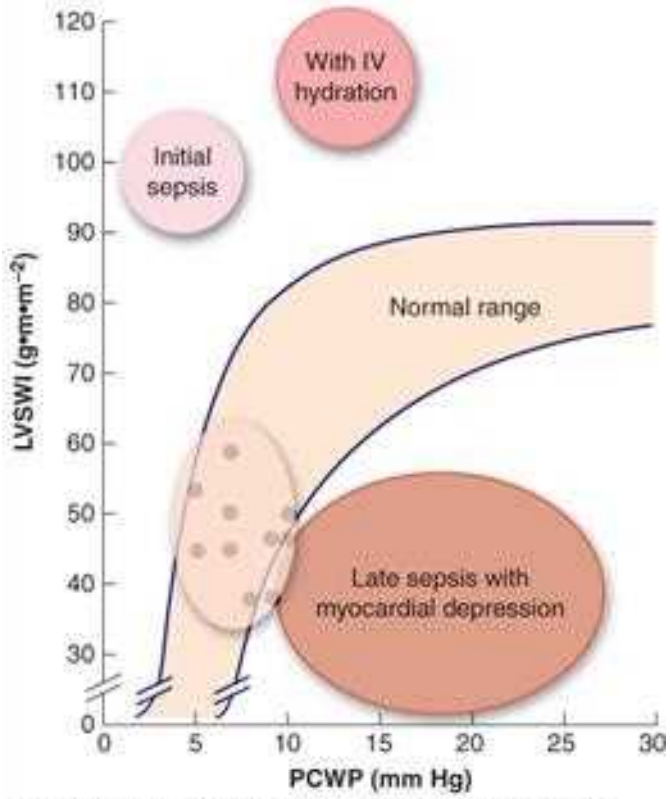
The sepsis syndrome has myriad clinical manifestations that, at least in part, are dependent on the specific invading microorganism and its particular endo- or exotoxins. Some of the general effects of LPS are as follows:

1. Central nervous system: confusion, delirium, somnolence, coma, combativeness, fever
2. Cardiovascular: tachycardia, hypotension
3. Pulmonary: tachypnea, arteriovenous shunting with dysoxia and hypoxemia, exudative infiltrates from endothelial-alveolar damage, pulmonary hypertension
4. Gastrointestinal: gastroenteritis—nausea, vomiting, and diarrhea; ileus; hepatocellular necrosis—jaundice, transaminitis
5. Renal: prerenal oliguria, azotemia, acute kidney injury, proteinuria
6. Hematological: leukocytosis or leukopenia, thrombocytopenia, activation of coagulation with disseminated intravascular coagulopathy
7. Endocrine: hyperglycemia, adrenal insufficiency
8. Cutaneous: acrocyanosis, erythroderma, bullae, digital gangrene.

Thus, although capillary leakage initially causes hypovolemia, if intravenous crystalloid is given at this point, then sepsis hemodynamically can be described as a high cardiac output, low systemic vascular resistance condition (Fig. 47-5). Concomitantly, pulmonary hypertension develops, and despite the high cardiac output, severe sepsis also causes myocardial depression (Munford, 2015; Ognibene, 1988). This is often referred to as the *warm phase* of septic shock. These findings are the most common cardiovascular manifestations of early sepsis, but they can be accompanied by some of the other clinical or laboratory aberrations listed above.

FIGURE 47-5

Hemodynamic effects of sepsis syndrome. Values for normal women at term are shown by dots. With early sepsis, there is high cardiac output and low vascular resistance. With fluid resuscitation, cardiac output increases even more, but so does capillary hydraulic pressure. With continued sepsis, there may be myocardial depression to further increase capillary hydraulic pressure. Decreased plasma oncotic pressure (serum albumin [g] × 6 mm Hg) contributes to interstitial lung fluid and endo/epithelial leak causes alveolar flooding. LVSWI = left ventricular stroke work index; PCWP = pulmonary capillary wedge pressure.



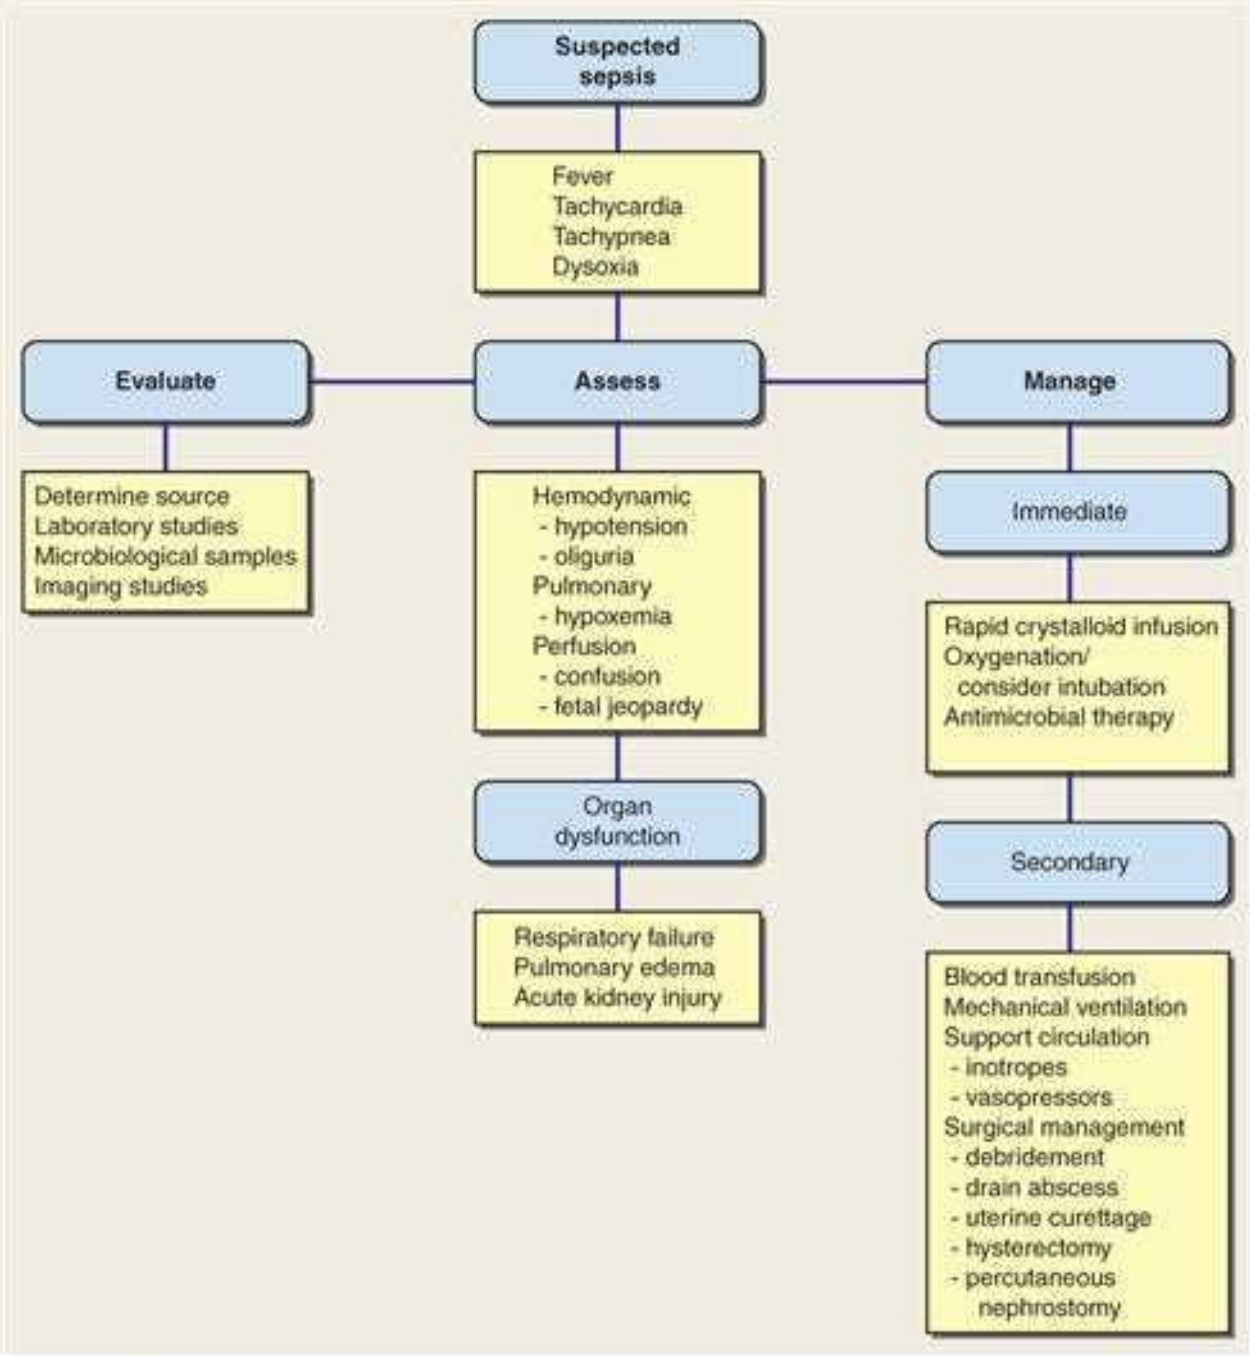
The response to initial intravenous hydration may be prognostic. Most pregnant women who have early sepsis show a salutary response with crystalloid and antimicrobial therapy, and if indicated, debridement of infected tissue. Conversely, if hypotension is not corrected following vigorous fluid infusion, then the prognosis is more guarded. At this juncture, if there also is no response to β-adrenergic inotropic agents, this indicates severe and unresponsive extracellular fluid extravasation with vascular insufficiency, overwhelming myocardial depression, or both. Oliguria and continued peripheral vasoconstriction characterize a secondary, *cold phase* of septic shock that is rarely survived. Another poor prognostic sign is continued renal, pulmonary, and cerebral dysfunction once hypotension has been corrected (Angus, 2013; Chebbo, 2016). The average risk of death increases by 15 to 20 percent with failure of each organ system. With three systems, mortality rates are 70 percent (Martin, 2003; Wheeler, 1999).

Management

In 2004, an international consensus effort was launched as the *Surviving Sepsis Campaign* (Dellinger, 2013). The cornerstone of management is *early goal-directed management,* and it stresses prompt recognition of serious bacterial infection and close monitoring of vital signs and urine flow. It remains controversial if institution of this protocol has improved survival rates (ARISE Investigators, 2014; Mouncey, 2015; ProCESS Investigators, 2014). Similar conclusions were reached with sets of early warning systems in obstetrics (Edwards, 2015; Mhyre, 2014). Albright and associates (2017) have validated the Sepsis in Obstetrics Score to identify the risk of ICU admission for sepsis.

An algorithm for management of sepsis syndrome is shown in Figure 47-6. The three basic steps are performed as simultaneously as possible and include evaluation of the sepsis source and its sequelae, cardiopulmonary function assessment, and immediate management. The most important step in sepsis management is rapid infusion of 2 L and sometimes as many as 4 to 6 L of crystalloid fluids to restore renal perfusion in severely affected women (Vincent, 2013). Simultaneously, appropriately chosen broad-spectrum antimicrobials are begun. Because hemoconcentration is caused by the capillary leak, if anemia coexists, then blood is given. Maintaining the hemoglobin concentration at ≥9 g/dL did not have superior outcomes compared with that of ≥7 g/dL (Holst, 2014). That said, fetal oxygenation is improved by the higher concentration.

FIGURE 47-6
Algorithm for evaluation and management of sepsis syndrome. Rapid and aggressive implementation is paramount for success. The three steps—Evaluate, Assess, and Manage—are carried out as simultaneously as possible.



The use of colloid solution such as hetastarch is controversial (Angus, 2013; Ware, 2000). One randomized trial comparing hydroxyethyl starch and Ringer acetate reported a higher mortality rate with the starch solution (Perner, 2012). Another study found equivalent results with 6-percent hydroxyethyl starch compared with normal saline (Myburgh, 2012). Albumin was not found to be superior to crystalloids (Caironi, 2014).

Aggressive volume replacement ideally is promptly followed by urinary output of at least 30 and preferably 50 mL/hr, as well as other indicators of improved perfusion. If not, then consideration is given for vasoactive drug therapy (Pacheco, 2014). Mortality rates are high when sepsis is further complicated by respiratory or renal failure. With severe sepsis, damage to pulmonary capillary endothelium and alveolar epithelium causes alveolar flooding and pulmonary edema. This may occur even with low or normal pulmonary capillary wedge pressures, as with the ARDS discussed in Acute Respiratory Distress Syndrome and depicted in Figure 47-1.

Broad-spectrum antimicrobials are chosen empirically based on the probable source of infection. They are given promptly in maximal doses after appropriate cultures are taken of blood, urine, or exudates not contaminated by normal flora. In severe sepsis, appropriate empirical coverage results in better survival rates (Barochia, 2010; MacArthur, 2004). In obstetrics acute pyelonephritis is usually caused by Enterobacteriaceae, as discussed in Chapter 53 (Cystitis and Urethritis). For pelvic infections, empirical coverage with regimens such as ampicillin plus gentamicin plus clindamycin generally suffices (Chap. 37, Pathogenesis and Clinical Course). Associated incisional and other soft-tissue infections are increasingly likely to be caused by methicillin-resistant *S aureus*, thus vancomycin therapy may be added (Klevens, 2007; Rotas, 2007). With a septic abortion, a Gram-stained smear may be helpful in identifying *Clostridium* species or group A streptococcal organisms. This is also true for deep fascial infections.

Surgical Treatment

Continuing sepsis may prove fatal, and debridement of necrotic tissue or drainage of purulent material is crucial (Nelson, 2015; Pacheco, 2014). In obstetrics, the major causes of sepsis are infected abortion, pyelonephritis, and puerperal pelvic infections, which include metritis and infections of perineal lacerations or of hysterotomy or laparotomy incisions. With a septic abortion, uterine contents must be removed promptly by curettage as described in Chapter 18 (Inevitable Abortion). Hysterectomy is seldom indicated unless gangrene has resulted.

For women with pyelonephritis, continuing sepsis should prompt a search for obstruction caused by calculi or by a perinephric or intrarenal phlegmon or abscess. Renal sonography or "one-shot" pyelography can help diagnose obstruction and calculi. With obstruction, ureteral catheterization, percutaneous nephrostomy, or flank exploration may be lifesaving (Chap. 53, Reflux Nephropathy). Computed tomography (CT) or magnetic-resonance imaging aids in identifying a phlegmon or abscess.

Puerperal Infections

Most cases of puerperal pelvic sepsis are clinically manifested in the first several days postpartum, and intravenous antimicrobial therapy without tissue debridement is generally curative. There are at least three exceptions.

First, massive uterine myonecrosis can be caused by group A β-hemolytic streptococcal or clostridial infections (Soper, 2011; Sugiyama, 2010; Yamada, 2010). Those with early-onset disease present with findings listed in Table 47-6. The mortality rate in these women with gangrene as shown in Figure 47-7 is high, and prompt hysterectomy may be lifesaving (Mabie, 1997; Nathan, 1993). Group A β-hemolytic streptococci and clostridial colonization or infection also cause toxic-shock syndrome without obvious gangrene (Mason, 2012). These are due to either streptococcal toxic-shock-syndrome-like toxin or clostridial exotoxin that evolved from *S aureus* (Chap. 37, Breast Infections). In many of these cases, there is bacteremia and widespread tissue invasion, but with an intact uterus and abdominal incision. If uterine necrosis can be excluded—usually by CT scanning—then in our experiences, as well as in others, hysterectomy may not be necessary (Soper, 2011). Still, these infections are highly lethal (Yamada, 2010).

TABLE 47-6

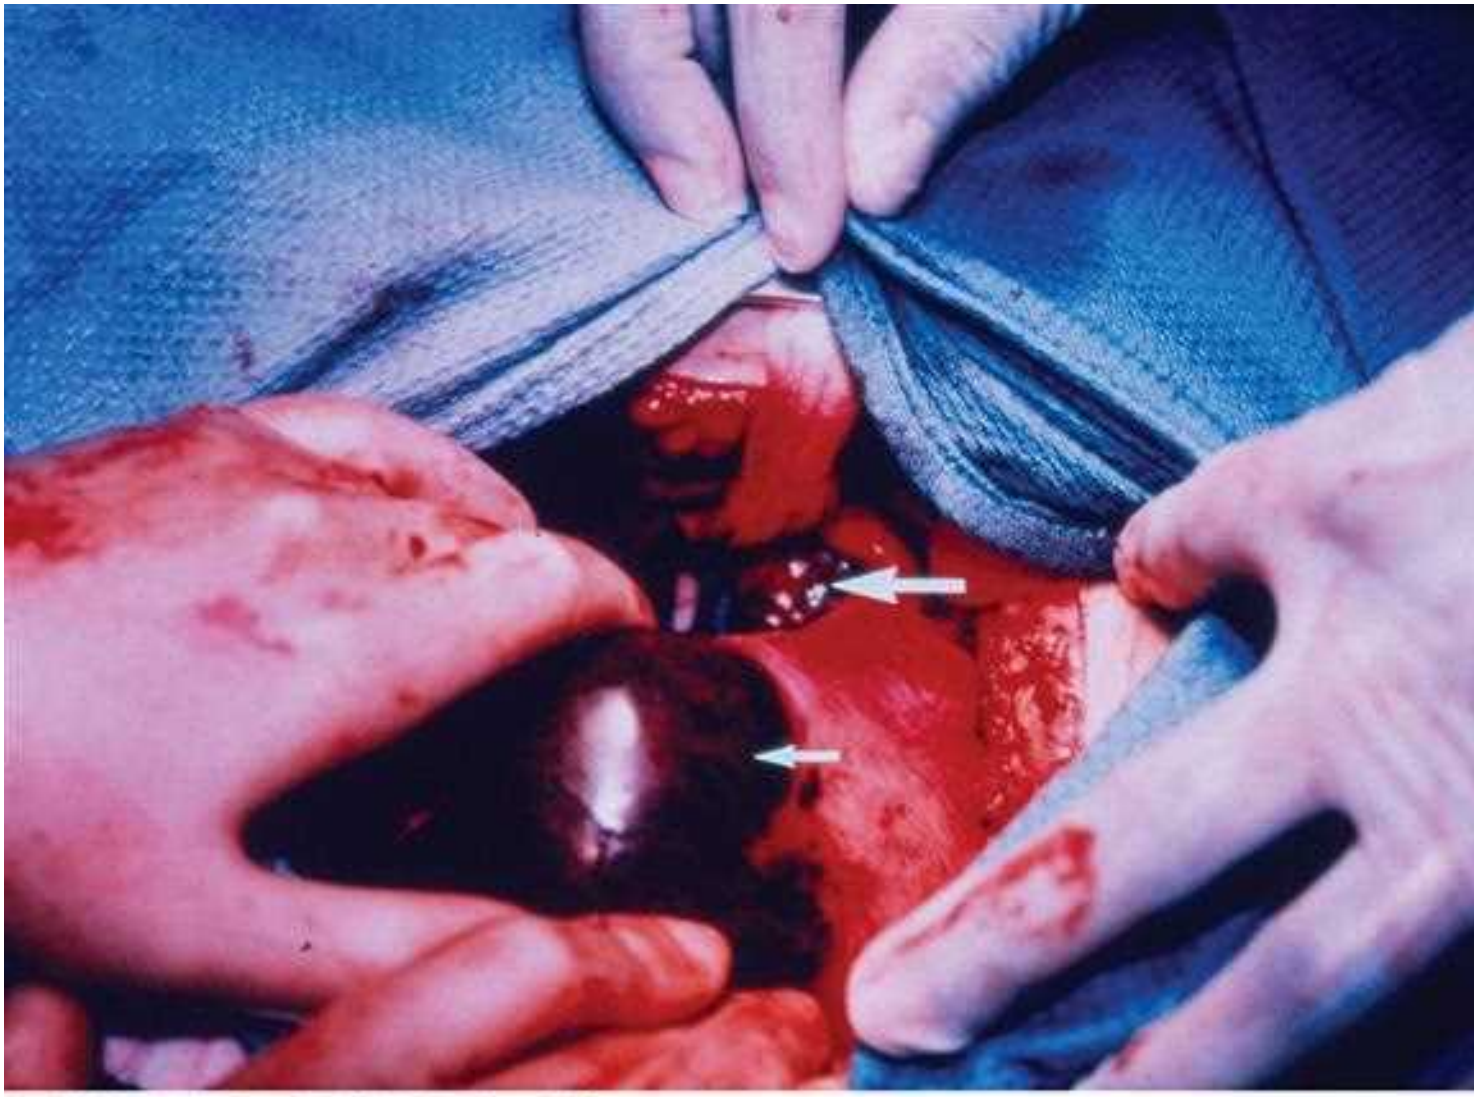
Clinical Findings in 55 Women with Group A β-Hemolytic Infection Manifest within 12 Hours of Delivery

Finding	Frequency (%)
Multiparous	83
Third-trimester	90
Flulike symptoms	
High fever	94
Upper respiratory	40
Gastrointestinal	49
Uterine hypertonus	73
Early-onset shock	91
Mortality	
Maternal	58
Perinatal	66

Data from Yamada, 2010.

FIGURE 47-7

A fatal case of group A β-hemolytic *Streptococcus pyogenes* puerperal infection following an uncomplicated vaginal delivery at term. The infection caused uterine gangrene and overwhelming sepsis syndrome. Arrows point to overtly "ballooned-out" black gangrenous areas of the postpartum uterus at the time of laparotomy for hysterectomy.



As a second exception, necrotizing fasciitis of the episiotomy site or of the abdominal surgical incision is a surgical emergency. As described by Gallup and coworkers (2002), these infections are aggressively managed as discussed in Chapter 37 (Necrotizing Fasciitis). Sinha and colleagues (2015) described a woman with *Fournier gangrene* who required radical debridement and colostomy.

As a final exception, persistent or aggressive postpartum uterine infection with necrosis, uterine incision dehiscence, and severe peritonitis may lead to sepsis (Chap. 37, Parametrial Phlegmon). In this regard, women following cesarean delivery who are suspected of having peritonitis should be carefully evaluated for uterine incisional necrosis or bowel perforation. These infections tend to be less aggressive than necrotizing group A streptococcal infections and develop later postpartum. CT imaging of the abdomen and pelvis can frequently disclose these. If either is suspected, then prompt surgical exploration is indicated. With incisional necrosis, hysterectomy is usually necessary (Fig. 37-5). Finally, peritonitis and sepsis much less commonly may result from a ruptured parametrial, intraabdominal, or ovarian abscess (Chap. 37, Necrotizing Fasciitis).

Adjunctive Therapy

As shown in Figure 47-6, a woman with severe sepsis syndrome is supported with continuing crystalloid infusion, blood transfusions, and ventilation. In some cases, other measures may be necessary. Vasoactive drugs are not given unless aggressive fluid treatment fails to correct hypotension and perfusion abnormalities. First-line vasopressors are norepinephrine, epinephrine, dopamine, dobutamine, or phenylephrine (Vincent, 2013).

The use of corticosteroids remains controversial. Some studies, but not all, show a salutary effect of corticosteroid administration. It is thought that *critical illness-related corticosteroid insufficiency—CIRCI*—may play a role in recalcitrant hypotension. Thus, corticosteroids may be considered for use in vasopressor-dependent patients (Angus, 2013; Munford, 2015).

Endotoxin stimulates endothelial cells to upregulate tissue factor and thus procoagulant production (Cunningham, 2015). Consumptive coagulopathy associated with sepsis is discussed in Chapter 41 (Obstetrical Coagulopathies). At the same time, it decreases the anticoagulant action of activated protein C. Several agents developed to block coagulation, however, did not improve outcomes. Some include *recombinant activated protein C, antithrombin III, platelet-activating factor antagonist,* and *tissue factor pathway inhibitor* (Munford, 2015; Wenzel, 2012).

TRAUMA

Depending on definitions used, 10 to 20 percent of gravidas suffer physical trauma (Jain, 2015; Lucia, 2016). Moreover, injury-related deaths are the most commonly identified nonobstetrical cause of maternal mortality (Brown, 2013a; Horon, 2001). In a California study of 4.8 million pregnancies, almost 1 in 350 women were hospitalized for injuries from assaults (El Kady, 2005). From Parkland Hospital, motor vehicle accidents and falls accounted for 85 percent of injuries sustained by 1682 pregnant women (Hawkins, 2007). From the National Violent Death Reporting System, Palladino and colleagues (2011) found 2.0 pregnancy-associated suicides per 100,000 live births. The rate was 2.9 per 100,000 for pregnancy-associated homicides. Notably, intimate-partner violence may be linked to these suicides (Martin, 2007). Finally, injury prevention and education of high-risk patients may help to decrease morbidity (Chisolm, 2017; Lucia, 2016).

Physical Abuse

According to the CDC, intimate-partner violence describes physical, sexual, or psychological harm by a current or former partner or spouse (Breiding, 2015). Such violence affects 1 in 5 women each year. One goal in violence prevention for *Healthy People 2010* was the reduction of physical abuse directed at women by male partners. The Pregnancy Risk Assessment Monitoring Systems (PRAMS) report showed some improvement in these areas (Suellentrop, 2006).

Even more appalling is that physical violence directed at women continues during pregnancy. Abuse is linked to poverty, poor education, and use of tobacco, alcohol, and illicit drugs (Centers for Disease Control and Prevention, 2008). Unfortunately, abused women tend to remain with their abusers, and the major risk factor for intimate-partner homicide is prior domestic violence (Campbell, 2007). Finally, women seeking pregnancy termination have a higher incidence of intimate-partner violence (Bourassa, 2007).

The woman who is physically abused tends to present late, if at all, for prenatal care. In one study, pregnant women hospitalized in California as a result of assault had significantly increased perinatal morbidity rates (El Kady, 2005). Immediate sequelae included uterine rupture, preterm delivery, and maternal and perinatal death. Subsequent outcomes included increased rates of placental abruption, preterm and low-birthweight newborns, and other adverse outcomes. Silverman and associates (2006) reported similar results from PRAMS, which included more than 118,000 pregnancies in 26 states.

Preventatively, the American College of Obstetricians and Gynecologists (2012) recommend universal screening for intimate-partner violence at the initial prenatal visit, during each trimester, and again at the postpartum visit (Chap. 9, Alcohol). Others recommend a case-finding approach based on clinical suspicion (Robertson-Blackmore, 2013).

Sexual Assault

According to the National Intimate Partner and Sexual Violence Survey (Black, 2014), an estimated 1.2 million women will be sexually assaulted each year. Satin and coworkers (1992) reviewed more than 5700 female sexual assault victims in Dallas County and reported that 2 percent were pregnant. Associated physical trauma is common (Sugar, 2004). From a forensic standpoint, the evidence collection protocol is not altered (Linden, 2011).

In addition to attention to physical injuries, exposure to sexually transmitted diseases must be considered. The CDC (2015) recommends antimicrobial prophylaxis against gonorrhea, chlamydial infection, bacterial vaginosis, and trichomoniasis (Table 47-7). If the woman is not pregnant, another very important aspect is emergency contraception, as recommended by the American College of Obstetricians and Gynecologists (2016; 2017a) and discussed in Chapter 38 (Emergency Contraception).

TABLE 47-7

Guidelines for Prophylaxis against Sexually Transmitted Disease in Pregnant Victims of Sexual Assault

Prophylaxis Against	Regimen	Alternative
Neisseria gonorrhoeae	Ceftriaxone 250 mg IM single dose ***plus*** Azithromycin 1 g orally single dose	Cefixime 400 mg orally single dose ***plus*** Azithromycin 1 g orally single dose
Chlamydia trachomatis	Azithromycin 1 g orally single dose[a] ***or*** Amoxicillin 500 mg orally three times daily for 7 days	Erythromycin-base 500 mg orally four times daily for 7 days ***or*** Levofloxacin 500 mg orally once daily for 7 days[b] ***or*** Ofloxacin 300 mg orally twice daily for 7 days[b]
Bacterial vaginosis	Metronidazole 500 mg orally twice daily for 7 days ***or*** Metronidazole gel 0.75%, one full applicator (5 g) intravaginally once daily for 5 days ***or*** Clindamycin cream 2%, one full applicator (5 g) intravaginally at bedtime for 7 days	Tinidazole 2 g orally once daily for 2 days[b] ***or*** Tinidazole 1 g orally daily for 5 days ***or*** Clindamycin 300 mg orally twice daily for 7 days ***or*** Clindamycin ovules 100 mg intravaginally at bedtime for 3 days
Trichomonas vaginalis	Metronidazole 2 g orally single dose ***or*** Tinidazole 2 g orally single dose[b]	Metronidazole 500 mg orally twice daily for 7 days
Hepatitis B (HBV)	If not previously vaccinated, give first dose HBV vaccine, repeat at 1–2 and 4–6 months	
HIV	Consider retroviral prophylaxis if risk for HIV exposure is high	

[a]For nonpregnant women, doxycycline, 100 mg orally twice daily for 7 days, can be given instead.

[b]Pregnancy category C.

HIV = human immunodeficiency virus; IM = intramuscularly.

Data from Centers for Disease Control and Prevention, 2015.

Finally, the importance of psychological counseling for the rape victim and her family cannot be overemphasized. A 30- to 35-percent lifetime risk each for posttraumatic stress disorder, major depression, and suicide contemplation follows sexual assault (Linden, 2011).

Automobile Accidents

At least 3 percent of pregnant women are involved in motor vehicle accidents each year in the United States. Using data from PRAMS, Sirin and colleagues (2007) estimated that 92,500 gravidas are injured annually. Motor-vehicle crashes are the most common causes of serious, life-threatening, or fatal blunt trauma during pregnancy (Brown, 2013a; Mendez-Figueroa, 2013, 2016; Vladutiu, 2013). Mattox and Goetzl (2005) report these accidents to be the leading cause of traumatic fetal deaths as well. This was also true from our experiences from Parkland Hospital (Hawkins, 2007). Traffic crashes are most frequent in the second trimester (Redelmeier, 2014). As with all motor vehicle crashes, alcohol use is often associated. But sadly, as many as half of accidents occur without seat-belt use, and many of these deaths would likely be preventable by the three-point restraints shown in Figure 47-8 (Luley, 2013; Schuster, 2016). Seat belts prevent contact with the steering wheel, and they reduce abdominal impact pressure (Motozawa, 2010).

FIGURE 47-8

Illustration showing correct use of three-point automobile restraint. The upper belt is *above* the uterus, and the lower belt fits snugly across the upper thighs and well *below* the uterus.

Original concerns regarding injuries caused by airbag deployment have been somewhat allayed (Luley, 2013; Matsushita, 2014). One study included 30 such women from 20 to 37 weeks' gestation whose airbag deployed in accidents with a median speed of 35 mph (Metz, 2006). A third did not use seat belts, and there was one

fetal death from the single case of placental abruption. In a retrospective cohort study that included 2207 pregnant women in crashes with airbag deployment, perinatal outcomes were not clinically different from 1141 controls without airbags (Schiff, 2010). Importantly, 96 percent of both groups used seat belts. Thus, it appears that injuries with airbag deployment are related to the severity of the crash (Mendez-Figueroa, 2016).

Other Blunt Trauma

Some other common causes of blunt trauma are falls and aggravated assaults. In the California review reported by El Kady and associates (2005), intentionally inflicted injuries were present in approximately a third of pregnant women who were hospitalized for trauma. Less common are blast or crush injury (Sela, 2008). With blunt trauma, intraabdominal injuries can be serious. Even so, bowel injuries are less frequent because of the protective effect of a large uterus. Still, diaphragmatic, splenic, liver, and kidney damage may also be sustained. Particularly worrisome is the specter of amnionic-fluid embolism, which has been reported with even mild trauma (Ellingsen, 2007; Pluymakers, 2007). Retroperitoneal hemorrhage is possibly more common than in nonpregnant women (Takehana, 2011).

Orthopedic injuries are also encountered with some regularity (Desai, 2007). From the Parkland Hospital trauma unit, 6 percent of 1682 pregnant women evaluated had orthopedic injuries. This subset was also at increased risk for placental abruption, preterm delivery, and perinatal mortality. In a review of 101 pelvic fractures during pregnancy, there was a 9-percent maternal and 35-percent fetal mortality rate (Leggon, 2002). In another study of pelvic and acetabular fractures during 15 pregnancies, there was one maternal death, and four of 16 fetuses died (Almog, 2007). Finally, head trauma and neurosurgical care raise unique issues (Qaiser, 2007).

Fetal Injury and Death

Perinatal death rates increase with the severity of maternal injuries. Fetal death is more likely with direct fetoplacental injury, maternal shock, pelvic fracture, maternal head injury, or hypoxia (Ikossi, 2005; Pearlman, 2008). Motor vehicle accidents caused 82 percent of fetal deaths from trauma. Death was caused by placental injury in half and by uterine rupture in 4 percent (Weiss, 2001).

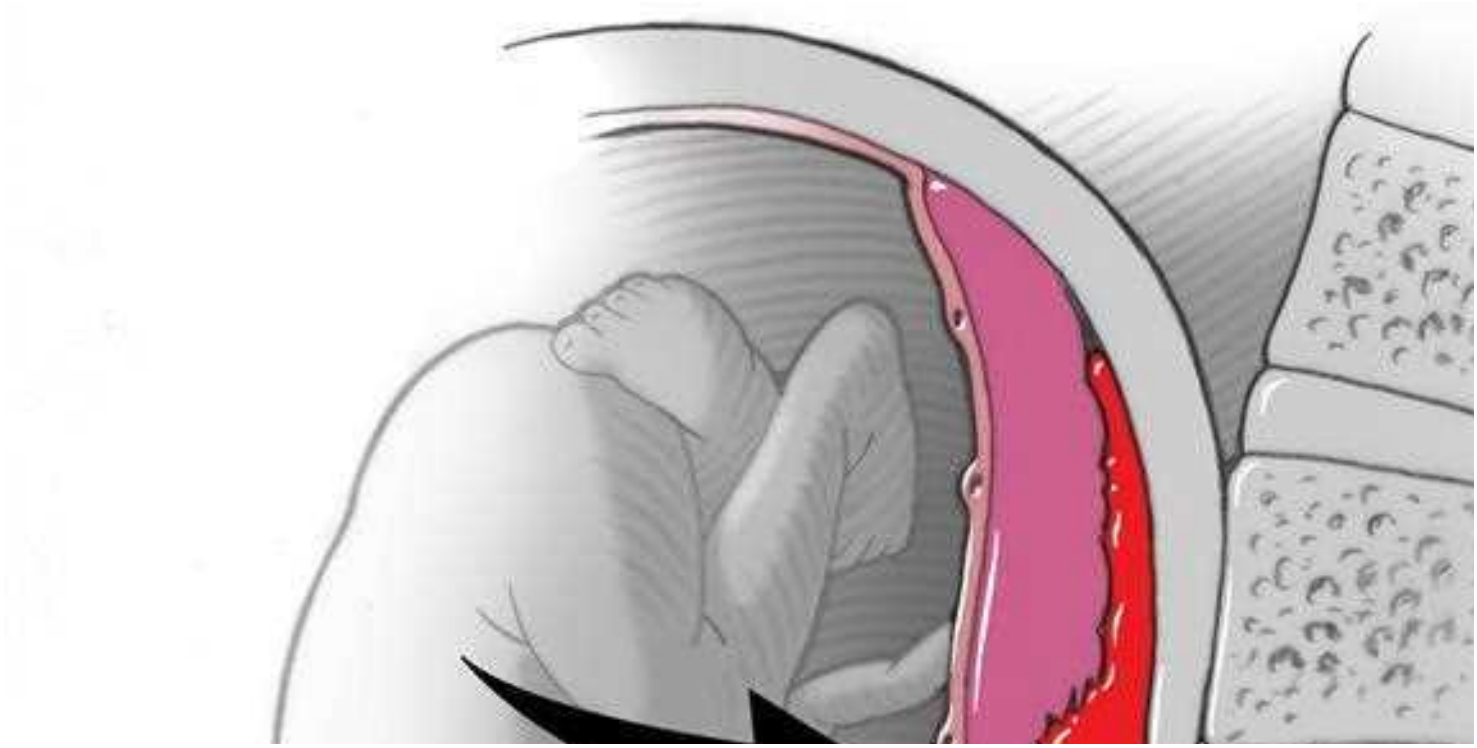
Although uncommon, fetal skull and brain injuries are more likely if the head is engaged and the maternal pelvis is fractured (Palmer, 1994). Conversely, fetal head injuries, presumably from a contrecoup effect, may be sustained in unengaged vertex or nonvertex presentations. Fetal skull fractures are rare and best seen using CT imaging (Sadro, 2012). One example is Figure 46-4. Other sequelae include intracranial hemorrhage (Gherman, 2014; Green-Thompson, 2005). A newborn with paraplegia and contractures associated with a motor vehicle accident sustained several months before birth was described by Weyerts and colleagues (1992). Other injuries have included fetal decapitation or incomplete midabdominal fetal transection at midpregnancy (Rowe, 1996; Weir, 2008).

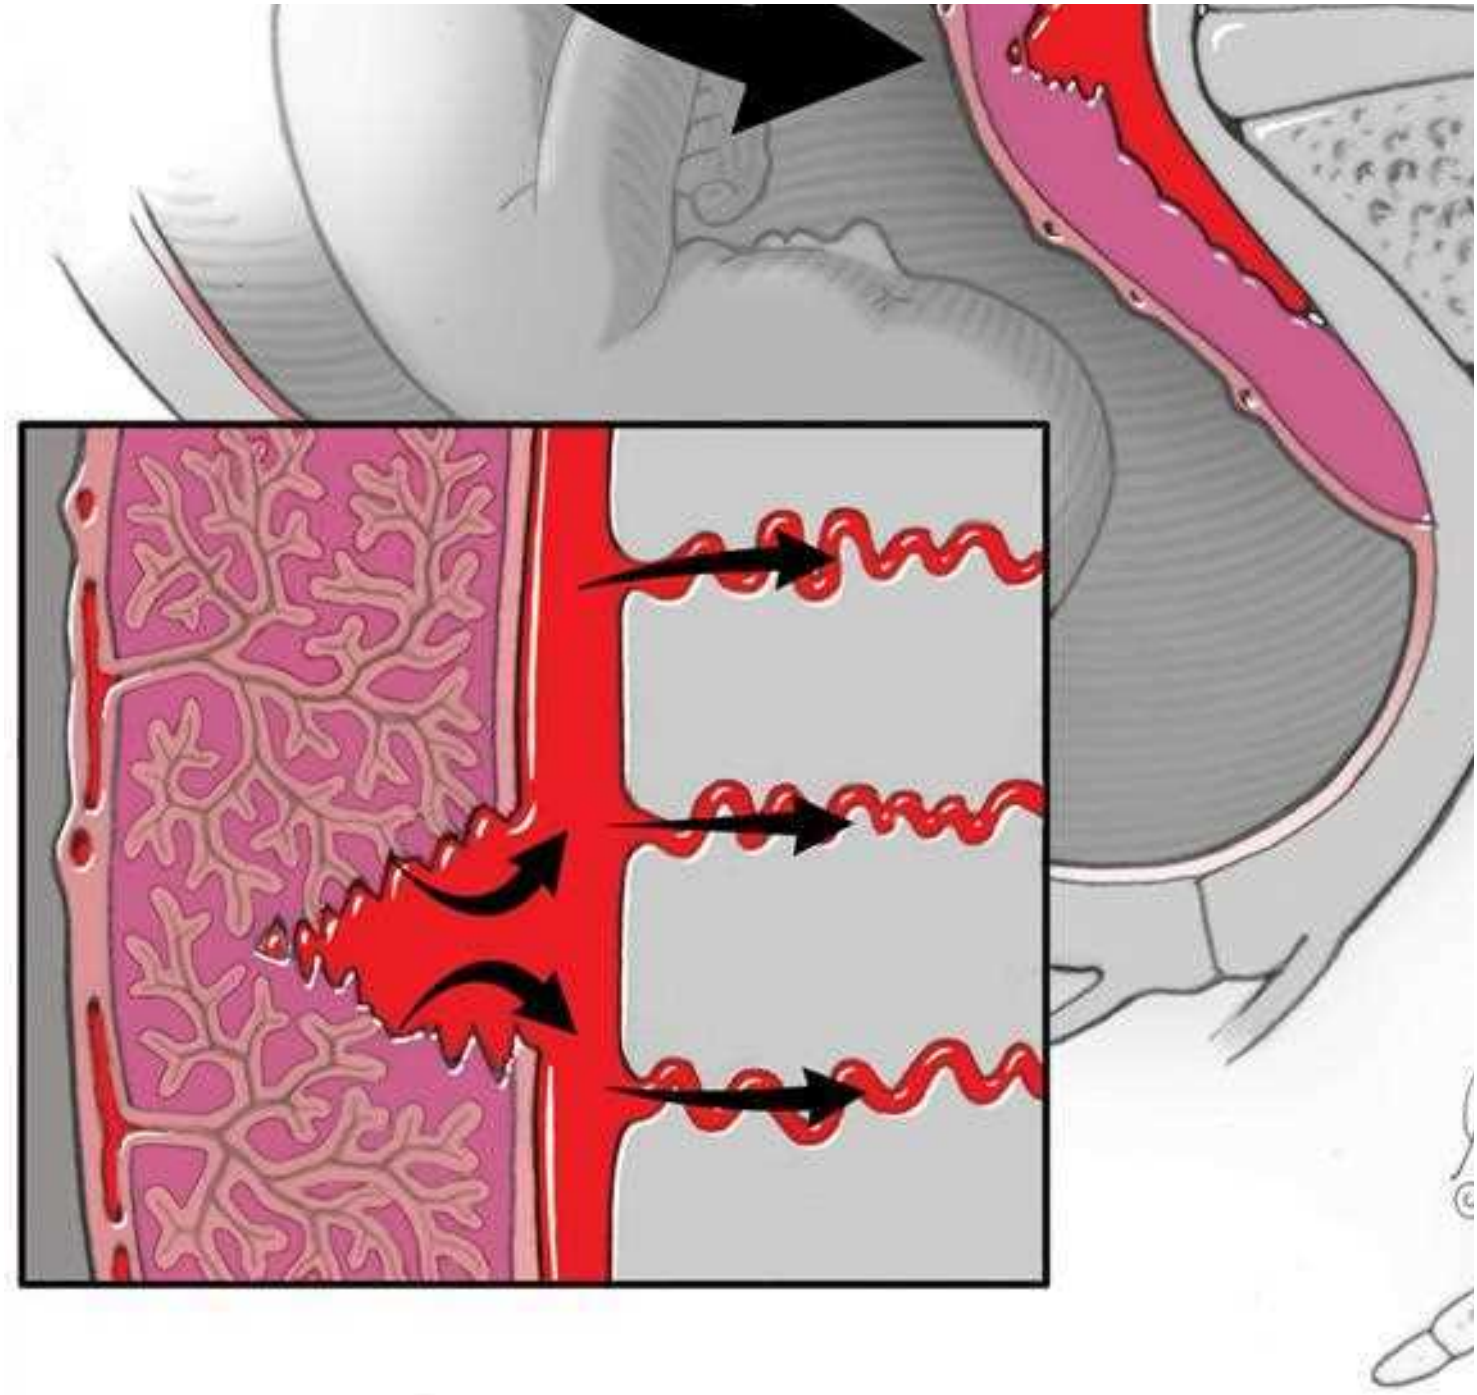
Placental Injuries

Catastrophic events that occur with blunt trauma include placental injuries—abruption or placental tears (Fig. 47-9). Placental separation from trauma is likely caused by deformation of the elastic myometrium around the relatively inelastic placenta (Crosby, 1968). This may result from a deceleration injury as the large uterus meets the immovable steering wheel or seat belt. Some degree of abruption complicates 1 to 6 percent of minor injuries and up to 50 percent of major injuries (Pearlman, 1990; Schiff, 2002). Abruption was found to be more likely if vehicle speed exceeded 30 mph (Reis, 2000).

FIGURE 47-9

Mechanism of placental tear or “fracture” caused by a deformation-reformation injury. Placental abruption is seen as blood collecting in the retroplacental space. **Inset**. From here, blood can be forced into placental bed venules and enter maternal circulation. Such fetomaternal hemorrhage may be identified with Kleihauer-Betke testing.



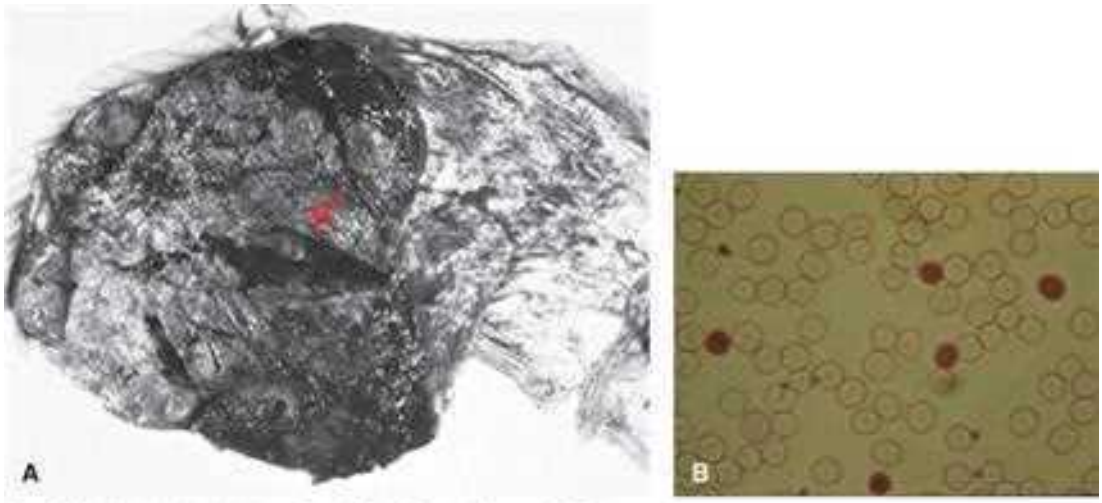


Clinical findings with traumatic abruption may be similar to those for spontaneous placental abruption (Chap. 41, Frequency). Kettel and coworkers (1988) emphasized that traumatic abruption may be occult and unaccompanied by uterine pain, tenderness, or bleeding. In our experiences with 13 such women at Parkland Hospital, 11 had uterine tenderness, but only five had vaginal bleeding. Because traumatic abruption is more likely to be concealed and generate higher intrauterine pressures, associated coagulopathy is more likely than with nontraumatic abruption (Cunningham, 2015). Partial separation may also generate uterine activity, which is described more fully in Thermal Injury. Other features are evidence of fetal compromise such as fetal tachycardia, sinusoidal pattern, late decelerations, acidosis, and fetal death.

If the abdominal force associated with trauma is considerable, then the placenta can be torn or “fractured” (see Fig. 47-9). If so, then life-threatening fetal hemorrhage may be encountered either into the amnionic sac or by fetomaternal hemorrhage (Pritchard, 1991). The tear is linear or stellate and is caused by rapid deformation and reformation (Fig. 47-10). Especially if there is ABO compatibility, fetomaternal hemorrhage is quantified using a Kleihauer-Betke stain of maternal blood. A small amount of fetal-maternal bleeding has been described in up to a third of trauma cases, and in 90 percent of these, the volume is <15 mL (Goodwin, 1990; Pearlman, 1990). Parenthetically, nontraumatic placental abruption is much less often associated with significant fetomaternal hemorrhage because only minimal fetal blood enters into the intervillous space. With traumatic abruption, however, massive fetomaternal hemorrhage may follow. In one study, the risk of associated uterine contractions and preterm labor was a 20-fold if there was evidence for a fetomaternal bleed (Muench, 2004). With severe fetal bleeding, long-term adverse neurological outcomes are frequent (Kadooka, 2014).

FIGURE 47-10

A. Partial placental abruption in which the adherent blood clot has been removed. Note the laceration of the placenta (*arrow*), which caused fetal death from massive fetomaternal hemorrhage. **B.** Kleihauer–Betke stain of a peripheral smear of maternal blood. The dark cells that constituted 4.5 percent of red blood cells are fetal in origin, whereas the empty cells are maternal.



Uterine Rupture

Blunt trauma leads to uterine rupture in <1 percent of severe cases (American College of Obstetricians and Gynecologists, 2017b). Rupture is more likely in a previously scarred uterus and is usually associated with a direct impact of substantial force. Decelerative forces following a 25-mph collision can generate up to 500 mm Hg of intrauterine pressure in a properly restrained woman (Crosby, 1968). Clinical findings may be identical to those for placental abruption with an intact uterus, and maternal and fetal deterioration are soon inevitable. Pearlman and Cunningham (1996) described uterine fundal "blowout" with fetal decapitation in a 20-week pregnancy following a high-speed collision. Similarly, Weir and colleagues (2008) described supracervical uterine avulsion and fetal transection at 22 weeks. CT scanning may be useful to diagnose uterine rupture with a dead fetus or placental separation (Kopelman, 2013; Manriquez, 2010; Sadro, 2012).

Penetrating Trauma

In a study of 321 pregnant women with abdominal trauma, Petrone (2011) reported a 9-percent incidence of penetrating injuries. Of these, 77 percent were gunshot wounds and 23 percent were stab wounds. The incidence of maternal visceral injury with penetrating trauma is only 15 to 40 percent compared with 80 to 90 percent in nonpregnant individuals (Stone, 1999). When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured. Indeed, although the fetus sustains injury in two thirds of cases with penetrating uterine injuries, maternal visceral injuries are seen in only 20 percent. Still, their seriousness is underscored in that maternal-fetal mortality rates are significantly higher than those seen with blunt abdominal injuries in pregnancy. Specifically, maternal mortality rates were 7 versus 2 percent, and fetal mortality rates were 73 versus 10 percent, respectively.

Management of Trauma

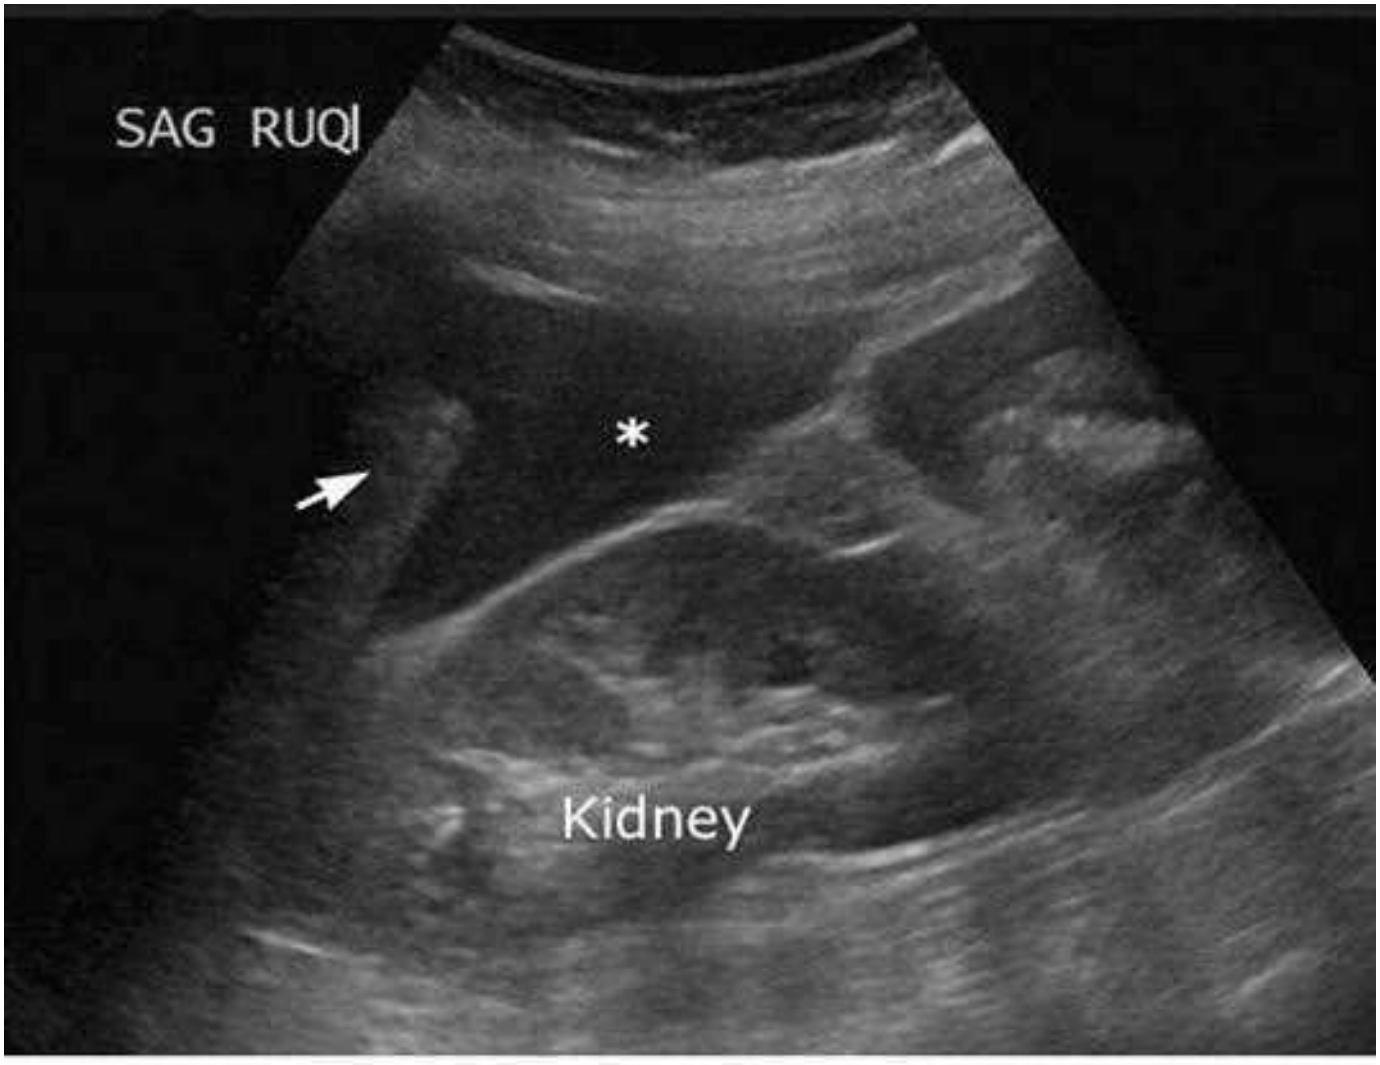
Maternal and fetal outcomes are directly related to the severity of injury. That said, commonly used methods of severity scoring do not take into account significant morbidity and mortality rates related to placental abruption and thus to pregnancy outcomes. In a study of 582 pregnant women hospitalized for injuries, the injury severity score did not accurately predict adverse pregnancy outcomes (Schiff, 2005). Importantly, relatively minor injuries were associated with preterm labor and placental abruption. Others have reached similar conclusions (Biester, 1997; Ikossi, 2005). In a study of 317 women at 24 weeks' gestation or more who had "minor trauma," 14 percent had clinically significant uterine contractions requiring extended fetal evaluation past 4 hours (Cahill, 2008).

With few exceptions, treatment priorities in injured pregnant women are multidisciplinary (Barraco, 2010; Mendez-Figueroa, 2016). Primary goals are evaluation and stabilization of maternal injuries. Attention to fetal assessment during the acute evaluation may divert attention from life-threatening maternal injuries (American College of Obstetricians and Gynecologists, 2017b; Brown, 2009). Basic rules of resuscitation include ventilation, arrest of hemorrhage, and treatment of hypovolemia with crystalloid and blood products. After midpregnancy, the large uterus is positioned off the great vessels to diminish its effect on vessel compression and cardiac output (Nelson, 2015).

Following emergency resuscitation, evaluation is continued for fractures, internal injuries, bleeding sites, and placental, uterine, and fetal trauma. Radiography is not proscribed, but special attention is given each indication. Not surprisingly, one report observed that pregnant trauma victims had less radiation exposure than nonpregnant controls (Ylagan, 2008). Some advocate screening abdominal sonography followed by CT scanning for positive sonographic findings (Brown, 2005; Saphier, 2014). Procedures used include the *FAST scan—focused assessment with sonography for trauma.* This examination is a 5-minute, four- to six-view imaging study that evaluates perihepatic, perisplenic, pelvic, and pericardial views (Mendez-Figueroa, 2016). In general, if fluid is seen in any of these views, then the volume is >500 mL (Fig. 47-11). Importantly, this amount has not been corroborated for pregnancy. In some cases, open peritoneal lavage may be informative (Tsuei, 2006).

FIGURE 47-11

Fast scan. Upper quadrant scan shows anechoic free fluid (asterisk) between the liver edge (arrow) and kidney (Morison pouch). The patient had 2500 mL of blood in the peritoneal cavity. (From Mendez-Figueroa H, Rouse DJ: Trauma in pregnancy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics 3rd ed, New York McGraw-Hill Education, 2016, In press.)



Penetrating injuries in most cases must be evaluated using radiography. Because clinical response to peritoneal irritation is blunted during pregnancy, an aggressive approach to exploratory laparotomy is pursued. Whereas exploration is mandatory for abdominal gunshot wounds, some clinicians advocate close observation for selected stab wounds. Diagnostic laparoscopy has also been used (Chap. 46, Medications and Surgeries).

Cesarean Delivery

The necessity for cesarean delivery depends on several factors. Laparotomy itself is not an indication for hysterotomy. Some considerations include gestational age, fetal condition, extent of uterine injury, and whether the large uterus hinders adequate management of other intraabdominal injuries (Tsuei, 2006).

Electronic Monitoring

Because fetal well-being may reflect the status of the mother, fetal monitoring is another "vital sign" that helps evaluate the extent of maternal injuries. Even if the mother is stable, electronic monitoring may suggest placental abruption. In a study by Pearlman and coworkers (1990), no woman had an abruption if uterine contractions were less often than every 10 minutes within the 4 hours after trauma was sustained. Almost 20 percent of women who had contractions more frequently than every 10 minutes in the first 4 hours had an associated placental abruption. In these cases, abnormal tracings were common and included fetal tachycardia and late decelerations. Conversely, no adverse outcomes were reported in women who had normal monitor tracings (Connolly, 1997). Importantly, if tocolytics are used for these contractions, they may obfuscate findings, and we do not recommend them.

Because placental abruption usually develops early following trauma, fetal monitoring is begun as soon as the mother is stable. The ideal duration of posttrauma monitoring is not precisely known. From data cited above, observation for 4 hours is reasonable with a normal tracing and no other sentinel findings such as contractions, uterine tenderness, or bleeding. Certainly, monitoring should be continued as long as there are uterine contractions, nonreassuring fetal heart patterns, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes (American College of Obstetricians and Gynecologists, 2017b). In rare cases, placental abruption has developed days after trauma (Higgins, 1984).

Fetal-Maternal Hemorrhage

It is unclear whether routine use of the Kleihauer-Betke or an equivalent test in pregnant trauma victims might modify adverse outcomes associated with fetal anemia, cardiac arrhythmias, and death (Pak, 1998). In a retrospective review of 125 pregnant women with blunt injuries, the Kleihauer-Betke test was judged to be of little value during acute trauma management (Towery, 1993). Others have reached similar conclusions, although a positive test with fetal cells of 0.1 percent was predictive of uterine contractions or preterm labor (Connolly, 1997; Muench, 2003, 2004).

For the woman who is D-negative, administration of anti-D immunoglobulin should be considered. This may be omitted if a test for fetal bleeding is negative. Even with anti-D immunoglobulin, alloimmunization may still develop if the fetal-maternal hemorrhage exceeds 15 mL of fetal cells (Chap. 15, Fetomaternal Hemorrhage).

For the pregnant trauma patient, confirmation of current tetanus immunization status is pertinent. When indicated, a dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) is preferred for its neonatal pertussis immunity benefits (Chap. 9, Automobile and Air Travel).

THERMAL INJURY

Treatment of the burned gravida is similar to that for nonpregnant patients (Mendez-Figueroa, 2016). With treatment, it is generally agreed that pregnancy does not alter maternal outcome from thermal injury compared with that of nonpregnant women of similar age. As perhaps expected, maternal and fetal survival parallels the percentage of burned surface area (Parikh, 2015). Karimi and colleagues (2009) reported higher mortality rates for both with suicidal attempts and with inhalational injuries. The composite mortality rate for nearly 400 women from seven studies increased in a linear fashion as the percent of burned body surface area increased (Fig. 47-12). For 20-, 40-, and 60-percent burns, the maternal mortality rates were approximately 4, 30, and 93 percent, respectively. The corresponding fetal mortality rates were 20, 48, and 96 percent, respectively. With severe burns, the woman usually enters labor spontaneously within a few days to a week and often delivers a stillborn. Contributory factors are hypovolemia, pulmonary injury, septicemia, and the intensely catabolic state (Radosevich, 2013).

FIGURE 47-12
Maternal and fetal mortality rates by burn severity in nearly 400 women. (Data from Akhtar, 1994; Amy, 1985; Mabrouk, 1977; Maghsoudi, 2006; Parikh, 2015; Rayburn, 1984; Rode, 1990.)

Following serious abdominal burns, skin contractures that develop may be painful during a subsequent pregnancy and may even require surgical decompression and split-skin autografts (Mitsukawa, 2015; Radosevich, 2013). Loss or distortion of nipples may cause problems in breastfeeding. Mitsukawa and associates (2015) reported that contracture release was indicated with scars spanning more than >75 percent of the total abdominal area. Alternatively, normal abdominal tissue expansion due to pregnancy appears to be an excellent source for obtaining skin grafts postpartum to correct scar deformities at other body sites (Del Frari, 2004).

Electrical and Lightning Injuries

Earlier case reports suggested a high fetal mortality rate with electric shock (Fatovich, 1993). In a prospective cohort study, however, Einarson and coworkers (1997) showed similar perinatal outcomes in 31 injured women compared with those of noninjured controls. They concluded that traditional 110-volt North American electrical current likely is less dangerous than the 220-volt currents available in Europe. A woman with iliofemoral thrombosis at 29 weeks' gestation that *may* have been related to a mild electrical shock at 22 weeks was described (Sozen, 2004). Another woman with brain death from cardiac arrest was reported (Sparic, 2014). Thermal burns with electrocution may be extensive.

The pathophysiological effects of lightning injuries can be devastating. García Gutiérrez and coworkers (2005) reviewed 13 case reports of lightning injuries during pregnancy and cited a 50-percent stillbirth rate.

CARDIOPULMONARY RESUSCITATION

According to estimates from the Nationwide Inpatient Sample, cardiac arrest complicates approximately 1 in 12,000 delivery admissions (Mhyre, 2014). The most common underlying causes were hemorrhage, heart failure, amnionic-fluid embolism, and sepsis. General topics regarding planning and equipment have been reviewed by the American College of Obstetricians and Gynecologists (2017b) and the Society for Obstetric Anesthesia and Perinatology (Lipman, 2014). Special considerations for cardiopulmonary resuscitation (CPR) conducted in the second half of pregnancy are outlined in the American Heart Association 2010 guidelines (Jeejeebhoy, 2015). The committee acknowledges the following as standards for critically ill gravidas: (1) relieve possible vena caval compression by left lateral uterine displacement, (2) administer 100-percent oxygen, (3) establish intravenous access above the diaphragm, (4) assess for hypotension that warrants therapy, which is defined as systolic blood pressure <100 mm Hg or <80 percent of baseline, and (5) review possible causes of critical illness and treat conditions as early as possible.

The position of the heart for external compressions is not different from that in nonpregnant women (Holmes, 2015). In nonpregnant women, external chest compression results in a cardiac output approximately 30 percent of normal. In late pregnancy, this may be even less with compressions because of uterine aortocaval compression (Clark, 1997; Nelson, 2015). Thus, it is paramount to accompany other resuscitative efforts with uterine displacement. This can be accomplished by tilting the operating table laterally, by placing a wedge under the patient's right hip, or by pushing the uterus to the left manually (Rees, 1988; Rose, 2015). If no equipment is available, an individual may kneel on the floor with the maternal back on his or her thighs to form a "human wedge" (Whitty, 2002).

Cesarean Delivery

During maternal resuscitation, because of pregnancy-induced hindrances on CPR efforts, emergent *perimortem cesarean delivery* for fetal salvage and improved maternal resuscitation may be considered. Some have stated that cesarean delivery is indicated within 4 to 5 minutes of beginning CPR if the fetus is viable (Drukker, 2014). In women delivered by perimortem cesarean, neurologically intact neonatal survival and the cardiac arrest-to-delivery interval are inversely related (Katz, 2012). Specifically, of newborns delivered within 5 minutes of arrest, 98 percent are neurologically intact; within 6 to 15 minutes, 83 percent are intact; within 16 to 25 minutes, 33 percent are intact; and within 26 to 35 minutes, only 25 percent are intact (Clark, 1997). This, coupled with some evidence that delivery *may* also enhance maternal resuscitation, has led the American College of Obstetricians and Gynecologists (2017b) to recommend *consideration* for cesarean delivery to begin within 4 minutes of cardiac arrest in these cases.

This serious and sometimes contentious issue is far from evidence based. To wit, Katz and associates (2005) reviewed 38 perimortem cesarean deliveries with a "large selection bias." They concluded that these reports supported—but "fell far from proving"—that perimortem cesarean delivery within 4 minutes of maternal cardiac arrest improves maternal and fetal outcomes. Even so, as emphasized by Clark (1997) and Rose (2015) and their coworkers, and in our experiences, these goals rarely can be met in actual practice. For example, most cases of cardiac arrest occur in uncontrolled circumstances, and thus, the time to CPR initiation alone would require the first 5 minutes. Thus "crash" cesarean delivery would supersede resuscitative efforts, would necessarily be done without appropriate anesthesia or surgical equipment, and more likely than not, would lead to maternal death. Moreover, the distinction between a perimortem versus postmortem cesarean operation is imperative (Katz, 2012; Rose, 2015). Last, in the balance, any choice *may* favor survival of the mother over the fetus, or vice versa, and thus there are immediate unresolvable ethical concerns. Katz (2012) has provided a scholarly review of perimortem cesarean delivery.

Maternal Brain Death

Occasionally, a pregnant woman with a supposedly healthy intact fetus will be kept on somatic support to await fetal viability or maturity. This is discussed in Chapter 60 (Idiopathic Intracranial Hypertension).

ENVENOMATION

According to their review, Brown and coworkers (2013b) reported that clinically significant envenomations in pregnant women are from snakes, spiders, scorpions, jellyfish, and hymenoptera such as bees, wasps, hornets, and ants. Adverse outcomes are related to maternal effects. These investigators conclude that limited evidence supports the use of a venom-specific approach that includes symptomatic care, antivenom administration when appropriate, anaphylaxis treatment, and fetal assessment. One management scheme for North American snakebites was provided by Lei and associates (2015).

CHAPTER 48: Obesity

I recently saw a patient who imagined herself in the last month of pregnancy, and who, while talking to me, exclaimed at the violence of the movements, but on examination I found that her uterus was normal in size, and that her enlarged abdomen was due to a rapidly increasing deposit of fat.

—J. Whitridge Williams (1903)

INTRODUCTION

At the beginning of the last century, obesity was not terribly problematic, and with few exceptions, Williams did not refer to its adverse obstetrical effects. Fast forward to today when excessive weight is a major health problem in many affluent societies (GBD 2015 Obesity Collaborators, 2017). Indeed, by 2014, more than a third of all adults in the United States were obese (Ogden, 2015).

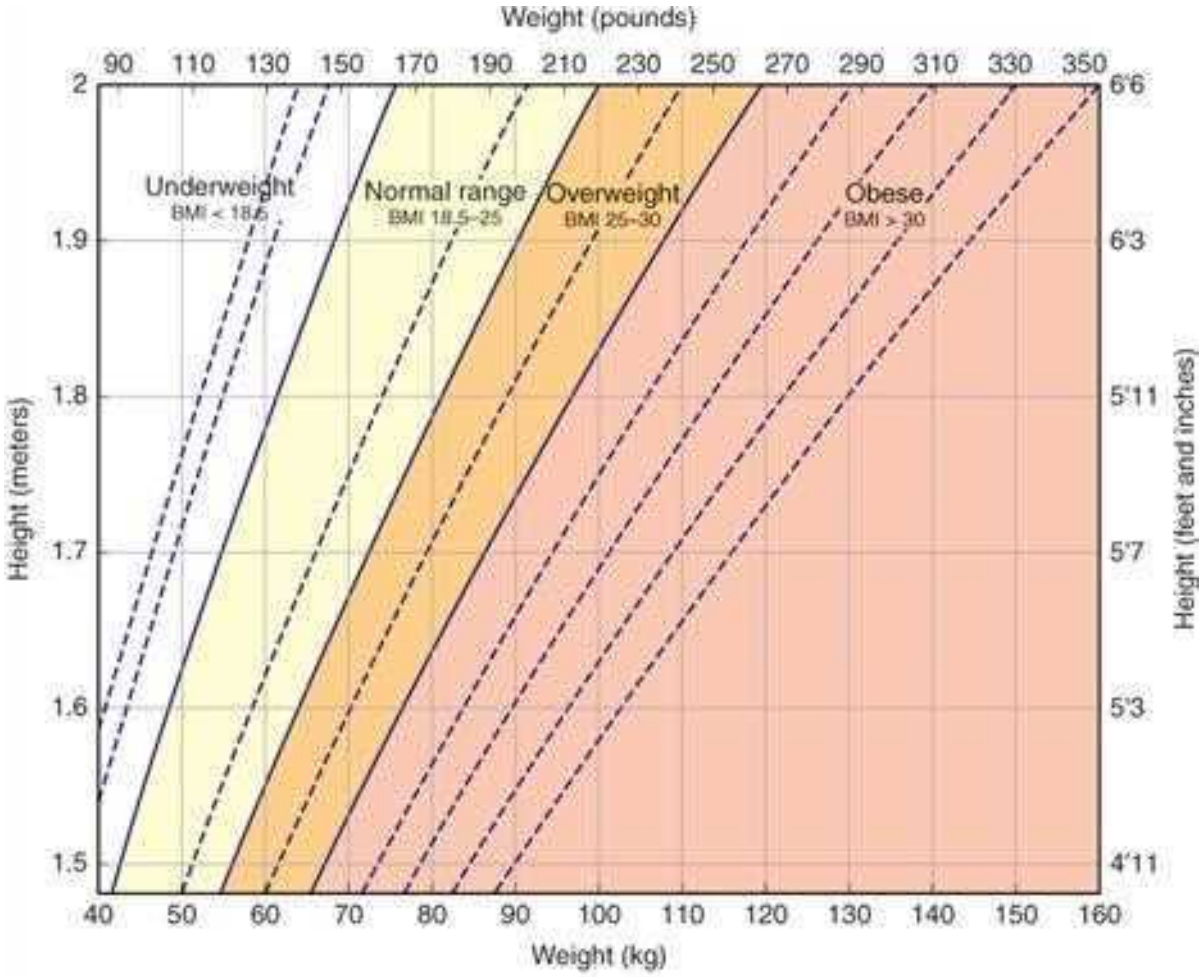
The adverse health aspects of obesity are staggering and include risks for diabetes mellitus, heart disease, hypertension, stroke, and osteoarthritis. Obese gravidas and their fetuses are predisposed to various serious pregnancy-related complications and to higher long-term morbidity and mortality rates.

GENERAL CONSIDERATIONS

Definitions and Prevalence

Of systems to classify obesity, the *body mass index* (*BMI*), also known as the *Quetelet index,* is most often used. The BMI is calculated as weight in kilograms divided by the square of the height in meters (kg/m^2). Calculated BMI values are available in various chart and graphic forms (Fig. 48-1). The National Institutes of Health (2000) classifies adults according to BMI as follows: *normal* is 18.5 to 24.9 kg/m^2, *overweight* is 25 to 29.9 kg/m^2, and *obese* is ≥30 kg/m^2. Obesity is further divided into: *class 1* is 30 to 34.9 kg/m^2, *class 2* is 35 to 39.9 kg/m^2, and *class 3* is ≥40 kg/m^2. Class 3 obesity is often referred to as morbid obesity, with *super-morbid obesity* describing a BMI ≥50 kg/m^2.

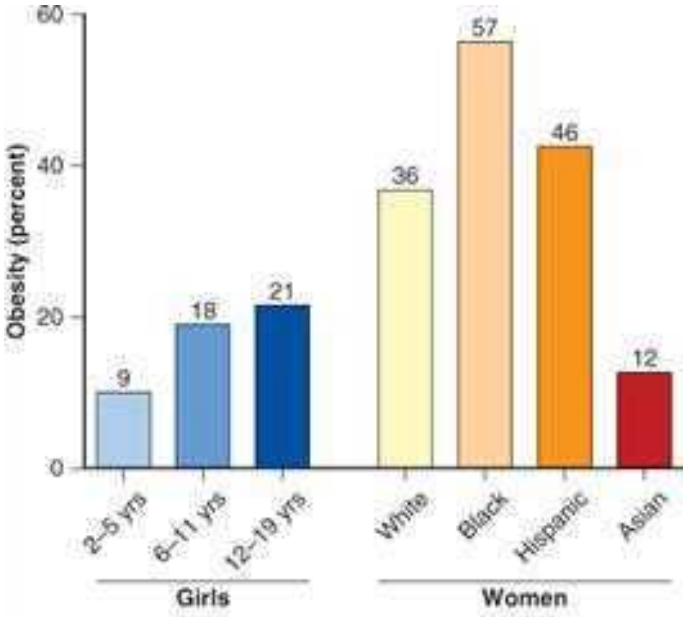
FIGURE 48-1
Chart for estimating body mass index (BMI). To find the BMI category for a particular subject, locate the point at which the height and weight intersect.



Using these definitions, from 2011 to 2014, slightly more women than men were designated obese—36 versus 34 percent (Ogden, 2015). Among girls and women, the prevalence of obesity rises with age and varies among ethnicities (Fig. 48-2). Although obesity is now common among all socioeconomic levels, the overall severity advances with increasing poverty (Bilger, 2017). Also, a genetic predisposition has been identified from several gene loci (Locke, 2015; Shungin, 2015).

FIGURE 48-2

Prevalence of obesity in girls and women in the United States for 2009–2014. (Data from Ogden, 2015.)



Adipose Pathophysiology

Fat tissue is much more complex than merely its energy storage function. Many fat tissue cells communicate with all other tissues via endocrine and paracrine factors, which are cytokines specifically termed *adipocytokines*. Also simply called *adipokines*, some of these with metabolic functions include adiponectin, leptin, tumor necrosis factor-α (TNF-α), interleukin 6 (IL-6), resistin, visfatin, apelin, vascular endothelium growth factor (VEGF), lipoprotein lipase, and insulin-like growth factor. A principal adipokine is adiponectin, which is a 30-kDa protein. It enhances insulin sensitivity, blocks hepatic glucose release, and has cardioprotective effects on circulating plasma lipids. An adiponectin deficit is linked with diabetes, hypertension, endothelial cell activation, and cardiovascular disease.

Cytokines that result in insulin resistance are leptin, resistin, TNF-α, and IL-6, and higher levels of these are found during pregnancy. Indeed, adipokines, especially the inflammatory cytokines, may be the primary stimulant of insulin resistance (Al-Badri, 2015; Yang, 2016). Conversely, adiponectin has antiinflammatory and insulin-sensitizing roles and is negatively regulated by fat mass. As one example of the discordant effects of these adipokines, gestational diabetes is associated with lower adiponectin but higher leptin levels. Placental production of these adipokines is also important and related to fetal growth and adiposity by mechanisms yet to be defined (Sartori, 2016).

Metabolic Syndrome

Given its multifaceted endocrine and paracrine functions, the detrimental effects of excessive adipose tissue are not surprising (Cornier, 2011; Gilmore, 2015). Obesity interacts with inherited factors to cause *insulin resistance*. This resistance is characterized by impaired glucose metabolism and a predisposition to type 2 diabetes. Insulin resistance also causes several subclinical abnormalities that predispose to cardiovascular disease and accelerate its onset. The most important among these are type 2 diabetes, dyslipidemia, and hypertension, which are constituents of the *metabolic syndrome*.

Criteria to define this syndrome are found in Table 48-1 (Alberti, 2009). Waist circumference is the preferred measurement for screening, but any three of five factors listed are sufficient to diagnosis the metabolic syndrome. Notably, most patients with type 2 diabetes have metabolic syndrome according to these criteria. Also, obese women with hypertension typically demonstrate elevated plasma insulin levels. These are even higher in women with central obesity (Fu, 2015).

TABLE 48-1

Criteria for Diagnosis of the Metabolic Syndrome

Patients with three or more of the following:	
Elevated waist circumference[a]	
Elevated triglycerides[b]:	≥150 mg/dL
Reduced high-density lipoprotein cholesterol[b]:	
	<40 mg/dL in males
	<50 mg/dL in females
Elevated blood pressure[b]: systolic ≥130 mm Hg and/or diastolic ≥85 mm Hg	
Elevated fasting glucose[b]: ≥100 mg/dL	

[a]According to country- and population-specific thresholds.

[b]Those with normal values while taking medications are considered to meet these criteria.

Data from Alberti, 2009.

The National Health Nutrition Examination Survey (NHANES) of the Centers for Disease Control and Prevention documented an overall 34-percent prevalence of the metabolic syndrome in the United States by 2012 (Moore, 2017). As expected, the prevalence rose with age. It was 20 percent for those aged 18 to 29 years and was 36 percent for those aged 30 to 49 years.

Nonalcoholic Fatty Liver Disease

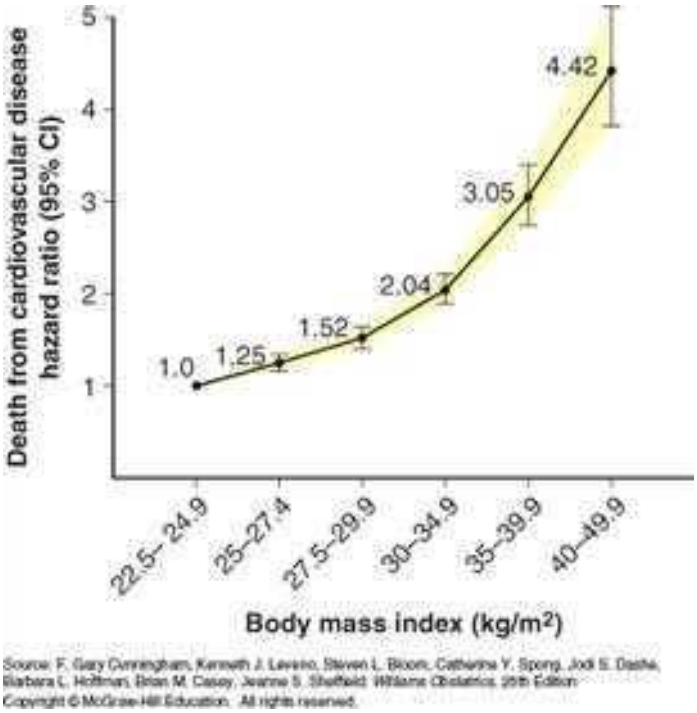
Generally speaking, visceral adiposity correlates with hepatic fat content (Cornier, 2011). With obesity, excessive fat accumulates in the liver—*hepatic steatosis*, which is also called nonalcoholic fatty liver disease (NAFLD). In persons with the metabolic syndrome, steatosis can progress to *nonalcoholic steatohepatitis (NASH)* and cirrhosis, as well as hepatocellular carcinoma. Indeed, one fourth of chronic liver disease cases worldwide are caused by NAFLD (Younossi, 2016). Moreover, NAFLD is strongly associated with both fatal and nonfatal cardiovascular disease (Targher, 2016).

Obesity-Associated Morbidity

Obese individuals suffer well-known consequences such as glucose intolerance, hypertension, dyslipidemia, and metabolic syndrome. Furthermore, metabolic syndrome and obesity are linked with cardiovascular disease, including myocardial infarction, atrial fibrillation, heart failure, and stroke (Long, 2016). Insulin resistance and metabolic syndrome cause structural cerebral changes and lower executive functioning and memory in adults. Similar consequences are also found in adolescents, suggesting that metabolic syndrome's effects on neurocognitive function are independent of significant occlusive vascular disease (Rusinek, 2014).

Obesity is associated with higher rates of all-cause early mortality (Fontaine, 2003; Peeters, 2003). Cardiovascular mortality data from 19 prospective studies are shown in Figure 48-3. In these and other studies, mortality risk from cardiovascular disease and cancer grew proportionally with increasing BMI. Importantly, however, an *obesity* paradox—whereby certain groups actually derive a survival advantage from being obese—has been hypothesized (Hainer, 2013). Despite this, the health benefits of weight normalization are well documented (Cheung, 2017).

FIGURE 48-3
Estimated hazard ratios (95% CI) for death due to cardiovascular disease according to body mass index among 1.46 million white adult men and women. (Data from de Gonzalez, 2010.)



Obesity Treatment

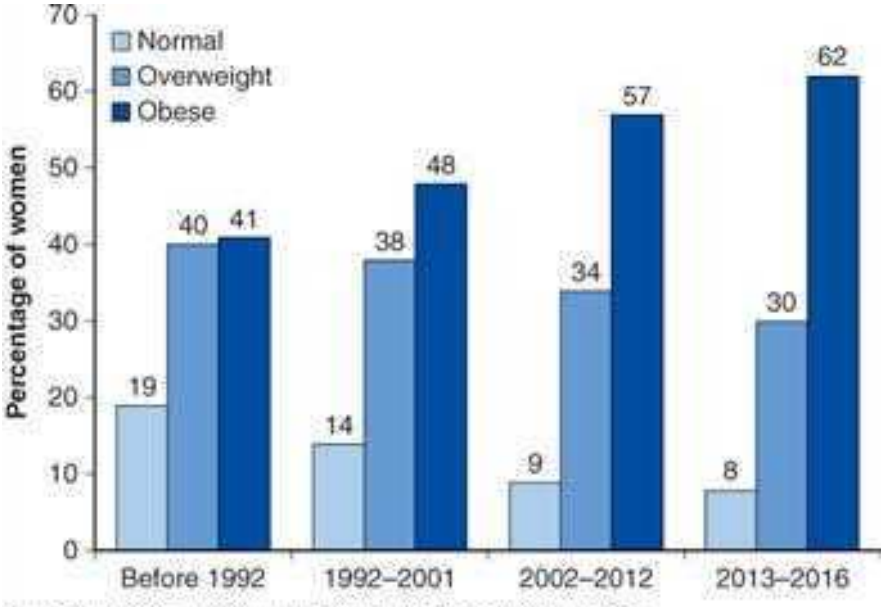
Weight loss is tremendously difficult for obese individuals. If achieved, long-term maintenance poses equally daunting challenges. Obstetrician-gynecologists are encouraged to aid weight loss in obese adult women. Successful approaches include behavioral, pharmacological, and surgical techniques or a combination of these methods (Dixon, 2016). Dietary changes and exercise reduce weight and rates of the associated metabolic syndrome (Garvey, 2016; Martin, 2016). When used in conjunction with bariatric surgery, glucose control in those with type 2 diabetes is improved (Schauer, 2014). However, both surgical and medical interventions are associated with appreciable long-term failure rates—up to 50 percent in patients with type 2 diabetes undergoing bariatric surgery (Mingrone, 2015).

PREGNANCY AND OBESITY

Obese women unequivocally have reproductive disadvantages (American Society for Reproductive Medicine, 2015). This translates into difficulty in achieving pregnancy, early and recurrent pregnancy loss, preterm delivery, and several obstetrical, medical, and surgical complications with pregnancy, labor, delivery, and the puerperium (American College of Obstetricians and Gynecologists, 2015). Also, oral contraceptive failure may be more likely in overweight women (Chap. 38, Method-Specific Effects). Last, infants—and later, adult children—of obese mothers have correspondingly higher morbidity rates (Godfrey, 2017; Reynolds, 2013).

Obesity complicating pregnancy has grown substantially in this country. Our experience at Parkland Hospital over three epochs is shown in Figure 48-4.

FIGURE 48-4
Increasing prevalence of obesity during four epochs in pregnant women classified at the time of their first prenatal visit at Parkland Hospital.



Maternal Morbidity

For *overweight women*, higher rates of adverse outcomes complicate pregnancy (Schummers, 2015). Shown in Table 48-2 are results from five studies including more than 1 million singleton pregnancies. Although not as magnified as in the obese cohort, rates of almost all complications are significantly greater in overweight women than in those whose BMI is normal.

TABLE 48-2

Adverse Pregnancy Effects in Overweight and Obese Women

Complication	Prevalence (%) Normal BMI 18.5–24.9 n = 621,048	Prevalence (%) with Odds Ratio and 95% Confidence Interval[a]	
		Overweight BMI 25–29.9 n = 228,945	Obese BMI > 30 n = 78,043
Gestational diabetes	2.3	4.3 (OR 1.91, 1.86–1.96)	8.6 (OR 4.04, 3.94–4.15)
Preeclampsia	2.7	4.3 (OR 1.60, 1.56–1.64)	8.1 (OR 3.17, 3.08–3.25)
Preterm birth	3.8	4.1 (OR 1.09, 1.05–1.13)	4.8 (OR 1.28, 1.23–1.34)
Labor induction	20.9	23.8 (OR 1.19, 1.17–1.21)	29.7 (OR 1.60, 1.57–1.64)
Prelabor or elective cesarean delivery	6.6	8.3 (OR 1.28, 1.26–1.31)	11.5 (OR 1.85, 1.81–1.89)
Cesarean delivery	25.2	31.5 (OR 1.37, 1.34–1.39)	39.3 (OR 1.92, 1.88–1.96)
Shoulder dystocia	2.0	2.4 (OR 1.22, 1.17–1.28)	2.3 (OR 1.14, 1.08–1.21)
Postpartum hemorrhage	6.7	8.4 (OR 1.29, 1.26–1.31)	8.7 (OR 1.34, 1.31–1.37)
Pelvic infection	0.6	0.7 (OR 1.16, 1.06–1.26)	0.8 (OR 1.28, 1.15–1.43)
Wound infection or complication	0.4	0.5 (OR 1.42, 1.28–1.58)	1.0 (OR 2.70, 2.42–3.01)
Large for gestational age	8.7	13.1 (OR 1.57, 1.54–1.61)	16.3 (OR 2.04, 1.99–2.10)
Macrosomia	2.0	3.6 (OR 1.81, 1.74–1.88)	5.1 (OR 2.60, 2.50–2.71)
Stillbirth	0.3	1.8 (OR 5.89, 5.57–6.22)	0.5 (OR 1.71, 1.56–1.87)

[a]Odds ratios with 95% CI are significant when compared to normal BMI group.

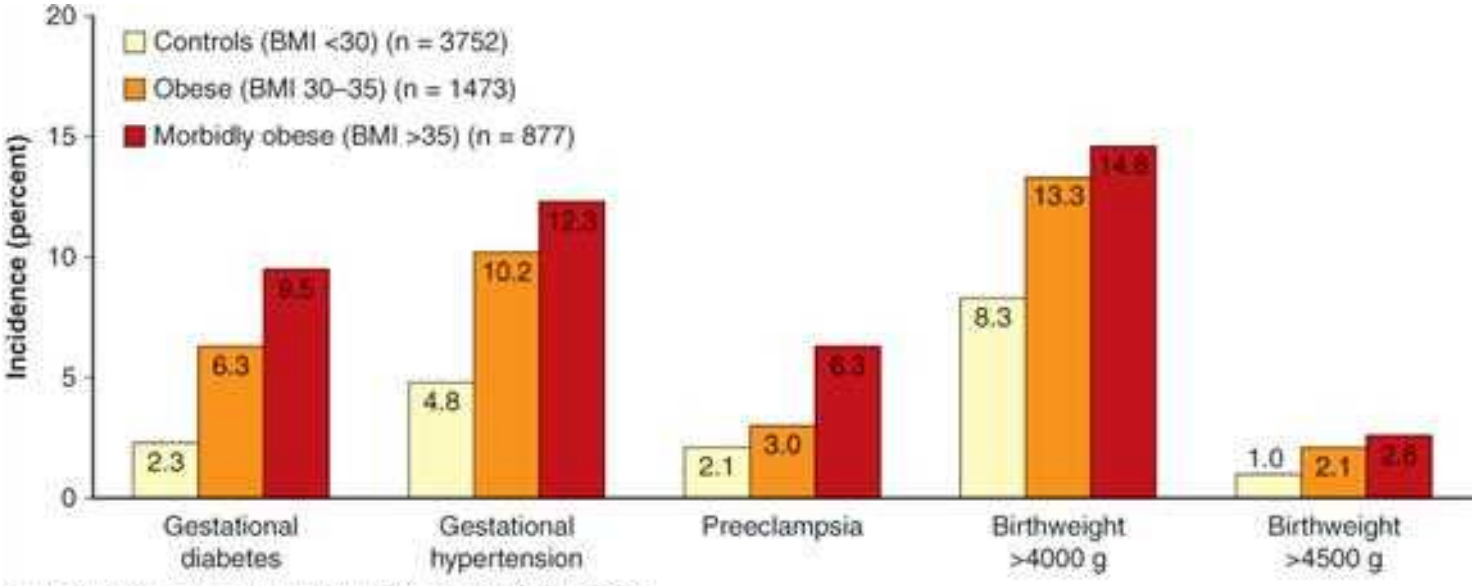
BMI = body mass index.

Data from Kim, 2016; Lisonkova, 2017; Ovesen, 2011; Schummers, 2015; Sebire, 2001.

For *obese women*, definitions used in studies of adverse outcomes vary widely, and BMIs from >30 kg/m^2 to >50 kg/m^2 have served as thresholds (Crane, 2013; Denison, 2008; Stamilio, 2014). Of outcomes, Mariona (2017) reviewed maternal deaths in Michigan and found that the risk of a maternal death was nearly fourfold higher in obese women. Women with super-morbid obesity experience very high rates of maternal and neonatal complications including preeclampsia, fetal overgrowth, and cesarean delivery, with even higher rates of meconium aspiration, ventilator support, and neonatal death (Marshall, 2014; Smid, 2016). Data from one large study is shown in Figure 48-5.

FIGURE 48-5

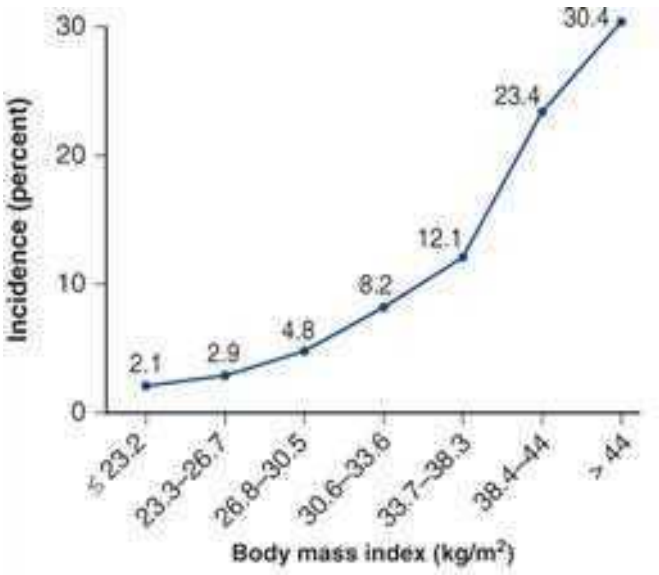
Incidence of selected pregnancy outcomes in 16,102 women enrolled in the FASTER (First- and Second-Trimester Evaluation of Risk) trial according to BMI. (Data from Weiss, 2004.)



Especially striking are the markedly elevated rates of hypertension and gestational diabetes. As discussed previously, obesity and the metabolic syndrome are characterized by insulin resistance, which causes low-grade inflammation and endothelial activation (Ma, 2016). These latter effects play a central role in preeclampsia (Chap. 40, Pathogenesis). The overwhelming evidence between rising maternal BMI and the incidence of preeclampsia is depicted in Figure 48-6. Similar observations were reported from a large Canadian study and by the Safe Labor Consortium (Kim, 2016; Schummers, 2015).

FIGURE 48-6

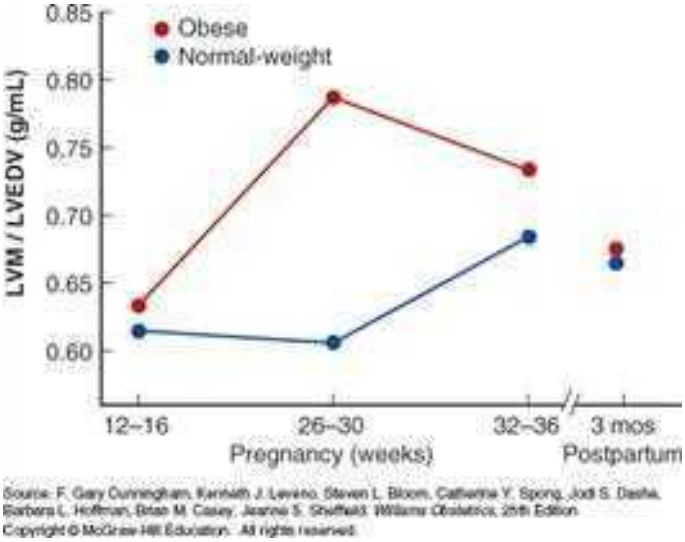
Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study: frequency of preeclampsia according to BMI. (Data from the HAPO Study Cooperative Research Group, 2008.)



Obesity and hypertension are common cofactors in peripartum heart failure (Cunningham, 1986, 2012). Stewart and colleagues (2016) prospectively studied the effect of obesity on cardiac remodeling in pregnancy among 14 normal and 9 overweight or obese women (Fig. 4-8). Concentric remodeling was greater in overweight or obese women (Fig. 48-7). This, however, regressed to normal by 3 months postpartum.

FIGURE 48-7

Geometric changes of ventricular remodeling across pregnancy in obese and normal-weight women. LVM = left ventricular mass, LVEDV = left ventricular end-diastolic volume. (Data from Stewart, 2016.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics, 25th Edition

Obesity and gestational diabetes are inextricably linked as shown in Table 48-2. Their coexistence with and adverse effects on pregnancy outcomes are discussed in Chapter 57 (Types of Diabetes and Management).

Nonalcoholic fatty liver disease is associated with several adverse pregnancy outcomes. In a cohort of 110 women with NAFLD, risks for preeclampsia, preterm birth, low-birthweight neonates, cesarean delivery, and gestational diabetes were elevated (Hagström, 2016). In one prospective study of 476 pregnancies, first-trimester sonographic evidence of maternal NAFLD was strongly associated with gestational diabetes (De Souza, 2016a,b). Meyer and associates (2013) found that overweight and obese gravidas had a higher proportion of low-density lipoprotein III (LDL-III) compared with that of normal-weight women. LDL-III predominance is a hallmark of ectopic liver fat accumulation that is typical of NAFLD. At Parkland Hospital, we are now frequently encountering obese gravidas who have NAFLD and evidence of steatohepatitis manifest by elevated serum hepatic transaminase levels. In rare cases, liver biopsy is necessary to exclude other causes.

In addition to these metabolic complications, quality-of-life measures are also negatively affected by obesity during pregnancy (Amador, 2008; Ruhstaller, 2017). One systematic review found significantly higher risks of depression in overweight and obese women during and after pregnancy (Molyneaux, 2014). Obese women were also significantly more likely to experience anxiety during pregnancy.

Perinatal Mortality

Stillbirths are more prevalent as the degree of obesity accrues (Ovesen, 2011; Schummers, 2015). In a review of almost 100 studies, obesity was the highest ranking modifiable risk factor for stillbirth (Flenady, 2011). In super-morbidly obese compared with normal-weight gravidas, Yao and associates (2014) found 5.7 and 13.6-fold higher stillbirth rates at 39 and 41 weeks' gestation, respectively. Remarkably, 25 percent of term stillbirths in this study involved obese women. Chronic hypertension with superimposed preeclampsia associated with obesity is one cause of excessive stillbirths.

