Fig. 10.14 The two sides of the body (A and B) often respond very differently to the same task, and therapy must be adapted accordingly.

persons to manage play activities and to supervise independent functioning that reinforce treatment goals.

The therapist working with these children becomes an important and trusted resource to the family. At times the therapist who has had the more consistent contact with the child becomes the facilitator of better communication between the parents and medical or health care professionals. The child who starts early and continues with the same therapist may make this person a confidant and share concerns that are difficult or uncomfortable for the child to explain to parents or others. It is a challenge for the therapist who follows the same child for an extended time to come up with appropriate goals and new activities to continue positive change. The therapist should always consider quality of life for each individual in their care. Part of direct intervention is to recognize when the amount of therapy can be reduced and replaced with recreational activities with peers or community involvement. In 2014, Gannotti and colleagues provided a framework for dosing in pediatric rehabilitation for children with CP. This model is strongly based on the ICF model of the World Health Organization and serves as a path to evaluate multiple parameters affecting dosing interventions.⁶⁵ This path-based model can serve as a guide for the therapist in decision making related to dosing. There remain many unanswered questions about dosing in children with CP and brain damage. Two papers published in 2014, including Giannotti's study, suggest that a "systematic and in-depth analysis of dosing questions" combined with an "interdisciplinary approach" is critical in advancing research in this area.^{65,66}

Case Management and Direct Intervention

Simple documentation of observed changes in a child over a series of regular clinic visits is still too common for many children with CP. Regular appointments, with periodic assignment of a new piece of equipment, do not constitute active treatment. Physical intervention in the form of direct handling of the child is considered a conservative treatment by most physicians. Therapists need to demonstrate their unique preparation and describe their interventions in ordinary language so that families as well as other health care professionals understand the importance of specific treatment versus general programs of early stimulation, which are designed for neurologically intact infants. Demonstrating a clear understanding of the foundational theories that your treatments are based on is essential for justification of your interventions.

The prognosis for change in CP is too often based on records of case management rather than on the effect of direct and dynamic treatment by a well-prepared therapist. Bobath,⁶⁷ back in 1965, accurately documented the developmental sequence expected in the presence of spasticity or athetosis. Her book consolidates some observations of older patients that help professionals understand the uninterrupted effects of the CP condition. In any institution, one can observe the tightly adducted and internally rotated legs, the shoulder retraction with flexion of the arms, and the chronic shortening of the neck so commonly seen as the long-term effects of CP. The long-term influence of fluctuating muscle tone results in compensatory stiffness or limited movement patterns to create a semblance of the missing postural stability, while a limited number of movement patterns with limited degrees of freedom are used to function (Fig. 10.15).

Within the clinical community there is increasing evidence that soft tissue restrictions further limit spontaneous movement in children with CP. The fact that these restrictions are often found in infants suggests that they originate early rather than as a gradual result of limited ranges in movement. Because of the tendency of soft tissue to change in response to any physical trauma or strong biochemical change, some of these characteristics might be influenced by the position in utero or originating with traumatic birth experiences, and they could be exacerbated by daily use of limited patterns of movement. Tissue restrictions can also occur with immobilization or general infectious processes.⁶⁸ Soft tissue responds to the application of gentle sustained pressure simply from the weight and heat of one's hand with careful consideration by the therapist of techniques used to manipulate the tissue and joints. A therapist must be prepared to defend his or her approach with a solid foundation, theory, and objective outcomes.

Fig. 10.15 Attempted movement activates atypical patterns and restrictions; restrictions are revealed with limited degrees of freedom available for function.

Objective documentation is important when dealing with any population but is essential for demonstrating therapeutic change.

Applying specific soft tissue treatment techniques to improve mobility and to decrease tonus for any person with a neuromotor disorder creates the need for immediate follow-up with practice of new functional skills using this improved available range of motion. The stretching of muscles in CP has been shown to change muscle tone and to improve range of motion, which can open a window of opportunity to practice functional skills.^{69–71} Caution should be exercised to avoid creating excessive tissue mobility in a given area of the body, which can destroy the delicate patterns of coordination that permit synergic function in the person with CP.

Functional activation of the body after each specific mobilization or stretching technique is strongly recommended to integrate the tissue change. Well documented in the literature on current motor control and motor learning is the need to practice, practice, practice.⁷² Practice time is related to skill performance; the amount and type of practice are determined by the stage of learning that an individual is in and the type of task to be learned (see Chapter 3 on motor control and learning).^{72–76} Interestingly, most of what we know about motor control and motor learning is based on individuals who are “typical,” and it is yet to be determined whether the same principles that are considered important in healthy individuals apply to people with disability. However, it makes sense that practice would influence the use of any new or relearned skill.

An occupational therapist, Josephine Moore, emphasized some important points for therapists regarding the concept of increasing functional demands on the central system and the importance of the neck structures in developmental movement sequences. Children with spasticity often have a lack of developmental elongation of the neck, whereas children with athetoid or dystonic movement lack neck stability and consistent postural activation. Tone changes often originate with changes in the delicate postural interrelationship between head/neck and body or with ambient visual processing. An alert therapist will observe these changes and be able to relate them to the initiation of movement and adapt the therapy session to facilitate or inhibit their influence.

Restak,⁷⁷ in his book *The New Brain*, confirms the continual reorganization of the brain in response to new input. Several animal and human studies on neuroplasticity have confirmed that the brain reorganizes after an injury and that this reorganization is shaped by rehabilitation and motor skill learning.^{78–80}

Our understanding of how the brain works and the mechanisms for neuroplasticity are ever changing. Hartwigsen suggested that having a better understanding of compensatory mechanisms in the brain would increase our understanding of how the brain reorganizes.⁸¹ In 2018, Gaberova and colleagues undertook a systematic review of the literature on task-related functional MRI in children with hemiplegia. The review included sensory, motor, and speech studies. They reported that the sensory system was the most rigid to reorganize and the speech system the most flexible. This appraisal of the literature concluded that reorganization is variable, and dependent on the severity and timing of injury, and the development of each of these individual systems.⁸²

In the child with CP, the therapist looks for subtle changes in the child’s response to determine newly integrated sensorimotor learning. For example, excessive emphasis on extensor responses in the prone posture for the older child can jeopardize the quality of neck elongation in sitting, so it is essential to work on the components necessary for control of the new posture desired and in reaching for a balance of function versus quality of movement when possible.

Therapy intervention is far from innocuous when it is responsibly applied. A truly eclectic treatment approach comes with clinical

experience and personal consideration of observations of the functional problems presented by the complex issue of CP at different ages. Priorities in intervention strategies have a practical aspect, and new developments in our knowledge lead us forward in clinical applications. Continued research and understanding of the intricacies of typical development offer many new clues for new effective interventions. With high-quality treatment intervention, the need for direct therapy service as a crucial aspect of case management for these children is confirmed. Clinical findings in individual case studies need to become part of the professional literature to strengthen the efficacy of intervention in this population.

Special Needs of Infants

The direct treatment of infants deserves special mention because there are significant differences in intervention strategies for the infant and the older child. Aside from the delicate situation of the new parents, the infant is less likely to have a diagnosis and often presents a mixture of typical and atypical characteristics. It is essential that the clinician have a strong foundation in the nuances of typical developmental movement and early postural control.^{4,46}

Direct intervention can be offered as a means of enhancing development and overcoming the effects of a difficult or preterm birth. However, it will be important to pursue a diagnosis for the infant who reaches 8 or 9 months of age and continues to need therapy because most third-party payers often require a diagnosis beyond that of developmental delay or prematurity.

Infants with early restrictions in motor control should be followed until they are walking independently, even if they no longer need weekly regular therapy. Infant responses can change rapidly as the therapist organizes the components that contribute to movement control. When present, soft tissue restrictions should be treated initially to have more success with facilitated movement responses. Careful observation is essential because all but the severely involved infant will change considerably between visits. The therapist should invest some time in training the parents to become skilled observers while appreciating the small gains made by their infant and reinforcing the positive changes with the family while remaining realistic and hopeful for the future of their child. It is better to not predict the future motor competency of a child in the early infant stages because the infant will change dramatically over the first year of life. Predictions often limit the therapist in their treatment approach when perceived expectations or limitations are placed on the patient. If one predicts that a child will not stand and walk, the therapist has little impetus to work on those skills. Physiotherapist Mary Quinton,⁸³ who developed a treatment regime for infants in 2002, wrote specific intervention strategies for babies (Fig. 10.16). In addition, infant massage can be an important adjunct to improve the bonding of mother and child and to improve physiological measures such as abdominal gas, restlessness, and general stiffness.^{85,85} Referral to other health care professionals is essential in the presence of possible allergies, new neurological signs, visual or auditory alterations, and persistent reflux or nutritional issues. There is always the possibility of seizures when some brain dysfunction is present, and neurological evaluation should be recommended if this is a concern.

ORIENTATION TO TREATMENT STRATEGIES

The child whose movement is bound within the limitations of hypertonicity suffers first of all from a paucity of movement experience. Because early attempts to move have resulted in the expression of limited typical synergistic postural patterns, the child often experiences the body as heavy or awkward and loses incentive to attempt

Fig. 10.16 Mary Quinton, British physiotherapist, is widely recognized as the originator of effective infant intervention.

movement. The therapist will want to focus on the child's ability to sustain postural control in the trunk in all positions. Central "core" stability to support directed arm movement or weight shifts for stepping may not have developed, so they need to be addressed during therapy intervention. Improved upper extremity control opens the possibility for new learning of more coordinated tasks. Specific work on hand preparation for reach and grasp follows use of the arm for directed movement and often results in improved balance in standing. Any freedom gained in upper body control results in more efficient balance in the upright posture.

Inhibiting or stopping the movement of one part or even one limb must be done in a way that permits the child to activate the body in a functional way. The child who lies in the supine position with extreme pushing back against the surface is rarely seen when alternative positions, emphasis on head control, and sometimes behavioral management have been implemented early on. The therapist initially may eliminate the supine position entirely but would incorporate into the treatment plan the activation of balanced flexion and extension in sitting with the ability to vary pelvic tilt for functional play and reaching (Fig. 10.17A–C). The child might later be reintroduced to a supine position with postural transitions that support balanced control of the body with more differentiated movement.

One of the primary considerations for the child with spasticity is adequate respiratory support for movement. Mobility of the thoracic cage and the mid-trunk must be combined with trunk rotation during basic postural transitions (Fig. 10.18). Consideration of age-appropriate movement velocity will guide the therapist in choosing activities that challenge better respiratory adaptability and prepare for speech breathing to support vocalization. The therapist will find it helpful to hum or sing or even make silly sounds that encourage sound production by the child during therapy. Movement of the child's body changes respiratory demands and frequently results in spontaneous sound production during therapy. Assessing the ability to sustain a breath to speak is easily done during a therapy session by reciting the letters in the alphabet that can be said with one breath. This should be done with the child supine and in an upright position because trunk control required while sustaining a breath changes with the posture attained against gravity. Consulting with the child's speech and language therapist can provide more ideas for encouraging language and breathing support during therapy sessions. Describing the chest shape and movement of the thorax observed can serve to assist the therapist in problem solving and prioritizing the treatment plan.

Fig. 10.17 Development of hand use first focuses on bilateral arm activity while keeping the affected hand well within the functional visual field. **(A)** Asymmetry, atypical tone, and disorganized movements in the supine position. **(B)** Simple seating can inhibit strong asymmetry and help to organize posture. **(C)** In a seated position with a work surface in front allows for reaching and play.

Fig. 10.18 Rotational patterns combined with transitional movements can be used to mobilize the thoracic cage and decrease muscle stiffness.

In some children, respiratory patterns remain immature and superficial, which may be related to the causative factors of the impairment. A lack of postural control limits even the physiological shaping of the rib cage itself because the ribs do not have an opportunity to change their angle at the spine. The therapist must give careful support to sustain the transitional posture of the older child during transient respiratory change. An active respiratory adaptation will increase the variability of postural adaptation. Improved respiratory adaptation will improve trunk muscle tone, just as dynamic trunk alignment facilitates better respiration. Trunk control influences the alignment of the thorax, resulting in the respiratory support and effort a child has to make to sustain adequate oxygenation. These components are closely related. Anytime a child is moved or their position is changed, it is likely to result in respiratory change. Always monitor auditorially (listening carefully to changes in breath sounds), visually, and through palpation as you are treating to pick up the subtle changes that occur.

Weight bearing changes postural tone. The trunk can be helped to experience weight bearing in a variety of alignments by using inflated balls or rolls that offer a contoured surface. The threshold of the original response is gradually altered so that the child begins to learn the new sensations and can follow guided postural transitions. When there are distinct differences between the two sides of the body, attention must be given to lateral weight shifts in sitting and standing. Changes near the vertical midline of the body seem to represent the more difficult input for the compromised system to integrate. It may be necessary to assist sustained weight over one side and then the other to initiate the change. It is important to assist the shoulders to align with the hips and that the visual orientation of the individual brings the head to a correct alignment with regard to the horizon. Young children need special help with segmental rotation of the trunk in the vertical alignment so that the weight-bearing side is relatively forward with dynamic balance of flexion and extension influences (see Fig. 10.13).

Children and adolescents with CP often require a more intense or prolonged sensory cue for a desired movement response to be obtained. Range of movement may require preparation beyond the essential range for the functional goal. In addition, weight bearing against the surface may need to be sustained for a prolonged period of

time in order to facilitate active initiation of movement from the support surface. The therapist is addressing a system that is deficient in its ability to receive, perceive, and use the available input. This makes careful analysis and functional orientation of the sensory input essential. If the microcosm of experience given the child during a therapy session is no more intense than an equal amount of time in her or his living environment, the therapist has failed to use this unique opportunity to deliver a meaningful message to encourage the learning of new motor behavior by striving to improve the child's endurance and tolerance to new movement experiences. During a treatment session, although therapists cannot provide every experience necessary for all movement scenarios, they should provide the component parts necessary for motor skills to be transferred or generalized to other activities in other environments. Recent literature has indicated that the complexity of the task that is practiced and the type of practice may very well enrich generalization. In 2018, Willey and Liu reported that varied practice appeared to influence generalization but not to all conditions, and the transfer effect was not maintained at a 2-week posttest.⁸⁶ Wang and Song⁸⁷ investigated impaired visuomotor generalization with attentional distraction. This study compared the generalization of two conditions by switching the practice from that of a dual task to a single task. They reported that attention and memory are critical components and should be incorporated into the intervention period to enhance generalization to other untrained tasks regardless of complexity. Kantak and colleagues demonstrated in a small study that training complex activities improved generalization to uncomplicated tasks.⁸⁸ Therapists will need to stay abreast of new research in this area to more fully understand the context for motor learning or relearning of new skills.

The therapist working with the child with CP constantly monitors the quality of the child's motor response. These continuing observations guide the manipulation of the environment and the assistance given the child to move toward a functional goal. Is the body tolerating the position? Does the child adapt to the supporting surface and use the supporting surface contact for movement initiation (Fig. 10.19)? Does the movement of a limb demonstrate smooth controlled movement without unwanted associated reactions in other parts of the body? By analyzing the answers to such questions, the therapist is guided to an appropriate sequence of the therapy session and is enabled to set functional treatment goals and to realistically change prognoses.

The therapist makes constant judgments as to the child's responses during therapy, challenging the child's system while ensuring success and moving toward improved control. By using specific intervention strategies, the therapist works to introduce new somatosensory and motor learning. The therapist may introduce a slight modification of the child's response, such as an elongation of a limb as it is being moved. At other times the therapist augments sensory information

Fig. 10.19 This child has little contact with the supporting surface, resulting in poor movement initiation.

that helps direct a movement. Weight bearing over the feet may be simulated with the young child's foot against the therapist's hand and pressure given through the knee. Visual-motor experiences may be altered with the child's use of prism lenses, prescribed by an optometrist for use during therapy if appropriate.

To be meaningful, sensory input must be contextual and meaningful to the individual who is receiving it. Multiple sensory systems are simultaneously activated by most therapeutic input, and a variety of sights and sounds may be available in the immediate environment. Memory, previous learning, and cognition are activated during the therapy interaction. The therapist makes a continuous reassessment of the child's experiential needs compared with the current input provided. When the therapist works with the child in a more upright alignment during at least part of the session, the CNS is alert and more receptive to the incoming information.

The developmental meaning attached to the sensation of typical movement is complex and starts with the ability to process contrasting stimuli. While several parts of the body are stable, another is moving. Stability of the proximal body permits a limb to extend forcefully or to be maintained in space. Each new level of developmental dissociation of movement increases the complexity of CNS processing. The process of self-feeding illustrates how internal and external stimuli impinge simultaneously on the CNS. The process of guiding a full spoon toward the mouth initially engages the child's attention. The arm is lifted at the shoulder to bring the fragrant food odor to the level of the mouth before elbow flexion takes the spoon to the face (Fig. 10.20). Between 2 and 6 years of age the self-feeding pattern is modified and the elbow moves down beside the body. Now the motor aspect of the task has become procedural and more efficient, permitting the child to participate in social exchanges with the family at the same time that she or he manages independent self-feeding. The complexity of the task increases with the secondary task of social exchange.

A solid understanding of typical developmental sequences is essential for the clinician providing direct treatment intervention.^{28,46} Early responses of the typical infant change from a self-orientation to an environmental orientation as new developmental competence emerges. More sophisticated balance in independent sitting occurs

Fig. 10.20 Maintaining the child's elbow in this high position initially permits forearm pronation and activates the shoulder in the typical developmental pattern for improved motor learning.

simultaneously as the ability to pull to standing at a support begins to develop. Such knowledge of developmental details and interplay between developing skills across domains supports the therapist in introducing postural activities at a higher developmental level to integrate more basic abilities. The assisted self-dressing process is an effective way to introduce and integrate new movement and sensorimotor learning while using established movement skills. To sit well, the child needs practice moving over the base of support and coming in and out of sitting, and control of coming to stand from sitting. To walk well, the child may need to practice running to allow practice in changing rate, direction, range, and balance. Sitting is made more dynamic by using a gymnastic ball as a seat. Transitional adaptations of posture may be elaborated during therapy sessions to include more complex alignments. Specific techniques are reviewed in Chapter 8.

With the child dominated by athetoid movement, the therapist's role relates primarily to the organization and grading of seemingly erratic movement responses and establishing function around midline. These children have the ability to balance, but their balance reactions are often extreme in range and velocity often resulting in an ineffective attempt to regain balance. Their movements are rarely in the midline, asymmetrical, and frequently dominated by primitive reflexes, with poor midrange control of the trunk and extremities. Cognitively they are eager to participate and usually are responsive to working on specific goals that relate to functional success. By working to improve central control, the therapist gradually introduces the taking of body weight over the limbs, with assistance, to grade the postural control of the central body. With knowledge of the development of the visual system the therapist can use visual input to improve the child's balance reactions. In these children the therapist may note that disruption of eye alignment or focusing results in a momentary disorganization of postural control (see Chapter 28).

Movement control must become procedural so that it is not interrupted by every environmental distraction. This is more likely to happen when balanced activity of the visual, vestibular, and proprioceptive systems has been achieved. Independent ambulation becomes a spontaneous learned skill when the individual is able to think of something else at the same time or perform a secondary task while ambulating. The therapist begins this process by carrying on a conversation with the child to engage the cognitive attention so that the motor behavior becomes more automatic. The concept of graded stress is discussed in Chapters 4 and 5.

Direct intervention for the hemiplegic child takes into account the obvious difference in postural tone between one side of the body and the other. Treatment for children that addresses itself only to the more affected side of the body will not prove to be effective. The critical therapeutic experience seems to be that of integration of the two sides of the body and the establishment of the midline (see Fig. 10.13). The child with hemiplegia differs from the adult stroke patient in that the adult had a clearly established midline and integration of both sides of the body by learning to cross the midline before the stroke episode. The child with hemiplegia has not had that experience and will need emphasis on this during intervention. The integration of both sides of the body begins early for the typical infant, with lateral weight shifts in a variety of developmental patterns, and leads to postural organization that permits later reaching for a toy while the body weight is supported with the opposite side of the body. The child with a contrast in the sensorimotor function of the two sides of the body needs to experience developmental patterns that include rotation within the longitudinal body axis and lateral flexion of the trunk, with the more affected side forward. The therapist will need to emphasize the experience of supporting the body on the affected side and the experience of initiating movement with this side.

Fig. 10.21 This boy with hemiplegia tries to move a chair by orienting only his more active side to the task and bearing weight only briefly on the more affected side.

Fig. 10.22 The use of prism lens helps inhibit an upward eye gaze and neck hyperextension in this young boy while maintaining an upright position of his head. He is now ready to interact with toys that might be presented and with his environment.

Development of hand use first focuses on bilateral arm activity while keeping the affected hand well within the functional visual field (Fig. 10.22). The infant or young child works primarily in sitting until dynamic trunk flexion is activated. Pelvic mobility is essential to activate the necessary trunk responses. The therapist may find that dynamic lateral flexion of the more affected side of the body is fully as

difficult for some children as the initial active elongation of that side. There tends to be a high incidence of soft tissue restrictions along the shoulder and neck of the affected side. Children with hemiplegia have difficulty in sustaining a balanced posture against the influence of gravity, and some begin to struggle to do everything with the less affected side (Fig. 10.21). This characteristic contrast in function may contribute to the development of seemingly hyperactive behavior related to the inability of the CNS to resolve contrasting incoming information. Hyperkinetic responses in one side of the body may compensate for relative inactivity in the opposite side. Leg length discrepancy, scoliosis, pelvic obliquity, and shortening between the ribs and pelvis may develop. One goal of treatment is to bring these divergent response levels closer together so that the child can experience more comfortable postural change and can adapt to later school demands. The limbs of the hemiplegic child will change in postural tone as the trunk reactions are brought under active control and lateral weight shifts more clearly to the more affected side. The two hands need the experience of sustaining the body weight simultaneously, as do the two feet. Although the more affected hand may not develop sensation adequate for skilled activity, an important treatment goal is sufficient shoulder mobility to move the arm across the body midline and to assume a relaxed alignment during ambulation. Early treatment increases the possibility that the more affected hand will be used as an assisting or helping hand. There are some children who have such severe sensory loss that active use is minimal, although considerable relaxation can be achieved.

The greater the discrepancy between the sensorimotor experience of one side of the body and the other, the more tendency the system seems to have to reject one of the messages. This can lead to distortions in verticality and is a major interference in bilateral integration. Functional vision evaluation is important to avoid the midline shift problem, which will distort postural control. As body weight is shifted to the more intact side, flexor withdrawal patterns of the limbs increase in frequency and strength in some children. These postural reactions are often associated with lack of full weight bearing on the more affected side. The presence of a lateral visual midline shift or some visual field loss may increase the avoidance of bearing weight on the more affected side. One important therapy goal is the achievement of controlled weight shift through the pelvis during ambulation (Fig. 10.23).

Treatment strategies must incorporate a wide variety of more basic developmental alignments in which pelvic weight shift is a factor. The choice of prone, transitioning from sitting to four-point support, or a simple weight shift while sitting on a bench for reaching will depend on the movement characteristics observed by the therapist during the evaluative session. Diagonal adaptations are useful in the redistribution of tone for upright function. Careful attention must be given to pelvic alignment and mobility because the pelvis has a tendency to be rotated posteriorly on the more affected side in children who have not had adequate early therapy interventions. This can cause increased hip flexion and incomplete hip extension at terminal stance later if the child begins to walk with the more affected side held posteriorly, a characteristic that may be observed during analysis of leg position in gait. Dynamic foot support will facilitate an improved alignment of the base of support and help to facilitate a more functional weight shift when the child is not in the treatment session. The goal of functional movement is best reached through a wide variety of weight-bearing postures, from the obvious developmental alignments to horizontal protective responses, or reaching above the shoulders in sitting and standing to incorporate practical and commonly used adaptations.

The child with low muscle tone is perhaps the greatest challenge for both therapist and parent. Adequate developmental stimulation is difficult unless positioning can be varied. Placing the child in a more

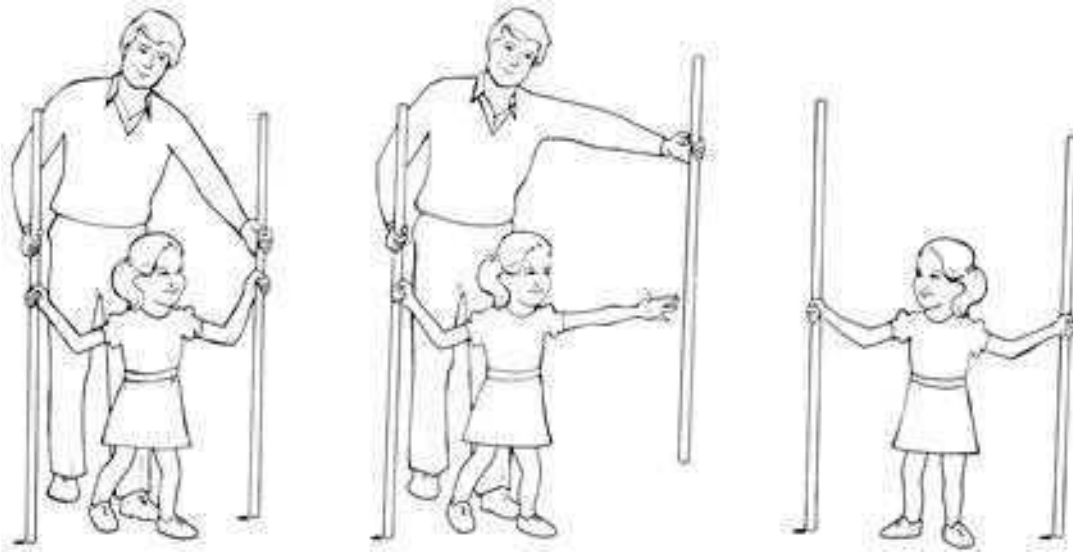

Fig. 10.23 The use of poles was introduced by the Bobaths as a way to achieve graded weight shift for increasingly complex postural adjustments in standing and walking.

upright alignment, although it is achieved with complete support initially, seems to aid the incremental development of postural control. To prepare the low-tone body for function, it is helpful to assess any possible soft tissue restrictions. However, equally important is not to take away muscle tightness that is providing a form of stability for the child without the ability to give him or her another form of stability for functional use. The neck and shoulder girdle are particularly vulnerable when low tone and instability are an issue. Strong proprioceptive input while providing accurate postural alignment is an important part of the treatment session. Strong proprioceptive input, such as axial compression, while accurate postural alignment is ensured as an important part of the treatment session. Gentle traction alternated with approximation as originally described by Bobath in 1975⁸⁹ also assists in maintaining antigravity positions and creates postural variance in the practice of antigravity postural reactions. Positioning at home may include a high table that supports the arms, allows for increased trunk extension in good alignment, and permits voluntary horizontal arm motion with the ability to weight bear through the upper extremities. The therapist must be cautious of the tendency of the child to “lock down joints” in the extremities and along the vertebral column for stability in response to trunk instability and initial hypotonicity. This appears as a stiffening response, which can be distributed in the deeper musculature, and contributes to limited adaptability rather than differentiated postural control. It is difficult to ramp up the corticomotor neuron pool even though the child’s motor output may remain limited; changes in positioning and opportunities for the child to have other sensory and visual experiences will often serve to motivate the child and contribute to motor learning.

Home handling needs to include a variety of positions during each day for seating and play. Adapting toys and positioning devices will be necessary, and working closely with the family to provide this will afford the child more opportunities to explore visually and motorically. Consistency in these practices is essential for the child with low tone to progress.

The process of undressing and dressing can be a dynamic part of the treatment program for any child and a functional skill that can easily be practiced in a home exercise program. (Fig. 10.24). Diagonal patterns of movement that are incorporated into the removal of socks and shoes assist in the organization of midline orientation. Weight shifts and changes in stability–mobility distribution occur throughout

Fig. 10.24 With assistance, this boy with right hemiplegia is helped to improve his self-esteem by exploring dressing.

the dressing process. Concepts of direction and spatial orientation are applied to the relationship of body parts and clothing. Directional vocabulary terms and names of clothing and body parts are learned with this experience. A bench is useful because it permits the adult to sit behind the child who is just beginning to participate actively. The older child with difficult balance reactions can use the bench in a straddle–sit alignment (Fig. 10.25). Aside from the physical and perceptual benefits, this achievement of dressing independently is one that offers the child a feeling of pride and independence. It is also a very practical preparation for the future when it is introduced in keeping with individual developmental and emotional needs (Fig. 10.26).

Fig. 10.25 Straddle-sitting on a bench gives this diplegic boy postural stability while he concentrates on the buttoning process.

Fig. 10.26 Organization of clothing within reach is essential for success in independent dressing.

Each treatment session regardless of age, severity, or type of CP may begin as a story begins with an introduction analogous to preparation of the body to move. The middle part of the session is the meat of the story providing assistance and facilitation as needed, but challenging the child with new movement experiences. Learning the rules of new movement strategies and making mistakes to form a reference of correctness for future attempts at new skills are all key components in treatment. Near the end of the treatment as in the story, everyone loves a happy ending by performing activities that are achievable and leave the child and family with a feeling of success and a desire to return for more exciting skills. Instruction for a home exercise program is essential to learning new skills. This program should include activities that can easily be incorporated into a daily routine to ensure practice, which is so critical for motor learning.

RESEARCH

Pediatric clinicians are faced with selecting treatments that are efficacious for children with CP. Increasing pressure on clinicians to establish that treatments are effective in improving functional abilities is often dictated by third-party payers. In the past there was little research on pediatric treatment approaches and protocols that withstood the rigors of scientific investigation. Today, several methods that warrant mentioning are undergoing systematic investigation. CIMIT

was developed from basic science experiments on deafferented monkeys to overcome learned nonuse of the upper extremity.^{90,91} This forced use approach was adapted for adult patients after a stroke; the affected upper extremity is forced to participate in activities and the less involved upper extremity is constrained. Practice is intense, with 6 hours of mass practice for a 2-week period.^{92–94} This protocol has been quite successful, with significant improvement in upper extremity movement and use of the affected limb. CIMIT is very popular and is now available in some clinical settings in modified dosing. The pediatric patient has also demonstrated a favorable response to this treatment protocol in several single-case studies.

