CHAPTER 57: Diabetes Mellitus

Diabetes may exist before the inception of pregnancy, or may not appear until labour. The prognosis is generally believed to be ominous for mother and child, but a review of the literature shows that less than 25 percent of the mothers died from diabetic coma, while premature labour occurred in only one third of the cases.

—J. Whitridge Williams (1903)

INTRODUCTION

In the early 1900s, overt diabetes complicating pregnancy was associated with horrific morbidity and mortality for a mother and her fetus. Although tremendously mitigated by the discovery of insulin, overt and gestational diabetes still are formidable complications of pregnancy.

According to the Centers for Disease Control and Prevention (2017), the number of adults diagnosed with diabetes in the United States is 23.1 million. And, almost a quarter of people with diabetes in the United States remain undiagnosed. Reasons for these substantial rates include an aging population more likely to develop type 2 diabetes, population growth within minority group at particular risk for type 2 diabetes, and a dramatic rise in obesity rates —also referred to as *diabesity*. The term reflects the strong relationship of diabetes and the current obesity epidemic in the United States and underlines the critical need for diet and lifestyle interventions to change the trajectory of both.

There is keen interest in events that precede diabetes, and this includes the intrauterine environment. Here, early imprinting is believed to have effects later in life (Saudek, 2002). For example, in utero exposure to maternal hyperglycemia leads to fetal hyperinsulinemia, causing an increase in fetal fat cells. This leads to obesity and insulin resistance in childhood (Feig, 2002). These factors in turn lead to impaired glucose tolerance and diabetes in adulthood. This cycle of fetal exposure to diabetes leading to childhood obesity and glucose intolerance is discussed further in Chapter 48 (Antepartum Management).

TYPES OF DIABETES

In nonpregnant individuals, the type of diabetes is based on its presumed etiopathogenesis and its pathophysiological manifestations. Absolute insulin deficiency, generally autoimmune in etiology, characterizes *type 1 diabetes*. In contrast, insulin resistance, relative insulin deficiency, or elevated glucose production characterizes *type 2 diabetes* (Table 57-1). Both types are generally preceded by a period of abnormal glucose homeostasis often referred to as prediabetes. The terms insulin-dependent diabetes mellitus (IDDM) and noninsulin-dependent diabetes mellitus (NIDDM) are now obsolete. Pancreatic β-cell destruction can begin at any age, but type 1 diabetes is clinically apparent most often before age 30. Type 2 diabetes usually develops with advancing age but is increasingly identified in younger obese adolescents.

TABLE 57-1

Etiological Classification of Diabetes Mellitus

Type 1: β-Cell destruction, usually absolute insulin deficiency
Immune-mediated
Idiopathic
Type 2: Ranges from predominantly insulin resistance to predominantly an insulin secretory defect with insulin resistance
Other types
Genetic mutations of β-cell function—MODY 1–6, others
Genetic defects in insulin action
Genetic syndromes—Down, Klinefelter, Turner
Diseases of the exocrine pancreas—pancreatitis, cystic fibrosis
Endocrinopathies—Cushing syndrome, pheochromocytoma, others
Drug or chemical induced—glucocorticosteroids, thiazides, β-adrenergic agonists, others
Infections—congenital rubella, cytomegalovirus, coxsackievirus
Gestational diabetes

MODY = maturity-onset diabetes of the young.

Data from Powers, 2012.

Classification During Pregnancy

Diabetes is the most common medical complication of pregnancy. Women can be separated into those who were known to have diabetes before pregnancy—*pregestational* or *overt*, and those diagnosed during pregnancy—*gestational diabetes*. The proportion of pregnancies complicated by diabetes more than doubled between 1994 and 2008, after which rates seem to have stabilized (Jovanovič, 2015). Almost 258,000—6.5 percent—of gravidas in the United States had pregnancies coexistent with some form of diabetes in 2015 (Martin, 2017). Prevalence of diabetes is highest among non-Hispanic blacks, Mexican-Americans, Puerto Rican-Americans, and Native Americans (Golden, 2012). The incidence of gestational diabetes during the past 20 years, shown in Figure 57-1, is reminiscent of similar statistics for obesity (Chap. 48, General Considerations).

White Classification in Pregnancy

Until the mid-1990s, the classification by Priscilla White (1978) for diabetic pregnant women was the linchpin of management. Today, the White classification is used less frequently but still provides simple and useful information on pregnancy risks and prognosis (Bennett, 2015). And, because most currently cited literature also contains data from these older classifications, the one previously recommended by the American College of Obstetricians and Gynecologists (1986) is provided in Table 57-2.

TABLE 57-2

Classification Scheme Used from 1986 through 1994 for Diabetes Complicating Pregnancy

		Plasma Glucose Level		
Class	**Onset**	**Fasting**	**2-Hour Postprandial**	**Therapy**
A_1	Gestational	<105 mg/dL	<120 mg/dL	Diet
A_2	Gestational	>105 mg/dL	>120 mg/dL	Insulin
Class	**Age of Onset (yr)**	**Duration (yr)**	**Vascular Disease**	**Therapy**
B	Over 20	<10	None	Insulin
C	10 to 19	10 to 19	None	Insulin
D	Before 10	>20	Benign retinopathy	Insulin
F	Any	Any	Nephropathy[a]	Insulin
R	Any	Any	Proliferative retinopathy	Insulin
H	Any	Any	Heart	Insulin

[a]When diagnosed during pregnancy: proteinuria ≥500 mg/24 hr before 20 weeks' gestation.

Beginning several years ago, the American College of Obstetricians and Gynecologists no longer recommended the White classification. Instead, the current focus is whether diabetes antedates pregnancy or is first diagnosed during pregnancy. Many now recommend adoption of the classification

proposed by the American Diabetes Association (ADA), which is shown in Table 57-3.

TABLE 57-3

Proposed Classification System for Diabetes in Pregnancy

Gestational diabetes: diabetes diagnosed during pregnancy that is not clearly overt (type 1 or type 2) diabetes	
Type 1 Diabetes: Diabetes resulting from β-cell destruction, usually leading to absolute insulin deficiency a. Without vascular complications b. With vascular complications (specify which)	**Type 2 Diabetes:** Diabetes from inadequate insulin secretion in the face of increased insulin resistance a. Without vascular complications b. With vascular complications (specify which)
Other types of diabetes: genetic in origin, associated with pancreatic disease, drug-induced, or chemically induced	

Data from American Diabetes Association, 2017a.

PREGESTATIONAL DIABETES

The rising prevalence of type 2 diabetes, particularly in younger people, has led to an increasing number of affected pregnancies. For example, the CDC (2015) estimates that more than 5000 new cases of type 2 diabetes are diagnosed each year in youths before the age of 20 years. Feig and coworkers (2014) reported that the incidence of pregestational diabetes doubled from 7 per 1000 women in 1996 to 15 per 1000 in 2010. When considering the previously mentioned high percentage of diabetes that is undiagnosed, then many women identified to have gestational diabetes likely have type 2 diabetes previously unrecognized. In fact, 5 to 10 percent of women with gestational diabetes are found to have diabetes immediately after pregnancy.

Diagnosis

Women with high plasma glucose levels, glucosuria, and ketoacidosis present no diagnostic challenge. Women with a random plasma glucose level >200 mg/dL plus classic signs and symptoms such as polydipsia, polyuria, and unexplained weight loss, or those with a fasting glucose level >125 mg/dL are considered by the ADA (2017a) and the World Health Organization (2013) to have overt diabetes first detected in pregnancy. Women with only minimal metabolic derangement may be more difficult to identify. To diagnose overt diabetes in pregnancy, The International Association of Diabetes and Pregnancy Study Groups (IADPSG) Consensus Panel (2010) recognizes the threshold values found in Table 57-4 for fasting or random plasma glucose and glycosylated hemoglobin (HbA_{1c}) levels at prenatal care initiation. The ADA (2017a) and the World Health Organization (2013) now also consider a plasma glucose level >200 mg/dL measured 2 hours after a 75 g oral glucose load to be diagnostic. No consensus has been reached as to whether such testing should be universal or limited to those women classified as high risk. Regardless, the tentative diagnosis of overt diabetes during pregnancy based on these thresholds should be confirmed postpartum. Risk factors for impaired carbohydrate metabolism in pregnant women include a strong familial history of diabetes, prior delivery of a large newborn, persistent glucosuria, or unexplained fetal losses.

TABLE 57-4

Diagnosis of Overt Diabetes in Pregnancy[a]

Measure of Glycemia	Threshold
Fasting plasma glucose	At least 7.0 mmol/L (126 mg/dL)
Hemoglobin A_{1c}	At least 6.5%
Random plasma glucose	At least 11.1 mmol/L (200 mg/dL) plus confirmation

[a]Apply to women without known diabetes antedating pregnancy. The decision to perform blood testing for evaluation of glycemia on all pregnant women or only on women with characteristics indicating a high risk for diabetes is based on the background frequency of abnormal glucose metabolism in the population and on local circumstances.

Data from International Association of Diabetes and Pregnancy Study Groups Consensus Panel, 2010.

Impact on Pregnancy

With overt diabetes, the embryo, fetus, and mother frequently experience serious complications directly attributable to diabetes. Peterson and colleagues (2015) estimate that thousands of these complications might be prevented each year by preconceptional care for improved glycemic control. The likelihood of successful outcomes with overt diabetes, however, is not simply related to glucose control. The degree of underlying cardiovascular or renal disease may be more important. Thus, advancing stages of the White classification, seen in Table 57-2, are inversely related to favorable pregnancy outcomes. Shown in Table 57-5 are data that chronicle the deleterious pregnancy outcomes with overt diabetes. These maternal and fetal complications are described in the following sections.

TABLE 57-5

Pregnancy Outcomes of Births in Nova Scotia from 1988 to 2002 in Women with and without Pregestational Diabetes

Factor	Diabetic (n = 516) %	Nondiabetic (n = 150, 598) %	*p* value
Gestational hypertension	28	9	<.001
Preterm birth	28	5	<.001
Macrosomia	45	13	<.001
Fetal-growth restriction	5	10	<.001
Stillbirth	1.0	0.4	.06
Perinatal death	1.7	0.6	.004

Data from Yang, 2006.

Fetal Effects

Spontaneous Abortion

Several studies have shown that early miscarriage is associated with poor glycemic control (Chap. 18, First-Trimester Spontaneous Abortion). Up to 25 percent of diabetic gravidas have an early pregnancy loss (Galindo, 2006; Rosenn, 1994). Those whose HbA_{1c} concentrations were >12 percent or whose preprandial glucose concentrations were persistently >120 mg/dL had an elevated risk. Bacon and associates (2015) reviewed 89 pregnancies in women with maturity-onset diabetes of the young (MODY), which is a monogenic form of diabetes. These investigators found that only women with the causative glucose kinase gene (GCK) mutation were more likely to have a miscarriage. These women are characterized by hyperglycemic variability that is difficult to control.

Preterm Delivery

Overt diabetes is an undisputed risk factor for preterm birth. Eidem and associates (2011) analyzed 1307 births in women with type 1 diabetes from the Norwegian Medical Birth Registry. More than 26 percent were delivered preterm compared with 6.8 percent in the general obstetrical population. Moreover, almost 60 percent were indicated preterm births, that is, due to obstetrical or medical complications. In one review of more than 500,000 California births, 19 percent of women with pregestational diabetes had a preterm birth compared with 9 percent in controls (Yanit, 2012). In the Canadian study shown in Table 57-5, the incidence of preterm birth was 28 percent.

Malformations

The incidence of major malformations in women with type 1 diabetes is at least doubled and approximates 11 percent (Jovanovič, 2015). These account for almost half of perinatal deaths in diabetic pregnancies. As shown in Table 57-6, cardiovascular malformations accounted for more than half of the anomalies. In a cohort study of more than 2 million births in Canada, the risk of an isolated cardiac defect was fivefold higher in women with type 1 diabetes (Liu, 2013). The caudal regression sequence, described in Chapter 10 (Face and Neck), is a rare malformation frequently associated with maternal diabetes (Garne, 2012).

TABLE 57-6

Major Congenital Anomalies in 36,345 Neonates Born to Women with Diabetes between 2004 and 2011

Organ System	Type 1 DM n = 482	Type 2 DM n = 4166	GDM n = 31,700
Total	55	454	2203
Cardiac	38	272	1129
Musculoskeletal	1	31	231
Urinary	3	28	260
CNS	1	13	64
GI	1	30	164
Other	11	80	355

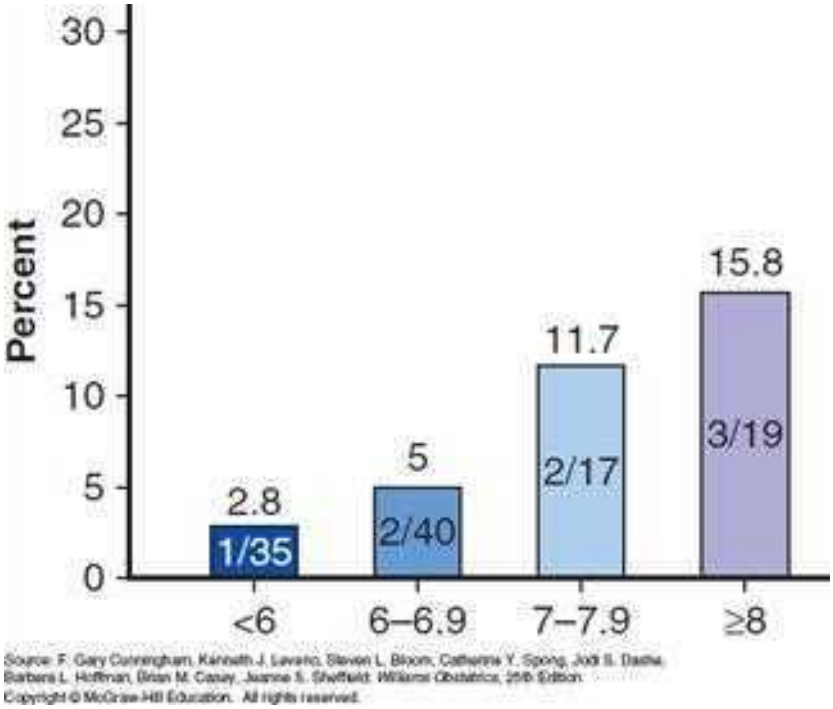
CNS = central nervous system; DM = diabetes mellitus; GDM = gestational diabetes; GI = gastrointestinal.

Data from Jovanovič, 2015.

Poorly controlled diabetes, both preconceptionally and early in pregnancy, is thought to underlie this elevated severe-malformation risk. As shown in Figure 57-2, increased maternal HbA_{1c} levels and major malformations clearly correlate. To explain this, at least three interrelated molecular chain reactions have been linked to maternal hyperglycemia (Reece, 2012). These include alterations in cellular lipid metabolism, excess production of toxic superoxide radicals, and activation of programmed cell death. In their review of molecular mechanisms underlying diabetic embryopathy, Yang and colleagues (2015) suggest that these cellular responses to oxidative stress represent potential therapeutic targets to prevent diabetes-induced embryopathy.

FIGURE 57-2

The frequency of major congenital malformations in newborns of women with pregestational diabetes stratified by hemoglobin A_{1c} levels at first prenatal visit. (Data from Galindo A, Burguillo AG, Azriel S, et al: Outcome of fetuses in women with pregestational diabetes mellitus, J Perinat Med. 2006;34(4):323–331.)

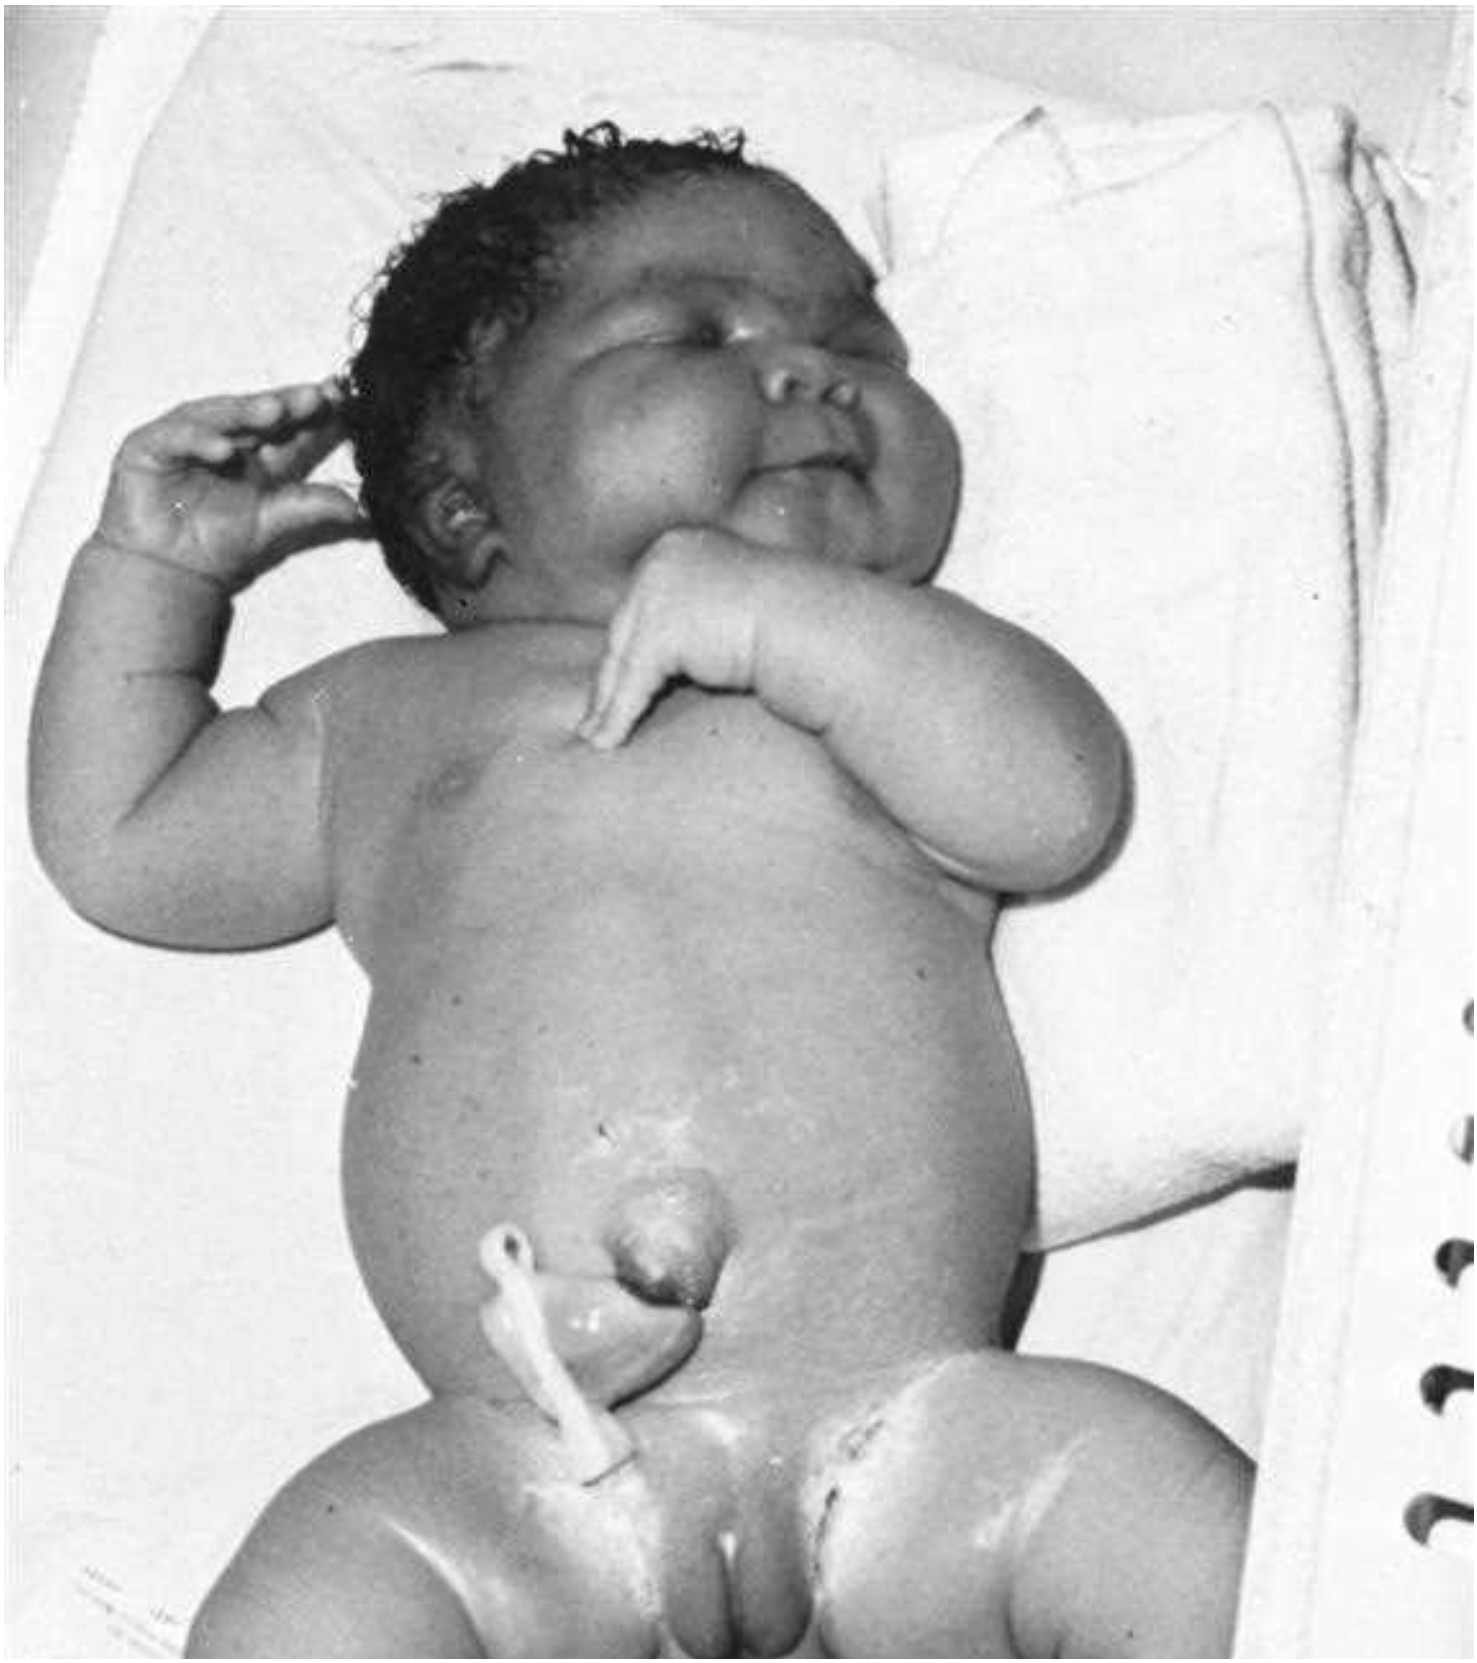


Altered Fetal Growth

Diminished growth may result from congenital malformations or from substrate deprivation due to advanced maternal vascular disease. That said, fetal overgrowth is more typical of pregestational diabetes. Maternal hyperglycemia prompts fetal hyperinsulinemia, and this in turn stimulates excessive somatic growth. Except for the brain, most fetal organs are affected by the macrosomia that characterizes the fetus of a diabetic woman. Newborns such as the one shown in Figure 57-3 are described as being anthropometrically different from other large-for-gestational age (LGA) neonates (Catalano, 2003; Durnwald, 2004). Specifically, those whose mothers are diabetic have excessive fat deposition on the shoulders and trunk, which predisposes to shoulder dystocia or cesarean delivery.

FIGURE 57-3

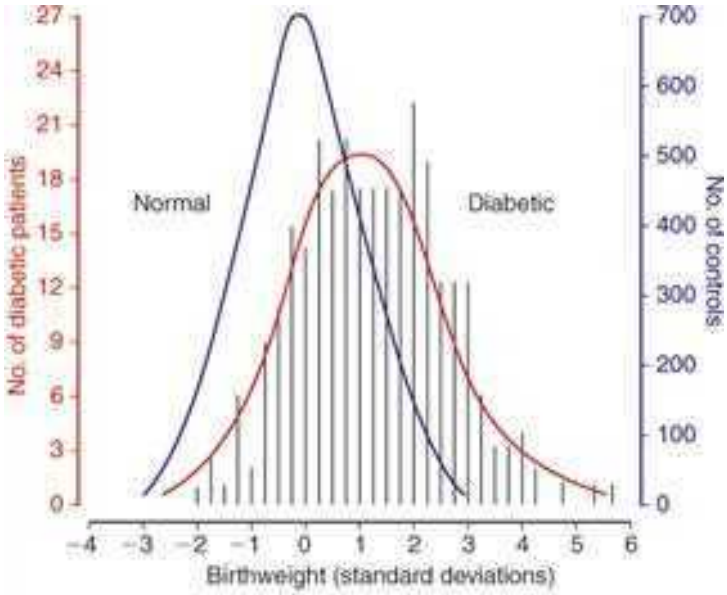
This 6050-g macrosomic infant was born to a woman with gestational diabetes.



The incidence of macrosomia rises significantly when mean maternal blood glucose concentrations chronically exceed 130 mg/dL (Hay, 2012). Hammoud and coworkers (2013) reported that the macrosomia rates for Nordic women with type 1, type 2, or gestational diabetes were 35 percent, 28 percent, and 24 percent, respectively. As shown in Figure 57-4, the birthweight distribution of neonates of diabetic mothers is skewed toward consistently heavier birthweights.

FIGURE 57-4

Distribution of birthweight standard deviations from the normal mean for gestational age in 280 newborns of diabetic mothers and in 3959 neonates of nondiabetic mothers. (Reproduced with permission from Bradley RJ, Nicolaides KH, Brudenell JM.: Are all infants of diabetic mothers “macrosomic”? BMJ 1988 Dec 17;297(6663):1583–1584.)



In the study by Hammoud and colleagues (2013), fetal growth profiles from 897 sonographic examinations in 244 women with diabetes were compared with 843 examinations in 145 control women. The abdominal circumference grew disproportionately larger in the diabetic groups. Analysis of head circumference/abdominal circumference (HC/AC) ratios shows that this disproportionate growth occurs mainly in diabetic pregnancies that ultimately yield macrosomic newborns. These findings comport with the observation that virtually all neonates of diabetic mothers are growth promoted, and accelerated fetal growth is particularly evident in women with poor glycemic control.

Unexplained Fetal Demise

Worldwide, the risk of fetal death is three to four times higher in women with pregestational diabetes (Gardosi, 2013; Patel, 2015). Stillbirth without an identifiable cause is a phenomenon relatively limited to pregnancies complicated by overt diabetes. These stillbirths are “unexplained” because common factors such as obvious placental insufficiency, placental abruption, fetal-growth restriction, or oligohydramnios are not identified. These fetuses are typically large for gestational age and die before labor, usually late in the third trimester.

These unexplained stillbirths are associated with poor glycemic control. Lauenborg and coworkers (2003) identified suboptimal glycemic control in two thirds of unexplained stillbirths between 1990 and 2000. Also, fetuses of diabetic mothers often have elevated lactic acid levels. Salvesen and colleagues (1992, 1993) analyzed fetal blood samples and reported that mean umbilical venous blood pH was lower in diabetic pregnancies and was significantly related to fetal insulin levels. Such findings support the hypothesis that hyperglycemia-mediated chronic aberrations in oxygen and fetal metabolite transport may underlie these unexplained fetal deaths (Pedersen, 1977).

Aside from hyperglycemia alone, maternal ketoacidosis can cause fetal death. Explicable stillbirths due to placental insufficiency also occur with increased frequency in women with overt diabetes, usually in association with severe preeclampsia. In the prior California study of nearly a half million singleton deliveries, the fetal death risk was sevenfold higher in women with hypertension and pregestational diabetes compared with the threefold increased risk associated with diabetes alone (Yanit, 2012). Stillbirth rates are also greater in women with advanced diabetes and vascular complications.

Hydramnios

Diabetic pregnancies are often complicated by excess amnionic fluid. According to Idris and coworkers (2010), 18 percent of 314 women with pregestational diabetes were identified to have hydramnios, defined as an amnionic fluid index (AFI) >24 cm in the third trimester. And, women with elevated HbA_{1c} values in the third trimester were more likely to have hydramnios. A likely—albeit unproven—explanation is that fetal hyperglycemia causes polyuria (Chap. 11, Etiology). In a study from Parkland Hospital, Dashe and colleagues (2000) found that the AFI parallels the amnionic fluid glucose level among women with diabetes. Further support for this association was provided by Vink and associates (2006), who linked poor maternal glucose control to macrosomia and hydramnios.

Neonatal Effects

Before tests of fetal health and maturity became available, delivery before term was deliberately selected for women with diabetes to avoid unexplained stillbirth. Although this practice has been abandoned, a higher frequency of preterm delivery in women with diabetes persists. Most are indicated deliveries due to advanced diabetes with superimposed preeclampsia. That said, Little and associates (2015) in their analysis of early-term delivery ($37^{0/7}$ to $38^{6/7}$ weeks) found a 13-percent reduction in such deliveries in women with diabetes between 2005 and 2011.

Although modern neonatal care has reduced neonatal death rates due to immaturity, neonatal *morbidity* due to preterm birth continues to be a serious consequence. In one Neonatal Research Network study of 10,781 extremely preterm neonates, those born to diabetic women treated with insulin prior to pregnancy were at greater risk for necrotizing enterocolitis and late-onset sepsis than neonates of mothers without diabetes (Boghossian, 2016).

Respiratory Distress Syndrome

Gestational age rather than overt diabetes is likely the most significant factor associated with respiratory distress syndrome (Chap. 33, Respiratory Distress). Indeed, in one analysis of 19,399 very-low-birthweight neonates delivered between 24 and 33 weeks' gestation, rates of respiratory distress syndrome in newborns of diabetic mothers were not higher compared with rates in neonates of nondiabetic mothers (Bental, 2011).

Hypoglycemia

Newborns of a diabetic mother experience a rapid drop in plasma glucose concentration after delivery. This is attributed to hyperplasia of the fetal β-islet cells induced by chronic maternal hyperglycemia. Low glucose concentrations—defined as <45 mg/dL—are particularly common in newborns of women with unstable glucose concentrations during labor (Persson, 2009). Frequent blood glucose measurements in the newborn and active early feeding practices can mitigate these complications.

Hypocalcemia

Defined as a total serum calcium concentration <8 mg/dL in term newborns, early onset hypocalcemia is one of the potential metabolic derangements in neonates of diabetic mothers. Its cause has not been explained. Theories include aberrations in magnesium–calcium economy, asphyxia, and preterm birth. In a randomized study, 137 pregnant women with type 1 diabetes were managed with strict versus customary glucose control (DeMarini, 1994). Almost a third of neonates in the customary control group developed hypocalcemia compared with only 18 percent of those in the strict-control group.

Hyperbilirubinemia and Polycythemia

The pathogenesis of hyperbilirubinemia in neonates of diabetic mothers is uncertain. A major contributing factor is newborn polycythemia, which raises the bilirubin load (Chap. 33, Polycythemia and Hyperviscosity). Polycythemia is thought to be a fetal response to relative hypoxia. According to Hay (2012), the sources of this fetal hypoxia are hyperglycemia-mediated elevations in maternal affinity for oxygen and fetal oxygen consumption. Together with insulin-like growth factors, this hypoxia leads to elevated fetal erythropoietin levels and red cell production. Fetal renal vein thrombosis is reported to result from polycythemia.

Cardiomyopathy

Newborns of diabetic pregnancies may have hypertrophic cardiomyopathy that primarily affects the interventricular septum (Rolo, 2011). Huang and coworkers (2013) propose that pathological ventricular hypertrophy in neonates born to women with diabetes is due to insulin excess. In severe cases, this cardiomyopathy may lead to obstructive cardiac failure. Russell and coworkers (2008) performed serial echocardiograms on fetuses of 26 women with pregestational diabetes. In the first trimester, fetal diastolic dysfunction was already evident in some. In the third trimester, the fetal interventricular septum and right ventricular wall were thicker in fetuses of diabetic mothers. Most affected newborns are asymptomatic following birth, and hypertrophy usually resolves in the months after delivery.

Long-Term Cognitive Development

Intrauterine metabolic conditions have long been linked to neurodevelopment in offspring. In a study of more than 700,000 Swedish-born men, the intelligence quotient of those whose mothers had diabetes during pregnancy averaged 1 to 2 points lower (Fraser, 2014). DeBoer and associates (2005) demonstrated impaired memory performance in infants of diabetic mothers at age 1 year. Results from the Childhood Autism Risks from Genetics and the Environment (CHARGE) study indicated that autism spectrum disorders or developmental delay were also more common in children of diabetic women (Krakowiak, 2012). Adane and colleagues (2016) confirmed a consistent relationship between maternal diabetes and diminished cognitive and language development in studies of younger children but not older children. Because interpreting effects of the intrauterine environment on neurodevelopment is confounded by postnatal factors, the link between maternal diabetes, glycemic control, and long-term neurocognitive outcome remains unconfirmed.

Inheritance of Diabetes

The risk of developing type 1 diabetes if either parent is affected is 3 to 5 percent. Type 2 diabetes has a much stronger genetic component. If both parents have type 2 diabetes, the risk of developing it approaches 40 percent. Both types of diabetes develop after a complex interplay between genetic predisposition and environmental factors. Type 1 diabetes is prompted by environmental triggers such as infection, diet, or toxins and heralded by the appearance of islet cell autoantibodies in genetically vulnerable individuals (Pociot, 2016; Rewers, 2016). Some but not all studies have shown a reduction in risk for type 1 or type 2 diabetes associated with breastfeeding (Owen, 2006; Rewers, 2016).

Maternal Effects

Diabetes and pregnancy interact significantly such that maternal welfare can be seriously jeopardized. With the possible exception of diabetic retinopathy, however, the long-term course of diabetes is not affected by pregnancy.

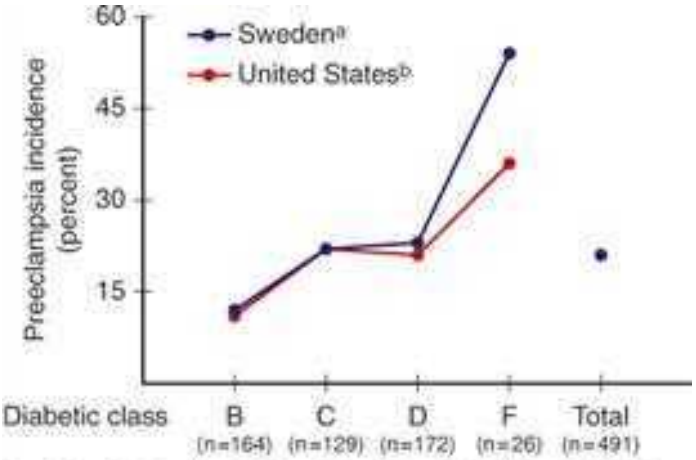
In an analysis of more than 800,000 pregnancies, Jovanovič and colleagues (2015) found that 1125 mothers with type 1 diabetes were at increased risk for hypertension and respiratory complications compared with nondiabetic women. And, 10,126 mothers with type 2 diabetes had an elevated risk for depression, hypertension, infection, and cardiac or respiratory complications compared with pregnant controls. Maternal death is uncommon, but rates in women with diabetes are still higher than those in unaffected gravidas. In one analysis of 972 women with type 1 diabetes, the maternal mortality rate was 0.5 percent, and deaths resulted from diabetic ketoacidosis, hypoglycemia, hypertension, and infection (Leinonen, 2001).

Preeclampsia

Pregnancy-associated hypertension is the complication that most often forces preterm delivery in diabetic women. The incidence of chronic and gestational hypertension—and especially preeclampsia—is remarkably increased (Chap. 40, Incidence and Risk Factors). In a systematic review and metaanalysis of 92 studies including more than 25 million pregnancies, Bartsch and associates (2016) calculated a pooled relative risk of 3.7 for preeclampsia in women with pregestational diabetes. In the study cited earlier by Yanit and colleagues (2012), preeclampsia developed three to four times more often in women with overt diabetes. Moreover, those diabetics with coexistent chronic hypertension were almost 12 times more likely to develop preeclampsia. As shown in Figure 57-5, women with type 1 diabetes in more advanced White classes of overt diabetes, who typically exhibit vascular complications and have preexisting nephropathy, are more likely to develop preeclampsia. This rising risk with duration of diabetes may be related to oxidative stress, which plays a key role in the pathogenesis of diabetic complications and preeclampsia. With this in mind, the Diabetes and Preeclampsia Intervention Trial (DAPIT) randomly assigned 762 women with type 1 diabetes to antioxidant vitamin C and E supplementation or placebo in the first half of pregnancy (McCance, 2010). Preeclampsia rates did not differ except in a few women with a low antioxidant status at baseline.

FIGURE 57-5

Incidence of preeclampsia in 491 type 1 diabetic women in Sweden and the United States. (Data from Hanson[a], 1993; Sibai[b], 2000.)



Diabetic Nephropathy

Diabetes is the leading cause of end-stage renal disease in the United States (Chap. 53, Chronic Kidney Disease). Clinically detectable nephropathy begins with microalbuminuria—30 to 300 mg/24 hours. This may manifest as early as 5 years after diabetes onset. Macroalbuminuria—more than 300 mg/24 hours—develops in patients destined to have end-stage renal disease. Hypertension almost invariably develops during this period, and renal failure

ensues typically in the next 5 to 10 years. The incidence of overt proteinuria is nearly 30 percent in individuals with type 1 diabetes and ranges from 4 to 20 percent in those with type 2 diabetes (Reutens, 2013). Regression is common and, presumably from improved glucose control, the incidence of nephropathy with type 1 diabetes has declined.

Approximately 5 percent of pregnant women with diabetes already have renal involvement. Approximately 40 percent of these will develop preeclampsia (Vidaeff, 2008). In those with microproteinuria, this incidence may not be as high (How, 2004). However, Ambia and associates (2018) reported that the rates of preterm delivery, birthweight <2500 g, and growth restriction were significantly higher in neonates of diabetic women with microproteinuria compared with those of diabetic gravidas without proteinuria.

In general, pregnancy does not appear to worsen diabetic nephropathy. In one prospective study of 43 women with diabetes, diabetic nephropathy did not progress through 12 months after delivery (Young, 2012). Most of these women had only mild renal impairment. Conversely, pregnancy in women with moderate-to-severe renal impairment may have accelerated progression of their disease (Vidaeff, 2008). As in women with glomerulopathies, hypertension or substantial proteinuria before or during pregnancy is a major predictive factor for ultimate progression to renal failure in women with diabetic nephropathy (Chap. 53, Nephrotic Syndromes).

Diabetic Retinopathy

Retinal vasculopathy is a highly specific complication of both type 1 and type 2 diabetes. In the United States, diabetic retinopathy is the most important cause of visual impairment in working-aged adults. The first and most common visible lesions are small microaneurysms followed by blot hemorrhages that form when erythrocytes escape from the aneurysms. These areas leak serous fluid that creates hard exudates. Such features are termed *background* or *nonproliferative retinopathy*. With increasingly severe retinopathy, the abnormal vessels of background eye disease become occluded, leading to retinal ischemia and infarctions that appear as *cotton wool exudates.* These are considered *preproliferative retinopathy.* In response to ischemia, neovascularization begins on the retinal surface and out into the vitreous cavity. Vision is obscured when these vessels bleed. Laser photocoagulation before hemorrhage reduces the rate of visual loss progression and blindness by half. The procedure may be performed during pregnancy when indicated.

Vestgaard and coworkers (2010) reported that almost two thirds of 102 pregnant women with type 1 diabetes examined by 8 weeks' gestation had background retinal changes, proliferative retinopathy, or macular edema. A fourth of these women developed progression of retinopathy in at least one eye during pregnancy. The same group of investigators evaluated 80 type 2 diabetics and identified retinopathy, mostly mild, in 14 percent during early pregnancy. Progression was identified in only 14 percent (Rasmussen, 2010). This complication is believed to be a rare example of a long-term adverse effect of pregnancy.

Other risk factors that have been associated with progression of retinopathy include hypertension, higher levels of insulin-like growth factor-1, placental growth factor, and macular edema identified in early pregnancy (Bargiota, 2011; Huang, 2015; Mathiesen, 2012; Ringholm, 2011; Vestgaard, 2010). The American Academy of Ophthalmology (2016) recommends that pregnant women with preexisting diabetes should routinely be offered retinal assessment after the first prenatal visit. Subsequent eye examinations depend on severity of retinopathy and level of diabetes control. Currently, most agree that laser photocoagulation and good glycemic control during pregnancy minimize the potential for deleterious effects of pregnancy. Ironically, "acute" rigorous metabolic control during pregnancy has been linked to acute worsening of retinopathy. In a study of 201 women with retinopathy, almost 30 percent suffered eye disease progression during pregnancy despite intensive glucose control (McElvy, 2001). That said, Wang and coworkers (1993) observed that although retinopathy worsened during the critical months of rigorous glucose control, long-term progression of eye disease actually slowed. Arun and Taylor (2008) found that only four women required laser photocoagulation during pregnancy, and none required laser in the next 5 years.

Diabetic Neuropathy

Peripheral symmetrical sensorimotor diabetic neuropathy is uncommon in pregnant women. But, a form of this, known as *diabetic gastropathy*, can be troublesome during pregnancy. It causes nausea and vomiting, nutritional problems, and difficulty with glucose control. Women with gastroparesis are advised that this complication is associated with a high risk of morbidity and poor perinatal outcome (Kitzmiller, 2008). Treatment with metoclopramide and D_2-receptor antagonists is sometimes successful. Gastric neurostimulators have also been successfully used during pregnancy (Fuglsang, 2015).

Treatment of *hyperemesis gravidarum* can be challenging, and we routinely provide insulin by continuous infusion for women who are admitted with this condition (Chap. 54, Complications).

Diabetic Ketoacidosis

This serious complication develops in approximately 1 percent of diabetic pregnancies and is most often encountered in women with type 1 diabetes (Hawthorne, 2011). It is increasingly being reported in women with type 2 or even those with gestational diabetes (Bryant, 2017; Sibai, 2014). Diabetic ketoacidosis (DKA) may develop with hyperemesis gravidarum, infection, insulin noncompliance, β-mimetic drugs given for tocolysis, and corticosteroids given to induce fetal lung maturation. DKA results from an insulin deficiency combined with an excess in counter-regulatory hormones such as glucagon. This leads to gluconeogenesis and ketone body formation. The ketone body β-hydroxybutyrate is synthesized at a much greater rate than acetoacetate, which is preferentially detected by commonly used ketosis-detection methods. Therefore, serum or plasma assays for β-hydroxybutyrate more accurately reflect true ketone body levels.

Of gravidas with DKA, fewer than 1 percent die, but perinatal mortality rates from a single episode of DKA may reach 35 percent (Guntupalli, 2015). Noncompliance is a prominent factor, and this and ketoacidosis were historically considered prognostically bad signs in pregnancy (Pedersen, 1974).

Importantly, pregnant women usually develop ketoacidosis at lower blood glucose thresholds than when nonpregnant. In a study from Parkland Hospital, the mean glucose level for pregnant women with DKA was 380 mg/dL, and the mean HbA_{1C} value was 10 percent (Bryant, 2017). Euglycemic ketoacidosis during pregnancy is possible but rare (Sibai, 2014).

One management protocol for diabetic ketoacidosis is shown in Table 57-7. An important cornerstone of management is vigorous rehydration with crystalloid solutions of normal saline or Ringer lactate.

TABLE 57-7

Management of Diabetic Ketoacidosis During Pregnancy

Laboratory Assessment
Obtain arterial blood gases to document degree of acidosis present; measure glucose, ketones, and electrolyte levels at 1- to 2-hour intervals
Insulin
Low-dose, intravenous
Loading dose: 0.2–0.4 U/kg
Maintenance: 2–10 U/hr
Fluids
Isotonic sodium chloride
Total replacement in first 12 hours of 4–6 L
1 L in first hour
500–1000 mL/hr for 2–4 hours
250 mL/hr until 80 percent replaced
Glucose
Begin 5-percent dextrose in normal saline when glucose plasma level reaches 250 mg/dL (14 mmol/L)
Potassium
If initially normal or reduced, an infusion rate up to 15–20 mEq/hr may be required; if elevated, wait until levels decrease into the normal range, then add to intravenous solution in a concentration of 20–30 mEq/L
Bicarbonate
Add one ampule (44 mEq) to 1 L of 0.45 normal saline if pH is <7.1

Data from Bryant, 2017; Landon, 2002; Sibai, 2014.

Infections

The rates of many infections are higher in diabetic pregnancies. Common ones include candidal vulvovaginitis, urinary and respiratory tract infections, and puerperal pelvic sepsis. However, in one study of more than 1250 diabetic gravidas screened before 16 weeks' gestation, rates of bacterial vaginosis or vaginal colonization with *Candida* or *Trichomonas* species were not increased (Marschalek, 2016). But, in their population-based study of almost 200,000 pregnancies, Sheiner and coworkers (2009) found a twofold greater risk of asymptomatic bacteruria in women with diabetes. Similarly, Alvarez and associates (2010) reported positive urine culture results in 25 percent of diabetic women. In a 2-year analysis of pyelonephritis at Parkland Hospital, 5 percent of women with diabetes developed pyelonephritis compared with 1.3 percent of the nondiabetic population (Hill, 2005). Fortunately, these latter infections can be minimized by screening and eradication of asymptomatic bacteriuria (Chap. 53, Asymptomatic Bacteriuria). Finally, Johnston and colleagues (2017) reported that 16.5 percent of women with pregestational diabetes had postoperative wound complications following cesarean delivery.

Management of Diabetes in Pregnancy

Preconceptional Care

Because of the close relationship between pregnancy complications and maternal glycemic control, efforts to achieve glucose targets are typically more aggressive during pregnancy. Management preferably should begin before pregnancy and include specific goals during each trimester.

To minimize early pregnancy loss and congenital malformations in offspring of diabetic mothers, optimal medical care and education are recommended before conception (Chap. 8, Counseling Session). The National Preconception Health and Healthcare Initiative Clinical Workgroup for the CDC established values for optimal glycemic control (Frayne, 2016). This was defined as HbA_{1c} <6.5 percent in women with pregestational diabetes. Unfortunately, nearly half of pregnancies in the United States are unplanned, and diabetic women frequently begin pregnancy with suboptimal glucose control (Finer, 2016; Kim, 2005).

The ADA (2017b) has also defined optimal preconceptional glucose control using insulin. Reflective values are self-monitored preprandial glucose levels of 70 to 100 mg/dL, peak 2-hour postprandial values of 100 to 120 mg/dL, and mean daily glucose concentrations <110 mg/dL. In one prospective population-based study of 933 pregnant women with type 1 diabetes, the risk of congenital malformations was not demonstrably higher with HbA_{1c} levels <6.9 percent compared with the risk in more than 70,000 nondiabetic controls (Jensen, 2010). These investigators also found a substantial fourfold greater risk for malformations at levels >10 percent.

If indicated, evaluation and treatment for diabetic complications such as retinopathy or nephropathy should also be instituted before pregnancy. Finally, folate, 400 µg/d orally, is given periconceptionally and during early pregnancy to decrease the risk of neural-tube defects.

First Trimester

Careful monitoring of glucose control is essential. For this reason, many clinicians hospitalize overtly diabetic women during early pregnancy to initiate an individualized glucose control program and provide education. This also provides an opportunity to assess the extent of diabetic vascular complications and precisely establish gestational age.

Insulin Treatment

The overtly diabetic gravida is best treated with insulin. While oral hypoglycemic agents have been used successfully for gestational diabetes (Diabetic Diet), these agents are not currently recommended for overt diabetes, although this is controversial (American College of Obstetricians and Gynecologists, 2016b). Maternal glycemic control can usually be achieved with multiple daily insulin injections and adjustment of dietary intake. The action profiles of commonly used short- and long-term insulins are shown in Table 57-8.

TABLE 57-8

Action Profiles of Commonly Used Insulins

Insulin Type	Onset	Peak (hr)	Duration (hr)
Short-acting (SC)			
Lispro	<15 min	0.5–1.5	3–4
Glulisine Aspart	<15 min <15 min	0.5–1.5 0.5–1.5	3–4 3–4
Regular	30–60 min	2–3	4–6
Long-acting (SC)			
Detemir	1–4 hr	Minimal[a]	Up to 24
Glargine NPH	1–4 hr 1–4 hr	Minimal[a] 6–10	Up to 24 10–16

[a]Minimal peak activity.

NPH = neutral protamine Hagedorn; SC = subcutaneous.

Data from Powers, 2012.

Subcutaneous insulin infusion by a calibrated pump does not yield better pregnancy outcomes compared with multiple daily injections. But, an infusion pump is a safe alternative in appropriately selected patients (Farrar, 2016; Sibai, 2014). With the advent of sensor-augmented insulin pumps and closed-loop insulin delivery systems, improved glycemic control with either manual or computer-generated insulin adjustments based on continuous glucose monitoring is now possible. One small randomized, crossover study of 16 pregnant women compared these two technologies (Stewart, 2016). Those with automatic closed-loop systems had glucose values within target range for a higher percentage of time and had lower daily median glucose values. Moreover, their rates of hypoglycemic episodes were not increased. Roeder and colleagues (2012) noted with insulin pump use in women with type 1 diabetes that total daily insulin doses declined in the first trimester but later rose more than threefold. Postprandial glucose elevations prompted most of the required daily-dose increases. If a continuous-infusion insulin pump is elected, it is best started before pregnancy to avoid the hypoglycemia and ketoacidosis risk associated with the learning curve (Sibai, 2014).

Monitoring

Self-monitoring of capillary glucose levels using a glucometer is recommended because this involves the woman in her own care. The ADA (2017b) recommends fasting and postprandial glucose monitoring. Glucose goals recommended during pregnancy are shown in Table 57-9. Advances in noninvasive glucose monitoring will undoubtedly render intermittent capillary glucose monitoring obsolete. Subcutaneous continuous glucose monitoring devices have shown that pregnant women with diabetes experience significant periods of daytime hyperglycemia and nocturnal hypoglycemia that are undetected by traditional monitoring (Combs, 2012). Such glucose monitoring systems, coupled with a continuous insulin pump, offer the potential of an “artificial pancreas” to avoid undetected hypo- or hyperglycemia during pregnancy.

TABLE 57-9

Self-Monitored Capillary Blood Glucose Goals

Specimen	Level (mg/dL)
Fasting	≤95
Premeal	≤100
1-hr postprandial	≤140
2-hr postprandial	≤120
0200–0600	≥60
Mean (average)	100
Hemoglobin A_{1c}	≤6%

Diet

Nutritional planning includes appropriate weight gain through carbohydrate and caloric modifications based on height, weight, and degree of glucose intolerance (American Diabetes Association, 2017b; Bantle, 2008). The mix of carbohydrate, protein, and fat is adjusted to meet the metabolic goals and individual patient preferences. A minimum of 175 g/d of carbohydrates ideally is provided. In one analysis of more than 200 obese pregnant women with glucose intolerance, a lower carbohydrate intake, particularly late in pregnancy, was associated with lower fat mass in offspring at birth (Renault, 2015). Allotted carbohydrates are distributed throughout the day in three small- to moderate-sized meals and two to four snacks. Weight loss is not recommended, but modest caloric restriction may be appropriate for overweight or obese women. An ideal dietary composition is 55 percent carbohydrate, 20 percent protein, and 25 percent fat, of which <10 percent is saturated fat.

Hypoglycemia

Diabetes tends to be unstable in the first half of pregnancy, and the incidence of hypoglycemia peaks during the first trimester. Chen and coworkers (2007) identified hypoglycemic events—blood glucose values <40 mg/dL—in 37 of 60 women with type 1 diabetes. A fourth of these were considered severe because the women were unable to treat their own symptoms and required assistance from another person. Caution is recommended when attempting euglycemia in women with recurrent episodes of hypoglycemia.

In a Cochrane database review, Middleton and colleagues (2016) determined that loose glycemic control, defined as fasting glucose values >120 mg/dL, was associated with greater risks for preeclampsia, cesarean delivery, and birthweight above the 90th percentile compared with women with tight or moderate control. Importantly, no obvious benefit were gained from very tight control, defined by fasting values <90 mg/dL, and there were more cases of hypoglycemia. Thus, women with overt diabetes who have glucose values that are viewed by some as “considerably above” this 90 mg/dL threshold can expect good pregnancy outcomes.

Second Trimester

Maternal serum alpha-fetoprotein determination at 16 to 20 weeks’ gestation is used in association with targeted sonographic examination to detect neural-tube defects and other anomalies (Chap. 14, Maternal Serum AFP Elevation: Neural-Tube Defect Screening). These levels may be lower in diabetic pregnancies, and interpretation is altered accordingly. Because the incidence of congenital cardiac anomalies is fivefold in mothers with diabetes, fetal echocardiography is an important part of second-trimester sonographic evaluation (Fouda, 2013). Despite advances in ultrasound technology, however, Dashe and associates (2009) cautioned that detection of fetal anomalies in obese diabetic women is more difficult than in similarly sized women without diabetes.

Regarding second-trimester glucose control, euglycemia with self-monitoring continues to be the goal in management. After the first-trimester instability, a stable period ensues. This is followed by a greater insulin requirement due to the elevated peripheral resistance to insulin described in Chapter 4 (Fat Metabolism).

Third Trimester and Delivery

During the past several decades, the threat of late-pregnancy stillbirth in women with diabetes has prompted recommendations for various fetal surveillance programs beginning in the third trimester. Such protocols include fetal movement counting, periodic fetal heart rate monitoring, intermittent biophysical profile evaluation, and contraction stress testing (Chap. 17, Fetal Movements). None of these techniques has been subjected to prospective

randomized clinical trials, and their primary value seems related to their low false-negative rates. The American College of Obstetricians and Gynecologists (2016b) suggests initiating such testing at 32 to 34 weeks' gestation.

At Parkland Hospital, women with diabetes are seen in a specialized obstetrical clinic every 2 weeks. During these visits, glycemic control records are evaluated and insulin adjusted. Women are routinely instructed to perform fetal kick counts beginning early in the third trimester. At 34 weeks, admission is offered to all insulin-treated women. While in the hospital, they continue daily fetal movement counts and undergo fetal heart rate monitoring three times a week. Delivery is planned for 38 weeks.

Labor induction may be attempted when the fetus is not excessively large and the cervix is considered favorable (Chap. 26, Labor Induction). Little and colleagues (2015) analyzed term singleton births from 2005 to 2011 and showed a higher percentage of diabetic women were delivered each year before 39 weeks compared with the entire cohort—37 versus 29 percent. Cesarean delivery at or near term has frequently been used to avoid traumatic birth of a large fetus in a woman with diabetes. In women with more advanced diabetes, especially those with vascular disease, the reduced likelihood of successful labor induction remote from term has also contributed to an increased cesarean delivery rate. In an analysis of pregnancy outcomes of diabetic women from University of Alabama at Birmingham according to the White classification, the rate of cesarean delivery and preeclampsia escalated with White class (Bennett, 2015). In another study, a HbA_{1c} level >6.4 percent at delivery was independently associated with urgent cesarean delivery. This suggests that tighter glycemic control during the third trimester might reduce late fetal compromise and cesarean delivery for fetal indications (Miailhe, 2013). The cesarean delivery rate for women with overt diabetes has remained at approximately 80 percent for the past 40 years at Parkland Hospital.

Reducing or withholding the dose of long-acting insulin to be given on the day of delivery is recommended. Regular insulin should be used to meet most or all of the insulin needs of the mother during this time, because insulin requirements typically drop markedly after delivery. We have found that continuous insulin infusion by calibrated intravenous pump is most satisfactory (Table 57-10). Throughout labor and after delivery, the woman should be adequately hydrated intravenously and given glucose in sufficient amounts to maintain normoglycemia. Capillary or plasma glucose levels are checked frequently, especially during active labor, and regular insulin is administered accordingly.

TABLE 57-10

Insulin Management During Labor and Delivery

- Usual dose of intermediate-acting insulin is given at bedtime.
- Morning dose of insulin is withheld.
- Intravenous infusion of normal saline is begun.
- Once active labor begins or glucose levels decrease to less than 70 mg/dL, the infusion is changed from saline to 5% dextrose and delivered at a rate of 100–150 cc/h (2.5 mg/kg/min) to achieve a glucose level of approximately 100 mg/dL.
- Glucose levels are checked hourly using a bedside meter allowing for adjustment in the insulin or glucose infusion rate.
- Regular (short-acting) insulin is administered by intravenous infusion at a rate of 1.25 U/h if glucose levels exceed 100 mg/dL.

Data from Coustan DR. Delivery: timing, mode, and management. In: Reece EA, Coustan DR, Gabbe SG, editors. Diabetes in women: adolescence, pregnancy, and menopause. 3rd ed. Philadelphia (PA): Lippincott Williams & Wilkins; 2004; and Jovanovic L, Peterson CM. Management of the pregnant, insulin-dependent diabetic woman. Diabetes Care 1980;3:63–8.

Puerperium

Often, women may require virtually no insulin for the first 24 hours or so postpartum. Subsequently, insulin requirements may fluctuate markedly during the next few days. Infection must be promptly detected and treated. When appropriate, oral agents can be restarted.

Counseling in the puerperium should include a discussion of birth control. Effective contraception is especially important in women with overt diabetes to allow optimal glucose control before subsequent conception.

GESTATIONAL DIABETES

In the United States in 2010, almost 5 percent of gravidas were affected by gestational diabetes (DeSisto, 2014). Worldwide, its prevalence differs according to race, ethnicity, age, and body composition and by screening and diagnostic criteria. There continue to be several controversies pertaining to the diagnosis and treatment of gestational diabetes. A National Institutes of Health (NIH) Consensus Development Conference (2013) was convened to study this. The American College of Obstetricians and Gynecologists (2017a) has also updated its recommendations. These two authoritative sources provide an analysis of the issues surrounding the diagnosis and bolster the approach to identifying and treating women with gestational diabetes.

The word *gestational* implies that diabetes is induced by pregnancy—ostensibly because of exaggerated physiological changes in glucose metabolism (Chap. 4, Fat Metabolism). Gestational diabetes is defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy (American College of Obstetricians and Gynecologists, 2017a). This definition applies whether or not insulin is used for treatment and undoubtedly includes some women with previously unrecognized overt diabetes.

Use of the term *gestational diabetes* has been encouraged to communicate the need for enhanced surveillance and to stimulate women to seek further testing postpartum. The most important perinatal correlate is excessive fetal growth, which may result in both maternal and fetal birth trauma. The likelihood of fetal death with appropriately treated gestational diabetes is not different from that in the general population. Importantly, more than half of women with gestational diabetes ultimately develop overt diabetes in the ensuing 20 years. And, as discussed in Types of Diabetes, evidence is mounting for long-range complications that include obesity and diabetes in their offspring.

Screening and Diagnosis

Despite almost 50 years of research, there is still no agreement regarding optimal gestational diabetes screening. The difficulty in achieving consensus is underscored by the controversy following publication of the single-step approach espoused by the International Association of Diabetes and Pregnancy Study Groups Consensus Panel (2010) and shown in Table 57-11. This strategy was greatly influenced by results of the Hypoglycemia and Pregnancy Outcomes (HAPO) Study, described later. Although the ADA (2017a) supports this new scheme, the American College of Obstetricians and Gynecologists (2017a) continues to recommend a two-step approach to screen and diagnose gestational diabetes. Similarly, the NIH Consensus Development Conference in 2013 concluded that evidence is insufficient to adopt a one-step approach.

TABLE 57-11

Threshold Values for Diagnosis of Gestational Diabetes

Plasma Glucose	Glucose Concentration Threshold[a]		Above Threshold (%)
	mmol/L	mg/dL	Cumulative
Fasting	5.1	92	8.3
1-hr OGTT	10.0	180	14.0
2-hr OGTT	8.5	153	16.1[b]

[a]One or more of these values from a 75-g OGTT must be equaled or exceeded for the diagnosis of gestational diabetes.

[b]In addition, 1.7% of participants in the initial cohort were unblinded because of fasting plasma glucose levels >5.8 mmol/L (105 mg/dL) or 2-hr OGTT values >11.1 mmol/L (200 mg/dL), bringing the total to 17.8%.

OGTT = oral glucose tolerance test.

Data from International Association of Diabetes and Pregnancy Study Groups, 2010.

The recommended two-step approach begins with either universal or risk-based selective screening using a 50-g, 1-hour oral glucose challenge test. Participants in the Fifth International Workshop Conferences on Gestational Diabetes endorsed use of *selective screening* criteria shown in Table 57-12. Conversely, the American College of Obstetricians and Gynecologists (2017a) recommends *universal screening* of pregnant women using a laboratory-based blood glucose test. It is suggested that attempts to identify the 10 percent of women who should *not* be screened would add unnecessary complexity. Screening should be performed between 24 and 28 weeks' gestation in those women not known to have glucose intolerance earlier in pregnancy. This *50-g screening test* is followed by a *diagnostic 100-g, 3-hour oral glucose tolerance test (OGTT)* if screening results meet or exceed a predetermined plasma glucose concentration.

TABLE 57-12

Risk-Based Recommended Screening Strategy for Detecting GDM[a]

GDM risk assessment: should be ascertained at the first prenatal visit
Low Risk: Blood glucose testing not routinely required if all the following are present:
Member of an ethnic group with a low prevalence of GDM
No known diabetes in first-degree relatives
Age <25 years
Weight normal before pregnancy
Weight normal at birth
No history of abnormal glucose metabolism
No history of poor obstetrical outcome
Average Risk: Perform blood glucose testing at 24 to 28 weeks using either:
Two-step procedure: 50-g oral glucose challenge test (GCT), followed by a diagnostic 100-g OGTT for those meeting the threshold value in the GCT
One-step procedure: diagnostic 100-g OGTT performed on all subjects
High Risk: Perform blood glucose testing as soon as feasible, using the procedures described above, if one or more of these are present:
Severe obesity
Strong family history of type 2 diabetes
Previous history of GDM, impaired glucose metabolism, or glucosuria If GDM is not diagnosed, blood glucose testing should be repeated at 24 to 28 weeks' gestation or at any time symptoms or signs suggest hyperglycemia

[a]Criteria of the Fifth International Workshop-Conference on Gestational Diabetes.

GDM = gestational diabetes mellitus; OGTT = oral glucose tolerance test.

Reproduced with permission from Metzger BE, Coustan DR, the Organizing Committee: Summary and recommendations of the Fourth International Workshop-Conference on Gestational Diabetes Mellitus, Diabetes Care. 1998 Aug; 21 Suppl 2:B161–B167.

For the 50-g screen, the plasma glucose level is measured 1 hour after a 50-g oral glucose load without regard to the time of day or time of last meal. In a recent review, the pooled sensitivity for a threshold of 140 mg/dL ranged from 74 to 83 percent depending on 100-g thresholds used for diagnosis (van Leeuwen, 2012). Sensitivity estimates for a 50-g screen threshold of 135 mg/dL improved only slightly to 78 to 85 percent. Importantly, specificity dropped from a range of 72 to 85 percent for 140 mg/dL to 65 to 81 percent for a threshold of 135 mg/dL. Using a threshold of 130 mg/dL marginally improves sensitivity with a further decline in specificity (Donovan, 2013). That said, in the absence of clear evidence supporting one cutoff value over another, the American College of Obstetricians and Gynecologists (2017a) sanctions using any one of the three 50-g screen thresholds. At Parkland Hospital, we continue to use 140 mg/dL as the screening threshold to prompt the 100-g test.

Justification for screening and treatment of women with gestational diabetes was strengthened by the study by Crowther and coworkers (2005). They assigned 1000 women with gestational diabetes between 24 and 34 weeks' gestation to receive dietary advice with blood glucose monitoring plus insulin therapy—the intervention group—or to undergo routine prenatal care. Women were diagnosed as having gestational diabetes if their blood glucose was >100 mg/dL after an overnight fast and was between 140 and 198 mg/dL 2 hours after ingesting a 75-g glucose solution. Women in the intervention group had a significantly lower risk of a composite adverse outcome that included perinatal death, shoulder dystocia, fetal bone fracture, and fetal nerve palsy. Macrosomia defined by birthweight ≥4000 g complicated 10 percent of deliveries in the intervention group compared with 21 percent in the routine prenatal care group. Cesarean delivery rates were almost identical in the two study groups.

Slightly different results were reported by the Maternal–Fetal Medicine Units Network randomized trial of 958 women (Landon, 2009). Dietary counseling plus glucose monitoring was compared with standard obstetrical care in women with mild gestational diabetes to reduce perinatal morbidity rates. Mild gestational diabetes was identified in women with fasting glucose levels <95 mg/dL. They reported no differences in rates of composite morbidity that included stillbirth; neonatal hypoglycemia, hyperinsulinemia, and hyperbilirubinemia; and birth trauma. Importantly, secondary analyses demonstrated a 50-percent reduction in macrosomia, fewer cesarean deliveries, and a significant decrease in shoulder dystocia rate—1.5 versus 4 percent—in treated versus control women.

Based largely on these two landmark studies, the U.S. Preventive Services Task Force (2014) now recommends universal screening in low-risk women after 24 weeks' gestation. However, the Task Force concluded that evidence is insufficient to assess the balance of benefits versus harms of screening before 24 weeks. For screening, the optimal OGTT to identify gestational diabetes has not been agreed upon. The World Health Organization (2013) and the ADA (2017a) recommend the 75-g, 2-hour OGTT, but acknowledge that the diagnosis can be accomplished using the two-step strategy. In the United States, however, the 100-g, 3-hour OGTT performed after an overnight fast is recommended by the American College of Obstetricians and Gynecologists (2017a). Proposed criteria for interpretation of the diagnostic 100-g OGTT are shown in Table 57-13. In a secondary analysis of the Maternal-Fetal Medicine Units Network treatment trial, Harper and colleagues (2016) showed that women diagnosed with either the National Diabetes Data Group (NDDG) or the Carpenter-Coustan criteria benefited from treatment. However, the number needed to treat to prevent a shoulder dystocia was higher for the Carpenter-Coustan criteria. At Parkland Hospital we continue to use the NDDG criteria for diagnosis. Criteria for the 75-g OGTT recommended are shown in Table 57-11.

TABLE 57-13

Diagnosis of GDM Using Threshold Glucose Values from 100-g Oral Glucose Tolerance Test[a,b]

	NDDG[c]		Carpenter–Coustan[d]	
Time	**(mg/dL)**	**(mmol/L)**	**(mg/dL)**	**(mmol/L)**
Fasting	105	5.8	95	5.3
1-hr	190	10.6	180	10.0
2-hr	165	9.2	155	8.6
3-hr	145	8.0	140	7.8

[a]The test should be performed when the patient is fasting.

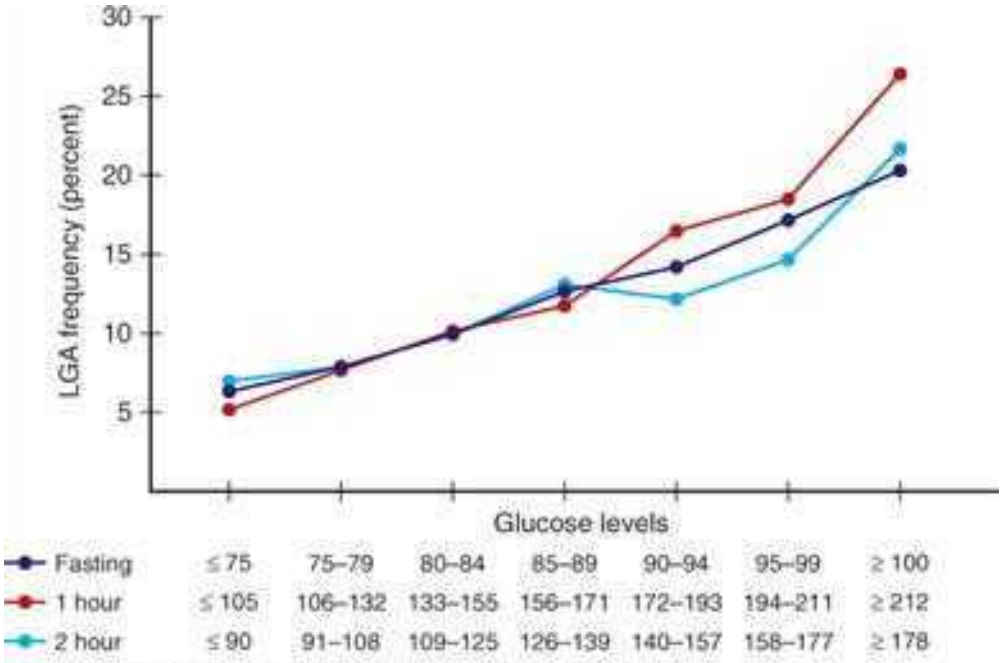
The Hyperglycemia and Adverse Pregnancy Outcome Study

This was a 7-year international epidemiological study of 23,325 pregnant women at 15 centers in nine countries (HAPO Study Cooperative Research Group, 2008). The investigation analyzed the association of various levels of glucose intolerance during the third trimester with adverse infant outcomes in women with gestational diabetes. Between 24 and 32 weeks' gestation, the general population of pregnant women underwent a 75-g OGTT after an overnight fasting. Blood glucose levels were measured fasting and then 1 and 2 hours after glucose ingestion. Caregivers were blinded to results except for women whose glucose levels exceeded values that required treatment and removal from the study. Glucose values at each of these three time posts were stratified into seven categories (Fig. 57-6). These values were then correlated with rates for birthweight >90th percentile (LGA), primary cesarean delivery, neonatal hypoglycemia, and cord-serum C-peptide levels >90th percentile. Odds of each outcome were calculated using the lowest category—for example, fasting plasma glucose ≤75 mg/dL—as the referent group. Their findings in general supported the supposition that increasing plasma glucose levels were associated with increasing adverse outcomes. Ecker and Greene (2008) concluded that it would be difficult to show that treating

lesser degrees of carbohydrate intolerance would provide any meaningful improvements in clinical outcomes. We agree that changes in criteria are not justified until clinical trials prove benefits. This position was also endorsed by the 2013 NIH Consensus Development Conference.

FIGURE 57-6

Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study. The frequency of newborn birthweight ≥90th percentile for gestational age plotted against glucose levels fasting and at 1- and 2-hr intervals following a 75-g oral glucose load. LGA = large for gestational age. (Reproduced with permission from HAPO Study Cooperative Research Group, Metzger BE, Lowe LP, et al: Hyperglycemia and adverse pregnancy outcomes, N Engl J Med. 2008 May 8;358(19):1991–2002.)



International Association of Diabetes and Pregnancy Study Group

The IADPSG sponsored a workshop conference on the diagnosis and classification of gestational diabetes in 2008. After reviewing the results of the HAPO study, a panel developed recommendations for the diagnosis and classification of hyperglycemia during pregnancy. This panel allowed for the diagnosis of overt diabetes during pregnancy as shown in Table 57-4. It also recommended a single-step approach to the diagnosis of gestational diabetes using the 75-g, 2-hour OGTT. Thresholds for fasting, 1-, and 2-hour values based on mean glucose concentrations from the entire HAPO study cohort were considered. These glucose level thresholds were derived using an arbitrary 1.75 odds ratio of outcomes such as LGA birthweight and cord serum C-peptide levels >90th percentile. Only one of these thresholds, shown in Table 57-11, would need to be met or exceeded to make the diagnosis of gestational diabetes.

It is estimated that implementation of these recommendations would raise the prevalence of gestational diabetes in the United States to 17.8 percent! Said another way, the number of women with mild gestational diabetes would grow almost threefold with no evidence of treatment benefit (Cundy, 2012). Feldman and coworkers (2016) evaluated the implementation of the IADPSG paradigm in a before-after analysis that included more than 6000 women. The new strategy was associated with a significant increase in gestational diabetes diagnosis rates but not with reduced macrosomia rates compared with a two-step approach. Remarkably, they identified a higher primary cesarean delivery rate associated with adoption of the IADPSG recommendations. The ADA (2013, 2017a) initially recommended adopting this new approach, however, based on benefits inferred from trials in women identified using a two-step approach described in Screening and Diagnosis, they now concede that data support a two-step strategy as well.

NIH Consensus Development Conference

Prompted by the disparate recommendations, the NIH Consensus Development Conference on Diagnosing Gestational Diabetes Mellitus (2013) was convened. This conference included input from a multidisciplinary planning committee, a systematic evidence review by the Agency for Healthcare Research and Quality Evidence-Based Practice Center, expert testimony, and a nonbiased panel to produce the overall report. The panel concluded that there were potential benefits to worldwide standardization. However, it found insufficient evidence to adopt a one-step diagnostic process such as the one proposed by the IADPSG. Moreover, as mentioned previously, after consideration of these findings, the American College of Obstetricians and Gynecologists (2017a) continues to recommend a two-step screening and diagnostic approach to gestational diabetes diagnosis. The College noted no significant improvements in maternal or perinatal outcomes that would offset the tripling of gestational diabetes incidence that would derive from the one-step approach. We applaud this decision.

Maternal and Fetal Effects

Adverse consequences of gestational diabetes differ from those of pregestational diabetes. Unlike in women with overt diabetes, women with gestational diabetes do not appear to have fetuses with substantially higher rates of anomalies than the general obstetrical population (Sheffield, 2002). In a study of more than 1 million women from the Swedish Medical Birth Registry, major malformation rates were marginally elevated in fetuses of gestational diabetics compared with those of nondiabetic controls—2.3 versus 1.8 percent (Fadl, 2010). The stillbirth rate was not greater in this study. Similarly, the stillbirth rate was not increased in an analysis by Jovanovič and associates (2015) of more than 800,000 pregnancies from 2005 through 2011. In contrast, and not unexpectedly, women with *elevated* fasting glucose levels have elevated rates of unexplained stillbirths similar to those of women with overt diabetes. This increasing risk with progressive maternal hyperglycemia emphasizes the importance of identifying women with evidence of preexisting diabetes early in pregnancy (see Table 57-4). Similar to women with overt diabetes, adverse maternal effects associated with gestational diabetes include a higher frequency of hypertension and cesarean delivery.

Fetal Macrosomia

The primary effect attributed to gestational diabetes is excessive fetal size or macrosomia that is variably defined and discussed further in Chapter 44 (Definition). The perinatal goal is to avoid difficult delivery from macrosomia and concomitant birth trauma associated with shoulder dystocia. In a retrospective analysis of more than 80,000 vaginal deliveries in Chinese women, Cheng and associates (2013) calculated a 76-fold greater risk for shoulder dystocia in newborns weighing ≥4200 g compared with the risk in those weighing <3500 g. Importantly, however, the odds ratio for shoulder dystocia in women with diabetes was <2. Although gestational diabetes is certainly a risk factor, it accounts for only a small number of pregnancies complicated by shoulder dystocia.

The excessive shoulder and trunk fat that commonly characterizes the macrosomic newborn of a diabetic mother theoretically predisposes such neonates to shoulder dystocia or cesarean delivery (Durnwald, 2004; McFarland, 2000). Landon and associates (2011) identified shoulder dystocia in approximately 4 percent of women with mild gestational diabetes compared with <1 percent of women with a 50-g glucose screen result <120 mg/dL. In a prospective study of fetal adipose measurements, however, Buhling and coworkers (2012) demonstrated no differences between measurements in 630 offspring of women with gestational diabetes and 142 without diabetes. The authors attributed this negative finding to successful treatment of gestational diabetes.

Extensive evidence supports that insulin-like growth factors also play a role in fetal-growth regulation (Chap. 44, Normal Birthweight). These proinsulin-like polypeptides are produced by virtually all fetal organs and are potent stimulators of cell differentiation and division. Luo and coworkers (2012) reported that insulin-like growth factor-1 strongly correlated with birthweight. The HAPO study investigators also reported dramatic increases in cord-serum C-peptide levels with rising maternal glucose levels following a 75-g OGTT. C-peptide levels above the 90th percentile were found in almost a third of newborns in the highest glucose categories. Other factors implicated in macrosomia include epidermal growth factor, fibroblast growth factor, platelet-derived growth factor, leptin, and adiponectin (Grissa, 2010; Loukovaara, 2004; Mazaki-Tovi, 2005).

Neonatal Hypoglycemia

Hyperinsulinemia may provoke severe hypoglycemia within minutes of birth, but only three fourths of these episodes occur in the first 6 hours (Harris, 2012). The definition of neonatal hypoglycemia is controversial, with recommended clinical thresholds ranging from 35 to 45 mg/dL. An NIH workshop conference on neonatal hypoglycemia supported using a threshold of 35 mg/dL in term newborns but cautioned that this practice is not strictly evidence based (Hay, 2009). Newborns described by the HAPO study (2008) had an incidence of clinical neonatal hypoglycemia that rose with increasing maternal OGTT result values defined in Figure 57-6. The frequency varied from 1 to 2 percent, but it was as high as 4.6 percent in women with fasting glucose levels ≥100 mg/dL. Similarly, Cho and colleagues (2016), analyzed more than 3000 Korean women who underwent a 50-g OGTT and found that neonates born to women with a screening result ≥200 mg/dL were 84 times more likely to have hypoglycemia than those born to women with a result <140 mg/dL. The risk of neonatal hypoglycemia correlates with umbilical cord C-peptide levels. But, importantly, the risk also rises with birthweight, independent of a maternal diabetes diagnosis (Mitanchez, 2014).

Maternal Obesity

In women with gestational diabetes, maternal body mass index (BMI) is an independent and more substantial risk factor for fetal macrosomia than is glucose intolerance (Ehrenberg, 2004; Mission, 2013). Stuebe and associates (2012) completed a secondary analysis of women with either untreated mild gestational diabetes or normal glucose tolerance testing results. They found that higher BMI levels were associated with rising birthweight, regardless of glucose levels. In one analysis of more than 600,000 pregnant women, gestational diabetes, compared with obesity or gestational weight gain, contributed the least to the population-attributable fraction of LGA neonates (Kim, 2014). The highest fraction of LGA neonates was attributable to maternal obesity plus excessive gestational weight gain. Similarly, Egan and colleagues (2014) found that excessive gestational weight gain is common in women with gestational diabetes and confers an additive risk for fetal macrosomia. Weight distribution also seems to play a role because the risk of gestational diabetes is greater with maternal truncal obesity. Suresh and colleagues (2012) verified that increased maternal abdominal subcutaneous fat thickness as measured by sonography at 18 to 22 weeks' gestation correlated with BMI and was a better predictor of gestational diabetes.

Management

Women with gestational diabetes can be divided into two functional classes using fasting glucose levels. Pharmacological methods are usually recommended if diet modification does not consistently maintain the fasting plasma glucose levels <95 mg/dL or the 2-hour postprandial plasma glucose <120 mg/dL (American College of Obstetricians and Gynecologists, 2017a). Whether pharmacological treatment should be used in women with lesser degrees of fasting hyperglycemia is unclear. There have been no controlled trials to identify ideal glucose targets for fetal risk prevention. On the other hand, the HAPO study (2008) did demonstrate increased fetal risk at glucose levels below the threshold used for diagnosis of diabetes. The Fifth International Workshop Conference recommended that fasting capillary glucose levels be kept ≤95 mg/dL (Metzger, 2007).

In a systematic review, Hartling and colleagues (2013) concluded that treating gestational diabetes resulted in a significantly lower incidence of preeclampsia, shoulder dystocia, and macrosomia. For example, the calculated risk ratio was 0.50 for delivering a newborn >4000 g after treatment. These investigators caution that the attributed risk for these outcomes is low, especially when glucose values are only moderately elevated. Importantly, they were unable to demonstrate an effect on neonatal hypoglycemia or on future metabolic outcomes in the offspring.

Diabetic Diet

Nutritional instructions generally include a carbohydrate-controlled diet sufficient to maintain normoglycemia and avoid ketosis. On average, this includes a daily caloric intake of 30 to 35 kcal/kg. Moreno-Castilla and associates (2013) randomly assigned 152 women with gestational diabetes to either a 40- or a 55-percent daily carbohydrate diet and found no difference in insulin levels and pregnancy outcomes. The American College of Obstetricians and Gynecologists (2017a) suggests that carbohydrate intake be limited to 40 percent of total calories. The remaining calories are apportioned to give 20 percent as protein and 40 percent as fat.

The most appropriate dietary approach for women with gestational diabetes has not been established. One metaanalysis of trials of low-glycemic index diets found that diets higher in complex carbohydrates and dietary fiber reduced the risk of macrosomia and likelihood of insulin use in women with gestational diabetes (Wei, 2016). That said, there clearly are limitations to what can be accomplished with various dietary approaches alone. Most and Langer (2012) found that insulin was effective in reducing the risk of excessive birthweight in offspring of obese women with gestational diabetes. Casey and colleagues (2015b) also found that dietary treatment alone for morbidly obese women with mild gestational diabetes did not reduce neonatal fat mass or LGA birthweights.

Exercise

Few trials have evaluated exercise specifically for women with gestational diabetes. The American College of Obstetricians and Gynecologists (2017a,b) recommends regular physical activity that incorporates aerobic and strength-conditioning exercise during pregnancy and extends this to women with gestational diabetes. Two recent metaanalyses demonstrate that structured exercise programs during pregnancy diminish weight gain during pregnancy and even reduce the risk of developing gestational diabetes (Russo, 2015; Sanabria-Martinez, 2015). Exercise during pregnancy in woman with gestational diabetes also lowers glucose levels (Jovanovic-Peterson, 1989).

Glucose Monitoring

Hawkins and colleagues (2008) compared outcomes in 315 women with diet-treated gestational diabetes who used personal glucose monitors with those of 615 gestational diabetics who were also diet-treated but who underwent intermittent fasting glucose evaluation during weekly obstetrical visits. Women using daily blood-glucose self monitoring had significantly fewer macrosomic newborns. They also gained less weight after diagnosis than women evaluated during clinic visits only. These findings support the common practice of blood-glucose self monitors for women with diet-treated gestational diabetes.

Postprandial surveillance for gestational diabetes has been shown to be superior to preprandial surveillance (DeVeciana, 1995). At Parkland Hospital, we reviewed the impact of changing to postprandial monitoring in women with diet-treated gestational diabetes and demonstrated a significant reduction in maternal weight gain per week—0.63 lb/week to 0.45 lb/week—in women managed with a postprandial monitoring schema. The American College of Obstetricians and Gynecologists (2017a) and the ADA (2017b) recommend glucose assessment four times daily. The first check is performed fasting, and the remainder are done 1 or 2 hours after each meal.

Insulin Treatment

Historically, insulin has been considered standard therapy in women with gestational diabetes when target glucose levels cannot be consistently achieved through nutrition and exercise. It does not cross the placenta, and tight glycemic control can typically be achieved. Insulin therapy is typically added if fasting levels persistently exceed 95 mg/dL in women with gestational diabetes. The American College of Obstetricians and Gynecologists (2017a) also recommends that insulin be considered in women with 1-hour postprandial levels that persistently exceed 140 mg/dL or those with 2-hour levels >120 mg/dL. Importantly, all of these thresholds are extrapolated from recommendations for managing women with overt diabetes.

If insulin is initiated, the starting dose is typically 0.7 to 1.0 units/kg/d and is given in divided doses (American College of Obstetricians and Gynecologists, 2017a). A combination of intermediate-acting and short-acting insulin may be used, and dose adjustments are based on glucose levels at particular times of the day. At Parkland Hospital, the starting daily dose is divided so that two thirds is given in the morning before breakfast and one third in the evening

before dinner. In the morning dose, one third is regular insulin and two thirds are NPH (neutral protamine Hagedorn). For the evening dose, one half is regular insulin and the other half is NPH. Insulin instruction for these women is accomplished either in a specialized outpatient clinic or during a short hospital stay. As shown in Table 57-8, insulin analogues such as insulin aspart and insulin lispro have a more rapid onset of action than regular insulin and theoretically could be helpful in postprandial glucose management. Experience with these analogues with gestational diabetes is limited, and Singh and coworkers (2009) were unable to demonstrate a benefit compared with conventional insulins.

Oral Hypoglycemic Agents

Insulin is the preferred first-line agent for persistent hyperglycemia in women with gestational diabetes. However, both the American College of Obstetricians and Gynecologists (2017a) and the ADA (2017b) acknowledge that several studies support the safety and efficacy of either glyburide (Micronase) or metformin (Glucophage) (Langer, 2000; Nicholson, 2009; Rowan, 2008). Balsells and colleagues (2015) performed metaanalyses of trials comparing both agents to insulin or to each other. In the seven trials comparing glyburide with insulin, glyburide was associated with higher birthweight, more macrosomia, and more frequent neonatal hypoglycemia. In the six trials comparing metformin with insulin, metformin was associated with less maternal weight gain, more preterm birth, and less severe neonatal hypoglycemia. On average from all trials, treatment failures occurred in 6 percent of women treated with glyburide and 34 percent of those treated with metformin. In the two studies comparing oral hypoglycemic agents with each other, metformin treatment was associated with less maternal weight gain, lower birthweight, and less macrosomia. In contrast to trials of each agent compared with insulin, treatment failure rates of both agents in these two studies were equivalent. Importantly, in a randomized trial of glyburide treatment as an adjunct to diet therapy in 395 women with mild gestational diabetes, Casey and coworkers (2015a) did not identify any significant improvements in pregnancy outcomes in women treated with glyburide.

Concerns have emerged regarding potential adverse outcomes among women treated with glyburide. First, like metformin, glyburide crosses the placenta and reaches concentrations in the fetus that are more than two thirds of maternal levels (Caritis, 2013). Additionally, a study of more than 9000 women with gestational diabetes treated with either insulin or glyburide showed a significant rise in rates of neonatal intensive care unit admission, respiratory distress, and neonatal hypoglycemia associated with glyburide use (Castillo, 2015).

Metformin reaches fetal serum concentrations similar to maternal levels. However, in one study of 751 women with gestational diabetes who were randomly assigned to metformin or insulin treatment, short-term perinatal adverse events did not differ between groups (Rowan, 2008). Outcomes included neonatal hypoglycemia, respiratory distress syndrome, phototherapy, birth trauma, 5-minute Apgar score ≤7, and preterm birth. Overall growth of offspring at age 2 years also did not differ (Rowan, 2011). Nevertheless, the fat distribution in children exposed to metformin showed a tendency toward a more favorable pattern. From a smaller randomized metformin trial, at 18 months, offspring exposed to metformin were slightly heavier, but markers of early motor or language development did not differ compared with those in offspring exposed to insulin (Ijäs, 2015).

The Food and Drug Administration has not approved glyburide and metformin use for treatment of gestational diabetes. However, the American College of Obstetricians and Gynecologists (2017a) recognizes both as reasonable choices for second-line glycemic control in women with gestational diabetes. Because long-term outcomes have not been fully studied, the committee recommends appropriate counseling, which includes disclosing the limitations in current safety data.

Obstetrical Management

In general, for women with gestational diabetes who do not require insulin, early delivery or other interventions are seldom required. There is no consensus regarding the value or timing of antepartum fetal testing. It is typically reserved for women with pregestational diabetes because of the greater stillbirth risk. The American College of Obstetricians and Gynecologists (2017a) endorses fetal surveillance in women with gestational diabetes and poor glycemic control. At Parkland Hospital, women with gestational diabetes are routinely instructed to perform daily fetal kick counts in the third trimester (Chap. 17, Clinical Application). Insulin-treated women are offered inpatient admission after 34 weeks' gestation, and antepartum monitoring is performed three times each week.

Women with gestational diabetes and adequate glycemic control are managed expectantly. Elective labor induction to prevent shoulder dystocia compared with spontaneous labor remains controversial. Alberico and colleagues (2017) recently described their truncated randomized trial of 425 women with gestational diabetes that compared labor induction between 38 and 39 weeks' and expectant management until 41 weeks' gestation. Although underpowered, this GINEXMAL Trial demonstrated no clinically meaningful difference in the cesarean delivery rate between the induction and expectant management groups—12.6 versus 11.8 percent. However, with early labor induction, neonatal hyperbilirubinemia rates were significantly higher, and ironically, there was a nonsignificant threefold greater shoulder dystocia rate. In a retrospective cohort study of 8392 Canadian women with gestational diabetes, Melamed and coworkers (2016) found that routine delivery at 38 or 39 weeks was associated with a lower rate of cesarean delivery but with an elevated rate of neonatal intensive care unit admission. The American College of Obstetricians and Gynecologists (2017a) recommends that routine labor induction in women with diet-treated gestational diabetes should not occur before 39 weeks' gestation. At Parkland Hospital, women with diet-treated gestational diabetes are not electively induced for this indication. However, those treated with insulin are delivered at 38 weeks' gestation.

Elective cesarean delivery to avoid brachial plexus injuries in overgrown fetuses is another important issue. The American College of Obstetricians and Gynecologists (2017a) has concluded that data are insufficient to determine whether cesarean delivery in women with *gestational* diabetes whose fetuses

have a sonographically estimated weight ≥4500 g should be performed to avoid risk of birth trauma. From their systematic review, Garabedian and coworkers (2010) estimated that as many as 588 cesarean deliveries in women with gestational diabetes and an estimated fetal weight of ≥4500 g would be necessary to avoid one case of permanent brachial plexus palsy. Scifres and colleagues (2015), in their retrospective analysis of 903 women with gestational diabetes who underwent sonographic evaluation within 1 month of delivery, demonstrated that sonographic estimates of fetal weight typically overdiagnosed fetuses as being LGA. Only 22 percent of women estimated to have an LGA fetus actually delivered an overgrown newborn. Still, the American College of Obstetricians and Gynecologists (2016a) acknowledges that prophylactic cesarean delivery may be considered in diabetic women with an estimated fetal weight ≥4500 g.

Postpartum Evaluation

Recommendations for postpartum evaluation are based on the 50-percent likelihood of women with gestational diabetes developing overt diabetes within 20 years (O'Sullivan, 1982). The Fifth International Workshop Conference on Gestational Diabetes recommended that women diagnosed with gestational diabetes undergo postpartum evaluation with a 75-g OGTT (Metzger, 2007). These recommendations are shown in Table 57-14 along with the classification scheme of the ADA (2017b). Eggleston and colleagues (2016) reviewed insurance claim data from 2000 to 2013 and found that only 24 percent of women with a pregnancy complicated by gestational diabetes underwent postpartum screening within a year, and less than half of those underwent a 75-g OGTT. The American College of Obstetricians and Gynecologists (2017a) recommends either a fasting glucose or the 75-g, 2-hour OGTT at 4 to 12 weeks postpartum for the diagnosis of overt diabetes. The ADA (2017a) recommends testing at least every 3 years in women with a history of gestational diabetes but normal postpartum glucose screening.

TABLE 57-14

Fifth International Workshop-Conference: Metabolic Assessments Recommended after Pregnancy with Gestational Diabetes

Time	**Test**	**Purpose**
Postdelivery (1–3 d)	Fasting or random plasma glucose	Detect persistent, overt diabetes
Early postpartum (6–12 wk)	75-g, 2-hr OGTT	Postpartum classification of glucose metabolism
1-yr postpartum	75-g, 2-hr OGTT	Assess glucose metabolism
Annually	Fasting plasma glucose	Assess glucose metabolism
Triannually	75-g, 2-hr OGTT	Assess glucose metabolism
Prepregnancy	75-g, 2-hr OGTT	Classify glucose metabolism
Classification of the American Diabetes Association (2013)		
Normal Values	**Impaired Fasting Glucose or Impaired Glucose Tolerance**	**Diabetes Mellitus**
Fasting <100 mg/dL	100–125 mg/dL	≥126 mg/dL
2 hr <140 mg/dL	2 hr ≥140–199 mg/dL	2 hr ≥200 mg/dL
Hemoglobin A_{1c}<5.7%	5.7–6.4%	≥6.5%

OGTT = oral glucose tolerance test.

Data from American Diabetes Association, 2013, 2017a; Metzger, 2007.

Women with a history of gestational diabetes are also at risk for cardiovascular complications associated with dyslipidemia, hypertension, and abdominal obesity—the *metabolic syndrome* (Chap. 48, Metabolic Syndrome). In a study of 47,909 parous women, Kessous and coworkers (2013) evaluated subsequent hospitalizations due to cardiovascular morbidity. They found that almost 5000 women with gestational diabetes were 2.6 times more likely to be hospitalized for cardiovascular morbidity. Another study evaluated 483 women between 5 and 10 years after being diagnosed with mild gestational diabetes (Varner, 2017). Investigators found no increased risk for developing metabolic syndrome associated with additional pregnancies. However, risk for subsequent diabetes rose almost fourfold if gestational diabetes complicated at least one subsequent pregnancy.

Recurrent Gestational Diabetes

In a metaanalysis of published reports from 1973 through 2014, the pooled gestational diabetes recurrence rate was 48 percent (Schwartz, 2015). Rates in primiparas were lower (40 percent) than in multiparas (73 percent). The same group of investigators identified maternal BMI, insulin use, fetal macrosomia, and weight gain between pregnancies as additional risk factors for gestational diabetes recurrence (Schwartz, 2016). Thus, lifestyle behavioral changes that include weight control and exercise between pregnancies would seem likely to prevent gestational diabetes recurrence. Guelfi and colleagues (2016) were unable to demonstrate a lower recurrence rate in women randomized to an exercise program that started before 14 weeks' gestation in a subsequent pregnancy. Conversely, Ehrlich and colleagues (2011) found that prepregnancy loss of at least two BMI units was associated with a lower subsequent risk of gestational diabetes in women who were overweight or obese in the first pregnancy.