Evaluating *perinatal death* rates, Lindam and coworkers (2016) reported that high maternal BMI in early pregnancy was a risk factor. The risk of neonatal death is also greater for obese women (Johansson, 2014; Meehan, 2014). Finally, Cnattingius and Villamor (2016) noted that accruing weight between pregnancies is a risk factor for perinatal mortality, whereas weight loss between pregnancies for overweight women lowers this risk.

Perinatal Morbidity

Both fetal and neonatal complications are increased in obese women. Two important and interrelated cofactors that contribute to excessive rates of perinatal morbidity are chronic hypertension and diabetes, both of which are associated with maternal obesity. These comorbidities each may play a role in the higher rates of fetal-growth restriction and indicated preterm birth that are seen in obese women (Schummers, 2015). Pregestational diabetes also raises the birth defect rate, and gestational diabetes is complicated by excessive numbers of large-for-gestational-age and macrosomic fetuses (Chap. 44, Definition).

Even when diabetes is not considered, the prevalence of macrosomic newborns is greater in obese women (Kim, 2016; Ovesen, 2011; Schummers, 2015). The group from MetroHealth Medical Center in Cleveland has extensively studied prepregnancy obesity, gestational weight gain, and diabetes and their relationship to adverse pregnancy outcomes and to greater newborn weight and fat mass (Catalano, 2009, 2015; Lassance, 2015; Ma, 2016; Yang, 2016). Although each of these variables is associated with larger and more corpulent newborns, prepregnancy BMI and its effect on inflammation and placental gene expression has the strongest influence on the prevalence of macrosomic neonates.

Rates of birth defects are also higher with comorbid obesity (Stothard, 2009). For neural-tube defects, elevated risks of 1.2-, 1.7-, and 3.1-fold are found in overweight, obese, and severely obese women, respectively (Rasmussen, 2008). The National Birth Defect Prevention Study reported a correlation between BMI and congenital heart defects (Gilboa, 2010). However, this may be related to diabetes as a cofactor (Biggio, 2010). Importantly, obesity is

detrimental to the accuracy of obstetrical sonographic examination and to antepartum identification of birth defects (Adekola, 2015; Dashe, 2009; Weichart, 2011).

Long-Term Offspring Morbidity

Obese women beget obese children, who themselves become obese adults. Catalano and coworkers (2009) studied offspring at a mean age of 9 years and found a direct association with maternal prepregnancy obesity and childhood obesity. They also reported associations with central obesity, elevated systolic blood pressure, increased insulin resistance, and lipid abnormalities—all elements of the metabolic syndrome. Reynolds and associates (2013) reported higher rates of cardiovascular disease and all-cause mortality in 37,709 adult offspring of overweight and obese mothers. Similar cardiometabolic health effects in offspring were echoed by Gaillard and colleagues (2016). Other data support that excessive maternal weight gain in pregnancy may predict obesity in adult offspring (Lawrence, 2014; Reynolds, 2010). Last, rates of glucose intolerance and metabolic syndrome are higher among offspring of obese women (Gaillard, 2016; Tan, 2015).

The potential biological mechanisms of these associations are unclear. But such studies raise the possibility of *fetal programming*, that is, the fetal environment may lead to adverse adult health outcomes. Elucidation is limited by insufficient data on potential maternal and genetic predisposing factors and on the environment of the infant and child in relation to diet and activity. The science of *epigenetics* has provided some support for the possibility that perturbations of the maternal-fetal environment can adversely alter postdelivery events (Kitsiou-Tzeli, 2017). Also possible are contributions of the maternal-child environment subsequent to birth (Gluck, 2009). These and other factors regarding fetal programming are discussed in Chapter 44 (Accelerated Lung Maturation).

ANTEPARTUM MANAGEMENT

Maternal Weight Gain

The Institute of Medicine (2009) has updated its previous maternal weight gain determinants (Table 9-4). For overweight women, weight gain of 15 to 25 pounds is suggested. For obese women, the Institute advocates a gain of 11 to 20 pounds. Intuitively, maternal weight must increase sufficiently to provide for fetal and placental tissue accrual and for amnionic fluid and maternal blood volume expansion. Thus, maternal weight loss is during pregnancy is discouraged. The American College of Obstetricians and Gynecologists (2015) endorses these Institute guidelines.

However, these recommendations were issued without firm scientific evidence to support them, and their value remains unproven (Rasmussen, 2010). For example, recent studies differ with respect to the effect of insufficient weight gain for obese women. Bodnar and colleagues (2016) reported no greater risk for low-birthweight or small-for-gestational-age newborns among 47,494 obese women who had inadequate weight gain during pregnancy. Bogaerts and associates (2015) found that even weight loss among obese women did not yield poor fetal growth. In contrast, however, Hannaford and coworkers (2017) reported that obese women who gained less than the Institute recommendations were almost three times more likely to deliver a small-for-gestational-age neonate. Another study similarly found an almost twofold greater risk among obese women who lost weight during pregnancy (Cox Bauer, 2016).

Apart from inadequate weight gain, excessive gestational weight gain may portend greater risks for the obese mother. Berggren and coworkers (2016) noted that overweight and obese women accrued maternal fat rather than lean mass with excessive gestational weight gain. From another analysis, overall higher rates of hypertensive disorders, cesarean delivery, and fetal overgrowth as well as lower rates of spontaneous preterm birth and fetal undergrowth were found among women gaining more than recommended (Johnson, 2013). However, when analyzed according to BMI category, significantly higher rates of preeclampsia, cesarean delivery, and fetal overgrowth were identified among the 1937 overweight women, but not for the 1445 obese women, who gained excess weight.

During pregnancy, overweight and obese women gain more weight than recommended compared with normal-weight gravidas (Endres, 2015). Moreover, overweight and obese women have excessive postpartum weight retention at 1 year, and one third retain at least 20 pounds more than their prepregnancy weight.

Dietary Intervention

Several dietary interventions can help limit and achieve the weight-gain targets listed in the previous section. Options include lifestyle interventions and physical activity. In one randomized trial of exercise in 300 overweight women, risks for gestational diabetes were lowered (Wang, 2017). That said, in another trial, 75 overweight women were randomly assigned to routine care or to a 16-week moderate-intensity stationary cycling program starting after midpregnancy. Maternal and neonatal outcomes did not differ between groups (Seneviratne, 2016). Also, a Cochrane database analysis of 11,444 women suggests that lifestyle interventions confer only a modest reduction in maternal weight gain, and their benefits for fetal overgrowth, cesarean delivery rate, and adverse neonatal outcome are not significant (Muktabhant, 2015). Regarding neonatal outcomes, the poor success of lifestyle interventions during pregnancy has been attributed to their late introduction, that is, after early gene expression within the placenta has already been programmed (Catalano, 2015).

Prenatal Care

Close prenatal monitoring detects most early signs of diabetes or hypertension. Standard screening tests for fetal anomalies are sufficient, while remembering the sonographic limitations for fetal anomaly detection in this group. Accurate fetal growth surveillance in obese women usually requires serial sonographic assessment. Antepartum external fetal heart rate monitoring is likewise more difficult.

INTRAPARTUM MANAGEMENT

Obese women are at increased risk for multiple labor or intrapartum complications. These include postterm pregnancy or labor abnormalities (Carpenter, 2016). In one study of 143,519 women, the odds of spontaneous labor at term in obese women was approximately half that of normal-weight women (Denison, 2008). In an analysis of more than 5000 parturients, women with a BMI >30 kg/m^2 had a longer duration of and slower early progression in first-stage labor (Norman, 2012).

Labor Induction

Compared with normal-weight women, obese women are twice as likely to undergo labor induction (Denison, 2008). Unfortunately, obese women are also twice as likely to experience a failed induction, and this risk rises with greater degrees of obesity (Wolfe, 2011). In a retrospective analysis of 470 nulliparous women with a BMI >30 kg/m^2 and an unfavorable cervix, those who underwent labor induction at 39 weeks' gestation were compared with those expectantly managed beyond 39 weeks (Wolfe, 2014). Two thirds of pregnancies expectantly managed either labored or had spontaneously ruptured membranes. Compared with this cohort, those who underwent planned labor induction had an elevated cesarean delivery rate—26 versus 40 percent. Moreover, their newborns were more frequently admitted to the neonatal intensive care unit—6 versus 18 percent. Conversely, Lee and associates (2016) reviewed statistics from 74,725 deliveries in obese women and reported that elective induction at 37 to 39 weeks in nulliparas and especially multiparas was actually associated with a lower cesarean delivery rate. These conflicting results highlight the difficulties faced by obstetrical providers as they contemplate the seemingly competing interests of the fetus and the obese mother. To address this, the Maternal-Fetal Medicine Units Network is conducting a randomized trial of planned labor induction at 39 weeks' gestation in nulliparous women.

Anesthesia Risks

Obese women present anesthesia challenges that include difficult epidural and spinal analgesia placement and complications from failed or difficult intubations. Evaluation of super-morbidly obese gravidas by the anesthesiologist is recommended during prenatal care or upon arrival to the labor unit (American College of Obstetricians and Gynecologists, 2017). Although the rationale for antepartum anesthesia consultation and early epidural analgesia access seems logical, little published data truly demonstrates benefits from these practices (Eley, 2016).

Regional analgesia for morbidly obese women is associated with longer neuraxial procedure times and more failed placement attempts (Tonidandel, 2014). Importantly, however, spinal analgesia in obese women for cesarean delivery does not appear to have benefits over combined spinal-epidural. For example, Ross and colleagues (2014) compared single-shot spinal analgesia with combined spinal-epidural analgesia and found that both methods could be placed with equal expediency and function similarly in morbidly obese patients.

Obese women who undergo regional analgesia that is complicated by relative hypotension more frequently have neonates with umbilical artery cord blood acidemia, probably due to delayed delivery. Edwards and colleagues (2013) studied 5742 obese women and found that pH significantly dropped, and base deficit rose, with increasing BMI. The rate of pH <7.1 doubled from 3.5 percent for a BMI <25 kg/m^2 to 7.1 percent for a BMI ≥40 kg/m^2. Anesthetic risks and complications are discussed in more detail in Chapter 25.

Cesarean Delivery

These rates are significantly greater in obese women. In one study, the primary rate was 33.8 percent for obese and 47.4 percent for morbidly obese women. These values compare strikingly with the rate of only 20.7 percent for normal-weight gravidas (Weiss, 2004). In an analysis of 226,958 women, cesarean delivery rates rose significantly for overweight (34 percent), class I (38 percent), class II (43 percent), and class III (50 percent) obesity (Schummers, 2015). In the same study, rates of gestational diabetes, itself a risk factor for cesarean delivery, increased from 6 percent for women with a BMI <25 kg/m^2 to 21 percent for those with a BMI of ≥40 kg/m^2. More worrisome is that obese women also have higher rates of *emergency* cesarean delivery, and obesity lengthens times for decision-to-incision and for delivery (O'Dwyer, 2013; Pulman, 2015). Girsen and associates (2014) found significantly increased incision-to-delivery times for both emergent and nonemergent cases.

Discussed in Chapter 31 (Prior Uterine Rupture), the incidence of failed trial of labor after cesarean is higher in obese women (Grasch, 2017; Hibbard, 2006). Women who gain weight between pregnancies also have significantly lower rates of vaginal birth after cesarean.

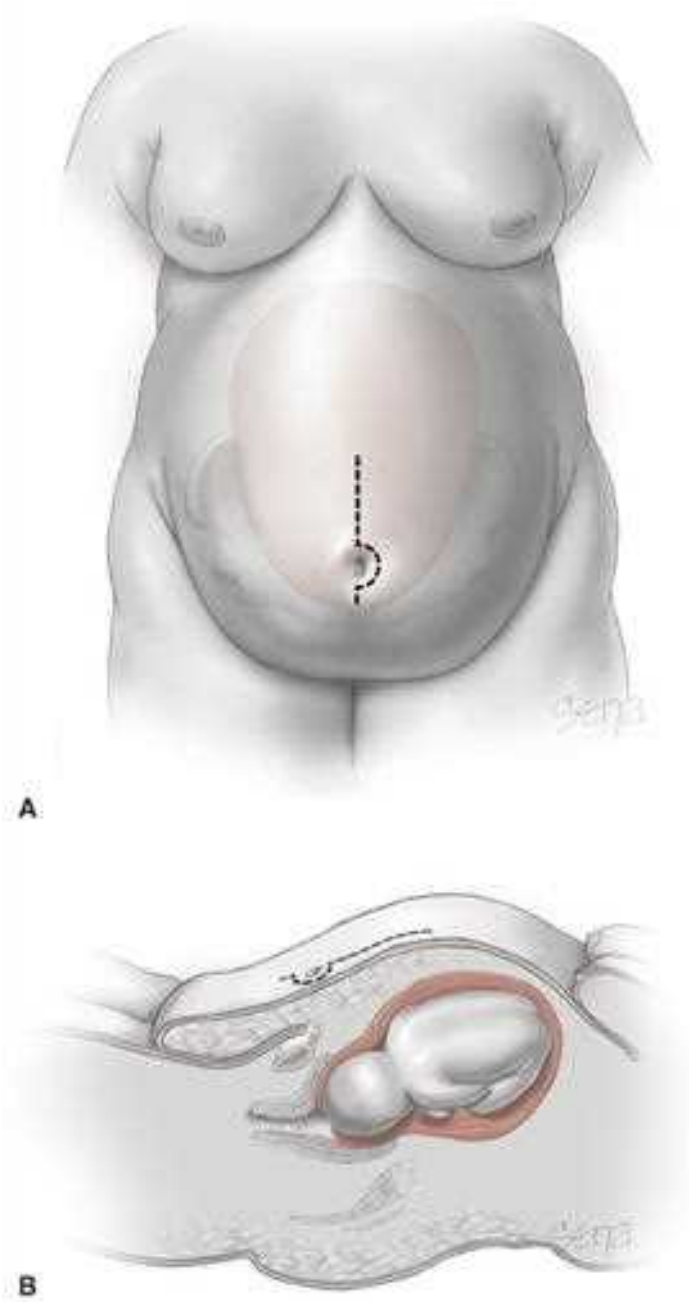
Surgical Concerns

For cesarean delivery, forethought is given to optimal placement and type of abdominal incision to allow access to the fetus and to effect the best wound closure. We prefer a vertical incision in obese women to provide the most direct access (Fig. 48-8). Others prefer a low transverse abdominal incision, with or without rostral taping of the pendulous abdomen. Individual differences in maternal body habitus preclude naming any one approach as superior

(McLean, 2012; Turan, 2016). Some observational studies have compared wound outcomes associated with vertical and transverse skin incisions, but results are conflicting as to a superiority of either (Brocato, 2013; Marrs, 2014; McClean, 2012; Sutton, 2016; Thornburg, 2012).

FIGURE 48-8

Abdominal incision for the obese woman. **A.** Frontal view. The dotted line indicates an appropriate skin incision for abdominal entry relative to the panniculus. As shown by the uterus in the background, selection of this periumbilical site permits access to the lower uterine segment. **B.** Sagittal view.



The frequency of abdominal wound infections is directly related to BMI. Conner and associates (2014) found the risk of wound infection is threefold higher for super-morbidly obese women compared with nonobese women—23 versus 7 percent. Among women with a BMI >45 kg/m^2, wound complication rates range from 14 to 19 percent (Smid, 2015; Stamilio, 2014). Comorbid diabetes apparently raises this risk (Leth, 2011). Other studies describe wound complication rates ranging from 2 to >40 percent in obese women (Conner, 2014; Marrs, 2014; Smid, 2015; Thornburg, 2012).

Several interventions may be preventive. Closure of subcutaneous tissue when at least 2 cm deep reduces wound complication rates (Tipton, 2011). Studies have also examined the use of higher doses of perioperative prophylactic antibiotics. Pharmacokinetic studies indicate that tissue concentrations of prophylactic antibiotics are lower with increasing BMI (Pevzner, 2011; Young, 2015). One prospective study showed that a 3-g dose of cefazolin resulted in higher tissue concentrations compared with a 2-g dose (Swank, 2015). That said, a retrospective analysis of 335 women with a median weight of 310 pounds found that the higher dose of cefazolin did not result in few surgical site infections (Ahmadzia, 2015). In one recent study, obese women

administered perioperative cephalosporin prophylaxis had a surgical infection rate of 13.4 percent compared with a rate of 6.4 percent for those given a 2-day course of oral cephalexin and metronidazole in addition to perioperative prophylaxis (Valent, 2017).

Negative-pressure wound therapy (NPWT) has also been used prophylactically (Mark, 2014). To address this, Hussamy and colleagues (2018) designed a randomized trial of NPWT versus routine dressing in more than 400 obese women undergoing cesarean delivery. Such therapy did not significantly lower the postoperative wound complication rate compared with routine care—19 versus 17 percent, respectively.

To lower thromboembolic complications, graduated compression stockings, hydration, and early mobilization after cesarean delivery in obese women are recommended by the American College of Obstetricians and Gynecologists (2015). Some also recommend "mini-dose" heparin prophylaxis, but we do not routinely use this (Chap. 52, Thromboprophylaxis).

BARIATRIC SURGERY

Several surgical procedures are designed to treat morbid obesity either by diminishing gastric volume—*restrictive*, or by bypassing gastrointestinal absorption—*restrictive malabsorptive*. In nonpregnant patients, these procedures improve or resolve diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea and reduce risks of myocardial infarction and death (Beamish, 2016).

Restrictive Procedures

Of options, the two approved laparoscopic adjustable silicone gastric banding (LASGB) procedures—*LAPBAND* and *REALIZE*—place a band 2 cm below the gastroesophageal junction to create a small stomach pouch above the ring. The ring diameter is controlled by a saline reservoir in the band.

These procedures can have positive effects on pregnancy outcomes. For example, Dixon and colleagues (2005) compared pregnancy outcomes in bariatric surgery patients against their preprocedural outcomes and those of a matched cohort of obese women. Following banding, the incidences of gestational hypertension—10 versus 45 percent—and gestational diabetes—6 versus 15 percent—were significantly lower in the bariatric surgery patients compared with their preprocedural pregnancies. The results from these and other studies are shown in Table 48-3.

TABLE 48-3

Pregnancy Outcomes Following Bariatric Surgery

Outcome[a]	Gastric Banding[b] (n = 651)	Roux-en-Y Gastric Bypass[c] (n = 361)
Hypertension	11%	4%
Gestational diabetes	7%	4%
Cesarean delivery	35%	33%
Mean birthweight	3206 g	3084 g
Low birthweight	7%	11%
Stillbirth	3/1000	3/1000

[a]Data not reported identically—frequencies are approximations.

[b]Data from Adams, 2015; Bar-Zohar, 2006; Carelli, 2011; Dixon, 2005; Ducarme, 2013; Facchiano, 2012; Lapolla, 2010; Pilone, 2014; Sheiner, 2009; Skull, 2004.

[c]Data from Adams, 2015; Ducarme, 2013; Facchiano, 2012; González, 2015; Sheiner, 2009.

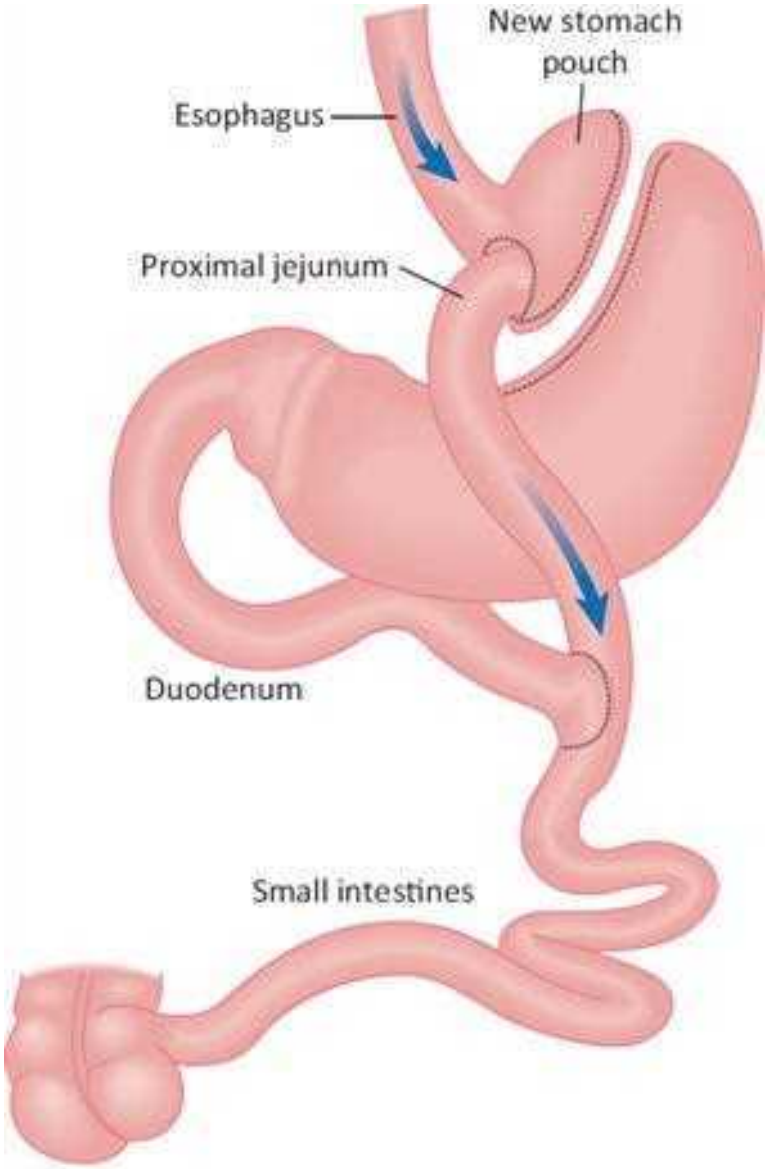
Deflation of the band during pregnancy affects maternal and fetal weight gain. Pilone and coworkers (2014) studied 22 pregnancies after band placement and reported that all women underwent full deflation of the band in the first trimester and gained an average of 14.7 kg during pregnancy. In another study, 42 women underwent deflation of the band, whereas 54 women maintained band inflation. A deflated band was associated with higher mean weight gain—15.4 kg versus 7.6 kg, increased birthweight—3712 versus 3380 g, and a twofold greater risk of macrosomia compared with an inflated one (Cornthwaite, 2015). Rarely, the band may slip from nausea and vomiting, especially with advancing gestation or postpartum (Pilone, 2014; Schmitt, 2016; Suffee, 2012). One fatal fetal cerebral hemorrhage developed from maternal vitamin K deficiency secondary to prolonged vomiting due to band slippage that created a gastric outlet obstruction (Van Mieghem, 2008).

Restrictive Malabsorptive Procedures

The laparoscopically performed *Roux-en-Y gastric bypass* is the most commonly used procedure for gastric restriction and selective malabsorption. Its surgical steps are described in Figure 48-9.

FIGURE 48-9

Roux-en-Y bypass. With this, the proximal stomach is completely transected to leave a 30-mL pouch. The proximal end of the distal jejunum is then connected to the small pouch. This bypasses a large part of the stomach and duodenum. At a site 60 cm distal to this gastrojejunostomy, a Roux-en-Y enteroenterostomy is also completed to allow drainage of secretions from the unused stomach and duodenum.



As with other bariatric procedures, pregnancy outcomes are changed remarkably following Roux-en-Y bypass (Adams, 2015). As shown in Table 48-3, rates of hypertension, gestational diabetes, and fetal macrosomia are reduced. Serious complications are uncommon, however, upper abdominal pain is frequent in pregnancy and often associated with internal herniation, which is protrusion of the bowel through a mesentery defect. Petersen and associates (2017) described outcomes in a birth cohort including 139 pregnancies. Upper abdominal pain complicated 46 percent, and a third of these had internal herniation. The preterm birth rate was 14 of 64 among those with upper abdominal pain versus 1 of 75 in those without pain. Intussusception and small bowel obstruction can develop from internal herniation, and maternal deaths from herniation and obstruction have been reported (Moore, 2004; Renault, 2012). Bowel obstruction is notoriously difficult to diagnose (Vannevel, 2016; Wax, 2013).

Pregnancy

Because of its associated health successes, bariatric surgery is popular, and many women subsequently become pregnant (Narayanan, 2016). From observational studies, fertility rates improve and obstetrical complication rates decline in women after bariatric surgery compared with morbidly obese controls (Kominiarek, 2017; Yi, 2015). In one these studies, despite surgical treatment, almost half of 670 women were still obese at the time of their first pregnancy after bypass (Johansson, 2015). Nevertheless, the frequency of large-for-gestational-age newborns dropped from 22 to 8.6 percent and of

small-for-gestational-age neonates *rose* from 7.6 to 15.6 percent. In a systematic review, Yi and colleagues (2015) confirmed these fetal weight trends after bariatric surgery. Also, risks for diabetes and preeclampsia were reduced.

Currently, the American College of Obstetricians and Gynecologists (2015) recommends that women who have undergone bariatric surgery be assessed for vitamin and nutritional sufficiency. When indicated, vitamins B_{12} and D, folic acid, and calcium supplementation are given. Vitamin A deficiency is also possible (Chagas, 2013). Women with a gastric band should be monitored by their bariatric team during pregnancy because adjustments of the band may be necessary. Finally, special vigilance is appropriate for signs of internal herniation with intestinal obstruction (Stuart, 2017; Wax, 2013).

CHAPTER 49: Cardiovascular Disorders

Some authorities recommend that women suffering from heart lesions be dissuaded from marriage. This, however, appears to be an extreme view, though, of course, when the lesion is serious and the compensation faulty, the dangers of childbearing should be carefully explained.

—J. Whitridge Williams (1903)

INTRODUCTION

As Williams recognized more than a century ago, pregnancy in those with significant heart disease can be extremely hazardous and may lead to decompensation and death. In an analysis of maternal mortality in the United States between 2011 and 2013, the causes previously responsible for most maternal deaths—hemorrhage, hypertensive disorders, and embolism—continued to show declining rates. In contrast, deaths attributable to cardiovascular diseases were responsible for approximately 26 percent of all pregnancy-related deaths (Creanga, 2017). Cardiovascular diseases also account for significant maternal morbidity and are a prominent reason for obstetrical intensive care unit admissions (Small, 2012).

The rising prevalence of cardiovascular diseases complicating pregnancy is likely multifactorial and includes the higher rates of obesity, hypertension, and diabetes (Klingberg, 2017). Indeed, according to the National Center for Health Statistics, almost half of adults aged 20 and older have at least one risk factor for cardiovascular disease (Fryar, 2012). Another related reason is delayed childbearing. Last, as discussed subsequently (Congenital Heart Disease), an increasing number of women with congenital heart disease are now becoming pregnant.

PHYSIOLOGICAL CONSIDERATIONS IN PREGNANCY

Cardiovascular Physiology

The marked pregnancy-induced anatomical and functional changes in cardiac physiology can have a profound effect on underlying heart disease (Chap. 4, Cardiovascular System). Some of these changes are listed in Table 49-1. Importantly, cardiac output increases approximately 40 percent during pregnancy. Almost half of this total takes place by 8 weeks' gestation and is maximal by midpregnancy (Capeless, 1989). This early rise stems from augmented stroke volume, which results from lowered vascular resistance. Later in pregnancy, resting pulse and stroke volume are even higher because of greater end-diastolic ventricular volume that results from pregnancy hypervolemia. These changes translate to a cardiac output that enlarges across pregnancy to average 40 percent higher at term. These adaptations are even more profound in multifetal pregnancies (Kametas, 2003; Kuleva, 2011). Importantly, intrinsic left ventricular contractility does not change. Thus, normal left ventricular function is maintained during pregnancy. Namely, pregnancy is not characterized by hyperdynamic function or a high cardiac-output state.

TABLE 49-1

Hemodynamic Changes in 10 Normal Pregnant Women at Term Compared with Repeat Values Obtained 12 Weeks Postpartum

Parameter	Change (%)
Cardiac output	+43
Heart rate	+17
Left ventricular stroke work index	+17
Vascular resistance	
Systemic	−21
Pulmonary	−34
Mean arterial pressure	+4
Colloid osmotic pressure	−14

Data from Clark, 1989.

Women with underlying cardiac disease may not always accommodate these changes, and ventricular dysfunction leads to cardiogenic heart failure. A few women with severe cardiac dysfunction can experience evidence of heart failure before midpregnancy. In others, heart failure may develop after 28 weeks' gestation, when pregnancy-induced hypervolemia and cardiac output reach their maximum. In most, however, heart failure develops peripartum, when labor, delivery, and several common obstetrical conditions add undue cardiac burdens. Some of these include preeclampsia, hemorrhage and anemia, and sepsis.

Ventricular Function in Pregnancy

Ventricular volumes and mass accrue to accommodate pregnancy-induced hypervolemia. This is reflected by greater end-systolic and end-diastolic dimensions. At the same time, however, septal thickness and ejection fraction are unchanged. This is because these alterations are accompanied by substantive ventricular remodeling—*plasticity*—which is characterized by eccentric expansion of left-ventricular mass that averages 30 to 35 percent near term. All of these adaptations return to prepregnancy values within a few months postpartum.

Certainly for clinical purposes, ventricular function during pregnancy is normal as estimated by the *Braunwald ventricular function* graph depicted in Figure 4-9. For given filling pressures, there is appropriate cardiac output so that cardiac function during pregnancy is eudynamic. In nonpregnant subjects with a normal heart who sustain a high-output state, the left ventricle undergoes *longitudinal remodeling,* and echocardiographic functional indices of its deformation provide normal values. In pregnancy, there instead appears to be *spherical remodeling,* and these calculated indices that measure longitudinal deformation are depressed. Thus, normal nonpregnant indices are likely inaccurate when used to assess function in pregnant women because they do not take into account the spherical remodeling characteristic of normal pregnancy (Savu, 2012; Stewart, 2016).

Adjusting for these geometrical changes, Melchiorre and coworkers (2016) studied normal cardiac echocardiographic findings in 559 nulliparas at four points during pregnancy and again at 1 year postpartum. At term, significant chamber diastolic dysfunction and impaired myocardial relaxation were evident in approximately 18 and 28 percent of the women studied, respectively. Moreover, a significant proportion of women studied demonstrated a drop in stroke volume index and a tendency toward eccentric remodeling. These findings suggest cardiovascular maladaptation to the increased volume demands in a substantial proportion of apparently normal pregnancies. Of note, significant dyspnea at rest was reported by 7.4 percent of the women at term, most of whom had chamber diastolic dysfunction. Cardiac function and all signs of dyspnea fully recovered at 1 year postpartum.

Cardiac magnetic resonance (MR) imaging increasingly is used to evaluate cardiac structure and function. Stewart and associates (2016) performed cardiac MR imaging studies in 23 women longitudinally across pregnancy and at 12 weeks postpartum. Compared with studies performed at 12 to 16 weeks' gestation, left ventricular mass grew significantly for both normal-weight and overweight women. The calculated geometrical ratio of left ventricular mass to left ventricular end-diastolic volume demonstrated concentric remodeling throughout gestation, which resolved by 12 weeks' postpartum. The right ventricle also remodels (Martin, 2017). Taken together, these observations likely mean that pregnancy causes a mixture of eccentric and concentric ventricular remodeling.

DIAGNOSIS OF HEART DISEASE

The physiological adaptations of normal pregnancy can induce symptoms and alter clinical findings that may confound the diagnosis of heart disease. For example, in normal pregnancy, functional systolic heart murmurs are common, respiratory effort is accentuated, edema frequently accrues in lower extremities after midpregnancy, and fatigue and exercise intolerance often develop. Some systolic flow murmurs can be loud, and normal changes in the various heart sounds depicted in Figure 49-1 may erroneously suggest cardiac disease. In contrast, clinical findings that are more likely to suggest heart disease are listed in Table 49-2.

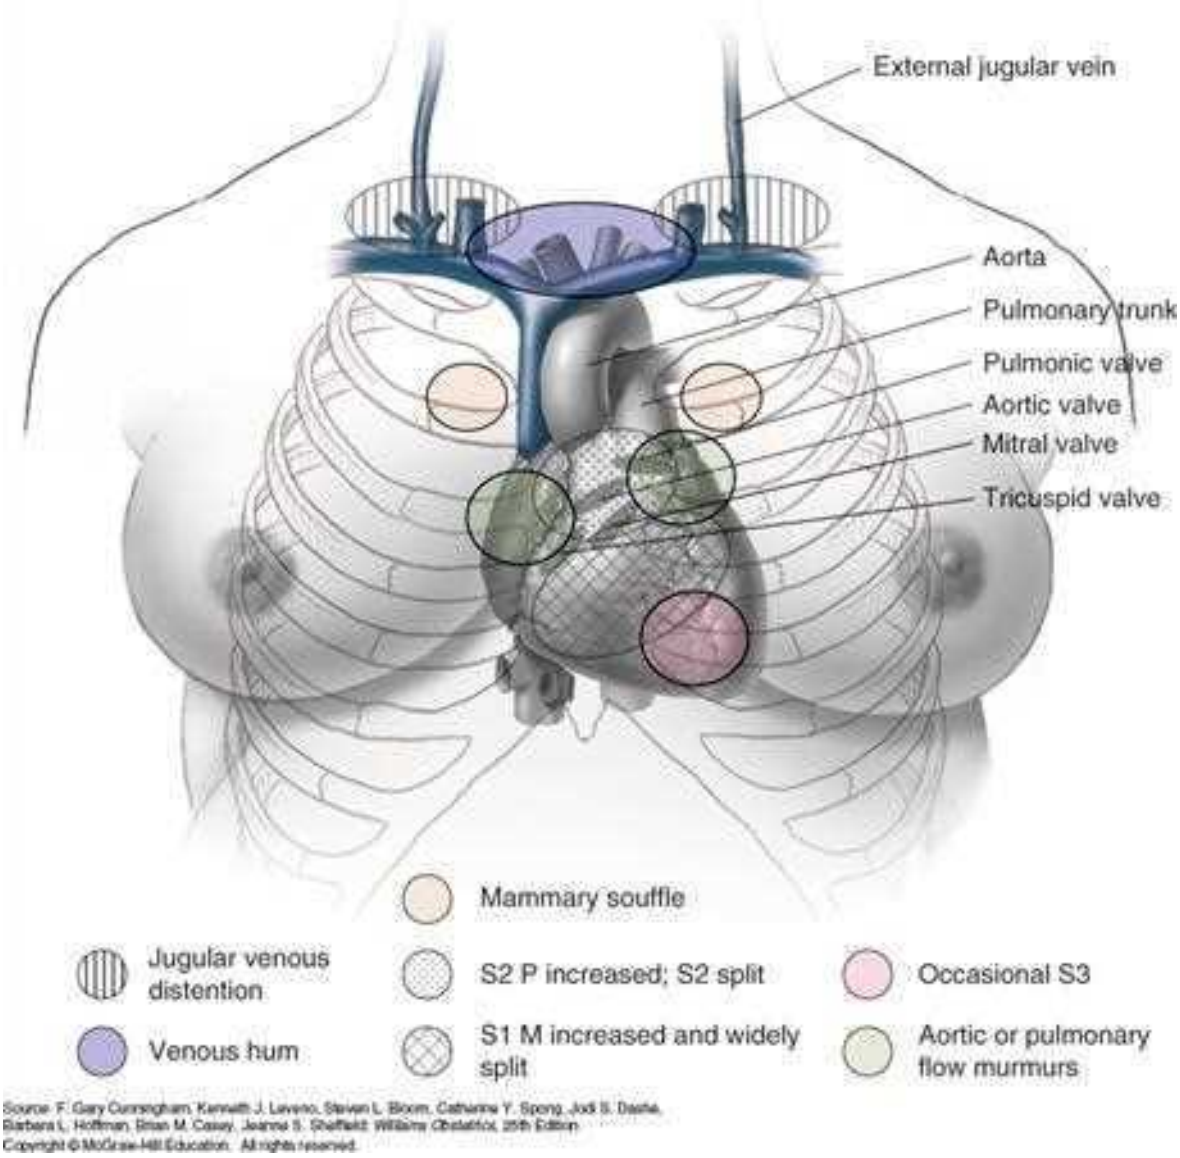
TABLE 49-2

Clinical Indicators of Heart Disease During Pregnancy

Symptoms
Progressive dyspnea or orthopnea
Nocturnal cough
Hemoptysis
Syncope
Chest pain
Clinical Findings
Cyanosis
Clubbing of fingers
Persistent neck vein distention
Systolic murmur grade 3/6 or greater
Diastolic murmur
Cardiomegaly
Persistent tachycardia and/or arrhythmia
Persistent split second sound
Fourth heart sound
Criteria for pulmonary hypertension

FIGURE 49-1

Normal cardiac examination findings in the pregnant woman. S_1 = first sound; M_1 = mitral first sound; S_2 = second sound; P_2 = pulmonary second sound. (Data from Gei, 2001; Hytten, 1991.)

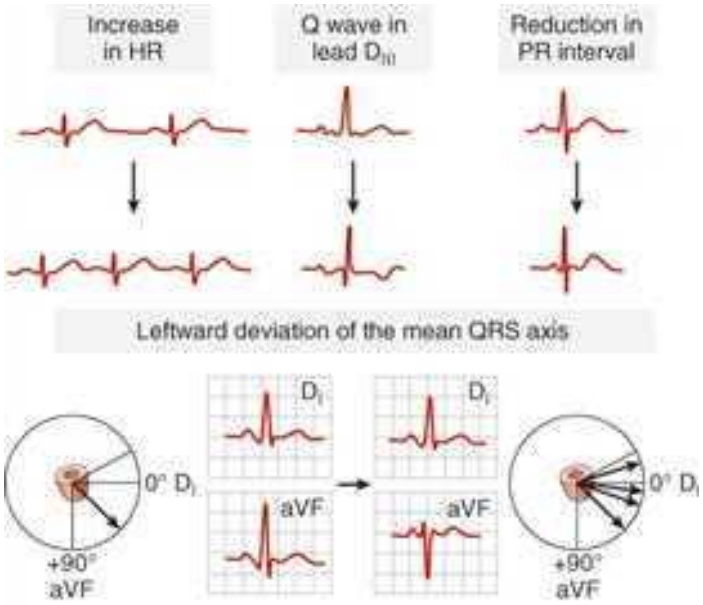


Diagnostic Studies

Noninvasive cardiovascular studies such as electrocardiography, chest radiography, and echocardiography will provide the data necessary for evaluation in most women.

In the *electrocardiogram (ECG)*, an average 15-degree left-axis deviation is found as the diaphragm is elevated in advancing pregnancy. Other findings, depicted in Figure 49-2, include a reduced PR interval, inverted or flattened T waves, and a Q wave in lead D_{III} (Angeli, 2014). Pregnancy does not alter voltage findings. Atrial and ventricular premature contractions are relatively frequent (Carruth, 1981).

FIGURE 49-2
Normal electrocardiograph (ECG) adaptations during pregnancy, including a reduced mean PR interval, increased heart rate, left axis deviation, inverted or flattened T waves and a Q wave in lead D_{III}. (Reproduced with permission from Angeli F, Angeli E, Verdecchia P: Electrocardiographic changes in hypertensive disorders of pregnancy, Hypertens Res. 2014 Nov;37(11):973–975.)



With *radiography*, anteroposterior (AP) and lateral chest radiographs are useful, and when a lead apron shield is used, fetal radiation exposure is minimal. Gross cardiomegaly can usually be excluded, but slight heart enlargement cannot be detected accurately because the heart silhouette normally is larger in pregnancy. This is accentuated further with a portable AP chest radiograph.

Echocardiography is now widely used and permits accurate diagnosis of most heart diseases during pregnancy. Some normal pregnancy-induced changes include a small increase in the dimensions of all cardiac chambers, a slight but significant growth in left ventricular mass, and greater tricuspid and mitral valve regurgitation (Grewal, 2014). Of note, systolic function normally does not change. Savu (2012) and Vitarelli (2011) and their colleagues have provided normal echocardiographic parameters for pregnancy, which are listed in the Appendix (Maternal Echocardiographic Measurements). In some situations, such as complex congenital heart disease, transesophageal echocardiography may be useful.

Cardiovascular MR imaging, compared with echocardiography, is associated with higher reproducibility and is less hindered by ventricular geometry and body habitus. The right ventricle can also be assessed (Nelson, 2017). Ducas and associates (2014) have published normal reference values for pregnancy.

Of other studies, albumin or red cells tagged with technetium-99m are rarely needed during pregnancy to evaluate ventricular function. That said, the estimated fetal radiation exposure from nuclear medicine studies of myocardial perfusion is negligible. It is safe to perform cardiac catheterization with limited fluoroscopy time. During coronary angiography, the mean radiation exposure to the unshielded abdomen is 1.5 mGy, and less than 20 percent of this reaches the fetus (European Society of Cardiology, 2011). Shortening the fluoroscopic time may help to minimize radiation exposure (Raman, 2015; Tuzcu, 2015). In women with clear indications, any minimal theoretical fetal risk is outweighed by maternal benefits (Chap. 46, X-Ray Dosimetry).

Classification of Functional Heart Disease

No clinically applicable test accurately measures functional cardiac capacity. The clinical classification of the New York Heart Association (NYHA) is based on past and present disability and is uninfluenced by physical signs:

Class I. *Uncompromised—no limitation of physical activity:* These women do not have symptoms of cardiac insufficiency or experience anginal pain.

Class II. *Slight limitation of physical activity:* These women are comfortable at rest, but if ordinary physical activity is undertaken, discomfort in the form of excessive fatigue, palpitation, dyspnea, or anginal pain results.

Class III. *Marked limitation of physical activity:* These women are comfortable at rest, but less than ordinary activity causes excessive fatigue, palpitation, dyspnea, or anginal pain.

Class IV. *Severely compromised—inability to perform any physical activity without discomfort*: Symptoms of cardiac insufficiency or angina may develop even at rest. If any physical activity is undertaken, discomfort is increased.

Siu and associates (2001b) expanded the NYHA classification and developed a scoring system for predicting cardiac complications during pregnancy. The system derives from a Canadian prospective analysis of 562 pregnant women with heart disease during 617 pregnancies. Predictors of cardiac complications included: (1) prior heart failure, transient ischemic attack, arrhythmia, or stroke; (2) baseline NYHA class III or IV or cyanosis; (3) left-sided obstruction defined as mitral valve area <2 cm^2, aortic valve area <1.5 cm^2, or peak left ventricular outflow tract gradient >30 mm Hg; and (4) ejection

fraction <40 percent. The risk of pulmonary edema, sustained arrhythmia, stroke, cardiac arrest, or cardiac death was substantially elevated with one of these factors and even more so with two or more. Khairy and colleagues (2006) reported similar findings.

An even more comprehensive risk stratification system is the modified World Health Organization (WHO) Risk Classification of Cardiovascular Disease and Pregnancy (Table 49-3). It is especially useful for assessing maternal risk and for preconceptional counseling. Lu (2015) and Pijuan-Domènech (2015) and their associates in their analyses concluded that the modified WHO classification provides the greatest predictive accuracy for cardiac complications during pregnancy.

TABLE 49-3

World Health Organization (WHO) Risk Classification of Cardiovascular Disease and Pregnancy with Management Recommendations

Risk Category	Associated Conditions
WHO 1—Risk no higher than general population	Uncomplicated, small, or mild: Pulmonary stenosis Ventricular septal defect Patent ductus arteriosus Mitral valve prolapse with no more than trivial mitral regurgitation Successfully repaired simple lesions: Ostium secundum atrial septal defect Ventricular septal defect Patent ductus arteriosus Total anomalous pulmonary venous drainage Isolated ventricular extrasystoles and atrial ectopic beats
• Cardiology consultation once or twice during pregnancy	
WHO 2—Small increase in risk of maternal mortality and morbidity	If otherwise uncomplicated: Unoperated atrial septal defect Repaired Fallot tetralogy Most arrhythmias
• Cardiology consultation each trimester	
WHO 2 or 3—Depends on individual case	Mild left ventricular impairment Hypertrophic cardiomyopathy Native or tissue valvular heart disease not considered WHO 4 Marfan syndrome without aortic dilation Heart transplantation
• Individualized care similar to WHO categories 2 or 3 depending on lesion and disease severity	
WHO 3—Significantly increased risk of maternal mortality or expert cardiac and obstetrical care required	Mechanical valve Systemic right ventricle—congenitally corrected transposition, simple transposition post Mustard or Senning repair Post-Fontan operation Cyanotic heart disease Other complex congenital heart disease
• Care directed by multispecialty team; monthly or bimonthly cardiac and obstetrical monitoring	
WHO 4—Very high risk of maternal mortality or severe morbidity; pregnancy contraindicated and termination discussed	Pulmonary arterial hypertension Severe systemic ventricular dysfunction (NYHA III-IV or LVEF <30%) Previous peripartum cardiomyopathy with any residual impairment of left ventricular function Severe left heart obstruction Marfan syndrome with aorta dilated >40 mm
• Pregnancy contraindicated. • If pregnancy occurs, monthly or bimonthly cardiac and obstetrical monitoring	

Summarized from European Society of Gynecology, 2011; Nanna, 2014; Thorne, 2006; World Health Organization, 2010.

Preconceptional Counseling

Women with severe heart disease will benefit immensely from counseling before pregnancy, and they usually are referred for maternal-fetal medicine or cardiology consultation (Clark, 2012; Seshadri, 2012). Maternal mortality rates generally correlate directly with functional classification, and this relationship may change as pregnancy progresses. From the previously described Canadian study, Siu and colleagues (2001b) observed significant worsening of NYHA class in 4.4 percent of 579 pregnancies in which the baseline class was I or II. As described later, some women have life-threatening cardiac abnormalities that can be reversed by corrective surgery, and subsequent pregnancy becomes less dangerous. In other cases, such as women with mechanical valves taking warfarin, fetal teratogenic concerns predominate. Last, many congenital heart lesions are inherited as polygenic characteristics (Chap. 13, Imprinting). Because of this, some women with congenital heart lesions give birth to similarly affected neonates, and the risk varies widely (Table 49-4).

TABLE 49-4

Risks for Fetal Heart Lesions Related to Affected Family Members

	Congenital Heart Disease in Fetus (%)		
Cardiac Lesion	**Previous Sibling Affected**	**Father Affected**	**Mother Affected**
Marfan syndrome	NS	50	50
Aortic stenosis	2	3	15–18
Pulmonary stenosis	2	2	6–7
Ventricular septal defect	3	2	10–16
Atrial septal defect	2.5	1.5	5–11
Patent ductus arteriosus	3	2.5	4
Coarctation of the aorta	NS	NS	14
Fallot tetralogy	2.5	1.5	2–3

NS = not stated.

Data from Lupton, 2002.

PERIPARTUM MANAGEMENT CONSIDERATIONS

In most instances, management involves a team approach with an obstetrician, cardiologist, anesthesiologist, and other specialists as needed. With complex lesions or other high-risk cases, evaluation by a multidisciplinary team is recommended early in pregnancy. Within this framework, both prognosis and management are influenced by the type and severity of the specific lesion and by the maternal functional classification. In some, pregnancy termination may be advisable.

With rare exceptions, women in NYHA class I and most in class II negotiate pregnancy without morbidity. Special attention is directed toward both prevention and early recognition of heart failure. Of specific risks, infection with sepsis syndrome can precipitate this. Moreover, bacterial endocarditis is a deadly complication of valvular heart disease (Infective Endocarditis). Each woman is instructed to avoid contact with persons who have respiratory infections, including the common cold, and to report at once any evidence for infection. Pneumococcal and influenza vaccines are recommended (Chap. 9, Immunization).

Cigarette smoking is prohibited. Illicit drug use may be particularly harmful, an example being the cardiovascular effects of cocaine or amphetamines. In addition, intravenous drug use raises the risk of infective endocarditis.

Fortunately, women in NYHA class III and IV are uncommon today. In the prior Canadian study, only 3 percent of the approximately 600 pregnancies were complicated by NYHA class III heart disease, and no women had class IV when first seen (Siu, 2001b). If a woman chooses pregnancy, she must understand the risks and is encouraged to be compliant with planned care. In some women, prolonged hospitalization or bed rest is often necessary.

Labor and Delivery

In general, vaginal delivery is preferred, and labor induction is usually safe (Thurman, 2017). From the large Registry on Pregnancy and Cardiac Disease, Ruys and coworkers (2015) compared pregnancy outcomes between 869 women who had a planned vaginal delivery and 393 gravidas who had a planned cesarean delivery. Planned cesarean delivery conferred no advantage for maternal or neonatal outcome.

Cesarean delivery is usually limited to obstetrical indications, and considerations are given for the specific cardiac lesion, overall maternal condition, and availability of experienced anesthesia personnel and hospital capabilities. Some of these women tolerate major surgical procedures poorly and are best delivered in a unit experienced with management of complicated cardiac disease. Occasionally, pulmonary artery catheterization may be needed for hemodynamic monitoring (Chap. 47, Obstetrical Critical Care). In our experiences, however, invasive monitoring is rarely indicated.

Based on her review, Simpson (2012) recommends cesarean delivery for women with the following: (1) dilated aortic root >4 cm or aortic aneurysm; (2) acute severe congestive heart failure; (3) recent myocardial infarction; (4) severe symptomatic aortic stenosis; (5) warfarin administration within 2 weeks of delivery; and (6) need for emergency valve replacement immediately after delivery. Although we agree with most of these, we have some caveats. For example, we prefer aggressive medical stabilization of pulmonary edema followed by vaginal delivery if possible. Also, warfarin anticoagulation can be reversed with vitamin K, plasma, or prothrombin concentrates.

During labor, the mother with significant heart disease should be kept in a semirecumbent position with a lateral tilt. Vital signs are taken frequently between contractions. Increases in pulse rate much above 100 beats per minute (bpm) or respiratory rate above 24 per minute, particularly when associated with dyspnea, may suggest impending ventricular failure. For evidence of cardiac decompensation, intensive medical management must be instituted immediately. Delivery itself does not necessarily improve the maternal condition and, in fact, may worsen it. Moreover, emergency cesarean delivery may be particularly hazardous. Clearly, both maternal and fetal status must be considered in the decision to hasten delivery under these circumstances.

Analgesia and Anesthesia

Relief from pain and from apprehension is important. Although intravenous analgesics provide satisfactory pain relief for some women, continuous epidural analgesia is recommended for most. The major problem with conduction analgesia is maternal hypotension (Chap. 25, Cesarean Delivery). This is especially dangerous in women with intracardiac shunts in whom flow may be reversed. Hypotension can also be life-threatening if there is pulmonary arterial hypertension or aortic stenosis because ventricular output is dependent on adequate preload. In women with these conditions, narcotic regional analgesia or general anesthesia may be preferable.

For vaginal delivery in women with only mild cardiovascular compromise, epidural analgesia given with intravenous sedation often suffices. This has been shown to minimize intrapartum cardiac output fluctuations and allows forceps or vacuum-assisted delivery. Subarachnoid blockade is not generally recommended in women with significant heart disease due to associated hypotension. For cesarean delivery, epidural analgesia is preferred by most clinicians with caveats for its use with pulmonary arterial hypertension (Cardiomyopathies).

Intrapartum Heart Failure

Cardiovascular decompensation during labor may manifest as pulmonary edema with hypoxia or as hypotension, or both. The proper therapeutic approach depends on the specific hemodynamic status and the underlying cardiac lesion. For example, decompensated mitral stenosis with pulmonary edema due to fluid overload is often best treated with aggressive diuresis. If precipitated by tachycardia, heart rate control with β-blocking agents is preferred. Conversely, the same treatment in a woman suffering decompensation and hypotension due to aortic stenosis could prove fatal. Unless the underlying pathophysiology is understood and the cause of the decompensation is clear, empirical therapy may be hazardous.

Puerperium

Women who have shown little or no evidence of cardiac compromise during pregnancy, labor, or delivery may still decompensate postpartum. Fluid mobilized into the intravascular compartment and reduced peripheral vascular resistance place higher demands on myocardial performance. Therefore, meticulous care is continued into the puerperium (Keizer, 2006; Zeeman, 2006). Postpartum hemorrhage, anemia, infection, and thromboembolism are much more serious complications with heart disease. Indeed, these factors often act in concert to precipitate postpartum heart failure. In addition, sepsis and severe preeclampsia cause or worsen pulmonary edema because of endothelial activation and capillary-alveolar leakage (Chap. 47, Acute Pulmonary Edema).

For puerperal tubal sterilization after vaginal delivery, the procedure can be delayed up to several days to ensure that the mother has normalized hemodynamically and that she is afebrile, not anemic, and ambulating normally. Alternatively, for those desiring future fertility, detailed contraceptive advice is available in the *U.S. Medical Eligibility Criteria for Contraceptive Use* guidelines (Curtis, 2016).

SURGICALLY CORRECTED HEART DISEASE

Most clinically significant congenital heart lesions are repaired during childhood. Examples of those frequently not diagnosed until adulthood include atrial septal defects, pulmonic stenosis, bicuspid aortic valve, and aortic coarctation (Brickner, 2014). In some cases, the defect is mild and surgery is not required. In others, a significant anomaly is amenable to corrective surgery, performed ideally before pregnancy. In rare instances, surgical corrections are necessary during pregnancy.

Valve Replacement before Pregnancy

Numerous reports describe subsequent pregnancy outcomes in women who have a prosthetic mitral or aortic valve. The type of valve, either mechanical or biological, is paramount. From one review, the overall estimated maternal mortality rate was 1.2 percent. The rate was 1.8 percent in the mechanical valve subgroup and 0.7 percent in the bioprosthetic subgroup (Lawley, 2015). Using the Registry of Pregnancy and Cardiac Disease, the maternal mortality rate was 1.4 percent in women with a mechanical heart valve and 1.5 percent in women with a tissue heart valve (van Hagen, 2015). Mechanical heart valve thrombosis complicated 4.7 percent. In total, only 58 percent with a mechanical heart valve had a pregnancy free of serious adverse events compared with 79 percent of patients with a tissue heart valve (Table 49-5). Because of thrombosis risks, anticoagulation may be requisite, but its complications are described in the next section. Thus, pregnancy is undertaken only after serious consideration for women with a prosthetic mechanical valve.

TABLE 49-5

Selected Outcomes in Pregnancies Complicated by Heart-Valve Replacement[a]

Outcome	Mechanical Valve (n = 212)	Tissue Valve (n = 134)
Maternal mortality	3 (1.4)	2 (1.5)
Heart failure	162 (7.5)	1 (8.2)
Thrombotic complication	13 (6.1)	1 (0.7)
Hemorrhagic complication	49 (23)	7 (5.1)
Pregnancy loss <24 weeks	33 (15.6)	2 (1.5)
Stillbirth	6 (2.8)	0 (0)
Preterm birth <37 weeks	29 (18)	24 (19)

Data presented as n (%).

[a]Data from the Registry of Pregnancy and Cardiac Disease.

Data from van Hagen, 2015.

Bouhout and coworkers (2014) reported the outcomes of 27 pregnancies in 14 women who underwent an *aortic valve* replacement prior to pregnancy. Seven of the 27 pregnancies occurred in five women with a mechanical prosthesis. Complications in this group included two embolic myocardial infarctions and one each of miscarriage, postpartum hemorrhage, placental abruption, and preterm birth. In the bioprosthetic group, nine miscarriages, two hospitalizations for syncope, and one preterm birth were noted.

Porcine tissue valves are safer during pregnancy, primarily because thrombosis is rare and anticoagulation is not required (see Table 49-5). Despite this, valvular dysfunction with cardiac deterioration poses a serious risk. Another drawback is that bioprostheses are less durable than mechanical ones, and valve replacement longevity averages 10 to 15 years. Cleuziou and colleagues (2010) concluded that pregnancy does not accelerate the risk for replacement. But, Nappi and associates (2014) found an association between pregnancy and valve deterioration in women with cryopreserved mitral homograft valves.

Anticoagulation

This is critical for women with mechanical prosthetic valves. Unfortunately, warfarin is the most effective anticoagulant for preventing maternal thromboembolism but causes harmful fetal effects (Chap. 12, Warfarin). Anticoagulation with heparin is less hazardous for the fetus, however, the risk of maternal thromboembolic complications is much higher (McLintock, 2011).

Warfarin is teratogenic and causes miscarriage, stillbirths, and fetal malformations. In one study of 71 women given warfarin throughout pregnancy, the rates of miscarriage were 32 percent; stillbirth, 7 percent; and embryopathy, 6 percent (Cotrufo, 2002). The risk was highest when the mean daily dose of warfarin exceeded 5 mg. Similarly, the American College of Cardiology and the American Heart Association estimate that the risk of embryopathy is dose dependent, with a lower risk—less than 3 percent—if the dose of warfarin is ≤5 mg/d (Nishimura, 2014). If the dosage is >5 mg/d, the risk of embryopathy exceeds 8 percent.

Anticoagulation for mechanical valves using *low-dose* unfractionated heparin is definitely inadequate and carries a high associated maternal mortality rate (Chan, 2000; Iturbe-Alessio, 1986). Even *full* anticoagulation with either unfractionated heparin (UFH) or one of the low-molecular-weight heparins (LMWH) is associated with valvular thrombosis (Leyh, 2002, 2003; Rowan, 2001). But, compliance with twice-daily dosing and therapeutic monitoring may have contributed (McLintock, 2014). Thus, if full anticoagulation with dose-adjusted UFH or LMWH is used, meticulous monitoring is recommended. The activated partial thromboplastin time (aPTT) should be at least 2 times control or anti-Xa levels should be 0.8 to 1.2 U/mL at 4 to 6 hours postdose (Nishimura, 2014).

Recommendations for Anticoagulation

Several different treatment options—none of which are completely ideal—are principally based on consensus opinion. Two are from the American College of Chest Physicians and the other jointly from the American College of Cardiology and the American Heart Association (Bates, 2012; Nishimura, 2014). Any of four regimens is recommended. First, adjusted-dose LMWH is given twice daily, with a peak anti-Xa level drawn 4 hours after dosing. In another, adjusted UFH is dosed every 12 hours to keep the midinterval aPTT twice control or anti Xa level between 0.35–0.70 U/mL. As a third option, LMWH or UFH is given as just described until 13 weeks, and then warfarin is substituted until near delivery, at which time it is replaced by LMWH or UFH. Last, in women judged to carry a high risk of thrombosis and for whom the efficacy and safety of heparins are concerns, warfarin is suggested throughout pregnancy. Heparin is then substituted close to delivery. In addition, aspirin, 75 to 100 mg, is given daily.

Heparin is discontinued just before delivery. If delivery supervenes while the anticoagulant is still effective, and extensive bleeding is encountered, then protamine sulfate is given intravenously. Anticoagulant therapy with warfarin or heparin may be restarted 6 hours following vaginal delivery, usually with no problems. Following cesarean delivery, full anticoagulation is withheld, but the optimal duration is not exactly known. The American College of Obstetricians and Gynecologists (2017) advises resuming unfractionated or low-molecular-weight heparin 6 to 12 hours after cesarean delivery. It is our practice, however, to wait at least 24 hours following a major surgical procedure.

Because warfarin, LMWH, and UFH do not accumulate in breast milk, they do not induce an anticoagulant effect in the newborn. These anticoagulants are compatible with breastfeeding (American College of Obstetricians and Gynecologists, 2017).

Cardiac Surgery During Pregnancy

Although usually postponed until after delivery, valve replacement or other cardiac surgery during pregnancy may be lifesaving. Several reviews confirm that such surgery is associated with major maternal and fetal morbidity and mortality. At the Mayo Clinic between 1976 and 2009, 21 pregnant women underwent cardiothoracic surgery requiring cardiopulmonary bypass (John, 2011). The procedures included valve replacements, myxoma excisions, aneurysm repairs, patent foramen ovale closure, prosthetic aortic valve thrombectomy, and septal myectomy. Median cardiopulmonary bypass time was 53 minutes, with a range of 16 to 185 minutes. One woman died 2 days after surgery, three fetuses died, and 52 percent were delivered before 36 weeks' gestation. Elassy and associates (2014) described 23 women who underwent urgent open cardiac surgery for severe valve malfunction. Two women and 10 fetuses—all at a gestational age below 28 weeks—died before hospital discharge. Only six fetuses were delivered at term. To optimize outcomes, Chandrasekhar and coworkers (2009) recommend that surgery be elective when possible, pump flow rate should remain >2.5 L/min/m^2, normothermic perfusion pressure should exceed 70 mm Hg, and hematocrit should be kept >28 volumes percent.

Pregnancy after Heart Transplantation

Many successful pregnancies have followed cardiac transplantation (Abdalla, 2014; Vos, 2014). The current recommendations from The International Society of Heart and Lung Transplantation do not discourage pregnancy in stable heart transplant recipients who are more than 1 year posttransplant (Costanzo, 2010). Obviously, a highly specialized level of care with a multidisciplinary team is necessary.

The transplanted heart appears to responds normally to pregnancy-induced alterations (Key, 1989; Kim, 1996). Despite this, complications are common during pregnancy (Dashe, 1998). Of 53 pregnancies in 37 heart recipients, almost half developed hypertension, and 22 percent suffered at least one rejection episode during pregnancy (Armenti, 2002; Miniero, 2004). They were delivered—usually by cesarean—at a mean of 37 to 38 weeks' gestation. Three fourths of neonates were liveborn. At follow-up, at least five women had died more than 2 years postpartum. Another analysis of 25 such women with 42 pregnancies found no maternal deaths. Major complications included two rejections during the early puerperium, two cases of renal failure, and 11 spontaneous abortions (Estensen, 2011). Five women died 2 to 12 years after delivery. And from the United Kingdom, Mohamed-Ahmed and colleagues (2014) identified 14 women with transplants between 2007 and 2011. Graft rejections occurred in two women, one of whom died.

VALVULAR HEART DISEASE

Rheumatic fever is uncommon in the United States because of less crowded living conditions, penicillin availability, and evolution of nonrheumatogenic streptococcal strains. Still, it remains the chief cause of serious mitral valvular disease in women of childbearing age in the nonindustrialized world (Nanna, 2014; Roeder, 2011).

Mitral Stenosis

Rheumatic endocarditis causes most mitral stenosis lesions. The normal mitral valve surface area is 4.0 cm^2, and when stenosis narrows this to <2.5 cm^2, symptoms usually develop (Desai, 2000). The contracted valve impedes blood flow from the left atrium to the ventricle.

With more severe stenosis, the left atrium dilates, left atrial pressure is chronically elevated, and significant passive pulmonary hypertension develops (Table 49-6). These women have a relatively fixed cardiac output, and thus the increased preload of normal pregnancy and other factors that raise cardiac output may cause ventricular failure and pulmonary edema. Indeed, a fourth of women with mitral stenosis have cardiac failure for the first time during pregnancy (Caulin-Glaser, 1999). The resulting pulmonary venous hypertension and pulmonary edema create symptoms of dyspnea, fatigue, palpitations, cough, and hemoptysis. The classic murmur may not be heard in some women, and this clinical picture at term may be confused with idiopathic peripartum cardiomyopathy (Cunningham, 1986, 2012).

TABLE 49-6

Major Cardiac Valve Disorders

Type	Cause	Pathophysiology	Pregnancy
Mitral stenosis	Rheumatic valvulitis	LA dilation and passive pulmonary hypertension Atrial fibrillation	Heart failure from fluid overload, tachycardia
Mitral insufficiency	Rheumatic valvulitis Mitral valve prolapse LV dilation	LV dilation and eccentric hypertrophy	Ventricular function improves with afterload decrease
Aortic stenosis	Congenital bicuspid valve	LV concentric hypertrophy, decreased cardiac output	Moderate stenosis is tolerated; severe is life-threatening with decreased preload, e.g., obstetrical hemorrhage or regional analgesia
Aortic insufficiency	Rheumatic valvulitis Connective tissue disease Congenital	LV hypertrophy and dilation	Ventricular function improves with afterload decrease
Pulmonary stenosis	Rheumatic valvulitis Congenital	Severe stenosis associated with RA and RV enlargement	Mild stenosis usually well tolerated; severe stenosis associated with right heart failure and atrial arrhythmias

LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

Also with significant stenosis, tachycardia shortens ventricular diastolic filling time and elevates the mitral gradient. This too may lead to pulmonary edema. Thus, sinus tachycardia is often treated prophylactically with β-blocking agents. Atrial tachyarrhythmias, including fibrillation, are common in mitral stenosis and are treated aggressively. Atrial fibrillation also predisposes to mural thrombus formation and cerebrovascular embolization that can cause stroke (Chap. 60, Ischemic Stroke). Atrial thrombosis can develop despite a sinus rhythm (Hameed, 2005).

Pregnancy Outcomes

In general, complications are directly associated with the degree of valvular stenosis. Women with a mitral-valve area <2 cm^2 are at greatest risk (Siu, 2001b). In one study of 46 gravidas with mitral stenosis, 43 percent developed heart failure, and 20 percent developed arrhythmias (Hameed, 2001). Fetal-growth restriction was more common in women with a mitral valve area <1.0 cm^2.

Prognosis is also related to maternal functional capacity. Among 486 pregnancies complicated by rheumatic heart disease—predominantly mitral stenosis—8 of 10 maternal deaths were in women in NYHA classes III or IV (Sawhney, 2003).

Management

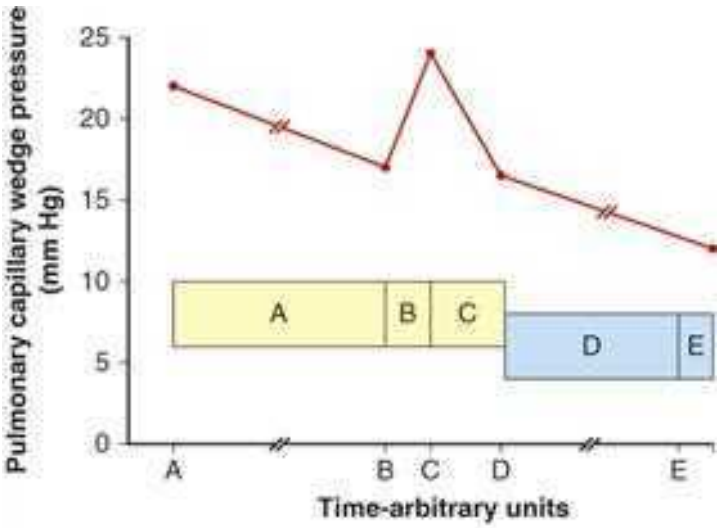
Limited physical activity is generally recommended in women with mitral stenosis. If symptoms of pulmonary congestion develop, activity is further reduced, dietary sodium is restricted, and diuretics are given (Siva, 2005). Also, β-blocker drug therapy slows the ventricular response to activity. If new-onset atrial fibrillation develops, intravenous verapamil, 5 to 10 mg, is given, or electrocardioversion is performed. For chronic fibrillation, digoxin, a β-blocker, or a calcium-channel blocker can slow ventricular response. Therapeutic anticoagulation is indicated with persistent fibrillation, left atrial thrombus, and/or a history of embolism (Nanna, 2014).

Surgical intervention is considered for women with symptomatic severe mitral stenosis and in those with lesser degrees of mitral stenosis—mitral-valve area 1.5 to 2.0 cm^2—complicated by recurrent systemic embolization or severe pulmonary hypertension. Balloon valvuloplasty is preferred if the valve is pliable (Bui, 2014). In one review of 71 pregnant women with tight mitral stenosis and heart failure who underwent percutaneous valvuloplasty, 98 percent were either NYHA class I or II at delivery (Esteves, 2006). At a mean of 44 months, the total event-free maternal survival rate was 54 percent. However, eight women required another surgical intervention. All of the 66 newborns who were delivered at term had normal growth and development.

Labor and delivery are particularly stressful for women with symptomatic mitral stenosis (Fig. 49-3). Uterine contractions increase cardiac output by increasing circulating blood volume. Pain, exertion, and anxiety cause tachycardia with possible rate-related heart failure. Epidural analgesia for labor is ideal, but fluid overload is avoided. Abrupt expansion in preload may raise pulmonary capillary wedge pressure and cause pulmonary edema. Wedge pressures rise immediately postpartum. One hypothesis for this suggests that the loss of the low-resistance placental circulation couples with venous "autotransfusion" from a now-empty, contracted uterus and from the lower extremities and pelvis (Clark, 1985).

FIGURE 49-3

Mean pulmonary capillary wedge pressure measurements (*red graph line*) in eight women with mitral valve stenosis. Shaded yellow and blue boxes are mean (± 1 SD) pressures in nonlaboring normal women at term. **A.** First-stage labor. **B.** Second-stage labor 15 to 30 minutes before delivery. **C.** Postpartum 5 to 15 minutes. **D.** Postpartum 4 to 6 hours. **E.** Postpartum 18 to 24 hours. (Data from Clark, 1985, 1989.)



Most prefer vaginal delivery in women with mitral stenosis. Elective induction is reasonable so that labor and delivery are attended by a scheduled, experienced team. With severe stenosis and chronic heart failure, insertion of a pulmonary artery catheter may help guide management.

Mitral Insufficiency

A trivial degree of mitral insufficiency is found in most normal patients. But if mitral valve leaflets align improperly during systole, abnormal degrees of mitral regurgitation can develop. This is eventually followed by left ventricular dilation and eccentric hypertrophy (see Table 49-6). *Acute mitral insufficiency* is caused by chordae tendineae rupture, papillary muscle infarction, or leaflet perforation from infective endocarditis. *Chronic mitral regurgitation*, in contrast, may derive from rheumatic fever, connective tissue diseases, mitral valve prolapse, or left ventricular dilation of any etiology—for example, dilated cardiomyopathy. Less common causes include a calcified mitral annulus, possibly some appetite suppressants, and in older women, ischemic heart disease. Mitral valve vegetations—*Libman-Sacks endocarditis*—are relatively common in women with antiphospholipid antibodies (Shroff, 2012). These sometimes coexist with systemic lupus erythematosus.

In nonpregnant patients, symptoms from mitral valve insufficiency are rare, and valve replacement is seldom indicated unless infective endocarditis develops. During pregnancy, mitral regurgitation is similarly well tolerated, probably because the lowered systemic vascular resistance yields less regurgitation. Heart failure rarely develops during pregnancy, and occasionally tachyarrhythmias or severely depressed systolic function require treatment.

Mitral Valve Prolapse

This diagnosis implies the presence of a pathological connective tissue disorder—often termed *myxomatous degeneration*—which may involve the valve leaflets themselves, the annulus, or the chordae tendineae. Mitral insufficiency may develop. Most women with mitral valve prolapse are asymptomatic and are diagnosed during routine examination or echocardiography. The few women with symptoms have anxiety, palpitations, atypical chest pain, dyspnea with exertion, and syncope (Guy, 2012).

Pregnant women with mitral valve prolapse rarely have cardiac complications. Hypervolemia may even improve alignment of the mitral valve, and women without pathological myxomatous degeneration generally have excellent pregnancy outcomes (Leśniak-Sobelga, 2004). For women who are symptomatic, β-blocking drugs diminish sympathetic tone, relieve chest pain and palpitations, and reduce the risk of life-threatening arrhythmias.

Aortic Stenosis

Usually a disease of aging, aortic stenosis in younger women is most likely a congenital lesion. Since the decline in rheumatic disease incidence, aortic stenosis is less common, and the most frequent cause in the United States is a bicuspid valve (Friedman, 2008). A normal aortic valve has an area of 3 to 4 cm^2, with a pressure gradient <5 mm Hg. If the valve area is <1 cm^2, there is severe obstruction to flow and a progressive pressure overload on the left ventricle (Roeder, 2011). Concentric left ventricular hypertrophy follows, and if it is severe, end-diastolic pressures become elevated, ejection fraction declines, and cardiac output is reduced (see Table 49-6). Characteristic manifestations develop late and include chest pain, syncope, heart failure, and sudden death from arrhythmias. Life expectancy averages only 5 years after exertional chest pain develops, and valve replacement is indicated for symptomatic patients.

Pregnancy

Clinically significant aortic stenosis is infrequent during pregnancy. Mild-to-moderate degrees of stenosis are well tolerated, however, severe disease is life-threatening. The principal underlying hemodynamic problem is the fixed cardiac output associated with severe stenosis. During pregnancy, several common events acutely lower preload further and thus aggravate the fixed cardiac output. These include vena caval occlusion from the gravid uterus, regional analgesia, and hemorrhage. Importantly, these also decrease cardiac, cerebral, and uterine perfusion. It follows that severe aortic stenosis may be extremely dangerous during pregnancy. From the earlier-cited Canadian study, complication rates were higher if the aortic valve area measured <1.5 cm^2 (Siu, 2001b). And in the report by Hameed and associates (2001), the maternal mortality rate with aortic stenosis was 8 percent. Women with valve pressure gradients >100 mm Hg appear to be at greatest risk.

Management

For asymptomatic women with aortic stenosis, no treatment except close observation is required. Management of a symptomatic woman includes strict limitation of activity and prompt treatment of infections. If symptoms persist despite bed rest, surgical intervention may be considered. Catheter-based valvuloplasty is associated with risks to both the mother and fetus and is not very effective in the long term (Pessel, 2014; Reich, 2004). The aortic valve can again narrow or new aortic regurgitation may develop. The alternative surgical approach—valve replacement—is associated with significant risk of fetal demise due to the effects of cardiac bypass (Datt, 2010). Accordingly, the American College of Cardiology, the American Heart Association, and the European Society of Cardiology recommend delaying conception until after surgical correction for severe aortic stenosis (Bonow, 2008).

For women with critical aortic stenosis, intensive monitoring during labor is essential. Pulmonary artery catheterization may be helpful because of the narrow margin separating fluid overload from hypovolemia. Women with aortic stenosis are dependent on adequate end-diastolic ventricular filling pressures to maintain cardiac output and systemic perfusion. Abrupt drops in end-diastolic volume may result in hypotension, syncope, myocardial infarction, and sudden death. Thus, avoiding diminished ventricular preload and maintaining cardiac output are key. During labor and delivery, affected women are best managed on the “wet” side. This provides a margin of safety in intravascular volume in anticipation of possible hemorrhage. In women with a competent mitral valve, pulmonary edema is rare.

During labor, narcotic epidural analgesia seems ideal and avoids potentially hazardous hypotension. Easterling and coworkers (1988) studied the effects of epidural analgesia in five women with severe stenosis and demonstrated immediate and profound effects from decreased filling pressures. Xia and associates (2006) emphasize slow administration of dilute local anesthetic agents into the epidural space. In hemodynamically stable women, forceps or vacuum delivery is used for standard obstetrical indications.

Aortic Insufficiency

Aortic valve regurgitation or insufficiency allows diastolic flow of blood from the aorta back into the left ventricle. Frequent causes of abnormal insufficiency are rheumatic fever, connective tissue abnormalities, and congenital lesions. With Marfan syndrome, the aortic root may dilate and create regurgitation (Diseases of the Aorta). Acute insufficiency may also develop with bacterial endocarditis or aortic dissection (Infective Endocarditis and Diseases of the Aorta). Last, aortic and mitral valve insufficiency have both been linked to the appetite suppressants fenfluramine and dexfenfluramine and to the ergot-derived dopamine agonists cabergoline and pergolide (Gardin, 2000; Schade, 2007; Zanettini, 2007). With chronic insufficiency, left ventricular hypertrophy and dilation develop and are followed by slow-onset fatigue, dyspnea, and pulmonary edema, although rapid deterioration usually follows (see Table 49-6).

Aortic insufficiency is generally well tolerated during pregnancy. Like mitral valve insufficiency, diminished vascular resistance is thought to improve hemodynamic function. If symptoms of heart failure develop, diuretics are given and bed rest is encouraged.

Pulmonic Stenosis

This lesion is usually congenital and also may be associated with Fallot tetralogy or Noonan syndrome. The greater hemodynamic burden of pregnancy can precipitate right-sided heart failure or atrial arrhythmias in women with severe stenosis. Surgical correction ideally is done before pregnancy, but if symptoms progress, a balloon valvuloplasty may be necessary antepartum (Galal, 2015; Siu, 2001a).

In studying pregnancy outcomes, Drenthen and colleagues (2006) found infrequent cardiac complications in a group of 81 pregnancies in 51 Dutch women with pulmonic stenosis. The NYHA classification worsened in two women, and nine experienced palpitations or arrhythmias. No changes in pulmonary valvular function or other adverse cardiac events were reported. However, noncardiac complication rates were significant—17 percent had preterm delivery, 15 percent had hypertension, and 4 percent developed thromboembolism.

CONGENITAL HEART DISEASE

The incidence of congenital heart disease in the United States approximates 11 per 1000 liveborn neonates (Egbe, 2014). With modern surgeries, approximately 90 percent of those born with congenital heart disease survive to childbearing age, and it is now the most common type of heart disease encountered during pregnancy (Brickner, 2014; Lindley, 2015). Specifically, analysis from the United States Nationwide Inpatient Sample database shows a linear rise in the prevalence of congenital heart disease between 2000 and 2010—from 6.4 to 9.0 per 10,000 women admitted for delivery (Thompson, 2015).

Of pregnancy outcomes in women with congenital heart disease compared with those without, the odds of cardiovascular and obstetrical complications were 10.5 to 35.5 and 1.2 to 2.1 times higher, respectively (Thompson, 2015). Moreover, maternal mortality rates were greater for women with congenital heart disease than for unaffected gravidas—17.8 and 0.7 per 10,000 deliveries, respectively. Opotowsky and coworkers (2012) reported similar risks.

Atrial Septal Defects

Approximately one fourth of all adults has a patent foramen ovale (Miller, 2015). Most atrial septal defects (ASDs) are asymptomatic until the third or fourth decade. The secundum-type defect accounts for 70 percent, and associated mitral valve myxomatous abnormalities with prolapse are common. Most recommend repair if ASD is discovered in adulthood. Pregnancy is well tolerated unless pulmonary hypertension has developed, but this is uncommon (Geva, 2014). Treatment of ASD during pregnancy is indicated for congestive heart failure or an arrhythmia. Based on their review, Aliaga and colleagues (2003) concluded that the risk of endocarditis with an ASD is negligible.

With the potential to shunt blood from right to left, a *paradoxical embolism,* that is, entry of a venous thrombus through the septal defect and into the systemic arterial circulation, is possible and may cause an embolic stroke (Erkut, 2006; Miller, 2015). In asymptomatic women with ASD, thromboembolism prophylaxis is problematic, and the heterogeneous recommendations have been summarized by Kizer and Devereux (2005). Compression stockings and prophylactic heparin have also been recommended for a pregnant woman with an ASD who is immobile or has another risk factor for thromboembolism (Head, 2005).

Ventricular Septal Defects

These lesions close spontaneously during childhood in 90 percent of cases. Most defects are paramembranous, and the degree of left-to-right shunt and associated physiological derangements are related to lesion size. In general, if the defect measures <1.25 cm^2, pulmonary hypertension and heart failure do not develop. If the effective defect size exceeds that of the aortic valve orifice, symptoms rapidly develop. For these reasons, most children undergo surgical repair before pulmonary hypertension develops. Adults with unrepaired large defects develop left ventricular failure and pulmonary hypertension and have a high incidence of bacterial endocarditis (Brickner, 2000, 2014).

Pregnancy is well tolerated with small-to-moderate sized shunts. If pulmonary arterial pressures reach systemic levels, however, there is reversal or bidirectional flow—*Eisenmenger syndrome* (Pulmonary Hypertension). When this develops, the maternal and fetal mortality rates are significantly higher,

and thus, pregnancy is not generally advisable. Bacterial endocarditis is more common with unrepaired defects, and antimicrobial prophylaxis is often required (Infective Endocarditis). As shown in Table 49-4, 10 to 16 percent of offspring born to these women also have a ventricular septal defect.

Atrioventricular Septal Defects

These account for approximately 3 percent of all congenital cardiac malformations and are distinct from isolated atrial or ventricular septal defects. An atrioventricular (AV) septal defect is characterized by a common, ovoid AV junction. This defect is associated with aneuploidy, Eisenmenger syndrome, and other malformations (Altin, 2015). Compared with simple septal defects, complications are more frequent during pregnancy. In a review of 48 pregnancies in 29 affected women, complications included persistent deterioration of NYHA class in 23 percent, significant arrhythmias in 19 percent, and heart failure in 2 percent (Drenthen, 2005b). Congenital heart disease was identified in 15 percent of the offspring.

Persistent (Patent) Ductus Arteriosus

The ductus connects the proximal left pulmonary artery to the descending aorta just distal to the left subclavian artery. Functional closure of the ductus from vasoconstriction occurs shortly after term birth. The physiological consequences with its persistence are related to its size. Most significant lesions are repaired in childhood, but for individuals who do not undergo repair, the mortality rate is high after the fifth decade (Brickner, 2014). In some younger women with an unrepaired ductus during pregnancy, however, pulmonary hypertension, heart failure, or cyanosis will develop if systemic blood pressure falls and leads to shunt reversal of blood from the pulmonary artery into the aorta (Vashisht, 2015). A sudden blood pressure decline at delivery—such as with regional analgesia or hemorrhage—may lead to fatal collapse. Accordingly, hypotension is ideally avoided but treated vigorously if it develops. Prophylaxis for bacterial endocarditis is indicated at delivery for unrepaired defects (Infective Endocarditis). As shown in Table 49-4, the incidence of inheritance approximates 4 percent.

Cyanotic Heart Disease

When congenital heart lesions produce right-to-left shunting of blood past the pulmonary capillary bed, cyanosis develops. The classic and most commonly encountered lesion in adults and during pregnancy is the *Fallot tetralogy* (Lindley, 2015). This is characterized by a large ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta that receives blood from both the right and left ventricles. The magnitude of the shunt varies inversely with systemic vascular resistance. Hence, during pregnancy, when peripheral resistance declines, the shunt increases and cyanosis worsens.

Generally, women with cyanotic heart disease do poorly during pregnancy. With uncorrected Fallot tetralogy, maternal mortality rates approach 10 percent. There is a relationship between chronic hypoxemia, polycythemia, and pregnancy outcomes such as miscarriage and perinatal morbidity. When hypoxemia is intense enough to stimulate a rise in hematocrit above 65 volumes percent, pregnancy wastage is virtually 100 percent.

Although not all cyanotic lesions are repairable, with satisfactory surgical correction before pregnancy, maternal and fetal outcomes are much improved. In a review of 197 pregnancies in 99 women with surgically corrected Fallot tetralogy, pregnancy was usually well tolerated, and no mothers died. Still, almost 9 percent of pregnancies were complicated by adverse cardiac events including new-onset or worsening arrhythmias and heart failure (Balci, 2011; Kamiya, 2012). For women with a pulmonary valve replacement, pregnancy does not adversely affect graft function (Oosterhof, 2006). Prior to or after conception, women with Fallot tetralogy are offered genetic counseling and evaluation for 22q11 deletion syndrome (Lindley, 2015).

Some women with *Ebstein anomaly,* characterized by a malpositioned and malformed tricuspid valve, may reach reproductive age. Right ventricular failure from volume overload and cyanosis are common during pregnancy. In the absence of cyanosis, heart failure, or significant arrhythmias, affected women usually tolerate pregnancy well (Brickner, 2014).

Pregnancy after Surgical Repair

Transposition of the Great Vessels

Pregnancy following surgical correction of transposition has prominent risks. Canobbio (2006) and Drenthen (2005a), each with their colleagues, described outcomes of 119 pregnancies in 68 women—90 percent had a prior Mustard procedure and 10 percent a previous Senning procedure. During pregnancy, one fourth had arrhythmias, 12 percent developed heart failure, and one subsequently required cardiac transplantation. One woman died suddenly a month after delivery, and another died 4 years later. A third of the newborns were delivered preterm. In another report of 60 pregnancies in 34 women who had undergone transposition repair, approximately a fourth ended in miscarriage or abortion, and another fourth delivered preterm (Trigas, 2014). Deterioration in functional class occurred in seven women, and documented deterioration in systolic function occurred in four women. Finally, two women required resuscitation during delivery, and one experienced supraventricular tachycardia during labor. Of other defects, in women with previously repaired *truncus arteriosus* and *double-outlet right ventricle,* successful—although eventful—pregnancies have also been described (Drenthen, 2008; Hoendermis, 2008).

Single Functional Ventricle

With *hypoplastic left heart syndrome,* almost 70 percent of affected women are now expected to survive into adulthood and frequently become pregnant (Feinstein, 2012). Those who have undergone a *Fontan repair* are at particularly high risk for complications. In brief, this procedure involves diverting blood via a surgical anastomosis from the vena cava to the pulmonary artery without passing through the right ventricle. Blood flows passively to the pulmonary vasculature. Thus, patients with a Fontan palliation are very preload dependent (Lindley, 2015).

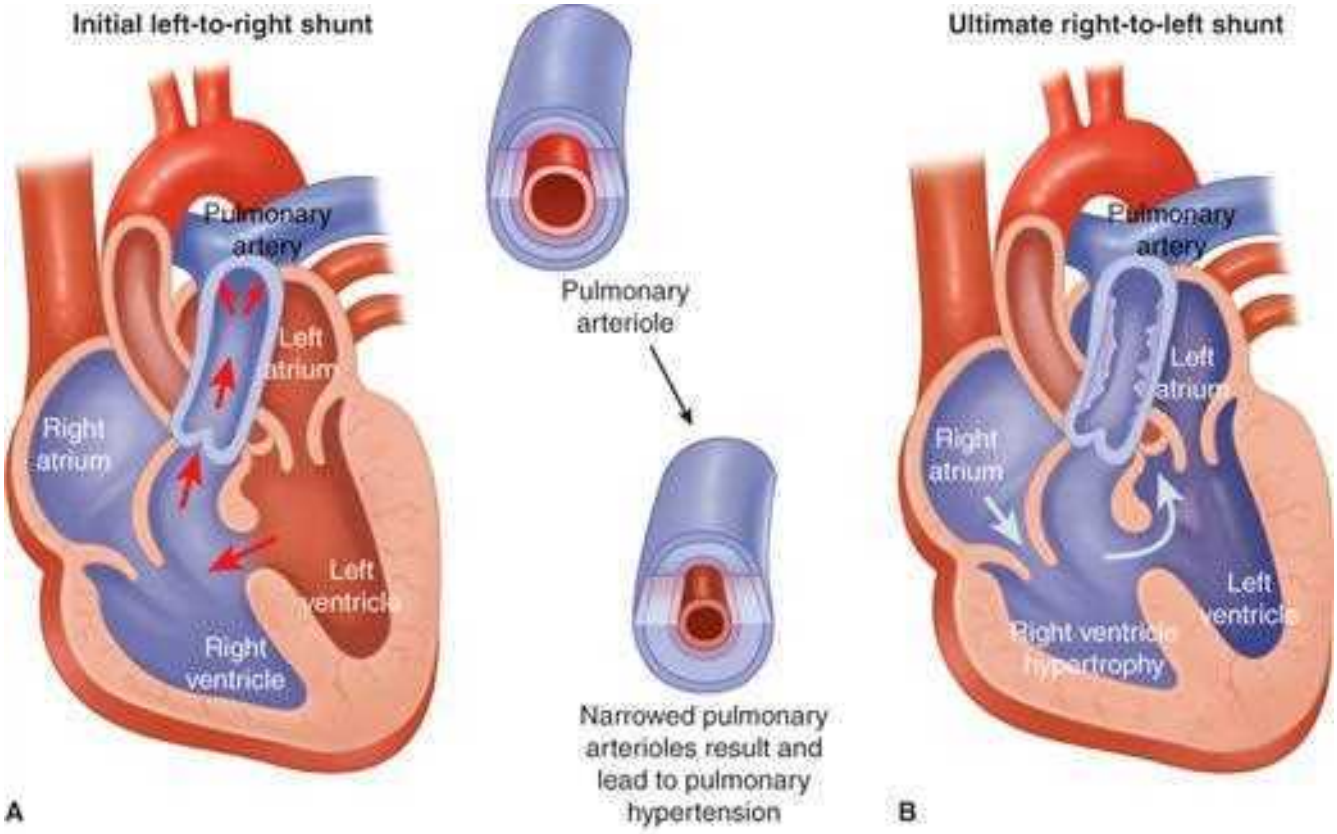
Of outcomes, one review of 14 women conceiving after a Fontan repair found that six spontaneously aborted all pregnancies, and eight others carried 14 pregnancies to viability (Cauldwell, 2016). Cardiac complications included arrhythmias and thromboembolism. Ten newborns delivered preterm, and eight neonates were small for gestational age. Similar complications attend a maternal systemic right ventricle, that is, one in which the right ventricle rather than the left pumps blood to the systemic circulation (Khan, 2015).

Eisenmenger Syndrome

This describes secondary pulmonary hypertension that arises from any cardiac lesion. The syndrome develops when pulmonary vascular resistance exceeds systemic resistance and leads to concomitant right-to-left shunting. The most common underlying defects are atrial or ventricular septal defects and persistent ductus arteriosus (Fig. 49-4). Patients are asymptomatic for years, but eventually pulmonary hypertension becomes severe enough to cause this shunting (Greutmann, 2015).

FIGURE 49-4

Eisenmenger syndrome due to a ventricular septal defect (VSD). **A.** Substantial left-to-right shunting through the VSD leads to morphological changes in the smaller pulmonary arteries and arterioles. Specifically, medial hypertrophy, intimal cellular proliferations, and fibrosis lead to narrowing or closure of the vessel lumen. These vascular changes create pulmonary hypertension and a resultant reversal of the intracardiac shunt **(B)**. With sustained pulmonary hypertension, extensive atherosclerosis and calcification often develop in the large pulmonary arteries. Although a VSD is shown here, Eisenmenger syndrome may also develop in association with a large atrial septal defect or patent ductus arteriosus.



Pregnant women with Eisenmenger syndrome tolerate hypotension poorly, and death usually is caused by right ventricular failure with cardiogenic shock. In a review of 44 cases through 1978, maternal and perinatal mortality rates approximated 50 percent (Gleicher, 1979). In a later review of 73 pregnancies, Weiss and associates (1998) cited a 36-percent maternal death rate. Three of 26 deaths were antepartum, and the remainder of women died intrapartum or within a month of delivery. In a subsequent study of 13 gravidas, one mother died 17 days after delivery, and there were five perinatal deaths (Wang, 2011). *Given such poor outcomes for both mother and fetus, Eisenmenger syndrome is considered to be an absolute contraindication to pregnancy* (Brickner, 2014; Lindley, 2015; Meng, 2017; Warnes, 2015). Management of those who do become pregnant has recently been detailed by Broberg (2016) and is discussed in the next section.

PULMONARY HYPERTENSION

Normal resting mean pulmonary artery pressure is 12 to 16 mm Hg. Pulmonary vascular resistance in late pregnancy approximates 80 dyne/sec/cm^{-5}, which is 34-percent less than the nonpregnant value of 120 dyne/sec/cm^{-5} (Clark, 1989). *Pulmonary hypertension* is defined in nonpregnant individuals as a resting mean pulmonary pressure >25 mm Hg.

The current clinical classification system, shown in Table 49-7, includes five groups of disorders that cause pulmonary hypertension (Galiè, 2016). There are important prognostic and therapeutic distinctions between group 1 pulmonary arterial hypertension and the other groups. Group 1 indicates that a specific disease affects pulmonary arterioles. It includes idiopathic or primary pulmonary arterial hypertension as well as those cases secondary to a known cause such as connective tissue disease. For example, approximately one third of women with scleroderma and 10 percent with systemic lupus erythematosus have pulmonary hypertension (Rich, 2005). Other causes in young women are human immunodeficiency virus (HIV) infection, sickle-cell disease, and thyrotoxicosis (Newman, 2015; Sheffield, 2004).

TABLE 49-7

Comprehensive Clinical Classification of Pulmonary Hypertension

1. **Pulmonary arterial hypertension**
   - Idiopathic
   - Heritable
   - Drug and toxin induced
   - Associated with connective tissue disease, HIV infections, portal hypertension, congenital heart diseases, schistosomiasis
   - **I' Pulmonary venoocclusive disease and/or pulmonary capillary hemangiomatosis**
   - Idiopathic
   - Heritable
   - Drugs, toxins and radiation induced
   - Associated with connective tissue disease, HIV infection
   - **I" Persistent pulmonary hypertension of the newborn**
2. **Pulmonary hypertension due to left heart disease**
   - Left ventricular systolic dysfunction
   - Left ventricular diastolic dysfunction
   - Valvular disease
   - Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
   - Congenital/acquired pulmonary vein stenosis
3. **Pulmonary hypertension due to lung diseases and/or hypoxia**
   - Chronic obstructive pulmonary disease
   - Interstitial lung disease
   - Other pulmonary diseases with mixed restrictive and obstructive pattern
   - Sleep-disoriented breathing
   - Alveolar hypoventilation disorder
   - Chronic exposure to high altitude
   - Developmental lung diseases
4. **Chronic thromboembolic pulmonary hypertension/other pulmonary artery obstructions**
   - Chronic thromboembolic pulmonary hypertension
   - Other pulmonary artery obstructions, i.e., tumors, arteritis, pulmonary stenosis, parasites
5. **Pulmonary hypertension with unclear and/or multifactorial mechanisms**
   - Hematological disorders: chronic hemolysis, myeloproliferative disorders, splenectomy
   - Systemic disorders: sarcoidosis, pulmonary histiocytosis, neurofibromatosis
   - Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
   - Others: fibrosing mediastinitis, chronic renal failure

HIV = human immunodeficiency virus.

Adapted from Galiè, 2016.

In pregnant women, group 2 disorders are the most common. These are secondary to pulmonary *venous* hypertension caused by left-sided atrial, ventricular, or valvular disorders. A typical example is mitral stenosis discussed earlier (Valvular Heart Disease). In contrast, groups 3 through 5 are seen

infrequently in young healthy women.

Diagnosis

Symptoms may be vague, and dyspnea with exertion is the most frequent. With group 2 disorders, orthopnea and nocturnal dyspnea are also usually present. Angina and syncope occur when right ventricular output is fixed, and they suggest advanced disease. Chest radiography often shows enlarged pulmonary hilar arteries and attenuated peripheral markings. It also may disclose parenchymal causes of hypertension. Noninvasive echocardiography can provide an estimate of pulmonary artery pressures, although cardiac catheterization remains the standard for measurement. In two studies with a combined 51 pregnant women who underwent both echocardiography and cardiac catheterization, pulmonary artery pressures were significantly overestimated by echocardiography in approximately one third of cases (Penning, 2001; Wylie, 2007).

Prognosis

Regardless of the etiology, the final common pathway of pulmonary hypertension is right heart failure and death. The average survival length after diagnosis is <4 years (Krexi, 2015). That said, longevity depends on the severity and cause of pulmonary hypertension at discovery. As discussed later, some disorders respond to medical interventions, which may improve quality of life. Preconceptional and contraceptive counseling are imperative (Gei, 2014).

Pregnancy

The maternal mortality rate is appreciable in affected women, and this is especially so with idiopathic pulmonary hypertension. In the past, there were frequently poor distinctions in identifying both causes and severity of hypertension. Thus, although most severe cases of idiopathic pulmonary arterial hypertension had the worst prognosis, it was erroneously assumed that all types of pulmonary hypertension were equally dangerous. With widespread use of echocardiography, less-severe lesions with a better prognosis are now discernible. Bédard and coworkers (2009) reported that maternal mortality rate statistics improved during the decade ending in 2007 (25 percent) compared with those for the decade ending in 1996 (38 percent). Importantly, almost 80 percent of the deaths were during the first month postpartum. More recently, Meng and associates (2017) reported mortality rates of 23 percent with group 1 and 5 percent with the other groups. Mortality was related to pulmonary hypertension severity.

As discussed, pregnancy is contraindicated with severe disease, especially in women with pulmonary arterial changes—most cases in group 1. With milder disease from other causes—group 2 being the most common—the prognosis is better (Meng, 2017). With the more frequent use of echocardiography and pulmonary artery catheterization in young women with heart disease, we have identified women with mild-to-moderate pulmonary hypertension who tolerate pregnancy, labor, and delivery well. One example described by Sheffield and Cunningham (2004) is that of pulmonary hypertension that develops with thyrotoxicosis but is reversible with treatment. Similarly, Boggess and colleagues (1995) described nine women with interstitial and restrictive lung disease with varying degrees of pulmonary hypertension, and all tolerated pregnancy reasonably well.