In a clinical randomized trial by Taub and colleagues,⁹⁵ children with hemiplegia or brain injury receiving CIMIT for 21 consecutive days, 6 hours a day, demonstrated significant improvement in the amount of use, quality of movement, and spontaneous use of the affected upper extremity. These results were sustained at 6-month follow-up. Several studies from around the world are beginning to appear in the literature with varied methods. Most of these studies are promising; however, further investigation is necessary to establish the critical threshold, adequate dosage, and selection process for subjects who will benefit the most.^{96–101} Clinicians have been adapting these studies to their therapeutic settings and modify the protocols for clinical use and reimbursement potential as needed. In 2018, Gillick and colleagues investigated combining transcranial direct current stimulation (tDCS) with CIMIT in a blinded randomized clinical trial.¹⁰² Twenty participants with a diagnosis of unilateral CP were randomly assigned to a group receiving a sham plus CIMIT or tDCS plus CIMIT. The results suggested that there were differences between the control group and the experimental group and that tDCS was feasible and safe to use in children.¹⁰² In 2018 Carlson and colleagues investigated the use of MRI and MRS to investigate potential biomarkers in children with perinatal stroke. They demonstrated that MRS may be a promising outcome measure to document the neurophysiology of developmental plasticity in children post perinatal stroke.¹⁰³

Another study by Eliasson and colleagues set out to determine whether CIMIT would be beneficial for young children less than 12 months of age with signs and symptoms of hemiplegia.¹⁰⁴ Thirty-seven infants were randomized to one of two groups: CIMIT or infant massage. Results indicated that CIMIT was more effective than baby massage.¹⁰⁴ Studies are becoming more sophisticated in their design and are looking more closely at mechanisms to explain plasticity. MRI revealed a change in the levels of metabolites serving as biomarkers after CIMIT. These results may be indicative of a mechanism for plasticity of the primary motor cortex.¹⁰³ Multiple studies have been undertaken in an effort to demonstrate the benefits of this type of therapy for children with hemiplegia. Many of these investigations have reached the level of randomized clinical trials with more stringent outcome measures. The majority of these studies support the use of CIMIT.^{96–99}

Dosing, delivery, frequency, and method of restraint are all variables that can be manipulated to provide this treatment. Continued study of this therapeutic approach will be ongoing to determine the best combination of modalities to use to maximize the benefits of this intervention. Bilateral training is also a popular approach to improving function in the upper extremities.^{105,106}

Treadmill training also has been used in children with CP. The treadmill has been instrumental in rehabilitation for many years with a variety of purposes. This treatment began with animal studies on spinalized cats and rats and their responses to training on a treadmill in the recovery of a walking pattern. Today this treatment is used in many populations, including those with spinal cord injury, traumatic brain injury, Parkinson disease, stroke, and CP. The use of the treadmill in children with CP has shown promising results: improvement in gait pattern, increased walking speed, decreased coactivation in lower extremity musculature, overall gross motor skill improvement, and

improved and stabilized energy expenditure. Treadmill training interventions have taken on many different faces, including use of a regular treadmill, commercial equipment, and high-tech body-weight support systems (Figs. 10.27–10.29). Commercial equipment is now available to assist with supporting the body weight of individuals who otherwise would not be candidates for such a treatment. Clinical adaptations also have been incorporated to accommodate smaller bodies on a treadmill, which allows the therapist to assist from behind or from the side. Setting goals for this treatment must be precise, with an understanding of the purpose intended for its use: improving endurance, changing the parameters of the gait pattern, strengthening, and gait training. Each goal must be based on a sound theoretical foundation, which should be referenced to recent research. Researchers currently are investigating the use of several different delivery models, including—but not limited to—virtual reality to improve gait in children with CP,¹⁰⁷ the use of the AlterG anti-gravity treadmill system, and the effects on a variety of outcome measures,^{108–110} feasibility of home-based body weight supported treadmill training,¹¹¹ and robotic resistance training on the treadmill. Future studies will need to focus on optimal dosing, frequency, ideal walking speed, percentage body weight support for improved gait efficiency, and generalization of improved outcomes. As with any intervention the practice schedule should include variability during the intervention with consideration for increasing the speed, changing the incline, changing of body weight support, walking sideways and backwards, practicing starting and stopping strategies to improve generalization, and introducing a secondary task as in stepping over obstacles presented on the treadmill. **▶** Video 1.1 is an example of treadmill training with body weight support and facilitation of a reciprocal pattern using roller skates to improve dissociate of the lower extremities in a young boy with spastic CP. Strength training was never

Fig. 10.27 This young girl who has a diagnosis of spastic diplegia is practicing walking on the treadmill without holding on, and incorporating arm swing to improve her stride length.

Fig. 10.28 This young girl, who is an independent ambulator with a rollator walker, is participating in partial body weight–supported locomotor training to improve her gait pattern.

Fig. 10.29 This young boy with spastic quadriplegia is walking on the treadmill with the use of roller skates to provide lower extremity dissociation and reciprocal movement of the legs to decrease muscle stiffness.

Fig. 10.30 Using free weights to strengthen the upper extremities while stabilizing the trunk while seated on an incline bolster.

Fig. 10.31 This young adult with athetoid type cerebral palsy is doing exercises to strengthen his rotator cuff muscles with his arms in scapular plane.

thought possible in the presence of spasticity in children with cerebral palsy. Several studies have now shown that strength can improve in children with spastic cerebral palsy.^{112,113} Functional power training was used for a group of 22 children with cerebral palsy for 14 weeks, three times a week for 1 hour of loaded functional exercises including walking, running, and climbing stairs at high movement velocity, resulting in improved strength and walking capacity.¹¹³ Strength was maintained in this group of individuals at a 14-week follow-up posttest. Strength training in the presence of spasticity is also documented in adults as beneficial not only for activity participation, improved range of motion, strength, and physical function but in some cases reduction of spasticity. Strength training in children and adolescents with cerebral palsy has continued with investigations into the intensity, type of contractions to practice, and dosage.¹¹⁴ In a study by Aviram et al 2017, they looked at the effects of a group progressive resistance circuit program compared to treadmill training.¹¹⁵ They found that in 95 children who

Fig. 10.32 This young man is using stretch cords to work on strengthening his shoulder girdle.

were adolescents, both groups demonstrated improved motor function as measured by the 10-meter walk test and the 6-minute walk test compared to baseline, end of intervention, and 6 months post. Interestingly, a systematic review of common physical therapy interventions in school-aged children found that strength training demonstrated significant improvements in selected muscle groups but no meaningful change in function. This may indicate that the function assessed was not targeted toward the muscles strengthened in this study. Martin and colleagues¹¹⁶ and Moreau and colleagues¹¹⁷ studied muscle architecture as a predictor of maximum strength and its relationship to activity levels in cerebral palsy.¹¹⁷ They found that ultrasound measures of the vastus lateralis muscle thickness adjusted for age and the GMFCS level were correlated and predictive of maximum torque in children with and without cerebral palsy. A variety of methods for strength training can be incorporated into a clinical treatment setting or home exercise program with anticipated improvement in muscle strength, which may also result in improved functional status for a child with cerebral palsy. Strength training encompasses free weights, aerobic workouts, stretch bands or tubing, and machines that address resistive exercise (Figs. 10.27 to 10.34).^{115,118–122} Note strengthening exercises in the “Cage” allowing for lower extremity isolation in Fig. 10.35. This type of therapy is often available with the Thera-suit™ intensive programs detailed in the section on alternative therapies.

Many adjunctive therapies that are popular in combination with other treatments are available to individuals with CP. Electrical stimulation (ES) has been used in a variety of ways with children with CP. In several case reports by Carmick,^{123–125} neuromuscular ES (NMES) used in conjunction with task-oriented practice was found to improve sensory awareness, strength, gait parameters, and passive and active range of motion. In a study by Mudge and colleagues, ES was used in conjunction with Botulinum toxin A (BtxA) to improve hamstring extensibility. Six children participated in the study, and no improvement was noted in passive hamstring extensibility as measured by the popliteal angle at 4 weeks compared to BtxA alone.¹²⁶ No conclusions can be drawn from the studies mentioned above nor generalized to the population of children with CP due to the small number of subjects and limited current investigations. NMES was used as an adjunct therapy with upper and lower extremity practice protocols.^{123–127} NMES has been used in conjunction with 4×/week for 4 weeks of neurodevelopmental therapy (NDT) to improve sitting posture and

Figs. 10.33 and 10.34 This young girl with mild cerebral palsy is strengthening her shoulder girdle using the pull up bar with her trunk inclined to increase resistance by using her own body weight. This type of exercise targets scapular stabilizers.

Fig. 10.35 This young patient receives intensive suit therapy. The suit provides varying degrees of compression and support. He is seen here standing with the suit on in the “Cage” using bungee cords to provide additional stability.

balance for 75 children with spastic CP. Significant changes were found in the sitting subset of the GMFM and kyphosis levels of the children with NMES and NDT compared to a control group.¹¹⁶ NMES was used successfully in combination with gait during an 8-week, daily training program to improve muscle strength and muscle volume of the ankle dorsiflexors in 32 children with unilateral spastic CP.¹¹⁷ However, although there were significant results found at the end of the 8-week program, only lateral gastrocnemius muscle volume stayed significant at a 14-week follow-up.

A recent study by Qi and co-workers found improved GMFM scores, decreased Comprehensive Spasticity Scale scores, and improved walking speed when NMES was combined with strength training

compared to NMES alone in 100 children with CP.¹²⁸ ES has been in the therapy arena for many years, and its selective use with children who have CP may supplement regular therapy sessions with enhanced results. (Therapeutic subthreshold ES at meridian points is discussed in the section on electroacupuncture treatments and in Chapter 39.) ES has had mixed reviews in the literature as a stand-alone therapy and in combination with other modalities. Therapists should be aware of the inconclusive data on ES using good judgment and caution with its use while evaluating its benefits carefully.^{117,126}

BtxA, a neurotoxin, has been used to assist in decreasing spasticity because it provides a permissive condition that improves and increases range of motion and practice of new motor patterns and achieves developmental milestones without interference from increased muscle tone. Other positive outcomes from the use of BtxA are decreasing pain, orthotic management, as well as the possible delay in the need for orthopedic surgery until achieving maximal ambulatory ability.²⁵ Gait, range of motion, and decreased spasticity were noted to be improved in 60 subjects with CP after one local injection of BtxA.¹²⁹

However, BtxA effectiveness is affected by the patient’s age, type of CP, and degree of impairment.¹²⁹ BtxA has a temporary effect, so the critical element is its combination with other treatment modalities. Dursun and colleagues demonstrated improved range of motion and decreased spasticity in ambulatory children with CP when BtxA was used in combination with serial casting compared to the use of BtxA alone.¹³⁰ BtxA injections when used in conjunction with a 2-week physiotherapy program demonstrated significant gross motor function scores in 46 ambulatory children with CP with improvements lasting up to 52 weeks.¹³¹ It has also been used as an alternative to control the progression of hip dislocation, hip pain, and prevention of foot deformities in children with CP.^{132–134}

Several studies have initiated comparisons of different products all containing BtxA to assess effectiveness, health costs, and safety as alternatives. All of these have been found to be safe for use in children with CP with reduced economic burden.^{132,135} Further studies are ongoing assessing the many uses of BtxA, alternatives, and combinations of therapies for best outcomes. Joint and trunk taping or strapping, and special garments, have been used to provide sensory input and alignment for posture, balance, and strengthening. To date, there is

mixed evidence that these adjunctive treatments actually provide the benefits mentioned above. Further objective investigation will be necessary to address the issues presented by these additives to therapy. These alternative adjuncts are considered noninvasive with few side effects other than those associated with adhesive allergy to tape and autonomic nervous system responses such as sweating and overheating. Several different types of tape (athletic, Leukotape P Patella Tape [Notoden, The Netherlands]; Kinesio Tape [Kinesio USA Corporation]) and strapping materials such as Fabrifoam, lycra garments, and compression garments are available commercially. In 2018, Elbasan and colleagues assigned 45 children with CP to one of three therapeutic groups for 6 weeks: (1) NDT; (2) NDT with NMES; and (3) NDT, NMES, plus Kinesio-taping. They found that all groups made significant improvements in postural control and sitting balance; however, group 3 made greater improvements than the other groups.¹³⁶ In 2016, Karabay and colleagues reported similar results for postural control and sitting when comparing Kinesio tape, NMES, and NDT conditions.¹¹⁶ Dos Santos and colleagues¹³⁷ investigated the use of Kinesio-taping on sit-to-stand tasks with three conditions in six children with hemiplegic type CP. There were three conditions: (1) Kinesio-tape, (2) no Kinesio tape, and (3) placebo. They reported that children in group 1 increased rectus femoris activity by electromyographic (EMG) monitoring; decreased peak flexion of the trunk, knee, hip, and ankle; and increased trunk extension in the end of sit-to-stand by kinematic measures. The time to complete the sit-to-stand maneuver was not changed. These studies provide the groundwork for further investigation into the use of Kinesio tape as part of a therapeutic intervention.^{116,136–138}

Soft tissue mobilization is a method of stretching tight structures that have become restricted from overuse, spasticity, deformities, muscle shortening, surgeries, trauma, and poor nutrition. Inclusive to this group of tissues are fascia, tendons, muscle, ligaments, fat, nerves, vessels, lymphatics, and synovial membranes. This type of stretching has strong roots in osteopathic medicine but is not limited to that area of expertise. Over decades, research investigating the cellular and tissue changes that occur with immobilization has revealed some interesting and shocking alterations in the muscle and collagen fibers. With immobilization, slow muscle fibers show greater atrophy than do fast fibers. There is atrophy, a decrease in peak torque, an increase in fatigue resistance, loss of strength, and reduced central activation when the plantar flexors of the ankle are immobilized.^{139,140} In a study of children with severe spasticity, muscle biopsies were performed on the vastus lateralis to determine collagen accumulation in the spastic muscle. An increased accumulation of collagen I fibers in the endomysium of the muscle was noted, with thickening and decreased muscle fiber content in the more severe cases.¹⁴¹ This study, in combination with what we understand about healthy muscle, reinforces the need to keep the muscles flexible and active to help prevent this accumulation of collagen. Current literature suggests that there is a “redistribution of active nNOS molecules from sarcolemma to sarcoplasm,” which serves to initiate other biochemical responses and stimulate the mechanism of muscle atrophy.¹⁴² A small study looked at eight patients who were immobilized for 4 weeks due to fifth metatarsal or fibular fractures. Yoshiko and colleagues found that intramuscular adipose tissue and intermuscular adipose tissue increased; however, this was not statistically significant. Although both intermuscular and intramuscular adipose tissue changed after the period of immobilization, this finding had little effect on muscle atrophy. These changes were studied via cross sectional area using MRI.¹⁴³

Soft tissue mobilization and deep tissue stretching are methods that may improve the ability of the tissue to lengthen and fold, allowing for a more efficient activation of the muscle fibers, thus optimizing the formation of typical synergies during practice of motor skills. It is important for the therapist to realize that these changes in flexibility and muscle stiffness may be only temporary due to multiple factors related to CP.

As mentioned earlier, children with CP often have visual difficulties that are not acuity problems and are not correctable with a standard lens. Vision therapy has demonstrated good results when emphasis is placed on ocular motility and accommodation.¹⁴⁴ When children were given intense visual-oculomotor training, improvement was noted in vision-oculomotor control.¹⁴⁵ Improvement in the child's ability to execute smooth pursuit precision and maximum velocity, improvement of saccadic movement precision and stability, and shortening of the saccadic reaction time were significant after training.¹⁴⁵ In a recent study, Kurz and colleagues began to quantify the temporal intricacies of the α and β cortical oscillations in children with CP.¹⁴⁶ They compared this data with children without neurological deficits. The study demonstrated that children with CP had “uncharacteristic alpha and beta oscillations” within the visuomotor networks of the brain accounting for abnormal motor performance.¹⁴⁶ The accommodative process in children with CP was also found to be slower with a larger error margin potentially interfering in participation in everyday life and classroom learning.¹⁴⁷ Although many clinicians are not experts in the area of vision, vision is an important part of every therapy session. Incorporating vision as an integral part of a therapy session will not only improve the child's orientation in space but will address his or her ability to scan the environment while learning to move through space. Consultation with an expert in this area is warranted when functional vision interferes with movement and cognitive learning abilities.

Many therapies become popular by purporting to be a “fix” for a particular problem associated with CP. The clinician accepts responsibility for making sound judgments concerning treatment and outcomes for children with CP. Not all the treatments used in therapy will be investigated rigorously in a scientific manner. However, when a treatment approach is presented as advantageous for many diagnoses and conditions, with claims of success beyond what is reasonable for those conditions, it is your duty to proceed with caution. Always stop and think what theory and frame of reference the “new” approach is grounded in. Does this “new” therapy make sense with the knowledge you have of anatomy, physiology, neurology, and motor learning? As clinicians we will always be tempted to try new approaches before the scientific community has investigated them thoroughly. Clinicians, because they are creative and innovative, have advanced our professions. It is essential to advance patient care with treatments that are safe and do no harm. Every environment affords research opportunities that contribute to the treatment of children with CP. Single-case reports and single-case studies are the beginning of this process and, although descriptive in nature and with limited generalization, they provide evidence for new therapeutic approaches and further systematic investigation.

MEDICAL INFLUENCES ON TREATMENT

Because the problems of CP are so varied, the condition lends itself to diverse interventions, some of which have a longer life than others. Management of spasticity has always been an area of great concern and interest, and over the years several treatments have been offered to control this positive sign. Various medications have been used to control spasticity and are commonly used together in combination; however, careful monitoring for proper dosage is necessary. Baclofen, benzodiazepines, and dantrolene remain the three most commonly used pharmacological agents in the treatment of spastic hypertonia.²⁵ (See Chapter 36 for additional information.) The use of the baclofen pump in children with excessive spasticity has gradually increased over the past 20 years. This pump is implanted in the lower abdomen with a catheter leading to the intrathecal space for the administration of the drug. This treatment for spasticity has been effective in children with CP, but it can lead to complications in some patients, such as in standing and gait impairment in ambulatory children, which is due to

excessive reduction of muscle tone in the lower extremities. Other adverse events have included headache, nausea, voiding difficulties, and dysarthria.¹⁴⁸ Only a small number of studies have found intrathecal baclofen to be an effective treatment for spasticity for the short term. Further studies are needed to see the true effectiveness of this intervention for children with CP and its long-term effects on spasticity.¹⁴⁹

Other spasticity management programs are often considered. In 1968 a posterior rhizotomy surgical intervention was developed, with some success reported in reducing spasticity.^{150,151} It remained for Peacock and Arens¹⁵² to apply the procedure more selectively and functionally, and to bring it to the United States from South Africa. On the basis of their experience, Peacock and Arens insisted on daily neurodevelopmental (Bobath) treatment for at least 1 year after the surgical intervention. EMG testing before and during the surgery is used to determine which posterior nerve rootlets are creating the spasticity in the lower extremities.¹⁵³ The foundations for success are accurate selection of the child, an experienced surgeon, and careful analysis of therapy goals.

An improvement in the surgical technique of the selective dorsal rhizotomy (SDR) procedure was developed by Lazareff and colleagues.¹⁵⁴ They preferred to enter a limited number of levels of the spinal column and work more closely to the cauda equina based on results from a longitudinal study by Fasano and colleagues.¹⁵⁵ Several studies have documented an improvement in function, a reduction of spasticity outcomes, and a significantly less functional decline lasting into adulthood. Research has found that those children who benefit best from SDR have diplegic rather than quadriplegic CP, are younger than 10 years of age, and are those with a GMFCS grade II to III.¹⁵⁶ In a more recent retrospective study by D'Aquino and co-workers,¹⁵⁷ it was found that SDR was safe and effective in reducing spasticity of both the upper and lower extremities without major complications. When combined with physical therapy and careful selection of candidates for the procedure, the functional outcomes over a period of 2 years were lasting.¹⁵⁷ Another study by Oudenhoven and colleagues following 36 children with spastic diplegia for 5 years post-SDR reported that baseline gait quality and GMFCS levels were the greatest positive predictors for good outcomes.¹⁵⁸ In 2018, a study by Park and co-workers found that simultaneous baclofen pump removal and SDR led to improved ambulation and reduced spasticity in a group of 13 children with CP.¹⁵⁹ Although the changes with the modified lower limb Ashworth scores in this study were not found to be significant, all patients had resolution of clonus at the ankles and lower limb hyperreflexia indicating a clear spasticity reduction.¹⁵⁹

Careful selection of the appropriate candidate for this surgery followed by intense therapy intervention is essential for the success of the procedure and for optimizing motor outcomes. The use of BtxA has gained popularity in this population of children with CP. It has been used locally to affect a change in the individual muscle or motor point injected.^{160–167} Both orthopedists and neurologists have taken an interest in the use of BtxA to block selected muscle responses for a temporary period. BtxA has been reported to have fewer side effects than the phenol blocks and is now considered a drug of choice for this type of procedure.¹⁶⁸ These conservative interventions serve to evaluate an individual prior to surgery or to delay surgery until the child is more capable of responding to postsurgical therapy programs.

BtxA is rarely used as the only therapy option and is commonly prescribed in combination with other interventions. Variable results have been found on the true impact of using BtxA in conjunction with rehabilitation interventions. In 2018, Becher and colleagues found no clinically significant changes in muscle strength, walking speed, kinematic gait parameters, and PROM when comparing a group of children with CP who received BtxA prior to a comprehensive physical

therapy program (12 weeks of 3×/week therapy) to a group who received only the comprehensive program.¹⁶⁹ However, another study found significant improvements in the Tardieu Scale, GMFCS, and Visual Analogue Scale for enhanced ambulatory capacity when BtxA and a rehabilitation protocol were combined, compared to those who followed the protocol alone.¹⁷⁰

BtxA injection combined with serial casting has been shown to improve range of motion, muscle tone, and dynamic spasticity in ambulatory children with CP.¹⁷¹ Dursun and colleagues looked into the effectiveness of serial casting combined with BtxA and physical therapy for spastic equinus foot in children with CP. They too found improvements in spasticity, passive range of motion, as well as gait function with the Modified Ashworth Scale and the Observational Gait Scale.¹³⁰ Therapists should be involved in the decision making process of determining interventions for reduction of spasticity because often they are the most familiar with the child's movement strategies and the postural changes that occur in muscle tone as the child moves against gravity.

Orthopedic surgical intervention continues to be effective in CP to address long-term complications of hypertonia and spasticity such as musculotendinous lengthening, transferring tendons to correct deformities, osteotomies, and joint fusions. Most often a child with CP will have multiple procedures to correct deformities as part of a single event multiple level surgery (SEMLS) to allow for the least amount of hospitalizations and rehabilitation.²⁵ In any surgery, the outcome is much improved by close coordination between therapist and surgeon, with a functional orientation toward goal setting for the child. A recent systematic review looked into predictors for positive outcomes after SEMLS for children with CP. When assessing the outcome measures of GMFCS, the preoperative Gait Profile Scale (GPS), and the age at surgery, it was found that lower levels of GMFCS and GPS were associated with greater gains in parent-reported satisfaction and gait kinematics.¹⁷² A study by Öunpuu and co-workers found both short- and long-term benefits for children with CP who received a SEMLS that included rectus femoris transfers, as well as gastrocnemius and hamstring lengthening. Significant changes in gait kinematics were found at 1-year postsurgery, as well as sustained improvements in ankle dorsiflexion and knee extension during initial contact found at 11 years postsurgery.¹⁷³ Bony surgeries that offer better joint stability are usually planned for the termination of growth. Bracing of the trunk, which is sometimes warranted for scoliosis or kyphosis, is prescribed by the orthopedist. Surgical intervention for spinal deformities is determined by the physician, with consideration of the child's age, condition, and health, and the degree of curvature.

Children with CP differ in their ability to relax completely during sleep, and a small number of these children can benefit from night splints. Consultation with an orthopedist and/or orthotist about the style of night splint to use is suggested. When range of motion is limited, serial casting is often utilized to improve range of motion, to reduce tone, and to decrease excitability of the passive and dynamic stretch reflex at the foot and ankle.¹⁷⁴ These short leg casts are usually applied for a week at a time over the course of 3 to 6 weeks, depending on the progress and response to wearing. New casting materials make it easier to tolerate wearing the casts 24/7; they are lightweight and allow the incorporation of weight-bearing activities while trying to improve range of motion. In addition, there is a variety of lower extremity bracing available, and its selection is dependent on the lower limb segment targeted for control and the outcomes sought in positioning that segment. Bracing also has been shown to improve some gait parameters including walking speed, stride length, and heel-toe gait during ambulation (Fig. 10.36).¹⁷⁵

Fig. 10.36 A supportive shoe with inserts provides a more stable base of support for this low-tone child, facilitating more typical trunk reactions and permitting use of the hands for play.

EQUIPMENT

Equipment recommendations must take into account the physical space in the home and the amount of direct treatment available to the child (see Fig. 10.29). Young children in particular can often use normal seating with slight adaptations. This is not only more socially and financially acceptable, but also permits changes as required by the child's developmental progress. The portability of supportive seats or standers encourages the family to take the apparatus along for weekend outings or visits to relatives Fig. 10.37. Chair designs should place children at an age-appropriate level in their environments Fig. 10.38. This permits a better quality of visual exploration and facilitates social exchange with siblings and visiting peers. When planning the amount of physical support needed by the child, the therapist considers varying the structural control in relation to activity (Fig. 10.38). The child who is merely watching the play of others or a television presentation may successfully control trunk and head balance independently with minimal support. However, concentration on hand skills or self-feeding may necessitate trunk control assistance via a chair insert to avoid the child's use of compensatory reactions. As postural reactions become more integrated and hence more automatic, support should be diminished. There are now several options available to the consumer on the internet. Families and therapists alike can search online for commercially available products and alternatives. Some communities may have a lending closet that recycles equipment of children that have outgrown it.

For the more severely disabled child, equipment should be easily and completely washable. Mothers should be able to place special seating inserts into wheelchairs or travel chairs with one hand while holding the child. Wheelchairs should be ordered with consideration for family needs and the child's environment. The most expensive does not always offer the best solution. Control straps and seating should be adaptable and allow for future change on the basis of growth and improved function. The severely limited child needs seating changes at least once every hour during the day to prevent pressure and to provide environment changes as in typical development. Pleasing color, good-quality upholstery, and professional finishing are important not

Fig. 10.37 An upright stander is easily incorporated into the home environment, providing the child with an upright position, stimulation, and an opportunity to participate in activities.

only for the child but also for the family members, who are accepting the equipment as part of their personal living environment. Electric wheelchairs provide for independence in the community and can be equipped with a number of different options for driving when there are physical limitations that prevent use of the upper extremities. Careful evaluation of which part of the body will access the switch to drive the chair should be done prior to installation of the device (refer to Video 10.2). Working closely with the vendor, the family, and the individual ensures success. Consulting with a therapist that specializes in wheelchair equipment or attending a wheelchair clinic is highly recommended since this durable medical equipment is always changing and requires justification of medical necessity. Third-party payers require specific documentation to process a claim for a wheelchair. It is essential that the therapist be fully informed about the requirements necessary for billing any durable medical equipment through all third-party payers. In addition, most large items covered through insurance or Medicaid are limited to a 5-year period; that is, wheelchair purchases are only covered every 5 years.

As prices rise and the applicability of insurance changes, the therapist must consider cost effectiveness more carefully. A recent study provided a self-report survey for families on equipment needs and out-of-pocket expenditures and found that most families of children with CP purchased up to 25 items in areas of positioning, mobility, transport, modifications to the home, communication devices, orthoses, self-care, medical, caregivers, and adapted toys. This survey demonstrated the highest number of items were for positioning followed by mobility and then adapted toys.¹⁷⁶ Parents are often desperate to do everything possible for the child and tend to be very susceptible to high-powered advertising and reassuring sales personnel. By providing

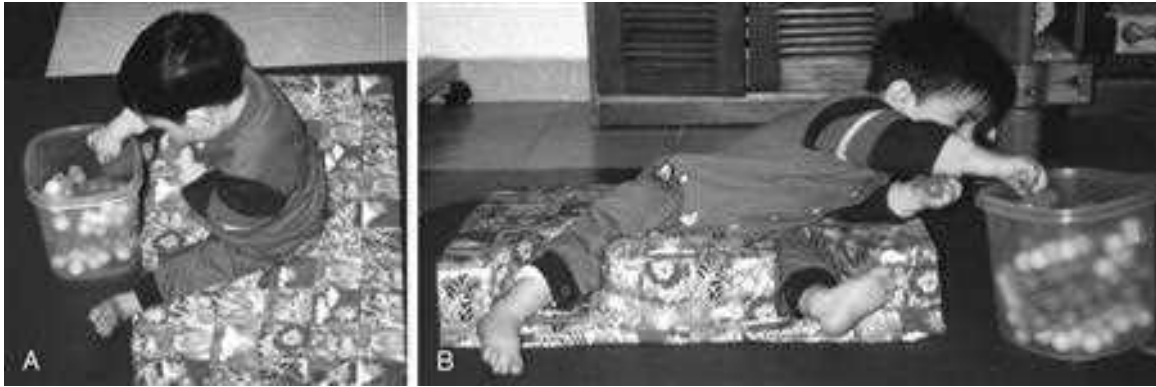

Fig. 10.38 (A, B) Use of a simple cut-out space in 3-inch foam gives this 1-year-old child security while requiring more active trunk adaptation during play.

a list of essential equipment features, the therapist will aid the parents in becoming informed consumers. Perusal of several catalogs online or in hard copy permits some comparison of quality and prices. Adaptive equipment fairs are often open to parents and therapists and are great opportunities to actually try the equipment without the burden of the cost. These are usually annual or semiannual events and can be found online or through your equipment vendor. Therapists can forge a relationship with a representative of a medical supply company and then access equipment on loan to try with their patients for short periods of time. Once the appropriate equipment has been purchased, periodic review of equipment used by the child can serve to encourage the family to pass along to someone else equipment items that are no longer needed. Investment in expensive equipment also has the hidden effect of influencing both parent and therapist to continue its use well beyond its effectiveness as a dynamic supplement to treatment. For this reason, more than any other, large investments must be thoroughly researched with regard to their long-term applicability for the child. Many pieces of equipment will be able to grow with the child, and this aspect should always be considered. When anticipating and considering the cost of adaptive equipment needs, it is important for the therapist and family to remember that some of the highest out-of-pocket expenditures come from home modifications and transportation vehicles, as well as the indirect cost of needing specialized care for their child. This typically falls to the mother or father who foregoes paid work to provide for their child.¹⁷⁶

Adaptive equipment is not the only type of equipment that the therapist must consider for patients. Conditioning and strengthening, now recognized as beneficial to children and adults with CP, open the door for equipment that lends itself to these parameters.^{177,178} (Refer to the section on research for evidence of the benefits.) Exercise bikes, treadmills (see Fig. 10.22), light weights (Fig. 10.30), and balance equipment (Fig. 10.39) are all valuable adjuncts to a home exercise program and should be considered, when appropriate, for a particular individual. Many of the commercially available items found at a sporting goods store can be well adapted to fit the needs of the higher functioning person with CP. With more emphasis on working out, sports equipment can even be found in discount stores. Offering to adapt equipment for your patients can encourage and increase compliance with exercises given for home exercise programs.