CHAPTER 58: Endocrine Disorders

In a small number of cases the thyroid gland increases markedly in size, though we are ignorant as to its significance.

—J. Whitridge Williams (1903)

INTRODUCTION

In 1903, little was known of many endocrine disorders. Still, endocrinopathies seem particularly closely related to pregnancy because of its gestational proclivity for prodigious hormone secretion. This is best illustrated by placental lactogen in diabetes, the most common endocrinopathy encountered in pregnancy (Chap. 57, Types of Diabetes). Pregnancy is also interrelated with some endocrinopathies that are at least partially due to autoimmune dysregulation. Clinical manifestations of this result from complex interplay among genetic, environmental, and endogenous factors that activate the immune system against targeted cells within endocrine organs. An extraordinary example of these interactions comes from studies that implicate maternal organ engraftment by fetal cells that were transferred during pregnancy. These cells later provoke antibody production, tissue destruction, and autoimmune endocrinopathies.

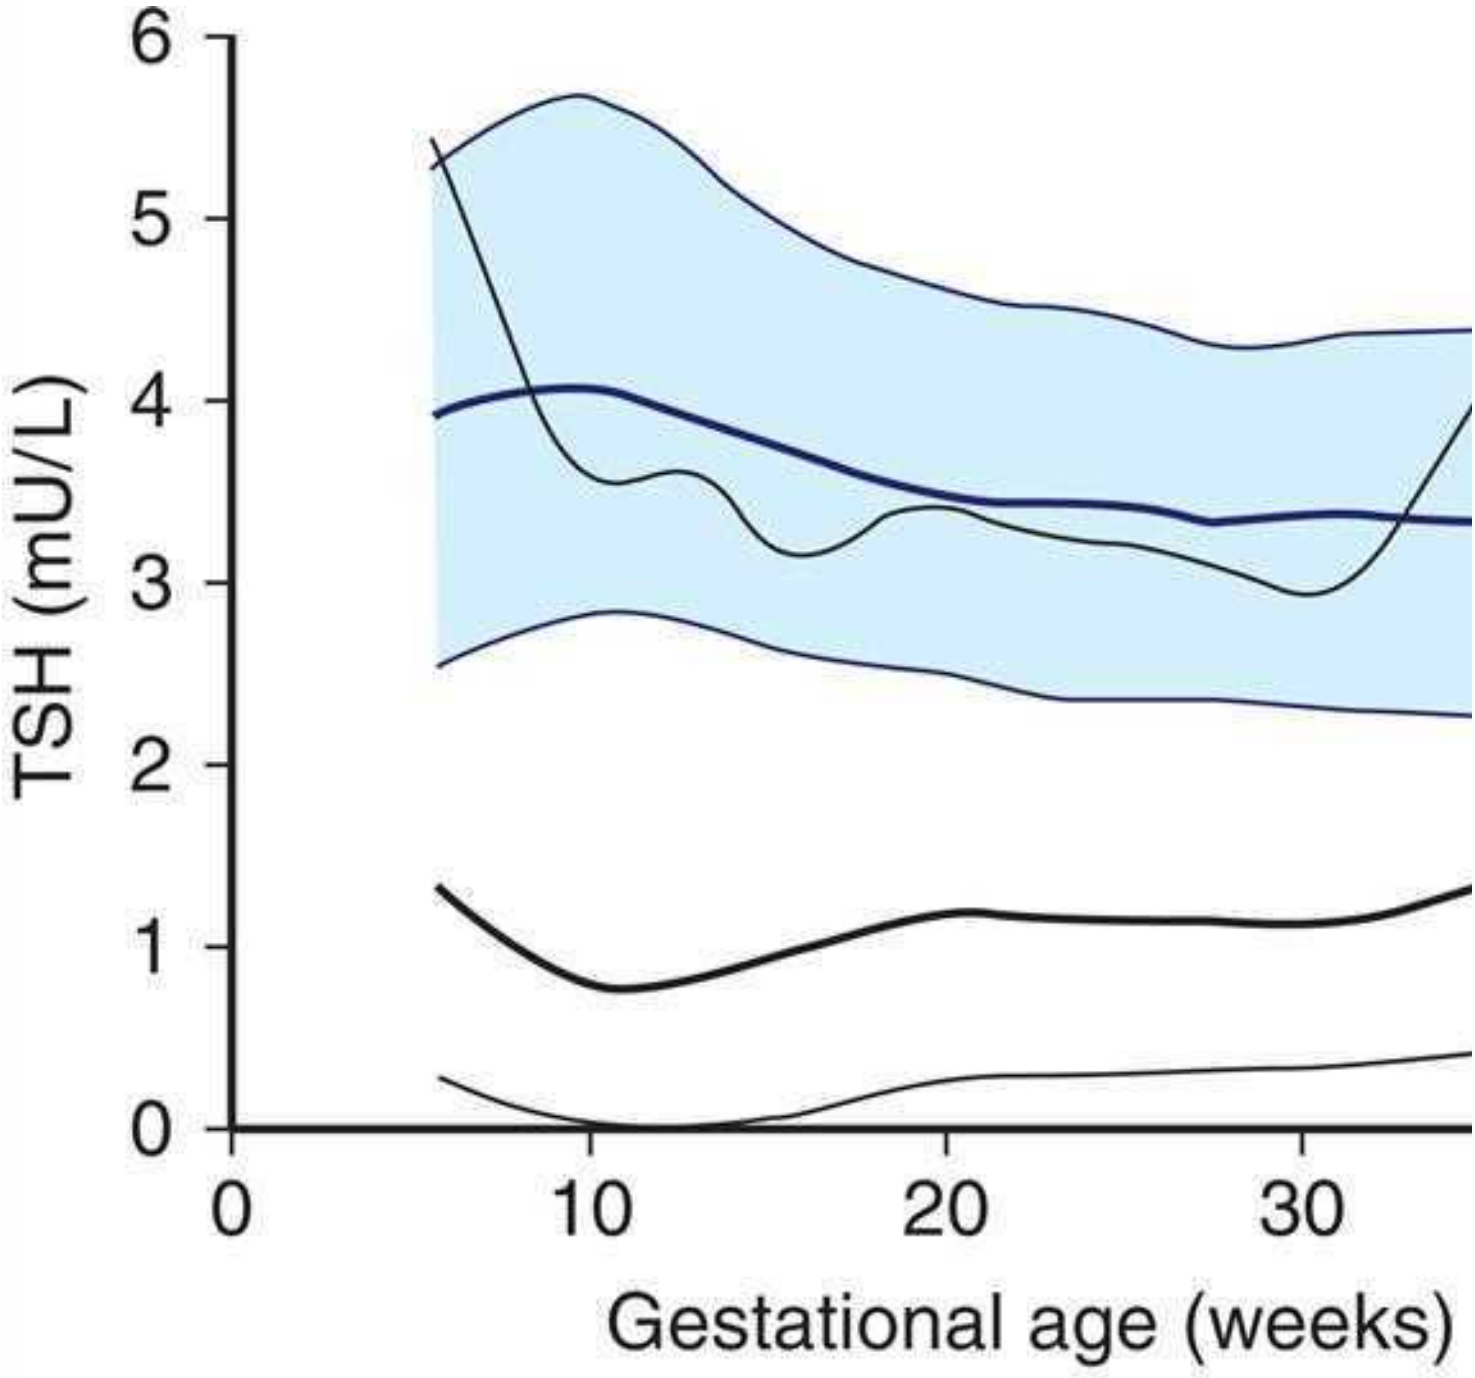
THYROID DISORDERS

Taken in aggregate, disorders of the thyroid gland are common in young women and thus frequently encountered in pregnancy. Maternal and fetal thyroid function are intimately related, and drugs that affect the maternal thyroid also affect the fetal gland. Moreover, thyroid autoantibodies have been associated with increased rates of early pregnancy wastage. Also, uncontrolled thyrotoxicosis and untreated hypothyroidism are both associated with adverse pregnancy outcomes. Finally, evidence suggests that the severity of some autoimmune thyroid disorders may be ameliorated during pregnancy, only to be exacerbated postpartum.

Thyroid Physiology and Pregnancy

Maternal thyroid changes are substantial, and normally altered gland structure and function are sometimes confused with thyroid abnormalities. These alterations are discussed in detail in Chapter 4 (Thyroid Gland), and normal serum hormone level values are found in the Appendix (Serum and Blood Constituents). First, maternal serum concentrations of thyroid binding globulin are increased concomitantly with total or bound thyroid hormone levels (Fig. 4-16). Second, *thyrotropin,* also called *thyroid-stimulating hormone (TSH),* currently plays a central role in screening and diagnosis of many thyroid disorders. Notably, TSH receptors are cross stimulated, albeit weakly, by massive quantities of human chorionic gonadotropin (hCG) secreted by placental trophoblast. Because TSH does not cross the placenta, it has no direct fetal effects. During the first 12 weeks of gestation, when maternal hCG serum levels are maximal, thyroid hormone secretion is stimulated. The resulting greater serum free thyroxine (T_4) levels act to suppress hypothalamic *thyrotropin-releasing hormone (TRH)* and in turn limit pituitary TSH secretion (Fig. 58-1). Accordingly, TRH is undetectable in maternal serum. Conversely, in fetal serum, beginning at midpregnancy, TRH becomes detectable, but levels are static and do not increase.

FIGURE 58-1
Gestational age specific values for serum thyroid stimulating hormone (TSH) levels (*black lines*) and free thyroxine (T_4) levels (*blue lines*). Data were derived from 17,298 women tested during pregnancy. For each color, the dark solid lines represent the 50th percentile, whereas the upper and lower light lines represent the 2.5th and 97.5th percentiles, respectively. (Data from Casey, 2005; Dashe, 2005.)



Throughout pregnancy, maternal thyroxine is transferred to the fetus (American College of Obstetricians and Gynecologists, 2017). Maternal thyroxine is important for normal fetal brain development, especially before the onset of fetal thyroid gland function (Bernal, 2007; Korevaar, 2016). And, even though the fetal gland begins concentrating iodine and synthesizing thyroid hormone after 12 weeks' gestation, maternal thyroxine contribution remains important. In fact, maternal sources account for 30 percent of thyroxine in fetal serum at term (Thorpe-Beeston, 1991). Still, developmental risks associated with maternal hypothyroidism after midpregnancy remain poorly understood (Morreale de Escobar, 2004; Sarkhail, 2016).

Autoimmunity and Thyroid Disease

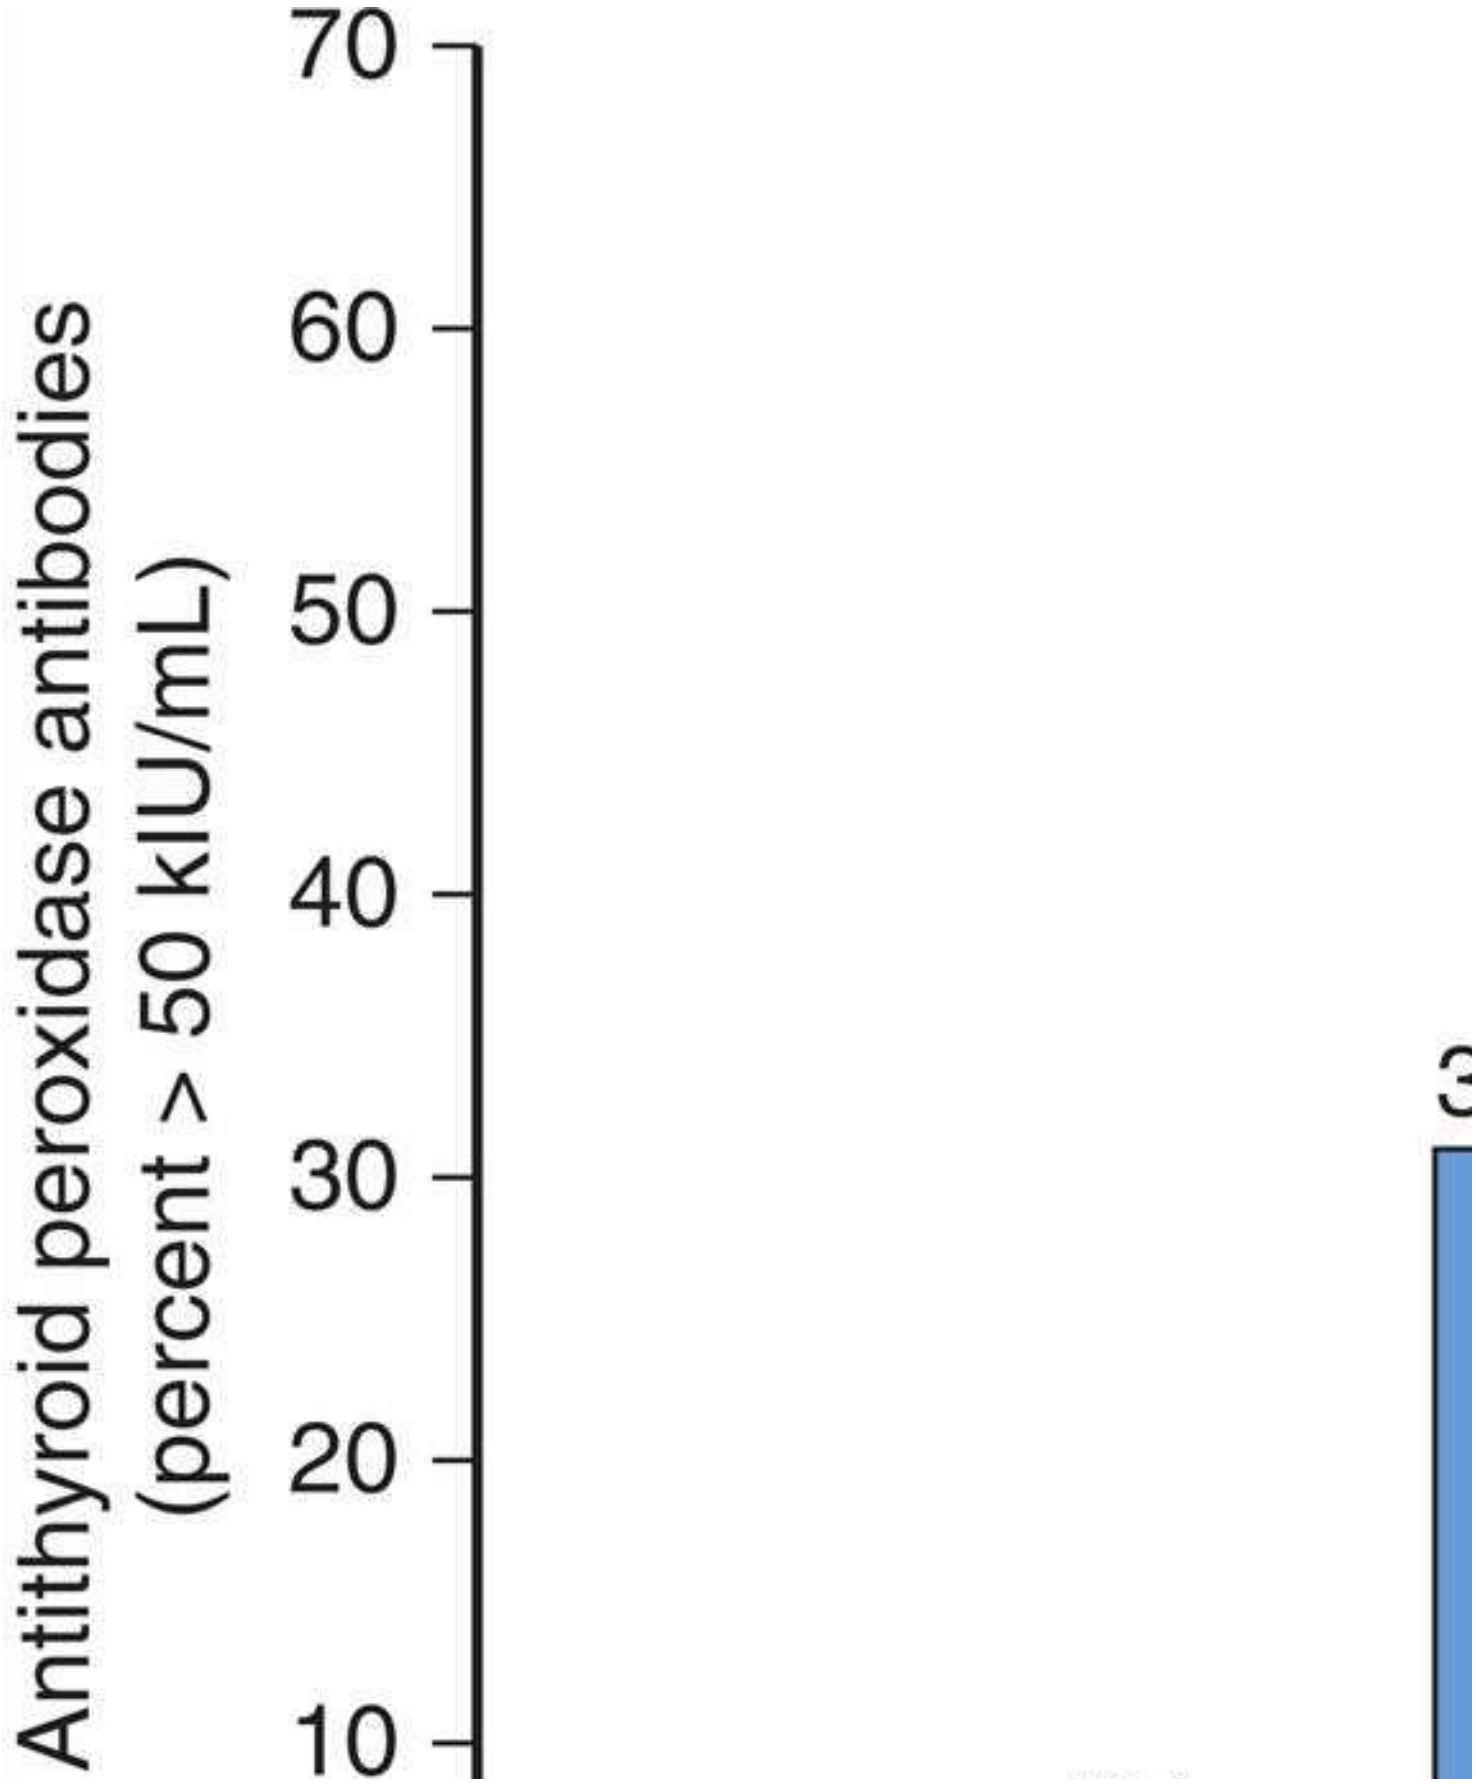
Most thyroid disorders are inextricably linked to autoantibodies against nearly 200 thyrocyte components. These antibodies variably stimulate thyroid function, block function, or cause thyroid inflammation that may lead to follicular cell destruction. Often, these effects overlap or even coexist.

Thyroid-stimulating autoantibodies, also called *thyroid-stimulating immunoglobulins (TSIs)*, bind to the TSH receptor and activate it, causing thyroid hyperfunction and growth. Although these antibodies are identified in most patients with classic Graves disease, simultaneous production of *thyroid-stimulating blocking antibodies* may blunt this effect (Jameson, 2015). *Thyroid peroxidase (TPO)* is a thyroid gland enzyme that normally functions in the production of thyroid hormones. *Thyroid peroxidase antibodies*, previously called *thyroid microsomal autoantibodies,* are directed against TPO and, as shown in Figure 58-2, have been identified in 5 to 15 percent of all pregnant women (Abbassi-Ghanavati, 2010; Sarkhail, 2016). These antibodies have been associated in some studies with early pregnancy loss and preterm birth (Negro, 2006; Korevaar, 2013; Plowden, 2017; Thangaratinam, 2011). In another study with more than 1000 TPO antibody-positive

pregnant women, the risk for preterm birth was not elevated, however, the risk for placental abruption was greater (Abbassi-Ghanavati, 2010). These women are also at high risk for postpartum thyroid dysfunction and at lifelong risk for permanent thyroid failure (Andersen, 2016; Jameson, 2015).

FIGURE 58-2

Incidence in percent of antithyroid peroxidase antibodies in 16,407 women who are normal or euthyroid, in 233 with isolated maternal hypothyroxinemia (IMH), in 598 with subclinical hypothyroidism (SCH), and in 134 with overt hypothyroidism. (Data from Casey, 2007).



Fetal Microchimerism

Autoimmune thyroid disease is much more common in women than in men. One intriguing explanation for this disparity is fetal-to-maternal cell trafficking (Greer, 2011). Fetal cells are known to enter maternal circulation during pregnancy. When fetal lymphocytes enter maternal circulation, they can live for more than 20 years. Stem cell interchange can lead to engraftment in several maternal tissues and is termed *fetal microchimerism.* In some cases, this may involve the thyroid gland (Bianchi, 2003; Boddy, 2015; Khosrotehrani, 2004). A high prevalence of Y-chromosome-positive cells has been identified using fluorescence in situ hybridization (FISH) in the thyroid glands of women with Hashimoto thyroiditis—60 percent, or with Graves disease—40 percent (Renné, 2004). In another study of women giving birth to a male fetus, Lepez and colleagues (2011) identified significantly more circulating male mononuclear cells in those with Hashimoto thyroiditis. Ironically, such microchimerism may have a protective role for autoimmune thyroid disorders (Cirello, 2015).

Hyperthyroidism

The incidence of thyrotoxicosis or hyperthyroidism in pregnancy is varied and complicates between 2 and 17 per 1000 births when gestational-age appropriate TSH threshold values are used (Table 58-1). Because normal pregnancy simulates some clinical findings similar to thyroxine excess, clinically mild thyrotoxicosis may be difficult to diagnose. Suggestive findings include tachycardia that exceeds that usually seen with normal pregnancy, thyromegaly, exophthalmos, and failure to gain weight despite adequate food intake. Laboratory testing is confirmatory. TSH levels are markedly depressed, while serum free T_4 (fT_4) levels are elevated (Jameson, 2015). Rarely, hyperthyroidism is caused by abnormally high serum triiodothyronine (T_3) levels—so-called *T_3-toxicosis.*

TABLE 58-1

Incidence of Overt Hyperthyroidism in Pregnancy

Study	Country	Incidence
Wang (2011)[a]	China	1%
Vaidya (2007)[a]	United Kingdom	0.7%
Lazarus (2007)[b]	United Kingdom	1.7%
Casey (2006)[c]	United States	0.4%

[a]Screened in the first trimester.

[b]Screened at 9–15 weeks.

[c]Screened before 20 weeks.

[d]Diagnosed in early versus later pregnancy.

Thyrotoxicosis and Pregnancy

The overwhelming cause of thyrotoxicosis in pregnancy is Graves disease, an organ-specific autoimmune process associated with thyroid-stimulating TSH-receptor antibodies as previously discussed (De Leo, 2016). Because these antibodies are specific to Graves hyperthyroidism, such assays have been proposed for diagnosis,

management, and prognosis in pregnancies complicated by hyperthyroidism (Barbesino, 2013). At Parkland Hospital, these receptor antibody assays are generally reserved for cases in which fetal thyrotoxicosis is suspected. With Graves disease, during the course of pregnancy, hyperthyroid symptoms may initially worsen because of hCG stimulation but then subsequently diminish with drops in receptor antibody titers in the second half of pregnancy (Mestman, 2012; Sarkhail, 2016). Amino and coworkers (2003) have found that levels of blocking antibodies also decline during pregnancy.

Treatment

Thyrotoxicosis during pregnancy can nearly always be controlled by thionamide drugs. *Propylthiouracil (PTU)* has been historically preferred because it partially inhibits the conversion of T_4 to T_3 and crosses the placenta less readily than *methimazole*. The latter has also been associated with a rare methimazole embryopathy, characterized by *esophageal* or *choanal atresia* as well as *aplasia cutis*, a congenital skin defect. Yoshihara and associates (2012, 2015) analyzed outcomes in Japanese women with first-trimester hyperthyroidism and found a twofold increased risk of major fetal malformations in pregnancies exposed to methimazole compared with either PTU or potassium iodide. Specifically, seven of nine cases with aplasia cutis and the only case of esophageal atresia were in the group of methimazole-exposed fetuses. There have also been reports of a PTU-associated embryopathy (Andersen, 2014).

In 2009, the Food and Drug Administration issued a safety alert on PTU-associated hepatotoxicity. This warning prompted the American Thyroid Association and the American Association of Clinical Endocrinologists (2011) to recommend PTU therapy during the first trimester followed by methimazole beginning in the second trimester. The obvious disadvantage is that this might lead to poorly controlled thyroid function. Accordingly, at Parkland Hospital, we continue to prescribe PTU treatment throughout pregnancy.

Transient leukopenia can be documented in up to 10 percent of women taking antithyroid drugs, but this does not require therapy cessation (American College of Obstetricians and Gynecologists, 2017). In approximately 0.3 percent, however, *agranulocytosis* develops suddenly and mandates drug discontinuance (Thomas, 2013). It is not dose related, and because of its acute onset, serial leukocyte counts during therapy are not helpful. *Thus, if fever or sore throat develops, women are instructed to discontinue medication immediately and report for a complete blood count.*

Therapy may have other side effects. First, as noted, hepatotoxicity is a possibility and develops in approximately 0.1 percent of treated women. Serial measurement of hepatic enzyme levels does not prevent fulminant PTU-related hepatotoxicity. Second, approximately 20 percent of patients treated with PTU develop *antineutrophil cytoplasmic antibodies (ANCA).* Despite this, only a small percentage of these subsequently develops serious vasculitis (Kimura, 2013). Finally, although thionamides have the potential to cause fetal complications, these are uncommon. In some cases, thionamides may even be therapeutic for the fetus, because TSH-receptor antibodies cross the placenta and can stimulate the fetal thyroid gland to cause thyrotoxicosis and goiter.

The initial thionamide dose is empirical. For nonpregnant patients, the American Thyroid Association recommends that methimazole be used at an initial higher daily dose of 10 to 20 mg orally followed by a lower maintenance dose of 5 to 10 mg. If PTU is selected, a dose of 50 to 150 mg orally three times daily may be initiated depending on clinical severity (Bahn, 2011). At Parkland Hospital, we usually initially give 300 or 450 mg of PTU daily in three divided doses for pregnant women. Occasionally, daily doses of 600 mg or higher are necessary. As discussed, we generally do not transition women to methimazole during the second trimester. The goal is treatment with the lowest possible thionamide dose to maintain thyroid hormone levels slightly above or in the high normal range, while TSH levels remains suppressed (Bahn, 2011). Serum free T_4 concentrations are measured every 4 to 6 weeks.

Subtotal thyroidectomy can be performed after thyrotoxicosis is medically controlled. This seldom is done during pregnancy but may be appropriate for the very few women who cannot adhere to medical treatment or in whom drug therapy proves toxic (Stagnaro-Green, 2012a). Surgery is best accomplished in the second trimester. Potential drawbacks of thyroidectomy include inadvertent resection of parathyroid glands and injury to the recurrent laryngeal nerve.

Thyroid ablation with therapeutic radioactive iodine is contraindicated during pregnancy. The necessary doses may also cause fetal thyroid gland destruction. Thus, when radioactive iodine is given unintentionally, many clinicians recommend abortion. Any exposed fetus must be carefully evaluated, and the incidence of fetal hypothyroidism depends on gestational age and radioiodine dose (Berlin, 2001). There is no evidence that radioiodine given before pregnancy causes fetal anomalies if enough time has passed to allow radiation effects to dissipate and if the woman is euthyroid (Ayala, 1998). The International Commission on Radiological Protection has recommended that women avoid pregnancy for 6 months after radioablative therapy (Brent, 2008). Moreover, during lactation, the breast also concentrates a substantial amount of iodine. This may pose neonatal risk due to ^{131}I-containing milk ingestion and maternal risk from significant breast irradiation. To limit the latter, a delay of 3 months after breastfeeding cessation will more reliably ensure complete breast involution.

Pregnancy Outcome

Women with thyrotoxicosis have pregnancy outcomes that largely depend on whether metabolic control is achieved. For example, excess thyroxine may cause miscarriage or preterm birth (Andersen, 2014; Sheehan, 2015). In untreated women or in those who remain hyperthyroid despite therapy, incidences of preeclampsia, heart failure, and adverse perinatal outcomes are higher (Table 58-2). A prospective cohort study from China showed that women with clinical hyperthyroidism had a 12-fold greater risk of delivering an infant with hearing loss (Su, 2011).

TABLE 58-2

Pregnancy Outcomes in Women with Overt Thyrotoxicosis

	Treated and Euthyroid[a] n = 380	Uncontrolled Thyrotoxicosis[a] n = 90
Maternal Outcome		
Preeclampsia	40 (10%)	15 (17%)
Heart failure	1	7 (8%)
Death	0	1
Perinatal Outcome

Growth restriction	37 (11%)	15 (17%)
Stillbirth	0/59	6/33 (18%)
Thyrotoxicosis	1	2
Hypothyroidism	4	0
Goiter	2	0

[a]Data presented as n (%).

Data from Davis, 1989; Kriplani, 1994; Luewan, 2011; Medici, 2014; Millar, 1994.

Fetal and Neonatal Effects

In most cases, the perinate is euthyroid. In some, however, hyper- or hypothyroidism can develop with or without a goiter (Fig. 58-3). Clinical hyperthyroidism develops in up to 1 percent of neonates born to women with Graves disease (Barbesino, 2013; Fitzpatrick, 2010). If fetal thyroid disease is suspected, nomograms are available for sonographically measured thyroid volume (Gietka-Czernel, 2012).

FIGURE 58-3

Term hypothyroid neonate delivered of a woman with a 3-year history of thyrotoxicosis that recurred at 26 weeks' gestation. The mother was given methimazole 30 mg orally daily and was euthyroid at delivery.

The fetus or neonate who was exposed to excessive maternal thyroxine may have any of several clinical presentations. First, *goitrous thyrotoxicosis* is caused by placental transfer of thyroid-stimulating immunoglobulins. Nonimmune hydrops and fetal demise have been reported with fetal thyrotoxicosis (Nachum, 2003; Stulberg, 2000). The best predictor of perinatal thyrotoxicosis is presence of thyroid-stimulating TSH-receptor antibodies in women with Graves disease (Nathan, 2014). This is especially true if their levels are more than threefold higher than the upper normal limit (Barbesino, 2013). In a study of 72 pregnant women with Graves disease, Luton and associates (2005) reported that none of the fetuses in 31 low-risk mothers had a goiter, and all were euthyroid at delivery. Low risk was defined as no requirement for antithyroid medications during the third trimester or an absence of antithyroid antibodies. Conversely, in a group of 41 women who either were taking antithyroid medication at delivery or had thyroid receptor antibodies, 11 fetuses—27 percent—had sonographic evidence of a goiter at 32 weeks' gestation. Seven of these 11 fetuses were determined to be hypothyroid, and the remaining fetuses were hyperthyroid. In response to these results, the American Thyroid Association and American Association of Clinical Endocrinologists (2011) recommend routine evaluation of TSH-receptor antibodies between 22 and 26 weeks' gestation in women with Graves disease. The American College of Obstetricians and Gynecologists (2017), however, does not recommend such testing. If the fetus is thyrotoxic, maternal thionamide drugs are adjusted even though maternal thyroid function may be within the targeted range (Mestman, 2012). Although usually short-lived, neonatal thyrotoxicosis may require short-course antithyroid drug treatment (Levy-Shraga, 2014; Nathan, 2014).

A second presentation is *goitrous hypothyroidism* caused by fetal exposure to maternally administered thionamides (see Fig. 58-3). Although there are theoretical neurological implications, reports of adverse fetal effects seem to have been exaggerated. Available data indicate that thionamides carry an extremely small risk for causing neonatal hypothyroidism (Momotani, 1997; O'Doherty, 1999). For example, in at least 239 treated thyrotoxic women shown in Table 58-1, evidence of hypothyroidism was found in only four newborns. Furthermore, at least four long-term studies report no abnormal intellectual and physical development of these children (Mestman, 1998). If maternal hypothyroidism developed, the fetus can be treated by a reduced maternal antithyroid medication dose and injections of intraamnionic thyroxine if necessary.

A third presentation, *nongoitrous hypothyroidism,* may develop from transplacental passage of maternal TSH-receptor blocking antibodies (Fitzpatrick, 2010; Gallagher, 2001). And finally, *fetal thyrotoxicosis* after maternal thyroid gland ablation, usually with ^{131}I radioiodine, may result from transplacental thyroid-stimulating antibodies. In one report of early fetal exposure to radioiodine, neonatal thyroid studies indicated transient hyperthyroidism from maternal transfer of stimulating antibodies (Tran, 2010).

Fetal Diagnosis

Evaluation of fetal thyroid function is somewhat controversial. Although the fetal thyroid volume can be measured sonographically in women taking thionamide drugs or in those with thyroid-stimulating antibodies, most investigators do not currently recommend this routinely (Cohen, 2003; Luton, 2005). Kilpatrick (2003) recommends umbilical cord blood sampling and fetal antibody testing only if the mother has previously undergone radioiodine ablation. Because fetal hyper- or hypothyroidism may cause hydrops, growth restriction, goiter, or tachycardia, fetal blood sampling may be appropriate if these are identified (Brand, 2005). The Endocrine Society clinical practice guidelines recommend umbilical cord blood sampling only when the diagnosis of fetal thyroid disease cannot be reasonably ascertained based on clinical and sonographic data (Garber, 2012). Diagnosis and treatment are considered further in Chapter 16 (Surgical Therapy).

Thyroid Storm and Heart Failure

Both of these are acute and life-threatening in pregnancy. Thyroid storm is a hypermetabolic state and is rare in pregnancy. In contrast, pulmonary hypertension and heart failure from cardiomyopathy caused by the profound myocardial effects of thyroxine are common in pregnant women (Sheffield, 2004). As shown in Table 58-2, heart failure developed in 8 percent of 90 women with uncontrolled thyrotoxicosis. In these women, cardiomyopathy is characterized by a high-output state, which may lead to a dilated cardiomyopathy (Fadel, 2000; Klein, 1998). The pregnant woman with thyrotoxicosis has minimal cardiac reserve, and decompensation is

usually precipitated by preeclampsia, anemia, sepsis, or a combination of these. Fortunately, thyroxine-induced cardiomyopathy and pulmonary hypertension are frequently reversible (Sheffield, 2004; Siu, 2007; Vydt, 2006).

Management

Treatment is similar for thyroid storm and heart failure and should be carried out in an intensive care area that may include special-care units within labor and delivery (American College of Obstetricians and Gynecologists, 2017). Shown in Figure 58-4 is our stepwise approach to medical management of thyroid storm or thyrotoxic heart failure. An hour or two after initial thionamide administration, iodide is given to inhibit thyroidal release of T_3 and T_4. It can be given intravenously as sodium iodide or orally as either saturated solution of potassium iodide (SSKI) or Lugol solution. With a history of iodine-induced anaphylaxis, lithium carbonate, 300 mg every 6 hours, is given instead. Most authorities recommend dexamethasone, 2 mg intravenously every 6 hours for four doses, to further block peripheral conversion of T_4 to T_3. If a β-blocker drug is given to control tachycardia, its effect on heart failure must be considered. Propranolol, labetalol, and esmolol have all been used successfully. Coexisting severe preeclampsia, infection, or anemia should be aggressively managed before delivery is considered.

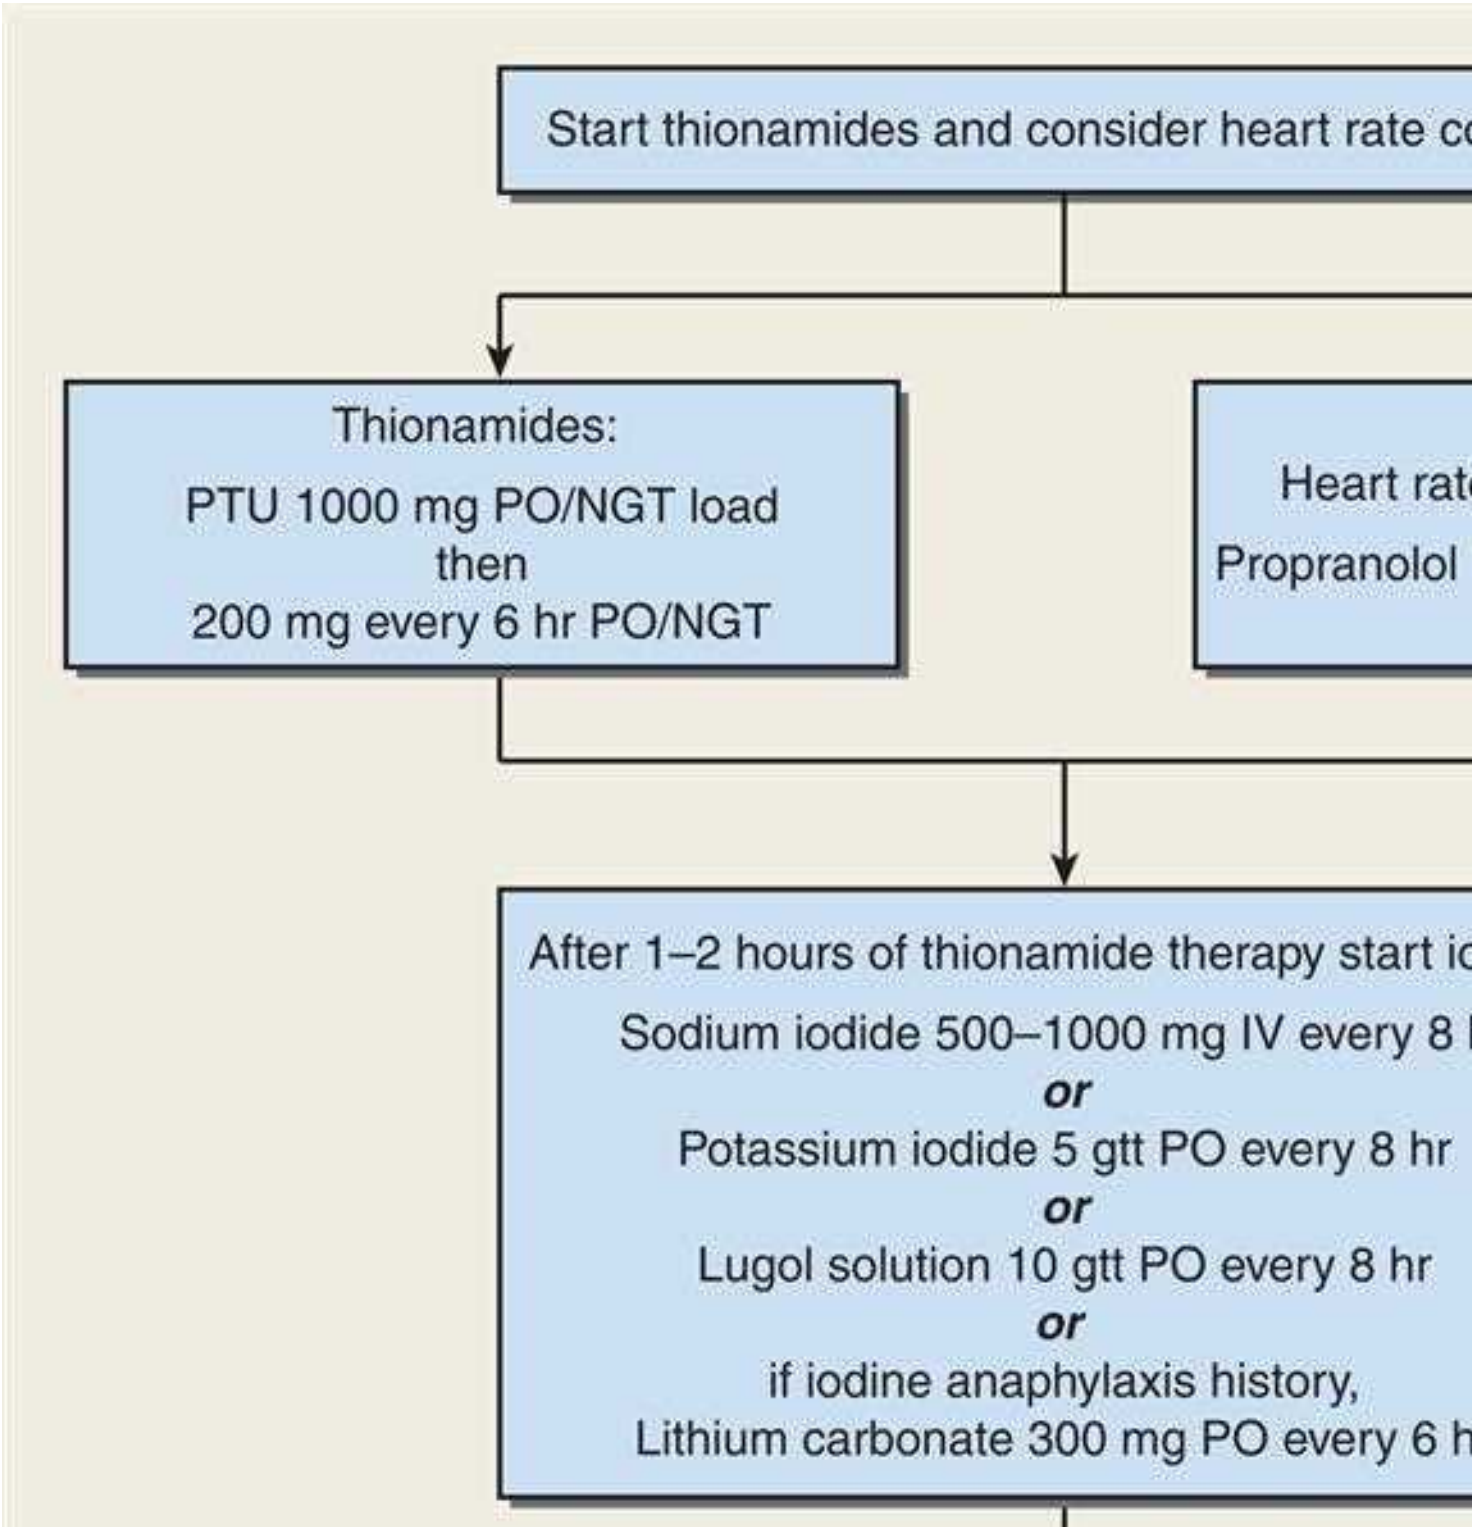
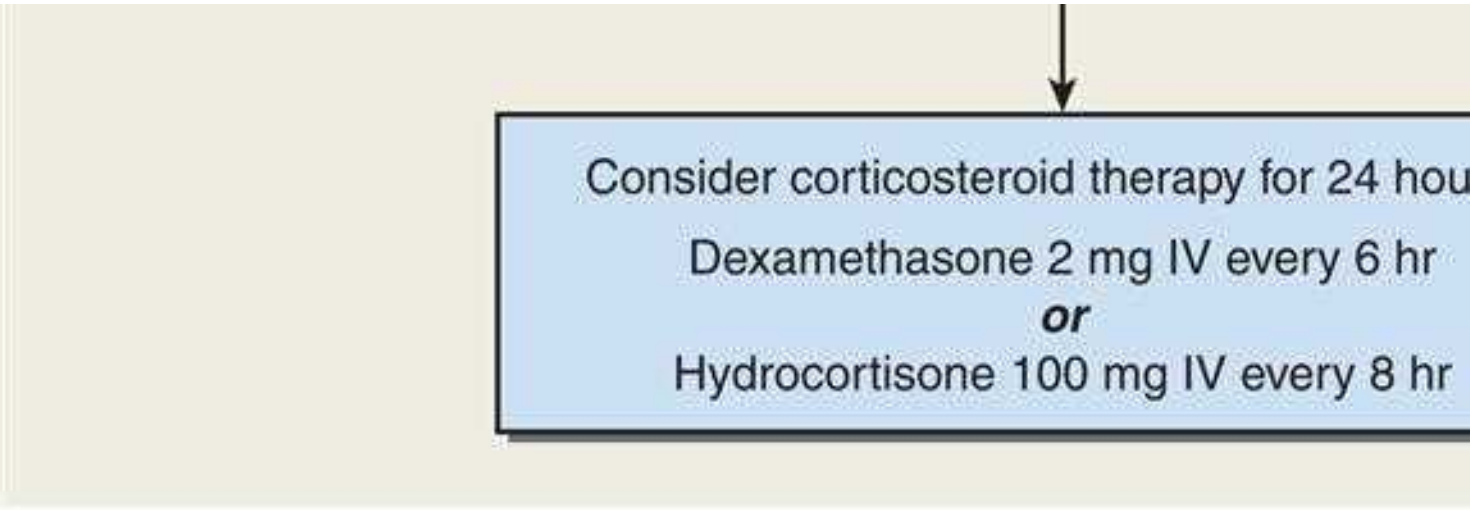
One management method for thyroid storm or thyrotoxic heart failure. gtt = drops; IV = intravenous; NGT = nasogastric tube; PO = orally; PTU = propylthiouracil.





Hyperemesis Gravidarum and Gestational Transient Thyrotoxicosis

Transient biochemical features of hyperthyroidism may be observed in 2 to 15 percent of women in early pregnancy (Fitzpatrick, 2010). Many women with hyperemesis gravidarum have abnormally high serum thyroxine levels and low TSH levels (Chap. 54, Management). This results from TSH-receptor stimulation from massive—but normal for pregnancy— concentrations of hCG. This transient condition is also termed *gestational transient thyrotoxicosis.* Even if associated with hyperemesis, antithyroid drugs are not warranted (American College of Obstetricians and Gynecologists, 2017). The degree of hCG level elevation does not correlate with thyroxine and TSH values, which become more normal by midpregnancy (Nathan, 2014; Yoshihara, 2015).

Thyrotoxicosis and Gestational Trophoblastic Disease

The prevalence of increased thyroxine levels in women with a molar pregnancy ranges between 25 and 65 percent (Hershman, 2004). As discussed, abnormally high hCG levels lead to overstimulation of the TSH receptor. Because these tumors are now usually diagnosed early, clinically apparent hyperthyroidism has become less common. With molar evacuation, serum free T_4 levels usually normalize rapidly in parallel with declining hCG concentrations. This is discussed further in Chapter 20 (Diagnosis).

Subclinical Hyperthyroidism

Third-generation TSH assays with an analytical sensitivity of 0.002 mU/mL permit identification of subclinical thyroid disorders. These biochemically defined extremes usually represent normal biological variations but may herald the earliest stages of thyroid dysfunction. *Subclinical hyperthyroidism* is characterized by an abnormally low serum TSH concentration in concert with normal thyroxine hormone levels (Surks, 2004). Long-term effects of persistent subclinical thyrotoxicosis include osteoporosis, cardiovascular morbidity, and progression to overt thyrotoxicosis or thyroid failure. Casey and Leveno (2006) reported that subclinical hyperthyroidism was found in 1.7 percent of pregnant women. Importantly, subclinical hyperthyroidism was not associated with adverse pregnancy outcomes. In separate retrospective analyses of almost 25,000 women who underwent thyroid screening throughout pregnancy, Wilson and colleagues (2012) and Tudela and coworkers (2012) also found no relationship between subclinical hyperthyroidism and preeclampsia or gestational diabetes.

Treatment of subclinical hyperthyroidism is unwarranted in pregnancy because antithyroid drugs may affect the fetus. These women may benefit from periodic surveillance, and approximately half eventually have normal TSH concentrations.

Hypothyroidism

Overt or symptomatic hypothyroidism, as shown in Table 58-3, has been reported to complicate between 2 and 12 per 1000 pregnancies. It is characterized by insidious nonspecific clinical findings that include fatigue, constipation, cold intolerance, muscle cramps, and weight gain. A pathologically enlarged thyroid gland depends on the etiology of hypothyroidism and is more likely in women in areas of endemic iodine deficiency or those with Hashimoto thyroiditis. Other findings include edema, dry skin, hair loss, and prolonged relaxation phase of deep tendon reflexes. *Clinical* or *overt hypothyroidism* is confirmed when an abnormally high serum TSH level is accompanied by an abnormally low thyroxine level. *Subclinical hypothyroidism,* discussed later, is defined by an elevated serum TSH level and *normal* serum thyroxine concentration (Jameson, 2015). Sometimes included in the spectrum of subclinical thyroid disease are asymptomatic individuals with high levels of anti-TPO or antithyroglobulin antibodies. Autoimmune euthyroid disease represents a new investigative frontier in screening and treatment of thyroid dysfunction during pregnancy.

TABLE 58-3

Frequency of Overt Hypothyroidism in Pregnancy

Study	Country	Incidence
Wang (2011)[a]	China	0.3%
Cleary-Goldman (2008)[a]	United States	0.3%

Andersen (2016)[d]	Denmark	1.2%

[a]Screened during first trimester.

[b]Screened before 20 weeks.

[c]Includes those treated before pregnancy.

[d]Diagnosed in early versus later pregnancy.

Overt Hypothyroidism and Pregnancy

The most common cause of hypothyroidism in pregnancy is Hashimoto thyroiditis, characterized by glandular destruction from autoantibodies, particularly anti-TPO antibodies. Another cause is postablative Graves disease. Clinical identification of hypothyroidism is especially difficult during pregnancy because many of the signs or symptoms are also common to pregnancy itself. Thyroid analyte testing should be performed on symptomatic women or those with a history of thyroid disease (American College of Obstetricians and Gynecologists, 2017). S*evere hypothyroidism* during pregnancy is uncommon, probably because it is often associated with infertility and higher spontaneous abortion rates (De Groot, 2012). Even women with treated hypothyroidism undergoing in vitro fertilization have a significantly lower chance of achieving pregnancy (Scoccia, 2012).

Treatment

The American Thyroid Association and American Association of Clinical Endocrinologists (2011) recommend replacement therapy for overt hypothyroidism beginning with levothyroxine in doses of 1 to 2 µg/kg/d or approximately 100 µg daily. Women who are athyreotic after thyroidectomy or radioiodine therapy may require higher doses. Surveillance is with TSH levels measured at 4- to 6-week intervals, and the thyroxine dose is adjusted by 25- to 50-µg increments until TSH values become normal. Pregnancy is associated with an increased thyroxine requirement in approximately a third of supplemented women (Abalovich, 2010; Alexander, 2004). The increased demand in pregnancy is believed to be related to augmented estrogen production (Arafah, 2001).

Greater thyroxine requirements begin as early as 5 weeks' gestation. In a randomized trial that provided an increased levothyroxine dose at pregnancy confirmation in 60 mothers, Yassa and coworkers (2010) found that a 29- to 43-percent increase in the weekly dose maintained serum TSH values <5.0 mU/L during the first trimester in all women. Importantly, however, this increase caused TSH suppression in more than a third of women. Significant hypothyroidism may develop early in women without thyroid reserve, such as those with a previous thyroidectomy, those with prior radioiodine ablation, or those undergoing assisted reproductive techniques (Alexander, 2004; Loh, 2009). Anticipatory 25-percent increases in thyroxine replacement at pregnancy confirmation will reduce this likelihood. All other women with hypothyroidism should instead undergo TSH testing at initiation of prenatal care.

Pregnancy Outcome with Overt Hypothyroidism

Observational studies, although limited, indicate that excessive adverse perinatal outcomes are associated with overt thyroxine deficiency (Table 58-4). Preterm birth rates, for example, are higher (Sheehan, 2015). With appropriate replacement therapy, however, rates of adverse effects are not increased in most reports (Bryant, 2015; Matalon, 2006; Tan, 2006). In one dissenting study, however, risks for some pregnancy complications were greater even in women taking replacement therapy (Wikner, 2008). Most experts agree that adequate hormone replacement during pregnancy minimizes the risk of adverse outcomes and most complications.

TABLE 58-4

Pregnancy Complications in 440 Women with Hypothyroidism

	Hypothyroidism (%)	
Complications	**Overt (n = 112)**	**Subclinical (n = 328)**
Preeclampsia	32	8
Placental abruption	8	1
Cardiac dysfunction	3	2
Birthweight <2000 g[a,b]	33	32
Stillbirths[c]	9	3[c]

[a]Preterm or term deliveries were the only outcomes reported by Abalovich, 2002.

[b]Low birthweight and stillbirth were outcomes reported by Su, 2011.

[c]One infant died from syphilis.

Data from Abalovich, 2002; Davis, 1988; Leung, 1993; Männistö, 2009; Su, 2011.

Fetal and Neonatal Effects

Undoubtedly, maternal and fetal thyroid abnormalities are related. In both, thyroid function is dependent on adequate iodide intake, and its deficiency early in pregnancy can cause both maternal and fetal hypothyroidism. And, as discussed, maternal TSH-receptor-blocking antibodies can cross the placenta and cause fetal thyroid dysfunction. Rovelli and colleagues (2010) evaluated 129 neonates born to women with autoimmune thyroiditis. They found that 28 percent had an elevated TSH level on the third or fourth day of life, and 47 percent of these had TPO antibodies on day 15. Still, autoantibodies were undetectable at 6 months of age. It seems paradoxical that despite these transient laboratory findings in the *neonate*, TPO and antithyroglobulin antibodies have little or no effect on *fetal* thyroid function (Fisher, 1997). Indeed, prevalence of fetal hypothyroidism in women with Hashimoto thyroiditis is estimated to be only 1 in 180,000 newborns (Brown, 1996).

Subclinical Hypothyroidism

Although common in women, the incidence of subclinical hypothyroidism varies depending on age, race, dietary iodine intake, and serum TSH thresholds used to establish the diagnosis (Jameson, 2015). In two large studies totaling more than 25,000 pregnant women screened in the first half of pregnancy, subclinical hypothyroidism was identified in 2.3 percent (Casey, 2005; Cleary-Goldman, 2008). The rate of progression to overt thyroid failure is affected by TSH level, age, other disorders such as diabetes, and presence and concentration of antithyroid antibodies.

Diez and Iglesias (2004) prospectively followed 93 nonpregnant women with subclinical hypothyroidism for 5 years and reported that in a third, TSH values became normal. In the other two thirds, those women whose TSH levels were 10 to 15 mU/L developed overt disease at a rate of 19 per 100 patient years. Those women whose TSH levels were <10 mU/L developed overt hypothyroidism at a rate of 2 per 100 patient years.

Regarding screening for subclinical hypothyroidism in nonpregnant individuals, the U.S. Preventative Services Task Force also reports that nearly all patients who develop overt hypothyroidism within 5 years have an initial TSH level >10 mU/L (Helfand, 2004; Karmisholt, 2008).

For gravidas, in a 20-year follow-up study of 5805 women who were screened in early pregnancy, only 3 percent developed thyroid disease. Of the 224 women identified with subclinical hypothyroidism during pregnancy, 17 percent developed thyroid disease in the next 20 years, and most of these had either TPO or thyroglobulin antibodies during pregnancy (Männistö, 2010). Thus, the likelihood of progression to overt hypothyroidism *during* pregnancy in otherwise healthy women with subclinical hypothyroidism seems remote.

Subclinical Hypothyroidism and Pregnancy

Earlier studies were suggestive that subclinical hypothyroidism might be associated with adverse pregnancy outcomes. In 1999, interest was heightened by two studies indicating that undiagnosed maternal thyroid hypofunction may impair fetal neuropsychological development. In one study, Pop and associates (1999) described 22 women with free T_4 levels <10th percentile whose offspring were at higher risk for impaired psychomotor development. In the other study, Haddow and coworkers (1999) retrospectively evaluated children born to 48 untreated women whose serum TSH values were >98th percentile. Some had diminished school performance, reading recognition, and intelligent quotient (IQ) scores. Although described as "subclinically hypothyroid," these women had an abnormally low mean serum free thyroxine level, and thus, many had *overt* hypothyroidism.

To further evaluate any adverse effects, Casey and colleagues (2005) identified subclinical hypothyroidism in 2.3 percent of 17,298 women screened at Parkland Hospital before midpregnancy. These women had small but significantly higher incidences of preterm birth, placental abruption, and neonates admitted to the intensive care nursery compared with euthyroid women. In another study of 10,990 similar women, however, Cleary-Goldman and associates (2008) did not find such associations.

Other studies subsequently confirmed a link between subclinical thyroid function and adverse outcomes (Chen, 2017; Maraka, 2016). One included 24,883 women screened throughout pregnancy and showed an almost twofold greater risk of severe preeclampsia (Wilson, 2012). In an analysis of the same cohort, a consistent relationship was shown between rising TSH levels and the risk for gestational diabetes (Tudela, 2012). Finally, Nelson and colleagues (2014) found an elevated risk for diabetes and stillbirth.

Lazarus and colleagues (2012) reported the findings of the international multicenter Controlled Antenatal Thyroid Screening (CATS) study. This study evaluated prenatal thyroid screening and randomized treatment of both subclinical hypothyroidism and isolated maternal hypothyroxinemia. They reported that offspring IQ scores at age 3 years were not superior in the treated pregnancies.

Despite these findings, the unanswered question concerned whether treatment of subclinical hypothyroidism would mitigate any or all of these reported adverse outcomes. To address this, the Maternal-Fetal Medicine Units Network screened more than 97,000 pregnant women for thyroid disorders and reported that 3.3 percent had subclinical hypothyroidism. These 677 women were randomly assigned to thyroxine replacement therapy or placebo. As reported by Casey and colleagues (2017), and shown in Table 58-5, maternal adverse pregnancy outcomes or cognitive development in the offspring at 5 years did not differ between groups. Annual developmental testing scores and behavioral and attention-deficit hyperactivity disorder results also did not differ.

TABLE 58-5

Pregnancy and Perinatal Outcomes According to Diagnosis and Treatment Group of Thyroid Disorders[a]

	Subclinical Hypothyroidism		Isolated Hypothyroxinemia	
Outcome	**Thyroxine**	**Placebo**	**Thyroxine**	**Placebo**
Maternal				
EGA at delivery (weeks)	39.1 ± 2.5	38.9 ± 3.1	39.0 ± 2.4	38.8 ± 3.1
Preterm birth <34 weeks	9.1%	10.9%	3.8%	2.7%
Placental abruption	0.3%	1.5%	1.1%	0.8%
Preeclampsia	6.5%	5.9%	3.4%	4.2%
Diabetes	7.4%	6.5%	8.0%	9.2%
Perinatal and Childhood				
Stillbirth	12/1000	21/1000	8/1000	19/1000
Neonatal death	0	3/1000	4/1000	4/1000
NICU admission	8.6%	6.2%	11.8%	11.9%
Birthweight <10th centile	9.8%	8.1%	8.8%	7.8%
IQ median (25th, 75th percentile)	97 (85,105)	94 (85,107)	94 (83,101)	91 (82,101)

[a]For all comparisons, $p > 0.05$.

EGA = estimated gestational age; IQ = intelligence quotient; NICU = neonatal intensive care unit.

Data from Casey, 2017.

Screening in Pregnancy

Because of the findings in the studies from 1999 cited above, some professional organizations began to recommend routine prenatal screening and treatment for subclinical hypothyroidism. Consequent to the Lazarus study, however, clinical practice guidelines from the Endocrine Society, the American Thyroid Association, and the American Association of Clinical Endocrinologists uniformly recommended screening only those at greater risk during pregnancy (De Groot, 2012; Garber, 2012). This has been and still is the recommendation of the American College of Obstetricians and Gynecologists (2017). The findings of Casey and colleagues (2017) further buttress these recommendations.

Isolated Maternal Hypothyroxinemia

Women with low serum free T_4 values but a normal-range TSH level are considered to have *isolated maternal hypothyroxinemia*. Its incidence in two large trials was 1.3 to 2.1 percent (Casey, 2007; Cleary-Goldman, 2008). As shown in Figure 58-2, unlike in subclinical hypothyroidism, these women had a low prevalence of antithyroid antibodies.

Evolution of the knowledge of this thyroid disorder was similar to that seen with subclinical hypothyroidism. Initial studies reported that offspring of women with isolated hypothyroxinemia had neurodevelopmental difficulties (Kooistra, 2006; Pop, 1999, 2003). In another study, Casey and colleagues (2007) found no higher risks for other adverse perinatal outcomes compared with those of euthyroid women. Also, the aforementioned CATS study did not find improved neurodevelopmental outcomes in women with isolated hypothyroxinemia who were then treated with thyroxine (Lazarus, 2012).

The randomized trial conducted by the Maternal-Fetal Medicine Units Network also provided data to settle this question. Casey and colleagues (2017) noted no higher rates of adverse outcomes between groups and found that early thyroxine treatment offered no benefits (see Table 58-5).

Euthyroid Autoimmune Thyroid Disease

Autoantibodies to TPO and thyroglobulin have been identified in 6 to 20 percent of reproductive-aged women (Thangaratinam, 2011). Most who test positive for such antibodies, however, are euthyroid. That said, such women carry a two- to fivefold increased risk for early pregnancy loss (Stagnaro-Green, 2004; Thangaratinam, 2011). The presence of thyroid antibodies has also been associated with preterm birth (Stagnaro-Green, 2009). In a randomized treatment trial of 115 euthyroid women with TPO antibodies, Negro and coworkers (2006) reported that treatment with levothyroxine astoundingly reduced the preterm birth rate from 22 to 7 percent. Contrarily, Abbassi-Ghanavati and associates (2010) evaluated pregnancy outcomes in more than 1000 untreated women with TPO antibodies and did not find an increased risk for preterm birth compared with the risk in 16,000 euthyroid women without antibodies. These investigators, however, did find a threefold greater risk of placental abruption in these women.

As with nonpregnant subjects with TPO antibodies, these women are also at increased risk for progression of thyroid disease and postpartum thyroiditis (Jameson, 2015; Stagnaro-Green, 2012a). Currently, universal screening for the thyroid autoantibodies is not recommended by any professional organization (De Groot, 2012; Stagnaro-Green, 2011a, 2012a).

Iodine Deficiency

Decreasing iodide fortification of table salt and bread products in the United States during the past 25 years has led to occasional iodide deficiency (Caldwell, 2005; Hollowell, 1998). Importantly, the most recent National Health and Nutrition Examination Survey indicated that, overall, the United States population remains iodine sufficient (Caldwell, 2011). Even so, experts agree that iodine nutrition in vulnerable populations, such as pregnant women, requires continued monitoring. In 2011, the Office of Dietary Supplements of the National Institutes of Health sponsored a workshop to prioritize iodine research. Participants emphasized the decline in median urinary iodine levels to 125 µg/L in pregnant women and the serious potential effects on developing fetuses (Swanson, 2012).

Dietary iodine requirements are higher during pregnancy due to augmented thyroid hormone production, increased renal losses, and fetal iodine requirements. Adequate iodine is requisite for fetal neurological development beginning soon after conception, and abnormalities are dependent on the degree of deficiency. The World Health Organization (WHO) has estimated that 38 million children are born every year at risk of lifelong brain damage associated with iodine deficiency (Alipui, 2008).

Although it is doubtful that *mild deficiency* causes intellectual impairment, supplementation does prevent fetal goiter (Stagnaro-Green, 2012b). *Severe deficiency*, on the other hand, is frequently associated with damage typically encountered with *endemic cretinism* (Delange, 2001). It is presumed that *moderate deficiency* has intermediate and variable effects. Berbel and associates (2009) began daily supplementation in more than 300 pregnant women with moderate deficiency at three time periods—4 to 6 weeks, 12 to 14 weeks, and after delivery. They found improved neurobehavioral development scores in offspring of women supplemented with 200 µg potassium iodide very early in pregnancy. Similarly, Velasco and coworkers (2009) found improved Bayley Psychomotor Development scores in offspring of women supplemented with 300 µg of iodine daily in the first trimester. In contrast, Murcia and colleagues (2011) identified lower psychomotor scores in 1-year-old infants whose mothers reported daily supplementation of more than 150 µg. To address this, randomized controlled trial of iodine supplementation in mildly to moderately iodine-deficient pregnant women in India and Thailand is nearing completion (Pearce, 2016).

Regarding daily iodine intake, the Institute of Medicine (2001) recommends 220 µg/d during pregnancy and 290 µg/d during lactation (Chap. 9, Minerals). The Endocrine Society recommends an average iodine intake of 150 µg/d in reproductive-aged women, and this should be increased to 250 µg during pregnancy and breastfeeding (De Groot, 2012). The American Thyroid Association has recommended that 150 µg of iodine be added to prenatal vitamins to achieve this average daily intake (Becker, 2006). According to Leung and coworkers (2011), however, only 51 percent of the prenatal multivitamins in the United States contain iodine. It has even been suggested that because most cases of maternal hypothyroxinemia worldwide are related to relative iodine deficiency, supplementation may obviate the need to consider thyroxine treatment in such women (Gyamfi, 2009). However, without evidence of benefit, it is hard to justify the cost of iodine supplementation of large numbers of pregnant women in areas with mild iodine deficiency (Pearce, 2016). Importantly, experts caution against oversupplementation. Teng and associates (2006) contend that excessive iodine intake—defined as >300 µg/d—may lead to subclinical hypothyroidism and autoimmune thyroiditis. The Endocrine Society, in accordance with the WHO, advises against exceeding twice the daily recommended intake of iodine, or 500 µg/d (De Groot, 2012; Leung, 2011).

Congenital Hypothyroidism

Universal newborn screening for neonatal hypothyroidism was introduced in 1974 and is now required by law in all states (Chap. 32, Routine Newborn Care). This develops in approximately 1 in 3000 newborns and is one of the most preventable causes of mental retardation (LaFranchi, 2011). Developmental disorders of the

thyroid gland such as agenesis and hypoplasia account for 80 to 90 percent of these cases. The remainder is caused by hereditary defects in thyroid hormone production (Moreno, 2008).

Early and aggressive thyroxine replacement is critical for newborns with congenital hypothyroidism. Still, some neonates identified by screening programs who were treated promptly will exhibit cognitive deficits into adolescence (Song, 2001). Therefore, in addition to timing of treatment, the severity of congenital hypothyroidism is an important factor in long-term cognitive outcomes. Olivieri and colleagues (2002) reported that 8 percent of 1420 newborns with congenital hypothyroidism also had other major congenital malformations.

Postpartum Thyroiditis

Transient autoimmune thyroiditis is consistently found in approximately 5 to 10 percent of women during the first year after childbirth (Nathan, 2014; Stagnaro-Green, 2011b, 2012a). Postpartum thyroid dysfunction with an onset within 12 months includes hyperthyroidism, hypothyroidism, or both. The propensity for thyroiditis antedates pregnancy and is directly related to increasing serum levels of thyroid autoantibodies. Up to 50 percent of women who are thyroid-antibody positive in the first trimester will develop postpartum thyroiditis (Stagnaro-Green, 2012a). In a Dutch study of 82 women with type 1 diabetes, postpartum thyroiditis developed in 16 percent and was threefold higher than in the general population (Gallas, 2002). Importantly, 46 percent of those identified with overt postpartum thyroiditis had TPO antibodies in the first trimester.

Clinical Manifestations

In clinical practice, postpartum thyroiditis is diagnosed infrequently because it typically develops months after delivery and causes vague and nonspecific symptoms (Stagnaro-Green, 2004). The clinical presentation varies, and classically two clinical phases that may develop in succession are recognized. The first and earliest is *destruction-induced thyrotoxicosis* with symptoms from excessive release of hormone from glandular disruption. The onset is abrupt, and a small, painless goiter is common. Although there may be many symptoms, only fatigue and palpitations are more frequent in thyrotoxic women compared with normal controls. This thyrotoxic phase usually lasts only a few months. Thionamides are ineffective, and if symptoms are severe, a β-blocking agent may be given. The second and usually later phase between 4 and 8 months postpartum is *hypothyroidism* from thyroiditis. Thyromegaly and other symptoms are common and more prominent than during the thyrotoxic phase. Thyroxine replacement at doses of 25 to 75 µg/d is typically given for 6 to 12 months.

Stagnaro-Green and associates (2011b) reported postpartum surveillance results in 4562 Italian gravidas who had been screened for thyroid disease in pregnancy. Serum TSH and anti-TPO antibody levels were measured again at 6 and 12 months. Overall, two thirds of 169 women (3.9 percent) with postpartum thyroiditis were identified to have hypothyroidism only. The other third were diagnosed with hyperthyroidism. Only 14 percent of all women demonstrated the “classic” biphasic progression described above. These findings are consistent with data compiled from 20 other studies between 1982 and 2008 (Stagnaro-Green, 2012a).

Importantly, women who experience either type of postpartum thyroiditis have a 20- to 30-percent risk of eventually developing permanent hypothyroidism, and the annual progression rate is 3.6 percent (Nathan, 2014). Women at greater risk for developing hypothyroidism are those with higher titers of thyroid antibodies and higher TSH levels during the initial hypothyroid phase. Others may develop subclinical disease, but half of those with thyroiditis who are positive for TPO antibodies develop permanent hypothyroidism by 6 to 7 years (Stagnaro-Green, 2012a).

An association between postpartum thyroiditis and postpartum depression has been proposed but remains unresolved. Lucas and coworkers (2001) found a 1.7-percent incidence of postpartum depression at 6 months in women with thyroiditis as well as in controls. Pederson and colleagues (2007) found a significant correlation between abnormal scores on the Edinburgh Postnatal Depression Scale and total thyroxine values in the low normal range during pregnancy in 31 women. Similarly unsettled is the link between depression and thyroid antibodies. Kuijpens and associates (2001) reported that TPO antibodies were a marker for postpartum depression in euthyroid women. In a randomized trial, however, Harris and coworkers (2002) reported no difference in postpartum depression in 342 women with TPO antibodies who were given either levothyroxine or placebo.

Nodular Thyroid Disease

Thyroid nodules can be found in 1 to 2 percent of reproductive-aged women (Fitzpatrick, 2010). Management of a palpable thyroid nodule during pregnancy depends on gestational age and mass size. Small nodules detected by sensitive sonographic methods are more common during pregnancy in some populations. Kung and associates (2002) used high-resolution sonography and found that 15 percent of Chinese women had nodules larger than 2 mm in diameter. Almost half were multiple, and the nodules usually enlarged modestly across pregnancy and did not regress postpartum. Biopsy of those >5 mm^3 that persisted at 3 months usually showed nodular hyperplasia, and none were malignant. In most studies, 90 to 95 percent of solitary nodules are benign (Burch, 2016).

Evaluation of thyroid nodules during pregnancy should be similar to that for nonpregnant patients. As discussed in Chapter 46 (Radiographic Contrast Agents), *radioiodine scanning* in pregnancy is usually not recommended (American College of Obstetricians and Gynecologists, 2017). *Sonographic* examination reliably detects nodules >5 mm, and their solid or cystic structure also is determined. According to the American Association of Clinical Endocrinologists, sonographic characteristics associated with malignancy include hypoechogenic pattern, irregular margins, and microcalcifications (Gharib, 2005). *Fine-needle aspiration (FNA)* is an excellent assessment method, and histological tumor markers and immunostaining are reliable to evaluate for malignancy (Hegedüs, 2004). If the FNA biopsy shows a follicular lesion, surgery may be deferred until after delivery.

Evaluation of thyroid cancer involves a multidisciplinary approach (Fagin, 2016). Most thyroid carcinomas are well differentiated and pursue an indolent course. Messuti and coworkers (2014) provided evidence that persistence or recurrence of these tumors may be more common in pregnant women. When thyroid malignancy is diagnosed during the first or second trimester, thyroidectomy may be performed before the third trimester (Chap. 63, Thyroid Cancer). In women without evidence of an aggressive thyroid cancer or in those diagnosed in the third trimester, surgical treatment can be deferred to the immediate puerperium (Gharib, 2010).

PARATHYROID DISEASE

The function of *parathyroid hormone (PTH)* is to maintain extracellular fluid calcium concentration. This 84-amino acid hormone acts directly on bone and kidney and indirectly on small intestine through its effects on synthesis of vitamin D (1,25-$(OH)_2$D) to increase serum calcium (Potts, 2015). Secretion is regulated by serum ionized calcium concentration through a negative feedback system. *Calcitonin* is a potent parathyroid hormone that acts as a physiological parathyroid hormone antagonist. The interrelationships between these hormones, calcium metabolism, and *PTH-related protein* produced by fetal tissue are discussed in Chapter 4 (Parathyroid Glands).

Of fetal demands, calcium requirements reach 300 mg/d in late pregnancy and 30 g for the entire gestation. These needs and greater renal calcium loss from augmented glomerular filtration substantively raise maternal calcium demands. Pregnancy is associated with a twofold rise in serum concentrations of 1,25-dihydroxyvitamin D, which increases gastrointestinal calcium absorption. The effectuating hormone is probably of placental and decidual origin because maternal PTH levels are low normal or decreased during pregnancy (Cooper, 2011; Molitch, 2000). Total serum calcium levels decline with serum albumin concentrations, but ionized calcium levels remain unchanged. Vargas Zapata and colleagues (2004) have suggested a role for insulin-like growth factor-1 (IGF-1) in maternal calcium homeostasis and bone turnover.

Hyperparathyroidism

Hypercalcemia is caused by hyperparathyroidism or cancer in 90 percent of cases (Potts, 2015). Because many automated laboratory systems include serum calcium measurement, hyperparathyroidism has changed from being a condition defined by symptoms to one that is discovered on routine screening (Pallan, 2012). It has a reported prevalence of 2 to 3 per 1000 women, but some have estimated the rate to be as high as 14 per 1000 when asymptomatic cases are included. Almost 80 percent are caused by a solitary adenoma, and another 15 percent by hyperfunctioning of all four glands. In the remainder, a malignancy as the cause of increased serum calcium levels is usually obvious. Of note, PTH produced by tumors is not identical to the natural hormone and may not be detected by routine assays.

In most patients, the serum calcium level is elevated to within only 1 to 1.5 mg/dL above the upper normal limit. This may help to explain why only 20 percent of those who have abnormally elevated levels are symptomatic (Bilezikian, 2004). In a fourth, however, symptoms become apparent when the serum calcium level continues to rise. *Hypercalcemic crisis* manifests as stupor, nausea, vomiting, weakness, fatigue, and dehydration.

All women with symptomatic hyperparathyroidism should be surgically treated (Potts, 2015). Indications for parathyroidectomy include a serum calcium level 1.0 mg/dL above the upper normal range, a calculated creatinine clearance <60 mL/min, reduced bone density, or age >50 years (Bilezikian, 2009). Those not meeting these criteria should undergo annual serum calcium and creatinine level measurement and bone density assessment every 1 to 2 years (Pallan, 2012).

Hyperparathyroidism in Pregnancy

In their review, Schnatz and Thaxton (2005) found fewer than 200 reported cases of hyperparathyroidism complicating pregnancy. As in nonpregnant patients, parathyroid adenoma is the most common etiology. Ectopic parathyroid hormone production and rare cases of parathyroid carcinoma have been reported in pregnancy (Montoro, 2000; Saad, 2014). Symptoms include hyperemesis, generalized weakness, renal calculi, and psychiatric disorders. Occasionally, pancreatitis is the presenting disorder (Cooper, 2011; Hirsch, 2015).

Pregnancy theoretically improves hyperparathyroidism because of significant calcium shunting to the fetus and augmented renal excretion (Power, 1999). When the “protective effects” of pregnancy are withdrawn, however, postpartum hypercalcemic crisis is a significant danger. This life-threatening complication can be seen with serum calcium levels greater than 14 mg/dL and is characterized by nausea, vomiting, tremors, dehydration, and mental status changes (Malekar-Raikar, 2011).

Early reports described excessive stillbirths and preterm deliveries in pregnancies complicated by hyperparathyroidism. More recent reports, however, described lower rates of stillbirth, neonatal death, and neonatal tetany (Kovacs, 2011). Other fetal complications include miscarriage, fetal-growth restriction, and low birthweight (Chamarthi, 2011). Schnatz (2005) reported a 25-percent incidence of preeclampsia.

Management in Pregnancy

Surgical removal of a symptomatic parathyroid adenoma is preferable. This should prevent fetal and neonatal morbidities and postpartum parathyroid crises (Kovacs, 2011). Elective neck exploration during pregnancy is usually well tolerated, even in the third trimester (Hirsch, 2015; Schnatz, 2005; Stringer, 2017). In at least two cases, a mediastinal adenoma was removed at midpregnancy (Rooney, 1998; Saad, 2014).

Medical management may be appropriate in asymptomatic pregnant women with mild hypercalcemia (Hirsch, 2015). If so, patients are carefully monitored in the puerperium for hypercalcemic crisis. Initial medical management might include *calcitonin* to decrease skeletal calcium release, or oral phosphate, 1 to 1.5 g daily in divided doses, to bind excess calcium. For women with dangerously elevated serum calcium levels or those who are mentally obtunded with *hypercalcemic crisis*, emergency treatment is instituted. Diuresis with intravenous normal saline is begun so that urine flow exceeds 150 mL/hr. *Furosemide* is given in conventional doses to block tubular calcium reabsorption. Importantly, hypokalemia and hypomagnesemia should be prevented. Adjunctive therapy includes *mithramycin,* which inhibits bone resorption.

Neonatal Effects

Normally, cord blood calcium levels are higher than maternal levels (Chap. 7, Placental Role in Embryofetal Development). With maternal hyperparathyroidism, abnormally elevated maternal and thus fetal levels further suppress fetal parathyroid function. Because of this, newborn calcium levels rapidly drop after birth, and 15 to 25 percent of these neonates develop severe hypocalcemia with or without tetany (Molitch, 2000). Neonatal hypoparathyroidism caused by maternal hyperparathyroidism is usually transient and is treated with calcium and 1,25-dihydroxyvitamin D_3 (calcitriol). The latter will not be effective in preterm infants,

however, because the intestinal vitamin D receptor is not sufficiently expressed (Kovacs, 2011). Neonatal tetany or seizures should stimulate an evaluation for maternal hyperparathyroidism (Beattie, 2000; Ip, 2003).

Hypoparathyroidism

The most common cause of hypocalcemia is hypoparathyroidism that usually follows parathyroid or thyroid surgery. Hypoparathyroidism is estimated to follow up to 7 percent of total thyroidectomies (Shoback, 2008). It is characterized by facial muscle spasms, muscle cramps, and paresthesias of the lips, tongue, fingers, and feet. This can progress to tetany and seizures (Potts, 2015). Chronically, hypocalcemic pregnant women may also have a fetus with skeletal demineralization resulting in multiple bone fractures in the neonatal period (Alikasifoglu, 2005).

Maternal treatment includes calcitriol, dihydrotachysterol, or large vitamin D doses of 50,000 to 150,000 U/d; calcium gluconate or calcium lactate in doses of 3 to 5 g/d; and a low-phosphate diet. Fetal risks from large doses of vitamin D have not been established. During treatment, the therapeutic challenge in women with known hypoparathyroidism is management of blood calcium levels. It is possible that the greater calcium absorption typical of pregnancy will result in lower calcium requirements or that the fetal demand for calcium will result in greater need. The goal during pregnancy is to maintain a corrected calcium level in the low normal range.

Pregnancy-Associated Osteoporosis

In most gravidas, even with their remarkably increased calcium requirements, it is uncertain whether pregnancy causes osteopenia (Kaur, 2003; To, 2003). In one study of 200 pregnant women in which bone mass was measured, Kraemer and colleagues (2011) demonstrated a decline in bone density during pregnancy. Women who breastfed, carried twin pregnancies, or had a low body mass index were at higher risk of bone loss. From their review, Thomas and Weisman (2006) cite a 3- to 4-percent average reduction in bone mineral density during pregnancy. Lactation also represents a period of negative calcium balance that is corrected through maternal skeletal resorption. Feigenberg and coworkers (2008) found cortical bone mass reductions using ultrasound in young primiparas in the puerperium compared with nulligravid controls. Rarely, some women develop idiopathic osteoporosis while pregnant or lactating (Hellmeyer, 2007).

The most common symptom of osteoporosis is back pain in late pregnancy or postpartum. Other symptoms are hip pain, either unilateral or bilateral, and difficulty in weight bearing until the woman is nearly immobilized (Maliha, 2012). In more than half of women, no apparent reason for osteopenia is found. Some known causes include heparin (unfractionated only), prolonged bed rest, and corticosteroid therapy (Cunningham, 2005; Galambosi, 2016). In a few cases, overt hyperparathyroidism or thyrotoxicosis eventually develops.

Treatment is problematic and includes calcium and vitamin D supplementation and standard pain management. Shown in Figure 58-5 is a hip radiograph from a woman treated at Parkland Hospital during the third trimester for transient osteoporosis of pregnancy. For women with pregnancy-associated osteopenia, long-term surveillance indicates that although bone density improves, these women and their offspring may have chronic osteopenia (Carbone, 1995). Related, prenatal supplementation of normal women with cholecalciferol, 1000 IU/d, did not increase offspring bone mineral content, although it did ensure maternal vitamin D repletion (Cooper, 2016).

FIGURE 58-5
Anteroposterior plain hip radiograph of a 25-year-old woman at 26 weeks' gestation. She complained of left hip and knee pain and progressive weakness. Transient osteoporosis of the left femur responded over 3 months to physical therapy combined with vitamin D and calcium supplementation.

ADRENAL GLAND DISORDERS

Pregnancy has profound effects on adrenal cortical secretion and its control or stimulation. These interrelationships were reviewed by Lekarev and New (2011) and are discussed in detail in Chapter 4 (Parathyroid Glands).

Pheochromocytoma

Pheochromocytomas are chromaffin tumors that secrete catecholamines and usually are located in the adrenal medulla, although 10 percent are located in sympathetic ganglia. They are called the *10-percent tumor* because approximately 10 percent are bilateral, 10 percent are extraadrenal, and 10 percent are malignant. These tumors can be associated with medullary thyroid carcinoma and hyperparathyroidism in some of the autosomally dominant or recessive *multiple endocrine neoplasia syndromes*, as well as in neurofibromatosis and von Hippel-Lindau disease (Neumann, 2015).

These tumors complicate approximately 1 per 50,000 pregnancies (Quartermaine, 2017). Notably, they are found in 0.1 percent of hypertensive patients (Abdelmannan, 2011). However, they are more commonly found at autopsy but with infrequent clinical recognition. Symptoms are usually paroxysmal and manifest as hypertensive crisis, seizure disorders, or anxiety attacks. Hypertension is sustained in 60 percent of patients, but half of these also have paroxysmal crises. Other symptoms during paroxysmal attacks are headaches, profuse sweating, palpitations, chest pain, nausea and vomiting, and pallor or flushing.

The standard screening test is quantification of metanephrines and catecholamine metabolites in a 24-hour urine specimen (Neumann, 2015). Diagnosis is established by measurement of a 24-hour urine collection with at least two of three assays for free catecholamines, metanephrines, or vanillylmandelic acid (VMA). Determination of plasma catecholamine levels is the most sensitive test. In nonpregnant patients, adrenal localization is usually successful with either computed tomography (CT) or magnetic resonance (MR) imaging. For most cases, preferred treatment is laparoscopic adrenalectomy (Neumann, 2015).

Pheochromocytoma Complicating Pregnancy

These tumors are rare but result in dangerous pregnancy complications. Geelhoed (1983) provided an earlier review of 89 cases in which 43 mothers died. Maternal death was much more common if the tumor was not diagnosed antepartum—58 versus 18 percent. As seen in Table 58-6, maternal mortality rates are now lower but still formidable. In their review of 77 cases, Biggar and Lennard (2013) reported that antepartum diagnosis is the most important determinant of maternal mortality risk. That said, Salazar-Vega and colleagues (2014) described good outcomes in women diagnosed after delivery.

TABLE 58-6

Outcomes of Pregnancies Complicated by Pheochromocytoma and Reported in Four Contiguous Epochs

	Incidence (%)			
Factor	**1980–87 Harper (1989) n = 48**	**1988–97 Ahlawat (1999) n = 42**	**1998–2008 Sarathi (2010) n = 60**	**2000–2001 Biggar (2013) n = 78**
Diagnosis				
Antepartum	51	83	70	73
Postpartum	36	14	23	28
Autopsy	12	2	7	
Maternal death	16	4	12	8
Fetal wastage	26	11	17	17

Diagnosis of pheochromocytoma in pregnancy is similar to that for nonpregnant patients. MR imaging is the preferred technique because it almost always locates adrenal and extraadrenal pheochromocytomas (Fig. 58-6). In many cases, the principal challenge is to differentiate preeclampsia from the hypertensive crisis caused by pheochromocytoma. Grimbert and colleagues (1999) diagnosed two pheochromocytomas during 56 pregnancies in 30 women with von Hippel-Lindau disease.

FIGURE 58-6

Coronal magnetic resonance image taken in a 32-week pregnant woman shows a right-sided pheochromocytoma (*arrow*) and its position relative to the liver above it.

Management

Immediate control of hypertension and symptoms with an α-adrenergic blocker such as *phenoxybenzamine* is imperative. The dose is 10 to 30 mg, two to four times daily. After α-blockade is achieved, β-blockers may be given for tachycardia. In many cases, surgical exploration and tumor removal are performed during pregnancy, preferably during the second trimester (Biggar, 2013; Dong, 2014). Successful laparoscopic removal of adrenal tumors has become the norm (Miller, 2012; Zuluaga-Gómez, 2012). If diagnosed later in pregnancy, either planned cesarean delivery with tumor excision or postpartum resection is appropriate.

Recurrent tumors are troublesome, and even with good blood pressure control, dangerous peripartum hypertension may develop. We have cared for three women in whom recurrent pheochromocytoma was identified during pregnancy. Hypertension was managed with phenoxybenzamine in all three. Two newborns were healthy, but a third was stillborn in a mother with a massive tumor burden who was receiving phenoxybenzamine, 100 mg daily. In all three women, tumor was resected postpartum.

Cushing Syndrome

This syndrome is rare and the female:male ratio is 3:1 (Arit, 2015). Most cases are iatrogenic from long-term corticosteroid treatment. *Cushing disease* refers to bilateral adrenal hyperplasia stimulated by corticotropin-producing pituitary adenomas. Corticotropin is also called adrenocorticotropic hormone (ACTH). Most adenomas are microadenomas measuring <1 cm, and half measure <5 mm. Rarely, abnormal secretion of hypothalamic corticotropin-releasing factor may cause corticotropic hyperplasia. Such hyperplasia may also be caused by nonendocrine tumors that produce polypeptides similar to either corticotropin-releasing factor or corticotropin. Less than a fourth of cases of Cushing syndrome are corticotropin independent, and most of these are caused by an adrenal adenoma. Tumors are usually bilateral, and half are malignant. Occasionally, associated androgen excess may lead to severe virilization.

The typical cushingoid body habitus is caused by adipose tissue deposition that characteristically results in *moon facies,* a *buffalo hump,* and *truncal obesity.* Fatigability and weakness, hypertension, hirsutism, and amenorrhea are each encountered in 75 to 85 percent of nonpregnant patients (Hatipoglu, 2012). Personality changes, easy bruisability, and cutaneous striae are common. Up to 60 percent may have impaired glucose tolerance. Diagnosis can be difficult and is suggested by elevated plasma cortisol levels that cannot be suppressed by dexamethasone or by elevated 24-hour urine free cortisol excretion (Arit, 2015; Loriaux, 2017). Neither test is totally accurate, and each is more difficult to interpret in obese patients. Serum corticotropin levels and CT and MR imaging are used to localize pituitary and adrenal tumors or hyperplasia.

Cushing Syndrome and Pregnancy

Because most women have corticotropin-dependent Cushing syndrome, associated androgen excess may cause anovulation, and pregnancy is rare. In their review, Lekarev and New (2011) identified fewer than 140 reported cases of Cushing syndrome in pregnancy. These differ compared with nonpregnant women in that half are caused by corticotropin-independent adrenal adenomas (Kamoun, 2014; Lacroix, 2015). Approximately 30 percent of cases are from a pituitary adenoma, and 10 percent from adrenal carcinomas. All reports stress difficulties in diagnosis because of pregnancy-induced increases in plasma cortisol, corticotropin, and corticotropin-releasing factor levels. Measurement of 24-hour urinary free cortisol excretion is recommended, with consideration for the normal elevation seen in pregnancy.

Pregnancy outcomes in women with Cushing syndrome are listed in Table 58-7. Heart failure is common during pregnancy and is a major cause of maternal mortality (Buescher, 1992). Hypercortisolism in pregnancy may also cause poor wound healing, osteoporotic fracture, and psychiatric complications (Kamoun, 2014).

TABLE 58-7

Maternal and Perinatal Complications in Pregnancies Complicated by Cushing Syndrome

Complication	Incidence (%)
Maternal	
Hypertension	68
Diabetes	25
Preeclampsia	15
Osteoporosis/fracture	5
Psychiatric disorders	4
Cardiac failure	3
Mortality	2
Perinatal	
Fetal-growth restriction	21
Preterm delivery	43
Stillbirth	6
Neonatal death	2

Data from Lindsay, 2005.

Long-term medical therapy for Cushing syndrome usually is ineffective, and definitive therapy is resection of the pituitary or adrenal adenoma or bilateral adrenalectomy for hyperplasia (Lacroix, 2015; Motivala, 2011). During pregnancy, management of hypertension in mild cases may suffice until delivery. In their review, Lindsay and associates (2005) described primary medical therapy in 20 women with Cushing syndrome. Most were successfully treated with *metyrapone* as an interim treatment until definitive surgery after delivery. A few cases were treated with oral *ketoconazole*. However, because this drug also blocks testicular steroidogenesis, treatment during pregnancy with a male fetus is worrisome. *Mifepristone,* the norethindrone derivative used for abortion and labor induction, has shown promise for treating Cushing disease but should not be used in pregnancy for obvious reasons. If necessary, pituitary adenomas can be treated by transsphenoidal resection (Boscaro, 2001; Lindsay, 2005). Unilateral adrenalectomy has been safely performed in the early third trimester and can also be curative (Abdelmannan, 2011).

Adrenal Insufficiency—Addison Disease

Primary adrenocortical insufficiency is rare because more than 90 percent of total gland volume must be destroyed for symptoms to develop. *Autoimmune adrenalitis* is the most common cause in the developed world, but tuberculosis is a more frequent etiology in resource-poor countries (Arit, 2015; Kamoun, 2014). The incidence has been cited as being as high as 1 in 3000 births in Norway (Lekarev, 2011). In the United States, the prevalence was 1 per 10,000 to 20,000 pregnancies (Schneiderman, 2017). There is an increased incidence of concurrent Hashimoto thyroiditis, primary ovarian insufficiency, type 1 diabetes, and Graves disease. These *polyglandular autoimmune syndromes* also include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis.

Untreated adrenal hypofunction frequently causes infertility, but with replacement therapy, ovulation is restored. If untreated, symptoms often include weakness, fatigue, nausea and vomiting, and weight loss. Because serum cortisol levels are increased during pregnancy, the finding of a low value should prompt a cosyntropin test to document the lack of response to infused corticotropin (Salvatori, 2005).

In a large Swedish cohort study, 1188 women with Addison disease were compared with more than 11,000 age-matched controls who delivered between 1973 and 2006 (Björnsdottir, 2010). Women diagnosed with adrenal insufficiency within 3 years of delivery were significantly more likely to deliver preterm, to deliver a low-birthweight newborn, and to undergo cesarean delivery. Others have reported similar adverse outcomes (Quartermaine, 2017). Most pregnant women with Addison disease are already taking glucocorticoid and mineralocorticoid replacement drugs. These should be continued and women observed for evidence of either inadequate or excessive corticosteroid replacement (Lebbe, 2013). During labor, delivery, and postpartum, or after a surgical procedure, corticosteroid replacement must be increased appreciably to approximate the normal adrenal response—the so-called *stress dose*. Hydrocortisone, 100 mg, is usually given intravenously every 8 hours for 48 hours. It is important that shock from causes other than adrenocortical insufficiency—for example, hemorrhage or sepsis—be recognized and treated promptly.

Primary Aldosteronism

Hyperaldosteronism is caused by an adrenal adenoma—Conn syndrome—in approximately 75 percent of cases. Idiopathic bilateral adrenal hyperplasia makes up the remainder, except for rare cases of adrenal carcinoma (Abdelmannan, 2011; Eschler, 2015). Findings include hypertension, hypokalemia, and muscle weakness. High serum or urine levels of aldosterone confirm the diagnosis.

In normal pregnancy, as discussed in Chapter 4 (Musculoskeletal System), progesterone blocks aldosterone action, and thus there are very high aldosterone levels (Appendix, Serum and Blood Constituents). Accordingly, the diagnosis of hyperaldosteronism during pregnancy can be difficult. Since renin levels are suppressed in pregnant women with hyperaldosteronism, a plasma aldosterone-to-renin activity ratio may be helpful for diagnosis (Kamoun, 2014). Hypertension worsens as pregnancy progresses, and medical management includes potassium supplementation and antihypertensive therapy. In many cases, hypertension responds to *spironolactone,* but β-blockers or calcium-channel blockers may be preferred because of the potential fetal antiandrogenic effects of spironolactone. Mascetti and coworkers (2011) reported successful use of *amiloride* in a pregnant woman. Use of *eplerenone*, a selective aldosterone-receptor antagonist, has also been reported (Cabassi, 2012). Laparoscopic tumor resection is curative (Eschler, 2015; Miller, 2012).

PITUITARY DISORDERS

The pituitary enlarges impressively during pregnancy, predominately from lactotrophic cellular hyperplasia induced by estrogen stimulation (Chap. 4, Gastrointestinal Tract). Several pituitary disorders can also complicate pregnancy.