Management

Treatment of symptomatic pregnant women includes activity limitation and avoidance of the supine position later in gestation. Diuretics, supplemental oxygen, and pulmonary vasodilator drugs are standard therapy for symptoms. Some recommend anticoagulation (Hsu, 2011). Several reports describe the successful use of intravenous pulmonary artery vasodilators (Badalian, 2000; Garabedian, 2010; Goya, 2014). Prostacyclin analogues that can be administered parenterally include epoprostenol and treprostinil, whereas iloprost is inhaled. Each has been used in gravidas. Inhaled nitric oxide is an option that has been employed in cases of acute cardiopulmonary decompensation (Lane, 2011). As reviewed by Običan and Cleary (2014), phosphodiesterase-5 inhibitors, such as sildenafil, cause vasodilation of both the pulmonary and systemic vascular beds and have an inotropic effect on the hypertrophic right ventricle. This also has been used to advantage during pregnancy (Goland, 2010; Hsu, 2011; Meng, 2017). Bosentan, an endothelin-receptor antagonist, is teratogenic in mice and contraindicated in pregnancy (Običan, 2014).

During labor and delivery, these women are at greatest risk when venous return and right ventricular filling are diminished. To avoid hypotension, assiduous attention is given to epidural analgesia induction and to blood loss prevention and treatment at delivery (Meng, 2017).

CARDIOMYOPATHIES

The American Heart Association defines these as a heterogeneous group of myocardial diseases associated with mechanical and/or electrical dysfunction. Affected women usually—but not invariably—have inappropriate ventricular hypertrophy or dilation. Cardiomyopathies stem from varied causes, some of which are genetic (Maron, 2006). Of the two major divisions, *primary cardiomyopathies* are solely or predominantly confined to heart muscle. Examples are hypertrophic cardiomyopathy, dilated cardiomyopathies, and peripartum cardiomyopathy. *Secondary cardiomyopathies* result from generalized systemic disorders that produce pathological myocardial involvement. Diabetes, systemic lupus erythematosus, chronic hypertension, and thyroid disorders are representative conditions.

Hypertrophic Cardiomyopathy

Epidemiological studies suggest that this disorder is common, affecting approximately 1 in 500 adults (Herrey, 2014; Maron, 2004). Characterized by cardiac hypertrophy, myocyte disarray, and interstitial fibrosis, the condition is caused by mutations in any one of more than a dozen genes that encode cardiac sarcomere proteins in up to 60 percent of affected patients. In such cases, inheritance is autosomal dominant, and genetic screening is complex (Elliott, 2014). Other genetic and nongenetic causes account for 5 to 10 percent of cases, and the cause is unknown in approximately 25 percent. The myocardial muscle abnormality is typified by left ventricular myocardial hypertrophy with a pressure gradient against left ventricular outflow. Diagnosis is established by echocardiographic identification of a hypertrophied and nondilated left ventricle in the absence of other cardiovascular conditions.

Most affected women are asymptomatic, but dyspnea, anginal or atypical chest pain, syncope, and arrhythmias may develop. Complex arrhythmias may progress to sudden death, which is the most frequent cause of death. Asymptomatic patients with runs of ventricular tachycardia are especially prone to sudden death. Symptoms usually worsen with exercise.

Although limited reports suggest that pregnancy is well tolerated, adverse cardiac events are frequent. In one analysis of 271 pregnancies in 127 affected women, there were no maternal deaths. However, more than a fourth had at least one adverse cardiac symptom—including dyspnea, chest pain, or palpitations (Thaman, 2003). Based on one systematic review that included 237 women with hypertrophic cardiomyopathy who had a combined 408 pregnancies, Schinkel (2014) calculated a maternal mortality rate of 0.5 percent. Worsening of symptoms or other complications occurred in 29 percent, and 26 percent delivered preterm.

Management is similar to that for aortic stenosis. Strenuous exercise is prohibited during pregnancy. Abrupt positional changes are avoided to prevent reflex vasodilation and decreased preload. Likewise, drugs that evoke diuresis or diminish vascular resistance are generally not used. If symptoms develop, especially angina, β-adrenergic or calcium-channel blocking drugs are given. The delivery route of the fetus is determined by obstetrical indications. Choice of anesthesia is controversial, and some authors consider general anesthesia the safest (Pitton, 2007). Neonates rarely demonstrate inherited lesions at birth.

Dilated Cardiomyopathy

This is characterized by left and/or right ventricular enlargement and reduced systolic function in the absence of coronary, valvular, congenital, or systemic disease known to cause myocardial dysfunction. Although there are many known causes of dilated cardiomyopathy—both inherited and acquired, the etiology remains undefined in approximately half of cases (Stergiopoulos, 2011). Some result from viral infections, including myocarditis and HIV (Barbaro, 1998; Felker, 2000). Other causes, which are potentially reversible, include alcoholism, cocaine abuse, and thyroid disease. Watkins and coworkers (2011) reviewed the many complex genetic mutations associated with inherited forms of dilated cardiomyopathy.

Peripartum Cardiomyopathy

This disorder is similar to other forms of nonischemic dilated cardiomyopathy except for its unique relationship with pregnancy (Pyatt, 2011). Indeed, peripartum cardiomyopathy shares a genetic predisposition with both familial and sporadic idiopathic dilated cardiomyopathy (Ware, 2016). Currently, it is a diagnosis of exclusion following a concurrent evaluation for peripartum heart failure.

Although the term peripartum cardiomyopathy has been used widely, at least until recently, little evidence supported a unique pregnancy-induced cardiomyopathy. Pearson (2000) reported findings of a workshop of the National Heart, Lung, and Blood Institute that established the following diagnostic criteria:

1. Development of cardiac failure in the last month of pregnancy or within 5 months after delivery,
2. Absence of an identifiable cause for the cardiac failure,
3. Absence of recognizable heart disease prior to the last month of pregnancy, and
4. Left ventricular systolic dysfunction demonstrated by classic echocardiographic criteria, such as depressed ejection fraction or fractional shortening along with a dilated left ventricle (Fig. 49-5).

FIGURE 49-5
Peripartum cardiomyopathy with mild pulmonary edema. Anterior-posterior projection chest radiograph of a woman with an abnormally enlarged heart and mild perihilar opacification consistent with dilated cardiomyopathy.

The etiology of peripartum cardiomyopathy remains unknown, and proposed causes include viral myocarditis, abnormal immune response to pregnancy, aberrant response to the greater hemodynamic burden of pregnancy, hormonal interactions, malnutrition, inflammation, and apoptosis (Elkayam, 2011). Another suggests that oxidative stress during late pregnancy leads to the proteolytic cleavage of prolactin (Hilfiker-Kleiner, 2014). The resulting 16-kDa prolactin fragment is cardiotoxic and can impair cardiomyocyte metabolism and contractility. Bromocriptine therapy has been suggested because it inhibits prolactin secretion. In one preliminary study, bromocriptine improved recovery of affected women, and a randomized trial is currently recruiting patients (Haghikia, 2015; Sliwa, 2010).

Hypertensive disorders frequently coexist with peripartum cardiomyopathy, and another proposed mechanism links peripartum cardiomyopathy to preeclampsia (Cunningham, 2012; Fong, 2014; Patten, 2012). Antiangiogenic factors—already known to be associated with preeclampsia—can induce peripartum cardiomyopathy in susceptible mice. Thus, cardiomyopathy may be precipitated by antiangiogenic factors in a host made susceptible because of insufficient proangiogenic factors.

Several investigators describe a common pathway linking these suggested etiologies (Arany, 2016; Hilfiker-Kleiner, 2014). Specifically, unbalanced oxidative stress and a high level of prolactin leads to production of the 16-kDa prolactin fragment that seems to both initiate and propagate the disease. The fragment, which mainly affects the endothelium, together with additional antiangiogenic factors might disturb the angiogenic balance during the puerperium and thereby impair cardiac function.

With no proven etiology, the diagnosis of peripartum cardiomyopathy currently requires that other causes of cardiac dysfunction be excluded. Bültmann and coworkers (2005) studied endomyocardial biopsy specimens from 26 women with peripartum cardiomyopathy and reported that more than half had histological evidence of “borderline myocarditis.” They noted viral genomic material for parvovirus B19, human herpesvirus 6, Epstein-Barr virus, and cytomegalovirus. From Parkland Hospital, otherwise “idiopathic” heart failure was found to be caused by hypertensive heart disease, clinically silent mitral stenosis, obesity, or viral myocarditis (Cunningham, 1986). Indeed, 20 percent of women with treated chronic hypertension in pregnancy have concentric hypertrophy (Ambia, 2017).

Ntusi and associates (2015) analyzed the clinical features of 30 women with peripartum cardiomyopathy compared with 53 women with hypertensive heart failure. With cardiomyopathy, the symptoms began postpartum in all women, whereas symptoms began antepartum in 85 percent of women with hypertensive heart failure. Peripartum cardiomyopathy was significantly linked with twin gestation, smoking, and echocardiographic abnormalities. In contrast, hypertensive heart failure patients more often had a family history of hypertension, hypertension and preeclampsia in a prior pregnancy, tachycardia, and left ventricular hypertrophy on echocardiography.

The incidence of peripartum cardiomyopathy varies considerably and depends on the diligence for the search of a cause. In a review of the Nationwide Inpatient Sample database, the incidence rose from 1 in 1181 live births in 2004 to 1 in 849 in 2011 (Kolte, 2014). Two other large population-based studies cite a frequency of 1 in 2000 to 2800 live births (Gunderson, 2011; Harper, 2012). In an earlier study from Parkland Hospital, we identified idiopathic cardiomyopathy in only approximately 1 in 15,000 deliveries—an incidence similar to that of idiopathic cardiomyopathy in young nonpregnant women (Cunningham, 1986).

Prognosis

Approximately half of women suffering from peripartum cardiomyopathy recover baseline ventricular function within 6 months of delivery. But in those with persistent cardiac failure, the mortality rate approaches 85 percent over 5 years (Moioli, 2010). In a group of 100 women with newly diagnosed peripartum cardiomyopathy, 72 percent had a left ventricular ejection fraction ≥50 percent, and 93 percent had event-free survival (McNamara, 2015). However, six women experienced nine major events that included four deaths, four left ventricular assist device implantations, and one heart transplantation. Recovery to a left ventricular ejection fraction ≥50 percent occurred in almost 90 percent of women whose baseline ejection fraction was at least 30 percent. This compared with <40 percent in women whose baseline ventricular ejection fraction was <30 percent. Recovery was also related to the baseline left ventricular end-diastolic diameter. Li and colleagues (2016) also found that a baseline left ventricular ejection fraction <34 percent and a brain natriuretic peptide (BNP) level >1860 pg/mL were associated with an approximately threefold greater risk of persistent left ventricular systolic dysfunction.

Subsequent Pregnancy

From the largest studies on the topic, approximately one third of women with a history of peripartum cardiomyopathy will suffer relapse with worsening of symptoms and deterioration of left ventricular function during another pregnancy (Elkayam, 2014a). The risk of relapse in women with persistent left ventricular dysfunction is substantially higher than in those who have developed normal ventricular function before a subsequent pregnancy (Hilfiker-Kleiner, 2017). But, normalization of left ventricular function does not guarantee an uncomplicated pregnancy, because approximately 20 percent of these women are at risk for deterioration in left ventricular function.

Other Cardiomyopathy Types

Arrhythmogenic right ventricular dysplasia is a unique cardiomyopathy defined histologically by progressive replacement of right ventricular myocardium with adipose and fibrous tissue. It has an estimated population prevalence of 1 in 5000, predisposes to ventricular tachyarrhythmias, and is a cause of sudden death, particularly in younger individuals (Agir, 2014; Elliott, 2008). The additional risk of pregnancy in women with arrhythmogenic right ventricular cardiomyopathy is unknown, however, based on their systematic review, Krul and coworkers (2011) counsel against pregnancy.

Restrictive cardiomyopathy is probably the least common type. This inherited cardiomyopathy is characterized by a ventricular filling pattern in which worsening myocardial stiffness raises ventricular pressure precipitously and allows only a small filling volume (Elliott, 2008). Because of the severe clinical course and poor prognosis in general, pregnancy is not advised (Krul, 2011). *Takotsubo cardiomyopathy* is a rare form of acute reversible left ventricular apical wall ballooning (Kraft, 2017).

HEART FAILURE

Regardless of the underlying condition that causes cardiac dysfunction, women who develop peripartum heart failure almost always have obstetrical complications that either contribute to or precipitate heart failure. For example, preeclampsia is common and may precipitate afterload failure. Indeed, findings from the Registry on Pregnancy and Cardiac Disease indicate that women with preexisting heart disease who develop preeclampsia have a 30-percent risk of developing heart failure during pregnancy (Ruys, 2014). Moreover, high-output states caused by hemorrhage and acute anemia elevate cardiac workload and magnify the physiological effects of compromised ventricular function. Similarly, infection and sepsis syndrome raise cardiac output and oxygen utilization and depress myocardial function.

In many populations, chronic hypertension with superimposed preeclampsia is the most frequent cause of heart failure in pregnancy. Many of these women have concentric left ventricular hypertrophy (Ambia, 2017). In some, mild antecedent undiagnosed hypertension causes covert cardiomyopathy, and when superimposed preeclampsia develops, together they may cause otherwise inexplicable peripartum heart failure. Obesity is a frequent cofactor with chronic hypertension, and it too is associated with ventricular hypertrophy (Kenchaiah, 2002).

Diagnosis

Congestive heart failure can have a gradual onset or may present as acute “flash” pulmonary edema. Heart failure onset is most likely at the end of the second/beginning of the third trimester and peripartum (Ruys, 2014). Of symptoms, dyspnea is universal and others are orthopnea, palpitations, substernal chest pain, a sudden decline in the ability to complete usual duties, and nocturnal cough. Clinical findings include persistent basilar rales, hemoptysis, progressive edema, tachypnea, and tachycardia (Sheffield, 1999). Hallmark radiographic findings usually are cardiomegaly and pulmonary edema (see Fig. 49-5). Acutely, there is usually systolic failure, and echocardiography shows an ejection fraction <0.45 or a fractional shortening <30 percent, or both, and an end-diastolic dimension >2.7 cm/m^2 (Hibbard, 1999). Coincidental diastolic failure may also be found, depending on the underlying cause (Redfield, 2016).

Management

Pulmonary edema from heart failure usually responds promptly with diuretic administration to reduce preload. Hypertension is common, and afterload reduction is accomplished with hydralazine or another vasodilator. Because of marked fetal effects, angiotensin-converting enzyme inhibitors are withheld until after delivery. With chronic heart failure, the incidence of associated thromboembolism is high, and thus prophylactic heparin is often recommended.

Left ventricular assist devices are now employed more frequently for acute and chronic heart failure treatment. A few reports describe their use during pregnancy (LaRue, 2011; Sims, 2011). *Extracorporeal membrane oxygenation (ECMO)* was reported to be lifesaving in a woman with fulminating peripartum cardiomyopathy, and it may be used in women with pulmonary hypertension (Meng, 2017; Smith, 2009).

INFECTIVE ENDOCARDITIS

In the United States, those at greatest risk for endocarditis are those with congenital heart lesions, intravenous drug use, degenerative valve disease, and intracardiac devices (Karchmer, 2015). *Subacute bacterial endocarditis* usually stems from a low-virulence bacterial infection superimposed on an underlying structural lesion. These are usually native valve infections. Organisms that cause indolent endocarditis are most often viridans-group streptococci or *Staphylococcus* or *Enterococcus* species. Among intravenous drug abusers and those with catheter-related infections, *Staphylococcus aureus* predominates. With prosthetic valve infections, *Staphylococcus epidermidis* is a frequent cause. *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* may occasionally cause acute, fulminating disease. Others have reported *Neisseria sicca* and *N mucosa*, group B streptococcus, and *Escherichia coli* endocarditis during pregnancy or peripartum (Cox, 1988; Deger, 1992; Kangavari, 2000; Kulaš, 2006).

Diagnosis and Management

Infective endocarditis symptoms vary and often develop insidiously. Fever, often with chills, is seen in 80 to 90 percent of cases, a murmur is heard in up to 85 percent, and anorexia, fatigue, and other constitutional symptoms are common (Karchmer, 2015). Clinical clues are anemia, proteinuria, and manifestations of embolic lesions that include petechiae, focal neurological changes, chest or abdominal pain, and ischemia in an extremity. In some cases, heart failure develops. Symptoms may persist for several weeks before the diagnosis is found, and a high index of suspicion is necessary.

Diagnosis is made using the *Duke criteria,* which include positive blood cultures for typical organisms and evidence of endocardial involvement (Hoen, 2013; Pierce, 2012). Echocardiography may be diagnostic, but lesions <2 mm or those on the tricuspid valve may be missed. If uncertain, transesophageal echocardiography is accurate and informative. Importantly, a negative echocardiographic study does not exclude endocarditis.

Treatment is primarily medical, and ascertainment of the infecting organism and its sensitivities is imperative for antimicrobial selection. Guidelines for appropriate antibiotic treatment are published by professional societies and updated regularly (Habib, 2015; Karchmer, 2015). Recalcitrant bacteremia and heart failure due to valvular dysfunction are but a few reasons that persistent valvular infection may require replacement.

Pregnancy

Infective endocarditis is uncommon during pregnancy and the puerperium. During a 7-year period, the incidence of endocarditis at Parkland Hospital approximated 1 in 16,000 births, and two of seven women died (Cox, 1988). Maternal and fetal mortality rates range from 25 to 35 percent (Habib, 2015; Seaworth, 1986). In a systematic review of infective endocarditis during pregnancy, risk factors were intravenous drug use (14 percent), congenital heart disease (12 percent), and rheumatic heart disease (12 percent) (Kebed, 2014). The most common pathogens were streptococcal (43 percent) and staphylococcal (26 percent) species. Among 51 pregnancies, the maternal mortality rate was 11 percent.

Endocarditis Prophylaxis

For years, patients with heart valve problems were given periprocedural antibiotics for endocarditis prophylaxis. Currently, however, recommendations are more stringent. The American Heart Association recommends prophylaxis for dental procedures in those with: (1) a prosthetic valve or prosthetic material used in a valve repair, (2) prior endocarditis, (3) unrepaired cyanotic heart defect or repaired lesion with residual defect at prosthetic sites, and (4) valvulopathy after heart transplantation (Nishimura, 2017). The American College of Obstetricians and Gynecologists (2016) does not recommend endocarditis prophylaxis for either vaginal or cesarean delivery in the absence of pelvic infection except with the lesions cited above. Women at highest

risk for endocarditis are those with cyanotic cardiac disease, prosthetic valves, or both. When indicated, and for women not already receiving intrapartum antimicrobial therapy for another indication that would also provide coverage against endocarditis, prophylactic regimens are shown in Table 49-8. These are administered as close to 30 to 60 minutes before the anticipated delivery time as is feasible.

TABLE 49-8

Antibiotic Prophylaxis for Infective Endocarditis in High-Risk Patients

American College of Obstetricians and Gynecologist (2016) Standard (IV): ampicillin 2 g ***or*** cefazolin or ceftriaxone 1 g Penicillin-allergic (IV): cefazolin or ceftriaxone 1 g ***or*** clindamycin 600 mg Oral: amoxicillin 2 g
American Heart Association/European Society of Cardiology (Karchmer, 2015)[a] Standard: amoxicillin 2 g PO ***or*** ampicillin 2 g IV or IM Penicillin-allergic: clarithromycin or azithromycin 500 mg PO; cephalexin 2 g PO; clindamycin 600 mg PO, IV, or IM; ***or*** cefazolin or ceftriaxone 1 g IV or IM

IM = intramuscularly; IV = intravenously.

[a]Cefazolin or ceftriaxone given 30 minutes and all others given 1 hour prior to procedure.

ARRHYTHMIAS

Both preexisting and new-onset cardiac arrhythmias are often encountered during pregnancy, labor, delivery, and the puerperium (Joglar, 2014; Knotts, 2014). In a study of 73 women with a history of supraventricular tachycardia (SVT), paroxysmal atrial flutter or fibrillation, or ventricular tachycardia, recurrence rates during pregnancy were 50, 52, and 27 percent, respectively (Silversides, 2006). The mechanism(s) responsible for the higher incidence of arrhythmias during pregnancy are not well elucidated. From some studies, estradiol and progesterone are proarrhythmic. Estrogen augments the number of adrenergic receptors in the myocardium, and adrenergic responsiveness seems to be greater in pregnancy (Enriquez, 2014). Perhaps the normal but mild hypokalemia of pregnancy and/or the physiological rise in heart rate serves to induce arrhythmias. Alternatively, detection of arrhythmias may be greater because of the frequent visits typical of routine prenatal care.

Bradyarrhythmias

Slow heart rhythms, including complete heart block, are compatible with a successful pregnancy outcome (Keepanasseril, 2015). Some women with complete heart block have syncope during labor and delivery, and occasionally temporary cardiac pacing is necessary (Hidaka, 2006). In our experiences and from others, women with permanent artificial pacemakers usually tolerate pregnancy well (Hidaka, 2011; Jaffe, 1987). With fixed-rate devices, cardiac output apparently is increased by augmented stroke volume.

Patients with pacemakers or other electrical implants require special precautions during surgery. Stray current may be interpreted as an intracardiac signal by the implanted device and lead to pacing changes. In addition, myocardial burns may result from conduction of current through the pacing electrode rather than through the grounding pad (Pinski, 2002). With these devices, preventive steps include cardiology consultation; bipolar electrosurgery or Harmonic scalpel use rather than monopolar current; if needed, minimal monopolar settings; continuous cardiac and pulse oximetry monitoring; contingency plans for arrhythmias; and close proximity of electrosurgery active and return electrodes (Crossley, 2011).

Supraventricular Tachycardias

The most common arrhythmia seen in reproductive-aged women is paroxysmal SVT. The prevalence during pregnancy is 24 cases per 100,000 hospital admissions, and approximately 20 percent will experience symptomatic exacerbations during pregnancy (Enriquez, 2014). Interestingly, the mean heart rate of pregnant women with paroxysmal SVT is faster compared with nonpregnant women—184 versus 166 bpm, respectively (Yu, 2015). From Hungary, Bánhidy and associates (2015) found that approximately half of women with paroxysmal SVT had an initial onset during pregnancy. Notably, maternal paroxysmal SVT was associated with a twofold greater risk of septal cardiac defects, particularly secundum atrial septal defects, in their offspring.

In contrast, rarely do *atrial fibrillation* and *atrial flutter* present for the first time during pregnancy. Indeed, new-onset atrial fibrillation should prompt a search for underlying etiologies that include cardiac anomalies, hyperthyroidism, pulmonary embolism, drug toxicity, and electrolyte disturbances (DiCarlo-Meacham, 2011). Major complications include embolic stroke, and when associated with mitral stenosis, pulmonary edema may develop in later pregnancy if the ventricular rate is increased.

For acute treatment, vagal maneuvers, which include Valsalva maneuver, carotid sinus massage, bearing down, and immersion of the face in ice water, raise vagal tone and block the atrioventricular node (Link, 2012; Page, 2015). Intravenous adenosine is a short-acting endogenous nucleotide that also blocks atrioventricular nodal conduction. Our experiences are similar to those of others in that adenosine is safe and effective for cardioversion in hemodynamically stable gravidas (Page, 2015; Robins, 2004). Transient fetal bradycardia has been described with adenosine (Dunn, 2000).

If pharmacological therapy is ineffective or contraindicated, the American College of Cardiology and the American Heart Association recommend synchronized cardioversion in pregnant women with hemodynamically unstable SVT (Page, 2015). And although electrical cardioversion with standard energy settings is not contraindicated in pregnancy, vigilance is important. Barnes and colleagues (2002) described a case in which direct current cardioversion led directly to a sustained uterine contraction and fetal bradycardia. As an aside, pregnancy has no effect on the operation of implantable cardioverter-defibrillator devices (Boulé, 2014).

If cardioversion fails or is unsafe because of concurrent thrombus, then long-term anticoagulation and heart rate control with medication are necessary (DiCarlo-Meacham, 2011). Other treatment options recommended by the American College of Cardiology and the American Heart Association (Page, 2015) include:

Intravenous metoprolol or propranolol when adenosine is ineffective or contraindicated

Intravenous verapamil when adenosine and β-blocking agents are ineffective or contraindicated

Intravenous procainamide

Intravenous amiodarone with potentially life-threatening SVT and when other therapies are ineffective or contraindicated.

Pregnancy may predispose otherwise asymptomatic women with *Wolff-Parkinson-White (WPW) syndrome* to exhibit arrhythmias. In a study of 25 women who had SVT diagnosed before pregnancy, three of 12 women with WPW syndrome and six of 13 without the condition developed SVT during pregnancy (Pappone, 2003). In some patients, accessory pathway ablation may be indicated. Driver and coworkers (2015) have provided a review.

Ventricular Tachycardia

This form of arrhythmia is uncommon in healthy young women without underlying heart disease. Brodsky and associates (1992) described seven pregnant women with new-onset ventricular tachycardia and reviewed 23 reports. Most of these women were not found to have structural heart disease. In 14 cases, tachycardia was precipitated by physical exercise or psychological stress. Abnormalities found included two cases of myocardial infarction, two of prolonged QT interval, and one of anesthesia-provoked tachycardia. They concluded that pregnancy events precipitated the tachycardia and recommended β-blocking agents for control. As previously discussed (Heart Failure), arrhythmogenic right ventricular dysplasia will result occasionally in ventricular tachyarrhythmias (Lee, 2006). If unstable, emergency cardioversion is indicated, and standard adult energy settings are adequate (Jeejeebhoy, 2011; Lin, 2015).

Prolonged QT-Interval

This conduction anomaly may predispose individuals to a potentially fatal ventricular arrhythmia known as *torsades de pointes* (Roden, 2008). Two studies comprised of 502 pregnant women with *long QT syndrome* both reported a significant increase in cardiac events postpartum but not during pregnancy (Rashba, 1998; Seth, 2007). The normal rise in heart rate during pregnancy may be partially protective. Paradoxically, β-blocking agents—preferably propranolol—lower the risk of torsades de pointes in patients with long QT syndrome and should be continued throughout pregnancy and the puerperium (Enriquez, 2014; Seth, 2007). Importantly, many medications, including some used during pregnancy such as azithromycin, erythromycin, and clarithromycin, may predispose to QT prolongation (Ray, 2012; Roden, 2004).

DISEASES OF THE AORTA

Aortic Dissection

Marfan syndrome and coarctation are two aortic diseases that place the pregnant woman at increased risk for aortic dissection (Russo, 2017). Indeed, half of dissection cases in young women are related to pregnancy (O'Gara, 2004). Other risk factors are bicuspid aortic valve and Turner or Noonan syndrome. A high rate of aortic dissection or rupture is also reported in patients with Ehlers-Danlos syndrome (Murray, 2014; Pepin, 2000). Although the mechanism(s) involved are unclear, the initiating event is a tear in the intimal layer of the aorta, followed by hemorrhage into the media, and finally rupture.

In most cases, aortic dissection presents with severe chest pain described as ripping, tearing, or stabbing. Diminution or loss of peripheral pulses coupled with a recently acquired aortic insufficiency murmur is an important physical finding. The differential diagnosis of aortic dissection in pregnancy includes myocardial infarction, pulmonary embolism, pneumothorax, aortic valve rupture, and obstetrical catastrophes, especially placental abruption and uterine rupture.

More than 90 percent of patients with aortic dissection have an abnormal chest radiograph. Aortic angiography is the most definitive method for diagnosis confirmation. However, sonography, computed tomography, and MR imaging are used more frequently depending on the urgency of the clinical situation.

Initial medical treatment is given to lower blood pressure. Proximal dissections most often need to be resected, and the aortic valve replaced if necessary. Distal dissections are more complex, and many may be treated medically. Among *nonpregnant* patients, survival is not improved by immediate elective repair compared with surveillance and delayed repair of abdominal aortic aneurysms <5.5 cm. But, Karthikesalingam and colleagues (2016) suggest that the size threshold for aneurysm repair should be revisited.

Marfan Syndrome

This autosomal dominant connective tissue disorder has an incidence of 2 to 3 cases per 10,000 individuals and is without racial or ethnic predilection (Ammash, 2008). As discussed in Chapter 59 (Hereditary Connective Tissue Disorders), Marfan syndrome is characterized by generalized tissue weakness that can result in dangerous cardiovascular complications. Because all tissues are involved, other defects are frequent and include joint laxity and scoliosis. Progressive aortic dilation causes aortic valve insufficiency, and there may be infective endocarditis and mitral valve prolapse with insufficiency. Aortic dilation and dissecting aneurysm are the most serious abnormalities. Early death is due either to valvular insufficiency and heart failure or to a dissecting aneurysm.

Pregnancy

Of outcomes, a study using the Nationwide Inpatient Sample from 2003 to 2010 found 339 deliveries in women with Marfan syndrome. There was one maternal death and six (1.8 percent) aortic dissections (Hassan, 2015). Russo and associates (2017) used Texas obstetrical discharge data and found that eight of 47 women with aortic dissection had Marfan syndrome. A study from the United Kingdom reported similar results (Curry, 2014).

The aortic root usually measures approximately 2 cm, and during normal pregnancy, it expands slightly (Easterling, 1991). With Marfan syndrome, aortic root repair is recommended at diameters of 4.0 to 4.5 cm (Smok, 2014). The guidelines of the American College of Cardiology, the American Heart Association, and the American Association of Thoracic Surgeons advise prophylactic aortic repair in women considering pregnancy if the diameter of the ascending aorta exceeds 4 cm (Hiratzka, 2010). The guidelines of the European Society of Cardiology (2011) advise repair of the aorta at diameters ≥4.5 cm. Because shorter patients have dissection at a smaller diameter, surgical repair is also considered using a formula indexed to height (Bradley, 2014; Smok, 2014).

For pregnant women with known thoracic aortic root or ascending aortic dilation, monthly or bimonthly echocardiographic measurements of the ascending aortic dimensions are recommended to detect expansion (Hiratzka, 2010). Prophylactic β-blocking agents have become standard for pregnant women with Marfan syndrome because they reduce hemodynamic stress on the ascending aorta and slow the dilation rate (Simpson, 2012). Ideally, pregnant women with aortic aneurysms are delivered at facilities in which cardiothoracic surgery is available. Vaginal delivery with regional analgesia and an assisted second stage seem safe for women with an aortic root diameter <4 cm.

When the aortic root measures 4 to 5 cm or greater, elective cesarean delivery is recommended with consideration of postpartum replacement of the proximal aorta with a prosthetic graft (Simpson, 2012). Successful aortic root replacement during pregnancy has been described, but the surgery has also been associated with fetal hypoxic-ischemic encephalopathy (Mul, 1998; Seeburger, 2007). Several case reports describe emergency cesarean deliveries in women with acute type A dissections that were repaired successfully at the time of delivery (Guo, 2011; Haas, 2011; Papatsonis, 2009).

To evaluate obstetrical outcomes, investigators for one study of 63 women with Marfan syndrome analyzed their 142 pregnancies. Of 111 pregnancies progressing past 20 weeks' gestation, 15 percent delivered preterm, and 5 percent had preterm prematurely ruptured membranes (Meijboom, 2006). There were eight perinatal deaths, and half of the neonatal survivors were subsequently diagnosed with Marfan syndrome.

Aortic Coarctation

In this relatively rare lesion, the aorta is abnormally narrowed and is often accompanied by abnormalities of other large arteries. A fourth of affected patients have a bicuspid aortic valve, and another 10 percent have cerebral artery aneurysms. Other associated lesions are persistent ductus arteriosus, septal defects, and Turner syndrome. The collateral circulation arising above the coarctation remodels and expands, often strikingly, to cause localized erosion of rib margins by hypertrophied intercostal arteries. Typical findings include hypertension in the upper extremities but normal or reduced pressures in the lower extremities. Authors have described diagnosis during pregnancy using MR imaging (Sherer, 2002; Zwiers, 2006). Moreover, Jimenez-Juan and associates (2014) found that aortic diameter measured by MR and the risk of adverse events during pregnancy were inversely correlated. Of note, no adverse outcomes occurred if the minimum diameter at the coarctation exceeded 15 mm.

Major complications with aortic coarctation include congestive heart failure after long-standing severe hypertension, bacterial endocarditis of the bicuspid aortic valve, and aortic rupture. Because hypertension may worsen in pregnancy, antihypertensive therapy using β-blocking drugs is usually required. Aortic rupture is more likely late in pregnancy or early puerperium. Cerebral hemorrhage from *circle of Willis aneurysms* may also occur.

Of outcomes from 188 pregnancies, a third of women had hypertension that was related to significant coarctation gradients, and one woman died from dissection at 36 weeks' gestation (Beauchesne, 2001). Of nearly 700 deliveries in women with coarctation from the Nationwide Inpatient Sample, hypertensive complications of pregnancy were increased three- to fourfold (Krieger, 2011). Importantly, almost 5 percent of women with coarctation had an adverse cardiovascular outcome—maternal death, heart failure, arrhythmia, cerebrovascular or other embolic event—compared with only 0.3 percent of controls. Of women with coarctation, 41 percent underwent cesarean delivery compared with 26 percent of controls.

Congestive heart failure demands vigorous efforts to improve cardiac function and may warrant pregnancy interruption. Some authors recommend that resection of the coarctation be undertaken during pregnancy to protect against the possibility of a dissecting aneurysm and aortic rupture. This poses significant perfusion risk, especially for the fetus, because all the arterial collaterals must be clamped for variable periods.

ISCHEMIC HEART DISEASE

Pregnant women with coronary artery disease commonly have the classic risk factors of diabetes, smoking, hypertension, hyperlipidemia, and obesity (James, 2006). Although relatively rare, the risk of acute myocardial infarction is approximately threefold higher in pregnant women compared with nonpregnant women of similar age (Elkayam, 2014b). From more than 50 million hospitalizations in the United States between 1998 and 2009, rates of acute myocardial infarction approximated 2 per 100,000 delivery hospitalizations and 4 per 100,000 postpartum hospitalizations (Callaghan, 2012). Ladner and colleagues (2005) reported a similar rate of 2.7 per 100,000 deliveries.

Myocardial Infarction During Pregnancy

The mortality rate with myocardial infarction in pregnancy is higher compared with age-matched nonpregnant women. In a Nationwide Inpatient Sample study totaling 859 pregnancies complicated by acute infarction, the death rate was 5.1 percent (James, 2006). Women who sustain an infarction <2 weeks before delivery are at especially high risk of death due to the greater myocardial demand of labor and delivery (Esplin, 1999).

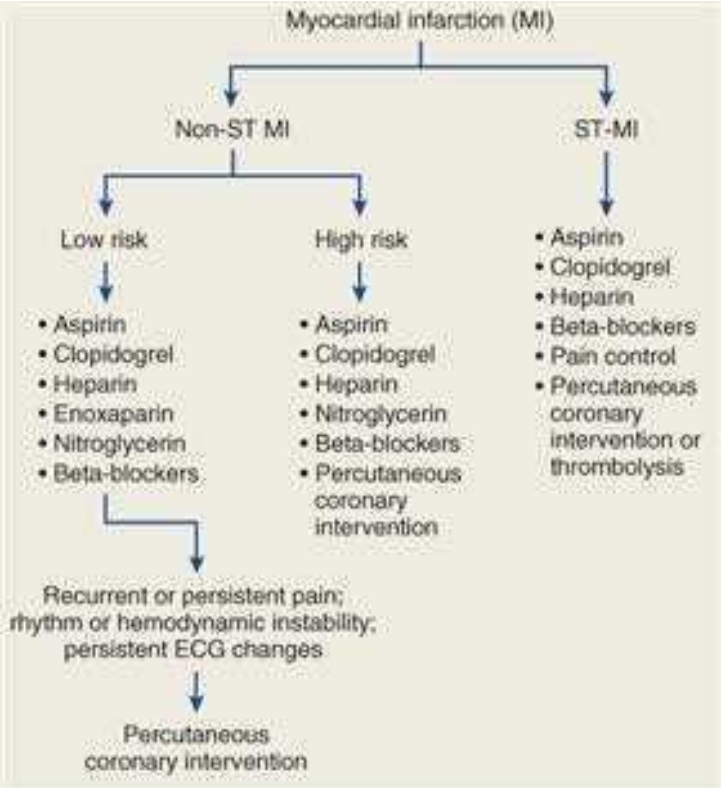
In a systematic review of 150 cases, most women developed an acute myocardial infarction (MI) during the third trimester or postpartum (Elkayam, 2014b). Approximately three fourths presented with ST segment-elevation MI (STEMI). The leading mechanisms of acute infarction included *spontaneous coronary dissection* (43 percent) and *atherosclerotic disease* (27 percent). Significant complications included heart failure/cardiogenic shock (38 percent), recurrent angina or infarction (19 percent), and ventricular arrhythmias (12 percent). The maternal and fetal mortality rates were 7 and 5 percent, respectively. Of other potential antecedents, coronary artery occlusion in two pregnant smokers with hypercholesterolemia has been described following ergometrine administration (Mousa, 2000; Ramzy, 2015; Sutaria, 2000). Schulte-Sasse (2000) reported myocardial ischemia associated with prostaglandin E_1 vaginal suppositories given for labor induction.

Diagnosis of acute myocardial infarction during pregnancy does not differ from that in nonpregnant patients and is based on clinical presentation, characteristic ECG changes, and evidence of myocardial necrosis reflected by elevated serum troponin levels (Pacheco, 2014). Of note, troponin I levels are undetectable near term in normal pregnancy and do not rise following either vaginal or cesarean delivery (Koscica, 2002; Shivvers, 1999). Importantly, however, troponin I levels are higher in preeclamptic women compared with normotensive controls (Atalay, 2005; Yang, 2006). With spontaneous coronary artery dissection, establishing the diagnosis requires a high index of suspicion in the gravida presenting with chest pain (Codsi, 2016). For this condition, coronary angiography is considered the diagnostic gold standard and should be expediently performed if acute coronary syndrome—defined as myocardial infarction or unstable angina—is present.

Treatment of acute myocardial infarction is similar to that for nonpregnant patients (Pacheco, 2014). An algorithm summarizing one approach to its management during pregnancy is shown in Figure 49-6. Several reports describe successful percutaneous transluminal coronary angioplasty and stent placement during pregnancy (Balmain, 2007; Duarte, 2011; Dwyer, 2005). Cardiopulmonary resuscitation may be required, as described in Chapter 47 (Cardiopulmonary Resuscitation). If the infarct has healed sufficiently, cesarean delivery is reserved for obstetrical indications, and epidural analgesia is ideal for labor (Esplin, 1999).

FIGURE 49-6

Initial management of acute myocardial infarction during pregnancy. Risk stratification refers to the risk of developing recurrent symptoms despite optimal medical management. (Adapted with permission from Pacheco LD, Saade GR, Hankins GD: Acute myocardial infarction during pregnancy, Clin Obstet Gynecol. 2014 Dec;57(4):835–843.)



Pregnancy with Prior Ischemic Heart Disease

The advisability of pregnancy after a myocardial infarction is unclear. Ischemic heart disease is characteristically progressive, and because it is usually associated with hypertension or diabetes, pregnancy in most of these women seems inadvisable. In a review of 30 pregnancies in women who had sustained an *infarction remote from pregnancy*, none of the women died, four had congestive heart failure, and four had worsening angina during pregnancy (Vinatier, 1994). Pombar and coworkers (1995) evaluated outcomes of women with diabetes-associated ischemic heart disease and infarction. Three had undergone coronary artery bypass grafting before pregnancy. Of 17 women, eight died during pregnancy. Certainly, pregnancy raises cardiac workload, and these investigators concluded that ventricular performance should be assessed using ventriculography, radionuclide studies, echocardiography, or coronary angiography before conception. Without significant ventricular dysfunction, pregnancy will likely be tolerated. For the woman who becomes pregnant before these studies are performed, echocardiography is done. Exercise tolerance testing may be indicated, and radionuclide ventriculography exposes the fetus to minimal radiation.

CHAPTER 50: Chronic Hypertension

A small proportion of women suffering from chronic nephritis had eclampsia. For the most part, autopsy will reveal the presence of renal changes usually of acute nephritis, though occasionally it may be engrafted upon a chronic process.

—J. Whitridge Williams (1903)

INTRODUCTION

At the time of *Williams Obstetrics*' first edition, little attention was paid to blood pressure changes, even with "toxemia." At that time, chronic hypertension was designated "senile" and thought to develop only in older individuals (Lindheimer, 2015). Indeed, chronic hypertension is not mentioned, per se, in Williams' 1903 textbook, except for some deference given to chronic anatomical renal changes occasionally associated with eclampsia.

It is now apparent that chronic hypertension is one of the most common serious complications encountered during pregnancy. This is not surprising because, according to the National Health and Nutrition Examination Survey (NHANES) from the Centers for Disease Control and Prevention (2011), the prevalence of hypertension in women aged 18 to 39 years approximates 7 percent.

The incidence of chronic hypertension complicating pregnancy varies depending on population vicissitudes. In a study of more than 56 million births from the Nationwide Patient Sample, the incidence was 1.8 percent (Bateman, 2012). And, in more than 878,000 pregnancies from the Medicaid Analytic Extract, 2.3 percent were complicated by chronic hypertension (Bateman, 2015). Despite this substantive prevalence, optimal management has not been well studied. It is known that chronic hypertension usually improves during early pregnancy. This is followed by variable behavior later in pregnancy and, importantly, by the unpredictable development of superimposed preeclampsia. The latter carries increased risks for maternal and perinatal morbidity and mortality.

GENERAL CONSIDERATIONS

To define chronic hypertension, the range of normal blood pressure must first be established. This is not a simple task because, like all polygenically determined biological variants, blood pressure norms differ between populations. And, within these norms, wide variations are found between individuals. Moreover, numerous epigenetic factors influence presentation. For example, not only do blood pressures vary between races and genders, but pressures—especially systolic—rise directly with increasing age and weight. Thus, pragmatically, normal adults have a broad range of blood pressures, but so do those with chronic hypertension. And finally, resting blood pressure measurements do not reflect daily activities.

After these variables are acknowledged, important considerations for any population are the attendant risks of chronic hypertension. It is a leading cause of death and accounts for nearly 15 percent of mortality worldwide. Approximately 65 million Americans have hypertension, and this number is growing concurrently with epidemic obesity (Kotchen, 2015). Hypertension increases substantively the risk of cardiovascular disease, coronary heart disease, congestive heart failure, stroke, renal failure, and peripheral arterial disease (Forouzanfar, 2017).

Definition and Classification

For the foregoing reasons, chronic hypertension would logically be defined as some level of sustained resting blood pressure that is associated with acute or long-term adverse effects. In this regard, most consider 140/90 mm Hg as the upper limit of normal for blood pressure values. But, in the United States, these values are based primarily on actuarial tables constructed using data derived from white adult males and compiled by life insurance companies. These "norms" disregard interrelated factors such as ethnicity, gender, and other important covariants. The importance of race, for example, was emphasized by Kotchen (2015), who cites the incidence of hypertension—defined as blood pressure >140/90 mm Hg—to be 34 percent in blacks, 29 percent in whites, and 21 percent in Mexican Americans.

For many years, the Joint National Committee has promulgated guidelines for diagnosis, classification, and management of chronic hypertension. In 2008, the National Heart, Lung, and Blood Institute discontinued these guidelines, and the Joint National Committee 8 (JNC 8) was instead asked to provide an evidence-based review (James, 2014). Findings pertinent to caring for young women with chronic hypertension are summarized in Table 50-1.

TABLE 50-1

Eighth Joint National Committee (JNC 8)—2014 Chronic Hypertension Guidelines and Recommendations

Evidence-based recommendations from randomized controlled trials
Definitions for hypertension and prehypertension not addressed
Lifestyle modifications endorsed from the Lifestyle Work Group (Eckel, 2013)
Recommend selection among four specific medication classes: angiotensin-converting enzyme inhibitors (ACE-I), angiotensin-receptor blockers (ARB), calcium-channel blockers, or diuretics:
General population: <60 years old—initiate pharmacological therapy to lower diastolic pressure ≤90 mm Hg and systolic pressure ≤140 mm Hg
Diabetics: lower pressure to <140/90 mm Hg
Chronic kidney disease: lower pressure to <140/90 mm Hg. Also add ACE-I or ARB to improve outcomes
General nonblack population: initial therapy should include thiazide-type diuretic, calcium-channel blocker, ACE-I, or ARB
General black population: primary antihypertensive therapy should include thiazide-type diuretic or calcium-channel blocker
Assess monthly, and after 1 month, if goals not met, then increase primary drug dose or add second drug. If no response, increase either or add third drug; then if no response, refer to hypertension specialist

Summarized from James, 2014.

Treatment and Benefits for Nonpregnant Adults

Proven benefits accrue with treatment of otherwise normal adults who have sustained hypertension. Numerous studies evaluating many combinations of antihypertensive therapy have been conducted. Importantly, these trials evaluated monotherapy versus combination therapeutic regimens and their ethnospecific benefits. Most evaluated cardiovascular outcomes, but many also confirmed risk reductions in rates of cerebrovascular accident, renal insufficiency, and mortality. Because of these incontrovertible benefits, the JNC 8 recommends the management outlined in Table 50-1.

Thus, even for mildly elevated blood pressure, interventions to reduce these sequelae are beneficial (SPRINT Research Group, 2015). Moreover, antihypertensive therapy in nonpregnant reproductive-aged women with sustained diastolic pressures ≥90 mm Hg is considered standard. Not clear from these observations, however, is what constitutes the best management for women being treated who contemplate pregnancy, for those undergoing treatment who become pregnant, or for those first identified to have chronic hypertension during pregnancy (August, 2015). In these women, the benefits and safety of instituting antihypertensive therapy are less clear, as subsequently discussed in Antihypertensive Treatment in Pregnancy.

Preconceptional Counseling

Women with chronic hypertension are ideally counseled before pregnancy. The duration of hypertension, degree of blood pressure control, and current therapy are ascertained. Those women who require multiple medications for control or those who are poorly controlled carry greater risk for adverse pregnancy outcomes. Home measurement devices are checked for accuracy. General health, daily activities, and dietary habits are also assessed (Table 50-2).

TABLE 50-2

Lifestyle Modifications for Hypertensive Patients

Weight reduction
Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts; limits sweets and red meats. Examples are DASH, USDA Food Pattern, or the AHA Diet
Lower sodium intake—consume no more than 2400 mg sodium/d; 1500 mg/d desirable
Engage in aerobic physical activity three to four sessions per week, lasting on average 40 minutes per session, and involving moderate-to-vigorous intensity physical activity
Moderation of alcohol consumption

AHA = American Heart Association; DASH = Dietary Approaches to Stop Hypertension; USDA = United States Department of Agriculture.

Summarized from Eckel, 2013; Kotchen, 2015.

For hypertensive women with disease lasting longer than 5 years or with comorbid diabetes, cardiovascular and renal function is assessed (August, 2015; Gainer, 2005). Women with evidence for organ dysfunction or those with prior adverse events such as a stroke, myocardial infarction (MI), arrhythmias, or ventricular failure are at markedly higher risk for a recurrence or worsening dysfunction during pregnancy. Renal function is evaluated by serum creatinine measurement. Also, if a urine spot protein/creatinine ratio is abnormally high (>0.3), proteinuria is further quantified with a 24-hour urine collection (Hladunewich, 2011; Kuper, 2016; Morgan, 2016a). The Working Group Report on High Blood Pressure in Pregnancy (2000) of the National Heart, Lung, and Blood Institute concluded that the risks of fetal loss and accelerated renal disease deterioration are increased if the serum creatinine level is above 1.4 mg/dL (Chap. 53, Chronic Kidney Disease).

Although pregnancy is considered by many to be contraindicated in women with severe, poorly controlled hypertension, there is no consensus. Certainly, women who maintain persistent diastolic pressures ≥110 mm Hg despite therapy; require multiple antihypertensives; have a serum creatinine level >2 mg/dL; or have a history of prior stroke, MI, or cardiac failure must be counseled as to the marked risks to themselves and to their pregnancy outcome.

DIAGNOSIS AND EVALUATION IN PREGNANCY

The hypertensive disorders that uniquely complicate pregnancy are discussed in Chapter 40 (Terminology and Diagnosis). Women are diagnosed with chronic hypertension if it is documented to precede pregnancy or if hypertension is identified before 20 weeks' gestation. Evidence also supports that *prehypertension* may herald adverse outcomes similar to those in women with chronic hypertension (Rosner, 2017). In some women without overt chronic hypertension, a history of repeated pregnancies complicated by gestational hypertension, with or without the preeclampsia syndrome, may be elicited. Each is a risk marker for latent chronic hypertension, and this is especially so for preeclampsia, and in particular early-onset preeclampsia. In many ways, gestational hypertension is analogous to gestational diabetes in that such women have a *chronic hypertensive diathesis*, in which heredity and environment play a major role.

Although uncommon, secondary causes of hypertension are always a possibility in affected women. Thus, consideration is given to underlying chronic renal disease, connective-tissue disease, primary aldosteronism, Cushing syndrome, pheochromocytoma, and myriad other causes. That said, most pregnant women with antecedent hypertension will have otherwise uncomplicated disease.

Associated Risk Factors

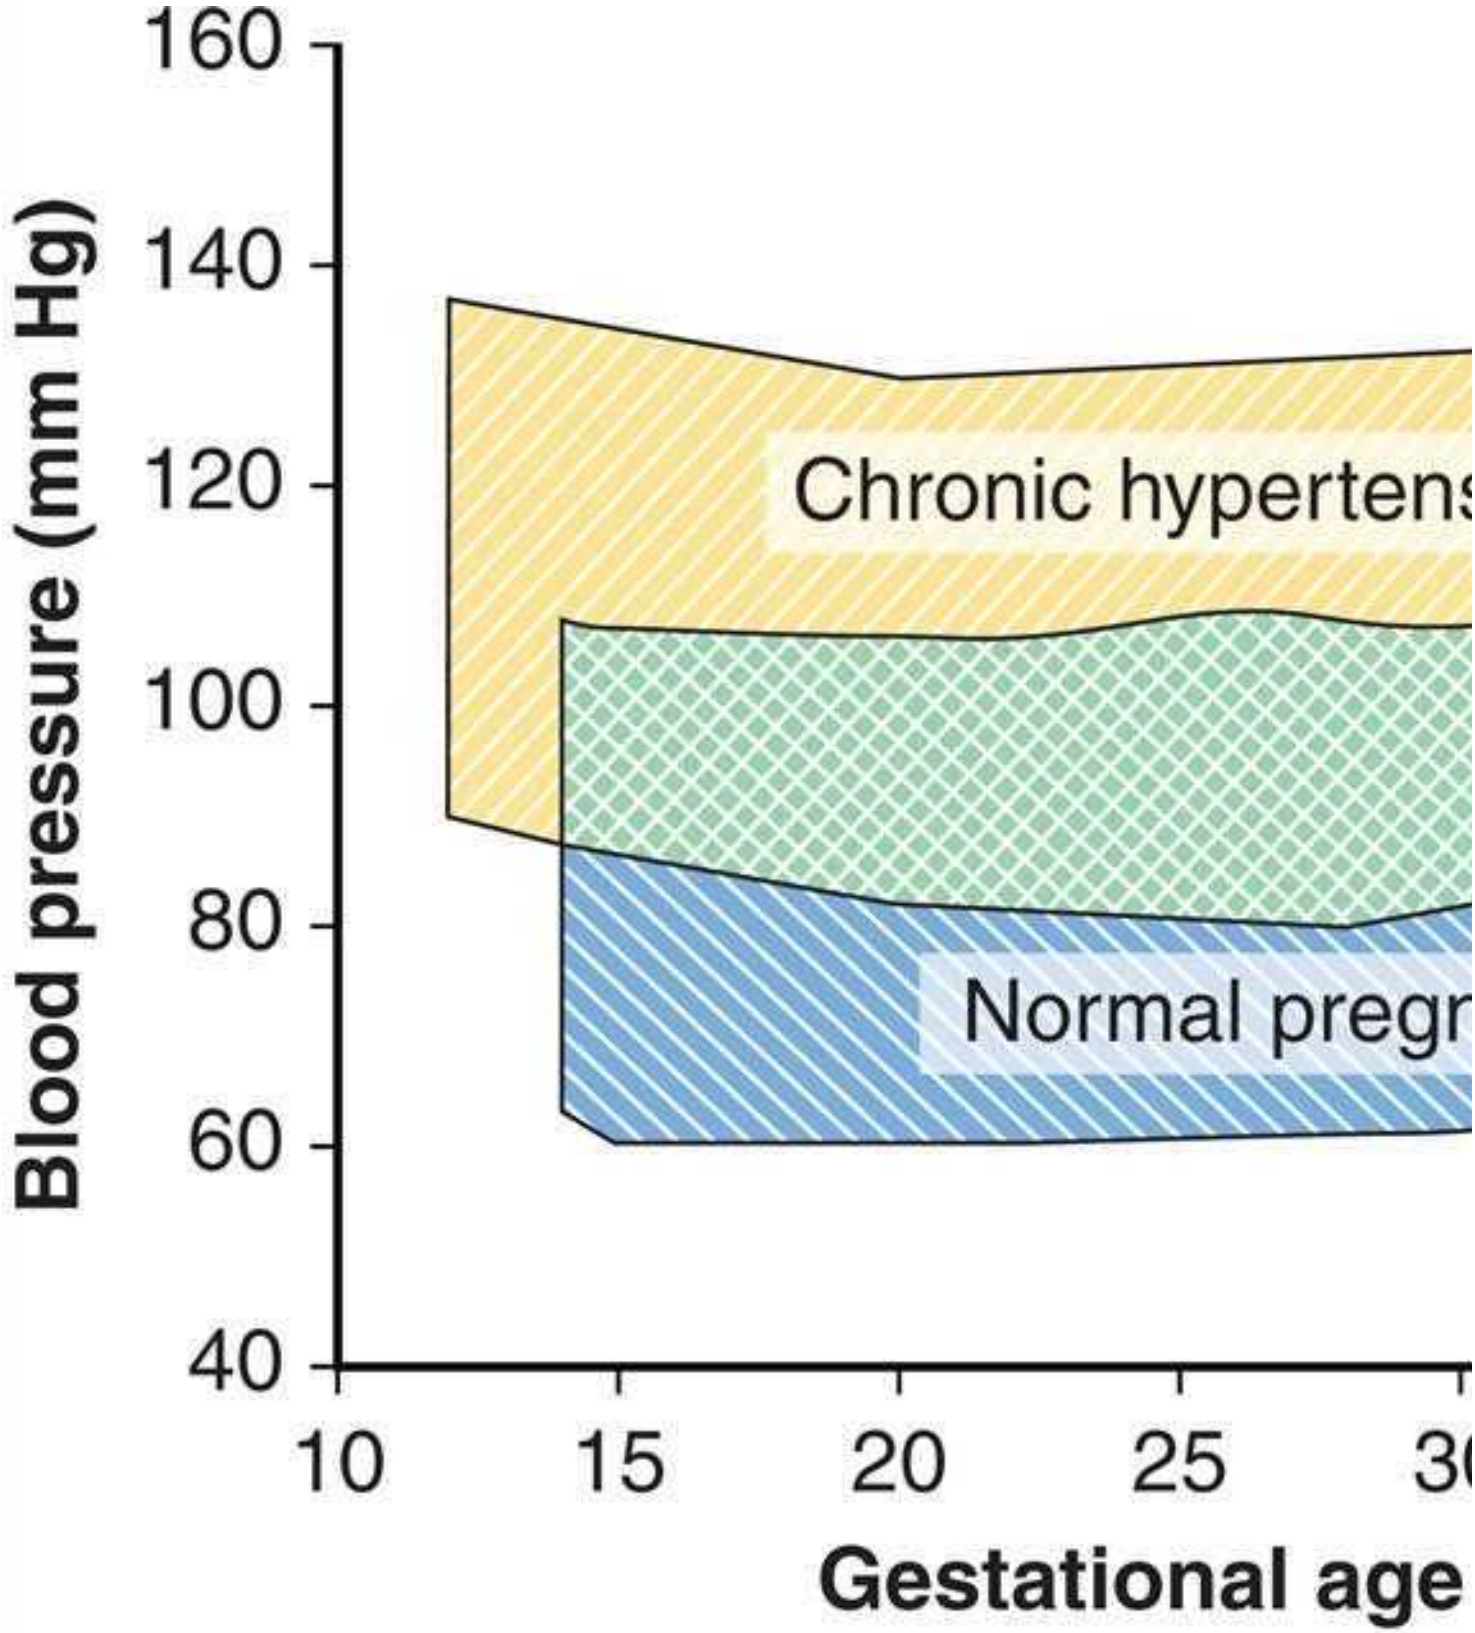
Several factors increase the likelihood that pregnant women will have chronic hypertension. Three of those most frequently cited are ethnicity, obesity, and diabetes. As previously discussed, chronic hypertension has a population incidence that is highest in black women and lowest in Mexican-American women (Kotchen, 2015). Related to this, hundreds of blood pressure-related phenotypes and genomic regions have been identified, including candidate genes for preeclampsia and chronic hypertension (Cowley, 2006; Ward, 2015).

The *metabolic syndrome* is a clinical cluster that includes hypertension, high blood sugar, excess fat at the waist, and abnormal cholesterol or triglyceride levels. This constellation is a risk marker for superimposed preeclampsia and for persistent postpartum hypertension (Jeyabalan, 2015; Spaan, 2012). This is not surprising because obesity may increase the prevalence of chronic hypertension tenfold (Chap. 48, Pregnancy and Obesity). In addition, obese women are more likely to develop superimposed preeclampsia. Diabetes is also prevalent in chronically hypertensive women, and its interplay with obesity and preeclampsia is overwhelming (Leon, 2016). In aforementioned study from the Nationwide Patient Sample, the most frequent comorbidities associated with chronic hypertension were pregestational diabetes—6.6 percent, thyroid disorders—4.1 percent, and collagen-vascular disease—0.6 percent (Bateman, 2012). Similar comorbidities were described by Cruz and associates (2011).

Effects of Pregnancy on Chronic Hypertension

Blood pressure drops in early pregnancy in most women with chronic hypertension, and it rises again during the third trimester (Fig. 50-1). According to studies by Tihtonen and coworkers (2007), women with chronic hypertension have persistently elevated vascular resistance and possibly reduced intravascular volume expansion. Adverse outcomes in these women are dependent largely on whether superimposed preeclampsia develops. This may be related to observations reported by Hibbard and colleagues (2005, 2015) that arterial mechanical properties are most marked in women with superimposed preeclampsia.

FIGURE 50-1
Mean systolic and diastolic blood pressures across pregnancy in 107 untreated chronically hypertensive women (*yellow*) compared with blood pressures across pregnancy in 4589 healthy nulliparas (*blue*). (Data from August, 2015; Levine, 1997; Sibai, 1990a.)



ADVERSE PREGNANCY EFFECTS

Chronic hypertension is associated with several adverse maternal and perinatal outcomes listed in Table 50-3. In sum, these adversities are directly related to severity and duration of hypertension before pregnancy and whether superimposed preeclampsia develops, especially early in gestation. Importantly, in women with mild chronic hypertension, outcomes are also related to blood pressure levels during pregnancy. At this time, however, there are no proven benefits of "tight" versus "less-tight" control of chronic hypertension during pregnancy, as discussed later ("Tight Control") (Magee, 2015).

TABLE 50-3

Some Adverse Effects of Chronic Hypertension on Maternal and Perinatal Outcomes

Maternal	Perinatal
Superimposed preeclampsia	Stillbirth
HELLP syndrome	Growth restriction
Placental abruption	Preterm delivery
Stroke	Neonatal death
Acute kidney injury	Neonatal morbidity
Heart failure	
Hypertensive cardiomyopathy	
Myocardial infarction	
Maternal death	

HELLP = hemolysis, elevated liver enzyme levels, low platelet count.

Maternal Morbidity and Mortality

Most women whose chronic hypertension is well controlled with therapy before pregnancy will do well. Even these women, however, are at increased risk for adverse outcomes. Complications are more likely with severe baseline hypertension and especially with documented end-organ damage (Czeizel, 2011; Odibo, 2013). In a study of pregnancy outcomes in nearly 30,000 chronically hypertensive women, Gilbert and associates (2007) reported markedly increased rates of maternal morbidity that included stroke, pulmonary edema, and renal failure. These observations were verified in the report from the Nationwide Patient Sample by Bateman and colleagues (2012). In this latter study, hypertension complications included stroke—2.7 per 1000, acute renal failure—5.9 per 1000, pulmonary edema—1.5 per 1000, mechanical ventilation—3.8 per 1000, and in-house maternal mortality—0.4 per 1000. The contribution of hypertension to pregnancy-related strokes is discussed in Chapter 60 (Cerebrovascular Diseases) and to hypertensive and idiopathic peripartum cardiomyopathy in Chapter 49 (Dilated Cardiomyopathy).

Pregnancy-aggravated hypertension may be due to gestational hypertension or to superimposed preeclampsia. In either instance, blood pressures can be dangerously elevated. As emphasized by Clark and Hankins (2012), systolic pressure ≥160 mm Hg or diastolic pressure ≥110 mm Hg will rapidly cause renal or cardiopulmonary dysfunction or cerebral hemorrhage. With superimposed severe preeclampsia or eclampsia, the maternal prognosis is poor unless the pregnancy is ended. Placental abruption is a common and serious complication (Chap. 41, Placental Abruption). In addition to hypertensive heart failure mentioned above, aortic dissection was described by Weissman-Brenner and coworkers (2004) and is discussed in Chapter 49 (Diseases of the Aorta).

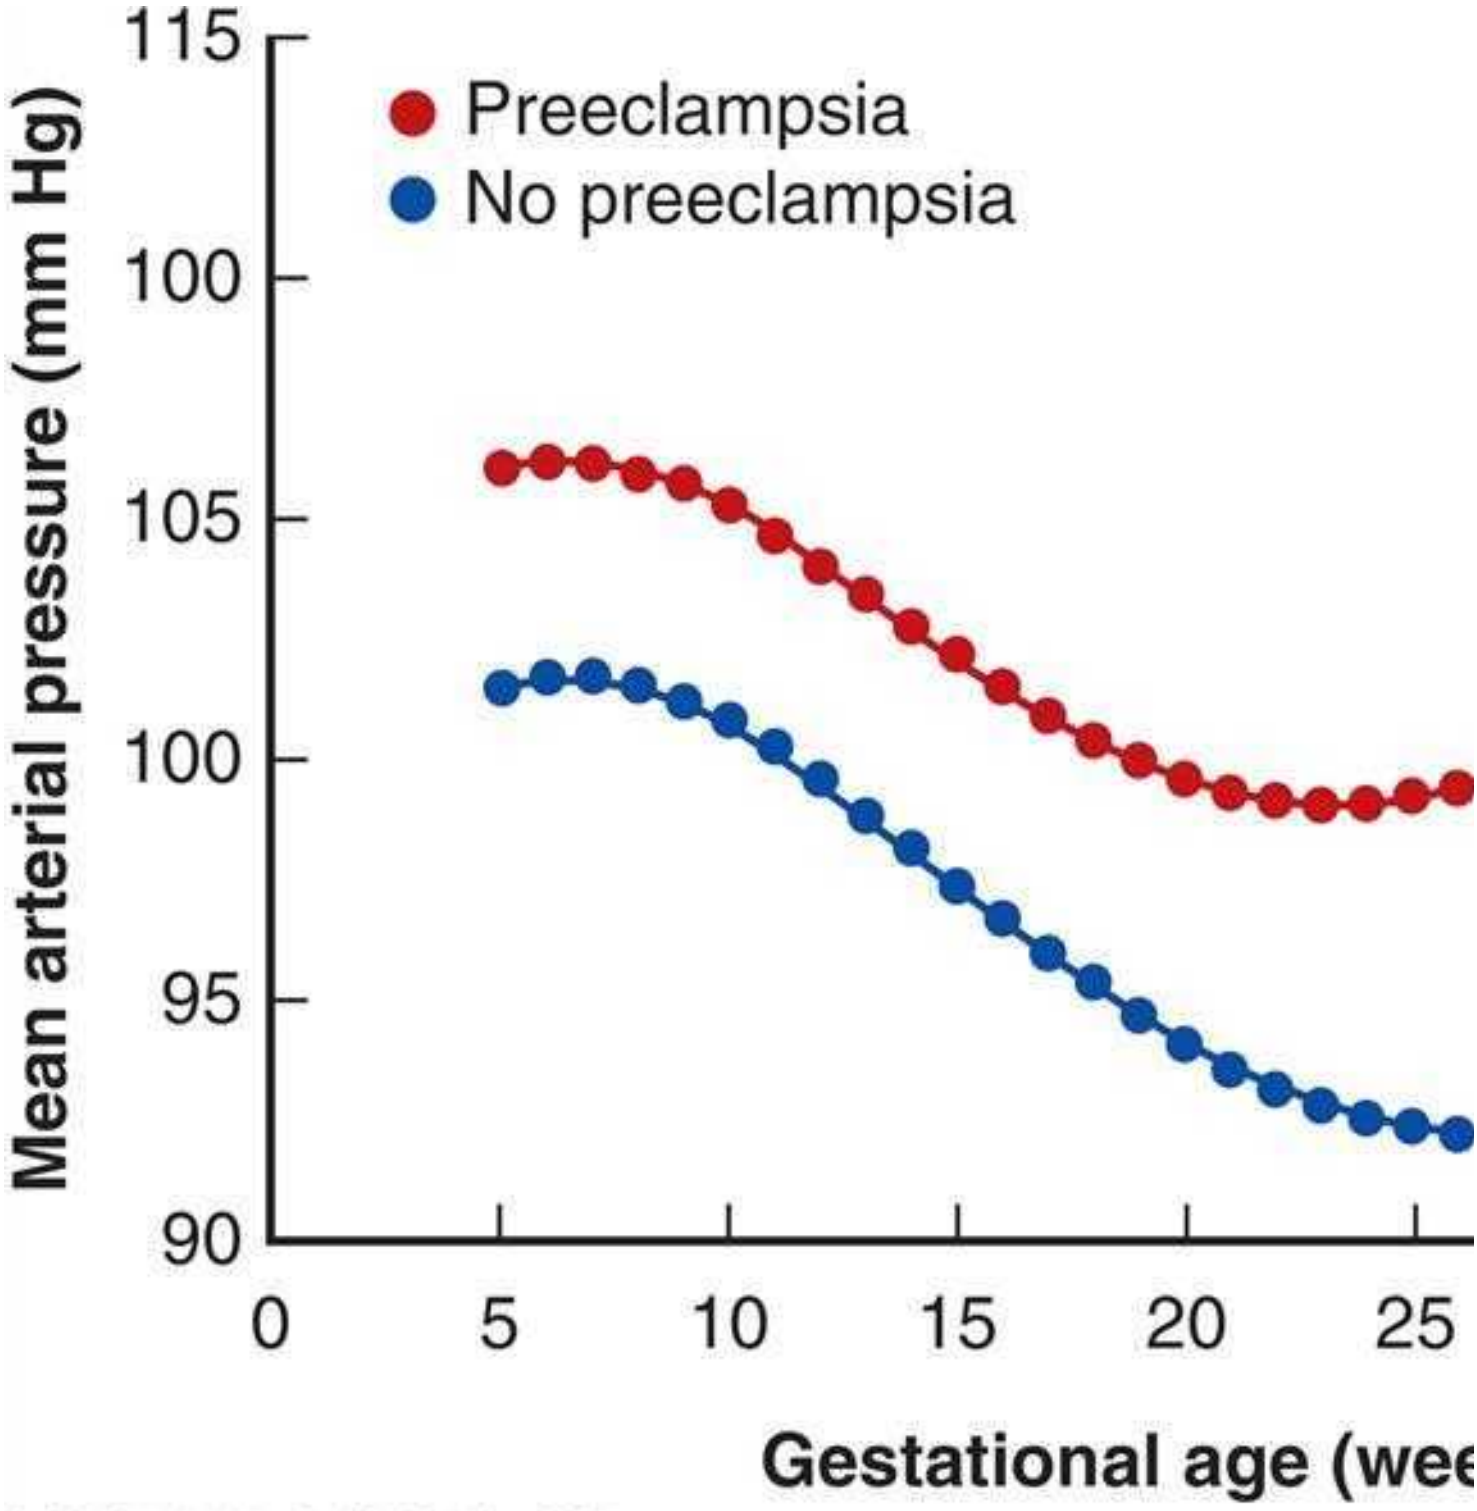
In aggregate, chronic hypertension is associated with a fivefold risk for maternal death (Gilbert, 2007). This is emphasized by the report by Creanga and colleagues (2015) describing 3358 pregnancy-related deaths in the United States from 2006 through 2010. Hypertensive disorders, including chronic hypertension and preeclampsia syndrome, accounted for 9.4 percent of these deaths. Undoubtedly related were other causes of death such as cardiovascular conditions—14.6 percent, cerebrovascular conditions—6.2 percent, and cardiomyopathy—11.8 percent. Moodley (2007) reported similar findings with 3406 maternal deaths from South Africa.

Superimposed Preeclampsia

Because superimposed preeclampsia is not precisely defined in women with chronic hypertension, the reported incidence varies from 13 to 40 percent (American College of Obstetricians and Gynecologists, 2013; Bramham, 2016; Kim, 2016b; Moussa, 2017). August and colleagues (2015) posit that this predilection may stem from similar genetic, biochemical, and metabolic abnormalities. For example, the risk for superimposed preeclampsia is directly related to the severity of baseline hypertension (Ankumah, 2014; Morgan, 2016b). In a Maternal-Fetal Medicine Units (MFMU) Network trial, Caritis and coworkers (1998) identified superimposed preeclampsia in 25 percent of hypertensive gravidas. The rate was 29 percent in a California database study (Yanit, 2012). And, women whose hypertension becomes severe enough to warrant chronic antihypertensive therapy during pregnancy are at inordinately high risk for superimposed preeclampsia (Morgan, 2016a). And, this risk is even higher if there is baseline proteinuria. Finally, and shown in Figure 50-2, chronically hypertensive women destined to develop severe superimposed preeclampsia have higher initial blood pressures that nadir earlier than those of women who do not develop severe disease.

FIGURE 50-2

Blood pressure trends in treated, chronically hypertensive women with and without superimposed preeclampsia. Mean maternal pressures (MAPs) at entry (p = 0.002) and throughout gestation (p <0.001) are significantly different for each group. MAP nadir at 23.3 weeks (95% CI, 22.5–24.1) for superimposed preeclampsia versus 26.4 weeks (95% CI, 22.5–27.6) for those without preeclampsia is significant (3.1 weeks, 95% CI, 2.3–4.3). (Data from Morgan, 2016a.)



Thus far, clinical prognostic and predictive tests for superimposed preeclampsia have been disappointing (Conde-Agudelo, 2015). Di Lorenzo and colleagues (2012) studied serum markers for Down syndrome to predict preeclampsia and calculated a sensitivity of 60 percent, with a 20-percent false-positive rate. Similar results were found using antiangiogenic factors to discriminate among chronic hypertension, gestational hypertension, and preeclampsia (Costa, 2016; Sibai, 2008). According to Anton and coworkers (2013), microRNA assays may prove valuable as predictors of pregnancy-associated hypertension.

Prevention

Trials of various medications to prevent preeclampsia in women with chronic hypertension have generally been disappointing and show little or no benefit. Low-dose aspirin has been evaluated most frequently (Mol, 2016; Staff, 2015). In the MFMU Network study by Caritis (1998) cited above, the incidence of superimposed preeclampsia, fetal-growth restriction, or both is similar in women given low-dose aspirin or placebo. Using the same database, Moore and associates (2015) found that early administration of low-dose aspirin (<17 weeks' gestation) resulted in a significant 41-percent lower frequency of superimposed preeclampsia in chronically hypertensive women—18 versus 31 percent. Duley (2007) and Meads (2008) and their colleagues performed systematic reviews and noted that low-dose aspirin was

beneficial in some high-risk women. Moderate benefits were also found from a metaanalysis by Askie and coworkers (2007). In a secondary analysis, Poon and associates (2017) noted that aspirin was ineffective to reduce the incidence of preterm preeclampsia.

The U.S. Preventive Services Task Force recommends treatment with low-dose aspirin for chronically hypertensive women at high risk for preeclampsia (Henderson, 2014). The recommendation to initiate 81 mg between 12 and 28 weeks' gestation and continue therapy until delivery was adopted by the American College of Obstetricians and Gynecologists (2016b). In addition to chronic hypertension, indications for aspirin prophylaxis for those at high-risk of preeclampsia include a history of preeclampsia, multifetal gestation, diabetes, renal disease, and autoimmune disease.

Antioxidants to prevent preeclampsia have been studied. Spinnato and coworkers (2007) randomly assigned 311 women with chronic hypertension to treatment with vitamins C and E or with a placebo. A similar number in both groups developed preeclampsia—17 versus 20 percent, respectively.

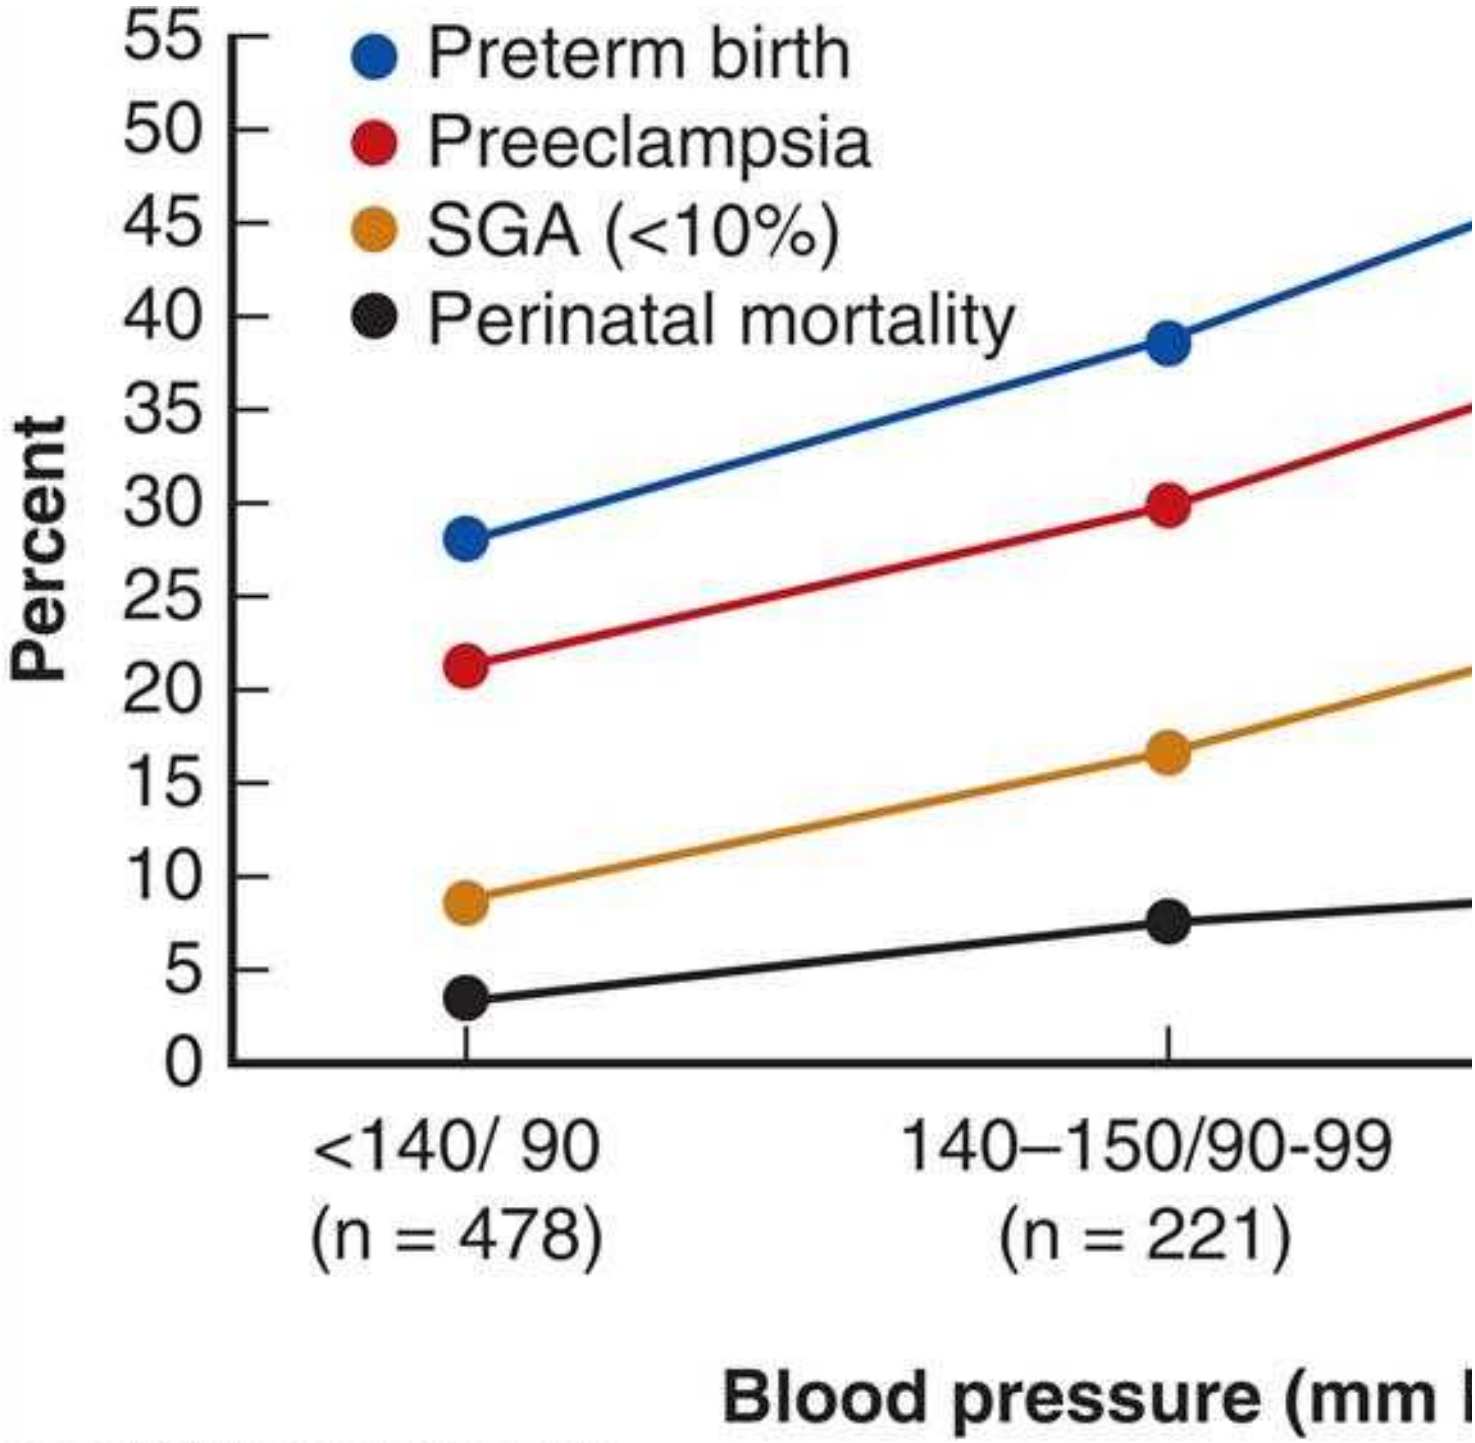
Placental Abruption

Chronic hypertension augments the risk two- to threefold for premature placental separation. The general obstetrical population risk is 1 in 200 to 300 pregnancies, and this rises to 1 in 60 to 120 pregnancies in women with chronic hypertension (Ankumah, 2014; Cruz, 2011; Magee, 2015). The abruption risk is elevated further if the woman smokes. Most abruptions are in women with worsening gestational hypertension or superimposed preeclampsia. The abruption risk is highest with severe hypertension, and Vigil-De Gracia and colleagues (2004) reported it to be 8.4 percent. From medical record data from the Norwegian Birth Registry, folic acid and/or multivitamin supplements slightly lowered the abruption incidence in women with chronic hypertension (Nilsen, 2008).

Perinatal Morbidity and Mortality

Rates of almost all adverse perinatal outcomes are greater in women with chronic hypertension than in nonaffected controls. As expected, for the entire group of hypertensive women, those who developed preeclampsia have substantially higher adverse outcome rates compared with those without preeclampsia. As shown in Figure 50-3, adverse outcome rates rise incrementally with rising blood pressures. Evidence also supports that chronic hypertension—treated or untreated—is associated with congenital anomalies. Bateman and coworkers (2015) from the Medicaid Analytic Extract cited earlier found an elevated risk for severe congenital malformations—especially cardiac defects. Moreover, severe hypertension and fetal esophageal atresia or stenosis have been associated (Bánhidy, 2011; Van Gelder, 2015).

FIGURE 50-3
Frequency of selected adverse maternal and perinatal outcomes by blood pressure stratification in women with mild chronic hypertension. SGA = small for gestational age. (Data from Ankumah, 2014.)



Source: F. Gary Cunningham, Kenneth J. Leveno, Steven L. Bloom, Catherine Y. Spong, Jodi S. Dashe, Barbara L. Hoffman, Brian M. Casey, Jeanne S. Sheffield: Williams Obstetrics: 25th Edition

The stillbirth frequency with chronic hypertension is substantively greater in most reports (Chap. 35, Risk Factors). In the Nationwide Patient Sample study, the stillbirth rate was 15.1 per 1000 births (Bateman, 2012). This is similar to that of 18 per 1000 from a Norwegian study by Ahmad and coworkers (2012) and of 24 per 1000 births from a Network study reported by Ankumah and colleagues (2014) and described in "Tight Control". Low-birthweight neonates are also common. They are due to fetal-growth restriction, preterm delivery that is largely clinically indicated, or both (see Fig. 50-3). In the California database study noted earlier, a fourth of fetuses were delivered preterm (Yanit, 2012).

These and other studies attest to the elevated risk for fetal-growth restriction, and the incidence averages 20 percent. Zetterström and coworkers (2006) reported a 2.4-fold risk for fetal-growth restriction in 2754 chronically hypertensive Swedish women compared with the risk in normotensive women. Broekhuijsen and associates (2012) found a 1.3-fold increased risk for 1609 Dutch nulliparas with chronic hypertension compared with that in normotensive controls. As with other complications, fetal-growth dysfunction is more likely in chronically hypertensive women who develop superimposed preeclampsia. In one study, the incidence of growth-restricted fetuses born to women with superimposed preeclampsia was almost 50 percent compared with only 21 percent in chronically hypertensive women without preeclampsia (Chappell, 2008). Finally, women with chronic hypertension severe enough to warrant treatment had an 11-percent incidence of fetal-growth restriction to a degree yielding birthweights ≤3rd percentile (Morgan, 2016a). For all of these reasons, neonates born to these women have a correspondingly high rate of intensive-care nursery admission.

All of these adverse perinatal effects of chronic hypertension contribute to the greater perinatal mortality rate, which is three- to fourfold higher than the rate in nonaffected gravidas (American College of Obstetricians and Gynecologists, 2013). In the Network study by Ankumah (2014) referenced in Figure 50-3, the perinatal death rate was 31 per 1000 births with mild hypertension, 72 per 1000 births with moderate disease, and 100 per 1000 births in women with severe chronic hypertension. And, in the study from Parkland Hospital by Morgan (2016a), the perinatal mortality rate was 32 per 1000 births in women who were treated for their chronic hypertension. Again, as expected, the highest rates are in women who develop superimposed preeclampsia, for whom the risk doubled from 4 to 8 percent. Finally, if diabetes coexists with chronic hypertension, then preterm delivery, fetal-growth restriction, and perinatal mortality rates are increased even more (Gonzalez-Gonzalez, 2008; Yanit, 2012).

MANAGEMENT DURING PREGNANCY

The diagnosis of chronic hypertension in pregnancy should be confirmed. The American College of Obstetricians and Gynecologists (2013) recommends use of ambulatory monitoring to exclude suspected white-coat hypertension before initiating antihypertensive therapy. Goals for chronic hypertension management include rate reductions of adverse maternal or perinatal outcomes just discussed. Treatment is targeted to prevent moderate or severe hypertension and to delay or dampen the severity of pregnancy-aggravated hypertension. To some extent, these goals can be achieved pharmacologically. Blood pressure self-monitoring is encouraged, but for accuracy, automated devices must be properly calibrated (Brown, 2004; Staessen, 2004). Personal health modification includes dietary counseling and reduction of behaviors such as tobacco, alcohol, cocaine, or other substance use (see Table 50-2). A low-sodium diet is not required (American College of Obstetricians and Gynecologists, 2013).

Some women—especially those with long-term or untreated hypertension—have complications that increase the risk of adverse pregnancy events. For example, in one study, a fourth of gravidas with chronic hypertension also had concentric ventricular hypertrophy (Ambia, 2017; Kim, 2016a). Thus, if not already accomplished, assessment during pregnancy is done for the cardiovascular and renal systems (Morgan, 2016a,b).

Antihypertensive Drugs

As concluded by the American College of Obstetricians and Gynecologists (2013, 2016a), treatment of hypertension during pregnancy has included every drug class, but information is still limited regarding safety and efficacy (Czeizel, 2011; Podymow, 2011). Although many studies indicate greater perinatal adverse effects in gravidas requiring treatment, it is still not known whether this is due to cause or effect (Orbach, 2013). The following summary of antihypertensive drugs is abstracted from several sources, including the *2016 Physicians' Desk Reference*. Many of these drugs are also discussed throughout Chapter 12 (Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs) and have been reviewed by Umans and associates (2015).

Adrenergic-Receptor Blocking Agents

Peripherally acting β-adrenergic-receptor blockers cause a generalized decline in sympathetic tone and decreased cardiac output. Examples are propranolol, metoprolol, and atenolol. Labetalol is a popular and commonly used α/β-adrenergic blocker that is considered safe.

Some adrenergic-blocking drugs act *centrally* by reducing sympathetic outflow to effect a generalized decreased vascular tone. These include clonidine and α-methyldopa. Drugs in this class most frequently used in pregnancy to treat hypertension are methyldopa or an α- or β-receptor blocking agent such as labetalol.

Calcium-Channel Blocking Agents

These drugs are divided into three subclasses based on their modification of calcium entry into cells and interference with binding sites on voltage-dependent calcium channels. Common agents include nifedipine—a dihydropyridine, and verapamil—a phenylalkyl amine derivative. These agents have negative inotropic effects and thus can worsen ventricular dysfunction and congestive heart failure. Theoretically, they may potentiate the vasoactive actions of magnesium sulfate that is given for eclampsia neuroprophylaxis. Although data are limited regarding their use during pregnancy, they appear to be safe therapy for chronic hypertension (Briggs, 2015; Umans, 2015).

Diuretics

Thiazide diuretics are sulfonamides, and these were the first drug group used to successfully treat chronic hypertension (Beyer, 1982). These agents and loop-acting diuretics such as furosemide are commonly used in nonpregnant hypertensive patients. In the short term, they provide sodium and water diuresis with volume depletion. But with time, there is *sodium escape,* and volume depletion is partially corrected. Some aspect of lowered peripheral vascular resistance likely contributes to their effectiveness in reducing long-term morbidity (Umans, 2015).

Thiazide drugs may be mildly diabetogenic, and expected volume expansion may be curtailed in pregnant women. Sibai and colleagues (1984) showed that plasma volume expanded only about 20 percent over time in hypertensive pregnant women who continued diuretic therapy compared with a 50-percent expansion in women who discontinued treatment. Although perinatal outcomes were similar in these women, such concerns have led to practices of withholding diuretics as first-line therapy for chronic hypertension, particularly after 20 weeks' gestation (Working Group Report, 2000). Even so, in a Cochrane review, Churchill and associates (2007) reported no differences in perinatal outcomes in 1836 nonhypertensive women randomly assigned to a thiazide diuretic or placebo for primary preeclampsia prevention. Overall, thiazide diuretics are considered safe in pregnancy (Briggs, 2015). But for preeclampsia treatment, they are considered to be ineffective (Umans, 2015).

Vasodilators

Hydralazine relaxes arterial smooth muscle and has been used parenterally for decades to safely treat severe peripartum hypertension (Chap. 40, Hydralazine). Oral hydralazine monotherapy for chronic hypertension is not generally used because of its weak antihypertensive effects and resultant tachycardia. It may be an effective adjunct for long-term use with other antihypertensives, especially if there is chronic renal insufficiency. In one study, vasodilator treatment of chronically hypertensive women was associated with a twofold rise in rates of low-birthweight and growth-restricted neonates (Su, 2013).

Angiotensin-Converting Enzyme Inhibitors

These drugs inhibit the conversion of angiotensin-I to the potent vasoconstrictor angiotensin-II. They can cause severe fetal malformations when given in the second and third trimesters. These include oligohydramnios, hypocalvaria, and renal dysfunction (Chap. 12, Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs). Some preliminary studies also suggest teratogenic effects, and because of this, they are not recommended at any time during pregnancy (Briggs, 2015; Podymow, 2011).

Angiotensin-receptor blockers act in a similar manner. But, instead of blocking the production of angiotensin-II, they inhibit binding to its receptor. They are presumed to have the same fetal effects as angiotensin-converting enzyme inhibitors and thus are also contraindicated.

Antihypertensive Treatment in Pregnancy

Severe Chronic Hypertension

The prognosis for pregnancy outcome with chronic hypertension is somewhat dependent on the severity of disease antedating pregnancy. This may be related to findings that many women with severe hypertension have renal disease—as either cause or effect (Cunningham, 1990; Morgan, 2016a). It follows that women whose hypertension is severe enough to require antihypertensive therapy are at inordinately high risk for superimposed preeclampsia.

Sibai and coworkers (1986) described outcomes from 44 pregnancies in women whose blood pressure at 6 to 11 weeks' gestation was ≥170/110 mm Hg. All were given oral treatment with α-methyldopa and hydralazine to maintain pressures <160/110 mm Hg. Of the 44 pregnancies, superimposed preeclampsia developed in half, and all adverse perinatal outcomes were in this group. Moreover, all neonates of women in the superimposed group were delivered preterm, nearly 80 percent were also growth restricted, and 48 percent suffered perinatal death. Conversely, those women with severe chronic hypertension who did not develop superimposed preeclampsia had reasonably good outcomes. There were no perinatal deaths, and only 5 percent of fetuses were growth restricted. Webster and colleagues (2017) found labetalol and nifedipine to be equally effective for chronic hypertension in pregnant women.

Morgan and coworkers (2016a) reported 447 women whose chronic hypertension required treatment beginning prior to 20 weeks. More than half of these women developed superimposed severe preeclampsia. The rate of preeclampsia was 53 percent for those whose 24-hour protein excretion was <300 mg. But for those with antecedent baseline proteinuria >300 mg/day, 79 percent developed severe preeclampsia.

Mild or Moderate Hypertension

Continuing prepregnancy antihypertensive treatment during pregnancy is debatable for those with mild or moderate hypertension. Although blood pressure reduction certainly benefits the mother long term, it at least theoretically can reduce uteroplacental perfusion. In older observational reports, most pregnancy outcomes in women with mild to moderate hypertension generally were good without treatment and unless superimposed preeclampsia developed (Chesley, 1978; Umans, 2015).

Newer data are accruing that address potential salutary effects on pregnancy outcomes by simply lowering blood pressure. Earlier studies were relatively small and had widely varying inclusion and outcome criteria. In a Cochrane review of 49 of these studies that included a total of 4723 women with mild to moderate hypertension, Abalos and coworkers (2014) confirmed that the risk for subsequent severe hypertension was lowered with therapy. Compared with untreated women, the frequencies of superimposed preeclampsia, eclampsia, abruption, preterm birth, fetal-growth restriction, and perinatal or maternal mortality did not differ. This latter Cochrane review raised concerns for fetal-growth restriction with **β**-blocking drugs, notably atenolol. It is not resolved, however, because diminished placental perfusion secondary to lowered maternal blood pressure is confounded by the fact that worsening blood pressure itself is associated with abnormal fetal growth. Some also posit that the drugs have a direct fetal action (Umans, 2015). In two of the larger randomized trials, however, the incidence of growth restriction was not altered in women randomly assigned to treatment (Gruppo di Studio Ipertensione in Gravidanza, 1998; Sibai, 1990a).

The observations of Morgan and colleagues (2016a) support the findings of the Cochrane review by Abalos. Specifically, they reported that despite therapy for chronic hypertension, there was frequent superimposed preeclampsia, fetal-growth restriction, preterm delivery, and perinatal mortality. Moreover, and as shown in Table 50-4, women with baseline proteinuria >300 mg/d had even worse obstetrical outcomes.

TABLE 50-4

Selected Pregnancy Outcomes in Women with Chronic Hypertension Treated During Pregnancy with and without Baseline Proteinuria[a]

Outcome	Baseline Proteinuria[a]	No Proteinuria	*P*-value
Superimposed preeclampsia	79%	49%	<0.001
Abruption	0	1%	0.45
EGA at delivery (mean)[b]	35.1 ± 4.3 wks	37.2 ± 3.3 wks	<0.001
≤30 weeks	18%	6%	0.001
≤34 weeks	34%	17%	0.005
≤37 weeks	48%	26%	0.002
Birthweight (mean)[b]	2379 ± 1028 g	2814 ± 807 g	<0.001
≤3rd percentile	20%	9%	0.01
≤10th percentile	41%	22%	<0.001
Perinatal mortality	36/1000	31/1000	0.47

[a]Defined as ≥300 mg/d protein excretion before 20 weeks' gestation.

[b]Mean ± standard deviations.

EGA = estimated gestational age.

Data from Morgan, 2016b.

"Tight Control"

During the past decade, the concept of *tight control* of blood pressure has been espoused as a means of optimizing maternal and perinatal outcomes. Such control is analogous to that of glycemic control for management of the pregnant diabetic patient. The observational study by Ankumah (2014) noted earlier lends credence to tighter control of blood pressure. These investigators showed that the risk of adverse pregnancy outcomes in 759 women with chronic hypertension was lower when blood pressures before 20 weeks were <140 mm Hg compared with higher pressure categories and increasing blood pressures. Unfortunately, this did not hold up when less-tight was compared with tight control. Specifically, Magee and coworkers (2015) randomized 987 women with chronic hypertension or gestational hypertension to either one of these two management schemes. Except for a lower rate of severe hypertension in the tightly controlled group, they found no significant differences between these two groups' other adverse pregnancy outcomes (Table 50-5). Tight control was also not more costly (Ahmed, 2016). These and similar findings prompted an ongoing randomized controlled trial—Project CHAP (ClinicalTrials.gov, 2016)—to answer this question.

TABLE 50-5

Selected Maternal and Perinatal Outcomes in Pregnant Women with Chronic Hypertension According to Less-Tight versus Tight Control

Outcome	Less-Tight Control (n = 493)	Tight Control (n = 488)
Maternal		
Placental abruption	2.2%	2.3%
Severe hypertension[a]Preeclampsia	41%	28%
Preeclampsia	49%	46%
HELLP syndrome	1.8%	0.4%
Perinatal		
Deaths	28/1000	23/1000
<10th percentile	16%	20%
<3rd percentile	4.7%	5.3%
Respiratory problem	17%	14%

[a] $p < 0.001$, all other comparisons $p > 0.05$.

HELLP = hemolysis, elevated liver enzyme levels, low platelet count.

Data from Magee, 2015.

Recommendations for Therapy

Until there are data to confirm any salutary effects of treatment of uncomplicated mild to moderate chronic hypertension in pregnancy, it seems reasonable to follow the guidelines of the American College of Obstetricians and Gynecologists (2013) and the Society for Maternal-Fetal Medicine (2015). Pregnant women with *severe hypertension* must be treated for maternal neuro-, cardio-, and renoprotection. Treatment is also mandatory for women with prior adverse outcomes such as strokes, MIs, and evidence for cardiac or renal dysfunction. With end-organ dysfunction, treatment to diastolic pressure level ≤90 mm Hg is reasonable to mitigate further organ damage.