ALTERNATIVE THERAPIES

Hyperbaric oxygen treatment has gained popularity as a treatment for CP in children. Clinics are beginning to spring up worldwide for this

Fig. 10.39 Balance equipment allows for increased complexity in the therapy program with the refinement of balance reactions.

type of therapy. Research on this treatment has been inconclusive, and scientific evidence for its efficacy is lacking.^{179,180} Clinicians should keep abreast of the latest developments in the treatment of CP and inform families about the pros and cons of designer treatments. Essentially the Undersea and Hyperbaric Medicine Society (UHM) statement remains unchanged from 2003; that there is not enough evidence to recommend the use of hyperbaric oxygen therapy for CP.^{181,182} A systematic review by McDonagh and colleagues¹⁸³ found that there was no significant difference between pressurized air and

room air pressure, and that the subjects in both groups made gains. In a recent report by Chantre and colleagues the types of conditions for the use of hyperbaric medicine were discussed: acute or long-term chronic pathologies. Continued caution is advised when using this little-known discipline of hyperbaric therapy.^{184,185} This topic remains controversial even within the UHM. Several articles and editorials have been written with the overwhelming conclusion that randomized clinical trials should be carried out to determine the effectiveness of this treatment.^{179–185}

The Adeli or Therasuit are compression garments with bungee cord–like elastic cords attached to the suit along the trunk and extremities Fig. 10-40. This suit, once referred to as the *therapeutic space suit* or *treatment-loading suit*, was developed for Russian cosmonauts to counteract the adverse effect of long-term zero gravity on the skeletal muscles and bone composition.¹⁸⁶ There remain few studies that suggest that there are benefits for children with CP when they receive therapy in the suit. Ko and colleagues reported in a single case report, that strengthening exercises and gait training in the Adeli suit led to significantly improved spatial-temporal gait parameters, 10-m walking speed, GMFM, and Pediatric Balance Scale from baseline.¹⁸⁷ Although this report demonstrates positive outcomes in this single subject design, it cannot be extrapolated to a larger population of children with CP.¹⁸⁷ The suit allows for controlled practice of activities with resistance, and assistance when necessary; the cords are attached in a variety of ways to give different types of practice repetitions, as well as allowing for the most optimal joint and limb alignment and to dissuade abnormal muscle patterns.¹⁸⁶ Utilizing the suit-orthosis during seated reaching exercises or daily activities may allow for improved postural control and more organized anticipatory postural adjustments, and may assist with arm control.¹⁸⁸ As is prescribed by the proponents of this approach, intense practice is warranted to reap the benefits. This therapy is expensive, and the suit, if bought to use at home, is also very expensive. Rosenbaum¹⁸¹ has suggested that the benefits of this therapy vary with the type and severity of the involvement, the child's ability to participate in controlled movement, and the tolerance to wearing the suit for extended periods of time. Active participation, initiation, and motivation are known to enhance the long-term learning of motor skills and should be taken into account when determining which patients may benefit from this approach.⁷⁴ As clinicians, it is important for us to stay abreast of the latest developments and to provide families with reasonable alternatives. Although intense practice is well known in the literature as being beneficial for motor learning, the addition of the suit brings in a component that “appears” to provide “an extra set of hands,” stability, and graded control during practice (Fig. 10.35). In Fig. 10.40 demonstrates the use of bungee cords in the “Cage,” which is utilized to accomplish isolated strengthening. In Fig. 10.41 notice how the therapist is utilizing a game to assist with functional skills as part of this intense therapy approach. Caution when describing this approach to families is warranted because some evidence suggests that it may not be appropriate for every child with CP. The long-term effects and measurable outcomes after the use of the Adeli suit are not well documented in the literature.^{181,186}

The following questions must be asked: What happens to the motor abilities of the child when the suit is removed? Has the suit actually prevented the development of postural antigravity coactivation of the trunk and proximal axial joints? Are there measurable goals met after intensive suit therapy?

In the mid-1980s Pape¹⁸⁹ published a case series involving five children with CP receiving therapeutic (subthreshold) ES. This case series reported that overnight use of low-intensity ES in combination with standard therapy demonstrated significant improvement in gross motor, balance, and locomotor skills as measured by the Peabody Developmental Motor Scales in children with mild CP.¹⁸⁹ The results

Fig. 10.40 This patient participates in isolated strengthening of lower extremity muscles in the Cage with the use of bungee cords to provide active assistive exercise.

Fig. 10.41 The therapist has followed up with a fun game to bring therapy back to functional skills.

reported were based on observations by individuals who were not blinded to the purpose of the study, and therefore the research design was biased. In a follow-up study, Steinbok and colleagues¹⁹⁰ followed children who had undergone selected dorsal rhizotomy and received therapeutic ES for 1 year. Although this study reported improvement in gross motor function, no other measures were changed: range of motion, spasticity, or strength. Two well-controlled clinical trials investigating this method of threshold electrical stimulation (TES) delivery

concluded that no objective effects on motor or ambulatory function or clinical benefit for children and youths with CP were detected.^{191,192} In two separate randomized placebo-controlled clinical trials using TES, the results indicated that no significant clinical benefit was observed when compared with NMES.^{191,193} (Refer to Chapter 8 for additional discussion.) Parents often report changes with this therapy, but the objective measures do not demonstrate significant results. Clinicians in the field have reported that overnight use of subthreshold ES builds muscle bulk, but unless combined with active participation of the musculature, overall improvement in movement may not be seen. This therapy, for children with CP, requires a special stimulation unit that is subthreshold and capable of being used at night, and which has a shutoff setting that is activated if the electrodes become disconnected from the child. The unit is costly and further requires a clinician who is specially trained in its use to evaluate and periodically update the treatment protocol. Significant benefits for this type of ES have not been documented. In a randomized clinical trial comparing NMES and TES the results demonstrated no statistical difference between the 60 children with CP assigned to either of the NMES, TES, or strengthening groups.¹⁹³ This study suggested that children with diplegia may benefit from ES when regular strengthening exercises are difficult to carry out. Another study carried out in 2002 demonstrated similar results and found no clinical benefits during the study.¹⁹¹ Another form of ES, functional electrical stimulation (FES), is an intervention used during ambulation to support the necessary muscle groups in gait. FES is direct ES to a motor nerve, commonly the peroneal nerve, to produce a functionally useful contraction to prevent drop foot during swing phase by activating the dorsiflexors. It is hoped that FES can improve walking patterns and correct deviations by increasing muscle strength and decreasing muscle spasticity during movement.¹⁹⁴ A literature review on FES as an alternative to orthotic use in patients with a diagnosis of CP found 15 studies that demonstrated a positive orthotic effect and improved dorsiflexion during swing phase. The studies presented here have limitations in their ability to support FES. Only one randomized controlled trial was found in this group, and inclusion criteria for subjects required available dorsiflexion ROM.¹⁹⁴ A systematic review on FES of the ankle dorsiflexors by Moll and colleagues also found evidence for a potential use of FES as an orthotic alternative; however, there lacked support for any functional or therapeutic gains on the child's overall activity and participation.¹⁹⁵ These studies suggest that FES may be a possible and more appealing intervention, with minimal adverse events, for children who are not compliant with brace wear; however, further research needs to be done on its efficacy and long-term effects.

The Peto method or "conductive education" (CE), developed by Andres Peto in Budapest, Hungary, after World War II, has been used in children with disabilities.¹⁹⁶ This approach is an educational versus medical model, as the name implies, and the focus is on the many aspects of child development. It is based on practice and repetition combined with verbal guidance of a trainer (conductor) and self-verbalization by the child as he or she performs the task or activity.¹⁸¹ Most of the claims that promote its value have come from the Peto Institute in Budapest. The institute has been very selective in choosing candidates for this approach on the basis of the child's potential for independent mobility and function with a good overall prognosis.^{181,196} Research into this method of delivery of services to children with CP has been sparse outside the Peto Institute's studies. This approach advocates intense practice of all skills, motor and educational, with an emphasis on self-doing regardless of whether a compensatory pattern is used. Various pieces of equipment are used to facilitate independent skills: wooden slatted beds to allow the child to pull and maneuver, and wooden ladders mounted on the wall to assist

with dressing and transitions. The literature on CE does stress the concept of intense practice for motor learning. Similarly, promoting practice in the CE environment must transfer to home and community for carryover to everyday life situations.⁷⁴ A study looking at the attainment of gross motor behaviors in children with CP over an 11-month period 5 days a week reported that children achieved 83% and 89% of their gross motor behaviors in the fall and spring terms, respectively. The evaluators found that all practiced tasks, especially stability and transfer tasks, were attained; however, unpracticed motor behaviors were not achieved.¹⁹⁷ In two recent randomized clinical trials the investigators found no significant long-term effects of CE.^{198,199} The authors were careful to point out that larger trials need to be carried out to more fully investigate this approach. In addition, to fully optimize the outcomes of CE, a commitment from the family is essential, as is the case in most therapeutic approaches. It is well understood that for motor learning to be beneficial, skills need to transfer to other environments outside of the treatment arena.^{74,197}

The Feldenkrais method was developed by an Israeli engineer, Moshe Feldenkrais, while looking for a solution to his own knee problem. (Refer to Chapter 39 for additional discussion.) He started analyzing body alignment for more efficient movement.^{200,201} This form of body work has been used to help dancers, gymnasts, and other skilled persons improve their performance. Some therapists have undertaken the long training necessary to understand typical movement in more detail and to improve the movement coordination of their patients with neuromotor challenges. There remains no published research on this method, but several books and training courses exist that promote its use. Anat Baniel adapted the Feldenkrais method for children, particularly children with disabilities in 2012.²⁰²

Ida Rolf was trained in physics and had a son with some postural disorganization.²⁰³ She developed a structural approach, called the Rolfing technique, to improve body alignment; the technique uses specific release of deep soft tissue to restore effortless postural control against gravity.²⁰⁴ She was able to make positive changes in the movement patterns of many children with CP, but she never claimed to treat the disorder itself. The Rolfing technique requires special training, which is a type of deep tissue massage.²⁰⁵ There are no published research articles on the use of either the Feldenkrais method or the Rolfing technique with children with disabilities.

Dr. William Sutherland,²⁰⁶ an osteopathic physician, developed direct treatment of the cranium, which is referred to commercially as *cranial therapy* or *cranial sacral treatment*. (Refer to Chapter 39 for additional information.) This type of therapy is purported to have wide application to many disabilities and conditions.^{207–209} Today, there are persons trained at many different levels of expertise, so the family of a child with CP seeking this treatment will need to be certain that the practitioner is a professional and that she or he has experience with small children. Cranial treatment has claimed to restore the physiological motion of the craniosacral system, improving circulation of fluids to the brain as well as respiratory function, to which it is believed to be closely linked. In 2011, Wyatt and colleagues investigated the use of cranial osteopathy in 142 children with CP. These children were between 5 and 12 years of age with each receiving 6 sessions of cranial osteopathy. This randomized clinical trial found no significant evidence in improved motor function, sleep patterns, report of pain, or quality of life.²⁰⁸ Research has been encouraged in this area to substantiate the claims of this approach; however, there remain few rigorous reported studies in the literature.

Equine-assisted therapy (hippotherapy) is a new and popular treatment option for children with CP; it provides motor and sensory input through the movement and gait of the horse. Hippotherapy is thought to affect multiple organ systems including the musculoskeletal, limbic,

vestibular, sensory, and ocular systems, allowing likely improvements in posture, mobility, and balance. This therapy approach is fun and provides an opportunity for kids to participate in a more social and community activity. The American Hippotherapy Association (AHA) was founded in 1992 and created an international protocol for use in therapy. Certification standards to become a Hippotherapy Clinical Specialist (HPSC) were established in 1999 with a three-step program and a 3-year training period. Many studies have found hippotherapy to be beneficially effective for coordination, muscle tone, flexibility, endurance, movement patterns, and postural control.²¹⁰ A study by Park and colleagues looked at 34 children with CP who received hippotherapy 2×/week for 8 weeks compared to a control group. Improved balance, postural control, and functional performance were found with significantly improved GMFM scores and Pediatric Functional Skill Scale (PEDI-FSS) in the experimental group from baseline.²¹¹ Another randomized controlled trial looked at the effect of hippotherapy on muscle spasticity found decreased scores on the Modified Ashworth Scale for hip adductors after 12 weeks. Decreased spasticity of the hip adductors is purported to allow for improved pelvic kinematics and to lead to improved postural control and balance.²¹² When assessing the short-term and long-term effects of riding on motor function for children with CP, it was found that long-term riders (~1 to 4 years of routine practice) demonstrated significant improvements in walking, running, and jumping. The long-term repetition of the horse's pelvic movements is suggested to help reorganize the child's CNS and lead to improved movement patterns during daily and functional activities.²¹³

It is important for families to look into the certification of therapists offering hippotherapy, as well as being aware that there are limited number of centers in the United States that provide these services. General health insurance coverage may not cover hippotherapy. Therefore this treatment option can be costly and may not be viable for some families of children with CP.²¹⁰ Some communities offer support through grants or through school programs for this type of therapy.

Another alternative treatment used for children with CP is acupuncture, which involves insertion of needles into specific target locations in the skin. Preliminary studies have stated that acupuncture may increase blood flow and oxygenation to surrounding blood vessels, and may play a role in regenerating and repairing injured areas of the brain in children with CP. Acupuncture is an adjunctive therapy for children with CP, and although health insurance may not cover this, it is relatively inexpensive, without serious adverse events, and is considered a simple office procedure. A recent meta-analysis on the effects of acupuncture for CP found that acupuncture in conjunction with rehabilitation training led to improvements in both gross motor function and activities of daily living, as well as reducing muscle spasms.²¹⁴ Due to the limited number of studies and sample size in each study, more research is needed to see the true efficacy of acupuncture and the long-term benefits. However, the apparent short-term benefits are encouraging and provide another treatment option or an adjunct to contemporary therapy that the child is already involved in.

Aquatic therapy is an alternative for children with CP diagnosed with all levels of motor impairment. Performing treatment interventions in water may be easier and more beneficial for children with CP due to water's thermal and mechanical properties, including decreased spasticity, improved soft tissue elasticity, and buoyancy, which decrease the effects of gravity and improve joint alignment.^{215,216} A recent study looking at aquatic therapy's effect on both motor function and enjoyment in children with CP found aquatic therapy to improve self-reported physical activity enjoyment and gross motor function.²¹⁵ Aquatic therapy with an aerobic exercise focus has also demonstrated preliminary results with meaningful changes in gross motor function

and walking endurance in ambulatory children with CP. This 14-week study utilized functional activities including running, jumping, stair climbing, deep water walking, and hopping at a moderate-to-vigorous exercise intensity.²¹⁷ For children with higher gross motor abilities, this alternative therapy may be the way to get more participation and motivation for increasing strength and endurance. Aquatic therapy is feasible, fun, more enjoyable, and inexpensive therapy option to land-based therapy with minimal adverse events. More research is needed to understand the dosing and effectiveness for different ages and gross motor levels. Children with varying levels of cognition, interests, spasticity, strength, flexibility, and motor control will react and adjust to aquatic interventions differently. These multiple aspects should be considered when contemplating the best therapy option for each child.²¹⁶

Stem cell therapy is a novel option for children with CP with an increased prevalence in both clinical trials and literature reviews over the past 5 years. Interest in this treatment option has grown in leaps and bounds due to the lack of restorative options for CP. The current belief is that stem cell and other cell-based therapies might be effective for children with CP through its ability to repair and replace damaged brain cells, promote cell survival, and provide immune modulation. Early clinical trials have shown stem cell therapy to be safe and well tolerated with short-term improvements on gross motor outcomes. Many different types of stem cells are being researched, including embryonic stem cells, human amnion epithelial cells, mesenchymal stem cells (umbilical cord blood, placenta, bone marrow, adipose tissue), neural stems cells, etc., with the primary goals of restoring circuitry and normalizing CNS activity.²¹⁸ Chahine and colleagues reported a significant improvement of ~1.3 levels on the GMFCS in 11 of 15 children with CP, as well as significant cognitive improvements in 6 of 15, when treated with intrathecal bone marrow mononuclear cells.²¹⁹ Although stem cell research appears to be a positive and effective therapy, extensive research is needed to document the efficacy and longitudinal gains of this approach. Establishing the effective dosing, the critical time period for administration of this treatment, the most effective delivery mode, and the criteria for patient selection is prudent before therapists should be advocating for this option with patients' families. Staying up to date on the research for stem cell therapy is in every therapist's best interest due to the possible controversial and ethical conflicts and the widespread interest and discussion in the media.

Whole body vibration (WBV) in oscillation therapy has become increasingly popular in the general population. It is commonly found in local gyms and fitness centers due to its known health benefits of improved flexibility and muscle strength. WBV/oscillation therapy exposes a person's whole body to repetitious low frequency, low amplitude mechanical stimuli while standing on a platform. The belief is that the vibration stimulates muscle spindles to initiate increased and improved muscle contractions through a tonic vibration reflex. Studies that have been performed on children with CP have found WBV improved mobility, posture, gait, leg strength, and decreased spasticity of the knee extensors. WBV is a noninvasive, easy to apply, and relatively safe alternative or adjunct treatment for children with CP.²²⁰

Cheng and colleagues found that WBV significantly improves ambulatory function with the TUG and 6MWT, as well as decreases spasticity of the lower extremities after an 8-week session with results lasting up to 3 days posttreatment. WBV appears to assist in controlling spasticity and walking function and can be used as a routine treatment or as a spasticity-reducing agent prior to a typical rehabilitation session.²²⁰ In 2015, Saquetto and colleagues reported a meta-analysis reviewing 6 randomized controlled trials with 176 subjects overall and found that WBV may improve gait speed and standing function in

children with CP.²²¹ Utilizing a continuous oscillating platform may also assist with improving both reactive and anticipatory postural control mechanisms that could enhance functional performance in children with CP.²²² Therapists must assess the use of WBV/oscillation therapy on a case-by-case basis for safety and effectiveness. Further research is needed for proper protocols and long-term effects with this population.

DEVELOPING A PERSONAL PHILOSOPHY OF TREATMENT

The practicing therapist continues to learn much about the nuances of typical human development (see Chapter 2).²²³ The dynamic interaction of developmental movement components becomes more significant as the therapist acquires greater clinical experience and recognizes developmental change as a reflection of CNS maturation. Increasing knowledge of the functional nature of sensory systems and CNS processing will influence the choice of treatment techniques. Direct intervention will have more depth and specificity to improve the child's control of posture and movement while the therapist appreciates the complex interaction of developmental factors in CP. On the basis of individual experience, each therapist develops a personal philosophy of treatment that incorporates new research findings and evolving perceptions of the problem of CNS dysfunction. Without a philosophical or theoretical orientation for decision making, the therapist may succumb to following each promising treatment idea that is learned without having a clear image of the potential benefits for the specific patient. "Commercial" programs may benefit the child whose needs match the program objectives. An "individualized" program adapts to the needs of the particular child and is shaped by the response of that child during therapy. Without an internalized treatment goal toward which independent techniques are applied, the result may remain ineffective and unconvincing. The therapist in a direct treatment situation must develop a concise visualization of what is to be achieved in each session with the individual child based on a sound foundation. The repetition and practice that are so critical for learning must often be carried out at home, and the therapist becomes responsible for family instruction. Home exercise programs must be tailored for both the child and the family situation, and must be in alignment with the goals and expectations of the family. These programs need to be practical, fun ideas for practice that can be incorporated into the child's home life with reasonable assurance that the activities can and will be carried out regularly. Utilizing the World Health Organization's design of the International Classification of Functioning framework^{29,30} allows for a program that improves the child's activities and impairments; however, it also increases their social participation within the family and community. Studies have found participation to be the parents' predominant goal or need.²²⁴ Creative therapeutic ideas for playtime, dressing, grooming, mealtime, and relaxation time are best addressed in the home exercise program because these are everyday tasks that every family encounters, and the family is likely to be compliant. It is important that the family be involved in the development of goals and POC. Most improvements in abilities and skills are accomplished when everyone is working toward common agreed-upon goals. The time spent in therapy throughout the week cannot substitute for all the hours spent at home and at school.

Specialized therapy, like typical development, is potentially a preparation for functional performance. Training in specific coordination skills may be necessary for the older child or adolescent and must begin with a thorough analysis of the whole person who happens to demonstrate the effects of CP. Some children have learned self-care along with brothers and sisters. Others have needed therapy guidance for each achievement. Intelligent children with strong motivation may

only need some assistance in avoiding the use of atypical reactions, whereas others have poor spatial orientation and minimal motivation to achieve independence. The therapist most often needs to create a dialog with the individual who has the problem because parents are often fatigued and without energy to solve the issue of adolescent life skills. Perseverance is key to success with these individuals.

INVOLVING THE FAMILY

To be successful, therapy for the child with CP includes active family participation. Variability of practice in different environments tends to promote more effective motor learning, and parents who learn to help their child early begin to understand the importance of their participation as well as the nature of their child's disability. Parents are in the process of healing their own self-image, which was so injured when they learned of their child's disability. They should not be expected to become therapists per se, but should learn to observe small gains in treatment sessions that offer insight into the child's current strengths and weaknesses.²⁷ Therapy services have gradually transitioned to this more family-centered approach to allow for family strengths, increased respect between all family members and the therapist, as well as to promote sharing of information to guarantee fully invested care for the child while also empowering the parents. This family-centered care has been associated with progress in both the health and development of the child with CP, as well as improved psychosocial functioning and adjustment in their daily activities.²²⁴

Parents need to adapt their expectations in keeping with the child's continuing change and emotional maturity. Parenting a child with CP is no easy task, and the therapist will do well to develop respect for this demanding role. No one provides more for the child with CP than the nurturing parent who guides the child to self-acceptance of limitations without destroying personal initiative. This is the child who most often becomes an independent working adult (Figs. 10.42 and 10.43). View [Video 10.3](#) of a young man with athetoid CP negotiating traffic and city streets on his way to the city bus stop to get to job training at the public library. A recent questionnaire completed by 303 caregivers of children with CP demonstrated that a majority of caregivers may not know or understand the GMFCS level assigned to their child, or understand how their child's gross motor development compares to other children. Caregivers preferred having picture references to better understand their child's diagnosis and GMFCS, and reported that it would be helpful to revisit this information routinely to monitor their child's development.²²⁵ It is important that the therapist regularly

Fig. 10.42 Therapy goals must incorporate functional activities that lead to personal independence if they are to be pertinent for the older child and adolescent.

Fig. 10.43 This young man is waiting for public transportation on his way to work at the library.

check in with caregivers and families of children with CP to allow them the opportunity to ask questions and to be fully informed on the child's current status. Families may feel most comfortable discussing and asking motor development questions of the therapist rather than other health care providers due to the amount of time and rapport they have built with the family.

The therapist must give serious thought to priorities in home recommendations. Therapists must consider the size of the family and whether there are siblings, the outside employment of the mother and father, the physical capabilities of the child, the general health status of the child, and the psychological acceptance of the problem within the family. The emotional needs of some parents demand a period of less, rather than more, direct involvement with the child. Other parents must be cautioned that repetition of an activity more times than recommended will not result in faster improvement. This impression is sometimes gained from wide advertising of commercial programs that offer the same activity sequence for every child and demand a large number of daily repetitions. Both parent and therapist must appreciate the need for the CNS to have some time to integrate new sensorimotor experiences and to perfect emerging control of postural adjustments. Excessive control of movement patterns and overprotection by an adult tends to reduce the child's initiation of postural change and decrease active sensorimotor learning. Health needs for good nutrition and adequate rest also must be considered by parents and professionals. The attitude of teachers in the first years is extremely important for the child with CP. Advocating for a positive environment across the settings is advantageous for the child's achievement.

ROLE OF THE THERAPIST IN INDIRECT INTERVENTION

For many children with CP, active treatment is not available. Geographical isolation, socioeconomic factors, poor or lack of insurance coverage, and lack of qualified therapists may interfere with the delivery of direct service. The therapist must then assume the role of

teacher, counselor, or consultant. More often the new role emerges as one in which the therapist tries to meet a combination of needs and is frequently frustrated by lack of time, energy, and community resources. The therapist may be a member of a community team that includes a psychologist, a social worker, and a public health nurse. This sometimes creates more of a behavioral than a traditional medical orientation. Therapists also can be primarily responsible to the public school systems, introducing therapeutic positioning to classroom teachers. For these types of situations, the clinician will find video recordings or photographs a valuable adjunct to direct instruction. The individual child may be filmed with equipment, adequate positions, or therapeutic procedures. Useful topic-oriented video recordings are also available for professionals and families through educational resources and media. Instruction of key personnel in these settings is critical to the success of the therapist's recommendations.

When children have no access to direct treatment, positioning is of paramount importance. The selected support is used to avoid contractures, scoliosis, and permanent limitations in range of movement. Even the most severely limited child should have a minimum of three positions that can be alternated during the day. In addition, the position selected should be as functional as possible for the individual child to allow access to the child's environment. In some cases, this may mean encouraging eye contact. For another child, hand use becomes a possibility with proper trunk support. Each program should be individualized to maximize potential for the child in that environment.

Communication for the nonverbal patient with CP must be an integral part of the therapy or school program.²²⁶ A simple start may be made with pictures to permit choices in food, clothing, and therapy activities. The parents need encouragement to begin the process of letting the child make some simple choices in food, clothing, or preferred activities. Although computers have their place, the child should have the communication device with him or her at all times. Language development in the young child is enhanced by having this type of alternative communication device available while articulation is still difficult. The use of head movement is a powerful influence on muscle tone changes that may cause negative regression in postural or visual control.²²⁷ Care and consideration should be taken when evaluating the body part to access the device. Postural and visual control is essential toward the goal of better function and communication.²²⁸ A solution that was successful with one 9-year-old athetoid girl was moving the elbow back to a switch mounted on the vertical bar of the wheelchair backrest to access her communication device. Any activity that is repeated on a daily basis should be examined in light of possible interference by atypical patterns.

Affordable electronic systems with voice recording, portability, and growth features are available.²²⁹ Communication, which can be achieved by coordinating efforts with the speech pathologist/language therapist, can make the difference between passivity and active participation in the environment. View [Video 10.4](#) of this young boy with dystonic CP using his communication system with eye gaze. His speed and accuracy are remarkable. Play can be encouraged with the use of switch toys and touch-screen computers. New programs have been developed for computers, electronic interactive books, and technology; also, the availability of Bluetooth on multiple devices opens an array of possibilities when an individual is accessing media and their home/office/school environments.

THERAPY IN THE COMMUNITY

Therapists are often concerned with body functions and structure, and neglect to address participation in real-life activities such as school attendance, sports, employment, and involvement in the

community.^{230,231} Children with mild dysfunction as a result of CP may be successfully incorporated into physical education (PE) classes if the teacher is prepared to make some small adaptations. Teachers generally appreciate the opportunity to discuss with the therapist the specific limitations of the child and those movements that should be encouraged. Taking the opportunity to meet with the PE coach to establish adaptations and modifications or appropriate participation in activities is time well spent for the child's integration into the class. PE class is often rewarding for the child and is important in establishing peer relationships. For better success the child with functional limitations can be incorporated into a class that follows the British form of movement education, which places much less emphasis on intragroup competition and encourages each child to progress at her or his own rate. The therapist and the PE coach can also utilize the Framework for Sustained Participation for strategies to facilitate more frequency and continuous attendance for physical activity. This framework assists in choosing the right activity, encouraging them to want to succeed, providing a sense of belonging, providing the right coach or coaching style, as well as encouraging continuity, passion, and support for the child.²³²

Many communities are now offering after-school programs in adaptive sports, for example, soccer, baseball, and wheelchair sports, to name a few. These programs rely on volunteers in the community to work as “buddies” on the field or on the court to assist as needed for participation by the child with CP. Become familiar with your community to offer suggestions to your patients.

Classroom teachers who lack experience with children who have special needs are understandably reluctant to incorporate a child with movement limitations into the classroom until they know the child. A meeting with the therapist might be used to help the child demonstrate his or her strengths, physical independence, and ability to participate in classroom activities. The child may often play an active role in the problem-solving process necessary for a successful classroom experience. Children often have developed their own ways of managing the water fountain, the locker door, or personal care needs. Demonstrating these abilities reinforces strengths rather than limitations and empowers the child to receive positive responses from curious peers.

As programs that hire therapists move into the fields of prevention and early intervention, the therapist is dealing directly with a population that is not familiar with therapy per se nor aware of the need for this intervention. The therapist may discover a need to reorient previously accepted concepts of general rehabilitation. Clarification of one's own ideas is essential to establish effective communication with others. In some instances, active intervention to help the child will precede the labeling or diagnostic process, and referral to other specialists becomes part of the therapist's responsibility. Philosophically, early therapy becomes an enhancement of typical development rather than a remedial process, and it is advocated in the natural environment by federal funding agencies for children 0 to 3 years of age. Part C of the IDEA provides services for children 0 to 3 years of age, which is family focused and delivered in natural environments.⁷ This implies introducing new concepts of quality in early child development to the public. Day care, church, preschool, and Head Start programs are all examples of early childhood settings that incorporate children with impairments.

It is important to keep direct, active treatment available for older children, adolescents, and adults who are motivated to change. Now that more effective procedures are available for changing some of the basic neurophysiological movement characteristics observed in children with CP, it is possible to achieve change with direct treatment of the older patient. The adolescent often responds best to short-term, goal-oriented therapy programs that are patient

centered. Motor learning concepts are better understood by both the therapist and the patient, and can be incorporated into activities after mobilizing tissues that have been unused for so many years (see Chapters 3 and 8). With current program directions, many older patients may not have had the opportunity for direct treatment over time by a qualified therapist. For the minimally involved teenager, young adult, and adult with CP the local gym offers an alternative to direct therapy. Muscle weakness is a common impairment all children and adults with CP deal with that affects their ability to perform their activities of daily living. General conditioning is very popular in community programs, including weight training, endurance training, water exercises, yoga, and walking programs. Studies looking into the effect of strengthening interventions for people with CP have found a large effect on strength and physical performance when assessing outcomes of gross motor function, spasticity, kinematic parameters of gait, and range of motion.¹¹⁴ Although further research needs to be completed to determine which interventions are associated with the greatest improvements in strength and performance, a systematic review assessing the impact of strength training on skeletal morphology in children with spastic CP associates strength training with an increased muscle size, as well as increased strength.¹¹² Van Vulpen and colleagues found that power training—described as functional high-velocity resistance training—had a significant and effective impact on muscle strength and walking capacity in children with CP. These functional activities were performed at maximal effort for three sets of 608 repetitions.¹¹³ A therapist can be consulted to establish an appropriate program for the individual who wants to work out at the gym on equipment whether typical strength training or power training, attend special classes that are offered, or work out in the pool. When asked, it is the therapist's area of expertise to help identify and make recommendations regarding functional movement and activity participation for adults with developmental disabilities such as CP. (See the section in Chapter 35 on adults with developmental disabilities.)