Prolactinomas

These adenomas are found often in nonpregnant women since the advent of widely available serum prolactin assays. Serum levels <25 pg/mL are considered normal in nonpregnant women (Motivala, 2011). Adenoma symptoms and findings include amenorrhea, galactorrhea, and hyperprolactinemia. Tumors are classified arbitrarily by their size measured by CT or MR imaging. A microadenoma is ≤10 mm, and a macroadenoma is >10 mm. Treatment for microadenomas is usually with bromocriptine, a dopamine agonist and powerful prolactin inhibitor, which frequently restores ovulation. For suprasellar macroadenomas, most recommend surgical resection before pregnancy is attempted (Araujo, 2015).

In a pooled analysis of more than 750 pregnant women with prolactinomas, only 2.4 percent with *microadenomas* developed symptomatic enlargement during pregnancy (Molitch, 2015). Symptomatic enlargement of *macroadenomas,* however, is more frequent and was found in 21 percent of 238 pregnant women. Schlechte (2007) also reported that 15 to 35 percent of suprasellar macroadenomas have tumor enlargement that causes visual disturbances, headaches, and diabetes insipidus. Nonfunctioning adenomas can also cause symptoms of pituitary expansion in pregnancy (Lambert, 2017).

Pregnant women with microadenomas should be queried regularly for headaches and visual symptoms. Those with macroadenomas are followed more closely and have visual field testing during each trimester. CT or MR imaging is recommended only if symptoms develop (Fig. 58-7). Serial serum prolactin levels serve little use because of normal rises during pregnancy (Appendix, Serum and Blood Constituents). Symptomatic tumor enlargement should be treated immediately with a dopamine antagonist. The safety of bromocriptine in pregnancy is well established. The safety profile is less well known for cabergoline, which is increasingly used in nonpregnant women because it is better tolerated and more effective. Cabergoline is generally considered safe for use in pregnancy (Araujo, 2015; Auriemma, 2013). Lebbe and colleagues (2010) described 100 pregnancies exposed to cabergoline and found no adverse effects. Similar findings were reported in 85 exposed Japanese pregnant women (Ono, 2010). Surgery is recommended for women with no response.

FIGURE 58-7
Magnetic resonance imaging of a pituitary adenoma: Sagittal T1-weighed image demonstrates a hyperintense sellar and suprasellar mass (*arrow*). Note the layering of complex fluid within the mass, which was found during surgery to be hemorrhage. (Used with permission from Dr. April Baily.)

Acromegaly

This is caused by excessive growth hormone, usually from an acidophilic or a chromophobic pituitary adenoma. In normal pregnancy, pituitary growth hormone levels decrease as placental epitopes are secreted. Diagnosis is confirmed by elevated IGF-1 serum levels (Katznelson, 2014). Fewer than 100 cases of acromegaly have been reported during pregnancy (Cheng, 2012; Dias, 2013; Motivala, 2011). Pregnancy is probably rare in women with acromegaly because half are hyperprolactinemic and anovulatory. During pregnancy, affected women are at marginally greater risk for gestational diabetes and hypertension (Caron, 2010; Dias, 2013).

Management is similar to that for prolactinomas, with close monitoring for symptoms of tumor enlargement. Dopamine agonist therapy is less effective than for prolactinomas. And, transsphenoidal resection, generally considered first-line treatment outside of pregnancy, may be necessary for symptomatic tumor enlargement during pregnancy (Motivala, 2011). Guven and associates (2006) reported a case of pituitary apoplexy necessitating emergent transsphenoidal adenoma resection and cesarean delivery at 34 weeks. Successful treatment of pregnant women with the somatostatin-receptor ligand *octreotide* and with the GH analogue *pegvisomant* has also been reported (Dias, 2013; Fleseriu, 2015).

Diabetes Insipidus

The vasopressin deficiency evident in diabetes insipidus is usually due to agenesis or destruction of the neurohypophysis (Robertson, 2015). True diabetes insipidus is a rare complication of pregnancy.

Diabetes insipidus therapy is intranasal administration of a synthetic analogue of vasopressin, *desmopressin,* which is 1-deamino- 8-d-arginine vasopressin (DDAVP). Ray (1998) reviewed 53 cases in which DDAVP was used during pregnancy with no adverse sequelae. Most women require increased doses during pregnancy because of an increased metabolic clearance rate stimulated by placental vasopressinase (Lindheimer, 1994). By this same mechanism, *subclinical diabetes insipidus* may become symptomatic or cases of *transient diabetes insipidus* may be encountered during pregnancy (Bellastella, 2012; Robertson, 2015). The prevalence of vasopressinase-induced diabetes insipidus is estimated at 2 to 4 per 100,000 pregnancies (Wallia, 2013).

In our experiences, as described in Chapter 55 (Acute Viral Hepatitis), transient secondary diabetes insipidus is more likely encountered with *acute fatty liver of pregnancy* (Nelson, 2013). This probably is due to altered vasopressinase clearance because of hepatic dysfunction.

Sheehan Syndrome

Sheehan (1937) reported that pituitary ischemia and necrosis associated with obstetrical blood loss could result in hypopituitarism. With modern methods of hemorrhagic shock treatment, Sheehan syndrome is now seldom encountered (Feinberg, 2005; Pappachan, 2015; Robalo, 2012). Affected women may have persistent hypotension, tachycardia, hypoglycemia, and lactation failure. Because deficiencies of some or all pituitary-responsive hormones may develop after the initial insult, Sheehan syndrome can be heterogenous and may not be identified for years (Tessnow, 2010). In one cohort study of 60 women from Costa Rica with Sheehan syndrome, the average time to diagnosis was 13 years (Gei-Guardia, 2011). Because adrenal insufficiency is the most life-threatening complication, adrenal function should be immediately assessed in any woman suspected of having Sheehan syndrome. After glucocorticoid replacement, subsequent analyses and replacement of thyroid, gonadal, and growth hormones is considered.

Lymphocytic Hypophysitis

This rare autoimmune pituitary disorder is characterized by massive infiltration by lymphocytes and plasma cells with parenchymal destruction of the gland. Many cases are temporally linked to pregnancy (Foyouzi, 2011; Honegger, 2015; Melmed, 2015). There are varying degrees of hypopituitarism or symptoms of mass effect, including headaches and visual field defects. A sellar mass is seen with CT or MR imaging. A mass accompanied by a modestly elevated serum prolactin level—usually <100 pg/mL—suggests lymphocytic hypophysitis. In contrast, levels >200 pg/mL are encountered with a prolactinoma. The etiology is unknown, but nearly 30 percent have a history of coexisting autoimmune diseases including Hashimoto thyroiditis, Addison disease, type 1 diabetes, or pernicious anemia. Treatment is with glucocorticoids and pituitary hormone replacement. The disease may be self-limited, and a careful withdrawal of hormone replacement is attempted after inflammation subsides (Foyouzi, 2011; Melmed, 2015).

CHAPTER 59: Connective Tissue Disorders

FIGURE 59-1

Owing to the great vascularity incident to pregnancy, the various pelvic joints always show a somewhat increased motility. In rare instances, particularly when the pelvis is contracted in the lower portion, spontaneous rupture of the symphysis pubis or one or both sacro-iliac joints has been observed.

—J. Whitridge Williams (1903)

INTRODUCTION

The principal concerns in the 1st edition of *Williams Obstetrics* with disorders of the joints were the obstructed pelvis caused by rickets. There is no mention of the arthritides complicating pregnancy. And of course, immune-mediated disease had not yet been elucidated.

Connective tissue disorders, which are also termed collagen vascular disorders, have two basic underlying causes. First are the *immune-complex diseases* in which connective tissue damage is caused by deposition of immune complexes. Because these are manifest by sterile inflammation—predominately of the skin, joints, blood vessels, and kidneys—they are referred to as rheumatic diseases. Many of these immune-complex diseases are more prevalent in women, for example, systemic lupus erythematosus (SLE) and rheumatoid arthritis. Second are the *inherited disorders* of bone, skin, cartilage, blood vessels, and basement membranes. Some examples include Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome.

IMMUNE-MEDIATED CONNECTIVE TISSUE DISEASES

These disorders can be separated into those associated with and those without autoantibody formation. The *rheumatoid factor (RF)* is an autoantibody found in many autoimmune inflammatory conditions such as SLE, rheumatoid arthritis, systemic sclerosis (scleroderma), mixed connective tissue disease, dermatomyositis, polymyositis, and various vasculitis syndromes. The *RF-seronegative spondyloarthropathies* are strongly associated with expression of the human leukocyte antigen B27 (HLA-B27) antigen and include ankylosing spondylitis, psoriatic arthritis, Reiter disease, and other arthritis syndromes.

Pregnancy may mitigate activity in some of these syndromes as a result of the immunosuppression that also allows successful engraftment of fetal and placental tissues. These changes are discussed in detail in Chapters 4 (Iron Metabolism) and 5 (Amnion). One example is pregnancy-induced predominance of T2 helper

cells compared with cytokine-producing T1 helper cells (Keeling, 2009). Pregnancy hormones also alter immune cells. Namely, estrogens upregulate and androgens downregulate T-cell response, and progesterone is immunosuppressive (Cutolo, 2006; Häupl, 2008a; Robinson, 2012).

In contrast, immune-mediated disease may contribute to obstetrical complications. One longitudinal cohort study found that unrecognized autoimmune systemic rheumatic disorders are associated with significant risk for preeclampsia and fetal-growth restriction (Spinillo, 2016). In this study, the prevalence of unrecognized rheumatic arthritis was 0.4 percent, and was 0.3 percent each for SLE, Sjögren syndrome, and antiphospholipid syndrome.

Last, some immune-mediated diseases may either be caused or activated as a result of prior pregnancies. To explain, fetal cells and free fetal DNA are detectable in maternal blood beginning early in pregnancy (Simpson, 2013; Sitar, 2005; Waldorf, 2008). *Fetal cell microchimerism* is the persistence of fetal cells in the maternal circulation and in organs following pregnancy. These fetal cells may become engrafted in maternal tissues and stimulate autoantibodies. This raises the possibility that fetal cell microchimerism leads to the predilection for autoimmune disorders among women (Adams, 2004). Evidence for this includes fetal stem cells engrafted in tissues in women with autoimmune thyroiditis and systemic sclerosis (Jimenez, 2005; Srivatsa, 2001). Such microchimerism has also been described in women with SLE and those with rheumatoid arthritis-associated HLA alleles (da Silva, 2016; Lee, 2010; Rak, 2009a). Conversely, engrafted maternal cells may provoke autoimmune conditions in a woman's offspring (Ye, 2012; Stevens, 2016).

SYSTEMIC LUPUS ERYTHEMATOSUS

Lupus is a heterogeneous autoimmune disease with a complex pathogenesis that results in interactions between susceptibility genes and environmental factors (Hahn, 2015). Immune system abnormalities include overactive B lymphocytes that are responsible for autoantibody production. These result in tissue and cellular damage when autoantibodies or immune complexes are directed at one or more cellular nuclear components (Tsokos, 2011). In addition, immunosuppression is impaired, including regulatory T-cell function (Tower, 2013). Some autoantibodies produced in patients with SLE are shown in Table 59-1.

TABLE 59-1

Some Autoantibodies Produced in Patients with Systemic Lupus Erythematosus (SLE)

Antibody	Prevalence (%)	Clinical Associations
Antinuclear (ANA)	84–98	Best screening test, multiple antibodies; a second negative test makes SLE unlikely
Anti-dsDNA	62–70	High titers SLE-specific; may correlate with disease activity, nephritis, and vasculitis
Anti-Sm (Smith)	25–38	Specific for SLE
Anti-RNP	33–40	Not SLE-specific, high titers associated with rheumatic syndromes
Anti-Ro (SS-A)	30–49	Not SLE-specific; associated with sicca syndrome, predisposes to cutaneous lupus, neonatal lupus with heart block, reduced risk of nephritis
Anti-La (SS-B)	10–35	Associated with anti-Ro
Antihistone	70	Common in drug-induced lupus
Antiphospholipid	21–50	Lupus anticoagulant and anticardiolipin antibodies associated with thrombosis, fetal loss, thrombocytopenia, valvular heart disease; false-positive test for syphilis
Antierythrocyte	60	Direct Coombs test, may develop hemolysis
Antiplatelet	30	Thrombocytopenia in 15%; poor clinical test

dsDNA = double-stranded DNA; RNP = ribonucleoprotein.

Data from Arbuckle, 2003; Hahn, 2015.

Almost 90 percent of SLE cases are in women, and its prevalence in those of childbearing age approximates 1 in 500 (Lockshin, 2000). Accordingly, the disease is encountered relatively frequently during pregnancy. The 10-year survival rate is 70 to 90 percent (Tsokos, 2011). Infection, lupus flares, end-organ failure, hypertension, stroke, and cardiovascular disease account for most deaths.

Genetic influences are implicated by a higher concordance with monozygotic compared with dizygotic twins —25 versus 2 percent, respectively. Moreover, frequency in patients with one affected family member is 10 percent. The relative risk of disease rises if there is inheritance of the “autoimmunity gene” on chromosome 16 that predisposes to SLE, rheumatoid arthritis, Crohn disease, and psoriasis. Susceptibility genes such as *HLA-A1, -B8, -DR3, -DRB1*, and -*TET3* explain only a portion of the genetic heritability (Tsokos, 2011; Yang, 2013). Interestingly, even maternal exposure to fetal genes elevates susceptibility to SLE development. A case-control study found that a child’s HLA-DRB1 genotype increases the risk of SLE in the mother (Cruz, 2016). Furthermore, neonatal lupus erythematosus has been reported in an infant conceived via oocyte donor to a mother with autoimmune disease with circulating anti-Ro and anti-La antibodies (Chiou, 2016).

Clinical Manifestations and Diagnosis

Lupus is notoriously variable in its presentation, course, and outcome (Table 59-2). Findings may be confined initially to one organ system, and others become involved later. Or, the disease may first be multisystem. Frequent findings are malaise, fever, arthritis, rash, pleuropericarditis, photosensitivity, anemia, and cognitive dysfunction. At least half of patients have renal involvement. SLE is also associated with declines in attention, memory, and reasoning (Hahn, 2015; Kozora, 2008).

TABLE 59-2

Some Clinical Manifestations of Systemic Lupus Erythematosus

Organ System	Clinical Manifestations	Percent
Systemic	Fatigue, malaise, fever, weight loss	95
Musculoskeletal	Arthralgias, myalgias, polyarthritis, myopathy	95
Hematological	Anemia, hemolysis, leukopenia, thrombocytopenia, lupus anticoagulant, splenomegaly	85
Cutaneous	Malar (butterfly) rash, discoid rash, photosensitivity, oral ulcers, alopecia, skin rashes	80
Neurological	Cognitive dysfunction, mood disorder, headache, seizures, stroke	60
Cardiopulmonary	Pleuritis, pericarditis, myocarditis, endocarditis, pneumonitis, pulmonary hypertension	60
Renal	Proteinuria, nephrotic syndrome, renal failure	30–50
Gastrointestinal	Nausea, pain, diarrhea, abnormal liver enzyme levels	40
Vascular	Thrombosis: venous (10%), arterial (5%)	15
Ocular	Conjunctivitis, sicca syndrome	15

Modified from Kasper, 2015.

Identification of antinuclear antibodies (ANA) is the best screening test, however, a positive result is not specific for SLE. For example, low titers are found in normal individuals, other autoimmune diseases, acute viral infections, and chronic inflammatory processes. Several drugs can also cause a positive reaction. Antibodies to double-stranded DNA (dsDNA) and to Smith (Sm) antigens are relatively specific for SLE, whereas other antibodies are not (see Table 59-1). Although hundreds of autoantibodies have been described in SLE, only a few have been shown to participate in tissue injury (Sherer, 2004; Tsokos, 2011). Currently, microarray profiles are being developed for more accurate SLE diagnosis (Putterman, 2016).

Anemia develops frequently, and there may be leukopenia and thrombocytopenia. Proteinuria and casts are found in the half of patients with glomerular lesions. Lupus nephritis can also cause renal insufficiency, which is more common if there are antiphospholipid antibodies (Moroni, 2004). Other laboratory findings

include false-positive syphilis serology, prolonged partial thromboplastin time, and higher RF levels. Elevated serum d-dimer concentrations often follow a flare or infection, but unexplained persistent elevations are associated with a high risk for thrombosis (Wu, 2008).

The diagnostic criteria for SLE are listed in Table 59-3. If any four or more of these 11 criteria are present, serially or simultaneously, the diagnosis of lupus is made. Importantly, numerous drugs can induce a lupus-like syndrome. These include proton-pump inhibitors, thiazide diuretics, antifungals, chemotherapeutics, statins, and antiepileptics. Drug-induced lupus is rarely associated with glomerulonephritis and usually regresses when the medication is discontinued (Laurinaviciene, 2017).

TABLE 59-3

Clinical Criteria for Classification of Systemic Lupus Erythematosus

Clinical Manifestations
Skin
Oral ulcers
Alopecia
Synovitis
Renal: proteinuria, casts, biopsy
Neurological: seizures, psychosis, myelitis, neuropathies, confusional state
Hemolytic anemia
Leukopenia or lymphopenia
Thrombocytopenia
Immunological Manifestations
ANA
Anti-dsDNA
Anti-Sm
Antiphospholipid
Hypocomplementemia
Direct Coombs

ANA = antinuclear antibodies; dsDNA = double-stranded DNA; Sm = Smith.

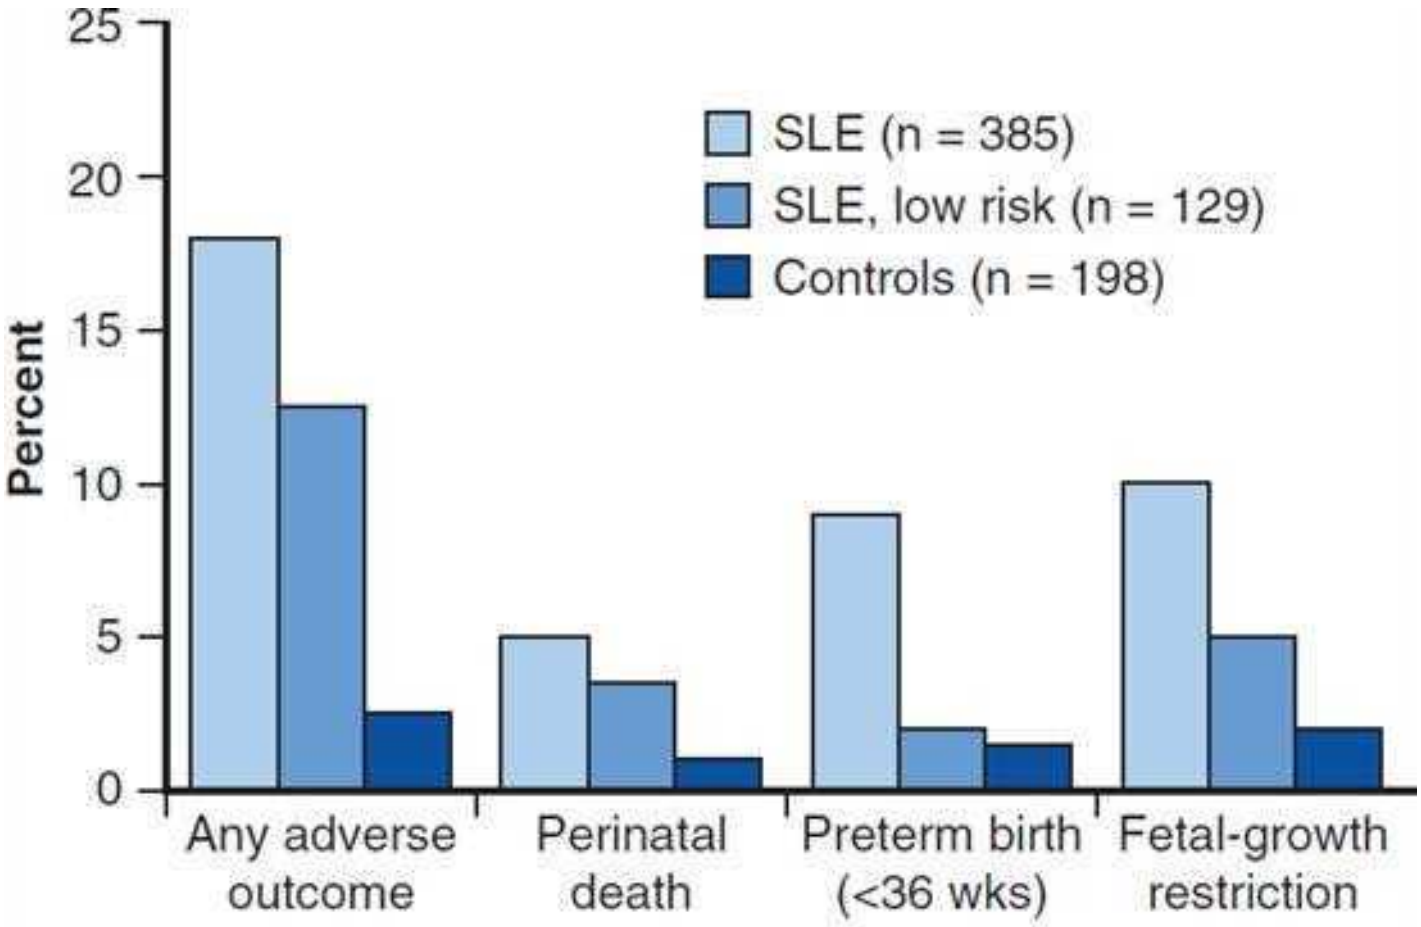
Data from Hahn, 2015; Hochberg, 1997.

Lupus and Pregnancy

Of nearly 16.7 million pregnancies from 2000 to 2003 in the United States, 13,555 were complicated by lupus—an incidence of approximately 1 in 1250 pregnancies (Clowse, 2008). During pregnancy, lupus improves in a third of women, remains unchanged in a third, and worsens in the remaining third. Thus, in any given pregnancy, the clinical condition can worsen or *flare* without warning (Hahn, 2015; Khamashta, 1997).

Petri (1998) reported a 7-percent risk of major morbidity during pregnancy. In a cohort of 13,555 women with SLE during pregnancy, the maternal mortality and severe morbidity rate was 325 per 100,000 (Clowse, 2008). In a review of 13 studies with 17 maternal deaths attributable to SLE and lupus nephritis, all occurred in those with active disease (Ritchie, 2012). Results of a prospective cohort study of 385 women are shown in Figure 59-1.

FIGURE 59-1
Frequency of adverse pregnancy outcomes. All women with systemic lupus erythematosus (SLE) in the PROMISSE study are compared with a subset of low-risk SLE patients and with control patients without SLE. (Data from Buyon, 2015.)



During the past several decades, pregnancy outcomes in women with SLE have improved remarkably. For most women with inactive or mild/moderate SLE, pregnancy outcomes are relatively favorable. Women who have confined cutaneous lupus do not usually have adverse outcomes (Hamed, 2013). However, newly

diagnosed SLE during pregnancy tends to be severe (Zhao, 2013). In general, pregnancy outcome is best in women for whom: (1) lupus activity has been quiescent for at least 6 months before conception; (2) there is no lupus nephritis manifest by proteinuria or renal dysfunction; (3) antiphospholipid syndrome or lupus anticoagulant is absent; and (4) superimposed preeclampsia does not develop (Peart, 2014; Stojan, 2012; Wei, 2017; Yang, 2014).

Lupus Nephritis

Active nephritis is associated with adverse pregnancy outcomes, although these have improved remarkably and especially if disease remains in remission (Moroni, 2002, 2005; Stojan, 2012). Of complications, women with renal disease have a high incidence of gestational hypertension and preeclampsia. Of 80 gravidas with SLE reported by Lockshin (1989), 63 percent of women with preexisting renal disease developed preeclampsia compared with only 14 percent of those without underlying renal disease. In a review of 309 pregnancies complicated by lupus nephritis, 30 percent suffered a flare, and 40 percent of these had associated renal insufficiency (Moroni, 2005). The maternal mortality rate was 1.3 percent. These findings were corroborated in a subsequent prospective study (Moroni, 2016b). In addition, a third of the 113 pregnancies were delivered preterm (Imbasciati, 2009; Moroni, 2016a). Wagner and coworkers (2009) compared outcomes of 58 women with 90 pregnancies and found that active nephritis was linked with a significantly higher incidence of maternal complications—57 versus 11 percent.

Most recommend continuation during pregnancy of immunosuppressive therapy for nephritis. New-onset nephritis or severe renal flare is treated aggressively with intravenous corticosteroids and consideration of immunosuppressive drugs or intravenous immunoglobulin (Lazzaroni, 2016).

Lupus versus Preeclampsia-Eclampsia

Chronic hypertension complicates up to 30 percent of pregnancies in women with SLE (Egerman, 2005). Also, as mentioned, preeclampsia is common, and superimposed preeclampsia is encountered even more often, and earlier, in those with nephritis or antiphospholipid antibodies (Bertsias, 2008). Preeclampsia and lupus nephritis share features of hypertension, proteinuria, edema, and renal function deterioration. However, the management is distinct, as lupus nephritis is treated with immunosuppression, and severe preeclampsia/eclampsia requires delivery (Lazzaroni, 2016). It may be difficult, if not impossible, to differentiate lupus flare with nephropathy from severe preeclampsia if the kidney is the only involved organ (Petri, 2007). Central nervous system involvement with lupus may culminate in convulsions similar to those of eclampsia. One proposed schema for differentiating the two is shown in Table 59-4. Management for preeclampsia-eclampsia is described in Chapter 40 (Preeclampsia).

TABLE 59-4

Some Distinctions between Lupus Flare and Preeclampsia Syndrome

Factor	Lupus	Preeclampsia
Clinical findings	Fatigue, headache, extra-renal signs (rash, serositis, arthritis)	Headaches, confusion, visual changes, convulsions
Blood pressure	Normal or high	High
Anemia	Hemolytic	Absent
Proteinuria	Present	Present
Creatinine	Normal or high	Normal or high
Transaminases	Normal	Normal or high
Complement	Decreased	Normal

Data from Andreoli, 2012.

Management During Pregnancy

Lupus management consists primarily of monitoring fetal well-being and maternal clinical and laboratory status (Lateef, 2012). Pregnancy-induced thrombocytopenia and proteinuria resemble SLE disease activity, and the identification of a lupus flare is confounded by the increased facial and palmar erythema of normal pregnancy (Lockshin, 2003).

For SLE activity monitoring, various laboratory techniques have been recommended, but interpretation may be challenging. The sedimentation rate may be misleading because of pregnancy-induced hyperfibrinogenemia. Serum complement levels are also normally increased in pregnancy (Appendix, Serum and Blood Constituents). And, although falling or low levels of complement components C_3, C_4, and CH_{50} are more likely to be associated with active disease, higher levels provide no assurance against disease activation. Our experiences and those of others suggest that clinical manifestations of disease and complement levels correlate poorly (Lockshin, 1995; Varner, 1983).

Serial hematological studies may detect changes in disease activity. Hemolysis is characterized by a positive Coombs test, anemia, reticulocytosis, and unconjugated hyperbilirubinemia. Thrombocytopenia, leukopenia, or both may develop. According to Lockshin and Druzin (1995), chronic thrombocytopenia in

early pregnancy may be due to antiphospholipid antibodies. Later, thrombocytopenia may indicate preeclampsia.

Urine is tested frequently to detect new-onset or worsening proteinuria. The fetus is closely observed for adverse effects such as growth restriction and oligohydramnios. Many recommend screening for anti-SS-A (anti-Ro) and anti-SS-B (anti-La) antibodies, because of associated fetal complications described subsequently. Antepartum, the fetus is surveilled as outlined by the American College of Obstetricians and Gynecologists (2016a) and described in Chapter 17 (Fetal Movements). Unless hypertension or evidence of fetal compromise or growth restriction develops, pregnancy is allowed to progress to term. Peripartum corticosteroids in “stress doses” are given to women who are taking these drugs or who recently have done so.

Pharmacological Treatment

There is no cure for SLE, and complete remissions are rare. Approximately a fourth of pregnant women have mild disease, which is not life threatening, but may be disabling because of pain and fatigue. Arthralgia and serositis can be managed by nonsteroidal antiinflammatory drugs (NSAIDs). However, chronic or large intermittent dosing is avoided due to related oligohydramnios or ductus arteriosus closure (Chap. 12, Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs). Low-dose aspirin can be used throughout gestation. Severe disease is managed with corticosteroids such as prednisone, 1 to 2 mg/kg/d orally. After the disease is controlled, this dose is tapered to a daily morning dose of 10 to 15 mg. Corticosteroid therapy can lead to gestational diabetes.

Immunosuppressive agents such as azathioprine are beneficial for active disease. These are usually reserved for lupus nephritis or disease that is corticosteroid resistant. Azathioprine has a good safety record during pregnancy (Fischer-Betz, 2013; Petri, 2007). Its recommended daily oral dose is 2 to 3 mg/kg. Teratogenic medications to be avoided include mycophenolate mofetil, methotrexate, and cyclophosphamide (Götestam Skorpen, 2016). However, cyclophosphamide can be considered in the second or third trimester for severe disease (Lazzaroni, 2016). In some situations, mycophenolate is the only treatment that achieves disease stability. In these cases, counseling is essential regarding fetal risks described in Chapter 12 (Immunosuppressant Medications) (Bramham, 2012).

Antimalarials reduced dermatitis, arthritis, and fatigue (Hahn, 2015). Although these agents cross the placenta, hydroxychloroquine is not associated with congenital malformations. Because of the long half-life of antimalarials and because discontinuing therapy can precipitate a lupus flare, most recommend their continuation during pregnancy (Borden, 2001).

When severe disease supervenes—usually a lupus flare—high-dose glucocorticoid therapy is given. Petri (2007) recommends pulse therapy consisting of methylprednisolone, 1000 mg given intravenously over 90 minutes daily for 3 days, then a return to maintenance doses if possible.

In nonpregnant subjects, antihypertensive therapy often includes an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker. For pregnancy, these should be changed to safer fetal options such as calcium-channel blockers, alpha methyldopa, or labetalol (Cabiddu, 2016).

Perinatal Mortality and Morbidity

Adverse perinatal outcome rates are significantly elevated in pregnancies complicated by SLE. Among these are preterm delivery, fetal-growth restriction, stillbirth, and neonatal lupus syndrome (Madazli, 2014; Phansenee, 2017). Perinatal outcome rates worsen in mothers with a lupus flare, significant proteinuria, or renal impairment and in those with chronic hypertension, preeclampsia, or both (Lazzaroni, 2016). Adverse outcomes are also more common in women with neuropsychiatric lupus (de Jesus, 2017). Reasons at least partially responsible for adverse fetal consequences include decidual vasculopathy with placental infarction and decreased perfusion (Hanly, 1988).

Neonatal Lupus Syndrome

This is characterized by newborn skin lesions—lupus dermatitis; a variable number of hematological and systemic derangements; and occasionally congenital heart block (Hahn, 2015). Cutaneous manifestations can be present in 30 to 40 percent of infants and appears at 4 to 6 weeks of age (Silverman, 2010). These are usually associated with anti-SS-A and SS-B antibodies, and approximately 40 percent of women with SLE are positive for these (Buyon, 2015). Thrombocytopenia and hepatic involvement are seen in 5 to 10 percent of affected infants.

In a review of outcomes in 91 infants born to women with lupus, eight of these were possibly affected—four had definite neonatal lupus and four had possible disease (Lockshin, 1988). Cutaneous lupus, thrombocytopenia, and autoimmune hemolysis are transient and clear within a few months (Zuppa, 2017). This is not always so for congenital heart block, discussed next. In subsequent offspring, the recurrence risk for neonatal lupus may near 25 percent (Julkunen, 1993).

Congenital Heart Block

Fetal and neonatal heart block results from diffuse myocarditis and fibrosis in the region between the atrioventricular (AV) node and bundle of His. Congenital heart block develops almost exclusively in fetuses of women with antibodies to the SS-A or SS-B antigens (Buyon, 1993). Even in the presence of such antibodies, however, the incidence of fetal myocarditis is only 2 to 3 percent but rises to 20 percent with a prior affected child (Bramham, 2012; Lockshin, 1988). Fetal cardiac monitoring is performed between 18 and 26 weeks' gestation in pregnancies with either of these antibodies. The cardiac lesion is permanent, and a pacemaker is generally necessary. Long-term prognosis is poor. Of 325 infants with cardiac neonatal lupus, nearly 20 percent died, and of these, one third was stillborn (Izmirly, 2011).

Maternal administration of corticosteroids, plasma exchange, or intravenous immunoglobulin does not reduce the risk of congenital heart block. Maternal corticosteroid administration for treatment congenital

heart block is controversial, is currently not recommended, and is discussed further in Chapter 16 (Tachyarrhythmias). Although this therapy to treat fetal heart block has not been studied in randomized trials, some evidence suggests that early fetal exposure to the mother's corticosteroid treatment for SLE may mitigate fetal myocarditis. Namely, Shinohara and coworkers (1999) reported no heart block in 26 neonates whose mothers received corticosteroids before 16 weeks' gestation as part of SLE maintenance therapy. By contrast, 15 of 61 neonates with heart block were born to women in whom corticosteroid therapy was begun after 16 weeks for an SLE exacerbation.

There are reports that maternal treatment with hydroxychloroquine (Plaquenil) is associated with a lower incidence of fetal heart block (Izmirly, 2012). Research in this area is ongoing.

Long-Term Prognosis and Contraception

The survival rate for women with SLE is 95 percent at 5 years, 90 percent at 10 years, and 78 percent at 20 years (Hahn, 2015). In general, women with lupus and chronic vascular or renal disease may limit family size because of morbidity associated with the disease and greater risks for adverse perinatal outcomes. For contraception, combination oral contraceptives did not increase the incidence of lupus flares in two large multicenter trials (Petri, 2005; Sánchez-Guerrero, 2005). Progestin-only implants and injections provide effective contraception with no known effects on lupus flares (Sammaritano, 2014). Concerns that intrauterine device (IUD) use and immunosuppressive therapy lead to greater infection rates in these patients are not evidenced-based. Notably, comorbid antiphospholipid antibodies are a contraindication to hormonal methods. Tubal sterilization may be advantageous and is performed with greatest safety postpartum or whenever SLE is quiescent.

ANTIPHOSPHOLIPID SYNDROME

This syndrome is an autoantibody-mediated acquired thrombophilia with recurrent thrombosis or pregnancy morbidity as part of its clinical constellation (Moutsopoulos, 2015). Specifically, antiphospholipid syndrome (APS) is diagnosed in women with persistently positive serum tests for antiphospholipid antibodies *and* with arterial and/or venous thromboses or obstetrical morbidity. Antibodies include lupus anticoagulant, anticardiolipin antibody, and anti-β_2 glycoprotein-I antibody.

Phospholipids are the main lipid constituents of cell and organelle membranes. There are proteins in plasma that associate noncovalently with these phospholipids. Antiphospholipid antibodies are directed against these phospholipids or phospholipid-binding proteins (Giannakopoulos, 2013; Tsokos, 2011). This antibody group may be of IgG, IgM, and IgA classes, alone or in combination. Antiphospholipid antibodies are most common with SLE, other connective tissue disorders, and APS. However, a small proportion of otherwise normal women and men have low levels of these antibodies.

The stimulus for autoantibody production is unclear, but it possibly is due to a preceding infection. The pathophysiology encountered is mediated by one or more of the following: (1) activation of various procoagulants, (2) inactivation of natural anticoagulants, (3) complement activation, and (4) inhibition of

syncytiotrophoblast differentiation (Tsokos, 2011). Clinically, these actions lead to arterial or venous thromboses or to pregnancy morbidity. Virtually every organ system may be affected.

Central nervous system involvement is one of the most prominent clinical manifestations. In addition to cerebrovascular arterial and venous thrombotic events, there may be psychiatric features and even multiple sclerosis (Binder, 2010). Renovascular involvement may lead to renal failure that can be difficult to differentiate from lupus nephritis (D'Cruz, 2009). Peripheral and visceral thromboses are also a feature. For example, Ahmed and associates (2009) reported a postpartum woman who developed spontaneous cecal perforation following a mesenteric vessel infarction. Obstetrical complications encompass recurrent pregnancy loss and placental dysfunction reflected by fetal-growth restriction, stillbirth, preeclampsia, and preterm birth. Treatment using aspirin, anticoagulation, and close monitoring has increased live birth rates to more than 70 percent in these women (Schreiber, 2016).

A small proportion of these patients develop the *catastrophic antiphospholipid antibody syndrome (CAPS)* or *Asherson syndrome.* This is defined as a rapidly progressive thromboembolic disorder simultaneously affecting three or more organ systems or tissues (Schreiber, 2016). It has a high mortality rate from activation of a cytokine storm. In half of cases, a "triggering" event is identified.

Specific Antiphospholipid Antibodies

As mentioned, several antibodies in APS are directed against a specific phospholipid or phospholipid-binding protein:

1. β_2-*Glycoprotein I*—also known as apolipoprotein H—is a phospholipid-binding plasma protein that inhibits prothrombinase activity within platelets and inhibits platelet aggregation (Giannakopoulos, 2013). Thus, its normal action is to limit procoagulant binding and thereby prevent coagulation cascade activation. Logically, antibodies directed against this glycoprotein would reverse its anticoagulant activity and promote thrombosis. This is important from an obstetrical viewpoint because β_2-glycoprotein I is expressed in high concentrations on the syncytiotrophoblast surface. Complement activation may contribute to its pathogenesis (Avalos, 2009; Tsokos, 2011). Teleologically, this seems appropriate because the decidua intuitively should be a critical area to prevent coagulation that might lead to intervillous space thrombosis. Another possibility is that β_2-glycoprotein I may be involved in implantation, and this glycoprotein may result in pregnancy loss via an inflammatory mechanism (Iwasawa, 2012; Meroni, 2011).

2. *Lupus anticoagulant (LAC)* is a heterogeneous group of antibodies directed against phospholipid-binding proteins. This antibody group induces prolongation in vitro of the prothrombin, partial thromboplastin, and Russell viper venom times. Thus, paradoxically, this so-called anticoagulant is actually powerfully thrombotic in vivo.

3. *Anticardiolipin antibodies (ACAs)* are directed against one of the many phospholipid cardiolipins found in mitochondrial membranes and platelets.

Antibodies against Natural Anticoagulants

Some antiphospholipid antibodies are also directed against the natural anticoagulant proteins C and S (Robertson, 2006). Another is directed against the anticoagulant protein annexin V, which is expressed in high concentrations by syncytiotrophoblast (Giannakopoulos, 2013). Testing for these other antibodies is not recommended (American College of Obstetricians and Gynecologists, 2017). However, some studies have evaluated these nonconventional antiphospholipid antibodies in women who clinically meet APS criteria but do not have the classic antibody profile. In one study, treatment of women with these nonconventional antibodies offered some benefits, such as a lower pregnancy loss rate (Mekinian, 2016).

Clinical features shown in Table 59-5 provide indications for testing. By international consensus, APS is diagnosed based on laboratory and clinical criteria found in Table 18-5. First, one of two clinical criteria—which are vascular thrombosis or certain pregnancy morbidity—must be present. With laboratory criteria, elevated levels of LAC, ACA, and anti-β_2-glycoprotein I should be confirmed on two occasions 12 weeks apart. The diagnosis can be further stratified based on the number of these tests that are positive (Miyakis, 2006).

TABLE 59-5

Some Clinical Features of Antiphospholipid Syndrome

Venous thrombosis—thromboembolism, thrombophlebitis, livedo reticularis
Arterial thrombosis—stroke, transient ischemic attack, Libman-Sacks cardiac vegetations, myocardial ischemia, distal extremity and visceral thrombosis and gangrene
Hematological—thrombocytopenia, autoimmune hemolytic anemia
Other—neurological manifestations, migraine headaches, epilepsy; renal artery, vein, or glomerular thrombosis; arthritis and arthralgia
Pregnancy—preeclampsia syndrome, recurrent miscarriage, preterm delivery, fetal-growth restriction, fetal death

Data from Giannakopoulos, 2013; Moutsopoulos, 2015.

Tests for LAC are nonspecific coagulation tests. The *partial thromboplastin time* is generally prolonged because the anticoagulant interferes with conversion of prothrombin to thrombin in vitro. Tests considered more specific are the *dilute Russell viper venom test* and the *platelet neutralization procedure*. There is currently disagreement as to which of these two is best for screening. If either is positive, then identification of LAC is confirmed.

Branch and Khamashta (2003) recommend conservative interpretation of results based on repeated tests from a reliable laboratory that are consistent with each clinical case. Only approximately 20 percent of patients with APS have a positive LAC assay alone. Thus, ACA enzyme-linked immunosorbent assay (ELISA) testing should also be performed. Efforts have been made to standardize ACA assays, however, these remain without international standards (Adams, 2013). For each APS test, interlaboratory variation can be large, and agreement between commercial kits is poor.

Pregnancy and Antiphospholipid Antibodies

As noted, nonspecific low levels of antiphospholipid antibodies are identified in approximately 5 percent of normal adults (Branch, 2010). When Lockwood and coworkers (1989) first studied 737 normal pregnant women, they reported that 0.3 percent had LAC and 2.2 percent had elevated concentrations of either IgM or IgG ACAs. Subsequent investigations confirmed this, and taken together, they totaled almost 4000 normal pregnancies with an average prevalence for antiphospholipid antibodies of 4.7 percent. This is similar to that for normal nonpregnant individuals (Harris, 1991; Yasuda, 1995).

In women with high ACA levels, and especially when LAC is identified, risks for decidual vasculopathy, placental infarction, fetal-growth restriction, early-onset preeclampsia, and recurrent fetal death are increased (Saccone, 2017). Some of these women, like those with SLE, also have a high incidence of venous and arterial thromboses, cerebral thrombosis, hemolytic anemia, thrombocytopenia, and pulmonary hypertension (American College of Obstetricians and Gynecologists, 2017; Clowse, 2008). In 191 LAC-negative women with APS, women with antibodies to cardiolipin and β_2-glycoprotein I had significantly higher miscarriage rates than if either one alone was positive (Liu, 2013). Women with higher titers tend to have more adverse outcomes (Hadar, 2017).

Pregnancy Pathophysiology

It is not precisely known how antiphospholipid antibodies cause damage, but it is likely that their actions are multifactorial. Platelets may be damaged directly by antiphospholipid antibody or indirectly by binding β_2-glycoprotein I, which causes platelets to be susceptible to aggregation (Giannakopoulos, 2013). One theory proposes that phospholipid-containing endothelial cell or syncytiotrophoblast membranes may be damaged directly by the antiphospholipid antibody or indirectly by antibody binding to either β_2-glycoprotein I or annexin V (Rand, 1997, 1998). This prevents the cell membranes from protecting the syncytiotrophoblast and endothelium. This exposes the basement membrane, to which damaged platelets can adhere and form a thrombus.

Pierro and associates (1999) reported that antiphospholipid antibodies decreased decidual production of the vasodilating prostaglandin E_2. Diminished protein C or S activity and greater prothrombin activation may also be contributory (Zangari, 1997). Evidence also supports that thrombosis with APS stems from activation of the tissue factor pathway (Amengual, 2003). Finally, uncontrolled placental complement activation by antiphospholipid antibodies may play a role in fetal loss and growth restriction (Holers, 2002).

Complications from APS cannot be completely explained by thrombosis alone. Animal models suggest that effects are due to inflammation rather than thrombosis (Cohen, 2011). Some investigators hypothesize that APS-associated clotting is triggered as a "second hit" from innate inflammatory immune responses. These investigators recommend treatment with antiinflammatory agents (Meroni, 2011).

Adverse Pregnancy Outcomes

Overall, antiphospholipid antibodies are generally associated with higher rates of fetal wastage (Chap. 18, Midtrimester Abortion). In most early reports that describe these outcomes, however, women were included *because* they had had repeated adverse outcomes. Both antibody prevalence and miscarriage are common—recall that the incidence of antiphospholipid antibodies in the general obstetrical population is about 5 percent and early pregnancy loss approximates 20 percent. Accordingly, current data are too limited to conclude the exact risks for adverse effects of these antibodies on pregnancy outcomes. Fetal deaths, however, are more characteristic with APS than are first-trimester miscarriages (Oshiro, 1996; Roque, 2004). Moreover, women with higher titers have worse obstetrical outcomes compared with those with low titers (Hadar, 2017; Nodler, 2009).

When otherwise unexplained fetal deaths are examined, the data are mixed. One study measured ACA levels in 309 pregnancies with fetal death and found no differences in their frequency compared with levels in 618 normal pregnancies (Haddow, 1991). In another of women with recurrent pregnancy loss, those with antiphospholipid antibodies had a higher rate of preterm delivery (Clark, 2007). In a case-control study of 582 stillbirths and 1547 live births, a three- to fivefold higher risk for stillbirth was found in women with elevated ACA and anti-β_2-glycoprotein I levels (Silver, 2013). In women with antiphospholipid antibodies, adverse outcomes are more common in the presence of: (1) all three classic antiphospholipid antibody types, (2) comorbid SLE or systemic autoimmune diseases, and (3) prior thrombosis and pregnancy morbidity. Logistic regression found the probability of pregnancy failure was 93 percent with two or more antiphospholipid antibody types but was 63 percent for those with only one (Ruffatti, 2011).

Thrombosis Prevention in Pregnancy

Because of study heterogeneity, current treatment recommendations for women with antiphospholipid antibodies can be confusing. Therapy is directed at thrombosis prevention. As discussed, antiphospholipid antibodies are immunoglobulins that may be of G, M, or A classes. Those directed against the phospholipids (PL) are termed GPL, MPL, and APL, respectively. During testing, these are reported as semiquantified phospholipid binding-unit levels and expressed as negative, low-positive, medium-positive, or high-positive (American College of Obstetricians and Gynecologists, 2017). Of the three, higher titers for GPL and MPL anticardiolipin antibodies are clinically important, whereas low-positive titers are of questionable clinical significance.

As discussed in Chapter 52 (Acquired Thrombophilias), women with prior thromboembolic events who have antiphospholipid antibodies are at risk for recurrence in subsequent pregnancies. For these women, prophylactic anticoagulation with heparin throughout pregnancy and then for 6 weeks postpartum with

either heparin or warfarin is recommended (American College of Obstetricians and Gynecologists, 2017). For those without prior thromboembolic events, recommendations for management from the American College of Obstetricians and Gynecologists (2017) and the American College of Chest Physicians (Bates, 2012) vary and are listed in Table 52-6. Some acceptable schemes include close antepartum maternal observation with or without prophylactic or intermediate-dose heparin, and some form of postpartum anticoagulation for 4 to 6 weeks. Sciascia and coworkers (2016) have presented preliminary salutary results with treatment with hydroxychloroquine.

Several trials have questioned the need for heparin for women with antibodies but no history of thrombosis (Branch, 2010). Although this is less clear, some recommend that women be treated if they have medium- or high-positive ACA titers or LAC activity and a prior second- or third-trimester fetal death not attributable to other causes (Dizon-Townson, 1998; Lockshin, 1995). Some report that women with recurrent early pregnancy loss and medium- or high-positive titers of antibodies may benefit from therapy (Robertson, 2006).

Described earlier (Antiphospholipid Syndrome), catastrophic antiphospholipid syndrome is treated aggressively with full anticoagulation, high-dose corticosteroids, plasma exchange, and/or intravenous immunoglobulins (Cervera, 2010; Tenti, 2016). If needed, rituximab may be added (Sukara, 2015).

Due to the risk of fetal-growth abnormalities and stillbirth, serial sonographic assessment of fetal growth and antepartum testing in the third trimester is recommended by the American College of Obstetricians and Gynecologists (2016a, 2017).

Specific Therapy in Pregnancy

There are other agents used to treat pregnant women with APS, but with no prior thromboembolic event. *Aspirin,* in doses of 60 to 80 mg orally daily, blocks conversion of arachidonic acid to thromboxane A_2 while sparing prostacyclin production. This reduces synthesis of thromboxane A_2, which usually causes platelet aggregation and vasoconstriction, and simultaneously spares prostacyclin, which normally has the opposite effect. There appear to be no major side effects from low-dose aspirin other than a slight risk of small-vessel bleeding during surgical procedures. Low-dose aspirin does not reduce adverse pregnancy outcomes in antiphospholipid antibody-positive women without the complete APS syndrome (Amengual, 2015). Its use is recommended for women with SLE or APS (American College of Obstetricians and Gynecologists, 2016b).

Unfractionated heparin is given subcutaneously in dosages of 5000 to 10,000 units every 12 hours. Some prefer low-molecular-weight heparin, such as 40 mg enoxaparin (Lovenox) once daily (Kwak-Kim, 2013). With therapeutic dosing, measurement of heparin levels may be useful because clotting tests can be altered by LAC. The rationale for heparin therapy is to prevent venous and arterial thrombotic episodes. Heparin therapy also prevents thrombosis in the microcirculation, including the decidual-trophoblastic interface (Toglia, 1996). As discussed, heparin binds to β_2-glycoprotein I, which coats the syncytiotrophoblast. This prevents binding of ACAs and anti-β_2-glycoprotein I antibodies to their surfaces, which likely prevents

cellular damage (Tsokos, 2011). Heparin also binds to antiphospholipid antibodies in vitro and likely in vivo. Aspirin plus heparin therapy is the most efficacious regimen (de Jesus, 2014). However, heparin therapy is associated with several complications that include bleeding, thrombocytopenia, osteopenia, and osteoporosis. A description of various heparins and their adverse effects is found in Chapter 52 (Management).

Corticosteroids generally should not be used with *primary APS*—that is, without an associated connective tissue disorder. For women with SLE or those being treated for APS who develop SLE, corticosteroid therapy is indicated (Carbone, 1999). In such cases of *secondary APS* seen with SLE, the dose of prednisone should be maintained at the lowest effective level to prevent flares.

Intravenous immunoglobulin therapy (IVIG) is controversial and has usually been reserved for women with overt disease—including CAPS or heparin-induced thrombocytopenia or both (Alijotas-Reig, 2013). It is used when other first-line therapies have failed, especially in the setting of preeclampsia and fetal-growth restriction. IVIG is administered by some in doses of 0.4 g/kg/d for 5 days—total dose of 2 g/kg. This is repeated monthly, or it is given as a single dose of 1 g/kg each month. Treatment is expensive, as one course costs more than $10,000. A recent literature review found no benefits from adding IVIG to low-dose aspirin and low-molecular-weight heparin (Tenti, 2016). And, a Cochrane review found no improvement in the live birth rate for immunotherapy given to women with recurrent pregnancy loss (Wong, 2014). Trials are needed before application of this expensive and cumbersome therapy becomes widespread.

Immunosuppression with hydroxychloroquine may be beneficial with APS by reducing the risk of thrombosis and improving pregnancy outcomes in women with APS (Mekinian, 2015; Sciascia, 2016). Hydroxychloroquine is commonly used with low-dose aspirin in the treatment of women with antiphospholipid antibodies and SLE.

Statins have been examined due to their protective effects on endothelium. In a small trial in 21 women with APS who developed fetal-growth restriction or preeclampsia, the addition of pravastatin to low-dose aspirin and low-molecular-weight heparin improved placental blood flow, preeclampsia features, and pregnancy outcomes (Lefkou, 2016). Larger trials are needed.

Treatment Efficacy

Fetal loss is common in women with APS if untreated (Rai, 1995). Even with treatment, recurrent fetal loss rates remain at 20 to 30 percent (Branch, 2003; Empson, 2005; Ernest, 2011). Shown in Table 59-6 are pregnancy outcomes from 750 treated women with primary APS—the PREGNANTS study (Saccone, 2017). Participants were treated with low-dose aspirin and prophylactic low-molecular-weight heparin starting in the first trimester. Importantly, some women with SLE and antiphospholipid antibodies have normal pregnancy outcomes without treatment. Also, it is emphasized that women with LAC and prior bad pregnancy outcomes have had liveborn neonates without treatment.

TABLE 59-6

Pregnancy Outcomes (%) in 750 Women Treated for the Antiphospholipid Syndrome—the PREGNANTS Study

Outcome	Triple-Positive (n = 20)	Double-Positive LAC Negative (n = 90)	LAC Alone (n = 54)	ACA Alone (n = 458)	Anti-β_2 Glycoprotein (n = 128)
Livebirth	30	43	80	56	48
Stillbirth	45	34	7	21	30
Preeclampsia[a]	55	54	11	34	48

ACA = anticardiolipin antibodies; LAC = lupus anticoagulant.

[a]Nonsevere only.

Data from Saccone, 2017.

In a manner similar to neonatal lupus syndrome (Perinatal Mortality and Morbidity), up to 30 percent of newborns demonstrate passively acquired antiphospholipid antibodies, and thus there is concern for their adverse neonatal effects (Nalli, 2017). One group found higher rates of learning disabilities in these children (Tincani, 2009). Simchen and colleagues (2009) reported a fourfold greater risk for perinatal strokes. Of 141 newborns followed in a European registry, the rate of preterm birth was 16 percent; low birthweight, 17 percent; and later behavioral abnormalities in 4 percent of the children. There were no cases of neonatal thrombosis (Motta, 2012). A 7-year study of 26 women who had APS with 36 pregnancies reported three cases of autism spectrum disorder, all associated with persistent neonatal anti-β_2-glycoprotein-1 IgG antibodies (Abisror, 2013).

RHEUMATOID ARTHRITIS

This chronic inflammatory disease stems from immunological dysfunction, and infiltrating T cells secrete cytokines to cause inflammation, polyarthritis, and systemic symptoms. The cardinal feature is inflammatory synovitis that usually involves the peripheral joints. The disease has a propensity for cartilage destruction, bony erosions, and joint deformities. Pain, aggravated by movement, is accompanied by swelling and tenderness. Extraarticular manifestations include rheumatoid nodules, vasculitis, and pleuropulmonary symptoms. Other complaints are fatigue, anorexia, and depression. The American College of Rheumatology criteria for rheumatoid arthritis diagnosis are shown in Table 59-7. A score of 6 or greater fulfills the requirements for definitive diagnosis.

TABLE 59-7

Criteria for Classification of Rheumatoid Arthritis

Factor	Criteria	Score
Joint involvement	1 large—shoulder, elbow, hip, knee, ankle	0
	2–10 large	1
	1–3 small—MCP, PIP, thumb IP, MTP, wrists	2
	4–10 small	3
	>10—at least 1 small	5
Serological testing	Negative RF and negative ACPA	0
	Low-positive RF or anti-CCP	2
	High-positive RF or anti-CCP	3
Acute-phase reactants	Normal CRP and ESR	0
	Abnormal CRP or ESR	1
Duration of symptoms	Less than 6 weeks	0
	6 weeks or longer	1

ACPA = anti-citrullinated peptide antibody; CCP = cyclic citrullinated peptides; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; IP = interphalangeal joint; MCP = metacarpophalangeal joint; MTP = metatarsophalangeal joint; PIP = proximal interphalangeal joint; RF = rheumatoid factor.

Criteria established in collaboration with the American College of Rheumatology and the European League Against Rheumatism. A score ≥ 6 fulfills criteria for diagnosis.

Data from Aletaha, 2010; Shah, 2015.

The worldwide prevalence of rheumatoid arthritis is 0.5 to 1 percent, women are affected three times more often than men, and peak onset is from 25 to 55 years (Shah, 2015). There is a genetic predisposition, and heritability is estimated at 15 to 30 percent (McInnes, 2011). Genome-wide associated studies have identified more than 30 loci involved in rheumatoid arthritis pathogenesis (Kurkó, 2013). There is an association with

the class II major histocompatibility complex molecule HLA-DR4 and HLA-DRB1 alleles (McInnes, 2011; Shah, 2015). Pregnancy provides a protection against rheumatoid arthritis development, and this may be related to HLA-disparate fetal microchimerism (Guthrie, 2010). Of other influences, cigarette smoking raises the risk of rheumatoid arthritis (Papadopoulos, 2005).

Management

Treatment is directed at pain relief, inflammation reduction, protection of articular structures, and preservation of function. Physical and occupational therapy and self-management instructions are essential. Until recently, aspirin and other NSAIDs were the cornerstone of therapy, but they do not retard disease progression. According to Shah and St. Clair (2015), methotrexate has become the preferred disease-modifying antirheumatic drug (DMARD). NSAIDs serve as adjunctive therapy but are important to pregnancy because methotrexate is contraindicated. Conventional NSAIDs nonspecifically inhibit both cyclooxygenase-1 (COX-1), which is an enzyme critical to normal platelet function, and COX-2, which mediates inflammatory response mechanisms. Because gastritis with acute bleeding is an unwanted side effect common to conventional NSAIDs, the more specific COX-2 inhibitors have been recommended. However, their long-term use is associated with higher risk for myocardial infarction and major vascular events (Patrono, 2016).

In one systematic review, a higher rate of cardiac malformations was found in newborns exposed to NSAIDs in the first trimester (Adams, 2012). In addition, NSAIDs are associated with early spontaneous abortions, ductus arteriosus constriction, and neonatal pulmonary hypertension. Thus, risks versus benefits of these medications must be considered.

Glucocorticoid therapy in low-to-moderate doses is given to achieve more rapid symptom control. Of these, prednisone, 7.5 mg orally daily for the first 2 years of active disease, substantively reduces progressive joint erosions (Kirwan, 1995; Shah, 2015).

The American College of Rheumatology recommends several DMARDs that may reduce or prevent joint damage (Singh, 2016). Leflunomide, like methotrexate, is teratogenic (Briggs, 2015) (Chap. 12, Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs). Sulfasalazine and hydroxychloroquine are safe for use in pregnancy (Partlett, 2011). These, combined with COX-2 inhibitors and with relatively low-dose prednisone—7.5 to 20 mg daily—usually successfully treat flares. In one review of drug exposure, a fourth of women with rheumatoid arthritis took a DMARD within 6 months of conception (Kuriya, 2011). During pregnancy, 4 percent of 393 pregnant women were given a category D or X medication. Methotrexate was the most common— 2.9 percent.

Biological DMARDs have revolutionized the treatment of rheumatoid arthritis. These include tumor necrosis factor alpha (TNF-α) inhibitors—infliximab, adalimumab, golimumab, certolizumab, and etanercept (Shah, 2015). Their use in pregnancy is limited, and fetal safety is a concern (Makol, 2011; Ojeda-Uribe, 2013). In one drug-exposure review, 13 percent of 393 women were given a biological cytokine-inhibiting DMARD—primarily etanercept (Kuriya, 2011). In another review of 300 exposures, no fetal effects were noted (Berthelot, 2009). A prospective study of 38 women found similar results (Hoxha, 2017). In 74 women exposed

to adalimumab during pregnancy, no risks were identified (Burmester, 2017). There is also little known regarding pregnancy effects of anakinra, an interleukin-1 receptor antagonist, or of rituximab, an antagonist to the B-cell CD20 antigen.

Pregnancy and Rheumatoid Arthritis

In up to 90 percent of women with rheumatoid arthritis, their disease will improve during pregnancy (de Man, 2008). Animal studies suggest this may be due to regulatory T-cell alterations (Munoz-Suano, 2012). Even so, some women develop disease during pregnancy, and others become worse (Nelson, 1997).

A downside to this respite during pregnancy is that postpartum exacerbation is common (Østensen, 2007). This may stem from postpartum alterations in innate immunity (Häupl, 2008b). In one review, a postpartum flare was more common if women were breastfeeding (Barrett, 2000a). These same investigators followed 140 women with rheumatoid arthritis during 1 to 6 months postpartum (Barrett, 2000b). There was only a modest fall in objective disease activity, and only 16 percent had complete remission. They observed that although overall disease actually did not exacerbate postpartum, the mean number of inflamed joints rose significantly.

Some studies report a protective effect of pregnancy against developing new-onset rheumatoid arthritis. In a case-control study of 88 affected women, there was a protective effect of pregnancy in the long term, but the likelihood of new-onset rheumatoid arthritis was increased sixfold during the first 3 postpartum months (Silman, 1992). Pikwer and colleagues (2009) reported a significant reduction in the risk of subsequent arthritis in women who breastfed longer than 12 months.

These findings may reflect the interference of sex hormones with several putative processes involved in arthritis pathogenesis, including immunoregulation (Häupl, 2008a,b). First, Unger and associates (1983) reported that amelioration of rheumatoid arthritis correlated with serum levels of *pregnancy-associated alpha$_2$-glycoprotein.* This compound has immunosuppressive properties. Second, Nelson and coworkers (1993) noted that amelioration of disease was associated with a disparity in HLA class II antigens between mother and fetus. They suggested that the maternal immune response to paternal HLA antigens may play a role in pregnancy-induced remission of arthritis. In addition to monocyte activations, there also may be T-lymphocyte activation (Förger, 2008).

Juvenile Rheumatoid Arthritis

This group of diseases is the most frequent cause of chronic arthritis in children and persists into adulthood. In 76 pregnancies of 51 affected Norwegian women, pregnancy had no effects on clinical presentation, but disease activity usually became quiescent or remained so during pregnancy (Østensen, 1991). Postpartum flares were common as was discussed for rheumatoid arthritis. Joint deformities often developed in these women, and 15 of 20 cesarean deliveries were done for contracted pelves or joint prostheses. Results from a summary of 39 Polish women with juvenile rheumatoid arthritis were similar (Musiej-Nowakowska, 1999).

This arthritis portends few adverse pregnancy outcomes. The risk for preterm birth is increased, but later fetal development is normal (Mohamed, 2016; Rom, 2014; Wallenius, 2014). Disease severity in early pregnancy was predictive of preterm delivery and fetal-growth restriction in a cohort study (Bharti, 2015). Another study of 190 pregnancies followed from first trimester to delivery found patients with low disease activity scores in the first trimester were likely to have low disease activity or remission in the third trimester (Ince-Askan, 2017). In a study of 1807 births, Remaeus and associates (2017) reported increased incidences of preterm birth, fetal-growth restriction, and preeclampsia.

Primary treatment of symptomatic women during pregnancy is with aspirin and NSAIDs. These are used with appropriate concerns for first-trimester effects, impaired hemostasis, prolonged gestation, premature ductus arteriosus closure, and persistent pulmonary circulation. Low-dose corticosteroids are also prescribed as indicated. Gold compounds have been administered in pregnancy (Almarzouqi, 2007).

Immunosuppressive therapy with azathioprine, cyclophosphamide, or methotrexate is not routinely used during pregnancy. Only azathioprine is considered during early pregnancy because the other agents are teratogens (Briggs, 2015). As discussed in Management, DMARDs including sulfasalazine and hydroxychloroquine are acceptable for use in pregnancy.

If the cervical spine is involved, particular attention is warranted during pregnancy. Subluxation is common, and pregnancy, at least theoretically, predisposes to this because of joint laxity. Importantly, there are anesthesia concerns during endotracheal intubation.

Following pregnancy in women with rheumatoid arthritis and its juvenile form, contraceptive counseling may include combination oral contraceptives. These are a logical choice because of their effectiveness and their potential to improve disease (Farr, 2010). That said, all methods of contraception are appropriate.

SYSTEMIC SCLEROSIS—SCLERODERMA

This is a chronic multisystem connective tissue disorder of unknown etiology. It is characterized by microvascular damage, immune system activation leading to inflammation, and excessive deposition of collagen in the skin and often in the lungs, heart, gastrointestinal tract, and kidneys. It is uncommon, displays a 5-to-1 female dominance, and typically affects those aged 30 to 50 years (Meier, 2012; Varga, 2015).

This strong prevalence of scleroderma in women and its greater incidence in the years following childbirth give credence to the hypothesis that *microchimerism* is involved as discussed earlier (Systemic Lupus Erythematosus) (Lambert, 2010). Artlett and coworkers (1998) demonstrated Y-chromosomal DNA in almost half of women with systemic sclerosis compared with only 4 percent of controls. Rak and colleagues (2009b) identified male microchimerism in peripheral blood mononuclear cells more frequently in women with limited versus diffuse scleroderma—20 versus 5 percent.

Clinical Course

The hallmark is overproduction of normal collagen. In the more benign form—*limited cutaneous systemic sclerosis*—progression is slow. With *diffuse cutaneous systemic sclerosis*, skin thickening progresses rapidly, and skin fibrosis is followed by gastrointestinal tract fibrosis, especially the distal esophagus (Varga, 2015). Pulmonary interstitial fibrosis along with vascular changes may cause pulmonary hypertension, which develops in 15 percent of patients. Antinuclear antibodies are found in 95 percent of patients, and immunoincompetence often develops.

Raynaud phenomenon, which includes cold-induced episodic digital ischemia, is seen in 95 percent of patients, and there may also be swelling of the distal extremities and face. Half of patients have symptoms from esophageal involvement, especially fullness and epigastric burning pain. Pulmonary involvement is frequent and causes dyspnea. The 10-year cumulative survival rate is 70 percent in those with pulmonary fibrosis, and pulmonary arterial hypertension is the main cause of death (Joven, 2010; Varga, 2015). Women with limited cutaneous disease such as the *CREST syndrome—calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia*—have milder disease.

Overlap syndrome refers to systemic sclerosis with features of other connective tissue disorders. *Mixed connective tissue disease* is a term used for the syndrome involving features of SLE, systemic sclerosis, polymyositis, rheumatoid arthritis, and high titers of anti-ribonucleoprotein (RNP) antibodies (see Table 59-1). The disorder is also termed *undifferentiated connective tissue disease* (Spinillo, 2008).

Although systemic sclerosis is incurable, treatment directed at end-organ involvement can sometimes relieve symptoms and improve function. Renal involvement and hypertension are often comorbid. At times, ACE inhibitors may be required for blood pressure control despite their known teratogenicity. *Scleroderma renal crisis* develops in up to a fourth of these patients and is characterized by obliterative vasculopathy of the renal cortical arteries. This leads to renal failure and malignant hypertension. Interstitial restrictive lung disease is common and frequently becomes life threatening. Associated pulmonary hypertension is treated with bosentan or sildenafil (Chap. 49, Pulmonary Hypertension).

Pregnancy and Systemic Sclerosis

The prevalence of scleroderma in pregnancy approximates 1 in 22,000 pregnancies (Chakravarty, 2008). These women usually have stable disease during gestation if their baseline function is good. As perhaps expected, dysphagia and reflux esophagitis are aggravated by pregnancy (Steen, 1999). Dysphagia results from loss of esophageal motility due to neuromuscular dysfunction. A decrease in amplitude or disappearance of peristaltic waves in the lower two thirds of the esophagus is seen using manometry. Symptomatic treatment for reflux is described in Chapter 54 (Gastroesophageal Reflux Disease).

Women with renal insufficiency and malignant hypertension have a higher incidence of superimposed preeclampsia. With rapidly worsening renal or cardiac disease, pregnancy termination should be considered. As discussed, renal crisis is life threatening and is treated with ACE inhibitors, but it does not improve with delivery (Gayed, 2007). Pulmonary hypertension usually contraindicates pregnancy.

Vaginal delivery may be anticipated, unless the soft tissue thickening wrought by scleroderma produces dystocia requiring cesarean delivery. Tracheal intubation for general anesthesia has special concerns because of limited ability of these women to open their mouths widely (Sobanski, 2016). Because of esophageal dysfunction, aspiration is also more likely, and epidural analgesia is preferable. Warming the delivery room and intravenous fluids, extra blankets, and socks and gloves are recommended to improve impaired circulation from Raynaud phenomenon. If corticosteroids were used frequently, stress doses of hydrocortisone are recommended (Sobanski, 2016).

Maternal and fetal outcomes correlate with underlying disease severity. In a review of 214 gravidas with systemic sclerosis, 45 percent had diffuse disease. Major complications included renal crisis in three and greater rates of preterm birth (Steen, 1989, 1999). Chung and coworkers (2006) also reported elevated rates of preterm delivery, fetal-growth restriction, and perinatal mortality. A multicenter study of 109 pregnancies from 25 centers reported higher rates of preterm delivery, fetal-growth restriction, and very-low-birthweight newborns (Taraborelli, 2012). These are likely related to placental abnormalities that include decidual vasculopathy, acute atherosis, and infarcts (Sobanski, 2016).

Scleroderma may be associated with subfertility (Bernatsky, 2008; Lambe, 2004). For women who do not choose pregnancy, several reversible contraceptive methods are acceptable. However, hormonal agents, especially combination oral contraceptives, probably should not be used, especially in women with pulmonary, cardiac, or renal involvement. Due to the often unrelenting progression of systemic sclerosis, permanent sterilization is also considered.

VASCULITIS SYNDROMES

Inflammation and damage to blood vessels may be primary or caused by another disease. Immune-complex deposition is presumed to underlie most cases (Langford, 2015). Primary types include polyarteritis nodosa, temporal or giant-cell arteritis, Takayasu arteritis, Henoch-Schönlein purpura, Behçet syndrome, and cutaneous or hypersensitivity arteritis (Goodman, 2014). Small vessel vasculitides such as *granulomatosis with polyangiitis* and *eosinophilic granulomatosis with polyangiitis* have antibodies directed against proteins in the cytoplasmic granules of leukocytes—*antineutrophil cytoplasmic antibodies—ANCA (Pagnoux, 2016)*.

Polyarteritis Nodosa

This necrotizing vasculitis of small and medium-sized arteries is characterized clinically by myalgia, neuropathy, gastrointestinal disorders, hypertension, and renal disease (Goodman, 2014). Of cases, approximately a third is associated with hepatitis B antigenemia (Langford, 2015). Symptoms are nonspecific, and fever, weight loss, and malaise are present in more than half of cases. Diagnosis is made by biopsy, and treatment consists of high-dose prednisone plus cyclophosphamide. Vasculitis due to hepatitis B antigenemia responds to antivirals, glucocorticosteroids, and plasma exchange (Chap. 55, Chronic Viral Hepatitis).

Only a few reports describe polyarteritis nodosa associated with pregnancy. Of 12 affected gravidas, polyarteritis first manifested during pregnancy in seven, and it was rapidly fatal by 6 weeks postpartum (Owen, 1989). The diagnosis was not made until autopsy in six of the seven women. Four women continued pregnancy, which resulted in one stillborn and three successful outcomes.

Granulomatosis with Polyangiitis

Formerly Wegener granulomatosis, this is a small-vessel necrotizing granulomatous vasculitis affecting the upper and lower respiratory tract and kidney (Pagnoux, 2016). Disease frequently includes sinusitis and nasal disease—90 percent; pulmonary infiltrates, cavities, or nodules—85 percent; glomerulonephritis—75 percent; and musculoskeletal lesions—65 percent (Sneller, 1995). At least 90 percent have polyangiitis (Langford, 2015). It is uncommon and usually encountered after age 50. Koukoura and associates (2008) reviewed 36 cases in association with pregnancy and found a higher preterm birth rate. In another report, a second woman had disease-related pneumonitis, but pregnancy did not appear to affect disease activity (Pagnoux, 2011). Because subglottic stenosis is found in up to a fourth of patients, the anesthesia team is ideally consulted antepartum (Engel, 2011).

Corticosteroids are standard treatment, but azathioprine, cyclosporine, and IVIG therapy may also be used. For severe disease in the late second or third trimester, cyclophosphamide in combination with prednisolone seems acceptable.

Takayasu Arteritis

Also called *pulseless disease,* this is a chronic inflammatory arteritis affecting large vessels (Goodman, 2014). Unlike *temporal arteritis*, which develops almost exclusively after age 55, the onset of Takayasu arteritis is almost always before age 40. It is associated with abnormal angiography of the upper aorta and its main branches and with upper extremity vascular impairment. Death usually results from congestive heart failure or cerebrovascular events. Computed tomography or magnetic resonance angiography can detect this disorder before the development of severe vascular compromise. Takayasu arteritis may respond symptomatically to corticosteroid therapy, however, it is not curative. Surgical bypass or angioplasty improves survival rates.

Comorbid severe renovascular hypertension, cardiac involvement, or pulmonary hypertension worsen pregnancy prognosis (Singh, 2015). Hypertension is relatively common and should be carefully controlled. Blood pressure is most accurately measured in the lower extremity. Overall, the prognosis for pregnancy is good (Johnston, 2002). A study of 58 women with Takayasu arteritis found an elevated risk of pregnancy-related hypertension and preeclampsia but overall favorable maternal and fetal outcomes (Gudbrandsson, 2017). A study of 52 patients comparing obstetrical outcomes before and after diagnosis reported higher rates of obstetrical complications after diagnosis. These included preeclampsia, preterm birth, and fetal-growth restriction or death (Comarmond, 2015). Involvement of the abdominal aorta portends worse perinatal outcome (Sharma, 2000). Vaginal delivery is preferred, and epidural analgesia has been advocated for labor and delivery.

Other Vasculitides

Henoch-Schönlein purpura is uncommon after childhood. Tayabali and associates (2012) reviewed 20 pregnancies complicated by this vasculitis and described cutaneous lesions in three fourths. Approximately half had arthralgias. For *Behçet disease,* Gungor and colleagues (2014) described 298 pregnancies in 94 women and found higher miscarriage rates and smaller babies compared with healthy controls. Formerly *Churg-Strauss vasculitis,* eosinophilic granulomatosis with polyangiitis is rare in pregnancy (Jennette, 2013). Hot and associates (2007) described a pregnant woman who responded to IVIG therapy. Corradi and associates (2009) described an affected 35-year-old woman at term whose necrotizing vasculitis involved the heart, and she subsequently underwent cardiac transplantation. Edwards (2015) described one woman who developed postpartum relapses of this vasculitis in each of two pregnancies.

INFLAMMATORY MYOPATHIES

These are acquired and potentially treatable causes of skeletal muscle weakness with a prevalence of 1 in 100,000 persons (Dalakas, 2012). There are three major groups: polymyositis, dermatomyositis, and inclusion-body myositis, which all present with progressive asymmetrical muscle weakness. They have a variable association with connective tissue diseases, malignancy, drugs, systemic autoimmune disease such as Crohn disease, and viral, bacterial, and parasitic infections.

Polymyositis is a subacute inflammatory myopathy that is frequently associated with one of the autoimmune connective tissue disorders. *Dermatomyositis* manifests as a characteristic rash accompanying or preceding weakness. Laboratory findings include elevated muscle enzyme levels in serum and an abnormal electromyogram. Confirmation is by biopsy, which shows perivascular and perimysial inflammatory infiltrates, vasculitis, and muscle fiber degeneration. It usually develops alone but can overlap with systemic sclerosis or mixed connective tissue disease.

Prevailing theories suggest that the syndromes are caused by viral infections, autoimmune disorders, or both. *Importantly, approximately 15 percent of adults who develop dermatomyositis have an associated malignant tumor.* The timing of myositis and tumor appearance may be separated by several years. The most common sites of associated cancer are breast, lung, stomach, and ovary. The disease usually responds to high-dose corticosteroid therapy, immunosuppressive drugs such as azathioprine or methotrexate, or IVIG (Dalakas, 2012; Linardaki, 2011).

Experiences in pregnancy are garnered mostly from case series and reviews. Chen and colleagues (2015) found 17 women with polymyositis/dermatomyositis in an Australian population-based cohort of births. These women had higher rates of hypertension (23 percent), antepartum hemorrhage (11 percent), cesarean delivery (88 percent), and preterm birth (35 percent). Another series of 60 women with dermatomyositis and 38 with polymyositis found that in 80 percent, pregnancy had no adverse effect on their disease. Similar results have been reported by others (Missumi, 2015; Pinal-Fernandez, 2014). Rosenzweig and colleagues (1989) reviewed 24 pregnancy outcomes in 18 women with primary disease. Of these, a fourth had an exacerbation in the second or third trimester. In 12 in whom disease became manifest first during pregnancy,

half of the eight pregnancies resulted in perinatal death, and one woman died postpartum. From their review, Doria and associates (2004) concluded that pregnancy outcome was related to dermatomyositis activity and that new-onset disease was particularly aggressive.

HEREDITARY CONNECTIVE TISSUE DISORDERS

Numerous inherited mutations involve genes that encode for structural proteins of bone, skin, cartilage, blood vessels, and basement membranes. Although connective tissues contain many complex macromolecules such as elastin and more than 30 proteoglycans, the most common constituents are fibrillar collagen types I, II, and III. Various mutations, some recessively and some dominantly inherited, result in clinical syndromes that include Marfan and Ehlers-Danlos syndromes, osteogenesis imperfecta, chondrodysplasias, and epidermolysis bulla. Of concern during pregnancy is the predilection for these disorders to result in aortic aneurysms (Schoenhoff, 2013).

Marfan Syndrome

This is an autosomal dominant connective tissue disorder that has a population prevalence of 1 in 3000 to 5000 (Prockop, 2015). Marfan syndrome affects both sexes equally. The syndrome is due to abnormal fibrillin—a constituent of elastin—caused by any of several different mutations in the *FBN1* gene (Biggin, 2004). Located on chromosome 15q21, the *FBN1* gene has a high mutation rate, and there are many mild, subclinical cases. A 50-percent risk of disease transmission to the offspring exists, however, the ability to predict disease severity in progeny is limited by the lack of distinct genotype-phenotype correlation and large clinical variability. Currently, preimplantation and prenatal diagnoses are limited to the 80 percent of cases in which the mutation in the *FBN1* gene is known (Smok, 2014).

In severe disease, there is degeneration of the elastic lamina in the media of the aorta. This weakness predisposes to aortic dilation or dissecting aneurysm, which appears more commonly during pregnancy (Curry, 2014; Roman, 2016). Marfan syndrome complicating pregnancy is discussed in more detail in Chapter 49, Diseases of the Aorta.

Ehlers-Danlos Syndrome

This disease is characterized by various connective tissue changes, including skin hyperelasticity. In the more severe types, rupture of any of several arteries can cause either stroke or bleeding. There are several disease types based on skin, joint, or other tissue involvement. Some are autosomal dominant, some recessive, and some X-linked (Solomons, 2013). Their aggregate prevalence approximates 1 in 5000 births (Prockop, 2015). Types I, II, and III are autosomally dominant, and each accounts for approximately 30 percent of cases. Type IV is uncommon but is known to predispose to preterm delivery, maternal great-vessel rupture, postpartum bleeding, and uterine rupture (Pepin, 2000). In most, the underlying molecular defect affects collagen or procollagen.

In general, women with Ehlers-Danlos syndrome reportedly have a higher frequency of preterm rupture of membranes, preterm delivery, and antepartum and postpartum hemorrhage (Volkov, 2006). That said, a recent cohort study of 314 women reported no greater risk of adverse pregnancy outcome, including preterm birth (Sundelin, 2017). Several cases of spontaneous uterine rupture have been described (Rudd, 1983). Tissue fragility makes episiotomy repair and cesarean delivery difficult. Hurst and colleagues (2014) surveyed 1769 respondents of the Ehlers-Danlos National Foundation and found a preterm birth rate of 25 percent and infertility rate of 44 percent. A maternal and fetal death from spontaneous rupture of the right iliac artery has been reported (Esaka, 2009). Bar-Yosef and associates (2008) described a newborn with multiple congenital skull fractures and intracranial hemorrhage caused by Ehlers-Danlos type VIIC.

Osteogenesis Imperfecta

This disorder has a prevalence of 1 in 20,000 births for type I and 1 in 60,000 for type II. It is characterized by brittle bones and affected patients often have blue sclerae, hearing loss, multiple prior bone fractures, and dental abnormalities. There are up to 15 subtypes based on the causative gene and clinical picture, which ranges from mild to severe (Van Dijk, 2010). Genetic inheritance includes autosomal dominant, autosomal recessive, and sporadic patterns. Type I is the mildest form, and the typical mutation affects the *COL1A1* gene (Sykes, 1990). Type II is typically lethal in utero (Prockop, 2015).

Women with osteogenesis imperfecta, most commonly type I, may have successful pregnancies. That said, several risks in pregnancy include fractures, complications related to scoliosis with restrictive lung disease, micrognathia, brittle teeth, an unstable cervical spine, uterine rupture, and cephalopelvic disproportion. A retrospective cohort of 295 women with osteogenesis imperfecta found greater risks of antepartum hemorrhage, abruption, fetal-growth restriction, congenital malformations, and preterm birth (Ruiter-Ligeti, 2016). It is not unusual for affected women to enter pregnancy having had 20 to 30 prior fractures. Most require minimal treatment other than management of the fractures and consideration of bisphosphonates to decrease bone loss.

Depending on the type of osteogenesis imperfecta, the fetus may be affected and may also suffer fractures in utero or during delivery (Chap. 10, Skeletal Abnormalities). Prenatal diagnosis is available in many situations, if desired, and in utero stem cell therapy is being evaluated (Couzin-Frankel, 2016).

CHAPTER 60: Neurological Disorders

Epilepsy appears to have no effect on pregnancy, though at the time of labour it may be mistaken for eclampsia by inexperienced observers. If the attacks are frequent the patient should be put upon large doses of potassium bromide and treated just as at other times.

—J. Whitridge Williams (1903)

INTRODUCTION

Although several neurological diseases are relatively common in women of childbearing age, less than two pages were devoted to Diseases of the Nervous System in this textbook's first edition. In the past, some may have precluded pregnancy, however, few do so now. Most encountered during pregnancy are the same as for nonpregnant women, however a few neurological disorders may be seen more frequently in pregnant women. Examples are Bell palsy, specific types of strokes, and benign intracranial hypertension or pseudotumor cerebri. Neurovascular disorders are an important cause of maternal mortality and accounted for nearly 7 percent of maternal deaths in the United States from 2011 through 2013 (Creanga, 2017).

Many neurological disorders frequently precede pregnancy. Most women with chronic neurological disease who become pregnant will have successful outcomes, but some disorders have specific risks. Conversely, other women will have new-onset neurological symptoms during pregnancy, and these often must be distinguished from pregnancy complications. Psychiatric disorders can also manifest with cognitive and neuromuscular abnormalities and should be considered in the evaluation.

CENTRAL NERVOUS SYSTEM IMAGING

Computed tomography (CT) and magnetic resonance (MR) imaging assist in the diagnosis, classification, and management of many neurological and psychiatric disorders. As discussed in Chapter 46 (Computed Tomography), these imaging methods can be used safely during pregnancy. CT scanning is often used when rapid diagnosis is necessary and is excellent for detecting recent hemorrhage. Because it does not use radiation, MR imaging is often preferred and is particularly helpful to diagnose demyelinating diseases, arteriovenous malformations, congenital and developmental nervous system abnormalities, posterior fossa lesions, and spinal cord diseases. Whenever either test is done, the woman with advanced pregnancy should be positioned in a left lateral tilt with a wedge under one hip to prevent hypotension and to diminish aortic pulsations, which may degrade the image.

Cerebral angiography with contrast injection, usually via the femoral artery, is a valuable adjunct to the diagnosis and treatment of some cerebrovascular diseases. Fluoroscopy delivers more radiation but can be performed with abdominal shielding. Positron emission tomography (PET) and functional MR imaging (fMRI) have not been evaluated for use in pregnant patients (Chiapparini, 2010).

HEADACHE

In one national survey in the United States in 2012, 17 percent of those aged 18 to 44 years reported a severe headache or migraine within the past 3 months (Blackwell, 2014). Burch and coworkers (2015) reported that 24 percent of nonpregnant women in this age group were similarly affected. Of pregnant women presenting with headache who received a neurological consultation, two thirds were due to primary disorders, with over 90 percent due to migraine. Of the other third due to secondary conditions, over half were due to hypertensive disorders (Robbins, 2015). Interestingly, Aegidius and associates (2009) reported a decline in the rate of all headache types during pregnancy in nulliparas, especially during the third trimester.

The classification by the International Headache Society (2013) is shown in Table 60-1. In pregnant women, primary headaches are more common than those stemming from secondary causes (Digre, 2013; Sperling, 2015). Migraine headaches are those most likely to be affected by the hormonal changes of pregnancy (Pavlovic, 2017). The incidences of severe headache causes in pregnancy are shown in Figure 60-1.

TABLE 60-1

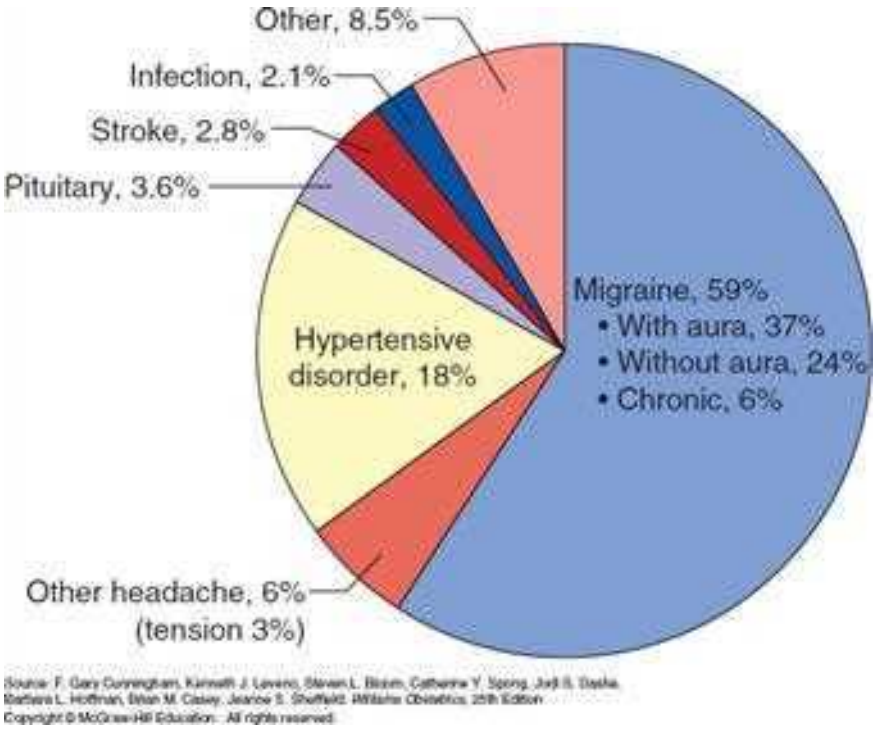
Headache Classification

Primary
Migraine
Tension-type
Trigeminal cephalalgia
Other
Secondary
Trauma
Vascular disorders
Substance abuse
Infection
Disorders of homeostasis
Craniofacial disorders
Psychiatric disorders

Data from International Headache Society, 2013.

FIGURE 60-1

Incidences of headache causes in 140 consecutive pregnant women for whom in-hospital neurology consultation was requested. (Data from Robbins, 2015.)



Tension-Type Headache

These are the most frequent cause of all headaches. Characteristic features include muscle tightness and mild-to-moderate pain in the back of the neck and head that can persist for hours. Neurological disturbances or nausea are typically absent. The pain usually responds to rest, massage, application of heat or ice, antiinflammatory medications, or mild tranquilizers. Hospital admission is seldom necessary.

Migraine Headache

The term *migraine* describes a periodic, sometimes incapacitating neurological disorder with episodic attacks of severe headache and autonomic nervous system dysfunction (Goadsby, 2015). The International Headache Society (2013) classifies three migraine types based on chronicity and on the presence or absence of an aura.

1. *Migraine without aura*—formerly termed common migraine—is characterized by a unilateral throbbing headache, nausea and vomiting, or photophobia.
2. *Migraine with aura*—formerly termed classic migraine—has similar symptoms preceded by premonitory neurological phenomena such as visual scotoma or hallucinations. A third of patients have this type of migraine, which sometimes can be averted if medication is taken at the first premonitory sign.

3. *Chronic migraine* is defined by a migraine headache occurring at least 15 days each month for more than 3 months.

These are the most common reason for admission for headache evaluation and management. Migraines may begin in childhood, peak in adolescence, and tend to diminish in both frequency and severity with advancing years. According to Lipton and associates (2007), their annual prevalence is 17 percent in women and 6 percent in men. Another 5 percent of women have *probable migraine,* that is, they have all criteria but one (Silberstein, 2007). Specific polymorphisms have been identified that modulate the risk of migraines (Chen, 2015; Schürks, 2010). These headaches are especially common in young women and have been linked to hormone levels (Charles, 2017; Pavlovic, 2017). They are frequently encountered during pregnancy.

Sensory sensitivity with migraines is likely caused by monoaminergic sensory control systems in the brainstem and hypothalamus (Goadsby, 2015). This exact pathophysiology is uncertain, but they occur when neuronal dysfunction leads to decreased cortical blood flow, activation of vascular and meningeal nociceptors, and stimulation of trigeminal sensory neurons (Brandes, 2007; D'Andrea, 2010). A predilection for the posterior circulation has been described (Kruit, 2004). Migraines—especially those with aura in young women—are associated with increased risk for ischemic strokes. The risk is greater in those who smoke or use combination oral contraceptives.

Migraine in Pregnancy

The prevalence of migraine headaches in the first trimester is 2 percent (Chen, 1994). Most migraineurs have improvement during pregnancy (Kvisvik, 2011). Still, migraines—usually those with an aura—occasionally appear for the first time during pregnancy. Pregnant women with preexisting migraine symptoms may have other symptoms suggestive of a more serious disorder, and new neurological symptoms should prompt a complete evaluation (Detsky, 2006; Heaney, 2010).

Although conventional thinking has been that migraine headaches do not pose increased maternal or fetal risks, several recent studies have refuted this (Allais, 2010). In these, rates of preeclampsia, gestational hypertension, preterm birth, and other cardiovascular morbidities, including ischemic stroke, were increased (Grossman, 2017; Wabnitz, 2015). Bushnell and coworkers (2009) identified an incidence of migraines during pregnancy of 185 per 100,000 deliveries. Of diagnoses associated in these gravid migraineurs, risks were significantly higher for stroke, 16-fold; myocardial infarction, fivefold; heart disease, twofold; venous thromboembolism, twofold; and preeclampsia/gestational hypertension, twofold.

Management

Data are limited regarding nonpharmacological management in pregnancy such as biofeedback techniques, acupuncture, and transcranial magnetic stimulation (Airola, 2010; Dodick, 2010). Effective medications include nonsteroidal antiinflammatory drugs (NSAIDs), and most migraine headaches respond to simple analgesics such as ibuprofen, acetaminophen, or Midrin, especially if given early.

Severe migraines are vexing for the patient and her caregivers. Multitargeted drug therapy is necessary in most cases for migraine relief (Gonzalez-Hernandez, 2014). Headaches are treated aggressively with intravenous hydration and parenteral antiemetics and opioids for immediate pain relief. Although a 2-g infusion of magnesium sulfate has gained favor in the past few years, a metaanalysis reported no benefits (Choi, 2014). Ergotamine derivatives are potent vasoconstrictors and are avoided in pregnancy because of their uterotonic effects (Briggs, 2015).

Triptans are serotonin 5-$HT_{1B/2D}$-receptor agonists that effectively relieve headaches by causing intracranial vasoconstriction (Contag, 2010). They also relieve nausea and vomiting and greatly reduce the need for analgesics. Triptans can be given as an oral tablet, injection, rectal suppository, or intranasal spray. They are best used in combination with NSAIDs (Goadsby, 2015). The greatest experience is with sumatriptan (Imitrex), and although not studied extensively in pregnancy, it appears to be safe (Briggs, 2015; Nezvalová-Henriksen, 2010). However, in one follow-up study at 36 months of children exposed to triptans in pregnancy, Wood and colleagues (2016) found neurodevelopment differences, including emotionality and activity problems.

Some women will benefit from peripheral nerve blocks, and Govindappagari and coworkers (2014) described their experiences with 13 pregnant women. For women with frequent migraine headaches, oral prophylactic therapy is warranted. Amitriptyline (Elavil), 10 to 175 mg daily; propranolol (Inderal), 40 to 120 mg daily; or metoprolol (Lopressor, Toprol), 25 to 100 mg daily, have been used with success (Contag, 2010; Goadsby, 2015; Lucas, 2009).

Cluster Headache

This rare primary headache disorder is characterized by severe unilateral lancinating pain radiating to the face and orbit, lasting 15 to 180 minutes, and occurring with autonomic symptoms and agitation. Pregnancy does not affect symptom severity. Affected women should avoid tobacco and alcohol. Acute management includes 100-percent oxygen therapy and sumatriptan given as a 6-mg dose subcutaneously (VanderPluym, 2016). If recurrent, prophylaxis is administered using a calcium-channel blocking agent.

SEIZURE DISORDERS

The Centers for Disease Control and Prevention reported that the prevalence of epilepsy in adults in 2005 was 1.65 percent—thus over 1 million American women of childbearing age are affected (Kobau, 2008). After headaches, seizures are the next most prevalent neurological condition encountered in pregnancy, and they complicate 1 in 200 births (Brodie, 1996; Yerby, 1994). Importantly, epilepsy accounted for 5 percent of maternal deaths in the United Kingdom for the 2011 to 2013 triennium (Knight, 2015).

Pathophysiology

A seizure is defined as a paroxysmal disorder of the central nervous system characterized by an abnormal neuronal discharge with or without loss of consciousness. Some identifiable causes of convulsive disorders in young adults include head trauma, alcohol- and other drug-induced withdrawals, cerebral infections, brain tumors, biochemical abnormalities, and arteriovenous malformations. A search for these is prudent with a new-onset seizure disorder in a pregnant woman. The diagnosis of idiopathic epilepsy is one of exclusion.

Epilepsy encompasses different syndromes whose cardinal feature is a predisposition to recurrent unprovoked seizures. The International League Against Epilepsy Commission on Classification and Terminology recently updated the following definitions (Fisher, 2014).

Focal Seizures

These originate in one localized brain area and affect a correspondingly localized area of neurological function. They are believed to result from trauma, abscess, tumor, or perinatal factors, although a specific lesion is rarely demonstrated. *Focal seizures without dyscognitive features* start in one region of the body and progress toward other ipsilateral areas of the body, producing tonic and then clonic movements. Simple seizures can affect sensory function or produce autonomic dysfunction or psychological changes. Cognitive function is not impaired, and recovery is rapid. *Focal seizures with dyscognitive features* are often preceded by an aura and followed by impaired awareness manifested by sudden behavioral arrest or motionless stare. Involuntary movements such as picking motions or lip smacking are common.