For most women with mild to moderate hypertension, the College recommends that treatment be withheld as long as systolic blood pressure is <160 mm Hg and diastolic blood pressure is <105 mm Hg. Some find it reasonable to begin antihypertensive treatment in otherwise healthy pregnant women with persistent systolic pressures >150 mm Hg or diastolic pressures of 95 to 100 mm Hg or greater (August, 2015; Working Group Report, 2000). At Parkland Hospital we initiate treatment with antihypertensive agents for blood pressures of 150/100 mm Hg or higher. Our preferred regimens include monotherapy with a β-blocking drug such as labetalol or a calcium-channel blocking agent such as amlodipine. For women in the first half of pregnancy, therapy with a thiazide diuretic seems reasonable. This is especially true in black women, in whom there is a high prevalence of salt-sensitive chronic hypertension.

It is controversial whether or not women who present early in pregnancy and who are already taking antihypertensive drugs should continue to take these (Rezk, 2016). According to the American College of Obstetricians and Gynecologists (2013) and the Society for Maternal-Fetal Medicine (2015), for women with mild to moderate hypertension, it is *reasonable* to discontinue medications during the first trimester and to restart them if blood pressures approach the severe range. Our practice at Parkland Hospital is to continue treatment if the woman is already taking drugs when she presents for prenatal care. Exceptions are discontinuation of angiotensin-converting enzyme inhibitors and receptor blockers.

Some women will have persistently worrisome hypertension despite usual therapy (Samuel, 2011; Sibai, 1990a). In these women, primary attention is given to the likelihood of pregnancy-aggravated hypertension, with or without superimposed preeclampsia. Other possibilities include inaccurate blood-pressure measurements, suboptimal treatment, and antagonizing substances such as chronic ingestion of nonsteroidal antiinflammatory drugs (NSAIDs) (Moser, 2006; Sowers, 2005).

Pregnancy-Aggravated Hypertension or Superimposed Preeclampsia

As discussed, the frequency of superimposed preeclampsia for women with chronic hypertension varies depending on the study population and hypertension severity (Ankumah, 2014). Importantly, in 40 to 50 percent of chronically hypertensive women, superimposed preeclampsia develops before 37 weeks (Chappell, 2008; Harper, 2016). This proportion is even higher in women who required hypertension treatment during pregnancy (Morgan, 2016a).

The diagnosis may be difficult to make, especially in women with hypertension who have underlying renal disease with chronic proteinuria (Cunningham, 1990; Morgan, 2016b). As discussed in Chapter 40 (Preeclampsia Superimposed on Chronic Hypertension), conditions that support the diagnosis of superimposed preeclampsia include worsening hypertension, new-onset proteinuria, neurological symptoms such as severe headaches and visual disturbances, generalized edema, oliguria, and certainly, convulsions or pulmonary edema. Making the diagnosis based on worsening proteinuria in women with baseline proteinuria is problematic. Supporting laboratory abnormalities are rising serum creatinine or hepatic transaminase levels, thrombocytopenia, or any of the facets of HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome. For women with chronic hypertension and superimposed preeclampsia with severe features, magnesium sulfate for maternal neuroprophylaxis is recommended (American College of Obstetricians and Gynecologists, 2013). Severe hypertension is treated as described in Chapter 40 (Management Considerations).

Some pregnant women with chronic hypertension have worsening hypertension with no other findings of superimposed preeclampsia. This is most commonly encountered near the end of the second trimester. In the absence of other supporting criteria for superimposed preeclampsia, this likely represents the higher end of the normal blood-pressure curve shown in Figure 50-1. In such women, if preeclampsia can be confidently excluded, it is reasonable to begin or to increase the dose of antihypertensive therapy.

Fetal Assessment

Women with well-controlled chronic hypertension who have no complicating factors can generally be expected to have a good pregnancy outcome. Because even those with mild hypertension have a greater risk of superimposed preeclampsia and fetal-growth restriction, serial antepartum assessment of fetal well-being is recommended by many. That said, according to the American College of Obstetricians and Gynecologists (2013), with the exception of sonographic fetal-growth monitoring, described in Chapter 44 (Fetal-Growth Restriction Recognition), no conclusive data address either benefit or harm associated with various antepartum surveillance strategies.

Expectant Management of Early-Onset Preeclampsia

Given that many women with chronic hypertension develop superimposed preeclampsia before term, considerations for expectant management may be reasonable in some cases. In a study from Magee-Women's Hospital, 41 carefully selected women with a median gestational age of 31.6 weeks were expectantly managed (Samuel, 2011). Despite liberal criteria to mandate delivery, 17 percent developed either placental abruption or pulmonary edema. The latency period was extended by a mean of 9.7 days. There were no perinatal deaths, however, salutary outcomes were similar. These investigators recommend randomized trials to study expectant management before this becomes usual care.

Delivery

For chronically hypertensive women who have complications such as fetal-growth restriction or superimposed preeclampsia, the decision to deliver is made by clinical judgment. The route of delivery is dictated by obstetrical factors. Certainly, most women with superimposed severe preeclampsia are better delivered even when the fetus is markedly preterm. Increased risk for placental abruption, cerebral hemorrhage, and peripartum heart failure attend delivery delays (Cunningham, 1986, 2005; Martin, 2005).

For women with chronic hypertension without preeclampsia, expectant management at later gestational ages was reported recently by Harper and colleagues (2016). They concluded that expectant management beyond 39 weeks' gestation was associated with an increasing incidence of severe preeclampsia and that planned delivery before 37 weeks was associated with a rise in rates of adverse neonatal outcomes.

For women with mild to moderate chronic hypertension who continue to have an uncomplicated pregnancy, the American College of Obstetricians and Gynecologists (2013) recommends delivery not be pursued until $38^{0/7}$ weeks. The consensus committee findings by Spong and associates (2011) recommend consideration for delivery at 38 to 39 weeks, that is, ≥37 completed weeks. A trial of labor induction is preferable, and many of these women respond favorably and will be delivered vaginally (Alexander, 1999; Atkinson, 1995).

Intrapartum Considerations

For women with severe preeclampsia, peripartum management is the same as described in Chapter 40 (Consideration for Delivery). Epidural analgesia for labor and delivery is optimal with the caveat that it is not given to treat hypertension (Lucas, 2001). That said, women with severe superimposed preeclampsia are more sensitive to the acute hypotensive effects of epidural analgesia (Vricella, 2012). Also in this group, magnesium sulfate neuroprophylaxis is initiated for prevention of eclampsia. Severe hypertension—diastolic blood pressure ≥110 mm Hg or systolic pressure ≥160 mm Hg—is treated with either intravenous hydralazine or labetalol. Some prefer to treat women when the diastolic pressure reaches 100 to 105 mm Hg. Vigil-De Gracia and colleagues (2006) randomly assigned 200 women to intravenous hydralazine or labetalol to acutely lower severe high blood pressure in pregnancy. Outcomes were similar except for significantly more maternal palpitations and tachycardia with hydralazine and significantly more neonatal hypotension and bradycardia with labetalol.

Postpartum Care

In most respects, postpartum observation, prevention, and management of adverse complications are similar in women with severe chronic hypertension and in those with severe preeclampsia–eclampsia. For persistent severe hypertension, consideration is given for a cause such as pheochromocytoma or Cushing disease (Sibai, 2012). And, in women with chronic end-organ damage, certain complications are more common. These include cerebral or pulmonary edema, heart failure, renal dysfunction, or cerebral hemorrhage, especially within the first 48 hours after delivery (Martin, 2005; Sibai, 1990b, 2012). These frequently are preceded by sudden elevations—"spikes"—of mean arterial blood pressure and of the systolic component (Cunningham, 2000, 2005).

Following delivery, as maternal peripheral resistance rises, left ventricular workload also grows. This elevation is further aggravated by appreciable and pathological amounts of interstitial fluid that are mobilized to be excreted as endothelial disruption from preeclampsia resolves. In these women, sudden hypertension—either moderate or severe—may exacerbate diastolic dysfunction, cause systolic dysfunction, and lead to pulmonary edema (Cunningham, 1986; Gandhi, 2001). Prompt hypertension control, along with furosemide-evoked diuresis, usually quickly resolves pulmonary edema.

The antihypertensive regimen given antepartum can be restarted in the puerperium. It is also possible in many women to forestall postpartum hypertension by administering intravenous or oral furosemide to augment the normal postpartum diuresis. In one study, 20-mg oral furosemide given daily for 5 days to postpartum women with severe preeclampsia aided blood pressure control (Ascarelli, 2005). Daily weights are helpful in this regard. On average, a woman should weigh 15 pounds less immediately after delivery. Excessive extracellular fluid can then be estimated. Other studies are in progress to determine aspects of postpartum blood pressure management (Cursino, 2015).

Some evidence supports that *chronic* ingestion of NSAIDs in the puerperium elevates blood pressure in women with severe preeclampsia (Vigil-De Gracia, 2017). This may not be problematic if these drugs are given only as needed (Wasden, 2014).

Women with chronic hypertension have special considerations for contraceptive and sterilization choices. These are discussed in detail throughout Chapters 38 and 39.

Long-Term Prognosis

Ultimately, women with chronic hypertension are at high risk for lifetime cardiovascular complications, especially when accompanied by diabetes, obesity, and the metabolic syndrome. Recent evidence also suggests that these women are at greater risk to develop cardiomyopathy remote from pregnancy (Behrens, 2016).

CHAPTER 51: Pulmonary Disorders

A lung which is partially destroyed or thrown out of function may suffice for the respiration of a normal individual, but be unable to respond to the added demands of pregnancy, particularly in the latter months, when the enlarged uterus restricts the mobility of the diaphragm.

—J. Whitridge Williams (1903)

INTRODUCTION

As indicated by the above, it has long been appreciated that women in advanced pregnancy tolerate lung disease poorly. Nevertheless, pulmonary disorders are frequently encountered during pregnancy. Chronic asthma or an acute exacerbation is the most common and affects up to 8 percent of pregnant women. Moreover, asthma along with community-acquired pneumonia accounted for almost 10 percent of nonobstetrical antepartum hospitalizations in one managed care plan (Gazmararian, 2002). Pneumonia is also a frequent postpartum complication requiring readmission (Belfort, 2010). These and other pulmonary disorders are superimposed on several important pregnancy-induced changes of ventilatory physiology. For example, pregnant women, especially those in the last trimester, are susceptible to complications of severe acute pneumonitis as evidenced by the disparate number of maternal deaths during influenza pandemics.

The important and sometimes marked changes in the respiratory system induced by pregnancy are reviewed in Chapter 4 (Respiratory Tract), and values for associated tests can be found in the Appendix (Serum and Blood Constituents). Lung volumes and capacities that are measured directly to assess pulmonary pathophysiology may be significantly altered. In turn, these change gas concentrations and acid-base values in blood. Some of the physiological alterations induced by pregnancy were summarized by Wise and associates (2006):

1. *Vital capacity* and *inspiratory capacity* increase by approximately 20 percent by late pregnancy.
2. *Expiratory reserve volume* decreases from 1300 mL to approximately 1100 mL.
3. *Tidal volume* increases approximately 40 percent as a result of respiratory stimulation by progesterone.
4. *Minute ventilation* increases 30 to 40 percent due to increased tidal volume. As a result, arterial P_{O_2} increases from 100 to 105 mm Hg.
5. Increasing metabolic demands cause a 30-percent rise in *carbon dioxide (CO2) production*. But, because of its concomitantly increased diffusion capacity and hyperventilation, the arterial P_{CO_2} decreases from 40 to 32 mm Hg.
6. *Residual volume* decreases approximately 20 percent from 1500 mL to approximately 1200 mL.
7. *Chest wall compliance* is reduced by a third by the expanding uterus and increased intraabdominal pressure. This causes a 10- to 25-percent decrease in *functional residual capacity*—the sum of expiratory reserve and residual volumes.

In a longitudinal cohort study, Grindheim and colleagues (2012) also showed that forced vital capacity and peak expiratory flow rose progressively across pregnancy after 14 to 16 weeks' gestation. The end result of these pregnancy-induced changes is substantively increased ventilation due to deeper but not more frequent breathing. These are thought to be stimulated by basal oxygen consumption as it rises incrementally from 20 to 40 mL/min in the second half of pregnancy.

ASTHMA

Reactive airway disease is seen frequently in young women and therefore often complicates pregnancy. Asthma prevalence grew steadily in many countries beginning in the mid-1970s but may have plateaued in the United States with a prevalence in adults of approximately 10 percent (Barnes, 2015; Centers for Disease Control and Prevention, 2010c, 2013). The estimated asthma prevalence during pregnancy ranges between 4 and 8 percent, and this appears to be rising (Kelly, 2015; Racusin, 2013). Finally, evidence is accruing that fetal and neonatal environmental exposures may contribute to the origins or mitigation of asthma (Grant, 2016; Litonjua, 2016; Spiegel, 2016).

Pathophysiology

Asthma is a chronic inflammatory airway syndrome with a major hereditary component. Increased airway responsiveness and persistent subacute inflammation are associated with polymorphism genes on chromosomes 5q that include cytokine gene clusters, β-adrenergic and glucocorticoid receptor

genes, and the T-cell antigen receptor gene (Barnes, 2015). Asthma is etiologically and clinically heterogeneous, and an *environmental allergic stimulant* such as influenza or cigarette smoke serves as a promoter for susceptible individuals (Bel, 2013).

The hallmarks of asthma are reversible airway obstruction from bronchial smooth muscle contraction, vascular congestion, tenacious mucus, and mucosal edema. Mucosal inflammation is characterized by infiltration with eosinophils, mast cells, and T lymphocytes. These causes airway inflammation and increased responsiveness to numerous stimuli that include irritants, viral infections, aspirin, cold air, and exercise. Several inflammatory mediators produced by these and other cells include histamine, leukotrienes, prostaglandins, cytokines, IgE, and many others. Importantly, because F-series prostaglandins and ergonovine exacerbate asthma, these commonly used obstetrical drugs should be avoided if possible.

Clinical Course

Pulmonary function changes are more pronounced in asthmatics compared with healthy women (Zairina, 2015). Asthma manifestations range from mild wheezing to severe bronchoconstriction, which obstructs airways and decreases airflow. This lowers the forced expiratory volume in 1 second/forced vital capacity (FEV_1/FVC) ratio and the peak expiratory flow (PEF). The work of breathing progressively increases, and patients note chest tightness, wheezing, or breathlessness. Subsequent alterations in oxygenation primarily reflect ventilation–perfusion mismatching because the distribution of airway narrowing is uneven.

Varied manifestations of asthma have led to a simple classification that considers severity, onset, and duration of symptoms (Table 51-1). With persistent or worsening bronchial obstruction, clinical stages progress as shown in Figure 51-1. Hypoxia initially is mitigated by hyperventilation, which maintains arterial P_{O_2} within a normal range but lowers P_{CO_2}, creating respiratory alkalosis. As airway narrowing worsens, ventilation–perfusion defects increase, and arterial hypoxemia ensues. With severe obstruction, ventilation becomes impaired as fatigue causes early CO_2 retention. Because of hyperventilation, this may only be seen initially as an arterial P_{CO_2} returning to the normal range. With continuing obstruction, respiratory failure follows from fatigue.

TABLE 51-1

Classification of Asthma Severity

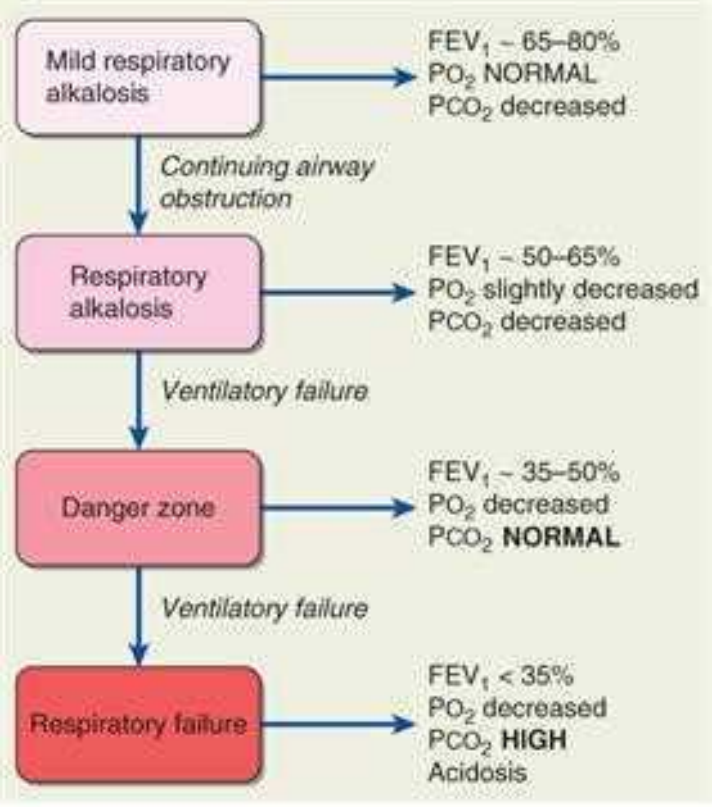
	Severity			
		Persistent		
Component	**Intermittent**	**Mild**	**Moderate**	**Severe**
Symptoms	≤2 day/wk	>2 day/wk, not daily	Daily	Throughout day
Nocturnal awakenings	≤2×/mo	3–4×/mo	>1×/wk, not nightly	Often 7×/wk
Short-acting β-agonist for symptoms	≤2 day/wk	≥2 day/wk, but not >1×/day	Daily	Several times daily
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal between exacerbations			
• FEV_1	>80% predicted	≥80% predicted	60–80% predicted	<60% predicted
• FEV_1/FVC	Normal	Normal	Reduced 5%	Reduced >5%

FEV = forced expiratory volume; FVC = forced vital capacity.

From National Heart, Lung, and Blood Institute, 2007.

FIGURE 51-1

Clinical stages of asthma. FEV_1 = forced expiratory volume in 1 second.



Although these changes are generally reversible and well tolerated by the healthy nonpregnant individual, even early asthma stages may be dangerous for the pregnant woman and her fetus. This is because smaller functional residual capacity and increased pulmonary shunting render the woman more susceptible to hypoxia and hypoxemia.

Effects of Pregnancy on Asthma

Pregnancy has an unpredictable effect on underlying asthma. In their review of six prospective studies of more than 2000 gravidas, Gluck and Gluck (2006) reported that approximately a third each improved, remained unchanged, or clearly worsened. Exacerbations are more common with severe disease (Ali, 2013). In a study by Schatz and associates (2003), baseline severity correlated with asthma morbidity during pregnancy. With mild disease, 13 percent of women had an exacerbation and 2.3 percent required admission; with moderate disease, these numbers were 26 and 7 percent; and for severe asthma, 52 and 27 percent. Others have reported similar observations (Charlton, 2013; Hendler, 2006). Finally, morbidity rates are disproportionately increased in black compared with white women.

Up to 20 percent of women with mild or moderate asthma have been reported to have an intrapartum exacerbation (Schatz, 2003). Conversely, Wendel and associates (1996) reported exacerbations at the time of delivery in only 1 percent of women. Mabie and coworkers (1992) reported an 18-fold increased exacerbation risk following cesarean versus vaginal delivery.

Pregnancy Outcome

Women with asthma have had improved pregnancy outcomes during the past 20 years. The incidence of spontaneous abortion in women with asthma may be slightly increased (Blais, 2013). Maternal and perinatal outcomes for nearly 30,000 pregnancies in asthmatic women are shown in Table 51-2. Findings are not consistent among these studies. For example, in some, but not all, the incidences of preeclampsia, preterm labor, growth-restricted infants, and perinatal mortality are slightly increased (Murphy, 2011). Other reports cited a small rise in the incidence of placental abruption and previa, preterm rupture of membranes, and gestational diabetes (Getahun, 2006; Wang, 2014). But, in a European report of 37,585 pregnancies of women with asthma, the risks for most obstetrical complications were not increased (Tata, 2007). Finally, Cossette and coworkers (2013) reported a nonsignificant trend between perinatal complications and increasing inhaled-corticosteroid dosage.

TABLE 51-2

Maternal and Perinatal Outcomes in Pregnancies Complicated by Asthma

	Perinatal Outcomes (%)			
Study	**No.**	**Gestational Hypertension[a]**	**Growth Restriction**	**Preterm Delivery**
Liu (2001)	2193	13	12	10
Dombrowski (2004a)	1739	12.2[b]	7.1[b]	16[b]
Mendola (2013)	17,044	10.2[c]	NS	14.8[c]
Cossette (2013)	7376	NS	13.5[c]	9.5[c]
Approximate average	28,352	~11	~11	~13

[a]Includes preeclampsia syndromes.

[b]Incidence not significantly different compared with control group or general obstetrical population.

[c]Incidence significantly greater than control group or general obstetrical population.

NS = not stated.

Increased morbidity appears to be significantly linked to severe disease, poor control, or both. In the study by the Maternal-Fetal Medicine Units (MFMU) Network, delivery before 37 weeks' gestation was not increased among the 1687 pregnancies of asthmatic women compared with those of 881 controls (Dombrowski, 2004a). But for women with severe asthma, the rate was increased approximately twofold. In a prospective evaluation of 656 asthmatic pregnant women and 1052 pregnant controls, Triche and coworkers (2004) found that women with moderate to severe asthma, regardless of treatment, are at increased risk of preeclampsia. Finally, the MFMU Network study suggests a direct relationship of baseline pregnancy FEV_1 with birthweight and an inverse relationship with rates of gestational hypertension and preterm delivery (Schatz, 2006).

Maternal morbidity includes life-threatening complications from status asthmaticus. This causes muscle fatigue with respiratory arrest, pneumothorax, pneumomediastinum, acute cor pulmonale, and cardiac arrhythmias. Not surprisingly, maternal and perinatal mortality rates rise substantively when mechanical ventilation is required.

Fetal Effects

As discussed, with reasonable asthma control, perinatal outcomes are generally good. In the Network study cited above, rates of adverse neonatal sequelae caused by asthma were not significantly increased (Dombrowski, 2004a). The caveat is that severe asthma was uncommon in this closely monitored group. When respiratory alkalosis develops, earlier animal and human studies suggest that fetal hypoxemia develops well before the alkalosis compromises maternal oxygenation (Rolston, 1974). It is hypothesized that the fetus is jeopardized by decreased uterine blood flow, decreased maternal venous return, and an alkaline-induced leftward shift of the oxyhemoglobin dissociation curve (Chap. 47, Positive End-Expiratory Pressure).

The fetal response to maternal hypoxemia is decreased umbilical blood flow, increased systemic and pulmonary vascular resistance, and decreased cardiac output. Observations by Bracken and colleagues (2003) confirm that the incidence of fetal-growth restriction increases with asthma severity. Because the fetus may be seriously compromised as asthma severity increases, the need for aggressive management is underscored. Monitoring the fetal response is, in effect, an indicator of maternal status.

Possible teratogenic or adverse fetal effects of drugs given to control asthma have been a concern. Several reports show a slightly greater risk for varied abnormalities such as cleft lip and palate and autism spectrum disorders. However, not all studies have verified this (Eltonsy, 2016; Gidaya, 2016; Murphy, 2013b; Wang, 2014). It is worrisome that up to half of these women discontinue essential treatment between 5 and 13 weeks' gestation (Enriquez, 2006).

Clinical Evaluation

The subjective severity of asthma frequently does not correlate with objective measures of airway function or ventilation. Although clinical examination can also be an inaccurate predictor, useful signs include labored breathing, tachycardia, pulsus paradoxus, prolonged expiration, and use of accessory muscles. Signs of a potentially fatal attack include central cyanosis and altered consciousness.

Arterial blood gas analysis provides objective assessment of maternal oxygenation, ventilation, and acid-base status. With this information, the severity of an acute attack can be assessed (see Fig. 51-1). That said, in a prospective evaluation, Wendel and associates (1996) found that *routine* arterial blood gas analysis did not help to manage most pregnant women who required admission for asthma control. If used, the results must be interpreted in relation to normal values for pregnancy. For example, a P_{CO_2}>35 mm Hg with a pH <7.35 is consistent with hyperventilation and CO_2 retention in a pregnant woman.

Pulmonary function testing should be routine in the management of chronic and acute asthma. Sequential measurement of the FEV_1 or of the *peak expiratory flow rate—PEFR*—is the best measure of severity. An FEV_1 less than 1 L, or less than 20 percent of predicted value, correlates with severe disease defined by hypoxia, poor response to therapy, and a high relapse rate. The PEFR correlates well with the FEV_1, and it can be measured reliably with inexpensive portable meters. It is advantageous for each woman to determine her own baseline when asymptomatic to compare with values when symptomatic.

Management of Chronic Asthma

Asthma management by an experienced team produces the most salutary outcomes (Bonham, 2017; Lim, 2014; Wendel, 1996). Management guidelines include:

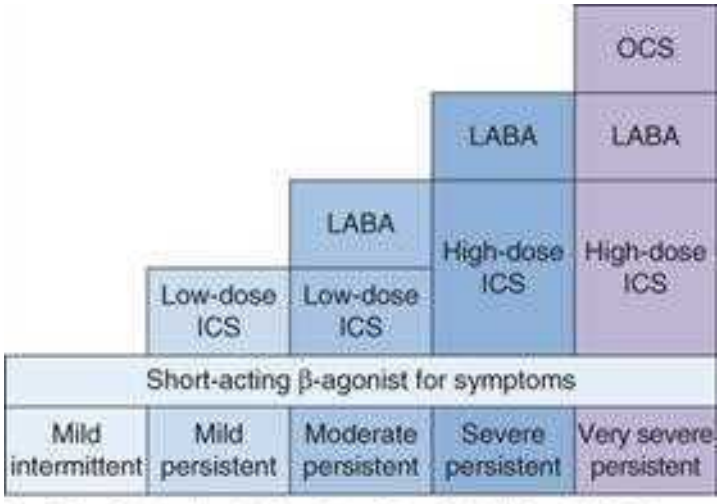
1. Patient education—general asthma management and its effect on pregnancy.
2. Environmental precipitating factors—avoidance or control. Viral infections that include the common cold are frequent triggering events (Ali, 2013; Murphy, 2013a).
3. Objective assessment of pulmonary function and fetal status—monitor with PEFR or FEV_1.
4. Pharmacological therapy—in appropriate combinations and doses to provide baseline control and treat exacerbations. Compliance may be a problem, and periodic medication reviews are helpful (Sawicki, 2012).

In general, women with moderate to severe asthma ideally measure and record either their FEV_1 or PEFR twice daily. The FEV_1 ideally is >80 percent of predicted. For PEFR, predicted values range from 380 to 550 L/min. Each woman has her own baseline value, and therapeutic adjustments can be made using this (American College of Obstetricians and Gynecologists, 2016a; Rey, 2007).

Treatment depends on disease severity. No therapeutic regimen for management of pregnant asthmatics is universally accepted (Bain, 2014). β-Agonists help abate bronchospasm, and corticosteroids treat inflammation. Regimens recommended for outpatient management are listed in Figure 51-2. For mild asthma, inhaled β-*agonists* as needed are usually sufficient. For persistent asthma, *inhaled corticosteroids* are administered every 3 to 4 hours. The goal is to reduce the use of β-agonists for symptomatic relief. A case-control study from Canada with a cohort of more than 15,600 nonpregnant women with asthma showed that inhaled corticosteroids reduced hospitalizations by 80 percent (Blais, 1998). At Parkland Hospital, Wendel and colleagues (1996) achieved a 55-percent reduction in readmissions for severe exacerbations with inhaled steroids.

FIGURE 51-2

Stepwise approach to asthma treatment. ICS = inhaled corticosteroids; LABA = long-acting β-agonists; OCS = oral corticosteroids. (Modified from Barnes PJ: Asthma. In Kasper D, Fauci A, Hauser SL, et al (eds): Harrison's Principles of Internal Medicine, 19th ed. New York, McGraw-Hill Education, 2015, p 1669.)



Theophylline has been used less frequently since inhaled corticosteroids became available. Minimal benefit is gained with use of these compounds and they have a high rate of side effects. However, some theophylline derivatives are considered useful for oral maintenance therapy if the initial response to

inhaled corticosteroids and β-agonists is not optimal (Dombrowski, 2004b).

Antileukotrienes inhibit leukotriene synthesis and include *zileuton, zafirlukast*, and *montelukast*. These drugs are given orally or by inhalation for prevention, but they are not effective for acute disease (Barnes, 2015). For maintenance, they are used in conjunction with inhaled corticosteroids to allow minimal dosing. Approximately half of asthmatics will improve with these drugs. These agents are not as effective as inhaled corticosteroids, and there is little experience with their use in pregnancy (Fanta, 2009).

Cromones include *cromolyn* and *nedocromil,* which inhibit mast cell degranulation. They are ineffective for acute asthma and are used primarily to treat childhood asthma.

Management of Acute Asthma

Treatment of acute asthma during pregnancy is similar to that for the nonpregnant asthmatic. Importantly, the threshold for hospitalization is significantly lower. Intravenous (IV) hydration may help clear pulmonary secretions, and supplemental oxygen is given by mask. The therapeutic aim is to maintain the Po_2 >60 mm Hg, and preferably normal, along with 90- to 95-percent oxygen saturation. Baseline pulmonary function testing includes FEV_1 or PEFR. Continuous pulse oximetry and electronic fetal monitoring, depending on gestational age, may provide useful information. Antibiotics are not given unless there is concomitant pneumonitis, which is caused by the same organisms discussed in Pneumonia (Terraneo, 2014).

First-line therapy for acute asthma includes a short-acting β-adrenergic agonist, such as terbutaline, albuterol, isoetharine, epinephrine, isoproterenol, or metaproterenol, which is given subcutaneously, taken orally, or inhaled. In severely ill women, these drugs can be given IV (Barnes, 2015). They bind to specific cell-surface receptors and activate adenylyl cyclase to increase intracellular cyclic AMP and modulate bronchial smooth muscle relaxation. Long-acting preparations are used for outpatient therapy.

If not previously given for maintenance, inhaled corticosteroids are commenced. A nebulized anticholinergic drug may be added if the response at this point is unsatisfactory (Barnes, 2015). Also, for severe exacerbations, IV magnesium sulfate or theophylline may prove efficacious. Corticosteroids are given early to all patients with severe acute asthma. Unless the response to bronchodilator and inhaled corticosteroid therapy is prompt, oral or parenteral corticosteroids are given (Lazarus, 2010). One regimen is oral prednisone or prednisolone or IV methylprednisolone in a dose of 30 to 45 mg daily for 5 to 10 days without tapering (Barnes, 2015). Because their onset of action is several hours, corticosteroids are given initially along with β-agonists for severe acute asthma.

At this juncture, further management depends on the severity and response to therapy. If initial therapy with β-agonists is associated with improvement of FEV_1 or PEFR to above 70 percent of baseline, then discharge can be considered. Some women may benefit from longer observation. Alternatively, for the woman with obvious respiratory distress, or if the FEV_1 or PEFR is <70 percent of predicted after three doses of β-agonist, admission is usually advisable (Lazarus, 2010). Intensive therapy is continued with inhaled β-agonists, IV corticosteroids, and close observation for worsening respiratory distress or fatigue in breathing (Racusin, 2013). The woman is cared for in the delivery unit or an intermediate or intensive care unit (ICU) (Dombrowski, 2006; Zeeman, 2003).

Status Asthmaticus and Respiratory Failure

Severe asthma of any type not responding after 30 to 60 minutes of intensive therapy is termed status asthmaticus. This has been termed by some as critical asthma symptoms (Kenyon, 2015). Generally, management of nonpregnant patients with status asthmaticus in an intensive care setting results in a good outcome. Consideration should be given to early intubation when maternal respiratory status worsens despite aggressive treatment (see Fig. 51-1). Fatigue, CO_2 retention, and hypoxemia are indications for mechanical ventilation (Chan, 2015). Although Lo and colleagues (2013) described a woman with status asthmaticus in whom cesarean delivery was necessary to effect ventilation, Andrews (2013) cautioned that such clinical situations are uncommon.

Labor and Delivery

For the laboring asthmatic, maintenance medications are continued through delivery. Stress-dose corticosteroids are administered to any woman given systemic corticosteroid therapy within the preceding 4 weeks. The usual dose is 100 mg of hydrocortisone given IV every 8 hours during labor and for 24 hours after delivery. The PEFR or FEV_1 is determined on admission, and serial measurements are taken if symptoms develop.

Oxytocin or prostaglandins E_1 or E_2 are used for cervical ripening and induction. A nonhistamine-releasing narcotic such as fentanyl may be preferable to meperidine for labor, and epidural analgesia is ideal. For surgical delivery, conduction analgesia is preferred because tracheal intubation can trigger severe bronchospasm. Postpartum hemorrhage is treated with oxytocin or prostaglandin E_1 or E_2. Prostaglandin $F_{2\alpha}$ or ergotamine derivatives are contraindicated because they may cause significant bronchospasm.

ACUTE BRONCHITIS

Infection of the large airways is manifest by cough without pneumonitis. It is common in adults, especially in winter months. Infections are usually caused by viruses, and of these, influenza A and B, parainfluenza, respiratory syncytial, coronavirus, adenovirus, and rhinovirus are frequent isolates (Wenzel, 2006). Bacterial agents causing community-acquired pneumonia are rarely implicated. The cough of acute bronchitis persists for 10 to 20 days (mean 18 days) and occasionally lasts for a month or longer. According to the 2006 guidelines of the American College of Chest Physicians, routine antibiotic treatment is not indicated (Smith, 2014).

PNEUMONIA

This is a leading cause of death in the United States (Heron, 2016). Current classification includes *community-acquired pneumonia (CAP),* which is typically encountered in otherwise healthy young women, including during pregnancy. *Health-care-associated pneumonia (HCAP)* develops in patients in outpatient care facilities and more closely resembles *hospital-acquired pneumonia (HAP).*

In most cases of community-acquired pneumonia, the offending pathogen is not identified. In a recent study from the Centers for Disease Control and Prevention (CDC), pathogens were identified in only 38 percent of nearly 2500 adults with pneumonia (Jain, 2015). These included viruses in 23 percent, bacteria in 11 percent, both in 3 percent, and fungi or protozoa in 1 percent. Half of bacterial isolates were *Streptococcus pneumoniae*.

Pneumonia in pregnant women is relatively common (Brito, 2011; Sheffield, 2009). Gazmararian and coworkers (2002) reported that pneumonia accounts for 4.2 percent of antepartum admissions for nonobstetrical complications. Pneumonia is also a frequent indication for postpartum readmission (Belfort, 2010). During influenza season, admission rates for respiratory illnesses double compared with rates in the remaining months (Cox, 2006). Regardless of etiology, mortality from pneumonia is infrequent in young women, but during pregnancy severe pneumonitis with appreciable loss of ventilatory capacity is not as well tolerated (Callaghan, 2015; Rogers, 2010). Hypoxemia and acidosis are also poorly accommodated by the fetus and frequently stimulate preterm labor after midpregnancy. Because many cases of pneumonia follow viral upper respiratory illnesses, worsening or persistence of symptoms may represent developing pneumonia. Any gravida suspected of having pneumonia should undergo chest radiography.

Bacterial Pneumonia

Many bacteria that cause community-acquired pneumonia, such as *Streptococcus pneumoniae*, are part of the normal resident flora. Some factors that perturb the symbiotic relationship between colonizing bacteria and mucosal phagocytic defenses include acquisition of a virulent strain or bacterial infections following a viral infection. Cigarette smoking and chronic bronchitis favor colonization with *S pneumoniae*, *Haemophilus influenzae*, and *Legionella* species. Other risk factors include asthma, binge drinking, and human immunodeficiency virus (HIV) infection (Sheffield, 2009).

Incidence and Causes

Pregnancy itself does not appear to predispose to pneumonia. Jin and colleagues (2003) reported the antepartum hospitalization rate for pneumonia in Alberta, Canada, to be 1.5 per 1000 deliveries—almost identical to the rate of 1.47 per 1000 for nonpregnant women. Likewise, Yost and associates (2000) reported an incidence of 1.5 per 1000 for pneumonia complicating 75,000 pregnancies cared for at Parkland Hospital. As discussed, at least half are caused by viruses. A fourth are bacterial, and *S pneumoniae* causes half of the latter. Over the past few years community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has emerged as a common pathogen that may cause necrotizing pneumonia (Mandell, 2015; Moran, 2013). Occasionally, Legionnaires disease is encountered (Close, 2016).

Diagnosis

Typical symptoms of pneumonia include cough, dyspnea, sputum production, and pleuritic chest pain. Mild upper respiratory symptoms and malaise usually precede these symptoms, and mild leukocytosis is usually present. Chest radiography is essential for diagnosis (Fig. 51-3). Radiographical findings do not accurately predict the etiology, and as discussed, the responsible pathogen is identified in fewer than half of cases. According to the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS), tests to identify a specific agent are optional (Mandell, 2007). Thus, sputum cultures, serological testing, cold agglutinin identification, and tests for bacterial antigens are not routinely recommended. The one exception to this may be rapid serological testing for influenza A and B (Sheffield, 2009).

FIGURE 51-3
Chest radiograph in a pregnant woman with right lower lobe and left upper lobe pneumonia. Rounded right basilar and left apical infiltrates are consistent with the diagnosis.

Management

Although many otherwise healthy young adults can be safely treated as outpatients, at Parkland Hospital we hospitalize all pregnant women with radiographically proven pneumonia. Another option is outpatient therapy or 23-hour observation, which is reasonable with optimal follow-up. At least for nonpregnant patients, the pneumonia severity index (PSI) and the CURB-65 scoring system are used as a guide to admission (Mandell, 2015). Neither has been studied in pregnancy. Given that, risk factors shown in Table 51-3 should prompt consideration for hospitalization.

TABLE 51-3

Criteria for Severe Community-Acquired Pneumonia[a]

Respiratory rate ≥30/min
Pao_2/Fio_2 ratio ≤250
Multilobular infiltrates
Confusion/disorientation
Uremia
Leukopenia: WBC <4000/μL
Thrombocytopenia—platelets <100,000/μL
Hypothermia—core temperature <36°C
Hypotension requiring aggressive fluid resuscitation

[a]Criteria of the Infectious Diseases Society of America/American Thoracic Society.

Pao_2/Fio_2 = partial pressure oxygen in arterial blood/fraction of inspired oxygen; WBC = white blood cell.

Adapted from Mandell, 2007.

With severe disease, admission to an intensive or intermediate care unit is advisable. Approximately 20 percent of pregnant women admitted to Parkland Hospital for pneumonia require this level of care (Zeeman, 2003). Severe pneumonia is a relatively common cause of acute respiratory distress syndrome (ARDS) during pregnancy, and mechanical ventilation may become necessary (Chap. 47, Clinical Course). Indeed, of the 51 gravidas who required mechanical ventilation in the review by Jenkins and coworkers (2003), 12 percent had pneumonia.

Initial antimicrobial and antiviral treatment is empirical (Mandell, 2015). Because most adult bacterial pneumonias are caused by pneumococci, mycoplasma, or chlamydophila, monotherapy initially is with a macrolide—azithromycin, clarithromycin, or erythromycin (Table 51-4). Yost and colleagues (2000) reported that erythromycin monotherapy, given IV and then orally, was effective in all but one of 99 pregnant women with uncomplicated pneumonia. During influenza season, we routinely administer oseltamivir treatment along with empirical therapy for bacterial pneumonia.

TABLE 51-4

Empirical Antimicrobial Treatment for Community-Acquired Pneumonia

Uncomplicated, otherwise healthy[a]
Macrolides[b]: clarithromycin or azithromycin ***PLUS*** Oseltamivir for suspected influenza A infection
Severe pneumonia[c]
Respiratory fluoroquinolones: moxifloxacin, gemifloxacin, or levofloxacin ***or*** β-lactams: amoxicillin/clavulanate, ceftriaxone, cefotaxime, or cefuroxime plus a macrolide ***PLUS*** Oseltamivir for suspected influenza A infection

[a]Use as inpatient or outpatient regimen.

[b]Doxycycline may be given instead if postpartum.

[c]See Table 51-3 for criteria.

For women with severe disease according to criteria in Table 51-3, Mandell and associates (2007) summarized IDSA/ATS guidelines, which call for either: (1) a respiratory fluoroquinolone—levofloxacin, moxifloxacin, or gemifloxacin; or (2) a macrolide plus a preferred β-lactam—either high-dose amoxicillin or amoxicillin-clavulanate. β-Lactam alternatives include ceftriaxone, cefpodoxime, or cefuroxime (see Table 51-4). In areas in which the resistance of pneumococcal isolates to macrolides is great, these latter regimens are preferred. The teratogenicity risk of fluoroquinolones is low, and these should be given if indicated (Briggs, 2015). If CA-MRSA is suspected, then vancomycin or linezolid is added (Mandell, 2015; Moran, 2013; Wunderink, 2013).

Clinical improvement is usually evident in 48 to 72 hours with resolution of fever in 2 to 4 days. Radiographic abnormalities may take up to 6 weeks to completely resolve (Torres, 2008). Worsening disease is a poor prognostic feature, and subsequent radiography is recommended if fever persists. Even with improvement, however, approximately 20 percent of women develop a pleural effusion. Treatment of uncomplicated pneumonia is recommended for 5 to 7 days (Musher, 2014). Treatment failure may occur in up to 15 percent of cases, and a wider antimicrobial regimen and more extensive diagnostic testing is warranted.

Pregnancy Outcome

During the preantimicrobial era, as many as a third of pregnant women with pneumonia died (Finland, 1939). Although much improved, maternal and perinatal morbidity and mortality remain formidable. In five studies with a total of 632 women published after 1990, almost 7 percent required intubation and mechanical ventilation, and the maternal mortality rate was 0.8 percent.

Prematurely ruptured membranes and preterm delivery are frequent complications and have been reported in up to a third of cases of acute lung infection (Getahun, 2007; Shariatzadeh, 2006). Likely related are older studies reporting a twofold increase in low-birthweight neonates (Sheffield, 2009). In one population-based study from Taiwan of nearly 219,000 births, incidences of preterm and growth-restricted newborns and of preeclampsia and cesarean delivery were significantly increased (Chen, 2012).

Prevention

Two pneumococcal vaccines, a 23-serotype older preparation and a newer 13-serotype vaccine, are used in children (Swamy, 2015). The 23-serotype vaccine is 60- to 70-percent protective, and its use lowers emergence of drug-resistant pneumococci (Kyaw, 2006). The 13-serotype vaccine is not recommended for otherwise healthy pregnant women. It is, however, recommended for women who are immunocompromised, including those with HIV infection; significant smoking history; diabetes; cardiac, pulmonary, or renal disease; and asplenia, such as with sickle-cell disease (Table 9-7). Protection against pneumococcal infection in women with chronic diseases may be less efficacious than in healthy patients (Moberley, 2013).

Influenza Pneumonia

Clinical Presentation

Each year, 10 percent of pregnant women develop influenza (Cantu, 2013). Influenza A and B are RNA viruses that cause respiratory infection, including pneumonitis, that is epidemic in the winter months. The virus is spread by aerosolized droplets and quickly infects ciliated columnar epithelium, alveolar cells, mucus gland cells, and macrophages. Disease onset is 1 to 4 days following exposure. Common symptoms include fever, cough, myalgia, and chills (Sokolow, 2015). In most healthy adults, infection is self-limited.

Pneumonia is the most frequent complication of influenza and mimics bacterial pneumonia. According to the CDC (2010a), infected pregnant women are more likely to be hospitalized and admitted to an ICU. Others have corroborated these observations (Mertz, 2017). At Parkland Hospital during the 2003 to 2004 influenza season, pneumonia developed in 12 percent of gravidas with influenza (Rogers, 2010).

The 2009 to 2010 pandemic with the influenza (A/H1N1)pdm09 strain was particularly severe (Rasmussen, 2014). In an MFMU Network study, 10 percent of pregnant or postpartum women admitted with H1N1 influenza were cared for in an ICU, and 11 percent of these patients died (Varner, 2011). Risk factors included late pregnancy, smoking, and chronic hypertension. Overall, influenza accounted for 12 percent of pregnancy-related deaths during the 2009 to 2010 pandemic (Callaghan, 2015). During the 2013 to 2014 influenza season, a fourth of pregnant women admitted to California ICUs died (Louie, 2015). Of 865 pregnant women with influenza, Oboho and coworkers (2016) noted that 7 percent of their cohort had severe disease, and four women died. If influenza causes ARDS, extracorporeal membrane oxygenation (ECMO) may be lifesaving (Anselmi, 2015; Saad, 2016).

Primary influenza pneumonitis is characterized by sparse sputum production and radiographic interstitial infiltrates (Cohen, 2015). More commonly, either secondary or mixed pneumonia develop from bacterial superinfection by streptococci or staphylococci after 2 to 3 days of initial clinical improvement. The CDC (2007) reported several cases in which CA-MRSA caused influenza-associated pneumonitis with a case-fatality rate of 25 percent. Other possible adverse effects of influenza A and B on pregnancy outcome are discussed in Chapter 64 (Influenza Virus).

Management

Supportive treatment is recommended for uncomplicated influenza, and early antiviral treatment is effective (Jamieson, 2011; Oboho, 2016). Hospitalization is considered for severely ill women, and for those with pneumonia. As discussed, influenza hospitalization rates for those with advanced pregnancy are increased compared with nonpregnant women (Dodds, 2007; Schanzer, 2007). The CDC (2016b) recommends neuraminidase inhibitors given within 2 days of symptom onset for chemoprophylaxis and treatment of influenza A and B (Chap. 64, Mumps Virus). The drugs interfere with release of progeny virus from infected host cells and thus prevent infection of new host cells (Cohen, 2015). Oseltamivir is given orally, 75 mg twice daily, or zanamivir is given by inhalation, 10 mg twice daily. Recommended treatment duration with either is 5 days. The drugs shorten the course of illness by 1 to 2 days, and they probably reduce the risk for pneumonitis (Belgi, 2014; Muthuri, 2014). Our practice is to treat all pregnant women with influenza whether or not pneumonitis is identified (Rasmussen, 2014). Few data guide use of these agents in pregnant women, but the drugs are not teratogenic in animal studies and are considered low risk (Briggs, 2015).

A major potential concern for viral resistance comes from avian influenza isolates. “Bird flu” with HPAI, H5N8, H5N2, and H5N1 isolates has been reported in the United States by the CDC (Jhung, 2015). In Asia, human infection has been documented with some of these, and mortality rates are high.

Preventively, vaccination for influenza A is recommended by the American College of Obstetricians and Gynecologists (2016b) and the CDC (2016b). Vaccination is discussed in detail in Chapter 64 (Mumps Virus). Prenatal vaccination also affords some temporary protection for infants (Madhi, 2014; Tita, 2016). During the 2014 to 2015 flu season, the CDC reported that only half of pregnant women received influenza vaccine (Ding, 2015).

Varicella Pneumonia

Infection with varicella-zoster virus, the same agent responsible for chicken pox, results in pneumonitis in 5 percent of gravidas (Harger, 2002). Diagnosis and management are considered in Chapter 64 (Varicella-Zoster Virus).

Fungal and Parasitic Pneumonia

Pneumocystis Pneumonia

Fungal and parasitic pulmonary infections are usually of greatest consequence in immunocompromised hosts, especially in women with acquired immunodeficiency syndrome (AIDS). Of these, lung infection with *Pneumocystis jiroveci*, formerly called *Pneumocystis carinii*, is a common complication. The opportunistic fungus causes interstitial pneumonia characterized by dry cough, tachypnea, dyspnea, and diffuse radiographic infiltrates. Although this organism can be identified by sputum culture, bronchoscopy with lavage or biopsy may be necessary.

In an earlier report from the AIDS Clinical Trials Centers, Stratton and colleagues (1992) described pneumocystis pneumonia as the most frequent HIV-related disorder in pregnant women. In some cases, tracheal intubation and mechanical ventilation may be required. Ahmad and coworkers (2001) reviewed 22 cases during pregnancy and cited a 50-percent mortality rate. Treatment is with trimethoprim-sulfamethoxazole for 14 to 21 days (Masur, 2015). Alternative agents include the more toxic pentamidine (Walzer, 2005).

For prophylaxis, several international health agencies recommend one double-strength trimethoprim-sulfamethoxazole tablet orally daily for certain groups of HIV-infected pregnant women. These include women with $CD4^+$ T-lymphocyte counts <200/µL, those whose $CD4^+$ T lymphocytes constitute <14 percent, or if there is an AIDS-defining illness, particularly oropharyngeal candidiasis (Centers for Disease Control and Prevention, 2016a).

Fungal Pneumonia

Any of several fungi can cause pneumonia. In pregnancy, this is usually seen in women with HIV infection or who are otherwise immunocompromised. Infection is usually mild and self-limited. It is characterized initially by cough and fever, and dissemination is infrequent (Mansour, 2015).

Histoplasmosis and *blastomycosis* do not appear to be more frequent or more severe during pregnancy (Youssef, 2013). Data concerning *coccidioidomycosis* are conflicting (Bercovitch, 2011; Patel, 2013). In a case-control study from an endemic area, Rosenstein and associates (2001) reported that pregnancy was a significant risk factor for disseminated disease. In another study, however, Caldwell and coworkers (2000) identified 32 serologically confirmed cases during pregnancy and documented dissemination in only three cases. Women with associated erythema nodosum have a better prognosis, whereas mediastinal lymphadenopathy may more likely reflect disseminated disease (Caldwell, 2000; Mayer, 2013). Finally, Crum and Ballon-Landa (2006) reviewed 80 cases of antepartum coccidioidomycosis and found that almost all women diagnosed in the third trimester had disseminated disease. Although the overall maternal mortality rate was 40 percent, it was only 20 percent for 29 cases reported since 1973. Spinello (2007) and Bercovitch (2011) with their colleagues have provided reviews of coccidioidomycosis in pregnancy.

Most cases of *cryptococcosis* reported during pregnancy manifest as meningitis. Otherwise healthy pregnant women occasionally have cryptococcal pneumonia (Asadi Gharabaghi, 2014; Ely, 1998). Diagnosis is difficult because clinical presentation is similar to that of other community-acquired pneumonias.

Treatment

The 2007 IDSA/ATS guidelines recommend itraconazole as preferred therapy for disseminated fungal infections (Mandell, 2007). Pregnant women have also been given IV amphotericin B or ketoconazole (Paranyuk, 2006; Pilmis, 2015). Amphotericin B has been used extensively in pregnancy with no embryofetal effects. Because of evidence that fluconazole, itraconazole, and ketoconazole may be embryotoxic in large doses in early pregnancy, Briggs and coworkers (2015) recommend that first-trimester use should be avoided if possible.

Three echinocandin derivatives—*caspofungin*, *micafungin*, and *anidulafungin*—are effective for invasive candidiasis (Pilmis, 2015; Reboli, 2007). They are embryotoxic and teratogenic in laboratory animals, and use in human pregnancies has not been reported (Briggs, 2015).

Severe Acute Respiratory Syndrome (SARS)

This coronaviral respiratory infection was first identified in China in 2002, but no new cases have been reported since 2005. It caused atypical pneumonitis with a case-fatality rate of approximately 10 percent (Dolin, 2012). SARS in pregnancy had a case-fatality rate of up to 25 percent (Lam, 2004; Wong, 2004). Ng and coworkers (2006) reported that the placentas from 7 of 19 cases showed abnormal intervillous or subchorionic fibrin deposition in three, and extensive fetal thrombotic vasculopathy in two.

TUBERCULOSIS

Tuberculosis is still a major worldwide concern. Indeed, it is estimated that a third of the world population is infected (Getahun, 2015). However, it is uncommon in the United States. The incidence of *active tuberculosis* in this country has plateaued since 2000 (Scott, 2015). More than half of active cases are in immigrants (Centers for Disease Control and Prevention, 2009b). Persons born in the United States have newly acquired infection, whereas foreign-born persons usually have reactivation of latent infection. In this country, tuberculosis is a disease of the elderly, the urban poor, minority groups—especially black Americans, and patients with HIV infection (Khan, 2013; Raviglione, 2015).

Infection is via inhalation of *Mycobacterium tuberculosis*, which incites a granulomatous pulmonary reaction. In more than 90 percent of patients, infection is contained and is dormant for long periods (Getahun, 2015; Zumla, 2013). In some, especially those who are immunocompromised or who have other diseases, tuberculosis becomes reactivated to cause clinical disease. Manifestations usually include cough with minimal sputum production, low-grade fever, hemoptysis, and weight loss. Various infiltrative patterns are seen on chest radiograph, and cavitation or mediastinal lymphadenopathy may be associated. Acid-fast bacilli are seen on stained smears of sputum in approximately two thirds of culture-positive individuals. Forms of extrapulmonary tuberculosis include lymphadenitis, pleural, genitourinary, skeletal, meningeal, gastrointestinal, and miliary or disseminated (Raviglione, 2015).

Treatment

Resistance to antituberculosis drugs in the United States in the early 1990s was associated with emergence of strains of *multidrug-resistant tuberculosis* (*MDR-TB*). Because of this, the CDC (2009a) now recommends a multidrug regimen for initial empirical treatment of patients with symptomatic tuberculosis. Isoniazid, rifampin, pyrazinamide, and ethambutol are given until susceptibility studies are performed (Horsburgh, 2015). Cure rates with 6-

month short-course *directly observed therapy*—DOT—approach 90 percent for new infections (Raviglione, 2015). Other second-line drugs may need to be added. Drug susceptibility is performed on all first isolates.

Tuberculosis and Pregnancy

The considerable influx of women into the United States from Asia, Africa, Mexico, and Central America has been accompanied by an increased frequency of tuberculosis in pregnancy. Sackoff and coworkers (2006) reported positive tuberculin test results in half of 678 foreign-born women attending prenatal clinics in New York City. Almost 60 percent were newly diagnosed. Pillay and colleagues (2004) stress the prevalence of tuberculosis in HIV-positive pregnant women. At Jackson Memorial Hospital in Miami, Schulte and associates (2002) reported that 21 percent of 207 HIV-infected pregnant women had a positive skin test result. Recall also that silent endometrial tuberculosis can cause tubal infertility (Levison, 2010; Raviglione, 2015).

Without therapy, active tuberculosis appears to have adverse effects on pregnancy (Mnyani, 2011). Several studies indicate that outcomes are dependent on the site of infection and gestational age at diagnosis. Jana and colleagues (1994) from India and Figueroa-Damian and Arrendondo-Garcia (1998) from Mexico City noted that active pulmonary tuberculosis was associated with increased incidences of preterm delivery, low-birthweight and growth-restricted newborns, and perinatal mortality. Others have found similar effects (El-Messidi, 2016; Lin, 2010; Sobhy, 2017). From her review, Efferen (2007) cited twofold greater rates of low birthweight, preterm delivery, and preeclampsia. The perinatal mortality rate was increased almost tenfold. Adverse outcomes correlate with late diagnosis, incomplete or irregular treatment, and advanced pulmonary lesions. Conversely, treated tuberculosis is associated with good pregnancy outcomes (Nguyen, 2014; Taylor, 2013).

Extrapulmonary tuberculosis is less common. Jana and coworkers (1999) reported outcomes in 33 pregnant women with renal, intestinal, and skeletal tuberculosis, and a third had low-birthweight newborns. Llewelyn and associates (2000) reported that nine of 13 pregnant women with extrapulmonary disease had delayed diagnoses. Prevost and Fung Kee Fung (1999) reviewed 56 cases of tuberculous meningitis in which a third of mothers died. Spinal tuberculosis may cause paraplegia, but vertebral fusion may prevent it from becoming permanent (Badve, 2011; Nanda, 2002). Psoas abscess develops in 5 percent of those with spinal infections (Nigam, 2013). Other presentations include widespread intraperitoneal tuberculosis simulating ovarian carcinomatosis and degenerating leiomyoma, and hyperemesis gravidarum from tubercular meningitis (Kutlu, 2007; Moore, 2008; Sherer, 2005).

Diagnosis

Two types of tests are used to detect latent or active tuberculosis. One is the time-honored *tuberculin skin test (TST),* and the others are *interferon-gamma release assays (IGRAs),* which are becoming preferred (Getahun, 2015; Horsburgh, 2011). IGRAs are blood tests that measure interferon-gamma release in response to antigens present in *M tuberculosis*, but not *bacille Calmette-Guérin (BCG)* vaccine (Levison, 2010). The CDC (2005b, 2010b) recommends either skin testing or IGRA testing of gravidas who are in any of the high-risk groups. For those who have received BCG vaccination, IGRA testing is used (Mazurek, 2010).

For skin testing, the preferred antigen is purified protein derivative (PPD) of intermediate strength of 5 tuberculin units. If the intracutaneously applied test result is negative, no further evaluation is needed. A positive skin test result measures ≥5 mm in diameter and requires evaluation for active disease, including a chest radiograph.

Two IGRAs are available: *QuantiFERON-TB Gold* and *T-SPOT.TB* tests are recommended by the CDC (2005a,b) for the same indications as skin testing. Although these tests have not been evaluated as extensively as tuberculin skin testing, Kowada (2014) concluded that the tests are cost effective.

Other essential laboratory methods for detection or verification of infection—both active and latent—include microscopy, culture, nucleic acid amplification assay, and drug-susceptibility testing (Horsburgh, 2015; Raviglione, 2015).

Treatment

Latent Infection

In nonpregnant tuberculin-positive patients with latent infection who are younger than 35 years and who have no evidence of active disease, isoniazid, 300 mg orally daily, is given for 9 months. Isoniazid has been used for decades, and it is considered safe in pregnancy (Briggs, 2015; Taylor, 2013). Compliance is a major problem, and Sackoff (2006) and Cruz (2005) and their associates reported a disappointing 10-percent treatment completion. One obvious disconnect is that care for tuberculosis is given in different health systems than prenatal care (Zenner, 2012). These observations are important because most recommend that isoniazid therapy be delayed until after delivery. Because of possibly increased isoniazid-induced hepatitis risk in postpartum women, some even recommend withholding treatment until 3 to 6 months after delivery. That said, neither method is as effective as antepartum treatment to prevent active infection. Boggess and colleagues (2000) reported that only 42 percent of 167 tuberculin-positive asymptomatic women delivered at San Francisco General Hospital completed 6-month therapy that was not begun until the first postpartum visit.

There are exceptions to delayed treatment for latent infection in pregnancy. Known recent skin-test convertors are treated antepartum because the incidence of active infection is 5 percent in the first year (Zumla, 2013). Skin-test-positive women exposed to active infection are also treated because the incidence of infection is 0.5 percent per year. Finally, HIV-positive women are treated because they have an approximate 10-percent annual risk of active disease.

Active Infection

Recommended initial treatment for active tuberculosis in pregnant women is a four-drug regimen with isoniazid, rifampin, ethambutol, and pyrazinamide, along with pyridoxine. For meningitis, levofloxacin may be added (Kalita, 2014). In the first 2-month phase, all four drugs are given—*bactericidal phase*. This is followed by a 4-month phase of isoniazid and rifampin—*continuation phase* (Raviglione, 2015; Zumla, 2013). A few reports describe MDR-TB during pregnancy, and treatment options have been reviewed (Horsburgh, 2015; Lessnau, 2003). Breastfeeding is not prohibited during antituberculous therapy.

Treatment of active disease is of special concern if there is antiretroviral naiveté. In these circumstances, beginning concomitant therapy with antituberculosis and antiretroviral therapy can cause the *immune reconstitution inflammatory syndrome (IRIS)* with toxic drug effects (Lai, 2016; Török, 2011). That said, recent studies support earlier administration of highly active antiretroviral therapy (HAART)—within 2 to 4 weeks—after beginning antituberculosis therapy (Blanc, 2011; Havlir, 2011; Karim, 2011). Also, for HIV-infected women, rifampin or rifabutin use may be contraindicated if certain protease inhibitors or nonnucleoside reverse transcriptase inhibitors are being administered. If there is resistance to rifabutin or rifampin, then pyrazinamide therapy is given. Of the second-line regimens, the aminoglycosides—streptomycin, kanamycin, amikacin, and capreomycin—are ototoxic to the fetus and are contraindicated (Briggs, 2015).

Neonatal Tuberculosis

Tubercular bacillemia can infect the placenta, but the fetus infrequently becomes infected—*congenital tuberculosis*. The term also applies to newborns who are infected by aspiration of infected secretions at delivery. Each route of infection constitutes approximately half of the cases. Neonatal tuberculosis simulates other congenital infections and manifests with hepatosplenomegaly, respiratory distress, fever, and lymphadenopathy (Dewan, 2014; Osowicki, 2016).

Cantwell and associates (1994) reviewed 29 cases of congenital tuberculosis reported since 1980. Only 12 of the mothers had active infection, and tuberculosis was frequently demonstrated by postpartum endometrial biopsy. Adhikari and colleagues (1997) described 11 South African postpartum women whose endometrial biopsy was culture-positive. Six of their neonates had congenital tuberculosis.

Neonatal infection is unlikely if the mother with active disease has been treated before delivery or if her sputum culture is negative. Because the newborn is susceptible to tuberculosis, most experts recommend isolation from the mother suspected of having active disease. If untreated, the risk of disease in the infant born to a woman with active infection is 50 percent in the first year (Jacobs, 1988).

SARCOIDOSIS

This is a chronic, multisystem inflammatory disease of unknown etiology characterized by an accumulation of T-helper lymphocytes and phagocytes within noncaseating granulomas (Baughman, 2015; Celada, 2015). Predisposition to the disease is genetically determined and characterized by an exaggerated response of helper T lymphocytes to environmental triggers. Pulmonary involvement is most common, followed by skin, eyes, lymph nodes, and then all other organ systems. The prevalence of sarcoid in the United States is 20 to 60 per 100,000, with equal sex distribution. It is more than 10 times more common for blacks than for whites (Baughman, 2015). Most patients are between 20 and 40 years. Clinical presentation varies, but more than half of patients have dyspnea and a dry cough without constitutional symptoms that develop insidiously over months. Disease onset is abrupt in approximately 25 percent of patients, and 10 to 20 percent are asymptomatic at discovery.

Pulmonary symptoms are dominant, and more than 90 percent of patients have an abnormal chest radiograph at some point. *Interstitial pneumonitis* is the hallmark of pulmonary involvement, and half of affected patients develop permanent radiological changes. *Lymphadenopathy*, especially of the mediastinum, is present in 75 to 90 percent of cases. A fourth each have uveitis and skin involvement, the latter usually manifest as *erythema nodosum*. In women, sarcoid causes approximately 10 percent of cases of erythema nodosum (Mert, 2007). Importantly, any other organ system may be involved (Kandolin, 2015; Powe, 2015; Wallmüller, 2012). Confirmation of the diagnosis is with biopsy—preferably a lymph node. However, because the lung may be the only obviously involved organ, tissue acquisition is often difficult.

The overall prognosis for sarcoidosis is good, and it resolves without treatment in 50 percent of patients. Still, quality of life is diminished (de Vries, 2007). In the other 50 percent, permanent organ dysfunction, albeit mild and nonprogressive, persists. Approximately 10 percent die because of their disease.

Glucocorticoids are the most widely used treatment for symptomatic disease. Permanent organ derangement is seldom reversed by their use (Paramothayan, 2002). Thus, the decision to treat is based on symptoms, physical findings, chest radiograph, and pulmonary function tests. Unless respiratory symptoms are prominent, therapy is usually withheld for a several-month observation period. If inflammation does not subside, then prednisone, 1 mg/kg, is given daily and tapered to <10 mg by 6 months (Baughman, 2015). For those with an inadequate response, immunosuppressive or cytotoxic agents and cytokine modulators can be used.

Sarcoidosis and Pregnancy

Because it is uncommon and frequently benign, sarcoidosis is not often seen in pregnancy. Although it seldom affects pregnancy adversely, meningitis, heart failure, and neurosarcoidosis have been described (Cardonick, 2000; Maisel, 1996; Wallmüller, 2012). In a study of the Nationwide Inpatient Sample of 678 cases of sarcoidosis in pregnancy, incidences of preeclampsia, preterm delivery, and thromboembolism were increased (Hadid, 2015). Selroos

(1990) studied 252 women with sarcoidosis in Finland, and 15 percent had sarcoidosis during pregnancy. Disease did not progress in the 26 pregnancies in women with active disease. Three aborted spontaneously, and the other 23 women were delivered at term. Agha and coworkers (1982) reported similar experiences with 35 pregnancies at the University of Michigan.

Active sarcoidosis is treated using the same guidelines as for the woman who is not pregnant. Severe disease warrants serial determination of pulmonary function. Symptomatic uveitis, constitutional symptoms, and pulmonary symptoms are treated with prednisone, 1 mg/kg orally per day.

CYSTIC FIBROSIS

This autosomal recessive exocrinopathy is one of the most common fatal genetic disorders in whites. Cystic fibrosis is caused by one of more than 2000 mutations in a 230-kb gene on the long arm of chromosome 7 that encodes an amino acid polypeptide (Patel, 2015; Sorscher, 2015). This peptide functions as a chloride channel and is termed the *cystic fibrosis transmembrane conductance regulator (CFTR)*. As discussed in Chapter 14 (Cystic Fibrosis), phenotypes vary widely, even among homozygotes for the common ΔF508 mutation (Rowntree, 2003). Approximately 10 to 20 percent of affected newborns are diagnosed shortly after birth because of *meconium peritonitis* (Boczar, 2015; Sorscher, 2015). Currently, the median predicted survival is 37 years, and nearly 80 percent of females with cystic fibrosis now survive to adulthood (Gillet, 2002; Patel, 2015).

Pathophysiology

Mutations in the chloride channel cause altered epithelial cell membrane transport of electrolytes. This affects all sites in which epithelium expresses CFTR-secretory cells. These include the sinuses, lung, pancreas, liver, and reproductive tract. Disease severity depends on which two alleles are inherited, and approximately 10 percent are disease-causing mutations (Sorscher, 2015). Homozygosity for Phe508del (ΔF508) is one of the most severe, and 90 percent of individuals with clinical disease carry at least one F508 allele.

Exocrine gland ductal obstruction develops from thick, viscid secretions (Rowe, 2005). In the lung, submucosal glandular ducts are affected. Eccrine sweat gland abnormalities are the basis for the diagnostic *sweat test*, characterized by elevated sodium, potassium, and chloride levels in sweat.

Lung involvement is commonplace and is usually the cause of death. Bronchial gland hypertrophy with mucous plugging and small-airway obstruction leads to subsequent infection that ultimately causes chronic bronchitis and bronchiectasis. For complex and not completely explicable reasons, chronic inflammation from *Pseudomonas aeruginosa* occurs in more than 90 percent of patients. In a minority, *S aureus, H influenzae,* and *Burkholderia cepacia* are recovered (Rowe, 2005). Colonization with the last has been reported to signify a worse prognosis, especially in pregnancy (Gillet, 2002). Acute and chronic parenchymal inflammation ultimately causes extensive fibrosis, and along with airway obstruction, ventilation–perfusion mismatch develops. Pulmonary insufficiency is the end result. Lung or heart–lung transplantation has a 5-year survival rate of only 50 to 60 percent (Sorscher, 2015). A few women have successfully undergone pregnancy following lung transplantation (Kruszka, 2002; Shaner, 2012).

Preconceptional Counseling

This CFTR2 resource delineates gene variants with a clear etiological role—http://www.cftr2.org. Women with clinical cystic fibrosis are subfertile because of tenacious cervical mucus. Males have oligospermia or aspermia from vas deferens obstruction, and 98 percent are infertile (Ahmad, 2013). Despite this, the North American Cystic Fibrosis Foundation estimated that 4 percent of affected women become pregnant every year (Edenborough, 1995). The endometrium and tubes express some CFTR but are functionally normal, and the ovaries do not express the *CFTR* gene (Edenborough, 2001). Both intrauterine insemination and in vitro fertilization can be successful for affected women (Rodgers, 2000). Several ethical considerations regarding plans for pregnancy by these women were reviewed by Wexler and colleagues (2007). One important factor is the long-term prognosis for the mother. For male infertility, Sobczyńska-Tomaszewska and associates (2006) have emphasized the importance of molecular diagnosis.

Screening

The American College of Obstetricians and Gynecologists (2017) recommends that carrier screening be offered to all women currently pregnant or considering conception (Chap. 14, Cystic Fibrosis). The CDC also added cystic fibrosis to newborn screening programs (Southern, 2009) (Chap. 32, Routine Newborn Care).

Prenatal Care

Pregnancy outcome is inversely related to severity of lung dysfunction. Advanced chronic lung disease, hypoxia, and frequent infections may prove deleterious. At least in the past, *cor pulmonale* was common, but even that does not preclude successful pregnancy (Cameron, 2005). In some women, *pancreatic dysfunction* may cause poor maternal nutrition. Otherwise normal pregnancy-induced insulin resistance frequently results in gestational diabetes after midpregnancy (Hardin, 2005). In one study of 48 pregnancies, half had pancreatic insufficiency and a third required insulin (Thorpe-Beeston, 2013). Up to 25 percent of patients develop diabetes by age 20, and diabetes is most frequent with the Phe508del homozygous mutation (Giacobbe, 2012; Patel, 2015).

Cystic fibrosis per se is not affected by pregnancy (Schechter, 2013). Early reports of a deleterious effect on the course of cystic fibrosis were related to severe disease (Olson, 1997). When matched with nonpregnant women by disease severity, recent reports indicate no deleterious effects on long-term survival (Schechter, 2013).

Management

Prepregnancy counseling is imperative. Women who choose to become pregnant require close surveillance for development of superimposed infection, diabetes, and heart failure. Serial pulmonary function testing assists management and estimating prognosis. When the FEV_1 is at least 70 percent, women usually tolerate pregnancy well. Emphasis is placed on postural drainage, bronchodilator therapy, and infection control.

β-Adrenergic bronchodilators help control airway constriction. Inhaled recombinant human deoxyribonuclease I improves lung function by reducing sputum viscosity (Sorscher, 2015). Inhaled 7-percent saline produces short- and long-term benefits (Elkins, 2006). Nutritional status is assessed and appropriate dietary counseling given. Pancreatic insufficiency requires replacement of oral pancreatic enzymes. Promising new therapy to correct CFTR protein dysfunction was recently described by Wainwright and colleagues (2015). Using a combination of lumacaftor and ivacaftor, these investigators showed that patients homozygous for the Phe508del mutation were significantly benefitted. No reports of either drug are available regarding pregnant women.

Infection is heralded by increasing cough and mucus production. Oral semisynthetic penicillins or cephalosporins usually suffice to treat staphylococcal infections. *Pseudomonas* infection is problematic, and inhaled tobramycin and colistin have been used successfully to control this organism. Immediate hospitalization and aggressive therapy are warranted for serious pulmonary infections. The threshold for hospitalization with other complications is low. For labor and delivery, epidural analgesia is recommended (Deighan, 2014).

Pregnancy Outcome

Earlier reports chronicled the poor maternal and perinatal outcomes of women with cystic fibrosis (Cohen, 1980; Kent, 1993). More recent reports describe better outcomes, but there still are serious complications. Disease severity is now quantified by pulmonary function studies, which are the best predictor of pregnancy and long-term maternal outcome. Edenborough and colleagues (2000) reported 69 pregnancies and found that if prepregnancy FEV_1 was <60 percent of predicted, the risk for preterm delivery, respiratory complications, and death of the mother within a few years of childbirth was substantive. Thorpe-Beeston (2013) and Fitzsimmons (1996) and their associates reported similar findings. Gillet and colleagues (2002) reported 75 pregnancies from the French Cystic Fibrosis Registry. Almost 20 percent of newborns were delivered preterm, and 30 percent had growth restriction. The one maternal death was due to *Pseudomonas* sepsis in a woman whose prepregnancy FEV_1 was 60 percent. Long-term, however, 17 percent of women died, and four infants had confirmed cystic fibrosis.

Maternal complications are daunting. Patel and coworkers (2015) recently queried the National Inpatient Sample database and reported that the prevalence of cystic fibrosis in pregnancy had a significant linear increase from 2000 to 2010. They analyzed 1119 affected women in more than 12 million births and reported a litany of risks (Table 51-5). In contrast, perinatal outcomes were surprisingly good.

TABLE 51-5

Odds Ratios for Maternal Complications in 1119 Pregnant Women with Cystic Fibrosis Compared with Controls

Complication	Odds Ratio
Asthma	5
Diabetes	14
Thrombophilia	6
Mechanical ventilation	32
Pneumonia	69
Respiratory failure	30
Acute kidney injury	16
Death	125

Data from Patel, 2015.

Lung Transplantation

Cystic fibrosis is a common antecedent disease leading to lung transplantation. Gyi and coworkers (2006) reviewed 10 pregnancies in such women and reported nine liveborn neonates. Maternal outcomes were less favorable. Of the three gravidas who developed rejection during pregnancy, all had progressively declining pulmonary function and died of chronic rejection by 38 months after delivery.

CARBON MONOXIDE POISONING

Carbon monoxide is a ubiquitous gas, and most nonsmoking adults have a carbon monoxyhemoglobin saturation of 1 to 3 percent. In cigarette smokers, levels may be as high as 5 to 10 percent. Carbon monoxide is the most frequent cause of poisoning worldwide (Stoller, 2007). Toxic levels are often encountered in inadequately ventilated areas warmed by space heaters.

Carbon monoxide is particularly toxic because it is odorless and tasteless and has a high affinity for hemoglobin binding. Thus, it displaces oxygen and impedes its transfer with resultant hypoxia. Besides acute sequelae including death and anoxic encephalopathy, cognitive defects develop in as many as half of patients following loss of consciousness or in those with carbon monoxide levels >25 percent (Weaver, 2002). Hypoxic brain damage has a predilection for the cerebral cortex and white matter and for the basal ganglia (Lo, 2007; Prockop, 2007). A Parkinson syndrome sometimes follows after recovery (Hemphill, 2015).

Pregnancy and Carbon Monoxide Poisoning

Through several physiological alterations, the rate of endogenous carbon monoxide production almost doubles in normal pregnancy (Longo, 1977). Although the pregnant woman is not more susceptible to carbon monoxide poisoning, the fetus does not tolerate excessive exposure (Friedman, 2015). With chronic exposure, maternal symptoms usually appear when the carboxyhemoglobin concentration is 5 to 20 percent. Symptoms include headache, weakness, dizziness, physical and visual impairment, palpitations, and nausea and vomiting. With acute exposure, concentrations of 30 to 50 percent produce symptoms of impending cardiovascular collapse. Levels >50 percent may be fatal for the mother.

Because hemoglobin F has an even higher affinity for carbon monoxide, fetal carboxyhemoglobin levels are 10 to 15 percent higher than those in the mother. This may be due to facilitated diffusion (Longo, 1977). Importantly, the half-life of carboxyhemoglobin is 2 hours in the mother but 7 hours in the fetus. Because carbon monoxide is bound so tightly to hemoglobin F, the fetus may be hypoxic even before maternal carbon monoxide levels are appreciably elevated. Several anomalies are associated with embryonic exposure, and anoxic encephalopathy is the primary sequela of later fetal exposure (Alehan, 2007; Aubard, 2000).

Treatment

For all victims, treatment of carbon monoxide poisoning is supportive along with immediate administration of 100-percent inspired oxygen. Indications for hyperbaric oxygen treatment in nonpregnant individuals are unclear (Kao, 2005). Weaver and associates (2002) reported that hyperbaric oxygen treatment minimized the incidence of cognitive defects in adults at both 6 weeks and 1 year compared with that with normobaric oxygen. Hyperbaric oxygen is generally recommended in pregnancy if carbon monoxide exposure has been "significant" (Aubard, 2000; Ernst, 1998). The problem is how to define significant exposure (Friedman, 2015). Although maternal carbon monoxide levels are not accurately predictive of those in the fetus, some clinicians recommend hyperbaric therapy if maternal levels exceed 15 to 20 percent. With fetal heart rate pattern evaluation, Towers and Corcoran (2009) described affected fetuses to have an elevated baseline, diminished variability, and absent accelerations and decelerations. Treatment of the affected newborn with hyperbaric oxygen is also controversial (Bar, 2007).

Elkharrat and colleagues (1991) reported successful hyperbaric treatments in 44 pregnant women. Silverman and Montano (1997) reported successful management of a woman whose abnormal neurological and cardiopulmonary findings abated in a parallel fashion with resolution of associated variable decelerations in fetal heart rate. Greingor and coworkers (2001) used 2.5-atm hyperbaric 100-percent oxygen for 90 minutes in a 21-week pregnant woman who was delivered of a healthy infant at term. According to the Divers Alert Network—DAN (2016)—at Duke University, 700 chambers are located in North and Central America. Emergency consultation from the Network is available at 919–684–9111.

CHAPTER 52: Thromboembolic Disorders

The patient complains of intense and sudden precordial pain, becomes livid in appearance, and presents symptoms of profound dyspnea and eventually of air hunger. These embolisms, however, are not always fatal, a small proportion of the patients recovering. The treatment is purely palliative.

—J. Whitridge Williams (1903)

INTRODUCTION

During the past century, the frequency of venous thromboembolism (VTE) during the puerperium decreased remarkably as early ambulation became more widely practiced. Despite this and other advances in prevention and treatment, however, thromboembolism remains a leading cause of maternal morbidity and mortality. Indeed, thrombotic pulmonary embolism accounted for 9.2 percent of pregnancy-related deaths in the United States between 2011 and 2013 (Creanga, 2017).

The absolute incidence of VTE during pregnancy is low—1 or 2 cases per 1000 pregnancies. However, the risk is approximately five times higher than that among women who are not pregnant (Greer, 2015). Approximately equal numbers of cases are identified antepartum and in the puerperium. Deep-vein thrombosis alone is more frequent antepartum, and pulmonary embolism is more common in the first 6 weeks postpartum (Jacobsen, 2008). During the puerperium, the estimated incidence of a thromboembolic complication is 22 events per 100,000 deliveries. Although still elevated, the risk falls to approximately 3 cases per 100,000 deliveries during the second 6-week postpartum period (Kamel, 2014).

PATHOPHYSIOLOGY

Rudolf Virchow (1856) postulated that stasis, local trauma to the vessel wall, and hypercoagulability predisposed to venous thrombosis. During normal pregnancy, the risk for each of these rises. Compression of the pelvic veins and inferior vena cava by the enlarging uterus renders the lower extremity venous system particularly vulnerable to stasis. From their review, Marik and Plante (2008) cite a 50-percent reduction in venous flow velocity in the legs that lasts from the early third trimester until 6 weeks postpartum. This stasis is the most constant predisposing risk factor for venous thrombosis. Venous stasis and delivery may also contribute to endothelial cell injury. Last, as listed in the Appendix (Serum and Blood Constituents), the synthesis of most clotting factors is markedly enhanced during pregnancy and favors coagulation.

Characteristics for developing thromboembolism during pregnancy are shown in Table 52-1. The most important of these is a personal history of thrombosis. Specifically, 15 to 25 percent of all VTE cases during pregnancy are recurrent events (American College of Obstetricians and Gynecologists, 2017b). In one study, the magnitude of other risks was estimated from 7177 VTE cases during pregnancy and 7158 events during the postpartum period (James, 2006). Calculated risks for thromboembolism were approximately doubled in women with multifetal gestation, anemia, hyperemesis, hemorrhage, and cesarean delivery. The risk was even greater in pregnancies complicated by postpartum infection. Waldman and associates (2013) found that the risk of VTE was slightly higher in women with advanced maternal age and approximately doubled in women with great parity, a hypertensive disorder, cesarean delivery, or obesity. Risks were significantly higher among women who had a stillbirth or who underwent peripartum hysterectomy.

TABLE 52-1

Some Risk Factors Associated with an Increased Risk for Thromboembolism

Obstetrical	General
Cesarean delivery	Age 35 years or older
Cesarean hysterectomy	Anatomical anomaly[a]
Diabetes	Cancer
Hemorrhage and anemia	Connective tissue disease
Hyperemesis	Dehydration
Immobility—prolonged bed rest	Immobility—long-distance travel
Multifetal gestation	Infection and inflammatory disease
Multiparity	Myeloproliferative disease
Preeclampsia	Nephrotic syndrome
Puerperal infection	Obesity
Stillbirth	Oral contraceptive use
	Orthopedic surgery
	Paraplegia
	Prior thromboembolism
	Sickle-cell disease
	Smoking
	Thrombophilia

[a]Includes May-Thurner syndrome (iliac vein compression syndrome).

The next most important individual risk factor is a genetically determined thrombophilia. An estimated 20 to 50 percent of women who develop a venous thrombosis during pregnancy or postpartum have an identifiable underlying genetic disorder (American College of Obstetricians and Gynecologists, 2017b).

THROMBOPHILIAS

Several important regulatory proteins act as inhibitors in the coagulation cascade (Fig. 52-1). Normal values for many of these proteins during pregnancy are found in the Appendix (Serum and Blood Constituents). Inherited or acquired deficiencies of these inhibitory proteins are collectively referred to as *thrombophilias*. These can lead to hypercoagulability and recurrent VTE (Connors, 2017). Although these disorders are collectively present in approximately 15 percent of white European populations, they are responsible for approximately 50 percent of all thromboembolic events during pregnancy (Lockwood, 2002; Pierangeli, 2011). Some aspects of the more common inherited thrombophilias are summarized in Table 52-2.

TABLE 52-2

Inherited Thrombophilias and Their Association with Venous Thromboembolism (VTE) in Pregnancy

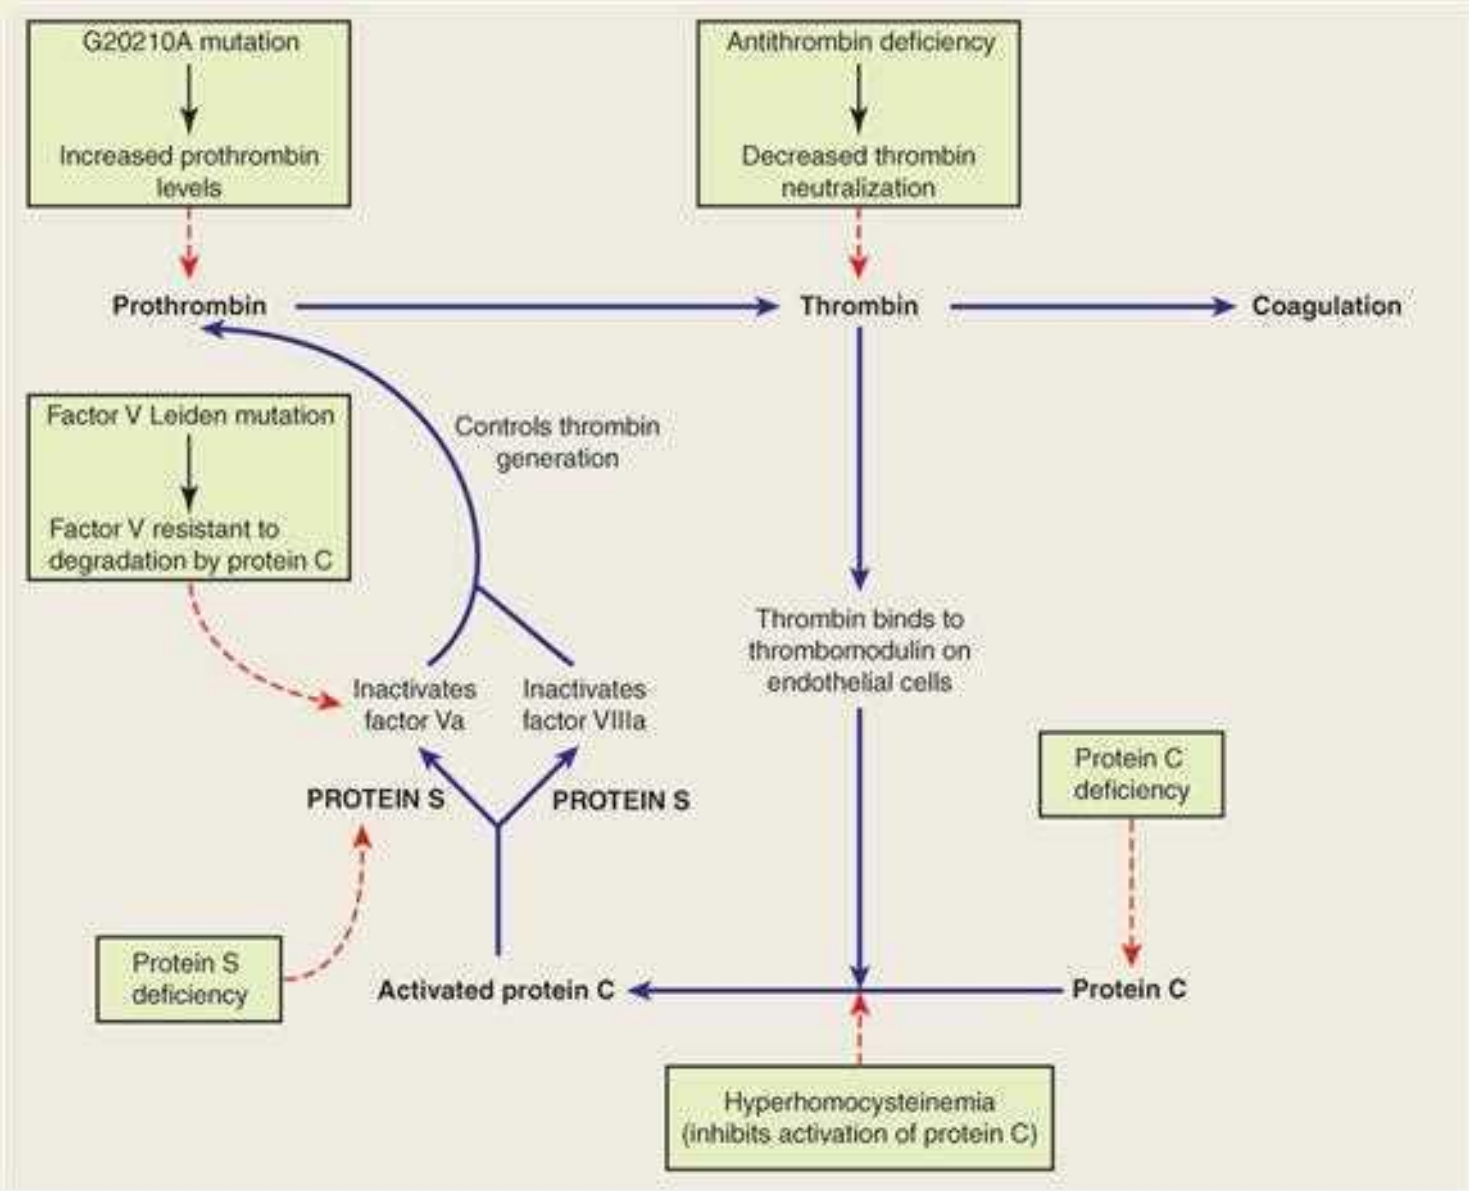
Mutation	VTE Risk per Pregnancy (No History) (%)	VTE Risk per Pregnancy (Prior VTE) (%)	VTE Odds Ratio[a]
Factor V Leiden heterozygote	0.5–1.2	10	6.4
Factor V Leiden homozygote	4	17	35.8
Prothrombin gene heterozygote	<0.5	>10	5.1
Prothrombin gene homozygote	2–4	>17	21.1
Factor V Leiden/prothrombin double heterozygote	4–5	>20	21.2
Antithrombin deficiency	3–7	40	9.5
Protein C deficiency	0.1–0.8	4–17	9.3
Protein S deficiency	0.1	0–22	7.0

[a]Odds ratio for pregnancy-associated VTE compared with gravid noncarriers.

Data from the American College of Obstetricians and Gynecologists, 2017c; Croles, 2017.

FIGURE 52-1

Inherited thrombophilias and their effect(s) on the coagulation cascade. (Data from Seligsohn, 2001.)



Inherited Thrombophilias

Patients with inherited thrombophilic disorders often have a family history of thrombosis. Inherited thrombophilias are also found in up to half of all patients who present with VTE before the age of 45 years, particularly in those whose event occurred in the absence of well-recognized risk factors. Of greatest significance is a family history of sudden death due to pulmonary embolism or a history of multiple family members requiring long-term anticoagulation therapy because of recurrent thrombosis (Anderson, 2011).

Antithrombin Deficiency

Synthesized in the liver, antithrombin is one of the most important inhibitors of thrombin and inactivates thrombin and factor Xa (Rhéaume, 2016). Notably, the rate of antithrombin interaction with its target is accelerated by heparin (Anderson, 2011). Antithrombin deficiency may result from hundreds of different mutations that are almost always autosomal dominant. Type I deficiency results from reduced synthesis of biologically normal antithrombin, and type II deficiency is characterized by normal levels of antithrombin with reduced functional activity (Anderson, 2011). Homozygous antithrombin deficiency is lethal.

Antithrombin deficiency is rare—it affects approximately 1 in 500 to 5000 individuals (Ilonczai, 2015; Rhéaume, 2016). It is the most thrombogenic of the heritable coagulopathies. Indeed, antithrombin deficiency is associated with a 25- to 50-fold higher relative risk of VTE in the general population and a sixfold increased risk of thromboembolic complications during pregnancy (Ilonczai, 2015). Those affected have approximately a 50-percent lifetime risk of VTE (Duhl, 2007).

Sabadell and associates (2010) studied the outcomes of 18 pregnancies complicated by antithrombin deficiency. Twelve of these women were treated with therapeutic doses of low-molecular-weight heparin (LMWH), and six were not treated because antithrombin deficiency had not yet been diagnosed. Three of the untreated patients suffered a thromboembolic episode compared with none in the treated group. Untreated women also had a 50-percent risk of stillbirth and fetal-growth restriction. By comparison, none of the treated women had a stillbirth, but a fourth developed fetal-growth restriction. Similar results were reported by Ilonczai and colleagues (2015). García-Botella and associates (2016) described a mesenteric vein thrombosis in a pregnant woman with antithrombin deficiency. In one review of outcomes in 23 newborns with antithrombin deficiency, there were 11 cases of thrombosis and 10 infant deaths (Seguin, 1994).

Given such risk, affected women are treated during pregnancy with heparin regardless of whether they have had a prior thrombosis. When anticoagulation is necessarily withheld, such as during surgery or delivery, Paidas and colleagues (2016) found that treatment with recombinant human antithrombin protected against VTE development. Sharpe and associates (2011) described successful use of antithrombin concentrate infusions plus therapeutic anticoagulation in a pregnant woman with antithrombin deficiency who developed a thrombosis during the third trimester despite therapeutic LMWH.

Protein C Deficiency

When thrombin is bound to thrombomodulin on endothelial cells of small vessels, its procoagulant activities are neutralized. This binding also activates protein C, a natural anticoagulant that in the presence of protein S controls thrombin generation, in part, by inactivating factors Va and VIIIa (see Fig. 52-1). Protein C activity increases modestly but significantly throughout the first half of pregnancy, and some have speculated that this augmentation may play a role in maintaining early pregnancy through both anticoagulant and inflammatory regulatory pathways (Said, 2010b).

More than 160 different autosomal dominant mutations for the protein C gene have been described (Louis-Jacques, 2016). The prevalence of protein C deficiency is 2 to 3 per 1000, but many of these individuals do not have a thrombosis history because the phenotypic expression is highly variable (Anderson, 2011). These prevalence estimates correspond with functional activity threshold values of 50 to 60 percent, which are used by most laboratories and which are associated with a six- to 12-fold higher risk for VTE (Lockwood, 2012).

Protein S Deficiency

This circulating anticoagulant is activated by protein C, which enhances the capacity of protein S to inactivate factors Va and VIIIa (see Fig. 52-1). Protein S deficiency may be caused by more than 130 different mutations, with an aggregate prevalence of approximately 0.3 to 1.3 per 1000 individuals (Louis-Jacques, 2016). Protein S deficiency may be measured by antigenically determined free, functional, and total S levels. All three decline substantively during normal gestation (Appendix, Serum and Blood Constituents). Thus, the diagnosis in pregnant women—as well as in those taking certain oral contraceptives—is difficult (Archer, 1999). If screening during pregnancy is necessary, threshold values for free protein S antigen levels in the second and third trimesters have been identified at <30 percent and <24 percent, respectively. Among those with a positive family history, the VTE risk in pregnancy is 6 to 7 percent (American College of Obstetricians and Gynecologists, 2017c).

Conard and coworkers (1990) described thrombosis in five of 29 pregnant women with protein S deficiency. They, as well as Burneo and colleagues (2002), reported maternal cerebral vein thrombosis. Neonatal homozygous protein C or S deficiency is usually associated with a fatal clinical phenotype known as *purpura fulminans* (Shanbhag, 2015).

Activated Protein C Resistance—Factor V Leiden Mutation

This is the most prevalent of the known thrombophilia syndromes and is characterized by resistance of plasma to the anticoagulant effects of activated protein C. There are several mutations that create this resistance, but the most common is the factor V Leiden mutation, which was named after the city in which it was described. This missense mutation in the factor V gene results from a substitution of glutamine for arginine at position 506 in the factor V polypeptide. As a result of this mutation, activated factor V is neutralized approximately tenfold more slowly by activated protein C (see Fig. 52-1). This leads to enhanced thrombin generation (MacCallum, 2014).

Heterozygous inheritance of factor V Leiden is the most common heritable thrombophilia. Found in 3 to 15 percent of select European populations and 3 percent of African Americans, it is virtually absent in African blacks and Asians (Lockwood, 2012). One theory for its relatively high prevalence suggests that the heterozygous state may confer a survival advantage, possibly because of reduced bleeding with childbirth or trauma (MacCallum, 2014).

Women who are heterozygous for factor V Leiden account for approximately 40 percent of VTE cases during pregnancy. However, the actual risk among pregnant women who are heterozygous and who do not have a personal history or a first-degree relative with a thrombotic episode before age 50 years is 5 to 12 events per 1000 gravidas (see Table 52-2). In contrast, this risk rises to at least 10 percent among pregnant women with a personal or family history. Pregnant women who are homozygous without a personal or family history have a 1- to 4-percent risk for VTE, whereas those with such a history have an approximately 17-percent risk (American College of Obstetricians and Gynecologists, 2017c).

Diagnosis during pregnancy is performed by DNA analysis for the mutant factor V gene. Bioassay is not used because of the normal resistance that develops after early pregnancy from alterations in other coagulation protein concentrations (Walker, 1997). Of note, activated protein C resistance can also be caused by antiphospholipid syndrome, which is described in Acquired Thrombophilias and also detailed in Chapter 59, Antiphospholipid Syndrome.

To assess the prognostic significance of maternal factor V Leiden mutation during pregnancy, Kjellberg and colleagues (2010) compared the outcomes of 491 carriers with those of 1055 controls. All three of the thromboembolic events occurred among the carriers. But, preterm birth rates, birthweights, or hypertensive complication rates did not differ between the two groups. In a prospective observational study of approximately 5000 women conducted by the Maternal-Fetal Medicine Units Network, the heterozygous mutant gene incidence was 2.7 percent (Dizon-Townson, 2005). Of three pulmonary emboli and one deep-vein thrombosis cases—a rate of 0.8 per 1000 pregnancies—none were among these carriers. Moreover, in the heterozygous women, the risks of preeclampsia, placental abruption, fetal-growth restriction, or pregnancy loss were not elevated. The investigators concluded that universal prenatal screening for the Leiden mutation and prophylaxis for carriers without a prior VTE is not indicated.

Prothrombin G20210A Mutation

This missense mutation in the prothrombin gene leads to excessive accumulation of prothrombin, which then may be converted to thrombin. Prothrombin levels are increased approximately 30 percent in heterozygotes and 70 percent in homozygotes (MacCallum, 2014). As with factor V Leiden, a personal or family history of VTE in a first-degree relative before age 50 years raises the risk of VTE during pregnancy (see Table 52-2). For a heterozygous carrier with such a history, the risk exceeds 10 percent. Without such a history, heterozygous carriers of the mutation have less than a 1-percent risk of VTE during pregnancy (American College of Obstetricians and Gynecologists, 2017c).