The movement toward a health orientation as opposed to crisis intervention for illness will also affect services for children and adults with CP. This population does not have an illness or an active disease process, and they strive to lead as normal a life as possible. Many adults with neuromotor disabilities express their preference to participate in the decisions that are made for them regarding their ultimate lifestyle and participation in the community. The therapist who works with this population should familiarize himself or herself with the patient's living situation—family home, group home, or independent living—as well as the support system and work environment if applicable. These factors should be considered when establishing a viable program. Many opportunities for employment and volunteerism exist in communities for individuals with disabilities. This may require that the therapist venture into the workplace to assess accessibility and modifications that can be done in that environment to make for successful integration of the individual into the community. Optimal health for the adult with CP has yet to be described, and much more data must be collected. However, it is an exciting time as our society moves forward in its views and acknowledgment of disability (see Chapter 35).

PSYCHOSOCIAL FACTORS IN CEREBRAL PALSY

We have defined CP as a condition existing from the time of birth or infancy. The developing child has no memory of life in a different body. Movement limitations circumscribe the horizon of the child's world unless the family is able to provide enriching experiences. The development of both intelligence and personality relies heavily on developmental experiences and the opportunity for self-expression.

Participation in fun and exciting family and recreational activities is a way for a child with CP to not only learn new skills, but also to play, to make new bonds with family or friends, and to improve their self-confidence and sense of belonging in their community. The frequency of a child's participation in an activity and their measured enjoyment of participation has been found to be associated with their communication level, gross motor function, and manual ability.²³³

The child with spastic diplegia or spastic quadriplegia may be hesitant in making decisions or reaching out for a new opportunity because the world may seem overwhelming and threatening. The child may find it easier to withdraw toward social isolation. Parents and professionals can help children, adolescents, and adults with CP to avoid these reactions by encouraging independence in thought and in physical tasks. Early choices can be made by the child regarding which clothes to wear or which task to do first. Understanding the child's limitations helps build successes rather than failures. To function in spite of the constraints of spasticity or other movement problems demands considerable effort on the part of the child.

Athetoid children, in contrast, have adapted to failures as a transient part of life. However disorganized their movements, they repeatedly attempt tasks and eventually succeed. Their social interactions reflect this life experience. Most people will sooner or later succumb to the positive smiling approach without analyzing the deeper communication offered by the child. These children are difficult for parents to discipline and structure during their early years. Early treatment with concomitant guidance for young parents ameliorates some of the problems by making the developmental expectations for the child more appropriate. The words of professionals who are in contact with the parents at the time of the diagnosis echo through time to influence future decision making for the child.

Intelligent children with low tone demand that the world be brought to them. Cognitively challenged children may fail to receive sufficient stimulation for optimal development at their functional levels. Many of these children need visual or auditory evaluations and intervention, and some of them need a special educational approach. Whatever the learning potential of the child with CP, it is not always evident early in the child's life. Parents find it difficult to know how to guide a child when they are not certain that an assigned task or calm explanation is understood by the child.

Parental guidance of the child with functional limitations is also influenced by the adults' adaptation to their offspring's problem. Parents need to resolve, in their own way, the emotional impact of the child's disability. Parents need time to grieve the loss of dreams they had for their child, and each person will approach this in his or her own way and time. Each major milestone anticipated in a typical child's life may bring on the grieving process again. Most parents feel inadequate, ignorant, and relatively helpless at being unable to remedy the situation for their child. They need help in feeling good about themselves before they can effectively guide the child toward self-acceptance as an adequate human being. Parents need guidance to provide themselves with opportunities to rest and renew their energies. Therapists can be instrumental during this process by remaining nonjudgmental. (Refer to Chapter 5 for additional information.)

The therapist plays an important role in the psychosocial development of children who receive regular treatment. The child may perceive the therapist as a confidant, disciplinarian, counselor, or friend at various stages of development. Some children accept the therapist as a member of their extended family. This is natural, considering the extent to which therapists influence patients' own self-awareness through changes in their physical bodies. However, it also places a personal responsibility on the therapist to be aware of the continuing interaction and its effect on the maturational process of the child. Long-term relationships with patients and their families must remain professional for the therapist to be effective.

Any evaluation of personality characteristics in a disabled child must take into account the unnatural lifestyle that is imposed by the need for therapy, medical appointments, limited environmental exploration, and hospitalization. The child is expected to separate from parents earlier than the average child and usually confronts many more novel situations. There is little time or physical opportunity for free play. Continuous demands are placed on children to prove their intellectual potential in evaluations of various types. Adults most often monitor their social interaction while they assume a dependent role. Nonetheless, these children's social acceptance frequently rests on their skill in interacting with persons in their environments. It is not fair to the child to evaluate the evolution of personality without considering these experiential factors.^{234,235}

DOCUMENTATION

Developing a POC with objective measurable goals is required for documentation of progress in intervention and reimbursement from third-party payers. Carefully extracting a child's strengths and weaknesses from the assessment should drive the POC. Using timed measures, distance, number of repetitions, standardized tools, and other measurable outcomes provides a source of encouragement for families and objective justification for continued intervention.

Data collection is an important task in the treatment of CP. Change occurs at variable rates, but it is important to document the cause and effect of change whenever possible. Photos or video recordings are useful in providing functional comparisons over time. Digital video now allows a specific analysis of movement sequences. Fancy equipment is not necessary to document movement for comparison later. A cell phone provides video and slow motion, which allows you to collect a sample of movement strategies that can be analyzed frame by frame once downloaded. Placing the subject against a spaced grid in varying postures allows for measurement and assessment of alignment. This "basic" method also can be used while filming to assess movement. These ideas may be applied to documentation of treatment effectiveness or be analyzed for an understanding of similar movement problems in other patients. When attempting to document using photographs or filming, consistency in the environment is critical to the outcome and analysis with repeated use. Reliable comparisons made between one time point and another requires the same testing environment, time of day, and conditions. Parental consent is required to use these forms of media.

Methods of intervention or treatment are measurable for research and applicable to the functional problems presented by a diagnosis of CP. Once a specific research question has been formulated, systematic recordings of appropriate data can be gathered over time to accumulate data for a viable study. There is value in longitudinal reporting of a single case or a small group of individuals who have some characteristics in common because this aids our understanding of what we need to inhibit and/or facilitate in the young child to permit optimal function later. Research strengthens our understanding of this condition and further helps to justify our treatments. Clinicians have a difficult time putting into words exactly what takes place during intervention, which further complicates research investigation into the efficacy of treatment. Descriptive analysis of treatment is essential to document and to begin to understand what a therapist does during a therapy session. Understanding what takes place in therapy will help identify questions that could be investigated more closely.

The way in which therapists learn to view a problem determines, to a large extent, the potential range of solutions available to them. CP is a complex of motor and movement inabilities that cluster

about the inadequacy of CNS control, visual and soft tissue restrictions, and the amazing ability of the human body to compensate. Therapists need to look critically at developmental processes, qualities of movement, postural adjustments, timing and limitations of movements, and the range of dynamic functional movement. The further development and understanding of motor learning theories offer the researcher novel approaches to the challenge of CP and the resultant disorder of posture control and movement learning. Environmental factors may have as much influence as specific CNS limitations. Early intervention should be analytical, specific, and based on a theoretical foundation. Posture and movement control begin to change with direct treatment. Analysis of the postural components and movement characteristics of children with CP will lead to meaningful research more quickly than will professional reliance on the traditional definitions of the medical condition. Thorough documentation of therapy progress using objective

measures is critical for the development of more effective intervention strategies in the future. In addition, third-party payers including private insurance, Medicaid, and public early intervention programs for children 0 to 3 years of age require either standardized tests and/or other objective measures that are reproducible and reliable.²³⁶

CASE STUDIES

To understand the problems of children with CP, it is essential to follow some children over time to capture the evolution of family problems. Functional treatment must change according to the developmental level, chronological age, and neuromotor responses of the child. Intervention must be specific to the presenting problem of the moment while the missing aspects of complete motor development are considered. The case studies presented below provide a case description.

CASE STUDY 10.1

AR was a full-term baby born by emergency cesarean section when during labor she developed prolonged bradycardia due to compression of the umbilical cord. Her APGAR scores were 3 at 1 min, 5 at 5 min, and again 5 at 10 min. Her vital signs were depressed with poor recovery at 10 min, and she was transferred to the neonatal intensive care unit (NICU). Her NICU course was unremarkable; however, she spent 4 weeks in the unit. This was the first baby born to this family, and as is common they were unfamiliar with the typical milestones that should occur in development. The Pediatrician was concerned with her initial hypotonia and later development of muscle stiffness, delayed acquisition of speech and language, and motor skills. The Pediatrician referred AR and her family to a neurologist. A diagnosis was subsequently made at 18 months of age of ataxic CP. A magnetic resonance imaging revealed generalized atrophy of the cerebellum also referred to as congenital cerebellum dysplasia. Therapy had been initiated prior to the diagnosis due to developmental delay, and a program was well established. The parents had support of family in the area and were compliant with home exercise recommendations. Mom worked full time, and Dad traveled on his job 2 days/week.

Today AR is 16 years old and walks independently short distances with a reverse rollator walker. She demonstrates timing issues with over- and under-targeting, difficulty with muscle grading interfering with smooth motor execution, and muscle stiffness in all extremities with the right side more involved than the left. AR requires extended processing time, which also influences her

motor planning skills. She remains at high risk for falling. Mom is still working full time, and Dad travels 2 days a week for his job spending 1 night a week out of town during those days. It has been difficult to keep her therapy at 1 day a week, so recently her therapy was reduced to every other week.

Refer to [Videos 10.5A–C](#). Take note in these videos of AR's general movement strategies during gait, transitions, and targeting. Begin to list her strengths and weaknesses related to her impairments and limitations. Use [Fig. 10.7](#) to record your data as you observe AR's movement.

Prioritize your findings. What did you identify as her strong foundation on which to develop your plan of care and to base your goals? Does AR have righting, equilibrium, and/or protective extension reactions? Does AR have midrange control, eccentric control, end range control? What skills does she demonstrate independently? What are the impairments that limit her activities? With her age in mind, what are the issues you see for her in the area of participation in her community?

View [Video 10.5D](#). Note in the video an example of treatment ideas for this child that emphasizes balance, weight shift, reaching outside her base of support, targeting, and problem solving—making this a complex task. How could this activity transfer to something in her own environment? Due to her age and the limited “free time” of the family, home exercises are rarely able to be carried out. What would you suggest to this family that would be beneficial for AR outside of therapy?

CASE STUDY 10.2

WT was born full term with heart complications leading to the need for open heart surgery at 6 days old, placement on the Berlin Heart at 2 months old, and a heart transplant at 9 months old. While on the Berlin Heart, WT had a blood clot travel to his brain causing a cerebral infarction, which resulted in a later diagnosis of spastic left hemiplegic cerebral palsy.

At 9 years of age, WT is now status post left Achilles tendon release and serial casting to promote improved left ankle range of motion. He presents with posturing of the left lower extremity in plantarflexion, mild knee flexion, hip internal rotation, as well as right weight shift with left hip hike and maintenance of left hand in a fist position. This is clearly demonstrated in the first picture of him standing on the half-BOSU in [Fig. 10.44](#). What impairment should be addressed first? Is the plantar flexed left foot and left hip hike due to the right weight shift or the other way around? Do you feel weakness or lack of proprioception/sensation of the left foot or extremity is more of a factor in his posturing and positioning during standing?

During a recent treatment session, WT participated in an intervention where he alternated between playing the goalie and the soccer kicker. Refer to [Videos 10.6A and B](#) for video clips on this patient. Bilateral 0.5-lb ankle weights were donned throughout the task, and he was asked to only dribble and kick with his left leg. Would the ankle weights worn in this task be more beneficial for strengthening or for body awareness? Although using only the left leg for kicking and dribbling encourages a right weight shift, which is already his preference, what are the benefits for performing this task?

See the final two pictures for after-session stance on both a solid surface and the unstable surface performed at the beginning of the session ([Figs. 10.45 and 10.46](#)). What are the differences noted? Was the intervention successful? Which aspects of the task impacted WT's impairments the most?

Fig. 10.44 WT (Case Study 10.2) prior to therapy intervention. Note the asymmetry as he stands on an unstable surface (BOSU) and posturing of his left arm. His weight is shifted toward his stronger side. *BOSU*, Both sides up.

Fig. 10.46 WT (Case Study 10.2) after intervention on the unstable surface of the BOSU. Although his weight is more equally distributed over both lower extremities, there is a slight lateral lean to the right. In spite of this he takes more weight through the left leg compared to preintervention. *BOSU*, Both sides up.

Fig. 10.45 WT (Case Study 10.2) after therapy intervention on a level stable surface. Note a more symmetrical distribution of his weight over both lower extremities.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 236 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

DEDICATION

This chapter is dedicated to Christine Nelson—master clinician, true friend, and mentor. Her gifts as a clinician and artistic eclectic approach to the treatment of children were unmatched and often seemed beyond what one could comprehend. She has forever changed those she touched and enlightened all those she taught. Christine will be forever missed, and yet her gift of touch will be everlasting and live on in her patients, students, and friends.

Abstract: This chapter on cerebral palsy (CP) provides a historical perspective of the diagnosis of CP dating back to the mid-1800s. The classification of CP and the general movement characteristics are described. Each child will need to be assessed with goals directed specifically for them. Direct intervention includes the role of the therapist, the family, and the special needs of infants. Important aspects of assessing a child with CP are highlighted, and examples of formats for collecting critical data are provided. There is a research update on common treatments that are available for the child with CP. Medical influences and alternative treatments are discussed since families will want to know as much as possible and they will expect a translation from the therapist. A personal philosophy develops over time, and part of this transformation will be shaped by families. Families are the core to treating the child with CP. As with any chronic condition there are psychosocial factors that come into play, required appropriate documentation for third-party payers, and the ever-present goal of participation in the community. Videos are offered throughout the chapter to illustrate assessment, intervention, equipment, and participation in the community. In addition, the chapter provides two case studies with video to allow the reader to think critically and problem solve each case with guided questions.

Genetic Disorders: A Pediatric Perspective

Sandra G. Reina-Guerra and Eunice Yu Chiu Shen

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the main types of genetic disorders and give an example of each type.
2. Differentiate between genetic disorders diagnosed with clinical versus laboratory methods.
3. Describe three modes of inheritance for single-gene disorders.
4. Recognize key impairments common to many genetic conditions in pediatric patients.
5. Explain the physical or occupational therapist's role in the recognition, referral, and multidisciplinary management of genetic conditions in pediatric patients.
6. Identify resources and strategies for use in clinical decision making, accessing information, and increasing knowledge about genetic disorders.
7. Explain why it is important to include family members in the planning and development of therapy programs for children with genetic disorders.
8. Describe and give examples of three types of assessment tools and state the intended purpose of each.
9. Describe the importance of developing therapy programs for children that are outcome-focused and emphasize functional skills in natural environments.

occupational therapist
physical therapist

The era of genomic medicine has arrived; however, its impact on health care delivery for pediatric patients has not yet been fully realized. Personalized medicine, now expanding to the concept of personalized physical and occupational therapy, is a challenging and exciting undertaking that incorporates evidence from population studies regarding the needs of the unique individual.¹ The Human Genome Project, completed in 2003, quantified an important measure of human “uniqueness”: of our approximately 20,500 genes, we are *at least* 99.5% genetically identical to one another.² With so little dissimilarity, one may question the hype about a personalized health care approach. The emerging fields of epigenetics and epigenomics offer a partial explanation; though the construction of a single gene may be complex, its work can still be influenced by the chemical compounds attached to it. But does the pediatric therapist have a role in the future of personalized medicine? Professional^{3,4} programs are tasked to prepare graduates to participate in translational medicine, and signs are clear that the profession is answering the call. For example, consider the research of physical therapists into mechanotransduction.^{5,6} Although the task of achieving clinical competence with genetics and genomics may seem daunting, the need to do so is imperative for the practitioner. After all, the need for personalized health care is as old a concept as “nature versus nurture,” and now scientific research is feeding our professional curiosity by facilitating the study of the gene-environment interactions behind many multifactorial genetic conditions.⁷

As in the past several editions of this textbook, this chapter focuses on genetic disorders in children that result in a wide variety of health conditions and associated movement limitations. The impact of such conditions on the child may be evident before or immediately after birth, whereas other conditions may not be diagnosed until later in life, when problems manifest. This chapter provides an overview of common neurological disorders of known genetic origin that pediatric physical and occupational therapists are likely to encounter. Tools such as vocabulary, illustrations, and internet-accessible resources are provided to help clinicians recall basic principles of genetic inheritance and genomics. Case studies are given to provide examples of clinical decision making, including diagnosis, therapy assessment, and prognosis. Last, this chapter includes highlights of advancements in genetics research ranging from the completion of the 2003 Human Genome Project² through the present day. See [Box 11.1](#) for a time line of milestones in genetics and genomic research, including gene therapy.

GENOMIC CONSIDERATIONS FOR PEDIATRIC THERAPISTS

An accurate diagnosis of a specific genetic condition is necessary to inform prognosis, as a basis for genetic counseling for the child's family, and often to establish eligibility for therapy and education services.⁸

BOX 11.1 Modern Advancements in Genomics

Human Genome Project, 1990–2003

The 3 million base pairs in human DNA were sequenced; that is, all genes of the human genome were identified and mapped.

1990: Gene Therapy Clinical Trials

The first clinical trial of gene therapy in the United States was approved for the treatment of inherited retinal dystrophy, a single-gene disease.

1995: Genetic Disabilities

The Americans with Disabilities Act (ADA) was extended to ban discrimination in the workplace based on genetic information.

2004: American Physical Therapy Association–Normative Model of Physical Therapist Professional Education

This model states that graduates of physical therapy programs are expected to use their knowledge of genetics to develop prognoses following physical therapy interventions

2002–09: HapMap Project

A catalog of 1 million single-nucleotide polymorphisms (SNPs) was produced to describe patterns of human genetic variation, including risk factors for the development of disease.

2007–08: Next-Generation Genetic Sequencing

NGS increased the output of gene sequences to 70 times faster than prior methods.

2008–15: 1000 Genomes Project

Whole-genome sequencing to catalog the genetic diversity of 2500 humans from 26 global populations. Its open resource database continues to grow and is maintained by the International Genome Sample Resource (IGSR).

2012: The ENCODE Study Publishes 30 Papers, Confirming That the Human Genome Contains Over 20,000 Protein-Coding Genes

2017: US Gene Therapy

December 2016: The US Food and Drug Administration (FDA) approves Spinraza to treat spinal muscular atrophy.

August 2017: The FDA approves the first gene therapy product to treat acute lymphoblastic leukemia in patients up to 25 years of age.

December 2017: The FDA approves the first gene therapy product to treat inherited retinal dystrophy, a single-gene disease.

2017: 48th Annual Mary McMillan Lecture by Dr. Richard K. Shields

“Turning Over the Hourglass”: Precision physical therapy and the relationship between movement interventions, human gene regulation, and recovery is described.

2018: National Institutes of Health ALL OF US Research Program–Genomics Working Group

Goal to recruit 1 million US research subjects from diverse backgrounds in order to compile longitudinal health data and promote advancements in precision medicine.

The diagnostic process for genetic disorders includes a combination of clinical assessments by the physician, who collects the child’s medical history, and a clinical geneticist, who may construct a family history or “pedigree” to recognize disorders with familiar inheritance patterns. Physical therapists are ideally trained and positioned to contribute to

the diagnosis of genetic movement disorders. They are professionally trained to observe, quantify, and interpret human movement across the life-span.⁹ Furthermore, pediatric therapists such as those in early intervention (EI) practice have the rare opportunity to spend extended time in the observation and therapeutic handling of involved infants and young children as they develop. Pediatric therapists’ evaluations include a comprehensive subjective evaluation, including family history, time line and course of the movement difficulty, a summary of body systems screening, quantified and qualified descriptions of the movements based on expected developmental performance, and measurements of the functional severity of the movement problem(s). Therapists cluster signs and symptoms of medical conditions and diseases and integrate those findings with observed movement to inform the next steps of medical diagnosis, which in many cases may lead to genetic testing.¹⁰

Genetic tests of varying complexity will be used to confirm a clinical diagnosis, differentiate between diagnoses with similar clinical presentations, and identify the genetic causes of disorders. Pediatric therapists should be prepared to use their knowledge of genetics to contribute clinical evidence that will assist the diagnostic process and choose targeted therapeutic interventions consistent with precision health care.^{6,7,11–20} Some genetic disorders are not easily identified, resulting in delayed diagnosis.^{21–23} Laboratory testing can be expensive, prolonged, and often inconclusive; therefore pediatricians may refer children to occupational and physical therapy before the nature of their condition is fully known.^{8,11–13} Patients are sometimes far removed from hospitals and specialized centers that perform genetic testing and diagnosis; therefore the pediatric therapist is often the first resource to whom families turn for help. Furthermore, many genetic diseases and syndromes are increasingly survivable into adulthood; thus it is vital that physical and occupational therapists incorporate knowledge of the genetic mechanisms that influence disease states and achieve competence in genetics and genomics to deliver care throughout the patient’s life-span.^{6,11–16}

AN OVERVIEW: CLINICAL DIAGNOSIS AND TYPES OF GENETIC DISORDERS WITH REPRESENTATIVE CLINICAL EXAMPLES

Genetic disorders are typically divided into four categories: chromosomal disorders, single-gene (monogenetic) disorders, multifactorial inheritance disorders, and mitochondrial disorders. **Chromosomal disorders** arise when there is an alteration in either the number or structure of an autosomal or sex (X, Y) chromosome.²¹ Numerical or large structural chromosomal abnormalities can be seen through a microscope; therefore a sample of the patient’s peripheral blood can be used to detect disorders such as Down syndrome (Fig. 11.1). When there is a suspicion of a clinical spectrum associated with some of the known chromosomal microdeletions, translocations, or inversions, direct deoxyribonucleic acid (DNA) analysis techniques such as fluorescence in situ hybridization (FISH) and microarrays can identify the defective genes and gene products.²¹

Monogenetic disorders are defects of one of the approximately 20,000 protein-coding genes^{2,24}; a single gene may be responsible for approximately 6000 known genetic traits.²³ Approximately 4000 of these known traits are diseases or disorders.²² Indirect DNA analysis techniques such as linkage analysis can be performed to confirm single-gene disorders when the gene or genomic region

Fig. 11.1 Chromosomes of a child with Down syndrome, (From https://openi.nlm.nih.gov/detailedresult?img=PMC3232533_IPC-4-3-g004&req=4.)

associated with the disorder is unknown.¹⁶ Single-gene disorders may be transmitted through three different patterns: autosomal dominant, autosomal recessive, and sex-linked. *Dominant* refers to the case in which a mutated gene from one parent is sufficient to produce the disorder in offspring. *Recessive* refers to the case in which the disorder will not be expressed unless the offspring inherits a mutated copy of that gene from both parents. It is incorrect to say that a *gene* is recessive or dominant; rather the *trait* or disorder is dominant or recessive.²¹

Inheritance is usually a term reserved for the transmission of a previously recognized family trait to subsequent offspring. However, many genetic disorders arise from new, spontaneous mutations in a *gamete*, the single egg cell from the mother or a sperm cell from the father. The remainder of the gametes of either parent is most likely normal. In the case of a germline mutation, the offspring will be the first in the family to display the *sporadic* or *de novo* disorder, and the faulty gene can then be passed onto subsequent generations. A disorder that results from a single copy of a mutated gene is referred to as a *dominant* disorder even if it is acquired by a spontaneous mutation. Not all literature sources will include spontaneous mutations in the description of *inherited* disorders.

It is important to understand how a disorder was acquired because the relative risks to other offspring for the disorder vary according to the mode of transmission. For example, the risk of having another child with the same genetic disorder that occurred as a result of a spontaneous mutation is low. However, when one parent is affected by an inherited dominant mutation, the risk of passing that faulty gene onto each child is 50%.²¹

Multifactorial Inheritance Disorders

Most congenital malformations and many serious diseases that have an onset in childhood or adulthood are not caused by single genes or chromosomal defects but rather by a combination of small inherited gene variants acting together with environmental factors.^{21,22}

Mitochondrial disorders are caused by alterations in genes that control mitochondrial function (i.e., converting food into energy). Mitochondrial DNA (mtDNA) codes for about 37 genes; mutations are transmitted by maternal inheritance. Mutations in nuclear DNA may follow an autosomal dominant, recessive, or X-linked pattern of inheritance. The clinical manifestations of mitochondrial genetic disorders are extremely variable in severity and timing of presentation. Organs having high energy demand—such as the heart, brain, and skeletal muscle—are more commonly affected than others. The incidence is reportedly 1 in 6000 live births and 1 in 5000 adults.²⁵ Nongenetic testing includes tests of urine, blood, and spinal fluid as well as muscle biopsy, magnetic resonance imaging (MRI) of the brain and spine, and whole-exome sequencing. Next-generation gene sequencing has led to the discovery of new nuclear genes linked to these disorders. Hence, it was found that disorders arising in children are more often due to mutations in nuclear DNA than mitochondrial DNA; the opposite appears to be true in cases of adult-onset disease.

Currently genetic testing is available for more than 2000 conditions in 500 US laboratories, including samples obtained directly from health care consumers.²⁶ Specific DNA testing may soon be able to identify nearly all human genetic disorders. This not only allows for accurate and more complete diagnosis but also paves the way for the development of mechanisms for the treatment, cure, and prevention of certain genetic conditions.²⁶ Table 11.1 lists examples of specific disorders in categories of the most common pattern of inheritance by which each occurs.

Chromosomal Disorders

Cytogenetics is the study of chromosomal abnormalities. A karyotype is prepared that displays the 46 chromosomes—22 pairs of autosomes arranged according to length and then the two sex chromosomes, which determine the sex. Modern methods of staining karyotypes enable analysis of the various numerical and structural abnormalities that can occur. Most chromosomal abnormalities appear as numerical abnormalities (aneuploidy) such as one missing chromosome (monosomy) or an additional chromosome, as in trisomy 21 (Down syndrome).¹⁶ Structural abnormalities occur in many forms. They include a missing or “extra portion” of a chromosome or a translocation error, which is an interchange of genetic material between non-homologous chromosomes. The incidence of chromosomal abnormalities among spontaneously aborted fetuses may be as high as 60%.²⁷ About one in 150 live-born infants has a detectable chromosomal abnormality; and in about half of these cases, the chromosomal abnormality is accompanied by congenital anomalies, intellectual disability, or phenotypical changes that manifest later in life.²⁷ Of the fetuses with abnormal chromosomes that survive to term, about half have sex chromosome abnormalities and the other half have autosomal trisomies.¹⁶

The following section provides a brief overview of common genetic disorders seen by physical and occupational therapists working with children.

Autosomal Trisomies

Trisomy is the condition of a single extranuclear chromosome. Trisomies occur frequently among live births, usually as a result of failure of the parental chromosomes to disjoin normally during meiosis. Trisomy can occur in autosomal or sex cells. Trisomies 21, 18, and 13 are the most frequently occurring; however, few children with trisomies 18 and 13 survive beyond 1 year of age.²⁷

TABLE 11.1 Partial Listing of Pediatric Genetic Conditions

Syndrome or Disease	Approximate Incidence (United States)
Chromosomal Abnormalities	
Autosomal Trisomy	
Trisomy 21	1:740
Trisomy 18	1:5000
Trisomy 13	1:16,000
Sex Chromosome Aneuploidy	
Turner syndrome	1:2500 females
Klinefelter syndrome	1:500–1000 males
Partial Deletion	
Prader-Willi syndrome	1:10,000–30,000
Angelman syndrome	1:12,000–20,000
Cri-du-chat syndrome	1:20,000–50,000
Single-Gene Abnormalities	
Autosomal Dominant	
Neurofibromatosis type 1	1:3500
Tuberous sclerosis	1:5800
Osteogenesis imperfecta	6–7:100,000
Autosomal Recessive	
Cystic fibrosis	1:2500–3500 Caucasians (highest ethnic incidence)
Spinal muscle atrophy	1:6000–10,000
Phenylketonuria	1:10,000–15,000
Hurler syndrome	1:100,000
Sex-Linked	
Duchenne muscular dystrophy	1:3500
Fragile X syndrome	1:4000 males, 1:8000 females
Hemophilia A	1:4000–5000 males
Rett syndrome	1:10,000–22,000 females
Multifactorial Abnormalities	
Cleft lip with or without cleft palate	1:1000
Clubfoot (talipes equinovarus)	1:1000
Spina bifida	7:10,000
Mitochondrial Abnormalities	
Mitochondrial myopathy	Rare
Kearns-Sayre disease	Rare

Trisomy 21 (Down syndrome). Trisomy 21 occurs in approximately 1 in every 700 live births,²⁸ and its incidence is distributed equally between the sexes.²⁸ The pathophysiological features of Down syndrome are caused by an overexpression of genes on human chromosome 21. Ninety-five percent of individuals have an extra copy in all of their body's cells. The remaining 5% have the mosaic and

translocation forms. In the United States, the incidence of Down syndrome increases with advanced maternal age.²⁸ Detection of Down syndrome is possible with various prenatal tests, and the diagnosis is confirmed by the presence of characteristic physical features present in the infant at birth.²⁹ Down syndrome is the most common chromosomal cause of moderate to severe intellectual disability.²⁹ The typical phenotypical features observable from birth are hypotonia, epicanthic folds, flat nasal bridge, upward-slanting palpebral fissures, small mouth, excessive skin at the nape of the neck, and a single transverse palmar crease (Fig. 11.2).