Generalized Seizures

These involve both brain hemispheres and may be preceded by an aura before an abrupt loss of consciousness. There is a strong hereditary component. In *generalized tonic-clonic seizures*, loss of consciousness is followed by tonic contraction of the muscles and rigid posturing, and then by clonic contractions of all extremities while the muscles gradually relax. Return to consciousness is gradual, and the patient may remain confused and disoriented for several hours. *Absence* seizures—also called *petit mal seizures*—are a form of generalized epilepsy that involve a brief loss of consciousness without muscle activity and are characterized by immediate recovery of consciousness and orientation.

Preconceptional Counseling

Women with epilepsy ideally are counseled before pregnancy and relevant points are presented also in Chapter 8 (Epilepsy). Folic acid supplementation with 0.4 mg per day is begun at least 1 month before conception. The dose is increased to 4 mg when the woman taking antiepileptic medication becomes pregnant. These medications are assessed and adjusted with a goal of monotherapy using the least teratogenic medication. If this is not feasible, then attempts are made to reduce the number of medications used and to use them at the lowest effective dose (Patel, 2016). Medication withdrawal should be considered if a woman is seizure free for 2 years or more.

Epilepsy During Pregnancy

The major pregnancy-related risks to women with epilepsy are fetal malformations and increased seizure rates. Seizure control is the main priority to avoid its attendant morbidity and mortality risks. Early studies described worsening seizure activity during pregnancy, however, this is less so now because of more effective drugs. Contemporary studies cite higher rates of seizure activity in only 20 to 30 percent of pregnant women (Mawer, 2010; Vajda, 2008). Women who are seizure free for at least 9 months before conception will likely remain so during pregnancy (Harden, 2009b).

Greater seizure frequency is often associated with decreased and thus subtherapeutic anticonvulsant serum levels, a lower seizure threshold, or both. An impressive number of pregnancy- associated alterations can result in subtherapeutic serum levels. These include nausea and vomiting, slower gastrointestinal motility, antacid use that diminishes drug absorption, pregnancy hypervolemia offset by protein binding, induction of hepatic enzymes such as cytochrome oxidases, placental enzymes that metabolize drugs, and increased glomerular filtration that hastens drug clearance. Importantly, some women discontinue medication because of teratogenicity concerns. Finally, the seizure threshold can be affected by pregnancy-related sleep deprivation and by hyperventilation and pain during labor.

Pregnancy Complications

Women with epilepsy have a small increased risk of pregnancy complications that include spontaneous abortion, hemorrhage, hypertensive disorders, preterm birth, fetal-growth restriction, and cesarean delivery (Harden, 2009b; Viale, 2015). Importantly, MacDonald (2015) also reports a tenfold higher maternal death rate, and, as mentioned earlier, epilepsy accounted for 5 percent of maternal deaths in the United Kingdom. Postpartum depression rates are also reportedly higher in epileptic women (Turner, 2009). Finally, children of epileptic mothers have a 10-percent risk of developing a seizure disorder.

Embryofetal Malformations

For years, it was difficult to separate effects of epilepsy from those of its therapy as the primary cause of fetal malformations. As discussed in Chapter 8 (Epilepsy), it is now believed that untreated epilepsy is not associated with an elevated fetal malformation rate (Thomas, 2008). That said, the fetus of an epileptic mother who takes certain anticonvulsant medications has an indisputably greater risk for congenital malformations. Moreover, monotherapy is associated with a lower birth defect rate compared with multiagent therapy. Thus, if necessary, increasing monotherapy dosage is at least initially preferable to adding another agent (Buhimschi, 2009).

Specific drugs, when given alone, increase the malformation rate (Chap. 12, Antiepileptic Medications). Some of these are listed in Table 60-2. Phenytoin and phenobarbital increase the major malformation rate two- to threefold above baseline (Perucca, 2005; Thomas, 2008). Valproate is a particularly potent teratogen, which has a dose-dependent effect and raises the malformation risk four- to eightfold (Eadie, 2008; Klein, 2014; Wyszynski, 2005). Valproate is also associated with

lower cognitive performance (Kasradze, 2017). In general, with polytherapy, the risk rises with each drug added. A metaanalysis of 31 studies found lamotrigine and levetiracetam to carry the lowest risk of malformations (Weston, 2016).

TABLE 60-2

Teratogenic Effects of Common Anticonvulsant Medications

Drug (Brand Name)	Abnormalities Described	Affected	Embryofetal Risks[a]
Valproate (Depakote)	Neural-tube defects, clefts, cardiac anomalies; associated developmental delay	10% with monotherapy; higher with polytherapy	Yes
Phenytoin (Dilantin)	Fetal hydantoin syndrome—craniofacial anomalies, fingernail hypoplasia, growth deficiency, developmental delay, cardiac anomalies, clefts	5–11%	Yes
Carbamazepine; oxcarbazepine (Tegretol; Trileptal)	Fetal hydantoin syndrome, as above; spina bifida	1–2%	Yes
Phenobarbital	Clefts, cardiac anomalies, urinary tract malformations	10–20%	Suggested
Lamotrigine (Lamictal)	Increased risk for clefts (Registry data)	Up to 1% (4- to 10-fold higher than expected)	Suggested
Topiramate (Topamax)	Clefts	2–3% (15- to 20-fold higher than expected)	Suggested
Levetiracetam (Keppra)	Theoretical—skeletal abnormalities; impaired growth in animals	Preliminary observations	Suggested

[a]Risk categories from Briggs, 2015; Food and Drug Administration, 2011; Harden, 2009b; Holmes, 2008; Hunt, 2008.

Management in Pregnancy

The American Academy of Neurology and the American Epilepsy Society have guidelines regarding treatment in pregnant women (Harden, 2009a–c). The major goal is seizure prevention. To accomplish this, treatment for nausea and vomiting is provided, seizure-provoking stimuli are avoided, and medication compliance is emphasized. The fewest necessary anticonvulsants are given at the lowest dosage effective for seizure control. Although some providers routinely monitor serum drug levels, these concentrations may be unreliable because of altered protein binding. Free or unbound drug levels, although perhaps more accurate, are not widely available. Importantly, there is no evidence that such monitoring improves seizure control (Adab, 2006). For these reasons, drug levels may be most informative if measured following seizures or if noncompliance is suspected.

For women taking anticonvulsant drugs, a targeted sonographic examination at midpregnancy is recommended by some to search for anomalies. Testing to assess fetal well-being is generally not indicated for women with uncomplicated epilepsy.

For women desiring to breastfeed, data regarding the safety of the various anticonvulsant medications are limited. That said, no obvious deleterious effects, such as long-term cognitive issues, have been reported (Briggs, 2015; Harden, 2009c). Of birth control methods, oral contraceptive pill failure rates are higher with some of the anticonvulsant agents, especially lamotrigine. Thus, other more reliable methods should be considered (Chap. 38, Introduction).

CEREBROVASCULAR DISEASES

Abnormalities of the cerebrovascular circulation include strokes—both ischemic and hemorrhagic, as well as anatomical anomalies, such as arteriovenous malformations and aneurysms. Cerebral ischemia is caused by reduction in blood flow that lasts longer than several seconds. Early, neurological symptoms may manifest. After a few minutes, however, infarction often follows. Hemorrhagic stroke is caused by bleeding directly into or around the brain. It produces symptoms by its mass effect, by toxic effects of blood, or by increasing intracranial pressure. Of strokes in pregnant women, roughly half are ischemic and the other half hemorrhagic (Zofkie, 2018).

The current obesity endemic in this country, along with concomitant increases in rates of heart disease, hypertension, and diabetes, has increased the prevalence of strokes (Centers for Disease Control and Prevention, 2012). Women have higher lifetime risk of stroke than men and greater associated mortality rates (Martínez-Sánchez, 2011; Roger, 2012). Moreover, pregnancy increases the immediate and lifetime risk of both ischemic and hemorrhagic stroke (Jamieson, 2010; Jung, 2010).

Stroke is relatively uncommon in pregnant women, occurring in 10 to 40 per 100,000 births, but it contributes disparately to maternal mortality rates (Leffert, 2016; Miller, 2016; Yoshida, 2017). The incidence is rising as measured by pregnancy-related hospitalizations for stroke (Callaghan, 2008; Kuklina, 2011). Importantly, most

are associated with hypertensive disorders or heart disease. Of the pregnancy-related mortality rate in the United States, 6.6 percent is due to cerebrovascular accidents, and 7.4 percent is associated with preeclampsia (Creanga, 2017). Of maternal deaths after 42 days postpartum, 9.8 percent were attributable to cerebrovascular accidents.

Risk Factors

Most strokes in pregnancy manifest either during labor and delivery or in the puerperium. In a study of 2850 pregnancy-related strokes, approximately 10 percent developed antepartum, 40 percent intrapartum, and almost 50 percent postpartum (James, 2005). In contrast, Leffert (2016) reports a timing of 45 percent antepartum, 3 percent intrapartum, and 53 percent postpartum in 145 women. Several risk factors—unrelated and related to pregnancy—have been reported from studies that included more than 10 million pregnancies. These include age; migraines, hypertension, obesity, and diabetes; cardiac disorders such as endocarditis, valvular prostheses, and patent foramen ovale; and smoking. Those related to pregnancy include hypertensive disorders, gestational diabetes, obstetrical hemorrhage, and cesarean delivery. *By far, the most common risk factors are pregnancy-associated hypertensive disorders.* A third of strokes are associated with gestational hypertension, and hypertensive women compared with normotensive counterparts have a three- to eightfold greater risk of stroke (Scott, 2012; Wang, 2011). Women with preeclampsia undergoing general anesthesia may be at higher risk of stroke compared with those given neuraxial anesthesia (Huang, 2010). Another risk factor for peripartum stroke is cesarean delivery, which raises the risk 1.5-fold compared with vaginal delivery (Lin, 2008).

Pregnancy-induced effects on cerebrovascular hemodynamics include enhanced autoregulation that maintains blood flow despite changes in systemic blood pressure (van Teen, 2016). Although cerebral blood flow *decreases* by 20 percent from midpregnancy until term, it *increases* significantly with gestational hypertension (Zeeman, 2003, 2004b). Such hyperperfusion at least intuitively would be dangerous for women with certain vascular anomalies.

Ischemic Stroke

Acute occlusion or embolization of an intracranial blood vessel causes cerebral ischemia, which may result in death of brain tissue (Fig. 60-2). The more common associated conditions and etiologies of ischemic stroke are shown in Table 60-3. A *transient ischemic attack (TIA)* is caused by reversible ischemia, and symptoms usually last less than 24 hours. Approximately 10 percent of these patients have a stroke by 1 year (Amarenco, 2016). Patients with a stroke usually have a sudden onset of severe headache, hemiplegia or other neurological deficits, or occasionally seizures. In contrast, focal neurological symptoms accompanied by an aura usually signify a first-episode migraine (Liberman, 2008).

TABLE 60-3

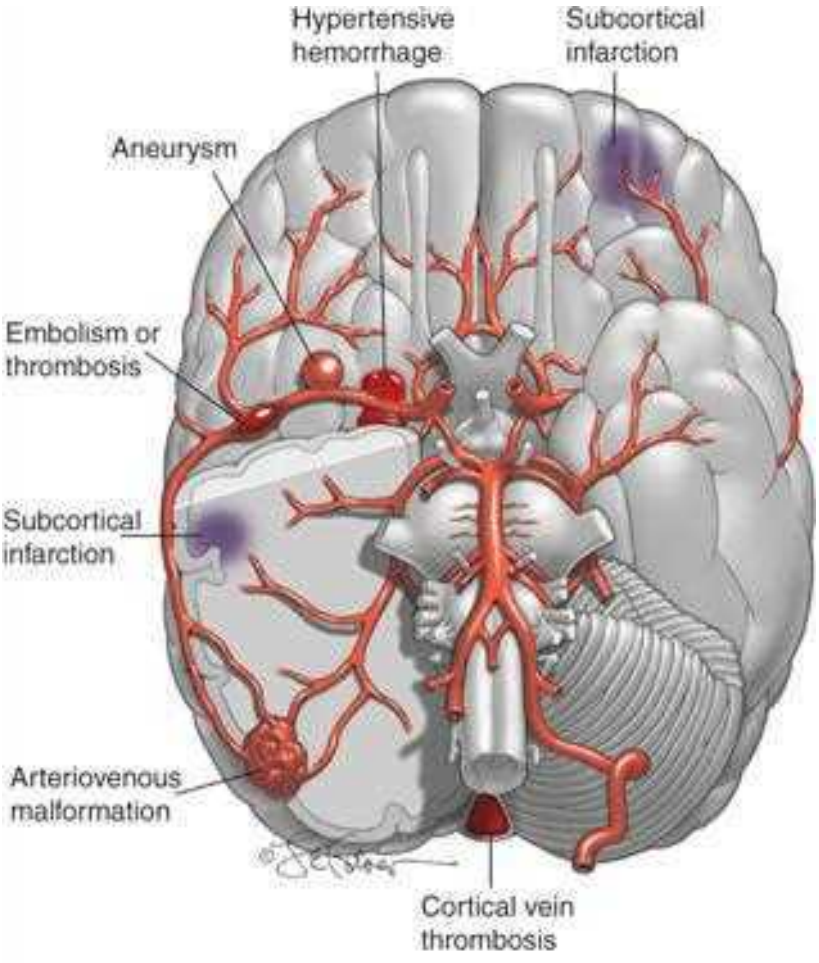
Some Associated Disorders or Causes of Ischemic and Hemorrhagic Strokes During Pregnancy or the Puerperium

Ischemic Stroke	Hemorrhagic Stroke
Preeclampsia syndrome	Chronic hypertension
Arterial thrombosis	Preeclampsia syndrome
Venous thrombosis	Arteriovenous malformation
Lupus anticoagulant	Saccular aneurysm
Antiphospholipid antibodies	Angioma
Thrombophilias	Cocaine, methamphetamines
Migraine induced	Vasculopathy
Paradoxical embolus	
Cardioembolic	
Sickle hemoglobinopathy	
Arterial dissection	
Vasculitis	
Moyamoya disease	
Cocaine, amphetamines	

From Smith, 2015; Yager, 2012.

FIGURE 60-2

Illustrations of a brain showing various types of strokes seen in pregnancy: (1) subcortical infarction (preeclampsia), (2) hypertensive hemorrhage, (3) aneurysm, (4) embolism or thrombosis in middle cerebral artery, (5) arteriovenous malformation, and (6) cortical vein thrombosis.



Evaluation of an ischemic stroke includes echocardiography and cranial imaging with CT, MR, or angiography. Serum lipids are measured with the caveat that their values are distorted by normal pregnancy (Appendix, Serum and Blood Constituents). Tests to detect antiphospholipid antibodies and lupus anticoagulant are performed. These underlie up to a third of ischemic strokes in otherwise healthy young women (Chap. 59, Antiphospholipid Syndrome). Also, sickle-cell syndromes are evaluated when indicated (Buonanno, 2016).

With a thorough evaluation, most causes of embolism can be identified, although treatment is not always available. Some of these include cardiac- associated embolism, vasculitis, or vasculopathy such as Moyamoya disease (Ishimori, 2006; Miyakoshi, 2009; Simolke, 1991). Outcomes of embolic strokes were reported to be favorable and similar to those of nonpregnant women (Leffert, 2016). Thrombolysis for ischemic stroke during pregnancy has been reported (Tversky, 2016).

Preeclampsia Syndrome

In reproductive-age women, a significant proportion of pregnancy-related ischemic strokes are caused by gestational hypertension and preeclampsia (Jeng, 2004; Miller, 2016). As shown in Figure 60-2, areas of subcortical perivascular edema and petechial hemorrhage may progress to cerebral infarction (Aukes, 2007, 2009; Zeeman, 2004a). Although these are usually clinically manifest by an eclamptic convulsion, a few women will suffer a symptomatic stroke from a larger cortical infarction (Chap. 40, Eclampsia).

Other conditions with findings similar to preeclampsia include *thrombotic microangiopathies* (Chap. 56, Thrombotic Microangiopathies) and the *reversible cerebral vasoconstriction syndrome* (Chap. 40, Long-Term Consequences). The latter, also termed *postpartum angiopathy,* can cause extensive cerebral edema with necrosis and widespread infarction with areas of hemorrhage (Edlow, 2013; Katz, 2014; Miller, 2016).

Cerebral Embolism

These strokes usually involve the middle cerebral artery (see Fig. 60-2). The diagnosis can be made with confidence only after thrombosis and hemorrhage have been excluded and is more certain if an embolic source is identified. Hemorrhage may be more difficult to exclude because embolization and thrombosis are both followed by hemorrhagic infarction. Paradoxical embolism is an uncommon cause, even considering that more than a fourth of adults have a patent foramen ovale through which right-sided venous thromboemboli are deported (Scott, 2012). Foraminal closure may not improve outcomes in these patients, however, this

procedure has been performed during pregnancy (Dark, 2011). Assorted cardioembolic causes of stroke include arrhythmias—especially atrial fibrillation, valvular lesions, mitral valve prolapse, mural thrombus, infective endocarditis, and peripartum cardiomyopathy.

Management of embolic stroke in pregnancy consists of supportive measures and antiplatelet therapy. Thrombolytic therapy and anticoagulation in pregnancy are controversial issues (Li, 2012).

Cerebral Artery Thrombosis

Most thrombotic strokes affect older individuals and are caused by atherosclerosis, especially of the internal carotid artery. Many are preceded by one or more TIAs. Thrombolytic therapy with a *recombinant tissue plasminogen activator (rt-PA)* is recommended. *Alteplase* is one of these and given within the first 3-hour window if there is measurable neurological deficit and if neuroimaging has excluded hemorrhage. This recombinant enzyme can be used in pregnancy. A principal risk is hemorrhagic transformation of an ischemic stroke in 3 to 5 percent of treated patients (Smith, 2015; van der Worp, 2007).

Cerebral Venous Thrombosis

In one study in the United States, 7 percent of cerebral venous thromboses were associated with pregnancy (Wasay, 2008). But, in the Nationwide Inpatient Sample of more than 8 million deliveries, James and associates (2005) reported that venous thrombosis caused only 2 percent of pregnancy-related strokes (Saposnik, 2011). There are numerous predisposing causes, and for gravidas, late pregnancy and the puerperium are times of greatest risk.

Thrombosis of the lateral or superior sagittal venous sinus usually occurs in the puerperium and often in association with preeclampsia, sepsis, or thrombophilia (see Fig. 60-2). It is more common in patients with inherited thrombophilias or antiphospholipid antibodies (Chaps. 52, Inherited Thrombophilias and 59, Antiphospholipid Syndrome). Headache is the most frequent presenting symptom, neurological deficits are common, and up to a third of patients have convulsions (Wasay, 2008). The diagnosis is made using MR venography (Saposnik, 2011).

Management includes anticonvulsants for seizures, and although heparinization is recommended by most, its efficacy is controversial (Saposnik, 2011; Smith, 2015). Antimicrobials are given if there is septic thrombophlebitis, and fibrinolytic therapy is reserved for those women failing systemic anticoagulation. The acute prognosis for venous thrombosis in pregnant women is better than in nonpregnant subjects, and mortality rates are less than 10 percent (McCaulley, 2011).

In women with a prior cerebral venous thrombosis, one systematic review found only one recurrence in 217 pregnancies and five noncerebral venous thrombotic events in 186 pregnancies (Aguiar de Sousa, 2016). In a study of 52 women on prophylactic anticoagulation with prior cerebral venous thrombosis, there were no cases of recurrent thrombosis or bleeding, however 24 percent had late obstetrical complications (Martinelli, 2016).

Recurrence Risk of Ischemic Stroke

Women with prior ischemic stroke have a low risk for recurrence during a subsequent pregnancy unless a specific, persistent cause is identified. During a 5-year follow-up of 373 women with arterial ischemic strokes, there were 187 pregnancies in 125 women. Thirteen women had a recurrent ischemic stroke, and of these, only two were associated with pregnancy. The authors concluded that the risk of stroke recurrence is low and a previous ischemic stroke is not a contraindication to pregnancy (Lamy, 2000). In one study of 1770 nonpregnant women with antiphospholipid-related ischemic stroke, investigators reported no difference in the recurrence risk as long as preventative treatment was given with warfarin or aspirin (Levine, 2004).

Currently, no firm guidelines define prophylaxis in pregnant women with a stroke history (Helms, 2009). The American Heart Association stresses the importance of controlling risk factors such as hypertension and diabetes (Furie, 2011). Women with antiphospholipid syndrome or certain cardiac conditions should be considered for prophylactic anticoagulation as discussed in Chapter 49 (Surgically Corrected Heart Disease) and 52 (Acquired Thrombophilias).

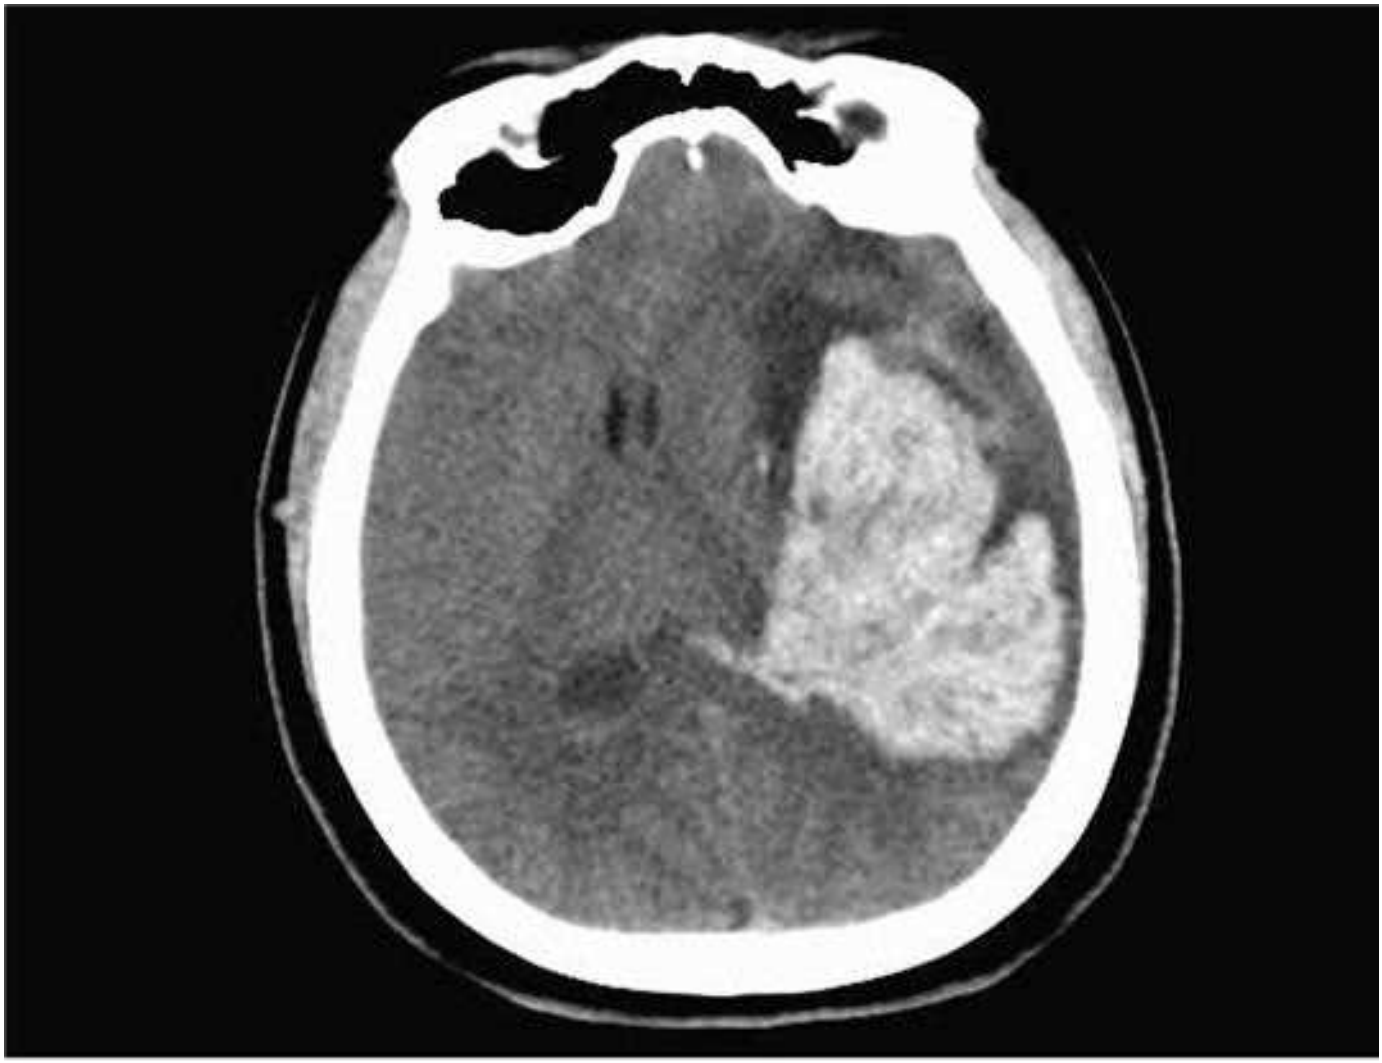
Hemorrhagic Stroke

The two distinct categories of spontaneous intracranial bleeding are intracerebral and subarachnoid hemorrhage. The symptoms of a hemorrhagic stroke are similar to those of an ischemic stroke, and their differentiation is only possible with CT or MR imaging (Morgenstern, 2010; Smith, 2015).

Intracerebral Hemorrhage

Bleeding into the brain parenchyma most often is caused by spontaneous rupture of small vessels previously damaged by chronic hypertension (see Fig. 60-2). Thus, pregnancy-associated hemorrhagic strokes such as the one shown in Figure 60-3 are often associated with chronic hypertension and superimposed preeclampsia (Cunningham, 2005; Martin, 2005). Because of its location, this type of hemorrhage has much higher morbidity and mortality rates than does subarachnoid hemorrhage (Smith, 2015). Pressure-induced rupture causes bleeding into the putamen, thalamus, adjacent white matter, pons, and cerebellum. In the 28 women described by Martin and associates (2005), half died and most survivors had permanent disabilities. This cautions for the importance of proper management for gestational hypertension—especially systolic hypertension—to prevent cerebrovascular pathology (Chap. 40, Management Considerations).

FIGURE 60-3
A 37-year-old gravida with intrapartum eclampsia at term. A noncontrast computed tomography axial head image demonstrates a large intraparenchymal hemorrhage.



Subarachnoid Hemorrhage

In a study of 639 cases of pregnancy-related subarachnoid hemorrhage from the Nationwide Inpatient Sample, the incidence was 5.8 per 100,000 pregnancies, with half occurring postpartum (Bateman, 2012). A remarkably similar incidence was reported in Japanese women (Yoshida, 2017). These bleeds are more likely caused by an underlying cerebrovascular malformation in an otherwise normal patient (see Fig. 60-2). Ruptured saccular or "berry" aneurysms cause 80 percent of all subarachnoid hemorrhages. The remaining cases are caused by a ruptured arteriovenous malformation, coagulopathy, angiopathy, venous thrombosis, infection, drug abuse, tumors, or trauma. Such cases are uncommon, and a ruptured aneurysm or angioma or bleeding from a vascular malformation has an incidence of 1 in 75,000 pregnancies. Although this frequency is not different from that in the general population, the mortality rate during pregnancy is reported to be as high as 35 percent (Yoshida, 2017).

Intracranial Aneurysm.

Approximately 1 to 2 percent of adults have this lesion (Lawton, 2017). Fortunately, only a small percentage rupture. The rate approximates 0.1 percent for aneurysms <10 mm and 1 percent for those >10 mm (Smith, 2015). Most aneurysms identified during pregnancy arise from the circle of Willis, and in 20 percent of case, there are multiple lesions. Pregnancy does not raise the risk for aneurysmal rupture. However, because of their high prevalence, they are more likely to cause subarachnoid bleeding than other etiologies (Hirsch, 2009; Tiel Groenestege, 2009). A systematic review of 44 women with 50 aneurysms in pregnancy reported that 72 percent ruptured during pregnancy, and 78 percent of these did so during the third trimester (Barbarite, 2016). This proclivity for rupture late in pregnancy was also reported by Yoshida and colleagues (2017).

The cardinal symptom of a subarachnoid hemorrhage from an aneurysm rupture is sudden severe headache that is accompanied by visual changes, cranial nerve abnormalities, focal neurological deficits, and altered consciousness. Patients typically have signs of meningeal irritation, nausea and vomiting, tachycardia, transient hypertension, low-grade fever, leukocytosis, and proteinuria. Prompt diagnosis and treatment may prevent potentially lethal complications. The American Heart Association recommends noncontrast cranial CT imaging as the first diagnostic test, although MR imaging may be superior (Connolly, 2012; Smith, 2015).

Treatment of subarachnoid hemorrhage includes bed rest, analgesia, and sedation, with neurological monitoring and strict blood pressure control. Repair of a potentially accessible aneurysm during pregnancy depends in part on the risk of recurrent hemorrhage versus the surgical risks. At least in nonpregnant patients, the risk of subsequent bleeding with conservative treatment is 20 to 30 percent for the first month and then 3 percent per year. The risk of rebleeding is highest within the first 24 hours, and recurrent hemorrhage leads to death in 70 percent.

Early repair after the sentinel hemorrhage is done by surgical clipping of the aneurysm. Also, an endovascular coil can be placed using fluoroscopic angiography, while attempting to limit fetal radiation exposure. Barbarite and colleagues (2016) report lower complication rates with coil embolization than clipping. For unruptured aneurysms, surgical management resulted in a third fewer complications than no treatment. For gravidas remote from term, repair without hypotensive anesthesia seems optimal. For women near term, cesarean delivery followed by aneurysm repair is a consideration, and we have successfully done this in several cases.

For aneurysms repaired either before or during pregnancy, most allow vaginal delivery if labor ensues remote from aneurysmal repair. Problems arise in defining "remote," and although some recommend 2 months, the time for complete healing is unknown. For women who survive subarachnoid hemorrhage, but in whom surgical repair is not done, we agree with Cartlidge (2000) and recommend against bearing down—put another way, we favor cesarean delivery.

Arteriovenous Malformations.

These are congenital focal abnormal conglomerations of dilated arteries and veins with subarteriolar disorganization (see Fig. 60-2). They lack capillaries and have resultant arteriovenous shunting. Although unclear, the risk of bleeding may rise with gestational age. When arteriovenous malformations (AVMs) bleed, half do so into the subarachnoid space, whereas half are intraparenchymal with subarachnoid extension (Smith, 2015). They are uncommon and are estimated to occur in 0.01 percent of the general population. Of 65 identified cases of AVM in pregnancy, 83 percent ruptured during pregnancy or postpartum, and more than 80 percent of these ruptured in the second or third trimester. Hemorrhage upon presentation is associated with poor maternal outcome (Lu, 2016).

Bleeding does not appear to be more likely during pregnancy. Although these malformations are correspondingly rare during pregnancy, AVM bleeding accounted for 17 percent of hemorrhagic strokes in one study (Yoshida, 2017). At Parkland Hospital in a 33-year period during which there were about 466,000 births, 57 women had a CVA, and five of these strokes were due to a bleeding AVM (Simolkie, 1991; Zofkie, 2018).

Treatment of AVMs in nonpregnant patients is largely individualized. No consensus guides whether all accessible lesions should be resected. Factors include AVM symptoms; its anatomy and size; presence of an associated aneurysm, which is found in up to 60 percent of cases; and especially, prior AVM bleeding. After hemorrhage, the risk of recurrent bleeding in unrepaired lesions is 6 to 20 percent within the first year, and 2 to 4 percent per year thereafter (Friedlander, 2007; Smith, 2015). The mortality rate with a bleeding AVM is 10 to 20 percent. In pregnancy, the decision to operate is usually based on neurosurgical considerations, and Friedlander (2007) recommends strong consideration for treatment if bleeding occurs. Because of the high risk of recurrent hemorrhage from an unresected or inoperable lesion, we favor cesarean delivery.

DEMYELINATING OR DEGENERATIVE DISEASES

The *demyelinating diseases* are neurological disorders characterized by immune-mediated focal or patchy destruction of myelin sheaths accompanied by an inflammatory response. The *degenerative diseases* are multifactorial and are characterized by progressive neuronal death.

Multiple Sclerosis

In the United States, multiple sclerosis (MS) is second only to trauma as a cause of neurological disability in middle adulthood (Hauser, 2015b). The disease affects women twice as often as men, and it usually begins in the 20s and 30s. The familial recurrence rate of MS is 15 percent, and the incidence in offspring is increased 15-fold. Studying California deliveries, Fong and colleagues (2018) reported that 0.03 percent of deliveries were complicated by MS between 2001 and 2009.

The demyelinating characteristic of this disorder results predominately from T cell-mediated autoimmune destruction of oligodendrocytes that synthesize myelin. There is a genetic susceptibility and likely an environmental trigger such as exposure to certain bacteria and viruses. Of these, *Chlamydophila pneumoniae,* human herpesvirus 6, or Epstein-Barr virus are implicated (Frohman, 2006; Goodin, 2009).

There are four clinical types of MS:

1. *Relapsing-remitting MS* accounts for initial presentation in 85 percent of affected individuals. With it, unpredictable recurrent episodes of focal or multifocal neurological dysfunction usually are followed by full recovery. Over time, however, relapses lead to persistent deficits.
2. *Secondary progressive MS* disease is relapsing-remitting disease that begins to pursue a progressive downhill course after each relapse. All patients likely develop this type eventually.
3. *Primary progressive MS* accounts for 15 percent of cases. With it, disability gradually progresses from the time of initial diagnosis.
4. *Progressive-relapsing MS* refers to primary progressive MS with apparent relapses.

Classic findings of MS include sensory loss, visual symptoms from optic neuritis, weakness, paresthesias, and a host of other neurological symptoms. Almost 75 percent of women with isolated optic neuritis develop MS within 15 years. Clinical diagnosis is confirmed by MR imaging and cerebrospinal fluid analysis. In greater than 95 percent of cases, MR imaging shows characteristic multifocal white matter plaques that represent discrete areas of demyelination (Fig. 60-4). Their appearance and extent are less helpful for predicting treatment response. Similarly, identification of serum antibodies against myelin oligodendrocyte glycoprotein and myelin basic protein is not predictive of recurrent disease activity (Kuhle, 2007).

FIGURE 60-4

Magnetic resonance cranial images from a woman with multiple sclerosis. **A.** T2-weighted axial image shows bright signal abnormalities in white matter, typical for multiple sclerosis. **B.** Sagittal T2-FLAIR image shows hyperintense areas within the corpus callosum that are representative of demyelination in multiple sclerosis. Effects of Pregnancy

The *PR*egnancy *I*n *M*ultiple *S*clerosis—*PRIMS*—study was a European prospective multicenter study in which 254 pregnancies were described (Vukusic, 2006). Relapse risk was reduced 70 percent during pregnancy, but with a significantly greater relapse rate postpartum. This may be related to higher pregnancy-induced numbers of T-helper lymphocytes and an increased T2/T1 ratio (Airas, 2008). In a metaanalysis of women with more than 1200 pregnancies complicated by MS, their relapse rate was 0.4 per year before pregnancy; 0.26 per year during pregnancy; and this increased to 0.7 per year after delivery (Finkelsztejn, 2011). Bove and associates (2014) reached similar conclusions after a systematic review. Factors associated with postpartum relapse include a high relapse rate before pregnancy, relapses during pregnancy, and a high MS disability score (Portaccio, 2014; Vukusic, 2006). Breastfeeding has no apparent effect on postpartum relapses (Hellwig, 2015; Portaccio, 2011).

Effects of Multiple Sclerosis on Pregnancy

With uncomplicated disease, there are usually no adverse effects on pregnancy outcome (Bove, 2014). Some women may become fatigued more easily, those with bladder dysfunction are predisposed to urinary infection, and women with spinal lesions at or above T_6 are at risk for autonomic dysreflexia. In one study of 449 pregnancies in affected women, the labor induction rate was higher, and second-stage labor was longer (Dahl, 2006). The greater induction rate and elective operations contributed to the overall higher cesarean delivery rate. In an analysis of 649 affected women, the mean birthweight was lower but the perinatal mortality rate was similar compared with that of controls (Dahl, 2005). Other studies have corroborated that MS does not significantly affect obstetrical and neonatal outcomes (Finkelsztejn, 2011; Fong, 2018).

Management in Pregnancy

Goals are to arrest acute or initial attacks, employ disease-modifying agents, and provide symptomatic relief. Some treatments may need to be modified during pregnancy. Acute or initial attacks are treated with high-dose intravenous methylprednisolone—500 to 1000 mg daily for 3 to 5 days, followed by oral prednisone for 2 weeks. Plasma exchange may be considered. Symptomatic relief can be provided by analgesics; carbamazepine, phenytoin, or amitriptyline for neurogenic pain; baclofen for spasticity; α_2-adrenergic blockade for bladder neck relaxation; and cholinergic and anticholinergic drugs to stimulate or inhibit bladder contractions.

Several disease-modifying therapies can be used for relapsing MS or for exacerbations. Examples include interferons β1a (Rebif), β1b (Betaseron), and glatiramer acetate (Copaxone), which lower relapse rates by a third (Rudick, 2011). Data concerning safety in pregnancy are limited but overall reassuring (Amato, 2010; Salminen, 2010). In clinical trials, natalizumab (Tysabri), an α_4-integrin antagonist, especially when combined with interferon β1a, significantly reduced MS clinical relapse rates (Polman, 2006; Rudick, 2006). In a review of 35 pregnancies, first-trimester drug exposure did not worsen outcomes (Hellwig, 2011). If these drugs are used in pregnancy, the neonate should be monitored for thrombocytopenia and anemia (Alroughani, 2016).

Fetal exposure in 89 pregnancies to fingolimod (Gilenya), another immune-modulating drug, was associated with six fetal malformations and nine spontaneous losses. Because of this and associated animal teratogenicity, its use in pregnancy is not recommended. Due to its prolonged persistence, contraception is recommended for 2 months after drug cessation (Alroughani, 2016; Karlsson, 2014).

Prevention of relapses postpartum is afforded by treatment with intravenous immunoglobulin (IVIG), given in a dose of 0.4 g/kg daily for 5 days during weeks 1, 6, and 12 (Argyriou, 2008).

Huntington Disease

This adult-onset neurodegenerative disease stems from an autosomal dominant expanded CAG trinucleotide repeat within the Huntington gene on chromosome 4. It is characterized by choreoathetotic movements, progressive dementia, and psychiatric manifestations. Because the mean age of onset is 40 years, Huntington

disease rarely complicates pregnancy. Prenatal diagnosis is discussed in Chapter 14 (Carrier Screening for Genetic Disorders). Prenatal screening is controversial, and because this usually is a late-onset adult disease, extensive counseling is important (Schulman, 2015).

Myasthenia Gravis

This autoimmune-mediated neuromuscular disorder affects approximately 1 in 7500 persons. It is more common in women, and its incidence peaks in their 20s and 30s. The etiology is unknown, but genetic factors likely play a role. Most patients demonstrate antibodies to the acetylcholine receptor, although 10 to 20 percent are seronegative (Drachman, 2015). The latter often have antibodies to muscle-specific tyrosine kinase (MuSK), which regulates assembly of the acetylcholine receptor subunits at the neuromuscular junction (Pal, 2011).

Cardinal features of myasthenia are weakness and easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. Deep tendon reflexes are preserved. Cranial muscles are involved early and disparately, and diplopia and ptosis are common. Facial muscle weakness causes difficulty in smiling, chewing, and speaking. In 85 percent of patients, the weakness becomes generalized. Other autoimmune diseases may coexist, and hypothyroidism should be excluded. The clinical course is marked by exacerbations and remissions, especially when it first becomes clinically apparent. Remissions are not always complete and are seldom permanent. Systemic diseases, concurrent infections, and even emotional upset may precipitate exacerbations, of which there are three types:

1. *Myasthenic crises*—characterized by severe muscle weakness, inability to swallow, and respiratory muscle paralysis.
2. *Refractory crises*—characterized by the same symptoms but unresponsive to the usual therapy.
3. *Cholinergic crises*—excessive cholinergic medication leads to nausea, vomiting, muscle weakness, abdominal pain, and diarrhea.

All three of these can be life threatening, but a refractory crisis is a medical emergency. Those with bulbar myasthenia are at particular risk because they may be unable to swallow or even ask for help.

Management

Myasthenia is manageable but not curable. Oral pyridostigmine is the first-line treatment. Thymectomy is recommended but postponed until after pregnancy (Sanders, 2016). Anticholinesterase medications improve symptoms by impeding acetylcholine degradation but seldom produce normal muscle function. Ironically, overdose is manifest by increased weakness—*cholinergic crisis*—that may be difficult to differentiate from myasthenic symptoms. Most of those refractory to anticholinesterase therapy respond to immunosuppressive therapy with glucocorticoids, azathioprine, or cyclosporine in pregnancy. When short-term, rapid clinical improvement is needed—such as for a surgical procedure or a myasthenic crisis—high-dose IVIG or plasma exchange is usually effective (Barth, 2011; Cortese, 2011; Sanders, 2016).

Myasthenia and Pregnancy

Because the greatest period of risk is within the first year following diagnosis, postponing pregnancy until there is sustained improvement is reasonable. Antepartum management of myasthenia includes close observation with liberal rest and prompt treatment of infections (Heaney, 2010; Kalidindi, 2007). Women in remission who become pregnant while taking corticosteroids or azathioprine should continue these. Thymectomy has been successfully performed during pregnancy in refractory cases (Ip, 1986). Acute onset of myasthenia or its exacerbation demands prompt hospitalization and supportive care. Plasmapheresis and high-dose IVIG are options for emergency situations (Drachman, 2015).

Although pregnancy does not appear to affect the overall course of myasthenia, fatigue common to most pregnancies may be exacerbated, and the expanding uterus may compromise respiration. Maternal hypotension or hypovolemia are ideally avoided as they can trigger crises. The clinical course of myasthenia during pregnancy is unpredictable, and frequent hospitalizations are the norm. Up to a third of women have worsening myasthenia during pregnancy, and exacerbations occur equally in all three trimesters (Djelmis, 2002; Podciechowski, 2005). In women with stable disease, most will remain stable throughout pregnancy but likely worsen in the first few months postpartum (Sanders, 2016).

Myasthenia gravis has no significant adverse effects on pregnancy outcomes (Wen, 2009). Preeclampsia is a concern because magnesium sulfate may precipitate a severe myasthenic crisis (Hamaoui, 2009; Heaney, 2010). Although phenytoin use is also problematic in this regard, its adverse effects are less troublesome. Thus, many choose it for neuroprophylaxis in women with severe preeclampsia.

Because smooth muscle is unaffected, most women have normal labor. Oxytocin is given for the usual indications, and cesarean delivery is reserved for obstetrical indications. Narcotics may cause respiratory depression, and close observation and respiratory support are essential during labor and delivery. Curariform drugs are avoided—examples include magnesium sulfate discussed above, muscle relaxants used with general anesthesia, and aminoglycosides. Neuraxial analgesia is accomplished with amide-type local agents. Regional analgesia is preferred unless there is significant bulbar involvement or respiratory compromise (Almeida, 2010; Blichfeldt-Lauridsen, 2012). During second-stage labor, some women may have impaired voluntary expulsive efforts that may warrant operative vaginal delivery.

Neonatal Effects

As discussed above, 80 percent of mothers with myasthenia gravis have anti-acetylcholine-receptor immunoglobulin G (IgG) antibodies. These and anti-MuSK antibodies cross transplacentally, and the fetus can be affected. Poor fetal swallowing may yield hydramnios (Heaney, 2010). Similarly, 10 to 20 percent of neonates manifest myasthenia symptoms (Jovandaric, 2016). Transient symptoms usually include a feeble cry, poor suckling, and respiratory distress. Symptoms usually respond to cholinesterase inhibitors and resolve within a few weeks as maternal IgG antibodies clear.

NEUROPATHIES

Peripheral neuropathy is a general term used to describe disorders of peripheral nerve(s) from various sources. *Polyneuropathies* can be axonal or demyelinating as well as acute, subacute, or chronic (Amato, 2015). These are often associated with systemic diseases such as diabetes, with drug or environmental toxin exposure, or with genetic disease.

Mononeuropathies are relatively common in pregnancy and signify focal involvement of a single nerve trunk. These imply local causation such as trauma, compression, or entrapment. Traumatic pudendal, obturator, femoral, and common fibular mononeuropathies are usually caused by childbirth and are discussed in Chapter 36 (Pain, Mood, and Cognition).

Guillain-Barré Syndrome

In 75 percent of cases, this acute demyelinating polyradiculoneuropathy has clinical or serological evidence for an acute infection. Commonly associated are infections with *Campylobacter jejuni*, cytomegalovirus, Zika virus, and Epstein-Barr virus; surgical procedures; and immunizations (Haber, 2009; Hauser, 2015a; Pacheco, 2016). Guillain-Barré syndrome is thought to be immune-mediated from antibodies formed against nonself antigens. Demyelination causes sensory and motor conduction blockade, and remyelination yields recovery in most cases.

Clinical features include areflexic paralysis—usually ascending—with or without sensory disturbances. Autonomic dysfunction is common. The full syndrome develops over 1 to 3 weeks. Some manifest as *chronic inflammatory demyelinating polyneuropathy,* and our experiences indicate that this may be relatively common in these young women.

Guillain-Barré syndrome is not more common in pregnancy, and its clinical course mirrors that for nonpregnant individuals. After an insidious onset, paresis and paralysis most often continue to ascend to cause ventilatory weakness. Management is supportive and incorporates venous thromboembolism prophylaxis, pressure ulcer prevention, and enteral nutrition. In the worsening phase, patients are hospitalized, and a fourth requires ventilatory assistance. IVIG or plasmapheresis is beneficial if begun within 1 to 2 weeks of motor symptoms, however, neither decreases mortality rates (Cortese, 2011; Gwathmey, 2011; Pritchard, 2016). Up to 10 percent of patients deteriorate after initial improvement on therapy, and retreatment with 2 g/kg IVIG over 5 days is recommended. Although most patients recover fully within several months to a year, the mortality rate is 5 percent, mainly due to pulmonary complications and arrhythmias (Hauser, 2015a; Pacheco, 2016).

Bell Palsy

This disfiguring palsy is usually a mononeuropathic acute facial paralysis that is relatively common in reproductive-aged women (Fig. 60-5). It has a female predominance, and pregnant women carry a fourfold risk compared with nonpregnant women (Cohen, 2000; Heaney, 2010). The disease is characterized by facial nerve inflammation and often is associated with reactivation of herpes simplex virus or herpes zoster virus.

FIGURE 60-5
Bell facial nerve palsy developing on the day of cesarean delivery for dichorionic twins. This woman was treated with prednisone and antiviral medication, and the palsy had almost resolved 3 weeks postpartum.

Bell palsy usually has an abrupt and painful onset with maximum weakness by 48 hours. In some cases, hyperacusis and loss of taste accompany paralysis (Beal, 2015). Management includes supportive care with facial muscle massage and eye protection against corneal lacerations from drying. There is general consensus that prednisone, 1 mg/kg given orally daily for 5 days, will improve outcomes and shorten the recovery period (Salinas, 2016; Sullivan, 2007). It is controversial whether addition of an antiviral medication will add benefits (de Almeida, 2009; Gagyor, 2015; Quant, 2009).

It is unclear if pregnancy alters the prognosis for spontaneous facial palsy recovery. Gillman and associates (2002) found that only half of pregnant women recovered to a satisfactory level after 1 year, compared with approximately 80 percent of nonpregnant women and men. Some prognostic markers for incomplete recovery are bilateral palsy, recurrence in a subsequent pregnancy, greater percentage of nerve function loss, and a faster rate of loss (Cohen, 2000; Gilden, 2004). Other than a fivefold greater rate for gestational hypertension or preeclampsia, women with Bell palsy do not have increased adverse pregnancy outcomes rates (Katz, 2011; Shmorgun, 2002).

Carpal Tunnel Syndrome

This syndrome results from compression of the median nerve and is the most frequent mononeuropathy in pregnancy (Padua, 2010). Symptoms include burning, numbness, or tingling along the inner half of one or both hands. Others are wrist pain and numbness extending into the forearm and sometimes into the shoulder (Katz, 2002). Symptoms are bilateral in 80 percent of gravidas, and 10 percent have evidence for severe denervation (Seror, 1998). Differential diagnosis includes cervical radiculopathy of C_6–C_7 and de Quervain tendonitis. The latter is caused by swelling of the conjoined tendons and their sheaths near the distal radius. Nerve conduction studies may be helpful for clarification (Alfonso, 2010).

In pregnancy, the reported incidence of carpal tunnel syndrome is 7 to 43 percent and varies greatly because the range of symptoms is marked (Meems, 2015; Padua, 2010). Symptomatic treatment with a splint applied to a slightly flexed wrist during sleep lightens pressure and usually provides relief. Although symptoms typically are self-limited, occasionally surgical decompression and corticosteroid injections are necessary (Keith, 2009; Shi, 2011). Symptoms may persist in more than half of patients at 1 year and in a third at 3 years (Padua, 2010).

SPINAL CORD INJURY

According to the National Spinal Cord Injury Statistical Center (2017), there are approximately 17,000 new spinal cord injuries each year. The average age is 42 years, and males account for 80 percent of new cases. Cord injury severity determines the short- and long-term prognosis as well as that for pregnancy. For women, many have altered sexual function and transient hypothalamic pituitary hypogonadism. That said, pregnancy is not uncommon if menstruation resumes (Bughi, 2008). In a review of nearly 2000 women in the National Spinal Cord Injury Database, 2 percent reported pregnancy in the prior 12 months (Iezzoni, 2015).

Gravidas with spinal cord injury have an increased frequency of pregnancy complications that include preterm and low-birthweight neonates. Recent observations in nonpregnant women note that the vaginal microbiota is altered in these women (Pires, 2016). Perhaps related, most have asymptomatic bacteriuria with sporadic symptomatic urinary infections. Bowel dysfunction causes constipation in more than half, and anemia and pressure-necrosis skin lesions are also common.

Two serious and life-threatening events can complicate spinal cord injuries. First, if the cord is transected above T_{10}, the cough reflex is impaired, respiratory function may be compromised, and pneumonitis from covert aspiration can be serious. Pulmonary function tests are considered to assess this risk, and some women may need ventilatory support in late pregnancy or in labor.

Second, women with lesions above T_5–T_6 are at risk for *autonomic dysreflexia*. With this, stimuli from structures innervated below the level of the spinal lesion lead to massive, disordered sympathetic stimulation. Abrupt catecholamine release can cause vasoconstriction with severe hypertension and symptoms that include throbbing headaches, facial flushing, sweating, bradycardia, tachycardia, arrhythmias, and respiratory distress. Dysreflexia can be precipitated by various stimuli. These include urethral catheterization, bladder distention from urinary retention, rectal or cervical stretch during digital examinations, uterine contractions and cervical dilation, or any manipulation of other pelvic structures (American College of Obstetricians and Gynecologists, 2016; Krassioukov, 2009). In one report, 12 of 15 women at risk for autonomic dysreflexia suffered at least one episode during pregnancy (Westgren, 1993).

Because uterine contractions are not affected by spinal cord lesions, labor is usually easy—even precipitous, and comparatively painless. If the lesion is below T_{12}, uterine contractions are felt normally. For lesions above T_{12}, the risk of out-of-hospital delivery is substantial and can be minimized by teaching women to palpate for uterine contractions. This is especially important because up to 20 percent of women deliver preterm (Westgren, 1993). Some recommend tocodynamometry and weekly cervical examinations beginning at 28 to 30 weeks. Another reasonable option that we frequently employ at Parkland Hospital is elective hospitalization after 36 to 37 weeks' gestation (Hughes, 1991).

Spinal or epidural analgesia extending to T_{10} prevents autonomic dysreflexia and should be instituted at the start of labor. If there are severe symptoms before epidural placement, steps are taken to abolish the provoking stimulus. A parenteral antihypertensive agent such as hydralazine or labetalol is given. Labor and vaginal delivery with epidural or spinal analgesia is preferable and will minimize autonomic dysreflexia (Kuczkowski, 2006). Operative vaginal delivery is frequently necessary.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Also known as *pseudotumor cerebri*, this disorder is typified by increased intracranial pressure without hydrocephalus. The cause is unknown, but it may result from overproduction or under absorption of cerebrospinal fluid (CSF). Symptoms include headache in at least 90 percent of cases, visual disturbances such as loss of a visual field or central visual acuity in 70 percent, and commonly occurring papilledema that may be sight-threatening (Evans, 2000; Heaney, 2010). Other complaints are stiff neck, back pain, pulsatile tinnitus, and cranial nerve palsies.

The syndrome is often found in young women and is prevalent in those who are obese, who recently gained weight, or both (Fraser, 2011). Along with symptoms, other criteria for diagnosis include elevated intracranial pressure >25 cm H_2O, normal CSF composition, normal cranial CT or MR imaging findings, papilledema, and no evidence for systemic disease. If papilledema is not present, other criteria are required (Friedman, 2013).

Idiopathic intracranial hypertension is usually self-limited. Visual defects can be prevented by lowering the CSF pressure, and agents include acetazolamide to reduce fluid production, furosemide, or topiramate. Corticosteroids are now rarely used. Surgical intervention is occasionally necessary and is accomplished by either lumboperitoneal shunting of spinal fluid or optic nerve sheath fenestration.

It is controversial if pregnancy is a risk factor for idiopathic intracranial hypertension. Certainly, symptoms may first appear in pregnancy, and women previously diagnosed may become symptomatic. Symptoms usually develop by midpregnancy, tend to be self-limited, and usually resolve postpartum.

Pregnancy does not alter management. Some recommend serial visual field testing to forestall permanent vision loss. In a report of 16 pregnant women, visual field loss developed in four, and it became permanent in one (Huna-Baron, 2002). Visual field loss is often coincident with the development of papilledema, for which acetazolamide is given. Lee and associates (2005) reported successful treatment of 12 pregnant women. Although outmoded for treatment of nonpregnant individuals, repeated lumbar punctures are generally successful in providing temporary relief throughout pregnancy. In some pregnant women, surgical therapy becomes necessary, and we and others have had promising results with optic nerve sheath fenestration (Thambisetty, 2007).

Pregnancy complications are likely due to associated obesity and not to intracranial hypertension. In a review of 54 pregnancies, rates of adverse perinatal outcomes were not elevated (Katz, 1989). The route of delivery depends on obstetrical indications, and conduction analgesia is safe (Aly, 2007; Karmaniolou, 2011).

MATERNAL VENTRICULAR SHUNTS

Pregnancies in women with previously placed ventricular shunts for obstructive hydrocephalus usually have satisfactory outcomes (Landwehr, 1994). Shunts may be ventriculoperitoneal, ventriculoatrial, or ventriculopleural. Partial obstruction of a shunt is common, especially late in pregnancy (Schiza, 2012). In one report of 17 such pregnancies, neurological complications were reported in 13 (Wisoff, 1991). Findings included headaches in 60 percent, nausea and vomiting in 35 percent, lethargy in 30 percent, and ataxia or gaze paresis, each in 20 percent. Most symptoms respond to conservative management. However, if CT scanning during symptom evaluation discloses acute hydrocephaly, then the shunt is tapped or pumped several times daily. In some cases, surgical revision is necessary and may be emergently indicated (Murakami, 2010).

Another shunting procedure is placement of an endoscopic third ventriculostomy for hydrocephalus (de Ribaupierre, 2007). With this, a small hole is created in the floor of the third ventricle to allow CSF to flow directly into lower cisterns. One report described successful results in five pregnant women who underwent endoscopic ventriculostomy (Riffaud, 2006). In a review, however, reproductive function and miscarriage rates were found to significantly worsen in these women (Bedaiwy, 2008).

Vaginal delivery is preferred in women with shunts, and unless there is a meningomyelocele, conduction analgesia is permitted. Antimicrobial prophylaxis is indicated if the peritoneal cavity is entered for cesarean delivery or tubal sterilization.

MATERNAL BRAIN DEATH

Brain death is rare in obstetrics. Life-support systems and parenteral alimentation for up to 15 weeks while awaiting delivery have been described (Hussein, 2006; Powner, 2003; Souza, 2006). Some women were treated with aggressive tocolysis and antimicrobial therapy. In one review of 17 women with persistent vegetative state who were given various levels of support, five women died after delivery, and most of the others remained in their vegetative state (Chiossi, 2006).

With a diagnosis of *brain death* using the uniform Determination of Death Act definition, there are no published reports of neurological recovery (Wijdicks, 2010). Few institutional brain-death policies address pregnancy (Lewis, 2016). The ethical, financial, and legal implications, both civil and criminal, that arise from attempting or not attempting such care are profound (Farragher, 2005; Feldman, 2000). In some women, perimortem cesarean delivery is performed as discussed in Chapter 47 (Cardiopulmonary Resuscitation).

CHAPTER 61: Psychiatric Disorders

FIGURE 61-1

The insanity of pregnancy is usually a manifestation of autointoxication, and may be accompanied by melancholic or maniacal symptoms. It usually persists throughout gestation, but disappears shortly after labour, unless the patient has an hereditary tendency to mental derangement.

—J. Whitridge Williams (1903)

INTRODUCTION

The subject of mental illness was only briefly addressed by Williams in 1903, when it appears that acute puerperal psychoses were manifestations of eclampsia or sepsis. More than 100 years later, we have learned that pregnancy and the puerperium are at times sufficiently stressful to provoke mental illness. Such illness may represent recurrence or exacerbation of a preexisting psychiatric disorder, or it may signal the onset of a new condition. This 25th edition of *Williams Obstetrics* marks only the second edition with a focused chapter dedicated to psychiatric illnesses. To emphasize the rising national interest, American College of Obstetricians and Gynecologists President Dr. Gerald F. Joseph Jr. declared postpartum depression as an initiative in 2009.

Psychiatric disorders during pregnancy are associated with less prenatal care, substance use, poor obstetrical and neonatal outcomes, and higher rates of postpartum psychiatric illness (Frieder, 2008). Despite these known risks, obstetrical providers often are reluctant to confront or fail to identify some of these mental health issues during pregnancy. For example, Lyell and colleagues (2012) found that the diagnosis of depression was not documented in nearly half of the records of depressed women. Yet, perinatal mood disorders can have far-reaching consequences beyond the immediate effect on maternal mental health and social function by adversely affecting the mother-child relationship (Weinberg, 1998).

Also, suicide is a primary cause of death among women during the perinatal period in the United States, and major depression is among the strongest predictors of suicidal ideation (Melville, 2010). Between 2004 and 2012, self-harm, suicide, or drug overdose was the leading cause of maternal death in Colorado (Metz, 2016). In a 10-year analysis of Washington state hospitalizations, Comtois and associates (2008) studied 355 women with a postpartum suicide attempt. Substance abuse was linked with a sixfold higher and prior psychiatric hospitalization with a 27-fold greater risk for suicide. These rates rose further if there were multiple hospitalizations. Also of note, 54 percent of pregnancy-associated suicides involve intimate-partner conflict (Palladino, 2011).

PSYCHOLOGICAL ADJUSTMENTS TO PREGNANCY

Biochemical factors and life stressors can markedly influence mental health and mental illness during the perinatal period. Intuitively, pregnancy exacerbates some coexisting psychological disorders. Namely, an increased risk for mood disorders is linked with pregnancy-related shifts in sex steroid and monoamine neurotransmitter levels, dysfunction of the hypothalamic-pituitary-adrenal axis, thyroid dysfunction, and alterations in immune response (Yonkers, 2011). These changes, coupled with familial clustering of depression cases, suggest that there may be a subgroup of women at risk for developing a unipolar major depressive disorder during pregnancy.

Women respond in various ways to stressors of pregnancy, and some express persistent concerns regarding fetal health, child care, lifestyle changes, or fear of childbirth pain. Anxiety, sleep disorders, and functional impairment are common (Romero, 2014; Vythilingum, 2008). However, according to Littleton and coworkers (2007), anxiety symptoms in pregnancy are associated with psychosocial variables similar to those for nonpregnant women. The level of perceived stress is significantly higher for women whose fetus is at high risk for a malformation, for those with preterm labor or delivery, and for those with other medical complications (Alder, 2007; Ross, 2006). Hippman and colleagues (2009) screened for depression in 81 women who had an increased risk for a fetus with aneuploidy. Half of these women had a positive depression screening score, whereas only 2.4 percent of those with a normal pregnancy did so.

Several steps can be taken to diminish psychological stress in the event of a poor obstetrical outcome. For example, following a stillbirth, Gold (2007) encouraged parental contact with the newborn and provision of photographs and other infant memorabilia. Addressing associated sleep disorders also seems reasonable (Juulia Paavonen, 2017; Romero, 2014).

The Puerperium

This is a particularly stressful time for women, and risks for mental illness are increased. Up to 15 percent of women develop a nonpsychotic postpartum depressive disorder within 6 months of delivery (Tam, 2007; Yonkers, 2011). A few have a psychotic illness following delivery, and half of these manifest a bipolar disorder. Depressive disorders are more likely in women with obstetrical complications such as severe preeclampsia or fetal-growth restriction, especially if associated with early delivery. Houston and coworkers (2015) found that expectations at delivery also increased the risk for postpartum depression.

Importantly, stressors beyond those directly related to the pregnancy can raise perinatal depression rates. Tarney and colleagues (2015) identified spouse deployment as a factor for postpartum depression in a study at Womack Army Medical Center. But, among women with a history of bipolar disorder, these elements play a lesser role in the development of mania or depression (Yonkers, 2011).

Maternity Blues

Also called *postpartum blues*, this is a time-limited period of heightened emotional reactivity experienced by half of women within the first week after parturition. Prevalence estimates for the blues range from 26 to 84 percent depending on diagnostic criteria (O'Hara, 2014). This emotional state generally peaks on the fourth or fifth postpartum day and normalizes by day 10 (O'Keane, 2011).

The predominant mood is happiness, but affected mothers are more emotionally labile. They also may have insomnia, weepiness, depression, anxiety, poor concentration, and irritability. Mothers may be transiently tearful for several hours and then recover completely, only to be tearful again the next day. Supportive treatment is indicated, and affected women are reassured that the dysphoria is transient and most likely due to biochemical changes. They should be monitored for development of depression and other severe psychiatric disturbances.

Perinatal Evaluation and Screening

Both the American College of Obstetricians and Gynecologists (2016a) and the United States Preventative Services Task Force now recommend screening at least once during the perinatal period for depression and anxiety (Siu, 2016). Identification of psychiatric disorders in pregnancy can be challenging because changes in behavior and mood are often attributed to pregnancy. To differentiate these, Yonkers (2011) recommends assessment of cognitive symptoms—for example, loss of concentration. Excessive symptoms of anxiety and insomnia—even during periods of infant sleep—can also suggest postpartum depression. Specific factors for depression are reviewed and include a prior personal or family history of depression.

Universal-screening programs for depression continue to evolve (Venkatesh, 2016). At Parkland Hospital, mental illness screening is generally done at the first prenatal visit using a brief risk-based query and again postpartum using a universal-applied screening tool for postpartum depression. Questions search for psychiatric disorders, related therapy, prior or current use of psychoactive medications, and current symptoms. Women with a history of sexual, physical, or verbal abuse; substance abuse; and personality disorders are also at greater risk for depression (Akman, 2007; Janssen, 2012). History of neglect and abuse are especially powerful antecedents of depression in adolescent pregnancy (Meltzer-Brody, 2014). Smoking and nicotine dependence and obesity also raise rates of ***all*** mental disorders in pregnancy (Goodwin, 2007; Molyneaux, 2014). Finally, because eating disorders may be exacerbated by pregnancy, affected women are followed closely (Schizophrenia Spectrum Disorders).

Several screening instruments shown in Table 61-1 are available and have been validated for use during pregnancy and the puerperium. Use of one of these screening tools is encouraged because symptom- or risk-based screening alone may be insufficient (American College of Obstetricians and Gynecologists, 2016a). Cerimele and colleagues (2013) found that obstetricians and gynecologists failed to identify 60 percent of depressed women in clinical practice. As mentioned earlier, at Parkland Hospital, all women are screened during their first postpartum visit using the Edinburgh Postnatal Depression Scale (EPDS). In an analysis of more than 17,000 women, 6 percent had scores that indicated either minor or major depressive symptoms, and 12 women had thoughts of self-harm (Nelson, 2013). Similarly, Kim and coworkers (2015) assessed suicidal ideation in more than 22,000 women screened using the EPDS both during pregnancy and postpartum. They found rates of depression as high as 3.4 percent during the puerperium. A small fraction of those with thoughts of self-harm had a

credible plan, intent, and means for attempted suicide. Obviously, suicidal ideation warrants prompt psychiatric consultation for evaluation and management.

Screening for perinatal depression without appropriate subsequent treatment is insufficient (American College of Obstetricians and Gynecologists, 2016a). That said, mechanisms to ensure adequate ensuing care can be problematic. In the study by Nelson and associates (2013) more than three fourths of the 1106 women with abnormally elevated EPDS scores did not keep their later appointment, which offered more formal psychiatric evaluation. Barriers include difficulties with access to care, personal perception of depression, and societal stigmata (Flynn, 2010; Smith, 2008). Women referred to a behavioral health provider located at the same site as their obstetrical care are four times more likely to access treatment than those referred elsewhere (Smith, 2009). To take advantage of this, at Parkland Hospital, mental health counselors also practice at postpartum clinic sites. Other promising interventions for puerperal depression include home visits, telephone-based peer support, and interpersonal psychotherapy (Dennis, 2013; Lavender, 2013; Yonemoto, 2017). A report from Kaiser Permanente, which describes the benefits and hurdles to system-based perinatal mental health care, provides a glimpse into the possible future of universal perinatal screening and treatment (Avalos, 2016; Flanagan, 2016).

Treatment Considerations

Many psychiatric disorders can be improved with counseling and psychotherapies. In some instances, psychotropic medications are needed. Treatment decisions are ideally shared between patients and their health-care providers. In particular, women taking psychotropic medication are informed of likely side effects. Many of these drugs are discussed in Chapter 12 and by the American College of Obstetricians and Gynecologists (2016b) in their Practice Bulletin No. 92. Some of these drugs are discussed subsequently.

Pregnancy Outcomes

Emerging information on psychiatric disorders and pregnancy outcomes suggest a link between maternal psychiatric illness and untoward outcomes such as preterm birth, low birthweight, and perinatal mortality (Grigoriadis, 2013; Steinberg, 2014; Straub, 2012; Yonkers, 2009). In a study of 16,334 deliveries, Shaw and coworkers (2014) identified a significant association between posttraumatic stress disorder and spontaneous preterm delivery. Domestic abuse—another aforementioned risk factor for perinatal mood disorder—is also linked with adverse perinatal outcomes (Yost, 2005). Finally, Littleton and associates (2007) reviewed 50 studies and concluded that anxiety symptoms, which are commonly comorbid with depression, had no adverse effect on perinatal outcomes.

MOOD DISORDERS

The *Diagnostic and Statistical Manual, Fifth Edition (DSM-5)* is the most recent version by the American Psychiatric Association (2013). It assists in classifying mental disorders and specifies criteria for each diagnosis.

Of categories, depressive disorders are common. According to the National Institute of Mental Health (2010), the lifetime prevalence of depressive disorders in the United States is 21 percent. Historically, depressive disorders include major depression—a unipolar disorder—and manic-depression—a bipolar disorder with both manic and depressive episodes. It also includes dysthymia, which is chronic, mild depression.

Major Depression

This is the most common depressive disorder, and the 12-month prevalence of major depressive episodes among U.S. women is 8.2 percent (Center for Behavioral Health Statistics and Quality, 2015). In 2011 to 2014, 16 percent of U.S. women had used an antidepressant in the prior month (Pratt, 2017). The diagnosis is made by identifying symptoms listed in Table 61-2, but very few patients manifest all of these.

TABLE 61-2

Symptoms of Depressive Illness[a]

Hopelessness and/or pessimism Persistent sad, anxious, or “empty” feelings
Guilt, worthlessness, and/or helplessness
Irritability, restlessness
Loss of interest in activities once pleasurable, including sex
Fatigue and decreased energy
Difficulty concentrating, remembering details, and making decisions
Insomnia, early-morning wakefulness, or excessive sleeping
Overeating or appetite loss
Thoughts of suicide, suicide attempts
Persistent aches or pains, headaches, cramps or digestive problems that do not ease with treatment

[a]Not all patients experience the same symptoms.

Modified with permission from National Institute of Mental Health, 2010.

Major depression is multifactorial and prompted by genetic and environmental factors. Families of affected individuals often also have members suffering with alcohol abuse and anxiety disorders. Provocative conditions leading to depression include life events that prompt grief reactions, substance abuse, use of certain medications, and other medical disorders. Although life events can trigger depression, genes influence the response to these events and render the distinction between genetic and environmental factors difficult. One genome-wide linkage analysis of more than 1200 mothers suggests that variation in chromosomes 1 and 9 raises susceptibility to postpartum mood symptoms (Mahon, 2009).

Pregnancy and Depression

It is unquestionable that pregnancy is a major life stressor that can precipitate or exacerbate depressive tendencies. In addition, various pregnancy-induced effects are implicated. Hormones certainly affect mood, as evidenced by premenstrual syndrome and menopausal depression. Estrogen has been linked to increased serotonin synthesis, decreased serotonin breakdown, and serotonin-receptor modulation (Deecher, 2008). Concordantly, women who experience postpartum depression often have higher predelivery serum estrogen and progesterone levels and experience a greater decline postpartum (Ahokas, 1999).

Dennis and associates (2007) queried the Cochrane Database and reported that the prevalence of antenatal depression averaged 11 percent. Melville and coworkers (2010) found it in nearly 10 percent of more than 1800 women enrolled for prenatal care at a single university clinic. Others have reported the incidence to be much higher depending on the population studied (Gavin, 2005; Hayes, 2012; Lee, 2007).

Postpartum Depression

Major or minor depression develops postpartum in 10 to 20 percent of women (Mental Health America, 2016). Available data indicate that unipolar major depression may be slightly more prevalent during the puerperium than among women in the general population (Yonkers, 2011). Postpartum depressive symptoms are associated with young maternal age, antenatal depression, unmarried status, smoking, newborns requiring intensive care, and those with a history of stressors during pregnancy (Ko, 2017; Silverman, 2017). Specifically, physical or verbal abuse during pregnancy is a potent risk for postpartum depression (McFarlane, 2014). Finally, serious adverse obstetrical events, especially those involving the neonate, are strongly linked to postpartum depression (Nelson, 2013, 2015).

Depression is frequently recurrent. Up to 70 percent of women with previous postpartum depression have a subsequent episode. Women with both prior puerperal depression and a current episode of "maternity blues" carry an inordinately high risk for major depression. Indeed, 2 to 9 months postpartum, assistance with postpartum depression was the fourth most common challenge identified in women in the Pregnancy Risk Assessment Monitoring System—PRAMS (Kanotra, 2007).

Postpartum depression is generally underrecognized and undertreated. Major depression during pregnancy or after delivery can have devastating consequences for affected women, their children, and families. One of the most significant contributions to the mortality rate among new mothers is suicide, which is most frequent among women with mental illness (Koren, 2012; Palladino, 2011). If left untreated, up to 25 percent of women with postpartum depression will be depressed 1 year later. As the duration of depression increases, so too does the number of sequelae and their severity. Maternal depression during the first weeks and months after delivery can lead to insecure attachment and later behavioral problems in the child.

Depression Treatment

Therapy for mood disorders during pregnancy and postpartum has undergone a significant evolution during the past decade. Babbitt (2014) and Pozzi (2014) and their associates have reviewed principles of antenatal and intrapartum care of women with major mental disorders. In general, for mild and mild-moderate depression, psychological treatment options, such as cognitive behavioral therapy, are considered first (Yonkers, 2011). Antidepressant medications together with some form of psychotherapy are indicated for moderate to severe depression during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2016b).

Shown in Figure 61-1 is one algorithm regarding treatment of mood disorders. Some of these medications are listed in Table 61-3. For women with severe depression, a selective serotonin-reuptake inhibitor (SSRI) is selected initially. In contrast, tricyclic antidepressants and monoamine oxidase inhibitors are infrequently selected in contemporary practice. If depressive symptoms improve during a 6-week trial, the medication is continued for a minimum of 6 months to prevent relapse (Wisner, 2002). At least 60 percent of women taking antidepressant medication before pregnancy have symptoms during pregnancy. According to Hayes and colleagues (2012), approximately three fourths of women taking antidepressants before pregnancy stopped taking them before or during early pregnancy. For those who discontinue treatment, almost 70 percent have a relapse compared with approximately 25 percent who continue therapy. If the response is suboptimal or a relapse occurs, another SSRI is substituted, or psychiatric referral is considered.

TABLE 61-3

Drugs Used for Treatment of Major Mood Disorders in Pregnant Women

Indication	Examples	Comments
Antidepressants		
SSRIs[a]	Citalopram, sertraline, fluoxetine	Some have possible neonatal link with heart defects, withdrawal syndrome, and pulmonary hypertension
Others	Bupropion, duloxetine, nefazodone, venlafaxine	
Tricyclics	Amitriptyline, desipramine, doxepin, imipramine, nortriptyline	No evidence of teratogenicity, not commonly used
Antipsychotics		
Typical	Chlorpromazine, fluphenazine, haloperidol, thiothixene	
Atypical	Aripiprazole, clozapine, olanzapine, risperidone, ziprasidone	
Bipolar Disorders		
Lithium[a]	Lithium carbonate	Manic episodes; teratogenic for cardiac defects (Ebstein anomaly)
Valproic acid[b]		Teratogenic—neural-tube defects
Carbamazepine[b]		Antiepileptic—hydantoin syndrome

[a]Chapter 12 (Retinoids).

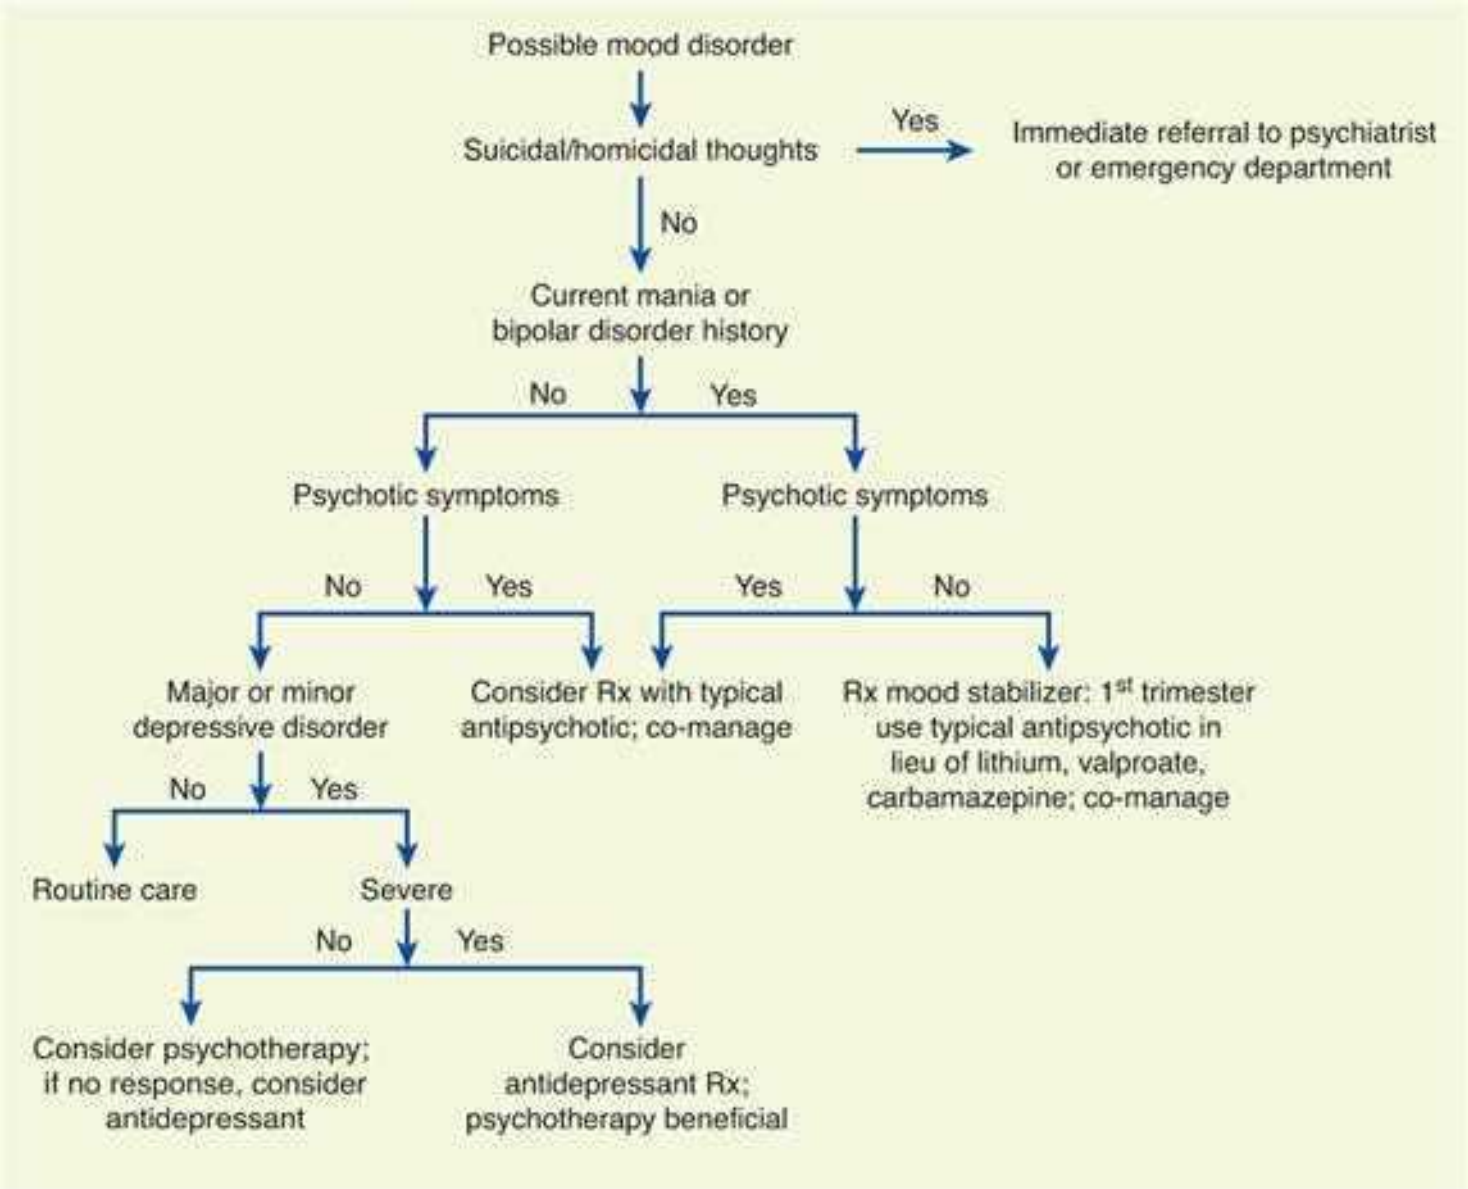
SSRI = Selective serotonin-reuptake inhibitor.

Data from Briggs, 2015; Huybrechts, 2015; Koren, 2012.

FIGURE 61-1

Treatment algorithm for pregnant women with mood disorders.



Various dietary deficiencies have suggested links to perinatal depression (Yonkers, 2011). Supplements that include omega-3 fatty acids, iron, folate, riboflavin, vitamin D, calcium, and docosahexaenoic acid (DHA) have been studied (Keenan, 2014; Miller, 2013). However, evidence currently is insufficient to support use of these dietary supplements for this purpose.

Importantly, in a metaanalysis by Huang and coworkers (2014), women using antidepressants during pregnancy have higher rates of preterm birth and low-birthweight neonates. Nevertheless, in their review, Ray and Stowe (2014) concluded that the relative reproductive safety data are reassuring and that antidepressants remain a viable treatment option. Furthermore, recurrence sometime after medication is discontinued develops in 50 to 85 percent of women with an initial postpartum depressive episode. Women with a history of more than one depressive episode carry greater risk (American Psychiatric Association, 2000). Surveillance includes monitoring for thoughts of suicide or infanticide, emergence of psychosis, and response to therapy. For some women, the course of illness is severe enough to warrant hospitalization.

Fetal and Neonatal Effects of Therapy

Some known and possible fetal and neonatal effects of treatment are listed in Table 61-3. Some studies suggest that SSRIs pose an elevated teratogenic risk for fetal cardiac defects, and these have mainly focused on paroxetine (Paxil). Associations were most consistent for ventricular septal defects. The estimated risk is no greater than 1 in 200 exposed newborns (Koren, 2012). Nevertheless, the American College of Obstetricians and Gynecologists (2016b) recommends that paroxetine be avoided in women who are either pregnant or planning pregnancy. In women exposed to paroxetine in the first trimester, fetal echocardiography is considered. Jimenez-Solem and coworkers (2013) in their analysis of SSRIs found no association between exposure to SSRIs during pregnancy and perinatal mortality. Andersen and

associates (2014) found that women discontinuing SSRI treatment in early pregnancy had a small increased risk of miscarriage, but that this was similar to the risk in women discontinuing SSRI treatment months before pregnancy. Taken together, these investigators concluded that treatment with SSRIs during pregnancy should not be discontinued for fear of miscarriage.

Of other potential effects, the risk of persistent pulmonary hypertension of the newborn rose sixfold in neonates exposed to SSRIs after 20 weeks' gestation (Chambers, 2006). This translates to an overall risk of pulmonary hypertension that would be less than 1 in 100 exposed newborns (Koren, 2012). In contrast, a population-based cohort study of 1.6 million pregnancies identified a twofold greater rate in exposed neonates. This yields an estimated attributable risk of 2 cases per 1000 births (Kieler, 2012). In a study of more than 120,000 gravidas prescribed antidepressants, Huybrechts and coworkers (2015) found an attributed risk of 1 case per 1000 births.

In sum, the maternal risk associated with discontinuing or tapering SSRI use during pregnancy must be weighed against marginally increased neonatal risks (Ornoy, 2017). Women who abruptly discontinue either serotonin- or norepinephrine-reuptake inhibitor therapy typically experience some form of withdrawal.

Not surprisingly, up to 30 percent of exposed neonates may also exhibit withdrawal symptoms. Symptoms are similar to opioid withdrawal, but typically are less severe. Neonatal SSRI withdrawal is usually self-limited, and the newborn rarely remains in the nursery more than 5 days (Koren, 2009). Currently, convincing evidence of long-term neurobehavioral effects of fetal exposure to these medications is lacking (Koren, 2012). Grzeskowiak and coworkers (2016) found no increased risk of behavioral problems in 7-year-old children exposed to antidepressants prior to their birth.

Some psychotropic medications pass into breast milk. In most cases, however, levels are very low or undetectable. Effects may be transient irritability, sleep disturbances, and colic.

Electroconvulsive Therapy

This form of depression treatment is occasionally necessary during pregnancy for women with major mood disorders unresponsive to pharmacotherapy. Women undergoing electroconvulsive therapy (ECT) should be fasting for at least 6 hours. They are given a rapid-acting antacid before the procedure, and their airway is protected to decrease the likelihood of aspiration. After midpregnancy, a wedge is placed under the right hip to prevent sudden maternal hypotension from aortocaval compression. Other important preparatory steps include assessment of the cervix, discontinuation of nonessential anticholinergic medication, uterine and fetal heart rate monitoring, and intravenous hydration. During the procedure, excessive hyperventilation is avoided. In most cases, maternal and fetal heart rate and maternal blood pressure and oxygen saturation remain normal throughout the procedure.

With proper preparation, the risks to both mother and fetus appear to be reasonable (Pinette, 2007). That said, adverse maternal and perinatal outcomes have followed ECT. Balki and associates (2006) reported a pregnancy in which fetal brain damage likely was caused by sustained maternal hypotension associated with treatment of status epilepticus stimulated by ECT.

At least two extensive reviews have evaluated ECT outcomes in pregnancy. In the earlier one, Miller (1994) found 300 cases and reported complications in 10 percent. These included fetal arrhythmias, vaginal bleeding, abdominal pain, and self-limited contractions. Women not adequately prepared had increased risks for aspiration, aortocaval compression, and respiratory alkalosis. In the more recent review, Andersen and Ryan (2009) described 339 cases, undoubtedly with some homology with the earlier study. In most cases, ECT therapy was done to treat depression, and it was 78-percent effective. They reported a 5-percent maternal ECT-related complication rate. There was a 3-percent associated perinatal complication rate, which included two fetal deaths. For all of these reasons, we agree with Richards (2007) that ECT in pregnancy is not "low risk" and that it should be reserved for women whose severe depression is resistant to intensive pharmacotherapy.

Bipolar and Related Disorders

According to the National Institute of Mental Health (2010), the lifetime prevalence for manic-depression illness is 3.9 percent. The prevalence of bipolar disorder does not vary between gravidas and nonpregnant reproductive-aged women (Yonkers, 2011). It has a strong genetic component and has been linked to possible mutations on chromosomes 16 and 8 (Jones, 2007). The risk that monozygotic twins are both affected is 40 to 70 percent, and the risk for first-degree relatives is 5 to 10 percent (Muller-Oerlinghausen, 2002).

Periods of depression last at least 2 weeks. At other times, patients are manic, in which mood is abnormally raised, expansive, or irritable. Potential organic causes of mania include substance abuse, hyperthyroidism, and central nervous system (CNS) tumors. These are all excluded during an acute event. Importantly, pregnancy frequently prompts medication discontinuation, which poses a twofold increased

risk for relapse (Viguera, 2007). Affected women are considered high risk, and as many as 20 percent of patients with manic-depression illness commit suicide.

Bipolar Disorder in Pregnancy

This has also been associated with adverse perinatal outcomes, for example, preterm birth (Mei-Dan, 2015). Di Florio and associates (2013) found that those women who experience pregnancy complications are more likely to exhibit periods of mania or depression. Women who tend to be manic present with exacerbations earlier in the postpartum period.

Typical therapy for bipolar disorder includes mood stabilizers such as lithium, valproic acid, and carbamazepine, as well as antipsychotic medications (see Table 61-3). Treatment of bipolar disorder in pregnancy is complex and is ideally managed concurrently with a psychiatrist. Decisions include risks versus benefits of using mood stabilizers, some of which are teratogenic. For example, lithium has been linked to Ebstein anomaly in exposed fetuses. More recent data, however, suggest a lower risk of cardiac malformations than previously indicated (Micromedex, 2016; Patorno, 2017). Nevertheless, many recommend fetal echocardiography for lithium-exposed fetuses. Some limited evidence suggests that lithium in breast milk, when its elimination is impaired as in dehydration or immaturity, can adversely affect the infant (Davanzo, 2011). However, lithium use in mothers with a healthy, term fetus is considered moderately safe. A more detailed discussion of other mood stabilizers and antipsychotic medications side effects can be found in Chapter 12 (Immunosuppressant Medications).

Postpartum Psychosis

This severe mental disorder is usually a bipolar disorder, but it may be due to major depression (American Psychiatric Association, 2013). Its incidence is estimated to be 1 in every 1000 deliveries, and it is more common in nulliparas, especially those with obstetrical complications (Bergink, 2011; Blackmore, 2006). In most cases, illness manifests within 2 weeks of delivery. In one study of postpartum women with their first lifetime episode of psychosis, the median onset of psychiatric symptoms was 8 days after delivery, and the median duration of the episode was 40 days (Bergink, 2011). Because those with underlying psychiatric disease have a 10- to 15-fold risk for recurrence postpartum, close monitoring is imperative.

The most important risk for postpartum psychosis is a history of bipolar disease. These women typically exhibit symptoms within 1 to 2 days after delivery (Heron, 2007, 2008). Manic symptoms include feeling excited or elated, being active or energetic, feeling “chatty,” and suffering insomnia. Affected women have signs of confusion and disorientation but may also have lucid episodes.

Postpartum psychosis has a 50-percent recurrence risk in the next pregnancy. As a result, Bergink and associates (2012) recommend initiating lithium therapy immediately after delivery in women with a history of postpartum psychosis.

The clinical course of bipolar illness with postpartum psychosis is comparable with that for nonpregnant women. Patients usually require hospitalization, pharmacological treatment, and long-term psychiatric care. Psychotic women may have delusions leading to thoughts of self-harm or harm to their infants. Unlike women with nonpsychotic depression, these women commit infanticide, albeit uncommonly (Kim, 2008). In most instances, women with postpartum psychosis ultimately develop relapsing, chronic psychotic manic-depression.

Anxiety Disorders

These relatively common disorders—18 percent prevalence overall—include panic attack, panic disorder, social anxiety disorder, specific phobia, separation anxiety disorder, and generalized anxiety disorder. All are characterized by irrational fear, tension, and worry, which are accompanied by physiological changes such as trembling, nausea, hot or cold flashes, dizziness, dyspnea, insomnia, and frequent urination (Schneier, 2006). They are treated with psychotherapy and medication, including SSRIs, tricyclic antidepressants, monoamine oxide inhibitors, or others.

Anxiety Disorders in Pregnancy

Despite the relative high prevalence in childbearing-aged women, little specific attention has been directed to anxiety disorders in pregnancy. Most reports conclude that rates between pregnant and nonpregnant women do not differ. One recent analysis of 268 gravidas with generalized anxiety disorder demonstrated that both symptoms and severity of anxiety decline across pregnancy (Buist, 2011).

From their review, Ross and McLean (2006) concluded that some of the anxiety disorders may have important maternal-fetal implications. Some have been linked to preterm birth, fetal-growth restriction, and poor neurobehavioral development (Van den Bergh, 2005). Children

with a history of in utero exposure to maternal anxiety are felt to be at increased risk for various neuropsychiatric conditions such as attention-deficit/hyperactivity disorder (ADHD). Hunter and coworkers (2012) analyzed infants of 60 mothers with an anxiety disorder and found that auditory sensory gating—a reflection of inhibitory neurotransmission—was impaired, particularly in offspring of untreated women. Conversely, Littleton and associates (2007) found no excessive adverse pregnancy outcomes with "anxiety symptoms." One important exception is their link with postpartum depression (Vythilingum, 2008).

Anxiety Disorder Treatment

Anxiety disorders can be effectively treated during pregnancy with psychotherapy, cognitive-behavioral therapy, or medications. Mood and anxiety disorders coexist in more than half of women identified with either diagnosis (Frieder, 2008). Thus, antidepressants listed in Table 61-3 are often the first line of pharmacotherapy.

Benzodiazepines are also commonly used to treat anxiety or panic disorders before and during pregnancy. Earlier case-control studies linked use of these CNS depressants to a possible increased risk for cleft lip and palate. A metaanalysis of more than 1 million exposed pregnancies, however, did not identify a teratogenic risk (Enato, 2011). Benzodiazepines, especially when taken during the third trimester, can cause neonatal withdrawal syndrome, which persists for days to weeks after delivery.

SCHIZOPHRENIA SPECTRUM DISORDERS

This major form of mental illness affects 1.1 percent of adults (National Institute of Mental Health, 2016). Schizophrenia spectrum disorders are defined by abnormalities in one or more of the following domains: delusions, hallucinations, disorganized thinking, grossly disorganized or abnormal motor behavior, and negative symptoms. Brain-scanning techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) show that schizophrenia is a degenerative brain disorder. Subtle anatomical abnormalities are present early in life and worsen with time.

Schizophrenia has a major genetic component, and there is a 50-percent concordance in monozygotic twins. If one parent has schizophrenia, the risk to offspring is 5 to 10 percent. Some data, including a strong association between schizophrenia and the velocardiofacial syndrome, suggest that associated genes are located on chromosome 22q11 (Murphy, 2002). But sophisticated gene mapping studies clearly show that schizophrenia is not related to a single gene or mutation. Instead, multiple DNA variants likely interact to lead to schizophrenia (Kukshal, 2012). Other putative risks for subsequent schizophrenia in an exposed fetus include maternal iron-deficiency anemia, diabetes, and acute maternal stress (Insel, 2008; Malaspina, 2008; Van Lieshout, 2008). These remain unproven, as does the association with maternal influenza A infection.

Signs of illness begin approximately at age 20 years, and commonly, work and psychosocial functioning deteriorate over time. Women have a slightly later onset than men and are less susceptible to autism and other neurodevelopmental abnormalities. Thus, many investigators theorize that estrogen is protective. Affected women may become pregnant before symptoms manifest. With appropriate treatment, patients can experience a decrease or cessation of symptoms. Within 5 years from the first signs of illness, 60 percent have social recovery, 50 percent are employed, 30 percent are mentally handicapped, and 10 percent require continued hospitalization (American Psychiatric Association, 2013).

Schizophrenia in Pregnancy

Most studies have not found adverse maternal outcomes, although researchers in a Swedish study noted increased rates of low birthweight, fetal-growth restriction, and preterm delivery (Bennedsen, 1999). In a study of more than 3000 pregnancies in schizophrenic women, Jablensky and coworkers (2005) reported that placental abruption was increased threefold and "fetal distress"—vaguely defined—was increased 1.4-fold.