Silver and coworkers (2010) tested nearly 4200 women for the prothrombin G20210A mutation. A total of 157—or 3.8 percent—of the women carried the mutation, and only one of these was homozygous. Carriers had similar rates of pregnancy loss, preeclampsia, fetal-growth restriction, and placental abruption compared with noncarriers. Three thromboembolic events occurred in women who tested negative for the mutation.

Homozygous patients, or those who coinherit a G20210A mutation with a factor V Leiden mutation, have a greater thromboembolism risk than heterozygous carriers (Connors, 2017). Lim and associates (2016) have provided detailed information on pregnancy outcomes in women with such rare compound thrombophilias.

Hyperhomocysteinemia

The most common cause of elevated homocysteine is the C667T thermolabile mutation of the 5,10-methylene-tetrahydrofolate reductase (MTHFR) enzyme. Inheritance is autosomal recessive. Elevated homocysteine levels may also result from deficiency of one of several enzymes involved in methionine metabolism and from correctible nutritional deficiencies of folic acid, vitamin B_6, or vitamin B_{12} (Hague, 2003). During normal pregnancy, mean homocysteine plasma concentrations decline (López-Quesada, 2003). Thus, to make a diagnosis during pregnancy, Lockwood (2002) recommends a fasting threshold >12 µmol/L to define hyperhomocysteinemia.

In an interesting metaanalysis, Den Heijer and associates (2005) found that international studies of MTHFR polymorphisms were collectively associated with slightly greater risks for thrombosis. In contrast, studies conducted in North America collectively demonstrated no such association. The authors speculated that folic acid supplementation could explain the difference. Recall that folic acid serves as a cofactor in the remethylation reaction of homocysteine to methionine. Similarly, the American College of Chest Physicians concluded that the lack of an association with thromboembolism could reflect the physiological reductions in homocysteine levels associated with pregnancy and the effects of widespread prenatal folic acid supplementation (Bates, 2012). The American College of Obstetricians and Gynecologists (2017c) has concluded that there is insufficient evidence to support assessment of MTHFR polymorphisms or measurement of fasting homocysteine levels in the evaluation for VTE.

Other Thrombophilia Mutations

Potentially thrombophilic polymorphisms are being discovered at an ever-increasing rate. Unfortunately, information regarding the prognostic significance of such newly discovered mutations is limited. For example, *protein Z* is a vitamin K-dependent protein that serves as a cofactor in factor Xa inactivation. Studies have found that low protein Z levels are associated with an elevated thromboembolism risk in nonpregnant patients and may be implicated in the pathogenesis of poor pregnancy outcomes (Almawi, 2013). Similarly, *plasminogen activator inhibitor type 1 (PAI-1)* is an important regulator of fibrinolysis. Certain polymorphisms in the gene promoter have been associated with slightly greater VTE risks. Although these thrombophilias may exacerbate risk among patients when coinherited with other thrombophilias, the American College of Obstetricians and Gynecologists (2017c) has concluded that evidence to recommend screening is insufficient.

As an interesting aside, Galanaud and coworkers (2010) hypothesized that a paternal thrombophilia could increase the risk of maternal thromboembolism. Specifically, these investigators found that a paternal thrombophilia—the PROCR 6936G allele—affects the endothelial protein C receptor. This receptor is expressed by villous trophoblast and thus is exposed to maternal blood. Although this research is preliminary, it could help explain the pathogenesis of recurrent idiopathic thromboses in pregnant women.

Acquired Thrombophilias

Some examples of acquired hypercoagulable states include antiphospholipid syndrome (APS), heparin-induced thrombocytopenia (Newer Agents), and cancer.

Antiphospholipid Syndrome

This prothrombotic disorder can affect both the venous and arterial circulations. The deeper veins of the lower limbs and the cerebral arterial circulation are the most frequent sites of venous and arterial thrombosis, respectively (Connors, 2017; Giannakopoulos, 2013). Besides thrombosis, the other major clinical manifestations of the APS are obstetrical (Table 18-5). Criteria include: (1) at least one otherwise unexplained fetal death at or beyond 10 weeks; (2) at least one preterm birth before 34 weeks' gestation because of eclampsia, severe preeclampsia, or placental insufficiency; or (3) at least three unexplained consecutive spontaneous abortions before 10 weeks.

Once one of the above clinical criteria—thrombosis or obstetrical—is met, antiphospholipid antibody testing should be performed to diagnose APS. These patients should be tested for the presence of three factors: (1) lupus anticoagulant, (2) anticardiolipin immunoglobulin G and M (IgG and IgM) antibodies, and (3) anti-β_2-glycoprotein I IgG and IgM antibodies. If any of these laboratory test results are positive, a confirmatory test is performed 12 weeks later (Connors, 2017).

Based on their study of 750 singleton pregnancies complicated by APS, Saccone and associates (2017) found that anticardiolipin antibody is the most common sole antiphospholipid antibody present; but anti-β_2-glycoprotein I is associated with the lowest live birth rate and highest incidences of preeclampsia, fetal-growth restriction, and stillbirth compared with anticardiolipin antibodies or lupus anticoagulant alone. These investigators also observed that despite therapy with low-dose aspirin and prophylactic LMWH heparin, the chance of a liveborn neonate was only 30 percent for women with positive test results for all three antibodies.

The thrombosis risk rises significantly during pregnancy in women with APS. Indeed, up to 25 percent of thrombotic events in women with APS occur during pregnancy or in the puerperium. Looking at this a different way, women with APS have a 5- to 12-percent risk of thrombosis during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2017a). This syndrome is discussed in more detail in Chapter 59 (Antiphospholipid Syndrome).

Thrombophilias and Pregnancy Complications

Attention has been directed toward possible relationships between inherited thrombophilias and pregnancy complications other than thromboses. Summarized in Table 52-3 are the findings of 25 studies systematically reviewed by Robertson and associates (2005) and incorporated into the recommendations of the American College of Chest Physicians (Bates, 2012). Importantly, the considerable heterogeneity and wide confidence intervals illustrate the uncertainty of these associations.

TABLE 52-3

Association between Pregnancy Complications and Thrombophilia

Type of Thrombophilia	Early Loss	Recurrent First-Trimester Loss	Nonrecurrent Second-Trimester Loss	Late Loss	Preeclampsia	Placental Abruption	Fetal-Growth Restriction
Factor V Leiden (homozygous)	**2.71(1.32–5.58)**	—[a]	—[a]	1.98 (0.40–9.69)	1.87 (0.44–7.88)	8.43 (0.41–171.20)	4.64 (0.19–115.68)
Factor V Leiden (heterozygous)	**1.68(1.09–2.58)**	**1.91 (1.01–3.61)**[a]	**4.12 (1.91–8.81)**[a]	**2.06 (1.10–3.86)**	**2.19 (1.46–3.27)**	**4.70 (1.13–19.59)**	2.68 (0.59–12.13)
Prothrombin gene mutation (heterozygous)	**2.49(1.24–5.00)**	**2.70 (1.37–5.34)**	**8.60 (2.18–33.95)**	**2.66 (1.28–5.53)**	**2.54 (1.52–4.23)**	**7.71 (3.01–19.76)**	2.92 (0.62–13.70)
MTHFR C677T (homozygous)	1.40(0.77–2.55)	0.86 (0.44–1.69)	NA	1.31 (0.89–1.91)	**1.37 (1.07–1.76)**	1.47 (0.40–5.35)	1.24 (0.84–1.82)
Antithrombin deficiency	0.88(0.17–4.48)	NA	NA	7.63 (0.30–196.36)	3.89 (0.16–97.19)	1.08 (0.06–18.12)	NA
Protein C deficiency	2.29(0.20–26.43)	NA	NA	3.05 (0.24–38.51)	5.15 (0.26–102.22)	5.93 (0.23–151.58)	NA
Protein S deficiency	3.55(0.35–35.72)	NA	NA	**20.09 (3.70–109.15)**	2.83 (0.76–10.57)	2.11 (0.47–9.34)	NA
Anticardiolipin antibodies	**3.40(1.33–8.68)**	**5.05 (1.82–14.01)**	NA	**3.30 (1.62–6.70)**	**2.73 (1.65–4.51)**	1.42 (0.42–4.77)	**6.91 (2.70–17.68)**

Other investigations underscore the heterogeneity of results. For example, Kahn and coworkers (2009) found no higher risk for early-onset or severe preeclampsia in women with factor V Leiden mutation, prothrombin G20210A mutation, MTHFR C677T polymorphism, or hyperhomocysteinemia. Said and associates (2010a) prospectively screened more than 2000 healthy nulliparous women for factor V Leiden, prothrombin gene mutation, MTHFR C677T, MTHFR A1298C, and thrombomodulin polymorphism. Women who carried the prothrombin gene mutation had a 3.6-fold greater risk of adverse pregnancy outcome, including severe preeclampsia, fetal-growth restriction, placental abruption, or stillbirth. But, none of the other polymorphisms conferred an elevated risk of these adverse outcomes. From the Stillbirth Collaborative Research Network, Silver and associates (2016) found a weak association between maternal factor V Leiden and stillbirth. There was no association between stillbirth and the other inherited thrombophilias. Based on their prospective study of 750 pregnancies complicated by stillbirth, Korteweg and colleagues (2010) concluded that routine thrombophilia testing after fetal death is inadvisable.

The American College of Obstetricians and Gynecologists (2017c) notes that a definitive causal link cannot be made between inherited thrombophilias and adverse pregnancy outcomes. Moreover, in one randomized trial, Rodger and associates (2014) found that antepartum prophylactic LMWH did not reduce a composite outcome of pregnancy loss, severe or early-onset preeclampsia, small-for-gestational age neonates, and VTE in thrombophilic women.

Thus, because of uncertainties in the magnitude of risk and in the benefits of prophylaxis given to prevent pregnancy complications in women with heritable thrombophilias, it remains unproven that universal screening is indicated (Louis-Jacques, 2016). In contrast, the association between APS and adverse pregnancy outcomes—including fetal loss, recurrent pregnancy loss, and preeclampsia—is much stronger.

Thrombophilia Screening

Given the relatively high incidence of thrombophilia in the population and the low incidence of VTE, universal screening during pregnancy is not cost effective (Carbone, 2010). Thus, a selective screening strategy is required. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that thrombophilia screening be considered in the following clinical circumstances: (1) a personal history of VTE that was associated with a nonrecurrent risk factor such as fractures, surgery, and/or prolonged immobilization; and (2) a first-degree relative (parent or sibling) with a history of high-risk thrombophilia or VTE before age 50 years in the absence of other risk factors.

The American College of Obstetricians and Gynecologists (2017c) notes that testing for inherited thrombophilias in women who have experienced recurrent fetal loss or placental abruption is not recommended because clinical evidence that antepartum heparin prophylaxis prevents recurrence is insufficient. Similarly, testing is not recommended for women with a history of fetal-growth restriction or preeclampsia. The American College of Chest Physicians also recommends against screening women with prior pregnancy complications (Bates, 2012). However, screening for antiphospholipid antibodies may be appropriate in women who have experienced a fetal loss or early-onset preeclampsia (Berks, 2015).

Methods of screening for the more common inherited thrombophilias are shown in Table 52-4. Whenever possible, laboratory testing is performed at least 6 weeks after the thrombotic event, while the patient is not pregnant, and when she is not receiving anticoagulation or hormonal therapy. Screening for hyperhomocysteinemia is not recommended (American College of Obstetricians and Gynecologists, 2017c).

TABLE 52-4

How to Test for Thrombophilias

Thrombophilia	Testing Method	Is Testing Reliable During Pregnancy?	Is Testing Reliable During Acute Thrombosis?	Is Testing Reliable with Anticoagulation?
Factor V Leiden mutation	Activated protein C resistance assay (second generation) If abnormal: DNA analysis	Yes Yes	Yes Yes	No Yes
Prothrombin gene mutation G20210A	DNA analysis	Yes	Yes	Yes
Protein C deficiency	Protein C activity (<60%)	Yes	No	No
Protein S deficiency	Functional assay (<55%)	No[a]	No	No
Antithrombin deficiency	Antithrombin activity (<60%)	Yes	No	No

[a]If screening in pregnancy is necessary, cutoff values for free protein S antigen levels in the second and third trimesters have been identified at less than 30% and less than 24%, respectively.

Reproduced with permission from American College of Obstetricians and Gynecologists Women's Health Care Physicians: ACOG Practice Bulletin No. 138: Inherited thrombophilias in pregnancy, Obstet Gynecol. 2013 Sep;122(3):706–717.

DEEP-VEIN THROMBOSIS

Clinical Presentation

During pregnancy, most venous thromboses are confined to the deep veins of the lower extremity. Approximately 70 percent of cases are located in the iliofemoral veins without involvement of the calf veins. Isolated iliac vein and calf vein thromboses occur in approximately 17 and 6 percent of cases, respectively (Chan, 2010). In contrast, in the general population, more than 80 percent of deep-vein thromboses involve calf veins, and iliofemoral or isolated iliac vein thromboses are uncommon (Huisman, 2015).

The signs and symptoms vary greatly and depend on the degree of occlusion and the intensity of the inflammatory response. Ginsberg and coworkers (1992) reported that 58 of 60 antepartum women—97 percent—had left leg thromboses. Blanco-Molina and coworkers (2007) reported left-leg involvement in 78 percent. Greer (2003) hypothesizes that this results from compression of the left iliac vein by the right iliac and ovarian artery, both of which cross the vein only on the left side. Yet, as described in Chapter 53 (Urinary Tract Infections), the ureter is compressed more on the right side.

Classically, thrombosis involving the lower extremity is abrupt in onset, and there is pain and edema of the leg and thigh. The thrombus typically involves much of the deep-venous system to the iliofemoral region. Occasionally, reflex arterial spasm causes a pale, cool extremity with diminished pulsations.

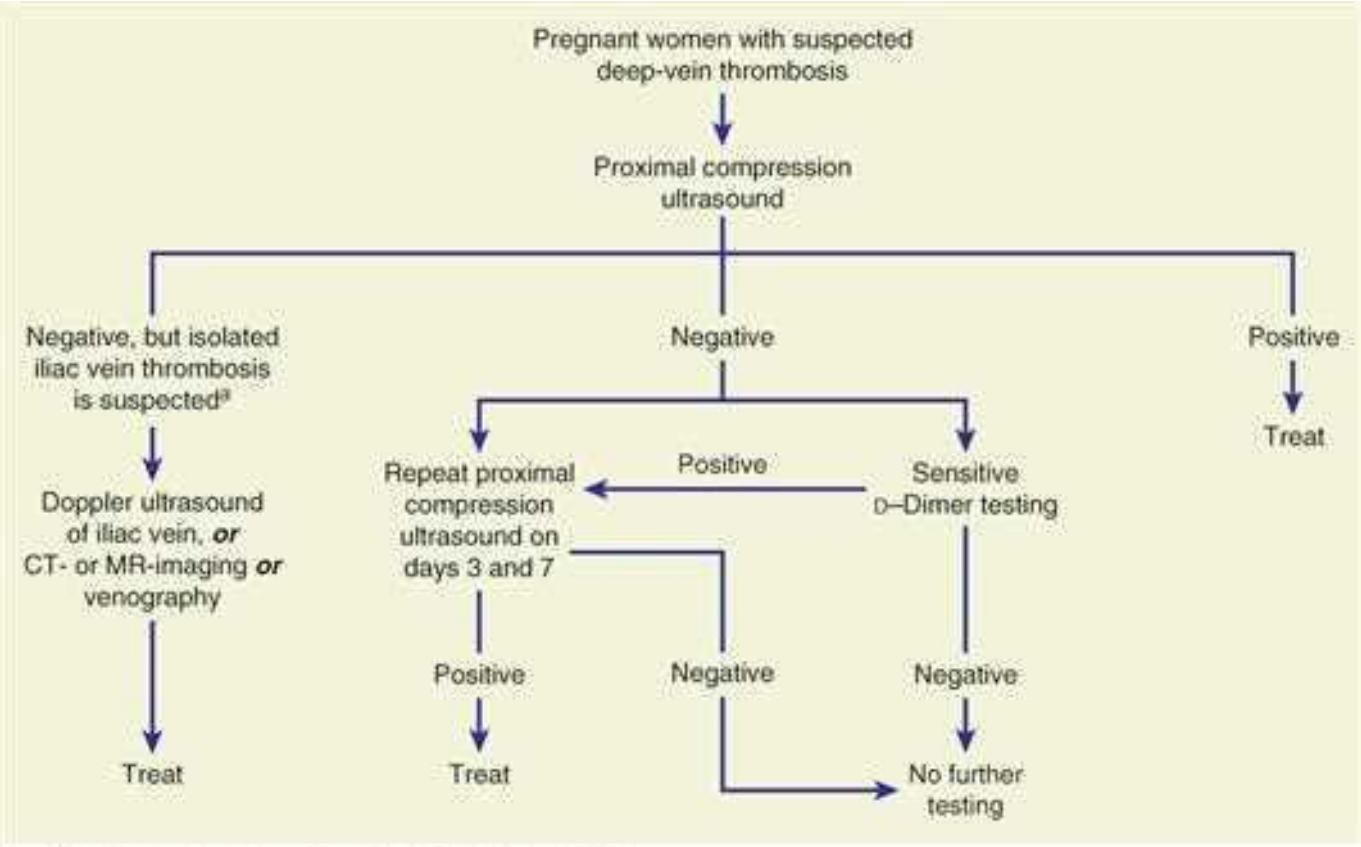
Alternatively, there may be appreciable clot, yet little pain, heat, or swelling. Importantly, calf pain, either spontaneous or in response to squeezing or to Achilles tendon stretching—*Homans sign*—may be caused by a strained muscle or contusion. Between 30 and 60 percent of women with a confirmed lower-extremity acute deep-vein thrombosis have an asymptomatic pulmonary embolism (Superficial Venous Thrombophlebitis).

Diagnosis

Clinical diagnosis of deep-vein thrombosis is difficult, and in an earlier study of pregnant women, the clinical diagnosis was confirmed in only 10 percent (Hull, 1990). Another challenge is that many of the common diagnostic tests that have been investigated extensively in nonpregnant patients have not been validated appropriately in pregnancy (Huisman, 2015). Shown in Figure 52-2 is one diagnostic algorithm recommended by the American College of Chest Physicians that can be used for evaluation of pregnant women (Guyatt, 2012). With a few modifications, we follow a similar evaluation at Parkland Hospital.

FIGURE 52-2

Algorithm for evaluation of suspected deep-vein thrombosis in pregnancy. CT = computed tomography; MR = magnetic resonance. [a]Signs and symptoms include swelling of the entire leg, with or without flank, buttock, or back pain. (Data from Guyatt GH, Akl EA, Crowther M, et al: Executive summary: Antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practice guidelines, Chest. 2012 Feb;141(2 Suppl):7S-47S.)



Compression Ultrasonography

In pregnant women with suspected deep-vein thrombosis, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend compression ultrasonography of the proximal veins as the initial diagnostic test. According to the American College of Chest Physicians, this noninvasive technique is currently the most-used first-line test to detect deep-vein thrombosis (Guyatt, 2012). The diagnosis is based on the noncompressibility and typical echoarchitecture of a thrombosed vein.

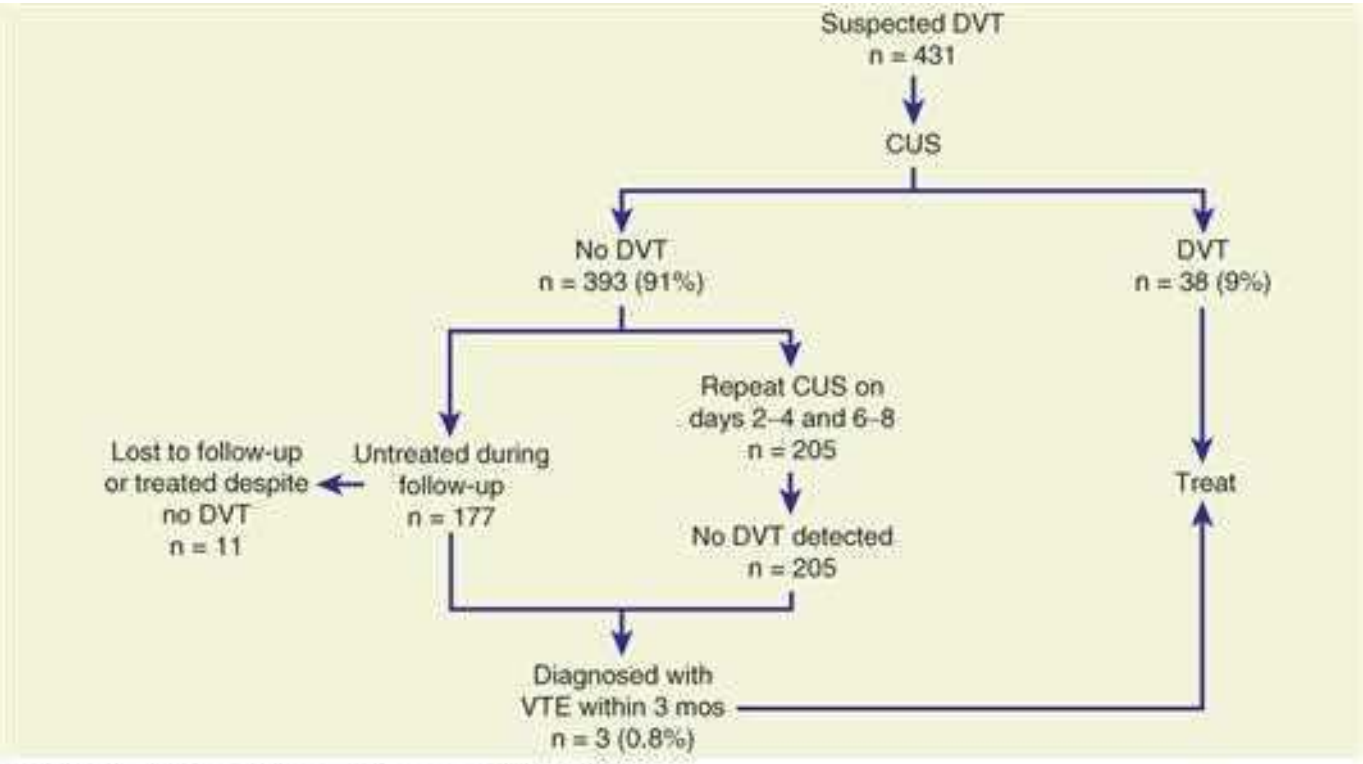
For *nonpregnant* patients with suspected thrombosis, the safety of withholding anticoagulation for 1 week has been established for those who have a compression ultrasound examination that is initially normal (Birdwell, 1998; Heijboer, 1993). Serial compression examinations are then performed because isolated undetected calf thromboses that ultimately extend into the proximal veins will do so within 1 to 2 weeks of presentation in approximately a fourth of patients.

In *pregnant* women, the important caveat is that normal findings with venous ultrasonography do not always exclude a pulmonary embolism. This is because the thrombosis may have already embolized or because it arose from iliac or other deep-pelvic veins, which are less accessible to ultrasound evaluation (Goldhaber, 2004). As discussed, thrombosis associated with pulmonary embolism during pregnancy commonly originates in the iliac veins.

The results of two studies are helpful for evaluating the need for serial examinations in pregnant women suspected of having a deep-vein thrombosis but who have a negative initial compression ultrasound examination. The combined results are depicted in Figure 52-3. Chan and coworkers (2013) studied 221 pregnant and postpartum women presenting with a suspected deep-vein thrombosis. The 205 women with a negative initial study result underwent serial testing, which was negative in all cases. Of these, one woman with normal serial testing had a pulmonary embolism 7 weeks later. Le Gal and colleagues (2012) studied 210 pregnant and postpartum women with a suspected deep-vein thrombosis. Of these, 177 women without a deep-vein thrombosis were not anticoagulated and did not undergo serial testing. Two had an objectively confirmed thrombosis diagnosed within 3 months. In sum, these preliminary data suggest that a negative single complete compression ultrasonography study may safely exclude the diagnosis of deep-vein thrombosis in most pregnant women.

FIGURE 52-3

Findings from two studies of serial and nonserial compression ultrasound examinations in pregnant and postpartum women. CUS = compression ultrasonography. DVT = deep vein thrombosis. VTE = venous thromboembolism. (Data from Chan, 2013; Le Gal, 2012.)



Magnetic Resonance Imaging

This imaging technique allows excellent delineation of anatomical detail above the inguinal ligament. Thus, in many cases, magnetic resonance (MR) imaging is immensely useful for diagnosis of iliofemoral and pelvic vein thrombosis. The venous system can also be reconstructed using MR venography (Chap. 46, Imaging During Pregnancy). Erdman and associates (1990) reported that MR imaging was 100-percent sensitive and 90-percent specific for detection of venographically proven deep-vein thrombosis in nonpregnant patients. Importantly, almost half of those without deep-vein thrombosis were found to have nonthrombotic conditions that included cellulitis, myositis, edema, hematomas, and superficial phlebitis.

Khalil and coworkers (2012) used MR venography to study the natural history of pelvic vein thrombosis after vaginal delivery. Among the 30 *asymptomatic* patients who were all within four days of delivery, 30 percent had a definitive thrombosis in either the iliac or ovarian veins, and another 37 percent had a suspected thrombosis. Our experiences with hundreds of postpartum MR scans do not support these findings. Thus, although the clinical significance of their findings is uncertain, it seems clear that some degree of pelvic vein intraluminal filling defect may be a normal finding.

d-Dimer Screening Tests

These specific fibrin degradation products are generated when fibrinolysin degrades fibrin, as occurs in thromboembolism (Chap. 41, Pregnancy-Induced Coagulation Changes). Their measurement is frequently incorporated into diagnostic algorithms for VTE in nonpregnant patients (Wells, 2003). Screening with the d-dimer test in pregnancy, however, is problematic for several reasons. As shown in the Appendix (Serum and Blood Constituents), depending on assay sensitivity, d-dimer serum levels rise with gestational age along with substantively elevated plasma fibrinogen concentrations (Murphy, 2015). Levels are also affected by multifetal gestation and cesarean delivery (Morikawa, 2011). d-Dimer concentrations can also be elevated in certain pregnancy complications such as placental abruption, preeclampsia, and sepsis syndrome. Moreover, higher levels have been observed in sickle-cell carriers and in

women of African and South Asian racial origin (Grossman, 2016). For all these reasons, their use during pregnancy remains uncertain, but a negative d-dimer test should be considered reassuring (Lockwood, 2012; Marik, 2008).

Management

Optimal management of VTE during pregnancy has not undergone major clinical study to provide evidence-based practices. There is, however, consensus for treatment with anticoagulation and limited activity. If thrombophilia testing is performed, it is done before anticoagulation. Heparin induces a decline in antithrombin levels, and warfarin lowers protein C and S concentrations. The results of these tests do not change treatment (Connors, 2017).

Anticoagulation is initiated with either unfractionated heparin (UFH) or LMWH. Although either type is acceptable, most recommend one of the LMWHs (Bates, 2016; Kearon, 2016). For example, the American College of Chest Physicians suggests preferential use of LMWH during pregnancy because of better bioavailability, longer plasma half-life, more predictable dose response, reduced risks of osteoporosis and thrombocytopenia, and less frequent dosing (Bates, 2012). Dosages are shown in Table 52-5.

TABLE 52-5

Anticoagulation Regimen Definitions

Anticoagulation Regimen	Definition
Prophylactic LMWH[a]	Enoxaparin, 40 mg SC once daily Dalteparin, 5,000 units SC once daily Tinzaparin, 4,500 units SC once daily
Therapeutic LMWH[b]	Enoxaparin, 1 mg/kg every 12 hours Dalteparin, 200 units/kg once daily Tinzaparin, 175 units/kg once daily Dalteparin, 100 units/kg every 12 hours May target an anti-Xa level in the therapeutic range of 0.6–1.0 units/mL for twice daily regimen; slightly higher doses may be needed for a once-daily regimen.
Minidose prophylactic UFH	UFH, 5,000 units SC every 12 hours
Prophylactic UFH	UFH, 5,000–10,000 units SC every 12 hours UFH, 5,000–7,500 units SC every 12 hours in first trimester UFH 7,500–10,000 units SC every 12 hours in the second trimester UFH, 10,000 units SC every 12 hours in the third trimester, unless the aPTT is elevated
Therapeutic UFH[b]	UFH, 10,000 units or more SC every 12 hours in doses adjusted to target aPTT in the therapeutic range (1.5–2.5) 6 hours after injection
Postpartum anticoagulation	Prophylactic LMWH/UFH for 4–6 weeks or vitamin K antagonists for 4–6 weeks with a target INR of 2.0–3.0, with initial UFH or LMWH therapy overlap until the INR is 2.0 or more for 2 days
Surveillance	Clinical vigilance and appropriate objective investigation of women with symptoms suspicious of deep-vein thrombosis or pulmonary embolism

Abbreviations: aPTT, activated partial thromboplastin time; INR, international normalized ratio; LMWH, low-molecular-weight heparin; SC, subcutaneously; UFH, unfractionated heparin.

[a]Although at extremes of body weight, modification of dose may be required.

[b]Also referred to as weight adjusted, full treatment dose.

TABLE 52-6

Some Recommendations for Thromboprophylaxis during Pregnancy

	Pregnancy		Postpartum	
Clinical Scenario	**ACOG[a]**	**ACCP[b]**	**ACOG[a]**	**ACCP[b]**
Prior single VTE				
Risk factor no longer present	Surveillance only	Surveillance only	Postpartum anticoagulation[c] "Surveillance only acknowledged by some experts."	Prophylactic or intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks
Pregnancy- or estrogen-related or no known association (idiopathic) ***and*** not receiving long-term therapy	Prophylactic UFH or LMWH ***or*** "Surveillance only acknowledged by some experts"	Prophylactic or intermediate-dose LMWH	Postpartum anticoagulation[c]	Prophylactic or intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks
Receiving long-term warfarin	NSS	Adjusted-dose LMWH ***or*** 75% of a therapeutic dose of LMWH	NSS	Resume long-term anticoagulation
Associated with a high-risk thrombophilia[d] ***and*** not receiving long-term anticoagulation or an affected first-degree relative	Prophylactic, intermediate-, or adjusted-dose LMWH or UFH	NSS	Postpartum anticoagulation[c] ***or*** intermediate- or adjusted-dose LMWH or UFH × 6 weeks[c]	Prophylactic or intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks
Associated with a low-risk thrombophilia[e] and not receiving treatment	Prophylactic or intermediate-dose LMWH or UFH ***or*** surveillance only	NSS	Postpartum anticoagulation[c] ***or*** intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks
Two or more prior VTEs with or without thrombophilia				
Not receiving long-term therapy	Prophylactic or therapeutic-dose UFH or LMWH	NSS	Postpartum anticoagulation[c] ***or*** therapeutic-dose LMWH or UFH × 6 weeks	Prophylactic or intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks
Receiving long-term anticoagulation	Therapeutic-dose LMWH or UFH	Adjusted-dose LMWH ***or*** 75% of a therapeutic dose of LMWH	Resumption of long- term anticoagulation	Resumption of long-term anticoagulation
No prior VTE				
High-risk thrombophilia[d]	Surveillance only ***or*** prophylactic or intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH	Postpartum anticoagulation[c]	Intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks
Positive family history VTE ***and*** homozygous factor V Leiden or prothrombin 20210A mutation	NSS	Prophylactic or intermediate-dose LMWH	NSS	Prophylactic or intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks

	Pregnancy		Postpartum	
Clinical Scenario	**ACOG[a]**	**ACCP[b]**	**ACOG[a]**	**ACCP[b]**
Negative family history VTE and homozygous factor V Leiden or prothrombin 20210A mutation	Surveillance only ***or*** prophylactic LMWH or UFH	Surveillance only	Postpartum anticoagulation[c]	Prophylactic- or intermediate-dose LMWH ***or*** warfarin target INR 2.0–3.0 × 6 weeks
Positive family history VTE and low-risk thrombophilias[e]	Surveillance only	Surveillance only	Postpartum anticoagulation[c] ***or*** intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH ***or*** in women not protein C or S deficient, warfarin target INR 2.0–3.0
Low-risk thrombophilia[e]	Surveillance only	Surveillance only if no family history	Surveillance only; postpartum anticoagulation with additional risk factors[f]	Surveillance only if no family history
Antiphospholipid antibodies				
History of VTE	Prophylactic anticoagulation with UFH or LMWH (?plus low-dose aspirin)	NSS	Prophylactic anticoagulation[c]; referral to specialist[g]	NSS
No prior VTE	Surveillance only ***or*** prophylactic LMWH or UFH ***or*** prophylactic LMWH or UFH plus low-dose aspirin if prior recurrent pregnancy loss or stillbirth	Prophylactic- or intermediate-dose UFH ***or*** prophylactic-dose LMWH, both given with 75–100 mg/day aspirin[h]	Prophylactic heparin plus low-dose aspirin × 6 weeks if prior recurrent pregnancy loss or stillbirth[g]	NSS

[a] American College of Obstetricians and Gynecologists, 2017a, c.

[b] American College of Chest Physicians (Bates, 2012).

[c] Postpartum treatment levels should be ≥ antepartum treatment.

[d] Antithrombin deficiency; doubly heterozygous or homozygous for prothrombin 20210A and factor V Leiden.

[e] Heterozygous factor V Leiden or prothrombin 20210A; protein S or C deficiency.

[f] First-degree relative with VTE at <50 years; other major thrombotic risk factors, e.g., obesity, prolonged immobility.

[g] Women with antiphospholipid syndrome should not use estrogen-containing contraceptives.

[h] Treatment is recommended if the diagnosis of antiphospholipid syndrome is based on three or more prior pregnancy losses.

LMWH = low-molecular-weight heparin; NSS = not specifically stated; UFH = unfractionated heparin; VTE = venous thromboembolism.

Prophylactic, intermediate-, and adjusted-dose regimens are listed in Table 52-5.

During pregnancy, heparin therapy is continued, and for postpartum women, anticoagulation is begun simultaneously with warfarin. Recall that pulmonary embolism develops in as many as 60 percent of patients with untreated venous thrombosis, and anticoagulation decreases this risk to less than 5 percent. In nonpregnant patients, the mortality rate with a pulmonary embolism approximates 1 percent (Douketis, 1998; Pollack, 2011).

Over several days, leg pain dissipates. After symptoms have abated, graded ambulation is begun. Elastic stockings are fitted, and anticoagulation is continued. Recovery to this stage usually takes 7 to 10 days. Graduated compression stockings are continued for 2 years after the diagnosis to reduce the incidence of postthrombotic syndrome (Brandjes, 1997). This syndrome can include chronic leg paresthesias or pain, intractable edema, skin changes, and leg ulcers.

Unfractionated Heparin

This agent should be considered for the initial treatment of thromboembolism and in situations in which delivery, surgery, or thrombolysis may be necessary (American College of Obstetricians and Gynecologists, 2017b). Unfractionated heparin can be administered by one of two alternatives: (1) initial intravenous therapy followed by adjusted-dose subcutaneous UFH given every 12 hours; or (2) twice-daily, adjusted-dose subcutaneous UFH with doses adjusted to prolong the activated partial thromboplastin time (aPTT) into the therapeutic range 6 hours postinjection (Bates, 2012). As shown in Table 52-5, the therapeutic dose for subcutaneous UFH is usually 10,000 units or more every 12 hours.

For intravenous therapy, several protocols are acceptable. In general, if UFH is used, it is initiated with a bolus intravenous dose of 70 to 100 U/kg, which is 5000 to 10,000 U. This is followed by continuous intravenous infusions beginning at 1000 U/hr or 15 to 20 U/kg/hr. This infusion rate is titrated to achieve an aPTT 1.5 to 2.5 times control values (Brown, 2010; Linnemann, 2016). Intravenous anticoagulation is maintained for at least 5 to 7 days, after which treatment is converted to subcutaneous heparin to maintain the aPTT to at least 1.5 to 2.5 times control throughout the dosing interval. For women with lupus anticoagulant, aPTT does not accurately assess heparin anticoagulation, and thus anti-factor Xa levels are preferred.

The duration of full anticoagulation varies, and no studies have defined the optimal duration for pregnancy-related thromboembolism. In nonpregnant patients with VTE, evidence supports a minimum treatment duration of 3 months (Kearon, 2012). For pregnant patients, the American College of Chest Physicians recommends anticoagulation throughout pregnancy and postpartum for a minimum total duration of 3 months (Bates, 2012). Lockwood (2012) recommends that full anticoagulation be continued for at least 20 weeks followed by prophylactic doses if the woman is still pregnant. Prophylactic doses of subcutaneous UFH can range from 5000 to 10,000 U every 12 hours titrated to maintain an anti-factor Xa level of 0.1 to 0.2 U/mL, measured 6 hours after the last injection. If the VTE occurs during the postpartum period, Lockwood (2012) recommends a minimum of 6 months of anticoagulation treatment.

Low-Molecular-Weight Heparin

This is a family of derivatives of unfractionated heparin, and their molecular weights average 4000 to 5000 daltons compared with 12,000 to 16,000 daltons for conventional heparin. None of these heparins cross the placenta, and all exert their anticoagulant activity by activating antithrombin. The primary difference is their relative inhibitory activity against factor Xa and thrombin. Specifically, UFH has equivalent activity against factor Xa and thrombin, but LMWHs have greater activity against factor Xa than against thrombin. They also have a more predictable anticoagulant response and fewer bleeding complications than UFH because of their better bioavailability, longer half-life, dose-independent clearance, and decreased interference with platelets (Tapson, 2008). These LMWH compounds are cleared by the kidneys and must be used cautiously when there is renal dysfunction.

Several studies have shown that VTE is treated effectively with LMWH (Quinlan, 2004; Tapson, 2008). Using serial venograms, Breddin and associates (2001) observed that these compounds were more effective than UFH in reducing thrombus size without increasing mortality rates or major bleeding complications. Several different treatment regimens using adjusted-dose LMWH for treatment of acute VTE are recommended by the American College of Obstetricians and Gynecologists (2017b,c) and are listed in Table 52-5.

Pharmacokinetics in Pregnancy

LMWHs available for use in pregnancy include enoxaparin, tinzaparin, and dalteparin. Enoxaparin (Lovenox) pharmacokinetics were studied in 36 women with VTE during pregnancy or immediately postpartum (Rodie, 2002). The dose was approximately 1 mg/kg given twice daily based on early pregnancy weight. Treatment was monitored by peak anti-factor Xa activity at 3 hours postinjection, with a target therapeutic range of 0.4 to 1.0 U/mL. In 33 women, enoxaparin provided satisfactory anticoagulation. In the other three women, dose reduction was necessary. None developed recurrent thromboembolism or bleeding complications. In postcesarean women with a body mass index (BMI) ≥35, Stephenson and associates (2016) found that weight-based dosing of enoxaparin 0.5 mg/kg twice daily more effectively achieved prophylactic peak anti-Xa levels between 0.2 to 0.6 U/mL than a fixed dose of 40 mg daily. Similar findings were reported by Overcash and colleagues (2015).

For tinzaparin (Innohep), a dosage of 75 to 175 U/kg/d was necessary to achieve peak anti-factor Xa levels of 0.1 to 1.0 U/mL (Smith, 2004). In studies of dalteparin (Fragmin) pharmacokinetics, conventional starting doses of dalteparin—100 U/kg every 12 hours—were likely insufficient to maintain full anticoagulation (Barbour, 2004; Jacobsen, 2003). Thus, slightly higher doses than that shown in Table 52-5 may be required.

Dosing and Monitoring

Standard prophylactic and therapeutic dosages recommended by the American College of Obstetricians and Gynecologists (2017b) for various LMWHs are listed in Table 52-5. Whether such dosages require adjustments during the course of pregnancy is controversial (Berresheim, 2014; Cutts, 2013). Some suggest periodic measurement of anti-factor Xa levels 4 to 6 hours after an injection with dose adjustment to maintain a therapeutic level. Large studies using clinical end points that demonstrate an optimal therapeutic range or show that dose adjustments increase therapy safety or efficacy are lacking.

Accordingly, the American College of Chest Physicians and others note that routine monitoring with anti-Xa levels is difficult to justify (Bates, 2012; McDonnell, 2017).

Safety in Pregnancy

Early reviews concluded that LMWHs were safe and effective (Lepercq, 2001; Sanson, 1999). Despite this, in 2002, the manufacturer of Lovenox warned that its use in pregnancy had been associated with congenital anomalies and a higher risk of hemorrhage. After its own extensive review, the American College of Obstetricians and Gynecologists (2017b) concluded that these risks were rare, that their incidence was not higher than expected, and that no cause-and-effect relationship had been established. It further concluded that enoxaparin and dalteparin could be given safely during pregnancy. Other reports confirm their safety (Andersen, 2010; Bates, 2012; Galambosi, 2012).

Nelson-Piercy and coworkers (2011) assessed the safety of tinzaparin through a comprehensive study of 1267 treated pregnant women. There were no maternal deaths or complications from regional analgesia. Although thrombocytopenia developed in 1.8 percent, there were no cases of heparin-induced thrombocytopenia (Newer Agents). The allergy incidence was 1.3 percent. Osteoporotic fractures in three women (0.2 percent) were judged to be related to tinzaparin (Newer Agents). A total of 43 women (3.4 percent) required medical intervention for bleeding. Of 15 stillbirths, four were judged as possibly being related to tinzaparin use. But, none of the neonatal deaths or congenital abnormalities was attributed to tinzaparin. The authors concluded that tinzaparin during pregnancy was safe for mother and fetus. LMWHs are also safe during breastfeeding (Lim, 2010).

However, LMWHs should be avoided in women with renal failure. Moreover, when given within 2 hours of cesarean delivery, these agents raise the risk of wound hematoma (van Wijk, 2002).

Labor and Delivery

Women receiving either therapeutic or prophylactic anticoagulation should be converted from LMWH to the shorter half-life UFH in the last month of pregnancy or sooner if delivery appears imminent. The purpose of conversion to UFH has less to do with any risk of maternal bleeding at the time of delivery, but rather with neuraxial blockade complicated by an epidural or spinal hematoma (Chap. 25, Safety). The American College of Chest Physicians recommends that women scheduled for a planned delivery who are receiving twice-daily adjusted-dose subcutaneous UFH or LMWH discontinue their heparin 24 hours before labor induction or cesarean delivery (Bates, 2012). Patients receiving once-daily LMWH should take only 50 percent of their normal dose on the morning of the day before delivery. The American College of Obstetricians and Gynecologists (2017c) advises that adjusted-dose subcutaneous LMWH or UFH can be discontinued 24 to 36 hours before an induction of labor or scheduled cesarean delivery. The American Society of Regional Anesthesia and Pain Medicine advises withholding neuraxial blockade for 10 to 12 hours after the last prophylactic dose of LMWH or 24 hours after the last therapeutic dose (Horlocker, 2010).

If a woman begins labor while taking UFH, clearance can be verified by an aPTT. Reversal of heparin with protamine sulfate is rarely required and is not indicated with a prophylactic dose of heparin. For women in whom anticoagulation therapy has temporarily been discontinued, pneumatic compression devices are recommended.

Anticoagulation with Warfarin Compounds

Vitamin K antagonists are generally contraindicated because they readily cross the placenta and may cause fetal death and malformations from hemorrhages (Chap. 12, Warfarin). They do not accumulate in breast milk and are thus safe during breastfeeding.

Postpartum venous thrombosis is usually treated with intravenous heparin and oral warfarin initiated simultaneously. The initial dose of warfarin is usually 5 to 10 mg for the first 2 days. Subsequent doses are titrated to achieve an international normalized ratio (INR) of 2 to 3. To avoid paradoxical thrombosis and skin necrosis from the early anti-protein C effect of warfarin, these women are maintained on therapeutic doses of UFH or LMWH for 5 days and until the INR is in a therapeutic range for 2 consecutive days (American College of Obstetricians and Gynecologists, 2017c; Stewart, 2010).

Treatment in the puerperium may require larger doses of anticoagulant. Brooks and colleagues (2002) compared anticoagulation in postpartum women with that of age-matched nonpregnant controls. The former required a significantly larger median total dose of warfarin—45 versus 24 mg—and a longer time—7 versus 4 days—to achieve the target INR.

Newer Agents

Of newer oral anticoagulants, dabigatran (Pradaxal) inhibits thrombin. Rivaroxaban (Xarelto) and apixaban (Eliquis) inhibit factor Xa. Currently, very few reports address these newer agents during pregnancy, and thus the human reproductive risks are essentially unknown (Bates, 2012). Dabigatran crosses the human placenta (Bapat, 2014). However, it is unknown whether any of these agents are excreted in breast milk. Because of the potential for infant harm, a decision should be made to either avoid breastfeeding or use an alternative anticoagulant, such as warfarin, in postpartum women (Burnett, 2016).

Complications of Anticoagulation

Three significant complications associated with anticoagulation are hemorrhage, thrombocytopenia, and osteoporosis. The latter two are unique to heparin, and their risk may be reduced with LMWHs. The most serious complication is hemorrhage, which is more likely if there has been recent surgery or lacerations. Troublesome bleeding also is more likely if the heparin dosage is excessive. Unfortunately, management schemes using laboratory testing to identify when a heparin dosage is sufficient to inhibit further thrombosis, yet not cause serious hemorrhage, have been discouraging.

Heparin-Induced Thrombocytopenia

There are two types—the most common is a nonimmune, benign, reversible thrombocytopenia that develops within the first few days of therapy and resolves in approximately 5 days without therapy cessation. The second is the severe form of heparin-induced thrombocytopenia (HIT), which results from an immune reaction involving IgG antibodies directed against complexes of platelet factor 4 and heparin. The diagnosis of HIT is based on a drop in the platelet count of more than 50 percent or thrombosis beginning 5 to 10 days after the start of heparin in association with the appearance of platelet-activating HIT antibodies. The fall in platelet count in HIT occurs rapidly—over a period of 1 to 3 days—and is assessed relative to the highest platelet count after the start of heparin. The typical nadir is 40,000 to 80,000 platelets per microliter (Greinacher, 2015).

Although the incidence of HIT is approximately 3 to 5 percent in nonpregnant individuals, it is <0.1 percent in obstetrical patients (Linkins, 2012). Fausett and coworkers (2001) reported no cases among 244 heparin-treated gravidas compared with 10 among 244 nonpregnant patients. Accordingly, the American College of Chest Physicians recommends against platelet count monitoring when the risk of HIT is considered to be less than 1 percent. In others, they suggest monitoring every 2 or 3 days from day 4 until day 14 (Linkins, 2012).

When HIT is diagnosed, heparin therapy is stopped and alternative anticoagulation initiated. Platelet transfusions are avoided (Greinacher, 2015). LMWH may not be entirely safe because it has some cross reactivity with UFH. The American College of Chest Physicians recommends danaparoid (Orgaran)—a sulfated glycosaminoglycan heparinoid (Bates, 2012; Linkins, 2012). In a review of nearly 50 pregnant women with either HIT or a skin rash, Lindhoff-Last and associates (2005) concluded that danaparoid was a reasonable alternative. However, they reported two fatal maternal hemorrhages and three fetal deaths. Magnani (2010) reviewed case reports of 83 pregnant women treated with danaparoid. Although it was generally effective, two patients died related to bleeding, three patients suffered nonfatal major bleeds, and three women developed thromboembolic events unresponsive to danaparoid. The drug has been removed from the U.S. market.

Other agents are *fondaparinux* (Arixtra)—a pentasaccharide factor Xa inhibitor and *argatroban* (Novastan)—a direct thrombin inhibitor (Kelton, 2013; Linkins, 2012). Successful use in pregnancy has been reported (Elsaigh, 2015; Knol, 2010). Tanimura and coworkers (2012) successfully used argatroban, and later fondaparinux, to manage HIT in a pregnant woman with hereditary antithrombin deficiency.

Heparin-Induced Osteoporosis

Bone loss may develop with long-term heparin administration—usually 6 months or longer—and is more prevalent in cigarette smokers. UFH can cause osteopenia, and this is less likely with LMWHs (Deruelle, 2007). Women treated with any heparin should be encouraged to take an oral daily 1500-mg calcium supplement (Cunningham, 2005; Lockwood, 2012). In one study, Rodger and colleagues (2007) found that long-term use of dalteparin for a mean of 212 days was not associated with a significant decline in bone mineral density.

Anticoagulation and Abortion

The treatment of deep-vein thrombosis with heparin does not preclude pregnancy termination by careful curettage. After the products are removed without trauma to the reproductive tract, full-dose heparin can be restarted in several hours.

Anticoagulation and Delivery

The effects of heparin on blood loss at delivery depend on several variables: (1) dose, route, and timing of administration; (2) number and depth of incisions and lacerations; (3) intensity of postpartum myometrial contractions; and (4) presence of other coagulation defects. Blood loss should not be greatly increased with vaginal delivery if the episiotomy is modest in depth, there are no lacerations, and the uterus promptly contracts. Unfortunately, such ideal circumstances do not always prevail. For example, Mueller and Lebherz (1969) described 10 women with antepartum thrombophlebitis treated with heparin. Three women who continued to receive heparin during labor and delivery bled remarkably and developed large hematomas. Thus, heparin therapy generally is stopped during labor and delivery. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend restarting UFH or LMWH no sooner than 4 to 6 hours after vaginal delivery or 6 to 12 hours after cesarean delivery. We wait at least 24 hours to restart therapy after cesarean delivery or after vaginal delivery with significant lacerations.

Slow intravenous administration of protamine sulfate generally reverses the effect of heparin promptly and effectively. It should not be given in excess of the amount needed to neutralize the heparin, because it also has an anticoagulant effect.

SUPERFICIAL VENOUS THROMBOPHLEBITIS

Thrombosis limited strictly to the superficial veins of the saphenous system is treated with analgesia, elastic support, heat, and rest. If it does not soon subside or if deep-vein involvement is suspected, appropriate diagnostic measures are performed. Superficial vein thrombosis raises the risk of deep-vein

thrombosis four- to sixfold. Heparin is given if deep-vein involvement is confirmed (Roach, 2013). Superficial thrombophlebitis is typically seen in association with varicosities or as a sequela of an indwelling intravenous catheter.

PULMONARY EMBOLISM

Although it causes approximately 10 percent of maternal deaths, pulmonary embolism is relatively uncommon during pregnancy and the puerperium. The incidence averages 1 in 7000 pregnancies. According to Marik and Plante (2008), 70 percent of gravidas presenting with a pulmonary embolism have associated clinical evidence of deep-vein thrombosis. And recall that between 30 and 60 percent of women with a deep-vein thrombosis will have a coexisting silent pulmonary embolism.

Clinical Presentation

In almost 2500 nonpregnant patients with a proven pulmonary embolism, symptoms included dyspnea in 82 percent, chest pain in 49 percent, cough in 20 percent, syncope in 14 percent, and hemoptysis in 7 percent (Goldhaber, 1999). Pollack and coworkers (2011) found similar symptoms. Other predominant clinical findings typically include tachypnea, apprehension, and tachycardia. In some cases, an accentuated pulmonic closure sound, rales, and/or friction rub is heard.

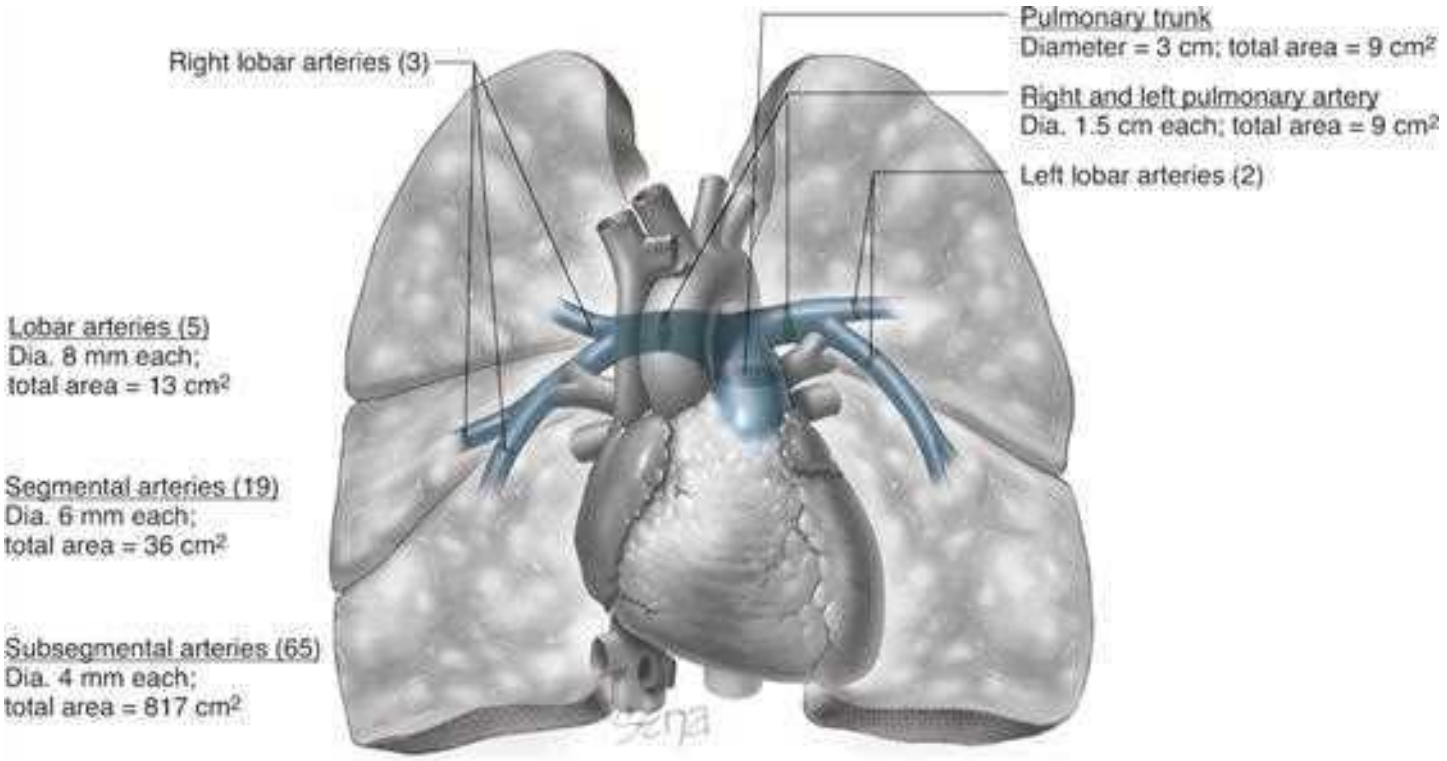
Right axis deviation and T-wave inversion in the anterior chest leads may be evident on the electrocardiogram. In at least 40 percent, chest radiography results are normal. In others, nonspecific findings may include atelectasis, an infiltrate, cardiomegaly, or an effusion (Pollack, 2011). Vascular markings in the lung region supplied by the obstructed artery can be lost. Although most women are hypoxemic, a normal arterial blood gas analysis does not exclude pulmonary embolism. Approximately a third of young patients have P_{O_2} values >80 mm Hg. Thus, the alveolar-arterial oxygen tension difference is a more useful indicator of disease. More than 86 percent of patients with acute pulmonary embolism will have an alveolar-arterial difference >20 mm Hg (Lockwood, 2012). Even with massive pulmonary embolism, signs, symptoms, and laboratory data to support the diagnosis may be deceptively nonspecific.

Massive Pulmonary Embolism

This is defined as embolism causing hemodynamic instability (Tapson, 2008). Acute mechanical obstruction of the pulmonary vasculature causes increased vascular resistance and pulmonary hypertension followed by acute right ventricular dilation. In otherwise healthy patients, significant pulmonary hypertension does not develop until 60 to 75 percent of the pulmonary vascular tree is occluded (Guyton, 1954). Moreover, circulatory collapse requires 75- to 80-percent obstruction. This is depicted schematically in Figure 52-4 and emphasizes that most acutely symptomatic emboli are large and likely a saddle embolism. These are suspected when the pulmonary artery pressure is substantively increased as estimated by echocardiography.

FIGURE 52-4

Schematic of pulmonary arterial circulation. Note that the cross-sectional area of the pulmonary trunk and the combined pulmonary arteries is 9 cm^2. A large saddle embolism could occlude 50 to 90 percent of the pulmonary tree, causing hemodynamic instability. As the arteries give off distal branches, the total surface area rapidly increases, that is, 13 cm^2 for the combined five lobar arteries, 36 cm^2 for the combined 19 segmental arteries, and more than 800 cm^2 for the total 65 subsegmental arterial branches. Thus, hemodynamic instability is less likely with emboli past the lobar arteries. (Data from Singhal S, Henderson R, Horsfield K, et al: Morphometry of the human pulmonary arterial tree, Circ Res. 1973 Aug;33(2):190–197.)



If there is evidence of right ventricular dysfunction, the mortality rate approaches 25 percent. This compares with a 1-percent rate without such dysfunction (Kinane, 2008). It is important in these cases to infuse crystalloids carefully and to support blood pressure with vasopressors. As discussed in Management, oxygen treatment, endotracheal intubation, and mechanical ventilation are completed preparatory to thrombolysis, filter placement, or embolectomy (Tapson, 2008).

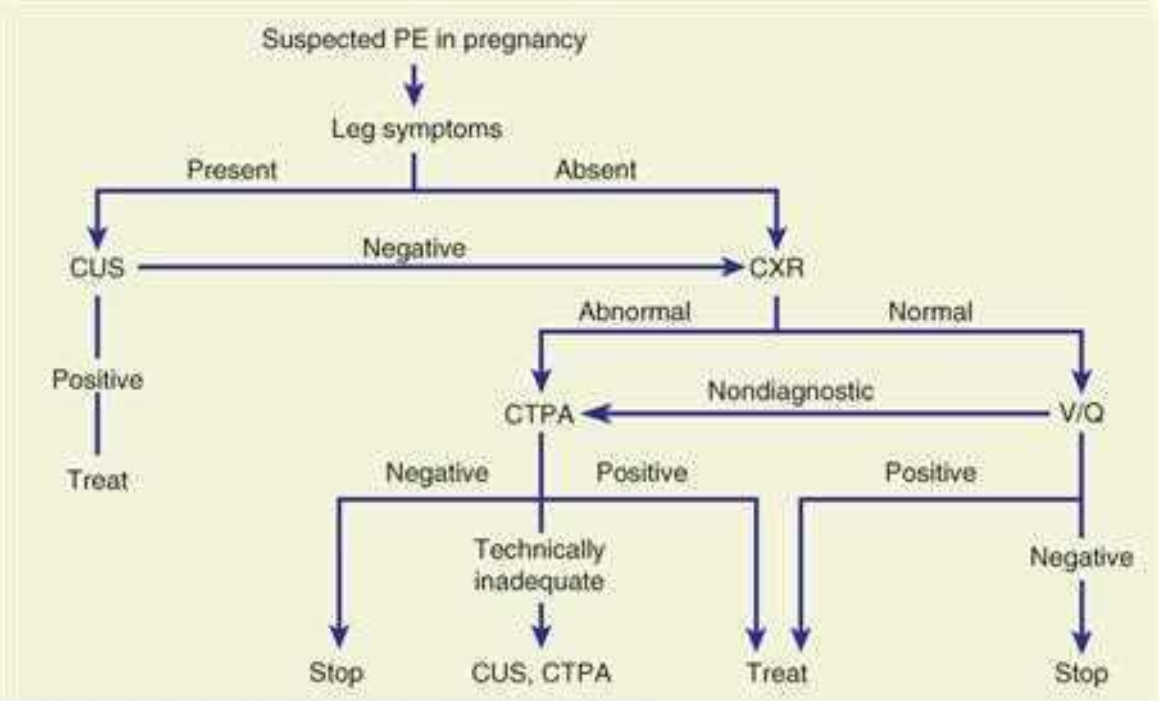
Diagnosis

In most cases, recognition of a pulmonary embolism requires a high index of suspicion that prompts objective evaluation. Exposure of the mother and fetus to ionizing radiation is a concern when investigating a suspected pulmonary embolism during pregnancy. However, this concern is largely overruled by the hazards of missing a potentially fatal diagnosis. Moveover, erroneously assigning a diagnosis of pulmonary embolism to a pregnant woman is also fraught with problems. It unnecessarily exposes the mother and fetus to the risks of anticoagulation treatment and will impact delivery plans, future contraception, and thromboprophylaxis during subsequent pregnancies. Therefore, investigations should aim at diagnostic certainty (Konstantinides, 2014).

In 2011, the American Thoracic Society and the Society of Thoracic Radiology developed an algorithm—shown in Figure 52-5 for the diagnosis of pulmonary embolism during pregnancy (Leung, 2011). In addition to compression ultrasonography, which was previously discussed (Deep-Vein Thrombosis), the algorithm includes computed-tomographic pulmonary angiography (CTPA) and ventilation-perfusion scintigraphy.

FIGURE 52-5

The American Thoracic Society and Society of Thoracic Radiology diagnostic algorithm for suspected pulmonary embolism during pregnancy. CTPA = computed tomographic pulmonary angiography; CUS = compression ultrasonography; CXR = chest x-ray; PE = pulmonary embolism; V/Q = ventilation/perfusion scintigraphy. (Modified with permission from Leung AN, Bull TM, Jaeschke R, et al: An official American Thoracic Society/Society of Thoracic Radiology Clinical Practice Guideline: Evaluation of suspected pulmonary embolism in pregnancy, Am J Respir Crit Care Med. 2011 Nov 15;184(10):1200–1208.)



Computed Tomographic Pulmonary Angiography

Multidetector computed tomography with pulmonary angiography is currently the most commonly employed technique used for pulmonary embolism diagnosis in nonpregnant patients (Bourjeily, 2012; Pollack, 2011). The technique is described further in Chapter 46 (Computed Tomography), and an imaging example is shown in Figure 52-6. The estimated fetal radiation exposure averages 0.45 to 0.6 mGy. The estimated maternal breast dose is 10 to 70 mGy (Waksmonski, 2014).

FIGURE 52-6

Axial image of the chest from a four-channel multidetector spiral computed tomographic scan performed after administration of intravenous contrast. There is enhancement of the pulmonary artery with a large thrombus on the right (*arrow*) consistent with pulmonary embolism. (Reproduced with permission from Dr. Michael Landay.)

Bourjeily and colleagues (2012) performed a follow-up study of 318 pregnant women who had a negative CTPA performed for a suspected pulmonary embolism. All were seen 3 months following their initial presentation or at 6 weeks postpartum. None of these women were subsequently diagnosed with a thromboembolism.

CTPA has many advantages, but we find that the higher resolution allows detection of previously inaccessible smaller distal emboli that have uncertain clinical significance. Similar observations have been reported by others (Anderson, 2007; Hall, 2009). Also, the hyperdynamic circulation and augmented plasma volume associated with pregnancy leads to a higher number of nondiagnostic studies compared with nonpregnant patients (Ridge, 2011; Scarsbrook, 2006).

Ventilation–Perfusion Scintigraphy—Lung Scan

This technique involves a small dose of radiotracer such as intravenously administered technetium-99m–macroaggregated albumin. There is negligible fetal and maternal breast radiation exposure—0.1 to 0.4 mGy. The scan may not provide a definite diagnosis because many other conditions can cause perfusion defects. Examples are pneumonia or local bronchospasm. Chan and coworkers (2002) found that a fourth of ventilation-perfusion scans in pregnant women were nondiagnostic. In these instances, CTPA is preferred (Tromeur, 2017).

To compare the performance of lung scintigraphy and CTPA, Revel and colleagues (2011) evaluated 137 pregnant women with suspected pulmonary embolism. The two modalities performed comparably and had no significant differences between the proportions of positive, negative, or indeterminate results. Specifically, the proportion of indeterminate results for both approximated 20 percent. By way of comparison, about a fourth of the nonpregnant

population had indeterminate studies. The investigators attributed this difference to the younger age of the pregnant patients. Similarly, one systematic review concluded that both CTPA and lung scintigraphy seem appropriate for exclusion of pulmonary embolism during pregnancy (van Mens, 2017).

Intravascular Pulmonary Angiography

This requires catheterization of the right side of the heart and is considered the reference test for pulmonary embolism. With newer generation multidetector CT scanners, however, the role of invasive pulmonary angiography has been questioned. This is especially true given the higher radiation exposure for the fetus (Konstantinides, 2014; Kuriakose, 2010). Other detractions are that it can be time consuming, uncomfortable, and associated with dye-induced allergy and renal failure. Indeed, the procedure-related mortality rate approximates 1 in 200 (Stein, 1992). It is reserved for confirmation when less invasive tests are equivocal.

Management

Immediate treatment for pulmonary embolism is full anticoagulation similar to that for deep-vein thrombosis as discussed in Unfractionated Heparin. Several complementary procedures may be indicated.

Vena Caval Filters

The woman who has very recently suffered a pulmonary embolism and who must undergo cesarean delivery presents a particularly serious problem. Reversal of anticoagulation may be followed by another embolus, and surgery while fully anticoagulated frequently results in life-threatening hemorrhage or troublesome hematomas. In these cases, placement of a vena caval filter should be considered before surgery (Marik, 2008). Moreover, in the very infrequent circumstances in which heparin therapy fails to prevent recurrent pulmonary embolism from the pelvis or legs, or when embolism develops from these sites despite heparin treatment, a vena caval filter may also be indicated. Such filters can also be used following massive emboli in patients who are not candidates for thrombolysis (Deshpande, 2002).

The device is inserted through either the jugular or femoral vein and can be inserted during labor (Jamjute, 2006). Routine filter placement has no added advantage to heparin given alone (Decousus, 1998). Retrievable filters may be used as short-term protection and then removed 1 to 2 weeks later (Liu, 2012). From their systematic review, Harris and associates (2016) found that complication rates in pregnant women with vena caval filters are comparable to those in nonpregnant patients.

Thrombolysis

Compared with heparin, thrombolytic agents provide more rapid lysis of pulmonary clots and improvement of pulmonary hypertension (Tapson, 2008). Konstantinides and coworkers (2002) studied 256 nonpregnant patients receiving heparin for an acute submassive pulmonary embolism. They also were randomly assigned to a placebo or the recombinant tissue plasminogen activator *alteplase*. Those given the placebo had a threefold greater risk of death or treatment escalation compared with those given alteplase. Agnelli and associates (2002) performed a metaanalysis of trials involving 461 nonpregnant patients. They reported that the risk of recurrence or death was significantly lower in patients given thrombolytic agents and heparin compared with those given heparin alone—10 versus 17 percent. Importantly, however, there were five—2 percent—fatal bleeding episodes in the thrombolysis group and none in the heparin-only group.

In their review, Leonhardt and colleagues (2006) identified 28 reports of tissue plasminogen activator use during pregnancy. Ten cases were for thromboembolism. Complication rates were similar to those in nonpregnant patients, and the authors concluded that such therapy should not be withheld during pregnancy if indicated. However, Akazawa and Nishida (2017) reviewed 13 cases of systemic thrombolytic therapy administered during the first 48 hours after delivery. Blood transfusion was required in five of the eight cesarean deliveries, including three cases of hysterectomy and two cases of hematoma removal.

Embolectomy

Given the efficacy of thrombolysis and filters, surgical embolectomy is uncommonly indicated. Published experience with emergency embolectomy during pregnancy is limited to case reports (Colombier, 2015; Saeed, 2014). From their review, Ahearn and associates (2002) found that although the operative risk to the mother is reasonable, the stillbirth rate is 20 to 40 percent.

THROMBOPROPHYLAXIS

Most recommendations regarding thromboprophylaxis during pregnancy stem from consensus guidelines. In one review of guidelines for thromboprophylaxis in pregnancy, the authors concluded that there is a lack of overall agreement about which women should be offered thromboprophylaxis or offered testing for thrombophilias (Okoroh, 2012). Bates and associates (2016) also conducted a review of guidelines for obstetrically associated VTE. They summarized that evidence-based recommendations are based largely on observational studies and extrapolated from data in nonpregnant patients. Similarly, a Cochrane review concluded that evidence is insufficient for firm recommendations regarding thromboprophylaxis during pregnancy (Bain, 2014).

The confusion that has ensued has provided fertile ground for litigators. Cleary-Goldman and associates (2007) surveyed 151 fellows of the American College of Obstetricians and Gynecologists and reported that intervention without a clear indication is common. Table 52-6 lists several consensus recommendations for thromboprophylaxis. In some cases, more than one option is listed, thus illustrating the confusion that currently reigns.

Prior Venous Thromboembolism

In general, either antepartum surveillance or heparin prophylaxis is recommended for women with prior VTE but without a recurrent risk factor, including no known thrombophilia. The study by Tengborn and coworkers (1989), however, suggested that such management may not be effective. They reported outcomes in 87 pregnant Swedish women who had prior thromboembolic disease and were not tested for thrombophilias. Despite unfractionated heparin prophylaxis, which was usually 5000 U twice daily, three of 20 women (15 percent) developed antepartum recurrence. This compared with eight of 67 women (12 percent) not given heparin.

Brill-Edwards and colleagues (2000) prospectively studied 125 pregnant women with a single prior VTE. Antepartum heparin was not given, but anticoagulant therapy was given for 4 to 6 weeks postpartum. Six women had a recurrent venous thrombosis—three antepartum and three postpartum. There were no recurrences in the 44 women without a known thrombophilia or whose prior thrombosis was associated with a temporary risk factor. These findings imply that prophylactic heparin may not be required for these two groups of women. In contrast, and as shown in Table 52-6, women with a prior thrombosis in association with a thrombophilia or in the absence of a temporary risk factor generally should be given both antepartum and postpartum prophylaxis (Connors, 2017).

De Stefano and coworkers (2006) studied 1104 nonpregnant women who had a first-episode VTE before the age of 40 years. After excluding those with antiphospholipid antibodies, 88 women were identified who subsequently had a total of 155 pregnancies and who were not given antithrombotic prophylaxis. There were 19 women (22 percent) who had a subsequent pregnancy- or puerperium-related VTE. Of 20 women whose original thrombosis was associated with a transient risk factor—not including pregnancy or oral contraceptive use—there were no recurrences during pregnancy, but two during the puerperium. These data also suggest that for women with a prior VTE, antithrombotic prophylaxis during pregnancy could be tailored according to the circumstances of the original event.

It is important to emphasize that VTE may recur despite antithrombotic prophylaxis. Galambosi and associates (2014) studied 270 women during 369 pregnancies who had at least one previous VTE. A total of 28 women (10.4 percent) suffered a recurrent VTE. Twelve of these recurrences occurred early in pregnancy before the initiation of antithrombotic prophylaxis, and 16 occurred despite prophylactic use of LMWH.

Our practice at Parkland Hospital for many years for women with a history of prior VTE was to administer subcutaneous UFH, 5000 to 7500 units two to three times daily. With this regimen, the recurrence of documented deep-vein thrombosis embolization was rare. Beginning approximately 10 years ago, we have successfully used 40 mg enoxaparin given subcutaneously daily for thromboprophylaxis.

Cesarean Delivery

The risk for deep-vein thrombosis and especially for fatal thromboembolism rises manyfold in women following cesarean compared with that after vaginal delivery. When considering that a third of women giving birth in the United States yearly undergo cesarean delivery, pulmonary embolism is understandably a major cause of maternal mortality (Creanga, 2017). That said, the “lack of high quality data” described earlier by Bates and colleagues (2016) creates considerable variation in the current recommendations promulgated by the American College of Obstetricians and Gynecologists, the Royal College of Obstetricians, and the American College of Chest Physicians (Palmerola, 2016).

In 2011, the American College of Obstetricians and Gynecologists (2017b) recommended placement of pneumatic compression devices before cesarean delivery for all women not already receiving thromboprophylaxis. This recommendation was based primarily on consensus and expert opinion. For patients undergoing cesarean delivery with additional risk factors for thromboembolism, both pneumatic compression devices and UFH or LMWH may be recommended. The College stipulated that cesarean delivery in an emergency setting should not be delayed because of the time necessary to implement thromboprophylaxis. Implementation of this strategy by the Hospital Corporation of America, the largest for-profit obstetrical health care delivery system in the United States, was associated with a reduction in deaths from pulmonary embolism from 7 of 458,097 cesarean births to 1 of 465,880 cesarean births (Clark, 2011, 2014).

In 2016, the National Partnership for Maternal Safety published several consensus recommendations for the prevention of maternal VTE (D’Alton, 2016). These recommendations included expanded use of antenatal prophylaxis for women hospitalized 3 days or longer, expanded use of prophylaxis during and after vaginal delivery, and expanded use of pharmacological prophylaxis to most women after cesarean delivery. In response, Sibai and Rouse (2016) expressed concern that these new recommendations derive from sparse data of questionable applicability to obstetrical patients. They called for better quality evidence to measure the benefits, harms, and costs of increased pharmacological thromboprophylaxis. As aptly expressed by Macones (2017), “an intervention, such as increased postcesarean pharmacologic thromboprophylaxis, where there are legitimate concerns about efficacy and safety, requires a much higher degree of evidence before a national guideline is implemented.” We agree with these sentiments.

CHAPTER 53: Renal and Urinary Tract Disorders

In rare instances in patients suffering from pyelitis, the pregnant uterus may so compress the ureter as to cause a damming back of the purulent discharge, and thus give rise to a pyelonephritis.

—J. Whitridge Williams (1903)

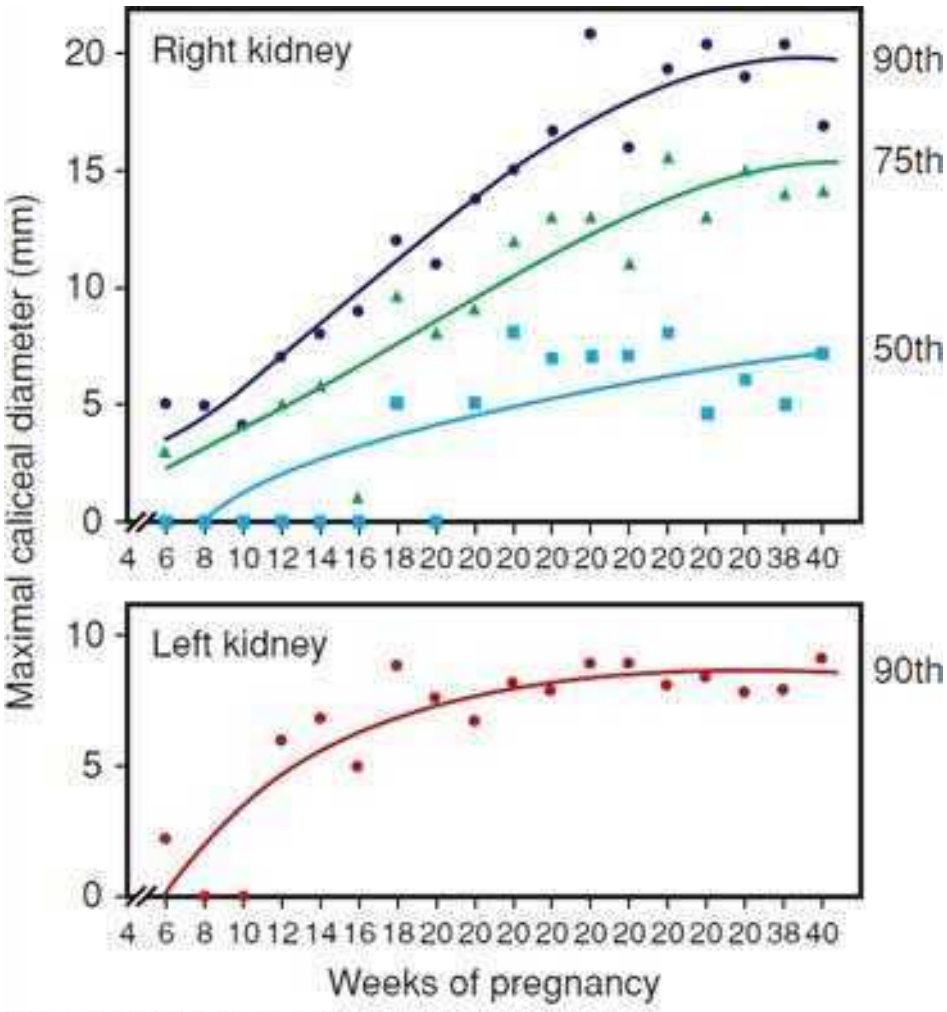
INTRODUCTION

Renal and urinary tract disorders are frequently encountered in pregnancy. Some precede pregnancy—one example being nephrolithiasis. In some women, pregnancy-induced changes may predispose to development or worsening of urinary tract disorders—an example is the markedly increased risk for pyelonephritis, described above by Williams. Finally, some renal pathology is unique to pregnancy, such as preeclampsia. With good prenatal care, however, most women with these disorders will likely have no long-term sequelae.

PREGNANCY-INDUCED URINARY TRACT CHANGES

Significant changes in both structure and function within the urinary tract during normal pregnancy are discussed in Chapter 4 (Urinary System). The kidneys become larger, and dilatation of the right renal calyces and ureters can be striking (Fig. 53-1). Some dilatation develops before 14 weeks and likely stems from progesterone-induced relaxation of the muscularis. More marked dilatation is apparent beginning in midpregnancy because of more distal ureteral compression, especially on the right side (Faúndes, 1998). There is also some *vesicoureteral reflux* during pregnancy. Because of these physiological changes, the risk of upper urinary infection rises. Also, imaging studies done to evaluate urinary tract obstruction may occasionally be erroneously interpreted.

FIGURE 53-1
The 50th, 75th, and 90th percentiles for maternal renal caliceal diameters measured using sonography in 1395 pregnant women from 4 to 42 weeks' gestation. (Redrawn and modified from Faúndes A, Bricola-Filho M, Pinto e Silva JC: Dilatation of the urinary tract during pregnancy: proposal of a curve of maximal caliceal diameter by gestational age. Am J Obstet Gynecol 178:1082, 1998.)



Evidence of functional renal hypertrophy becomes apparent very soon after conception. Glomeruli are larger, although cell numbers do not grow (Strevens, 2003). Pregnancy-induced intrarenal vasodilatation develops, and both afferent and efferent resistances decline. This leads to greater effective renal plasma flow and glomerular filtration (Helal, 2012; Hussein, 2014). By 12 weeks' gestation, the glomerular filtration rate (GFR) is already augmented 20 percent above nonpregnant values (Hladunewich, 2004). Ultimately, plasma flow and GFR rise by 40 and 65 percent, respectively. Consequently, serum concentrations of creatinine and urea drop substantively across pregnancy, and values within a nonpregnant normal range may be abnormal for pregnancy (Appendix, Serum and Blood Constituents). Other alterations include those related to maintaining normal acid-base homeostasis, osmoregulation, and fluid and electrolyte retention.

Assessment of Renal Function During Pregnancy

Urinalysis results are essentially unchanged during pregnancy, except for occasional glucosuria. Although protein excretion normally rises, it seldom reaches levels that are detected by usual screening methods. Higby and colleagues (1994) reported 24-hour protein excretion in pregnancy to be 115 mg/d with a 95-percent confidence level of 260 mg/d. Values did not significantly differ by trimester (Fig. 4-14). Albumin constitutes only a small part of total protein excretion and ranges from 5 to 30 mg/d. Airoldi and Weinstein (2007) concluded that proteinuria must exceed 300 mg/d to be considered abnormal. Many consider 500 mg/d to be important with gestational hypertension. Investigators have correlated a urinary protein-to-creatinine ratio of ≥0.3 in a spot urine sample—ideally from a first morning void—with a 24-hour protein excretion rate of ≥300 mg (Kuper, 2016).

In one study, 3 percent of 4589 nulliparas screened before 20 weeks had *idiopathic hematuria*, defined as 1+ or greater blood on urine dipstick (Stehman-Breen, 2002). These women had a twofold risk of developing preeclampsia. In another study of 1000 women screened during pregnancy, the incidence of dipstick hematuria was 15 percent (Brown, 2005). Most women had only trace levels of hematuria, and the false-positive rate was 40 percent.

If the serum creatinine level in pregnancy persistently exceeds 0.9 mg/dL (75 µmol/L), then intrinsic renal disease is suspected. In these cases, some determine the creatinine clearance as an estimate of the GFR. Of other assessment tools, s*onography* provides imaging of renal size, relative consistency, and elements of obstruction (see Fig. 53-1). *Magnetic resonance (MR) imaging* of renal masses provides excellent anatomic information (Putra, 2009). Full-sequence *intravenous pyelography* is not done routinely, but injection of contrast media with one or two abdominal radiographs may be indicated by the clinical situation. The usual clinical indications for *cystoscopy* are followed. *Ureteroscopy* is another available tool when indicated.

Although *renal biopsy* is relatively safely performed during pregnancy, it usually is postponed unless results may change therapy. From a review of 243 biopsies in pregnant women, the incidence of complications was 7 percent—this compares with 1 percent in postpartum women (Piccoli, 2013). Some consider biopsy for rapid deterioration of renal function with no obvious cause or for symptomatic nephrotic syndrome (Lindheimer, 2007a). We and others have found biopsy helpful in

selected cases to direct management (Chen, 2001; Piccoli, 2013). In one series, renal biopsy in 12 *normal* pregnant volunteers showed that five had slight to moderate glomerular endotheliosis (Strevens, 2003). Recall this is the histopathological lesion that is putatively typical of preeclampsia and is characterized by fibrin deposition within the glomerular endothelium leading to capillary occlusion. In contrast, all 27 women with proteinuric hypertension had endotheliosis, and in all but one, it was moderate to severe.

Pregnancy after Unilateral Nephrectomy

In these cases, if the remaining kidney is normal, renal function becomes augmented. However, women who have donated a kidney have a higher frequency of gestational hypertension or preeclampsia in subsequent pregnancy—11 versus 5 percent compared with non-donors (Garg, 2015). Otherwise, women with one normal kidney most often have no difficulty in pregnancy. Moreover, kidney donation does not lead to long-term adverse consequences. That said, thorough functional evaluation of the remaining kidney is essential (Ibrahim, 2009).

URINARY TRACT INFECTIONS

These infections are the most frequent bacterial infections complicating pregnancy. Although *asymptomatic bacteriuria* is the most common, symptomatic infection includes *cystitis*, or it may involve the renal calyces, pelvis, and parenchyma to cause *pyelonephritis*. Organisms that cause urinary infections are those from the normal perineal flora. Approximately 90 percent of *Escherichia coli* strains that cause nonobstructive pyelonephritis have adhesins such as P- and S-fimbriae. These are cell-surface protein structures that enhance bacterial adherence and, thereby, virulence (Foxman, 2010; Hooton, 2012). Data suggest that pregnant women have more severe sequelae from urosepsis. One possible underlying factor is the T-helper cell—Th1/Th2 ratio—reversal of normal pregnancy, which is discussed in Chapter 4 (Leukocytes and Lymphocytes). Other perturbations of cytokine or of adhesin expression may be contributory (Chaemsaithong, 2013; Sledzińska, 2011). But even if pregnancy itself does not enhance these virulence factors, urinary stasis, vesicoureteral reflux, and diabetes predispose to symptomatic upper urinary infections (Czaja, 2009).

In the puerperium, several risk factors predispose to urinary infections. Bladder sensitivity to intravesical fluid tension is often diminished due to labor trauma or epidural analgesia. Bladder sensations can also be obscured by discomfort from vaginal or perineal injury. Normal postpartum diuresis may worsen bladder overdistention, and catheterization to relieve retention often leads to urinary infection. Postpartum pyelonephritis is treated in the same manner as antepartum renal infections (McDonnold, 2012).

Asymptomatic Bacteriuria

This refers to persistent, actively multiplying bacteria within the urinary tract in asymptomatic women. The incidence during pregnancy is similar to that in nonpregnant women. It varies from 2 to 7 percent, and it is characteristically population dependent. The highest incidence is in African-American multiparas with sickle-cell trait, and the lowest is in affluent white women of low parity. Asymptomatic infection is also more common in diabetics (Schneeberger, 2014).

Bacteriuria is typically present at the first antepartum visit. An initial positive urine culture result done as a part of prenatal care should prompt treatment. After this, fewer than 1 percent of women develop a urinary tract infection (Whalley, 1967). A clean-voided specimen containing more than 100,000 organisms/mL is diagnostic. It may be prudent to treat when lower concentrations are identified, because pyelonephritis develops in some women despite colony counts of only 20,000 to 50,000 organisms/mL (Lucas, 1993).

Most studies indicate that if asymptomatic bacteriuria is not treated, approximately 25 percent of infected women will develop symptomatic infection during pregnancy (Smaill, 2015). In a more recent study, only 2.4 percent of *treated* women developed pyelonephritis (Kazemier, 2015). Eradication of bacteriuria with antimicrobial agents prevents most of these serious infections. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017), as well as the U.S. Preventive Services Task Force (2008), recommend screening for bacteriuria at the first prenatal visit. Standard urine cultures may not be cost effective when the prevalence is low. Less expensive screening tests such as the leukocyte esterase/nitrite dipstick are cost effective when the prevalence is ≤2 percent (Rogozinska, 2016; Rouse, 1995). Also, a dipstick culture technique has excellent positive- and negative-predictive values (Mignini, 2009). With this, a special agar-coated dipstick is first placed into urine and then also serves as the culture plate. Because of a high prevalence—5 to 8 percent—at Parkland Hospital, most women are screened by traditional urine culture. Susceptibility determination is not necessary because initial treatment is empirical (Hooton, 2012).

In some but not all studies, covert bacteriuria has been associated with preterm or low-birthweight infants. It is even more controversial whether eradication of bacteriuria decreases these complications. Evaluating a cohort of 25,746 mother-infant pairs, Schieve and coworkers (1994) reported urinary tract infection to be associated with greater risks for low-birthweight infants, preterm delivery, pregnancy-associated hypertension, and anemia. These findings vary from those of others (Gilstrap, 1981b; Whalley, 1967). Notably, in most studies, cohorts with asymptomatic infection are not evaluated separately from those with acute renal infection (Banhidy, 2007). One Cochrane database review noted insufficient data to answer this question (Smaill, 2015).

Treatment

Bacteriuria responds to empirical treatment with any of several antimicrobial regimens listed in Table 53-1. Although selection can be based on in vitro susceptibilities, in our extensive experience, empirical oral treatment for 10 days with nitrofurantoin macrocrystals, 100 mg at bedtime, is usually effective. Satisfactory results are also achieved with a 7-day oral course of nitrofurantoin, 100 mg given twice daily (Lumbiganon, 2009). Single-dose antimicrobial therapy is less successful (Widmer, 2015). *The important caveat is that, regardless of regimen given, the recurrence rate is approximately 30 percent.* This may indicate covert upper tract infection and the need for longer therapy. Thus, after initial therapy, periodic surveillance is necessary to prevent recurrent urinary infections (Schneeberger, 2015).

TABLE 53-1

Oral Antimicrobial Agents Used for Treatment of Pregnant Women with Asymptomatic Bacteriuria

Single-dose treatment
Amoxicillin, 3 g
Ampicillin, 2 g
Cephalosporin, 2 g
Nitrofurantoin, 200 mg
Trimethoprim-sulfamethoxazole, 320/1600 mg
3-day course
Amoxicillin, 500 mg three times daily
Ampicillin, 250 mg four times daily
Cephalosporin, 250 mg four times daily
Ciprofloxacin, 250 mg twice daily
Levofloxacin, 250 or 500 mg daily
Nitrofurantoin, 50 to 100 mg four times daily or 100 mg twice daily
Trimethoprim-sulfamethoxazole, 160/800 mg twice daily
Other
Nitrofurantoin, 100 mg four times daily for 10 days
Nitrofurantoin, 100 mg twice daily for 5 to 7 days
Nitrofurantoin, 100 mg at bedtime for 10 days
Treatment failures
Nitrofurantoin, 100 mg four times daily for 21 days
Suppression for bacterial persistence or recurrence
Nitrofurantoin, 100 mg at bedtime for pregnancy remainder

For recurrent bacteriuria, we have had success with nitrofurantoin, 100 mg orally at bedtime for 21 days (Lucas, 1994). For women with persistent or frequent bacteriuria recurrences, suppressive therapy for the remainder of pregnancy can be given. We routinely use nitrofurantoin, 100 mg orally at bedtime. This drug may rarely cause an acute pulmonary reaction that dissipates on its withdrawal (Boggess, 1996).

Cystitis and Urethritis

Lower urinary infection during pregnancy may develop without antecedent covert bacteriuria (Harris, 1981). Cystitis produces dysuria, urgency, and frequency, but with few associated systemic findings. Pyuria and bacteriuria are usually found. Microscopic hematuria is common, and occasionally there is gross hematuria from hemorrhagic cystitis. Although cystitis is usually uncomplicated, the upper urinary tract may become involved by ascending infection. Almost 40 percent of pregnant women with acute pyelonephritis have preceding symptoms of lower tract infection (Gilstrap, 1981a).

Women with cystitis respond readily to any of several regimens. Most of the 3-day regimens listed in Table 53-1 are usually 90-percent effective (Fihn, 2003). Single-dose therapy is less effective, and if it is used, concomitant pyelonephritis must be confidently excluded.

Lower urinary tract symptoms with pyuria accompanied by a sterile urine culture may stem from urethritis caused by *Chlamydia trachomatis*. Mucopurulent cervicitis usually coexists, and azithromycin therapy is effective (Chap. 65, Chlamydial Infections).

Acute Pyelonephritis

Renal infection is one of the most frequent serious medical complications of pregnancy. Data from the 2006 Nationwide Inpatient Sample showed that nearly 29,000 pregnancy-associated hospitalizations were for acute pyelonephritis (Jolley, 2012). In one hospital-system database of nearly 550,000 births, its incidence was 0.5 percent (Wing, 2014). Importantly, pyelonephritis is a leading cause of septic shock during pregnancy (Snyder, 2013). In one Parkland Hospital Obstetrical Intensive Care Unit review, 12 percent of antepartum admissions were for sepsis syndrome caused by renal infections (Zeeman, 2003). Urosepsis may be related to an increased incidence of cerebral palsy in preterm infants (Jacobsson, 2002). Fortunately, affected mothers suffer no serious long-term sequelae (Raz, 2003).

Clinical Findings

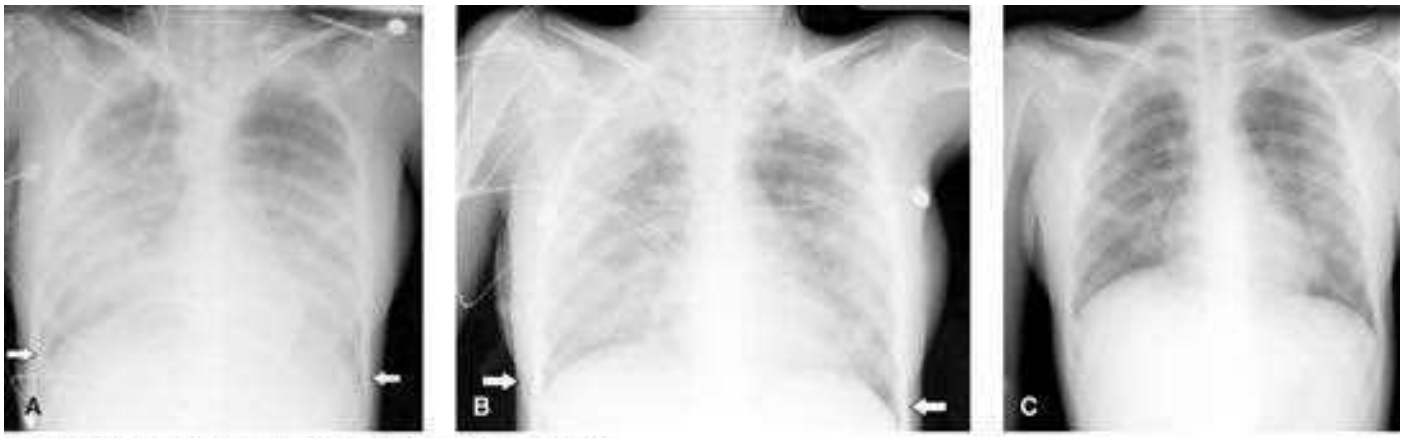
Renal infection develops more frequently in the second trimester, and nulliparity and young age are risks (Hill, 2005). Pyelonephritis is unilateral and right-sided in more than half of cases, and it is bilateral in a fourth. Fever and shaking chills usually develop rather abruptly, and patients have aching pain in one or both lumbar regions. Anorexia, nausea, and vomiting may worsen dehydration. Tenderness usually can be elicited by percussion in one or both costovertebral angles. The differential diagnosis includes, among others, labor, chorioamnionitis, adnexal torsion, appendicitis, placental abruption, or infarcted leiomyoma. Evidence of the sepsis syndrome is common (Chap. 47, Sepsis Syndrome).

If this infection is suspected, a urine sample obtained by catheterization may be preferred to avoid obscuring contamination from the lower genital tract. The urinary sediment contains many leukocytes, frequently in clumps, and numerous bacteria. Bacteremia is demonstrated in 15 to 20 percent of these women. *E coli* is isolated from urine or blood in 70 to 80 percent of infections, *Klebsiella pneumoniae* in 3 to 5 percent, *Enterobacter* or *Proteus* species in 3 to 5 percent, and gram-positive organisms, including group B *Streptococcus* and *Staphylococcus aureus*, in up to 10 percent of cases (Hill, 2005; Wing, 2000).

Plasma creatinine is monitored because early studies reported that 20 percent of pregnant women developed acute kidney injury. More recent findings, however, show this to be only 5 percent if aggressive fluid resuscitation is provided (Hill, 2005). Follow-up studies have demonstrated that this endotoxin-induced damage is reversible long term. As shown in Figure 53-2, varying degrees of *respiratory distress syndrome* from endotoxin-induced alveolar injury are manifest in up to 2 percent of women (Cunningham, 1987; Snyder, 2013; Wing, 2014).

FIGURE 53-2

A series of anterior-posterior projection chest radiographs of improving acute respiratory distress syndrome (ARDS) in a second-trimester pregnant woman with severe pyelonephritis. **A.** An extensive infiltrative process and complete obliteration of the diaphragm (*white arrows*) is seen. **B.** Improved aeration of lung fields bilaterally is noted as pleural disease resolves (*arrows*). **C.** Markedly improved visualization of the lung fields with residual platelike atelectasis and normal appearance of the diaphragm.



Uterine activity from endotoxin is common and is related to fever severity (Graham, 1993). In one study, women with pyelonephritis averaged five contractions per hour at admission, and this decreased to two per hour within 6 hours of intravenous fluid and antimicrobial administration (Millar, 2003). Notably, β-agonist therapy for tocolysis increases the likelihood of respiratory insufficiency from permeability edema (Lamont, 2000). The incidence of pulmonary edema in women with pyelonephritis who were given β-agonists was reported to be 8 percent—a fourfold increase over that expected (Towers, 1991). Endotoxin-induced *hemolysis* is common, and approximately a third of these women with pyelonephritis develop anemia (Cox, 1991). With recovery, hemoglobin regeneration is normal, and acute infection does not affect erythropoietin production (Cavenee, 1994).

Management

One scheme for management of acute pyelonephritis is shown in Table 53-2. Urine cultures are taken, but prospective trials show that blood cultures are of limited clinical utility (Gomi, 2015; Wing, 2000). We obtain blood cultures if the temperature is >39°C. *Intravenous hydration to ensure adequate urinary output is the cornerstone of treatment.* Antimicrobials are also begun promptly with the caveat that they may initially worsen endotoxemia from bacterial lysis. Surveillance for worsening sepsis syndrome includes serial monitoring of urinary output, blood pressure, pulse, temperature, and oxygen saturation. High fevers are lowered with a cooling blanket and acetaminophen. This is especially important in early pregnancy because of possible teratogenic effects from hyperthermia.