Information compiled by the Centers for Disease Control and Prevention during 1968–2007 indicates that the median survival age of individuals with Down syndrome is 47 years, compared with 1 year in 1968. Improvements in the median survival age were less in races other than white, although the reasons for this remain unclear.²⁸ Half of all children with Down syndrome have congenital heart defects.^{28,29} Congenital heart problems, respiratory infection, and leukemia are the most common factors associated with morbidity and mortality in childhood, whereas a possible increased tendency for premature cellular aging and Alzheimer disease may account for higher mortality rates later in life.³⁰

Impairments of visual and sensory systems are also common in individuals with Down syndrome. As many as 77% of children with Down syndrome have a refractive error (myopia or hyperopia), astigmatism, or problems in accommodation.³¹ Hearing losses that interfere with language development are reportedly present in 80% of children with Down syndrome. In most cases the hearing loss is conductive; in up to 20% of cases the loss is sensorineural or mixed.^{32,33} Obstructive sleep apnea has been reported to exist frequently in young children³² and adults with Down syndrome.³⁴ Craniofacial impairments such as a shortened palate and midface hypoplasia—along with oral hypotonia, tongue thrusting, and poor lip closure—frequently result in feeding difficulties at birth.³⁵ Bell and colleagues studied the prevalence of obesity in adults with Down syndrome and reported it in 70% of male subjects and 95% of female subjects.³⁶ Children with Down syndrome also appear to have a higher risk of being overweight or obese,^{33,37,38} which may be partly a result of the retarded growth and endocrine and metabolic disorders associated with trisomy 21.³³ In a small population study of children with Down syndrome, Dyken and co-workers³⁹ reported that there was a high prevalence of obstructive sleep apnea associated with a higher body mass index.

Children with Down syndrome may have musculoskeletal anomalies such as metatarsus primus varus, pes planus, thoracolumbar scoliosis, and patellar instability and have an increased risk for atlantoaxial dislocation,^{40–42} which has been observed through radiography in up to 10% to 30% of individuals with this syndrome,^{40,41} with and without neurological compromise.⁴³ There is some controversy in the medical community regarding the necessity and efficacy of radiographic screening for the instability.^{41,42} Proponents of radiographic screening argue that neurological symptoms of atlantoaxial instability may often go undetected in this population because symptoms are masked by the wide-based gait and motor dysfunction already associated with the disorder. If the child is unable to verbalize complaints or is uncooperative with physical and neurological examinations, symptoms may be missed. There is particular concern about cervical instability if these children undergo surgical procedures requiring general anesthesia⁴² and participate in recreational sports such as the Special Olympics.⁴¹ Symptomatic instability can result in spinal cord compression, leading to myelopathy with leg weakness, decreased walking ability,⁴³ spasticity, or incontinence. Although reportedly rare,

Fig. 11.2 (A) A 10-month-old girl with Down syndrome. **(B)** A 21-month-old boy with the mosaic form of trisomy 18. (Reprinted with permission of Tucker ME, Garringer HJ, Weaver DD. Phenotypic spectrum of mosaic trisomy 18: two new patients, a literature review, and counseling issues. *Am J Med Genet A*. 2007;143:505–517.)

there have been cases where atlantoaxial dislocation has resulted in quadriplegia.⁴⁰

Several researchers have explored the neuropathology associated with Down syndrome. Changes in brain shape, size, weight, and function occur during the prenatal and infant development of babies with Down syndrome, with important differences apparent by 6 months of age.⁴⁴ The relatively small size of the cerebellum and brain stem was reported by Crome and Stern in the 1970s.⁴⁵ Marin-Padilla⁴⁶ studied the neuronal organization of the motor cortex of a 19-month-old child with Down syndrome and found various structural abnormalities in the dendritic spines of the pyramidal neurons of the motor cortex. He suggested that these structural differences may underlie the motor incoordination and intellectual disability characteristic of individuals with Down syndrome. Loesch-Mdzewska⁴⁷ also found neurological abnormalities of the corticospinal system (in addition to reduced brain weight) in his neuropathological study of 123 individuals with Down syndrome aged 3 to 62 years. Crome⁴⁸ reported lesser brain weight in comparison with normal persons. Finally, Benda⁴⁹ noted a lack of myelination of the nerve fibers in the precentral area, frontal lobe, and cerebellum of infants with Down syndrome. According to McGraw,⁵⁰ the amount of myelin in the brain reflects the stage of developmental maturation. The delayed myelination characteristic of neonates and infants with Down syndrome is thought to be a contributing factor to the generalized hypotonicity and persistence of primitive reflexes characteristic of this syndrome.

Trisomy 18. Trisomy 18, or Edwards syndrome, is the second most common of the trisomic syndromes to occur in term deliveries, although it is far less prevalent than Down syndrome. It occurs in one in 5000 newborns, and approximately 80% of affected

infants are female.⁵¹ As with Down syndrome, advanced maternal age is positively correlated with trisomy 18. Most cases of Edwards syndrome occur as random events during the formation of reproductive cells; fewer cases occur as errors in cell division during early fetal development; and inherited, translocation forms rarely occur.⁵¹ Only 10% of infants born with trisomy 18 survive past the first year of life; female and non-Caucasian children survive the longest.⁵² The survival of girls averages 7 months, and the survival of boys averages 2 months.⁵² Individuals surviving past infancy most often have the mosaic form, and there is high variance in phenotype (see Fig. 11.2).⁵³

Individuals with trisomy 18 generally have far more serious organic malformations than seen in those with Down syndrome.⁵⁴ Typical malformations affect the cardiovascular, gastrointestinal, urogenital, and skeletal systems. Infants with trisomy 18 have low birth weight and small stature, with a long narrow skull, low-set ears, flexion deformities of the fingers, and rocker-bottom feet. Muscle tone is initially hypotonic, but it becomes hypertonic in children with longer than the typical life-span.⁵⁴ The period of hypertonicity in the early years may change to low tone and joint hyperextensibility by preschool and school age. Microcephaly, abnormal gyri, cerebellar anomalies, myelomeningocele, hydrocephaly, and corpus callosum defects have been reported in individuals with trisomy 18.⁵⁵

Common skeletal malformations that may warrant attention from the developmental physical or occupational therapist include scoliosis,⁵⁵ limited hip abduction, flexion contractures of the fingers, rocker-bottom feet, and talipes equinovarus.⁵⁴ Infants with trisomy 18 may also have feeding difficulties as a result of a poor suck.⁵⁶ Profound intellectual disability is another clinical factor that will affect the developmental therapy programs for children with trisomy 18.^{55,56}

Trisomy 13. Trisomy 13, also commonly called *Patau syndrome*, is the least common of the three major autosomal trisomies, with an incidence of one in 10,000 to 20,000 live births.^{21,51} As in the other trisomic syndromes, advanced maternal age is correlated with the incidence of trisomy 13.⁵⁷ Fewer than 10% of individuals with trisomy 13 survive past the first year of life^{51,52}; girls and non-Caucasian infants appear to survive longer.^{51,52} Individuals surviving past infancy most often have the mosaic form, and there is high variance in phenotype.⁵² As with Edwards syndrome, most cases of Patau syndrome occur as random events during the formation of eggs and sperm, such as nondisjunction errors during cell division.⁵⁷

Trisomy 13 is characterized by microcephaly, deafness, anophthalmia or microphthalmia, coloboma, and cleft lip and palate.⁵⁷ As in trisomy 18, infants with trisomy 13 frequently have serious cardiovascular and urogenital malformations and typically have severe to profound intellectual disability.⁵⁸ Skeletal deformities and anomalies include flexion contractures of the fingers and polydactyly of the hands and feet.⁷ Rocker-bottom feet have also been reported, although less frequently than in individuals with trisomy 18. Reported central nervous system (CNS) malformations include arhinencephalia, cerebellar anomalies, defects of the corpus callosum, and hydrocephaly.⁵⁹

Sex Chromosome Aneuploidy

The human X chromosome is large, containing approximately 5% of a human's nuclear DNA. The Y chromosome, much smaller, contains few known genes.²¹ Females, with genotype XX, are mosaic for the X chromosome, meaning that one copy of their X chromosome is inactive in a given cell; some cell types will have a paternally derived active chromosome and others a maternally derived X chromosome. Males, with genotype XY, have only one copy of the X chromosome; therefore diseases caused by genes on the X chromosome, called *X-linked diseases* (see section on sex-linked disorders), can have a devastating impact in males and less severe in females.²¹ In the presence of abnormal numbers of sex chromosomes, neither male nor female individuals will be phenotypically normal.²¹ Two of the most prevalent sex chromosome anomalies are Turner and Klinefelter syndromes.

Turner syndrome. Turner syndrome affects females with monosomy of the X chromosome. The syndrome, also known as *gonadal dysgenesis*, occurs in one in 2500 live female births.^{60,61} Turner syndrome is the most common chromosomal anomaly among spontaneous abortions.^{62,63} Most infants who survive to term have the mosaic form of this syndrome, with a mix of cell karyotypes, 45,X and 46,XX. The *SHOX* gene, found on both the X and Y chromosomes, codes for proteins essential to skeletal development. Deficiency of the *SHOX* gene in females accounts for most of the characteristic abnormalities of this disorder.^{61–64} Three characteristic impairments of the syndrome are sexual infantilism, a congenital webbed neck, and cubitus valgus.⁶⁵ Other clinical characteristics noted at birth include dorsal edema of hands and feet, hypertelorism, epicanthal folds, ptosis of the upper eyelids, elongated ears, and shortening of all the hand bones.^{60,66} Growth retardation is particularly noticeable after the age of 5 or 6 years, and sexual infantilism—characterized by primary amenorrhea, lack of breast development, and scanty pubic and axillary hair—is apparent during the pubertal years. Ovarian development is severely deficient, as is estrogen production.⁶⁷ Congenital heart disease is present in 20% to 30% of individuals with Turner syndrome,⁶⁶ with a smaller number of cardiovascular malformations in individuals with the mosaic form⁶⁸; 33% to 60% of individuals with Turner

syndrome have kidney malformations.⁶⁰ Hypertension is common even in the absence of cardiac or renal malformations.^{66–69}

There are numerous types of skeletal anomalies, some of which may be significant enough to require the attention of a pediatric therapist. Included among these are hip dislocation, pes planus and pes equinovarus, dislocated patella,⁶⁰ deformity of the medial tibial condyles,⁵⁵ idiopathic scoliosis,⁶⁶ and deformities resulting from osteoporosis.⁶⁶

Sensory impairments include decrease in gustatory and olfactory sensitivity^{70,71} and deficits in spatial perception and orientation,⁷⁰ and up to 90% of adult females have moderate sensorineural hearing loss. Recurrent ear infections are common and may result in future conductive hearing loss.⁶⁹ Although the average intellect of individuals with Turner syndrome is within normal limits, the incidence of intellectual disability is higher than in the general population.⁵⁴ Noonan syndrome, once thought to be a variant of Turner syndrome, has several common clinical characteristics; however, advancements in genetics research have shown that the syndromes have different genetic causes.^{72,73}

Klinefelter syndrome. Klinefelter syndrome, which occurs in males, is an example of aneuploidy with an excessive number of chromosomes. The most common type, 47,XXY, is usually not clinically apparent until puberty, when the testes fail to enlarge and gynecomastia occurs.⁷⁴ Nearly 90% of males with Klinefelter syndrome possess a karyotype of 47,XXY, and the other 10% have variants.⁷⁵ The incidence of Klinefelter syndrome (XXY) is about one in 500 to 1000 males, and an estimated half of 47,XXY conceptions are spontaneously aborted.¹⁶ The extra X chromosome(s) can be derived from either the mother or the father, with nearly equal occurrence.⁷⁶ Advanced maternal age is widely accepted as a causal factor.^{21,75} FISH analysis of spermatozoa from fathers of boys with Klinefelter syndrome suggests that advanced paternal age increases the frequency of aneuploid offspring.^{77–79}

Most individuals with karyotype XXY have normal intelligence, a somewhat passive personality, and a reduced libido. Eighty-five percent of individuals with nonmosaic karyotype are sterile. Individuals with karyotypes 48,XXXXY and 49,XXXXXY tend to display a more severe clinical picture. Individuals with 48,XXXXY karyotype usually have severe intellectual disability, along with multiple congenital anomalies, including microcephaly, hypertelorism, strabismus, and cleft palate.⁷⁴ Skeletal anomalies include radioulnar synostosis, genu valgum, malformed cervical vertebrae, and pes planus. According to a 2010 systematic review of the literature,⁸⁰ the neurocognitive outcomes of people with Klinefelter syndrome include problems of delayed walking in children, persistent deficits in fine and gross motor development, and problems in motor planning.^{80,81} Giedd and co-workers published the results of a case-control study examining brain magnetic resonance imaging (MRI) scans of 42 males with Klinefelter syndrome in which they found cortical thinning in areas of the motor strip associated with impaired control of the upper trunk, shoulders, and muscles involved in speech production.⁸²

Partial Deletion Disorders

Deletions are examples of mutations that cause changes in the sequence of DNA in human cells. A sequence change that affects a gene's function can cause the final protein product to be altered or not produced at all.

Cri-du-chat syndrome. Cri-du-chat syndrome, also referred to as *cat-cry syndrome* and *5p minus syndrome*, results from a partial deletion of the short arm of chromosome 5. Example nomenclature for a female with this syndrome is (46,XX,del[5p]). The incidence of the syndrome is estimated to be one case per 20,000 to 50,000 live births.⁸³ Although approximately 70% of individuals with cri-du-chat syndrome are

female, there is an unexplained higher prevalence of older males with this disorder.⁸⁴ Advanced parental age is not a causal factor. A study completed in 1978 indicated that life expectancy was 1 year for 90% of infants born with this disorder, but now life expectancy is nearly normal with routine medical care.

Primary identifying characteristics at birth include a definitive high-pitched catlike cry, microcephaly, evidence of intrauterine growth retardation, and subsequent low birth weight.⁸⁵ Abnormal laryngeal development accounts for the characteristic cry, which is present in most individuals and disappears in the first few years of life. Other features of individuals with this syndrome include hypertelorism, strabismus, “moon facies,” and low-set ears.⁸⁵ Associated musculoskeletal deformities include scoliosis, hip dislocations, club feet, and hyperextensibility of the fingers and toes. Muscular hypotonicity is associated with this syndrome, although cases with hypertonicity have also been noted.⁸⁶ Also, severe respiratory and feeding problems have been reported. Postnatal growth retardation has been documented, with the median near the fifth percentile of the normal growth curve.⁸⁷

Although intellectual disability and physical deformities are more severe with larger deletions,⁸³ there is evidence that, with early developmental intervention, these children can develop language, functional ambulation, and self-care skills.^{88,89}

Prader-Willi syndrome and Angelman syndrome. Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are discussed together because they result from a structural or functional loss of the PWS and AS region of chromosome 15 (15q11-13), which can occur by one of several genetic mechanisms.^{90,91} PWS has an incidence of 1 in 15,000 to 30,000,⁹⁰ and AS has an incidence of 1 in 12,000 to 20,000.^{90,91} These two syndromes illustrate the effect of *genomic imprinting*, which is the differential activation of genes of the same chromosome and location, depending on the sex of the parent of origin (Fig. 11.3).¹⁶

Fig. 11.3 The Effect of imprinting on chromosome 15 deletions. **(A)** Inheritance of the deletion from the father produces Prader-Willi syndrome. **(B)** Inheritance of the deletion from the mother produces Angelman syndrome. (From Jorde L, Carey J, Bamshad M, et al. *Medical Genetics*. 3rd ed. St. Louis: Mosby; 2005.)

PWS results from a failure of expression of paternally inherited genes in the PWS region of chromosome 15.⁹⁰ Conversely, AS results when the maternal contribution in the 15q11.2-q13 region is lost.⁹¹ *OCA2* is a gene located within the PWS and AS region of chromosome 15 that codes for the protein involved in melanin production. With loss of one copy of this gene, individuals with PWS or AS will have light hair and fair skin. In the rare case that both copies of the gene are lost, these individuals may have a condition called *oculocutaneous albinism* type 2, which causes severe vision problems.⁹¹

Characteristics of PWS in infancy include hypotonia, poor feeding, lethargy, and hypogonadism.^{92,93} Developmental milestones in the first 2 years of life are not acquired until approximately twice the normal age.^{94,95} Between 1 and 4 years of age, hyperphagia is apparent; if uncontrolled, it will lead to morbid obesity and its associated health complications.⁹³⁻⁹⁶ Most individuals with PWS have mild to moderate intellectual disability, although some have IQ scores within normal limits.⁹⁷ Maladaptive behaviors such as temper tantrums, aggression, self-abuse, and emotional lability have been reported.⁹⁸ As a result of extreme obesity, many individuals with PWS have impaired breathing, which can produce sleepiness, cyanosis, cor pulmonale, and heart failure.⁹⁸ Scoliosis is common but does not appear to be related to obesity.⁹⁹

Clinical diagnosis is confirmed by laboratory genetic testing techniques, including DNA-based methylation testing, FISH probe, and pyrosequencing assays.^{93,100} Most cases of PWS are caused by random mutations in parental reproductive cells⁹⁴; others may result from translocation errors.^{93,101} Parental studies are important in translocation cases because 20% of those cited in the literature involved familial rearrangements, which may significantly increase the risk of recurrence.¹⁰²

Angelman syndrome, named after Harry Angelman, who first described children with AS in 1965, is characterized by developmental delay or intellectual disability, seizures, ataxia, progressive microcephaly, and severe speech impairments. Tongue thrusting, drooling, and sucking and swallowing disorders occur in 20% to 80% of these children. Individuals often display spontaneous bouts of laughter accompanied by hand-flapping movements and a characteristic walking posture of arms overhead and flexed elbows.^{16,91,103} Infants with AS appear normal at birth, but severe developmental delay becomes apparent by 6 to 12 months of age. More unique features of the disorder do not appear until after 1 year of age. Children with AS typically have structurally normal brains on MRI and computed tomography (CT) scans, but electroencephalogram (EEG) findings are often abnormal, showing a characteristic pattern that may assist with diagnosis before other clinical symptoms emerge^{91,104}; molecular studies can also confirm the disorder before all of the clinical criteria for this diagnosis are met.⁹¹

Most cases of AS occur as a result of mutations involving deletion or deficient function of the maternally inherited *UBE3A* gene. This gene codes for ubiquitin protein ligase, an enzyme involved in the normal process of removing damaged or unnecessary proteins from healthy cells. In most of the body's tissues except the brain, both copies (maternal and paternal) of the *UBE3A* gene are active. Only the maternal copy of the gene is normally active in the brain, so if this copy is absent or deficient, the normal cellular housekeeping process breaks down.⁹¹ The risk of having another child with AS can vary from 1% to 50% depending on which of the six known genetic mechanisms is responsible for the disorder.

Translocation Disorders

Translocation errors have been identified in many childhood hematological cancers and sarcomas.^{105,106} Such errors are also commonly seen in couples with infertility.¹⁰⁷ Translocation abnormalities occur when genetic material is exchanged and rearranged between two nonhomologous chromosomes (those not in the same numbered

pair). The structural abnormality can result in the loss or gain of chromosomal material (an unbalanced arrangement) or no loss or gain of material (a balanced arrangement). Unbalanced arrangements can produce serious disease or deformity in individuals or their offspring. Carriers of balanced arrangements—estimated at one in 500 individuals—often have a normal phenotype, but their offspring may have an abnormal one.¹⁶ There are two basic types of translocations: reciprocal and robertsonian. Reciprocal translocations occur when two different chromosomes break, and the genetic material is mutually exchanged. A robertsonian translocation occurs when there is a break in a portion of two different chromosomes, with the longest remaining portions of both chromosomes forming a single chromosome. The shorter portions that break usually do not contain vital genetic information; therefore the individual may be phenotypically normal.¹⁶ An example notation of a reciprocal translocation is 46,XY,t(7;9)(q36;q34). This individual is male with a normal number of chromosomes but a translocation of genetic material on chromosomes 7 and 9; “q” refers to the short arm of these chromosomes, and the numbers “36” and “34” refer to the location.

Translocations occur in children seen in therapy settings, including about 3% to 5% of children with Down syndrome, and they are found in 40% of all cases of acute lymphoblastic leukemia (ALL).¹⁰⁸

Acute lymphoblastic leukemia. ALL accounts for one-fourth of all childhood cancers, and it is the most common type of childhood cancer.^{109–111} ALL occurs when the DNA of immature lymphoblasts is altered and they reproduce in abnormal numbers, crowding out the formation of normal cells in the bone marrow.^{109,112} Sixty percent of cases of ALL occur in children, with the peak incidence in the first 5 years of life. A rise in the incidence of ALL has been reported during major periods of industrialization worldwide^{112,113} and is hypothesized to be associated with exposure to radiation¹¹⁴ and other environmental teratogens^{115,116} in the preconception, gestational, and postpregnancy periods.^{110,113}

With advancements in medical treatment protocols for pediatric patients, 5-year survival rates have improved to 80%.¹¹¹ Children aged 1 to 9 years at diagnosis have a better prognosis than infants, adolescents, or adults diagnosed with ALL.¹¹⁰ Survival rate statistics since the approval of the gene therapy drug *tisagenlecleucel* for children and adults up to age of 25 years with B-cell ALL are expected to change from previously reported survival rates. Numerous forms¹¹⁷ of translocation mutations are associated with ALL. Some translocation forms of ALL do not respond well to combination chemotherapy treatment; an example is the translocation that occurs between chromosomes 9 and 22, known as the Philadelphia chromosome.^{111,118} Other translocations that result in hyperdiploidy (more than 50 chromosomes)—in particular within chromosomes 4, 10, and 17—may confer a more favorable outcome.¹¹⁹

Frequent diagnosis is made when a physician relates the child’s history of a persistent viral respiratory infection with other characteristic clinical signs and symptoms consistent with hematopoietic leukemia. The key symptoms of ALL are pallor, poor appetite, lethargy, easy fatigue and bruising, fever, mucosal bleeding, and bone pain.¹⁰⁶ A complete blood count will show a shortage of all types of blood cells, including red, white, and platelets. Diagnosis is confirmed by the presence of lymphoblasts in bone marrow. Radiographs may be necessary to determine metastases, and cerebrospinal fluid will be examined as early involvement of the CNS has important prognostic implications.¹¹³ Cytogenetic studies will be performed to aid in the selection of treatment protocols and determination of prognosis.¹¹¹

Referral to physical and occupational therapists is made for other common problems such as muscle cramps, muscle weakness, impaired

gross and fine motor performance, decreased energy expenditure, osteopenia, and osteoporosis.¹²⁰

Monogenetic Disorders

The previous section described genetic disorders that occur because of chromosomal abnormalities involving more than one specific gene. Other genetic disorders commonly seen among children in a therapy setting include those that result from specific gene defects, also known as single-gene disorders. The inheritance patterns of single-gene traits were described by Gregor Mendel in the 19th century. These patterns—autosomal dominant, autosomal recessive, and sex-linked—are discussed separately, and specific examples of syndromes or disorders associated with each type are presented.

Autosomal Dominant Disorders

Mutations on one of the 22 numbered pairs of autosomes may result in isolated anomalies that occur in otherwise normal individuals, such as extra digits or short fingers. Each child of a parent with an autosomal dominant trait has a 50:50 chance of inheriting that trait.²¹ Other autosomal dominant disorders include syndromes characterized by profound musculoskeletal and neurological impairments that may require intervention from a physical or an occupational therapist. Three examples of autosomal dominant disorders are osteogenesis imperfecta (OI), tuberous sclerosis, and neurofibromatosis (NFM).

Osteogenesis imperfecta. OI is a spectrum of diseases that result from deficits in collagen synthesis associated with single-gene defects, most commonly of *COL1A1* and *COL1A2*, which are located on chromosomes 17 and 7, respectively.¹²¹ OI is characterized by brittle bones resulting from impaired quality, quantity, and geometry of bone material and hyperextensible ligaments.^{122,123} Deafness, resulting from otosclerosis, is found in 35% of individuals by the third decade of life.⁵⁴ New knowledge about this disease from molecular genetic studies and bone histomorphometry has expanded the classification subtypes of OI into types I through VIII.^{121,124} These classifications are helpful in determining prognosis and management, although there is a continuum of severity of clinical features and much overlap in the features among the different classifications.¹²⁴ Types I, IV, V, and VI occur in the autosomal dominant pattern, whereas type VII occurs as a recessive trait and types II and III can occur as either dominant or recessive traits.¹²¹ OI types V and VI account for only 5% of cases, and type VII has been found only in Native Canadian population to date.¹²⁴ In 2007, an autosomal recessive OI, designated type VIII, was characterized by white sclerae, severe growth deficiency, extreme skeletal undermineralization, and bulbous metaphyses.²³ This section compares and contrasts only types I through IV.

The overall incidence of OI is one in 10,000 live births in the United States, with types I and IV accounting for almost 95% of all patients with OI.¹²¹ Ninety percent of dominant forms of OI can be confirmed by DNA analysis.¹²⁴ Type I is the least severe form, followed by types IV and III, with type II being the most severe.

Type I is characterized by blue sclerae, mild to moderate bone fragility, joint hyperextensibility, and hearing loss in young adulthood.¹²⁴ There are no significant deformities; individuals with this type may not sustain fracture until they are ambulatory, and the incidence of fractures decreases with age.¹²⁴ Type IV OI is characterized by more severe bone fragility and joint hyperextensibility than in type I. Bowing of long bones, scoliosis, dentinogenesis imperfecta, and short stature are common.^{122,124,125}

Children with type IV OI are often ambulatory but may require splinting or crutches.¹²²

Children with type III OI have severe bone fragility and osteoporosis; often there are fractures in utero. Type III occurs primarily in

autosomal dominant inheritance in North Americans and Europeans.¹²⁴ The less frequent autosomal recessive form of OI, type III, is characterized by progressive skeletal deformity, scoliosis, triangular facies, large skull, normal cognitive ability, short stature, and limited ambulatory ability.^{122,124,126} The long bones of the lower extremities are most susceptible to fractures, particularly between the ages 2 to 3 years and 10 to 15 years,⁵⁴ after which the frequency of fractures diminishes. Intramedullary rods inserted in the tibia or femur may minimize recurrent fractures.³³

Type II, the most severe form, is most often lethal before or shortly after birth, although there are a few cases of children living up to 3 years.^{124,126} Infants with type II OI have multiple fractures, often in utero, and underdeveloped lungs and thorax; therefore many die from respiratory complications soon after birth. Most type II cases are the result of spontaneous mutations. As only one copy of the gene is sufficient to cause the disorder, it is still commonly classified as an autosomal dominant condition. There are fewer cases of autosomal recessive inheritance.¹⁶

Prevention of fractures is an important goal in working with individuals with OI, but fear of handling and overprotection by caregivers may limit a child's optimal functional independence. Caregiver education in careful handling and positioning should begin in the patient's early infancy, and training in the use of protective orthoses and assistive devices is appropriate from the period of crawling through ambulation.^{123,124,127} Aquatic therapy can be a valuable treatment strategy for children with OI.^{124,127}

Tuberous sclerosis complex. Tuberous sclerosis complex (TSC) is characterized by a triad of impairments: seizures, intellectual disability, and sebaceous adenomas; however, there is a wide variability in expression, with some individuals displaying skin lesions only.¹²⁸ Infants are frequently normal in appearance at birth, but 70% of those who go on to show the complete triad of symptoms display seizures during the first year of life. Although tuberous sclerosis is inherited as an autosomal dominant trait, 86% of cases occur as spontaneous mutations, with older paternal age being a contributing factor. TSC affects both sexes equally, with a frequency of one in 5800 births.¹²⁹ Mutations in the *TSC1* and *TSC2* genes are known to cause tuberous sclerosis. The normal function of these genes is to regulate cell growth; if they are defective, cellular overgrowth and noncancerous tumor formation can occur.¹²⁹ Tumor formation in the CNS is responsible for most of the morbidity and mortality due to TSC,¹²⁹ followed by renal disease associated with the formation of benign angiomyolipomas.¹²⁸ Diagnostic criteria for TSC have been established, and the determination can be made clinically; results of genetic testing are currently viewed as corroborative.¹²⁸ Hypopigmented macules are often the initial finding. These lesions vary in number and are small and ovoid. Larger lesions, known as *leaf spots*, may have jagged edges.¹²⁹ Sebaceous adenomas first appear at the age of 4 to 5 years, with early individual brown, yellow, or red lesions of firm consistency in the nose and upper lip. These isolated lesions may later coalesce to form a characteristic butterfly pattern on the cheeks. Also known as hamartomas (tumor-like nodules of superfluous tissue), the skin lesions are present in 83% of individuals with tuberous sclerosis.⁴⁷

Delayed development is another characteristic during infancy,¹³⁰ particularly in the achievement of motor and speech milestones. Cerebral cortical tubers are present in over 80% of patients and account for cognitive disability, including autism.¹²⁸ Ultimately 93% of individuals who are severely affected will have seizures, usually of the myoclonic type, in early life, progressing in later life to grand mal seizures. Seizure development is the result of formation of nodular lesions in the cerebral cortex and white matter.⁴⁷ Tumors are also found in the walls of the ventricles. Neurocytological examination reveals a decreased number of

neurons and an increased number of glial cells and enlarged nerve cells with abnormally shaped cell bodies. Surgical excision of seizure-producing tumors has been successful in some cases.¹²⁸

Other associated impairments include retinal tumors and hemorrhages, glaucoma, and corneal opacities.¹²⁹ Cyst formation in the long bones and in the bones of the fingers and toes contributes to osteoporosis. Cardiac and lung tissues are also affected by TSC, and these effects are included in the major diagnostic criteria.¹²⁸

Neurofibromatosis. Three genetically distinct disorders that cause tumors to grow in the nervous system compose the neurofibromatosis group. There are three recognized forms of NFM: neurofibromatosis 1 (NFM1), neurofibromatosis 2 (NFM2), and schwannomatosis.^{131–133} This section focuses on NFM1 and NFM 2. Neurofibromas¹³⁴ or connective tissue tumors of the nerve fiber fasciculus impede the development and growth of neural cell tissues^{132,133} and are the hallmark feature of NFM1. Neurofibromas are noncancerous, and malignant changes are rare in children,¹³⁵ but an increased risk of malignancy has been observed in adult patients with NFM1, and this is a major contributor to decreased average life expectancy, which is shortened by approximately 15 years.¹³⁶ Tumors typically increase in number with the rising age. About half of all cases of NFM are caused by a sporadic mutation in parental germ cells or during fetal development.^{131–133} Schwannomas are the main tumor type of NFM2 and classically appear bilaterally on the vestibular nerves.^{133,137} NFM1 is also known as *von Recklinghausen disease*. Compared with type II, type I is more common (one per 3000 births)¹³² and usually identified in younger children. It is associated with mutations in the *NF1* gene, which produces a protein called neurofibromin, the complete function of which is not yet understood. However, it is suspected to be a tumor suppressor. Diagnostic criteria for NFM1 include the presence of two of the following features: six or more café-au-lait spots, two or more fibromas, freckling in the axillary or inguinal region, optic pathway glioma, two or more Lisch nodules, specific osseous lesions, and a first-degree relative with NFM1.¹³² Infants usually appear normal at birth, but initial café-au-lait spots appear by the age of 3 years in 95% of affected individuals (Fig. 11.4).¹³⁸ Cognitive impairment is the most common

Fig. 11.4 A 4-year-old boy with neurofibromatosis and the characteristic café-au-lait spots on his trunk.

neurological complication of NFM1¹³⁸ and is postulated to be caused by altered expression of neurofibromin in the brain and/or by brain lesions, which appear hyperintense on MRI.¹³⁸ These focal areas of high signal intensity on T2-weighted MRI, known as *unidentified bright objects* (UBOs), are seen in 60% of children and young adults with NFM1. These lesions—commonly found in the basal ganglia, internal capsule, thalamus, cerebellum, and brain stem^{135,139}—tend to disappear in adulthood and often do not cause other overt neurological symptoms.¹³⁵ Fewer than 10% of these individuals are mentally retarded, but about 30% to 60% of affected children have mild and nonprogressive learning disabilities.^{135,140} Poorer social skills and differences in personality, behavior, and quality-of-life perception have been reported in children with NFM1 compared with children without the disorder.¹³²

In older children and adolescents, pain, itching, and stinging can occur from cutaneous neurofibromas. In approximately half of all patients, neurological motor deficits occur from plexiform neurofibromas when the growth puts pressure on peripheral nerves, spinal nerve roots, and the spinal cord.¹³⁸ One percent to 5% of children aged 0 to 6 years develop symptoms associated with optic pathway glioma.^{132,135} Neurofibromatous vasculopathy interferes with arterial and venous circulation in the brain.^{132,138,141} Hydrocephalus occurs in some individuals.^{132,135} Hypertension is common and may develop at any age,¹³² and cardiovascular disease is a major cause of premature death.^{136,138,142} Headaches are a commonly reported symptom in children, adolescents, and adults with neurofibromatosis.^{132,134,143,144}

Scoliosis may develop in 10% of patients and is rapidly progressive from ages 6 to 10 years, or it may manifest in a milder form without vertebral anomalies during adolescence.¹³² Other skeletal deformities include pseudarthrosis of the tibia and fibula, tibial bowing, craniofacial and vertebral dysplasia, rib fusion, and dislocation of the radius and ulna.¹³² Differences in leg length¹³² have also been noted and may contribute to scoliosis. NFM2 occurs less frequently than NFM1 (one in 25,000 to 40,000 births)⁷ and is caused by a mutation in the gene encoding the protein neurofibromin 2, also called *Merlin*. Merlin is produced in the nervous system, particularly in Schwann cells that surround and insulate the nerve cells of the brain and spinal cord. Although type II shares characteristics with type I, it is commonly characterized by tumors of the eighth cranial nerve (usually bilateral), meningiomas of the brain, and schwannomas of the dorsal roots of the spinal cord. Contrary to first descriptions of NFM1 and NFM2, café-au-lait spots are seldom a singular feature of NFM2¹³³; rather, signs and symptoms of tinnitus, hearing loss, and balance dysfunction usually appear during adolescence or in early 20s.^{131,133} Problems with visual acuity caused by strabismus and refractive errors are common in young children.¹⁴⁵ NFM2 may be underrecognized in children up to 10 years of age because early hearing loss and tinnitus are present in only 20% of cases; otherwise only singular features of the condition are observed. Infants may have cataracts, and children may demonstrate unilateral facial paralysis, eye squinting, mononeuropathy (foot or hand drop), meningioma, spinal tumor, or cutaneous tumor. It is recommended that children of parents with NFM2 should be considered to be at 50% risk for NFM2 and screened from birth.¹²⁴

Autosomal Recessive Disorders

An unaffected carrier of a disease-causing trait is *heterozygous* for the abnormal gene (possessing one normal and one mutated copy of the gene). If both parents are unaffected carriers of the gene, each of their offspring has a 25% risk of exhibiting the disorder.²¹ Consanguinity involving close relatives increases the chance of passing on autosomal recessive traits.²¹ Certain types of limb defects, familial microcephaly, and a variety of syndromes are passed on through autosomal recessive

genes. Four examples of autosomal recessive disorders affecting children in therapy settings are presented in this section: cystic fibrosis (CF), Hurler syndrome, phenylketonuria (PKU), and spinal muscle atrophy (SMA).