Because schizophrenia has a high recurrence if medications are discontinued, continued therapy during pregnancy is advised. After 40 years of use, no evidence links the conventional or "typical" antipsychotic drugs listed in Table 61-3 and adverse fetal or maternal sequelae (McKenna, 2005; Robinson, 2012; Yaeger, 2006). Because less is known about "atypical" antipsychotics, the American College of Obstetricians and Gynecologists (2016b) recommends against their routine use in pregnant and breastfeeding women. In response to adverse event reports, the Food and Drug Administration (2011) issued a safety communication alerting health-care providers concerning some antipsychotic medications. These have been associated with neonatal extrapyramidal and withdrawal symptoms similar to the neonatal behavioral syndrome seen in those exposed to SSRIs.

EATING DISORDERS

These include *anorexia nervosa*, in which the patient refuses to maintain minimally normal body weight, and *bulimia nervosa*, in which binge eating is usually followed by purging or excessive fasting to maintain normal body weight (Zerbe, 2008). Eating behavior disturbances largely affect adolescent females and young adults. With anorexia and bulimia, the lifetime prevalence for each is 2 to 3 percent (National Institute of Mental Health, 2016).

Bulik and coworkers (2009) studied pregnancy outcomes in almost 36,000 Norwegian women screened for eating disorders. Approximately 0.1 percent had anorexia nervosa, 0.85 percent had bulimia nervosa, and 5.1 percent reported a binge-eating disorder. This 6-percent pregnancy prevalence is similar to the 6-month prevalence for nonpregnant individuals (National Institute of Mental Health, 2016). The last subtype had a higher risk for large-for-gestational age neonates with a concomitantly increased cesarean delivery rate. All eating disorders begin with the desire to be slim, and women with chronic eating disorders may migrate between subtypes (Andersen, 2009).

Eating Disorders in Pregnancy

Early pregnancy complication rates are increased with both eating disorders, but especially in women with bulimia nervosa (Andersen, 2009; Hoffman, 2011). Generally, eating disorder symptoms improve during pregnancy, and remission rates may reach 75 percent. In contrast, typical cases of hyperemesis gravidarum may actually be a new or relapsing case of bulimia nervosa or of binge-purge type anorexia nervosa (Torgerson, 2008). As perhaps expected, anorexia is associated with low-birthweight neonates (Micali, 2007). Additional risks associated with eating disorders include poor wound healing and difficulties with breastfeeding (Andersen, 2009). At a minimum, closely monitoring gestational weight gain in women with a suspected history of an eating disorder seems prudent.

Care for these women involves a multidisciplinary team that includes an obstetrician, mental health provider, and either dietician or nutritionist (American Dietetic Association, 2006). Psychological treatment is the cornerstone for treatment in women with eating disorders and frequently includes cognitive-behavioral therapy. Anorexia nervosa often responds to motivational interactions with meal planning (Cardwell, 2013). After delivery, women with eating disorders are more prone to postpartum depression. Women with bulimia are at particular risk for disease rebound after delivery because of body image concerns.

PERSONALITY DISORDERS

These disorders are characterized by the chronic use of certain coping mechanisms in an inappropriate, stereotyped, and maladaptive manner. They are rigid and unyielding personality traits. The American Psychiatric Association (2013) recognizes three clusters of personality disorders:

1. Paranoid, schizoid, and schizotypal personality disorders, which are characterized by oddness or eccentricity.
2. Histrionic, narcissistic, antisocial, and borderline disorders, which are all characterized by dramatic presentations along with self-centeredness and erratic behavior.
3. Avoidant, dependent, compulsive, and passive-aggressive personalities, which are characterized by underlying fear and anxiety.

Genetic and environmental factors are important in the genesis of these disorders, whose prevalence may be as high as 20 percent. Although management is through psychotherapy, most affected individuals do not recognize their problem, and thus only 20 percent seek help. In an observational study of 202 women with borderline personality disorder, De Genna and associates (2012) noted that such women become pregnant during the most severe trajectory of their illness. They are at increased risk for teen and unintended pregnancies.

Personality disorders during pregnancy are probably no different than in nonpregnant women. Akman and colleagues (2007) reported that avoidant, dependent, and obsessive-compulsive disorders are associated with an excessive prevalence of postpartum major depression. Magnusson and associates (2007) found a link between some *personality traits*—not disorders—and excessive alcohol consumption, but not necessarily addiction or dependence. Conroy and coworkers (2010) found that a mother's ability to care for her newborn was impaired only when a personality disorder was coupled with depression.

CHAPTER 62: Dermatological Disorders

Herpes Gestationis—This disease, more frequently known as dermatitis herpetiformis is an inflammatory superficially seated multiform herpetiform eruption, which is characterized by erythematous, vesicular, pustular, and bullous lesions.

—J. Whitridge Williams (1903)

PREGNANCY-SPECIFIC DERMATOSES

Four dermatoses considered unique to pregnancy include intrahepatic cholestasis of pregnancy, pruritic urticarial papules and plaques of pregnancy (PUPPP), atopic eruption of pregnancy (AEP), and pemphigoid gestationis (PG). Descriptions of these are given in Table 62-1. As a group, these are diagnosed in up to 5 percent of pregnancies (Chander, 2011). Their gross appearance may be similar to each other or to other skin disorders, and pruritus is a common feature of all four. Only intrahepatic cholestasis and pemphigoid gestationis have been linked with adverse fetal outcomes.

TABLE 62-1

Pregnancy-specific Dermatoses

Disorder	Frequency	Characteristic Lesion	Adverse Pregnancy Effects	Treatment
Cholestasis of pregnancy	Common	No primary lesions, secondary excoriations from scratching	Increased perinatal morbidity	Antipruritics, cholestyramine, ursodeoxycholic acid
Pruritic urticarial papules and plaques of pregnancy (PUPPP)	Common	Erythematous pruritic papules or plaques; patchy or generalized on abdomen, thighs, buttocks, especially within striae, but with umbilical sparing	None	
Atopic eruptions of pregnancy (AEP)			None	Antipruritics, emollients, topical corticosteroids, oral steroids if severe
Eczema of pregnancy	Common	Dry, red scaly patches on extremity flexures, neck, face		
Prurigo of pregnancy	Common	1–5 mm pruritic red papules on extensor surfaces, trunk		
Pruritic folliculitis of pregnancy	Rare	Small red papules, sterile pustules on trunk		
Pemphigoid gestationis	Rare	Erythematous pruritic papules, plaques, vesicles, and bullae; abdomen often with umbilical involvement, extremities	Preterm birth, fetal-growth restriction, transient neonatal lesions	

Intrahepatic Cholestasis of Pregnancy

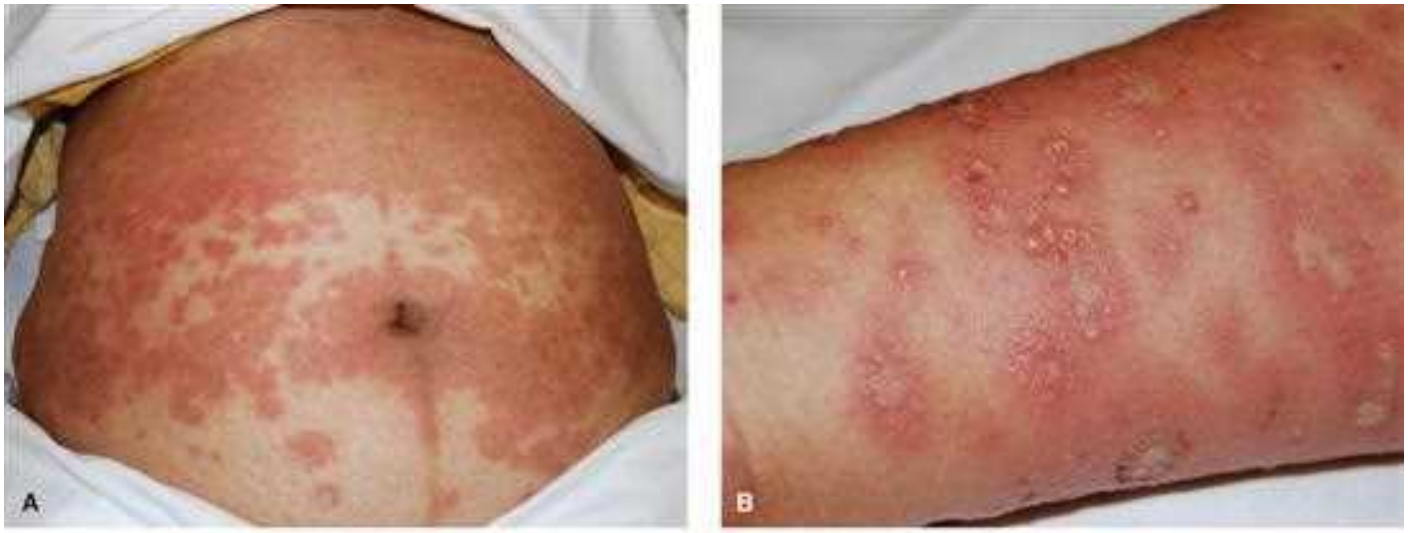
Previously termed pruritus gravidarum, this condition is found in 0.5 percent of pregnancies (Wikström Shemer, 2013). In contrast to the other pregnancy-specific dermatoses, intrahepatic cholestasis of pregnancy generally has no primary skin lesions. Rarely, a rash precedes pruritus, which is usually associated with abnormally elevated serum bile acid levels and mildly increased hepatic aminotransferase levels (Chao, 2011). Adverse fetal effects have been linked to this condition, and it is discussed in detail in Chapter 55 (Intrahepatic Cholestasis of Pregnancy).

Pemphigoid Gestationis

This rare autoimmune bullous disease is notable for its maternal and fetal effects. Initially, pruritic papules and urticarial plaques form and are then followed in most cases after 1 to 2 weeks by vesicles or bullae. Lesions are frequently distributed periumbilically, often develop on other skin surfaces, but spare mucous membranes, scalp, and face (Fig. 62-1).

FIGURE 62-1

Pemphigoid gestationis. **A.** Abdominal plaques classically involve the umbilicus. **B.** Blistered lesions on the wrist and forearm. (Used with permission from Dr. Kara Ehlers.)



Previously termed *herpes gestationis*, pemphigoid gestationis is not related to the herpesvirus. Instead, maternal immunoglobulin G (IgG) antibodies target collagen XVII found in the basement membrane of skin and amnionic epithelium (Kelly, 1988; Shimanovich, 2002). Collagen XVII is also termed bullous pemphigoid 180 (BP 180). Autoantibody binding to collagen XVII activates complement to promote eosinophil chemotaxis to the antigen-antibody complexes. Eosinophilic degranulation damages the dermal-epidermal junction and leads to blistering (Engineer, 2000).

Pregnancy

In most cases, PG develops during a first pregnancy. It may rarely be associated with gestational trophoblastic disease (Matsumoto, 2013; Takatsuka, 2012). Most subsequent pregnancies are also affected, usually earlier and more severely (Tani, 2015). Whites have a higher incidence, and other autoimmune diseases are frequent in affected women (Shornick, 1984, 1992).

PG usually begins during the second or third trimester, but postpartum onset or exacerbation is common (Lawley, 1978). The disease course is often marked by antepartum flares and remissions. And, especially in cases with early-onset and blistering, PG has an association with preterm birth and fetal-growth restriction (Al-Saif, 2016; Chi, 2009). One theory for this is mild placental insufficiency that stems from IgG and complement deposition along the amnionic basement membrane (Huilaja, 2013). Accordingly, antepartum surveillance of affected pregnancies is reasonable.

In 5 to 10 percent of cases, IgG antibodies passively transfer from the mother to cause similar skin lesions in the newborn (Erickson, 2002). These eruptions in the neonate require only wound care and clear spontaneously within a few weeks as the passively acquired IgG levels decline. Slowly following delivery, maternal lesions resolve without scarring, and most women are disease-free after 6 months (Jenkins, 1999). In some, however, resolution is protracted, and disease may be exacerbated during menses or by oral contraceptives (Semkova, 2009).

Diagnosis and Treatment

Before bullae form, these lesions may resemble pruritic urticarial papules and plaques of pregnancy. Other diagnoses include pustular psoriasis, dermatitis herpetiformis, erythema multiforme, linear IgA bullous dermatosis, urticaria, allergic contact dermatitis, bullous pemphigoid, and atopic eruption of pregnancy (Lipozenčić, 2012). Drug-induced blistering syndromes must also be excluded as some are life-threatening, for example, Stevens-Johnson syndrome and toxic epidermal necrolysis (Stern, 2012).

Skin biopsy and serum antibody assays are informative. Immunofluorescent staining of a skin punch biopsy sample is the gold standard, and C3 complement and sometimes IgG are seen deposited along the basement membrane between the epidermis and the dermis (Katz, 1976). Also, in many cases, circulating IgG antibodies against collagen XVII can be detected in maternal serum (Powell, 2005; Sitaru, 2004).

Pruritus can be severe. Early in its course, topical high-potency corticosteroids and oral antihistamines may be effective. Oral prednisone, 0.5 to 1 mg/kg daily gradually tapered to a maintenance dose, may be needed for relief and also for inhibition of new lesions. Plasmapheresis, high-dose intravenous immunoglobulin (IVIG) therapy, or cyclosporine has been used in intractable cases (Huilaja, 2015; Ko, 2014; Van de Wiel, 1980).

Pruritic Urticarial Papules and Plaques of Pregnancy

This relatively common pregnancy-specific dermatosis is characterized by its benign effects on pregnancy and by intensely pruritic 1- to 2-mm erythematous papules that coalesce to form urticarial plaques. Also known as *polymorphic eruption of pregnancy*, PUPPP usually appears late in pregnancy (Rudolph, 2005). Rarely, postpartum onset has been described (Park, 2013). The rash affects the abdomen and proximal thighs in 97 percent of women (Fig. 62-2). Lesions often initially form within striae but show periumbilical sparing. The face, palms, and soles also are rarely involved (High, 2005). It is more frequent in white and nulliparous women, those with multifetal gestation, and those carrying a male fetus (Regnier, 2008). PUPPP seldom recurs in subsequent pregnancies (Ahmadi, 2005). Its cause is unknown, but an autoimmune basis is not implicated (Lawley, 1979).

FIGURE 62-2

Pruritic urticarial papules and plaques of pregnancy (PUPPP) shows small papules on the buttock and proximal thigh and within abdominal striae.

PUPPP may be compared with several skin eruptions. Some include contact dermatitis, drug eruption, viral exanthem, insect bites, scabies infestation, pityriasis rosea, and the other pregnancy-specific dermatoses. It also may appear similar to early PG that has not yet blistered. In unclear cases, skin biopsy and negative serum collagen XVII antibody levels help to differentiate the two. Pruritus will usually respond to treatment with oral antihistamines, skin emollients, and topical corticosteroids. A few women will need systemic corticosteroids to relieve severe itching (Scheinfeld, 2008).

PUPPP usually resolves within several days following delivery and leaves no scarring. In 15 to 20 percent of women, however, symptoms persist for 2 to 4 weeks postpartum (Vaughan Jones, 1999).

Atopic Eruption of Pregnancy

This umbrella term encompasses three conditions previously considered separate: eczema in pregnancy, prurigo of pregnancy, and pruritic folliculitis of pregnancy (Ambros-Rudolph, 2006). Two thirds of women with atopic eruption have widespread eczematous changes, whereas the other third have papular lesions (American Academy of Dermatology, 2011). As a group, these pose no risk to the fetus. Diagnosis is greatly aided by a history of atopy and by rash characteristics.

Eczema in pregnancy has the appearance of traditional eczema but with a pregnancy onset. It is the most common pregnancy-specific dermatosis, and affected skin shows dry, thickened, scaly, red patches involving extremity flexures, nipples, neck, and face. In contrast, *prurigo of pregnancy*, also known as prurigo gestationis, is characterized by 5- to 10-mm, itchy, erythematous papules or nodules commonly found on the extensor surfaces and trunk. Last, *pruritic folliculitis of pregnancy* is rare and notable for small, erythematous follicular papules and sterile pustules predominantly on the trunk. Onset for all is during the second or third trimester, although eczema in pregnancy may develop earlier than the other two. All lesions commonly resolve with delivery, but may persist for up to 3 months postpartum. Recurrence with subsequent pregnancies is variable but common.

Diagnosis is one of exclusion. Serum bile acid levels are elevated but not greater than concentrations expected for normal pregnancy, and aminotransferase levels are normal. Serology specific for PG is negative. Many women with eczema of pregnancy have elevated serum IgE levels, which are not seen with the two other AEP dermatoses (Ambros-Rudolph, 2011).

For all three manifestations, skin lesions and pruritus are usually controlled with low- or moderate-potency topical corticosteroids and oral antihistamines. For severe eczema, second-line agents include short-course ultrapotent topical corticosteroids. In some cases, however, an oral corticosteroid, narrow-band ultraviolet B, or cyclosporine is required (Lehrhoff, 2013).

DERMATOLOGICAL CONDITIONS NOT SPECIFIC TO PREGNANCY

Any acute or chronic dermatological disorders can complicate pregnancy. Some of those chronic conditions are considered here.

Acne Vulgaris

This common chronic dermatosis is unpredictably affected by pregnancy and, if necessary, is treated with benzoyl peroxide alone or coupled with either topical erythromycin or topical clindamycin (Zaenglein, 2016). In these combinations, benzoyl peroxide minimizes *Propionibacterium acnes* drug resistance. Azelaic acid is another comedolytic agent, which is category B. Topical salicylic acid is category C, but amounts in over-the-counter products are considered safe (Murase, 2014). Topical retinoids, which include tretinoin and adapalene, also appear safe, are category C drugs, but are probably best avoided during pregnancy, especially during the first trimester (Kaplan, 2015; Panchaud, 2012). Topical tazarotene is contraindicated. For more severe cases, oral antibiotics that include erythromycin, azithromycin, cephalexin, or amoxicillin may be coupled with benzoyl peroxide. Systemic antibiotics are ideally delayed until the second trimester, and therapy duration limited to 4 to 6 weeks (Chien, 2016).

Psoriasis and Pustular Psoriasis

This chronic dermatosis also has a variable course during pregnancy, however, postpartum flares are common (Oumeish, 2006). Emollients alone are given initially, and low- or moderate-potency topical corticosteroids can be added. In resistant cases, restrained use of high-potency or ultrapotent corticosteroids appears safe in the second and third trimesters. Ultraviolet B phototherapy can be used as a second-line option. Last, cyclosporine, systemic corticosteroids, or tumor necrosis factor (TNF)-α antagonists that include adalimumab, etanercept, and infliximab are third-tier agents for pregnancy (Bae, 2012). Overall, data do not support an increased risk of adverse pregnancy outcomes with psoriasis (Bobotsis, 2016). With severe disease, a small increased risk for low-birthweight neonates was found by some (Lima, 2012; Yang, 2011). Also, in general, psoriatic patients have higher associated rates of depression (Bandoli, 2017; Cohen, 2016).

Psoriasis is most commonly of the chronic plaque variety. In contrast, with *generalized pustular psoriasis of pregnancy,* severe systemic symptoms may develop. Formerly called impetigo herpetiformis, this rare pustular form has erythematous, sometimes pruritic plaques ringed by sterile pustules that enlarge and then crust (Fig. 62-3). Lesions initially involve intertriginous areas but may spread to the torso, extremities, and oral mucosa. Comorbid constitutional symptoms are common. Laboratory testing may reveal hypocalcemia, elevated erythrocyte sedimentation rate, leukocytosis, and hypoalbuminemia (Lehrhoff, 2013). Extensive lesions can lead to sepsis from secondary infection and to massive fluid loss with hypovolemia and placental insufficiency. First-line treatment is with oral prednisone, cyclosporine, infliximab, topical corticosteroids, or topical calcipotriene (Robinson, 2012). Phototherapy is a second-line option. For secondary infections, intravenous antibiotics are added (Huang, 2011). Pustular psoriasis typically resolves quickly in the puerperium, but recurrences have been reported in subsequent pregnancies and with menstruation or oral contraceptive use (Roth, 2011).

FIGURE 62-3
Generalized pustular psoriasis of pregnancy displays erythematous, sometimes pruritic plaques ringed by sterile pustules that enlarge and then form a scaling crust. (Used with permission from Dr. Paul Slocum.)

Erythema Nodosum

This skin condition represents inflammation of subcutaneous fat associated with numerous disorders, including pregnancy. Other triggers are infections, sarcoidosis, drugs, Behçet syndrome, inflammatory bowel disease, or a malignancy (Mert, 2007; Papagrigoraki, 2010). Characteristically, 1- to 6-cm tender, red, warm nodules and plaques develop rapidly on the extensor surface of the legs and arms. Within a few days, lesions flatten and undergo the color evolution of a bruise—from dark red and purple to yellow green. Constitutional symptoms may also be present. Initial evaluation and treatment focuses on the underlying etiology. Symptoms spontaneously resolve in 1 to 6 weeks without scarring but may leave residual hyperpigmentation (Acosta, 2013).

Pyogenic Granuloma

This lesion is frequently seen in pregnancy (Fig. 62-4). Poorly named, pyogenic granuloma is actually a lobular capillary hemangioma commonly forming on the mouth or hand in response to low-grade local irritation or traumatic injury. They grow quickly and bleed with minimal provocation. Active bleeding can be controlled with pressure and application of a silver nitrate stick or Monsel paste (ferric subsulfate). These growths often resolve within months postpartum. But with a symptomatic antepartum growth, a persistent postpartum lesion, or with an unclear diagnosis, excision can be done using suture and scalpel, electrosurgical curettage, laser photocoagulation, or cryotherapy. Oral lesions are best referred to oral health-care specialists.

FIGURE 62-4

Pyogenic granuloma is characterized grossly by a lobulated red growth on a pedunculated or sessile base. With minimal trauma, these vascular lesions bleed easily. (Used with permission from Dr. Abel Moron.)

Neurofibromatosis

These lesions are typified by benign cutaneous neurofibromas, café-au-lait spots, axillary and inguinal freckling, benign nodules of the iris (Lisch nodules), and optic nerve gliomas. Neurofibromas may increase in size and number during pregnancy (Cesaretti, 2013; Dugoff, 1996). With the more common neurofibromatosis type 1, higher rates of preclampsia and preterm birth complicate pregnancy (Leppävirta, 2017; Terry, 2013). With neurofibromatosis type 2, some evidence suggests a risk for preeclampsia (Terry, 2015). Prenatal genetic diagnosis is available for both types (Merker, 2015; Spits, 2007).

Miscellaneous Conditions

Rosacea fulminans is also known as *pyoderma faciale.* It is rare and characterized by facial pustules and coalescing draining sinuses. Topical or oral antimicrobials are primary treatment, although surgical drainage and corticosteroids have also been used (Fuentelsaz, 2011; Jarrett, 2010).

Hidradenitis suppurativa is said to improve with pregnancy, but in our experiences, it is not appreciably changed. Twice daily topically applied 1-percent clindamycin gel for 12 weeks aims to prevent new lesions. This can be supplemented by 7- to 10-day courses of oral amoxicillin plus clavulanic acid or oral clindamycin to reduce lesion progression (Margesson, 2014). Other options are reviewed by Perng and coworkers (2017).

Other skin conditions that are discussed elsewhere in this book include hirsutism and melanoma (Chap. 63, Malignant Melanoma), cutaneous lupus (Chap. 59, Lupus and Pregnancy), hyperpigmentation (Chap. 4, Breasts), and skin lesions seen with infections (Chaps. 64 and 65).

DERMATOLOGICAL TREATMENT

Local skin care, oral antihistamines, and topical corticosteroids are commonly used for many dermatoses. Oral antihistamines are given for pruritus. Suitable options include first-generation agents such as diphenhydramine (Benadryl), 25 to 50 mg every 6 hours, or chlorpheniramine (Chlor-Trimeton), 4 mg every 6 hours. Second-generation agents—loratadine (Claritin) 10 mg daily or cetirizine (Zyrtec) 5 or 10 mg daily—may produce less sedation and are also pregnancy category B.

Hundreds of topical corticosteroid preparations are available, and in the United States, these are categorized by potency into seven groups. For initial treatment of dermatological disorders, low- or moderate-potency agents are preferred. Low-potency agents include those in groups 6 and 7, such as 1-percent hydrocortisone or 0.05-percent desonide (DesOwen). Moderate-potency drugs are in groups 5, 4, and 3—such as 0.1-percent triamcinolone acetonide (Aristocort) or 0.1-percent mometasone furoate (Elocon). High-potency medications are in group 2, such as 0.05-percent betamethasone dipropionate (Diprolene). Ultrapotent agents in group 1, such as 0.05-percent clobetasol propionate (Temovate), are best reserved for refractory disorders and used for only 2 to 4 weeks on small surface areas.

Mild and moderate strengths are not associated with adverse pregnancy outcomes, whereas high- and ultrapotent agents pose a small risk for fetal-growth restriction with large cumulative doses (Chi, 2013, 2015). Even then, this risk is less than that with systemic corticosteroids. Importantly, with any topical agent, factors that increase systemic absorption include a large surface area treated, compromised epidermal barrier, occlusive dressings, prolonged treatment duration, and coadministration of topical agents that increase absorption.

The list of other agents used for dermatological conditions is extensive. For use in pregnancy and lactation, Murase (2014) and Butler (2014) have compiled tables and evidence-based descriptions of most. Notable therapeutic agents to avoid during pregnancy include methotrexate, psoralen plus ultraviolet A, mycophenolate mofetil, podophyllin, and systemic retinoids. These are discussed in more detail in Chapter 12. Bacterial infections are a potential secondary complication of skin disorders and are treated promptly with oral antimicrobial agents with gram-positive coverage.

CHAPTER 63: Neoplastic Disorders

Any excessive enlargement of the abdomen or the appearance of pressure symptoms should always lead one to make a careful examination, and in not a few cases a tumour will be found occupying the pelvic cavity. In rare instances malignant tumours of the rectum may so obstruct the pelvic canal as to render caesarean section imperative.

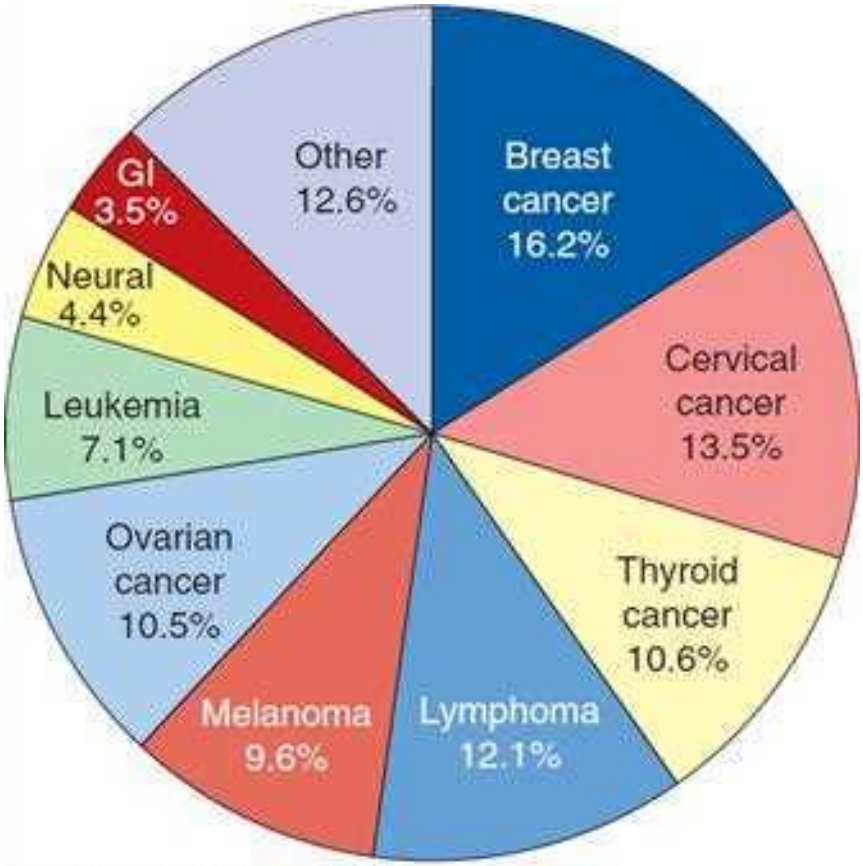
—J. Whitridge Williams (1903)

INTRODUCTION

Any neoplasm can complicate pregnancy, and as written by Williams, physical examination often suggests the diagnosis. Current imaging also allows a greater number of these to be identified antepartum. Most encountered neoplasms are benign, and uterine leiomyomas and ovarian cysts are the most frequent.

Cancer has an incidence approximating 1 per 1000 pregnancies (Parazzini, 2017; Salani, 2014). One third are diagnosed prenatally, and the others within 12 months of delivery. Some of the more frequent ones are shown in Figure 63-1. Breast cancer is found in 1 in 5000 pregnancies, thyroid—1 in 7000, and cervical—1 in 8500 (Smith, 2003). These, along with lymphoma and melanoma, account for 65 percent of malignancy cases in pregnancy (Eibye, 2013). For some cancers—ovary, endometrium, and breast—evidence suggests that high parity is protective (Högnäs, 2014).

FIGURE 63-1
Proportion of malignancies during pregnancy and within 12 months of delivery in 4.85 million women from the California Cancer Registry. GI = gastrointestinal. (Data from Smith, 2003.)



During pregnancy, cancer management poses unique problems related to fetal concerns, and treatment must be individualized. Considerations include the type and stage of malignancy, the desire for pregnancy continuation, and inherent risks associated with modifying or delaying cancer treatment.

CANCER THERAPY IN PREGNANCY

Surgery

Operative procedures indicated for cancer include those for diagnosis, staging, or therapy. Fortunately, most procedures that do not interfere with the reproductive tract are well tolerated by both mother and fetus (Chap. 46, Medications and Surgeries). Although many operations have classically been deferred until after 12 to 14 weeks' gestation to minimize miscarriage risks, this probably is not necessary. We are of the opinion that surgery should be performed regardless of gestational age if maternal well-being is imperiled.

Both pregnancy and malignancy are risk factors for venous thromboembolism (VTE). In one study, Bleau and coworkers (2016) reported a higher risk of VTE in gravidas with myeloid leukemia, Hodgkin disease, cervical cancer, and ovarian cancer compared with that in pregnant women without a malignancy. The risk was not increased in those with brain or thyroid cancer, melanoma, or lymphoid leukemia. That said, current guidelines lack specific recommendations for pregnant women undergoing surgeries for cancer. Thus, depending on the complexity of the planned procedure, it seems reasonable to use prophylactic low-molecular-weight heparin combined with elastic stockings and/or intermittent pneumatic compression as described in Chapter 52 (Thromboprophylaxis).

Diagnostic Imaging

Sonography is a preferred imaging tool during pregnancy. Even so, according to the American College of Obstetricians and Gynecologists (2017a), most diagnostic radiographic procedures deliver very low x-ray doses and should not be delayed if they would directly affect therapy (Chap. 46, X-Ray Dosimetry). Magnetic resonance (MR) imaging can safely be performed in any trimester, but delay until after the first trimester may lower potential risks. Gadolinium should not be used in the first trimester and should be used later in pregnancy only when the benefits overwhelmingly outweigh the risks (American College of Radiology, 2016; Kanal, 2013). Computed tomography (CT) is less often selected due to ionizing radiation, and procedure-related doses are listed in Chapter 46 (Computed Tomography). Accordingly, CT is used in pregnancy most often to evaluate acute concerns that include pulmonary embolism, bowel or renal obstruction, and acute neurological events. To enhance CT, oral and intravenous contrasts may be added. These lack known fetal harm, and postpartum breastfeeding need not be interrupted. Last, some radioisotopes are relatively safe in pregnancy and are listed in Table 46-8.

Radiation Therapy

Therapeutic radiation often results in significant fetal exposure depending on the dose, tumor location, field size, and gestational age. Potential adverse effects include fetal malformation, intellectual disability, growth restriction, sterility, and carcinogenesis (Brent, 1999; Stovall, 1995). In the 2 weeks following fertilization, exposure typically leads to chromosomal damage and embryonic death. The next most susceptible period is during organogenesis in weeks 2 through 8, and exposure can cause malformation. These might develop above a threshold dose of 0.1 to 0.2 Gy. During weeks 8 through 25, the fetal central nervous system is especially vulnerable. The threshold dose for intellectual disability at 8 to 15 weeks' gestation approximates 0.06 Gy, and at 16 to 25 weeks it is about 0.25 Gy (Kal, 2005; Otake, 1996). After 25 weeks' gestation, susceptibility is less, although no gestational age is considered safe for therapeutic radiation exposure. Thus, radiotherapy to the maternal abdomen is contraindicated. With some head and neck cancers, however, radiotherapy to supradiaphragmatic areas can be used relatively safely with abdominal shielding of the fetus (Amant, 2015a).

Chemotherapy

Various antineoplastic drugs may be given for primary treatment or for adjunctive therapy. Although chemotherapy often improves long-term maternal outcomes, many are reluctant to employ it during pregnancy. Concerns for the fetus include malformations, growth restriction, intellectual disability, and the risk of future childhood malignancies. Risks are dependent primarily on fetal age at exposure, and most agents are potentially detrimental in the first trimester during organogenesis. Indeed, in one review, 14 percent of major malformations were attributable to first-trimester exposure to cytotoxic drugs (National Toxicology Program, 2013).

After the first trimester, most antineoplastic drugs are without immediate obvious adverse fetal sequelae (Abdel-Hady, 2012; Vercruysse, 2016). Similarly, late mutagenic effects appear limited (Amant, 2015b; Cardonick, 2015). Although not always practicable, some recommend that chemotherapy be withheld in the 3 weeks before expected delivery because neutropenia or pancytopenia might cause undue risk for maternal infection or hemorrhage. Another concern is that neonatal hepatic and renal clearance of chemotherapy metabolites is limited (Ko, 2011). For these reasons, most cytotoxic chemotherapy agents are contraindicated with breastfeeding (Pistilli, 2013).

Molecular Therapy

Drugs designed to stimulate hemopoiesis are commonly used with cancer treatments. Some of these include the granulocyte colony-stimulating factors filgrastim (Neupogen) and pegfilgrastim (Neulasta). If required in pregnancy, limited data support the safety of these agents (Boxer, 2015). Red blood cells can be stimulated by erythropoietin alfa (Procrit), which from case reports also appears safe in pregnancy (Sienas, 2013). However, maternal hypertension is a known potential risk.

Targeted Therapy

The two main types of targeted therapy are monoclonal antibodies and small molecule inhibitors. Both block the actions of specific enzymes, proteins, or other molecules involved in cancer cell growth. These drugs are designed to treat an ever-expanding list of cancers, and some are described in later discussions of specific tumors. Most of these compounds are labeled by the Food and Drug Administration (FDA) as class D, and data are limited regarding their pregnancy or breastfeeding effects.

Many of these drugs target tyrosine kinase, an important enzyme that regulates signaling pathways involved with cell division, differentiation, and apoptosis. With first-trimester use, embryo toxicity or teratogenicity has been attributed to these. Thus, this specific group of targeted agents is considered for use in pregnancy only if the potential benefit to the pregnant woman justifies the potential risk to the fetus (Lodish, 2013).

Of other agents, the monoclonal antibody trastuzumab (Herceptin) inhibits the human epidermal growth factor receptor type 2 (HER2), which some breast cancers express. Although not teratogenic, its use in the second and third trimesters is associated with oligohydramnios, which appears to be reversible upon stopping the drug (Sarno, 2013; Zagouri, 2013b). Because of sparse available data, other HER2 inhibitors are best avoided in pregnancy (Lambertini, 2015).

Fertility and Pregnancy after Cancer Therapy

Fertility may be diminished after chemotherapy or radiotherapy. Counseling ideally takes place before cancer treatment, and guidelines for this have been developed (American Society for Reproductive Medicine, 2013a; Lambertini, 2016; Loren, 2013; Peccatori, 2013). Prior to therapy, cryopreservation of embryos or of oocytes is a recognized fertility-preserving option (American Society for Reproductive Medicine, 2013b,c). Surgical transposition of the ovaries can be considered if pelvic radiation is planned. For this, ovaries and their intact primary blood supply are carried out of the pelvis and fixed to the lateral abdominal wall at a site 3 to 4 cm above the level of the umbilicus. In one review, functional preservation was reported in 65 to 94 percent, depending on radiotherapy type (Gubbala, 2014). Also, such transposition requires transabdominal egg retrieval if later in vitro fertilization is planned (American Society for Reproductive Medicine, 2013a).

Ovarian suppression with gonadotropin-releasing hormone agonists is not beneficial, according to a recent review (Elgindy, 2015). At this time, cryopreservation of ovarian tissue is considered investigational. These methods currently are limited to referral centers.

In counseling cancer survivors, evidence suggests that exposure to most radiotherapy or chemotherapy agents in childhood or adulthood does not significantly increase the risk of congenital anomalies or genetic disease in their offspring (Haggar, 2014; Signorello, 2012; Stensheim, 2013; Winther, 2012). In those treated as children with chemotherapy, studies also do not show a consistent link to adverse obstetrical outcomes (Melin, 2015; Reulen, 2009). Data are limited regarding those with cancer treated as an adult, and some studies have shown slightly higher rates of preterm birth and cesarean delivery (Haggar, 2014; Stensheim, 2013).

Notably, prior abdominopelvic radiation more convincingly affects neonatal outcomes. Adverse effects include elevated rates of abortion, low birthweight, stillbirth, and preterm birth (Signorello, 2006, 2010; Winther, 2008). Radiation may lower reproductive potential by creating reduced uterine volume, a thinned endometrium, and impaired uterine blood flow (Critchley, 1992; Larsen, 2004). Greater effects are seen with direct uterine radiation and with radiotherapy at younger ages (Teh, 2014).

Importantly, many cancer survivors conceive by assisted reproductive technology, which by itself has associated obstetrical risks. This is discussed in Chapter 8 (Reproductive History).

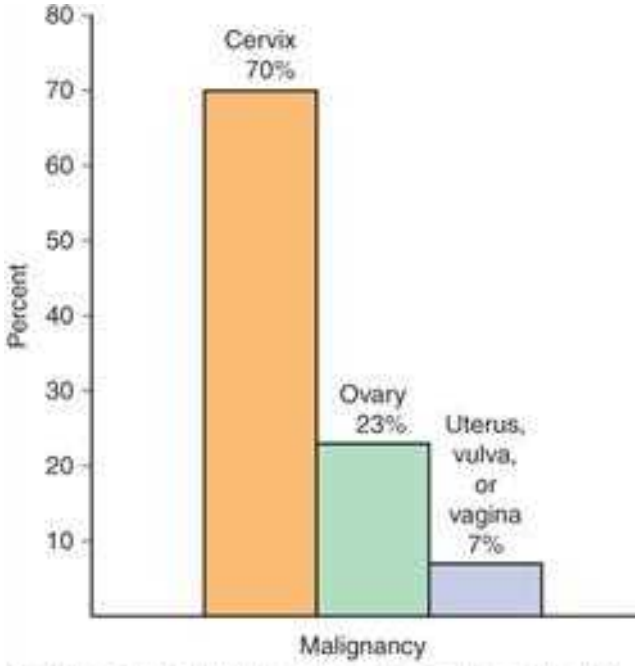
Placental Metastases

Tumors infrequently metastasize to the placenta. As described in Chapter 6 (Amniochorion), the most common types are malignant melanomas, leukemias, lymphomas, and breast cancer (Al-Adnani, 2007). Placentas from pregnancies in these and all other women with a malignancy should be sent for histological evaluation. Because tumor cells are usually confined within the intervillous spaces, fetal metastases are infrequent.

REPRODUCTIVE TRACT NEOPLASMS

Benign neoplasms are common and include leiomyomas, ovarian neoplasms, and endocervical polyps. Cancer in these organs may also complicate pregnancy, and of these, cervical neoplasia makes up the majority (Fig. 63-2).

FIGURE 63-2
Frequency of reproductive-tract malignancies in 844 pregnant women. (Data from Haas, 1984; Lutz, 1977; Smith, 2003.)



Cervix

Endocervical Polyp

These are overgrowths of endocervical stroma covered by epithelium. They typically appear as single, red, elongated fleshy masses of variable size that extend outward from the endocervical canal. Usually benign, they can bleed and can be a source of Pap test results describing *atypical glandular cells of undetermined significance—AGUS*. With removal and histological evaluation of these polyps, dysplasia is diagnosed in up to 0.5 percent, and there is malignant transformation in up to 0.1 percent (Esim Buyukbayrak, 2011; Long, 2013).

Few formal data guide management in pregnancy. Small asymptomatic lesions may be left alone to slough during delivery or puerperal remodeling. Removal and histological evaluation is reasonable if malignancy is suspected or if bleeding is troublesome. For those with a slender stalk, the polyp is grasped with ring forceps and twisted repeatedly about its base to strangulate feeding vessels. With repeated twisting, the base narrows and avulses. Monsel paste, which is ferric subsulfate, can be applied with pressure to the stalk stub for hemostasis. A thick-pedicle polyp may sometimes warrant surgical ligation and excision.

Epithelial Neoplasia

Pregnancy provides an opportune time to screen for cervical intraepithelial neoplasia (CIN), especially in women without regular access to health care. With Pap test screening, pregnancy status is noted on the requisition form because interpretation may be hindered by pregnancy-associated physiological changes. Some of these changes include presence of decidual cells and less often, Arias-Stella reaction. The latter gives an appearance of endocervical gland hyperplasia, which can make differentiating this from truly atypical glandular cells difficult.

Screening guidelines also applicable in pregnant women were updated in 2012 by the American Society for Colposcopy and Cervical Pathology (ASCCP). These include: (1) no screening until age 21, (2) cytology alone every 3 years in those aged 21 to 29 years, and (3) in those older than 30, human papillomavirus (HPV) *and* cytology co-testing every 5 years, or cytology alone every 3 years (Massad, 2013). High-risk conditions for cervical neoplasia include human immunodeficiency virus (HIV) infection, other immunocompromised states, and in utero diethylstilbestrol (DES) exposure. For women with HIV infection, initiation of cervical cancer screening with cytology alone begins within the first year after HIV diagnosis (American College of Obstetricians and Gynecologists, 2016b).

Human Papillomavirus

This virus infects cervical epithelia. In most instances, the infection clears, but in a smaller number, the virus may promote benign, premalignant, or cancerous neoplastic growth. The prevalence of HPV infection in pregnant women approximates 15 percent (Hong, 2013; Liu, 2014). There are more than 100 serotypes, and several are associated with high-grade intraepithelial lesions and invasive cancer. The most prominent of these are serotypes 16 and 18. Cervical cancer screening that combines both cytology and testing for high-risk HPV serotypes is termed *co-testing* and is suitable for women 30 years and older. Notably, as a new paradigm for screening, primary HPV testing alone can be considered an appropriate sole method for women older than 25 years (Huh, 2015). With this, identification of serotypes 16 or 18 prompts colposcopic evaluation.

Serotypes HPV 6 and 11 are linked with benign maternal genital warts. Congenital HPV infection from vertical transmission—mother to fetus or newborn—beyond transient skin colonization is rare. Still, conjunctival, laryngeal, vulvar, or perianal warts present at birth in the neonate or that develop within 1 to 3 years of birth are most likely due to perinatal exposure to these maternal HPV serotypes. This is described further in Chapter 65 (Vaginitis). Importantly, cesarean delivery does not lower the risk of neonatal laryngeal papillomatosis.

The clear link between HPV infection and cervical neoplasia has prompted development of three approved vaccines. These are not administered during pregnancy, are compatible with breastfeeding, and are discussed in Chapter 65 (Vaginitis).

Abnormal Cytology and Histology

The incidence of abnormal cervical cytology during pregnancy is at least as high as that reported for nonpregnant women. Abnormal cytological findings and their suggested management according to consensus guidelines are summarized in Table 63-1. Many of these cytological abnormalities should prompt colposcopy, and the main goal during pregnancy is exclusion of invasive cancer. Accordingly, lesions suspicious for high-grade disease or cancer should undergo biopsy. Unsatisfactory colposcopic evaluation is less common during pregnancy because the transformation zone is better exposed due to cervical eversion. With insufficient visualization of the zone, colposcopy is repeated in 6 to 8 weeks. During this time, the squamocolumnar junction usually will further evert to permit satisfactory examination.

TABLE 63-1

Management of Pap Test Abnormalities in Pregnancy

Abnormality	Women Aged 25+ Years	Women Aged 21 to 34 Years
NILM/HPV positive[a]	Repeat Pap in 1 year; colposcopy if current Pap is 2nd NILM/HPV positive	Not applicable
ASC-US		
HPV positive	Colposcopy preferred; deferral of colposcopy until 6 weeks postpartum acceptable	Repeat Pap in 1 year
HPV negative	Routine screening	Routine screening
HPV unknown	Repeat cytology 1 year; colposcopy if current Pap is 2nd ASC-US	
LSIL	Colposcopy preferred; deferral of colposcopy until 6 weeks postpartum acceptable	Repeat Pap in 1 year
ASC-H HSIL SCCA AGC AIS adenoCA	Colposcopy during pregnancy[b]	

[a]Women aged 30+ years.

[b]Endocervical curettage and endometrial sampling are contraindicated in pregnancy.

adenoCA = adenocarcinoma; AGC = atypical glandular cells; AIS = adenocarcinoma in situ; ASC-H = atypical squamous cells, cannot exclude high-grade squamous intraepithelial lesion; ASC-US = atypical squamous cells of undetermined significance; HPV = human papillomavirus; HSIL = high-grade squamous intraepithelial lesion; LSIL = low-grade squamous intraepithelial lesion; NILM = negative for intraepithelial lesion or malignancy; SCCA = squamous cell carcinoma.

Adapted from American Society for Colposcopy and Cervical Pathology (ASCCP) 2012 Consensus Guidelines; Massad, 2013.

Table summarized and used with permission from Dr. Claudia L. Werner.

Women with histologically confirmed CIN during pregnancy may be allowed to deliver vaginally, with further evaluation planned after delivery. For those with CIN 1, the recommended management is reevaluation postpartum. For those with CIN 2 or 3 in which invasive disease has been excluded, deferring reevaluation until at least 6 weeks postpartum is acceptable. Alternatively, repeat colposcopic and cytological evaluations are performed at intervals no more frequent than 12 weeks. Repeat biopsy is recommended only if appearance of the lesion worsens or if cytology suggests invasive cancer (Massad, 2013).

Regression of a CIN lesion is common during pregnancy or postpartum. In a study of 1079 pregnant women with cervical dysplasia in which biopsy correlated with colposcopic findings, 61 percent of lesions reverted to normal postpartum (Fader, 2010). In another study, Yost and colleagues (1999) reported postpartum lesion regression in 70 percent of women with CIN 2 or 3. And, although 7 percent of women had CIN 2 lesions that progressed to CIN 3, no lesion progressed to invasive carcinoma. In another study of 77 women with carcinoma in situ (CIS) diagnosed during pregnancy, a third had postpartum regression of their lesion, two thirds had persistent CIS, and only two women had microinvasive cancer on cone biopsy after delivery (Ackermann, 2006).

Adenocarcinoma in situ (AIS) is managed similarly to CIN 3 (Dunton, 2008). Thus, unless invasive cancer is identified, treatment of AIS is not recommended until 6 weeks postpartum.

Cervical Conization

If invasive epithelial lesions are suspected, conization is indicated and may be done with loop electrosurgical excisional procedure (LEEP) or by cold-knife conization. However, the epithelium and underlying stroma within the endocervical canal cannot be extensively excised without the risk of membrane rupture. Logically, residual disease is common. Of 376 cone biopsies during pregnancy, Hacker and associates (1982) found residual neoplasia in 43 percent of subsequent specimens. In addition, nearly 10 percent of 180 pregnant women required transfusion after conization (Averette, 1970). Thus, if possible, conization is avoided in pregnancy because of its higher risks for abortion, membrane rupture, hemorrhage, and preterm delivery.

Women with CIN treated *before* pregnancy may also encounter pregnancy complications. First, cicatricial cervical stenosis is uncommon but may follow conization, LEEP, or laser surgery. Cervical stenosis almost always yields during labor. A so-called *conglutinated cervix* may undergo almost complete intrapartum effacement without dilation, and the presenting part is separated from the vagina by only a thin layer of cervical tissue. Spontaneous dilation usually promptly follows firm pressure with a fingertip, although instrumented dilation or cruciate incisions may be required.

Second, preconceptional cold-knife conization is associated with cervical insufficiency and preterm birth. That said, the relationship between preterm birth and LEEP continues to be debated (Castanon, 2012; Conner, 2014; Stout, 2015; Werner, 2010). The size of tissue excised seems to be directly related to adverse outcomes (Weinmann, 2017).

Invasive Cervical Cancer

The incidence of invasive cervical carcinoma has dramatically declined in the United States as a result of PAP testing (American College of Obstetricians and Gynecologists, 2016b). This cancer is found in approximately 1 in 8500 pregnancies (Bigelow, 2017; Pettersson, 2010). The diagnosis is confirmed with biopsies taken during colposcopy, with conization, or from a grossly abnormal lesion. Of the histological types, squamous cell carcinomas account for 75 percent of all cervical cancers, whereas adenocarcinomas compose the remainder. Cancers may appear as exophytic or endophytic growth; as a polypoid mass, papillary tissue, or barrel-shaped cervix; or as focal ulceration or necrosis. A watery, purulent, foul, or bloody discharge may also be present. Biopsy with Tischler forceps is warranted for suspicious lesions. Abnormal tumor vessels may cause heavier than expected biopsy-site bleeding, which is usually controlled by Monsel paste and pressure.

Cervical cancer is staged clinically, and 70 to 75 percent of cases that are diagnosed in pregnancy are stage I (Bigelow, 2017; Morice, 2012). Physiological pregnancy changes may impede accurate staging, and the extent of cancer is more likely to be underestimated in pregnant women. Specifically, induration of the broad ligament base, which characterizes tumor spread beyond the cervix, may be less prominent due to cervical, paracervical, and parametrial pregnancy-induced softening. Staging in pregnancy typically incorporates findings from pelvic examination and from renal sonography, chest radiography, cystoscopy, proctoscopy, and perhaps cone biopsy. Although MR imaging is not formally considered for clinical staging, it can be used without gadolinium contrast to ascertain involvement of the urinary tract and lymph nodes (Fig. 63-3).

FIGURE 63-3
Sagittal T2-weighted magnetic resonance image of a gravid uterus at 32 weeks' gestation with a large cervical carcinoma (*arrows*).

Management and Prognosis

Cervical cancer treatment in pregnant women is individualized, and factors include the clinical stage, fetal age, and individual desire to continue pregnancy. Stage IA1 is termed *microinvasive disease* and describes lesions with deepest invasion ≤3 mm and widest lateral extension ≤7 mm (FIGO Committee on Gynecologic

Oncology, 2009). If diagnosed by cone biopsy, then treatment follows guidelines similar to those for intraepithelial disease. In general, continuation of pregnancy and vaginal delivery are considered safe, and definitive therapy is reserved until 6 weeks postpartum.

In contrast, invasive cancer demands relatively prompt therapy. During the first half of pregnancy, immediate treatment is advised by most, but this depends on the decision whether to continue pregnancy. During the latter half of pregnancy, most agree that pregnancy can safely be continued until fetal lung maturity is attained (Greer, 1989). In two studies with a total of 40 women past 20 weeks' gestation with either stage I or stage IIA carcinoma, delayed treatment was considered reasonable in women without bulky lesions (Takushi, 2002; van Vliet, 1998). Another option is to complete staging using laparoscopic lymphadenectomy and to delay treatment if metastases are excluded (Alouini, 2008; Favero, 2010). In a metaanalysis, neoadjuvant chemotherapy, that is, prior to surgery, with platinum derivatives was found to be promising for treatment in pregnancy (Zagouri, 2013a).

Although surgical therapy and radiation are equally effective, radical hysterectomy plus pelvic lymphadenectomy is the preferred treatment for invasive cervical cancer in most young women with stage I and early stage IIA lesions. Disadvantageously, radiotherapy for cervical cancer destroys ovarian and possibly sexual function, and frequently causes intestinal and urinary tract injury. In 49 women with pregnancy-associated stage IB cancer, a 30-percent severe complication rate accompanied radiotherapy compared with that of only 7 percent with radical surgery (Nisker, 1983). With surgery before 20 weeks' gestation, radical hysterectomy is usually performed with the fetus in situ. In later pregnancy, however, hysterotomy is often performed first.

Although less commonly selected during pregnancy, other procedures have been investigated for early-stage cervical cancers. Ungár and colleagues (2006) performed abdominal radical trachelectomy before 20 weeks' gestation for stage IB1 cancer in five pregnant women. Yahata and associates (2008) treated four women at 16 to 23 weeks for stage IA1 adenocarcinoma with laser conization, and all delivered at term. Van Calsteren and coworkers (2008) reported similar success.

For more advanced-stage cancer, radiotherapy is given. External beam radiation in early in pregnancy typically leads to spontaneous abortion. If miscarriage does not ensue, curettage is performed. During the second trimester, spontaneous abortion may not promptly occur and may necessitate hysterotomy in up to a fourth of cases. This is selected because labor induction or dilation and evacuation may pose serious hemorrhage risks.

Pregnancy does not have a negative effect on the prognosis of cervical cancer, and survival outcomes are similar for pregnant and nonpregnant women (Amant, 2014; Mogos, 2013). In a case-control study of 44 women with pregnancy-associated cervical cancer, the overall 5-year survival rate approximated 80 percent in both pregnant women and nonpregnant controls (van der Vange, 1995).

Delivery

Any adverse prognostic effects that vaginal delivery through a cancerous cervix might have are unknown. For this reason, the mode of delivery is controversial, especially for small, early-stage lesions. In some cases of bulky or friable tumors, significant hemorrhage from the cancer may complicate vaginal delivery. Also, recurrences have been reported in the episiotomy scar, which result from tumor cells apparently "seeding" the episiotomy (Goldman, 2003). Thus, most favor cesarean delivery.

Pregnancy after Radical Trachelectomy

There is growing experience with pregnancy in women who have undergone fertility-sparing radical trachelectomy for stage IB1 and IB2 cervical cancer before conception. During the typically vaginal procedure, the cervix is amputated at the level of the internal os, and a permanent-suture cerclage is placed around the isthmus for support in future pregnancies. The uterine isthmus is then reconstructed to the vagina. Because of the permanent cerclage, a classical cesarean incision is required for delivery.

Shepherd and colleagues (2006) presented outcomes for 123 such women cared for at their institution. Of 63 women who attempted pregnancy, 19 had 28 live births. All underwent classical cesarean delivery, and one fourth delivered before 32 weeks. Similar findings were reported by Kim (2012) and Park (2014) and their coworkers.

Uterus

Leiomyomas

Also known as myomas and somewhat erroneously called *fibroids*, uterine leiomyomas are common benign smooth-muscle tumors. Their incidence during pregnancy approximates 2 percent, and the cited range depends on the frequency of routine sonography and population characteristics (Qidwai, 2006; Stout, 2010). In one study of 4271 women, the first-trimester leiomyoma prevalence was highest in black women—18 percent—and lowest in whites—8 percent (Laughlin, 2009).

Leiomyomas vary in location and may develop as submucous, subserosal, or intramural growths. Less often, these develop in the cervix or broad ligament. Some become parasitic and their blood supply is derived from adjacent structures such as the highly vascularized omentum. In one rare manifestation–*leiomyomatosis peritonealis disseminata*–numerous, small, benign subperitoneal smooth-muscle tumors appear similar to carcinomatosis. The tumors are likely caused by estrogen stimulation of multicentric subcoelomic mesenchymal cells to become smooth-muscle cells (Bulun, 2015). These growths often regress after pregnancy.

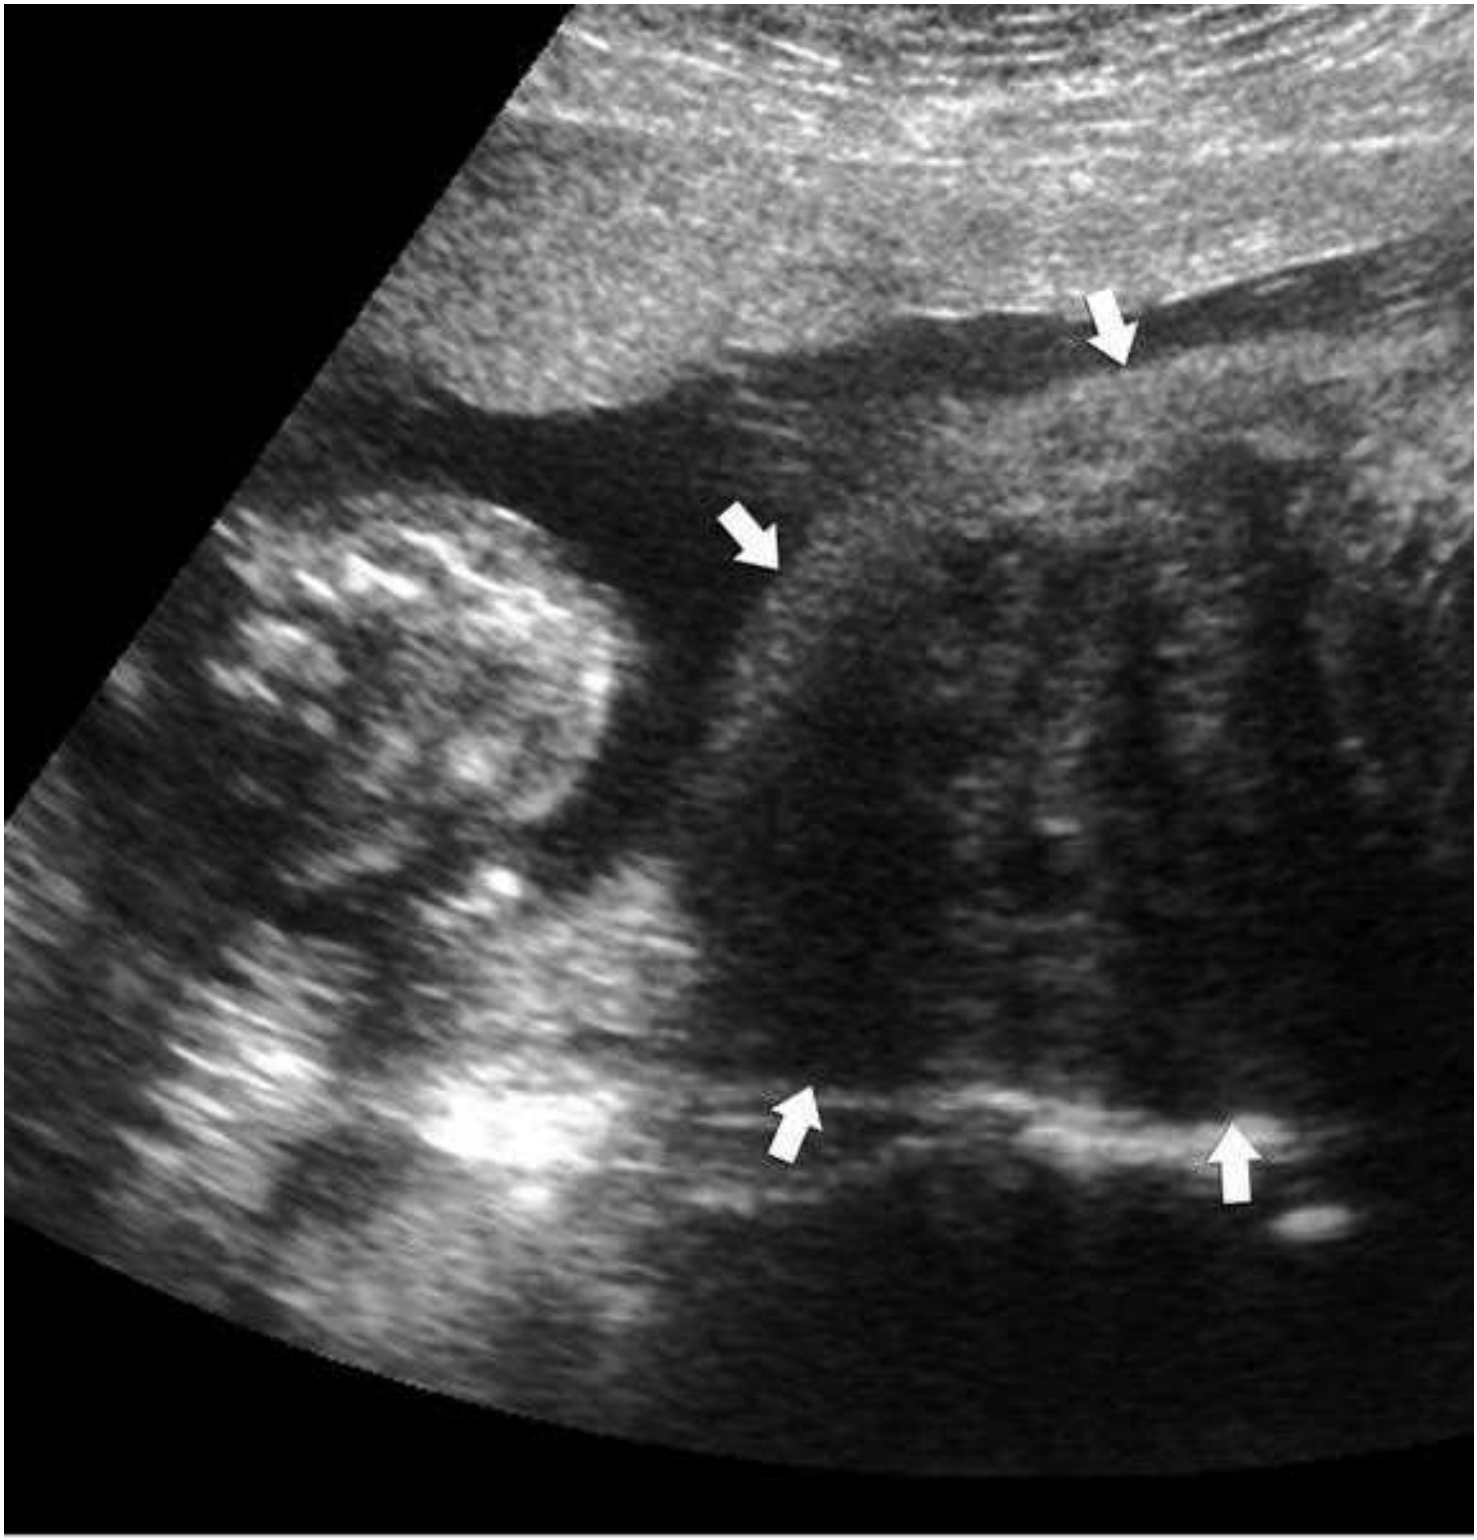
The stimulatory effects of pregnancy progesterone on myoma growth are unpredictable and can be impressive. These tumors respond differently in individual women and may grow, regress, or remain unchanged in size during pregnancy (Laughlin, 2009; Neiger, 2006).

Especially during pregnancy, myomas can be confused with other adnexal masses, and sonographic imaging is indispensable (Fig. 63-4). In women in whom sonographic findings are unclear, MR imaging performed after the first trimester may be necessary. Once diagnosed, leiomyomas do not require surveillance with serial sonography unless associated complications are anticipated.

FIGURE 63-4

Sonogram of a pregnant uterus with a large uterine leiomyoma. The heterogeneous mass (*arrows*) lies beside the fetus (seen in cross section) and has the classic appearance of a leiomyoma in pregnancy. The placenta is located anteriorly, and the mass originates from the posterior lower uterine segment and occupies more

than half of the total uterine volume.



Symptoms

Most leiomyomas are asymptomatic, but acute or chronic pain or pressure may develop. Large myomas more often require admission for pain (Doğan, 2016). For chronic pain secondary to large tumor size, nonnarcotic analgesic drugs usually suffice. More acutely, some myomas can outgrow their blood supply and hemorrhagic infarction follows, which is termed *red* or *carneous degeneration*. Clinically, there is acute focal abdominal pain and tenderness, and sometimes a low-grade fever and leukocytosis. As such, tumor degeneration may be difficult to differentiate from appendicitis, placental abruption, ureteral stone, or pyelonephritis. Sonographic imaging can be helpful, but close observation is requisite because an infarcted myoma is essentially a diagnosis of exclusion. In some women, preterm labor is stimulated by associated inflammation.

Treatment of a degenerated myoma is analgesic medications, and symptoms usually abate within a few days. In severe cases, close observation may be needed to exclude a septic cause. Although surgery is rarely necessary during pregnancy, myomectomy in highly selected cases has resulted in good outcomes. Of 23 reported

cases, women were 14 to 20 weeks' gestation, and in almost half, surgery was performed because of pain (Celik, 2002; De Carolis, 2001). In some, an intramural leiomyoma was in contact with the implantation site. Except for one loss immediately following surgery at 19 weeks, most underwent cesarean delivery later, at term.

Occasionally, a pedunculated subserosal myoma will undergo torsion with subsequent painful necrosis. Laparoscopy or laparotomy can be used to ligate the stalk and resect the necrotic tumor. That said, we believe that surgery should be limited to tumors with a discrete pedicle that can be easily clamped and ligated.

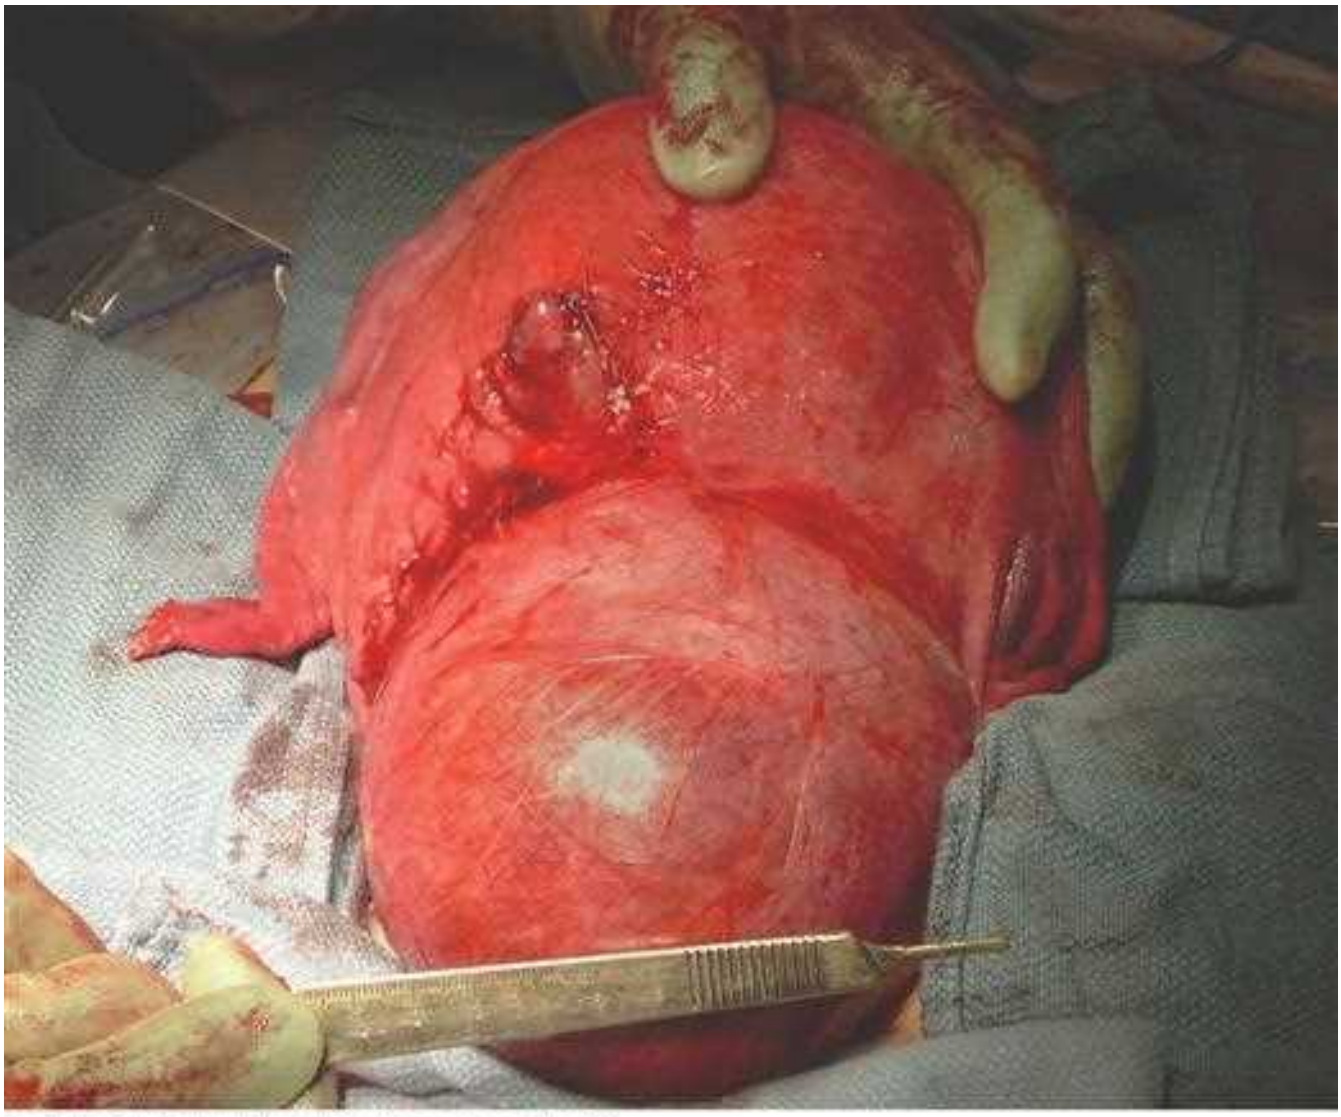
Pregnancy Complications

Myomas are associated with several complications that include preterm labor, placental abruption, fetal malpresentation, obstructed labor, cesarean delivery, and postpartum hemorrhage. In a review of pregnancy outcomes in 2065 women with leiomyomas, Coronado and colleagues (2000) reported that placental abruption and breech presentation were each increased fourfold; first-trimester bleeding and dysfunctional labor, twofold; and cesarean delivery, sixfold. Salvador and associates (2002) reported an eightfold higher second-trimester abortion risk in these women.

Factors most important in determining morbidity in pregnancy are leiomyoma number, size, and location (Ciavattini, 2015; Jenabi, 2018; Lam, 2014). If the placenta is adjacent to or implanted over a leiomyoma, rates of abortion, preterm labor, placental abruption, and postpartum hemorrhage are all increased. Retroplacental myomas are also associated with fetal-growth restriction (Knight, 2016). Tumors in the cervix or lower uterine segment may obstruct labor, as did the one shown in Figure 63-5. Despite these complications, Qidwai and associates (2006) reported a 70-percent vaginal delivery rate in women in whom myomas measured ≥10 cm. These data argue against empirical cesarean delivery for leiomyomas, and we allow a trial of labor unless myomas clearly obstruct the birth canal. If cesarean delivery is indicated, uterine malrotation should be excluded prior to hysterotomy. Myomas are generally left alone unless they cause recalcitrant bleeding. An important caveat is that cesarean hysterectomy may be technically difficult because of lateral ureteral displacement by the masses.

FIGURE 63-5

Cesarean delivery performed because of a large leiomyoma in the lower uterine segment. A classical vertical uterine incision, seen to the left of the myoma, was required for delivery of the fetus.



Bleeding due to myomas may develop during pregnancy from any of several factors. Especially common is bleeding with miscarriage, preterm labor, placenta previa, and placental abruption. Much less often, bleeding may result from a submucous myoma that has prolapsed from the uterus and into the cervix or vagina. In this

unusual circumstance, although heavy or persistent bleeding may require earlier intervention, the stalk, if accessible, can be ligated vaginally near term to avoid tumor avulsion during delivery.

Fortunately, myomas rarely become infected (Genta, 2001). When infection develops, it usually is postpartum, especially if the tumor is located immediately adjacent to the implantation site (Lin, 2002). They also may become infected with an associated septic abortion and myoma perforation by a sound, dilator, or curette.

Fertility Considerations

Despite the relatively high prevalence of myomas in young women, it is not clear whether they diminish fertility, other than by possibly causing miscarriage. In a review of 11 studies, Pritts (2001) concluded that submucous myomas did significantly affect fertility. He also found that hysteroscopic myomectomy improved infertility and early miscarriage rates in these women. If truly implicated in infertility, myomas in other locations may require laparoscopy or laparotomy for excision.

Some of these methods of treatment for infertility may affect subsequent pregnancies. For example, after myomectomy, the gravid uterus can rupture either before or during labor (American College of Obstetricians and Gynecologists, 2016a). Management is individualized, and review of the prior operative report is prudent. If resection resulted in a defect into or immediately adjacent to the endometrial cavity, then cesarean delivery is usually done before labor begins.

Although less effective than surgery, uterine artery embolization of myomas has also been used to treat infertility or symptoms (Mara, 2008). Women so treated have higher rates of miscarriage, cesarean delivery, and postpartum hemorrhage (Homer, 2010). The Society of Interventional Radiology considers myoma embolization relatively contraindicated in women who plan future pregnancies (Stokes, 2010).

Finally, outside the United States, *ulipristal*—a selective progesterone-receptor modulator—can be used for myoma regression. Successful subsequent pregnancies without tumor regrowth have been reported (Luyckx, 2014).

Endometrial Lesions

Occasionally, *endometriosis* can develop after delivery from endometrial tissue implanted within cesarean delivery or episiotomy scars (Bumpers, 2002). Here, they form a palpable mass and can cause cyclic localized pain. Endometriomas within an ovary are discussed in the next section.

Adenomyosis is traditionally found in late reproductive life and beyond. Its acquisition may be at least partially related to disruption of the endometrial-myometrial border during sharp curettage for abortion (Curtis, 2002). In a case-control study, Hashimoto and colleagues (2017) reported significantly higher associated rates of second-trimester abortion, preeclampsia, fetal malposition, and preterm delivery.

Endometrial carcinoma is an estrogen-dependent neoplasia also usually found in women older than 40 years. Thus, it is seen only rarely with pregnancy. Of 27 cases that were identified during pregnancy or within the first 4 months postpartum, most were found in first-trimester curettage specimens (Hannuna, 2009). These are usually early-stage, well-differentiated adenocarcinomas for which treatment consists primarily of total abdominal hysterectomy and bilateral salpingo-oophorectomy. Much less commonly, to preserve future fertility, curettage with or without postprocedural progestational therapy has been used for the rare patient with cancer identified in a miscarriage curettage specimen (Schammel, 1998).

Many more studies describe a conservative approach for well-selected *nonpregnant* women diagnosed with endometrial cancer who wish to preserve fertility. One study followed 13 women treated with progestins for early-stage, well-differentiated adenocarcinoma who then later conceived after apparent remission (Gotlieb, 2003). Nine had liveborn neonates, and four of six women with a recurrence responded to another course of therapy. Similar outcomes were described in 12 women by Niwa (2005) and in 21 women by Signorelli (2009), each with their coworkers. Despite these acceptable pregnancy rates, recurrences and death have been reported, and conservative management is not considered standard (Erkanli, 2010).

Ovary

Ovarian masses found during pregnancy are relatively common. Among studies, incidences vary depending on the frequency of prenatal sonography, the ovarian size threshold used to define a clinically significant “mass,” and whether the study site is tertiary or primary care. Thus, the incidence of ovarian masses not surprisingly ranges from 1 in 100 to 2000 pregnancies (Whitecar, 1999; Zanetta, 2003). Of ovarian malignancies, the absolute incidence in the California Cancer Registry was 1 in 19,000 pregnancies (Smith, 2003).

The most frequent types of ovarian masses are corpus luteum cysts, endometriomas, benign cystadenomas, and mature cystic teratomas. Because pregnant women are usually young, malignant tumors and those of low malignant potential are proportionately uncommon. Our experiences from Parkland Hospital are similar to those of Leiserowitz and associates (2006), who found that 1 percent of 9375 ovarian masses were frankly malignant and that another 1 percent were of low malignant potential. In surgically excised masses, rates of malignancy are higher, vary from 4 to 13 percent, and probably reflect a greater preoperative concern for cancer (Hoffman, 2007; Sherard, 2003).

Most ovarian masses are asymptomatic in pregnant women. Some cause pressure or chronic pain, and acute abdominal pain may be due to torsion, rupture, or hemorrhage. Seldom is blood loss significant enough to cause hypovolemia.

Diagnosis

Many ovarian masses are detected during routine prenatal sonography or during imaging done for other indications, including evaluation of symptoms. The typical sonographic appearance of these masses is shown in Figure 63-6. In some instances, MR imaging can be used to evaluate complicated anatomy.

FIGURE 63-6

Sonographic characteristics of common adnexal masses in pregnancy. **A.** A simple anechoic cyst with smooth walls is characteristic of a physiological corpus luteum cyst or benign cystadenoma. **B.** Cystic structure with diffuse internal low-level echoes suggestive of an endometrioma or hemorrhagic corpus luteum. **C.** Mature

cystic teratoma appears as an adnexal cyst (*marked by calipers*) with accentuated lines and dots that represent hair in both longitudinal and transverse planes. At the central inferior aspect of this cyst, a mural nodule—Rokitansky protuberance—is seen. These typically rounded protuberances range in size from 1 to 4 cm, they are predominantly hyperechoic, and they create an acute angle with the cyst wall. Although not seen here, fat-fluid levels are often identified with cystic teratomas. (Used with permission from Dr. Elysia Moschos.)

Cancer antigen 125 (CA125) serves as a tumor marker, and levels are frequently elevated with ovarian malignancy. Importantly, concentrations of CA125 in early pregnancy and early puerperium are normally elevated, possibly from the decidua (Aslam, 2000; Spitzer, 1998). As shown in the Appendix (Serum and Blood Constituents), from the second trimester until term, levels are not normally higher than those in the nonpregnant woman (Szecsi, 2014). With severe preeclampsia, however, levels are abnormally elevated (Karaman, 2014). Other tumor markers that are not useful for diagnosis or posttreatment surveillance in pregnancy include human chorionic gonadotropin (hCG), alpha-fetoprotein, inhibins A and B, and the multimarker OVA1 test (Liu, 2011).

Complications

The two most common are torsion and hemorrhage. Torsion usually causes acute constant or episodic lower abdominal pain that frequently is accompanied by nausea and vomiting. Sonography often aids the diagnosis. With color Doppler, presence of an ovarian mass with absent flow strongly correlates with torsion. However, minimal or early twisting may compromise only venous flow, thus leaving the arterial supply intact. If torsion is suspected, laparoscopy or laparotomy is warranted. Contrary to prior teaching, adnexectomy is generally unnecessary to avoid clot release, thus, most recommend attempts at untwisting (McGovern, 1999; Zweizig, 1993). With a salvageable ovary, within minutes, congestion is relieved, and ovarian volume and cyanosis diminish. If cyanosis persists, however, then removal of the infarcted adnexum is typically indicated.

If the adnexum is healthy, there are options. First, neoplasms are resected. However, ovarian cystectomy in an ischemic, edematous ovary may be technically difficult, and adnexectomy may be necessary. Second, unilateral or bilateral oophoropexy has been described to minimize the risk of repeated torsion (Djavadian, 2004; Germain, 1996). Techniques described include shortening of the uteroovarian ligament or fixing the uteroovarian ligament to the posterior uterus, the lateral pelvic wall, or the round ligament (Fuchs, 2010; Weitzman, 2008).

The most common cause of ovarian hemorrhage follows rupture of a corpus luteum cyst. If the diagnosis is certain and symptoms abate, then observation and surveillance is usually sufficient. Concern for ongoing bleeding will typically prompt surgical evaluation. If the corpus luteum is removed before 10 weeks' gestation, progestational support is recommended to maintain the pregnancy. Suitable regimens include: (1) micronized progesterone (Prometrium) 200 or 300 mg orally once daily; (2) 8-percent progesterone vaginal gel (Crinone), one premeasured applicator vaginally daily plus micronized progesterone 100 or 200 mg orally once daily; or (3) intramuscular 17-hydroxyprogesterone caproate, 150 mg. The first two regimens are given until 10 completed weeks. For the last, if given between 8 and 10 weeks' gestation, only one injection is required immediately after surgery. If the corpus luteum is excised between 6 and 8 weeks' gestation, then two additional doses should be given 1 and 2 weeks after the first.

Asymptomatic Adnexal Mass During Pregnancy

Because most of these are incidental findings, management considerations include whether resection is necessary and its timing. A cystic benign-appearing mass that is <5 cm often requires no additional antepartum surveillance. Early in pregnancy, this is likely a corpus luteum cyst, which typically resolves by the early second trimester. For cysts ≥10 cm, because of the substantial risk of malignancy, torsion, or labor obstruction, surgical removal is reasonable. Tumors between 5 and 10 cm should be carefully evaluated by sonography along with color Doppler and possibly MR imaging. If they have a simple cystic appearance, these cysts can be managed expectantly with sonographic surveillance (Schmeler, 2005; Zanetta, 2003). Resection is done if cysts grow, begin to display malignant qualities, or become symptomatic. Those with classic findings of endometrioma or mature cystic teratoma may be resected postpartum or during cesarean for obstetrical indications.

On the other hand, if sonographic characteristics suggest cancer—thick septa, nodules, papillary excrescences, or solid components—immediate resection is indicated (Caspi, 2000). In one review of 563 masses, approximately half were simple, and the other half complex (Webb, 2015). Among simple masses, 1 percent were malignant, and of complex masses, 9 percent were cancerous.

Approximately 1 in 1000 pregnant women undergoes surgical exploration for an adnexal mass (Boulay, 1998). In general, we plan resection at 14 to 20 weeks' gestation because most masses that will regress will have done so by this time. As outlined in Chapter 46 (Medications and Surgeries), laparoscopic removal is ideal (Naqvi, 2015; Sisodia, 2015). Importantly, in any instance in which cancer is strongly suspected, the American College of Obstetricians and Gynecologists (2017b) recommends consultation with a gynecologic oncologist.

Pregnancy-Related Ovarian Tumors

Pregnancy Luteoma

One group of ovarian masses results directly from the stimulating effects of various pregnancy hormones on ovarian stroma. These include pregnancy luteoma, hyperreactio luteinalis, and ovarian hyperstimulation syndrome.

Of these, pregnancy luteoma is a rare, benign ovarian neoplasm that arises from luteinized stromal cells and classically causes elevated testosterone levels (Hakim, 2016; Irving, 2011). Up to 25 percent of affected women will be virilized, and of these affected women, nearly half of their female fetuses will have some degree of virilization. However, most mothers and their fetuses are unaffected because the placenta rapidly converts testosterone to estrogen (Kaňová, 2011).

In typical cases, an adnexal mass along with maternal virilization will prompt sonography and measurement of testosterone and CA125 levels. Luteomas range in size from microscopic to >20 cm. They appear as solid tumors, may be multiple or bilateral, and may be complex because of internal hemorrhage (Choi, 2000). Concerns for malignancy may be further investigated with MR imaging (Kao, 2005; Tannus, 2009).

Total testosterone levels are increased, but notably, levels in normal pregnancy can be substantially elevated (Appendix, Serum and Blood Constituents). Differential diagnoses include granulosa cell tumors, thecomas, Sertoli-Leydig cell tumors, Leydig cell tumors, stromal hyperthecosis, and hyperreactio luteinalis.

Generally, luteomas do not require surgical intervention unless there is torsion, rupture, or hemorrhage (Masarie, 2010). These tumors spontaneously regress during the first few months postpartum, and androgen levels drop precipitously during the first 2 weeks following delivery (Wang, 2005). Lactation may be delayed a week or so by hyperandrogenemia (Dahl, 2008). Recurrence in subsequent pregnancies is rare.

Hyperreactio Luteinalis

In this condition, one or both ovaries develop multiple, large theca-lutein cysts, typically after the first trimester. Cysts are caused by luteinization of the follicular theca interna layer, and most are in response to stimulation by exceptionally high hCG levels (Russell, 2009). For this reason, they are more common with gestational trophoblastic disease, twins, fetal hydrops, and other conditions with increased placental mass. Maternal virilization may develop, but fetal virilization has not been reported (Kaňová, 2011; Malinowski, 2015).

As reported by Baxi and coworkers (2014), these ovarian tumors appear sonographically to have a “spoke wheel” pattern (Fig. 20-3). If the diagnosis is confident, and unless complicated by torsion or hemorrhage, surgical intervention is not required. These masses resolve after delivery. Few data allow prediction of risk in a subsequent pregnancy, but in one case report, a woman had hyperreactio with three pregnancies (Bishop, 2016).

Ovarian Hyperstimulation Syndrome

This is typified by multiple ovarian follicular cysts accompanied by increased capillary permeability. It most often is a complication of ovulation-induction therapy for infertility, although it rarely may develop in an otherwise normal pregnancy. It has also been reported with a partial molar pregnancy (Suzuki, 2014). Its etiopathogenesis is thought to involve hCG stimulation of vascular endothelial growth factor (VEGF) expression in granulosa-lutein cells (Soares, 2008). This causes greater vascular permeability that can lead to ascites, pleural or pericardial effusion, hypovolemia with acute kidney injury, and hypercoagulability. Serious complications are renal dysfunction, adult respiratory distress syndrome, ovarian rupture with hemorrhage, and VTE. Unlike hyperreactio lutealis, virilization is absent (Suzuki, 2004).

Detailed guidelines for management are outlined by the American Society for Reproductive Medicine (2016). Treatment is primarily supportive with attention to maintaining vascular volume and thromboprophylaxis. In severe cases, paracentesis can be helpful.

Ovarian Cancer

Malignancies of the ovary are the leading cause of death from genital-tract cancers in all women (American Cancer Society, 2017). Still, it is uncommon in young women, and the incidence of ovarian malignancy ranges from 1 in 20,000 to 1 in 50,000 births (Eibye, 2013; Palmer, 2009). Fortunately, 75 percent of these found in pregnancy are early-stage cancers that carry a 5-year survival rate between 70 and 90 percent (Brewer, 2011). The types of malignancy are also markedly different in pregnant women compared with those in older women. In gravidas, these are, in decreasing order of frequency, germ cell and sex cord-stromal tumors, low-malignant-potential tumors, and epithelial tumors (Morice, 2012).

Pregnancy apparently does not alter the prognosis of most ovarian malignancies. Management is similar to that for nonpregnant women, with the usual proviso that it may be modified depending on gestational age. Thus, if frozen section histopathological analysis verifies malignancy, surgical staging is done with careful inspection of all accessible peritoneal and visceral surfaces (Giuntoli, 2006). Peritoneal washings are taken for cytology, biopsies are obtained from the diaphragmatic surface and peritoneum, omentectomy is completed, and pelvic and infrarenal paraaortic lymph nodes are sampled, if accessible.

If there is advanced disease, bilateral adnexectomy and omentectomy will decrease most tumor burden. In early pregnancy, hysterectomy and aggressive surgical debulking procedures may be elected. In other cases, minimal debulking as described in the previous paragraph is done and the operation terminated. In some cases of aggressive or large-volume disease, chemotherapy can be given during pregnancy while awaiting pulmonary maturation. Monitoring maternal CA125 serum levels during chemotherapy is not accurate in pregnancy (Aslam, 2000; Morice, 2012).

Adnexal Cysts

Paratubal and paroovarian cysts are either distended remnants of the paramesonephric ducts or are mesothelial inclusion cysts. Although most measure ≤3 cm, they occasionally attain worrisome dimensions. Their reported incidence is influenced by size, but one autopsy series in nonpregnant women cited this to be 5 percent (Dorum, 2005). The most common paramesonephric cyst is the hydatid of Morgagni, which is pedunculated and typically dangles from one of the fimbria. These cysts infrequently cause complications and are most often identified at the time of cesarean delivery or puerperal sterilization. In these instances, they can simply be

excised or drained by creating a large window in the cyst wall. Neoplastic paraovarian cysts are rare, sonographically and histologically resemble tumors of ovarian origin, and rarely are of borderline potential or frankly malignant (Korbin, 1998).

Vulva and Vagina

Preinvasive disease in young women—vulvar intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN)— are seen more often than invasive disease and are commonly associated with HPV infection. As with cervical neoplasia, these premalignant conditions are treated after delivery.

Cancer of the vulva or vagina is generally a malignancy of older women, and thus, these are rarely associated with pregnancy. Even so, any suspicious lesions should be biopsied. Treatment is individualized according to the clinical stage and depth of invasion. In a review of 23 cases, investigators concluded that radical surgery for stage I disease was feasible during pregnancy—including in the last trimester (Heller, 2000).

We and others question the necessity of resection in late pregnancy because definitive therapy can often be delayed due to these cancers' typically slow progression (Anderson, 2001). It appears that vaginal delivery is not contraindicated if vulvar and inguinal incisions are well healed. Vulvar sarcoma, vulvar melanoma, and vaginal malignancies are rare in pregnancy and are the subjects of case reports (Alexander, 2004; Kuller, 1990; Matsuo, 2009).

BREAST CARCINOMA

Breast cancer rates rise most acutely between ages 40 and 80 years. However, because of its overall high frequency, breast cancer is relatively common even in younger women and is the most frequent cancer found in gravidas. From the Nationwide Inpatient Sample of 11.8 million births, the incidence approximated 1 in 15,000 (Maor, 2017). And, as more women choose to delay childbearing, the frequency of associated breast cancer is certain to grow. Postponed childbearing was considered partially responsible for the increase in pregnancy-associated breast cancer in Sweden and Denmark (Andersson, 2015; Eibye, 2013).

Some studies suggest that women with a family history of breast cancer—especially those with *BRCA1* and *BRCA2* breast cancer gene mutations—are more likely to develop breast malignancy during pregnancy (Wohlfahrt, 2002). However, it may be that it is parity that modifies this risk. Namely, parous women older than 40 years with these mutations have a significantly lower cancer risk than nulliparas with these mutated genes (Andrieu, 2006; Antoniou, 2006). Women with *BRCA1* and *BRCA2* gene mutations who undergo induced abortion or those who breastfeed do not have an increased breast cancer risk (Friedman, 2006). Moreover, Jernström and associates (2004) found that breastfeeding conveyed a protective effect against this cancer in those with *BRCA1* gene mutation, but not in those with *BRCA2* mutations. Of other congenital factors, it is controversial whether DES exposure raises breast cancer risks (Hoover, 2011; Titus-Ernstoff, 2006).

Diagnosis

More than 90 percent of gravidas with breast cancer have a palpable mass, and greater than 80 percent of cases are self-reported (Brewer, 2011). In pregnancy, clinical assessment, diagnostic procedures, and treatment of women with breast tumors are often slightly delayed (Berry, 1999). This can be partially attributed to pregnancy-induced breast tissue that obscures masses.

The evaluation of pregnant women with a breast mass does not differ from that for nonpregnant women (Loibl, 2015). Thus, any suspicious breast mass should be pursued to diagnosis. Pragmatically, a palpable discrete mass can be biopsied or excised. If imaging is desirable to distinguish between a solid mass and a cystic lesion, sonography has high sensitivity and specificity (Navrozoglou, 2008). Mammography is appropriate if indicated, and the fetal radiation risk is negligible—0.04 mGy—with appropriate shielding (Krishna, 2013). But, because breast tissue is denser in pregnancy, mammography has a false-negative rate of 35 to 40 percent (Woo, 2003). If the decision to biopsy is uncertain, then MR imaging may be used. With such techniques, masses can usually be described as either solid or cystic.

Cystic breast lesions are simple, complicated, or complex (Berg, 2003). Simple cysts do not require special management or monitoring, but they may be aspirated if symptomatic. Complicated cysts show internal echoes during sonography, and they sometimes are indistinguishable from solid masses. These are typically aspirated, and if the sonographic abnormality does not resolve completely, a core-needle biopsy is usually performed. Complex cysts have septa or intracystic masses seen sonographically. Because some breast cancer may form complex cysts, excision is usually recommended.

For solid breast masses, evaluation is with the triple test, that is, clinical examination, imaging, and core needle biopsy. If all three suggest a benign lesion or if all three suggest a breast cancer, the test is said to be concordant. A concordant benign triple test is ≥99-percent accurate, and breast lumps in this category can be followed by clinical examination alone. Fortunately, most masses in pregnancy have these three reassuring features. In contrast, if any of the three assessments suggests malignancy, the mass should be excised.

Management

Once breast cancer is diagnosed, a limited search of the most common metastatic sites is completed. For most women, this includes a chest radiograph, liver sonography, and skeletal MR imaging (Becker, 2016; Krishna, 2013).

Treatment of breast cancer is multidisciplinary and includes an obstetrician, breast surgeon, and medical oncologist. Initially, desires for pregnancy continuation are addressed, and data indicate that pregnancy interruption does not influence the course or prognosis of breast cancer (Cardonick, 2010). With pregnancy continuation, treatment in general mirrors that for nonpregnant women. Important caveats are that chemotherapy and surgery are postponed to the second trimester, and adjuvant radiotherapy is withheld until after delivery (Brewer, 2011).

Surgical treatment may be definitive. In the absence of metastatic disease, either a wide excision or a modified or total mastectomy—each with axillary node staging—can be performed (Rosenkranz, 2006). Staging by sentinel lymph node biopsy and lymphoscintigraphy with technetium-99m is safe. Breast reconstruction, if

desired, is typically delayed until after delivery (Viswanathan, 2011). That said, Caragacianu and coworkers (2016) described good results in 10 pregnant women who underwent immediate reconstruction after mastectomy.