TABLE 53-2

Management of the Pregnant Woman with Acute Pyelonephritis

Hospitalize patient
Obtain urine and possibly blood cultures
Evaluate hemogram, serum creatinine, and electrolytes
Monitor vital signs frequently, including urinary output—consider indwelling catheter
Establish urinary output ≥50 mL/hr with intravenous crystalloid solution
Administer intravenous antimicrobial therapy (see text)
Obtain chest radiograph if there is dyspnea or tachypnea
Repeat hematology and chemistry studies in 48 hours
Change to oral antimicrobials when afebrile
Discharge when afebrile 24 hours, consider antimicrobial therapy for 7 to 10 days
Repeat urine culture 1 to 2 weeks after antimicrobial therapy completed

Modified from Lucas, 1994; Sheffield, 2005.

Antimicrobial therapy usually is empirical, and ampicillin plus gentamicin; cefazolin or ceftriaxone; or an extended-spectrum antibiotic are all 95-percent effective in randomized trials (Sanchez-Ramos, 1995; Wing, 1998, 2000). Fewer than half of *E coli* strains are sensitive to ampicillin in vitro, but cephalosporins and gentamicin generally have excellent activity. Serum creatinine levels are monitored if nephrotoxic drugs are given. Initial treatment at Parkland Hospital is ampicillin plus gentamicin. Some recommend suitable substitutes if bacterial studies show in vitro resistance. With any of the regimens discussed, response is usually prompt, and 95 percent of women are afebrile by 72 hours (Hill, 2005; Sheffield, 2005). After discharge, most recommend oral therapy for a total of 7 to 14 days (Hooton, 2012).

Persistent Infection

Generally, intravenous hydration and antimicrobial therapy are followed by stepwise defervescence of approximately 1°F per day. With persistent spiking fever or lack of clinical improvement by 48 to 72 hours, urinary tract obstruction, another complication, or both are considered. In these women, renal sonography is recommended to search for obstruction, which is manifest by abnormal ureteral or pyelocaliceal dilatation (Seidman, 1998). Although most women with continuing infection have no evidence of obstruction, some are found to have calculi. Although renal sonography will detect hydronephrosis, stones are not always seen in pregnancy (Butler, 2000; Maikranz, 1987). If stones are strongly suspected despite a nondiagnostic sonographic examination, a plain abdominal radiograph will identify nearly 90 percent. Another option is the modified *one-shot intravenous pyelogram*—a single radiograph obtained 30 minutes after contrast injection—which usually provides adequate imaging (Butler, 2000).

In some women, MR imaging may disclose the cause of persistent infection (Spencer, 2004). Even without urinary obstruction, persistent infection can be due to an intrarenal or perinephric abscess or phlegmon (Cox, 1988; Rafi, 2012). Obstruction relief is important, and one method is cystoscopic placement of a double-J ureteral stent (Rodriguez, 1988). Because these stents are usually left in place until after delivery, they frequently become encrusted and require replacement. We have found that percutaneous nephrostomy is preferable because the stents are more easily replaced. Finally, surgical removal of stones may be required in some women (Nephrolithiasis).

Outpatient Management

This is sometimes done for nonpregnant women with uncomplicated pyelonephritis (Hooton, 2012). Outpatient management was described in 92 pregnant women who were first given in-hospital intramuscular ceftriaxone, two 1-g doses 24 hours apart (Wing, 1999). After this, only a third of the group was considered suitable for outpatient therapy, and these women were randomly assigned either to discharge home and oral antimicrobials or to continued hospitalization with intravenous therapy. A third of the outpatient management group was unable to adhere to the treatment regimen and required readmission. This suggests that outpatient management is applicable to very few gravidas.

Recurrent urinary tract infection—either covert or symptomatic—develops in 30 to 40 percent of women following completion of pyelonephritis treatment (Cunningham, 1973). Unless other measures are taken to ensure urine sterility, nitrofurantoin, 100 mg orally at bedtime given for the remainder of the pregnancy, reduces bacteriuria recurrence (Van Dorsten, 1987).

Reflux Nephropathy

Vesicoureteral reflux in early childhood can cause recurrent urinary tract infections, and subsequent chronic interstitial nephritis is attributed to *chronic pyelonephritis*. Moreover, high-pressure sterile reflux impairs normal renal growth. Combined, this leads to patchy interstitial scarring, tubular atrophy, and loss of

nephron mass and is termed *reflux nephropathy*. In some cases—especially those with staghorn calculi—*xanthogranulomatous pyelonephritis* causes suppurative destruction of renal tissue. In adults, long-term complications of chronic pyelonephritis include hypertension, which may be severe (Beck, 2015; Diamond, 2012).

Perhaps half of women with reflux nephropathy were treated during childhood for renal infections. Many also had surgical correction of reflux as children, and these women commonly have bacteriuria when pregnant (Mor, 2003). In the other half of women with reflux nephropathy, a clear history of recurrent cystitis, acute pyelonephritis, or obstructive disease is lacking. Reports describing 939 pregnancies in 379 women with reflux nephropathy indicate that impaired renal function and bilateral renal scarring were associated with increased maternal complications (El-Khatib, 1994; Jungers, 1996; Köhler, 2003). Chronic renal disease and pregnancy outcome are discussed in Chronic Kidney Disease.

NEPHROLITHIASIS

Kidney stones develop in up to 9 percent of women during their lifetime with an average age of onset in the third decade (Curhan, 2015). Calcium salts make up approximately 90 percent of stones, and hyperparathyroidism should be excluded. Although calcium oxalate stones in young nonpregnant women are most common, most stones in pregnancy—65 to 75 percent—are calcium phosphate or hydroxyapatite (Ross, 2008; Tan, 2013). Patients who have a stone typically form another one every 2 to 3 years. One study found pregnancy was a risk factor for stone formation (Reinstatler, 2017).

Contrary to past teachings, a low-calcium diet *promotes* stone formation. Thiazide diuretics diminish stone formation. In general, obstruction, infection, intractable pain, and heavy bleeding are indications for stone removal, discussed later.

Stone Disease During Pregnancy

The incidence of stone disease complicating pregnancy varies. At the low end, the incidence was 0.3 admissions per 1000 pregnancies at Parkland Hospital (Butler, 2000). In an Israeli study, the incidence in nearly 220,000 pregnancies was 0.8 per 1000 (Rosenberg, 2011). In Washington state, the incidence was 1.7 per 1000 pregnancies (Swartz, 2007). Bladder stones are rare, but recurrent infection and labor obstructed by stones have been reported (Ait Benkaddour, 2006; Ruan, 2011).

Data are conflicting whether women with kidney stones have an increased risk for low-birthweight and preterm newborns. In one study of 2239 women with nephrolithiasis compared with normal controls, stones were associated with a significantly elevated preterm delivery rate—10.6 versus 6.4 percent (Swartz, 2007). The more recent nationwide study from Taiwan also found 20- to 40-percent increases in rates of low birthweight and preterm birth (Chung, 2013). In contrast, a study from Hungary reported that pregnancy outcomes, including preterm delivery, were similar in women with stones and normal controls (Banhidy, 2007). Comparable conclusions were drawn from the Israeli study discussed above (Rosenberg, 2011).

Diagnosis

Pregnant women may have fewer symptoms with stone passage because of urinary tract dilatation (Hendricks, 1991; Tan, 2013). That said, more than 90 percent of pregnant women with symptomatic nephrolithiasis present with pain. Gross hematuria is less common than in affected nonpregnant women. It was a presenting symptom in 23 percent of women described by Butler and associates (2000). In another study, however, only 2 percent had gross hematuria (Lewis, 2003). Sonography is usually selected to visualize stones, but many are not detected because hydronephrosis may obscure findings (McAleer, 2004). Transabdominal color Doppler sonography to detect presence or absence of ureteral "jets" of urine into the bladder may exclude obstruction (Asrat, 1998).

If the ureter is abnormally dilated but no stone is seen, then other imaging studies are indicated. While helical computed tomography (CT) scanning is the preferred imaging method for nonpregnant individuals, the associated x-ray exposure has led some to recommend MR imaging as a second-line test in pregnancy (Masselli, 2015). Thus CT scanning is usually avoided during pregnancy if possible (Curhan, 2015; Masselli, 2015). If it is used, the slices can be tailored as needed. White and colleagues (2007) recommend unenhanced helical CT and cite an average fetal radiation dose to be 7 mGy.

Management

Treatment depends on symptoms and gestational age (Semins, 2014). Intravenous hydration and analgesics are given. In up to half of women with symptomatic stones, infection will be identified, and this is treated vigorously as described earlier (Reflux Nephropathy). Although stones infrequently cause symptomatic obstruction during pregnancy, persistent pyelonephritis should prompt a search for obstruction due to nephrolithiasis. Urinary obstruction with concomitant infection is an emergency—"pus under pressure" (Curhan, 2015).

Approximately 65 to 80 percent of symptomatic women will improve with conservative therapy, and the stone usually passes spontaneously (Tan, 2013). Others require an invasive procedure such as ureteral stenting, ureteroscopy, percutaneous nephrostomy, transurethral laser lithotripsy, or basket extraction (Butler, 2000; Johnson, 2012; Semins, 2014). Removal by a flexible basket via cystoscopy, although used less often than in the past, is still a reasonable consideration for pregnant women. In one study, 623 various procedures were performed in 2239 symptomatic pregnant women, but less than 2 percent required surgical exploration (Swartz, 2007). Of other treatments, the need for fluoroscopy limits the utility of percutaneous nephrolithotomy (Toth, 2005). Extracorporeal shock-wave lithotripsy is contraindicated in pregnancy.

PREGNANCY AFTER RENAL TRANSPLANTATION

Following transplantation, the 1-year graft survival rate is 95 percent for grafts from living donors and 89 percent for those from deceased donors. Survival rates approximately doubled between 1988 and 1996, due in large part to the introduction of cyclosporine and muromonab-CD3 (OKT3 monoclonal antibody) to prevent and treat organ rejection. Since then, mycophenolate mofetil and tacrolimus have further reduced acute rejection episodes, however, the former is considered teratogenic (Briggs, 2014). The National Transplant Pregnancy Registry reports that 23 percent of fetuses exposed to mycophenolate had birth defects (Coscia, 2010).

Importantly, resumption of renal function after transplantation promptly restores fertility in reproductive-aged women (Hladunewich, 2011; Rao, 2016). But, more than half of transplant recipients in one study reported that they were not counseled regarding contraception (French, 2013).

Pregnancy Outcomes

Women after transplantation do better with pregnancy than those with end-stage renal disease receiving dialysis (Saliem, 2016). In one review of 2000 pregnancies in transplant recipients, most were treated with cyclosporine and tacrolimus, and approximately 75 percent of pregnancies resulted in a live birth (Coscia, 2010). Studies from other countries describe similar outcomes (Bramham, 2013; Wyld, 2013). In a study from Uruguay, 62 percent of liveborns were preterm (Orihuela, 2016). Two other reports also cited a high prevalence of preterm delivery (Erman Akar, 2015; Stoumpos, 2016). Notably, the incidence of fetal malformations was not increased, except in those who took mycophenolate mofetil (Coscia, 2010).

The incidence of preeclampsia is increased in all transplant recipients (Brosens, 2013). In the UK National Cohort Study, the incidence of preeclampsia was 22 percent (Bramham, 2013). From their review, Josephson and McKay (2011) cite an incidence of a third of pregnancies but question the validity of this frequency. Importantly, in some cases, rejection is difficult to distinguish from preeclampsia. That said, the incidence of rejection episodes approximates 2 to 5 percent (Bramham, 2013; Orihuela, 2016). Viral infections—especially those by *polyomavirus hominis 1*, also called *BK virus*, are frequent. In kidney transplant recipients, this virus can cause nephropathy and graft loss, and affected patients generally have an asymptomatic decline in renal function (Wright, 2016). Gestational diabetes is also found in approximately 5 percent of transplant recipients. Both are likely related to immunosuppression therapy. Similar outcomes are reported by other investigators (Al Duraihimh, 2008; Cruz Lemini, 2007; Ghafari, 2008).

Several requisites should be satisfied by renal transplantation patients before attempting pregnancy (Josephson, 2011; López, 2014). First, women should be in good general health for at least 1 to 2 years after transplantation. Also, renal function should be stable and without severe renal insufficiency. Thus, serum creatinine is <2 mg/dL and preferably <1.5 mg/dL, and proteinuria is <500 mg/d. Evidence for graft rejection should be absent for 6 months, and pyelocalyceal distention by urography should not be seen. Moreover, hypertension should be absent or well controlled. And last, women should be taking no teratogenic drugs, and drug therapy should be reduced to maintenance levels.

Cyclosporine, tacrolimus, prednisone, and azathioprine are given routinely to renal transplantation recipients (Jain, 2004; López, 2014). Cyclosporine blood levels decline during pregnancy, although this was not reported to be associated with rejection episodes (Aktürk, 2015; Kim, 2015). Unfortunately, these agents are nephrotoxic and also may cause renal hypertension. In fact, they likely contribute substantively to chronic renal disease that develops in 10 to 20 percent of patients with nonrenal solid-organ transplantation (Goes, 2007). Concern persists regarding the possible late effects in offspring subjected to immunosuppressive therapy in utero. These include malignancy, germ cell dysfunction, and malformations in the children of the offspring. In addition, cyclosporine is secreted in breast milk (Moretti, 2003).

Finally, although pregnancy-induced renal hyperfiltration theoretically may impair long-term graft survival, Sturgiss and Davison (1995) found no evidence for this in a case-control study of 34 allograft recipients followed for a mean of 15 years. Others have reported similar findings (Debska-Ślizień, 2014; Stoumpos, 2016).

Management

Close surveillance is necessary. Covert bacteriuria is treated, and if it is recurrent, suppressive therapy is given for the remainder of the pregnancy. Serial hepatic enzyme concentrations and blood counts are monitored for toxic effects of azathioprine and cyclosporine. Some recommend measurement of serum cyclosporine levels. Gestational diabetes is more common if corticosteroids are taken, and overt diabetes must be excluded with glucose tolerance testing done at approximately 26 weeks' gestation. Surveillance for opportunistic infections from herpesvirus, cytomegalovirus, and toxoplasmosis is important because these infections are common. Some recommend surveillance for BK virus, however, treatment is problematic (Josephson, 2011).

Renal function is monitored, and the GFR usually increases 20 to 25 percent. If a significant rise in the serum creatinine level is detected, then its cause must be determined. Possibilities include acute rejection, cyclosporine toxicity, preeclampsia, infection, and urinary tract obstruction. Evidence of pyelonephritis or graft rejection should prompt aggressive management. Imaging studies and kidney biopsy may be indicated. The woman is carefully monitored for development or worsening of underlying hypertension, and especially superimposed preeclampsia. Management of hypertension during pregnancy is the same as for patients without a transplant.

Because of increased incidences of fetal-growth restriction and preterm delivery, vigilant fetal surveillance is indicated (Chaps. 42, Diagnosis and 44, Fetal-Growth Restriction Recognition). Although cesarean delivery is reserved for obstetrical indications, occasionally the transplanted kidney obstructs labor. In all women with a renal transplant, the cesarean delivery rate exceeds 60 percent (Bramham, 2013; Rocha, 2013).

POLYCYSTIC KIDNEY DISEASE

This usually autosomally dominant systemic disease primarily affects the kidneys. The disease is found in 1 in 800 live births and causes approximately 5 to 10 percent of end-stage renal disease in the United States. Although genetically heterogeneous, almost 85 percent of cases are due to *PKD1* gene mutations on chromosome 16, and the other 15 percent to *PKD2* mutations on chromosome 4 (Zhou, 2015). Prenatal diagnosis is available if the mutation has been identified in a family member or if linkage is established in the family.

Renal complications are more common in men than in women, and symptoms usually appear in the third or fourth decade. Flank pain, hematuria, proteinuria, abdominal masses, and associated calculi and infection are common. Hypertension develops in 75 percent, and progression to renal failure is a major problem. Superimposed acute kidney injury may also develop from infection or obstruction from ureteral angulation by cyst displacement.

Other organs are frequently involved. Asymptomatic *hepatic cysts* coexist in a third of patients with polycystic kidneys. Hepatic involvement is more common and more aggressive in women, and massive polycystic liver disease is almost exclusively found in multiparous women (Zhou, 2015). Approximately 10 percent of patients with polycystic kidney disease die from rupture of an associated *intracranial berry aneurysm.* Up to a fourth of patients have *cardiac valvular lesions* that involve valve prolapse or incompetence.

Pregnancy Outcomes

Because of its generally late onset, adult polycystic kidney disease is uncommon in pregnancy (Banks, 2015). The prognosis for pregnancy in these women depends on the degree of associated hypertension and renal insufficiency. Urinary tract infections are common. One study compared pregnancy outcomes in 235 affected women who had 605 pregnancies with those of 108 unaffected family members who had 244 pregnancies (Chapman, 1994). Composite perinatal complication rates were similar—33 versus 26 percent. However, hypertension, including preeclampsia, was significantly more frequent in women with polycystic kidneys. Pregnancy does not seem to accelerate the natural disease course (Lindheimer, 2007b).

GLOMERULAR DISEASES

The glomerulus and its capillaries are subject to various conditions and stimuli that can lead to acute and chronic diseases. Glomerular damage can be caused by toxins or infections or from systemic diseases that include hypertension, diabetes, or systemic lupus erythematosus (Lewis, 2015). It may also be idiopathic. When there is capillary inflammation, the process is termed g*lomerulonephritis,* and often, an autoimmune process is involved.

Persistent glomerulonephritis eventually leads to worsening renal function. Progression is variable and often does not manifest until chronic renal insufficiency is diagnosed. Lewis and Neilson (2015) group glomerular injuries into six syndromes based on clinical patterns (Table 53-3). Within each of these categories, there are disorders encountered in young women, and thus, these may antedate or first appear during pregnancy.

TABLE 53-3

Patterns of Clinical Glomerulonephritis

Acute Nephritic Syndromes: poststreptococcal, infective endocarditis, SLE, antiglomerular basement membrane disease, IgA nephropathy (Berger disease), ANCA vasculitis, Henoch-Schönlein purpura, cryoglobulinemia, membranoproliferative and mesangioproliferative glomerulonephritis
Pulmonary-Renal Syndromes: Goodpasture, ANCA vasculitis, Henoch-Schönlein purpura, cryoglobulinemia
Nephrotic Syndromes: minimal change disease, focal segmental glomerulosclerosis, membranous glomerulonephritis, diabetes, amyloidosis, others
Basement Membrane Syndromes: anti-GBM disease, others
Glomerular Vascular Syndromes: atherosclerosis, chronic hypertension, sickle-cell disease, thrombotic microangiopathies, antiphospholipid antibody syndrome, ANCA vasculitis, others
Infectious Disease-Associated Syndromes: poststreptococcal, infective endocarditis, HIV, HBV, HCV, syphilis, others

ANCA = antineutrophilic cytoplasmic antibodies; anti-GBM = anti-glomerular basement membrane; HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus; IgA = immunoglobulin A; SLE = systemic lupus erythematosus.

Adapted from Lewis, 2015.

Acute Nephritic Syndromes

Acute glomerulonephritis may result from any of several causes (see Table 53-3). The clinical presentation usually includes hypertension, hematuria, red-cell casts, pyuria, and proteinuria. Varying degrees of renal insufficiency and salt and water retention result in edema, hypertension, and circulatory congestion (Lewis, 2015). The prognosis and treatment of nephritic syndromes depends on their etiology. Some recede spontaneously or with treatment. However, in some patients, *rapidly progressive glomerulonephritis* leads to end-stage renal failure, whereas in others, *chronic glomerulonephritis* develops with slowly progressive renal disease.

Lupus nephritis identified before pregnancy has a 50- percent chance of flaring during pregnancy (Koh, 2015). *IgA nephropathy*, also known as *Berger disease*, is the most common form of acute glomerulonephritis worldwide (Wyatt, 2013). The isolated form occurs sporadically, and it may be related to *Henoch-Schönlein purpura* as the systemic form (Donadio, 2002). Isolated nephritis may be due to anti-glomerular basement membrane (anti-GBM) antibodies. These may also involve the lungs to manifest as a pulmonary-renal syndrome with alveolar hemorrhage, which is termed *Goodpasture syndrome* (Friend, 2015; Huser, 2015).

Pregnancy

Acute nephritic syndromes during pregnancy can be difficult to differentiate from severe preeclampsia or eclampsia (Cabiddu, 2016). One example is systemic lupus erythematosus with a flare during the second half of pregnancy (Bramham, 2012; Zhao, 2013). In some of these cases, renal biopsy is sometimes needed to determine etiology and direct management (Lindheimer, 2007a; Ramin, 2006).

Whatever the underlying etiology, acute glomerulonephritis has profound effects on pregnancy outcome. One older study described 395 pregnancies in 238 women with *primary* glomerulonephritis diagnosed before pregnancy (Packham, 1989). The most frequent lesions on biopsy were membranous glomerulonephritis, IgA glomerulonephritis, and diffuse mesangial glomerulonephritis. Although most of these women had normal renal function, half developed hypertension, a fourth were delivered preterm, and the perinatal mortality rate after 28 weeks' gestation was 80 per 1000. As expected, the worst perinatal outcomes were in women with impaired renal function, early or severe hypertension, and nephrotic-range proteinuria. Similar outcomes have been reported for pregnancies in women with IgA nephropathy. From their review of more than 300 such pregnancies, Lindheimer and colleagues (2000) concluded that pregnancy outcome was related to the degree of renal insufficiency and hypertension. Liu and coworkers (2014) reached similar conclusions.

Nephrotic Syndromes

Heavy proteinuria is the hallmark of the nephrotic syndromes. These result from several primary and secondary kidney disorders that cause immunological or toxin-mediated injury with glomerular capillary wall breakdown to allow excessive filtration of plasma proteins. In addition to heavy urine protein excretion, the syndrome is characterized by hypoalbuminemia, hypercholesterolemia, and edema. There frequently is hypertension, and along with albumin nephrotoxicity, renal insufficiency eventually develops.

Some of the more frequent causes of the nephrotic syndrome are minimal change disease (10–15 percent), focal segmental glomerulosclerosis (35 percent), membranous glomerulonephritis (30 percent), and diabetic nephropathy. In most cases, renal biopsy will disclose microscopic abnormalities that may help direct treatment (Chen, 2015; Lo, 2014). Edema is problematic, especially during pregnancy. Normal amounts of dietary protein of high biological value are encouraged. The incidence of thromboembolism is increased and varies with the severity of hypertension, proteinuria, and renal insufficiency (Stratta, 2006). Although both arterial and venous thromboses may develop, renal vein thrombosis is particularly worrisome. The value, if any, of prophylactic anticoagulation is unclear. Some cases of nephrosis from primary glomerular disease respond to glucocorticosteroids and other immunosuppressants or cytotoxic drug therapy. In most of those cases caused by infection or drugs, proteinuria recedes when the underlying cause is corrected.

Pregnancy

Maternal and perinatal outcomes in women with the nephrotic syndromes depend on its underlying cause and severity. Whenever possible, these should be ascertained, and renal biopsy may be indicated to determine if the etiology will respond to treatment. Half of women with nephrotic-range proteinuria will have a rise in daily protein excretion as pregnancy progresses (Packham, 1989). In women with nephrosis cared for at Parkland Hospital, we reported that two thirds had protein excretion that exceeded 3 g/d (Stettler, 1992). At the same time, however, if these women had only mild degrees of renal dysfunction, they had normally augmented GFR across pregnancy (Cunningham, 1990).

Management of edema during pregnancy can be particularly challenging as it is intensified by normally increasing hydrostatic pressure in the lower extremities. In some women, massive vulvar edema may develop. An example of massive vulvar edema associated with the nephrotic syndrome caused by secondary syphilis is shown in Figure 53-3. Another major problem is that up to half of these women have chronic hypertension that may require treatment. In these, as well as in previously normotensive women, preeclampsia is common and often develops early in pregnancy.

FIGURE 53-3
Massive vulvar edema in a pregnant woman with the nephrotic syndrome due to secondary syphilis. (Used with permission from Dr. George Wendel, Jr.)

Most women with nephrotic syndromes who do not have severe hypertension or renal insufficiency will have successful pregnancy outcomes. Conversely, if there is renal insufficiency, moderate to severe hypertension, or both, the prognosis is much worse. In a group of such women with 65 pregnancies cared for at Parkland Hospital, complications were frequent (Stettler, 1992). Protein excretion during pregnancy averaged 4 g/d, and a third of the women had classic nephrotic syndrome. There was some degree of renal insufficiency in 75 percent, chronic hypertension in 40 percent, and persistent anemia in 25 percent. Importantly, preeclampsia developed in 60 percent, and 45 percent had preterm deliveries. Even so, after excluding abortions, 53 of 57 neonates were born alive. In another series, fetal-growth restriction was noted in a third of pregnancies in affected women (Stratta, 2006).

Serious long-term adverse outcomes are a risk for women identified to have nephrotic syndromes either before or during pregnancy (Su, 2017). In our series above, at least 20 percent of women followed for 10 years progressed to end-stage renal disease (Stettler, 1992). Similarly, in another group of 15 women, by 2 years postpartum, three had died, three had developed chronic renal failure, and two had progressed to end-stage renal disease (Chen, 2001). Of predictors, serum creatinine level >1.4 mg/dL and 24-hour protein excretion >1 g/d are associated with the shortest renal survival times following pregnancy (Imbasciati, 2007).

CHRONIC KIDNEY DISEASE

This describes a pathophysiological process that can progress to end-stage renal disease. The National Kidney Foundation describes six stages of chronic kidney disease defined by decreasing GFR. It progresses from stage 0—GFR >90 mL/min/1.73 m^2 to stage 5—GFR <15 mL/min/1.73 m^2. Several diseases can worsen renal function, and many result from one of the glomerular diseases discussed earlier. Those that most frequently lead to end-stage disease requiring dialysis and kidney transplantation and their approximate percentages include: diabetes, 35 percent; hypertension, 25 percent; glomerulonephritis, 20 percent; and polycystic kidney disease, 15 percent (Abboud, 2010; Bargman, 2015).

Most reproductive-aged women with these diseases have varying degrees of renal insufficiency, proteinuria, or both. To counsel regarding fertility and pregnancy outcome, the degree of renal functional impairment and of associated hypertension are assessed. Successful pregnancy outcome in general may be more related to these two factors than to the specific underlying renal disorder. A general prognosis can be estimated by considering women with chronic renal disease in arbitrary categories of renal function (Davison, 2011). These include normal or *mild impairment*—defined as a serum creatinine <1.5 mg/dL; *moderate impairment*—defined as a serum creatinine 1.5 to 3.0 mg/dL; and *severe renal insufficiency*—defined as a serum creatinine >3.0 mg/dL. Although some have suggested adopting the classification of the National Kidney Foundation, others recommend using the older categories (Davison, 2011; Piccoli, 2010a, 2011). Thus, the obstetrician is ideally familiar with both.

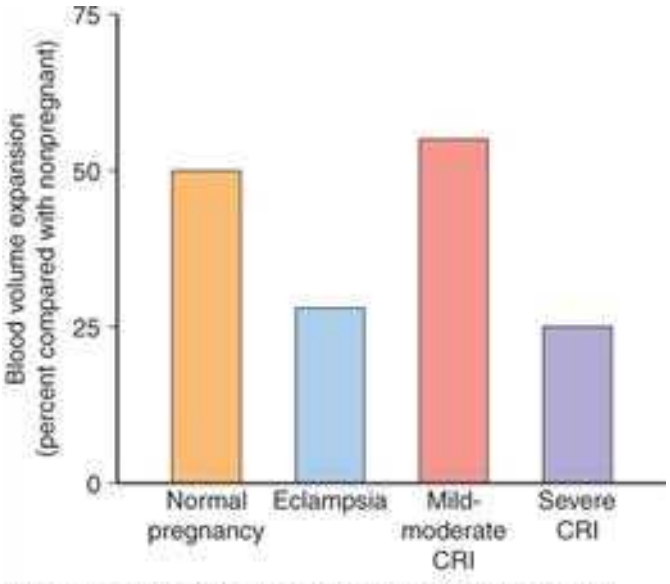
Pregnancy and Chronic Renal Disease

Most women have relatively mild renal insufficiency, and its severity along with any underlying hypertension is prognostic of pregnancy outcome. Renal disease with comorbidities secondary to a systemic disorder—for example, diabetes or systemic lupus erythematosus—portends a worse prognosis (Davison, 2011; Koh, 2015). For all women with chronic renal disease, the incidences of hypertension and preeclampsia, preterm and growth-restricted newborns, and other problems are high (Kendrick, 2015). Despite these, the National High Blood Pressure Education Program (2000) concluded that the prognosis has substantively improved since the 1980s. This has been verified by several reviews (Hladunewich, 2016a; Nevis, 2011; Ramin, 2006).

Loss of renal tissue is associated with compensatory intrarenal vasodilation and hypertrophy of the surviving nephrons. The resultant hyperperfusion and hyperfiltration eventually damage surviving nephrons to cause *nephrosclerosis* and worsening renal function. With mild renal insufficiency, pregnancy causes greater augmentation of renal plasma flow and GFR (Baylis, 2003; Helal, 2012). With progressively declining renal function, there is little, if any, augmented renal plasma flow. In one study, only half of women with moderate renal insufficiency demonstrated a pregnancy-augmented GFR, and women with severe disease had no increase (Cunningham, 1990).*Importantly, severe chronic renal insufficiency curtails normal pregnancy-induced hypervolemia.* Blood volume expansion during pregnancy is related to disease severity and correlates inversely with serum creatinine concentration. As shown in Figure 53-4, women with mild to moderate renal dysfunction have normal blood volume expansion that averages 55 percent. With severe renal insufficiency, however, volume expansion averages only 25 percent, which is similar to that seen with hemoconcentration from eclampsia. In addition, these women have variable degrees of chronic anemia due to intrinsic renal disease.

FIGURE 53-4

Blood volume expansion in 44 normally pregnant women at term compared with 29 who had eclampsia; 10 with moderate chronic renal insufficiency (CRI)—serum creatinine 1.5 to 2.9 mg/dL; and four with severe CRI—serum creatinine ≥3.0 mg/dL. (Data from Cunningham, 1990; Zeeman, 2009.)



Renal Disease with Preserved Function

In some women, although glomerular disease has not yet caused renal dysfunction, incidences of pregnancy complications are still increased. As shown in Table 53-4, these problems are less frequent than in cohorts of women with moderate and severe renal insufficiency. Two earlier studies illustrate this. In one describing 123 pregnancies in women with biopsy-proven glomerular disease, only a few of the women had renal dysfunction, yet 40 percent developed obstetrical or renal complications (Surian, 1984). In another study of 395 pregnancies in women with preexisting glomerulonephritis and minimal renal insufficiency, impaired renal function developed in 15 percent during pregnancy, and 60 percent had worsening proteinuria (Packham, 1989). Only 12 percent had antecedent chronic hypertension, however, more than half of the 395 pregnancies were complicated by hypertension. The perinatal mortality rate was 140 per 1000, but even without early-onset or severe hypertension or nephrotic-range proteinuria, the perinatal death rate was 50 per 1000. Importantly, in 5 percent of these women, worsening renal function was permanent.

TABLE 53-4

Complications (Percent) Associated with Chronic Renal Disease During Pregnancy

		Renal Insufficiency	
Complication	**Preserved Function**	**Moderate and Severe**	**Severe**
Chronic HTN	25	30–70	50
Gestational HTN	20–50	30–50	75
Worsening renal function	8–15	0–43	26–35
Permanent dysfunction	4–5	10–20	35
Preterm delivery	7	30–60	73–89
Fetal-growth restriction	8–14	30–38	57
Perinatal mortality	5–14	4–7	—

HTN = hypertension.

Data from Alsuwaida, 2011; Cunningham, 1990; Farwell, 2013; Feng, 2015; Imbasciati, 2007; Maruotti, 2012; Nevis, 2011; Packham, 1989; Piccoli, 2010a, 2011; Stettler, 1992; Surian, 1984; Trevisan, 2004.

Chronic Renal Insufficiency

In women with chronic kidney disease who also have renal insufficiency, adverse outcomes are generally directly related to the degree of renal impairment. Outcomes of women with moderate versus severe renal insufficiency are usually not separated (Table 53-5). That said, Piccoli and associates (2010a) described 91 pregnancies complicated by stage 1 chronic kidney disease. Primarily because of hypertension, 33 percent were delivered preterm, and 13 percent had fetal-growth restriction. Alsuwaida and colleagues (2011) reported similar observations. Other investigators have described pregnancies complicated by moderate or severe renal insufficiency (Cunningham, 1990; Imbasciati, 2007; Zhang, 2015). Despite a high incidence of chronic hypertension, anemia, preeclampsia, preterm delivery, and fetal-growth restriction, perinatal outcomes were generally acceptable. As shown in Figure 53-5, fetal growth is frequently impaired and related to renal dysfunction severity.

TABLE 53-5

Outcomes in 179 Pregnancies in Women Undergoing Dialysis

	Pregnancies			Pregnancy Outcomes (%)			
Study	**N**	**Delivery (wk)**	**Birthweight (g)**	**Hypertension**	**Hydramnios**	**Perinatal Mortality**	**Surviving Infants**
Chao (2002)	13	32	1540	72	46	31	69

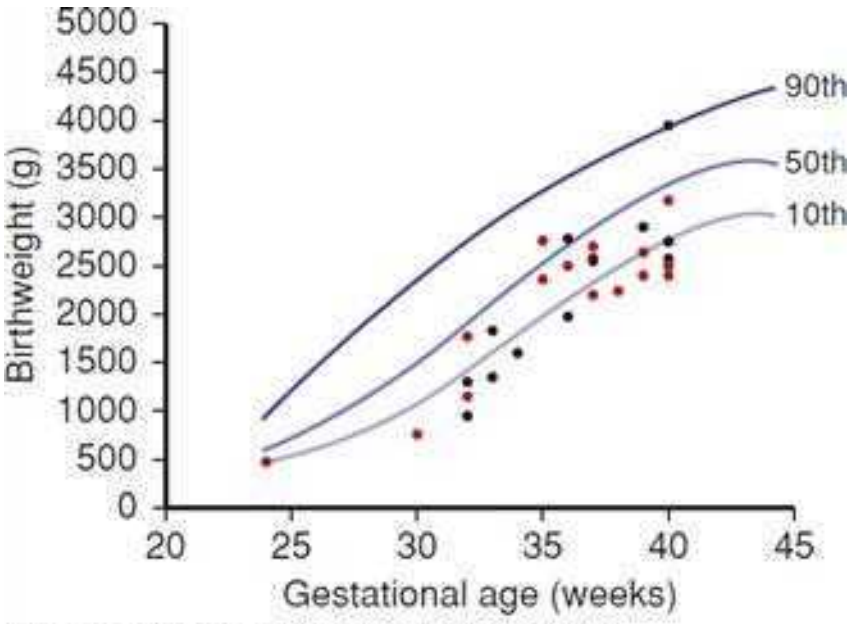
[a]Preeclampsia only.

NS = not stated.

FIGURE 53-5

Birthweight percentiles of infants born to 29 women at Parkland Hospital with mild to moderate renal insufficiency—serum creatinine 1.4 to 2.4 mg/dL (*black points*) and severe renal insufficiency—serum creatinine ≥2.5 mg/dL (*red points*). (Data from Cunningham, 1990; Stettler, 1992. Growth curves are those reported by Alexander, 1996.)



Management

Prenatal care is tailored for women with chronic renal disease. Frequent monitoring of blood pressure is paramount, and serum creatinine levels, protein/creatinine ratio, and 24-hour protein excretion are quantified as indicated. Bacteriuria is treated to decrease the risk of pyelonephritis and further nephron loss. Protein-rich diets are recommended (Jim, 2016; Lindheimer, 2000). In some women with anemia from chronic renal insufficiency, a response is seen with recombinant erythropoietin, however, hypertension is a common side effect. Serial sonography is performed to follow fetal growth. The differentiation between worsening hypertension and superimposed preeclampsia is problematic. Preliminary data indicate that the angiogenic biomarkers placental growth factor (PlGF) and its soluble antiangiogenic receptor (sFlt-1) may be useful to separate chronic from gestational hypertension. This is described in Chapter 40 (Endothelial Cell Injury).

Long-Term Effects

In some women, pregnancy may accelerate chronic renal disease progression by increasing hyperfiltration and glomerular pressure to worsen nephrosclerosis (Baylis, 2003; Helal, 2012). This is more likely in women with severe chronic renal insufficiency (Abe, 1991; Jones, 1996). For example, Jungers and associates (1995) reported few long-term pregnancy-related adverse effects in 360 women with chronic glomerulonephritis and antecedent normal renal function. However, at 1 year after pregnancy, Jones and Hayslett (1996) reported that 10 percent of such women with moderate or severe renal insufficiency had developed end-stage renal failure—stage 5 chronic kidney disease. In a study from Parkland Hospital, we found that 20 percent of pregnant women with similar insufficiency had developed end-stage renal failure by a mean of 4 years (Cunningham, 1990). Similar findings in women with a median follow-up of 3 years were described by Imbasciati and coworkers (2007). By this time, end-stage disease was apparent in 30 percent of women whose serum creatinine was ≥1.4 mg/dL and who had proteinuria >1 g/d. Chronic proteinuria is also a marker for subsequent development of renal failure. In another report from Parkland Hospital, 20 percent of women with chronic proteinuria discovered during pregnancy progressed to end-stage renal failure within several years (Stettler, 1992).

Dialysis During Pregnancy

Significantly impaired renal function is accompanied by subfertility that may be corrected with chronic renal replacement therapy—either hemodialysis or peritoneal dialysis (Hladunewich, 2016b; Shahir, 2013). Not unexpectedly, these pregnancies can be complicated. In one review of 131 cases, mean fetal birthweights were higher in women who conceived while undergoing dialysis—1530 g versus 1245 g—than in women who conceived before starting dialysis (Chou, 2008). This was also true for 77 pregnancies described by Jesudason and coworkers (2014). Similar outcomes from several reports are shown in Table 53-5.

Outcomes are similar with either hemodialysis or peritoneal dialysis. Thus, for the woman already undergoing either method, it seems reasonable to continue that method with consideration for its increasing frequency. In the woman who has never been dialyzed, the threshold for initiation during pregnancy is unclear. Lindheimer and colleagues (2007a) recommend dialysis when serum creatinine levels are between 5 and 7 mg/dL. Because it is imperative to avoid abrupt volume changes that cause hypotension, dialysis frequency may be extended to five to six times weekly (Reddy, 2007).

Certain protocols emphasize attention to replacement of substances lost through dialysis (Jim, 2016). Multivitamin doses are doubled, and calcium and iron salts are provided along with sufficient dietary protein and calories. Chronic anemia is treated with erythropoietin. To meet pregnancy changes, extra calcium is added to the dialysate along with less bicarbonate.*Maternal complications are common and include severe hypertension, placental abruption, heart failure, and sepsis.* In a

review of 90 pregnancies in 78 women, as well as those shown in Table 53-5, high incidences of maternal hypertension and anemia, preterm and growth-restricted infants, stillbirths, and hydramnios were reported (Piccoli, 2010b).

ACUTE KIDNEY INJURY

Previously termed *acute renal failure,* acute kidney injury (AKI) is now used to describe suddenly impaired kidney function with retention of nitrogenous and other waste products normally excreted by the kidneys (Waikar, 2015). Severe AKI associated with pregnancy is less frequent today. For example, in a 6-year period, the overall incidence at the Mayo Clinic was 0.4 percent (Gurrieri, 2012). It is even less common for women who require dialysis—1 case per 10,000 births (Hildebrand, 2015). But, it still occasionally causes significant obstetrical morbidity, and women who require acute dialysis have increased maternal mortality rates (Kuklina, 2009; Van Hook, 2014). Outcomes are available from four older studies comprising a total of 266 women with renal failure (Drakeley, 2002; Nzerue, 1998; Sibai, 1990; Turney, 1989). Nearly 70 percent had preeclampsia, 50 percent had obstetrical hemorrhage, and 30 percent had a placental abruption. Almost 20 percent required dialysis, and the maternal mortality rate was 15 percent.

Although obstetrical cases of AKI that require dialysis have become less prevalent, acute renal ischemia is still often associated with severe preeclampsia and hemorrhage (Gurrieri, 2012; Jim, 2017). Particularly contributory are HELLP (hemolysis, elevated liver enzymes, low platelet levels) syndrome and placental abruption (Audibert, 1996; Drakely, 2002). Septicemia is another frequent comorbidity, especially in resource-poor countries (Acharya, 2013; Srinil, 2011; Zeeman, 2003). AKI is also common in women with acute fatty liver of pregnancy (Sibai, 2007). Some degree of renal insufficiency was found in virtually all of 52 such women cared for at Parkland Hospital (Nelson, 2013). Another woman from Parkland Hospital developed AKI from dehydration caused by severe hyperemesis gravidarum at 15 weeks (Hill, 2002). Other causes include thrombotic microangiopathies (Balofsky, 2016; Ganesan, 2011) (Chap. 56, Thrombotic Microangiopathies).

Diagnosis and Management

In most women, AKI develops postpartum, thus management is usually not complicated by fetal considerations. An abrupt rise in serum creatinine level is most often due to renal ischemia. Oliguria is an important sign. In obstetrical cases, both prerenal and intrarenal factors are often contributory. For example, with total placental abruption, severe hypovolemia from massive hemorrhage is common, and preexistent renal ischemia from preeclampsia is often comorbid. In addition, disseminated intravascular coagulopathy may be contributory.

When azotemia is evident and severe oliguria persists, some form of renal replacement treatment is indicated. Hemofiltration or dialysis is initiated before marked deterioration occurs. Hemodynamic measurements are normalized. Importantly, medication doses are adjusted, and magnesium sulfate, iodinated contrast agents, aminoglycosides, and nonsteroidal antiinflammatory drugs (NSAIDs) are prominent examples (Waikar, 2015). Early dialysis appears to reduce the maternal mortality rate appreciably and may enhance the extent of renal function recovery. With time, renal function usually returns to normal or near normal.

Prevention

AKI in obstetrics is most often due to acute blood loss, especially that associated with preeclampsia. Thus, it may often be prevented by the following means:

1. Prompt and vigorous volume replacement with crystalloid solutions and blood in instances of massive hemorrhage, such as in placental abruption, placenta previa, uterine rupture, and postpartum uterine atony (Chap. 41, Hypovolemic Shock).
2. Delivery or termination of pregnancies complicated by severe preeclampsia or eclampsia, and careful blood transfusion if loss is more than average (Chap. 40, Blood Volume).
3. Close observation for early signs of sepsis syndrome and shock in women with pyelonephritis, septic abortion, chorioamnionitis, or sepsis from other pelvic infections (Chap. 47, Sepsis Syndrome).
4. Avoidance of loop diuretics to treat oliguria before ensuring that blood volume and cardiac output are adequate for renal perfusion.
5. Judicious use of vasoconstrictor drugs to treat hypotension, and only after it has been determined that pathological vasodilatation is the cause.

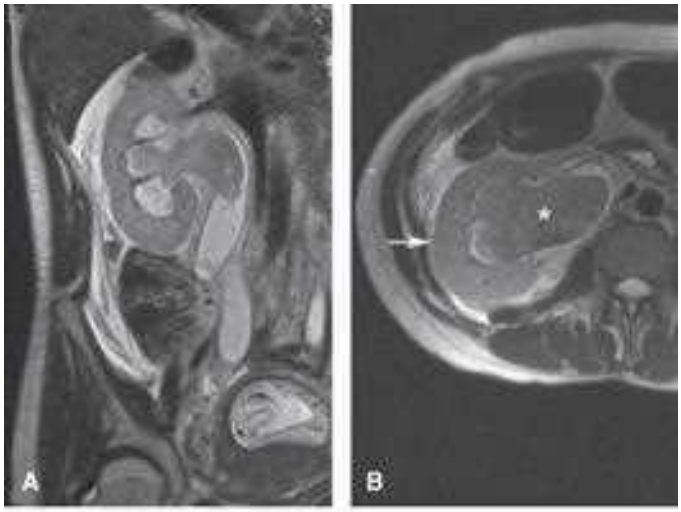
Irreversible ischemic renal failure caused by *acute cortical necrosis* is rare now in obstetrics (Frimat, 2016). Before widespread availability of dialysis, it complicated a fourth of obstetrical renal failure cases (Grünfeld, 1987; Turney, 1989). Most cases followed placental abruption, preeclampsia-eclampsia, and endotoxin-induced shock. Once common with septic abortion, this is a rare cause in this country today (Lim, 2011; Srinil, 2011). Histologically, the lesion appears to result from thrombosis of segments of the renal vascular system. The lesions may be focal, patchy, confluent, or gross. Clinically, renal cortical necrosis follows the course of AKI, and its differentiation from acute tubular necrosis is not possible during the early phase. The prognosis depends on the extent of the necrosis. Recovery of function is variable, and stable renal insufficiency may result (Lindheimer, 2007a).

Obstructive Renal Failure

Rarely, bilateral ureteral compression by a very large pregnant uterus is greatly exaggerated. Resultant ureteral obstruction in turn may cause severe oliguria and azotemia. An extreme example is shown in Figure 53-6. In their series of 13 obstruction cases, Brandes and Fritsche (1991) described one woman with twins who developed anuria and a serum creatinine level of 12.2 mg/dL at 34 weeks' gestation. After amniotomy, urine flow resumed at 500 mL/hr, and her serum creatinine levels rapidly dropped to normal range. Eckford and Gingell (1991) described 10 women in whom ureteral obstruction was relieved by stenting. The stents were left in place for a mean of 15.5 weeks and removed 4 to 6 weeks postpartum. Others have reported similar experiences (Sadan, 1994; Satin, 1993). Partial ureteral obstruction may be accompanied by fluid retention and significant hypertension. When the obstructive uropathy is relieved, diuresis ensues and hypertension dissipates. In our experience, women with previous urinary tract surgery for reflux are more likely to have such obstructions.

FIGURE 53-6

A. Magnetic resonance image in a coronal plane of a pregnant woman with unilateral hydronephrosis caused by ureteral obstruction. The serum creatinine level was 8 mg/dL and decreased to 0.8 mg/dL after a percutaneous nephrostomy tube was placed. **B.** Left kidney (*arrow*) and associated hydronephrosis (*asterisk*) are again noted in this axial plane image from the same patient.



LOWER GENITAL TRACT LESIONS

Urethral Diverticulum

Although infrequently complicating pregnancy, this type of diverticulum originates from an enlarging paraurethral gland abscess that ruptures into the urethral lumen. As infection clears, the remaining dilated diverticular sac and its ostium into the urethra persist. Urine collecting within and dribbling from the sac, pain, a palpable mass, and recurrent urinary infections may be associated findings. In general, a diverticulum is managed expectantly during pregnancy. Rarely, drainage may be necessary, or surgery required (Iyer, 2013). If additional antepartum evaluation is needed, MR imaging is preferred for its superior soft tissue resolution and ability to define complex diverticula (Dwarkasing, 2011; Pathi, 2013).

Urogenital Tract Fistulas

Fistulas found during pregnancy likely existed previously, but in rare cases, they form during pregnancy. In developed countries, *vesicovaginal or cervicovaginal fistula* following a McDonald cerclage has been reported (Massengill, 2012; Zanconato, 2015). These fistulas may also form with prolonged obstructed labor that is more often seen in resource-poor countries (Cowgill, 2015). In these cases, the genital tract is compressed between the fetal head and bony pelvis. Brief pressure is not significant, but prolonged pressure leads to tissue necrosis with subsequent fistula formation (Wall, 2012). *Vesicouterine fistulas* can develop after prior vaginal or cesarean delivery (DiMarco, 2006; Harfouche, 2014; Manjunatha, 2012). Rarely, *vesicocervical fistula* can follow cesarean delivery or may form if the anterior cervical lip is compressed against the symphysis pubis (Dudderidge, 2005). Finally, an *ileouterine fistula* from a degenerating posterior wall fibroid tumor has been described (Shehata, 2016).

CHAPTER 54: Gastrointestinal Disorders

The diagnosis of acute appendicitis is more difficult than at other times, as the enlarged uterus renders it almost impossible to explore the right iliac region satisfactorily.

—J. Whitridge Williams (1903)

INTRODUCTION

These words summarize that during normal pregnancy, the gastrointestinal tract and its appendages undergo remarkable anatomical, physiological, and functional alterations. These changes, which are discussed in detail in Chapter 4 (Gastrointestinal Tract), can appreciably alter clinical findings normally relied on for diagnosis and treatment of gastrointestinal disorders such as appendicitis. Moreover, as pregnancy progresses, gastrointestinal symptoms become more difficult to assess. Physical findings are often obscured by a large uterus that displaces abdominal organs and can alter the location and intensity of pain and tenderness.

GENERAL CONSIDERATIONS

Diagnostic Techniques

Endoscopy

Fiberoptic endoscopic instruments have revolutionized diagnosis and management of most gastrointestinal conditions, and these are particularly well suited for pregnancy. Endoscopy in pregnancy is associated with a slightly increased risk for preterm birth, but this is likely due to the disease itself (Ludvigsson, 2017). With endoscopy, the esophagus, stomach, duodenum, and colon can be inspected (Cappell, 2011; Savas, 2014). The proximal jejunum can also be studied, and the ampulla of Vater cannulated to perform *endoscopic retrograde cholangiopancreatography—ERCP* (Akcakaya, 2014; Fogel, 2014). Preliminary data suggest that postendoscopic pancreatitis following gallstone removal may have a higher incidence in pregnant women (Inamdar, 2016). Experience in pregnancy with *videocapsule endoscopy* for small-bowel evaluation remains limited (Storch, 2006).

Upper gastrointestinal endoscopy is used for management as well as diagnosis of several problems. Common bile duct exploration and drainage are used for choledocholithiasis as described in Chapter 55 (Pancreatic Disorders). It is also used for sclerotherapy and for placement of *percutaneous endoscopic gastrostomy (PEG)* tubes. Several concise reviews have been provided (Cappell, 2011; Fogel, 2014; Gilinsky, 2006).

For visualization of the large bowel, *flexible sigmoidoscopy* can be used safely in pregnant women (Siddiqui, 2006). *Colonoscopy* is indispensible for viewing the entire colon and distal ileum to aid diagnosis and management of several bowel disorders. Except for the midtrimester, reports of colonoscopy during pregnancy are limited, but most results indicate that it should be performed if indicated (Cappell, 2010, 2011; De Lima, 2015). Bowel preparation is completed using polyethylene glycol electrolyte or sodium phosphate solutions. With these, serious maternal dehydration that may cause diminished uteroplacental perfusion should be avoided.

Noninvasive Imaging Techniques

The obvious ideal technique for gastrointestinal evaluation during pregnancy is abdominal sonography. Because computed tomography (CT) use is limited in pregnancy due to radiation exposure, magnetic resonance (MR) imaging is now commonly used to evaluate the abdomen and retroperitoneal space (Khandelwal, 2013). One example is magnetic resonance cholangiopancreatography—MRCP (Oto, 2009). Another is magnetic resonance enterography—MRE (Stern, 2014). These and other imaging modalities, and their safe use in pregnancy, are considered in more detail in Chapter 46.

Laparotomy and Laparoscopy

Surgery is lifesaving for certain gastrointestinal conditions— perforative appendicitis being the most common example. Laparoscopic procedures have replaced traditional surgical techniques for many abdominal disorders during pregnancy. These are shown in detail with descriptions of surgical technique in Chapter 46 (Perinatal Outcomes) and in *Cunningham and Gilstrap's Operative Obstetrics, 3rd edition* (Kho, 2016). Guidelines for diagnosis, treatment, and use of laparoscopy for surgical problems during pregnancy have been provided by the Society of American Gastrointestinal and Endoscopic Surgeons—SAGES (Pearl, 2017).

Nutritional Support

Specialized nutritional support can be delivered *enterally,* usually via nasogastric tube feedings, or *parenterally* with nutrition given by venous catheter access, either peripherally or centrally.

When possible, enteral alimentation is preferable because it has fewer serious complications (Bistrian, 2012; Stokke, 2015). In obstetrical patients, very few conditions prohibit enteral nutrition as a first effort to prevent catabolism. For extreme cases, such as recalcitrant hyperemesis gravidarum, percutaneous endoscopic gastrostomy with a jejunal port (PEG-J tube) has been described (Saha, 2009).

The purpose of *parenteral feeding*, or *hyperalimentation*, is to provide nutrition when the intestinal tract must be quiescent. Central venous access is necessary for total parenteral nutrition because its hyperosmolarity requires rapid dilution in a high-flow vascular system. These solutions provide 24 to 40 kcal/kg/d, principally as a hypertonic glucose solution.

Various conditions may prompt total parenteral nutrition during pregnancy (Table 54-1). Not surprisingly, gastrointestinal disorders are the most common indication, and in the many studies cited, feeding duration averaged approximately 33 days.

TABLE 54-1

Some Conditions Treated with Enteral or Parenteral Nutrition During Pregnancy[a]

Achalasia
Anorexia nervosa
Appendiceal rupture
Bowel obstruction
Burns
Cholecystitis
Crohn disease
Diabetic gastropathy
Esophageal injury
Hyperemesis gravidarum
Jejunoileal bypass
Malignancies
Ostomy obstruction
Pancreatitis
Preeclampsia syndrome
Short gut syndrome
Stroke
Ulcerative colitis

[a]Disorders are listed alphabetically.

Data from Folk, 2004; Guglielmi, 2006; Manhadevan, 2015; Ogura, 2003; Porter, 2014; Russo-Stieglitz, 1999; Saha, 2009; Spiliopoulos, 2013.

Importantly, complications of parenteral nutrition are frequent, and they may be severe (Guglielmi, 2006). An early report of 26 pregnancies described a 50-percent rate of complications, which included pneumothorax, hemothorax, and brachial plexus injury (Russo-Stieglitz, 1999). The most frequent serious complication is catheter sepsis, and Folk (2004) reported a 25-percent incidence in 27 women with hyperemesis gravidarum. Although bacterial sepsis is most common, *Candida* septicemia has been described (Paranyuk, 2006). The Centers for Disease Control and Prevention has updated its detailed guidelines to prevent catheter-related sepsis, and these serve to lessen the dangers of serious infections (O'Grady, 2011). Perinatal complications are uncommon, however, fetal subdural hematoma caused by maternal vitamin K deficiency has been described (Sakai, 2003).

Appreciable morbidity is also associated with long-term use of a *peripherally inserted central catheter (PICC)*. Infection is the most common serious long-term complication (Holmgren, 2008; Ogura, 2003). In a series of 84 such catheters inserted in 66 pregnant women, Cape and coworkers (2014) reported a 56-percent complication rate, of which bacteremia was the most frequent. From a review of 48 reports of nonpregnant adults, Turcotte and associates (2006) concluded that peripherally placed catheters provided no advantages compared with centrally placed ones. Still, for short-term nutrition lasting a few weeks, it seems reasonable that PICC placement has a greater benefit-versus-risk ratio (Bistrian, 2012).

UPPER GASTROINTESTINAL TRACT DISORDERS

Hyperemesis Gravidarum

Mild to moderate nausea and vomiting are especially common in pregnant women until approximately 16 weeks' gestation (Chap. 9, Caffeine). In a small but significant proportion of these, however, it is severe and unresponsive to simple dietary modification and antiemetics. Severe unrelenting nausea and

vomiting—*hyperemesis gravidarum*—is defined variably as being sufficiently severe to produce weight loss, dehydration, ketosis, alkalosis from loss of hydrochloric acid, and hypokalemia. Acidosis develops from partial starvation. In some women, transient hepatic dysfunction develops, and biliary sludge accumulates (Matsubara, 2012). Other causes should be considered because ultimately hyperemesis gravidarum is a diagnosis of exclusion (Benson, 2013).

Study criteria have not been homogeneous, thus reports of population incidences vary. There does, however, appear to be an ethnic or familial predilection (Grjibovski, 2008). In population-based studies from California, Nova Scotia, and Norway, the hospitalization rate for hyperemesis gravidarum was 0.5 to 1 percent (Bailit, 2005; Fell, 2006; Vikanes, 2013). Up to 20 percent of those hospitalized in a previous pregnancy for hyperemesis will again require hospitalization (Dodds, 2006; Trogstad, 2005). In general, obese women are less likely to be hospitalized for this (Cedergren, 2008).

The etiopathogenesis of hyperemesis gravidarum is unknown and is likely multifactorial. It apparently is related to high or rapidly rising serum levels of pregnancy-related hormones. Putative culprits include human chorionic gonadotropin (hCG), estrogen, progesterone, leptin, placental growth hormone, prolactin, thyroxine, and adrenocortical hormones (Verberg, 2005). More recently implicated are other hormones that include ghrelins, leptin, nesfatin-1, and peptide YY (3–36) (Albayrak, 2013; Gungor, 2013).

Superimposed on this hormonal cornucopia are an imposing number of biological and environmental factors. Moreover, in some but not all severe cases, interrelated psychological components play a major role (Christodoulou-Smith, 2011; McCarthy, 2011). Other factors that increase the risk for admission include hyperthyroidism, previous molar pregnancy, diabetes, gastrointestinal illnesses, some restrictive diets, and asthma and other allergic disorders (Fell, 2006; Mullin, 2012). An association of *Helicobacter pylori* infection has been proposed, but evidence is not conclusive (Goldberg, 2007). Chronic marijuana use may cause the similar *cannabinoid hyperemesis syndrome* (Alaniz, 2015; Andrews, 2015). And for unknown reasons—perhaps estrogen-related—a female fetus increases the risk by 1.5-fold (Schiff, 2004; Tan, 2006; Veenendaal, 2011). Finally, some but not all studies have reported an association between hyperemesis gravidarum and preterm labor, placental abruption, and preeclampsia (Bolin, 2013; Vandraas, 2013; Vikanes, 2013).

Complications

Vomiting may be prolonged, frequent, and severe, and a list of potentially fatal complications is given in Table 54-2. Various degrees of acute kidney injury from dehydration are encountered (Nwoko, 2012). An extreme example was a woman we cared for who required 5 days of dialysis when her serum creatinine level rose to 10.7 mg/dL (Hill, 2002). One complication from continuous retching is a Mallory-Weiss tear. Others are pneumothorax, pneumomediastinum, diaphragmatic rupture, and gastroesophageal rupture—*Boerhaave syndrome* (American College of Obstetricians and Gynecologists, 2015; Chen, 2012).

TABLE 54-2

Some Serious and Life-Threatening Complications of Recalcitrant Hyperemesis Gravidarum

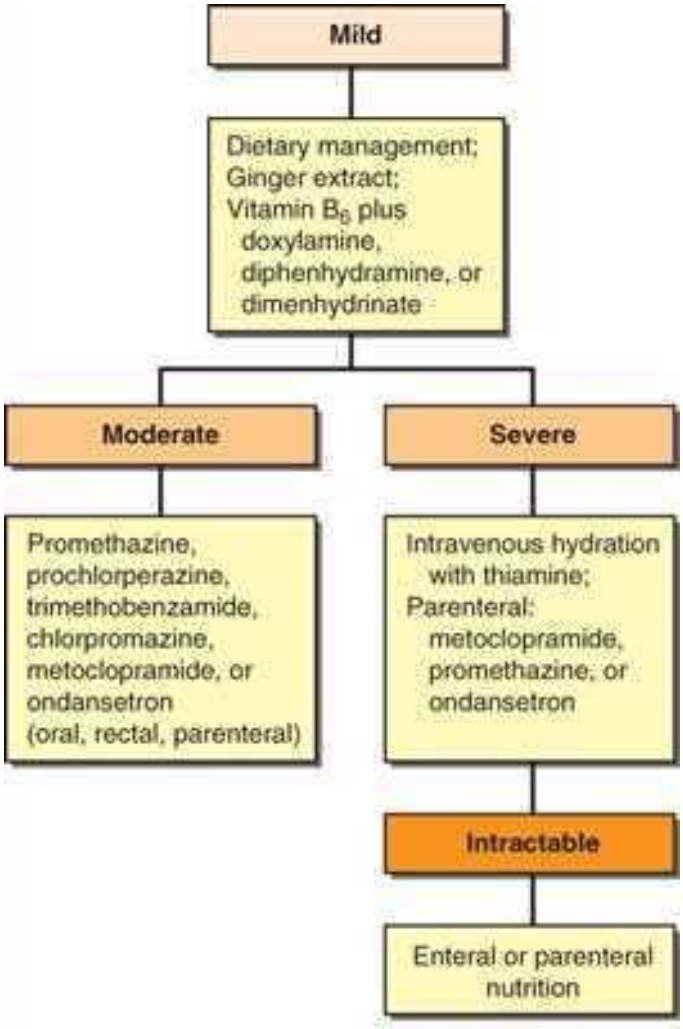
Acute kidney injury—may require dialysis Depression—cause versus effect? Diaphragmatic rupture
Esophageal rupture—Boerhaave syndrome
Hypoprothrombinemia—vitamin K deficiency
Hyperalimentation complications
Mallory-Weiss tears—bleeding, pneumothorax, pneumomediastinum, pneumopericardium
Rhabdomyolysis
Wernicke encephalopathy—thiamine deficiency

At least two serious vitamin deficiencies have been reported with hyperemesis in pregnancy. One is *Wernicke encephalopathy* from thiamine deficiency that has been recognized with increasing frequency (Di Gangi, 2012; Palacios-Marqués, 2012). In two reviews, ocular signs, confusion, and ataxia were common, but only half had this triad (Chiossi, 2006; Selitsky, 2006). With this encephalopathy, an abnormal electroencephalogram (EEG) may be seen, and usually MR imaging shows findings (Vaknin, 2006; Zara, 2012). At least three maternal deaths have been described, and long-term sequelae include blindness, convulsions, and coma (Selitsky, 2006). The second is *vitamin K deficiency* that has been reported to cause maternal coagulopathy and fetal intracranial hemorrhage, as well as vitamin K embryopathy (Kawamura, 2008; Lane, 2015; Sakai, 2003).

Management

One algorithm for management of nausea and vomiting of pregnancy is shown in Figure 54-1. Most women with mild to moderate symptoms respond as outpatients to any of several first-line antiemetic agents (Clark, 2014; Matthews, 2014). One that is becoming a mainstay is *Diclegis*—a combination of doxylamine (10 mg) plus pyridoxine (10 mg). It has been proven safe and effective (Briggs, 2015; Koren, 2014). The usual dose is two tablets orally at bedtime. If relief is insufficient, then additional doses, first in the morning, and then in the morning and midafternoon can be added each day to the bedtime dose. At our institution, for cost savings, we prescribe these two agents individually: Unisom (doxylamine) ½ of a 50-mg tablet plus a 25-mg vitamin B_6 tablet. The same graduated dosing is used but does not exceed three total daily doses.

FIGURE 54-1
Algorithm for outpatient and inpatient management of hyperemesis gravidarum.



Ondansetron (Zofran) also does not appear to be teratogenic. It was slightly more efficacious than a combination of doxylamine and pyridoxine in a randomized trial (Oliveira, 2014; Pasternak, 2013). Its drawbacks include potential maternal effects from prolonged QT-interval and serotonin syndrome (Koren, 2014).

When simple measures fail, intravenous crystalloid solutions are given to correct dehydration, ketonemia, electrolyte deficits, acid-base imbalances, and hypokalemia. No benefits are gained by infusing 5-percent dextrose along with crystalloids (Tan, 2013). Thiamine, 100 mg, is given to prevent Wernicke encephalopathy (Giugale, 2015; Niebyl, 2010). This is usually diluted in 1 L of the selected crystalloid and infused at the maintenance rate desired for patient hydration.

If vomiting persists after rehydration and failed outpatient management, hospitalization is recommended (American College of Obstetricians and Gynecologists, 2015). Day care has also been shown to be effective in one randomized study (McCarthy, 2014). Intravenous hydration is continued and antiemetics such as promethazine, prochlorperazine, chlorpromazine, or metoclopramide are given parenterally (Table 54-3). The bulk of evidence is that treatment with *glucocorticosteroids* is not effective (Yost, 2003). Because of their putative teratogenicity, they are not routinely recommended (American College of Obstetricians and Gynecologists, 2015).

TABLE 54-3

Medications for Gastric Disorders in Pregnancy

Medication (Brand Name)	Usual Dosing	Route(s)
Options for Nausea and Vomiting		
Antihistamine Doxylamine + pyridoxine (Diclegis)[a]	At bedtime; up to 4 times daily	PO
Phenothiazines	**Every 6 hr**	
Promethazine (Phenergan)[c]	12.5–25 mg	IM, IV, PO, PR
Prochlorperazine (Compazine)[c]	5–10 (25 PR) mg	IM, IV, PO, PR
Serotonin antagonist	**Every 8 hr**	
Ondansetron (Zofran)[b]	8 mg	IV, PO
Benzamides	**Every 6 hr**	
Metoclopramide (Reglan)[b]	5–15 mg	IM, IV, PO
Oral Options for Gastroesophageal Reflux (GERD)		
H2 receptor antagonists		
Ranitidine (Zantac)[b]	150 mg twice daily	
Cimetidine (Tagamet)[b]	400 mg 4 times daily for up to 12 wks 800 mg twice daily for up to 12 wks	
Nizatidine (Axid)[b]	150 mg twice daily	
Famotidine (Pepcid)[b]	20 mg twice daily up to 6 wks	
Proton-pump inhibitors		
Pantoprazole (Protonix)[b]	40 mg daily for up to 8 wks	
Lansoprazole (Prevacid)[b]	15 mg daily for up to 8 wks	
Omeprazole (Prilosec, Zegerid)[c]	20 mg daily for 4–8 wks	
Dexlansoprazole (Dexilant)[c]	30 mg daily for up to 4 wks	

[a]Food and Drug Administration category A.

[b]Food and Drug Administration category B.

[c]Food and Drug Administration category C.

With persistent vomiting after hospitalization, appropriate steps should be taken to exclude possible underlying diseases as a cause of hyperemesis. That said, in one study, endoscopy did not change management in 49 women (Debby, 2008). Other potential causes of vomiting include gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer, and pyelonephritis. In addition, severe preeclampsia and fatty liver are more likely after midpregnancy.

And although clinical thyrotoxicosis has been implicated as a cause of hyperemesis, it is more likely that abnormally elevated serum thyroxine levels are a surrogate for higher-than-average serum hCG levels (Sun, 2014). This is discussed further in Chapter 5 (Human Placental Lactogen). In our experiences, serum free thyroxine levels normalize quickly with hydration and emesis treatment.

With treatment, most women will have a salutary response and may be sent home with antiemetic therapy. Their readmission rate is 25 to 35 percent in most prospective studies. If associated psychiatric and social factors contribute to the illness, the woman usually improves remarkably while hospitalized (Swallow, 2004). That said, symptoms may relapse in these women, and some go on to develop *posttraumatic stress syndrome* (Christodoulou-Smith, 2011; McCarthy, 2011). For some women, hyperemesis can be an indication for elective termination (Poursharif, 2007).

In the small percentage of women who continue to have recalcitrant vomiting after intensive therapy, consideration is given for *enteral nutrition* (Upper Gastrointestinal Tract Disorders). Stokke and associates (2015) described successful use of nasojejunal feeding for up to 41 days in 107 such women. Use of sonography to confirm correct placement of the tube has been described (Swartzlander, 2013). Percutaneous endoscopic gastrostomy with a jejunal port has also been reported (Saha, 2009; Schrag, 2007). A randomized trial failed to show any advantages from early enteral feeding (Grooten, 2017).

In our experiences, only a very few women will require *parenteral nutrition* (Yost, 2003). In a study of 599 women, however, Peled and coworkers (2014) reported that 20 percent required central venous access to be established for nutrition.

Gastroesophageal Reflux Disease

Symptomatic reflux is seen in up to 15 percent of nonpregnant individuals (Kahrilas, 2015). The spectrum of sequelae includes esophagitis, stricture, Barrett esophagus, and adenocarcinoma. The main symptom of reflux is heartburn, or *pyrosis*, which is especially common in pregnancy. Its prevalence rose from 26 percent in the first trimester to 36 percent in the second and 51 percent in the third trimesters (Malfertheiner, 2012). The retrosternal burning sensation stems from esophagitis caused by gastroesophageal reflux related to relaxation of the lower esophageal sphincter.

Reflux symptoms usually respond to tobacco and alcohol abstinence, small meals, head of the bed elevation, and avoidance of postprandial recumbency. So-called “trigger” foods are also avoided and usually include fatty foods, tomato-based foods, and coffee. Oral antacids are first-line therapy. If severe symptoms persist, sucralfate (Carafate) is given along with a proton-pump inhibitor or an H_2-receptor antagonist (see Table 54-3). Both classes are generally safe for use in pregnancy (Briggs, 2015; Mahadevan, 2006b). Of these, a 1-g sucralfate tablet is taken orally 1 hour before each of the three meals and at bedtime for up to 8 weeks. Antacids are not used within ½ hour before or after sucralfate doses. If relief is not attained, then endoscopy should be considered. *Misoprostol* is contraindicated because it stimulates labor (Chap. 26, Methods of Induction and Augmentation).

In nonpregnant patients, surgical fundoplication is performed (Kahrilas, 2015). Although the procedure is not done during pregnancy, Biertho and colleagues (2006) described 25 women who had undergone laparoscopic Nissen fundoplication before pregnancy. Only 20 percent had reflux symptoms during pregnancy.

Hiatal Hernia

The older literature is informative regarding hiatal hernias in pregnancy. Upper gastrointestinal radiographs performed in 195 women in late pregnancy showed that 20 percent of 116 multiparas and 5 percent of 79 nulliparas had a hiatal hernia (Rigler, 1935). Of 10 women studied postpartum, hernia persisted in three at 1 to 18 months.

The relationship of hiatal hernia with reflux esophagitis, and thus symptoms, is not clear. One study demonstrated no relationship between reflux and hernia and showed that the lower esophageal sphincter functioned effectively even when displaced intrathoracically (Cohen, 1971). Nevertheless, during pregnancy, these hiatal hernias may cause vomiting, epigastric pain, and bleeding from ulceration. Schwentner (2011) reported severe herniation requiring surgical repair in a woman with a 12-week gestation. Curran and coworkers (1999) described a 30-week pregnancy complicated by gastric outlet obstruction from a paraesophageal hernia.

Diaphragmatic Hernia

These are caused by herniations of abdominal contents through either the foramen of Bochdalek or Morgagni. Fortunately, they rarely complicate pregnancy. Kurzel and associates (1988) reviewed the outcomes of 18 pregnant women with such a hernia and who developed acute obstruction. Because the maternal mortality rate was 45 percent, they recommend repair during pregnancy even if a woman is asymptomatic. Herniation has been reported in one pregnant woman from a previous traumatic diaphragmatic defect and in another who had antireflux surgery in early pregnancy (Brygger, 2013; Flick, 1999). Several case reports also describe spontaneous diaphragmatic rupture from increased intraabdominal pressure during delivery (Chen, 2012; Sharifah, 2003).

Achalasia

This is a rare motility disorder in which the lower esophageal sphincter does not relax properly with swallowing. There is also nonperistaltic contraction activity of the esophageal muscularis to cause symptoms (Kahrilas, 2015; Khudyak, 2006). The defect is caused by inflammatory destruction of the myenteric (Auerbach) plexus within smooth muscle of the lower esophagus and its sphincter. Postganglionic cholinergic neurons are unaffected, thus,

sphincter stimulation is unopposed. Symptoms are dysphagia, chest pain, and regurgitation. Barium swallow radiography demonstrates *bird beak* or *ace of spades* narrowing at the distal esophagus. Endoscopy is performed to exclude gastric carcinoma, and manometry is confirmatory. If dilatation of the esophagus and medical therapy does not provide relief, myotomy is considered (Torquati, 2006).

During pregnancy, normal relaxation of the lower esophageal sphincter in women with achalasia theoretically should not occur. Even so, in most women, pregnancy does not seem to worsen achalasia. One report of 20 affected pregnant women found no excessive reflux esophagitis (Mayberry, 1987). Khudyak and coworkers (2006) reviewed 35 cases and described most women as symptom free, although esophageal dilatation was needed in a few. A maternal death was reported at 24 weeks' gestation associated with perforation of a 14-cm diameter megaesophagus (Fassina, 1995).

Management of achalasia includes soft diet and anticholinergic drugs. With persistent symptoms, other options include nitrates, calcium-channel antagonists, and botulinum toxin A injected locally (Hooft, 2015; Kahrilas, 2015). Balloon dilatation of the sphincter may be necessary, and 85 percent of nonpregnant patients respond to this. Satin (1992) and Fiest (1993) and their associates reported successful use of pneumatic dilatation in pregnancy. *One caveat is that esophageal perforation is a serious complication of dilatation.* Spiliopoulos and colleagues (2013) described a 29-week pregnant woman with achalasia treated for 10 weeks with parenteral nutrition. Surgical correction was performed postpartum.

Peptic Ulcer Disease

The lifetime prevalence of acid peptic disorders in women is 10 percent (Del Valle, 2015). Erosive ulcer disease involves the stomach and duodenum. Gastroduodenal ulcers may be caused by chronic gastritis from *H pylori,* or they develop from nonsteroidal antiinflammatory drug (NSAID) use. Neither is common in pregnancy (McKenna, 2003; Weyermann, 2003). Acid secretion is also important, and thus underlies the efficacy of antisecretory agents (Suerbaum, 2002). Gastroprotection during pregnancy probably originates from physiological changes that include reduced gastric acid secretion, decreased motility, and considerably increased mucus secretion (Hytten, 1991). Despite this, ulcer disease may be underdiagnosed because of frequent treatment for reflux esophagitis (Mehta, 2010). In the past 50 years at Parkland Hospital, during which time we have cared for more than 500,000 pregnant women, we have encountered very few who had proven ulcer disease. Perforation is rare (Goel, 2014). Before appropriate therapy was commonplace, Clark (1953) studied 313 pregnancies in 118 women with ulcer disease and noted a clear remission during pregnancy in almost 90 percent. However, benefits were short lived. Symptoms recurred in more than half by 3 months postpartum and in almost all by 2 years.

The mainstay of management is eradication of *H pylori* and prevention of NSAID-induced disease. Antacids are usually self-prescribed, but first-line therapy is with H_2-receptor blockers or proton-pump inhibitors (Del Valle, 2015). *Sucralfate* is the aluminum salt of sulfated sucrose that inhibits pepsin. It provides a protective coating at the ulcer base. Approximately 10 percent of the aluminum salt is absorbed, and it is considered safe for pregnant women (Briggs, 2015).

With active ulcers, a search for *H pylori* is undertaken. Diagnostic aids include the urea breath test, serological testing, or endoscopic biopsy. If any of these yield positive results, combination antimicrobial and proton-pump inhibitor therapy is indicated. Several effective oral treatment regimens do not include tetracycline and can be used during pregnancy. These 14-day regimens include amoxicillin, 1000 mg twice daily plus clarithromycin, 250 to 500 mg twice daily, plus metronidazole, 500 mg twice daily given along with the proton-pump inhibitor omeprazole (Del Valle, 2015).

Upper Gastrointestinal Bleeding

In some women, persistent vomiting is accompanied by worrisome upper gastrointestinal bleeding. Occasionally, a peptic ulceration is the source. However, most of these women have small linear mucosal tears near the gastroesophageal junction—*Mallory-Weiss tears*, described earlier. Bleeding usually responds promptly to conservative measures, including iced-saline irrigations, topical antacids, and intravenously administered H_2-blockers or proton-pump inhibitors. Transfusions may be needed, and if bleeding persists, then endoscopy is usually indicated (O'Mahony, 2007). With sustained retching, the less common, but more serious, esophageal rupture—*Boerhaave syndrome*—may develop from greatly increased esophageal pressure.

SMALL BOWEL AND COLON DISORDERS

The small bowel has diminished motility during pregnancy. Using a nonabsorbable carbohydrate, Lawson (1985) showed that small bowel mean transit times were 99, 125, and 137 minutes in each trimester, compared with 75 minutes when nonpregnant. In a study cited by Everson (1992), mean transit time for a mercury-filled balloon from the stomach to the cecum was 58 hours in term pregnant women compared with 52 hours in nonpregnant women.

Muscular relaxation of the colon is accompanied by increased absorption of water and sodium that predisposes to constipation. This complaint is reported by almost 40 percent of women at some time during pregnancy (Everson, 1992). Such symptoms are usually only mildly bothersome, and preventive measures include a high-fiber diet and bulk-forming laxatives. Wald (2003) has reviewed treatment options. We have encountered several pregnant women who developed megacolon from impacted stool. These women almost invariably had chronically abused stimulatory laxatives.

Acute Diarrhea

The estimated monthly prevalence of diarrhea among adults is 3 to 7 percent (DuPont, 2014). Diarrhea can be classified as acute (<2 weeks), persistent (2 to 4 weeks), and chronic (>4 weeks). Most cases of acute diarrhea are caused by infectious agents, and a third result from foodborne pathogens. The large variety of viruses, bacteria, helminths, and protozoa that cause diarrhea in adults inevitably also afflict pregnant women. Some of these are discussed in

Chapter 64. Evaluation of acute diarrhea depends on its severity and duration. Some indications for evaluation include profuse watery diarrhea with dehydration, grossly bloody stools, fever >38°C, duration >48 hours without improvement, recent antimicrobial use, and diarrhea in the immunocompromised patient (Camilleri, 2015; DuPont, 2014). Cases of moderately severe diarrhea with fecal leukocytes or gross blood may best be treated with empirical antibiotics rather than evaluation. Some features of the more common acute diarrheal syndromes and their treatment are shown in Table 54-4.

TABLE 54-4

Etiology, Clinical Features, and Treatment of Common Acute Diarrheal Syndromes

Agents	Incubation	Emesis	Pain	Fever	Diarrhea	Treatment
Toxin producers 1. *Staphylococcus* 2. *C perfringens* 3. *E coli* (*enterotoxin)* 4. *B cereus*	1–72 hr	3–4+	1–2+	0–1+	3–4+, watery	 1. None 2. None 3. Ciprofloxacin 4. None
Enteroadherent 1. *E coli* 2. *Giardia* 3. Helminths	1–8 days	0–1+	1–3+	0–2+	1–2+, watery, mushy	 1. Ciprofloxacin 2. Tinidazole 3. As detected
Cytotoxin producers 1. *C difficile* 2. *E coli* (hemorrhagic)	1–3 days	0–1+	3–4+	1–2+	1–3+, watery, then bloody	 1. Metronidazole 2. None
Inflammatory ***Minimal*** 1. *Rotavirus* 2. *Norovirus*	1–3 days	1–3+	2–3+	3–4+	1–3+, watery	 1. None 2. None
Variable 3. *Salmonella* 4. *Campylobacter* 5. *Vibrio*	1–11 days	0–3+	2–4+	3–4+	1–4+ watery or bloody	 3. Ciprofloxacin 4. Azithromycin 5. Doxycycline
Severe 6. *Shigella* 7. *E coli* 8. *Entamoeba histolytica*	1–8 days	0–1+	3–4+	3–4+	1–2+, bloody	 6. Ciprofloxacin 7. Ciprofloxacin 8. Metronidazole

B cereus = Bacillus cereus; C difficile = Clostridium difficile; C perfringens = Clostridium perfringens; E coli = Escherichia coli.

Data from Camilleri, 2015; DuPont, 2014.

The mainstay of treatment is intravenous hydration using normal saline or Ringer lactate with potassium supplementation in amounts to restore maternal blood volume and to ensure uteroplacental perfusion. Vital signs and urine output are monitored for signs of sepsis syndrome. For moderately severe nonfebrile illness without bloody diarrhea, antimobility agents such as loperamide (Imodium) may be useful. Bismuth subsalicylate (Pepto-Bismol) may also alleviate symptoms.

Judicious use of antimicrobial agents is warranted. For moderate to severely ill women, some recommend empirical treatment with ciprofloxacin, 500 mg twice daily for 3 to 5 days. Specific pathogens are treated as needed when identified (see Table 54-4). Syndromes for which treatment is usually unnecessary include those caused by *Escherichia coli*, staphylococcal species, *Bacillus cereus*, and Norwalk-like virus. Severe illness caused by *Salmonella* spp is treated with ciprofloxacin or trimethoprim-sulfamethoxazole; by *Campylobacter* spp with azithromycin; by *Clostridium difficile* with oral metronidazole or vancomycin; and by *Giardia* spp and *Entamoeba histolytica* with metronidazole (DuPont, 2014; Rocha-Castro, 2016).

***Clostridium Difficile* Infection**

This anaerobic gram-positive bacillus is transmitted by the fecal-oral route. It is the most frequent nosocomial infection in the United States. In 2011, 453,000 cases of *C difficile* and 29,000 associated deaths were reported by the Centers for Disease Control and Prevention (CDC) (Lessa, 2015). The most important risk factor is antibiotic use, and the highest risk is with aminopenicillins, clindamycin, cephalosporins, and fluoroquinolones. Other risk factors include inflammatory bowel disease, immunosuppression, advanced age, and gastrointestinal surgery. Most cases are hospital-acquired, however, community-acquired cases are becoming common (Leffler, 2015). With severe colitis, the infection-related mortality rate is 5 percent.

Diagnosis is by enzyme immunoassay for toxins in the stool, or by DNA-based tests that identify toxin genes. Only patients with diarrhea should be tested, and posttreatment testing is not recommended. Prevention is by soap-and-water hand washing, and infected individuals are isolated. Treatment is oral vancomycin or metronidazole. The risk of recurrence after an initial episode is 20 percent. Fecal microbial transplantation may become standard for recurrent clostridial colitis.

Inflammatory Bowel Disease

Two presumably noninfectious forms of intestinal inflammation are ulcerative colitis and Crohn disease. Differentiation between these is important because treatment differs. That said, they both share common features, and sometimes are indistinguishable if Crohn disease involves the colon. The salient clinical and laboratory features shown in Table 54-5 permit a reasonably confident diagnostic differentiation in most cases. The etiopathogenesis is enigmatic in both, but a genetic predisposition is suspected. Inflammation is thought to result from dysregulated mucosal immune function in response to commensal microbiota, with or without an autoimmune component (Friedman, 2015).

TABLE 54-5

Some Shared and Differentiating Characteristics of Inflammatory Bowel Disease

	Ulcerative Colitis	Crohn Disease
Shared Characteristics		
Hereditary	More than 100 disease-associated genetic loci–a third shared; Jewish predominance; familial in 5–10% of cases; Turner syndrome; immune dysregulation	
Other	Chronic and intermittent with exacerbations and remissions; extraintestinal manifestations: arthritis, erythema nodosum, uveitis	
Differentiating Characteristics		
Major symptoms	Diarrhea, tenesmus, rectal bleeding, cramping pain; chronic, intermittent	Fibrostenotic–recurrent RLQ colicky pain; fever Fistulizing–cutaneous, bladder, interenteric
Bowel involvement	Mucosa and submucosa of large bowel; usually begins at rectum (40% proctitis only); continuous disease	Deep layers small and large bowel; commonly transmural; discontinuous involvement; strictures and fistulas
Endoscopy	Granular and friable erythematous mucosa; rectal involvement	Patchy; rectum spared; perianal involvement
Serum antibodies	Antineutrophil cytoplasmic (pANCA) ~70%	Anti-*S cerevisiae* ~50%
Complications	Toxic megacolon; strictures; arthritis; cancer (3–5%)	Fistulas; arthritis; toxic megacolon
Management	Medical; proctocolectomy curative	Medical; segmental and fistula resection

RLQ = right lower quadrant; *S cerevisiae* = Saccharomyces cerevisiae.

Data from Friedman, 2015; Lichtenstein, 2009; Podolsky, 2002.

Ulcerative Colitis

This is a mucosal disorder with inflammation confined to the superficial luminal layers of the colon. It typically begins at the rectum and extends proximally for a variable distance. In approximately 40 percent of cases, disease is confined to the rectum and rectosigmoid, but 20 percent have pancolitis. For unknown reasons, prior appendectomy protects against development of ulcerative colitis (Friedman, 2015). Endoscopic findings include mucosal granularity and friability that is interspersed with mucosal ulcerations and a mucopurulent exudate (Fig. 54-2).

FIGURE 54-2

Causes of colitis. **A.** Chronic ulcerative colitis with diffuse ulcerations and exudates. **B.** Crohn colitis with deep ulcers. (Reproduced with permission from Song LM, Topazian M: Gastointestinal endoscopy. Kasper DL, Fauci AS, Hauser SL, et al (eds): Harrison's Principles of Internal Medicine, 19th ed. New York: McGraw-Hill Education; 2015.)

Major symptoms of ulcerative colitis include diarrhea, rectal bleeding, tenesmus, and abdominal cramps. The disease can be acute or intermittent and is characterized by exacerbations and remissions. *Toxic megacolon* and catastrophic hemorrhage are particularly dangerous complications that may necessitate colectomy. *Extraintestinal manifestations* include arthritis, uveitis, and erythema nodosum. Another serious problem is that the risk of colon cancer approaches 1 percent per year. With either ulcerative colitis or Crohn disease, there is also concern for possible increased risks for venous thromboembolism (Kappelman, 2011; Novacek, 2010).

Crohn Disease

Also known as regional enteritis, Crohn ileitis, and granulomatous colitis, Crohn disease has more protean manifestations than ulcerative colitis. It involves not only the bowel mucosa but also the deeper layers, and sometimes involvement is transmural (see Fig. 54-2). Lesions can be seen throughout the entire gastrointestinal tract, from the mouth to the anus, but it typically is segmental (Friedman, 2015). Approximately 30 percent of patients have small-bowel involvement, 25 percent have isolated colonic involvement, and 40 percent have both, usually with the terminal ileum and colon involved. Perianal fistulas and abscesses develop in a third of those with colonic involvement.

Symptoms depend on which bowel segment(s) is involved. Thus, complaints may include lower-right-sided cramping abdominal pain, diarrhea, weight loss, low-grade fever, and obstructive symptoms. The disease is chronic with exacerbations and remissions, and importantly, it cannot be cured medically or surgically. Approximately a third of patients require surgery within the first year after diagnosis, and thereafter, 5 percent per year. Reactive arthritis is common, and the gastrointestinal cancer risk, although not as great as with ulcerative colitis, is increased substantially.

Inflammatory Bowel Disease and Fertility

Subfertility is commonly linked to chronic medical disease, but Mahadevan (2006a) cited a normal fertility rate for inflammatory bowel disease unless severe disease warranted surgery. Similarly, Alstead (2003) reported that decreased female fertility from active Crohn disease returned to normal with remission. For women requiring surgical resection, laparoscopic anastomosis has a higher subsequent fertility rate (Beyer-Berjot, 2013). With colectomy, however, even though fertility is improved, up to half of women will be persistently infertile (Bartels, 2012). Sexual function and fertility are only modestly affected by ileal pouch-anal anastomosis (Hor, 2016). Subfertility may also be partially due to sulfasalazine, which causes reversible sperm abnormalities (Feagins, 2009).

Inflammatory Bowel Disease and Pregnancy

Because ulcerative colitis and Crohn disease are relatively common in young women, they are encountered with some frequency in pregnancy. In this regard, a few generalizations can be made. First, consensus supports that pregnancy does not increase the likelihood of an inflammatory bowel disease flare (Mahadevan, 2015). Indeed, in a 10-year surveillance of women in the European Collaborative on Inflammatory Bowel Disease, the likelihood of a flare during pregnancy was decreased compared with the preconceptional rate (Riis, 2006). Although most women with quiescent disease in early pregnancy do not have relapses, when a flare develops, it may be severe. Also, active disease in early pregnancy increases the likelihood of poor pregnancy outcome, which is discussed subsequently. In general, most usual treatment regimens may be continued during pregnancy. Diagnostic evaluations should be undertaken if needed to direct management, and surgery should be performed if indicated. For women who successfully complete pregnancy, about half experience improvement in their health-related quality of life (Ananthakrishnan, 2012).

At first glance, it appears that adverse pregnancy outcomes are increased with inflammatory bowel disease (Boyd, 2015; Cornish, 2012; Getahun, 2014). Initially, this was attributed to the fact that most studies included women with either form of disease. Specifically, Crohn disease was noted to be linked to excessive morbidity (Dominitz, 2002; Stephansson, 2010). But, according to Reddy (2008) and others, these adverse outcomes were in women with severe disease and multiple recurrences. Indeed, in the prospective European case-control *ECCO-EpiCom study* of 332 pregnant women with inflammatory bowel

disease, Bortoli and coworkers (2011) found similar outcomes in women with ulcerative colitis or Crohn disease compared with normally pregnant women. Importantly, perinatal mortality rates are not appreciably increased.

Ulcerative Colitis and Pregnancy

Ulcerative colitis does not significantly alter the course of pregnancy in affected women. In one review of 755 pregnancies, colitis that was quiescent at conception worsened in approximately a third of pregnancies (Fonager, 1998). In women with active disease at the time of conception, approximately 45 percent worsened, 25 percent remained unchanged, and only 25 percent improved. These observations are similar to those previously described in an extensive review by Miller (1986) and a later report from Oron and colleagues (2012).

Osteoporosis is a significant complication in up to a third of these women, and thus vitamin D—800 IU daily—and calcium—1200 mg daily—are given. Folic acid, 4 mg orally daily, is recommended preconceptionally and during the first trimester for neural-tube defect prevention. This high dose counteracts the antifolate actions of sulfasalazine. Flares may be caused by psychogenic stress, and reassurance is important.

Management for colitis for the most part mirrors that outside of pregnancy. Treatment of active colitis and maintenance therapy incorporate drugs that deliver 5-aminosalicyclic acid (5-ASA) or mesalamine. *Sulfasalazine (Azulfidine*) is the prototype, and its 5-ASA moiety inhibits prostaglandin synthase in colonic mucosa. Others include *olsalazine (Dipentum), balsalazide (Colazal),* and delayed-release 5-ASA derivatives *(Apriso, Asacol, Pentasa, Lialda).* Glucocorticoids are given orally, parenterally, or by enema for moderate or severe disease that does not respond to 5-ASA. However, these latter drugs are not given for maintenance therapy. Recalcitrant disease is managed with immunomodulating drugs, including *azathioprine*, *6-mercaptopurine*, or *cyclosporine*, which appear relatively safe in pregnancy (Briggs, 2015; Mozaffari, 2015). Importantly, *methotrexate* is contraindicated in pregnancy.

In the past, biological therapy was reserved for recalcitrant moderate to severe disease. Because of their considerable efficacy, these medications are now frequently given *initially* for severe disease to prevent future complications. These agents are antibodies against tumor necrosis factor-alpha (TNF-alpha). Those approved for treatment of ulcerative colitis include *infliximab (Remicade)*, *adalimumab* (*Humira)*, and *golinumab (Simponi).* These drugs are administered intravenously or subcutaneously. Several studies indicate that they are safe for use in pregnancy, although there are concerns that their discontinuance may prompt a relapse (Torres, 2015). Another worry is that they may cause immunosuppression in the neonate (Bröms, 2016; Diav-Citrin, 2014; Gisbert, 2013).

Colorectal endoscopy is performed as indicated (Katz, 2002). During pregnancy, colectomy and ostomy creation for fulminant colitis may be needed as a lifesaving measure, and it has been described during each trimester. Dozois (2006) reviewed 42 such cases and found that, in general, outcomes have been good in recent reports. Most women underwent partial or complete colectomy, but Ooi and colleagues (2003) described decompression colostomy with ileostomy in a 10- and a 16-week pregnancy. Parenteral nutrition discussed in Upper Gastrointestinal Tract Disorders is occasionally necessary for women with prolonged exacerbations.

For women with an ileal pouch and an anal anastomosis performed before pregnancy, sexual function and fertility are improved (Cornish, 2007). Disadvantages that temporarily worsen in pregnancy include frequent bowel movements, fecal incontinence, and pouchitis. The last is an inflammatory condition of the ileoanal pouch probably due to bacterial proliferation and stasis. Pouchitis usually responds to cephalosporins or metronidazole. In one rare case, adhesions to the growing uterus led to ileal pouch perforation (Aouthmany, 2004).

Women who have had a prior proctocolectomy and ileal pouch–anal anastomosis can be safely delivered vaginally (Ravid, 2002). Hahnloser (2004) reviewed routes of delivery in women with 235 pregnancies before and 232 pregnancies after ileoanal pouch surgery. Functional outcomes were similar, and it was concluded that cesarean delivery should be reserved for obstetrical indications. Postcesarean delivery ileoanal pouch obstruction has been described (Malecki, 2010).

To reiterate, ulcerative colitis likely has minimal adverse effects on pregnancy outcome. Modigliani (2000) reviewed perinatal outcomes in 2398 pregnancies and reported them to be not substantively different from those in the general obstetrical population. Specifically, the incidences of spontaneous abortion, preterm delivery, and stillbirth were remarkably low. In a population-based cohort study of 107 women from Washington state, perinatal outcomes, with two exceptions, were similar to those of 1308 normal pregnancies (Dominitz, 2002). One exception was an inexplicably increased incidence of congenital malformations. These authors and others also describe a cesarean delivery rate that was substantially increased compared with that for normal controls (Mahadevan, 2015). The previously described ECCO-EpiCom study reported similar outcomes in 187 gravidas with ulcerative colitis compared with normal pregnant controls (Bortoli, 2011).

Crohn Disease and Pregnancy

In general, Crohn disease activity during pregnancy is related to its status around the time of conception. In a cohort study of 279 pregnancies in 186 women whose disease was inactive at conception, a fourth relapsed during pregnancy (Fonager, 1998). In 93 with active disease at conception, however, two thirds either remained active or worsened. Miller (1986) had described similar findings from his earlier review, as did Oron and associates (2012).

Calcium, vitamin D, and folic acid supplementation mirror that for ulcerative colitis. For maintenance during asymptomatic periods, no regimen is universally effective. *Sulfasalazine* is effective for some, but the newer 5-ASA formulations are better tolerated. *Prednisone* therapy may control moderate to severe flares but is less effective for small-bowel involvement. Immunomodulators such as *azathioprine*, *6-mercaptopurine*, and *cyclosporine* are used for active disease and for maintenance. These appear relatively safe during pregnancy (Briggs, 2015; Chande, 2015). As discussed in Chapter 12 (Antimicrobial Drugs and Immunosuppressant Medications), methotrexate, mycophenolate mofetil, and mycophenolic acid are contraindicated in pregnancy (Briggs, 2015; Food and Drug Administration, 2008).

As with ulcerative colitis, treatment with antitumor necrosis factor monoclonal antibodies is often used initially for active Crohn disease and maintenance (Casanova, 2013; Cominelli, 2013; Friedman, 2015). These biological compounds include *infliximab*, *adalimumab*, *certolizumab (Cimzia)*, *natalizumab (Tysabri),* and *vedolizumab (Entyvio).* As discussed in Inflammatory Bowel Disease and Fertility, this class of immunomodulators is considered safe in pregnancy (Briggs, 2015; Clowse, 2015). Their discontinuance may be followed by a relapse (Torres, 2015).

Endoscopy or conservative surgery is indicated for complications. Patients with small-bowel involvement are more likely to require surgery for complications that include fistulas, strictures, abscesses, and intractable disease. An abdominal surgical procedure was required during 5 percent of pregnancies described by Woolfson (1990). Parenteral hyperalimentation has been used successfully during severe recurrences (Russo-Stieglitz, 1999). Those with an ileal loop colostomy may have significant problems. Women with a perianal fistula—unless these are rectovaginal—usually can undergo vaginal delivery without complications (Forsnes, 1999; Takahashi, 2007).

As discussed, the likelihood is greater that Crohn disease is associated with adverse pregnancy outcomes compared with ulcerative colitis (Stephansson, 2010). Outcomes are probably related to disease activities. In a case-control Danish study, Norgård (2007) reported a twofold risk of preterm births. Dominitz (2002) reported a two- to threefold increased risk for preterm delivery, low birthweight, fetal growth restriction, and cesarean delivery in 149 women with Crohn disease. Recall, however, that the prospective ECCO-EpiCom study found outcomes to be similar to those for normal pregnancies.