Cystic fibrosis. CF is one of the most common autosomal recessive disorders and is more often seen in Caucasians, affecting one in 2000 to 4000. The CF gene has been mapped to chromosome 7 and its protein product, CF transmembrane regulator (CFTR).²¹ CFTR is involved in the regulation of chloride channels of the bowel and lung, which are dysfunctional in patients with CF. Although CF has markedly variable expression, the overall median survival time has improved from about 6 years of age in the 1940s to an average of 36 years of age in 2006.¹⁴⁶ In addition to the phenotypical features of CF, diagnosis of CF is made when two or more disease-causing mutations exist on the CFTR gene.¹⁴⁶ Newborn screening tests for CF are required in all states in the United States.¹⁴⁷

Fibrotic lesions of the pancreas cause pancreatic insufficiency in the majority of patients, which leads to chronic malnutrition. Ten percent to 20% of newborn infants with CF also have intestinal tract involvement with a meconium ileus. The sweat glands are commonly affected; high levels of chloride found in the sweat are the basis for the sweat chloride test used in diagnosis. The most serious impairment in CF is obstruction of the lungs by thick mucus, which leads to chronic pulmonary obstruction, infections that destroys lung tissue, and eventual death from pulmonary disease in 90% of these individuals.²¹

Improved survival rates in recent decades are the result of improved antibiotic management, aggressive chest physical therapy, and pancreatic replacement therapy. Postural drainage, percussion, vibration, and breathing exercises are key components of the management program provided by the therapist and caregivers.¹⁴⁸ Modern and less labor-intensive devices such as those that provide positive expiratory pressure (PEP device) may not be as effective at clearing secretions as conventional chest physiotherapy,¹⁴⁸ but patient and caregiver compliance with a regular program may be improved.¹⁴⁹ Attention to diet is important, and every attempt should be made to maintain a routine exercise program with a goal of helping the children be more active to improve their respiratory status and prevent secondary impairments of adolescence and adulthood, such as stress incontinence in young women caused by excessive coughing,^{150,151} chronic back pain, and osteopenia and osteoporosis.¹⁵² New gene therapy research in the United Kingdom to treat CF appears promising; however, application of its results has not been approved to date.¹⁵³

Massery¹⁵⁰ describes the relationship between respiration, postural control, and secondary impairments in the musculoskeletal and neuromuscular systems that develop in individuals with CF. She addresses the threefold problems faced by such patients: (1) lung dysfunction leading to increased respiratory demand, (2) increased workload of respiration as a deforming force on the immature musculoskeletal frame, and (3) resultant impaired motor strategies for postural control during physical activity. Patients were once widely cautioned to avoid overexertion and fatigue with exercise, but as they are living longer, more evidence supports the benefits of regular, even vigorous exercise for children and adults with CF. Guidelines for exercise frequency and intensity have been published by the Association of Chartered Physiotherapists in Cystic Fibrosis.¹⁵⁴

Hurler syndrome (mucopolysaccharidosis I, severe type). Hurler syndrome is an inborn error of metabolism that results in the abnormal storage of mucopolysaccharides in many different tissues of the body.¹⁰⁴ The incidence is estimated to be 1 in 100,000 live births for the severe forms⁷ and 1 in 500,000 for milder forms.¹⁵⁵ *IDUA* is the only gene currently known to be associated with this multisystemic disorder.¹⁵⁵

Infants born with Hurler syndrome are usually normal in appearance at birth, may have inguinal or umbilical hernias,¹⁵⁵ and may have higher birth weights than their siblings. Symptoms of this progressively debilitating disease usually appear during the latter half of the first year of life,¹⁵⁵ with the full disease picture apparent by 2 to 3 years of age.¹⁵⁵ Diagnosis is made by identification of deficiency in lysosomal enzymes.^{155,156} Premature death, usually from cardiorespiratory failure, occurs within the first 10 years of life.¹⁵⁵

Characteristic physical features are caused by the storage of glycosaminoglycans (GAGs)¹⁵⁵ and include a large skull with frontal bossing, heavy eyebrows, edematous eyelids, corneal clouding, a small upturned nose with a flat nasal bridge, thick lips, low-set ears, hirsutism, and gargoyle-like facial features. Growth retardation results in characteristic dwarfism.¹⁵⁵ Some individuals with the physical characteristics of Hurler syndrome have normal intelligence, but most have progressive and profound intellectual disability.¹⁵⁵

Spastic paraparesis or paraplegia and ataxia have been observed in individuals with Hurler syndrome.²¹ Commonly reported orthopedic deformities include flexion contractures of the extremities, thoracolumbar kyphosis, genu valgum, pes cavus, hip dislocation, and claw hands as a result of joint deformities.⁵⁴ Defective ossification centers of the vertebral bodies result in spinal deformity, complications of nerve entrapment, atlanto-occipital instability, and restricted cervical range of motion.¹⁵⁵ Conductive and sensorineural hearing loss is common.¹⁵⁵ Delayed motor milestones have been noted as early as 10 months of age,¹⁵⁶ with severe disabilities occurring with increasing age. Adaptive equipment is often needed, and most children with Hurler syndrome become wheelchair users in their later years.¹⁵⁶

Phenylketonuria. PKU is the result of one of the more common inborn errors of metabolism. Mutations of the *PAH* gene located on chromosome 12 cause a deficiency in the production of phenylalanine hydroxylase.¹⁵⁷ Without this enzyme there is no conversion of phenylalanine to tyrosine, resulting in an abnormally excessive accumulation of phenylalanine in the blood and other body fluids.^{157,158} If untreated, this metabolic error results in mental and growth retardation, seizures, and pigment deficiency of hair and skin.¹⁵⁹ PKU is most prevalent among individuals of northern European ancestry, with a frequency of one in 10,000 to 15,000 births in the United States.¹⁵⁷ It is estimated that one of every 50 individuals is heterozygous for PKU.²¹

Children born with PKU are usually normal in appearance, with microcephaly and delayed development becoming apparent toward the end of the first year. Parents usually become concerned with the child's slow development during the preschool years.¹⁵⁹ If PKU is untreated, the affected child may go on to develop hypertonicity (75%), hyperactive reflexes (66%), hyperkinesia (50%), or tremors (30%)¹⁶⁰ in addition to intellectual disability. IQ levels generally fall between 10 and 50, although rare cases of untreated individuals with normal intelligence have been reported.¹⁵⁹

A simple blood plasma analysis, which is mandatory for newborn infants in all 50 US states,¹⁴⁷ can detect the presence of elevated phenylalanine levels in nearly 100% of cases.¹⁵⁸ This test is ideally performed when the infant is at least 72 hours old. If elevated phenylalanine levels are found, the test is repeated and further diagnostic procedures are performed. Placing the infant on a low phenylalanine diet (low protein) can prevent the intellectual disability and other neurological sequelae characteristic of this disorder.¹⁵⁹ Follow-up management by an interdisciplinary team consisting of a nutritionist, psychologist, and appropriate medical personnel is advised in addition to special diet. Individuals with poor compliance with the recommended diet have a greater risk of osteopenia in adulthood.¹⁵⁸

Spinal muscle atrophy. SMA (5q SMA) is characterized by progressive muscle weakness due to degeneration and loss of the anterior

horn cells in the spinal cord and brain stem nuclei.^{161,162} Diagnosis of SMA is based on molecular genetic testing for deletion of the *SMN1* gene (named for "survival of motor neuron 1"), located at 5q13. Another gene, *SMA2*, can modify the course of SMA. Individuals with multiple copies of *SMA2* can have less severe symptoms or symptoms that appear later in life as the number of copies of the *SMN2* gene increases.¹⁶³ The overall disease incidence of SMA is 5 in 10,000 live births.¹⁶³

The clinical classifications of SMA are still evolving.^{161,162,164} At present, four subtypes (I to IV) are well accepted, and a fifth, type 0, is being explored. The subtypes are based on age at symptom onset and expectations for maximum physical function, the latter being more closely related to life expectancy.¹⁶⁴

SMA type 0 is characterized by extreme muscle weakness apparent before 6 months of age that likely had a prenatal onset.^{153,154} Some infants have a prenatal history of decreased fetal movements during the third trimester.¹⁵³

SMA type I, otherwise known as *Werdnig-Hoffmann disease* or *acute infantile SMA*, has an onset before 6 months of age.^{161,164} Incidence is estimated to be one in 20,000 live births. It is characterized clinically by severe hypotonicity, generalized symmetrical muscle weakness, absent deep tendon reflexes, and markedly delayed motor development. Intellect, sensation, and sphincter function, however, are normal.¹⁶¹ Children usually cannot sit without support and have poor head control.¹⁶⁴ They have a weak cry and cough as well as problems with swallowing, feeding, and the handling of oral secretions.¹⁶² The diaphragm is spared, but combined with weakness in intercostal muscles, infants exhibit paradoxical breathing, abdominal protrusion, as well as a bell-shaped trunk with chest wall collapse.¹⁶² Overall, this pattern of chest wall weakness and poor respiratory function contributes to the greatly increased susceptibility to pulmonary infection, which usually results in death before the age of 2 years.^{162,163}

SMA type II, otherwise known as *intermediate* or *chronic infantile SMA*, has an onset at age 6 to 18 months and is associated with delayed motor milestones.¹⁶⁴ Seventy percent of children diagnosed with SMA type II are alive at 25 years of age.¹⁶¹

Children with SMA type II can usually sit independently if placed but cannot stand unsupported.¹⁶² Bulbar weakness with swallowing difficulties, poor weight gain, and diaphragmatic breathing are common.¹⁶³ Finger trembling is almost always present.^{161,162} Joint contractures are present in most individuals. Severe kyphoscoliosis that requires bracing and/or surgery often develops, but patients are at risk of postanesthesia complications.¹⁶² Respiratory failure is the major cause of morbidity and mortality. Nocturnal oxygen desaturation and hypoventilation occur before daytime hypercarbia and are early indications of the need for ventilator support.¹⁶²

SMA type III is characterized by onset of symptoms in childhood after 18 months.¹⁶¹ It is also known as *juvenile SMA* or *Kugelberg-Welander syndrome*. These individuals have a normal life-span and usually attain independent ambulation and maintain it until the third or fourth decade of life.¹⁶¹ Lower extremities are often more severely affected than the arms. Strength is often not sufficient for stair climbing, and balance problems are common.¹⁶¹ Muscle aches and joint overuse symptoms are frequently reported.¹⁶²

SMA type IV typically has an onset beyond 10 years of age and is associated with a normal life expectancy and no respiratory complications.^{162,164} Individuals maintain ambulation during the adult years.¹⁶²

Variants of SMA occur in individuals with similar phenotypes and clinical diagnostic features on EMG testing that are not associated with the deletion of *SMN1*.¹⁶⁴ Genetic testing for *SMN* gene deletion achieves up to 95% sensitivity and nearly 100% specificity.¹⁶² For cases that remain unclear, a clinical diagnosis may be accomplished through

EMG and muscle biopsy, which reveal neurogenic atrophy. Key physical signs are common: symmetrical weakness in the more proximal musculature versus distal and lower extremity weakness that is greater than in the arms.¹⁶² Traditional strength measurements are not practical for children with SMA. The Gross Motor Function Measure¹⁶⁵ has excellent reliability on studies of gross motor evaluation in this population.^{162,166} Consensus guidelines on pulmonary care, including assessment, monitoring, and treatment; feeding and swallowing and gastrointestinal dysfunction and nutrition; and orthopedic management have been published by the Standard of Care Committee for Spinal Muscle Atrophy.¹⁶² In 2004, at the University of Massachusetts Medical School, it was discovered that the drug nusinersen (Spinraza) could treat the symptoms of SMA by correcting *SMN2* exon 7 splicing. Twelve years later, in December 2016, the drug was approved for patient use.¹⁶⁷ Before 2016 there were no drugs to effectively treat the symptoms of SMA.^{168,169} Studies of long-term treatment efficacy of the drug will be important, with a remaining concern regarding its affordability.

Sex-Linked Disorders

The third mechanism for transmission of specific gene defects is through sex-linked inheritance. In most sex-linked disorders, the abnormal gene is carried on the X chromosome. Female individuals carrying one abnormal gene usually do not display the trait because of the presence of a normal copy on the other X chromosome. Each son born to a carrier mother, however, has a 50:50 chance of inheriting the abnormal gene and thus exhibiting the disorder. Each daughter of a carrier mother has a 50:50 chance of becoming a carrier of the trait.²¹ Four syndromes that result in disability are discussed in this section: hemophilia, fragile X syndrome (FXS), Lesch-Nyhan syndrome (LNS), and Rett syndrome (RS).

Hemophilia. Hemophilia is a bleeding disorder caused by a deficient clotting process. Affected individuals will have hemorrhage in joints and muscles, easy bruising, and prolonged bleeding from wounds. The term *hemophilia* refers to hemophilia A (coagulation factor VIII deficiency) and hemophilia B or Christmas disease (coagulation factor IX deficiency). There are numerous other clotting diseases, and some that were once referred to as hemophilia are now genomically distinguished. For example, von Willebrand disease has a distinctly different genetic basis from hemophilia; it follows an autosomal recessive or autosomal dominant pattern and involves mutation of the von Willebrand factor (VWF) gene, located on chromosome 12. VWF plays a role in stabilizing blood coagulation factor VIII.¹⁷⁰ Hemophilia A and B occur as X-linked recessive traits owing to mutations of genes *F8* and *F9*, respectively, both of which are located on the X chromosome.¹⁷¹

Hemophilia A is reported to affect 1 in 4000 to 5000 males worldwide.¹⁷¹ Hemophilia B is less common, affecting 1 in 20,000 males worldwide.¹⁷¹ Hemophilia can affect females, though in milder form. The severity and frequency of bleeding in hemophilia A are inversely related to the amount of residual factor VIII (less than 1%, severe; 2% to 5%, moderate; and 6% to 35%, mild).¹⁷¹ The proportions of cases that are severe, moderate, and mild are about 50%, 10%, and 40%, respectively.¹⁷² The joints (ankles, knees, hips, and elbows) are frequently affected, causing swelling, pain, decreased function, and degenerative arthritis. Similarly, muscle hemorrhage can cause necrosis, contractures, and neuropathy by entrapment. Hematuria and intracranial hemorrhage, although uncommon, can occur even after mild trauma. Bleeding from tongue or lip lacerations is often persistent.²¹

Hemophilia is usually diagnosed during childhood, with the most severe cases diagnosed in the first year of life: bleeding from minor mouth injuries and large “goose eggs” from minor head bumps are the most frequent presenting signs in untreated children.¹⁷¹ Children are

especially vulnerable to bleeding episodes owing to the nature of their physical activity combined with periods of rapid growth.¹⁷¹

Treatment includes guarding against trauma and replacement with factor VIII derived from human plasma or recombinant techniques.²¹ In the late 1970s to mid-1980s it was estimated that half of the affected individuals in the United States contracted hepatitis B or C or human immunodeficiency virus (HIV) infection when treated with donor-derived factor VIII. The initiation of donor blood screening and use of heat treatment of donor-derived factor VIII have almost completely eliminated the threat of infection.²¹ Although replacement therapy is effective in most cases, 30% of treated individuals with hemophilia A and 3% of those with hemophilia B have neutralizing antibodies that decrease its effectiveness.¹⁷¹ Before treatment with clotting factor concentrates was available, the average life expectancy was 11 years¹⁷¹; currently, excluding death from HIV, life expectancy for those with severe hemophilia who receive adequate treatment is 63 years.¹⁷¹ Factor replacement therapy is credited for increasing the ease and safety of vigorous exercise and sports participation for such individuals.¹⁷³ The benefits of regular exercise are the same as those for unaffected individuals and outweigh the risks in treated persons.¹⁷⁴ A 2002 pilot study by Tiktinsky and colleagues¹⁷⁴ found decreased episodes of bleeding in a population of young adults with a long-term history of resistance training that began in adolescence.

Fragile X syndrome. FXS is the most common sex-linked inherited cause of intellectual disability, affecting 1 in 4000 males and one in 8000 females.¹⁷⁵ Males manifest a more severe form than females. A fragile site on the long arm of an X chromosome is present, with breaks or gaps shown on chromosome analysis. A region of the X chromosome, named *FMRI*, normally codes for proteins that may play a role in the development of synapses in the brain. Mutations of this region are errors of trinucleotide repeats, in which the number of CGG triplets at this region is expanded, thereby making the gene segment unable to produce the necessary protein.¹⁷⁵

Developmental milestones are slightly delayed in affected males.¹⁷⁵ Eighty percent of males are reported to have intellectual disability, with IQs of 30 to 50 being common but ranging up to the mildly retarded to borderline range.¹⁷⁵ *Penetrance* (the proportion of individuals with a mutation that actually exhibit clinical symptoms) in the female is reported to be only 30%.²¹ Other impairments include epilepsy, emotional lability, attention-deficit/hyperactivity disorder (ADHD), and clinical autistic disorder in 30% of males.^{175,176} Life-span is normal for individuals with this condition.¹⁷⁵

Lesch-Nyhan syndrome. Also known as *hereditary choreoathetosis*,¹⁷⁷ LNS leads to profound neurological deterioration. First described in 1964 by Lesch and Nyhan,¹⁷⁸ it is associated with a mutation in the *HPRT1* gene on the X chromosome. This gene codes for an enzyme called hypoxanthine guanine phosphoribosyltransferase, which allows cells to recycle purines, some of the building blocks of DNA and ribonucleic acid (RNA).¹⁷⁹ Without this gene's normal function, there is an overproduction of uric acid (hyperuricemia),¹⁷⁹ which accumulates in the body. High uric acid levels are thought to cause neurological damage.^{177,179}

The prevalence of LNS is 1 in 380,000 individuals.¹⁷⁹ Females born to carrier mothers have a 25% chance of inheriting the mutation. There are rare reports of females demonstrating this syndrome as a result of X chromosome inactivation. Most female carriers are considered to be asymptomatic, but some may have symptoms of hyperuricemia in adulthood.¹⁷⁹

LNS is detectable through amniocentesis, and genetic counseling is advisable for parents who have already given birth to an affected son.¹⁸⁰

The prenatal and perinatal course is typical for affected individuals. Hypotonia and delayed motor skills are noticeable by the age of 3

to 6 months.¹⁷⁹ Dystonia, choreoathetosis, and opisthotonus indicative of extrapyramidal involvement emerge during the first few years of life.¹⁷⁹ Many children are initially diagnosed with athetoid cerebral palsy when pyramidal signs such as spasticity, hyperreflexia, and abnormal plantar reflexes emerge.¹⁷⁹ Most children never walk. A hallmark of the disease is severe and frequent self-injurious behaviors such as lip and finger biting, which emerge in almost all affected children by their third year.¹⁷⁹ Because of the extreme self-mutilation that characterizes this disorder, it has been questioned whether these children have normal pain perception.¹⁸¹ Although they have the abnormal catecholamine metabolism seen in other patients with congenital pain insensitivity,¹⁸² behaviors documented in children with LNS suggest that they do sense pain, demonstrated by their apparent relief when they are restrained from hurting themselves. Children may actually request the restraining device¹⁸³ even when the device may be one that would not physically prevent biting, such as a glove or bandaid.¹⁷⁹ A reported survey of parents of children with LNS indicated that parents often find behavioral programming techniques helpful in modifying aggression toward self or others.¹⁸³ However, there is no consensus on the best kind of behavioral treatments, as any reward, either positive or negative, may increase the frequency of self-injury.¹⁸⁴ Some parents have reported that they elected tooth extraction as a means to prevent biting. Other impairments in children with LNS include severe dysarthria and dysphagia. Bilateral dislocation of the hips may occur as a result of the spasticity.¹⁷⁹ Growth retardation is also apparent, along with moderate to severe intellectual disability. Individuals may have gouty arthritis and kidney and bladder stones.

Blood and urine levels of uric acid have been decreased successfully through the administration of allopurinol, with a resultant decrease in kidney damage. With current management techniques, most individuals survive into the second or third decade of life.¹⁷⁹

Rett syndrome. RS is inherited in an X-linked pattern and affects females almost exclusively, as it is most often lethal in boys before 2 years of age. Males may inherit RS with an extra X chromosome in many or all of the body's cells.^{185–188} The estimated incidence is one in 15,000 to 20,000 females.¹⁸⁹ It has been reported that 99% of all cases of RS are the result of sporadic mutations.^{188,190} Most cases of RS, called *classic RS*, are caused by mutations in the *MECP2* gene, which is responsible for directing proteins critical for normal synaptic development; however, it is unclear how these mutations lead to all the signs and symptoms of the syndrome.^{188,191} Several variants of RS exist; they have overlapping features with classic RS but may have a much milder or more severe course.¹⁸⁸

Classic RS is characterized by apparently normal development during the first 6 months of life, followed by a short period of developmental plateau and then rapid deterioration of language and motor skills typically occurring at 6 to 18 months of age.^{188,192} Most girls survive into adulthood.¹⁸⁸ The hallmark of the syndrome is that during the period of regression, previously acquired purposeful hand skills are also lost and replaced by stereotypical hand movements. These non-specific hand movements have been described as hand wringing, clapping, waving, or mouthing. Virtually all language ability is lost, although some children may produce echolalic sounds and learn simple manual signing. Evidence of minimal receptive language skills may be observed. Autistic behaviors, inconsolable crying and screaming, and bruxism are common features of individuals with RS.¹⁸⁸ Almost all individuals with RS function in the range of severe to profound intellectual disabilities.

Head circumference is normal at birth, and its increase may decelerate in early childhood, but microcephaly is not a consistent feature of RS.¹⁸⁸ Retarded growth and muscle wasting are observed in most girls, likely associated with poor food intake and gastrointestinal problems.¹⁸⁸

Almost one-fourth of girls with RS never develop independent ambulation skills; otherwise the onset of walking is usually delayed until about 19 months of age.¹⁹³ Initially hypotonia may be evident, but with advancing age, spasticity of the extremities develops.¹⁹⁴ Increased muscle tone is usually observed first in the lower extremities, with continued greater involvement than in the upper extremities. Peripheral vasomotor disturbances, especially in the lower limbs, are often noted.¹⁸⁸

Scoliosis, which is often severe enough to require surgical correction, occurs in most girls by adolescence, characterized by a long C-shaped thoracolumbar curve, kyphoscoliosis, and an early onset of posterior pelvic tilt and abducted shoulder girdles.^{193,195–199} Heel cord tightening and hip instability have also been identified as areas of potential concern.¹⁹⁵ Abnormal EEG and seizures occur in 70% of individuals with RS in the first 5 years of life. Cranial CT results are normal or show mild generalized atrophy. Breathing dysfunction, including wake apnea and intermittent hyperventilation,¹⁹⁶ is also associated with RS. Interventions reported in the literature have focused on splinting,²⁰⁰ behavioral modification techniques to teach self-feeding skills,²⁰¹ aquatic therapy,²⁰² occupational therapy,²⁰³ music therapy,²⁰⁴ physical therapy,^{188,197,198,204} and the first two combined in a dual-intervention approach.²⁰⁵

Mitochondrial Deoxyribonucleic Acid Disorders

In addition to the nuclear genome, humans have another set of genetic information within their mitochondria. Nuclear genes exist in pairs of one maternal and one paternal allele. In contrast, there are hundreds or thousands of copies of mtDNA in every cell. mtDNA is small, circular, and double-stranded. It has been well studied and was mapped long before the human nuclear genome. mtDNA contains 37 genes responsible for normal function of the mitochondria in all body cells.²⁰⁶ Humans inherit mtDNA maternally. It is highly susceptible to mutation, and the molecule has limited ability to repair itself. Tissues that have a high demand for oxidative energy metabolism, such as brain and muscle, appear to be most vulnerable to mtDNA mutations.¹⁷ Normal and mutated versions of mtDNA can coexist within a patient's body, but when a certain critical number of mutations exist, the body's tissues will show clinical signs of dysfunction. These disorders affect the metabolic functions of the mitochondria, such as the generation of adenosine triphosphate, the body's energy currency. Many patients with point mutations of mtDNA exhibit symptoms in early childhood; these mutations may be the most frequent cause of metabolic abnormality in children.¹⁷ The minimum minimal birth prevalence of childhood mitochondrial respiratory chain disorders is reported to be 6.2 per 100,000.^{18,207–209} Medical intervention for mitochondrial encephalomyopathies cannot treat the underlying disease, but rehabilitative therapies have been reported to be of value.^{210,211} An example of a childhood disorder that can result from an mtDNA mutation is Leigh syndrome.

Leigh Syndrome

Leigh syndrome or subacute necrotizing encephalomyopathy may also be transmitted by X-linked recessive and autosomal recessive inheritance. Approximately 20% of all cases of Leigh syndrome are caused by mitochondrial mutations.²¹² The discussion in this section focuses on characteristics of mtDNA-associated Leigh syndrome.

Leigh syndrome has an onset in infancy, typically at 3 to 12 months of age. Initial features may be nonspecific, such as a failure to thrive and persistent vomiting.^{212,213} It is a progressive disorder caused by lesions that can occur in the brain stem, thalamus, basal ganglia, cerebellum, and spinal cord. Common clinical features include seizures, epilepsy, muscle weakness, peripheral neuropathy, speech and feeding difficulties,

gastrointestinal and digestive problems, and heart problems. Most affected children have hypotonia, movement disorders such as chorea, and ataxia. Life expectancy is 2 to 3 years; death most often results from respiratory or cardiac failure.²¹²

Multifactorial Disorders

Multifactorial disorders are believed to be a result of the combined effects of mutations in multiple genes as well as environmental factors.²¹ Environmental factors may be those that have an impact on a developing fetus, such as prenatal diet, or those that have an impact on humans as we age, such as cigarette smoking. Disorders in this category can result in congenital malformations such as spina bifida and clubfoot. An in-depth discussion of spina bifida can be found in Chapter 13. Management information on clubfoot can be found in pediatric textbooks that include orthopedic information.^{214–217}

Many diseases such as cancer can result when the environment interacts with genetic variations that exist in all humans.²¹ Scientists are exploring genetic contributions to premature births,^{218,219} the leading cause of infant mortality and morbidity.^{220,221} It is most likely a result of multiple genetic and environmental determinants that tend to run in families.^{218,219} Premature infants are at higher risk of neurological, musculoskeletal, and respiratory problems than are term infants. Management of infants with low birth weight is discussed in Chapter 9 of this text.