Chemotherapy is usually given with both positive- and negative-node breast cancers. In premenopausal women, survival rates with this approach are improved, even if lymph nodes are cancer free. For node-positive disease, multiagent chemotherapy is begun if delivery is not anticipated within several weeks. Cyclophosphamide, doxorubicin, and cisplatin are currently used (Euhus, 2016). If an anthracycline-based agent such as doxorubicin is used, pretherapy maternal echocardiography is performed because of associated cardiotoxicity (Brewer, 2011). Good maternal and perinatal results have been reported (Berry, 1999; Hahn, 2006).

Immunotherapy for breast cancers is now commonplace. Trastuzumab (Herceptin) is a monoclonal antibody to the HER2/neu receptor, which is found in approximately a third of invasive breast cancers (Hudis, 2007). The drug is not recommended in pregnancy. This is because HER2/neu is strongly expressed in fetal renal epithelium, and trastuzumab has been linked with miscarriage, fetal renal failure and related oligohydramnios, and preterm birth (Amant, 2010; Azim, 2010).

The effects of pregnancy on the course of breast cancer and its prognosis are complex. Breast cancer is more aggressive in younger women, but whether it is more aggressive during pregnancy in these same women is debatable (Azim, 2014). Clinically, most studies indicate little difference in overall survival rates with pregnancy-associated breast cancer compared with similarly aged and staged nonpregnant women (Beadle, 2009). Other reports note worse overall survival rates with pregnancy-associated breast cancer (Rodriguez, 2008). These investigators do conclude, however, that later disease stages are more prevalent in pregnant women.

Indeed, breast cancer is usually found at a more advanced stage in pregnant women, and thus overall prognosis is diminished (Andersson, 2015). The aggregate of studies published after 1990 indicate that up to 60 percent of pregnant women have concomitant axillary node involvement at diagnosis. And although, stage for stage, the 5-year survival rate is comparable in pregnant and nonpregnant women, the more advanced stages that are typical of pregnant women worsen their prognosis (Kuo, 2017; Zemlickis, 1992).

Pregnancy Following Breast Cancer

After breast cancer treatment, chemotherapy will render some women infertile, and options for childbearing are limited (Kim, 2011). For those who become pregnant, long-term maternal survival rates are not adversely affected (Averette, 1999; Velentgas, 1999). One metaanalysis of 10 studies found that for women with early breast cancer, pregnancy that occurs 10 months after diagnosis may, in fact, confer a survival benefit (Valachis, 2010). Data do not indicate that breastfeeding adversely alters the course.

In women successfully treated for breast cancer, recurrence is a concern. Because recurrences are more common soon after treatment, it seems reasonable to delay conception for 2 to 3 years. Hormonal contraceptive methods are contraindicated, and a copper-containing intrauterine device is an excellent long-acting reversible method for many. That said, women who conceive do not appear to have diminished survival rates (Ives, 2006). Notably, women treated with tamoxifen are at risk for several months after its discontinuation to have a newborn with congenital anomalies. This drug has an extremely long half-life, and thus delaying conception is recommended for at least 2 months after tamoxifen completion (Braems, 2011).

THYROID CANCER

Palpable thyroid nodules are detected in 4 to 7 percent of the population, and approximately 10 percent are malignant (Burman, 2015). Clinical nodules are typically evaluated with sonography and measurement of serum thyroid-stimulating hormone (TSH) and free thyroxine levels. Fine-needle aspiration is indicated for a suspicious nodule (Alexander, 2017; Gharib, 2016).

With a diagnosis of thyroid malignancy, pregnancy termination is not necessary. Primary therapy is thyroidectomy performed ideally during the second trimester. Postoperatively, replacement thyroxine is given. Most thyroid cancers are well differentiated and follow an indolent course. Thus, delayed surgical treatment does not usually alter outcome (Yazbeck, 2012; Yu, 2016).

In some types of thyroid cancer, radioiodine is used for primary or postoperative treatment. This is contraindicated in both pregnancy and lactation for several reasons. First, transplacental ^{131}I is avidly trapped by the fetal thyroid gland to cause hypothyroidism. Second, during lactation, the breast also concentrates a substantial amount of iodide. This may pose neonatal risk due to radioiodine-contaminated milk ingestion and maternal risk from significant breast irradiation. To limit maternal exposure, a delay of 3 months between lactation and thyroid ablation will more reliably ensure complete breast involution (Sisson, 2011). In women with thyroid cancer who ultimately receive ^{131}I doses, pregnancy should be avoided for 6 months to 1 year. This time ensures thyroid function stability and permits confirmation of cancer remission (Abalovich, 2007).

LYMPHOMAS

Hodgkin Disease

This lymphoma is probably B-cell derived and is cytologically distinguished from other lymphomas by Reed–Sternberg cells. Of cancers in pregnancy, lymphomas are common, and gestational rates are rising because of delayed childbearing (Horowitz, 2016). In pregnant women, Hodgkin lymphomas are more frequent than non–Hodgkin lymphomas. In one population-based review of 7.9 million births from the Nationwide Inpatient Sample, El-Messidi and colleagues (2015) reported its incidence to be 1 in 12,400.

In more than 70 percent of Hodgkin disease cases, lymph nodes painlessly enlarge at sites above the diaphragm, that is, in the axillary, cervical, or submandibular chains. Approximately one third of patients have symptoms such as fever, night sweats, malaise, weight loss, and pruritus. Diagnosis is by histological examination of involved nodes (Longo, 2015).

The Ann Arbor staging system, shown in Table 63-2, is applied to Hodgkin and other lymphomas. For staging, pregnancy limits the use of some radiographic studies, but at minimum, chest radiography, abdominal imaging with sonography or MR imaging, and bone marrow biopsy are completed (Williams, 2001). MR imaging is excellent for evaluating thoracic and abdominal paraaortic lymph nodes (Brenner, 2012). Staging laparotomy is seldom done today (Longo, 2015).

TABLE 63-2

Ann Arbor Staging System for Hodgkin and Other Lymphomas

Stage	Findings
I	Involvement in a single lymph node region or lymphoid site—e.g., spleen or thymus
II	Involvement of two or more lymph node groups on the same side of the diaphragm—the mediastinum is a single site
III	Involvement of lymph nodes on both sides of the diaphragm 1. Limited to spleen or splenic hilar, celiac, or portal nodes 2. Includes paraaortic, iliac, or mesenteric nodes plus those in III
IV	Extralymphatic involvement—e.g., liver or bone marrow

Substage A = no symptoms; substage B = fever, sweats, or weight loss; substage E = extralymphatic involvement excluding liver and bone marrow.

The current trend for nonpregnant individuals is to administer chemotherapy for all stages of Hodgkin disease. In pregnancy, for early-stage disease in the first trimester, options include observation until after 12 weeks' gestation, single-agent vinblastine until the second trimester, pregnancy termination followed by multiagent chemotherapy, or radiotherapy alone for isolated neck or axillary sites (El-Hemaidi, 2012; Eyre, 2015).

For advanced-stage disease, chemotherapy is recommended regardless of gestational age. Before 20 weeks, therapeutic abortion is a consideration, but if termination is unacceptable, then treatment with vinblastine followed by multiagent therapy in the second trimester can be used (Eyre, 2015). For most advanced-stage disease after the first trimester, cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine are given, and radiotherapy can be added postpartum (Cohen, 2011). In general, postponement of therapy until fetal maturity is achieved seems justifiable only when the diagnosis is made late in pregnancy.

Women with Hodgkin lymphoma have a higher incidence of VTE (El-Messidi, 2015; Horowitz, 2016). Also, in our experiences, pregnant women with Hodgkin disease —even after they are "cured"—are inordinately susceptible to infection and sepsis. Active antineoplastic therapy only increases this vulnerability.

The overall prognosis with Hodgkin lymphoma is good, and survival rates exceed 70 percent. Pregnancy does not adversely affect the cancer course or pregnancy outcomes in women with this lymphoma. Specifically, neither chemotherapy after the first trimester nor mediastinal and neck irradiation has adverse fetal effects (Brenner, 2012; El-Messidi, 2015; Pinnix, 2016). For women with disease in remission, pregnancy does not stimulate a relapse (Weibull, 2016).

Non-Hodgkin Lymphomas

Although usually B-cell tumors, non-Hodgkin lymphomas can also be T-cell or natural-killer-cell neoplasms. Their biology, classification, and treatment are complex (Longo, 2015; O'Gara, 2009). They are associated with viral infections, and indeed, their incidence has risen sharply at least partly because 5 to 10 percent of HIV-infected persons develop lymphoma. Other associated viruses include Epstein-Barr virus, hepatitis C virus, and human herpes virus 8. Some of these lymphomas are aggressive, and survival rates vary with the type of cell line involved (Longo, 2015).

Non-Hodgkin lymphomas are infrequent during pregnancy (Brenner, 2012; Pinnix, 2016). They are also staged according to the Ann Arbor system. If diagnosed in the first trimester, pregnancy termination followed by multiagent chemotherapy is recommended for all but indolent or very early disease. These less aggressive forms may either be observed or be temporized with focal supradiaphragmatic radiotherapy and then full treatment in the second trimester. If one of these lymphomas is diagnosed after the first trimester, chemotherapy and immunotherapy with rituximab are given (Cohen, 2011; Rizack, 2009). In one follow-up of 55 individuals at 6 to 29 years after exposure to chemotherapy in utero during maternal lymphoma treatment, no congenital, neurological, or psychological abnormalities were noted (Avilés, 2001).

Burkitt lymphoma is an aggressive B-cell tumor associated with Epstein-Barr virus infection. Prognosis is poor, and treatment is given with multiagent chemotherapy. In a review of 19 women whose pregnancies were complicated by this lymphoma, 17 died within a year of diagnosis (Barnes, 1998).

Leukemias

In general, these malignancies arise either from lymphoid tissues—lymphoblastic or lymphocytic leukemias, or from bone marrow—myeloid leukemias. They can be acute or chronic. Although adult leukemias are more prevalent after age 40, they still are among the most common malignancies of young women (see Fig. 63-1).

Leukemia was diagnosed in 1 in 40,000 pregnancies reported to the California Cancer Registry (Smith, 2003). In a review of 72 pregnancies complicated by leukemia from 1975 until 1988, 44 had acute myelogenous leukemia; 20 had acute lymphocytic leukemia; and eight had one of the chronic leukemias (Caligiuri, 1989).

Acute leukemias almost always cause marked peripheral blood count abnormalities, and often the white blood cell count is elevated with readily recognizable circulating blast cells. The diagnosis is made from bone marrow biopsy.

With current multiagent chemotherapy, remission during pregnancy is common, compared with an almost 100-percent mortality rate before 1970. Pregnancy termination does not further improve the prognosis, however, abortion is a consideration in early pregnancy to avoid potential chemotherapy teratogenesis. One example of the latter is treatment of acute promyelocytic leukemia with all-*trans*-retinoic acid, also known as tretinoin (Carradice, 2002; Sanz, 2015). This potent teratogen causes retinoic acid syndrome (Chap. 12, Retinoids). In another example, acute myeloid leukemia is treated with tyrosine kinase inhibitors, another teratogen group (Palani, 2015). In other cases, pregnancy termination before viability may simplify management of an acutely ill woman.

Other than these caveats, treatment of gravidas with leukemia is similar to that for nonpregnant women. Acute myeloid leukemia is treated without delay (Ali, 2015). After induction chemotherapy, postremission maintenance therapy is mandatory to prevent a relapse, which is then usually treated with stem-cell transplantation. If allogeneic stem-cell transplantation is indicated, early delivery is considered. With some chronic leukemias, it may be possible to delay therapy until after delivery (Fey, 2008). As with lymphoma, infection and hemorrhage are significant complications that should be anticipated in women with active disease.

Most descriptions of leukemia treatment in pregnancy are single cases or small series (Routledge, 2016; Sanz, 2015). In an earlier review of 58 cases, 75 percent were diagnosed after the first trimester (Reynoso, 1987). Half were acute myelogenous leukemia, which had a remission rate of 75 percent with chemotherapy. Only 40 percent of these pregnancies resulted in liveborn neonates (Caligiuri, 1989).

MALIGNANT MELANOMA

These most frequently originate from a preexisting skin nevus and its pigment-producing melanocytes. Melanomas should be suspected in pigmented lesions that show changes in contour, surface elevation, discoloration, bleeding, or ulceration, which should prompt biopsy (Richtig, 2017). They are most common in light-skinned whites and develop relatively frequently in women of childbearing age.

In some population studies, melanoma is the most frequent malignancy complicating pregnancy (Andersson, 2015; Bannister-Tyrrell, 2015). Still, the reported incidence ranges widely from 0.03 to 2.8 per 1000 live births (Eibye, 2013; Smith, 2003). One explanation is that many are treated as outpatients and thus are not entered into tumor registries. As noted earlier (Reproductive Tract Neoplasms), malignant melanoma is one of the tumors that is known to metastasize to the placenta and fetus. Placental evaluation for metastases should be performed after delivery.

Staging is clinical. Stage I is a melanoma with no palpable lymph nodes; in stage II, lymph nodes are palpable; and in stage III, there are distant metastases. For patients with stage I, tumor thickness is the single most important predictor of survival. The Clark classification includes five levels of involvement by depth into the epidermis, dermis, and subcutaneous fat. The Breslow scale measures tumor thickness and size, in addition to depth of invasion.

Primary surgical treatment for melanoma is determined by the stage and includes wide local resection, sometimes with extensive regional lymph node dissection. Schwartz and associates (2003) recommend sentinel lymph node mapping and biopsy using ^{99m}Tc-sulfur colloid, which has a calculated fetal dose of 0.014 mSv or 0.014 mGy. Routine regional node dissection reportedly improves survival rates in nonpregnant patients with microscopic metastases (Cascinelli, 1998). For pregnant patients, an algorithm has been proposed that begins with resection of the primary tumor under local anesthesia but postpones sentinel lymph node biopsy until after delivery (Broer, 2012). Although prophylactic chemotherapy or immunotherapy is usually avoided during pregnancy, it may be given if indicated by tumor stage and maternal prognosis. In most cases of distant metastatic melanoma, treatment is at best palliative. Currently, the role of estrogen receptor-β in melanoma progression is under investigation, and it may be a target for future therapeutic intervention (de Giorgi, 2011).

Stage-for-stage, survival is equivalent between pregnant and nonpregnant women (Driscoll, 2016; Johansson, 2014). In one study, half of pregnant women had stage III or IV lesions (de Haan, 2017). Therapeutic abortion does not improve maternal survival rates. Clinical stage is the strongest determinant of survival, and women with deep cutaneous invasion or regional node involvement have the worst prognosis. Approximately 60 percent of recurrences will manifest within 2 years, and 90 percent by 5 years. Thus, most recommend that pregnancy be avoided for 3 to 5 years after surgical resection. Interim contraception can include combination oral contraceptives, as they do not appear to have adverse cancer effects (Gandini, 2011). Related, subsequent pregnancies in women with localized melanoma do not lower cancer survival rates (Driscoll, 2009).

GASTROINTESTINAL TRACT CANCER

Carcinomas of the colon and rectum are the third most frequent in women of all age groups in the United States (American Cancer Society, 2016). Their incidence in pregnancy is rising because of delayed childbearing (Rogers, 2016). Even so, colorectal tumors are uncommon before age 40. Smith and colleagues (2003) reported an approximate incidence of 1 per 150,000 deliveries in the California Cancer Registry. The incidence approximated 1 per 35,000 births in a Danish Registry (Eibye, 2013). Most—80 percent—of colorectal carcinomas in pregnant women arise from the rectum. In one review, only 41 cases in pregnancy were colon cancers above the peritoneal reflection (Chan, 1999).

The most frequent symptoms of colorectal cancer are abdominal pain, distention, nausea, constipation, and rectal bleeding. If symptoms of colon disease persist, digital rectal examination, stool tests for occult blood, and flexible sigmoidoscopy or colonoscopy are done. Some malignancies of the gastrointestinal tract are discovered because of metastases to the ovary. *Kruckenberg tumors* are tumor-laden ovaries from another primary, often gastrointestinal, and have a bleak prognosis (Glišić, 2006; Kodama, 2016).

Treatment of colon cancer in pregnant women mirrors the same general guidelines as for nonpregnant women. Without evidence of metastatic disease, surgical resection is preferred, but most gravidas have advanced lesions (Al-Ibrahim, 2014). During the first half of pregnancy, hysterectomy is not necessary to perform colon or rectal resection, and thus, therapeutic abortion is not mandated. During later pregnancy, therapy may be delayed until fetal maturation, however, bowel hemorrhage, obstruction, or perforation may force surgical intervention (Minter, 2005).

Gastric cancer is rarely associated with pregnancy, and most reported cases are from Japan. Hirabayashi and coworkers (1987) reviewed outcomes in 60 pregnant women during a 70-year period from 1916 to 1985. Delayed diagnosis during pregnancy is common, and the prognosis is consistently poor (Lee, 2009). Esophageal cancer has similar symptoms, but it is rare (Sahin, 2015). It is axiomatic that persistent unexplained upper gastrointestinal symptoms should be evaluated by endoscopy.

MISCELLANEOUS TUMORS

Various other neoplasms have been reported in pregnancy and are usually the subject of case reports. Examples include carcinoid tumors, which are usually of gastrointestinal origin (Durkin, 1983). Both pancreatic and hepatocellular cancer are rare during pregnancy (Kakoza, 2009; Marinoni, 2006; Papoutsis, 2012; Perera, 2011). Another report described a massive intrahepatic cholangiocarcinoma masquerading as HELLP syndrome (Bladerston, 1998). Except for thyroid cancer, malignant tumors of the head and neck are rare (Cheng, 2015). Lung cancer is also uncommon (Boussios, 2013). Central nervous system neoplasms had a reported frequency of 1 in 10,000 to 28,000 births (Eibye, 2013; Smith, 2003). Bladder and urachal duct carcinoma are rarely coincident with pregnancy (McNally, 2013; Yeaton-Massey, 2013). Last, bone tumors have been described (Kathiresan, 2011).

CHAPTER 64: Infectious Diseases

According to many authorities, influenza exerts a very pernicious influence upon pregnancy. It would appear that the effects of influenza must vary with the severity of the epidemic, and more particularly with the frequency of pneumonic complications. As a rule, any septic condition offers a worse prognosis in pregnancy. Several instances have been reported of transmission of the offending bacteria to the foetus.

—J. Whitridge Williams (1903)

INTRODUCTION

Infections have historically been a major cause of maternal and fetal morbidity and mortality worldwide, and they remain so in the 21st century. The unique maternal–fetal vascular connection in some cases serves to protect the fetus from infectious agents, whereas in other instances it provides a conduit for their transmission to the fetus. Maternal serological status, gestational age at the time infection is acquired, the mode of acquisition, and the immunological status of both the mother and her fetus all influence disease outcome.

MATERNAL AND FETAL IMMUNOLOGY

Pregnancy-Induced Immunological Changes

Even after intensive study, many of the maternal immunological adaptations to pregnancy are not well elucidated. It is known that pregnancy is associated with an increase in the CD4+ T cells that secrete Th2-type cytokines—for example interleukins (Fragiadakis, 2016). Th1-type cytokine production—for example, interferon gamma and interleukin 2—appears to be somewhat suppressed, leading to a *Th2 bias* in pregnancy. This bias affects the ability to rapidly eliminate certain intracellular pathogens during pregnancy, although the clinical implications of this suppression are unknown (Kourtis, 2014; Svensson-Arvelund, 2014). Importantly, the Th2 humoral immune response remains intact. It also appears that human leukocyte antigen (HLA)-C expressed by extravillous trophoblasts elicits responses from decidual natural killer (dNK) and decidual CD8+ T cells (Crespo, 2017).

In describing infections, *horizontal transmission* is the spread of an infectious agent from one individual to another. *Vertical transmission* refers to passage from the mother to her fetus of an infectious agent through the placenta, during labor or delivery, or by breastfeeding. Thus, preterm rupture of membranes, prolonged labor, and obstetrical manipulations may enhance the risk of neonatal infection (Centers for Disease Control and Prevention, 2010). Table 64-1 details specific infections by mode and timing of acquisition. A final term, the *secondary attack rate*, is the probability that infection develops in a susceptible individual following known contact with an infectious person.

TABLE 64-1

Specific Causes of Some Fetal and Neonatal Infections

Intrauterine
Transplacental
Viruses: varicella-zoster, coxsackie, human parvovirus B19, rubella, CMV, HIV, Zika
Bacteria: *Listeria*, syphilis, *Borrelia*
Protozoa: toxoplasmosis, malaria
Ascending infection
Bacteria: group B *streptococcus*, coliforms
Viruses: HIV
Intrapartum
Maternal exposure
Bacteria: gonorrhea, chlamydia, group B *streptococcus*, tuberculosis, mycoplasmas
Viruses: HSV, HPV, HIV, hepatitis B, hepatitis C, Zika
External contamination
Bacteria: staphylococcus, coliforms
Viruses: HSV, varicella zoster
Neonatal
Human transmission: staphylococcus, HSV
Respirators and catheters: staphylococcus, coliforms

CMV = cytomegalovirus; HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus.

Fetal and Newborn Immunology

The active immunological capacity of the fetus and neonate is compromised compared with that of older children and adults. That said, fetal cell-mediated and humoral immunity begin to develop by 9 to 15 weeks' gestation (Warner, 2010). The primary fetal response to infection is immunoglobulin M (IgM). Passive immunity is provided by IgG transferred across the placenta. By 16 weeks, this transfer begins to rise rapidly, and by 26 weeks, fetal concentrations are equivalent to those of the mother. After birth, breastfeeding is protective against some infections, although this protection begins to decline at 2 months of age. Current World Health Organization (2013) recommendations are to exclusively breastfeed for the first 6 months of life with partial breastfeeding until 2 years of age.

Neonatal infection, especially in its early stages, may be difficult to diagnose because these newborns often fail to express classic clinical signs. If the fetus was infected in utero, there may be depression and acidosis at birth for no apparent reason. The neonate may suck poorly, vomit, or show abdominal distention. Respiratory insufficiency can develop, which may present similarly to idiopathic respiratory distress syndrome. The neonate may be lethargic or jittery. The response to sepsis may be hypothermia rather than hyperthermia, and the total leukocyte and neutrophil counts may be depressed.

VIRAL INFECTIONS

Cytomegalovirus

Several viruses cause severe maternal infections, and some can also cause devastating fetal infections. Of these, cytomegalovirus (CMV) is a ubiquitous DNA herpes virus that eventually infects most humans. CMV is also the most common perinatal infection in the developed world. Specifically, some evidence of fetal infection is found in 0.2 to 2.2 percent of all neonates (American College of Obstetricians and Gynecologists, 2017). The virus is secreted into all body fluids, and person-to-person contact with viral-laden saliva, semen, urine, blood, and nasopharyngeal and cervical secretions can transmit infection. The fetus may become infected by transplacental viremia, or the neonate is infected at delivery or during breastfeeding. Moreover, acquisition continues to accrue. Day-care centers, for example, are a frequent source. Revello and coworkers (2008) reported that amniocentesis in women whose blood is positive for CMV DNA does not result in iatrogenic fetal transmission.

Up to 85 percent of women from lower socioeconomic backgrounds are seropositive by the time of pregnancy, whereas only half of women in higher income groups are immune. Following primary CMV infection, and in a manner similar to other herpesvirus infections, the virus becomes latent with periodic reactivation characterized by viral shedding. This occurs despite high serum levels of anti-CMV IgG antibody. These antibodies do not prevent maternal recurrence, reactivation, or reinfection, nor do they totally mitigate fetal or neonatal infection.

Maternal Infection

Women who are seronegative before pregnancy, but who develop primary CMV infection during pregnancy, are at greatest risk to have an infected fetus. It is estimated that 25 percent of congenital CMV infections in the United States are from primary maternal infection (Wang, 2011). Most CMV infections are clinically silent, but they can be detected by seroconversion, and this may be as high as 1 to 7 percent annually (Hyde, 2010). Conversely, diagnosis of CMV nonprimary infection is a challenge (Picone, 2017).

Pregnancy does not increase the risk or severity of maternal CMV infection. Most infections are asymptomatic, but 10 to 15 percent of infected adults have a mononucleosis-like syndrome characterized by fever, pharyngitis, lymphadenopathy, and polyarthritis. Immunocompromised women may develop myocarditis, pneumonitis, hepatitis, retinitis, gastroenteritis, or meningoencephalitis. Nigro and associates (2003) reported that most women in a cohort with primary infection had elevated serum aminotransferases or lymphocytosis. Reactivation disease usually is asymptomatic, although viral shedding is common.

Transmission rates for primary infection are 30 to 36 percent in the first trimester, 34 to 40 percent in the second, and 40 to 72 percent in the third trimester (American College of Obstetricians and Gynecologists, 2017; Picone, 2017). In contrast, recurrent maternal infection infects the fetus in only 0.15 to 1 percent of cases. Naturally acquired immunity during pregnancy results in a 70-percent risk reduction of congenital CMV infection in future pregnancies (Fowler, 2003; Leruez-Ville, 2017). However, as noted earlier, maternal immunity does not prevent recurrences, and maternal antibodies do not prevent fetal infection (Ross, 2011).

Fetal Infection

Newborns with apparent sequelae of in-utero-acquired CMV infection are described as having *symptomatic CMV infection*. Congenital infection is a syndrome that may include growth restriction, microcephaly, intracranial calcifications, chorioretinitis, mental and motor retardation, sensorineural deficits, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenic purpura (Cheeran, 2009). An example of periventricular calcifications is shown in Figure 64-1. Of the estimated 40,000 infected neonates born each year, only 5 to 10 percent demonstrate this syndrome (Fowler, 1992). Thus, most infected infants are asymptomatic at birth, but some develop late-onset sequelae. Complications may include hearing loss, neurological deficits, chorioretinitis, psychomotor retardation, and learning disabilities. Infections in dichorionic twins most likely are nonconcordant (Egaña-Ugrinovic, 2016).

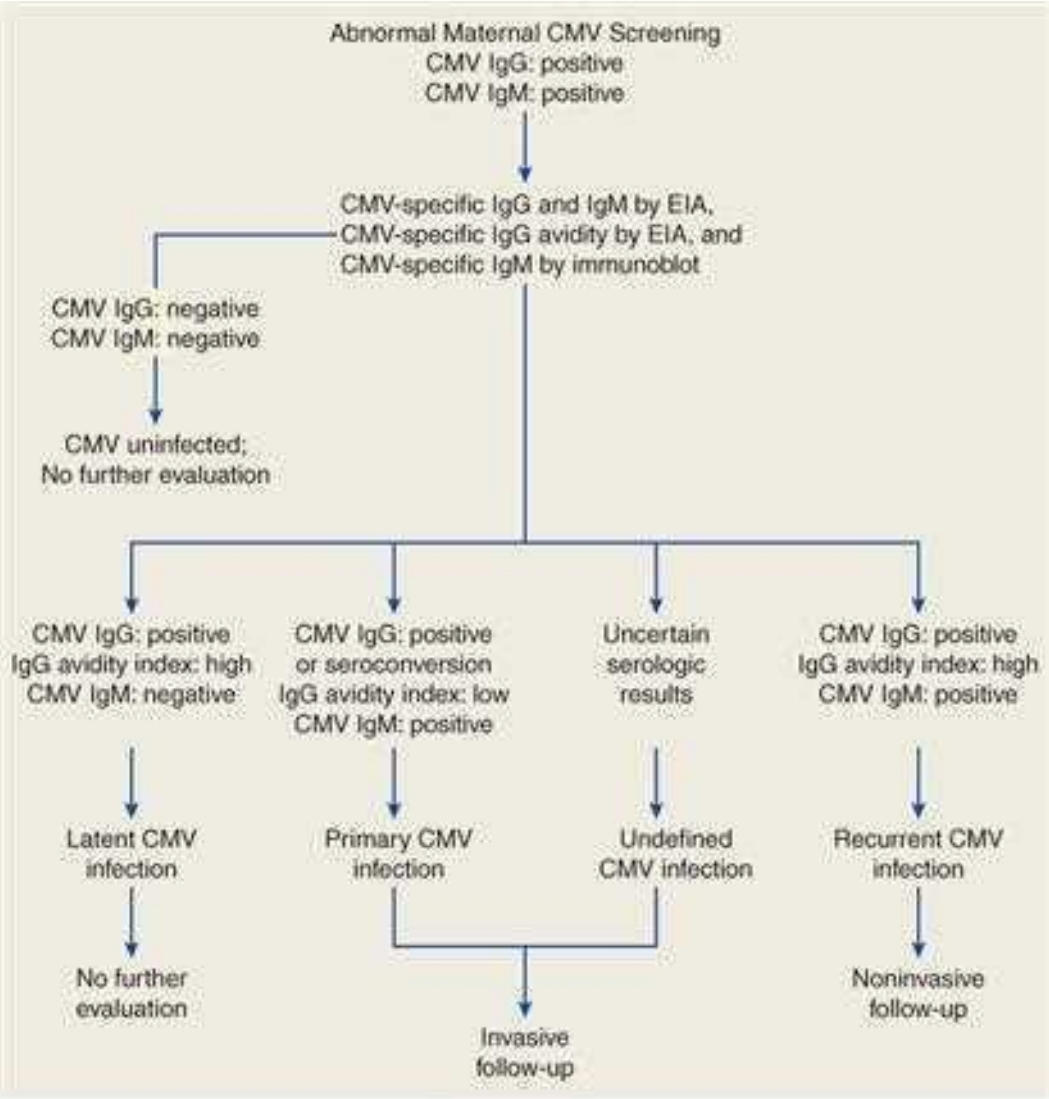
FIGURE 64-1
Coronal view of cranial sonogram from a neonate with congenital cytomegalovirus infection showing multiple periventricular calcifications.

Prenatal Diagnosis

Routine prenatal CMV serological screening is currently not recommended by the Society for Maternal–Fetal Medicine (2016). An algorithm for management is shown in Figure 64-2. Pregnant women should be tested for CMV if they present with a mononucleosis-like illness or if congenital infection is suspected based on abnormal sonographic findings. Primary infection is diagnosed using CMV-specific IgG testing of paired acute and convalescent sera. CMV IgM does not accurately reflect timing

of seroconversion because IgM antibody levels may be elevated for more than a year (Stagno, 1985). Moreover, CMV IgM may be found with reactivation disease or reinfection with a new strain. Thus, specific CMV IgG avidity testing is valuable in confirming primary CMV infection. High anti-CMV IgG avidity indicates primary maternal infection >6 months before testing (Kanengisser-Pines, 2009). Finally, viral culture may be useful, although a minimum of 21 days is required before findings are considered negative.

FIGURE 64-2
Algorithm for evaluation of suspected maternal primary cytomegalovirus (CMV) infection in pregnancy. EIA = enzyme immunoassay; IgG = immunoglobulin G; IgM = immunoglobulin M.



Several fetal abnormalities associated with CMV infection may be seen with sonography, computed tomography, or magnetic resonance imaging. In some cases, they are found at the time of routine prenatal sonographic screening, but in others they are part of a specific evaluation in women with CMV infection. Findings include microcephaly, ventriculomegaly, and cerebral calcifications; ascites, hepatomegaly, splenomegaly, and hyperechoic bowel; hydrops; and oligohydramnios (Society for Maternal-Fetal Medicine, 2016). Abnormal sonographic findings seen in combination with positive findings in fetal blood or amniotic fluid are predictive of an approximate 75-percent risk of symptomatic congenital infection (Enders, 2001).

CMV nucleic acid amplification testing (NAAT) of amniotic fluid is considered the gold standard for the diagnosis of fetal infection. Sensitivities range from 70 to 99 percent and depend on amniocentesis timing. Sensitivity is highest when amniocentesis is performed at least 6 weeks after maternal infection and after 21 weeks' gestation (Azam, 2001; Guerra, 2000). A negative result from amniotic fluid polymerase chain reaction (PCR) testing does not exclude fetal infection and may need to be repeated if suspicion for fetal infection is high.

Management and Prevention

The management of the immunocompetent pregnant woman with primary or recurrent CMV is limited to symptomatic treatment. If recent primary CMV infection is confirmed, amniotic fluid analysis should be offered. Counseling regarding fetal outcome depends on the gestational age during which primary infection is documented. Despite the high infection rate with primary infection in the first half of pregnancy, most fetuses develop normally. However, pregnancy termination may be an option for some.

Currently, no proven treatments are available for CMV infection (Society for Maternal–Fetal Medicine, 2016). Leruez-Ville and associates (2016) recently reported that oral treatment with valacyclovir, 8 g daily, apparently mitigated adverse outcomes in eight of 11 affected fetuses treated beginning at median of 25.9 weeks' gestation. Kimberlin and colleagues (2015) previously showed that intravenous valganciclovir administered for 6 weeks to neonates with symptomatic central nervous system (CNS) disease prevented hearing deterioration at 6 months and possibly later. Passive immunization with CMV-specific hyperimmune globulin may lower the risk of congenital CMV infection when given to pregnant women with primary disease (Nigro, 2005, 2012; Visentin, 2012). The Maternal–Fetal Medicine Units Network currently is conducting a randomized trial designed to address this.

There is no CMV vaccine, although several clinical trials are underway (Arvin, 2004; Schleiss, 2016). Prevention of congenital infection relies on avoiding maternal primary infection, especially in early pregnancy. Basic measures such as good hygiene and hand washing have been promoted, particularly for women with toddlers in day-care settings (Fowler, 2000). CMV may be sexually transmitted among infected partners, but no data address the efficacy of preventive strategies.

Varicella-Zoster Virus

Maternal Infection

Varicella–zoster virus (VZV) is a double-stranded DNA herpesvirus acquired predominately during childhood, and 90 percent of adults have serological evidence of immunity (Whitley, 2015). The incidence of adult varicella declined by 82 percent after the introduction of varicella vaccination, and this has resulted in a drop in maternal and fetal varicella rates (American College of Obstetricians and Gynecologists, 2017). In the United States between 2003 and 2010, the incidence of maternal varicella among 7.7 million pregnancy admissions was 1.21 per 10,000 (Zhang, 2015).

Primary infection—*varicella* or *chickenpox*—is transmitted by direct contact with an infected individual, although respiratory transmission has been reported. The incubation period is 10 to 21 days, and a nonimmune woman has a 60- to 95-percent risk of becoming infected after exposure (Whitley, 2015). Primary varicella presents with a 1- to 2-day flulike prodrome, which is followed by pruritic vesicular lesions that crust after 3 to 7 days. Infection tends to be more severe in adults (Marin, 2007). Affected patients are then contagious from 1 day before the onset of the rash until the lesions become crusted.

Mortality is predominately due to VZV pneumonia, which is thought to be more severe during adulthood and particularly in pregnancy. Although the incidence was once thought to be higher, only 2 to 5 percent of infected pregnant women develop pneumonitis (Marin, 2007; Zhang, 2015). Risk factors for VZV pneumonia include smoking and having more than 100 cutaneous lesions. Maternal mortality rates with pneumonia have decreased to 1 to 2 percent (Chandra, 1998).

Symptoms of VZV pneumonia usually appear 3 to 5 days into the course of illness. Fever, tachypnea, dry cough, dyspnea, and pleuritic pain are characteristic. Nodular infiltrates are similar to other viral pneumonias (Chap. 51, Influenza Pneumonia). Although resolution of pneumonitis parallels that of skin lesions, fever and compromised pulmonary function may persist for weeks.

If primary varicella is reactivated years later, it causes *herpes zoster* or *shingles* (Whitley, 2015). This presents as a unilateral dermatomal vesicular eruption associated with severe pain. Zoster does not appear to be more frequent or severe in pregnant women. Congenital varicella syndrome rarely develops in cases of maternal herpes zoster (Ahn, 2016; Enders, 1994). Zoster is contagious if blisters are broken, although less so than with primary varicella.

Fetal and Neonatal Infection

In women with varicella during the first half of pregnancy, the fetus may develop *congenital varicella syndrome*. Some features include chorioretinitis, microphthalmia, cerebral cortical atrophy, growth restriction, hydronephrosis, limb hypoplasia, and cicatricial skin lesions as shown in Figure 64-3 (Ahn, 2016; Auriti, 2009). Enders and coworkers (1994) evaluated 1373 pregnant women with varicella. When maternal infection developed before 13 weeks, only two of 472 pregnancies—0.4 percent—had neonates with congenital varicella syndrome. The highest risk was between 13 and 20 weeks, during which time seven of 351 exposed fetuses—2 percent—had evidence of congenital varicella. After 20 weeks' gestation, the researchers found no clinical evidence of congenital infection. Ahn and colleagues (2016) recently described similar findings. That said, sporadic reports have described CNS abnormalities and skin lesions in fetuses who developed congenital varicella in weeks 21 to 28 of gestation (Lamont, 2011a; Marin, 2007).

FIGURE 64-3
Atrophy of the lower extremity with bony defects and scarring in a fetus infected during the first trimester by varicella. (Reproduced with permission from Paryani SG, Arvin AM: Intrauterine infection with varicella zoster virus after maternal varicella, N Engl J Med. 1986 Jun 12;314(24):1542–1546.)

If the fetus or neonate is exposed to active infection just before or during delivery, and therefore before maternal antibody has been formed, the newborn faces a serious threat. Attack rates range from 25 to 50 percent, and mortality rates approach 30 percent. In some instances, neonates develop disseminated visceral and CNS disease, which is commonly fatal. For this reason, *varicella-zoster immune globulin* (VZIG) should be administered to neonates born to mothers who have clinical evidence of varicella 5 days before and up to 2 days after delivery.

Diagnosis

Maternal varicella is usually diagnosed clinically. Infection may be confirmed by NAAT of vesicular fluid, which is very sensitive. The virus may also be isolated by scraping the vesicle base during primary infection and performing a Tzanck smear, tissue culture, or direct fluorescent antibody testing. Congenital varicella may be diagnosed using NAAT analysis of amnionic fluid, although a positive result does not correlate well with the development of congenital infection (Mendelson, 2006). A detailed anatomical sonographic evaluation performed at least 5 weeks after maternal infection may disclose abnormalities, but the sensitivity is low (Mandelbrot, 2012).

Management

Maternal Viral Exposure

Several aspects of maternal VZV exposure and infection in pregnancy affect management. Exposed gravidas with a negative history for chickenpox should undergo VZV serological testing. At least 70 percent of these women will be seropositive, and thus immune. Exposed pregnant women who are susceptible (seronegative) should be given varicella-zoster immune globulin (VariZIG). Although best given within 96 hours of exposure, its use is approved for up to 10 days to prevent or attenuate varicella infection (Centers for Disease Control and Prevention, 2012, 2013d). Passive immunization appears to be highly effective (Jespersen, 2016). In women with known history of varicella, VariZIG is not indicated.

Maternal Infection

Any patient diagnosed with primary varicella infection or herpes zoster should be isolated from pregnant women. Because VZV pneumonia often presents with few symptoms, a chest radiograph is recommended by many. Most women require only supportive care, but those who require intravenous (IV) fluids and especially those with pneumonia are hospitalized. IV acyclovir therapy is given to women requiring hospitalization—500 mg/m^2 or 10 to 15 mg/kg every 8 hours.

Vaccination

An attenuated live-virus vaccine is recommended for nonpregnant adolescents and adults with no history of varicella. Two doses of *Varivax* are given 4 to 8 weeks apart, and the seroconversion rate is 98 percent (Marin, 2007). Importantly, vaccine-induced immunity diminishes over time, and the breakthrough infection rate approximates 5 percent at 10 years (Chaves, 2007).

The vaccine is not recommended for pregnant women or for those who may become pregnant within a month following each vaccine dose. That said, a registry of more than 1000 vaccine-exposed pregnancies reports no cases of congenital varicella syndrome or other associated congenital malformations (Marin, 2014; Wilson, 2008). The attenuated vaccine virus is not secreted in breast milk. Thus, postpartum vaccination should not be delayed because of breastfeeding (American College of Obstetricians and Gynecologists, 2016c).

Influenza Virus

These respiratory infections are caused by members of the family Orthomyxoviridae. *Influenza A* and *B* form one genus of these RNA viruses, and both cause epidemic human disease (Cohen, 2015b). Influenza A viruses are subclassified further by hemagglutinin (H) and neuraminidase (N) surface antigens. Influenza outbreaks occur annually, and the most recent epidemic was in 2016 to 2017 caused by an influenza A/H_3N_2 strain (Shang, 2016).

Maternal and Fetal Infection

Fever, dry cough, and systemic symptoms characterize this infection, which usually is not life-threatening in otherwise healthy adults. However, pregnant women appear to be more susceptible to serious complications, particularly pulmonary involvement (Cohen, 2015b; Mertz, 2017; Rasmussen, 2012). Severe infection has a maternal mortality rate of 1 percent (Duryea, 2015). And from 2009 to 2010, widespread influenza A infection affected pregnant women and caused 12 percent of pregnancy-related deaths (Callaghan, 2015).

No firm evidence links influenza A virus and congenital malformations (Irving, 2000; Zerbo, 2017). Conversely, Lynberg and colleagues (1994) reported higher rates of neural-tube defects in neonates born to women with influenza early in pregnancy. This was possibly associated with hyperthermia. Viremia is infrequent, and transplacental passage is rare (Rasmussen, 2012). Stillbirth, preterm delivery, and first-trimester abortion have all been reported, but usually correlate with the severity of maternal infection (Centers for Disease Control and Prevention, 2011; Fell, 2017; Meijer, 2015).

Influenza may be detected in nasopharyngeal swabs using viral antigen rapid detection assays (Table 64-2). Reverse transcriptase–polymerase chain reaction (RT-PCR) is the more sensitive and specific test, although not widely available (Cohen, 2015b). In contrast, rapid influenza diagnostic tests (RIDTs) are least indicative, with sensitivities of 40 to 70 percent. *Decisions to administer antiviral medications for influenza treatment or chemoprophylaxis should be based on clinical symptoms and epidemiological factors.* Specifically, the start of therapy should not be delayed pending testing results (Centers for Disease Control and Prevention, 2017e).

TABLE 64-2

Outpatient Influenza A and B Virus Testing Methods

Method[a]	Test Time
Viral cell culture	3–10 d
Rapid cell culture	1–3 d
Direct (DFA) or indirect (IFA) fluorescent antibody assay	1–4 hr
RT-PCR and other molecular assays	1–6 hr
Rapid influenza diagnostic tests (RIDT)	<30 min

[a]Nasopharyngeal or throat swab.

RT-PCR = reverse transcription-polymerase chain reaction.

Data from Centers for Disease Control and Prevention, 2017e.

Management

Two classes of antiviral medications are currently available. *Neuraminidase inhibitors* are highly effective for the treatment of early influenza A and B. These include *oseltamivir* (Tamiflu), which is taken orally for treatment and for chemoprophylaxis; z*anamivir* (Relenza), which is inhaled for treatment; and *peramivir* (Rapivab), which is administered intravenously.

The *adamantanes* include amantadine and rimantadine, which were used for years for treatment and chemoprophylaxis of influenza A. In 2005, influenza A resistance to adamantine was reported to exceed 90 percent in the United States. Thus, its use is not currently recommended. It is possible that these drugs may again be effective for subsequently mutated strains. Patterns of resistance are available at cdc.gov/flu.

Experience with all of these antiviral agents in pregnant women is limited (Beau, 2014; Beigi, 2014; Dunstan, 2014). They are Food and Drug Administration category C drugs and thus used when potential benefits outweigh risks. At Parkland Hospital, we start oral oseltamivir treatment within 48 hours of symptom onset—75 mg twice daily for 5 days. Early administration may reduce length of hospital stays (Meijer, 2015; Oboho, 2016). Prophylaxis with oseltamivir, 75 mg orally once daily for 7 days, is also recommended for significant exposures. Antibacterial medications are added when a secondary bacterial pneumonia is suspected (Chap. 51, Pregnancy Outcome).

Vaccination

Effective vaccines are formulated annually. Vaccination against influenza throughout the influenza season, but optimally in October or November, is recommended by the Centers for Disease Control and Prevention (CDC) (2013a) and the American College of Obstetricians and Gynecologists (2016b) for all women who will be pregnant during the influenza season. This is especially important for those affected by chronic medical disorders such as diabetes, heart disease, asthma, or human immunodeficiency virus (HIV) infection. Inactivated vaccine prevents clinical illness in 70 to 90 percent of healthy adults. Importantly, there is no evidence of teratogenicity or other adverse maternal or fetal events (Chambers, 2016; Fell, 2017; Kharbanda, 2017; Polyzos, 2015; Sukumaran, 2015). Moreover, for mothers vaccinated during pregnancy, several studies found lower rates of influenza in their infants up to 6 months of age (Nunes, 2017; Steinhoff, 2012; Zaman, 2008). Immunogenicity of the trivalent inactivated seasonal influenza vaccine in pregnant women is similar to that in the nonpregnant individual. A live attenuated influenza virus vaccine is available for intranasal use but is not recommended for pregnant women (Cohen, 2015b).

Mumps Virus

This uncommon adult infection is caused by an RNA paramyxovirus. Because of childhood immunization, up to 90 percent of adults are seropositive (Rubin, 2012). The virus primarily infects the salivary glands but also may involve the gonads, meninges, pancreas, and other organs. It is transmitted by direct contact with respiratory secretions, saliva, or through fomites. Most transmission occurs before and within 5 days of parotitis onset, and droplet isolation is recommended during this time (Kutty, 2010). Treatment is symptomatic, and mumps during pregnancy is no more severe than in nonpregnant adults.

Women who develop mumps in the first trimester may have a greater risk of spontaneous abortion. Infection in pregnancy is not associated with congenital malformations, and fetal infection is rare (McLean, 2013).

The live attenuated Jeryl-Lynn vaccine strain is part of the MMR vaccine—measles, mumps, and rubella. This vaccine is contraindicated in pregnancy according to the CDC (McLean, 2013). No malformations attributable to MMR vaccination in pregnancy have been reported, but pregnancy should be avoided for 30 days after mumps vaccination. The vaccine may be given to susceptible women postpartum, and breastfeeding is not a contraindication.

Measles Virus

This is a highly contagious RNA virus of the family Paramyxoviridae that only infects humans. In endemic areas, annual outbreaks of measles, also called rubeola, occur in late winter and early spring, transmission is primarily by respiratory droplets, and the secondary attack rate among contacts exceeds 90 percent (Rainwater-Lovett, 2015). Resurgences in measles have been linked to clusters of vaccine-eligible but unvaccinated individuals (Fiebelkorn, 2010; Phadke, 2016). Fever, coryza, conjunctivitis, and cough are typical symptoms. The characteristic erythematous maculopapular rash develops on the face and neck and then spreads to the back, trunk, and extremities. *Koplik spots* are small white lesions with surrounding erythema found within the oral cavity. Immediate or delayed neurological sequelae of measles may manifest in several forms, making diagnosis difficult (Buchanan, 2012; Chiu, 2016). Diagnosis of acute infection is most commonly performed by serological evidence of IgM antibodies, although RT-PCR tests are available. Treatment is supportive.

Pregnant women without evidence of measles immunity should be administered passive immunoprophylaxis with immune globulin, 400 mg/kg intravenously (Centers for Disease Control and Prevention, 2017d). Active vaccination is not performed during pregnancy, however, susceptible women can be vaccinated routinely postpartum, and breastfeeding is not contraindicated (Ohji, 2009).

The virus does not appear to be teratogenic (Siegel, 1973). However, rates of spontaneous abortion, preterm delivery, and low-birthweight neonates are increased with maternal measles (Rasmussen, 2015). If a woman develops measles shortly before birth, risk of serious infection developing in the neonate is considerable, especially in a preterm neonate.

Rubella Virus

This RNA togavirus causes rubella, also called German measles, which is of minor importance in the absence of pregnancy. *Rubella infection in the first trimester, however, poses significant risk for abortion and severe congenital malformations.* Transmission occurs via nasopharyngeal secretions, and the transmission rate is 80 percent to susceptible individuals. The peak incidence is late winter and spring in endemic areas (Lambert, 2015).

Maternal rubella is usually a mild febrile illness with a generalized maculopapular rash beginning on the face and spreading to the trunk and extremities. That said, 25 to 50 percent of infections are asymptomatic. Other symptoms may include arthralgias or arthritis, head and neck lymphadenopathy, and conjunctivitis. The incubation period is 12 to 23 days. Viremia usually precedes clinical signs by about a week, and adults are infectious during viremia and through 7 days after the rash appears. Up to half of maternal infections are subclinical despite viremia that may cause devastating fetal infection (McLean, 2013).

Diagnosis

Rubella virus may be isolated from the urine, blood, nasopharynx, and cerebrospinal fluid for up to 2 weeks after rash onset. The diagnosis is usually made, however, with serological analysis. In one study, 6 percent of nonimmune women seroconverted to rubella virus during pregnancy (Hutton, 2014). Specific IgM antibody can

be detected using enzyme-linked immunoassay for 4 to 5 days after onset of clinical disease, but antibody can persist for up to 6 weeks after appearance of the rash. Importantly, rubella virus reinfection can give rise to transient low levels of IgM. With this, fetal infection can rarely occur, but no adverse fetal effects have been described. Serum IgG antibody titers peak 1 to 2 weeks after rash onset. This rapid antibody response may complicate serodiagnosis unless samples are initially collected within a few days after the onset of the rash. If, for example, the first specimen was obtained 10 days after the rash, detection of IgG antibodies would fail to differentiate between very recent disease and preexisting immunity to rubella. IgG avidity testing is performed concomitant with the serological tests above. High-avidity IgG antibodies indicate an infection at least 2 months in the past.

Fetal Effects

The rubella virus is one of the most complete teratogens, and effects of fetal infection are worst during organogenesis (Adams Waldorf, 2013). Pregnant women with rubella and a rash during the first 12 weeks of gestation have an affected fetus with congenital infection in up to 90 percent of cases (Miller, 1982). At 13 to 14 weeks' gestation, this incidence is 50 percent, and by the end of the second trimester, it is 25 percent. Defects are rare after 20 weeks' gestation. Features of congenital rubella syndrome amenable to prenatal diagnosis are cardiac septal defects, pulmonary stenosis, microcephaly, cataracts, microphthalmia, and hepatosplenomegaly (Yazigi, 2017). Other abnormalities include sensorineural deafness, intellectual disability, neonatal purpura, and radiolucent bone disease. *Neonates born with congenital rubella may shed the virus for many months and thus be a threat to other infants and to susceptible adults who contact them.* Reports of delayed morbidities associated with congenital rubella syndrome may include a rare, progressive panencephalitis, insulin-dependent diabetes mellitus, and thyroid disorders (Sever, 1985; Webster, 1998).

Management and Prevention

There is no specific treatment for rubella. Droplet precautions for 7 days after the onset of the rash are recommended. Postexposure passive immunization with polyclonal immunoglobulin may be of benefit if given within 5 days of exposure (Young, 2015).

Although large epidemics of rubella have virtually disappeared in the United States because of immunization, up to 10 percent of women in the United States are susceptible. Cluster outbreaks during the 1990s mainly involved persons born outside the United States, as congenital rubella is still common in developing nations (Centers for Disease Control and Prevention, 2013f). To eradicate rubella and prevent congenital rubella syndrome completely, a comprehensive approach is recommended for immunizing the adult population (Grant, 2015).

MMR vaccine should be offered to nonpregnant women of childbearing age who do not have evidence of immunity whenever they make contact with the health-care system. Vaccination of all susceptible hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant women is important. Rubella vaccination should be avoided 1 month before or during pregnancy because the vaccine contains attenuated live virus. No observed evidence links the vaccine and induced malformations, although the overall theoretical risk is up to 2.6 percent (McLean, 2013; Swamy, 2015). MMR vaccination is not an indication for pregnancy termination.

Prenatal serological screening for rubella is indicated for all pregnant women. Women found to be nonimmune are offered the MMR vaccine postpartum.

Respiratory Viruses

More than 200 antigenically distinct respiratory viruses cause the common cold, pharyngitis, laryngitis, bronchitis, and pneumonia. Rhinovirus, coronavirus, and adenovirus are major causes of the common cold. The RNA-containing rhinovirus and coronavirus usually produce a trivial, self-limited illness characterized by rhinorrhea, sneezing, and congestion. The DNA-containing adenovirus is more likely to produce cough and lower respiratory tract involvement, including pneumonia.

The potential teratogenic effects of respiratory viruses are controversial. In a case-control study using data from the Finnish Register of Congenital Malformations, 393 gravidas with a common cold had a four- to fivefold greater risk of fetal anencephaly (Kurppa, 1991). In another population study of California births from 1989 to 1991, low attributable risks for neural-tube defects were associated with many illnesses in early pregnancy (Shaw, 1998). Adams and colleagues (2012) performed amnionic fluid viral PCR studies in 1191 women undergoing amniocentesis for fetal karyotyping. Viral PCR was positive in 6.5 percent, with adenovirus being the virus most frequently identified. There was an association with fetal-growth restriction, nonimmune hydrops, foot/hand abnormalities, and neural-tube defects. Adenoviral infection is a known cause of childhood myocarditis. Towbin (1994) and Forsnes (1998) and their associates used PCR tests to identify and link adenovirus to fetal myocarditis and nonimmune hydrops.

Hantaviruses

These RNA viruses are members of the family Bunyaviridae. They are associated with a rodent reservoir, and transmission involves inhalation of virus excreted in rodent urine and feces. Outbreaks of hantaviruses including Sin Nombre virus and Seoul virus have been reported in the United States, the most recent in early 2017 (Centers for Disease Control and Prevention, 2017b). Hantaviruses are a heterogenous group of viruses with low and variable rates of transplacental transmission. Howard and associates (1999) reported the *Hantavirus pulmonary syndrome* to cause maternal death, fetal demise, and preterm birth. They found no evidence of vertical transmission of the causative Sin Nombre virus.

Enteroviruses

These viruses are a major subgroup of RNA picornaviruses that include coxsackievirus, poliovirus, and echovirus. They are trophic for intestinal epithelium but can also cause widespread maternal, fetal, and neonatal infections that may include the CNS, skin, heart, and lungs. Most maternal infections are subclinical yet can be fatal to the fetus–neonate (Tassin, 2014). Hepatitis A is an enterovirus that is discussed in Chapter 55 (Chronic Viral Hepatitis).

Coxsackievirus infections with group A and B are usually asymptomatic. Symptomatic infections—usually with group B—include aseptic meningitis, polio-like illness, hand foot and mouth disease, rashes, respiratory disease, pleuritis, pericarditis, and myocarditis. No treatment or vaccination is available (Cohen, 2015a). Coxsackievirus may be transmitted by maternal secretions to the fetus at delivery in up to half of mothers who seroconverted during pregnancy (Modlin, 1988). Transplacental passage has also been reported (Ornoy, 2006).

Congenital malformation rates may be slightly increased in fetuses of pregnant women who had serological evidence of coxsackievirus (Brown, 1972). Viremia can cause fetal hepatitis, skin lesions, myocarditis, and encephalomyelitis, all of which may be fatal. Some have reported higher rates of cardiac anomalies and of low-birthweight, preterm, and small-for-gestational-age newborns (Chen, 2010; Koro'lkova, 1989). Maternal–fetal infection has been associated with massive perivillous fibrin deposition and fetal death (Yu, 2015). Finally, a rare association between maternal coxsackievirus infection and insulin-dependent diabetes in offspring has been described (Viskari, 2012).

Polioviruses cause highly contagious infections that are subclinical or mild. The virus is trophic for the CNS, and it can cause paralytic poliomyelitis (Cohen, 2015a). Siegel (1955) demonstrated that pregnant women not only were more susceptible to polio but also had a higher death rate. Perinatal transmission has been observed, especially when maternal infection developed in the third trimester (Bates, 1955). Inactivated subcutaneous polio vaccine is recommended for susceptible pregnant women who must travel to endemic areas or are placed in other high-risk situations. Live oral polio vaccine has been used for mass vaccination during pregnancy without harmful fetal effects (Harjulehto, 1989).

Parvovirus

This B19 virus causes *erythema infectiosum*, or *fifth disease*. It is a small, single-stranded DNA virus that replicates in rapidly proliferating cells such as erythroblast precursors (Brown, 2015). This can lead to anemia, which is its primary fetal effect. Only individuals with the erythrocyte globoside membrane P antigen are susceptible. In women with severe hemolytic anemia—for example, sickle-cell disease—parvovirus infection may cause an aplastic crisis.

The main mode of parvovirus transmission is respiratory or hand-to-mouth contact, and the infection is common in spring months. The maternal infection rate is highest in women with school-aged children and in day-care workers, but not in schoolteachers. An infected person develops viremia 4 to 14 days after exposure, and an otherwise immunocompetent individual is no longer infectious at the onset of the rash. By adulthood, only 40 percent of women are susceptible. The annual seroconversion rate is 1 to 2 percent but is >10 percent during epidemic periods (Brown, 2015). The secondary attack rate approaches 50 percent.

Maternal Infection

In 20 to 30 percent of adults, infection is asymptomatic. Fever, headache, and flulike symptoms may begin in the last few days of the viremic phase. Several days later, a bright red rash with erythroderma affects the face and gives a slapped-cheek appearance. The rash becomes lacelike and spreads to the trunk and extremities. Adults often have milder rashes and develop symmetrical polyarthralgia that may persist several weeks. Mayama and associates (2014) described a pregnant woman in whom B19 infection was associated with hemophagocytic lymphohistiocytosis. No evidence suggests that parvovirus infection is altered by pregnancy. With recovery, IgM antibody is generated 7 to 10 days postinfection, and production persists for 3 to 4 months. Several days after IgM is produced, IgG antibody is detectable and persists for life with natural immunity (American College of Obstetricians and Gynecologists, 2017).

Fetal Infection

There is vertical transmission to the fetus in up to a third of maternal parvovirus infections (de Jong, 2011; Lamont, 2011b). Fetal infection has been associated with abortion, nonimmune hydrops, and stillbirth (Lassen, 2012; Mace, 2014; McClure, 2009). According to the American College of Obstetricians and Gynecologists (2017), the rate of fetal loss with serologically proven parvovirus infection is 8 to 17 percent before 20 weeks' gestation, and 2 to 6 percent after midpregnancy. Currently, no data support evaluating asymptomatic mothers and stillborn fetuses for parvovirus infection.

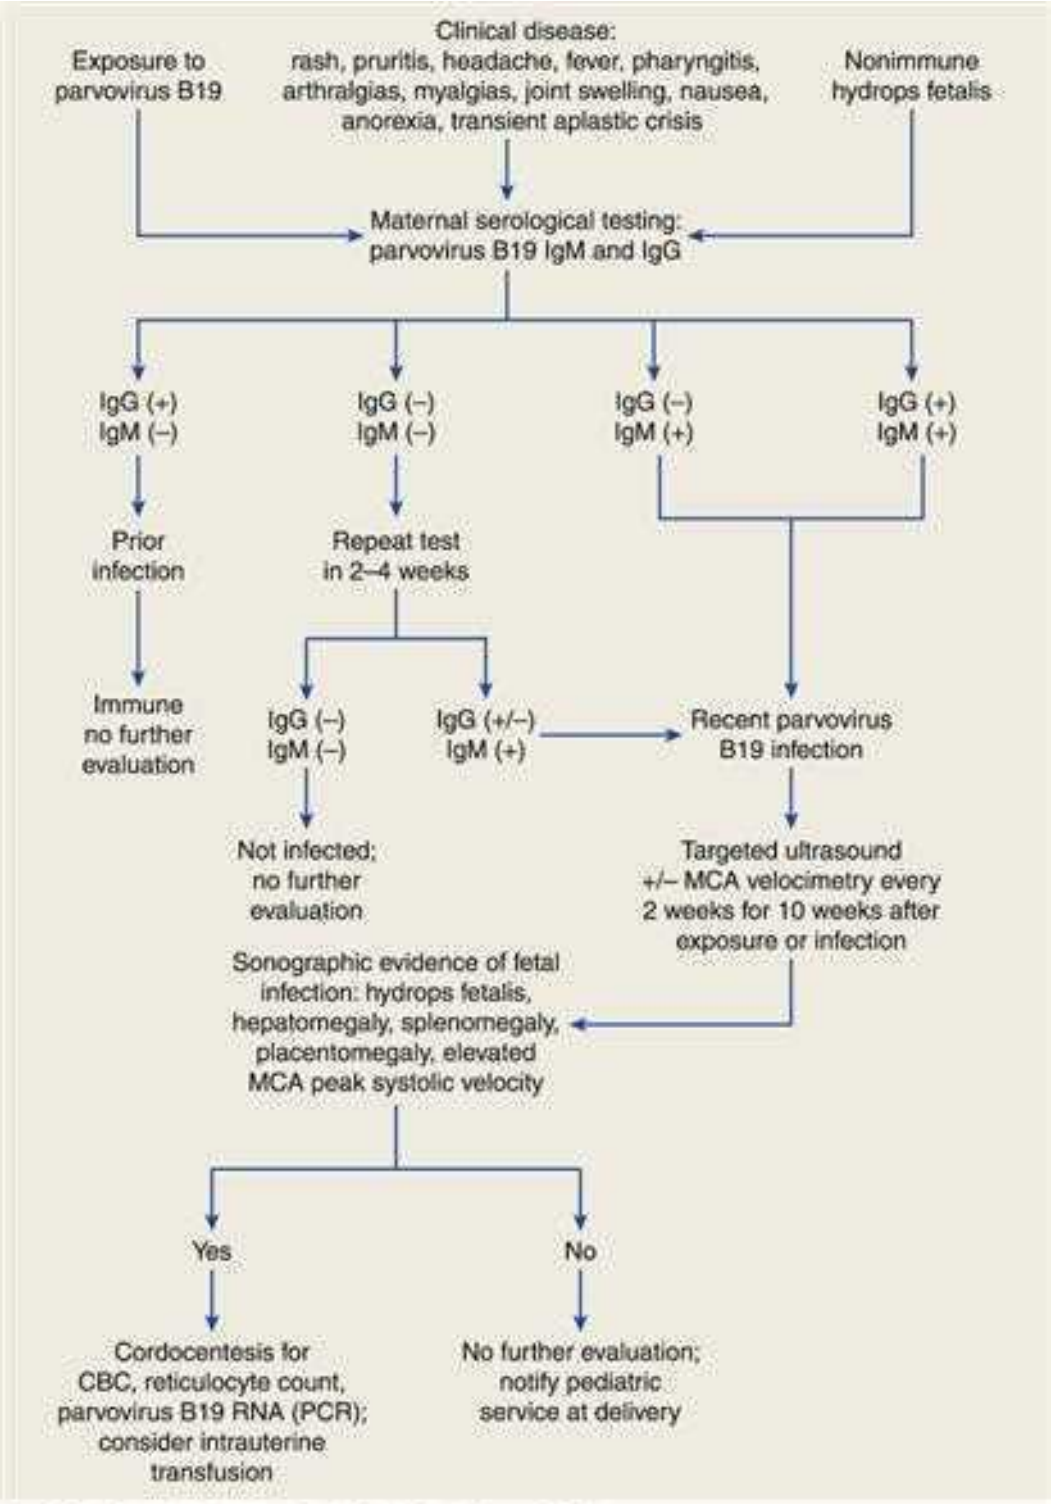
Hydrops develops in only approximately 1 percent of fetuses of women infected with parvovirus (American College of Obstetricians and Gynecologists, 2017; Pasquini, 2016; Puccetti, 2012). Still, it is the most frequent infectious agent of nonimmune hydrops in autopsied fetuses (Rogers, 1999). Hydrops usually stems from infection in the first half of gestation. In one report, more than 80 percent of hydrops cases were found in the second trimester, with a mean gestational age of 22 to 23 weeks (Yaegashi, 2000). At least 85 percent of cases of fetal infection developed within 10 weeks of maternal infection, and the mean interval was 6 to 7 weeks. The critical period for maternal infection leading to fetal hydrops was estimated to be between 13 and 16 weeks' gestation, which coincided with the period in which fetal hepatic hemopoiesis is greatest.

Diagnosis and Management

An algorithm for diagnosis of maternal parvoviral infection is illustrated in Figure 64-4. Diagnosis is generally made by maternal serological testing for specific IgG and IgM antibodies (Bonvicini, 2011; Brown, 2015). Viral DNA may be detectable by PCR in maternal serum during the prodrome and persist for months to years after infection. Fetal infection is diagnosed by detection of B19 viral DNA in amnionic fluid or IgM antibodies in fetal serum obtained by cordocentesis (de Jong, 2011; Weiffenbach, 2012). Fetal and maternal viral loads do not predict fetal morbidity and mortality (de Haan, 2007).

FIGURE 64-4

Algorithm for evaluation and management of human parvovirus B19 infection in pregnancy. CBC = complete blood count; IgG = immunoglobulin G; IgM = immunoglobulin M; MCA = middle cerebral artery; PCR = polymerase chain reaction; RNA = ribonucleic acid.



Most cases of parvovirus-associated hydrops develop in the first 10 weeks after infection. Thus, serial sonography every 2 weeks should be performed in women with recent infection (see Fig. 64-4). As discussed in Chapter 10 (Ductus Arteriosus), middle cerebral artery (MCA) Doppler interrogation can also be used to predict fetal anemia (Chauvet, 2011). Fetal blood sampling is warranted with hydrops to assess the degree of fetal anemia. Comorbid fetal myocarditis may induce hydrops with lesser degrees of anemia.

Depending on gestational age, fetal transfusion for hydrops may improve outcome in some cases (Enders, 2004). Mortality rates as high as 30 percent have been reported in hydropic fetuses without transfusions. With transfusion, 94 percent of hydrops cases resolve within 6 to 12 weeks, and the overall mortality rate is <10 percent. Most fetuses require only one transfusion because hemopoiesis resumes as infection resolves. Concurrent fetal thrombocytopenia worsens the prognosis (Melamed, 2015).

Long-Term Prognosis

Reports describing neurodevelopmental outcomes in fetuses transfused for B19 infection-induced anemia are conflicting. In one review of 24 transfused hydropic fetuses, abnormal neurodevelopment was noted in five of 16 survivors—32 percent—at 6 months to 8 years (Nagel, 2007). Outcomes were not related to severity of fetal anemia or acidemia, and these investigators hypothesized that the infection itself induced cerebral damage. In another study of 28 children treated with intrauterine transfusion, 11 percent had neurodevelopmental impairment during evaluation at a median age of 5 years (de Jong, 2012). Conversely, Dembinski (2003) found no significant neurodevelopmental delay despite severe fetal anemia.

Prevention

Currently, no parvovirus vaccine is available, and no evidence suggests that antiviral treatment prevents maternal or fetal infection. Decisions to avoid higher-risk work settings are complex and require assessment of exposure risks. Pregnant women should be counseled that risks for infection approximate 5 percent for casual, infrequent contact; 20 percent for intense, prolonged work exposure such as for teachers; and 50 percent for close, frequent interaction such as in the home. Workers at day-care centers and schools need not avoid infected children because infectivity is greatest before clinical illness. Finally, infected children do not require isolation.

West Nile Virus

This mosquito-borne RNA flavivirus is a human neuropathogen. It has become the most common cause of arthropod-borne viral encephalitis in the United States (Centers for Disease Control and Prevention, 2017f; Krow-Lucal, 2017). West Nile viral infections are typically acquired through mosquito bites in late summer or perhaps through blood transfusion. The incubation period is 2 to 14 days, and most persons have mild or no symptoms. Fewer than 1 percent of infected adults develop meningoencephalitis or acute flaccid paralysis (Granwehr, 2004). Presenting symptoms may include fever, mental status changes, muscle weakness, and coma (Stewart, 2013).

Diagnosis of West Nile infection is based on clinical symptoms and the detection of viral IgG and IgM in serum and IgM in cerebrospinal fluid. There is no known effective antiviral treatment, and management is supportive. The primary strategy for preventing exposure in pregnancy is the use of insect repellant containing *N,N*-diethyl-*m*-toluamide (DEET). This is considered safe for use among pregnant women (Wylie, 2016). Avoiding outdoor activity and stagnant water and wearing protective clothing are also recommended.

Adverse effects of West Nile viremia on pregnancy are unclear. Animal data suggest that embryos are susceptible, and a case report of human fetal infection at 27 weeks' gestation described chorioretinitis and severe temporal and occipital lobe leukomalacia (Alpert, 2003; Julander, 2006). In 77 maternal infections initially reported to the West Nile Virus Pregnancy Registry, there were four miscarriages, two elective abortions, and 72 live births, 6 percent of which were preterm (O'Leary, 2006). Three of these 72 newborns were shown to have West Nile infection, and it could not be established conclusively that infection was acquired congenitally. Of three major malformations *possibly* associated with viral infection, none was definitively confirmed. Similar conclusions were reached by Pridjian and colleagues (2016), who analyzed data from the CDC West Nile Virus Registry. Transmission of West Nile virus through breastfeeding is rare.

Coronavirus Infections

These are single-stranded RNA viruses that are prevalent worldwide. In 2002, an especially virulent strain of coronavirus—*severe acute respiratory syndrome (SARS–CoV)* was first noted in China. It rapidly spread throughout Asia, Europe, and North and South America. The case-fatality rate approached 10 percent in the nonpregnant population and was as high as 25 percent in pregnant women (Lam, 2004; Wong, 2004). Although no additional cases have been confirmed since 2004, the CDC (2013b) now lists SARS-CoV as a "select agent" that has the potential to pose a severe threat to public health and safety.

Another novel regional coronavirus with a high case-fatality rate was detected in 2012—Middle East respiratory syndrome coronavirus (MERS-CoV) (Arabi, 2017). Although experience with MERS-CoV is sparse in pregnancy, infection has been reported to cause maternal and perinatal deaths (Assiri, 2016).

Ebola Virus

A member of the RNA Filoviridae family, the Ebola virus is transmitted by direct person-to-person contact (Kuhn, 2015). Infection produces a severe hemorrhagic fever with pronounced immunosuppression and disseminated intravascular coagulopathy. Treatment is supportive, and the mortality rate approaches 50 percent.

Data are few concerning Ebola viral infection in pregnancy (Beigi, 2017; Money, 2015; Oduyebo, 2015). The CDC concludes that pregnant women are at increased risk for severe illness and death (Jamieson, 2014). That said, no evidence suggests that pregnant women are more susceptible to Ebola virus infection. One report described trophoblast infection (Muehlenbachs, 2017).

Zika Virus

This RNA virus of the Flavivirdae family has recently been recognized as the first major mosquito-borne teratogen (Rasmussen, 2016). Although Zika virus is primarily transmitted by mosquito bite, sexual transmission is also possible, and the virus may be detected in body fluids for months following acute infection (Hills, 2016; Joguet, 2017; Paz-Bailey, 2017).

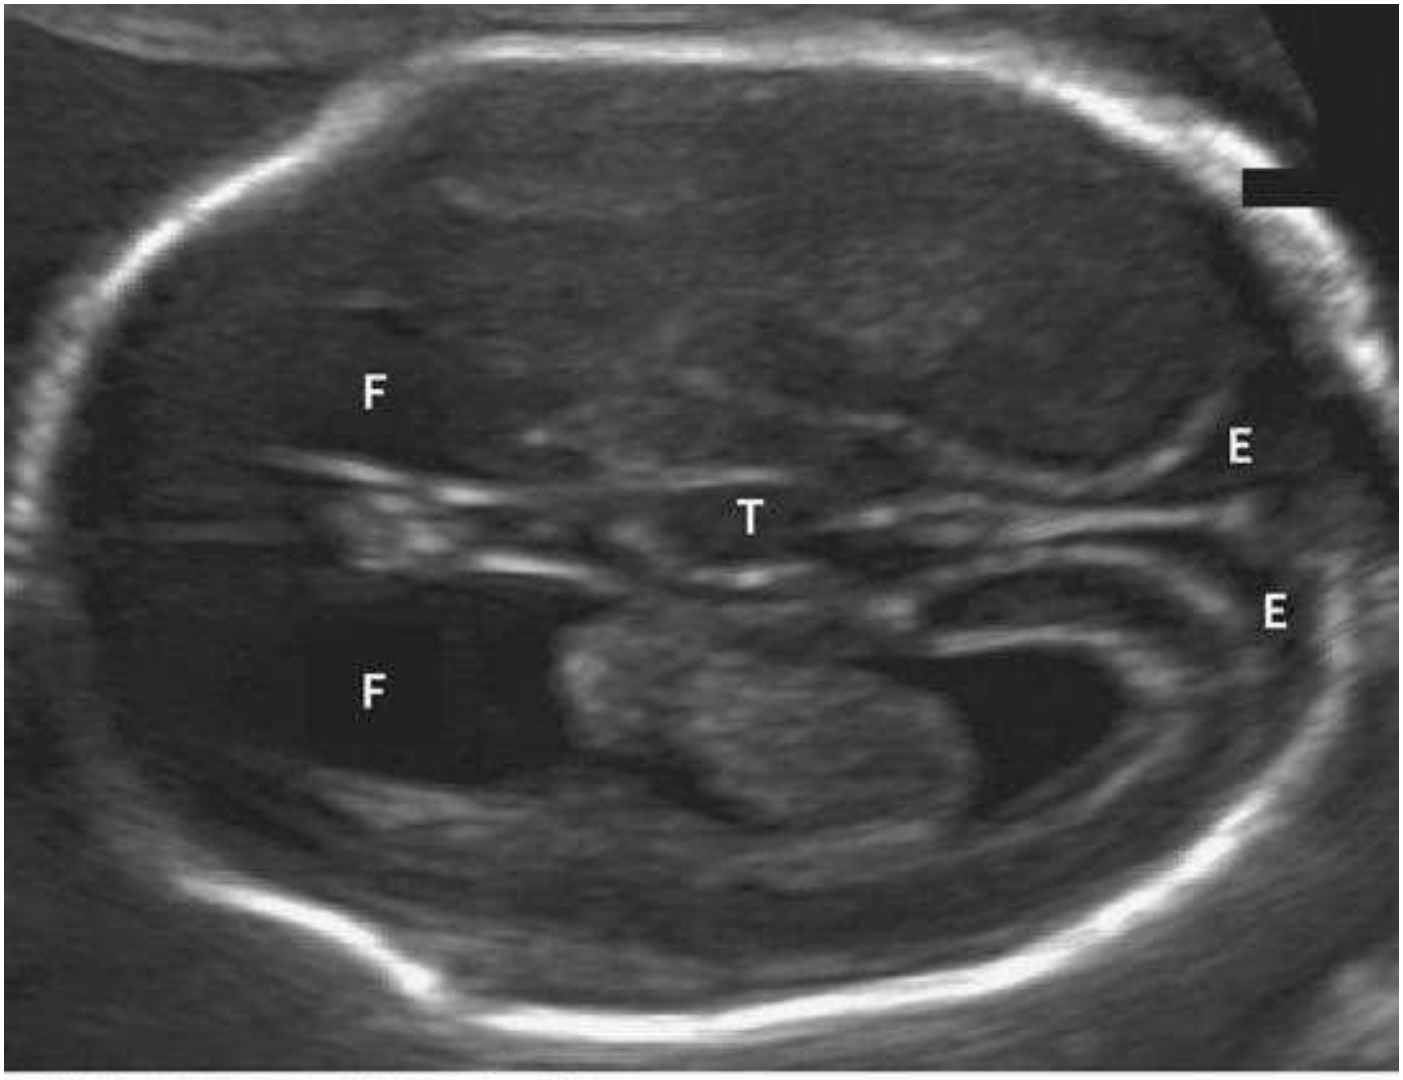
Maternal–Fetal Infection

Reminiscent of the rubella epidemic in the 1960s, in adults Zika infection may be asymptomatic or cause mild symptoms of rash, fever, headache, arthralgia, and conjunctivitis lasting a few days. Virus is typically detectable in blood around the time of symptom onset and may persist days to months in pregnant women (Driggers, 2016; Meaney-Delman, 2016). Serum IgM antibodies typically become detectable within the first two weeks after symptom onset and remain a median of four months (Oduyebo, 2017). Rarely, Guillain-Barré syndrome may develop following infection (da Silva, 2017; Parra, 2016).

The fetus can be severely infected whether or not the mother is symptomatic. Honein and coworkers (2017) describe a 6-percent overall fetal infection rate. In one report of 134 women with positive RT-PCR results, fetal mortality was 7 percent (Brasil, 2016). Among live births, the rate of fetal birth defects ranges from 5 percent—among women with possible Zika infection—to 15 percent among pregnant women with laboratory-confirmed infection in the first trimester (Reynolds, 2017). In the most severely affected fetuses, a congenital Zika syndrome has been described that includes microcephaly, lissencephaly, ventriculomegaly, intracranial calcifications, ocular abnormalities, and congenital contractures (Honein, 2017; Moore, 2017; Soares de Oliveira-Szejnfeld, 2016). Sonographic findings from a Zika-infected fetus are shown in Figure 64-5.

FIGURE 64-5

Sonographic transverse view of the cranium from a fetus with congenital Zika infection. Findings shown include a thin cerebral cortex, increased extraaxial space (*E*), dilated ventricles (*F,T*), and absent cavum septum pellucidum. (Reproduced with permission from Driggers RW, Ho CY, Korhonen EM, et al: Zika virus infection with prolonged maternal viremia and fetal brain abnormalities, N Engl J Med. 2016 Jun 2;374(22):2142–2151.)



Diagnosis and Management

Diagnosis of this infection in pregnant women is made with detection of Zika virus RNA in blood or urine or by serological testing. Detection of Zika virus RNA by PCR confirms infection. Serological assays for Zika IgM antibodies may cross react with other flaviviruses. Thus, a positive assay result is followed by another assay containing virus-specific neutralizing antibodies (Oduyebo, 2017). Testing recommendations and interpretation have evolved for pregnant women who are symptomatic and those who are asymptomatic but have ongoing exposure risk. This risk includes living in or traveling to an area with active local transmission. Large-scale screening programs have been described to identify women at high risk for travel-associated Zika infection (Adhikari, 2017).

Currently, no specific treatment or vaccine is available for Zika infection, although several vaccine candidates are in development (Beigi, 2017; World Health Organization, 2017). Prophylaxis includes protective netting and insect spray to control the vector mosquito and avoidance of sexual contact with partners recently exposed. The CDC has established a pregnancy hotline (770–488–7100) and U.S. Zika Pregnancy Registry (ZikaPregnancy@cdc.gov) for clinicians with concerns related to management of women with Zika infection or exposure.

BACTERIAL INFECTIONS

Group A *Streptococcus*

Infections caused by *Streptococcus pyogenes* are important in pregnant women. This organism is the most frequent bacterial cause of acute pharyngitis and is associated with several systemic and cutaneous infections. *S pyogenes* produces numerous toxins and enzymes responsible for its local and systemic toxicity. Pyrogenic exotoxin-producing strains are usually associated with severe disease (Shinar, 2016; Wessels, 2015). In most cases, streptococcal pharyngitis, scarlet fever, and erysipelas are not life threatening. Treatment, usually with penicillin, is similar in pregnant and nonpregnant women.

In the United States, *S pyogenes* infrequently causes puerperal infection. Still, it remains the most common cause of severe maternal postpartum infection and death worldwide, and the incidence of these infections is rising (Deutscher, 2011; Hamilton, 2013; Wessels, 2015). Puerperal infections are discussed in detail in Chapter 37. The early 1990s saw the emergence of streptococcal toxic shock syndrome, manifested by hypotension, fever, and evidence of multiorgan failure with associated bacteremia. Group A puerperal sepsis is seriously complicated in 20 percent of cases (Shinar, 2016). The case-fatality rate approximates 30 percent, and morbidity and mortality rates are improved with early recognition. Treatment includes clindamycin plus penicillin therapy and often surgical debridement (Chapter 47, Management). No vaccine for group A streptococcus is commercially available.

Group B *Streptococcus*

Streptococcus agalactiae is a group B organism that can be found to colonize the gastrointestinal and genitourinary tract in 10 to 25 percent of pregnant women (Kwatra, 2016). Throughout pregnancy, group B *Streptococcus* (GBS) is isolated in a transient, intermittent, or chronic fashion. Although the organism is most likely always present in these same women, their isolation is not always homologous.

Maternal and Perinatal Infection

The spectrum of maternal and fetal GBS effects ranges from asymptomatic colonization to septicemia. *S agalactiae* has been implicated in adverse pregnancy outcomes that include preterm labor, prematurely ruptured membranes, clinical and subclinical chorioamnionitis, and fetal infections (Randis, 2014). GBS can also cause maternal bacteriuria, pyelonephritis, osteomyelitis, postpartum mastitis, and puerperal infections. It remains the leading infectious cause of morbidity and mortality among infants in the United States (Centers for Disease Control and Prevention, 2010; Schrag, 2016).

Neonatal sepsis has received the most attention due to its devastating consequences and available effective preventative measures. Infection <7 days after birth is defined as *early-onset disease* and is seen in 0.21/1000 live births (Centers for Disease Control and Prevention, 2015). Many investigators use a threshold of <72 hours of life as most compatible with intrapartum acquisition of disease (Stoll, 2011). We and others have also encountered unexpected intrapartum stillbirths from GBS infections (Nan, 2015). Tudela and associates (2012) reported that newborns with early-onset GBS infection often had clinical evidence of fetal infection during labor or at delivery.

In many neonates, septicemia involves signs of serious illness that usually develop within 6 to 12 hours of birth. These include respiratory distress, apnea, and hypotension. At the outset, therefore, neonatal infection must be differentiated from respiratory distress syndrome caused by insufficient surfactant production (Chap. 34, Respiratory Distress Syndrome). The mortality rate with early-onset disease has declined to approximately 4 percent, and preterm newborns are disparately affected.

Late-onset disease caused by GBS is noted in 0.32 per 1000 live births and usually manifests as meningitis 1 week to 3 months after birth (Centers for Disease Control and Prevention, 2015). The mortality rate, although appreciable, is less for late-onset meningitis than for early-onset sepsis. Unfortunately, it is not uncommon for surviving infants of both early- and late-onset disease to exhibit devastating neurological sequelae.

Prophylaxis for Perinatal Infections

As GBS neonatal infections evolved beginning in the 1970s and before widespread intrapartum chemoprophylaxis, rates of early-onset sepsis ranged from 2 to 3 per 1000 live births. By 2010, these outcomes led to a policy of universal rectovaginal culture screening for GBS at 35 to 37 weeks' gestation followed by intrapartum antibiotic prophylaxis for women identified to be carriers. These outcomes stimulated development of expanded laboratory identification criteria for GBS; updated algorithms for screening and intrapartum chemoprophylaxis for women with preterm prematurely ruptured membranes, preterm labor, or penicillin allergy; and described new dosing for penicillin G chemoprophylaxis. Following these changes, the incidence of early-onset GBS neonatal sepsis decreased to 0.21 cases per 1000 live births by 2015 (Centers for Disease Control and Prevention, 2015).

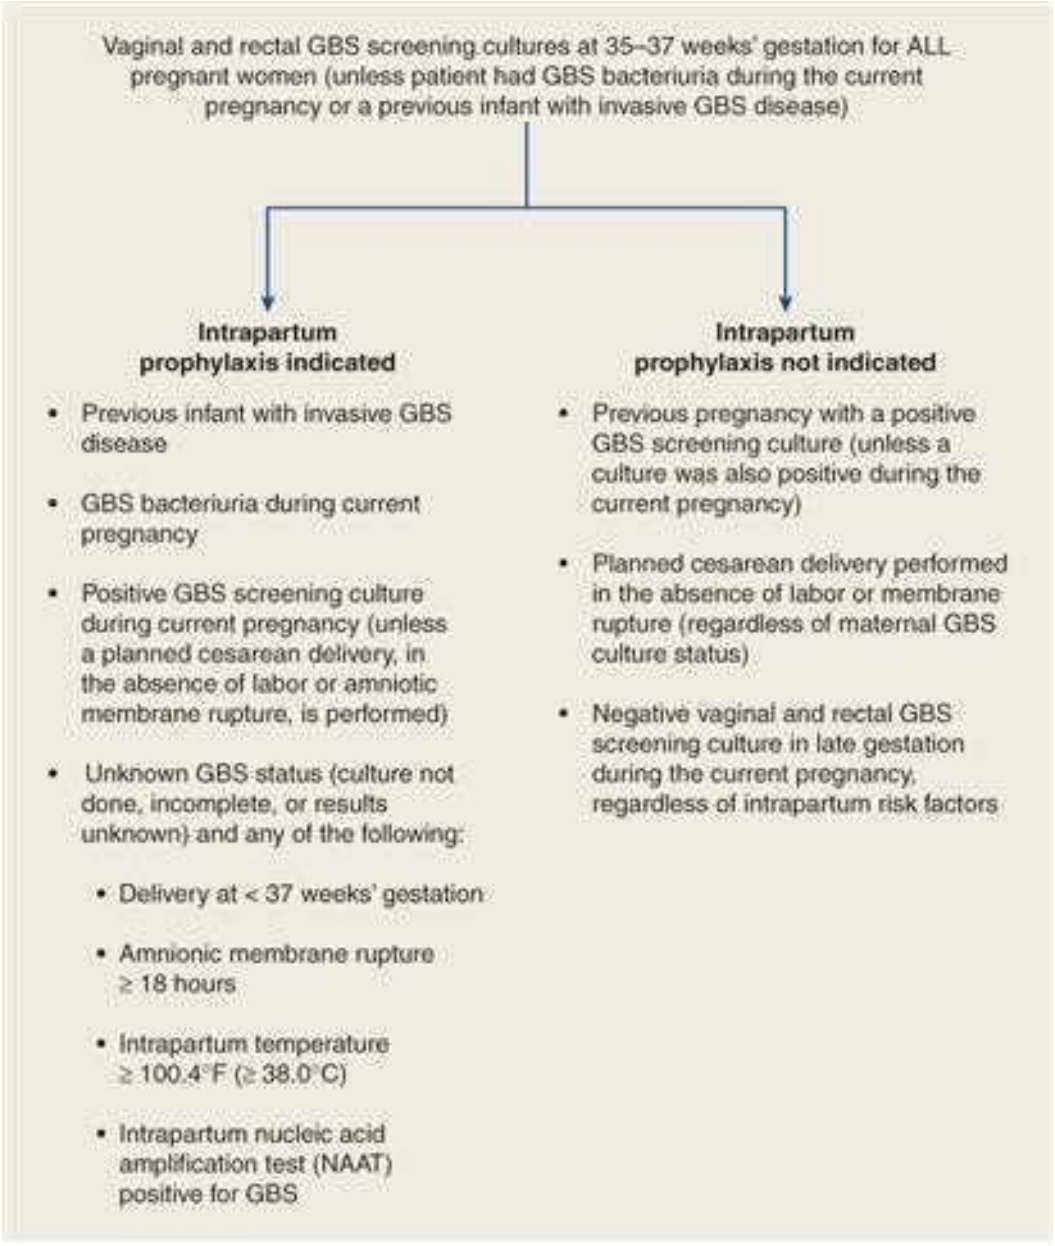
Thus, during the past three decades, several strategies have been proposed to prevent perinatal acquisition of GBS infections. These strategies have not been compared in randomized trials and are either culture-based or risk-based guidelines (Ohlsson, 2014). These methods have been adopted in the United States, but not all European countries have guidelines (Di Renzo, 2015).

Culture-Based Prevention

The CDC (2010) GBS guidelines recommend a culture-based approach, which was also adopted by the American College of Obstetricians and Gynecologists (2016e). Shown in Figure 64-6, this strategy is designed to identify women who should be given intrapartum antimicrobial prophylaxis. Women are screened for GBS colonization at 35 to 37 weeks' gestation, and intrapartum antimicrobials are given to women with rectovaginal GBS-positive cultures. Selective enrichment broth followed by subculture improves detection. In addition, more rapid techniques such as DNA probes and NAATs are being developed (Helali, 2012). A previous sibling with GBS invasive disease and identification of GBS bacteriuria in the current pregnancy are also considered indications for prophylaxis.

FIGURE 64-6

Indications for intrapartum prophylaxis to prevent perinatal group B streptococcal (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures obtained at 35 to 37 weeks' gestation. (From Centers for Disease Control and Prevention, 2010.)



Risk-Based Prevention

This approach is recommended for women in labor and whose GBS culture results are not known. It relies on risk factors associated with intrapartum GBS transmission. Intrapartum chemoprophylaxis is given to women who have any of the following: delivery <37 weeks, ruptured membranes ≥18 hours, or intrapartum temperature ≥100.4°F (≥38.0°C). Women with GBS during the current pregnancy and women with a prior infant with invasive early-onset GBS disease are also given chemoprophylaxis.

At Parkland Hospital in 1995—and prior to consensus guidelines—we adopted and continue to use the risk-based approach for intrapartum treatment of women at high risk. Importantly, in addition, all term neonates who were not given intrapartum prophylaxis were treated in the delivery room with aqueous penicillin G, 50,000 to 60,000 units intramuscularly. Rates of early-onset GBS sepsis decreased to 0.4 to 0.66 per 1000 live births (Stafford, 2012; Wendel, 2002). Non-GBS early-onset sepsis decreased from 0.66 to 0.24 per 1000 live births (Stafford, 2012). Thus, this approach has results similar to those reported by the CDC (2010) for culture-based prevention.

GBS Vaccine

Serotype-specific capsular antibody concentrations clinically correlate with GBS neonatal disease. Antibody-producing vaccines have been tested, but none are clinically available (Donders, 2016; Kobayashi, 2016; Madhi, 2016).

Intrapartum Antimicrobial Prophylaxis

Preventive antimicrobials administered 4 or more hours before delivery are highly effective (Fairlie, 2013). Regardless of screening method, penicillin remains the first-line agent for prophylaxis, and ampicillin is an acceptable alternative (Table 64-3). Women with a penicillin allergy and no history of anaphylaxis are given cefazolin (Briody, 2016). Those at high risk for anaphylaxis should have antimicrobial susceptibility testing performed to exclude clindamycin resistance.

Clindamycin-sensitive but erythromycin-resistant isolates should have a D-zone test performed to assess for inducible clindamycin resistance. If clindamycin resistance is confirmed, vancomycin should be administered. *Erythromycin is no longer used for penicillin-allergic patients.*

TABLE 64-3

Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal GBS Disease

Regimen	Treatment
Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 to 3.0 million units IV every 4 hours until delivery
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV every 4 hours or 2 g every 6 hours until delivery
Penicillin allergic Patients not at high risk for anaphylaxis Patients at high risk for anaphylaxis and with GBS susceptible to clindamycin Patients at high risk for anaphylaxis and with GBS resistant to clindamycin or susceptibility unknown	 Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hours until delivery Clindamycin, 900 mg IV every 8 hours until delivery Vancomycin, 1 g IV every 12 hours until delivery

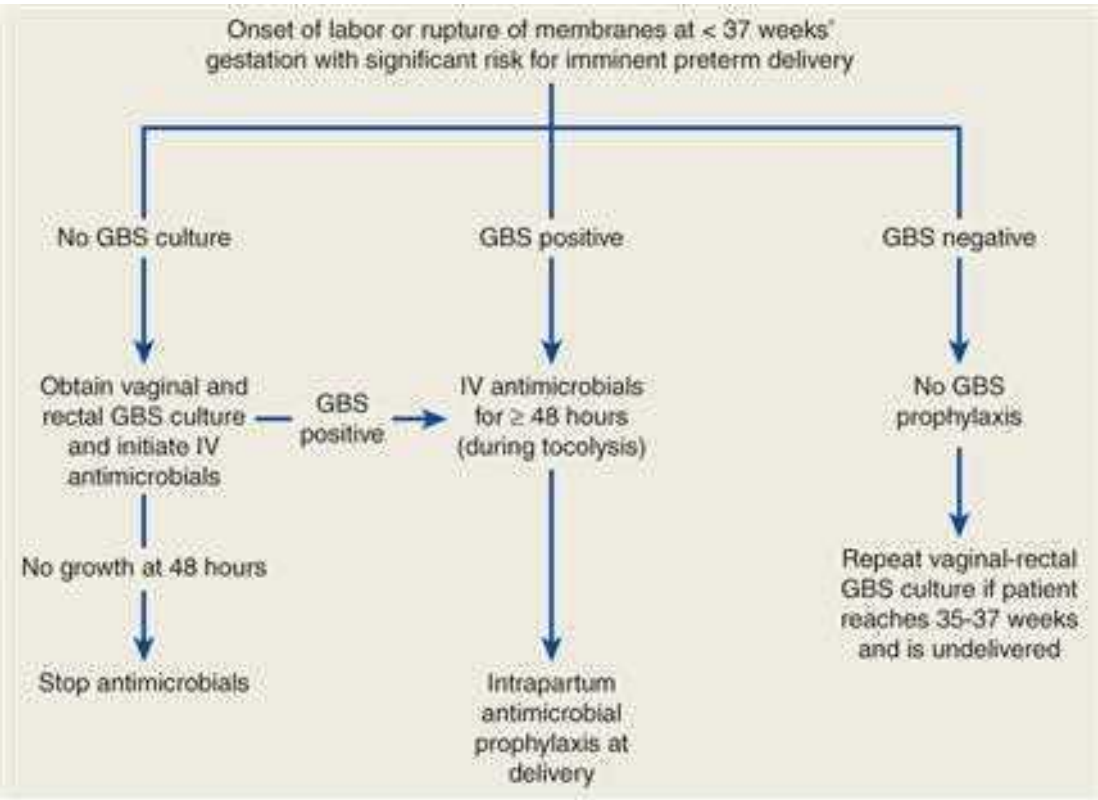
GBS = group B *Streptococcus*; IV = intravenous.

Data from the Verani, 2010

Further recommendations for management of spontaneous preterm labor, threatened preterm delivery, or preterm prematurely ruptured membranes are shown in Figure 64-7. Women undergoing cesarean delivery before labor onset with intact membranes do not need intrapartum GBS chemoprophylaxis, regardless of GBS colonization status or gestational age.