Ostomy and Pregnancy

A colostomy or an ileostomy can be problematic during pregnancy because of its location (Hux, 2010). In a report of 82 pregnancies in 66 women with an ostomy, *stomal dysfunction* was common, but it responded to conservative management in most cases (Gopal, 1985). Surgical intervention was necessary, however, in three of six women who developed *bowel obstruction* and in another four with *ileostomy prolapse*—almost 10 percent overall. In this older study, only a third of 82 women underwent cesarean delivery, but Takahashi (2007) described six of seven cesarean deliveries in women with Crohn disease and a stoma. Although adhesions usually are involved with an obstructed ileostomy, the enlarging uterus may act to obstruct (Porter, 2014). Finally, Farouk and coworkers (2000) reported that pregnancy did not worsen long-term ostomy function.

Intestinal Obstruction

The incidence of bowel obstruction is not increased during pregnancy, although it generally is more difficult to diagnose. Meyerson (1995) reported a 20-year incidence of 1 in 17,000 deliveries at two Detroit hospitals. In one study, adhesive disease leading to small-bowel obstruction was the second most common cause of an acute abdomen in pregnancy following appendicitis—15 versus 30 percent, respectively (Unal, 2011). Approximately half of cases are due to adhesions from previous pelvic surgery that includes cesarean delivery (Al-Sunaidi, 2006; Andolf, 2010; Lyell, 2011). Another 25 percent of bowel obstruction cases are caused by volvulus—sigmoid, cecal, or small bowel. These have been reported in late pregnancy or early puerperium (Bade, 2014; Biswas, 2006; Al Maksoud, 2015). Small-bowel obstruction has been reported in pregnancy following the currently popular Roux-en-Y gastric bypass for weight loss (Bokslag, 2014; Wax, 2013). Intussusception is occasionally encountered (Bosman, 2014; Harma, 2011). Bowel obstruction subsequent to colorectal surgery for cancer was increased threefold in women who had open versus laparoscopic surgery (Haggar, 2013). Finally, Serra and colleagues (2014) described a massive ventral hernia with intestinal obstruction.

Most cases of intestinal obstruction during pregnancy result from pressure of the growing uterus on intestinal adhesions. According to Davis and Bohon (1983), this more likely occurs around midpregnancy when the uterus becomes an abdominal organ; in the third trimester when the fetal head descends; or immediately postpartum when uterine size acutely shrinks. Perdue (1992) reported that 98 percent of affected pregnant women had either continuous or colicky abdominal pain, and 80 percent had nausea and vomiting. Abdominal tenderness was found in 70 percent, and abnormal bowel sounds noted in only 55 percent. Plain abdominal radiographs following soluble contrast showed evidence of obstruction in 90 percent of women (Fig. 54-3). Plain radiographs, however, are less accurate for diagnosing small-bowel obstruction, and we and others have found that CT and MR imaging can be diagnostic (Biswas, 2006; Essilfie, 2007; McKenna, 2007). Colonoscopy can be both diagnostic and therapeutic for colonic volvulus (Dray, 2012; Khan, 2012).

FIGURE 54-3
Characteristic “bent inner tube” seen with sigmoid volvulus on abdominal radiograph. (Reproduced with permission from Song LM, Topazian M: Gastointestinal endoscopy. Kasper DL, Fauci AS, Hauser SL, et al (eds): Harrison’s Principles of Internal Medicine, 19th ed. New York: McGraw-Hill Education; 2015.)

During pregnancy, mortality rates with obstruction can be excessive because of difficult and thus delayed diagnosis, reluctance to operate during pregnancy, and the need for emergency surgery (Firstenberg, 1998; Shui, 2011). In an older report of 66 pregnancies, Perdue and associates (1992) described a 6-percent maternal mortality rate and 26-percent fetal mortality rate. Two of the four women who died were in late pregnancy, and they had bowel perforation from sigmoid or cecal volvulus caused by adhesions.

Colonic Pseudo-obstruction

Also known as *Ogilvie syndrome,* pseudo-obstruction is caused by adynamic colonic ileus. It is characterized by massive abdominal distention with cecal and right-hemicolon dilatation. Approximately 10 percent of all cases are associated with pregnancy, and its frequency has been reported as high as 1 in 1500 deliveries (Reeves, 2015). The syndrome usually develops postpartum—most commonly after cesarean delivery—but it has been reported antepartum (Tung, 2008). Rarely, the large bowel may rupture (Singh, 2005). Treatment with an intravenous infusion of neostigmine, 2 mg, usually results in prompt decompression (Song, 2015). In some cases, colonoscopic decompression is performed, and laparotomy is needed for perforation (De Giorgio, 2009; Rawlings, 2010).

Appendicitis

The lifetime incidence for appendicitis ranges from 7 to 10 percent (Flum, 2015). Thus, it is not surprising that an evaluation for possible appendicitis is relatively common during pregnancy. Theilen and colleagues (2015) studied 171 such women during a 5-year period, but only 12 women ultimately were found to have pathologically confirmed appendicitis. After clinical and imaging evaluation, the frequency of suspected appendicitis is much lower and that of confirmed appendicitis in more than 8 million women ranged from 1 in 1000 to 1 in 5500 births (Abbasi, 2014; Hée, 1999; Mazze, 1991).

It is repeatedly—and appropriately—emphasized that pregnancy makes the diagnosis of appendicitis more difficult. Nausea and vomiting accompany normal pregnancy, but also, as the uterus enlarges, the appendix commonly moves upward and outward from the right lower quadrant (Baer, 1932; Erkek, 2015; Pates, 2009). Another often-stated reason for late diagnosis is that some degree of leukocytosis accompanies normal pregnancy. For these and other reasons, pregnant women—especially those late in gestation—frequently do not have clinical findings “typical” for appendicitis. Thus, it commonly is confused with cholecystitis, labor, pyelonephritis, renal colic, placental abruption, or uterine leiomyoma degeneration.

Most reports indicate increasing morbidity and mortality rates with advancing gestational age. And as the appendix is progressively deflected upward by the growing uterus, omental containment of infection becomes increasingly unlikely. It is indisputable that appendiceal perforation is more common during later pregnancy (Abbasi, 2014). In the studies by Andersson (2001) and Ueberrueck (2004), the incidence of perforation was approximately 8, 12, and 20 percent in successive trimesters.

Diagnosis

Persistent abdominal pain and tenderness are the most reproducible findings. Right-lower quadrant pain is the most frequent, although pain migrates upward with appendiceal displacement (Mourad, 2000). For initial evaluation, sonographic abdominal imaging is reasonable in suspected appendicitis, even if to exclude an obstetrical cause of pain (Butala, 2010). That said, *graded compression sonography* is difficult because of cecal displacement and uterine imposition (Pedrosa, 2009). *Appendiceal computed tomography* is more sensitive and accurate than sonography to confirm suspected appendicitis (Katz, 2012; Raman, 2008). Specific views can be designed to diminish fetal radiation exposure (Chap. 46, Computed Tomography). It is generally accepted that when available, MR imaging is the preferred modality for evaluation of suspected appendicitis in pregnancy (Fig. 54-4). MR imaging has high diagnostic yield and accuracy, and it also provides alternative diagnoses (Fonseca, 2014; Theilen, 2015). One metaanalysis cited positive- and negative-predictive values for MR imaging of 90 and 99.5 percent, respectively (Blumenfeld, 2011). Burke and associates (2015) reported similar findings. Using a decision-analysis model, CT and MR imaging were found to be cost effective (Kastenberg, 2013). This was verified in the clinical study of more than 7000 cases reported by Fonseca and coworkers (2014).

FIGURE 54-4
Anterior-posterior magnetic resonance image of a periappendiceal abscess in a midtrimester pregnancy. The abscess is approximately 5 × 6 cm, and the appendiceal lumen (*arrow*) is visible within the right-lower quadrant mass. The gravid uterus is seen to the right of this mass.

Management

When appendicitis is suspected, treatment is prompt surgical exploration. Although diagnostic errors may lead to removal of a normal appendix, surgical evaluation is preferable to postponed intervention and generalized peritonitis (Abbasi, 2014). In earlier reports, the diagnosis was verified in only 60 to 70 percent of pregnant women. As indicated above, however, with CT and MR imaging, these figures have improved (Blumenfeld, 2011; Theilen, 2015). Still and importantly, the accuracy of diagnosis is inversely proportional to gestational age.

Currently, laparoscopy is almost always used to treat suspected appendicitis during the first two trimesters. In a report from a Swedish database of nearly 2000 laparoscopic appendectomies, perinatal outcomes were similar to those of more than 1500 open laparotomies done before 20 weeks' gestation (Reedy, 1997). Conversely, in their review, Wilasrusmee and coworkers (2012) reported a higher rate of fetal loss with laparoscopy. Authors of a more recent systematic review indicate that the level of evidence is not strong enough to demonstrate a preferred approach to appendectomy. They concede that laparoscopy may be associated with a higher risk of miscarriage (Walker, 2014). It has evolved that in many centers, laparoscopic appendectomy is also performed in most cases during the third trimester (Donkervoort, 2011). This is encouraged by the Society of American Gastrointestinal and Endoscopic Surgeons (Pearl, 2017; Soper, 2011). That said, most are of the opinion that laparoscopic surgery in pregnancy after 26 weeks' gestation should be performed only by the most experienced endoscopic surgeons (Parangi, 2007).

Before exploration, intravenous antimicrobial therapy is begun, usually with a second-generation cephalosporin or third-generation penicillin. Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can usually be discontinued after surgery. Without generalized peritonitis, the prognosis is excellent. Seldom is cesarean delivery indicated at the time of appendectomy. Uterine contractions are common, and although some clinicians recommend tocolytic agents, we do not. De Veciana (1994) reported that tocolytic use substantially increased the risk for pulmonary-permeability edema caused by sepsis syndrome (Chap. 47, Acute Pulmonary Edema).

Antimicrobial versus Surgical Treatment

Because of European studies, some have advocated that many cases of appendicitis can be treated successfully with intravenous antimicrobials alone (Flum, 2015; Joo, 2017). At this time, we discourage this practice until appropriate studies have been done with pregnant women. In one study, 6 percent of pregnant women with appendicitis were treated medically, and these gravidas had "considerably" elevated risks for septic shock, peritonitis, and venous thromboembolism compared with surgically managed cases (Abbasi, 2014).

Pregnancy Outcomes

Appendicitis increases the likelihood of abortion or preterm labor, especially if peritonitis has developed. In two studies, spontaneous labor after 23 weeks ensued with greater frequency following surgery for appendicitis compared with surgery for other indications (Cohen-Kerem, 2005; Mazze, 1991). In one study, the fetal loss rate was 22 percent if surgery was performed after 23 weeks' gestation. Two large population-based studies attest to the adverse outcomes from appendicitis in pregnancy. From the California Inpatient File of 3133 pregnant women undergoing surgery for suspected appendicitis, the fetal loss rate was 23 percent, and it was doubled—6 versus 11 percent—with simple versus complicated disease (McGory, 2007). A nationwide study from Taiwan found that risks for low birthweight and preterm delivery rose 1.5- to 2-fold when outcomes in 908 women with acute appendicitis were compared with those of controls (Wei, 2012).

Long-term complications are not common. The possible link between sepsis and neonatal neurological injury has not been verified (Mays, 1995). Finally, appendicitis during pregnancy does not appear to be associated with subsequent infertility (Viktrup, 1998).

CHAPTER 55: Hepatic, Biliary, and Pancreatic Disorders

Pregnancy is comparatively seldom complicated by jaundice. Notwithstanding the fact that in most cases the jaundice disappears without treatment, too favorable a prognosis should not be ventured, for the reason that now and again the condition may represent the initial symptom of acute yellow atrophy of the liver.

—J. Whitridge Williams (1903)

INTRODUCTION

Even though Williams only mentions acute hepatic fatty metamorphosis, in practice, disorders of the liver, gallbladder, and pancreas together comprise a formidable list of complications that may arise in pregnancy. Some stem from preexisting conditions and some are unique to gestation. The relationships of several of these with pregnancy can be fascinating, intriguing, and challenging.

HEPATIC DISORDERS

Customarily, liver diseases complicating pregnancy are placed into three general categories. The first includes those specifically related to pregnancy that resolve either spontaneously or following delivery. Examples are intrahepatic cholestasis and acute fatty liver, both discussed in the next sections. Also, hepatic dysfunction from hyperemesis gravidarum may involve the liver. Mild hyperbilirubinemia with elevated serum transaminase levels is seen in up to half of affected women requiring hospitalization. However, these levels seldom exceed 200 U/L (Table 55-1). Liver biopsy may show minimal fatty changes. Hyperemesis gravidarum is discussed in detail in Chapter 54 (Upper Gastrointestinal Tract Disorders). Another in this first category is hepatocellular damage with preeclampsia—the *HELLP syndrome*—which is characterized by hemolysis, elevated serum liver enzyme levels, and low platelet counts. These changes are discussed in detail in Chapter 40 (Liver).

TABLE 55-1

Clinical and Laboratory Findings with Acute Liver Diseases in Pregnancy

			Hepatic		Renal	Hematological and Coagulation					
Disorder	**Onset in Pregnancy**	**Clinical Findings**	**AST (U/L)**	**Bili (mg/dL)**	**Cr (mg/dL)**	**Hct**	**Plat**	**Fib**	**DD**	**PT**	**Hemolysis**
Hyperemesis	Early	Severe N&V	NL–300	NL–4	↑	↑↑	NL	NL	NL	NL	No
Cholestasis	Late	Pruritus, jaundice	NL–200	1–5	NL	NL	NL	NL	NL	NL	No
Fatty liver	Late	Moderate N&V, ± HTN, liver failure	200–800	4–10	↑↑↑	↑↑↑	↓↓	↓↓↓	↑	↑↑	↑↑↑
Preeclampsia	Mid to late	HA, HTN	NL–300	1–4	↑	↑	↓↓	NL	↑	NL	↑–↑↑
Hepatitis	Variable	Jaundice	2000+	5–20	NL	↑	↓	NL	NL	↑	No

↑ = increased levels; ↓ = decreased levels; AST = aspartate transaminase; Bili = bilirubin; Cr = creatinine; DD = d-dimers; Fib = fibrinogen; HA = headache; Hct = hematocrit; HTN = hypertension; N&V = nausea and vomiting; NL = normal; Plat = platelets; PT = prothrombin time.

The second category involves acute hepatic disorders that are coincidental to pregnancy, such as acute viral hepatitis. The third category includes chronic liver diseases that predate pregnancy, such as chronic hepatitis, cirrhosis, or esophageal varices.

Importantly, several normal pregnancy-induced physiological changes induce appreciable liver-related clinical and laboratory manifestations (Chap. 4, Gastrointestinal Tract, and Appendix, Serum and Blood Constituents). Findings such as elevated serum alkaline phosphatase levels, palmar erythema, and spider angiomas, which might suggest liver disease, are common during normal pregnancy. Metabolism is also affected, due to altered expression of the cytochrome P450 system. This alteration is mediated by higher levels of estrogen, progesterone, and other pregnancy hormones. For example, hepatic CYP1A2 expression declines, whereas that of CYP2D6 and CYP3A4 rises. Importantly, cytochrome enzymes are expressed in many organs besides the liver, most notably the placenta. The net effect is complex and likely influenced by gestational age and organ of expression (Isoherranen, 2013). Despite all of these functional changes, no major hepatic histological changes are induced by normal pregnancy.

Intrahepatic Cholestasis of Pregnancy

This condition has been called recurrent jaundice of pregnancy, cholestatic hepatosis, and icterus gravidarum and is characterized by pruritus, icterus, or both. It may be more common in multifetal pregnancy, and there is a significant genetic influence (Lausman, 2008; Webb, 2014). Because of this, its incidence varies by population. For example, cholestasis is infrequent in North America, with an overall incidence approximating 1 case in 500 to 1000 pregnancies. But, its rate nears 5.6 percent among Latina women in Los Angeles (Lee, 2006). Historically, indigenous women from Chile and Bolivia also have a relatively high incidence. For unknown reasons, this incidence has declined since the 1970s and is now less than 2 percent (Reyes, 2016). In other countries, for example Sweden, China, and Israel, the incidence varies from 0.25 to 1.5 percent (Glantz, 2004; Luo, 2015; Sheiner, 2006).

Pathogenesis

The cause of obstetrical cholestasis is unclear, but changes in various sex steroid levels are implicated. However, current research focuses on the numerous mutations in the many genes that control hepatocellular transport systems. Examples include mutations of the *ABCB4* gene, which encodes multidrug resistance protein 3 (MDR3) associated with *progressive familial intrahepatic cholestasis,* and errors of the *ABCB11* gene, which encodes a bile-salt export pump (Anzivino, 2013; Dixon, 2014). Other potential gene products are the farnesoid X receptor and transporting ATPase encoded by *ATP8B1* (Abu-Hayyeh, 2016; Davit-Spraul, 2012). Some drugs that similarly decrease canalicular transport of bile acids aggravate the disorder. We have encountered impressive cholestatic jaundice in gravidas taking azathioprine following renal transplantation.

Whatever the inciting cause(s), bile acids are cleared incompletely and accumulate in plasma. Hyperbilirubinemia results from retention of conjugated pigment, but total plasma concentrations rarely exceed 4 to 5 mg/dL. Alkaline phosphatase levels are usually elevated even more than in normal pregnancy. Serum transaminase levels are normal to moderately elevated but seldom exceed 250 U/L (see Table 55-1). Liver biopsy shows mild cholestasis with bile plugs in the hepatocytes and canaliculi of the centrilobular regions, but without inflammation or necrosis. These changes disappear after delivery but often recur in subsequent pregnancies or with estrogen-containing contraceptives.

Clinical Presentation

Pruritus develops in late pregnancy, although it occasionally manifests earlier. Constitutional symptoms are absent, and generalized pruritus shows predilection for the soles. Skin changes are limited to excoriations from scratching. Biochemical tests may be abnormal at presentation, but pruritus may precede laboratory findings by several weeks. Approximately 10 percent of women have jaundice.

With normal liver enzymes, the differential diagnosis of pruritus includes other skin disorders (Table 62-1). Findings are unlikely to stem from preeclamptic liver disease if blood pressure elevation or proteinuria is absent. Sonography may be warranted to exclude cholelithiasis and biliary obstruction. Moreover, *acute viral hepatitis* is an unlikely diagnosis because of the usually low serum transaminase levels seen with cholestasis. Conversely, *chronic hepatitis C* is associated with a significantly increased risk of cholestasis, which may be as high as 20-fold among women who test positively for hepatitis C RNA (Marschall, 2013).

Management

Pruritus may be troublesome and is thought to result from elevated serum bile salt concentrations. *Antihistamines* and *topical emollients* may provide some relief. Although cholestyramine is reported to be effective, this compound also lowers absorption of fat-soluble vitamins, which may lead to vitamin K deficiency. Fetal coagulopathy with subsequent intracranial hemorrhage and stillbirth have been reported (Matos, 1997; Sadler, 1995).

A recent metaanalysis suggests that *ursodeoxycholic acid* relieves pruritus, lowers bile acid and serum enzyme levels, and may reduce certain neonatal complications. These include preterm birth, fetal distress, respiratory distress syndrome, and neonatal intensive care unit (NICU) admission (Bacq, 2012). Kondrackiene and associates (2005) randomly assigned 84 symptomatic women to receive either ursodeoxycholic acid (8 to 10 mg/kg/d) or cholestyramine. They reported superior relief with ursodeoxycholic acid—67 versus 19 percent, respectively. Similarly, Glantz and coworkers (2005) found superior benefits to women randomly assigned to ursodeoxycholic acid versus dexamethasone. The American College of Obstetricians and Gynecologists (2015) has concluded that ursodeoxycholic acid relieves pruritus and improves fetal outcomes, although evidence for the latter is not compelling.

Pregnancy Outcomes

Earlier reports describe excessive adverse pregnancy outcomes in women with cholestatic jaundice. That said, data accrued during the past two decades are ambiguous concerning increased perinatal mortality rates and whether close fetal surveillance is preventative. Several studies also illustrate this. In one

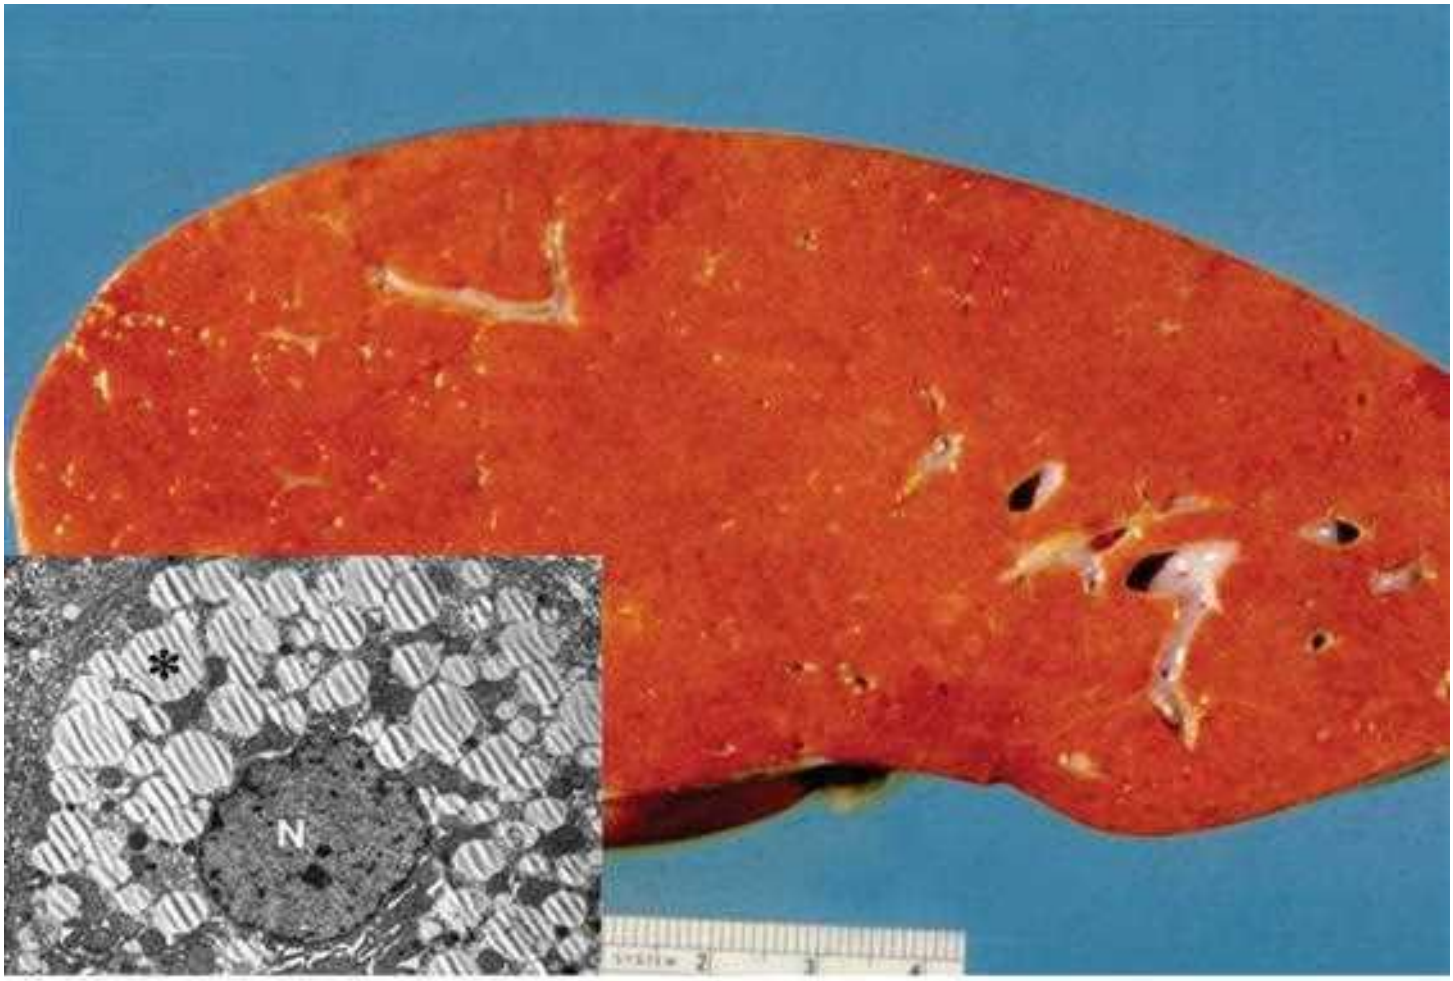
evaluation of 693 Swedish women, perinatal mortality rates were slightly increased, but only in mothers with severe disease (Glantz, 2004). Sheiner and coworkers (2006) described no differences in perinatal outcomes in 376 affected pregnancies compared with their overall obstetrical population. However, rates of labor induction and cesarean delivery in affected women significantly rose. Lee and associates (2009) described two cases of sudden fetal death not predicted by nonstress testing. In another study of 101 affected women, no term fetuses died, but 87 percent of women underwent labor induction, ostensibly to avoid adverse outcomes (Rook, 2012). Nonetheless, neonatal complications developed in a third of the pregnancies, particularly respiratory distress, fetal distress, and meconium-stained amnionic fluid. These problems were noted more frequently in those with higher total bile acid levels. Herrera and coworkers (2017) reported similar results. Finally, Wikström Shemer and colleagues (2013) reported outcomes in 5477 women with cholestasis from a database of 1,213,668 births. They described novel associations of cholestasis with preeclampsia and gestational diabetes. Although neonates were more likely to have a low 5-minute Apgar score and to be large for gestational age, the stillbirth rate was not increased. This was thought to reflect higher induction and preterm birth rates. Thus, by this time, many had now recommended early labor induction to avoid stillbirth. Reflecting this, at Parkland Hospital, some maternal-fetal specialists offer induction at 38 weeks, whereas others suggest 39 weeks.

As discussed, some evidence supports that high serum bile acid levels may contribute to fetal death. Bile acids typically remain <10 µmol/L throughout normal pregnancy (Egan, 2012). Elevated levels have been associated with meconium passage and stillbirth. For example, in the prior study of 693 Swedish women, stillbirths were limited to women with bile acid levels >40 µmol/L (Glantz, 2004). More recent data indicate that adverse outcomes are associated with even higher bile acid levels. For instance, Brouwers and coworkers (2015) reported high rates of spontaneous preterm birth (19 percent), meconium-stained amnionic fluid (48 percent), and perinatal death (10 percent) with bile acids levels >100 µmol/L despite active management leading to earlier delivery. Kawakita and colleagues (2015) found a similar stillbirth link. In particular, among 233 women followed with cholestasis of pregnancy, there were four stillbirths, all of which were among women with bile acid levels >100 µmol/L. Gao and associates (2014) implicated bile acids in cardiac dysfunction. Namely, in an ex-vivo preparation of cardiac myocytes, cholic acid lowered the beating rates in a dose-dependent manner, while increasing intracellular calcium levels. Intriguingly, studies have shown prolongations in the PR interval during fetal echocardiography among affected women (Rodríguez, 2016; Strehlow, 2010).

Acute Fatty Liver of Pregnancy

The most frequent cause of acute liver failure during pregnancy is acute fatty liver—also called *acute fatty metamorphosis* or *acute yellow atrophy.* It is characterized by accumulation of microvesicular fat that literally “crowds out” normal hepatocytic function (Fig. 55-1). Grossly, the liver is small, soft, yellow, and greasy. In its worst form, the incidence approximates 1 case in 10,000 pregnancies (Nelson, 2013). Fatty liver recurring in subsequent pregnancy is rare, but a few cases have been described (Usta, 1994).

FIGURE 55-1
Acute fatty liver of pregnancy. Cross section of the liver from a woman who died as the result of pulmonary aspiration and respiratory failure. The liver has a greasy yellow appearance, which was present throughout the entire specimen. Inset: Electron photomicrograph of one swollen hepatocyte containing numerous microvesicular fat droplets (*). The nuclei (*N*) remain centered within the cell, in contrast to the case with macrovesicular fat deposition. (Used with permission from Dr. Don Wheeler.)



Etiopathogenesis

Although much has been learned about this disorder, interpretation of conflicting data has led to incomplete but interesting observations. For example, some if not most cases of maternal fatty liver are associated with recessively inherited mitochondrial abnormalities of fatty acid oxidation. These are similar to those in children with Reye-like syndromes. Several mutations have been described for the mitochondrial trifunctional protein enzyme complex that catalyzes the last oxidative steps in the pathway. The most common are the *G1528C* and *E474Q* mutations of the gene on chromosome 2 that codes for long-chain-3-hydroxyacyl-CoA-dehydrogenase—known as LCHAD. There are other mutations for medium-chain acyl-CoA dehydrogenase—MCAD, as well as for carnitine palmitoyltransferase 1 (CPT1) deficiency (Santos, 2007; Ylitalo, 2005).

Sims and coworkers (1995) observed that some *homozygous* LCHAD-deficient children with Reye-like syndromes had *heterozygous* mothers with fatty liver. This was also seen in women with a compound heterozygous fetus. Although some conclude that *only* heterozygous LCHAD-deficient mothers are at risk when their fetus is homozygous, this is not always true (Baskin, 2010).

There is a controversial association between fatty acid β-oxidation enzyme defects and severe preeclampsia—especially in women with HELLP syndrome (Chap. 40, Liver). Most of these observations derive from retrospective study of mothers delivered of a child who later developed Reye-like syndrome. For example, one case-control study compared 50 mothers of children with a fatty-acid oxidation defect and 1250 mothers of matched control infants (Browning, 2006). During their pregnancy, 16 percent of mothers with an affected child developed liver problems compared with only 0.9 percent of control women. Problems included HELLP syndrome in 12 percent and fatty liver in 4 percent. Despite these findings, the clinical, biochemical, and histopathological findings are sufficiently disparate to suggest that severe preeclampsia, with or without HELLP syndrome, and fatty liver are distinct syndromes (American College of Obstetricians and Gynecologists, 2015; Sibai, 2007).

Clinical Findings

Acute fatty liver almost always manifests late in pregnancy. Nelson and colleagues (2013) described 51 affected women at Parkland Hospital with a mean gestational age of 37 weeks (range 31.7 to 40.9). Almost 20 percent were delivered at 34 weeks' gestation or earlier. Of these 51 women, 41 percent were nulliparous, and two thirds carried a male fetus. From other data, 10 to 20 percent of cases are in women with a multifetal gestation (Fesenmeier, 2005; Vigil-De Gracia, 2011).

Fatty liver has a clinical spectrum of severity. In the worst cases, symptoms usually develop over several days. Persistent nausea and vomiting are major complaints, and degrees of malaise, anorexia, epigastric pain, and progressive jaundice vary. Perhaps half of affected women have hypertension, proteinuria, and edema, alone or in combination—signs suggestive of preeclampsia. As shown in Tables 55-1 and 55-2, degrees of moderate to severe liver dysfunction are manifest by hypofibrinogenemia, hypoalbuminemia, hypocholesterolemia, and prolonged clotting times. Serum bilirubin levels usually are <10 mg/dL, and serum transaminase levels are modestly elevated and usually <1000 U/L.

TABLE 55-2

Laboratory Findings in 215 Women with Acute Fatty Liver of Pregnancy

	Most Abnormal Laboratory Values Mean ± 1 SD (range)[a]				
Series	**No.**	**Fibrinogen (mg/dL)**	**Platelets (10^3/μL)**	**Creatinine (mg/dL)**	**AST (U/L)**
Pereira (1997)	32	ND	123 (26–262)	2.7 (1.1–8.4)	99 (25–911)
Fesenmeier (2005)	16	ND	88 (22–226)	3.3 (0.5–8.6)	692 (122–3195)
Vigil-De Gracia (2011)	35	136 ± 80	86	—	280 ± 236
Nelson (2013)	51	147 ± 96 (27–400)	99 ± 68 (9–385)	2.0 ± 0.8 (0.7–5.0)	449 ± 375 (53–2245)
Xiong (2015)	25	ND	82 (16–242)	2.4 (0.8–5.9)	385 (10–2144)
Zhang (2016)	56	246 ± 186	145 ± 75	1.4 ± 0.9	260 ± 237
Estimated average	215	140	102	2.5	330

[a]Fibrinogen and platelet values listed reflect the nadir for each patient, whereas creatinine and AST values reflect peak values for each patient.

AST = aspartate transaminase; ND = not done.

In almost all severe cases, profound endothelial cell activation with capillary leakage causes hemoconcentration, acute kidney injury, ascites, and sometimes pulmonary permeability edema (Bernal, 2013). With severe hemoconcentration, uteroplacental perfusion is reduced and this, along with maternal acidosis, can cause fetal death even before presentation for care. Both maternal and fetal acidemia are associated with a high incidence of fetal jeopardy and a concordantly high cesarean delivery rate.

Hemolysis can be severe and evidenced by leukocytosis, nucleated red cells, mild to moderate thrombocytopenia, and elevated serum levels of lactic acid dehydrogenase (LDH). Because of hemoconcentration, however, the hematocrit is often within the normal range. The peripheral blood smear demonstrates echinocytosis, and hemolysis is thought to stem from effects of hypocholesterolemia on erythrocyte membranes (Cunningham, 1985).

The degree of clotting dysfunction also varies and can be serious and life threatening, especially if operative delivery is undertaken. Coagulopathy is caused by diminished hepatic procoagulant synthesis, although some evidence supports increased consumption from disseminated intravascular coagulopathy. As shown in Table 55-2, hypofibrinogenemia sometimes is profound. Of 51 women with fatty liver cared for at Parkland Hospital, almost a third had a plasma fibrinogen level nadir to <100 mg/dL (Nelson, 2014). Modest level elevations of serum d-dimers or fibrin-split products indicate an element of consumptive coagulopathy. Although usually modest, occasionally thrombocytopenia is marked (see Table 55-2). Again, among the group from Parkland Hospital, 20 percent had platelet counts <100,000/μL and 10 percent had platelet counts <50,000/μL (Nelson, 2014).

Various liver imaging techniques have been used to confirm the diagnosis, however, none are particularly reliable. Specifically, Castro and associates (1996) reported poor sensitivity for confirmation by sonography—three of 11 patients, computed tomography (CT)—five of 10, and magnetic resonance (MR) imaging—none of five. Similarly, in a prospective evaluation of the Swansea criteria proposed by Ch'ng and coworkers (2002), only a quarter of women had classic sonographic findings that include maternal ascites or an echogenic hepatic appearance (Knight, 2008). Our experiences are similar (Nelson, 2013).

The syndrome typically continues to worsen after diagnosis. Hypoglycemia is common, and obvious hepatic encephalopathy, severe coagulopathy, and some degree of renal failure each develop in approximately half of women. Fortunately, delivery arrests liver function deterioration.

We have encountered several women with a *forme fruste* of this disorder. Clinical involvement is relatively minor and laboratory aberrations—usually only hemolysis and a decreased plasma fibrinogen level—herald the syndrome. Thus, the spectrum of liver involvement varies from milder cases that go unnoticed or are attributed to preeclampsia, to overt hepatic failure with encephalopathy.

Management

Intensive supportive measures and good obstetrical care are essential. In some cases, the fetus may already be dead when the diagnosis is made, and the route of delivery is less problematic. Often, living fetuses tolerate labor poorly. Because significant procrastination in effecting delivery may increase maternal and fetal risks, we prefer a trial of labor induction with close fetal surveillance. Although some recommend cesarean delivery to hasten hepatic healing, this increases maternal risk when coagulopathy is severe. Nonetheless, cesarean delivery is common, and rates approach 90 percent. Transfusions with whole blood or packed red cells, along with fresh-frozen plasma, cryoprecipitate, and platelets, are usually necessary if surgery is performed or if obstetrical lacerations complicate vaginal delivery (Chap. 41, Hypovolemic Shock).

Hepatic dysfunction resolves postpartum. It usually normalizes within a week, and in the interim, intensive medical support may be required. Two associated conditions can be seen around this time. Perhaps a fourth of women have evidence for *transient diabetes insipidus.* This presumably stems from elevated vasopressinase concentrations caused by diminished hepatic production of its inactivating enzyme. Finally, *acute pancreatitis* develops in approximately 20 percent.

With supportive care, recovery usually is complete. Maternal deaths are caused by sepsis, hemorrhage, aspiration, renal failure, pancreatitis, and gastrointestinal bleeding. Two women died in the series from Parkland Hospital. One was an encephalopathic woman who aspirated before intubation during transfer to our care. The other was in a woman with massive liver failure and nonresponsive hypotension (Nelson, 2013). In some centers, other measures have included plasma exchange and even liver transplantation (Fesenmeier, 2005; Franco, 2000; Martin, 2008).

Maternal and Perinatal Outcomes

Although maternal mortality rates with acute fatty liver of pregnancy have approached 75 percent in the past, the contemporaneous outlook is much better. From his review, Sibai (2007) cites an average mortality rate of 7 percent. He also cited a 70-percent preterm delivery rate and a perinatal mortality rate of 15 percent, which in the past was nearly 90 percent. At Parkland Hospital, the maternal and perinatal mortality rates during the past four decades have been 4 percent and 12 percent, respectively (Nelson, 2013).

Acute Viral Hepatitis

Although most viral hepatitis syndromes are asymptomatic, during the past 30 years, acute symptomatic infections have become even less common in the United States (Daniels, 2009). There are at least five distinct types of viral hepatitis: A (HAV), B (HBV), D (HDV) caused by the hepatitis B-associated delta agent, C (HCV), and E (HEV). The clinical presentation is similar in all, and although the viruses themselves probably are not hepatotoxic, the immunological response to them causes hepatocellular necrosis (Dienstag, 2015a,b).

Acute infections are most often subclinical and *anicteric*. When they are clinically apparent, nausea and vomiting, headache, and malaise may precede jaundice by 1 to 2 weeks. Low-grade fever is more common with hepatitis A. By the time jaundice develops, symptoms are usually improving. Serum transaminase levels vary, and their peaks do not correspond with disease severity (see Table 55-1). Peak levels that range from 400 to 4000 U/L are usually reached by the time jaundice develops. Serum bilirubin values typically continue to rise, despite falling serum transaminase levels, and peak at 5 to 20 mg/dL.

Any evidence for severe disease should prompt hospitalization. These include persistent nausea and vomiting, prolonged prothrombin time, low serum albumin level, hypoglycemia, high serum bilirubin level, or central nervous system symptoms. In most cases, however, clinical and biochemical recovery is complete within 1 to 2 months in all cases of hepatitis A, in most cases of hepatitis B, but in only a small proportion of cases of hepatitis C.

When patients are hospitalized, their feces, secretions, bedpans, and other articles in contact with the intestinal tract should be handled with glove-protected hands. Extra precautions, such as double gloving during delivery and surgical procedures, are recommended. Due to significant exposure of health-care personnel to hepatitis B, the Centers for Disease Control and Prevention (CDC) (2016a) recommend active and passive vaccination, described later. There is no vaccine for hepatitis C, so recommendations are for postexposure serosurveillance only.

Acute hepatitis has a case-fatality rate of 0.1 percent. For patients ill enough to be hospitalized, it may reach 1 percent. Most fatalities are due to *fulminant hepatic necrosis,* which in later pregnancy may resemble acute fatty liver. In these cases, hepatic encephalopathy is the usual presentation, and the mortality rate is 80 percent. Approximately half of patients with fulminant disease have hepatitis B infection, and co-infection with the delta agent is common.

Chronic Viral Hepatitis

The CDC (2016b) estimated that more than 4 million Americans were living with chronic viral hepatitis. Although most chronically infected persons are asymptomatic, approximately 20 percent develop cirrhosis within 10 to 20 years (Dienstag, 2015b). When present, symptoms are nonspecific and usually include fatigue. In some patients, cirrhosis with liver failure or bleeding varices may be the presenting finding. Indeed, asymptomatic chronic viral hepatitis as a group remains the leading cause of liver cancer and the most frequent reason for liver transplantation.

Chronic viral hepatitis is usually diagnosed serologically (Table 55-3). With persistently abnormal biochemical tests, liver biopsy usually discloses active inflammation, continuing necrosis, and fibrosis that may lead to cirrhosis. Chronic hepatitis is classified by cause; by grade, defined by histological activity; and by stage, which is the degree of progression (Dienstag, 2015b).

TABLE 55-3

Simplified Diagnostic Approach in Patients with Hepatitis

	Serological Test			
Diagnosis	**HBsAg**	**IgM Anti-HAV**	**IgM Anti-HBc**	**Anti-HCV**
Acute hepatitis A	–	+	–	–
Acute hepatitis B	+	–	+	–
Chronic hepatitis B	+	–	–	–
Acute hepatitis A with chronic B	+	+	+	–
Acute hepatitis A and B	+	+	+	
Acute hepatitis C	–	–	–	+

HAV = hepatitis A virus; HBc = hepatitis B core; HBsAg = hepatitis B surface antigen; HCV = hepatitis C virus.

Compiled from the Centers for Disease Control and Prevention, 2016b; Dienstag, 2015a.

Most young women with chronic viral hepatitis either are asymptomatic or have only mild liver disease. For seropositive asymptomatic women, there usually are no problems with pregnancy. With *symptomatic* chronic active hepatitis, pregnancy outcome depends primarily on disease and fibrosis severity, and especially on the presence of portal hypertension. The few women whom we have managed have done well, but their long-term prognosis is poor. Accordingly, they should be counseled regarding possible liver transplantation as well as abortion and sterilization options.

Hepatitis A

Vaccination has reduced the incidence of hepatitis by 95 percent since 1995. In 2014, the rate was 0.4 per 100,000 individuals (Centers for Disease Control and Prevention, 2016b). This 27-nm RNA picornavirus is transmitted by the fecal–oral route, usually by ingestion of contaminated food or water. The incubation period is approximately 4 weeks. Individuals shed virus in their feces, and during the relatively brief period of viremia, their blood is also infectious. Signs and symptoms are often nonspecific and usually mild, although jaundice develops in most patients. Symptoms usually last less than 2 months, although 10 to 15 percent of patients may remain symptomatic or relapse for up to 6 months (Dienstag, 2015a). Early serological testing identifies IgM anti-HAV antibody, which may persist for several months. During convalescence, IgG antibody predominates, and it persists and provides subsequent immunity. There is no chronic stage of hepatitis A.

Management of hepatitis A in pregnancy includes a balanced diet and diminished physical activity. Women with less severe illness may be managed as outpatients. In developed countries, the effects of hepatitis A on pregnancy outcomes are not dramatic (American College of Obstetricians and Gynecologists, 2015, 2016). Both perinatal and maternal mortality rates, however, are substantively increased in resource-poor countries. Hepatitis A virus is not teratogenic, and transmission to the fetus is negligible. Preterm birth rates may be increased, and neonatal cholestasis has been reported (Urganci, 2003). Although hepatitis A RNA has been isolated in breast milk, no cases of neonatal hepatitis A have been reported secondary to breastfeeding (Daudi, 2012).

Preventatively, vaccination during childhood with formalin- inactivated hepatitis viral vaccine is more than 90-percent effective. HAV vaccination is recommended by the American College of Obstetricians and Gynecologists (2016) and the Advisory Committee on Immunization (Kim, 2015a) for high-risk adults. This category includes behavioral and occupational populations and travelers to high-risk countries. These countries are listed in the CDC (2016c) Health Information for International Travel “yellow book,” which is available on the CDC website. Passive immunization for the pregnant woman recently exposed by close personal or sexual contact with a person with hepatitis A is provided by a 0.02 mL/kg dose of immune globulin (Kim, 2015a). Victor and colleagues (2007) reported that a single dose of HAV vaccine given in the usual dosage within 2 weeks of contact with an affected person was as effective as immune serum globulin to prevent hepatitis A. In both groups, HAV developed in 3 to 4 percent.

Hepatitis B

This double-stranded DNA virus is found worldwide. It is endemic in Africa, Central and Southeast Asia, China, Eastern Europe, the Middle East, and certain areas of South America, where prevalence rates reach 5 to 20 percent. The World Health Organization (WHO) (2009) estimates that more than 2 billion people worldwide are infected with HBV, and of these, 370 million have chronic infection. The CDC (2016b) estimated nearly 18,100 cases of acute hepatitis B in the United States in 2014. This is a substantial decline since vaccination was introduced in the 1980s.

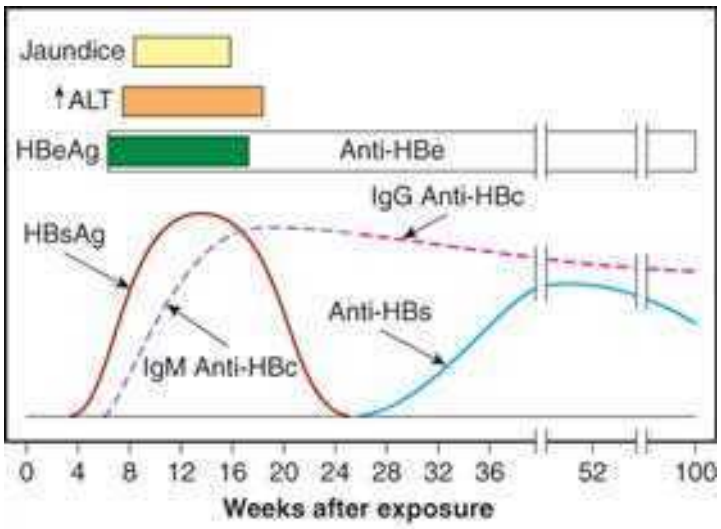
The hepatitis B virus is transmitted by exposure to blood or body fluids from infected individuals. In endemic countries, vertical transmission, that is, from mother to fetus or newborn, accounts for at least 35 to 50 percent of chronic HBV infections. In low-prevalence countries such as the United States, which has a prevalence <2 percent, the more frequent mode of HBV transmission is by sexual transmission or by sharing contaminated needles. HBV can be transmitted in any body fluid, but exposure to virus-laden serum is the most efficient.

Acute hepatitis B develops after an incubation period of 30 to 180 days with a mean of 8 to 12 weeks. At least half of acute infections are asymptomatic. If symptoms are present, they are usually mild and include anorexia, nausea, vomiting, fever, abdominal pain, and jaundice. Acute HBV accounts for half of cases of fulminant hepatitis. Symptoms completely resolve within 3 to 4 months in more than 90 percent of patients.

Figure 55-2 details the sequence of the various HBV antigens and antibodies in acute infection. The first serological marker to be detected is the hepatitis B surface antigen (HBsAg), often preceding the increase in transaminase levels. As HBsAg disappears, antibodies to the surface antigen develop (anti-HBs), marking complete resolution of disease. Hepatitis B core antigen is an intracellular antigen and not detectable in serum. However, anti-HBc is detectable within weeks of HBsAg appearance. The hepatitis Be antigen (HBeAg) is present during times of high viral replication and often correlates with detectable HBV DNA. After acute hepatitis, approximately 90 percent of adults recover completely. The 10 percent who remain chronically infected are considered to have chronic hepatitis B.

FIGURE 55-2

Sequence of various antigens and antibodies in acute hepatitis B. ALT = alanine transaminase; anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to hepatitis B e antigen; anti-HBs = antibody to hepatitis B surface antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen. (Reproduced with permission from Dienstag JL: Acute viral hepatitis. In Kasper DL, Fauci AS, Hauser SL, et al (eds): Harrison's Principles of Internal Medicine, 19th ed. New York, McGraw-Hill Education, 2015).



Chronic HBV infection is often asymptomatic but may be clinically suggested by persistent anorexia, weight loss, fatigue, and hepatosplenomegaly. Extrahepatic manifestations may include arthritis, generalized vasculitis, glomerulonephritis, pericarditis, myocarditis, transverse myelitis, and peripheral neuropathy. One risk factor for chronic disease is age at acquisition. It is more than 90 percent in newborns, 50 percent in young children, and less than 10 percent in immunocompetent adults. Another risk is an immunocompromised state such as those with human immunodeficiency virus (HIV) infection, transplant recipients, or persons receiving chemotherapy. Chronically infected persons may be asymptomatic carriers or have chronic disease with or without cirrhosis. Patients with chronic disease have persistent HBsAg serum positivity. The patients with evidence of high viral replication—HBV DNA with or without HBeAg—have the highest likelihood of developing cirrhosis and hepatocellular carcinoma. The WHO considers hepatitis B to be second only to tobacco among human carcinogens. HBV DNA has been found to be the best correlate of liver injury and disease progression risk.

Pregnancy and Hepatitis B

Hepatitis B infection is not a cause of excessive maternal morbidity and mortality. It is often asymptomatic and found only on routine prenatal screening (Stewart, 2013). A review of data from the National Inpatient Sample reported a modest increase in preterm birth rates in HBV-positive mothers but no effect on fetal growth restriction or preeclampsia rates (Reddick, 2011). Others have shown similar results (Chen, 2015). Transplacental viral infection is uncommon, and Towers and associates (2001) reported that viral DNA is rarely found in amnionic fluid or cord blood. Interestingly, HBV DNA has been found in the ovaries of HBV-positive pregnant women, although this may not be a significant factor in perinatal transmission (Jin, 2016b). The highest HBV DNA levels were found in women who transmitted the virus to their fetuses (Dunkelberg, 2015; Society for Maternal-Fetal Medicine, 2016).

In the absence of HBV immunoprophylaxis, 10 to 20 percent of women positive for HBsAg transmit viral infection to their infant. This rate increases to almost 90 percent if the mother is HBsAg and HBeAg positive. Immunoprophylaxis and hepatitis B vaccine given to newborns of HBV-infected mothers has

decreased transmission dramatically and prevented approximately 90 percent of infections (Smith, 2012). But, women with high HBV viral loads—10^6 to 10^8 copies/mL—or those who are HBeAg positive still have approximately a 10-percent vertical transmission rate, regardless of immunoprophylaxis (Yi, 2016).

The Society for Maternal–Fetal Medicine (2016) recommends antiviral therapy to decrease vertical transmission in women at highest risk because of high HBV DNA levels. Although lamivudine, a cytidine nucleoside analogue, significantly lowers the risk of fetal HBV infection in women with high HBV viral loads, recent data indicate that lamivudine may be less effective in the third trimester. Moreover, it is associated with the development of resistant mutations and is no longer recommended at a first-line agent. Newer drugs include the adenosine nucleoside analogue tenofovir and the thymidine analogue telbivudine. Both are associated with a lower risk of resistance than lamivudine (Ayres, 2014; Yi, 2016). Tenofovir has been recommended as the first-line agent during pregnancy by the Society for Maternal-Fetal Medicine (2016). These antiviral medications appear safe in pregnancy and are not associated with higher rates of congenital malformations or adverse obstetrical outcomes (Brown, 2016). Hepatitis B immunoglobulin (HBIG) given antepartum to women at highest risk of transmission is also cost-effective (Fan, 2016).

Newborns of seropositive mothers are given HBIG very soon after birth. This is accompanied by the first of a three-dose hepatitis B recombinant vaccine. Hill and colleagues (2002) applied this strategy in 369 infants and reported that the 2.4-percent transmission rate was not increased with breastfeeding if vaccination was completed. Although virus is present in breast milk, the incidence of transmission is not lowered by formula feeding (Shi, 2011). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) does not consider maternal HBV infection a contraindication to breastfeeding.

For high-risk mothers who are seronegative, hepatitis B vaccine can be given during pregnancy. The efficacy is similar to that for nonpregnant adults, and overall seroconversion rates approach 95 percent after three doses (Stewart, 2013). The traditional vaccination schedule of 0, 1, and 6 months may be difficult to complete during pregnancy, and compliance rates decline after delivery. Sheffield and coworkers (2011) reported that the three-dose regimen given prenatally—initially and at 1 and 4 months—resulted in seroconversion rates of 56, 77, and 90 percent, respectively. This regimen was easily completed during routine prenatal care.

Hepatitis D

Also called *delta hepatitis*, this is a defective RNA virus that is a hybrid particle with an HBsAg coat and a delta core. The virus must co-infect with hepatitis B either simultaneously or secondarily. It cannot persist in serum longer than hepatitis B virus. Transmission is similar to hepatitis B. Chronic co-infection with B and D hepatitis is more severe and accelerated than with HBV alone, and up to 75 percent of affected patients develop cirrhosis. HDV infection is detected by the presence of anti-HDV and HDV DNA. Neonatal transmission is unusual, as neonatal HBV vaccination usually prevents delta hepatitis.

Hepatitis C

This is a single-stranded RNA virus, and transmission occurs via blood and body fluids, although sexual transmission is inefficient. Up to a third of anti-HCV positive persons have no identifiable risk factors (Dienstag, 2015b). Screening for HCV is recommended for HIV-infected individuals, persons with injection drug use, hemodialysis patients, children born to mothers with HCV, persons exposed to HCV-positive blood or body fluids, persons with unexplained elevations in transaminase values, and recipients of blood or transplants before July 1992. Prenatal screening is recommended for high-risk women, and in the United States, seroprevalence rates reach 1 to 2.4 percent (American College of Obstetricians and Gynecologists, 2016; Arshad, 2011). It is higher in women who are infected with HIV. Santiago-Munoz and associates (2005) found that 6.3 percent of HIV-infected pregnant women at Parkland Hospital were co-infected with hepatitis B or C.

Acute HCV infection is usually asymptomatic or yields mild symptoms. Only 10 to 15 percent develop jaundice. The incubation period ranges from 15 to 160 days with a mean of 7 weeks. Transaminase levels are elevated episodically during the acute infection. Hepatitis C RNA testing is now preferred for HCV diagnosis. RNA levels may be found even before elevations of transaminase and anti-HCV levels. Specifically, anti-HCV antibody is not detected for an average of 15 weeks and in some cases up to a year (Dienstag, 2015a).

Nearly 80 to 90 percent of patients with acute HCV will be chronically infected. Although most remain asymptomatic, approximately 20 to 30 percent progress to cirrhosis within 20 to 30 years. Transaminase values fluctuate, and HCV RNA levels vary over time. Liver biopsy reveals chronic disease and fibrosis in up to 50 percent, however, these findings are often mild. Overall, the long-term prognosis for most patients is excellent.

Pregnancy and Hepatitis C

As expected, most pregnant women diagnosed with HCV have chronic disease. HCV infection was initially thought to have limited pregnancy effects. However, more recent reports have chronicled modestly increased fetal risks for low birthweight, NICU admission, preterm delivery, and mechanical ventilation (Berkley, 2008; Pergam, 2008; Reddick, 2011). In some women, these adverse outcomes may have been influenced by concurrent high-risk behaviors associated with HCV infection.

The primary adverse perinatal outcome is vertical transmission of HCV infection to the fetus-infant. This is higher in mothers with viremia (Indolfi, 2014; Joshi, 2010). Airoldi and Berghella (2006) cited a rate of 1 to 3 percent in HCV-positive, RNA-negative women compared with 4 to 6 percent in those who were RNA-positive. In a report from Dublin, the vertical transmission rate in 545 HCV-infected women was 7.1-percent in RNA-positive women compared with none in those who were RNA-negative (McMenamin, 2008). Some have found an even greater risk when the mother is co-infected with HIV (Snidjewind, 2015;

Tovo, 2016). Invasive prenatal diagnostic procedures have not been reported to increase transmission to the fetus. However, Rac and Sheffield (2014) note that few studies have addressed this possibility, and they recommend avoiding traversing the placenta during amniocentesis. Approximately two thirds of prenatal transmission cases occur peripartum. HCV genotype, invasive prenatal procedures, breastfeeding, and delivery mode are not associated with mother-to-child transmission. That said, invasive procedures such as internal electronic fetal heart rate monitoring are avoided. HCV infection is not a contraindication to breastfeeding.

No licensed vaccine is available for HCV prevention. The chronic HCV infection treatment has traditionally included alpha interferon (standard and pegylated), alone or in combination with ribavirin. This regimen is contraindicated in pregnancy because of the teratogenic potential of ribavirin in animals (Joshi, 2010). The initial 5-year review of the Ribavirin Pregnancy Registry found no evidence for human teratogenicity. However, the registry has enrolled fewer than half of the necessary numbers to allow a conclusive statement to be made (Roberts, 2010). The development and study of direct-acting and host-targeted antiviral drugs in the past decade shows great promise for chronic hepatitis C management (Liang, 2013; Lok, 2012; Poordad, 2013). Current interferon-free, ribavirin-free regimens are being evaluated, although no data are available for pregnant women.

Hepatitis E

This water-borne RNA virus usually is enterically transmitted by contaminated water supplies. Hepatitis E is probably the most common cause of acute hepatitis (Hoofnagle, 2012). It causes epidemic outbreaks in third-world countries with substantial morbidity and mortality rates. Pregnant women have a higher case-fatality rate than nonpregnant individuals. In a metaanalysis of nearly 4000 subjects from Asia and Africa, Jin and coworkers (2016a) reported maternal and fetal case-fatality rates of 21 and 34 percent, respectively. Fulminant hepatitis, although rare overall, is more common in gravidas and contributes to the increased mortality rates. An altered innate immune response to incipient hepatitis E infection during pregnancy, affecting macrophage function and toll-like receptor signaling, may be a factor in the development of fulminant hepatitis (Sehgal, 2015).

A recombinant HEV vaccine has been developed and licensed in China. It is >95 percent effective for 12 months after vaccination. Long-term efficacy is 87 percent, and protective titers are maintained for up to 4.5 years (Zhang, 2015). Preliminary data from inadvertently vaccinated pregnant women show no adverse maternal or fetal events (Wu, 2012). At this time, it is unclear if this Chinese-licensed vaccine is effective in other areas of the world where other genotypes predominate. Genotype 4 is most common in China, and types 2 and 3 are more common in the Americas. A Food and Drug Administration (FDA) approved vaccine is not available at this time.

Hepatitis E is found worldwide, and although the highest prevalence is in east Asia, the CDC (2015) lists Mexico as a highly endemic country. Seroprevalence rates vary by age and geography, but overall seroprevalence rates of 10 percent have been reported. Durango State has the highest rate (37 percent) (Fierro, 2016).

Hepatitis G

Hepatitis G is the former name of an RNA flavivirus now known as HPvG or human pegivirus. This blood-borne infection of the liver, spleen, bone marrow, and mononuclear cells of the peripheral blood does not actually cause hepatitis (Chivero, 2015). It is thought to infect 750 million people worldwide, with up to two times that many with evidence of past infection. It may modulate the immune response, particularly during co-infection with HIV. Currently, no treatment aside from basic blood and body fluid precautions is recommended. Vertical transmission (to the fetus/infant) and horizontal transmission (to peers) has been described (Trinks, 2014).

Autoimmune Hepatitis

This is a generally progressive chronic hepatitis that is important to distinguish from other forms. Autoimmune hepatitis is more common in women and frequently coexists with other types of autoimmune disease, particularly autoimmune thyroid disease and Sjögren syndrome. Symptoms are typical of acute and chronic hepatitis, but one quarter may be asymptomatic. Rates of cirrhosis vary worldwide, but in western countries autoimmune hepatitis is more common and is characterized by multiple autoimmune antibodies such as antinuclear antibodies (ANA) and anti–smooth muscle antibody. Type 2 autoimmune hepatitis has an even higher prevalence in females and typically a more aggressive presentation. The incidence peaks in childhood and adolescence, before peak reproductive years. Treatment employs corticosteroids, alone or combined with azathioprine. Failure to respond to these two agents is more frequent in those with type 2 disease, and nearly all women with type 2 disease require more intensive therapy that is sustained long term (Vierling, 2015). In some patients with progressive disease and cirrhosis, hepatocellular carcinoma develops. In general, autoimmune hepatitis—especially when severe—increases the risk of adverse pregnancy outcomes.

Westbrook and coworkers (2012) reported the outcomes of 81 pregnancies in 53 women. A third had a flare, and these were more common in those not taking medication and those with active disease in the year before conception. Maternal and fetal complications were higher among women with cirrhosis, particularly with respect to the risks of death or need for liver transplantation during the pregnancy or within 12 months postpartum. From one Swedish national database analysis, frequencies of preterm birth, low birthweight, and diabetes were higher, but not those of preeclampsia or cesarean delivery (Stokkeland, 2016). Danielsson Borssén (2016) reported stable or mild disease in 84 percent of 58 women who delivered 100 newborns. Nearly a fourth of cases were delivered before 38 weeks, and a postpartum flare developed in a third. Cirrhosis was present in 40 percent, and these women experienced more complications during pregnancy.

Iron and Copper Overload

Chronic hepatitis and cirrhosis can result from iron and copper overload. Iron overload may stem from a primary cause that is generally inherited, such as hereditary hemochromatosis, or originates secondary to complications of certain hemoglobinopathies. Many of the gene mutations underlying hereditary hemochromatosis involve hepcidin and result in dysregulated iron transport (Chap. 4, Iron Metabolism). Some of these mutations are more common in certain populations originating from northern Europe (Pietrangelo, 2016; Salgia, 2015). Cardiomyopathy, diabetes, joint disease, and skin changes can coexist with liver disease. Pregnancy outcomes associated with iron overload in hereditary hemochromatosis are driven by the degree of liver dysfunction, although higher iron levels may affect birthweight (Dorak, 2009).

A form of neonatal hemochromatosis that does not affect the mother is now thought to be alloimmune and is called *gestational alloimmune liver disease* (Anastasio, 2016). With this, maternal autoantibodies cross to the fetus and mediate dysfunction of iron homeostasis, although the antigenic target of these alloantibodies remains unclear. It is associated with significant neonatal morbidity and mortality, and frequently recurs in subsequent pregnancies. In these cases, antepartum treatment with intravenous immunoglobulin (IVIG) may improve outcomes (Feldman, 2013; Roumiantsev, 2015).

Copper overload leading to chronic hepatitis and cirrhosis is Wilson disease. This systematic condition can also manifest with cardiomyopathy, renal disease, neuropsychiatric symptoms, and certain endocrine abnormalities. A Kayser-Fleischer ring surrounding the iris is highly specific, but a suspected diagnosis generally requires genetic analysis. Autosomal recessive mutations of the *ATP7B* gene underlie this disorder. This gene codes for the P-type ATPase involved in copper transport to ceruloplasmin and bile (Bandman, 2015).

With Wilson disease, infertility may be present, but pregnancy outcomes among affected women who do conceive are influenced by disease severity. Malik and colleagues (2013) reported four cases in pregnancy, and three had associated gestational hypertension or preeclampsia. Maternal and neonatal outcomes were good, and the authors review chelation therapy with penicillamine and zinc sulfate in pregnancy. The American College of Gastroenterology states that few data guide which of the various chelating agents is best (Tran, 2016). These include penicillamine, zinc, and trientine, and any theoretical risks are outweighed by the risks of discontinuing therapy. The latter include not only hepatic decompensation, but also injury to the placenta and fetal liver. Accordingly, the American College of Gastroenterology recommends that pregnant women should continue their chelation therapy, although a dose reduction of 25 to 50 percent should be considered to promote wound healing in the event of a surgical delivery. As a reminder, copper ions regulate the activity of proteins essential to wound repair.

Nonalcoholic Fatty Liver Disease

This condition is frequently comorbid with obesity and is the most common chronic liver disease in the United States (Diehl, 2017). Its most severe form—*nonalcoholic steatohepatitis (NASH)*—is an increasingly recognized condition that may occasionally progress to hepatic cirrhosis. Nonalcoholic fatty liver disease (NAFLD) is a macrovesicular fatty liver condition that resembles alcohol-induced liver injury but is seen without this substance abuse. Obesity, type 2 diabetes, and hyperlipidemia—*syndrome X*—frequently coexist (Chap. 48, Pregnancy and Obesity). The current hypothesis suggests that these conditions may interact with other unknown etiological agents to cause multiple insults or "hits" leading to hepatic injury. For example, half of persons with type 2 diabetes have NAFLD, and insulin resistance has been postulated to act as one possible "hit" (Buzzetti, 2016). Browning and associates (2004) used MR spectroscopy to determine the prevalence of NAFLD in Dallas County and found that approximately a third of adults were affected. This varied by ethnicity, with 45 percent of Hispanics, 33 percent of whites, and 24 percent of blacks being affected. Most people—80 percent—found to have steatosis had normal liver enzymes. In a study of obese adolescents undergoing bariatric surgery, more than a third had fatty liver without hepatitis, whereas an additional 20 percent had borderline or definite NASH (Xanthakos, 2015).

Liver damage follows a progressive continuum from NAFLD to NASH and then to hepatic fibrosis that may progress to cirrhosis (Goh, 2016). Still, in most persons, the disease is usually asymptomatic, and it is a frequent explanation for elevated serum transaminase levels found in blood donors and during other routine screening. Indeed, NAFLD is the cause of elevated asymptomatic transaminase levels in up to 90 percent of cases in which other liver disease is ultimately excluded. It also is the most common cause of abnormal liver tests among adults in this country. Currently, weight loss along with control of diabetes and dyslipidemia is the only recommended treatment.

Fatty liver infiltration is probably much more common than realized in obese and diabetic gravidas. During the past decade, we encountered an increasing number of pregnant women with these disorders. Once severe liver injury, that is, acute fatty liver of pregnancy, is excluded, gravidas with fatty liver infiltration have no greater rates of adverse outcomes relative to liver involvement compared with pregnant women of similar weight. That said, some emerging data indicate that this condition may portend adverse pregnancy outcomes. In 110 pregnancies with NAFLD from the Swedish Medical Birth and the National Patient Registries, risks of gestational diabetes, preeclampsia, preterm birth, and low-birthweight newborns were two- to threefold greater than in unaffected women (Hagström, 2016). Yarrington and associates (2016) reported a high rate of gestational diabetes among nonobese women without liver disease, alcohol use, or diabetes, and who had elevated alanine transaminase levels in the first trimester. As the obesity endemic worsens, adverse effects of this liver disorder on pregnancy will be clarified.

Cirrhosis

Irreversible chronic liver injury with extensive fibrosis and regenerative nodules is the final common pathway for several disorders. *Laënnec cirrhosis* from chronic alcohol exposure is the most frequent cause in the general population. But in young women—including pregnant women—most cases are caused by

postnecrotic cirrhosis from chronic hepatitis B and C. Many cases of *cryptogenic cirrhosis* are now known to be caused by NAFLD (Goh, 2016). Clinical manifestations of cirrhosis include jaundice, edema, coagulopathy, metabolic abnormalities, and portal hypertension with gastroesophageal varices and with splenomegaly that may cause thrombocytopenia. The incidence of deep-vein thromboembolism is increased (Søgaard, 2009). The prognosis is poor, and 75 percent have progressive disease that leads to death in 1 to 5 years.

Women with symptomatic cirrhosis frequently are infertile. Those who become pregnant generally have poor outcomes. Common complications include transient hepatic failure, variceal hemorrhage, preterm delivery, fetal growth restriction, and maternal death (Tan, 2008). Outcomes are generally worse if esophageal varices coexist.

Another potentially fatal complication of cirrhosis arises from associated splenic artery aneurysms. Up to 20 percent of ruptures occur during pregnancy, and 70 percent of these rupture in the third trimester (Palatnik, 2017; Tan, 2008). In a review of 32 gravidas with aneurysm rupture, the mean aneurysm diameter was 2.25 cm, and in half of cases, the diameter was <2 cm (Ha, 2009). The 22-percent maternal mortality rate was likely related to the emergent presentation of these events. Parrish and colleagues (2015) described embolization of a 13 × 9 mm aneurysm in the third trimester leading to a splenic abscess and sepsis 3 weeks later.

Portal Hypertension and Esophageal Varices

In pregnant women, approximately half of cases of esophageal varices originate from cirrhosis or extrahepatic portal vein obstruction, which leads to portal system hypertension. Some cases of extrahepatic hypertension develop following portal vein thrombosis associated with one of the *thrombophilia syndromes* (Chap. 52, Thrombophilias). Others follow thrombosis from umbilical vein catheterization when the woman was a neonate, especially if she was born preterm.

With either intrahepatic or extrahepatic resistance to flow, portal vein pressure rises from its normal range of 5 to 10 mm Hg, and values may exceed 30 mm Hg. Collateral circulation develops that carries portal blood to the systemic circulation. Blood drains into the gastric, intercostal, and other veins to the esophageal system, where varices develop. Bleeding is usually from varices near the gastroesophageal junction, and hemorrhage can be torrential. Bleeding during pregnancy from varices occurs in a third to half of affected women and is the major cause of maternal mortality within this group (Tan, 2008).

Maternal prognosis with esophageal varices largely depends on whether these rupture. Mortality rates are higher if varices are associated with cirrhosis compared with rates for varices without cirrhosis—18 versus 2 percent, respectively. Perinatal mortality rates are high in women with varices and are worse if cirrhosis caused the varices. Increased rates of neonatal demise, preterm birth, low birthweight, preeclampsia, and postpartum hemorrhage have been reported (Puljic, 2016).

Treatment is the same as for nonpregnant patients. Preventatively, all patients with cirrhosis, including pregnant women, should undergo endoscopic screening for identification of variceal dilatation (Bacon, 2015). Beta-blocking drugs such as propranolol are given to reduce portal pressure and hence the bleeding risk (Bissonnette, 2015; Tran, 2016).

For acute bleeding and for prophylaxis, endoscopic band ligation is preferred to sclerotherapy as it avoids any potential risks of injecting sclerotherapeutic chemicals (Bissonnette, 2015; Tan, 2008). Acute medical management for bleeding varices verified endoscopically includes the intravenous (IV) vasoconstrictors octreotide or somatostatin along with endoscopic banding. Vasopressin is less often used (Bacon, 2015). *Balloon tamponade* using a triple-lumen tube placed into the esophagus and stomach to compress bleeding varices can be lifesaving if endoscopy is not available. An interventional radiology procedure—*transjugular intrahepatic portosystemic stent shunting (TIPSS)*—can also control bleeding from gastric varices that is unresponsive to other measures (Bissonnette, 2015; Tan, 2008). This procedure can be done electively in patients with prior variceal hemorrhage.

Acetaminophen Overdose Hepatotoxicity

This drug is the most common cause of acute liver failure in the United States (Lee, 2013). Acetaminophen is often used during pregnancy, and overdose–either accidentally or by attempted suicide–may lead to hepatocellular necrosis and acute liver failure (Bunchorntavakul, 2013). Massive necrosis causes a cytokine storm and multiorgan dysfunction. Early symptoms of overdose are nausea, vomiting, diaphoresis, malaise, and pallor. With an acute overdose, after a latent period of 24 to 48 hours, liver failure ensues and usually begins to resolve in 5 days. In a prospective Danish study, only 35 percent of patients who were treated for fulminant hepatic failure spontaneously recovered before being listed for liver transplantation (Schmidt, 2007).

The antidote is *N-acetylcysteine*, which must be given promptly. The drug is thought to increase glutathione levels, which aid metabolism of the toxic metabolite, *N*-acetyl-*p*- benzoquinoneimine. The need for treatment is based on projections of possible plasma hepatotoxic levels as a function of the time from acute ingestion. For this, many poison control centers use the nomogram established by Rumack and Matthew (1975). A plasma level is measured 4 hours after ingestion, and if the level is >150 µg/mL, treatment is given (Smilkstein, 1988). If plasma determinations are not available, empirical treatment is given if the ingested amount exceeded 7.5 g. An oral loading dose of 140 mg/kg of N-acetylcysteine is followed by 17 maintenance doses of 70 mg/kg every 4 hours for 72 hours of total treatment time. Both the oral and an equally efficacious IV dosing regimen have been reviewed by Hodgman and Garrard (2012). The drug has been reported to reach therapeutic concentrations in the fetus (Wiest, 2014).

After 14 weeks' gestation, the fetus has some cytochrome P450 activity necessary for metabolism of acetaminophen to the toxic metabolite. Riggs and colleagues (1989) reported follow-up data from the Rocky Mountain Poison and Drug Center in 60 women suffering overdose. The likelihood of maternal and

fetal survival was better if the antidote was given soon after overdose. At least one 33-week fetus appears to have died as a direct result of hepatotoxicity 2 days after maternal ingestion. In another case, Crowell and associates (2008) reported a case of acetaminophen overdose at 32 weeks' gestation. The woman had taken 9.75 grams of acetaminophen approximately 1.5 hours prior to arrival. With treatment, the patient survived and went on to deliver a healthy term neonate.

Focal Nodular Hyperplasia

This benign lesion of the liver is characterized in most cases by a well-delineated accumulation of normal but disordered hepatocytes that surround a central stellate scar. These usually can be differentiated from hepatic adenomas by magnetic resonance (MR) or computed tomographic (CT) imaging. Except in the rare situation of unremitting pain, surgery is rarely indicated, and most women remain asymptomatic during pregnancy. In one review of 20 cases in Germany, no woman had related complications during pregnancy (Rifai, 2013). Three women showed 20-percent tumor growth; in 10 patients, the tumor decreased in size; and the remaining seven were unchanged across pregnancy. Ramírez-Fuentes and associates (2013) studied 44 lesions with MR imaging in 30 women. Of the lesions, 80 percent were unchanged in size, and most of the remainder decreased in size. They concluded that size changes were unrelated to pregnancy, combination oral contraceptive (COC) use, or menopause. Notably, this lesion is not a contraindication to estrogen-containing contraceptives (Chap. 38, Transdermal Patch).

Hepatic Adenoma

This is an uncommon benign neoplasm but has a 5-percent risk of malignant transformation and a significant risk of rupture-associated hemorrhage, particularly in pregnancy. As just discussed, adenomas can usually be differentiated from focal nodular hyperplasia by MR or CT imaging. Adenomas have a 9:1 predominance among women and are strongly linked with COC use. The rupture risk progresses with lesion size, and surgery is generally recommended for tumors measuring >5 cm (Agrawal, 2015). Tran and colleagues (2016) recommend sonographic surveillance of hepatic adenomas during pregnancy. In one review of 27 cases in pregnancy, 23 became apparent in the third trimester and puerperium (Cobey, 2004). Bleeding complicated no tumors measuring <6.5 cm. However, 16 of 27 women (60 percent) with an adenoma presented with tumor rupture that resulted in seven maternal deaths and six fetal deaths. Of note, 13 of 27 women presented within 2 months postpartum, and in half, hemorrhage heralded rupture. Wilson and coworkers (2011) described two cases of bleeding hepatic adenoma during pregnancy. One was managed by laparoscopic segmental resection, and another, which followed liver biopsy, required open surgery. The authors discourage biopsy during pregnancy for suspected hepatic adenomas, and emphasize the feasibility of resection for problematic lesions.

Liver Transplantation

In 2013 in the United States, 5921 adult liver transplants were performed, and 34 percent of patients were women (Kim, 2015b). Currently, more than 65,000 recipients of liver transplant are living, and one literature review cited 450 pregnancies in 3026 women who had undergone transplantation (Deshpande, 2012). Although their live-birth rate of 80 percent and miscarriage rate compare favorably with those of the general population, risks of preeclampsia, cesarean delivery, and preterm birth are significantly elevated. A fourth of pregnancies were complicated by hypertension, approximately a third resulted in preterm birth, and in 10 percent, there was one or more rejection episodes (Table 55-4). Importantly, 4 percent of mothers had died within a year after delivery, but this rate is comparable to that in nonpregnant liver transplantation patients. Ghazali and associates (2016) analyzed the National Inpatient Sample database and found 2.1 liver transplants per 100,000 deliveries. Pregnancies after liver transplant had significantly greater risks of maternal and fetal complications, including hypertensive disorders, gestational diabetes, and postpartum hemorrhage. Rates of preterm birth, fetal growth restriction, and congenital anomalies were also increased. Mattila and colleagues (2017) found that half of the women they cared for had maternal complications.

TABLE 55-4

Pregnancy Complications (%) in 558 Pregnancies after Liver Transplantation

Series	No.	Preeclampsia/Hypertension	Cesarean Delivery	Rejection	Live Birth
Jain (2003)	49	2–8	45	24	100
Nagy (2003)	38	21	46	17	63
Christopher (2006)	71	13–28	28	17	70
Coscia (2010)	281	22–33	32	6	75
Jabiry-Zieniewicz (2011)	39	8–26	79	8	100
Blume (2013)	62	6	30	13	77
Weighted Average:	540	16–28	38	10	78

GALLBLADDER DISORDERS

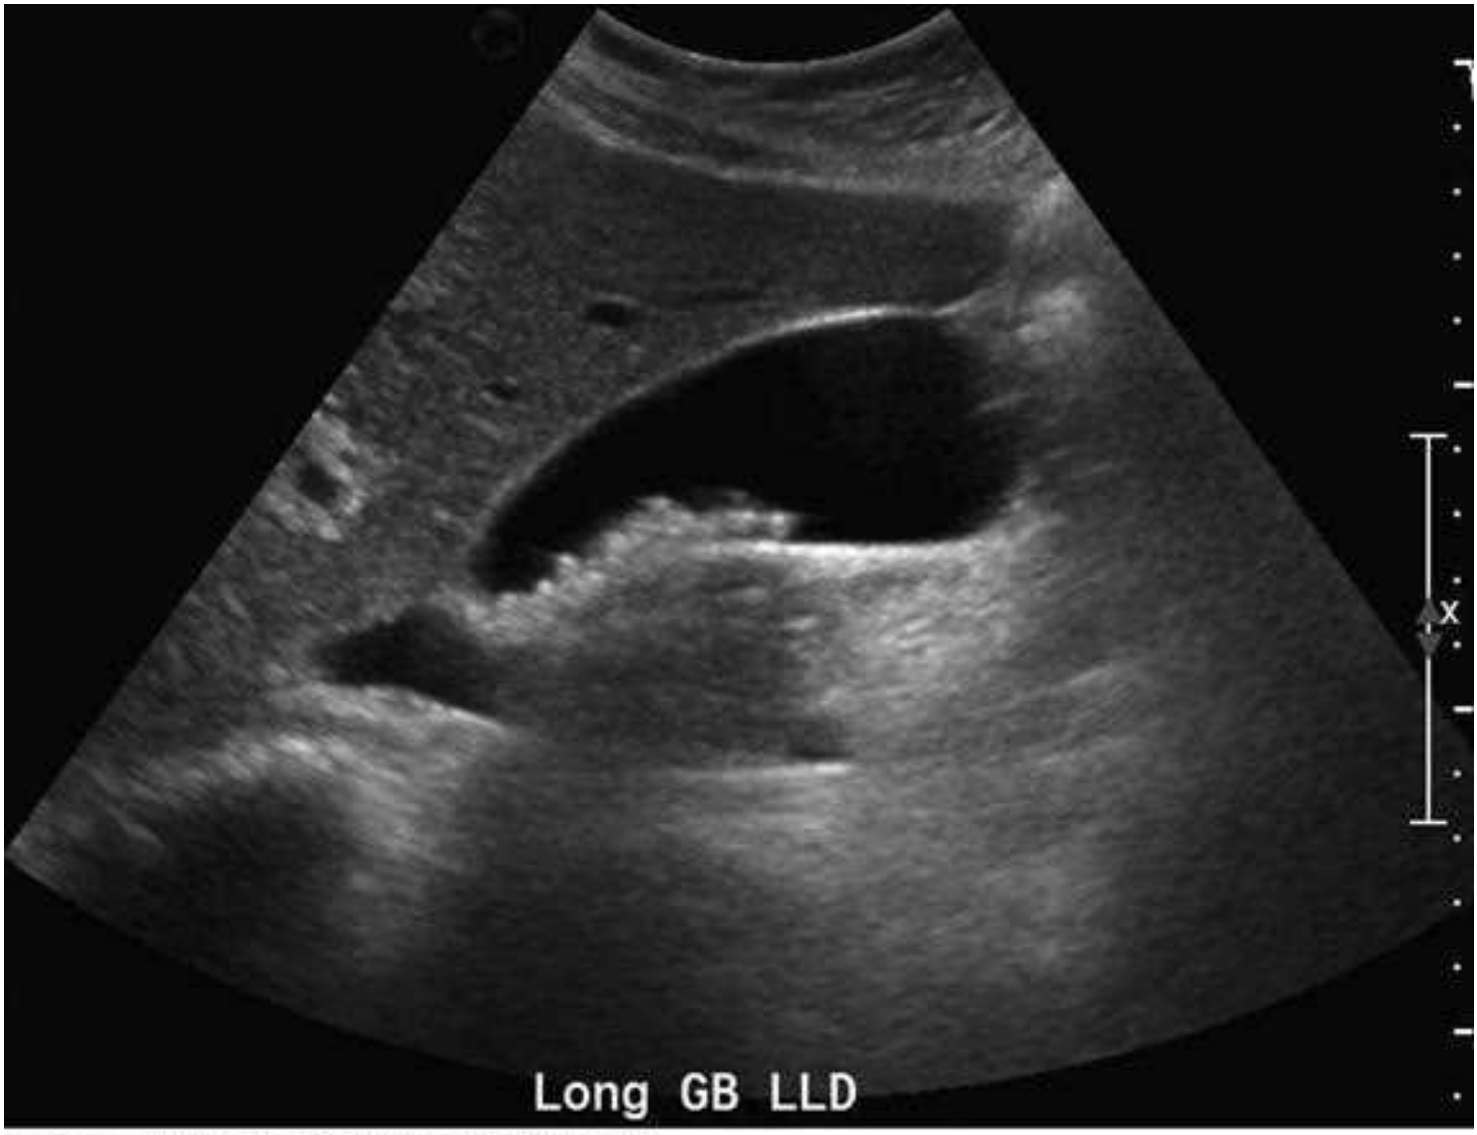
Cholelithiasis and Cholecystitis

In the United States, 20 percent of women older than 40 years have gallstones. Most stones contain cholesterol, and its oversecretion into bile is thought to be a major factor in stone formation. The cumulative risk of all patients with silent gallstones to require surgery for symptoms or complications is 10 percent at 5 years, 15 percent at 10 years, and 18 percent at 15 years (Greenberger, 2015). For these reasons, prophylactic cholecystectomy is not warranted for *asymptomatic* stones. For *symptomatic* gallstone disease, nonsurgical approaches have been used and include oral bile acid therapy with ursodeoxycholic acid and extracorporeal shock wave lithotripsy. Experience with these during pregnancy is lacking.

Acute cholecystitis usually develops when the cystic duct is obstructed. Bacterial infection plays a role in 50 to 85 percent of cases. In more than half of patients with acute cholecystitis, a history of prior right upper quadrant pain from cholelithiasis is elicited. With acute disease, pain is accompanied by anorexia, nausea and vomiting, low-grade fever, and mild leukocytosis. As shown in Figure 55-3, sonography can help visualize stones, and both false-positive and false-negative rates range from 2 to 4 percent (Greenberger, 2015). In acute cases, medical therapy consists of IV fluids, antimicrobials, analgesics, and in some instances, nasogastric suction, before surgical therapy. Laparoscopic cholecystectomy is the preferred treatment for most patients.

FIGURE 55-3

This sonogram shows multiple hyperechoic gallstones filling an anechoic gallbladder.



Gallbladder Disease During Pregnancy

After the first trimester, the gallbladder fasting volume and the residual volume after postprandial emptying are doubled. Incomplete emptying may result in retention of cholesterol crystals, a prerequisite for cholesterol gallstones. Maringhini and colleagues (1993) showed that the incidence of biliary sludge—which can be a forerunner to gallstones—and gallstones in pregnancy are 31 and 2 percent, respectively. Ko and colleagues (2014), however, cited a combined incidence of <5 percent. Others have identified asymptomatic gallstones in 2.5 to 10 percent of more than 1500 pregnant or postpartum women (Maringhini, 1993; Valdivieso, 1993).

Postpartum, sludge frequently regresses, and occasionally gallstones will resorb. Still, within a year after delivery, hospitalization for gallbladder disease remains relatively common, particularly for women managed conservatively in pregnancy. Jorge and coworkers (2015) reported that half of 53 women with symptomatic gallstones in pregnancy underwent postpartum cholecystectomy. In 80 percent of these women, recurrent symptoms developed prior to surgery, requiring readmission in half.

Medical versus Surgical Management

Acute cholecystitis during pregnancy or the puerperium is common and usually associated with gallstones or biliary sludge. Symptomatic cholecystitis is initially managed in a manner similar to that for nonpregnant women. In the past, most favored medical therapy. However, the recurrence rate during the same pregnancy is high, and 25 to 50 percent of women ultimately required cholecystectomy for persistent symptoms. Moreover, if cholecystitis recurs later in gestation, preterm labor is more likely and cholecystectomy is technically more difficult.

For these reasons, operative and endoscopic interventions are increasingly favored over conservative measures. Othman and coworkers (2012) showed that women managed conservatively had more pain, more recurrent visits to the emergency department, more hospitalizations, and a higher rate of cesarean delivery. Dhupar and associates (2010) reported more complications with conservative management of gallbladder disease compared with laparoscopic

cholecystectomy in pregnancy. These included multiple admissions, prolonged total parenteral nutrition, and unplanned labor induction for worsening gallbladder symptoms. Cholecystectomy was performed safely in all trimesters. Only one of 19 patients who underwent laparoscopic cholecystectomy had a complication, which did not require further surgery. A metaanalysis found that cholecystectomy does not increase the risk of preterm labor or of maternal or fetal mortality (Athwal, 2016). Management at Parkland Hospital has evolved to a more aggressive surgical approach, especially if there is concomitant biliary pancreatitis as subsequently discussed. During the past two decades, laparoscopic cholecystectomy has evolved as the favored surgical approach and is discussed in Chapter 46 (Medications and Surgeries).

Endoscopic Retrograde Cholangiopancreatography

Relief from symptomatic biliary duct gallstones during pregnancy has been greatly aided by use of endoscopic retrograde cholangiopancreatography (ERCP) (Fogel, 2014; Menees, 2006). The procedure is performed if common duct obstruction is suspected or proven. Approximately 10 percent of patients with symptomatic stone disease have common duct stones (Stinton, 2012). ERCP can be modified in many cases so that radiation exposure from fluoroscopy is avoided (Sethi, 2015).

Tang and associates (2009) reported results from 68 ERCP procedures performed in 65 pregnant women at Parkland Hospital. All but two women had gallstones, and sphincterotomy was performed in all but one woman. Common duct stones were identified in half of these 65 women, and in all but one, the stones were successfully removed. A biliary stent was placed in 22 percent of cases and removed after delivery. Complications were minimal, and post-ERCP pancreatitis developed in 16 percent. Pregnancy outcomes were not different than for the general obstetrical population. As a less invasive approach, MR cholangiopancreatography (MRCP) has been reported to have utility in pregnancy in small, retrospective case series. Wu and colleagues (2014) caution against its use in pregnancy, particularly for seriously ill women. Also, MRCP is not readily available, and this may lead to delayed definitive management.

Ascending cholangitis can complicate acute biliary obstruction. Nearly 70 percent of affected patients develop *Charcot triad*—jaundice, abdominal pain, and fever. The diagnosis is aided by sonography, and treatment is broad-spectrum antibiotics and biliary drainage by ERCP (Greenberger, 2015).

PANCREATIC DISORDERS

Pancreatitis

Acute pancreatic inflammation is triggered by factors that cause activation of pancreatic trypsinogen followed by autodigestion. It is characterized by cell-membrane disruption and proteolysis, edema, hemorrhage, and necrosis (Conwell, 2015; Fogel, 2014). Up to 10 percent of women develop necrotizing pancreatitis, which carries a mortality risk of 15 percent. This rate rises if infection develops (Cain, 2015).

In nonpregnant patients, acute pancreatitis is almost equally associated with gallstones and alcohol abuse. During pregnancy, however, cholelithiasis is almost always the predisposing condition. Other causes are hyperlipidemias, usually hypertriglyceridemia; hyperparathyroidism; congenital ductal anomalies; ERCP; some drugs; and rarely autoimmune pancreatitis (Cain, 2015; Ducarme, 2014). Nonbiliary pancreatitis occasionally develops postoperatively, or it is associated with trauma, drugs, or some viral infections. Certain metabolic conditions, including acute fatty liver of pregnancy and familial hypertriglyceridemia, also predispose to pancreatitis (Nelson, 2013). Cases of acute and chronic pancreatitis have been linked to numerous mutations of the cystic fibrosis transmembrane conductance regulator gene (Chang, 2015).

The incidence of pancreatitis varies with the population studied. At Parkland Hospital, with a predominant Mexican American population, acute pancreatitis complicated approximately 1 in 3300 pregnancies (Ramin, 1995). At Brigham and Women's Hospital, with a more diversely ethnic population, Hernandez and colleagues (2007) reported an incidence of 1 in 4450. In a multiple-institution Midwestern three-state review, the incidence of acute pancreatitis was 1 in 3450 (Eddy, 2008). In contrast, from California birth certificate data, the incidence approximated only 1 case in 6000 pregnancies (Hacker, 2015).

Diagnosis

Acute pancreatitis is characterized by mild to incapacitating epigastric pain, nausea and vomiting, and abdominal distention. Patients are usually distressed and have low-grade fever, tachycardia, hypotension, and abdominal tenderness. As many as 10 percent have systemic inflammatory response syndrome (SIRS), which causes endothelial activation and can lead to acute respiratory distress syndrome (Chap. 47, Sepsis Syndrome).

Of laboratory tests, serum amylase levels usually measure three times values considered the upper limit of normal. In 173 pregnant women with pancreatitis, the mean amylase value approximated 2000 IU/L, and the mean lipase value approached 3000 IU/L (Table 55-5). *Importantly, the degree of enzyme elevation and disease severity do not reliably correlate.* Indeed, by 48 to 72 hours, amylase levels may return to normal despite other evidence for continuing pancreatitis. Serum lipase activity is also increased and usually remains elevated with continued inflammation. Leukocytosis is usually found, and 25 percent of patients have hypocalcemia. Elevated serum bilirubin and aspartate transaminase levels may signify gallstone disease.

TABLE 55-5

Laboratory Values in 173 Pregnant Women with Acute Pancreatitis

Analyte	Mean	Range	Normal
Serum amylase (IU/L)	1980	111–8917	28–100
Serum lipase (IU/L)	3076	36–41,824	7–59
Total bilirubin (mg/dL)	1.7	0.1–8.71	0.2–1.3
Aspartate transferase (U/L)	115	11–1113	10–35
Leukocytes (per µL)	10,700	1000–27,200	3900–10,700

From Ramin, 1995; Tang, 2010; Turhan, 2010.

Several prognostic scoring systems have been used to classify pancreatitis severity, but not all of these are useful in pregnancy. For instance, two of the five Ranson criteria determined at admission include variables specific to nonpregnant patients. Similarly, certain criteria for the Apache II scoring system do not account for the changes in pregnancy physiology. In contrast, the Atlanta Classification incorporates the degree of organ failure as a measure of severity and may be more applicable in pregnancy (Banks, 2013; Cain, 2015).

Management

Medical treatment mirrors that for nonpregnant patients. This includes analgesics, IV hydration, and measures to decrease pancreatic secretion by interdiction of oral intake. Other than supportive therapy, antibiotics when appropriate, and targeted surgical interventions in the case of gallstone pancreatitis, no particular treatment schemes have improved outcomes. In a series by Ramin and colleagues (1995), all 43 affected pregnant women responded to conservative treatment and were hospitalized for a mean of 8.5 days. Nasogastric suction does not improve outcomes of mild to moderate disease, but enteral feeding may be helpful once pain improves and associated ileus resolves. For women with more severe pancreatitis and a prolonged disease course, total enteral nutrition using nasojejunal feeding is superior to total parenteral nutrition (Cain, 2015; Conwell, 2015). If there is bacterial superinfection of necrotizing pancreatitis, sepsis, or cholangitis, then broad-spectrum antimicrobials are administered. If common duct stones are found, then ERCP is indicated (Fogel, 2014; Tang, 2010). Cholecystectomy is considered after inflammation subsides because women with gallstonic pancreatitis carry an increased risk of recurrent pancreatitis (Cain, 2015).

Pregnancy outcomes are affected by acute pancreatitis severity. Eddy and associates (2008) reported a 30-percent preterm delivery rate, and 11 percent were delivered before 35 weeks' gestation. There were two pancreatitis-related maternal deaths. Importantly, almost a third of 73 women had recurrent pancreatitis during pregnancy. Of the 342 pregnancies complicated by pancreatitis in the California study, preterm delivery and fetal mortality rates were increased (Hacker, 2015). Also, preeclampsia risk was increased fourfold.

Pancreatic Transplantation

Few reports describe pregnancy following pancreas transplantation. Of 44 pregnancies in 73 women following pancreas-kidney transplantation, outcomes are encouraging, and vaginal delivery has been described (Mastrobattista, 2008). Although the incidence of hypertension, preeclampsia, preterm delivery, and fetal-growth restriction are high, there was only one perinatal death. Four rejection episodes developed during pregnancy and were treated successfully. Pancreatic islet autotransplantation may be performed to prevent diabetes following pancreatectomy, and at least three successful pregnancies have been reported (Jung, 2007).

CHAPTER 56: Hematological Disorders

In the later months of pregnancy there is a slight increase in the amount of hemoglobin and red corpuscles and a slight increase in the number of white corpuscles, which become markedly accentuated during the first few days of the puerperium.

—J. Whitridge Williams (1903)

INTRODUCTION

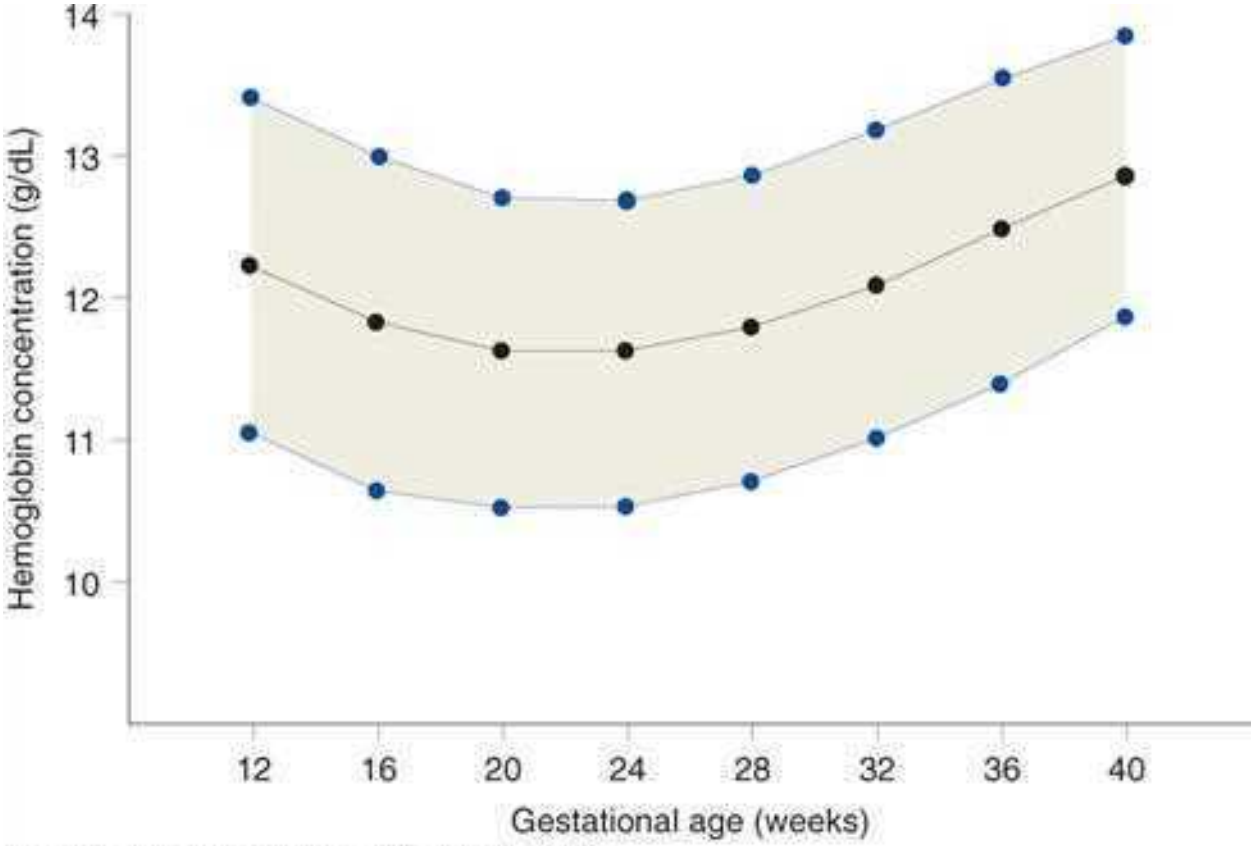
There is virtually nothing from the first edition of Williams' 1903 textbook that addresses the common anemias of pregnancy. Only pernicious anemia is devoted two paragraphs to say it occasionally appeared in pregnancy. Today, it is well known that pregnant women are susceptible to hematological abnormalities that may affect any woman of childbearing age. These include chronic disorders such as hereditary anemias, immunological thrombocytopenia, and malignancies such as leukemias and lymphomas. Other disorders arise during pregnancy because of pregnancy-induced demands. Two examples are iron deficiency and megaloblastic anemias. Pregnancy may also unmask underlying hematological disorders. Finally, any hematological disease may first arise during pregnancy. Importantly, pregnancy induces physiological changes that often confuse the diagnosis of these hematological disorders and assessment of their treatment (Chap. 4, Hematological Changes).