BODY STRUCTURE AND FUNCTION PROBLEMS COMMON TO MANY PEDIATRIC GENETIC DISORDERS

Specific examples of genetic disorders in children were presented in the foregoing section. Although there are many disorders that physical and occupational therapists may see often, others are rare and may only be suspected based on clustered problems of body structure, function, and activity limitations. Decisions about which interventions to implement and the expected outcomes will be largely influenced by the diagnosis of the specific disorder, once attained. Many genetic conditions share in common a short list of primary problems that will negatively affect the child's physical movement and daily activities and participation, both immediately and in the long term. [Table 11.2](#) summarizes the problems common to many genetic disorders that are most relevant for physical or occupational therapists.

The term *pediatric movement disorders* (PMDs) in the scientific literature is no longer a generic term; instead, these conditions are now defined and classified largely as a result of the work of the NIH Taskforce on Childhood Movement Disorders.²²² PMDs are classified based on movement phenomenology such as hyperkinetic movement (e.g., dystonic or tics).

PMDs have one or more of the characteristics of abnormal posturing, unintended excessive movement, movement at unintended or inappropriate time, dysfunction in the target, and velocity of an intended movement.^{223,224} The knowledge of a genetic causation of PMDs is growing since the definitions of movement disorders have been clarified and their phenotypes are better understood. Specific genes are implicated in movement disorders based on how the movement appears; for example, a mutation in the PPRT2 gene (chromosome 16) is responsible for many instances of paroxysmal kinesigenic dyskinesia (PKD).²²⁵

Hypertonicity

Abnormalities of tone may result from dysgenesis or injury to developing motor pathways. Hypertonia is common to many motor disorders

and is defined as “abnormally increased resistance to externally imposed movement about a joint.”²²⁶ Examples of externally imposed movement are passive movement by the therapist or changes in ankle and knee position resulting from ground reaction forces during ambulation. Children with hypertonus generally display stiff or jerky movements that are limited in variety, speed, and coordination. Controlled, voluntary movements tend to be limited to the middle ranges of a joint. Total patterns of flexion or extension may dominate, with limited ability for selective joint movements. The motor development of children with hypertonicity may be further complicated by the retention of primitive reflexes, which can result in stereotyped movements associated with sensory input.²²⁶

Sanger and colleagues²²⁶ proposed a classification system to objectively define and distinguish different types of hypertonicity. Three general types of hypertonicity—spasticity, dystonia, and rigidity—may occur alone or in combination. Spasticity is a velocity-dependent increased resistance to muscle stretch that may occur above a given threshold of speed and/or joint angle and may depend on the direction of joint movement. Dystonia is also an involuntary alteration in the pattern of muscle activation during voluntary movement or maintenance of posture. The observable disorder is demonstrated by intermittent muscle contractions causing twisting or repetitive movement, postures, or both.²²⁶ Dystonia may be triggered by attempts at voluntary movement or to prevent the movement of a joint (e.g., to prevent knee buckling in stance). The pattern and magnitude of the abnormal muscle activity may change with the child's arousal, emotional state, and tactile contact.²²⁶ Rigidity is a form of hypertonus in which the speed of movement and joint angle do not affect the quality of the movement. Stiffness caused by diminished tissue length and extensibility of muscles and connective tissue is not included in the recent definitions of hypertonus but may exist alongside hypertonicity.^{226,227}

Children may learn to use stereotypical patterns of movement and hypertonus to achieve functional goals by activating the muscle synergies of a reflex without sensory feedback.²²⁸ If a goal of therapy is to facilitate functional movement that is not dominated by persistent reflexes, it is critical to practice new motor patterns to accomplish the functional activity for which that reflex is being used. The focus of therapy activities must be on active movement of the child and not on passive inhibition techniques of abnormal reflexes for the sake of “normalization” of tone and movement.^{228–231}

Hypotonicity

In contrast to hypertonia, low tone or hypotonia is not clearly defined. The “floppy” infant or child is commonly characterized as having hypermobility of joints that lack resistance to passive movement, with diminished antigravity movement and postural stability. Hypotonia may occur because of central or peripheral nervous system dysfunction, as is the case in newborns with PWS and toddlers with SMA type II, respectively. Many genetic disorders are revealed in newborns based on the common features of severe, global hypotonia and low Apgar scores.²³² Retrospective studies of newborns report key features of absence of antigravity movements and decreased reflexes. The presence of fetal hypokinesia and/or polyhydramnios is reported to be predictive of neonatal hypotonia in many cases.²³³ In full-term neonates with hypotonia, studies report that 30% to 60% of cases are associated with a genetic disorder. A clinical neurological examination such as described by Dubowitz and the use of dysmorphic data bases can identify the majority of cases.^{233,234} First-line genetic testing is indicated in neonates with hypotonia plus facial dysmorphism or signs of peripheral hypotonia (e.g., as seen in SMA).²³³

Martin and colleagues²³⁵ surveyed physical and occupational pediatric therapists and reported that the majority of therapists do not use

formal examination methods to quantify hypotonia directly; instead, they use measurements for various expressions of hypotonia, most often muscle strength and developmental milestones. This study also confirmed that most therapists agree that children with hypotonicity have diminished postural control and thus tend to lean on supports to maintain a position. Examples of this behavior are locking out weight-bearing joints and assuming positions that provide a broad base of support to maximize their stability (Fig. 11.5). Although retention of primitive reflexes is less likely in children with hypotonia compared with those with hypertonia, delays in the development of postural reactions are a major concern. Limited strength and lack of endurance are often concerns with children who have hypotonicity. Hypotonicity and joint laxity are often associated with motor delay; however, therapists should not assume that hypotonia and joint laxity are absolutely predicative of persistent motor delay.²³⁶ For example, many premature infants, with or without a genetic disorder, have global hypotonia at birth that resolves and does not cause long-term functional impairment.^{236,237} Hypotonicity is a persistent problem in many children with developmental delay. Therapists may address hypotonia and problems of postural control with a variety of treatment modalities and techniques, including aquatic therapy,²³⁸ hippotherapy,²³⁹ and neurodevelopmental therapy.²⁴⁰

Hyperextensible Joints

Hyperextensible joints are commonly observed in children with hypotonicity and are noted in many children with a variety of genetic disorders, representing different underlying organ structure problems. Activities should be modified to avoid undue stress to these joints and the surrounding ligaments, tendons, and fascia. For example, positions that allow the knee or elbow joints to lock into extension should be modified so that weight bearing occurs through more neutral alignment. Varying the placement of toys and support surfaces, providing physical assistance, and using adaptive equipment can help modify weight-bearing forces to achieve more neutral alignment.²⁴¹ For example, if hyperextensibility of ligaments leads to excessive pronation in stance (Fig. 11.6), the use of ankle-foot orthoses may provide enough support to the structures to allow functional activities in standing (see the discussion of orthotics in Chapter 32). For a child who stands with knee hyperextension, a vertical stander may allow that child to stand and play at a water table with her or his classmates for extended periods with the knees in a more neutral position. Rather than restricting a child's repertoire of upright positions, it is preferable to modify an activity or provide external support to enable a child to participate fully (Fig. 11.7).²⁴²

Contractures and Musculoskeletal Deformities

Skeletal anomalies and deformities are associated with many genetic disorders. The therapist should be aware of factors that can contribute to the development of deformities to prevent or minimize such problems. The physical or occupational therapist may work with orthopedists, prosthetists, and orthotists to detect and prevent the progression of a variety of conditions.

Conditions that cause hypertonicity or spasticity are well known to place children at risk for joint contracture.²⁴³ Children with hemophilia are at great risk of joint contractures associated with hemarthroses and intramuscular hemorrhages.²⁴⁴ Spinal deformities, such as lumbar lordosis and thoracic kyphosis and scoliosis, are also common concerns in children with hypertonia or hypotonia. Although joint contractures are less likely to occur in a child with hypotonicity, habitual positioning may lead to soft tissue restrictions. For example, children with hypotonia often adopt a constant position of wide abduction, external rotation, and flexion at the hips ("frog" or "reverse

W" position)²⁴⁵; in these children, soft tissue contractures can develop at the hips and knees. Children whose hips are maintained in a position of adduction, flexion, and internal rotation are at a risk for hip subluxation or dislocation.²⁴⁵

Deformation of the anterior chest wall and shoulder girdles may result from primary problems in the cardiopulmonary system in children with CF. When coupled with hypotonicity and poor postural control, the anterior chest wall muscles tighten as a result of the long-term rounded, internally rotated shoulders and protracted scapulas, in which case therapeutic interventions should target improving chest wall and scapulothoracic mobility as well as strengthening postural muscles (Fig. 11.8).²⁴⁶⁻²⁴⁸ In general contractures and deformities are a concern for most children who display a limited variety of postures and movements. While choosing treatment techniques, therapists should consider the nature of the disorder that places the child at risk for contractures; disorder-specific techniques can be found in textbooks on pediatric occupational and physical therapy.^{214,249}

Respiratory Problems

A genetic risk for respiratory distress in infancy has been suggested by reports of family clusters.²⁵⁰ Furthermore, comparison of short- and long-term respiratory function in infants with respiratory distress syndrome suggests that if all other factors of nutrition, previous mechanical ventilation, and gestational development are comparable, genetic risk may account for cases of chronic and potentially irreversible respiratory failure.²⁵⁰

Respiratory problems are often observed in children with limited mobility. If the mobility impairments are the result of hypotonicity or hypertonicity, impaired respiration may be a result of chest and skeletal deformities. Many infants with genetic disorders are born prematurely and are more susceptible to respiratory problems than infants born at full term.^{218,219,245} Prolonged mechanical ventilation and other medical procedures may increase the time neonates spend in the supine position, thus increasing the risk of gravity-induced deformity of the rib cage and inefficiency of the respiratory musculature.^{246,251,252}

Some children may find it difficult to tolerate one position for an extended time owing to respiratory difficulties. For these children, frequent changes of position and use of adapted positioning devices may be necessary. Premature infants in the neonatal intensive care unit may benefit from regular prone positioning to facilitate restorative sleep,²⁵²⁻²⁵⁴ improved arterial oxygen saturation,²⁵⁵ and improved respiratory synchrony.²⁵⁶ Children with respiratory problems may require mobilization techniques, deep breathing, chest expansion exercises, and postural drainage. In the case of children with CF, a comprehensive program of respiratory care is the primary therapeutic goal.²⁵⁷

Developmental Delay

Genetic disorders that affect neuromuscular, somatosensory, and cognitive function are frequently associated with developmental delays in children. The genetic basis for multisystem syndromes such as Down syndrome or LNS can be identified by cytogenetic and molecular techniques. Congenital malformations, hearing impairment, and mental or growth retardation are examples of common components of developmental delay that often have a genetic basis.

Developmental delay is typified by the failure to meet expected age-related milestones in one or more of five areas: physical, social and emotional, intellectual, speech and language, and adaptive life skills. Developmental milestones that are typically assessed in the first 5 years of life are listed in Box 11.2.

Physical and occupational therapists can observe the interaction between each of the five areas of development in an infant or child. For

TABLE 11.2 Characteristic Features of Selected Genetic Conditions

Genetic Condition	Typical Age at Diagnosis	Craniofacial Dysmorphism	Musculoskeletal Involvement	Neuromuscular System Involvement and Tone	Cardiopulmonary Involvement
Trisomy 21	Prenatal or infancy	Yes	Joint laxity and instability	Hypotonia	Yes
Trisomy 18	Prenatal, neonatal	Yes	Yes	Hypotonia	Yes
Turner syndrome	Infancy, adolescence; girls	Yes	Short stature, hip dislocation, scoliosis		Yes
Klinefelter syndrome	Adolescence; adulthood; males	Yes	Yes	Varies with age	
Cri-du-chat syndrome	Infancy	Yes	Yes	Hypotonia	Yes
Prader-Willi syndrome	Infancy	Yes	Scoliosis	Hypotonia	Secondary to obesity
Angelman syndrome	Infancy	Microcephaly		Hypotonia and seizures, ataxia	
Acute lymphoblastic leukemia	Childhood		Bone pain and muscle cramps		
Osteogenesis imperfecta	Varies with type and severity		Multiple fractures and muscle weakness		Yes
Tuberous sclerosis complex	Infancy, early childhood		Yes, cyst formation	Hypertonia; seizures	Yes, cyst formation
Neurofibromatosis type 1	Infancy, childhood		Yes		
Cystic fibrosis	Infancy		Chest wall deformity, muscle and bone pain		Yes
Hurler syndrome	Infancy	Yes	Yes	Yes	Yes
Spinal muscle atrophy type II	Infancy		Yes	Hypotonia	Yes
Hemophilia type A	Childhood or earlier if severe		Joint pain and hemarthroses		
Fragile X syndrome	Childhood	Yes	Joint laxity		Yes
Lesch-Nyhan syndrome	Infancy		Gouty arthritis	Varies	
Rett syndrome	Late infancy to early childhood		Scoliosis	Hypotonia, ataxia, seizures	

example, a child with severe hypotonia who has limited movement experiences will not develop a well-adapted sensory system. Children with problems processing sensory information often withdraw from social interaction, through which they would otherwise find opportunities to develop speech, language, and social skills. Dynamic systems theory²⁵⁸ explains the relationship among all of these developing components in a child; language does not develop independently of gross motor skills, and the ability to feed or dress oneself is as related

to social, emotional, and intellectual development as it is to fine motor skills.

Suspicion of developmental delay often leads to physician referral. An accurate medical diagnosis is important as it facilitates knowledgeable surveillance for potentially associated health problems. A delayed diagnosis can preclude timely implementation of beneficial medical, therapeutic, and educational services. Children who are identified to be at risk for developmental delay may be referred to EI programs.

Other Systemic Involvement	Other Disease Processes	Sensory Dysfunction	Motor Delay	Cognitive Delay	Hallmark Feature(s)
	Alzheimer disease, sleep apnea, obesity	Vision, hearing	Yes	Yes	Facial features, simian crease
Yes		Yes	Yes	Yes	Life-span <1 year
Distal lymphedema; reproductive system		Hearing			Webbed neck appearance and short stature
Endocrine and reproductive system			Yes	Yes	Intellectual disability; course of gonadal development
		Vision			"Cat cry"
Reproductive system	Morbid obesity	Vision	Yes	Yes	Hypotonia, obesity
			Yes	Yes	Happy demeanor, sleep disorders
	Osteopenia, osteoporosis				Lethargy, fever, respiratory infections
	Dentinogenesis	Hearing (type I)			Multiple fractures
Skin lesions, adenomas; renal disease		Vision	Yes	Yes	Sebaceous adenomas, seizures
Café-au-lait spots and cutaneous neurofibromas; vasculopathy		Vision			Café-au-lait spots, neurofibromas
Gastrointestinal system; urinary stress incontinence in females	Osteoporosis, osteopenia				Lung and digestive dysfunction
Yes		Vision, hearing	Yes	Yes	Progressive craniofacial abnormalities and developmental deterioration
Yes			Yes		Progressive loss of peripheral motor function
Skin bruising					Bleeding, bruising, joint pain, and loss of motion
		Yes		Yes	Intellectual disability, autism
Urogenital system		Yes	Yes	Yes	Self-injurious behavior, gouty arthritis
		Yes	Yes	Yes	Regressive developmental delay; stereotypical, purposeless hand movements

Examples of assessment techniques and interventions for children with developmental delay can be found in textbooks on pediatric physical therapy.^{259,260}

Behavioral Phenotypes in Genetic Syndromes

Study of the cognitive and behavioral aspects of individuals with certain genetic syndromes has given rise to the term *behavioral phenotype*. Certain clusters of behavior that characterize a given syndrome can aid

in the early recognition and diagnosis of a syndrome and guide in intervention. Aspects of behavioral phenotypes include social interaction, sleeping patterns, mood, attention, motivation, adaptive and maladaptive strategies, intellect, and memory.^{261–265}

Down syndrome, PWS, AS, FXS, and LNS are examples of genetic disorders discussed in this chapter with delineated behavioral phenotypes.^{262,263} Compulsive overeating in children with PWS, sleep disturbances in children with AS, and self-injury in children with LNS are

Fig. 11.6 Excessive bilateral pronation and flat feet associated with hyperextensibility in an 8-year-old boy with global hypotonia.

Fig. 11.8 (A) Note improved post-intervention scapular position and improved glenohumeral range of motion. **(B)** Note improved post-intervention reduction of forward-head posture and reduction of rounded shoulders.

Fig. 11.7 Equipment Adapted to Promote Participation in Upright Activities for Children With Trunk Weakness and Poor Postural Control. **(A)** The corner chair gives this child with Rett syndrome the proper back support; toys can be placed within her reach on the tray. **(B)** This particular gait trainer allows appropriate patterns of weight shifting to occur while providing her with stability in the pelvis and lower trunk.

BOX 11.2 Failure to Meet Developmental Milestones**By 1 Month**

Sucks poorly and feeds slowly
 Lower jaw trembles constantly even when infant is not crying or excited
 Does not respond to loud sounds or bright light
 Does not focus on and follow a nearby object moving side to side
 Rarely moves
 Extremities seem loose and floppy or very stiff

By End of Third Month

No Moro reflex
 Does not notice own hands by 2 months
 Does not grasp and hold objects
 Eyes cross most of the time or eyes do not track well together
 Does not coo or babble

By End of Fourth Month

Head flops back when infant is pulled up to sitting by his or her hands
 Does not turn head to locate sounds
 Does not bring object to mouth
 Does not smile spontaneously
 Inconsolable at night

By End of Fifth Month

Persistent tonic neck reflexes
 Cannot maintain head up when placed on stomach or in supported sitting position
 Does not reach for objects
 Does not roll in both directions

By End of Seventh Month

Reaches with one hand only
 Cannot sit with help by 6 months
 Does not follow objects at a distance
 Does not bear some weight on legs
 Does not laugh; does not try to attract attention through actions
 Refuses to cuddle; shows no affection for caregiver

By End of Twelfth Month

Does not creep on all fours
 Cannot stand when supported
 Does not search for toy hidden while he or she watches
 Says no single words (e.g., “mama” or “dada”)
 Does not use gestures such as waving hand or shaking head; does not point to objects or pictures

By End of Second Year

Cannot walk by 18 months
 Failure to develop heel-toe walking pattern after several months of walking

Does not speak at least 15 words by 18 months
 Does not use two-word sentences by 2 years
 Does not know the function of common objects (brush, telephone, spoon) by 15 months
 Does not imitate actions or words; does not follow simple instructions

By End of Third Year

Frequent falling and difficulty with stairs
 Persistent drooling or unclear speech
 Inability to build a tower of more than four blocks
 Difficulty manipulating small objects
 Cannot copy a circle
 Cannot communicate in short phrases
 No pretend play
 Little interest in other children
 Extreme difficulty separating from caregiver

By End of Fourth Year

Cannot throw a ball overhand
 Cannot jump in place with both feet
 Cannot ride a tricycle
 Cannot grasp a crayon between thumb and fingers; cannot scribble
 Resists dressing, sleeping, using the toilet
 Does not use sentences of more than three words; does not use “me” and “you” appropriately
 Ignores other children or people outside the family
 Does not pretend in play; no interest in interactive games
 Persistent poor self-control when angry or upset

By End of Fifth Year

Does not engage in a variety of physical activities
 Has trouble eating, sleeping, using the toilet
 Cannot differentiate between fantasy and reality
 Seems unusually passive or aloof with others
 Cannot correctly give her or his first and last names
 Does not use plurals or past tense when speaking
 Does not talk about daily experiences
 Does not understand two-part commands
 Cannot brush teeth efficiently
 Cannot take off clothing
 Cannot wash and dry hands
 Cannot build a tower of six to eight blocks
 Does not express a wide range of emotions
 Seems uncomfortable holding a crayon

behavioral problems that can have a significant negative impact on quality of life for children and their families. Although children with Down syndrome have fewer maladaptive behaviors than most children with intellectual disabilities,^{261,263,265} they have been shown to abandon challenging tasks sooner than other children at similar developmental levels in exchange for peer social interaction.²⁶⁴ Furthermore, this strength of sociability in children with Down syndrome contributes to the child’s learning through modeling and peer collaboration. A knowledgeable, observant therapist can use peer groups to motivate and model for a child with Down syndrome, but he or she should also recognize that the child may be distracted by other children and default to a social strategy, thus avoiding the task at hand.²⁶⁴

MEDICAL MANAGEMENT AND GENETIC COUNSELING

The physical or occupational therapist should have general knowledge of both medical management of children with genetic disorders and genetic counseling for family members. This information allows the therapist to answer the family’s general questions and refer family members to the appropriate persons for more specific information.

Medical Management

Early detection of genetic disorders has improved the health and survival of individuals with certain genetic disorders such as PKU, hemophilia,

and CF. Medical treatment for the other disorders is not curative but rather palliative or directed at specific associated anomalies.

Surgical Intervention

The congenital heart defects present in many individuals with Down syndrome can in most instances be corrected by cardiac surgery.²⁶ Orthopedic surgery in the form of insertion of intramedullary rods in the tibia or femur may minimize the recurrence of repeated fractures associated with OI.^{123,265} Surgical correction of dystrophic scoliosis may be warranted in individuals with NFM,¹¹⁹ RS,^{193,196,198,199,204} or Werdnig-Hoffmann disease¹⁶² if the deformity is severe and bracing is not successful. Radiographic screening for atlantoaxial instability in children with Down syndrome can be initiated beginning at 2 years of age.²² If atlantoaxial instability is excessive or results in a neurological deficit, a posterior fusion of the cervical vertebrae is recommended.³⁶ Surgical removal of obstructive or malignant tumors is advisable in certain cases of NFM and removal of cerebral nodular growths for the control of seizures in individuals with tuberous sclerosis.¹²⁸ Surgical interventions such as gastric bypass, small intestinal bypass, and jaw wiring have been attempted for weight control in children with PWS but have had limited success.^{90,97}

Pharmaceutics

Second-generation bisphosphonates can reduce fracture frequency, improve bone quality, and improve outcomes after orthopedic surgery in children and lessen the severity of osteoporosis in adults.¹²³ Antibiotics and pneumo-ostachian tubes to lessen the frequency and severity of otitis media can reduce the incidence of hearing loss in individuals with Down syndrome²⁶ and Turner syndrome.⁶⁶ The use of appetite-regulating drugs for individuals with PWS has had equivocal results. Reproductive hormone therapy can promote pubertal development in girls with Turner syndrome^{66,69} and boys with Klinefelter syndrome.^{76,266} Growth hormone has been shown to improve stature in girls with Turner syndrome.⁶⁶ The use of anticonvulsants is an important part of seizure management for individuals with RS^{193,197} and tuberous sclerosis.¹²⁹ Allopurinol has been used for individuals with LNS to prevent urological complications, although it has no effect on the progressive neurological symptoms.¹⁷⁹ The use of large, potentially toxic amounts of vitamins and minerals (the orthomolecular hypothesis) has been proposed for children with many different types of developmental disabilities. This approach has been rejected for children with Down syndrome on the basis of the results of several investigations. In addition, supplementation of individual metabolites such as 5-hydroxytryptophan or pyridoxine for children with Down syndrome is ineffective.²⁶⁷

Pharmacogenetics is a new field of scientific research that helps provide a biochemical explanation for why some patients respond well to a medication and others with the same condition being treated do not. “Personalized medicine” is an approach whereby doctors may make decisions regarding which medications, dosages, and combinations with other drugs to prescribe based on the analysis of selected genes in their patients.²¹

The Age of Precision Medicine

Advancements in cell therapy are rapid; therefore the information describing them in this section are likely to be quickly outdated.

The purpose of gene therapy is to correct defective genes responsible for disease by replacing missing or mutated genes, changing gene regulation, or enhancing the “visibility” of disease genes to improve the body’s immune response. Gene therapy trials have been approved for use in humans only on somatic cells. A vector carries the gene product to the person’s cells; vectors may be either an altered virus, stem cells, or liposomes.²⁶⁸

The oversight of gene therapy falls under the US Department of Health and Human Services, which oversees agencies that, in turn, are responsible for establishing research protocols (National Institutes of Health [NIH]), evaluating investigational gene products (US Food and Drug Administration [FDA]), monitoring ethics (Recombinant DNA Advisory Committee), and educating human subjects (Office for Human Research Protections).²⁶⁹ The clinical development of a gene product that could be widely dispensed must include four phases: phase 1 consists of regulatory approval of the protocol and then human pharmacology focusing on safety and tolerability and pharmacokinetics; phase 2 examines the effectiveness in terms of dose and regimen and target populations; phase 3 determines a basis for licensure and marketing of the product; and phase 4 establishes therapeutic use in a wider population.²⁶⁹ A list of approved cellular and gene therapy products can be found on the US FDA’s website. The interested reader can obtain an up-to-date listing of current gene therapy protocols from the NIH’s Genetic Modification Clinical Research Information System (GeMCRIS) on the World Wide Web at www.gemcris.od.nih.gov/Contents/GC_HOME.asp.

In light of the limited medical treatment strategies available for children with genetic disorders, the physical or occupational therapist must be concerned with maximizing the child’s developmental or functional potential within the limitations imposed by the lack of possible cures and the prospect of the shortened life-span that characterizes many of these disorders. When deterioration of skills is expected, therapy must be directed at maintaining current functioning levels, minimizing decline, and minimizing caregiver support as much as possible.

Genetic Counseling

Developmental, physical, or occupational therapists must have an understanding of the modes of inheritance of the various genetic disorders and information about the services that can be offered through genetic counseling. Although the physician has primary responsibility for informing the parents about the availability of genetic counseling, the close professional and personal relationships that therapists often develop with families may prompt family members to seek this type of information from the therapist.

Although a physical or occupational therapist cannot fill the role of a qualified genetic counselor, it is important that therapists be aware of the availability and location of genetic counseling services so that they may be assured that parents of a child with a genetic disorder have this information. Most major university-affiliated medical centers provide genetic counseling.

Process of Genetic Counseling

Six steps or procedures in genetic counseling were introduced in the 1970s by Novitski; they included descriptions of various genetic tests and a clinical interview.²⁷⁰ The desired outcome of genetic counseling is to make an accurate medical diagnosis of the child’s disorder. In the case of a suspected chromosomal abnormality, this usually involves determining the karyotype of the child and possibly the karyotypes of the parents. Other diagnostic procedures may include a medical examination, FISH, DNA studies, biochemical studies, muscle biopsy, and other laboratory tests.

A pedigree or family tree is constructed of all known relatives and ancestors of both parents.²⁷⁰ Pedigree information includes the age at death and cause of death of ancestors, a history of stillbirths and spontaneous abortions, and a history of appearance of any other genetic defects or unknown causes of intellectual disability. The country of origin of ancestors is also important because certain genetic defects, such as PKU, are far more prevalent in families of a particular ethnic

origin. Once the defect has been identified and a pedigree constructed, Novitski²⁷⁰ advises that further information be obtained from one of the comprehensive resource texts on genetic disorders. Informing family members about the characteristics of the disorder and its natural history may diminish fears of the unknown.

The third procedure in genetic counseling is to estimate the risk of recurrence of the disorder.²⁷¹ In specific gene defects, the probability of recurrence is fairly straightforward, with a risk of 25% for autosomal recessive disorders and a 50% risk for each male child in sex-linked disorders. These percentages, however, do not hold true in cases of spontaneous mutations. In cases of chromosomal abnormalities such as Down syndrome, karyotyping is mandated to determine whether the child has the translocation type of Down syndrome. In that case the risk of recurrence is much greater than with a history of standard trisomy 21 Down syndrome.

Informing parents of the probability of recurrence is the next procedure. Novitski²⁷⁰ points out the common misunderstanding that if a risk is one in four for a child to be affected, as in an autosomal recessive disorder, many parents assume that if they have just given birth to a child with the disorder, the next three children should be normal. It is important to explain that each subsequent child faces a one in four risk of inheriting the disorder regardless of how many siblings with the disorder have already been born. Estimating the risk of multifactorial disorders is a complex process. Although these conditions tend to cluster in families, there is no clear-cut pedigree pattern. The risk of recurrence of a multifactorial disorder is typically low, but if a couple has had two children with the same condition, the recurrence risk is presumed to be higher, with either a high genetic susceptibility or a chronic environmental insult suspected.

The fifth step in genetic counseling is for the parents to decide on the course of action they will take for future pregnancies once the counselor has presented all available facts to them.²⁷¹ Some parents may choose not to have any more children; others may elect to undergo prenatal diagnostic procedures for subsequent pregnancies. These decisions rest entirely with the parents and may be influenced by their individual religious or ethical preferences.

Follow-up counseling and review of the most recent advances in medical genetics are the final steps in the genetic counseling procedure.²⁷⁰ Genetic counseling can play an important role in opening channels of communication among parents as well as other family members and their friends; connecting parents and siblings to support groups; and helping families to address their grief, sadness, or anger.²⁷² The effect of a child's disability on the family may modify the parents' earlier decision regarding whether to have more children. Recent medical advances may allow a more certain prenatal diagnosis of specific genetic disorders.^{273,274}

Early Detection of Genetic Conditions

Diagnosis of many genetic disorders is made clinically, as in observation of a congenital malformation; however, many serious conditions are not immediately apparent after birth. Detection of genetic conditions is performed through various screening procedures, followed by specific diagnostic testing to confirm a suspected disorder. With technological advancements in genetics, these procedures have been expanded for the unborn and the newborn. Couples planning to have children can be tested for specific genetic disorders before conception or embryonic implantation.²⁷⁵ Health care professionals and parents should be informed about both the positive and the negative aspects of using this new knowledge and technology. The American College of Medical Genetics has published lists of the more common reasons for genetics referral as guidelines for health care providers working with infants, children, or couples planning to have children.²⁷⁶

Newborn Screening

Routine newborn screening is required in the United States and is performed on whole populations for common disorders. The purpose of screening is the early identification of infants who are affected by a certain condition for which early treatment is warranted and available. Of the 4 million newborn infants screened each year, approximately 3000 have detectable disorders.²⁷⁷ Currently all 50 states require screening for three disorders: PKU, congenital hypothyroidism, and galactosemia.¹⁴⁷ Some populations known to be at higher risk of certain disorders may be screened automatically, or individuals may elect state-specific screening.²⁷⁷ Most states screen for eight or fewer disorders.²⁷⁸ Tandem mass spectrometry (MS/MS) is a laboratory technique that allows for the identification of several metabolic disorders using a single analysis of a small blood sample drawn from the neonate. Many states use MS/MS for newborn screening for various disorders and have expanded their list of those that are mandated and those that are part of limited pilot programs.²⁷⁹ Some genetic screening is performed primarily for research purposes when the disorder is not preventable, for example, type I diabetes. Screening for type I diabetes is available in some states, and early reports are that 90% of parents consent to the test.²⁸⁰

Benefits of newborn screening are earlier definitive diagnosis and medical intervention for the affected child. Concerns about expanded newborn screening include hasty medical decisions before conclusive evidence is available and parental stress because of a lag time between screening and definitive results. A study by Waisbren and colleagues²⁸¹ conducted on parents of children screened for biochemical genetic disorders recognized that parents generally reported less stress the earlier a diagnosis could be made. However, in the same study, in cases in which the test yielded a false-positive result, parents reported a higher stress index and their children were twice as likely to experience hospitalization (usually the emergency department) than in mothers of children with normal screening results.²⁸¹ In the case of a positive screening result, infants will typically undergo more definitive genetic testing.