FIGURE 64-7

Sample algorithm for prophylaxis for women with group B streptococcal (GBS) disease and threatened preterm delivery. This algorithm is not an exclusive course of management, and variations that incorporate individual circumstances or institutional preferences may be appropriate. IV = intravenous. (Adapted from Centers for Disease Control and Prevention, 2016a.)



Methicillin-Resistant *Staphylococcus aureus*

Staphylococcus aureus is a pyogenic gram-positive organism and is considered the most virulent of the staphylococcal species. It primarily colonizes the nares, skin, genital tissues, and oropharynx. Approximately 20 percent of normal individuals are persistent carriers, 30 to 60 percent are intermittent carriers, and 20 to 50 percent are noncarriers (Gorwitz, 2008). Colonization is considered the greatest risk factor for infection (Marzec, 2016; Sheffield, 2013). Methicillin-resistant *S aureus* (MRSA) colonizes only 2 percent of adults but is a significant contributor to the health-care burden (Gorwitz, 2008). MRSA infections are associated with increased cost and higher mortality rates compared with those by methicillin-sensitive *S aureus* (MSSA) (Beigi, 2009; Butterly, 2010).

Community-acquired MRSA (CA-MRSA) is diagnosed when identified in an outpatient setting or within 48 hours of hospitalization in a person without traditional risk factors. Such risk factors include prior MRSA infection, hospitalization, dialysis or surgery within the past year, and indwelling catheters or devices (Dantes, 2013). Hospital-associated MRSA (HA-MRSA) infections are nosocomial. Most cases of MRSA in pregnant women are CA-MRSA.

MRSA and Pregnancy

Anovaginal colonization with *S aureus* is identified in 10 to 25 percent of obstetrical patients (Top, 2010). Skin and soft tissue infections are the most common presentation of MRSA in pregnant women (Fig. 64-8). Mastitis and breast abscesses have been reported in up to a fourth of cases of MRSA complicating pregnancy (Laibl, 2005; Lee, 2010). Perineal abscesses, wound infections at sites such as abdominal and episiotomy incisions, and chorioamnionitis are also associated with MRSA (Pimentel, 2009; Thurman, 2008). Finally, osteomyelitis has been reported (Nguyen, 2015; Tanamai, 2016).

FIGURE 64-8

This antepartum patient presented with multiple small microabscesses for which culture identified methicillin-resistant *Staphylococcus aureus*. (Reproduced with permission from Dr. Stephan Shivvers.)

A rise in CA-MRSA infections has been reported in neonatal intensive care units and newborn nurseries. In these settings, infection is frequently associated with maternal and health-care worker skin infections and infected breast milk. Vertical transmission is rare (Jimenez-Truque, 2012; Pinter, 2009).

Management

The Infectious Diseases Society of America has published guidelines for the treatment of MRSA infections (Liu, 2011). Uncomplicated superficial infections are primarily managed by drainage and local wound care. Although historically de-emphasized, recent evidence suggests benefit from antibiotic therapy in addition to incision and drainage of smaller abscesses (Daum, 2017; Forcade, 2012). Severe superficial infections, especially those that fail to respond to local care or those in patients with medical comorbidities, are treated with MRSA-appropriate antibiotics. Purulent cellulitis should be treated empirically for CA-MRSA until culture results are available.

Most CA-MRSA strains are sensitive to trimethoprim-sulfamethoxazole and clindamycin (Miller, 2015; Talan, 2016). Rifampin rapidly develops resistance and should not be used for monotherapy. Linezolid, although effective against MRSA, is expensive, and there is little information regarding its use in pregnancy. Doxycycline, minocycline, and tetracycline, although effective for MRSA infections, should not be used in pregnancy. Vancomycin remains the first-line therapy for inpatient serious MRSA infections.

The control and prevention of HA-MRSA and CA-MRSA rely on appropriate hand hygiene and prevention of skin-to-skin contact or contact with wound dressings. Decolonization should be considered only in cases in which a patient develops recurrent superficial infections despite optimal hygiene measures or if ongoing

transmission occurs among household or close contacts (Liu, 2011). Decolonization measures include nasal treatment with mupirocin, chlorhexidine gluconate baths, and oral rifampin therapy if previous measures have failed. Routine decolonization is not effective in the general obstetrical population. For women with culture-proven CA-MRSA infection during pregnancy, we add single-dose vancomycin to routine beta-lactam perioperative prophylaxis for cesarean deliveries and higher-order perineal lacerations. Breastfeeding in these women is not prohibited, but optimal hygiene and attention to minor skin breaks is encouraged.

Listeriosis

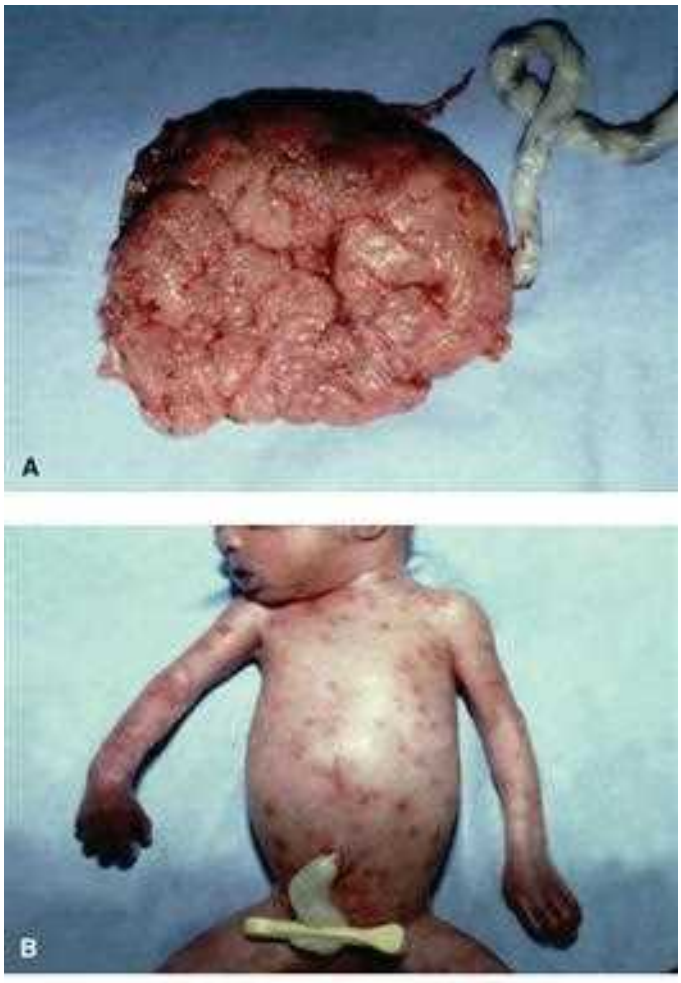
Listeria monocytogenes is an uncommon but probably underdiagnosed cause of neonatal sepsis (Kylat, 2016). This facultative intracellular gram-positive bacillus can be isolated from the feces of 1 to 5 percent of adults. Nearly all cases of listeriosis are thought to be foodborne. Outbreaks have been caused by raw vegetables, coleslaw, apple cider, melons, milk, fresh Mexican-style cheese, smoked fish, and processed foods such as pâté, hummus, wieners, and sliced deli meats (Centers for Disease Control and Prevention, 2013e).

Listerial infections are more common in pregnant women, immunocompromised patients, and the very old or young. The incidence of such infections in pregnancy is estimated to be up to 100 times that in the general population (Kourtis, 2014; Rouse, 2016). In 1651 cases reported in 2009 to 2011, the CDC found that 14 percent were in pregnant women (Silk, 2013). It is unclear why pregnant women still account for a significant number of these reported cases. One hypothesis is that pregnant women are susceptible because of decreased cell-mediated immunity (Baud, 2011).

Maternal and Fetal Infection

Listeriosis during pregnancy may be asymptomatic or may cause a febrile illness that is confused with influenza, pyelonephritis, or meningitis (Centers for Disease Control and Prevention, 2013e). The diagnosis usually is not apparent until blood cultures are reported as positive. Occult or clinical infection also may stimulate labor. Discolored, brownish, or meconium-stained amnionic fluid is common with fetal infection, even in preterm gestations. Maternal listeriosis causes fetal infection that characteristically produces disseminated granulomatous lesions with *microabscesses* (Fig. 64-9). Chorioamnionitis is common, and placental lesions include multiple, well-demarcated macroabscesses. Early- and late-onset neonatal infections are similar to group B streptococcal sepsis. In a review of 222 cases, infection resulted in abortion or stillbirth in 20 percent, and neonatal sepsis developed in 68 percent of surviving newborns (Mylonakis, 2002). In one large, prospective cohort study, 24 percent of mothers experienced fetal loss, but none after 29 weeks' gestation (Charlier, 2017). However, a neonatal-case fatality rate of 21 percent has been reported (Sapuan, 2017).

FIGURE 64-9
The pale placenta **(A)** and stillborn infant **(B)** resulted from maternal listeriosis.



Treatment with ampicillin plus gentamicin is usually recommended because of synergism against *Listeria* species (Rouse, 2016). Trimethoprim-sulfamethoxazole can be given to penicillin-allergic women. Maternal treatment in most cases is also effective for fetal infection (Chan, 2013). No vaccine is available. Prevention is by washing raw vegetables, cooking all raw food, and avoiding the implicated foods listed previously (American College of Obstetricians and Gynecologists, 2016d).

Salmonellosis

Infections from *Salmonella* species continue to be a major cause of foodborne illness (Peques, 2012). Six serotypes, including *Salmonella* subtypes *typhimurium* and *enteritidis,* account for most cases in the United States. Nontyphoid *Salmonella* gastroenteritis is contracted through contaminated food. Symptoms that include nonbloody diarrhea, abdominal pain, fever, chills, nausea, and vomiting begin 6 to 48 hours after exposure. Diagnosis is made by stool studies (Chap. 54, Inflammatory Bowel Disease). Intravenous crystalloid solutions are given for rehydration. Antimicrobials are not given in uncomplicated infections because they do not commonly shorten illness and may prolong the convalescent carrier state. If gastroenteritis is complicated by bacteremia, antimicrobials are given as discussed below. Rare case reports have linked *Salmonella* bacteremia with abortion (Coughlin, 2002).

Typhoid fever caused by *Salmonella typhi* remains a global health problem, although it is uncommon in the United States. Infection is spread by oral ingestion of contaminated food, water, or milk. In pregnant women, the disease is more likely to be encountered during epidemics or in those with HIV infection (Hedriana, 1995). In former years, antepartum typhoid fever resulted in abortion, preterm labor, and maternal or fetal death (Dildy, 1990).

Fluoroquinolones and third-generation cephalosporins are the preferred treatment. For enteric (typhoid) fever, antimicrobial susceptibility testing is important because of the development of drug-resistant strains (Crump, 2015). Typhoid vaccines appear to exert no harmful effects when administered to pregnant women and are given in an epidemic or before travel to endemic areas.

Shigellosis

Bacillary dysentery caused by *Shigella* is a relatively common, highly contagious cause of inflammatory exudative diarrhea in adults. Shigellosis is more common in children attending day-care centers and is transmitted via the fecal-oral route. Clinical manifestations range from mild diarrhea to severe dysentery, bloody stools, abdominal cramping, tenesmus, fever, and systemic toxicity. Although shigellosis may be self-limited, careful attention to treatment of dehydration is essential in severe cases. We have cared for pregnant women in whom secretory diarrhea exceeded 10 L/day! Antimicrobial therapy is imperative, and effective treatment during pregnancy includes fluoroquinolones, ceftriaxone, or azithromycin. Antimicrobial resistance is rapidly emerging, and antibiotic susceptibility testing can help guide appropriate therapy (Centers for Disease Control and Prevention, 2016). Shigellosis can stimulate uterine contractions and cause preterm birth (Parisot, 2016).

Hansen Disease

Also known as leprosy, this chronic infection is caused by *Mycobacterium leprae* and is rare in this country. Diagnosis is confirmed by PCR. Multidrug therapy with dapsone, rifampin, and clofazimine is recommended for treatment and is generally safe during pregnancy (Gimovsky, 2013; Ozturk, 2017). Duncan (1980) reported an excessive incidence of low-birthweight newborns among infected women. The placenta is not involved, and neonatal infection apparently is acquired from skin-to-skin or droplet transmission (Duncan, 1984). Vertical transmission is common in untreated mothers (Moschella, 2004).

Lyme Disease

Caused by the spirochete *Borrelia burgdorferi*, Lyme disease is the most commonly reported vectorborne illness in the United States (Centers for Disease Control and Prevention, 2017c). Lyme borreliosis follows tick bites of the genus *Ixodes*. There are three stages (Steere, 2015). Early infection—stage 1—causes a distinctive local skin lesion, *erythema migrans*, which may be accompanied by a flulike syndrome and regional adenopathy. If untreated, disseminated infection—stage 2—follows in days to weeks. Multisystem involvement is frequent, but skin lesions, arthralgia, myalgia, carditis, and meningitis predominate. If still untreated after several weeks to months, late or persistent infection—stage 3—manifests in perhaps half of patients. Native immunity is acquired, and the disease enters a chronic phase in about 10 percent. Some patients remain asymptomatic, but others in the chronic phase develop various skin, joint, or neurological manifestations (Shapiro, 2014).

Clinical diagnosis is important because serological and PCR testing has many pitfalls (Steere, 2015). IgM and IgG serological testing is recommended in early infection and is followed by Western blotting for confirmation. Ideally, acute and convalescent serological evaluation is completed if possible, however, false-positive and -negative rates are high.

Optimal treatment of Lyme disease was published by the Infectious Diseases Society of America (Sanchez, 2016). For early infection, treatment with doxycycline, amoxicillin, or cefuroxime is recommended for 14 days, although doxycycline is usually avoided in pregnancy. A 14- to 28-day course of IV ceftriaxone, cefotaxime, or penicillin G is given for complicated early infections that include meningitis, carditis, or disseminated infections. Chronic arthritis and post-Lyme disease syndrome are treated with prolonged oral or IV regimens, however, symptoms respond poorly to treatment (Steere, 2015).

No vaccine is commercially available. Avoiding areas with endemic Lyme disease and improving tick control in those areas is the most effective prevention. Self-examination with removal of unengorged ticks within 36 hours of attachment reduces infection risk (Hayes, 2003). For tick bites recognized within 72 hours, a single 200-mg oral dose of doxycycline may reduce infection development.

Several reports describe Lyme disease in pregnancy, although large series are lacking. Transplacental transmission has been confirmed, but no congenital effects of maternal borreliosis have been conclusively identified (Shapiro, 2014; Walsh, 2006). Prompt treatment of maternal early infection should prevent most adverse pregnancy outcomes (Mylonas, 2011).

Tuberculosis

Diagnosis and management of tuberculosis during pregnancy is discussed in detail in Chapter 51 (Tuberculosis).

PROTOZOAL INFECTIONS

Toxoplasmosis

The obligate intracellular parasite *Toxoplasma gondii* has a life cycle with two distinct stages (Kim, 2015). The *feline* stage takes place in the cat—the definitive host—and its prey. Unsporulated oocysts are excreted in feces. In the *nonfeline* stage, tissue cysts containing bradyzoites or oocysts are ingested by the intermediate host, including humans. Gastric acid digests the cysts to release bradyzoites, which infect small-intestinal epithelium. Here, they are transformed into rapidly dividing tachyzoites, which can infect all cells within the host mammal. Humoral and cell-mediated immune defenses eliminate most of these, but tissue cysts develop. Their lifelong persistence is the chronic form of toxoplasmosis.

Human infection is acquired by eating raw or undercooked meat infected with tissue cysts or by contact with oocysts from cat feces in contaminated litter, soil, or water. Prior infection is confirmed by serological testing, and its prevalence depends on geographic locale and parasite genotype. In the United States, seroprevalence in persons aged 10 to 19 years is 5 to 30 percent, and this can exceed 60 percent in those older than 50 (Kim, 2015). Thus, a significant segment of pregnant women in this country are susceptible to infection. The incidence of prenatal infection resulting in birth of a newborn with congenital toxoplasmosis varies from 0.8 per 10,000 live births in the United States to 10 per 10,000 in France (Cook, 2000). Between 400 and 4000 cases of congenital toxoplasmosis are diagnosed annually in the United States (Jones, 2014).

Maternal and Fetal Infection

Most acute maternal infections are subclinical and are detected only by prenatal or newborn serological screening. In some cases, maternal symptoms may include fatigue, fever, headache, muscle pain, and sometimes a maculopapular rash and posterior cervical lymphadenopathy. In immunocompetent adults, initial infection confers immunity, and prepregnancy infection nearly eliminates any risk of vertical transmission. Infection in immunocompromised women, however, may be severe, and reactivation may cause encephalitis, retinochoroiditis, or mass lesions. Maternal infection is associated with a fourfold increased preterm delivery rate before 37 weeks (Freeman, 2005).

The incidence and severity of fetal toxoplasmosis depend on gestational age at the time of maternal infection. Risks for fetal infection rise with gestational age. A metaanalysis estimated the risk to be 15 percent at 13 weeks, 44 percent at 26 weeks, and 71 percent at 36 weeks (SYROCOT Study Group, 2007). Conversely, the severity of fetal infection is much greater in early pregnancy, and these fetuses are much more likely to have clinical findings of infection (American College of Obstetricians and Gynecologists, 2017).

Importantly, most infected fetuses are born without obvious stigmata of toxoplasmosis. Clinically affected neonates usually have generalized disease expressed as low birthweight, hepatosplenomegaly, jaundice, and anemia. Some primarily have neurological disease with intracranial calcifications and with hydrocephaly or microcephaly (Dhombres, 2017). Many eventually develop chorioretinitis and exhibit learning disabilities. This classic triad—chorioretinitis, intracranial calcifications, and hydrocephalus—is often accompanied by convulsions. Infected neonates with clinical signs are at risk for long-term complications (Abdoli, 2014; Wallon, 2014).

Screening and Diagnosis

With IgG antibody confirmed before pregnancy, there is no risk for a congenitally infected fetus. The American College of Obstetricians and Gynecologists (2017) does not recommend prenatal screening for toxoplasmosis in areas of low prevalence, including the United States. Screening should be performed in immunocompromised pregnant women, including those with HIV infection. In areas of high toxoplasmosis prevalence—for example, France and Austria—routine screening has resulted in diminished congenital disease (Kim, 2015; Wallon, 2013).

Pregnant women with suspected toxoplasmosis should be tested. The parasite is rarely detected in tissue or body fluids. Antitoxoplasma IgG develops within 2 to 3 weeks after infection, peaks at 1 to 2 months, and usually persists for life—sometimes in high titers. Although IgM antibodies appear by 10 days after infection and usually become negative within 3 to 4 months, they may remain detectable for years. Thus, IgM antibodies are not used alone to diagnose acute toxoplasmosis (Dhakal, 2015). Best results are obtained with the Toxoplasma Serologic Profile performed at the Palo Alto Medical Foundation Research Institute (www.toxolab@pamf.org). Toxoplasma IgG avidity increases with time. Thus, if a high-avidity IgG result is found, infection in the preceding 3 to 5 months is excluded. Multiple tests are available that allow high avidity results to confirm latent infection with a 100-percent positive-predictive value (Villard, 2013).

Congenital toxoplasmosis is suspected when sonography reveals findings such as hydrocephaly, intracranial or hepatic calcifications, ascites, placental thickening, hyperechoic bowel, and growth restriction. Prenatal diagnosis of congenital toxoplasmosis is performed using PCR amplification of toxoplasma DNA in amnionic fluid (Filisetti, 2015; Montoya, 2008). The sensitivity of PCR varies with gestational age and is lowest before 18 weeks (Romand, 2001).

Management

No randomized clinical trials have assessed the benefit and efficacy of treatment to decrease the risk for congenital infection. A systematic review of data from 1438 treated pregnancies found weak evidence for early treatment to reduce congenital toxoplasmosis risks (SYROCOT Study Group, 2007). Treatment has been associated with a reduction in rates of serious neurological sequelae and neonatal demise (Cortina-Borja, 2010).

Prenatal treatment is based on two regimens—spiramycin alone or a pyrimethamine–sulfonamide combination given with folinic acid (American College of Obstetricians and Gynecologists, 2017). These two regimens have also been used consecutively (Hotop, 2012). Little evidence supports the use of a specific regimen

(Montazeri, 2017; Valentini, 2015). That said, most experts will use spiramycin in women with acute infection early in pregnancy to reduce vertical transmission. Because it does not cross the placenta, spiramycin may not be used to treat fetal infection. Pyrimethamine–sulfadiazine with folinic acid is selected for maternal infection after 18 weeks' gestation or if fetal infection is suspected.

Prevention

There is no vaccine for toxoplasmosis, so avoidance of infection is necessary if congenital infection is to be prevented. Efforts include: (1) cooking meat to safe temperatures; (2) peeling or thoroughly washing fruits and vegetables; (3) cleaning all food preparation surfaces and utensils that have contacted raw meat, poultry, seafood, or unwashed fruits and vegetables; (4) wearing gloves when changing cat litter, or else delegating this duty; and (5) avoiding feeding cats raw or undercooked meat and keeping cats indoors. Although these preventive steps are recommended, no data support their effectiveness (American College of Obstetricians and Gynecologists, 2017; Di Mario, 2015).

Malaria

This protozoan infection remains a global health crisis and causes 2000 deaths per day worldwide (White, 2015). Malaria has been effectively eradicated in Europe and in most of North America, and worldwide mortality rates have fallen more than 25 percent. In the United States, most cases of malaria are imported—some in returning military personnel (Mace, 2017). Transmitted by infected *Anopheles* mosquitoes, six species of *Plasmodium* cause human disease—*falciparum, vivax,* two species of *ovale, malariae,* and *knowlesi*.

Malaria and Pregnancy

Pregnant women have increased susceptibility to malarial infections (Kourtis, 2014). Antibodies to the parasite surface antigen VAR2CSA mediate placental accumulation of infected erythrocytes and lead to the harmful effects of malaria (Mayor, 2015). Through this mechanism, some immunity accrues with parity and is called *pregnancy-specific antimalarial immunity.* Ironically, malaria treatment dampens this immunity, and resurgence in pregnancy has been documented in Mozambique (Mayor, 2015).

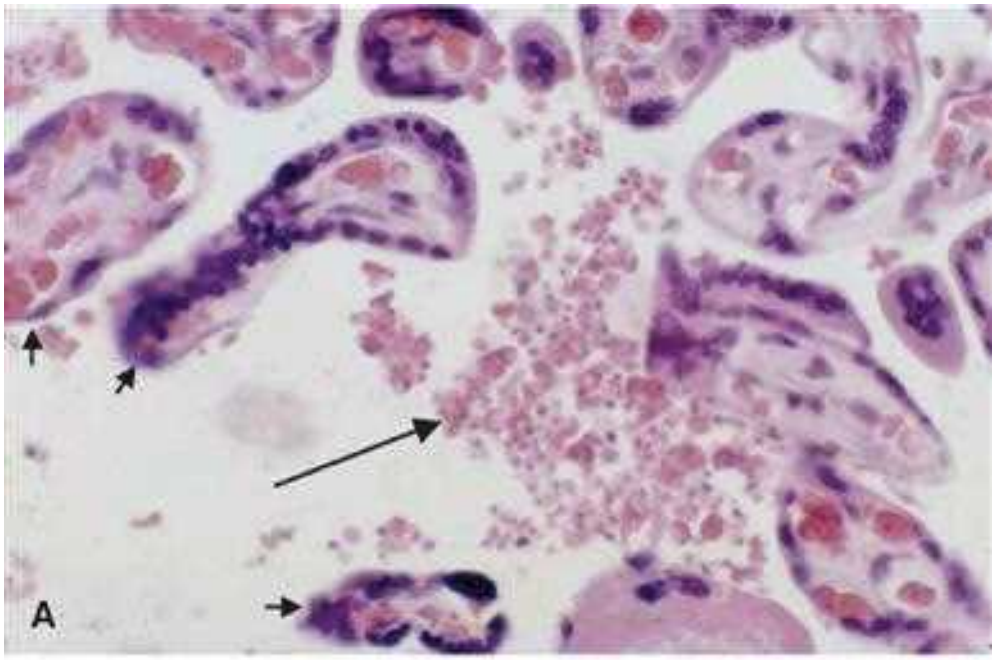
Maternal and Fetal Infection

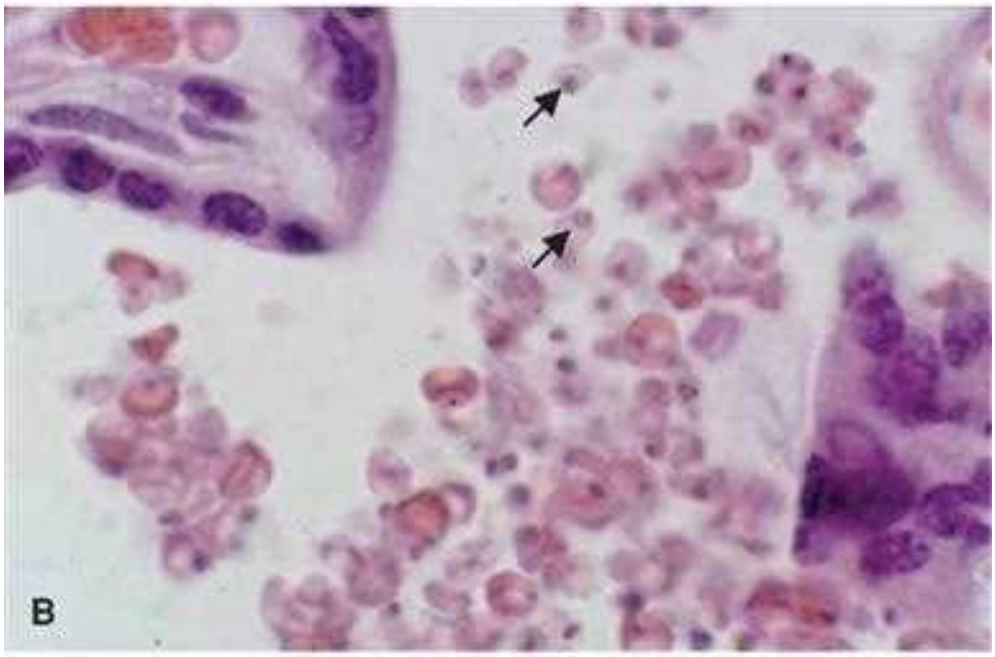
Clinical findings are fever, chills, and flulike symptoms including headaches, myalgia, and malaise, which may occur at intervals. Symptoms are less severe with recurrences. Malaria may be associated with anemia and jaundice, and *falciparum* infections may cause kidney failure, coma, and death. That said, many otherwise healthy but infected adults in endemic areas are asymptomatic because of partial immunity. Pregnant women, although often asymptomatic, are said to be more likely to develop traditional symptoms (Desai, 2007).

Malarial infections during pregnancy—whether symptomatic or asymptomatic—are associated with higher rates of perinatal morbidity and mortality (Menéndez, 2007; Nosten, 2007). Adverse outcomes include stillbirth, preterm birth, low birthweight, and maternal anemia. The latter two are documented most frequently (Machado Filho, 2014; McClure, 2013). Maternal infection is associated with a 14-percent rate of low-birthweight newborns worldwide (Eisele, 2012). These adverse perinatal outcomes correlate with high levels of placental parasitemia (Rogerson, 2007). The latter occurs when parasitized erythrocytes, monocytes, and macrophages accumulate in the vascular areas of the placenta (Fig. 64-10). Infections with *P falciparum* are the worst, and early infection raises the risk for abortion. The incidence of malaria increases significantly in the latter two trimesters and postpartum (Diagne, 2000). Despite this, congenital malaria occurs in <5 percent of neonates born to infected mothers.

FIGURE 64-10

Photomicrograph of placental malaria. **A.** Multiple infected red blood cells (*long black arrow*) are seen in the intervillous space of this placenta. Multiple villi cut in cross section are shown, and three are highlighted (*short arrows*). **B.** Increased magnification of image **(A).** Multiple infected erythrocytes are seen, and two are identified (*arrows).*





Diagnosis and Management

Identification of parasites by microscopical evaluation of a thick and thin blood smear remains the gold standard for diagnosis. In women with low parasite densities, however, the sensitivity of microscopy is poor. Malaria-specific antigens are now being used for rapid diagnostic testing. Not only is their sensitivity still an issue in pregnancy, but these tests are not routinely available (Kashif, 2013; White, 2015).

For treatment, the most frequently used antimalarial drugs are not contraindicated in pregnancy. The World Health Organization recommends that all infected patients living in or traveling from endemic areas be treated with an artemisinin-based regimen for uncomplicated falciparum malaria (Tarning, 2016). The CDC (2013c) recommends using atovaquone-proguanil or artemether-lumefantrine only if other treatment options are not available or tolerated.

The CDC (2013c) recommends that pregnant women diagnosed with uncomplicated malaria caused by *P vivax, malariae, ovale,* and chloroquine-sensitive *P falciparum* should be treated with chloroquine or hydroxychloroquine. For women infected with multidrug-resistant *P falciparum*, one first-line agent for nonpregnant persons is artemether-lumefantrine. Another primary option is artesunate plus mefloquine or artesunate plus dihydroartemisinin-piperaquine (White, 2015). The PREGACT Study Group (2016) recently compared four artemisinin-based drugs in 3428 pregnant women with falciparum malaria and reported no serious maternal or perinatal adverse effects. Second-line treatment regimens are artesunate; quinine plus either tetracycline, doxycycline, or clindamycin; or atovaquone-proguanil. Chloroquine-resistant *P vivax* should be treated with mefloquine. Chloroquine-sensitive *P vivax* or *P ovale* should be treated with chloroquine throughout

pregnancy and then primaquine postpartum. Resistance to all the antimalarial drugs has been reported, including the recently added artemisinin-based compounds.

Treatment regimens for uncomplicated and severe malarial infections in pregnancy are detailed at: www.cdc.gov/malaria/diagnosis_treatment. The CDC also maintains a malaria hotline for treatment recommendations (855–856–4713).

Prevention and Chemoprophylaxis

Malaria control and prevention relies on chemoprophylaxis when traveling to or living in endemic areas. Vector control is also important. Insecticide-treated netting, pyrethroid insecticides, and DEET-based insect repellent lower malarial rates in endemic areas. These are well tolerated in pregnancy (Menéndez, 2007). If travel is necessary, chemoprophylaxis is recommended.

Chloroquine and hydroxychloroquine prophylaxis is safe and well tolerated in pregnancy. Prophylaxis lowers placental infection rates from 20 percent to 4 percent in asymptomatic infected women in areas without chloroquine resistance (Cot, 1992). For travelers to areas with chloroquine-resistant *P falciparum*, mefloquine prophylaxis is recommended (Freedman, 2016). One evaluation compared prophylaxis during pregnancy with either sulfadoxine-pyrimethamine or dihydroartemisinin-piperaquine and found the latter to be more effective (Kakuru, 2016). Primaquine and doxycycline are contraindicated in pregnancy, and data are insufficient for atovaquone/proguanil use. The latest chemoprophylaxis regimens for pregnancy can be obtained from the CDC *Travelers' Health* website at: www.cdc.gov/malaria/travelers/drugs.html. The CDC also publishes *Health Information for International Travel* (The Yellow Book) at: www.cdc.gov/yellowbook. For women living in endemic areas, intermittent preventive treatment was found to be superior to intermittent screening with treatment (Desai, 2015).

Amebiasis

Approximately 10 percent of the world population is infected with *Entamoeba histolytica*, and most are asymptomatic (Andrade, 2015). Amebic dysentery, however, may take a fulminant course during pregnancy, with fever, abdominal pain, and bloody stools. Prognosis is worse if complicated by a hepatic abscess. Diagnosis is made by identifying *E histolytica* cysts or trophozoites within a stool sample. Therapy is similar to that for the nonpregnant woman, and metronidazole or tinidazole are the preferred drugs for amebic colitis and invasive disease. Noninvasive infections may be treated with iodoquinol or paromomycin.

MYCOTIC INFECTIONS

Disseminated fungal infection—usually pneumonitis—during pregnancy is uncommon with coccidiomycosis, blastomycosis, cryptococcosis, or histoplasmosis. Their identification and management are considered in Chapter 51 (Tuberculosis).

TRAVEL PRECAUTIONS DURING PREGNANCY

Pregnant travelers face general medical, obstetrical, and potentially hazardous destination risks. Several sources provide travel information (Freedman, 2016). The International Federation for Tropical Medicine has comprehensive information available at www.iftm-hp.org, and the International Society of Travel Medicine publishes information at www.istm.org/bodyofknowledge. Also, *The Yellow Book*, mentioned earlier, by the CDC has extensive travel information regarding pregnancy and breastfeeding.

BIOTERRORISM

The concept of bioterrorism involves the deliberate release of bacteria, viruses, or other infectious agents to cause illness or death. These natural agents are often altered to increase their infectivity or their resistance to medical therapy. Health-care providers should be alert for significant increases in the number of persons with febrile illnesses accompanied by respiratory symptoms or with rashes not easily associated with common illnesses. Clinicians are urged to contact their state health department or the CDC for current information and recommendations. The American College of Obstetricians and Gynecologists (2016a) has addressed disaster preparedness for obstetricians. It provides both general considerations and recommendations for hospital readiness and obstetrics-specific issues.

Smallpox

The variola virus causes smallpox and is considered a serious weapon. The virus is highly transmissible and carries an overall 30-percent case-fatality rate. The last case of smallpox in the United States was reported in 1949, and worldwide it was reported in Somalia in 1977. Nishiura (2006) has reviewed the severe perinatal and maternal morbidity and mortality caused by smallpox. The case-fatality rate of smallpox in pregnancy is 61 percent if the pregnant woman is unvaccinated. Rates of stillbirth, abortion, preterm labor and delivery, and neonatal demise rise significantly in pregnancies complicated by this infection.

Because the smallpox vaccine currently available is made with live vaccinia virus, pregnancy should be delayed for 4 weeks in recipients. It is generally not given to pregnant women because of the risk of fetal vaccinia, a rare but serious complication. Inadvertent smallpox vaccination during pregnancy has not, however, been convincingly associated with fetal malformations or preterm birth (Badell, 2015). Moreover, no cases of fetal vaccinia have been reported with second-generation smallpox vaccine exposure. The Smallpox Vaccine in Pregnancy Registry remains active, and vaccinated women are still being enrolled: DOD.NHRC-birthregistry@mail.mil.

Anthrax

Bacillus anthracis is a gram-positive, spore-forming, aerobic bacterium. It can cause three main types of clinical anthrax: inhalational, cutaneous, and gastrointestinal (Centers for Disease Control and Prevention, 2017a). The bioterrorist anthrax attacks of 2001 involved inhalational anthrax (Inglesby, 2002). Spores

are inhaled and deposited in the alveoli. They are engulfed by macrophages and germinate in mediastinal lymph nodes. The incubation period is usually less than 1 week but may be as long as 2 months. Within 1 to 5 days of symptom onset, the second stage is heralded by the abrupt onset of severe respiratory distress and high fevers. Mediastinitis and hemorrhagic thoracic lymphadenitis are common. Chest radiographs show a widened mediastinum. Case-fatality rates with inhalational anthrax are high, even with aggressive antibiotic and supportive therapy (Holty, 2006).

Anthrax affecting pregnant women and its treatment were reviewed by Meaney-Delman and coworkers (2012, 2013). They reported data on 20 pregnant and postpartum women. The overall mortality rate was 80 percent, with a 60-percent fetal or neonatal loss rate. Of note, most cases were published before the advent of antibiotics.

Regimens for postexposure anthrax prophylaxis are given for 2 months. The CDC recommend that asymptomatic pregnant and lactating women with documented exposure to *B anthracis* be given postexposure prophylaxis with ciprofloxacin, 500 mg orally twice daily for 60 days (Hendricks, 2014; Meaney-Delman, 2013). Amoxicillin, 500 mg orally three times daily, can be substituted if the strain is proven sensitive. In the case of ciprofloxacin allergy and either penicillin allergy or resistance, doxycycline, 100 mg orally twice daily, is given for 60 days. Risks from anthrax far outweigh any fetal risks from doxycycline (Meaney-Delman, 2013).

The anthrax vaccine is an inactivated, cell-free product that requires three injections over 28 days. Vaccination is generally avoided in pregnancy because safety data are limited. Inadvertent vaccination of pregnant women with the vaccine has not been linked with a significant increase in fetal malformation or miscarriage rates (Conlin, 2015; Ryan, 2008). The anthrax vaccine is an essential adjunct to postexposure antimicrobial prophylaxis, even in pregnancy.

Other Bioterrorism Agents

Other category A bioterrorism agents include *Francisella tularensis*—tularemia, *Clostridium botulinum*—botulism, *Yersinia pestis*—plague, and viral hemorrhagic fevers—for example, Ebola, Marburg, Lassa, and Machupo. The guidelines for these biological agents are evolving and are detailed at the CDC Bioterrorism website: emergency.cdc.gov/bioterrorism/index.asp.

CHAPTER 65: Sexually Transmitted Infections

Syphilis is one of the most important complications of pregnancy, as it is one of the most frequent causes of abortion or premature labour. Syphilis is the most common cause of foetal death in the later months of pregnancy, and may be maternal or paternal in origin.

—J. Whitridge Williams (1903)

INTRODUCTION

Syphilis and gonorrhea were prominently mentioned in the first edition of this book, with special consideration for their harmful effects on fetal development. Although Williams confined his discussion to these two infections, today, sexually transmitted diseases (STDs) include chlamydial and trichomonal infections and viral STDs such as hepatitis B, human immunodeficiency virus (HIV), herpes simplex virus (HSV), and human papillomavirus (HPV) infections. In some form, all can be injurious to the mother or fetus and thus should be aggressively sought and treated. In many instances, recommended therapies are provided in guidelines from the Centers for Disease Control and Prevention (CDC) and listed throughout the chapter.

Vertical transmission refers to passage from the mother to her fetus of an infectious agent through the placenta, during labor or delivery, or by breastfeeding. Treatment of most STDs is clearly associated with improved pregnancy outcome and prevention of perinatal morbidity. Logically, education, screening, treatment, and prevention are essential components of prenatal care.

SYPHILIS

Despite the availability of adequate therapy for decades, syphilis remains a major issue for both mother and fetus. From 2001 through 2015, the primary and secondary syphilis rates have risen almost yearly (Centers for Disease Control and Prevention, 2016c). In the United States in 2015, the combined rate for both of these among women was 1.8 cases per 100,000 persons (de Voux, 2017). For congenital syphilis, after a nadir in 2012, rates have also risen yearly to reach 12.4 cases per 100,000 live births in 2015. Of risks, higher congenital syphilis rates are linked to inadequate prenatal care, black or Hispanic race, and lack of treatment (Su, 2016). Similarly, syphilis remains a significant global health problem, with many countries reporting high numbers of new infections (Newman, 2015; World Health Organization, 2012).

Pathogenesis and Transmission

Syphilis is caused by the spirochetal bacterium *Treponema pallidum.* Minute abrasions on the vaginal mucosa provide an entry portal, and cervical eversion, hyperemia, and friability raise transmission risk. Spirochetes replicate and then disseminate through lymphatic channels within hours to days. The incubation period is 3 to 4 weeks depending on host factors and inoculum size.

The early stages of syphilis include primary, secondary, and early latent syphilis. These are associated with high spirochete loads, and partner transmission rates approximate 30 to 60 percent (Garnett, 1997; Singh, 1999). In late-stage disease, transmission rates decline because of smaller inoculum sizes.

Maternal syphilis can cause fetal infection by several routes. Spirochetes readily cross the placenta to cause congenital infection. Although transplacental transmission is the most common route, neonatal infection may follow after contact with spirochetes through lesions at delivery or across the placental membranes. Fetal infection develops in >50 percent of untreated early syphilis cases and in 10 percent of late latent disease (Fiumara, 1975; Hollier, 2001).

Clinical Manifestations

Maternal Syphilis

This is staged according to clinical features and disease duration.

1. *Primary syphilis* is diagnosed by its characteristic chancre, which develops at the inoculation site. This solitary, painless lesion typically has a raised, firm border and a red, smooth ulcerated base without significant pus (Fig. 65-1). Nonsuppurative lymphadenopathy may develop. A chancre will usually resolve spontaneously in 2 to 8 weeks, even if untreated. Multiple lesions, if found, are predominantly in HIV-1 co-infected women.

2. *Secondary syphilis* stems from dissemination of spirochetes to affect multiple organ systems. Manifestations develop 4 to 10 weeks after the chancre appears and include dermatological abnormalities in up to 90 percent of women. A diffuse macular rash, plantar and palmar targetlike lesions, patchy alopecia, and mucous patches may be seen (Fig. 65-2). *Condylomata lata* are flesh-colored papules and nodules found on the perineum and perianal area (Fig. 65-3). These papules are teeming with spirochetes and are highly infectious. Most women with secondary syphilis also express constitutional symptoms such as fever, malaise, headache, and myalgias. Hepatitis, nephropathy, ocular changes, anterior uveitis, and periostitis can also develop.

3. *Latent syphilis* develops when primary or secondary syphilis is not treated but clinical manifestations still resolve. It is identified instead by serological testing. *Early latent syphilis* is subclinical disease acquired within the preceding 12 months. Disease diagnosed beyond 12 months is either *late latent syphilis* or *latent syphilis of unknown duration.*

4. *Tertiary syphilis* is a slowly progressive disease affecting any organ system but is rarely seen in reproductive-aged women.

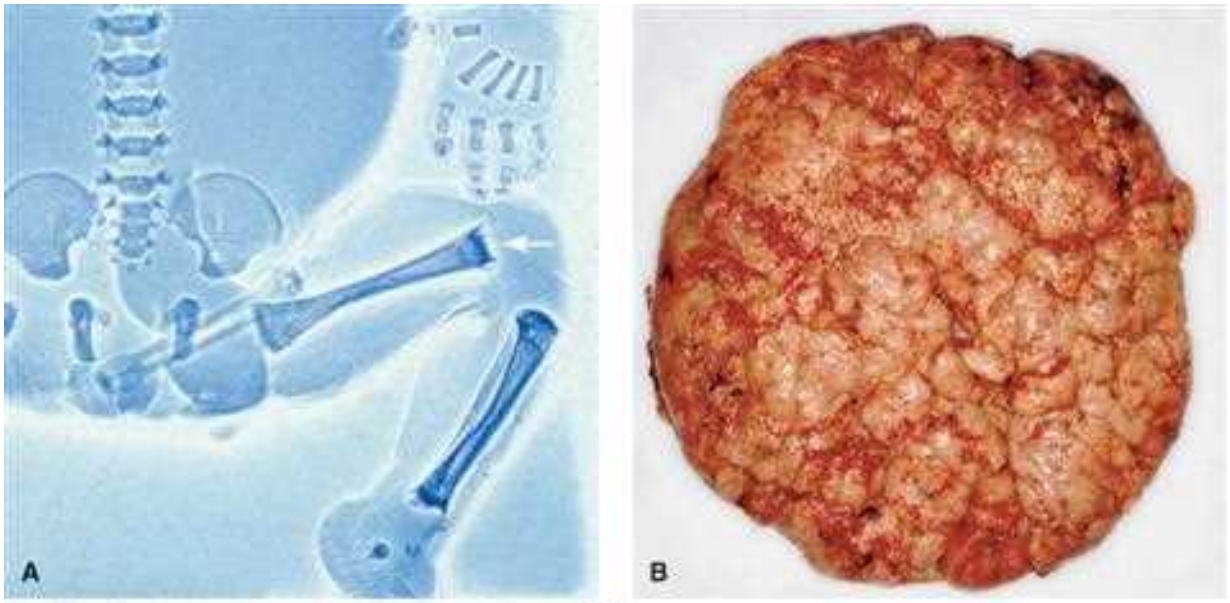
Congenital Syphilis

Without screening and treatment, approximately 70 percent of infected women will have an adverse pregnancy outcome (Hawkes, 2011). Maternal infection can lead to preterm labor, fetal death, fetal-growth restriction, or fetal infection (Gomez, 2013). Because of immune incompetence prior to midpregnancy, the fetus generally does not manifest the immunological inflammatory response characteristic of clinical disease before this time (Silverstein, 1962). Once fetal syphilis develops, however, it manifests as a continuum. Fetal hepatic abnormalities are followed by anemia and thrombocytopenia, then ascites and hydrops (Hollier, 2001). Stillbirth remains a major complication (Lawn, 2016; Su, 2016). The newborn may have jaundice with petechiae or purpuric skin lesions, lymphadenopathy, rhinitis, pneumonia, myocarditis, nephrosis, or long-bone involvement (Fig. 65-4).

FIGURE 65-4

Congenital syphilis. **A.** Fetogram of a stillborn infant infected with syphilis showing the "moth-eaten" appearance of the femurs (*arrow*). **B.** Enlarged hydropic placenta of a syphilis-infected neonate.



With syphilitic infection, the placenta becomes large and pale (see Fig. 65-4). Microscopically, villi lose their characteristic arborization and become thicker and clubbed. Sheffield and colleagues (2002c) described these villi in more than 60 percent of syphilitic placentas. Blood vessels markedly diminish in number, and in advanced cases, they almost entirely disappear as a result of endarteritis and stromal cell proliferation. Likely related, Lucas and coworkers (1991) demonstrated increased vascular resistance in uterine and umbilical arteries of infected pregnancies. The cord may also show evidence of infection. In a study of 25 untreated women, Schwartz and associates (1995) reported that necrotizing funisitis was present in a third.

Diagnosis

The United States Preventative Services Task Force recommends that clinicians screen all pregnant women for syphilis to prevent congenital infection (Wolff, 2009). Testing is ideally performed at the first prenatal visit. In populations with a high prevalence of syphilis, serological testing is repeated in the third trimester and again at delivery (Workowski, 2015).

Treponema pallidum cannot be cultured from clinical specimens. However, direct diagnosis of early-stage disease from lesion exudate, tissue, or body fluid can be completed by dark-field microscopic examination, by polymerase chain reaction (PCR), or by direct fluorescent antibody tests for *T pallidum* (DFA-TP) (Tsang, 2015). These methods are not widely available and are less sensitive for blood specimens (Grange, 2012; Henao-Martínez, 2014). Thus, in practice, diagnoses are mainly derived from clinical findings coupled with serological blood testing.

Serological testing is used for diagnostic and for screening purposes. There are two types. If the first of these is positive, then the second type is also performed. This combination identifies infection and clarifies disease stage. Traditionally, the first type is *nontreponemal testing,* and either the Venereal Disease Research Laboratory (VDRL) or the rapid plasma reagin (RPR) is selected. Both tests measure patient immunoglobulin M and G (IgM and IgG) antibodies formed against cardiolipin that is released from damaged host cells and possibly also from treponemes. Notably, these same antibodies can also be produced in response to other acute events that include recent vaccination, febrile illness, and pregnancy itself or in response to chronic conditions such as intravenous drug abuse, systemic lupus erythematosus, aging, leprosy, or cancer. As such, these all serve as potential sources of false-positive results (Larsen, 1995). Conversely, seroconversion occurs at around 3 weeks, but can take up to 6 weeks (Peeling, 2004). Thus, women with very early primary syphilis can have initially false-negative serological test results.

With positive nontreponemal test results, findings are quantified and expressed as titers. Because titers reflect disease activity, they increase during early syphilis and often exceed levels of 1:32 in secondary syphilis. Following treatment of primary and secondary syphilis, serological testing at 3 to 6 months usually confirms a fourfold drop in VDRL or RPR titers (Rac, 2014a). Because VDRL titers do not correspond directly to RPR titers, consistent use of the same test for surveillance is recommended. Those with treatment failure or reinfection may lack this expected decline. Importantly, some successfully treated

patients may still exhibit persistently low-level positive titers, which are referred to as “serofast.” This state is more likely in older individuals, those with lower initial nontreponemal antibody titers, and those with later stages of syphilis (Seña, 2015).

The second type of serological testing is *treponemal-specific.* It seeks patient antibodies formed specifically against *T pallidum.* The antibodies detected by treponemal assays appear up to a few weeks earlier than those detected by nontreponemal tests (Levett, 2015). Tests includes the fluorescent treponemal-antibody absorption tests (FTA-ABS), the *T pallidum* passive particle agglutination (TP-PA) test, and various immunoassays (Association of Public Health Laboratories, 2015). *Of note, these treponemal-specific tests generally remain positive throughout life.*

Each of the serological tests has limitations including false-positive and -negative results. Traditionally, nontreponemal tests have been used for screening in the United States, and results are then confirmed by a specific treponemal test. Within the past several years, some laboratories have implemented a reverse screening algorithm, namely, screening first with a treponemal-specific test (Binnicker, 2012; Centers for Disease Control and Prevention, 2011). Both approaches are effective if there is a program for appropriate screening, follow-up, and treatment.

In contrast to these tests, rapid “point-of-care” (POC) syphilis screening of blood or serum samples is being developed (Singh, 2015; Tucker, 2010). These may be best used for women with limited prenatal care. Most tests are treponemal-specific, and positive POC results can then be confirmed by a laboratory nontreponemal test. In hard-to-reach populations, some countries immediately treat women with positive POC results. This practice, however, risks overtreating previously cured women who still have residual persistent treponemal antibodies. This limitation may be overcome by newer POC dual tests, which simultaneously assess nontreponemal and treponemal antibodies (Causer, 2015).

Following maternal diagnosis, sonographic evaluation is performed for fetuses >20 weeks’ gestation to search for signs of congenital syphilis. Rac and associates (2014b) noted that 31 percent of infected women diagnosed at ≥18 weeks’ gestation had abnormal fetal sonographic findings. Hepatomegaly, placental thickening, hydramnios, ascites, hydrops fetalis, and elevated middle cerebral artery Doppler velocimetry measurements are indicative of fetal infection. Before 20 weeks, treatment is highly successful, and sonographic findings are rare (Nathan, 1997).

For fetuses of viable age with sonographic findings, antepartum fetal heart rate monitoring prior to treatment is recommended. Spontaneous late decelerations or a nonreactive tracing likely reflects an extremely ill fetus that may poorly tolerate a Jarisch-Herxheimer reaction, described next. In this extreme case, consultation with a neonatologist regarding a plan of delaying treatment, pursuing delivery, and then treating in the nursery is a consideration (Wendel, 2002).

Treatment

Syphilis therapy during pregnancy is given to eradicate maternal infection and to prevent or treat congenital syphilis. Parenteral penicillin G remains the preferred treatment for all stages of syphilis during pregnancy (Table 65-1). During pregnancy, authorities recommend that a second dose of benzathine penicillin G be given 1 week after the initial dose. Such treatment is also given for women with concomitant HIV infection (Workowski, 2015).

TABLE 65-1

Recommended Treatment for Pregnant Women with Syphilis

Category	Treatment
Early syphilis[a]	Benzathine penicillin G, 2.4 million units as a single injection—some recommend a second dose 1 week later
More than 1-year duration[b]	Benzathine penicillin G, 2.4 million units intramuscularly weekly for three doses

[a]Primary, secondary, and early latent syphilis of less than 1-year duration.

[b]Latent syphilis of unknown or more than 1-year duration; tertiary syphilis. Missed doses are not acceptable for pregnant women, and those who miss any dose of therapy must repeat the full course of therapy.

Data from Workowski, 2015.

Benzathine penicillin G is highly effective for early maternal infection. In a study of 340 pregnant women so treated, Alexander and associates (1999) reported six cases—1.8 percent—of congenital syphilis. Four of these six neonates were from a group of 75 women with secondary syphilis. The other two were identified in those delivered from a group of 102 women with early latent syphilis. Congenital syphilis was generally confined to neonates of women treated after 26 weeks and is likely related to the duration and severity of fetal infection. Sheffield and coworkers (2002b) reported that high maternal serological titers, preterm delivery, and delivery shortly after antepartum therapy are all risks for failure of maternal treatment to prevent neonatal infection.

There are no proven alternatives to penicillin therapy during pregnancy. Erythromycin and azithromycin may be curative for the mother, but because of limited transplacental passage, these drugs do not prevent all congenital disease (Berman, 2004; Wendel, 1988; Zhou, 2007). Moreover, in several countries, macrolide-resistant strains of *T pallidum* are now prevalent (Stamm, 2015). Cephalosporins may prove useful, but data are limited (Liang, 2016).

Tetracyclines, including doxycycline, are effective but generally not recommended during pregnancy, because of the risk for fetal deciduous-teeth discoloration.

All women with syphilis are offered counseling and testing for HIV and other STDs. Following syphilis treatment, serological testing to detect treatment failures is done at 3 to 6 months and usually confirms a fourfold drop in VDRL or RPR titers. During pregnancy, serological titers can be checked monthly in women at high risk for reinfection (Workowski, 2015).

In some instances, a woman may present without symptoms but describes recent sexual contact with a person who has been diagnosed with syphilis. She should be evaluated clinically and serologically. If her partner is diagnosed and their sexual contact occurred within the preceding 90 days, the gravida is treated presumptively for early syphilis, even if serological test results are negative. This accounts for early infection but before seroconversion. If contact was earlier than 90 days ago, treatment is based on serological results (Workwoski, 2015).

Penicillin Reactions

Women with a history of penicillin allergy should have either an oral stepwise penicillin-dose challenge or skin testing performed to confirm the risk of immunoglobulin E (IgE)-mediated anaphylaxis. If confirmed, penicillin desensitization, shown in Table 65-2, is recommended and then followed by benzathine penicillin G treatment (Wendel, 1985).

TABLE 65-2

Penicillin Allergy—Oral Desensitization Protocol for Patients with a Positive Skin Test

Penicillin V Suspension Dose[a]	Amount[b] (units/mL)	mL	Units	Cumulative Dose (units)
1	1000	0.1	100	100
2	1000	0.2	200	300
3	1000	0.4	400	700
4	1000	0.8	800	1500
5	1000	1.6	1600	3100
6	1000	3.2	3200	6300
7	1000	6.4	6400	12,700
8	10,000	1.2	12,000	24,700
9	10,000	2.4	24,000	48,700
10	10,000	4.8	48,000	96,700
11	80,000	1.0	80,000	176,700
12	80,000	2.0	160,000	336,700
13	80,000	4.0	320,000	656,700
14	80,000	8.0	640,000	1,296,700

[a]Interval between doses: 15 minutes. Elapsed time: 3 hours and 45 minutes. Cumulative dose: 1.3 million units. Observation period: 30 minutes before parenteral administration of penicillin.

[b]The specific amount of drug was diluted in approximately 30 mL of water and administered orally.

From Wendel, 1985, with permission.

Distinct from allergy, a *Jarisch-Herxheimer reaction* develops following penicillin treatment in most women with primary syphilis and approximately half with secondary infection. Uterine contractions, mild maternal temperature elevation, decreased fetal movement, and fetal heart rate decelerations are

findings. Reaction treatment is supportive with antipyretics as needed, hydration, and oxygen supplementation (Klein, 1990). In a study of 50 gravidas who received benzathine penicillin for syphilis, Myles and associates (1998) reported a 40-percent incidence of Jarisch-Herxheimer reactions. Of the 31 women monitored electronically, 42 percent developed regular uterine contractions, and 39 percent developed variable decelerations. All contractions resolved within 24 hours of therapy. Accordingly, for fetuses of viable age, some recommend administering the first dose of antibiotic in labor and delivery and with continuous fetal monitoring for at least 24 hours (Rac, 2017). Others recommend this only if sonographic signs of fetal syphilis, described earlier, are found (Duff, 2014; Wendel, 2002). If this second plan is elected, patients are counseled on reaction signs and encouraged to seek evaluation if they develop.

GONORRHEA

Of notifiable STDs, infections caused by *Neisseria gonorrhoeae* are the second most common. The incidence of gonorrhea in the United States has continued to rise since 2009, and in 2015, the rate was 124 cases per 100,000 persons (Centers for Disease Control and Prevention, 2016c). The highest rates in women of any ethnicity were in those aged 15 to 24 years. In pregnant women, its prevalence approximates 0.6 percent (Blatt, 2012). In most pregnant women, infection is limited to the lower genital tract—the cervix, urethra, and periurethral and vestibular glands. Acute salpingitis is rare in pregnancy. But, pregnant women account for a disproportionate number of disseminated gonococcal infections (Bleich, 2012).

Gonococcal infection can have deleterious effects in any trimester. Untreated gonococcal cervicitis is associated with septic abortion as well as infection after voluntary abortion (Burkman, 1976). Preterm delivery, prematurely ruptured membranes, chorioamnionitis, and postpartum infection are more frequent in women with gonococcal infection (Alger, 1988; Johnson, 2011).

Vertical transmission of gonorrhea is predominantly due to fetal contact with vaginal infection during birth. The predominant sequela is gonococcal ophthalmia neonatorum, which can lead to corneal scarring, ocular perforation, and blindness. Transmission rates are high and approximate 40 percent (Laga, 1986). Accordingly, as discussed in Chapter 32 (Preventive Care), ocular prophylaxis is provided to newborns (Mabry-Hernandez, 2010).

Screening and Treatment

Pregnant women who live in high-prevalence areas or who are at risk for gonorrhea should undergo first-trimester screening. Risk factors include age ≤25 years; prior gonococcal infection; other STDs; prostitution; new or multiple sexual partners; drug abuse; black, Hispanic, or American Indian or Alaska Native ethnicity; and inconsistent condom use (American Academy of Pediatrics, 2017). For women who test positive, screening for syphilis, chlamydial infection, and HIV should precede treatment, if possible. Gonococcal infection is a marker for concomitant chlamydial infection. Thus, if chlamydial testing is unavailable, presumptive chlamydial therapy is given to women treated for gonorrhea.

Screening for gonorrhea in women is by culture or nucleic acid amplification tests (NAATs). NAATs have replaced culture in most laboratories, and kits are available for specific collection from the vagina, endocervix, or urine. Of these, vaginal or cervical samples are preferred, as urine collection may detect up to 10 percent fewer infections (Papp, 2014). If used, the initial urine stream, not midstream, is collected. NAATs are also recommended for diagnosis of rectal or pharyngeal disease, but participating laboratories must be CLIA (Clinical Laboratory Improvement Amendments) compliant with required test modifications. Culture is also available for these anatomical sites. Rapid POC tests for gonorrhea, although available, do not yet reach the sensitivity or specificity of culture or NAAT and have not been rigorously studied in pregnant women (Herbst de Cortina, 2016).

Gonorrhea treatment has evolved during the past decade due to the ability of *N gonorrhoeae* to rapidly develop antimicrobial resistance. The current treatment for uncomplicated gonococcal infection during pregnancy is 250 mg of ceftriaxone intramuscularly plus 1 g of azithromycin orally (Workowski, 2015). The latter provides another drug with a different mechanism of action against *N gonorrhoeae* and treats chlamydial co-infections. Patients are instructed to abstain from sexual intercourse for 7 days after they and their sexual partners have completed treatment. As an alternative regimen, a single, 400-mg oral dose of cefixime plus 1 g of azithromycin should be reserved for situations that preclude ceftriaxone treatment. With cephalosporin allergy, a 240-mg intramuscular dose of gentamicin can be coupled with a 2-g oral azithromycin dose. Repeat testing is recommended in the third trimester for any woman treated for gonorrhea in the first trimester and for any uninfected woman who is at high risk for gonococcal infection (American Academy of Pediatrics, 2017).

Treatment is recommended for sexual contacts. Expedited therapy, discussed in Herpes Simplex Virus, is a less-desirable option due to the now-preferred injectable regimen.

Disseminated Gonococcal Infections

Gonococcal bacteremia may cause disseminated infections that manifest as petechial or pustular skin lesions, arthralgias, or septic arthritis. For treatment of septic arthritis, the CDC recommends ceftriaxone, 1 g intramuscularly or intravenously (IV) every 24 hours plus a single 1-g oral dose of azithromycin (Workowski, 2015). Treatment is continued for 24 to 48 hours after clinical improvement, and therapy is then changed to an oral agent to complete 1 week of therapy. Prompt recognition and antimicrobial treatment will usually yield favorable outcomes in pregnancy (Bleich, 2012). Meningitis and endocarditis rarely complicate pregnancy, but they may be fatal (Bataskov, 1991; Burgis, 2006). For gonococcal *endocarditis*, ceftriaxone 1 to 2 g IV every 12 hours should be continued for at least 4 weeks, and for *meningitis*, 10 to 14 days. A single 1-g oral dose of azithromycin is also provided for chlamydial co-infection (Workowski, 2015).

CHLAMYDIAL INFECTIONS

Chlamydia trachomatis is an obligate intracellular bacterium that has several serotypes, including those that cause lymphogranuloma venereum. The most commonly encountered strains are those that attach only to columnar or transitional cell epithelium and cause cervical infection. It is the most common reportable STD in the United States, and the overall chlamydial infection rate among women was 646 cases per 100,000 females in 2015 (Centers for Disease Control and Prevention, 2016c).

Most pregnant women have asymptomatic infection, but a third have urethral syndrome, urethritis, or Bartholin gland infection (Peipert, 2003). Mucopurulent cervicitis may be due to chlamydial or gonococcal infection or both. Other chlamydial infections not usually seen in pregnancy are endometritis, salpingitis, reactive arthritis, and Reiter syndrome.

The role of chlamydial infection in pregnancy complications remains controversial. A few studies have reported a direct association between *C trachomatis* and miscarriage, whereas most show no correlation (Baud, 2011; Coste, 1991; Paukku, 1999). It is disputed whether untreated cervical infection increases the risk of preterm delivery, preterm ruptured membranes, low birthweight, or perinatal mortality (Andrews, 2000, 2006; Blas, 2007; Johnson, 2011; Moodley, 2017; Silva, 2011). Chlamydial infection has not been associated with a greater risk of chorioamnionitis or with peripartum pelvic infection (Berman, 1987; Gibbs, 1987). However, delayed postpartum uterine infection has been described by Hoyme and associates (1986). The syndrome, which develops 2 to 3 weeks postpartum, is distinct from early postpartum metritis. It is characterized by vaginal bleeding or discharge, low-grade fever, and uterine tenderness.

Infection poses a higher risk to the newborn than to the mother. Vertical transmission leads to infection in 8 to 44 percent of neonates delivered vaginally from affected women (Rosenman, 2003). Of neonatal infections, conjunctivitis is the most common (Chap. 32, Preventive Care). Perinatal transmission to newborns can also cause pneumonia.

Screening and Treatment

Currently, the U.S. Preventive Services Task Force (LeFevre, 2014) as well as the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2017) recommend chlamydia screening for all women at the first prenatal visit. The College further suggests testing in the third trimester for those treated in the first trimester; all women aged ≤25 years; and those aged ≥25 years with behavioral factors, which mirror those for women at risk for gonorrhea. In one review of repeat chlamydial infections among women, the reinfection rate was 14 percent, and most recurred within the first 8 to 10 months (Hosenfeld, 2009).

Diagnosis is made predominantly by culture or NAAT. Cultures are more expensive and less accurate than newer NAATs (Greer, 2008). Of samples for NAAT, vaginal or cervical samples are preferred, as urine collection may detect up to 10 percent fewer infections (Papp, 2014; Wiesenfeld, 2017). However, Roberts and associates (2011) evaluated NAAT of urine specimens compared with cervical secretions in more than 2000 pregnant women and found them to be equivalent. As with gonorrhea, the first portion of the urine stream is collected.

Currently recommended treatment regimens for chlamydial infections are shown in Table 65-3. Azithromycin is first-line treatment and is safe and effective in pregnancy. The fluoroquinolones and doxycycline are usually avoided in pregnancy, and erythromycin estolate is contraindicated because of drug-related hepatotoxicity. Chlamydial testing is repeated 3 to 4 weeks after therapy completion and again 3 months after treatment. In high-risk individuals, third-trimester rescreening is recommended (Workowski, 2015).

TABLE 65-3

Oral Treatment of *Chlamydia trachomatis* Infections During Pregnancy

Regimen	Drug and Dosage
Preferred	Azithromycin, 1 g as a single dose
Alternative	Amoxicillin, 500 mg three times daily for 7 d
	or
	Erythromycin base, 500 mg four times daily for 7 d
	or
	Erythromycin ethylsuccinate, 800 mg four times daily for 7 d
	or
	Erythromycin base, 250 mg four times daily for 14 d
	or
	Erythromycin ethylsuccinate, 400 mg four times daily for 14 d

Data from Workowski, 2015.

Expedited Partner Therapy

To prevent STD transmission, guidelines for expedited partner therapy (EPT) have been created by the Centers for Disease Control and Prevention (2006a) and are endorsed by the American College of Obstetricians and Gynecologists (2015). With EPT, a prescription is provided to the diagnosed patient for their partner. It is delivered by the patient to their partner without medical assessment of the partner or professional counseling. EPT ideally does not replace traditional strategies, such as standard patient referral with screening for other STDs.

EPT is acceptable for treatment of sexual contacts with chlamydial infection. In light of new guidelines that recommend injectable ceftriaxone, EPT for gonorrhea is less desirable unless the partner will otherwise not seek treatment (Centers for Disease Control and Prevention, 2016a). Fewer data are available to assess this strategy for trichomoniasis (Kissinger, 2006; Schwebke, 2010). EPT is not recommended for syphilis (Workowski, 2015).

Although sanctioned by the CDC, EPT is not legal in several states. Moreover, the risk of litigation in the event of adverse outcomes may be elevated when a practice has uncertain legal status or is outside formally accepted community practice standards (Centers for Disease Control and Prevention, 2006a). The legal status of EPT in each of the 50 states can be found at: http://www.cdc.gov/std/ept/legal/default.htm.

Lymphogranuloma Venereum

L_1, L_2, and L_3 serovars of *C trachomatis* cause *lymphogranuloma venereum (LGV).* The primary genital infection is transient, is seldom recognized, and is not linked with vertical transmission to the fetus. It can be confused with chancroid. Classically, matted inguinal adenitis may develop on either side of the inguinal ligament to give rise to the “groove sign.” At times, these nodes may suppurate. Ultimately, the lymphatics of the lower genital tract and perirectal tissues may be involved. Here, sclerosis and fibrosis can cause vulvar elephantiasis and severe rectal stricture. Fistula formation involving the rectum, perineum, and vulva may also evolve.

For treatment during pregnancy, erythromycin base, 500 mg orally four times daily, is given for 21 days (Workowski, 2015). Some authorities instead use szithromycin, 1 g orally weekly for 21 days, although data regarding efficacy are scarce.

HERPES SIMPLEX VIRUS

This virus poses a disproportionately higher risk to the newborn than to the mother. Thus, strategies in pregnancy aim to curb rates of vertical transmission.

Adult Disease

Two types of herpes simplex viruses are distinguished based on immunological differences. Yet, the two viruses have significant DNA sequence homology, and thereby, prior infection with one type attenuates a primary infection with the other. Type 2 HSV is recovered almost exclusively from the genital tract and is usually transmitted by sexual contact. Type 1 is responsible for most nongenital infections and typically is acquired in childhood. However, more than half of new cases of genital herpes in adolescents and young adults are now caused by HSV-1 infection (Bernstein, 2013). This rise in the prevalence of HSV-1 genital disease is thought to stem from an increase in oral-genital sexual practices. Another explanation is that HSV-1 acquisition has declined in childhood as a result of improved living conditions and hygiene (Bradley, 2014; Xu, 2007). Without prior exposure, this renders young people without HSV-1 antibodies susceptible to *genital* acquisition of HSV-1 or -2.

Genital herpes simplex virus affects an estimated 50 million adolescents and adults (Workowski, 2015). Most women are unaware of their infection, but HSV-2 seroprevalence among non-Hispanic white females in the United States was 15.3 from 2007 to 2010 and among black females, it was 53 percent (Fanfair, 2014; Schulte, 2014). In one study of nearly 16,000 pregnant women from 2000 to 2010, the overall seroprevalence of HSV-2 was 16 percent, and for HSV-1, it was 66 percent (Delaney, 2014). Seronegative pregnant women have a 4 to 5 percent risk to acquire HSV-1 or -2 during pregnancy (Brown, 1997; Kulhanjian, 1992). For those who are HSV-1 seropositive, acquisition risk for HSV-2 approximates 2 percent (Brown, 1997).

Clinical Manifestations

Once transmitted by contact, HSV-1 or -2 replicates at the entry site. Following mucocutaneous infection, the virus moves retrograde along sensory nerves. It then remains latent in cranial nerves or dorsal spinal ganglia, but recurrences are common. HSV infections may be categorized into three groups.

First episode primary infection describes the case in which HSV-1 or 2 is isolated from a lesion in the absence of HSV-1 or -2 serological antibodies. The typical incubation period of 6 to 8 days (range 1 to 26 days) may be followed by a papular eruption with itching or tingling, which then becomes painful and vesicular. Multiple vulvar and perineal lesions may or may not coalesce, and then ulcerate (Fig. 65-5). Associated inguinal adenopathy can be severe. Many women do not present with typical lesions. Instead, a pruritic or painful abraded area or knife-cut may be found. Cervical involvement is common, although it may be inapparent clinically. Transient systemic influenza-like symptoms are frequent and are presumably caused by viremia. Some cases are severe enough to require hospitalization. Hepatitis, encephalitis, or pneumonia infrequently develop, and disseminated disease is rare. After 2 to 4 weeks, all signs and symptoms of infection disappear. Instead of these classic symptoms, the percentage of asymptomatic primary HSV-2 genital infections may be as high as 90 percent (Fanfair, 2013).

FIGURE 65-5
First-episode primary genital herpes simplex virus infection. Vesicles and knife-cut lesions are indicated by arrows. Small ulcers rim the anus. Similar lesions can typically be seen on the vulva.

First episode nonprimary infection is diagnosed when one HSV type is isolated from a lesion in a woman who has only the other serological HSV-type antibody present. In general, compared with primary infection, nonprimary infections are characterized by fewer lesions, less pain, fewer systemic manifestations, and briefer duration of lesions and viral shedding. This is likely because of some immunity from cross-reacting antibodies, for example, from childhood-acquired HSV-1 infection.

Recurrent disease is characterized by isolation of HSV-1 or -2 from the genital tract in women with the same serotype antibodies. During the latency period, in which viral particles reside in nerve ganglia, reactivation is common and mediated through poorly understood stimuli. The resulting lesions generally are fewer in number, are less tender, and shed virus for a shorter period than those of primary infection. Typically, they recur at the same sites. Genital disease recurrences are more frequently caused by HSV-2 compared with HSV-1. Recurrences are most frequent in the first year after initial infection, and rates slowly decline subsequently (Benedetti, 1999). Gravidas with a known prior history of genital HSV often experience recurrences (Sheffield, 2006).

Asymptomatic viral shedding is defined by the absence of clinical findings. Most infected women shed virus intermittently over time, and most HSV transmission to a partner occurs during these periods of asymptomatic viral shedding.

Vertical Transmission

The virus can be passed to the fetus/neonate by three routes: (1) peripartum in 85 percent, (2) postnatal in 10 percent, or (3) intrauterine in 5 percent (James, 2015). As discussed in Chapter 18 (First-Trimester Spontaneous Abortion), evidence does not suggest an obvious link between HSV infection and miscarriage (Zhou, 2015).

Peripartum transmission is by far the more frequent route of infection, and the fetus is exposed to virus shed from the cervix or lower genital tract. HSV-1 or -2 invades the uterus following membrane rupture or is transmitted by contact at delivery. The newborn is mainly infected, but rare cases of maternal endometritis have been described (Hollier, 1997; McGill, 2012). Neonatal manifestations vary. First, infection may be localized to the skin, eye, or mouth—SEM disease—in approximately 40 percent of cases. Second, central nervous system disease with encephalitis is seen in 30 percent. Last, disseminated disease with involvement of multiple major organs is found in 32 percent. Localized infection is usually associated with a good outcome. Conversely, even with

acyclovir treatment, disseminated infection has a mortality rate of nearly 30 percent (Corey, 2009; Kimberlin, 2011). Of disseminated or cerebral infection survivors, serious developmental and central nervous system morbidity is seen in 20 to 50 percent.

The neonatal infection rate is 0.5 to 1 per 10,000 births in the United States (Flagg, 2011; Mahnert, 2007). Most infected newborns are born to mothers with no reported history of HSV infection (Gardella, 2010). The risk of neonatal infection correlates with the presence of HSV in the genital tract, the HSV type, invasive obstetrical procedures, and stage of maternal infection (Brown, 2005, 2007). For example, neonates born to women who acquire genital HSV near the time of delivery have a 30- to 50-percent risk of infection. This is attributed to higher viral loads and the lack of transplacental protective antibodies (Brown, 1997, 2000). Women with recurrent HSV have less than a 1-percent risk of neonatal infection (Pasternak, 2010; Prober, 1987).

Postpartum transmission is uncommon and passed to the newborn by contact with an infected mother, family member, or health-care worker. The clinical presentation mirrors that with peripartum transmission.

In utero transmission of HSV-1 or HSV-2 is rare and is part of the TORCH (toxoplasmosis, other, rubella, cytomegalovirus, herpes virus) collection of infections. Intrauterine HSV infection classically leads to disease involving the skin (blisters, scarring), the central nervous system (hydranencephaly, microcephaly, intracranial calcification), or the eyes (chorioretinitis, microphthalmia) (Hutto, 1987). Bone and viscera can be involved (Marquez, 2011). If seen sonographically, findings should prompt viral serological testing as described next. PCR analysis of an amniocentesis sample is another potential tool (Diguet, 2006).

Diagnosis

Several organizations recommend against routine serological HSV screening in asymptomatic gravidas (American College of Obstetricians and Gynecologists, 2016b; Workowski, 2015; U.S. Preventive Services Task Force, 2016). However, for those with a clinically suspicious lesion, a diagnosis should be confirmed by laboratory testing. Available HSV tests are either virological or type-specific serological tests.

Direct virological tests are can be performed on a specimen from the mucocutaneous lesion. PCR or culture of the sample is a testing option. Of the two, PCR assays are more sensitive, the results generally are available in 1 to 2 days, and specimen handling is easier. In contrast, for viral culture, the sensitivity of HSV isolation is relatively low as vesicular lesions ulcerate and then crust. Also, results sometimes are not available for 7 to 14 days (Strick, 2006). Regardless of the test performed, HSV viral types should be differentiated (LeGoff, 2014). Importantly, a negative culture or PCR result does not exclude infection. In contrast, false-positive results are rare.

Serological assays are available to detect antibodies produced against specific HSV glycoproteins, G1 and G2. These proteins evoke type-specific antibody responses to HSV-1 and HSV-2 infection, respectively, and they reliably differentiate the two. IgG antibodies develop 1 to 2 weeks after a primary infection and then persist. This permits confirmation of clinical infection and identification of asymptomatic carriers. Providers should request type-specific glycoprotein G-based assays when serology is being performed. Sensitivity approaches 90 to 100 percent, and specificity is 99 to 100 percent (Wald, 2002). IgM antibody detection is not a useful test.

Management

In nonpregnant patients, antiviral therapy with acyclovir, valacyclovir, or famciclovir is used to treat first-episode genital herpes. Oral or parenteral preparations attenuate clinical infection and viral shedding duration. Suppressive therapy is also an option to limit recurrent infections and to reduce heterosexual transmission (Corey, 2004).

In pregnant women, acyclovir is safe (Briggs, 2015). Through 1999, the manufacturers of acyclovir and valacyclovir maintained a registry of outcomes following exposure to these drugs during pregnancy. More than 700 neonates exposed during the first trimester were evaluated, and there were no adverse effects attributable to acyclovir (Stone, 2004). At this time, data are insufficient regarding famciclovir exposure, although a pregnancy registry is being maintained (1–888–669–6682).

For a primary outbreak during pregnancy, women may be given antiviral therapy to attenuate and decrease the duration of symptoms and viral shedding (Table 65-4). Women with HIV co-infection may require a longer duration of treatment. Those with severe or disseminated HSV are given IV acyclovir, 5 to 10 mg/kg every 8 hours for 2 to 7 days until clinically improved. This is followed by oral antiviral drugs to complete at least 10 days of total therapy (Workowski, 2015). For intense discomfort, oral analgesics and topical anesthetics may provide some relief, and comorbid urinary retention is treated with an indwelling bladder catheter.

TABLE 65-4

Oral Antiviral Medications for Herpesvirus Infection in Pregnancy[a]

Indication	Pregnancy Recommendation
Primary or first episode infection	Acyclovir, 400 mg three times daily for 7–10 d ***or*** Valacyclovir, 1 g twice daily for 7–10 days
Symptomatic recurrent infection (episodic therapy)	Acyclovir, 400 mg three times daily for 5 days ***or*** Acyclovir, 800 mg twice daily for 5 days ***or*** Acyclovir, 800 mg three times daily for 2 d ***or*** Valacyclovir, 500 mg twice daily for 3 days ***or*** Valacyclovir, 1 g once daily for 5 days
Daily suppression	Acyclovir, 400 mg three times daily from 36 weeks until delivery ***or*** Valacyclovir, 500 mg twice daily from 36 weeks until delivery

[a]Famciclovir not preferred during pregnancy due to fewer safety data.

Data from Workowski, 2015.

For recurrent HSV infections during pregnancy, antiviral treatment is provided mainly for symptom relief (see Table 65-4). Although uncommon, acyclovir resistance has been reported, predominantly with HSV-2 and in immunocompromised patients (Andrei, 2013).

During pregnancy, amniocentesis, percutaneous cord blood sampling, or transabdominal chorionic villus sampling may be performed even with active genital lesions. With active lesions, however, internal electronic monitoring during labor is not recommended. Transcervical procedures may best be delayed until lesions have resolved (American College of Obstetricians and Gynecologists, 2016b).

Peripartum Shedding Prophylaxis

To diminish vertical transmission risks, cesarean delivery is indicated for women with active genital lesions or prodromal symptoms (American College of Obstetricians and Gynecologists, 2016b). Several studies have shown that acyclovir or valacyclovir suppression initiated at 36 weeks' gestation for gravidas with recurrences during pregnancy lowers the number of HSV outbreaks at term. The goal is to decrease the need for cesarean delivery (Hollier, 2008). This suppressive therapy will also decrease viral shedding (Scott, 2002; Sheffield, 2006; Watts, 2003). One systematic review evaluated acyclovir prophylaxis given from 36 weeks to delivery to women with HSV recurrence during pregnancy. Sheffield and colleagues (2003) found that suppressive therapy was associated with significantly lower rates of clinical HSV recurrence, cesarean deliveries for HSV recurrences, total HSV detection, and asymptomatic shedding. Subsequent studies using valacyclovir suppression have shown similar results (Andrews, 2006; Sheffield, 2006). Because of these studies, the American College of Obstetricians and Gynecologists (2016b) recommends viral therapy at or beyond 36 weeks for women who had primary genital herpes infection or active recurrent genital herpes during pregnancy. It is unclear whether suppression is needed for women with outbreaks before but not during pregnancy. Notably, despite maternal antiviral suppression, several cases of atypical neonatal herpes infection have been reported (Pinninti, 2012).

On presentation for delivery, a woman with a history of HSV should be questioned regarding prodromal symptoms such as vulvar burning or itching. A careful examination of the vulva, vagina, and cervix is performed, and women without genital lesions may proceed with labor and delivery. Use of a fetal scalp electrode can raise the transmission risk. But, electrode placement is reasonable if needed in the absence of active lesions (American College of Obstetricians and Gynecologists, 2016b).

Suspicious lesions should be cultured or PCR tested. Cesarean delivery is indicated for women with genital lesions or prodromal symptoms. It is not recommended for women with a history of HSV infection but no active genital disease at the time of delivery. Moreover, an active lesion in a nongenital area is not an indication for cesarean delivery. Instead, an occlusive dressing is placed, and vaginal delivery is allowed.

With preterm ruptured membranes, no evidence suggests that external lesions cause ascending fetal infection. Major and associates (2003) described expectant management of preterm premature membrane rupture in 29 women at gestational ages <31 weeks. There were no cases of neonatal HSV, and the maximum infection risk was calculated to be 10 percent. Antiviral treatment is recommended. For women with a clinical recurrence at delivery, there is not

an absolute duration of membrane rupture beyond which the fetus would not benefit from cesarean delivery (American College of Obstetricians and Gynecologists, 2016d).

Women with active HSV may breastfeed if there are no active breast lesions. Strict hand washing is essential. Valacyclovir and acyclovir may be used for symptomatic maternal lesions during breastfeeding, as drug concentrations in breast milk are low. One study found the acyclovir concentration to be only 2 percent of that used for therapeutic dosing of the neonate (Sheffield, 2002a).

CHANCROID

Haemophilus ducreyi can cause painful, nonindurated genital ulcers termed soft chancres. At times, these are accompanied by painful suppurative inguinal lymphadenopathy. Although common in some developing countries, only 11 cases were reported in the United States in 2015 (Centers for Disease Control and Prevention, 2016c). Appropriate media are not widely accessible, and no Food and Drug Administration (FDA)-cleared PCR test is yet available. Instead, painful genital ulcer(s) and negative screening for syphilis or HSV leads to a presumptive diagnosis. Treatment in pregnancy is azithromycin, 1 g orally as a single dose; erythromycin base, 500 mg orally three times daily for 7 days; or ceftriaxone, 250 mg in a single intramuscular dose (Workowski, 2015).

HUMAN PAPILLOMAVIRUS

This is a common STD, and more than 40 types infect the genital tract. In the United States from 2005 to 2006, the overall HPV prevalence was 40 percent in females aged 14 to 59 years (Liu, 2016). Prevalence is highest in younger women, and some of this seroprevalence now reflects HPV vaccination in this age group (Brouwer, 2015). Most reproductive-aged women become infected within a few years of becoming sexually active, and most infections are asymptomatic and transient. High-risk types are those with the most oncogenic potential. Of these, HPV types 16 and 18 are often associated with dysplasia (Chap. 63, Epithelial Neoplasia). Mucocutaneous external genital warts termed condyloma acuminata are usually caused by types 6 and 11.

For unknown reasons, genital warts frequently increase in number and size during pregnancy. These lesions may sometimes grow to fill the vagina or cover the perineum, thus making vaginal delivery or episiotomy difficult. Maternal HPV infection does not appear to be related to preterm labor (Subramaniam, 2016).

Condyloma Acuminata Treatment

Genital wart eradication during pregnancy is usually not necessary unless they are symptomatic. Therapy is directed toward debulking symptomatic warts yet minimizing treatment toxicity to the mother and fetus. Several agents are available, but no definitive evidence supports superiority of one over another (Workowski, 2015). Response to treatment during pregnancy may be incomplete, but lesions frequently improve or regress rapidly following delivery.

Trichloroacetic or bichloracetic acid, 80- to 90-percent solution, applied topically weekly, is an effective regimen for external warts. Some prefer *cryotherapy, laser ablation*, or *surgical excision*. Agents not recommended in pregnancy because of concerns for maternal and fetal safety include podophyllin resin, podofilox solution or gel, imiquimod cream, and sinecatechins.

There are three vaccines available for long-term prevention. Gardasil (HPV4) is a quadrivalent vaccine against HPV types 6, 11, 16, and 18. This is being replaced by Gardasil 9 (HPV9), a nonavalent vaccine that protects against all the types in HPV4 plus types 31, 33, 45, 52, and 58. Cervarix (HPV2) is a bivalent vaccine against HPVs 16 and 18. One of these vaccines is selected and given as a three-dose series on a schedule of 0, 1–2, and 6 months for those aged 15 to 26 years. A two-dose regimen, given at 0 and again at 6 to 12 months, is now recommended for girls aged 9 to 14 years (Meites, 2016). Vaccines are licensed for females aged 9 to 26 years, and the target age is 11 to 12 years. The vaccines are not recommended for pregnant women, however, inadvertent exposures do occur. No adverse pregnancy outcomes are associated with the vaccines (Moreira, 2016; Panagiotou, 2015; Vichnin, 2015). If a woman is found to be pregnant after starting the vaccination series, the remaining doses are delayed and given after delivery (American College of Obstetricians and Gynecologists, 2017a). Women who are breastfeeding may receive the vaccine.

Neonatal Infection

Vertical transmission rates of HPV to the newborn are minimal. Juvenile-onset recurrent respiratory papillomatosis (JoRRP) is a rare, benign neoplasm of the larynx. It can cause hoarseness and respiratory distress in children and is most often caused by HPV 6 or 11. Risks for infection are maternal genital HPV infection and longer labors (Niyibizi, 2014). Many newborns are likely exposed to HPV, but few develop JoRRP (Silverberg, 2003; Smith, 2004; Tenti, 1999). For example, the national incidence of JoRRP in 2006 in the United States ranged from 0.5 to 1 per 100,000 children (Marsico, 2014).

The benefit of cesarean delivery to decrease transmission risk is unknown, and thus it is currently not recommended solely to prevent HPV transmission (Workowski, 2015). HPV vaccination may ultimately decrease JoRRP rates in the future (Matys, 2012).

VAGINITIS

Pregnant women frequently develop increased vaginal discharge. This may be a physiological discharge, described in Chapter 4 (Cervix), but should be differentiated from symptomatic vaginitis, which is also common in pregnancy. Fortunately, vaginitis is prevented in part by normal vaginal flora. To better

understand this, studies of the composition and function of the normal vaginal microflora are currently underway with the Vaginal Human Microbiome Project (Huang, 2014).

Bacterial Vaginosis

Diagnosis

Not an infection in the ordinary sense, bacterial vaginosis (BV) is a maldistribution of normal vaginal flora. With BV, numbers of lactobacilli are decreased, and anaerobic bacteria species are overrepresented. These anaerobes include *Gardnerella, Prevotella, Mobiluncus,* and *Bacteroides* species; *Atopobium vaginae*; and BV-associated bacteria, provisionally named BVAB1, BVAB2, and BVAB3. These last three are newly recognized bacteria found in women with BV (Fredricks, 2005).

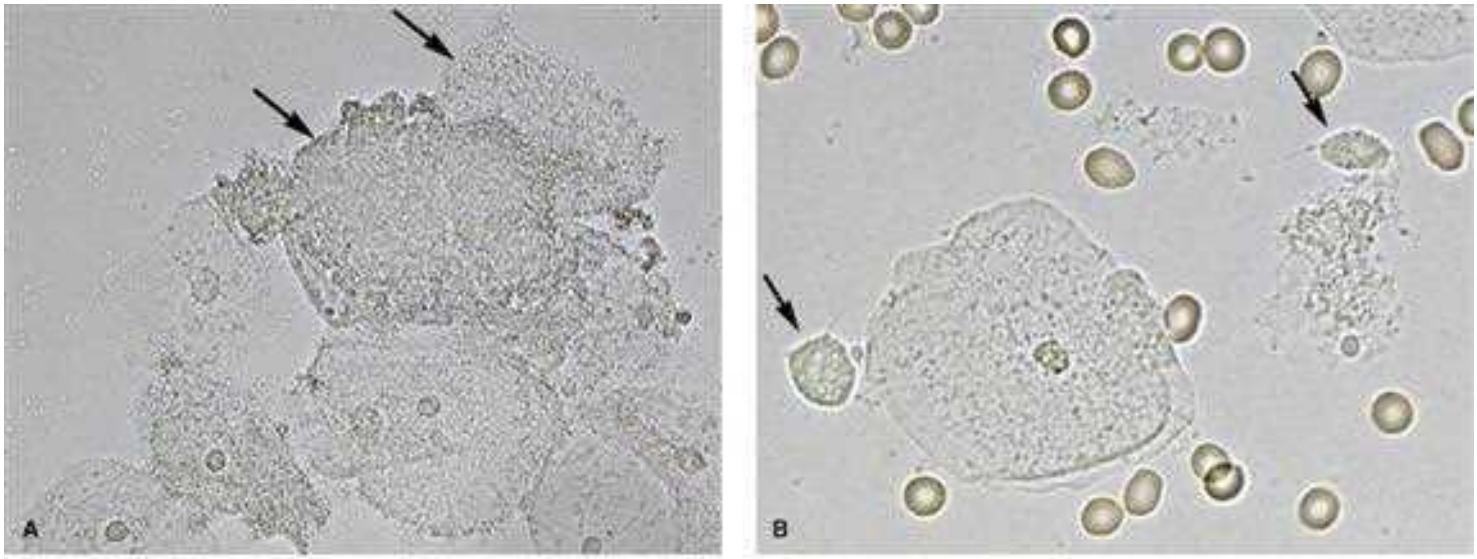
Molecular ribosomal RNA gene sequencing techniques have greatly aided this understanding of the vaginal flora, also called the *vaginal microbiota*. Five types of vaginal microbiota exist, referred to as *community state types (CSTs)*. And, a woman can be categorized to one of these five CSTs based on her vaginal microbiota composition (Ravel, 2011). Researchers have begun to quantify the risk of BV by these CST groups. Specifically, CSTs I, II, III, and V are rich in lactobacilli. In contrast, CST IV is a heterogeneous microbiota of strict anaerobes and is associated with BV. CSTs vary racially, and CST IV is also the most common in asymptomatic, healthy black women (Fettweis, 2014). Pregnancy-related changes in vaginal microbiota are also being defined and may hold keys to adverse BV-related pregnancy outcomes, discussed subsequently (Romero, 2014).

Of childbearing-aged women in the United States, nearly 30 percent have BV. In black women, the prevalence approximates 50 percent (Allsworth, 2007). Most women are asymptomatic, but a foul, thin vaginal discharge is a typical complaint. Associated risk factors are douching, multiple partners, smoking, and altered host immunity (Desseauve, 2012; Koumans, 2007; Murphy, 2016).

For clinical diagnosis of BV, three of the four following criteria are present: (1) vaginal pH >4.5; (2) a thin, milky, noninflammatory vaginal discharge; (3) >20 percent clue cells seen microscopically; and (4) a fishy odor after addition of 10-percent potassium hydroxide to vaginal secretion samples (Amsel, 1983). The last is described as a positive “whiff test.” Likewise, alkalinity of seminal fluid and blood are responsible for foul-odor complaints after intercourse and with menses in affected women. Clue cells are vaginal epithelial cells containing many attached bacteria, which create a poorly defined stippled cellular border (Fig. 65-6). The higher vaginal pH stems from diminished acid production by lactobacilli. Similarly, *Trichomonas vaginalis* infection is also associated with anaerobic overgrowth and resultant elaborated amines. Thus, women diagnosed with BV should have no microscopic evidence of trichomoniasis (see Fig. 65-6).

FIGURE 65-6

A. Bacterial vaginosis. Microscopy reveals several squamous cells heavily studded with bacteria. Clue cells are covered to the extent that cell borders are blurred and nuclei are not visible (*arrows*). **B.** Trichomonads (*arrows*). (Reproduced with permission from McCord E, Rahn DD, Hoffman BL: Gynecologic infection. In Hoffman BL, Schorge JO, Bradshaw KD, et al (eds): Williams Gynecology, 3rd ed. New York, McGraw Hill Education, 2016. Photo contributors: Lauri Campagna and Mercedes Pineda, WHNP.)



The Nugent score, used primarily in research studies rather than clinical practice, is a system employed for diagnosing BV (Nugent, 1991). During microscopic examination of a gram-stained vaginal discharge smear, scores are calculated by assessing bacteria staining and morphology.

Treatment

Several adverse pregnancy-related health outcomes associated with BV are preterm birth, premature rupture of the membranes, and postpartum endometritis (Hillier, 1995; Leitich, 2003; Watts, 1990). It also increases susceptibility to STDs, including HIV (Atashili, 2008; Brotman, 2010). For women at low risk for preterm birth, however, treatment of BV does not reduce preterm birth rates (Brocklehurst, 2013; Carey, 2000). For high-risk women, evidence is conflicting. Currently, the American College of Obstetricians and Gynecologists (2016c), CDC, and U.S. Preventive Services Task Force do not recommend routine BV screening of asymptomatic gravidas—at either high or low risk for preterm delivery—to prevent preterm birth (Nygren, 2008; Workowski, 2015).

Treatment is reserved for symptomatic women. Preferred drugs are metronidazole, 500 mg twice daily orally for 7 days; metronidazole 0.75-percent gel, one applicator intravaginally, daily for 5 days; or clindamycin 2-percent cream, one applicator intravaginally nightly for 7 days. Alternatives are clindamycin, 300 mg orally twice daily for 7 days, or 100-mg clindamycin ovules placed intravaginally nightly for 3 days (Workowski, 2015). It is still debated whether BV is a sexually transmitted infection. But, treatment of a male partner does not appear to lower recurrence rates (Amaya-Guio, 2016).

Trichomoniasis

Diagnosis

Vaginitis caused by *Trichomonas vaginalis* is common, and its prevalence in the United States approximates 3 percent in nonpregnant and pregnant women (Allsworth, 2009; Satterwhite, 2013). The prevalence is higher in those older than 30 years compared with younger women. Risks include black race, douching, and greater number of lifetime sexual partners (Sutton, 2007). Among women, frequent sites of infection include the urethra, endocervix, and vagina. Symptomatic vaginitis is characterized by yellow purulent discharge, pruritus, vulvovaginal erythema, and colpitis macularis, which is often termed a "strawberry cervix" and reflects a patchy, maculoerythematous ectocervix (Wølner-Hanssen, 1989).