ANEMIAS

Definition and Incidence

Normal values for concentrations of many cellular elements during pregnancy are listed in the Appendix (Serum and Blood Constituents). The Centers for Disease Control and Prevention (1998) defined anemia in iron-supplemented pregnant women using a cutoff of the 5th percentile—11 g/dL in the first and third trimesters, and 10.5 g/dL in the second trimester (Fig. 56-1). The modest fall in hemoglobin levels and hematocrit values during pregnancy is caused by a relatively greater expansion of plasma volume compared with the increase in red cell volume. The disproportion between the rates at which plasma and erythrocytes are added to the maternal circulation is greatest during the second trimester. Late in pregnancy, plasma expansion essentially ceases, while hemoglobin mass continues to accrue.

FIGURE 56-1
Mean hemoglobin concentrations (*black line*) and 5th and 95th percentiles (*blue lines*) for healthy pregnant women taking iron supplements. (Data from the Centers for Disease Control and Prevention, 1989.)



The causes of more common anemias encountered in pregnancy are listed in Table 56-1. Their frequency is dependent on multiple factors such as geography, ethnicity, socioeconomic level, nutrition, preexisting iron status, and prenatal iron supplementation (American College of Obstetricians and Gynecologists, 2017a). In the United States, the prevalence of anemia in pregnancy is 3 to 38 percent (Centers for Disease Control and Prevention, 1989). In Latin America and the Caribbean, anemia prevalence ranges from 5 to 45 percent among women of childbearing age (Mujica-Coopman, 2015). Rates are also high in Israel, China, India, South Asia, and Africa (Azulay, 2015; Kumar, 2013, Stevens, 2013). Figure 56-2 highlights the global trends in hemoglobin concentrations and anemia thresholds in pregnant and nonpregnant women.

TABLE 56-1

Causes of Anemia During Pregnancy

Acquired
Iron-deficiency anemia
Anemia caused by acute blood loss
Anemia of inflammation or malignancy
Megaloblastic anemia
Acquired hemolytic anemia
Aplastic or hypoplastic anemia
Hereditary
Thalassemias

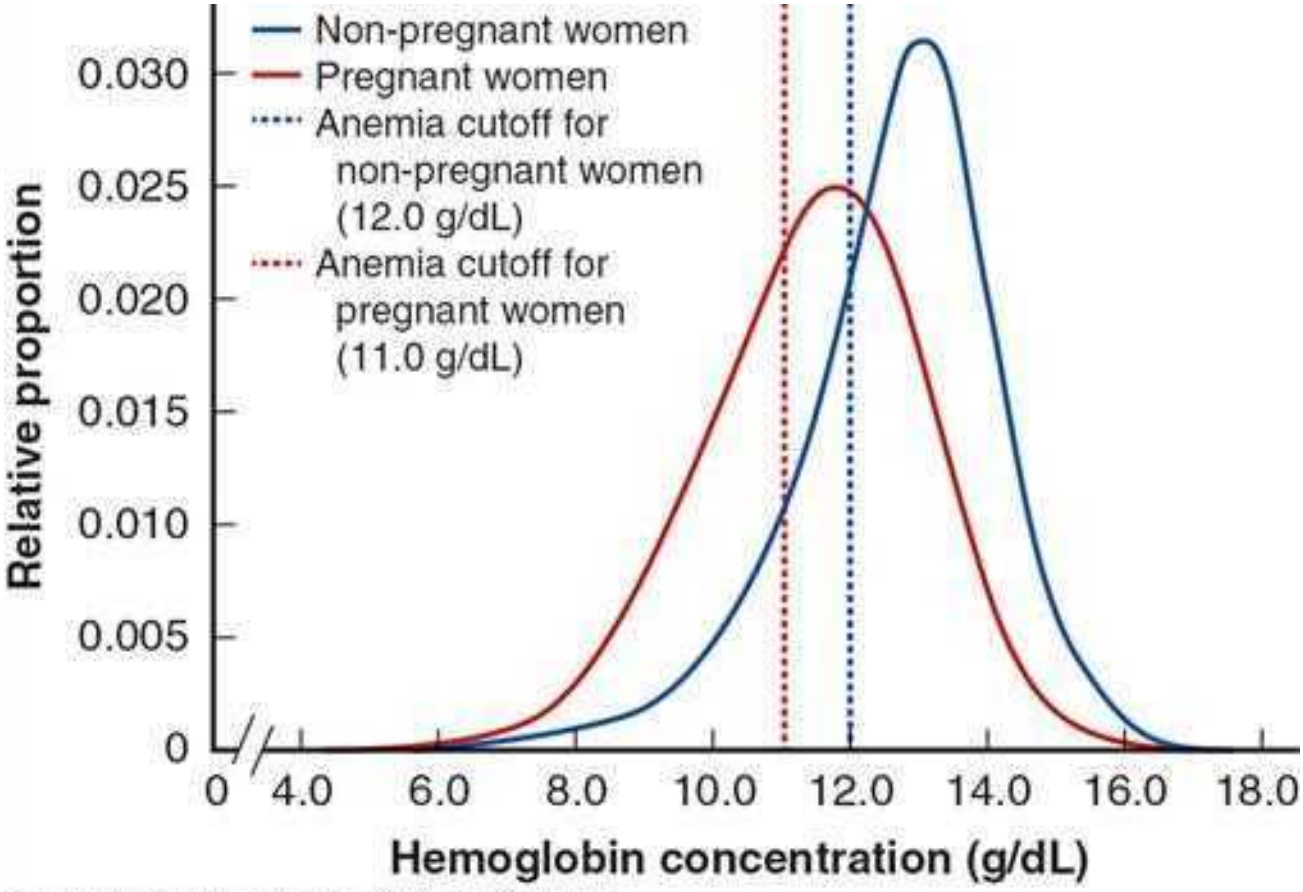
Global trends in hemoglobin concentrations in pregnant and nonpregnant women. (Reproduced with permission from Stevens GA, Finucane MM, De-Regil LM, et al: Global, regional, and national trends in haemoglobin concentration and prevalence of total and severe anaemia in children and pregnant and non-pregnant women for 1995–2011: a systematic analysis of population-representative data, Lancet Glob Health. 2013 Jul;1(1):e16–25.)



Effects on Pregnancy Outcomes

Most studies of anemia during pregnancy describe large populations and deal with nutritional anemias. Anemia is associated with several adverse pregnancy outcomes including preterm birth (Kidanto, 2009; Kumar, 2013; Rukuni, 2016). Children born to iron-deficient women and without iron supplementation are reported to have lower mental development scores (Drassinower, 2016; Tran, 2014).

A seemingly paradoxical finding is that healthy pregnant women with a higher hemoglobin concentration are also at greater risk for adverse perinatal outcomes (Murphy, 1986; von Tempelhoff, 2008). This may result from lower than average plasma volume expansion of pregnancy concurrent with normal red cell mass accrual. Scanlon and associates (2000) studied the relationship between maternal hemoglobin levels and rates of preterm or growth-restricted newborns in 173,031 pregnancies. Women whose hemoglobin concentration was three standard deviations *above* the mean at 12 or 18 weeks' gestation had a 1.3- to 1.8-fold greater incidence of fetal-growth restriction. Placental weight correlates negatively with maternal hemoglobin concentration (Larsen, 2016). These findings have led some to the illogical conclusion that withholding iron supplementation to cause iron-deficiency anemia will improve pregnancy outcomes (Ziaei, 2007).

Iron-Deficiency Anemia

The two most common causes of anemia during pregnancy and the puerperium are iron deficiency and acute blood loss. In a study of more than 1300 women, 21 percent had third-trimester anemia, and 16 percent had iron-deficiency anemia (Vandevijvere, 2013). In a typical singleton gestation, the maternal need for iron averages nearly 1000 mg. Multifetal gestational requirements are considerably higher (Ru, 2016). These amounts exceed the iron stores of most women and result in iron-deficiency anemia unless supplementation is given.

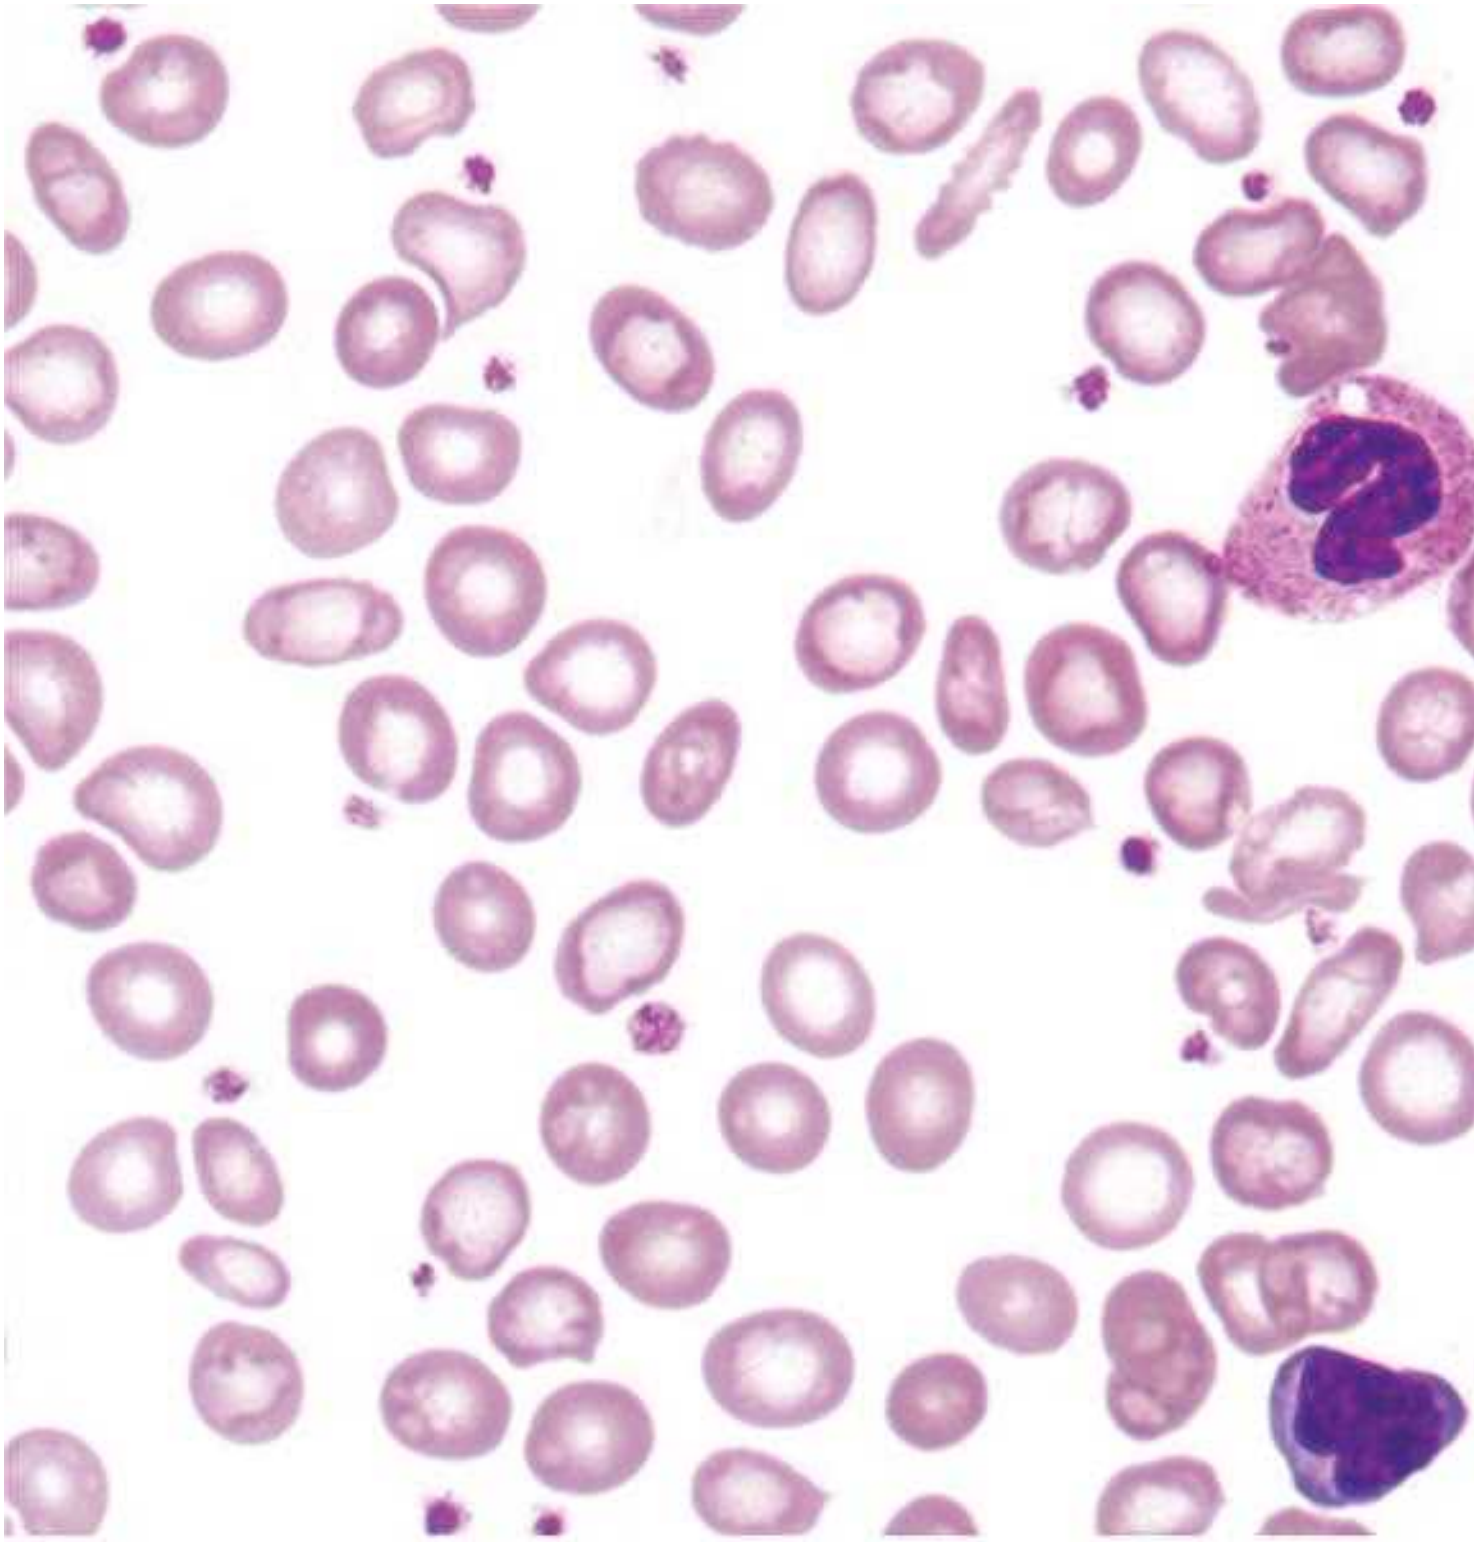
Iron deficiency is often manifested by an appreciable drop in hemoglobin concentration. In the third trimester, additional iron is needed to augment maternal hemoglobin and for transport to the fetus. Because the amount of iron diverted to the fetus is similar in a normal and in an iron-deficient mother, the newborn of a severely anemic mother does not suffer from iron-deficiency anemia. Neonatal iron stores are related to maternal iron status and to timing of cord clamping.

Diagnosis

Classic morphological evidence of iron-deficiency anemia is erythrocyte hypochromia and microcytosis (Fig. 56-3). This may be less prominent in the pregnant woman. Serum ferritin levels are lower. And, levels of *hepcidin*—the master regulator of iron availability—are decreased normally in pregnancy. With iron deficiency, hepcidin levels follow those of serum ferritin (Camaschella, 2015; Koenig, 2014).

FIGURE 56-3
This peripheral blood smear from a women with iron-deficiency anemia contains many scattered microcytic and hypochromic red cells with characteristic central pallor. These exhibit moderate anisopoikilocytosis, namely, varying sizes and shapes including occasional elliptocytes, which can be oval or pencil-shaped.

(Reproduced with permission from Werner CL, Richardson DL, Chang SY, et al (eds): Perioperative Considerations. In Williams Gynecology Study Guide, 3rd ed. New York, McGraw-Hill Education, 2016: Photo contributor: Dr. Weina Chen.)



The initial evaluation of a pregnant woman with moderate anemia includes measurements of hemoglobin, hematocrit, and red cell indices; careful examination of a peripheral blood smear; a sickle-cell preparation if the woman has African origin; and evaluation of serum iron or ferritin levels, or both (Appendix, Serum and Blood Constituents). Serum ferritin levels normally decline during pregnancy, and levels <10 to 15 mg/L confirm iron-deficiency anemia.

When pregnant women with moderate iron-deficiency anemia are given adequate iron therapy, a hematological response is detected by an elevated reticulocyte count. The rate of rise of hemoglobin concentration or hematocrit is typically slower than in nonpregnant women due to the increasing and larger blood volumes during pregnancy.

Treatment

Routinely in pregnancy, daily oral supplementation with 30 to 60 mg of elemental iron and 400 µg of folic acid is recommended (World Health Organization, 2012). A Cochrane review found that intermittent oral iron supplementation may also be appropriate (Peña-Rosas, 2015). For iron-deficiency anemia, resolution and restitution of iron stores can be accomplished with simple iron salts that provide approximately 200 mg daily of *elemental iron*. These include ferrous sulfate, fumarate, or gluconate. If a woman cannot or will not take oral iron preparations, then parenteral therapy is given. Although both are administered intravenously, ferrous sucrose is safer than iron-dextran (American College of Obstetricians and Gynecologists, 2017a; Camaschella, 2015; Shi, 2015). Hemoglobin and ferritin levels show equivalent rises in women treated with either oral or parenteral iron therapy (Breymann, 2017; Daru, 2016).

Anemia from Acute Blood Loss

In early pregnancy, anemia caused by acute blood loss is common with abortion, ectopic pregnancy, and hydatidiform mole. Postpartum, anemia commonly stems from obstetrical hemorrhage. Massive hemorrhage demands immediate treatment as described in Chapter 41 (Hypovolemic Shock). If a moderately anemic woman —defined by a hemoglobin value of approximately 7 g/dL—is hemodynamically stable, is able to ambulate without adverse symptoms, and is not septic, then blood transfusions are not indicated. Instead, oral iron therapy is given for at least 3 months (Krafft, 2005).

Anemia Associated with Chronic Disease

Various disorders, such as chronic renal insufficiency, cancer and chemotherapy, human immunodeficiency virus (HIV) infection, and chronic inflammation result in moderate and sometimes severe anemia, usually with slightly hypochromic and microcytic erythrocytes. It is the second most common form of anemia worldwide (Weiss, 2005).

During pregnancy, women with chronic disorders may develop anemia for the first time. In those with preexisting anemia, it may be intensified as plasma volume expands. Causes include chronic renal insufficiency, inflammatory bowel disease, and connective-tissue disorders. Others are granulomatous infections, malignant neoplasms, rheumatoid arthritis, and chronic suppurative conditions.

Chronic renal insufficiency is the most common disorder that we have encountered as a cause of this type of anemia during pregnancy. Some cases are accompanied by erythropoietin deficiency. As discussed in Chapter 53 (Chronic Kidney Disease), during pregnancy in women with mild chronic renal insufficiency, the degree of red cell mass expansion is inversely related to renal impairment. At the same time, plasma volume expansion usually is normal, and thus anemia is intensified (Cunningham, 1990).

For treatment, adequate iron stores must be ensured. *Recombinant erythropoietin* has been used successfully to treat anemia stemming from chronic disease (Weiss, 2005). In pregnancies complicated by chronic renal insufficiency, recombinant erythropoietin is usually considered when the hematocrit approximates 20 percent (Cyganek, 2011; Ramin, 2006). One worrisome side effect of this agent is hypertension, which is already prevalent in women with renal disease. Red cell aplasia and antierythropoietin antibodies have also been reported (Casadevall, 2002; McCoy, 2008).

Megaloblastic Anemia

These anemias are characterized by blood and bone-marrow abnormalities from impaired DNA synthesis. This leads to large cells with arrested nuclear maturation, whereas the cytoplasm matures more normally. Worldwide, the prevalence of megaloblastic anemia during pregnancy varies considerably. It is rare in the United States.

Folic Acid Deficiency

Megaloblastic anemia developing during pregnancy almost always results from folic acid deficiency. In the past, this condition was referred to as *pernicious anemia of pregnancy*. It usually is found in women who do not consume fresh green leafy vegetables, legumes, or animal protein. As folate deficiency and anemia worsen, anorexia often becomes intense and further aggravates the dietary deficiency. Drugs and excessive ethanol ingestion either cause or contribute (Hesdorffer, 2015).

In nonpregnant women, the folic acid requirement is 50 to 100 µg/d. During pregnancy, requirements are increased, and 400 µg/d is recommended. The earliest biochemical evidence is low plasma folic acid concentrations (Appendix, Serum and Blood Constituents). Early morphological changes usually include neutrophils that are hypersegmented and newly formed erythrocytes that are macrocytic. With preexisting iron deficiency, macrocytic erythrocytes cannot be detected by measurement of the mean corpuscular volume. Careful examination of a peripheral blood smear, however, usually demonstrates some macrocytes. As the anemia becomes more intense, peripheral nucleated erythrocytes appear, and bone marrow examination discloses megaloblastic erythropoiesis. Anemia may then become severe, and thrombocytopenia, leukopenia, or both may develop. The fetus and placenta extract folate from maternal circulation so effectively that the fetus is not anemic despite severe maternal anemia.

For treatment, folic acid is given along with iron, and a nutritious diet is encouraged. By 4 to 7 days after beginning folic acid treatment, the reticulocyte count is increased, and leukopenia and thrombocytopenia are corrected.

For prevention of megaloblastic anemia, a diet should contain sufficient folic acid. The role of folate deficiency in the genesis of neural-tube defects has been well studied (Chap. 13, Genetic Tests). Since the early 1990s, nutritional experts and the American College of Obstetricians and Gynecologists (2016a) have recommended that all women of childbearing age consume at least 400 µg of folic acid daily. More folic acid is given with multifetal pregnancy, hemolytic anemia, Crohn disease, alcoholism, and inflammatory skin disorders. Women with a family history of congenital heart disease may also benefit from higher doses (Huhta, 2015). Women who previously have had infants with neural-tube defects have a lower recurrence rate if a daily 4-mg folic acid supplement is given.

Vitamin B_{12} Deficiency

During pregnancy, vitamin B_{12} levels are lower than nonpregnant values because of decreased levels of binding proteins, namely, the transcobalamins. During pregnancy, megaloblastic anemia is rare from deficiency of vitamin B_{12}, that is, cyanocobalamin. Instead, a typical example is *Addisonian pernicious anemia,* which results from absent intrinsic factor that is requisite for dietary vitamin B_{12} absorption. This autoimmune disorder usually has its onset after age 40 years (Stabler, 2013).

In our limited experience, vitamin B_{12} deficiency in pregnancy is more likely encountered following gastric resection. Those who have undergone total gastrectomy require 1000 µg of vitamin B_{12} given intramuscularly each month. Those with a partial gastrectomy usually do not need supplementation, but adequate serum vitamin B_{12} levels should be ensured (Appendix, Serum and Blood Constituents). Other causes of megaloblastic anemia from vitamin B_{12} deficiency include Crohn disease, ileal resection, some drugs, and bacterial overgrowth in the small bowel (Hesdorffer, 2015; Stabler, 2013).

Hemolytic Anemia

Several conditions feature accelerated erythrocyte destruction. Damage may be stimulated by a congenital red-cell abnormality or in other cases by antibodies directed against red-cell membrane proteins. Hemolysis may be the primary disorder, and sickle-cell disease and hereditary spherocytosis are examples. In other cases, hemolysis develops secondary to an underlying condition such as systemic lupus erythematosus or preeclampsia. Microangiopathic hemolytic anemia due to malignancy has been reported in pregnancy (Happe, 2016).

Autoimmune Hemolysis

The cause of aberrant antibody production is unknown. Typically, both the direct and indirect antiglobulin (Coombs) tests are positive. Anemias caused by these factors may be due to warm-active autoantibodies (80 to 90 percent), cold-active antibodies, or a combination. These syndromes also may be classified as primary (idiopathic) or secondary due to underlying diseases or other factors. Examples of the latter include lymphomas and leukemias, connective-tissue diseases, infections, chronic inflammatory diseases, and drug-induced antibodies (Provan, 2000). *Cold-agglutinin disease* may be induced by infectious etiologies such as *Mycoplasma pneumoniae* or Epstein-Barr viral mononucleosis (Dhingra, 2007). Hemolysis and positive antiglobulin test results may be the consequence of either immunoglobulin M (IgM) or immunoglobulin G (IgG) antierythrocyte antibodies. When thrombocytopenia is comorbid, it is termed *Evans syndrome* (Wright, 2013).

In pregnancy, hemolysis can be markedly accelerated. Rituximab, along with prednisone, is first-line treatment (Luzzatto, 2015). Coincidental thrombocytopenia usually corrects with therapy. Transfusion of red cells is complicated by antierythrocyte antibodies, but warming the donor cells to body temperature may decrease their destruction by cold agglutinins.

Drug-Induced Hemolysis

These hemolytic anemias must be differentiated from other causes of autoimmune hemolysis. In most cases, hemolysis is mild, it resolves with drug withdrawal, and recurrence is prevented by avoidance of the drug. One mechanism is hemolysis induced through drug-mediated immunological injury to red cells. The drug may act as a high-affinity hapten when bound to a red-cell protein to which antidrug antibodies attach—for example, IgM antipenicillin or anticephalosporin antibodies. Some other drugs act as low-affinity haptens and adhere to cell membrane proteins. Examples include probenecid, quinidine, rifampin, and thiopental. A more common mechanism for drug-induced hemolysis is related to a congenital erythrocyte enzymatic defect. An example is glucose-6-phosphate dehydrogenase deficiency, which is common in African-American women and discussed later (Aplastic and Hypoplastic Anemia).

Drug-induced hemolysis is usually chronic and mild to moderate, but occasionally acute hemolysis is severe. Garratty and coworkers (1999) described seven women with severe Coombs-positive hemolysis stimulated by cefotetan given as prophylaxis for obstetrical procedures. Alpha-methyldopa can cause similar hemolysis (Grigoriadis, 2013). Moreover, maternal hemolysis has been reported after intravenous immune globulin therapy (Rink, 2013). Withdrawal of the offending drug frequently halts the hemolysis.

Pregnancy-Induced Hemolysis

Unexplained severe hemolytic anemia can develop during early pregnancy, and it resolves within months postpartum. A clear immune mechanism or red cell defects are not contributory (Starksen, 1983). Because the fetus-neonate also may demonstrate transient hemolysis, an immunological cause is suspected. Maternal corticosteroid treatment is often—but not always—effective (Kumar, 2001). We have cared for a woman who during each pregnancy developed intense severe hemolysis with anemia that was controlled by prednisone. Her fetuses were not affected, and in all instances, hemolysis abated spontaneously after delivery.

Pregnancy-Associated Hemolysis

In some cases, hemolysis is induced by conditions unique to pregnancy. Mild microangiopathic hemolysis with thrombocytopenia is relatively common with severe preeclampsia and eclampsia (Cunningham, 2015; Kenny, 2015). This HELLP (*hemolysis, elevated liver enzyme levels, low platelet count*) syndrome is discussed in Chapter 40 (Maternal Thrombocytopenia). Another is acute fatty liver of pregnancy, which is associated with moderate to severe hemolytic anemia (Nelson, 2013). It is discussed in Chapter 55 (Acute Fatty Liver of Pregnancy).

Paroxysmal Nocturnal Hemoglobinuria

Although commonly regarded as a hemolytic anemia, this hemopoietic stem cell disorder is characterized by formation of defective platelets, granulocytes, and erythrocytes. Paroxysmal nocturnal hemoglobinuria is acquired and arises from one abnormal clone of cells, much like a neoplasm (Luzzatto, 2015). One mutated X-linked gene responsible for this condition is termed *PIG-A* because it codes for phosphatidylinositol glycan protein A. Resultant abnormal anchor proteins of the

erythrocyte and granulocyte membrane make these cells unusually susceptible to lysis by complement (Provan, 2000). The most serious complication is thrombosis, which is heightened in the hypercoagulable state of pregnancy.

Chronic hemolysis has an insidious onset, and its severity ranges from mild to lethal. Hemoglobinuria develops at irregular intervals and is not necessarily nocturnal. Hemolysis may be initiated by transfusions, infections, or surgery. Almost 40 percent of patients suffer venous thromboses and may also experience renal failure, hypertension, and Budd-Chiari syndrome. Because of the thrombotic risk, prophylactic anticoagulation is recommended (Parker, 2005). The treatment of choice is eculizumab, an antibody that inhibits complement activation (Kelly, 2015). Median survival after diagnosis is 10 years, and bone marrow transplantation is the definitive treatment.

During pregnancy, paroxysmal nocturnal hemoglobinuria can be serious and unpredictable. Complications have been reported in up to three fourths of affected women, and the maternal mortality rate in the past was 10 to 20 percent (De Gramont, 1987; de Guibert, 2011). Complications more often develop postpartum, and half of affected women develop venous thrombosis (Fieni, 2006; Ray, 2000). Kelly and colleagues (2015) described 75 pregnancies in 61 affected women treated with eculizumab. In half of these, the dose was increased during pregnancy. They described no maternal deaths but 4 percent stillbirths.

Bacterial Toxins

The most fulminant acquired hemolytic anemia encountered during pregnancy is caused by the exotoxin of *Clostridium perfringens* or by group A β-hemolytic streptococcus (Chap. 47, Clinical Manifestations). Endotoxin of gram-negative bacteria, that is, lipopolysaccharide, may be accompanied by hemolysis and mild-to-moderate anemia (Cox, 1991). For example, anemia often accompanies acute pyelonephritis. With normal erythropoietin production, red cell mass is restored following infection resolution as pregnancy progresses (Cavenee, 1994; Dotters-Katz, 2013).

Inherited Erythrocyte Membrane Defects

The normal erythrocyte is a flexible biconcave disc that allows numerous cycles of reversible deformations. Several genes encode expression of erythrocyte structural membrane proteins or intraerythrocytic enzymes. Various mutations of these genes may result in inherited membrane defects or enzyme deficiencies that destabilize the lipid bilayer. The loss of lipids from the erythrocyte membrane causes a surface area deficiency and poorly deformable cells that undergo hemolysis. Anemia severity depends on the degree of rigidity or decreased distensibility. Erythrocyte morphology similarly is dependent on these factors, and these disorders are usually named after the most dominant red-cell shape characteristic of the disorder. Three examples are *hereditary spherocytosis, pyropoikilocytosis*, and *ovalocytosis*.

Hereditary Spherocytosis

Hemolytic anemias that compose this group of inherited membrane defects are among the most common hemolytic anemias found in gravidas. Mutations are usually an autosomally dominant, variably penetrant *spectrin* deficiency. Others are autosomally recessive or de novo gene mutations that result from deficiency of ankyrin, protein 4.2, moderate band 3, or combinations of these (Gallagher, 2010; Rencic, 2017; Yawata, 2000). The degrees of anemia and jaundice vary, and diagnosis is confirmed by identification of spherocytes on peripheral smear and increased osmotic fragility.

Spherocytic anemias may be associated with a so-called crisis that is characterized by severe anemia from accelerated hemolysis, and it develops in patients with an enlarged spleen. Infection can also accelerate hemolysis or suppress erythropoiesis to worsen anemia. An example of the latter is infection with parvovirus B19 (Chap. 64, Respiratory Viruses). In severe cases, splenectomy reduces hemolysis, anemia, and jaundice.

Pregnancy

In general, women with inherited red-cell membrane defects do well during pregnancy. Folic acid supplementation of 4 mg daily is given orally to sustain erythropoiesis. Women with hereditary spherocytosis cared for at Parkland Hospital had hematocrits ranging from 23 to 41 volumes percent—mean 31 (Maberry, 1992). Reticulocyte counts ranged from 1 to 23 percent. Among 50 pregnancies in 23 women, eight women miscarried. Four of 42 infants were born preterm, but none was growth restricted. Infection in four women intensified hemolysis, and three of these required transfusions. Similar results were reported by Pajor and coworkers (1993).

Because these disorders are inherited, the newborn may be affected. Celkan and Alhaj (2008) report prenatal diagnosis via cordocentesis at 18 weeks' gestation and testing for osmotic fragility. Newborns with hereditary spherocytosis may manifest hyperbilirubinemia and anemia shortly after birth.

Erythrocyte Enzyme Deficiencies

An intraerythrocytic deficiency of enzymes that permit anaerobic glucose metabolism may cause *hereditary nonspherocytic anemia*. Most of these mutations are autosomal recessive traits. As discussed earlier (Hemolytic Anemia), most episodes of severe anemia with enzyme deficiencies are induced by drugs or infections.

Pyruvate kinase deficiency is associated with variable anemia and hypertensive complications (Wax, 2007). Due to recurrent transfusions in homozygous carriers, iron overload is frequent, and associated myocardial dysfunction should be monitored (Dolan, 2002). The fetus that is homozygous for this mutation may develop *hydrops fetalis* from anemia and heart failure (Chap. 15, Hydrops Fetalis).

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is complex because there are more than 400 known enzyme variants. The most common are caused by a base substitution that leads to an amino acid replacement and a broad range of phenotypic severity (Luzzatto, 2015; Puig, 2013). In the homozygous or A variant, both X chromosomes are affected, and erythrocytes are markedly deficient in G6PD activity. Approximately 2 percent of African-American women are affected, and the heterozygous variant is found in 10 to 15 percent (Mockenhaupt, 2003). In both instances, random X-chromosome inactivation—*lyonization*—results in variable enzyme activity.

During pregnancy, infections or drugs can induce hemolysis in G6PD deficiency heterozygotes or homozygotes, and severity is related to enzyme activity. Anemia is usually episodic, although some variants induce chronic nonspherocytic hemolysis. Because young erythrocytes contain more enzyme activity, anemia ultimately stabilizes and is corrected soon after the inciting cause is eliminated. Newborn screening for G6PD deficiency is not recommended by the American College of Obstetricians and Gynecologists (2016b).

Aplastic and Hypoplastic Anemia

Aplastic anemia is a grave complication that is characterized by pancytopenia and markedly hypocellular bone marrow (Young, 2015). There are multiple etiologies, and at least one is linked to autoimmune diseases (Stalder, 2009). The inciting cause can be identified in approximately a third of cases. These include drugs and other chemicals, infection, irradiation, leukemia, immunological disorders, and inherited conditions such as *Fanconi anemia* and *Diamond-Blackfan syndrome* (Green, 2009; Lipton, 2009). The functional defect appears to be a marked decrease in committed marrow stem cells.

Hematopoietic stem-cell transplantation is optimal therapy in a young patient (Killick, 2016). Immunosuppressive therapy is given, and in some nonresponders, *eltrombopag* has been successful (Olnes, 2012; Townsley, 2017). Definitive treatment is bone marrow transplantation, and approximately three fourths of patients have a good response and long-term survival (Rosenfeld, 2003). Umbilical cord blood-derived stem cells can also serve as a potential transplant source (Moise, 2005; Pinto, 2008). Previous blood transfusions and even pregnancy enhance the risk of graft rejection (Young, 2015).

Pregnancy

Hypoplastic or aplastic anemia complicating pregnancy is rare. A study of 60 pregnancies complicated by aplastic anemia found that half were diagnosed during pregnancy (Bo, 2016). There are a few well-documented cases of *pregnancy-induced hypoplastic anemia,* and the anemia and other cytopenias improve or remit following delivery or pregnancy termination (Bourantas, 1997; Choudhry, 2002). In some cases, anemia recurred in a subsequent pregnancy.

Diamond-Blackfan anemia is a rare form of pure red-cell hypoplasia. Approximately 40 percent of cases are familial and have autosomal dominant inheritance (Orfali, 2004). The response to glucocorticoid therapy is usually good. Continuous treatment is necessary, and most become at least partially transfusion dependent (Vlachos, 2008). In 64 pregnancies complicated by this syndrome, Faivre and associates (2006) reported that two thirds had problems related to placental vascular etiologies that included miscarriage, preeclampsia, preterm birth, fetal-growth restriction, or stillbirth.

Gaucher disease is an autosomally recessive lysosomal enzyme deficiency characterized by deficient activity of *acid* β-*glucosidase*. Affected women have anemia and thrombocytopenia that is usually worsened by pregnancy (Granovsky-Grisaru, 1995). Elstein and colleagues (1997) described six pregnant women whose disease improved when they were given *alglucerase* enzyme replacement. *Imiglucerase* therapy, which is human recombinant enzyme replacement therapy, has been available since 1994. European guidelines recommend treatment in pregnancy, whereas the Food and Drug Administration states it may be given with “clear indications” (Granovsky-Grisaru, 2011).

The major risks with hypoplastic anemia are hemorrhage and infection. Rates of preterm labor, preeclampsia, fetal-growth restriction, and stillbirth are increased (Bo, 2016). Management depends on gestational age, and supportive care includes continuous infection surveillance and prompt antimicrobial therapy. Granulocyte transfusions are given only during infections. Red cells are transfused to improve symptomatic anemia and routinely to maintain the hematocrit at or above 20 volumes percent. Platelet transfusions may be needed to control hemorrhage. Maternal mortality rates reported since 1960 have averaged nearly 50 percent, however, better outcomes have been reported more recently (Choudhry, 2002; Kwon, 2006).

Pregnancy after Bone Marrow Transplantation

Several reports describe successful pregnancies in women who have undergone bone marrow transplantation (Borgna-Pignatti, 1996; Eliyahu, 1994). In their review, Sanders and coworkers (1996) reported 72 pregnancies in 41 women who had undergone transplantation. In the 52 pregnancies resulting in a liveborn neonate, almost half were complicated by preterm delivery or hypertension. Our experiences with a few of these women indicate that they have normal pregnancy-augmented erythropoiesis and total blood volume expansion.

POLYCYTHEMIAS

Secondary Polycythemia

Excessive erythrocytosis during pregnancy is usually related to chronic hypoxia from maternal congenital cardiac disease or a chronic pulmonary disorder. Unusually heavy cigarette smoking can cause polycythemia. We have encountered otherwise healthy pregnant women who were heavy smokers, had chronic bronchitis, and had hematocrits ranging from 55 to 60 volumes percent! If polycythemia is severe, the probability of a successful pregnancy outcome is low.

Polycythemia Vera

This is a primary clonal myeloproliferative hemopoietic stem-cell disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic precursors (Spivak, 2015; Vannucchi, 2015). Virtually all patients have either a *JAK2*V617F or a *JAK2* exon 12 gene mutation (Harrison, 2009). Symptoms are related to increased blood viscosity, and thrombotic complications are common. Treatment of nonpregnant patients is with hydroxyurea or ruxolitinib (Vannucchi, 2015).

Fetal loss rates are high in women with polycythemia vera, and pregnancy outcome may be improved with aspirin therapy (Griesshammer, 2006; Robinson, 2005; Tefferi, 2000). Women with a history of venous thrombosis are given prophylaxis with low-molecular-weight heparin. If cytoreduction is required during pregnancy, interferon alpha may be considered (Kreher, 2014).

HEMOGLOBINOPATHIES

Sickle-Cell Hemoglobinopathies

Hemoglobin A is the most common hemoglobin tetramer and consists of two α- and two β-chains. In contrast, sickle hemoglobin (hemoglobin S) originates from a single β-chain substitution of glutamic acid by valine, which stems from an A-for-T substitution at codon 6 of the β-globin gene. Hemoglobinopathies that can result in clinical features of the *sickle-cell syndrome* include sickle-cell anemia (Hb SS); sickle-cell hemoglobin C disease (Hb SC); sickle-cell β-thalassemia disease (either Hb S/B^0 or Hb S/B^+); and sickle-cell E disease (Hb SE) (Benz, 2015). All are also associated with increased pregnancy morbidity.

Sickle-cell anemia results from the inheritance of the gene for S hemoglobin from each parent. In the United States, 1 of 12 African-Americans has sickle-cell trait, which results from inheritance of one gene for hemoglobin S and one for normal hemoglobin A. The computed incidence of sickle-cell anemia among African-Americans is 1 in 576 (1/12 × 1/12 × 1/4 = 1/576). But, the disease is less common in adults because of earlier mortality. Hemoglobin C originates from a single β-chain substitution of glutamic acid by lysine, which stems from a T-for-C substitution at codon 6 of the β-globin gene. Approximately 1 in 40 African-Americans has the gene for hemoglobin C. Thus, the theoretical incidence for coinheritance of the gene for hemoglobin S and an allelic gene for hemoglobin C in an African-American child is about 1 in 2000 (1/12 × 1/40 × 1/4). β-Thalassemia minor is approximately 1 in 40, thus S-β-thalassemia also is found in approximately 1 in 2000 (1/12 × 1/40 × 1/4).

Pathophysiology

Red cells with hemoglobin S undergo sickling when they are deoxygenated, and the hemoglobin aggregates. Constant sickling and unsickling cause membrane damage, and the cell may become irreversibly sickled. Events that slow erythrocyte transit through the microcirculation include adhesion to endothelial cells, erythrocytic dehydration, and vasomotor dysregulation. Clinically, the hallmarks of sickling episodes are periods during which there is ischemia and infarction in various organs. The *sickle-cell crisis* produces clinical symptoms, predominately pain, which is often severe. There may be aplastic, megaloblastic, sequestration, and hemolytic crises.

Chronic and acute changes from sickling include bony abnormalities such as osteonecrosis of femoral and humeral heads, renal medullary damage, autosplenectomy in homozygous SS patients and splenomegaly in other variants, hepatomegaly, ventricular hypertrophy, pulmonary infarctions, pulmonary hypertension, cerebrovascular accidents, leg ulcers, and a propensity for infection and sepsis (Benz, 2015; Gladwin, 2004). Other sequelae are cerebrovascular aneurysms and sickle-cell vasculopathy (Buonanno, 2016). Pulmonary hypertension can develop and is found in 20 percent of adults with SS hemoglobin (Gladwin, 2008).

Treatment

Good supportive care is essential to prevent mortality. Specific therapies are evolving, and many are still experimental. One treatment is hemoglobin F induction with drugs that stimulate gamma-chain synthesis. This increases hemoglobin F, which inhibits hemoglobin S polymerization. One example is *hydroxyurea,* which augments hemoglobin F production and reduces the number of sickling episodes (Platt, 2008). Hydroxyurea is teratogenic in animals, although a preliminary 17-year surveillance of antenatally exposed children was reassuring (Ballas, 2009; Briggs, 2015; Italia, 2010). A randomized trial showed no benefit from treatment with *prasugrel*, a platelet inhibitor (Henney, 2016). Treatment with *crizanlizumab*, an antibody against P-selectin, significantly lowered the incidence of adverse events (Ataga, 2017).

Various forms of hemopoietic cell transplantation are emerging as “cures” for sickle-cell syndromes and severe thalassemias (Hsieh, 2009). Oringanje and coworkers (2013) performed a Cochrane review and found that only observational studies have been reported. *Bone marrow transplantation* has 5-year survival rates that exceed 90 percent (Dalle, 2013). *Cord-blood stem-cell transplantation* from related donors also shows great promise (Shenoy, 2013). Finally, successful gene therapy has been accomplished by lentiviral vector-mediated addition of a beta globin gene into stem cells (Ribeil, 2017).

Pregnancy and Sickle-Cell Syndromes

Pregnancy is a serious burden to women with any of the major sickle hemoglobinopathies, particularly those with hemoglobin SS disease. Several large studies have defined this relationship. Villers and colleagues (2008) studied 17,952 births in women with sickle-cell syndromes. Chakravarty and associates (2008) studied 4352 pregnancies. A more recent cohort study of 1526 women was reported by Boulet and coworkers (2013). Last, a cohort study taken from more than 2 million women compared those with sickle-cell disease to normal controls (Kuo, 2016). Common obstetrical and medical complications and their relative risks from a composite of most of these studies are shown in Table 56-2.

TABLE 56-2

Pregnancy Morbidity with Hemoglobin SS and SC Disease

	Odds Ratios	
Outcome	**Hb SS**	**Hb SC**
Preeclampsia	2–3.1	2.0
Stillbirth	6.5	3.2
Preterm delivery	2–2.7	1.5
Growth restriction	2.8–3.9	1.5
Maternal mortality	11–23	11

Data from metaanalyses by Boafor, 2016; Oteng-Ntim, 2015.

Maternal morbidity common in pregnancy includes ischemic necrosis of multiple organs, especially bone marrow that causes episodes of severe pain. Pyelonephritis, pneumonia, and pulmonary complications are frequent. Although the maternal mortality rate has improved, perinatal morbidity and mortality rates remain formidable (Boga, 2016; Lesage, 2015; Yu, 2009). Perinatal outcomes include increased risks for preterm birth, fetal-growth restriction, and perinatal mortality.

Hemoglobin SC

In nonpregnant women, morbidity and mortality rates from SC disease are appreciably lower than those from sickle-cell anemia. Indeed, fewer than half of these women have symptoms before pregnancy. In our experiences, affected gravidas suffer attacks of severe bone pain and episodes of pulmonary infarction and embolization more commonly than when they are not pregnant (Cunningham, 1983). Some adverse pregnancy outcomes are shown in Table 56-2.

Management During Pregnancy

Women with sickle-cell hemoglobinopathies require close prenatal observation. Any factor that impairs erythropoiesis or increases red cell destruction aggravates the anemia. Prenatal folic acid supplementation with 4 mg daily is needed to support rapid red blood cell turnover.

One danger is that a symptomatic woman may categorically be considered to be suffering from a “sickle-cell crisis.” As a result, serious obstetrical or medical problems that cause pain, anemia, or both may be overlooked. Examples are ectopic pregnancy, placental abruption, pyelonephritis, or appendicitis. Thus, a diagnosis of sickle-cell crisis should be applied only after all other possible causes have been excluded. Pain with sickle-cell syndromes is caused by intense sequestration of sickled erythrocytes and infarction in various organs, especially bone marrow. These episodes may develop acutely, especially late in pregnancy, during labor and delivery, and early in the puerperium.

Guidelines for care of these women have been appropriately stressed by Rees and colleagues (2003). Marti-Carvajal and coworkers (2009) performed a Cochrane review and reported that no randomized trials have evaluated treatment during pregnancy. At minimum, intravenous fluids are given, and opioids are administered promptly for severe pain. Oxygen via nasal cannula may decrease the intensity of sickling at the capillary level. We have found that red cell transfusions after the onset of severe pain do not dramatically improve pain intensity and may not shorten its duration. Conversely, as discussed later, prophylactic transfusions almost always prevent further vasoocclusive episodes and pain crises. Recent reports suggest benefits from epidural analgesia (Verstraete, 2012; Winder, 2011). Long term, affected women can become habituated to narcotics. This problem is highlighted by the increased rates of neonatal abstinence syndrome, which is a constellation of withdrawal symptoms (Shirel, 2016).

Rates of covert bacteriuria and acute pyelonephritis are elevated substantively, and screening and treatment for bacteriuria are essential. If pyelonephritis develops, sickle cells are extremely susceptible to bacterial endotoxin, which can cause dramatic and rapid red cell destruction while simultaneously suppressing erythropoiesis. Pneumonia, especially due to *Streptococcus pneumoniae,* is common. The Centers for Disease Control and Prevention recommends specific vaccination for those with sickle-cell disease and all asplenic patients (Kim, 2016). These are polyvalent pneumococcal, *Haemophilus influenzae* type B, and meningococcal vaccines, and administration guidelines are found in Table 9-7.

Pulmonary complications are frequent. Of these, *acute chest syndrome* is characterized by pleuritic chest pain, fever, cough, lung infiltrates, and hypoxia, and usually also by bone and joint pain (Vichinsky, 2000). In addition to symptoms, radiographs show a new pulmonary infiltrate. There are four precipitants: infection, marrow emboli, thromboembolism, and atelectasis (Medoff, 2005). Bacterial or viral infection causes approximately half of cases. When acute chest syndrome develops, the mean duration of hospitalization is 10.5 days. Mechanical ventilation is required in approximately 15 percent, and the mortality rate approximates 3 percent (Gladwin, 2008). At least for nonpregnant adults, some recommend rapid simple or exchange transfusions to remove the “trigger” for acute chest syndromes (Gladwin, 2008). In a study of nonpregnant patients, Turner and colleagues (2009) reported that there were no increased benefits of exchange versus simple transfusions, and the former were associated with fourfold increased blood usage.

Women with sickle-cell disease usually have some degree of *cardiac dysfunction* from ventricular hypertrophy. Chronic hypertension worsens the dysfunction (Gandhi, 2000). During pregnancy, the basal hemodynamic state characterized by high cardiac output and increased blood volume is augmented (Veille, 1994). Although most women tolerate pregnancy without problems, complications such as severe preeclampsia or serious infections may result in ventricular failure (Cunningham, 1986). Heart failure caused by pulmonary hypertension must also be considered (Chakravarty, 2008).

In 4352 pregnancies in women with sickle-cell syndromes, Chakravarty and associates (2008) reported significantly higher pregnancy complication rates. Compared with controls, women with sickling disorders had a 63-percent rate of nondelivery-related admissions. They had a 1.8-fold greater incidence of hypertensive disorders—19 percent; a 2.9-fold higher rate of fetal-growth restriction—6 percent; and a 1.7-fold increased cesarean delivery rate—45 percent.

Prophylactic Red Cell Transfusions

Chronic transfusion therapy prevents strokes in high-risk children (DeBaun, 2014). During pregnancy, the most dramatic benefit of prophylactic transfusions has been on maternal morbidity rates (Benites, 2016). In an observational 10-year prospective study at Parkland Hospital, we offered prophylactic transfusions to all pregnant women with sickle-cell syndromes. Transfusions were given throughout pregnancy to maintain the hematocrit above 25 volumes percent and the portion of hemoglobin S <60 percent (Cunningham, 1979). Maternal morbidity was minimal, and erythropoiesis suppression was not problematic. Their outcomes were compared with historical controls who were not routinely transfused. Overall, morbidity and hospitalization rates were significantly reduced in the transfused group (Asma, 2015; Cunningham, 1983; Grossetti, 2009). Still, adverse perinatal outcomes are prevalent (Ngô, 2010).

In a multicenter trial, Koshy and coworkers (1988) randomly assigned 72 pregnant women with sickle-cell syndromes to prophylactic or indicated transfusions. They reported a significant decline in the incidence of painful sickle-cell crises with prophylactic transfusions but no differences in perinatal outcomes. Because of risks inherent with blood administration, they concluded that prophylactic transfusions were not indicated. A metaanalysis of 12 studies found prophylactic transfusions improved rates of some adverse maternal and neonatal outcomes, including maternal mortality, pulmonary complications, and perinatal mortality (Malinowski, 2015).

Undoubtedly, morbidity from multiple transfusions is significant. Up to 10 percent of women had a delayed hemolytic transfusion reaction, and infections are major concerns. Garratty (1997) reviewed 12 studies and found alloimmunization developed in a fourth of women. Finally, in liver biopsies in these women, we found no evidence of transfusion-related iron overload, hemochromatosis, or chronic hepatitis (Yeomans, 1990).

Because of what some consider marginal benefits, routine prophylactic transfusions during pregnancy remain controversial (American College of Obstetricians and Gynecologists, 2015; Okusayna, 2013). Current consensus is that their use should be individualized.

Fetal Assessment

Because of the high incidence of fetal-growth restriction and perinatal mortality, serial fetal assessment with sonography and antepartum surveillance is recommended (American College of Obstetricians and Gynecologists, 2015). Anyaegbunam and colleagues (1991) reported nonreactive stress tests during sickling crises, which resumed reactivity with crisis resolution. They concluded that transient effects of sickle-cell crisis do not compromise umbilical blood flow.

Labor and Delivery

Management is essentially identical to that for women with cardiac disease (Chap. 49, Labor and Delivery). Women should be kept comfortable, but not oversedated. Conduction analgesia is ideal (Camous, 2008). Compatible blood should be available. If a difficult vaginal or cesarean delivery is contemplated, and the hematocrit is <20 volumes percent, then packed erythrocyte transfusions are administered. There is no categorical contraindication to vaginal delivery, and cesarean delivery is reserved for obstetrical indications (Rogers, 2010).

Contraception and Sterilization

Many clinicians do not recommend combination hormonal contraception because of potential adverse vascular and thrombotic effects. In their systematic review, however, Haddad and coworkers (2012) found that complication rates were not higher with their use in women with sickle-cell syndromes. The Centers for Disease Control and Prevention categorizes combination hormonal contraception, intrauterine devices, implants, and progestin-only contraception as having no risk or as having advantages that generally outweigh theoretical or proven risks (Curtis, 2016).

Sickle-Cell Trait

The frequency of sickle-cell trait among African-Americans averages 8 percent. Carriers have occasional hematuria, renal papillary necrosis, and hyposthenuria, which is urine of low specific gravity (Tsaras, 2009). And although controversial, sickle-cell trait does not appear to be associated with increased rates of abortion, perinatal mortality, low birthweight, or pregnancy-induced hypertension (Pritchard, 1973; Tita, 2007; Tuck, 1983). One unquestioned relationship is the twofold increased incidence of asymptomatic bacteriuria and urinary infection. Sickle-cell trait should not be considered a deterrent to pregnancy or to hormonal contraception.

Inheritance is a concern for the fetus of a mother with sickle-cell trait whenever the father carries a gene for abnormal hemoglobins that include S, C, and D or for β-thalassemia trait. Prenatal diagnosis is discussed in Chapter 14 (Sickle Hemoglobinopathies).

Hemoglobin C and C-β-Thalassemia

Approximately 2 percent of African-Americans are heterozygous for hemoglobin C, but even if homozygous, hemoglobin C is innocuous (Nagel, 2003). Only when coinherited with sickle-cell trait to yield hemoglobin SC is the trait problematic. Pregnancy in women with homozygous hemoglobin CC disease or C-β-thalassemia carries relatively benign associations. Table 56-3 shows our experiences from Parkland Hospital (Maberry, 1990). Other than mild-to-moderate anemia, pregnancy outcomes were not abnormal. Supplementation with folic acid and iron is indicated.

TABLE 56-3

Outcomes in 72 Pregnancies Complicated by Hemoglobin CC and C-β-Thalassemia

	Hemoglobin CC	C-β-Thalassemia
Women (no.)	15	5
Pregnancies (no.)	49	23
Hematocrit (range)	27 (21–33)	30 (28–33)
Birthweight (g)		
Mean	2990	2960
Range	1145–4770	2320–3980
Perinatal deaths	1	2
Surviving infants	42	20

Data from Maberry, 1990.

Hemoglobin E

Although uncommon in the United States, hemoglobin E is the second most frequent hemoglobin variant worldwide. The heterozygous E trait is common in Southeast Asia. Hurst and coworkers (1983) identified homozygous hemoglobin E, hemoglobin E plus β-thalassemia, or hemoglobin E trait in 36 percent of Cambodians and 25 percent of Laotians. Hemoglobin EE is associated with little or no anemia, hypochromia, marked microcytosis, or erythrocyte targeting. Kemthong and colleagues (2016) studied 1073 women and 2146 controls and found that hemoglobin E trait does not increase pregnancy risks other than asymptomatic bacteriuria. Conversely, doubly heterozygous E-β-thalassemia is a common cause of severe childhood anemia in Southeast Asia (DeLoughery, 2014). In a cohort study of 54 women with singleton pregnancies, Luewan and associates (2009) reported a threefold greater risk of preterm birth and fetal-growth restriction in affected women. It is unclear if hemoglobin SE disease is ominous during pregnancy.

Hemoglobinopathy in the Newborn

Neonates with homozygous SS, SC, and CC disease can be identified accurately at birth by cord blood electrophoresis. The United States Preventive Services Task Force recommends that all newborns be tested for sickle-cell disease (Lin, 2007). In most states, such screening is mandated by law and performed routinely (Chap. 32, Routine Newborn Care).

Prenatal Diagnosis

Many tests are available to detect sickle-cell disease antenatally. Most are DNA based and use chorionic villus samples or amnionic fluid specimens (American College of Obstetricians and Gynecologists, 2015). Several mutations that encode hemoglobin S and other abnormal hemoglobins can be detected by targeted mutation analysis and polymerase chain reaction-based techniques (Chap. 13, Genetic Tests).

THALASSEMIA SYNDROMES

Hundreds of mutations affect genes that control hemoglobin production. Some of these impair synthesis of one or more of the normal globin peptide chains and may result in a clinical syndrome characterized by varying degrees of ineffective erythropoiesis, hemolysis, and anemia (Benz, 2015). Thalassemias are classified according to the globin chain that is deficient. The two major forms involve impaired production or instability of α-peptide chains to cause α-thalassemia or of β-chains to cause β-thalassemia. These may form from point mutations, deletions, or translocations involving the α- or non-α-globin gene (Leung, 2012).

Alpha Thalassemias

Because there are four α-globin genes, the inheritance of α-thalassemia is more complicated than for β-thalassemia (Piel, 2014). Possible genotypes and phenotypes are shown in Table 56-4. Clinical severity closely correlates with the degree of α-globin chains synthesis impairment. In most populations, the α-globin chain "cluster" or gene loci are doubled on chromosome 16. Similarly, the γ chains are duplicated. Thus, the normal genotype for diploid cells can be expressed as αα/αα and γγ/γγ. There are two main groups of α-thalassemia determinants: α^0-thalassemia is the deletion of both loci from one chromosome

TABLE 56-4

Genotypes and Phenotypes of α-Thalassemia Syndromes

Genotype	Genotype	Phenotype
Normal	αα/αα	Normal
α^+-Thalassemia heterozygote	–α/αα αα/–α	Normal; silent carrier
α^+-Thalassemia homozygote[a] α^0-Thalassemia heterozygote[b]	–α/–α ––/αα	α-Thalassemia minor—mild hypochromic microcytic anemia
Compound heterozygous α^0/α^+	––/–α	Hgb H (β_4) with moderate-to-severe hemolytic anemia
Homozygous α-thalassemia	––/––	Hgb Bart (γ_4) disease, hydrops fetalis

[a]More common in African Americans.

[b]More common in Asian Americans.

(––/αα), whereas α^+-thalassemia is the loss of a single locus from one allele (–α/αα heterozygote) or a loss from each allele (–α/–α homozygote).

There are two major phenotypes. The deletion of all four α-globin chain genes (––/––) characterizes *homozygous* α-thalassemia. Because α-chains are contained in fetal hemoglobin, the fetus is affected. When none of the four genes are expressed, no α-globin chains are produced, and instead hemoglobin Bart (γ_4) and hemoglobin H (β_4) are formed as abnormal tetramers that cannot transport oxygen (Chap. 7, Hemopoiesis).

Frequency

The relative frequency of α-thalassemia minor, hemoglobin H disease, and hemoglobin Bart disease varies remarkably among racial groups. All of these variants are encountered in Asians. In those of African descent, although α-thalassemia minor has a frequency approximating 2 percent, hemoglobin H disease is rare and hemoglobin Bart disease is unreported. This is because Asians usually have α^0-thalassemia minor inherited with both gene deletions typically from the same chromosome (––/αα), whereas blacks usually have α^+-thalassemia minor in which one gene is deleted from each chromosome (–α/–α).

Diagnosis of β-thalassemia minor and α-thalassemia major in the fetus can be accomplished by DNA analysis using molecular techniques (Piel, 2014). Fetal diagnosis of hemoglobin Bart has been described using capillary electrophoresis or high-performance liquid chromatography techniques (Sirichotiyakul, 2009; Srivorakun, 2009). Molecular genetic testing for *HBA1* and *HBA2* identifies 90 percent of deletions and 10 percent of point mutations in affected individuals (Galanello, 2011b).

Pregnancy

Important obstetrical aspects of some α-thalassemia syndromes depend on the number of gene deletions in a given woman. The silent carrier state with one gene deletion is of no consequence. Deletion of two genes resulting in *α*-thalassemia minor is characterized by minimal-to-moderate hypochromic microcytic anemia. This is due to either α^0- or α^+-thalassemia trait, and thus genotypes may be –α/–α or ––/αα. Differentiation is possible only by DNA analysis (Piel, 2014). Because no other clinical abnormalities accompany either form of α-thalassemia minor, it often goes unrecognized and is usually of no maternal consequence (Hanprasertpong, 2013). The fetus with these forms of thalassemia minor will have hemoglobin Bart at birth, but as its levels drop, it is not replaced by hemoglobin H. Red cells are hypochromic and microcytic, and the hemoglobin concentration is normal to slightly depressed.

Hemoglobin H disease (β_4) results from the compound heterozygous state for α^0- plus α^+-thalassemia with deletion of three of four alpha genes (––/–α). With only one functional α-globin gene per diploid genome, the newborn will have abnormal red cells containing a mixture of hemoglobin Bart (γ_4), hemoglobin H (β_4), and hemoglobin A. The neonate appears normal but soon develops hemolytic anemia as most of the hemoglobin Bart is replaced by hemoglobin H. In adults, anemia is moderate to severe and usually worsens during pregnancy.

Inheritance of all four abnormal α genes causes homozygous α-thalassemia with predominant production of hemoglobin Bart, which has an appreciably increased affinity for oxygen. This is incompatible with extended survival. Hsieh and colleagues (1989) reported that blood obtained by funipuncture from 20 hydropic fetuses contained 65 to 98 percent Bart hemoglobin. These fetuses are stillborn, or they are hydropic and usually die very soon after birth.

Sonographic measurement of the fetal cardiothoracic ratio at 12 to 13 weeks' gestation can be used to identify affected fetuses (Lam, 1999; Zhen, 2015). Sonographic assessment of myocardial performance—the *Tei index*—in the first half of pregnancy has been evaluated. Changes predate hydrops in affected fetuses (Luewan, 2013). Severe anemia can be detected using Doppler velocimetry of the middle cerebral artery. Hemopoietic cell transplantation has been described for treatment (Galanello, 2011a).

Beta Thalassemias

The β-thalassemias are the consequences of impaired β-globin chain production or α-chain instability. Genes that encode control of β-globin synthesis are in the δγβ-gene "cluster" located on chromosome 11 (Chap. 7, Hemopoiesis). More than 150 point mutations in the β-globin gene have been described (Weatherall, 2010). In β-thalassemia, β-chain production is decreased, and excess α-chains precipitate to cause cell-membrane damage. Other forms of β-thalassemias are caused by α-chain instability (Kihm, 2002).

The heterozygous trait is β-thalassemia minor, and those most commonly encountered have elevated hemoglobin A_2 levels. This hemoglobin is composed of two α- and two δ-globin chains, and concentrations are usually more than 3.5 percent. Hemoglobin F—composed of two α- and two γ-globin chains—also usually has increased concentrations that exceed 2 percent. Some patients with heterozygous β-thalassemia minor do not have anemia, and others have mild-to-moderate anemia characterized by hypochromia and microcytosis.

Homozygous β-thalassemia—also called β-thalassemia major or *Cooley anemia*—is a serious and frequently fatal disorder. Hemolysis is intense and leads to severe anemia. Many patients become transfusion dependent, and the subsequent iron load, along with abnormally increased gastrointestinal iron absorption, leads to hemochromatosis, which is fatal in many cases. Stem cell transplantation has been used to treat β-thalassemia major (Jagannath, 2014). A heterozygous form of β-thalassemia that clinically manifests as *thalassemia intermedia* produces moderate anemia.

Pregnancy

During pregnancy, women with β-thalassemia minor may have mild anemia (Charoenboon, 2016). Iron and folate supplements are given. In some women, anemia will worsen because normal plasma volume expansion may be accompanied by slightly subnormal erythropoiesis.

Thalassemia major and some of the other severe forms were uncommonly encountered during pregnancy before the advent of transfusion and iron chelation therapy. With such management, 63 pregnancies were reported and suffered no serious complications (Aessopos, 1999; Daskalakis, 1998). Pregnancy is considered reasonably safe if maternal cardiac function is normal. Transfusions are given throughout pregnancy to maintain the hemoglobin concentration at 10 g/dL. This is coupled with surveillance of fetal growth (American College of Obstetricians and Gynecologists, 2015; Sheiner, 2004).

Prenatal Diagnosis

Because β-thalassemia major is caused by numerous mutations, prenatal diagnosis is difficult. For a given individual, targeted mutation analysis is done that requires prior identification of the familial mutation. The analysis is done using chorionic villus sampling and other techniques discussed in Chapter 14 (Chorionic Villus Sampling). Noninvasive testing of circulating fetal nucleic acids in maternal plasma for the diagnosis of β-thalassemia has been described (Leung, 2012; Xiong, 2015).

PLATELET DISORDERS

Thrombocytopenia

Platelet abnormalities may precede pregnancy, develop during pregnancy coincidentally, or be induced by pregnancy. Thrombocytopenia—defined by a platelet count <150,000/μL—is identified in nearly 10 percent of gravidas (American College of Obstetricians and Gynecologists, 2016c). Of these cases, 75 percent are *gestational thrombocytopenia,* whereas 25 percent are due to other various causes. One other common cause is HELLP syndrome. Thrombocytopenia may be inherited or idiopathic, acute or chronic, and primary or associated with other disorders. Examples are shown in Table 56-5.

TABLE 56-5

Some Causes of Thrombocytopenia in Pregnancy

Gestational thrombocytopenia—75 percent
Preeclampsia and HELLP syndromes—20 percent
Obstetrical coagulopathies—DIC, MTP
Immune thrombocytopenic purpura
Systemic lupus erythematosus and APAS
Infections—viral and sepsis syndrome
Drugs
Hemolytic anemias
Thrombotic microangiopathies
Malignancies

APAS = antiphospholipid antibody syndrome; DIC = disseminated intravascular coagulopathy; HELLP = hemolysis, elevated liver enzyme levels, low platelet count; MTP = massive transfusion protocol.

Data from American College of Obstetrics and Gynecologists, 2016c; Aster, 2007; Diz-Küçükkāya, 2016.

Gestational Thrombocytopenia

Burrows and Kelton (1993) reported that 6.6 percent of 15,471 pregnant women had a platelet count <150,000/μL, and in 1.2 percent, it was <100,000/μL. They further noted that almost 75 percent of 1027 women whose platelet counts were <150,000/μL were found to have normal-variant incidental thrombocytopenia. Of the remainder, 21 percent had a hypertensive disorder of pregnancy, and 4 percent had an immunological disorder. A platelet count of <80,000/μL should trigger an evaluation for etiologies other than incidental or gestational thrombocytopenia, which is unlikely to have a platelet count <50,000/μL (Gernsheimer, 2013).

The physiological decline in platelet concentration seen with gestational thrombocytopenia is usually evident in the third trimester and is thought to be predominantly due to hemodilution. The normal increased splenic mass characteristic of pregnancy may also be contributory (Maymon, 2006). Most evidence shows that platelet life span is unchanged in normal pregnancy (Kenny, 2015).

Inherited Thrombocytopenias

Bernard-Soulier syndrome is characterized by lack of platelet membrane glycoprotein (GPIb/IX) and causes severe dysfunction. Moreover, women exposed to fetal platelets carrying this glycoprotein can develop antibodies against this fetal GPIb/IX antigen to cause alloimmune fetal thrombocytopenia (Fujimori, 1999; Peng, 1991).

A systematic review of 30 pregnancies in 18 women reported a 33-percent rate of primary postpartum hemorrhage, and half of women with bleeding required blood transfusion (Peitsidis, 2010). The reviewers also described six cases of neonatal alloimmune thrombocytopenia and two perinatal deaths. Close monitoring throughout pregnancy and 6 weeks postpartum is critical due to the possibility of life-threatening hemorrhage (Prabu, 2006).

May-Hegglin anomaly is an autosomal dominant disorder characterized by thrombocytopenia, giant platelets, and leukocyte inclusions (Chatwani, 1992). Urato and Repke (1998) described such a woman who was delivered vaginally. Despite a platelet count of 16,000/μL, she did not bleed excessively. The neonate inherited the anomaly but also had no bleeding despite a platelet count of 35,000/μL. A systematic review of 26 studies containing 75 pregnancies in 40 women reported four cases of postpartum hemorrhage, 34 cases of neonatal thrombocytopenia, and two fetal deaths (Hussein, 2013).

Immune Thrombocytopenic Purpura

The primary form—also termed *idiopathic thrombocytopenic purpura (ITP)*—is usually caused by a cluster of IgG antibodies directed against one or more platelet glycoproteins (Konkle, 2015). Antibody-coated platelets are destroyed prematurely in the reticuloendothelial system, especially the spleen. Although not proven, the disorder is probably mediated by autoantibodies directed at platelet-associated immunoglobulins—PAIgG, PAIgM, and PAIgA. In adults, immune thrombocytopenia most often is a chronic disease that rarely resolves spontaneously.

As shown in Table 56-5, secondary forms of immune-mediated chronic thrombocytopenia appear in association with systemic lupus erythematosus, lymphomas, leukemias, and several systemic diseases. Approximately 2 percent of thrombocytopenic patients have positive serological tests for lupus, and in some cases, levels of anticardiolipin antibodies are high. Finally, approximately 10 percent of HIV-positive patients have associated thrombocytopenia (Scaradavou, 2002).

Diagnosis and Management

Only a few adults with primary immune thrombocytopenia recover spontaneously, and for those who do not, platelet counts usually range from 10,000 to 100,000/μL (George, 2014). Evidence does not suggest that pregnancy increases the risk of relapse in women with previously diagnosed disease or worsens thrombocytopenia in women with active disease. That said, it is certainly not unusual for women who have been in clinical remission for several years to have recurrent thrombocytopenia during pregnancy. Although this may be from closer surveillance, hyperestrogenemia has also been implicated.

Therapy is considered if the platelet count is below 30,000 to 50,000/μL (American College of Obstetricians and Gynecologists, 2016c). Primary treatment includes corticosteroids or intravenous immune globulin (IVIG) (Neunert, 2011). Initially, prednisone, 1 mg/kg daily, is given to suppress the phagocytic activity of the splenic monocyte-macrophage system. IVIG given in a total dose of 2 g/kg during 2 to 5 days is also effective.

In pregnant women with no response to corticosteroid or IVIG therapy, open or laparoscopic splenectomy may be effective. In late pregnancy, cesarean delivery may be necessary for surgical exposure. Improvement usually follows splenectomy in 1 to 3 days and peaks at approximately 8 days. Cytotoxic agents are typically avoided in pregnancy due to teratogenicity risks. Azathioprine and rituximab, however, which are used in nonpregnant persons with ITP, have been used for other conditions in pregnancy. Finally, the thrombopoietin agonist *romiplostim* has stimulated responses in some patients (Decrooq, 2014; Imbach, 2011; Kuter, 2010).

Fetal and Neonatal Effects

Pregnancy complications that are increased with ITP include stillbirth, fetal loss, and preterm birth (Wyszynski, 2016). Platelet-associated IgG antibodies cross the placenta, and fetal death from hemorrhage occurs occasionally (Webert, 2003). The severely thrombocytopenic fetus is at increased risk for intracranial hemorrhage with labor and delivery, but fortunately this is unusual. Payne and associates (1997) reviewed studies of maternal ITP published since 1973. Of 601 newborns, 12 percent had severe thrombocytopenia with counts <50,000/μL. Six infants had intracranial hemorrhage, and in three, their initial platelet count was >50,000/μL. This is consistent with a study of 127 pregnancies in women with ITP in which 10 to 15 percent of neonates had transient ITP (Koyama, 2012).

Investigators concur that fetal and maternal platelet counts lack strong correlation (George, 2009; Hachisuga, 2014). Because of this, maternal IgG free platelet antibody levels and platelet-associated antibody levels have been evaluated to predict fetal platelet counts. Again, however, there is little concurrence with these.

Investigators have also examined the association between the specific cause of thrombocytopenia and risk of a thrombocytopenic fetus. Four researched causes include gestational thrombocytopenia, hypertension-associated thrombocytopenia, immune thrombocytopenia, and alloimmune thrombocytopenia. Burrows and Kelton (1993) reported neonatal umbilical cord platelet counts measuring <50,000/μL in 19 of 15,932 consecutive newborns (0.12 percent). Only one of 756 mothers with gestational thrombocytopenia had an affected newborn. Of 1414 hypertensive women with thrombocytopenia, five neonates had thrombocytopenia. In

contrast, of 46 mothers with immunological thrombocytopenia, four infants had thrombocytopenia. Alloimmune thrombocytopenia was associated with profound thrombocytopenia and cord platelet counts <20,000/µL. One of these fetuses died, and two others had intracranial hemorrhage.

Detection of Fetal Thrombocytopenia

Because no test accurately predicts fetal platelet counts, direct fetal blood sampling is necessary. Scott and coworkers (1983) obtained intrapartum scalp blood samples and recommended cesarean delivery for fetuses with platelet counts <50,000/µL. Daffos and colleagues (1985) reported that percutaneous umbilical cord blood sampling (PUBS) for this indication had a high complication rate (Chap. 14, Fetal Blood Sampling). Conversely, Berry and associates (1997) reported no complications and described poor reliability to predict severe thrombocytopenia, but noted a high negative-predictive value. Payne and coworkers (1997) summarized six studies in which fetal blood sampling was done for platelet estimation. Of the total of 195 fetuses, severe neonatal thrombocytopenia <50,000/µL was found in 7 percent. But, serious complications from cordocentesis were noted in 4.6 percent. Because of the low incidence of severe neonatal thrombocytopenia and morbidity, fetal platelet determinations and cesarean delivery are not recommended (Neunert, 2011).

Alloimmune Thrombocytopenia

Disparity between maternal and fetal platelet antigens can stimulate maternal production of antiplatelet antibodies. Such platelet alloimmunization can be severe, and its pathophysiology is identical to that caused by red cell antigens (Chap. 15, Fetal Thrombocytopenia).

Thrombocytosis

Also called *thrombocythemia*, thrombocytosis generally is defined as persistent platelet counts >450,000/µL. Common causes of *secondary* or *reactive thrombocytosis* are iron deficiency, infection, inflammatory diseases, and malignant tumors (Deutsch, 2013). Platelet counts seldom exceed 800,000/µL in these secondary disorders, and prognosis depends on the underlying disease. On the other hand, *primary* or *essential thrombocytosis* accounts for most cases in which platelet counts exceed 1 million/µL. It is a clonal disorder frequently due to an acquired mutation in the *JAK2* gene (Konkle, 2015). Thrombocytosis usually is asymptomatic, but arterial and venous thromboses may develop, and thrombosis is associated with pregnancy complications (Rabinerson, 2007; Randi, 2014). These cases must be differentiated from the *sticky platelet syndrome,* which is also associated with thromboses (Rac, 2011).

Normal pregnancies have been described in women whose mean platelet counts were >1.25 million/µL (Beard, 1991; Randi, 1994). Others report more adverse outcomes. Niittyvuopio and associates (2004) described 40 pregnancies in 16 women with essential thrombocythemia. Almost half had a spontaneous abortion, fetal demise, or preeclampsia. In 63 pregnancies in 36 women cared for at the Mayo Clinic, a third had a spontaneous miscarriage, but other pregnancy complications were uncommon (Gangat, 2009). In this observational study, aspirin therapy was associated with a significantly lower abortion rate than that in untreated women—1 versus 75 percent, respectively.

Suggested treatments during pregnancy include aspirin, low-molecular-weight heparin, and interferon-α (Finazzi, 2012). Interferon-α therapy during pregnancy was successful in 11 women in the review by Delage and coworkers (1996). One of these women had transient blindness at midpregnancy when her platelet count was 2.3 million/µL.

Thrombotic Microangiopathies

Although not a primary platelet disorder, some degree of thrombocytopenia accompanies the thrombotic microangiopathies, which include *thrombotic thrombocytopenic purpura (TTP)* and *hemolytic uremic syndrome (HUS).* These syndromes have an incidence of 2 to 6 per million persons per year (Miller, 2004). Their similarities to HELLP syndrome allude to their obstetrical ramifications (George, 2014).

Etiopathogenesis

Although different causes account for the variable findings within these syndromes, clinically, they frequently are indistinguishable. Most cases of TTP are thought to be caused by antibodies to or a plasma deficiency of ADAMTS13 (Ganesan, 2011; Sadler, 2010). This endothelium-derived protease cleaves von Willebrand factor (vWF) to decrease its activity. Conversely, HUS is usually due to endothelial damage incited by viral or bacterial infections and is seen primarily in children (Ardissino, 2013; George, 2014).

With TTP, intravascular platelet aggregation stimulates a cascade of events leading to end-organ failure. There is endothelial activation and damage, but it is unclear whether this is a consequence or a cause. Elevated levels of unusually large multimers of vWF are identified with active TTP. Various defects in the *ADAMTS13* gene create differing clinical presentations of thrombotic microangiopathy (Camilleri, 2007; Moake, 2002, 2004). In another scheme, antibodies raised against ADAMTS13 neutralize its action to cleave vWF multimers during an acute episode. The end result is microthrombi of hyaline material consisting of platelets and small amounts of fibrin within arterioles and capillaries. When sufficient in number or size, these aggregates produce ischemia or infarctions in various organs.

Clinical and Laboratory Manifestations

Thrombotic microangiopathies are characterized by thrombocytopenia, fragmentation hemolysis, and variable organ dysfunction. TTP is characterized by the pentad of thrombocytopenia, fever, neurological abnormalities, renal impairment, and hemolytic anemia. HUS typically has more profound renal involvement and fewer neurological aberrations.

Thrombocytopenia is usually severe, but fortunately, even with very low platelet counts, spontaneous severe hemorrhage is uncommon. Microangiopathic hemolysis is associated with moderate-to-marked anemia, and erythrocyte transfusions are frequently necessary. The blood smear is characterized by erythrocyte fragmentation with schizocytosis. Reticulocytes and nucleated red blood cells are increased, lactate dehydrogenase (LDH) levels are high, and haptoglobin concentrations are decreased. Consumptive coagulopathy, although common, is usually subtle and clinically insignificant.

Treatment

The cornerstone of treatment is plasmapheresis with fresh-frozen plasma replacement. Plasma exchange removes inhibitors and replaces the ADAMTS13 enzyme (George, 2014; Michael, 2009). Treatment with caplacizumab, the anti-vWF immunoglobulin, inhibits the interaction between ultralarge vWF multimers and platelets (Peyandi, 2016).

These treatments have remarkably improved outcomes in patients with these formerly fatal syndromes. Red cell transfusions are imperative for life-threatening anemia. Treatment is usually continued until the platelet count is >150,000/μL. Unfortunately, relapses are common. Additionally, there may be long-term sequelae such as renal impairment (Dashe, 1998; Vesely, 2015). Treatment for pregnancy-associated HUS, which is complement mediated, uses the anti-C5 humanized monoclonal antibody eculizumab (Ardissino, 2013; Cañigral, 2014; Fakhouri, 2016).

Pregnancy

As shown in the Appendix (Serum and Blood Constituents), ADAMTS13 enzyme activity decreases across pregnancy by up to 50 percent (Sánchez-Luceros, 2004). Levels drop even further with the preeclampsia syndrome. This is consonant with prevailing opinions that TTP is more commonly seen during pregnancy. The Parkland Hospital experiences were described by Dashe and coworkers (1998), who identified 11 pregnancies complicated by these syndromes among nearly 275,000 obstetrical patients—a frequency of 1 in 25,000.

It seems likely that some of the disparately higher incidence in pregnancy reported by others is because of inclusion of women with severe preeclampsia and eclampsia (Hsu, 1995; Magann, 1994). Differences that usually allow appropriate diagnosis are listed in Table 56-6. For example, moderate-to-severe hemolysis is a rather constant feature of thrombotic microangiopathies. But, this is seldom severe with the preeclampsia syndrome, even when complicated by HELLP syndrome (Chap. 40, Maternal Thrombocytopenia). And, although there is deposition of hyaline microthrombi within the liver with thrombotic microangiopathy, hepatocellular necrosis with elevated serum hepatic aminotransferase levels characteristic of preeclampsia is not a common feature (Ganesan, 2011; Sadler, 2010). Importantly, whereas delivery is imperative to reverse the preeclampsia syndrome, no evidence shows that thrombotic microangiopathy is improved by delivery (Dashe, 1998; Letsky, 2000). Finally, microangiopathic syndromes are usually recurrent and frequently unassociated with pregnancy. For example, seven of 11 women described by Dashe and colleagues (1998) had recurrent disease either when not pregnant or within the first trimester of a subsequent pregnancy. George (2009) reported recurrent TTP in only five of 36 subsequent pregnancies. That said, the risk for preeclampsia in these women is increased (Jiang, 2014).

TABLE 56-6

Some Differential Factors between HELLP Syndrome and Thrombotic Microangiopathies[a]

	HELLP Syndrome	Thrombotic Microangiopathies
Thrombocytopenia	Mild/mod.	Mod./severe
Microangiopathic hemolysis (schizocytosis)	Mild	Severe
ADAMTS13 def.	Mild/mod.	Severe
DIC	Mild	Mild
Transaminitis (AST, ALT)	Mod./severe	None/mild
Treatment	Delivery	Plasmapheresis

[a]Includes thrombotic thrombocytopenia purpura (TTP) and hemolytic uremic syndrome (HUS).

ADAMTS13 = ADAM metallopeptidase with thrombospondin type 1 motif, 13; AST = aspartate transaminase; ALT = alanine transaminase; def. = deficiency; DIC = disseminated intravascular coagulopathy; HELLP = hemolysis, elevated liver enzyme levels, low platelet count; Mod. = moderate.

Unless the diagnosis is unequivocally one of these thrombotic microangiopathies, rather than severe preeclampsia, the response to pregnancy termination should be evaluated before resorting to plasmapheresis and exchange transfusion, massive-dose glucocorticoid therapy, or other therapy. Unfortunately, recall that determination of ADAMTS13 enzyme activity may be difficult to interpret with HELLP syndrome (Franchini, 2007*). Plasmapheresis is not indicated for preeclampsia-eclampsia complicated by hemolysis and thrombocytopenia.*

During the past two decades, and coincidental with plasmapheresis and plasma exchange, maternal survival rates from thrombotic microangiopathy have improved dramatically (Dashe, 1998). Although previously fatal in up to half of mothers, with such treatment, Egerman and coworkers (1996) reported two maternal and three fetal deaths in 11 pregnancies. Hunt and associates (2013) reported that TTP accounted for 1 percent of maternal deaths in the United Kingdom from 2003 to 2008.

Long-Term Prognosis

Women who are diagnosed with thrombotic microangiopathy during pregnancy are at risk for serious long-term complications (Egerman, 1996). The Parkland experiences included a mean 9-year surveillance period (Dashe, 1998). These women had multiple recurrences; renal disease requiring dialysis, transplantation, or both; severe chronic hypertension; and transfusion-acquired infectious diseases. Two women died remote from pregnancy—one from dialysis complications and one from transfusion-acquired HIV infection.

In nonpregnant women who have recovered from thrombotic microangiopathies, persistent cognitive defects and physical disabilities have been reported (Kennedy, 2009; Lewis, 2009). Interestingly, as discussed in Chapter 40 (Renal Sequelae), these cognitive defects are very similar to those found in long-term surveillance studies of women who had eclampsia (Aukes, 2009, 2012; Wiegman, 2012).

INHERITED COAGULATION DEFECTS

Hemophilias A and B

Obstetrical hemorrhage may infrequently be the consequence of an inherited defect in a protein that controls coagulation. Both types of hemophilia are examples. Severity reflects plasma factor levels and is categorized as mild—levels of 6 to 30 percent; moderate—2 to 5 percent; or severe—less than 1 percent (Arruda, 2015).

Hemophilia A is an X-linked recessively transmitted disorder characterized by a marked deficiency of factor VIII. It is rare among women compared with men, in whom the heterozygous state is responsible for the disease. Heterozygous women have diminished factor VIII levels, but almost invariably, the homozygous state is requisite for hemophilia A. In a few instances, it appears in women spontaneously from a newly mutated gene. Pregnancy-associated acquired hemophilia A from antibodies may result in severe bleeding-related morbidity (Tengborn, 2012). *Christmas disease* or *hemophilia B* is caused by severe deficiency of factor IX and has similar genetic and clinical features.

Pregnancy

The risk of obstetrical bleeding with these is directly related to factor VIII or IX levels. Affected women have a range of activity that is determined by random X-chromosome inactivation—lyonization—although activity is expected to average 50 percent (Letsky, 2000). Levels below 10 to 20 percent pose hemorrhage risks. If levels fall to near zero, this risk is substantial. Pregnancy does afford some protection, however, because concentrations of both these clotting factors rise appreciably during normal pregnancy (Appendix, Serum and Blood Constituents). Treatment with desmopressin may also stimulate factor VIII release. Risks are further reduced by avoiding lacerations, minimizing episiotomy use, and maximizing postpartum uterine contractions. Operative vaginal deliveries should be avoided.

There are few published experiences during pregnancy. Kadir and coworkers (1997) reported that 20 percent of carriers had postpartum hemorrhage. Guy and associates (1992) reviewed five pregnancies in women with hemophilia B, and in all, outcomes were favorable. They recommended factor IX administration if levels are below 10 percent. Desmopressin has been shown in selected cases to reduce obstetrical bleeding complications (Trigg, 2012).

If a male fetus has hemophilia, the risk of hemorrhage increases after delivery in the neonate. This is especially true if circumcision is attempted.

Inheritance

If a mother has hemophilia A or B, all of her sons will have the disease, and all of her daughters will be carriers. If she is a carrier, half of her sons will inherit the disease, and half of her daughters will be carriers. Prenatal diagnosis of hemophilia is possible in some families using chorionic villus biopsy (Chap. 14, Chorionic Villus Sampling). Preimplantation genetic diagnosis for hemophilia was reviewed by Lavery (2009).

Factor VIII or IX Inhibitors

Rarely, antibodies directed against factor VIII or IX are acquired and may lead to life-threatening hemorrhage. Patients with hemophilia more commonly develop antibodies, and their acquisition in patients without hemophilia is extraordinary. It has been identified rarely in women during the puerperium (Santoro, 2009). The prominent clinical feature is severe, protracted, repetitive hemorrhage from the reproductive tract starting a week or so after an apparently uncomplicated delivery (Gibson, 2016). The activated partial thromboplastin time is markedly prolonged. Treatment has included multiple transfusions of blood component, immunosuppressive therapy, and attempts at various surgical procedures, especially curettage and hysterectomy. A recombinant activated factor VII (NovoSeven) stops bleeding in up to 75 percent of patients with these inhibitors (Arruda, 2015; Gibson, 2016).

Von Willebrand Disease

There are at least 20 heterogeneous clinical disorders involving aberrations of factor VIII complex and platelet dysfunction—collectively termed *von Willebrand disease (vWD)*. These abnormalities are the most frequently inherited bleeding disorders, and their prevalence is as high as 1 to 2 percent (Arruda, 2015; Pacheco, 2010). Most von Willebrand variants are inherited as autosomal dominant traits, and types I and II are the most common. Specifically, type I accounts for 75 percent of von Willebrand variants. Type III, which is the most severe, is a recessive trait. Although most cases of acquired vWD develop after age 50 years, some have been reported in pregnant women (Lipkind, 2005).

Pathogenesis

The *von Willebrand factor* is a series of large plasma multimeric glycoproteins that form part of the factor VIII complex. It is essential for normal platelet adhesion to subendothelial collagen and formation of a primary hemostatic plug. It also plays a major role in stabilizing the coagulant properties of factor VIII. The procoagulant component is factor VIII, a glycoprotein synthesized by the liver. Conversely, von Willebrand precursor, which is present in platelets and plasma, is synthesized by endothelium and megakaryocytes. The von Willebrand factor antigen (vWF:Ag) is the antigenic determinant measured by immunoassays.

Clinical Presentation

Symptomatic patients typically present with easy bruising, epistaxis, mucosal hemorrhage, and excessive bleeding with trauma, including surgery. The classic autosomal dominant forms usually cause symptoms in the heterozygous state. With vWD, laboratory features often include a prolonged bleeding time, prolonged partial thromboplastin time, decreased vWF antigen levels, decreased factor VIII immunological and coagulation-promoting activity, and inability of platelets from an affected person to react to various stimuli.

Pregnancy

During normal pregnancy, maternal levels of both factor VIII and vWF antigen increase substantively (Appendix, Serum and Blood Constituents). Because of this, pregnant women with vWD often develop normal levels of factor VIII coagulant activity and vWF antigen, although their measured bleeding time still may be prolonged. If factor VIII activity is very low or if there is bleeding, treatment is recommended. Desmopressin by infusion transiently increases factor VIII and vWF levels (Arruda, 2015; Kujovich, 2005). With significant bleeding, 15 or 20 units of cryoprecipitate are transfused every 12 hours. Alternatively, factor VIII concentrates (Alfanate, Hemate-P) may be given that contain high-molecular-weight vWF multimers. Lubetsky and colleagues (1999) described continuous infusion with Hemate-P in a woman during a vaginal delivery. According to Chi and coworkers (2009), conduction analgesia can be provided safely if coagulation defects have normalized or if hemostatic agents are administered prophylactically.

Pregnancy outcomes in women with vWD are generally good, but postpartum hemorrhage is encountered in up to half of cases. In a fourth of 38 cases summarized by Conti and associates (1986), bleeding was reported with abortion, with delivery, or in the puerperium. Kadir and coworkers (1998) reported their experiences with 84 pregnancies. They described a 20-percent incidence of immediate postpartum hemorrhage and another 20-percent incidence of late hemorrhage. Most cases were associated with low vWF levels in untreated women, and none given treatment peripartum had hemorrhage. More recently, Stoof and colleagues (2015) reviewed 185 deliveries in 154 affected women and found the risk for postpartum hemorrhage to be highest in deliveries with lowest factor levels.

Inheritance

Although most patients with vWD have heterozygous variants and associated minor bleeding complications, the disease can be severe. Moreover, homozygous offspring develop serious clotting dysfunction. Chorionic villus sampling with DNA analysis to detect the missing genes has been described. Some authorities recommend cesarean delivery to avoid trauma to a possibly affected fetus if the mother has severe disease.

Other Factor Deficiencies

In general, the activity of most procoagulant factors rises across pregnancy (Appendix, Serum and Blood Constituents). *Factor VII deficiency* is a rare autosomal recessive disorder. Levels of this factor normally increase during pregnancy, but these may rise only mildly in women with factor VII deficiency (Fadel, 1989). A systematic review of 94 births found no difference in postpartum hemorrhage rates with or without prophylaxis with recombinant factor VIIa (Baumann Kreuziger, 2013).

Factor X or *Stuart-Prower factor* deficiency is rare and is inherited as an autosomal recessive trait. Factor X levels typically rise by 50 percent during normal pregnancy. Konje and colleagues (1994) described a woman who had 2-percent factor activity. She was given prophylactic treatment with plasma-derived factor X, which raised her plasma levels to 37 percent. Despite this, she suffered an intrapartum placental abruption. Bofill and coworkers (1996) gave intrapartum fresh-frozen plasma to a woman with less than 1-percent factor X activity. She delivered spontaneously without incident. Beksaç and associates (2010) described a woman with severe factor X deficiency who was successfully managed with prophylactic prothrombin complex concentrate. Nance and colleagues (2012) reported on 24 pregnancies, of which 18 resulted in a healthy baby.

Factor XI—plasma thromboplastin antecedent—deficiency is inherited as an autosomal trait. It manifests as severe disease in homozygotes but only as a minor defect in heterozygotes. It is most prevalent in Ashkenazi Jews and is rarely seen in pregnancy. Musclow and coworkers (1987) reported 41 deliveries in 17 affected women, and none required transfusion. In 105 pregnancies from 33 affected women, Myers and colleagues (2007) reported an uneventful pregnancy and delivery in 70 percent. They recommended peripartum treatment with factor XI concentrate if cesarean delivery is performed and advised against epidural analgesia unless factor XI is given. From their review, Martin-Salces and associates (2010) found that factor XI levels and bleeding severity correlated poorly in women with severe deficiency. Wiewel-Verschueren and colleagues (2015) performed a systematic review of 27 studies with 372 women and reported that 18 percent had postpartum hemorrhage.

Factor XII deficiency is another autosomal recessive disorder that rarely complicates pregnancy. A greater incidence of thromboembolism is encountered in nonpregnant patients with this deficiency. Lao and coworkers (1991) reported an affected pregnant woman in whom placental abruption developed at 26 weeks' gestation.

Factor XIII deficiency is an autosomal recessive trait and may be associated with maternal intracranial hemorrhage (Letsky, 2000). In their review, Kadir and associates (2009) cited an increased risk of recurrent miscarriage and placental abruption. It has also been reported to cause umbilical cord bleeding (Odame, 2014). Treatment is fresh frozen plasma. Naderi and colleagues (2012) described 17 successful pregnancies in women receiving weekly prophylaxis with Factor XIII concentrate.

Fibrinogen abnormalities—either qualitative or quantitative—also may cause coagulation abnormalities. Autosomally inherited abnormalities usually involve the formation of a functionally defective fibrinogen—commonly referred to as *dysfibrinogenemia* (Edwards, 2000). Familial *hypofibrinogenemia* and sometimes *afibrinogenemia* are infrequent recessive disorders. In some cases, both are found—*hypodysfibrinogenemia* (Deering, 2003). Our experience suggests that hypofibrinogenemia represents a heterozygous autosomal dominant state. The thrombin-clottable protein level in these patients typically ranges from 80 to 110 mg/dL when nonpregnant, and this increases by 40 or 50 percent in normal pregnancy. Those pregnancy complications that give rise to acquired

hypofibrinogenemia, such as placental abruption, are more common with fibrinogen deficiency. Trehan and Fergusson (1991) and Funai and coworkers (1997) described successful outcomes in two affected women in whom fibrinogen or plasma infusions were given throughout pregnancy.

Conduction Analgesia with Bleeding Disorders

Most serious bleeding disorders would logically preclude the use of epidural or spinal analgesia for labor or delivery. If the bleeding disorder is controlled, however, conduction analgesia may be considered. Chi and colleagues (2009) reviewed intrapartum outcomes in 80 pregnancies in 63 women with an inherited bleeding disorder. These included those with factor XI deficiency, hemophilia carrier status, vWD, platelet disorders, or a deficiency of factor VII, XI, or X. Regional block was used in 41. Of these, 35 had spontaneously normalized hemostatic dysfunction, and others were given prophylactic replacement therapy. The reviewers reported no unusual complications. Singh and associates (2009) reviewed 13 women with factor XI deficiency. Nine received neuraxial analgesia without complications, but only after fresh-frozen plasma was transfused to most to correct the activated partial thromboplastin time.

THROMBOPHILIAS

Several important regulatory proteins act as inhibitors at strategic sites in the coagulation cascade to maintain blood fluidity. Inherited deficiencies of these inhibitory proteins are caused by gene mutations. Because they may be associated with recurrent thromboembolism, they are collectively referred to as *thrombophilias.* These are discussed in Chapter 52 (Thrombophilias) and reviewed by the American College of Obstetricians and Gynecologists (2017b).