Trichomonads are flagellated, pear-shaped, motile organisms that are somewhat larger than leukocytes. These parasites can readily be seen microscopically moving briskly in a sample mixed on a slide with saline. Prompt inspection of vaginal secretions is advantageous because trichomonads slow with cooling. At times, *T vaginalis* may be found incidentally on a Pap test slide. Both of these microscopic slide tests have low diagnostic sensitivity that approximates only 60 percent (Krieger, 1988; Wiese, 2000). And, Pap tests can yield false-positive results. Thus, Pap test trichomonad findings warrant wet-prep microscopy or other diagnostic confirmation (American College of Obstetricians and Gynecologists, 2017c). Of other tests, culture is expensive, lengthy, and sensitivities are 75 to 95 percent (Association of Public Health Laboratories, 2016; Huppert, 2007). Laboratory NAAT analysis of a vaginal, endocervical, or urine sample is available, is completed in minutes to hours, and offers superior sensitivity of 95 to 100 percent (Schwebke, 2011; Van Der Pol, 2014). Rapid POC testing is also available but may sacrifice sensitivity for speed. The OSOM Trichomonas Rapid Test provides results in 10 minutes, is suitable for office use, and has sensitivities of 88 to 98 percent (Herbst de Cortina, 2016).

Treatment

Metronidazole, administered orally in a single 2-g dose, is effective in eradicating *T vaginalis.* For those with HIV infection, treatment instead with metronidazole 500 mg orally twice daily for 7 days improves efficacy. Because of the high rate of reinfection among women treated for trichomoniasis, retesting for *T vaginalis* is recommended for all sexually active women within 3 months following initial treatment (Workowski, 2015).

Metronidazole, an FDA category B drug, is not teratogenic or fetotoxic, but has displayed some tumorigenicity in animal studies (Briggs, 2015; Czeizel, 1998). For this reason, the manufacturer recommends against its use during the first trimester (Pfizer, 2016). Fewer data are available for tinidazole, which is a category C drug, and thus metronidazole is preferred. Metronidazole and tinidazole have similar chemical structures, and those allergic to metronidazole may also react to tinidazole. For allergic patients, metronidazole desensitization is effective, and one scheme is outlined in the study by Helms and coworkers (2008). With postpartum breastfeeding, feeds are delayed for 24 hours following the last oral metronidazole dose per manufacturer prescribing information. For tinidazole, the delay is 72 hours.

Perinatal transmission of trichomoniasis by direct contact in the birth canal is rare but may lead to neonatal respiratory or genital infection (Bruins, 2013; Trintis, 2010). Some studies have linked trichomonal infection with preterm birth. A few other studies implicate this infection with preterm premature rupture of membranes and small-for-gestational age newborns (Silver, 2014). However, treatment did not lower preterm birth rates in a randomized study by Klebanoff and colleagues (2001). Also, in this study, but not one by Mann and coworkers (2009), treatment for trichomoniasis was associated instead with a higher preterm birth rate.

In sum, treatment for symptomatic women is reasonable and outlined above. For most asymptomatic women during pregnancy, screening is not recommended. However, for pregnant women with HIV infection, screening at the first prenatal visit and prompt treatment are encouraged. This is because *T vaginalis* infection in pregnant women with HIV may be a risk factor for vertical HIV transmission (Gumbo, 2010; Workowski, 2015).

Candidiasis

Candida albicans or other candidal species can be identified by culture from the vagina during pregnancy in approximately 20 percent of women. A link between candidiasis and preterm birth is not robust (Cotch, 1998; Kiss, 2004; Roberts, 2015). Thus, asymptomatic colonization requires no treatment. The organism, however, can create an extremely profuse, irritating discharge.

For symptoms, effective treatment is a 100-mg miconazole vaginal suppository or a 2-percent butoconazole, 1-percent clotrimazole, 2-percent miconazole, or 0.4-percent terconazole cream, any of which is used daily for 7 days. A shorter, 3-day regimen is daily 2-percent clotrimazole, 4-percent miconazole, or 0.8-

percent tioconazole cream, or daily 200-mg miconazole or 80-mg terconazole suppository (Workowski, 2015). In some women, infection is likely to recur and require repeated treatment during pregnancy. In these cases, symptomatic infection usually subsides after pregnancy (Sobel, 2007). For treatment, the American College of Obstetricians and Gynecologists (2017c) and the CDC recommend topical rather than oral azoles for symptoms. As discussed further in Chapter 12 (Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs), oral fluconazole is generally not considered teratogenic, but in 2016, the FDA released a safety alert regarding a possible link with miscarriage (Mølgaard-Nielsen, 2016).

HUMAN IMMUNODEFICIENCY VIRUS

Etiopathogenesis and Epidemiology

Causative agents of acquired immunodeficiency syndrome (AIDS) are RNA retroviruses termed *human immunodeficiency viruses*, *HIV-1* and *HIV-2*. Most cases worldwide are caused by HIV-1 infection. Sexual intercourse is the major mode of transmission. The virus also is passed by blood, and infected mothers may infect their fetuses during labor and delivery or by breast milk. The primary determinant of transmission is the plasma HIV-1 viral load.

For sexual transmission, the viral HIV envelope binds to mucosal dendritic cells. These cells then present the viral particle to specific T lymphocytes. These lymphocytes are defined phenotypically by their *cluster of differentiation 4 (CD4)* glycoprotein surface antigens. The CD4 site serves as a receptor for the virus. Once infected, CD4 T lymphocytes may die, and the common denominator of clinical illness with AIDS is profound immunodeficiency that gives rise to various opportunistic infections and neoplasms.

In the United States, the CDC (2016c) estimated that more than 1.2 million individuals were infected in 2013, and new cases numbered more than 39,000. Approximately 8500 women with HIV give birth annually in the United States. However, the estimated number of perinatally acquired HIV cases has decreased dramatically, and the perinatal transmission rate in 2013 was 1.8 percent (Centers for Disease Control and Prevention, 2016b, 2017). This is predominantly due to the implementation of prenatal HIV testing and antiretroviral therapy (ART) for the woman and then her neonate.

Clinical Manifestations

The incubation period from exposure to clinical disease averages 3 to 6 weeks. Acute HIV infection is similar to many other viral syndromes and usually lasts less than 10 days. Common symptoms, if any, include fever, fatigue, rash, headache, lymphadenopathy, pharyngitis, myalgias, nausea, and diarrhea. After symptoms abate, the level of viremia usually decreases to a set point, and patients with the highest viral burden at this time progress more rapidly to AIDS and death (Fauci, 2007). According to the CDC, AIDS is defined by a CD4 T-cell count <200 cells/μL, by CD4 T-cells comprising <14 percent of all lymphocytes, or one of several AIDS-defining illnesses (Schneider, 2008; Selik, 2014). Route of infection, the pathogenicity of the infecting viral strain, the initial viral inoculum, and the immunological status of the host all affect the rapidity of progression.

Prenatal HIV Screening

The CDC (2006b) and the American College of Obstetricians and Gynecologists (2016e) recommend prenatal HIV screening using an *opt-out approach*. This means that a woman is notified that HIV testing is included in a comprehensive set of antenatal tests, but that testing may be declined. Women are given information regarding HIV but are not required to sign a specific consent. Through the use of such opt-out strategies, HIV testing rates have increased. Specific state laws concerning screening vary and can be found at: www.cdc.gov/hiv/policies/law/states/testing.html.

Repeat testing during the third trimester, preferably before 36 weeks' gestation, is *considered* for all pregnant women. Retesting is *recommended* for those at risk for acquiring HIV or for women in high-risk areas, namely, those with rates of HIV infection of 1 per 1000 pregnant women screened (Workowski, 2015). At-risk factors include injection drug use, prostitution, a suspected or known HIV-infected sexual partner, multiple sexual partners, or a diagnosis of another STD (American College of Obstetricians and Gynecologists, 2016e).

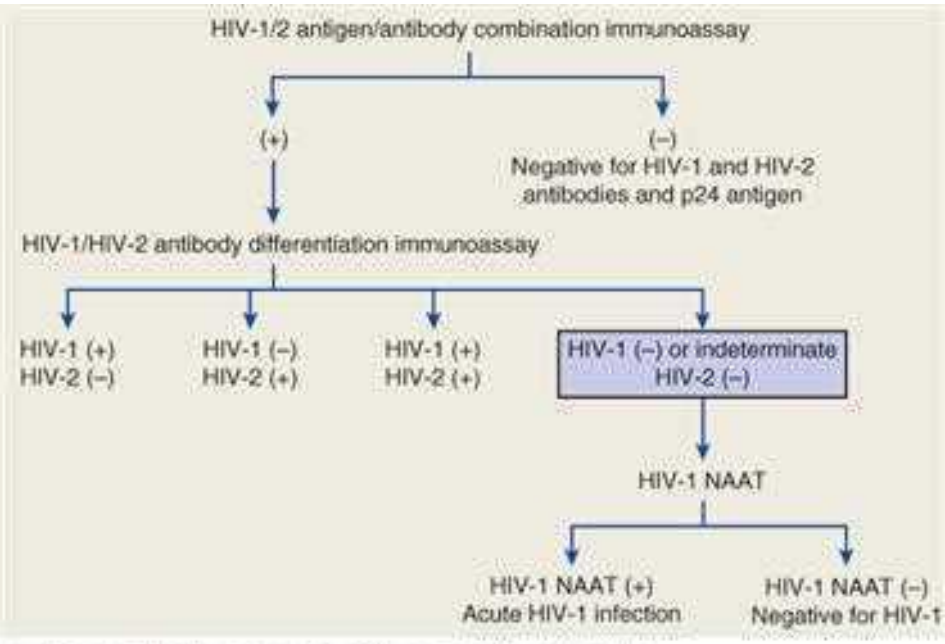
The initial laboratory screening test for HIV is an antigen/antibody combination immunoassay that detects antibodies against HIV-1 and HIV-2 and detects HIV-1 p24 antigen (Centers for Disease Control and Prevention, 2014). Antibody can be detected in most patients within 1 month of infection, and thus, antibody serotesting may not exclude early infection. Instead, for acute primary HIV infection, identification of viral p24 core antigen or viral RNA is possible. No further testing is required for specimens that are negative on the initial immunoassay unless a known exposure to HIV has occurred.

As shown in Figure 65-7, specimens with a "reactive" (that is, a positive) antigen/antibody combination immunoassay result should be tested with an antibody immunoassay that differentiates HIV-1 antibodies from HIV-2 antibodies. The HIV-1/HIV-2 antibody differentiation immunoassay is resulted as positive or negative for HIV-1 antibodies, for HIV-2 antibodies, or for HIV antibodies, undifferentiated. If these two serial immunoassays are discordant, an HIV-1 NAAT—qualitative or quantitative HIV RNA test—is performed (Centers for Disease Control and Prevention, 2014).

FIGURE 65-7

Algorithm for HIV testing. In the pathway colored light-blue, for specimens that are reactive on the initial antigen/antibody combination immunoassay and nonreactive or indeterminate on the HIV-1/HIV-2 antibody differentiation immunoassay, a nucleic acid amplification test (NAAT) is implemented. A positive HIV-1 NAAT result and nonreactive HIV-1/HIV-2 antibody differentiation immunoassay result indicate laboratory evidence for acute HIV-1 infection. A positive HIV-1 NAAT result and indeterminate HIV-1/HIV-2 antibody differentiation immunoassay result indicate the presence of HIV-1 infection confirmed by HIV-1

NAAT. A negative HIV-1 NAAT result and nonreactive or indeterminate HIV-1/HIV-2 antibody differentiation immunoassay result indicate a false-positive result on the initial antigen/antibody combination immunoassay. (Reproduced with permission from Centers for Disease Control and Prevention, 2014.)



Women with undocumented HIV status at delivery should have a fourth-generation HIV antigen/antibody combination screening test performed on a blood sample. A negative screening test result does not need confirmation. However, in cases of recent HIV exposure, consideration is given to peripartum interventions to reduce perinatal transmission despite negative HIV testing. Repeat interval testing is recommended to exclude very early infection not identified with the initial screen. With a positive fourth-generation HIV testing result, peripartum and neonatal interventions to reduce perinatal transmission are initiated. This includes avoidance of breastfeeding, although breast milk may be stored until confirmatory test results are available. Interventions can be discontinued if confirmatory testing is negative. To confirm a positive result from any initial HIV test, the laboratory testing algorithm in Figure 65-7 should be used and begins with the antigen/antibody combination immunoassay.

Vertical Transmission

Viral burden and neonatal infection rates are directly related. In one cohort, neonatal infection was 1 percent with <400 copies/mL, and it was 23 percent when maternal viral RNA levels were >30,000 copies/mL (Cooper, 2002). Among 2615 infants born to mothers taking ART before conception and during pregnancy, there were no cases of vertical transmission with maternal viral loads <50 copies/mL at delivery (Mandelbrot, 2015). Transmission of HIV infection, however, has been observed at all HIV RNA levels, including those that were nondetectable by current assays. Transplacental HIV transmission can occur early, and the virus has even been identified in specimens from elective abortion (Lewis, 1990). Kourtis and colleagues (2001) estimated that 20 percent of vertical transmission occurs before 36 weeks' gestation, 50 percent in the days before delivery, and 30 percent intrapartum. Transmission rates for breastfeeding may be as high as 30 to 40 percent and are associated with increasing HIV viral burden (Kourtis, 2006, 2007; Slyker, 2012). In nonpregnant individuals, concomitant STDs and horizontal HIV transmission are linked. Evidence also supports that vertical transmission rates may be increased by comorbid STDs (Schulte, 2001; Watts, 2012).

Antepartum Care

Pregnant women with HIV infection need special attention and are seen in consultation by physicians with special interest in this field. An additional resource is the National Perinatal HIV Hotline (1–888–448–8765), which is a federally funded service that provides free antepartum, intrapartum, or postpartum consultation to providers. At Parkland Hospital, an HIV-infected pregnant woman is initially assessed with the following:

Standard prenatal laboratory surveys that include serum creatinine, complete blood count, and bacteriuria screening

Plasma HIV RNA quantification—"viral load"—CD4 T-cell count, and antiretroviral resistance testing

Serum hepatic aminotransferase levels

HSV-1 and 2, cytomegalovirus, toxoplasmosis, and hepatitis B and C serological screening

Baseline chest radiograph

Tuberculosis testing with purified protein derivative (PPD) skin testing, or interferon-gamma release assay

Evaluation of need for pneumococcal, hepatitis A, hepatitis B, Tdap, and influenza vaccines

Sonographic evaluation to establish gestational age.

During pregnancy, the risk of HIV transmission does not appear to be increased with amniocentesis or other invasive diagnostic procedures in women receiving effective ART resulting in viral suppression (Floridia, 2017). For women not receiving ART, the risk rises approximately twofold (Mandelbrot, 1996). If amniocentesis is performed, efforts are taken to avoid passing through the placenta (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2016).

Antiretroviral Therapy

In overview, the ideal strategy to suppress viral load and minimize vertical HIV transmission includes: (1) preconceptional ART, (2) antepartum ART, (3) intrapartum continuation of the antepartum oral ART regimen plus IV zidovudine, and (4) newborn ART prophylaxis. ART is recommended for all HIV-infected pregnant women, and it should be initiated as early in pregnancy as possible. Treatment reduces the risk of perinatal transmission regardless of CD4 T-cell count or HIV RNA level. Adherence is essential because the risk of viral drug resistance is lessened. As for nonpregnant adults, pregnant women are treated with at least three antiviral agents.

The Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission (2016) has issued guidelines for four different scenarios during pregnancy (Table 65-5).

TABLE 65-5

Recommendations for HIV Antiviral Drug Use During Pregnancy

Clinical Scenario	Recommendations
Taking ART and becomes pregnant	Continue current medication if viral suppression adequate and patient tolerating
ART naïve	Initiate ART: combine two NRTIs with either a ritonavir-boosted PI or an integrase inhibitor – Preferred NRTI dual combinations: abacavir/lamivudine, tenofovir disoproxil fumarate (TDF)/emtricitabine, or TDF/lamivudine. If abacavir is used, HLA-B*5701 testing is completed to identified potential hypersensitivity reaction – Preferred PI: atazanavir/ritonavir or darunavir/ritonavir – Preferred integrase inhibitor: raltegravir
Prior ART use but not currently	Initiate ART with regimen based on prior therapy history and resistance testing
No ART use and presents in labor	IV ZDV (see Intrapartum Care)
Antepartum care	See antepartum screening test list (Delivery Planning)
	ART should be initiated as early as possible
	For those with HIV RNA levels >500–1000 copies/mL, order HIV antiretroviral drug-resistance testing but do not delay ART initiation awaiting results
	Repeat HIV RNA levels 2–4 weeks after initiating (or changing) ART drugs; monthly until RNA levels are undetectable; then at least every 3 mo; and finally at 34–36 weeks' gestation for delivery planning
	CD4+ count should be monitored at the initial visit and every 3–6 mo
Intrapartum care	If HIV RNA level >1000 copies/mL or is unknown before labor or ROM, plan cesarean delivery at 38 weeks' gestation
	If HIV RNA levels >1000 or is unknown but labor or ROM has ensued, benefits of cesarean delivery are unclear and labor plans are individualized
	If HIV RNA level ≤1000 copies/mL, vaginal delivery is permitted; cesarean delivery not routinely recommended
	Start IV ZDV if HIV RNA level >1000 copies/mL near delivery or is unknown. Dosing is 2 mg/kg IV load over 1 hr, then 1 mg/kg/hr until delivery. IV ZDV should begin 3 hr before scheduled cesarean delivery
	Those taking oral antepartum ART should take this during labor with sips of water

ART = antiretroviral therapy; NRTI = nucleoside reverse transcriptase inhibitor; ROM = rupture of membranes; ZDV = zidovudine.

Adapted from the Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2016. Department of Health and Human Services.

The following paragraphs summarize these recommendations. First, women already taking ART at pregnancy onset are encouraged to continue the regimen if viral suppression is adequate. Didanosine, stavudine, and full-dose ritonavir, which differs from ritonavir-boosted agents, are exceptions due to pregnancy toxicity but not teratogenicity.

Second, women who have never received antiretroviral therapy—*antiretroviral naïve*—are given ART regardless of trimester. In general, the starting regimen comprises two nucleoside reverse transcriptase inhibitors plus either a ritonavir-boosted protease inhibitor or an integrase inhibitor.

Third, women who have previously received antiretroviral therapy but are currently not taking medications should undergo HIV resistance testing because prior ART use raises their risk of drug resistance. Typically, ART is initiated prior to receiving results of these drug-resistance tests. In this case, initial ART

selection should factor results of prior resistance testing, if available; prior ART regimen; and current ART pregnancy guidelines, that is, those for ART-naïve women. Drug-resistance testing may then modify the initial regimen.

For these three categories of women taking antepartum ART, therapy surveillance is outlined in Table 65-5. Most patients with adequate viral response have at least a 1-log viral load decline within 1 to 4 weeks after starting therapy. For those who fail to achieve this decline, options include review of drug resistance study results, confirmation of regimen compliance, and ART modification.

During labor and delivery, oral medications can be taken with sips of water. Additionally, IV zidovudine is given to women with an HIV RNA viral load >1000 copies/mL or who have an unknown viral load near delivery. At Parkland Hospital, we administer intrapartum IV zidovudine to all HIV-positive women, regardless of viral load. A 2 mg/kg load is infused over 1 hour followed by zidovudine 1 mg/kg/hr until delivery. In this instance, for gravidas already taking antepartum oral zidovudine, their oral dose can be held, and IV drug is instead administered. HIV-infected women undergoing a scheduled cesarean delivery are given IV zidovudine as a loading dose followed by 2 more hours of continuous maintenance therapy—a total of 3 hours of infused zidovudine.

The fourth group includes women who present in labor and who are taking no medications. These women are given IV zidovudine intrapartum as just described.

Delivery Planning

During labor, artificial membrane rupture, fetal scalp electrode placement, episiotomy, and operative vaginal delivery are reserved for clear obstetrical indications (Mandelbrot, 1996; Peters, 2016). Labor augmentation is used when needed to shorten the interval to delivery to further lower the transmission risk. Delayed cord clamping in preterm neonates is acceptable. Neuraxial analgesia is suitable. Postpartum hemorrhage is best managed with oxytocin and prostaglandin analogues. *Methylergonovine (Methergine) and other ergot alkaloids adversely interact with reverse transcriptase and protease inhibitors to cause severe vasoconstriction.*

In some cases, cesarean delivery lowers HIV prenatal transmission (European Mode of Delivery Collaboration, 1999; International Perinatal HIV Group, 1999). The American College of Obstetricians and Gynecologists (2017b) recommends that scheduled cesarean delivery be discussed and recommended for HIV-infected women with HIV-1 RNA loads >1000 copies/mL. Scheduled delivery is recommended at 38 weeks' gestation in these women to avert spontaneous labor.

For women with HIV RNA levels ≤1000 copies/mL, data are insufficient to predict similar benefits, and scheduled cesarean delivery is unlikely to confer additional risk reduction for women already taking ART and achieving viral suppression (Briand, 2013; Jamieson, 2007; Read, 2005). Vaginal delivery in this group may be elected. However, if cesarean delivery is instead chosen for a well-counseled woman in this group, it should be performed at 39 weeks. Similarly, cesarean delivery performed for obstetrical indications in this lower-viral-load group should be done at 39 weeks when possible.

Postpartum Care

Vertical transmission is increased by breastfeeding, and it generally is not recommended for HIV-positive women in the United States, where formula is readily available (Read, 2003). In nutritionally deprived countries, where infectious disease and malnutrition are primary causes of infant death, the World Health Organization (2016) recommends exclusive breastfeeding during the first 6 to 12 months.

The Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission (2016) strongly recommends that ART regimens not be discontinued postpartum but continued lifelong for the advantages of viral suppression. Ideally, all those planning pregnancy should be receiving ART and have a plasma viral load below detectable levels before conception. As one benefit, interpregnancy viral load suppression is associated with less vertical transmission in a subsequent pregnancy (French, 2014; Mandelbrot, 2015; Stewart, 2014; Townsend, 2014). Reassuringly, for those seeking subsequent pregnancy, when ART is available, repeated pregnancy in a healthy woman with HIV has no significant effect on disease progression (Calvert, 2015). Linkage to general HIV care postpartum is critical to maintain viral suppression (Swain, 2016).

For women who do not have HIV infection, but whose partner is seropositive, current guidance supports the use of highly active antiretroviral therapy with viral suppression in the infected partner (treatment as prevention), and consideration of antiretroviral preexposure prophylaxis (PreP) for the HIV-negative partner. The well-counseled couple can consider periovulatory condomless intercourse, or uterine insemination or in vitro fertilization after sperm washing for assisted conception (Brooks, 2017; Kawwass, 2017).

If, instead, pregnancy is undesired, effective contraception is discussed (Chap. 38, Introduction). Counseling also includes education for decreasing high-risk sexual behaviors to prevent transmission and to decrease other STD acquisition. Similarly, women with HIV have unique gynecological issues, such as genital neoplasia, which require special attention (American College of Obstetricians and Gynecologists, 2016a; Werner, 2016).

APPENDIX I: Serum and Blood Constituents

HEMATOLOGY					
	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Erythropoietin[b] (U/L)	4–27	12–25	8–67	14–222	7, 10, 47
Ferritin[b] (ng/mL)	10–150d	6–130	2–230	0–116	7, 10, 39, 42, 45, 47, 62, 70
Folate, red blood cell (ng/mL)	150–450	137–589	94–828	109–663	45, 46, 72
Folate, serum (ng/mL)	5.4–18.0	2.6–15.0	0.8–24.0	1.4–20.7	7, 43, 45, 46, 53, 58, 72
Haptoglobin (mg/mL)	25–250	130 ± 43	115 ± 50	135 ± 65	26A
Hemoglobin[b] (g/dL)	12–15.8d	11.6–13.9	9.7–14.8	9.5–15.0	10, 45, 47, 58, 62
Hematocrit[b] (%)	35.4–44.4	31.0–41.0	30.0–39.0	28.0–40.0	6, 7, 10, 42, 45 58, 66
Iron, total binding capacity (TIBC)[b] (µg/dL)	251–406	278–403	Not reported	359–609	62
Iron, serum[b] (µg/dL)	41–141	72–143	44–178	30–193	10, 62
Mean corpuscular hemoglobin (MCH) (pg/cell)	27–32	30–32	30–33	29–32	42
Mean corpuscular volume (MCV) (×m^3)	79–93	81–96	82–97	81–99	6, 42, 45, 58
Platelet (×10^9/L)	165–415	174–391	155–409	146–429	4, 6, 16, 42, 45
Mean platelet volume (MPV) (μm^3)	6.4–11.0	7.7–10.3	7.8–10.2	8.2–10.4	42

HEMATOLOGY					
	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Red blood cell count (RBC) ($\times 10^6/mm^3$)	4.00–5.20[d]	3.42–4.55	2.81–4.49	2.71–4.43	6, 42, 45, 58
Red cell distribution width (RDW) (%)	<14.5	12.5–14.1	13.4–13.6	12.7–15.3	42
White blood cell count (WBC) ($\times 10^3/mm^3$)	3.5–9.1	5.7–13.6	5.6–14.8	5.9–16.9	6, 9, 42, 45, 58
Neutrophils ($\times 10^3/mm^3$)	1.4–4.6	3.6–10.1	3.8–12.3	3.9–13.1	4, 6, 9, 42
Lymphocytes ($\times 10^3/mm^3$)	0.7–4.6	1.1–3.6	0.9–3.9	1.0–3.6	4, 6, 9, 42
Monocytes ($\times 10^3/mm^3$)	0.1–0.7	0.1–1.1	0.1–1.1	0.1–1.4	6, 9, 42
Eosinophils ($\times 10^3/mm^3$)	0–0.6	0–0.6	0–0.6	0–0.6	6, 9
Basophils ($\times 10^3/mm^3$)	0–0.2	0–0.1	0–0.1	0–0.1	6, 9
Transferrin (mg/dL)	200–400[c]	254–344	220–441	288–530	39, 42
Transferrin, saturation without iron (%)	22–46[b]	Not reported	10–44	5–37	47
Transferrin, saturation with iron (%)	22–46[b]	Not reported	18–92	9–98	47

COAGULATION

RENAL FUNCTION TESTS					
	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Effective renal plasma flow (mL/min)	492–696[d,e]	696–985	612–1170	595–945	19, 22
Glomerular filtration rate (GFR) (mL/min)	106–132[d]	131–166	135–170	117–182	19, 22, 50
Filtration fraction (%)	16.9–24.7[l]	14.7–21.6	14.3–21.9	17.1–25.1	19, 22, 50
Osmolarity, urine (mOsm/kg)	500–800	326–975	278–1066	238–1034	61
24–hr albumin excretion (mg/24 hr)	<30	5–15	4–18	3–22	27, 61
24–hr calcium excretion (mmol/24 hr)	<7.5[e]	1.6–5.2	0.3–6.9	0.8–4.2	66
24–hr creatinine clearance (mL/min)	91–130	69–140	55–136	50–166	22, 66
24–hr creatinine excretion (mmol/24 hr)	8.8–14[e]	10.6–11.6	10.3–11.5	10.2–11.4	61
24–hr potassium excretion (mmol/24 hr)	25–100[e]	17–33	10–38	11–35	66
24–hr protein excretion (mg/24 hr)	<150	19–141	47–186	46–185	27
24–hr sodium excretion (mmol/24 hr)	100–260[e]	53–215	34–213	37–149	17, 66

[a]Unless otherwise specified, all normal reference values are from the seventeenth edition of Harrison's Principles of Internal Medicine (37).

[b]Range includes references with and without iron supplementation.

[c]Reference values are from Laboratory Reference Handbook, Pathology Department, Parkland Hospital, 2005.

[d]Normal reference range is specific range for females.

[e]Reference values are from the 15th edition of Harrison's Principles of Internal Medicine (12).

[f]Range is for premenopausal females and varies by menstrual cycle phase.

[g]Reference values are from Cerneca et al: Coagulation and fibrinolysis changes in normal pregnancy increased levels of procoagulants and reduced levels of inhibitors during pregnancy induce a hypercoagulable state, combined with a reactive fibrinolysis (15).

[h]Reference values are from Cerneca et al and Choi et al: Tissue plasminogen activator levels change with plasma f-ibrinogen concentrations during pregnancy (15, 16).

[i]Reference values are from Mannucci et al: Changes in health and disease of the metalloprotease that cleaves von Willebrand factor (44A).

[j]Reference values are from Bacq et al: Liver function tests in normal pregnancy: a prospective study of 102 pregnant women and 102 matched controls (5).

[k]Reference values are from Leiserowitz et al: Creatine kinase and its MB isoenzyme in the third trimester and the -peripartum period (41).

[l]Reference values are from Dunlop: Serial changes in renal haemodynamics during normal human pregnancy (19).

Appendix courtesy of Dr. Mina Abbassi-Ghanavati and Dr. Laura G. Greer.

APPENDIX II: Maternal Echocardiographic Measurements

	Pregnancy			
Left Ventricle	**1st Trimester**	**2nd Trimester**	**3rd Trimester**	**Postpartum**
Geometry				
IVS_d (mm)	7.3 ± 1.0	7.4 ± 1.1	7.8 ± 1.2	7.1 ± 0.9
LVEDD (mm)	45–47.8	47–48.9	47–49.6	46–48.8
LVESD (mm)	28–30	29–30.1	30–30.8	28–30.6
PW_d	6.3 ± 0.7	6.6 ± 0.7	6.9 ± 1.0	6.1 ± 0.6
RWT	0.26–0.36	0.27–0.37	0.28–0.38	0.25–0.35
LV mass (g)	111–121	121–135	136–151	114–119
LV mass (g/m^2)	66 ± 13	70 ± 12	76 ± 16	67 ± 11
Systolic function				
FS (%)	37–38	76–78	80–85	67–69
SW thickening (%)	47 ± 17	53 ± 16	51 ± 15	54 ± 19
PW thickening (%)	66 ± 16	72 ± 16	74 ± 16	71 ± 14
VCFC (circ/sec)	1.15–0.3	1.18–0.16	1.18–0.12	1.18–0.12
ESS (g/cm^2)	59 ± 9	53 ± 11	52 ± 11	66 ± 12
Diastolic function				
Heart rate	75–76	76–78	80–85	67–69
Mitral E wave (m/sec)	0.85 ± 0.13	0.84 ± 0.16	0.77 ± 0.15	0.77 ± 0.11
Mitral A wave (m/sec)	0.5 ± 0.09	0.5 ± 0.1	0.55 ± 0.1	0.46 ± 0.1
Deceleration time (ms)	176 ± 44	188 ± 40	193 ± 33	201 ± 48

	Pregnancy			
Left Ventricle	**1st Trimester**	**2nd Trimester**	**3rd Trimester**	**Postpartum**
IVRT (ms)	90 ± 19	79 ± 18	72 ± 16	69 ± 10
E wave duration (ms)	263 ± 50	276 ± 43	282 ± 37	288 ± 48
E and A wave duration (ms)	454 ± 121	412 ± 79	375 ± 63	523 ± 88

Values are ranges or means ± SD.

Circ = circumference; d = diastolic; ESS = end-systolic wall stress; FS = fractional shortening; IVRT = isovolumic relaxation time; IVS_d = interventricular septum–diastole; LV = left ventricle; LVEDD = left ventricular end-diastolic dimension; LVESD = left ventricular end-systolic dimension; PW = posterior wall; RWT = relative wall thickening; SW = septal wall; VCFC = rate-adjusted mean velocity of circumferential fiber thickening.

Data from Savu (62A) and Vitarelli (71A).

APPENDIX III: Fetal Sonographic Measurements

TABLE III-1

Mean Gestational Sac Diameter and Crown-Rump Length and Corresponding Menstrual Age

Menstrual Age (day)	Menstrual Age (wk)	Gestational Sac Size (mm)	Crown-Rump Length (cm)
30	4.3		
32	4.6	3	
34	4.9	5	
36	5.1	6	
38	5.4	8	
40	5.7	10	0.2
42	6.0	12	0.35
44	6.3	14	0.5
46	6.6	16	0.7
48	6.9	18	0.9
50	7.1	20	1.0
52	7.4	22	1.2
54	7.7	24	1.4
56	8.0	26	1.6
58	8.3	27	1.8
60	8.6	29	2.0
62	8.9	31	2.2
64	9.1	33	2.4
66	9.4	35	2.6
68	9.7	37	2.9
70	10.0	39	3.1
72	10.3	41	3.4
74	10.6	43	3.7
76	10.9	45	4.0
78	11.1	47	4.2
80	11.4	49	4.6
82	11.7	51	5.0
84	12.0	53	5.4

Data from Nyberg, 1992; Hadlock, 1992; Robinson; 1975; Daya, 1991.

TABLE III-2

Mean Gestational Age Percentiles Corresponding to Crown-Rump Length (CRL) Measurements

CRL (mm)	Gestational Age (wk)			CRL (mm)	Gestational Age (wk)

Figure and Table Gallery

FIGURE 2-20

The four parent pelvic types of the Caldwell-Moloy classification. A line passing through the widest transverse diameter divides the inlets into posterior (P) and anterior (A) segments.

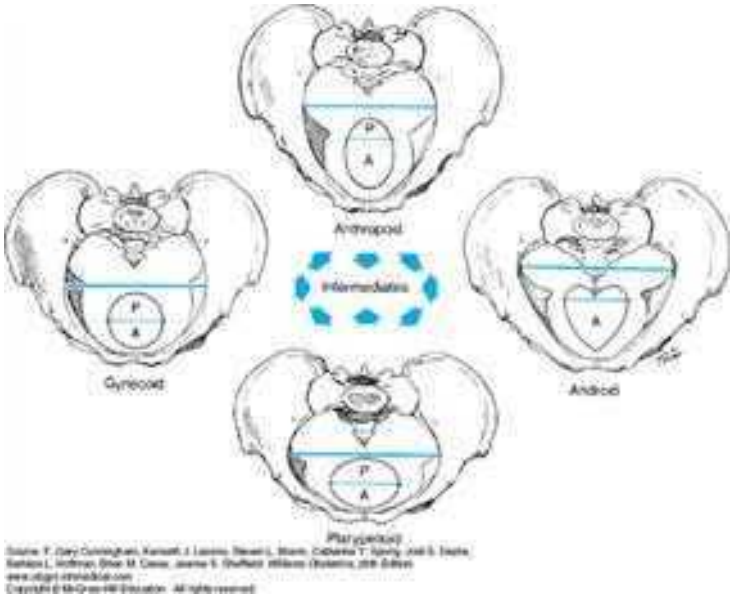

FIGURE 10-10

Alobar holoprosencephaly. **A.** Transverse cranial image of a 26-week fetus with alobar holoprosencephaly, depicting fused thalami (*Th*) encircled by a monoventricle (*V*). The midline falx is absent. **B.** In this profile view of the face and head, a soft tissue mass—a proboscis (*arrow*), protrudes from the region of the forehead.

FIGURE 10-12

Sacrococcygeal teratoma. Sonographically, this tumor appears as a solid and/or cystic mass that arises from the anterior sacrum and tends to extend inferiorly and externally as it grows. In this image, a 7 × 6 cm inhomogeneous solid mass is visible below the normal-appearing sacrum. There is also an internal component to the tumor.

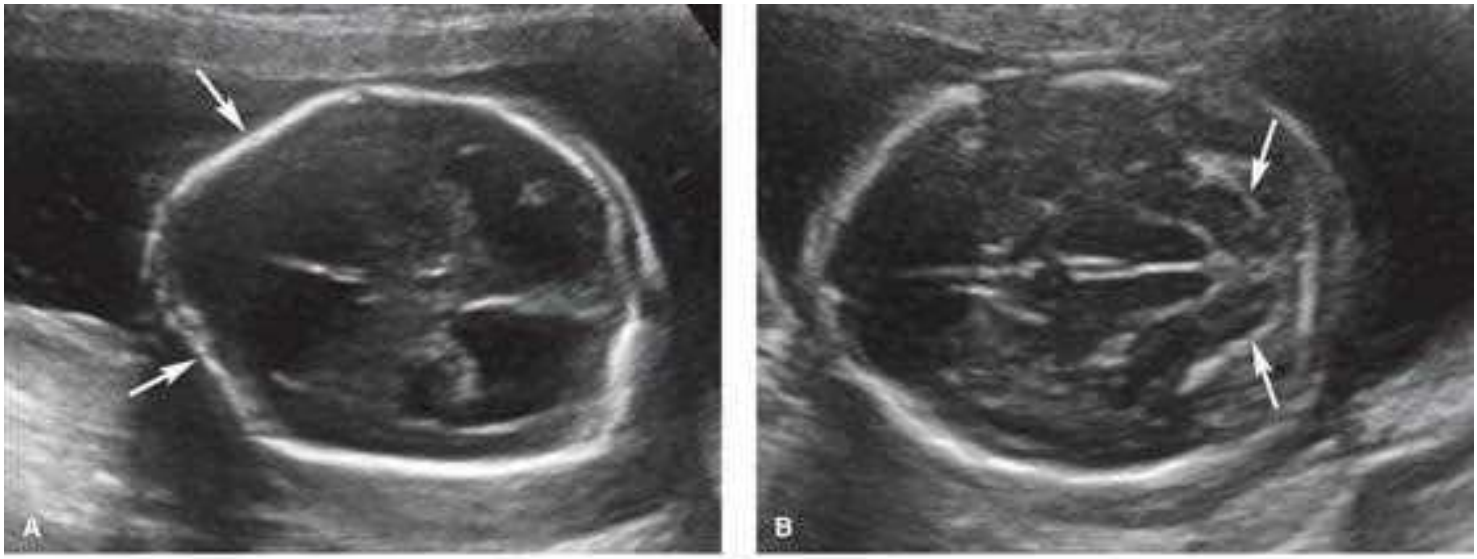

FIGURE 10-14

Fetal profile. **A.** This image depicts a normal fetal profile. **B.** This fetus has severe micrognathia, which creates a severely recessed chin.

FIGURE 10-16

Cystic hygromas. **A.** This 9-week fetus with a cystic hygroma (*arrow*) was later found to have Noonan syndrome. **B.** Massive multiseptated hygromas (*arrowheads*) in the setting of hydrops fetalis at 15 weeks.

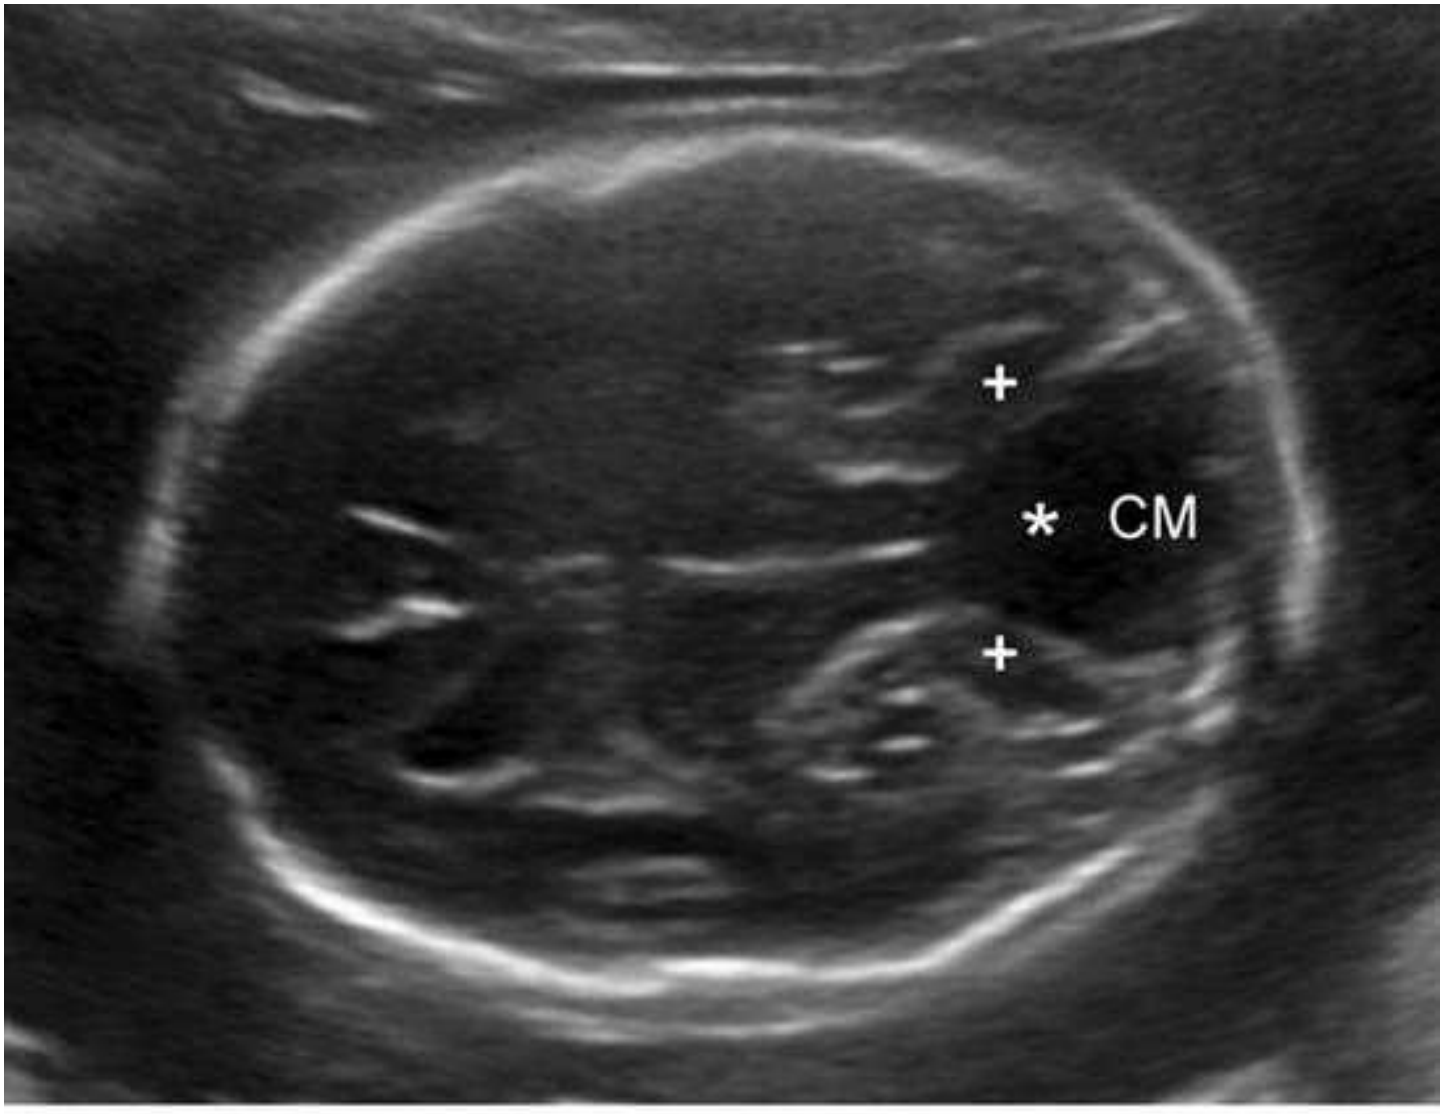

FIGURE 10-17

Congenital diaphragmatic hernia. In this transverse view of the thorax, the heart is shifted to the far right side of the chest by a left-sided diaphragmatic hernia containing stomach (S), liver (*L*), and bowel (*B*).

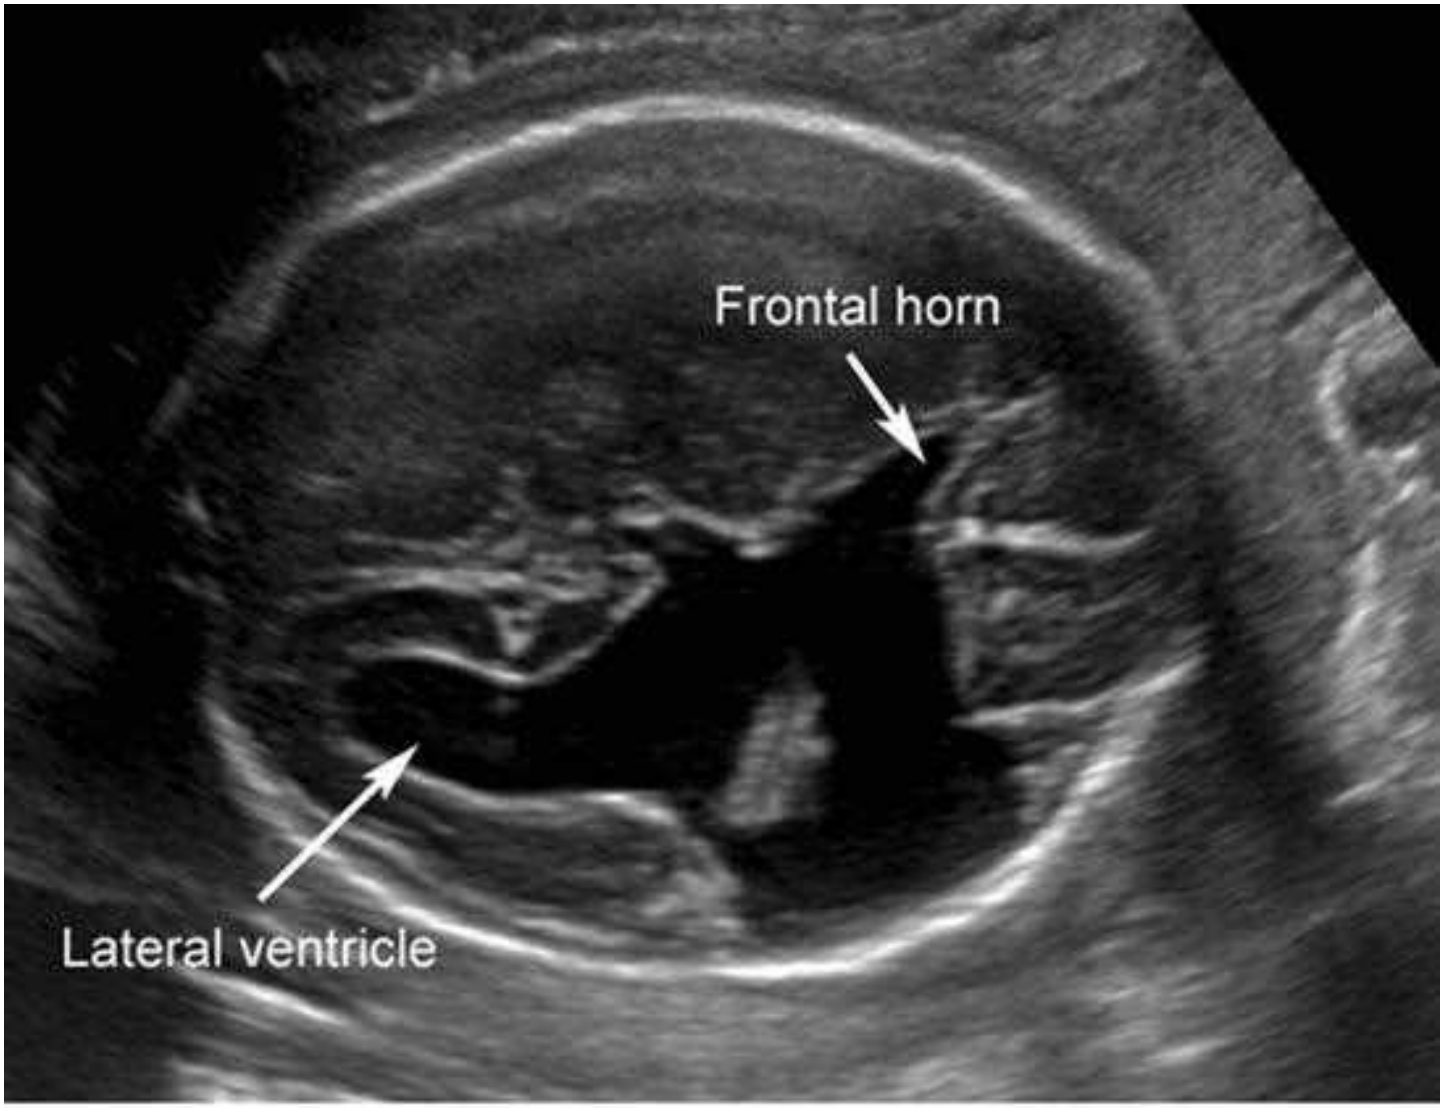

FIGURE 10-18

Transverse **(A)** and sagittal **(B)** images of a 26-week fetus with a very large left-sided microcystic congenital cystic adenomatoid malformation (CCAM). The mass (*C*) fills the thorax and has shifted the heart to the far right side of the chest, with development of ascites (*asterisks*). Fortunately, the mass did not continue to grow, the ascites resolved, and the infant was delivered at term and did well following resection.

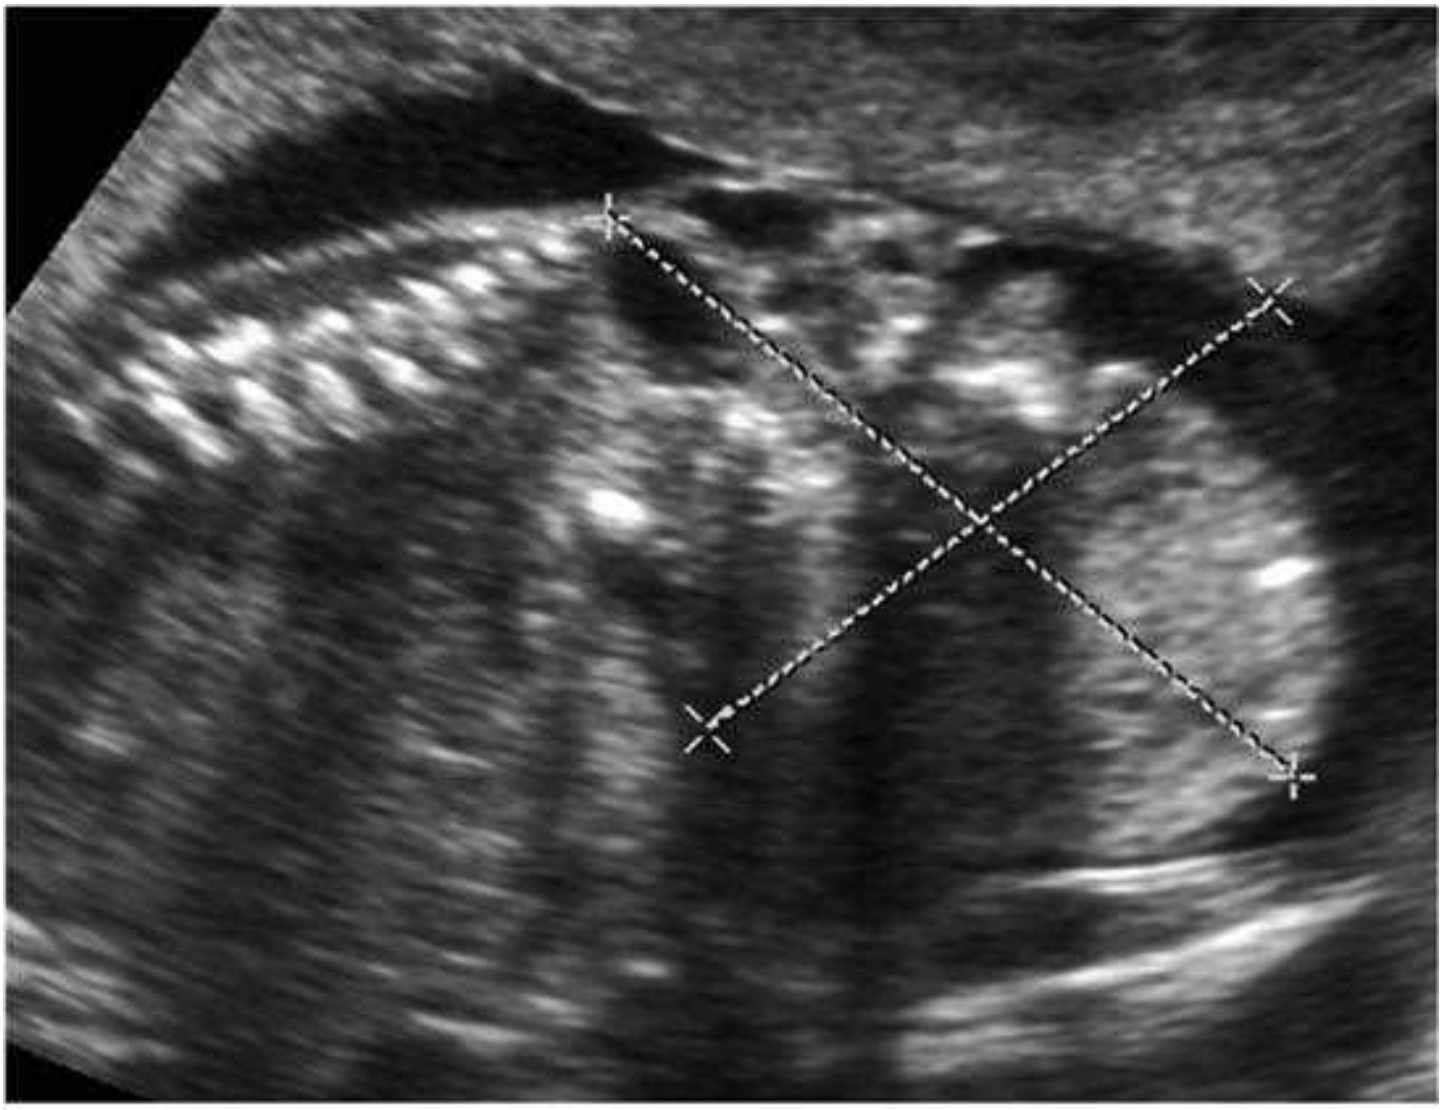

FIGURE 10-19

Congenital high airway obstruction sequence (CHAOS). The lungs appear brightly echogenic, and one is marked by an “L.” The bronchi, one of which is noted by an arrow, are dilated with fluid. Flattening and eversion of the diaphragm is common, as is ascites (*asterisks*).

FIGURE 10-22

Ventricular septal defect. **A.** In this four-chamber view of a 22-week fetus, a defect (*arrow*) is noted in the superior (membranous) portion of the interventricular septum. **B.** The left-ventricular outflow tract view of the same fetus demonstrates a break (*arrow*) in continuity between the interventricular septum and the anterior wall of the aorta.

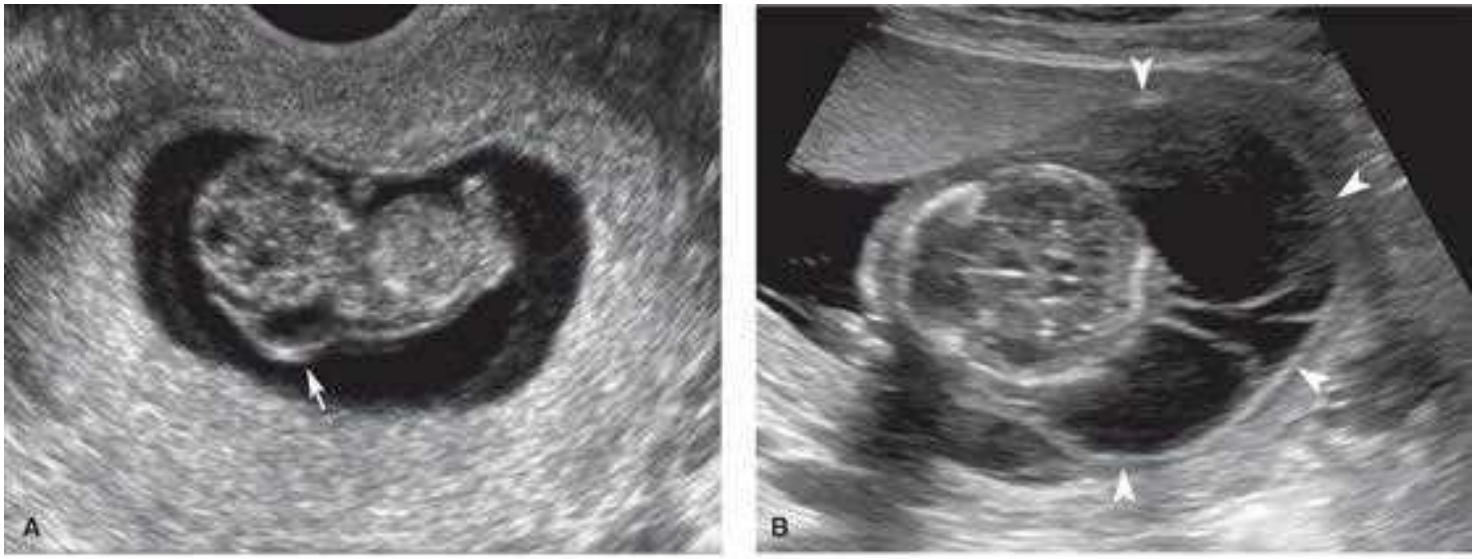

FIGURE 10-23

Endocardial cushion defect. **A.** During ventricular systole, the lateral leaflets of the mitral and triscuspid valves come together in the midline. But the atrioventricular valve plane is abnormal, a common atrium (*A*) is observed, and there is a visible defect (*arrow*) in the interventricular septum. **B.** During diastolic filling, opening of the atrioventricular valves more clearly demonstrates the absence of their medial leaflets.

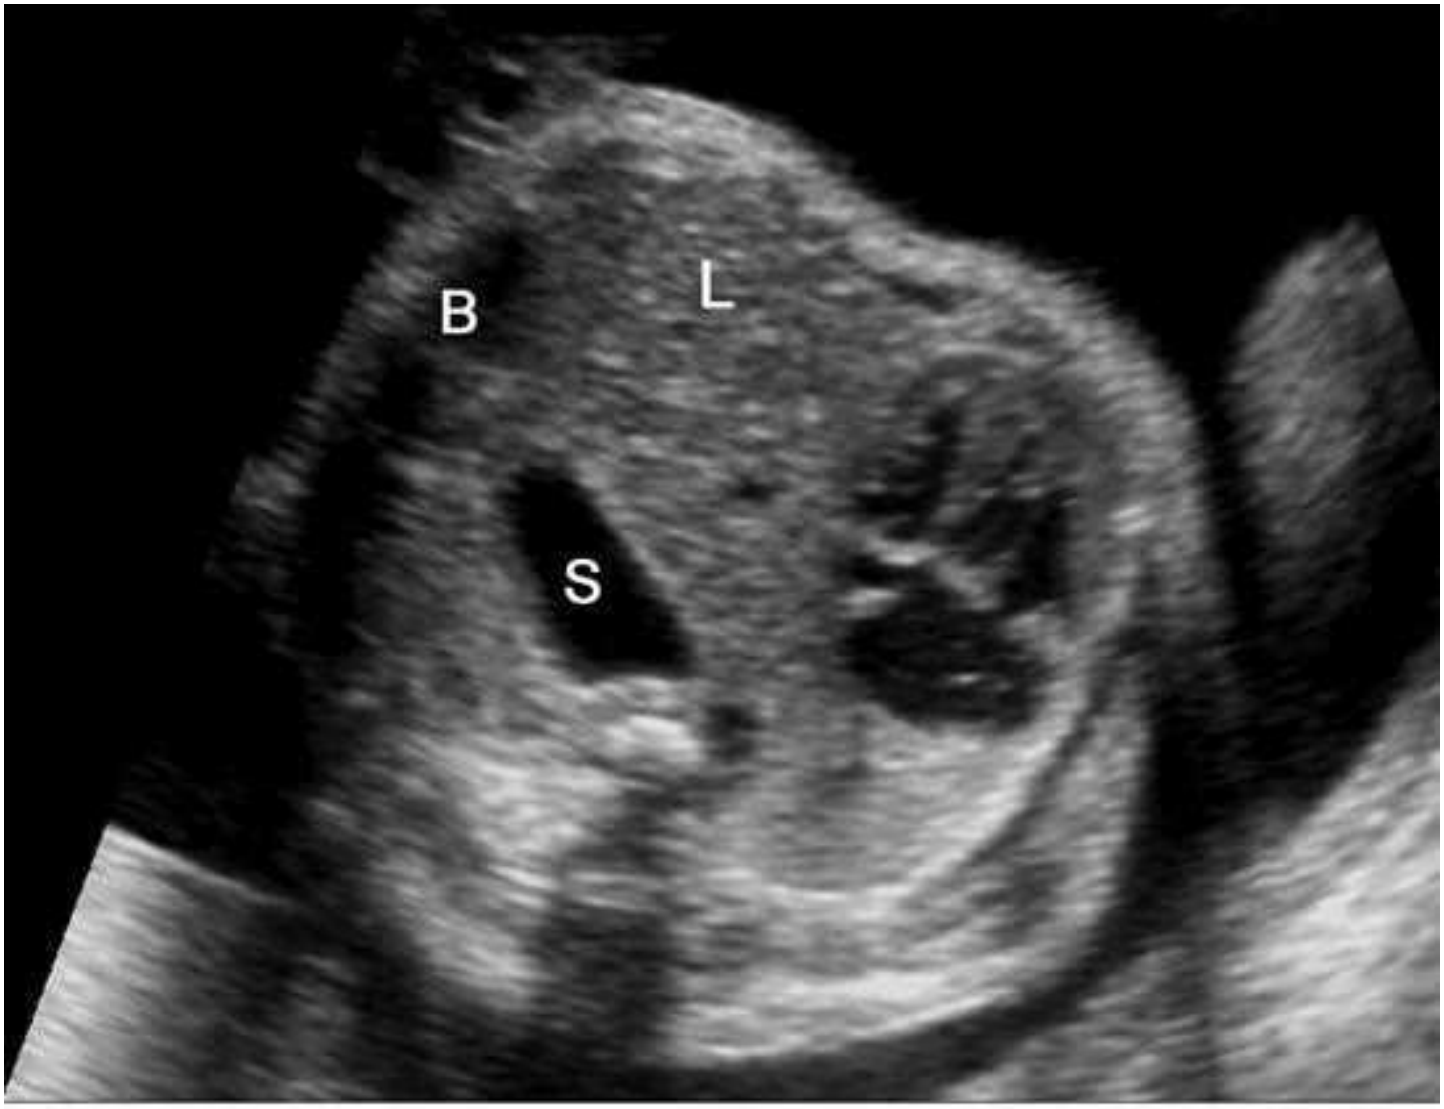

FIGURE 10-24

M-mode, or motion mode, is a linear display of the events of the cardiac cycle, with time on the x-axis and motion on the y-axis. M-mode is used commonly to measure the fetal heart rate. In this image, there is normal concordance between atrial (*A*) and ventricular contractions (*V*). Movement of the tricuspid valve (*T*) is also shown. There is also a premature atrial contraction (*arrow*) and a subsequent early ventricular contraction, followed by a compensatory pause.

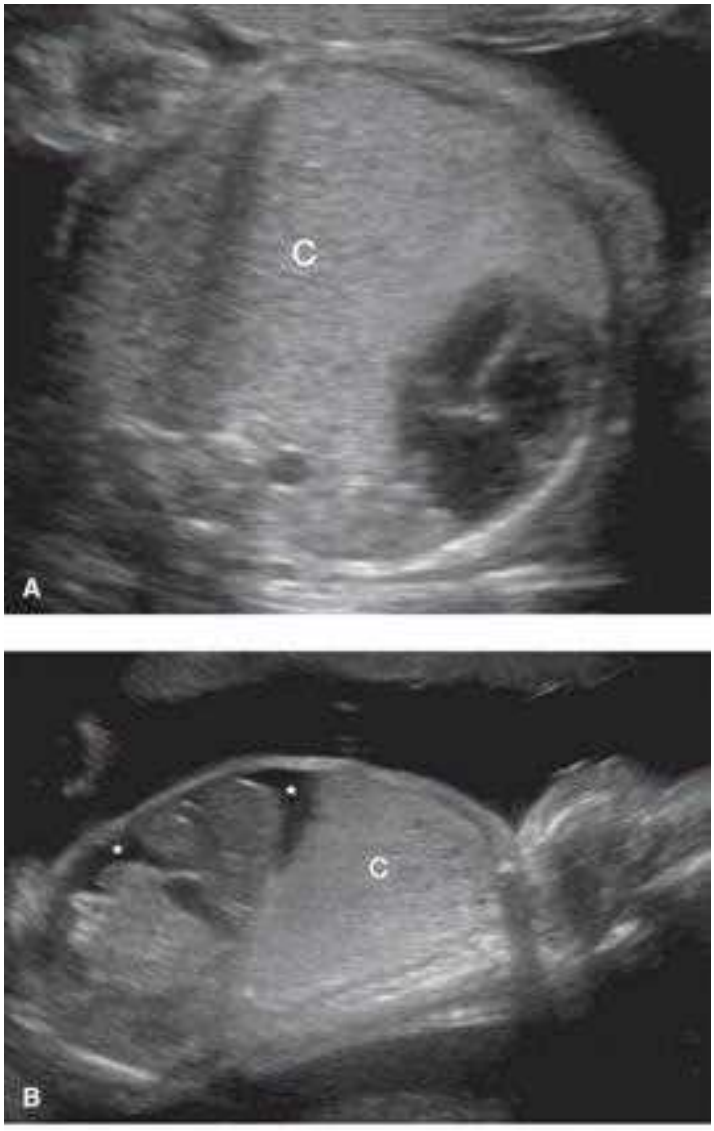

FIGURE 10-26

Gastroschisis. This 18-week fetus has a fullthickness ventral wall defect to the right of the cord insertion (*arrowhead*), through which multiple small bowel loops (*B*) have herniated into the amnionic cavity.

FIGURE 10-33

Posterior urethral valve. In this 19-week fetus with severe bladder outlet obstruction, the bladder is dilated and thick-walled, with dilatation of the proximal urethra that resembles a “keyhole.” Adjacent to the bladder is an enlarged kidney with evidence of cystic dysplasia, conferring a poor prognosis.

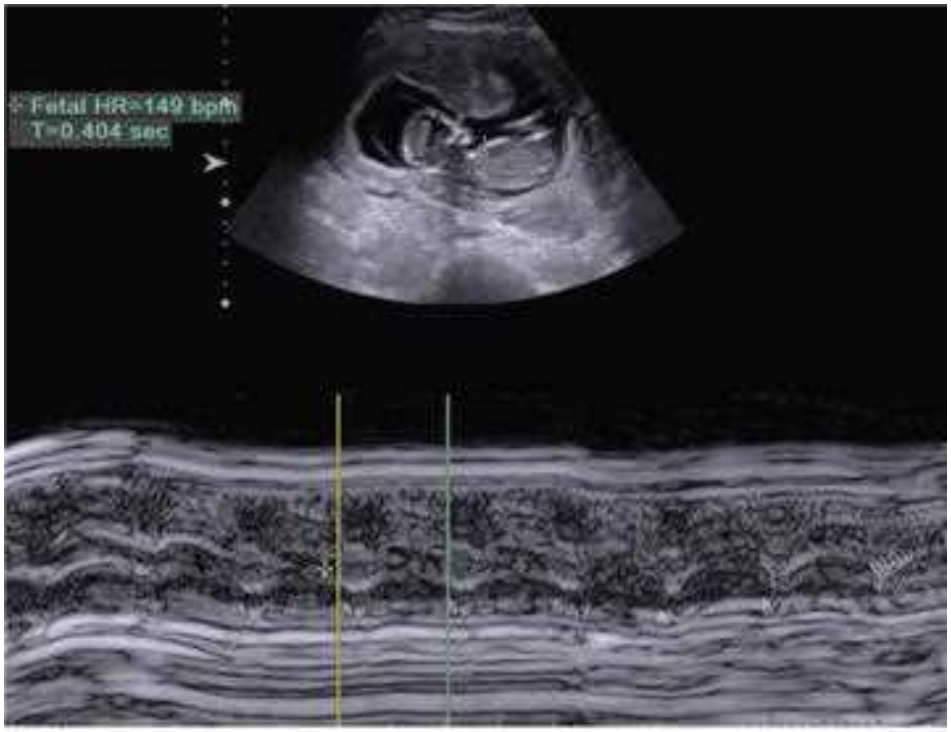

FIGURE 10-39

Umbilical artery Doppler waveforms. **A.** Normal diastolic flow. **B.** Absence of end-diastolic flow. **C.** Reversed enddiastolic flow.

FIGURE 10-44

Congenital diaphragmatic hernia **A.** A HASTE image of a 26-week fetus with congenital diaphragmatic hernia involving the liver (*arrows*). **B.** Coronal STIR image through a 33-week fetal chest demonstrates multiple loops of bowel filling the left chest (*dashed lines*).

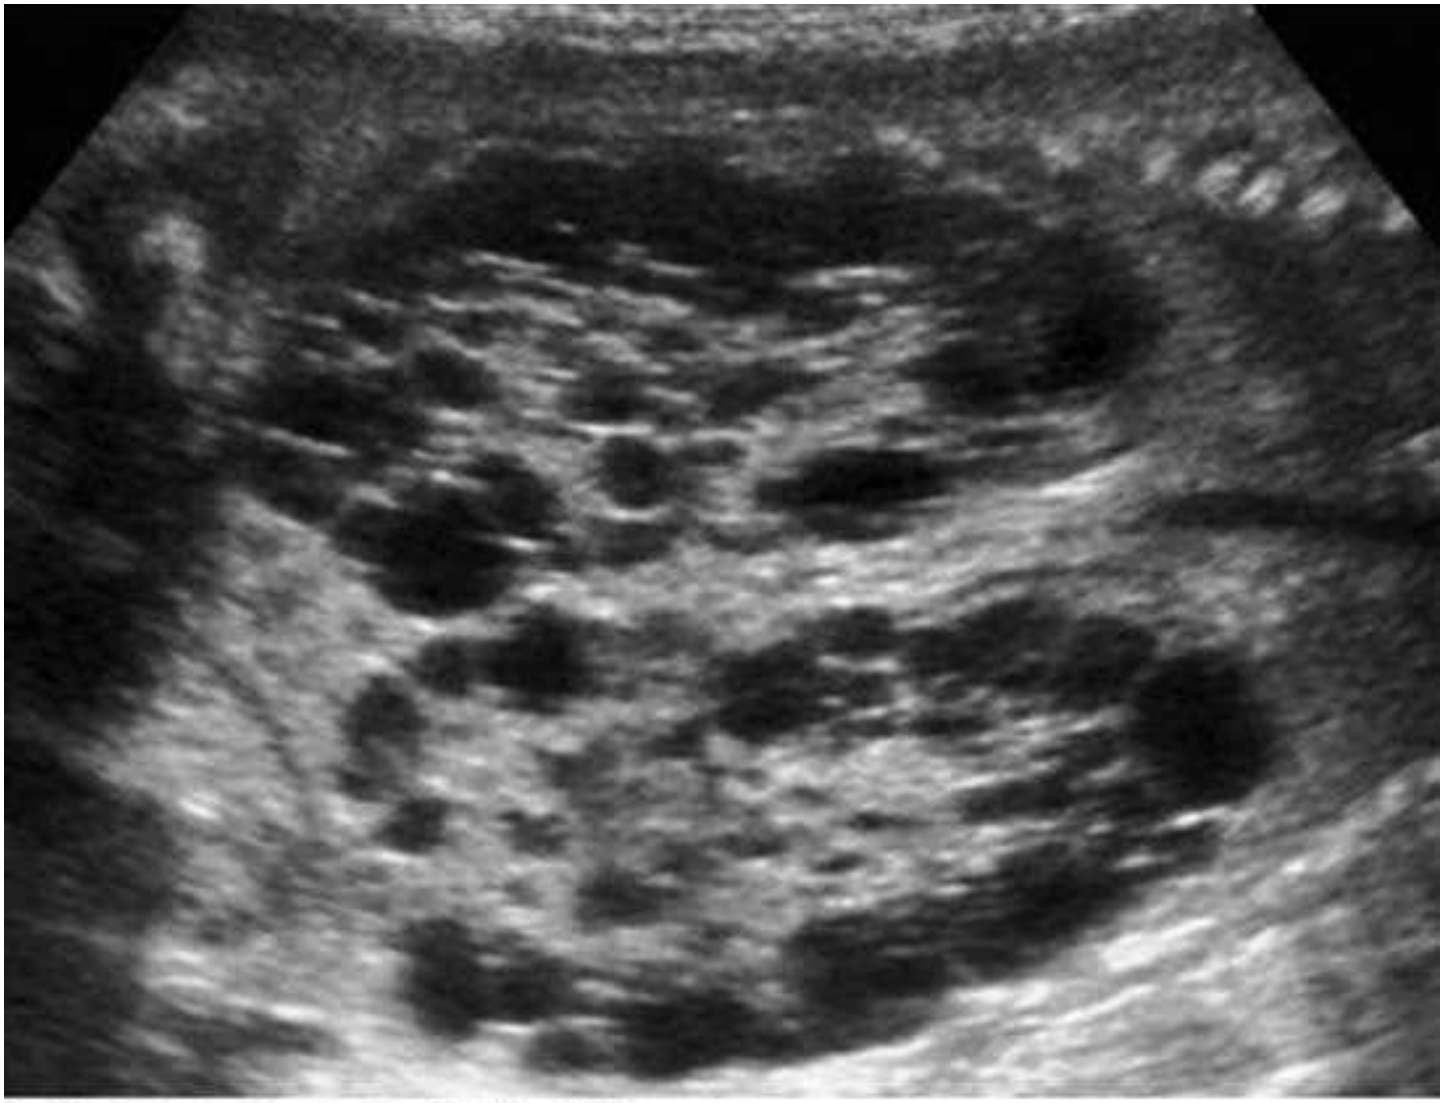

FIGURE 41-11

Schematic showing types of puerperal hematoma. **A.** Coronal view showing supralevator and anterior perineal triangle hematomas on the right. **B.** Perineal view shows anterior perineal triangle anatomy and an ischioanal fossa hematoma on the left.

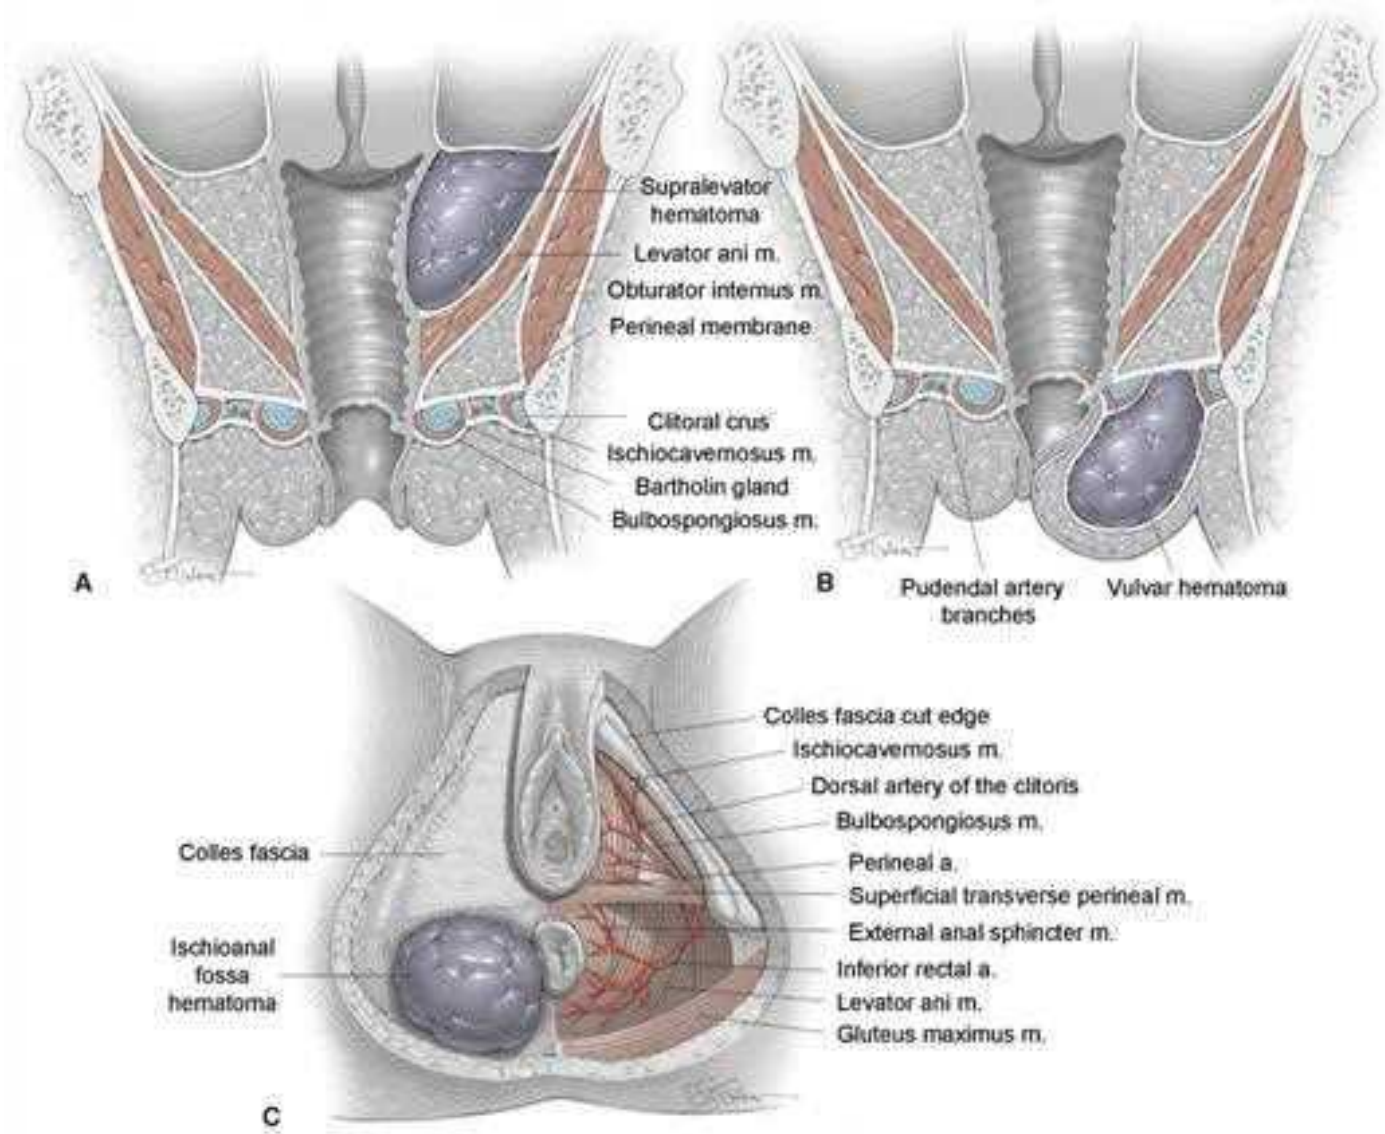

FIGURE 48-1

Chart for estimating body mass index (BMI). To find the BMI category for a particular subject, locate the point at which the height and weight intersect.

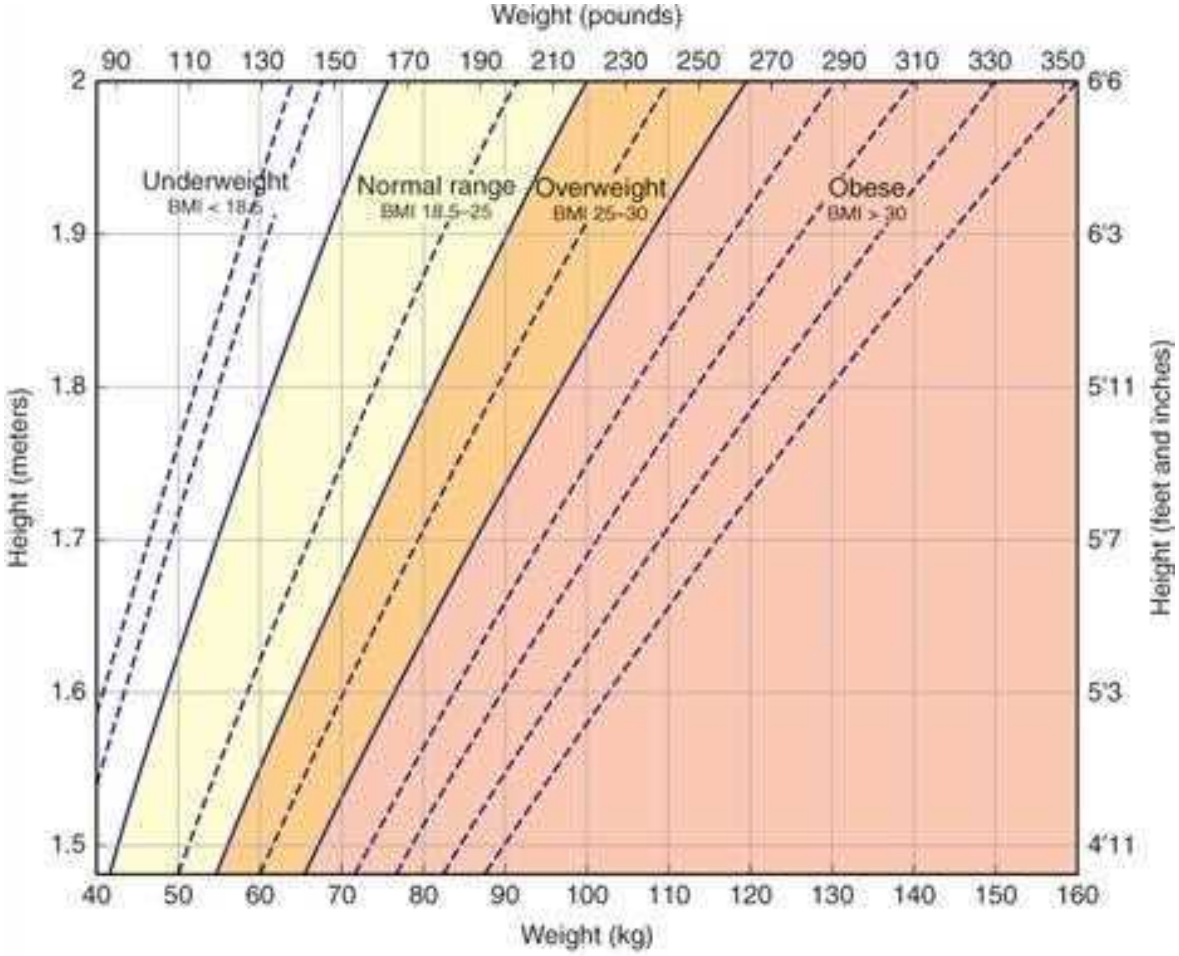

TABLE 9-9

Recommendations for Immunization During Pregnancy

Immunobiological Agent	Indications for Immunization During Pregnancy	Dose Schedule	Comments
Live Attenuated Virus Vaccines			
Measles	Contraindicated—see immune globulins	Single dose SC, preferably as MMR[a]	Vaccinate susceptible women postpartum. Breast feeding is not a contraindication
Mumps	Contraindicated	Single dose SC, preferably as MMR	Vaccinate susceptible women postpartum
Rubella	Contraindicated, but congenital rubella syndrome has never been described after vaccine	Single dose SC, preferably as MMR	Teratogenicity of vaccine is theoretical and not confirmed to date; vaccinate susceptible women postpartum
Poliomyelitis: Oral = live attenuated; injection = enhanced-potency inactivated virus	Not routinely recommended for women in the United States, except women at increased risk of exposure[a]	Primary: Two doses of enhanced-potency inactivated virus SC at 4–8 week intervals and a 3rd dose 6–12 months after 2nd dose Immediate protection: One dose oral polio vaccine (in outbreak setting)	Vaccine indicated for susceptible women traveling in endemic areas or in other high-risk situations
Yellow fever	Travel to high-risk areas	Single dose SC	Limited theoretical risk outweighed by risk of yellow fever
Varicella	Contraindicated, but no adverse outcomes reported in pregnancy	Two doses needed. 2nd dose given 4–8 weeks after 1st dose	Teratogenicity of vaccine is theoretical. Vaccination of susceptible women should be considered postpartum
Smallpox (vaccinia)	Contraindicated in pregnant women and in their household contacts	One dose SC, multiple pricks with lancet	Only vaccine known to cause fetal harm
Other			
Influenza	All pregnant women, regardless of trimester during flu season (October–May)	One dose IM every year	Inactivated virus vaccine
Rabies	Indications for prophylaxis not altered by pregnancy; each case considered individually	Public health authorities to be consulted for indications, dosage, and route of administration	Killed-virus vaccine
Human papillomavirus	Not recommended	Three-dose series IM at 0, 1, and 6 months	Quadrivalent or bivalent vaccines, both are inactivated virus. No teratogenic effects have been observed with either
Hepatitis A	Recommended not contraindicated	Three-dose series IM at 0, 1,	Used with hepatitis B vaccine

Hepatitis C	Preexposure and postexposure for women at risk of infection	Three dose schedule at 0, 1, and 6 months	Give with hepatitis B immune globulin for some exposures. Exposed newborn needs birth dose vaccination and immune globulin as soon as possible. All infants should receive birth dose of vaccine
Hepatitis A	Preexposure and postexposure if at risk (international travel)	Two dose schedule IM, 6 months apart	Inactivated virus
Inactivated Bacterial Vaccines			
Pneumococcus	Indications not altered by pregnancy. Recommended for women with asplenia, metabolic, renal, cardiac, or pulmonary diseases; immunosuppression; or smokers	In adults, one dose only; consider repeat dose in 5 years for high-risk women	Polyvalent polysaccharide vaccine; safety in the first trimester has not been evaluated
Meningococcus	Indications not altered by pregnancy; vaccination recommended in unusual outbreaks	One dose; tetravalent vaccine	Antimicrobial prophylaxis if significant exposure
Typhoid	Not recommended routinely except for close, continued exposure or travel to endemic areas	Killed Primary: 2 injections IM 4 weeks apart Booster: One dose, schedule not yet determined	Killed, injectable vaccine or live attenuated oral vaccine. Oral vaccine preferred
Anthrax	See text	Six-dose primary vaccination, then annual booster vaccination	Preparation from cell-free filtrate of *B anthracis*, No dead or live bacteria. Teratogenicity of vaccine theoretical
Toxoids			
Tetanus-diphtheria-acellular pertussis (Tdap)	Recommended in every pregnancy, preferably between 27 and 36 weeks to maximize passive antibody transfer	Primary: Two doses IM at 1-2 month interval with 3rd dose 6-12 months after the 2nd Booster: Single dose IM every 10 years, as a part of wound care if ≥ 5 years since last dose, or once per pregnancy	Combined tetanus-diphtheria toxoids with acellular pertussis (Tdap) preferred. Updating immune status should be part of antepartum care
Specific Immune Globulins			
Hepatitis B	Postexposure prophylaxis	Depends on exposure (Chap. 55, p. 1090)	Usually given with hepatitis B virus vaccine; exposed newborn needs immediate prophylaxis
Rabies	Postexposure prophylaxis	Half dose at injury site; full dose in deltoid	Used in conjunction with rabies killed virus vaccine
Tetanus	Postexposure prophylaxis	One dose IM	Used in conjunction with tetanus toxoid
Varicella	Should be considered for exposed pregnant women to protect against maternal, not congenital, infection	One dose IM within 96 hours of exposure	Indicated also for newborns or women who developed varicella within 4 days before delivery or 2 days following delivery
Standard Immune Globulins			
Hepatitis A Hepatitis A virus vaccine should be used with hepatitis A immune globulin	Postexposure prophylaxis and those at high risk	0.02 mL/kg IM in one dose	Immune globulin should be given as soon as possible and within 2 weeks of exposure; infants born to women who are incubating the virus or are acutely ill at delivery should receive one dose of 0.5 mL as soon as possible after birth

*Two doses necessary for students entering institutions of higher education, newly hired medical personnel, and travel abroad.
†Inactivated polio vaccine recommended for nonimmunized adults at increased risk.
ID = intradermally; IM = intramuscularly; MMR = measles, mumps, rubella; PO = orally; SC = subcutaneously
Adapted from the Centers for Disease Control and Prevention, 2013a,b,c.

TABLE 10-3

Guidelines for Nuchal Translucency (NT) Measurement

The margins of NT edges must be clear enough for proper caliper placement
The fetus must be in the midsagittal plane
The image must be magnified so that it is filled by the fetal head, neck, and upper thorax
The fetal neck must be in a neutral position, not flexed and not hyperextended
The amnion must be seen as separate from the NT line
Electronic calipers must be used to perform the measurement
The + calipers must be placed on the inner borders of the nuchal space with none of the horizontal crossbar itself protruding into the space
The calipers must be placed perpendicular to the long axis of the fetus
The measurement must be obtained at the widest space of the NT

TABLE 49-4

Risks for Fetal Heart Lesions Related to Affected Family Members

	Congenital Heart Disease in Fetus (%)		
Cardiac Lesion	Previous Sibling Affected	Father Affected	Mother Affected
Marfan syndrome	NS	50	50
Aortic stenosis	2	3	15–18
Pulmonary stenosis	2	2	6–7
Ventricular septal defect	3	2	10–16
Atrial septal defect	2.5	1.5	5–11
Patent ductus arteriosus	3	2.5	4
Coarctation of the aorta	NS	NS	14
Fallot tetralogy	2.5	1.5	2–3

NS = not stated.
Data from Lupton, 2002.

TABLE 52-8

Some Recommendations for Thromboprophylaxis during Pregnancy

	Pregnancy		Postpartum	
Clinical Scenario	ACOG[a]	ACCP[b]	ACOG[a]	ACCP[b]
Prior single VTE				
Risk factor no longer present	Surveillance only	Surveillance only	Postpartum anticoagulation[c] "Surveillance only acknowledged by some experts."	Prophylactic or intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks
Pregnancy- or estrogen-related or no known association (idiopathic) **and** not receiving long-term therapy	Prophylactic UFH or LMWH **or** "Surveillance only acknowledged by some experts"	Prophylactic or intermediate-dose LMWH	Postpartum anticoagulation[c]	Prophylactic or intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks

Receiving long-term warfarin	NSS	Adjusted-dose LMWH **or** 75% of a therapeutic dose of LMWH	NSS	Resume long-term anticoagulation
Associated with a high-risk thrombophilia[a] **and** not receiving long-term anticoagulation or an affected first-degree relative	Prophylactic, intermediate-, or adjusted-dose LMWH or UFH	NSS	Postpartum anticoagulation[c] **or** intermediate- or adjusted-dose LMWH or UFH × 6 weeks[c]	Prophylactic or intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks
Associated with a low-risk thrombophilia[b] and not receiving treatment	Prophylactic or intermediate-dose LMWH or UFH **or** surveillance only	NSS	Postpartum anticoagulation[c] **or** intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks
Two or more prior VTEs with or without thrombophilia				
Not receiving long-term therapy	Prophylactic or therapeutic-dose UFH or LMWH	NSS	Postpartum anticoagulation[c] **or** therapeutic-dose LMWH or UFH × 6 weeks	Prophylactic or intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks
Receiving long-term anticoagulation	Therapeutic-dose LMWH or UFH	Adjusted-dose LMWH **or** 75% of a therapeutic dose of LMWH	Resumption of long-term anticoagulation	Resumption of long-term anticoagulation
No prior VTE				
High-risk thrombophilia[a]	Surveillance only **or** prophylactic or intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH	Postpartum anticoagulation[c]	Intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks
Positive family history VTE **and** homozygous factor V Leiden or prothrombin 20210A mutation	NSS	Prophylactic or intermediate-dose LMWH	NSS	Prophylactic or intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks
Negative family history VTE and homozygous factor V Leiden or prothrombin 20210A mutation	Surveillance only **or** prophylactic LMWH or UFH	Surveillance only	Postpartum anticoagulation[c]	Prophylactic or intermediate-dose LMWH **or** warfarin target INR 2.0–3.0 × 6 weeks
Positive family history VTE and low-risk thrombophilias[b]	Surveillance only	Surveillance only	Postpartum anticoagulation[c] **or** intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH **or** in women not protein C or S deficient, warfarin target INR 2.0–3.0
Low-risk thrombophilia[b]	Surveillance only	Surveillance only if no family history	Surveillance only; postpartum anticoagulation with additional risk factors[c]	Surveillance only if no family history
Antiphospholipid antibodies				
History of VTE	Prophylactic anticoagulation with UFH or LMWH (?plus low-dose aspirin)	NSS	Prophylactic anticoagulation[c]; referral to specialist[d]	NSS
No prior VTE	Surveillance only **or** prophylactic LMWH or UFH **or** prophylactic LMWH or UFH plus low-dose aspirin if prior recurrent pregnancy loss or stillbirth	Prophylactic- or intermediate-dose UFH **or** prophylactic-dose LMWH, both given with 75–100 mg/day aspirin[e]	Prophylactic heparin plus low-dose aspirin × 6 weeks if prior recurrent pregnancy loss or stillbirth[f]	NSS

[a]American College of Obstetricians and Gynecologists, 2012, 2013.
[b]American College of Chest Physicians (Bates, 2012).
[c]Postpartum treatment levels should be ≥ antepartum treatment.
[d]Antithrombin deficiency, doubly heterozygous or homozygous for prothrombin 20210A and factor V Leiden.
[e]Heterozygous factor V Leiden or prothrombin 20210A, protein S or C deficiency.
[f]First-degree relative with VTE at < 50 years; other major thrombotic risk factors, e.g., obesity, prolonged immobility.
[g]Women with antiphospholipid syndrome should not use estrogen-containing contraceptives.
[h]Treatment is recommended if the diagnosis of antiphospholipid syndrome is based on three or more prior pregnancy losses.
LMWH = low molecular weight heparin; NSS = not specifically stated; UFH = unfractionated heparin; VTE = venous thromboembolism.

Prophylactic, intermediate-, and adjusted-dose regimens are listed in Table 52-5 (p. 1037).