Genetic Testing in Infants and Children

Many genetic disorders can be diagnosed by clinical criteria specific to that disorder. If a diagnosis cannot be made on the basis of the patient's clinical presentation, then genetic testing may be warranted. The number of human genes being studied for disorders, as of time of this edition, is 16,454. In more than 516 labs, there are 55,913 tests for 11,414 known conditions.

Specific information can be found at <https://www.ncbi.nlm.nih.gov/gtr>. In the United States, the standards and methods of all laboratories performing clinical genetic tests are governed at the federal level.²⁷⁵

Prenatal Testing

Tests to diagnose a genetic disorder in a developing fetus can be placed into two broad categories: invasive and noninvasive procedures. Currently, in contrast to the most common invasive procedures, noninvasive methods typically cannot permit a definitive diagnosis, but they can be performed with less risk to the fetus. Invasive procedures are recommended in cases of high risk for a serious disorder, when definitive diagnosis could lead to treatment, and to allow parents to make decisions about the pregnancy.²⁸² The ethical implications for prenatal testing are many. Parents are often given information that requires a sophisticated understanding of biology and medicine to fully clarify the implications and results of a diagnostic procedure. For example, amniocentesis can detect many chromosomal abnormalities, but the functional outcome of some disorders can have great variety.²⁸³

Invasive procedures. The most common prenatal diagnostic procedure is amniocentesis, which is used to detect early genetic disorders in the fetus at 11 to 20 weeks of gestation.²⁸² This method involves inserting a long, slender needle through the mother's abdominal wall and into the placenta to extract a small amount of amniotic fluid.²⁸⁴ Laboratory tests of amniotic fluid reveal all types of chromosome abnormalities and a number of specific gene defects, including LNS, and some disorders of multifactorial inheritance, such as neural tube defects. This procedure carries a risk of miscarriage of about 0.5% to 1.7%,²⁸⁵ and the risk increases the earlier that it is performed.²⁸²

Chorionic villus sampling involves extracting and examining a portion of the placental tissue. It has nearly a 99% detection rate for chromosomal abnormalities²⁸² and can be definitive earlier than amniocentesis; however, the risk of severe limb defects (amniotic band syndrome) increases the earlier that it is performed. The miscarriage rate with this procedure is estimated to be 0.5%.²⁸²

Noninvasive procedures. Ultrasonographic examination of a fetus has been used to identify congenital malformations since 1956. It is currently offered to most women in the United States. It is currently believed that there is no inherent risk from this procedure. First-semester sonography is performed mainly to confirm the gestational age, identify multiple pregnancy, and measure nuchal thickness (NT). NT is a measure of the subcutaneous space between the skin and the cervical spine in the fetus; increased NT is often associated with trisomies. Second-trimester ultrasonography can detect problems in the quantity of amniotic fluid, large fetal structural defects, and certain smaller defects associated with a genetic disorder. A definitive diagnosis is not made on the basis of the presence of small defects alone; rather, the findings are considered along with the other risk factors present.²⁸⁶ Again, there are ethical questions about the risk to the parents (emotional stress and uncertainty) versus the benefits of early detection.

Tests of maternal serum screening done at about 15 to 20 weeks of gestation can detect chromosomal abnormalities, but their accuracy depends on many factors including gestational age, maternal weight, ethnicity, multiple pregnancy, maternal type I diabetes, and maternal smoking.²⁸² Finally, it is possible to perform cytogenetic analysis of fetal blood cells, which can be isolated from a sample of the mother's blood; however, this requires expensive equipment and expertise.²⁸²

Assisted Reproductive Technology and Preimplantation Genetic Diagnosis

Couples who want to conceive often seek genetic counseling if one or more parents is aware of a familial genetic condition, if they are having difficulty conceiving, and commonly in cases of advanced maternal or paternal age. More than 1 million babies have been born worldwide as a result of in vitro fertilization (IVF).²⁸⁷ IVF has enabled couples with fertility problems to conceive and more recently has been used to diagnose a genetic disease or condition in an embryo when it has differentiated into just eight cells.²⁸⁸ Chromosomal abnormalities are the most commonly detected aberrations, and approximately 100 single-gene disorders have been diagnosed.²⁸⁸ The ultimate purpose of preimplantation genetic diagnosis is to implant only mutation-free embryos into the mother's uterus; however, infants conceived with assisted reproductive technology (ART) are two to four times more likely to have certain types of birth defects than children conceived naturally.²⁸⁷ The reasons for the increased risk of birth defects is unknown, but it may be that ART results more often in multiple births, which are at higher risk regardless of the use of ART.²⁸⁷ Intracytoplasmic sperm injection (ICSI) is another form of ART used often in cases of paternal infertility. Male infertility caused by azoospermia or oligozoospermia is associated with several genetic factors, such as paternal sex chromosome aneuploidy in the case of Klinefelter syndrome.^{79,289} Preimplantation genetic testing is

optional in the United States but recommended in cases of family history and in men with nonobstructive azoospermia.²⁸⁹

Ethical, Social, and Legal Issues in Genetics

Advancements in genetics have led to important ethical questions about testing and screening for genetic disorders during the course of a couple's family planning and after the birth of their child. Ethical debates about genetic testing are inevitable. The persistent ethical issue in newborn screening surrounds mandatory or voluntary approaches taken by the states.⁸ All states require newborn screening, usually without parental consent for the tests. Thirty-three states have newborn screening statutes or regulations that allow exemptions from screening for religious reasons, and 13 additional states have newborn screening statutes or regulations that allow exemptions for any reason. The majority of states have statutes that contain confidentiality provisions, but these provisions are often subject to exceptions.²⁷⁸

In pediatric medicine, parents are traditionally presumed to be best suited to decide whether to pursue genetic testing. Organizations such as the American Academy of Pediatrics (AAP) have argued that parental autonomy should not be absolute in cases of life-threatening situations coupled with clear medical treatment benefit, but the AAP supports efforts to make informed parental consent a standard in the United States. Furthermore, the AAP does not support the broad use of carrier screening in children or adolescents or the position that newborn screening should be used to identify carrier status in parents of newborns identified as having disorders through newborn testing.⁸ The American Society of Human Genetics has recommended that family members not be informed of misattributed paternity revealed through testing for the purpose of screening for disorders and that informed consent should include cautions regarding the unexpected finding of a different disease.²⁹⁰

Pediatricians and other health care professionals should be prepared to equip families with the appropriate information to use in the decision making process regarding genetic testing. From a medical standpoint, Ross and Moon²⁹¹ propose a decision algorithm that weighs the risks and benefits. A decision to pursue genetic testing would be advised if the child were symptomatic, had a suspected genetic condition, or was from a high-risk family; if early diagnosis would decrease morbidity or mortality; and if the testing method were considered ethical and would lead to a beneficial treatment. Last, practitioners and researchers should be prepared to educate families on the protections and limitations of the Genetic Information Nondiscrimination Act of 2008 (GINA). This federal law, which sets a nationwide level of protection for US citizens, does not preempt state law, which usually provides broader safeguards. GINA prohibits health insurers from using the results of *predictive* genetic testing done for an individual to determine policy rates for that individual or for persons in a similar population; this includes information discovered in the course of medical testing and research. However, it does not protect a person's right to insurance for a genetic illness that is diagnosed. GINA prohibits insurers from requesting or requiring that person to undergo a genetic test. It prohibits employers from requesting, requiring, or using a person's genetic information in making employment decisions, including information about the employee's family's genetic information. GINA does not apply to decisions about life, disability, or long-term care insurance, nor does it apply to members of the military.²⁹²

INTEGRATING GENETICS INFORMATION FOR PRACTICAL USE IN PEDIATRIC CLINICAL SETTINGS

Therapists in all settings frequently find it challenging to keep up with practice issues and the growing body of knowledge and evidence in rehabilitative medicine. In clinical settings where most of a

therapist's day is spent in actual hands-on treatment, the wealth of information that is available may seem burdensome and practically inaccessible. Patients and their families will present the therapist with many questions about medical interventions, diagnostic procedures, and research. Although therapists know that a working knowledge of all of these areas is important, often time and access to resources are limited.

Pediatric therapists know the importance of collaboration with other professionals, including a type of collective knowledge about the child and his or her diagnosis, impairments, functional limitations, and quality-of-life issues identified by the family. A 1998 survey of individuals from six different health professions, including physical therapists, revealed that most professionals are not confident in their

education and working knowledge in the field of genetics.²⁹³ Additional studies have indicated that there are not enough genetic counselors^{281,291} to meet the growing needs of patients and families and that patients often express the most stress and dissatisfaction because their primary care physician does not appear to be informed about their child's disorder.^{281,294} See Case Study 11.1, Part 1.

Basic Knowledge and Skills Competence for Physical and Occupational Therapists

The National Coalition for Health Professional Education in Genetics (NCHPEG) is an organization of individuals from approximately 120 health professions. They have proposed basic competencies for all health care professionals.¹⁵ With a working knowledge about genetics,

CASE STUDY 11.1, PART 1 Therapists' Role in the Early Recognition and Clinical Diagnosis of Genetic Disorders

This case study series portrays how basic knowledge and skills competence in genetics are essential for therapists in the delivery of services for pediatric patients with genetic disorders. Two female patients with presenting signs of developmental delay received physical therapy services before and after receiving a definitive diagnosis.

Screening for Genetic Disorders at Initial Visit

Developmental delay is a common classification for infants and young children entering into physical therapy services before a definitive diagnosis of a particular genetic disorder has been made. Family history and course of pregnancy are key areas for the physical therapists to consider during ongoing assessment. The sensitive nature of this information requires that appropriate trust and rapport have been established between practitioner and family.

For the female patients discussed in this case, no remarkable information was revealed to indicate that a genetic disorder was suspected: Each of the girls was the first-born child and lived with her biological parents, in whom there was no previous family history of a genetic disorder. This was the first pregnancy for the mothers of both girls. The mothers each became pregnant in their late 20s without the assistance of reproductive technology, and they received the recommended course of prenatal care without specialized prenatal testing. The course of the mothers' pregnancies and deliveries was unremarkable, as was the neonatal period for the children.

Both girls were Caucasian, with blond hair, blue eyes, and no notable dysmorphism. Figs. 11.9A and B show the two girls. The first child was 16 months old and the second 14 months before given a medical diagnosis.

Medical Records Review

	Dylen: Contrasting Features	Danika: Contrasting Features	Features of Both Girls
0–6 Months of Age			
Parental concerns	Vomiting and abnormal eye movements		Low muscle tone and slow motor development.
Tests and measures	Normal brain MRI scan and EEG at 3 months	No tests	
Development			Normal head control. Purposeful reach, grasp, and object release. Good eye contact and "happy" disposition. Some babbling and one-syllable sounds.
6–8 Months of Age			
Parental concerns	Tongue thrusting and episodic nystagmus; parents suspect seizures	Sleep disturbances; visual disturbance suspected	Both girls are slow to achieve independent sitting and crawling.
Tests and measures			
Development	Pivots in prone position at 8 months. Sits without support at 8 months.	Not yet sitting	Delayed trunk control. Both girls roll over by 7 months.

EEG, Electroencephalogram; *MRI*, magnetic resonance imaging.

Pediatric therapists should recognize that marked developmental delay and global hypotonia are two features common to many genetic disorders. However, in the case of both girls, the urgency of a genetics referral was lessened by the following factors: no dysmorphic features, healthy neonatal development,

absence of family history of genetic disorders, and no other major presenting risk factors (e.g., no prior loss of pregnancies, young maternal age, and normal course of pregnancy).

Fig. 11.9 (A) Dylon at 16 months of age, approximately the age she was diagnosed with Rett syndrome. (B) Danika at 14 months of age, approximately the age at which she was diagnosed with Angelman syndrome.

therapists can develop competence in eliciting and accessing genetic information from subjective interviews with proper patient consent, can learn how to protect patient privacy while making appropriate recommendations to genetics professionals, and can understand the social and psychological implications of genetic services.^{293,295}

Professional education for physical¹¹ and occupational therapists²⁹⁶ faces challenges to prepare practitioners who meet the minimum competencies set forth by NCHPEG.¹⁵ Most physical therapists responding to the survey by Long and colleagues²⁹³ reported that they received most of their information through nonscientific media and that they had limited or no education in genetics. Some of the barriers to the implementation of genetics content in professional programs include lack of faculty qualified to teach the content and time limitations within a didactic program.¹¹ Continuing education courses for practicing clinicians are in short supply. Physical therapists have identified needs for continuing education in genetics to include topics such as the role of genetics in common disorders such as cancer and heart disease, an overview of human genetics, what treatments were available, and how to direct patients to information resources. Although occupational therapists were not part of Long's study, it is felt that colleagues would stress similar needs.²⁹³

Service Delivery for Children With Genetic Disorders and Their Families

For therapists to be supportive of families they are working with, they must acknowledge the importance of family priorities, respect the family's cultural values and beliefs,^{297–299} include families as integral team members, and promote and deliver services that build on family and community resources.

This section includes strategies for supporting families of children with genetic disorders, assessment strategies, the construction of therapeutic goals and objectives, and guiding principles for pediatric interventions.

Family-Centered Service

Family-centered service is both a philosophy and an approach to service delivery that is considered to be a best practice in EI and pediatric rehabilitation.^{300–302} Children with genetic disorders have complex, long-term needs that can be addressed by a family-centered service delivery model. At the core of this model is the manner in which therapists interact with the children and their families—the therapist's mindfulness, attentiveness, and respectfulness—elements that are as important as the actual interventions delivered.^{303,304} Therapists educated in the family-centered approach are also able to understand the impact of

disability on a family as well as the value of support systems such as family and community.²⁷²

Bailey and colleagues²⁷² highlight the particular needs of families who have children diagnosed with genetic disorders; such families must have productive partnerships with health care providers. Therapists should not be reluctant to learn about a rare condition from parents, as many are not “passive recipients of information” but rather “coproducers” of what and how information available may be used in their child's care.^{272,305} Parents can be trusted to be a reliable source in the recognition of their child's condition and needs,³⁰⁶ but in some instances the therapist's role may be to steer families to accurate information or assist with interpreting information that they have discovered. For example, the term *untreatable condition* may be misinterpreted by parents to mean that there are no reasonable interventions that might benefit their child (see Case Study 11.1, Part 4).

The *Relational Goal-Oriented Model* (RGM) of service delivery links the “what” with a more in-depth consideration of the “how” (how service providers and organizations can optimize both the process and outcomes of service delivery).³⁰⁷ The role of the family in the child's life and the importance of the insights of parents into their child's abilities and needs³⁰⁸ are crucial. Three important aspects of caregiving—information exchange, respectful and supportive care, and partnership or enabling—are foundational to family-centered care.³⁰⁹ Family-centered service recognizes that each family is unique, that the family is the constant in the child's life, and that the family members have expert knowledge of the child's abilities and needs. The family works together with service providers to make informed decisions about the services and supports that the child and family receive. The strengths and needs of all family members are considered in family-centered service.³¹⁰ In the interactional exchange between the child/family and therapists, understandings occur, commitments and decisions are made, the child and family receive affirmation and support, and information is translated into meaningful, usable knowledge through the process of communication.^{311,312} Developing mutual trust and open communication between the child, the family, and the physical and occupational therapists as well as other practitioners is at the core of clinical practice.

Therapists working with children must recognize and acknowledge the multitude of tasks that all families work to accomplish. In addition to tasks specifically related to caring for a child with a disability, families must perform functions to address the economic, daily care, recreational, social, and educational and vocational needs of both individual members and the family as a whole.

As Turnbull and Turnbull³¹³ have cautioned, each time professionals intervene with families and children, they can potentially enhance or hinder the family's ability to meet important family functions. For example, intervention that promotes a child's social skills can be an important support to positive family functioning. On the other hand, intervention that focuses on the child's deficits can have a negative impact on how the family perceives that child and the place of the child in the family. The RGM emphasizes the importance for therapists to join with parents to provide responsive and flexible therapy services in accordance with changing family needs and circumstances.³¹⁴

The *Life Needs Model*^{302,307} acknowledges the need for therapists to work collaboratively with service providers in other disciplines to improve community participation and quality of life for children and youth with disabilities, based on the expressed needs of the child and his or her family members. Helping the family to identify a support group is often useful for adjustment and continuing encouragement in coping with issues. Support groups can be found at www.geneticalliance.org, a comprehensive website provided by the Alliance of Genetic Support Groups. Family

empowerment mediates relationships between family-centered care and improvements in children's behaviors³¹⁵ and directly affects families' satisfaction with services for their children and their well-being.³¹⁶

Assessment Strategies

Knowledge of a child's diagnosis can aid in the selection of appropriate assessment tools and can alert the therapist to any potential medical problems or contraindications associated with the specific syndrome that might affect the assessment procedures (tests and measures). Therapists must be careful, however, not to develop preconceived opinions about a child's capabilities on the basis of how other children with similar diagnoses have performed. It is critical to remember that there is wide behavioral and performance variability among children within each genetic disorder. For example, wide variability in the achievement of developmental milestones has been reported among children with Down syndrome.³¹⁷

The assessment process includes many components that in certain areas are specific to the practice of either physical or occupational therapy. For the physical therapist, use of the *Guide to Physical Therapist Practice*³¹⁸ is recommended as a framework to identify appropriate tests and measures for impairments or disabilities. For the occupational therapist a useful reference is the assessment section of the textbook *Occupational Therapy for Children*.²⁴⁹

Typically a therapist's assessment begins with movement observation and analysis followed by testing of the neuromuscular status of the child, such as primitive reflexes, automatic reactions, and muscle tone. For children with orthopedic involvement, assessment of muscle strength, joint range of motion, joint play, and soft tissue mobility is also important. An assessment of the child's developmental level and functional ability should be completed. Such assessments can be used to discriminate between typical and delayed development, to identify the constraints interfering with the achievement of functional skills, and to guide the development of treatment goals and strategies. Most developmental assessment tools fall into one of the following categories: (1) discriminative, (2) predictive, and (3) evaluative measures.³¹⁹ Each of these three types of developmental assessment tools yields a different type of information. It is important to understand these differences and the intended purpose of each type of assessment to ensure that evaluation tools are used appropriately. A list of tests and measures commonly used by pediatric physical therapists is given in [Table 11.3](#).

Discriminative Assessment

A discriminative assessment is used to compare the ability of an individual with the ability of members of a peer group or with a criterion selected by the test author.³¹⁹ Such instruments provide information necessary to document children's eligibility for special services but rarely provide information useful for planning or evaluating therapy programs.³²⁰ Norm-referenced tests such as the Alberta Infant Motor Scale,³²¹ the Bayley Scales of Infant Development (motor and mental scales),³²² and the Peabody Developmental Motor Scales³²³ are examples of tests used with infants and young children to verify developmental delay or to assign age levels. The Test of Infant Motor Performance is used to identify the risk of developmental delay in infants from 32 weeks postconception to 16 weeks after term.³²⁴ An example of a norm-referenced assessment tool for older children is the Bruininks-Oseretsky Test of Motor Proficiency.³²⁵

It may be possible to detect improved motor performance by administering a developmental test used to identify children who have motor delays. Such tests, however, usually cannot detect small increments of improvement because there are relatively few test items at each age level and developmental gaps between items are often large.

In assessing whether intervention has been effective, the use of most discriminative tools does not examine a child's performance of functional activities in natural environments.³²⁰

Predictive Assessments

Predictive measures are used to classify individuals according to a set of established categories and to verify whether an individual has been classified correctly.³¹⁹ Measures designed to predict future performance are often used to detect early signs of motor impairment in infants who are at risk for neuromotor dysfunction.³²⁰ Knowledge of developmental milestones and the ability to identify typical and atypical movement at various ages is paramount to the therapist's competency in administering a structured assessment such as those used to predict future disability in children. Prechtl and others³²⁶ have described how assessment of "general movements" in infants can be used to identify children with cerebral palsy.³²⁷ The Movement Assessment of Infants³²⁸ was designed to assess muscle tone, reflex development, automatic reactions, and volitional movement and has value in predicting future neurodevelopmental problems in high-risk infants when administered during the first year of life.^{329,330} The Test of Infant Motor Performance³²⁴ and the Alberta Infant Motor Scale³²¹ are other instruments commonly used to predict poor motor outcomes.

Evaluative Assessments

An evaluative measure is used to document change within an individual over time or change occurring as the result of intervention.³¹⁹ Helping Babies Learn³³¹ is a curriculum-referenced test that provides information about a child's developmental progress relative to a pre-specified curriculum sequence.

To determine whether a child's ability to perform meaningful skills in everyday environments has improved, a functional assessment should be used. Functional assessments focus on the accomplishment of specific daily activities rather than on the achievement of developmental milestones. Emphasis is placed on the end result in terms of the achievement of a functional task, although the form or quality of the movement should never be ignored by the therapist. Assistance in the form of people or devices is incorporated into the assessment of progress, with the measurement of progress focusing on the achievement of independence.³³² Qualitative aspects of movement that have important functional implications—such as accuracy, speed, endurance, and adaptability—are also considered.

Functional assessments can be used to screen, diagnose, or describe functional deficits and to determine the resources needed to allow the child to function optimally in specific environments (e.g., school, home). Another use of functional assessments is to evaluate the nature of the problem and the specific task requirements limiting function to develop educational plans and teaching strategies.³³² A final use of functional assessments is to examine and monitor for changes in functional status. Such assessments can be used for program evaluation and for determining the cost-effectiveness of services or programs. (See Chapter 7 for additional information regarding evaluation tools.)

The Functional Independence Measure (FIM) is an example of a functional assessment. The FIM assesses the effectiveness of therapy on functional dependence in the areas of self-care, sphincter control, mobility, locomotion, communication, and social cognition.³³³ Seven levels of functional dependence ranging from needing total assistance to complete independence are used to determine an individual's status. An adaptation of the FIM places greater emphasis on functional gains as opposed to the level of care. The WeeFIM³³⁴ has been developed for use with children through the age of 6 years.

The Pediatric Evaluation of Disability Inventory (PEDI) is a functional assessment that focuses on the domains of self-care, mobility,

TABLE 11.3 Pediatric Tests and Measures and What They Measure

Developmental Screening Tools

Name of Tool	Age Range	References
Ages and Stages Questionnaires	1 month to 5 years	Parent-completed tool Rydz D, Shevell M, Majnemer A, et al. Developmental screening. <i>J Child Neurol.</i> 2005;20(1):4–21. Squires J, Bricker D, Twombly E. <i>Ages and Stages Questionnaires: Social-Emotional (ASQ-SE)</i> . Baltimore, MD: PH Brookes Publishing Co; 2002. www.pbrookes.com
Parent Evaluation of Developmental Status	Birth to 8 years	Parent-completed tool Glascoe FP. <i>Collaborating With Parents: Using Parents' Evaluation of Developmental Status (PEDS) to Detect and Address Developmental and Behavioral Problems</i> . Nolensville, TN: PEDStest.com, LLC; 2013. www.pedstest.com .
Child Developmental Inventory (CDI)	Used with high-risk infants' follow-up	Parents' observations Doig KB, Macias MM, Saylor CF, et al. The Child Development Inventory: a developmental outcome measure for follow-up of the high-risk infant. <i>J Pediatr.</i> 1999;135(3):358–362.
Infant Development Inventory (part of the CDI)	Birth to 18 months	Parents' observations Doig KB, Macias MM, Saylor CF, et al. The Child Development Inventory: a developmental outcome measure for follow-up of the high-risk infant. <i>J Pediatr.</i> 1999;135(3):358–362.
Bayley Infant Neurodevelopmental Screener	3–24 months	Pediatrician or health care provider Weiss LG, Oakland T, Aylward GP. <i>Bayley-III Clinical Use and Interpretation</i> . Boston, MA: Academic; 2010.
Denver Developmental Screening Test	Birth to 6 years	Pediatrician or health care provider Bryant GM, Davies KJ, Newcombe RO. The Denver Developmental Screening Test. Achievement of test items in the first year of life by Denver and Cardiff infants. <i>Dev Med Child Neurol.</i> 1974;16(4):475–484.

Screening for developmental delay in primary care is inconsistent and often insufficient to direct the family physician. The American Academy of Pediatrics recommends surveillance at all well-child visits combined with screening for developmental delay at 9, 18, 24, or 30 months of age using a **standardized developmental screening tool**. Two of the most extensively evaluated parent-completed tools are the Parent Evaluation of Developmental Status (PEDS) and Ages and States Questionnaires (ASQ). The literature supports screening for developmental delay with parent-completed tools rather than directly administered tools. (Mackrides and Ryherd, 2011)^{334a}

The following are suggested developmental screening tools.

Developmental Tests for Measuring Activity (According to the International Classification of Functioning, Disability, and Health (ICF) Model)

Tests/Tools	Description	References
Gross Motor		
Alberta Infant Motor Scales (AIMS)	Identifies motor delays and measures changes in motor performance over time; birth to 18 months.	Piper MC, Darah J. <i>Motor Assessment of Developing Infant</i> . Philadelphia: WB Saunders; 1993.
Bruininks-Oseretsky Test of Motor Proficiency (BOTP-2)	Identifies motor abilities and can be used for program planning, to monitor change over longer periods of time for child with mild disabilities; 4.5–14.5 years of age.	Bruininks RH. <i>Bruininks-Oseretsky Test of Motor Proficiency: Examiners' Manual</i> . Circle Pines, MN: American Guidance Service; 1978.
Gross Motor Function Measure (GMFM)	Measures change in gross motor function over time; especially children with cerebral palsy; 5 months to 16 years.	Russell D, Rosenbaum PL, Cadman DT, et al. The gross motor function measure: a mean to evaluate the effects of physical therapy. <i>Dev. Med Child Neurol.</i> 1989;1:341–352.
Motor Function Measure	Developed to assess children with neuromuscular diseases. Measures three dimensions: standing and transfers, axial and proximal motor function, and distal motor function.	Bérard C, Payan C, Hodgkinson I, et al. A motor function measure for neuromuscular diseases. Construction and validation study. <i>Neuromuscul Disord.</i> 2005;15:463–470.
Peabody Developmental Motor Scales, 2nd ed.	Identifies gross and fine motor delays; used to monitor program; birth to 5 years.	Folio MR, Fewell RR. <i>Peabody Developmental Motor Scales: Examiner's Manual</i> . 2nd ed. Austin, TX: Pro-Ed; 2000.
Test of Infant Motor Performance (TIMP)	Provides early identification of motor delays; assesses postural control for early skill acquisitions; 32 weeks to 4 months.	Campbell SK, Hedeker D. Validity of the Test of Infant Motor Performance for discriminating among infants with varying risk for poor motor outcome. <i>J Pediatr.</i> 2001;139:546–551.

Functional Balance Tests

Test and Measures	What It Measures	Reference
Early clinical Assessment of Balance (ECAB)	Consist of items from the PBS and the Movement Assessment for infants; ECAB measures of head, trunk, sitting, and standing postural control for children up to 7 years and 11 months of age.	McCoy S, Bartlett D, Yocum A, et al. Development and validity of the early clinical assessment of balance for young children with cerebral palsy. <i>Dev Neurorehabil.</i> 2014;17(6):375–383.
5-Repetitions Sit-to-Stand	Measures time to complete five consecutive cycles of sit-to-stand.	Wang TH, Liao HF, Peng YC. Reliability and validity of the five-repetition sit-to-stand test for children with cerebral palsy. <i>Clin Rehabil.</i> 2011;26(7):664–671
Functional Reach Test (FRT)	Measures distance one or both hands can reach forward while maintaining standing balance.	Norris RA, Wilder E, Norton J. The functional reach tests in 3 to 5 year-old children without disabilities. <i>Pediatr Phys Ther.</i> 2008;20:47–52.
Pediatric Balance Scale (PBS)	Provides 14 different activities to test balance from simple (sitting to standing) to relatively more complex (retrieving object from the floor).	Franjoine MR, Darr N, Held SL et al. The performance of children developing typically on the pediatric balance scale. <i>Pediatr Phys Ther.</i> 2010;22:350–359.
Pediatric Reach Test (PRT)	Measures distance one hand can reach forward and laterally while maintaining sitting or standing balance.	Bartlett D, Birmingham T. Validity and reliability of a pediatric reach test. <i>Pediatr Phys Ther.</i> 2003;15(2):84–92.
Segmental Assessment of Trunk Control (SATCO)	Measures the ability to maintain trunk control while sitting in a steady, active, and reactive state of sitting; the test determines the highest level of trunk support at which child loses postural control.	Butler P, Saavedra S, Sofranac M, et al. Refinement, reliability, and validity of segmental assessment of trunk control. <i>Pediatr Phys Ther.</i> 2010;22(3):246–257.
Timed Floor to Stand (TFTS)	Measures the time it takes to get up from the floor, walk 3 m, turn around, and walk back to sit down in the same spot on the floor.	Weingarten G, Lieberstein M, Itzkowitz A, et al. Timed floor to stand-natural: reference data for school age children. <i>Pediatr Phys Ther.</i> 2016;28(1):71–76.
Timed Up and Down Stairs (TUDS)	Measures the time it takes to ascend one flight of stairs, turn around in the landing, and descend the same flight of stairs.	Zaino CA, Marchese VG, Westcott SL. Timed Up and Down Stairs Test: preliminary reliability and validity of a new measure of functional mobility. <i>Pediatr Phys Ther.</i> 2004;16(2):90–98.
Timed Up and Go (TUG)	Measures time it takes for an individual to get up from a seat, walk 3 m, turn around, and walk back to sit down on the same seat.	Steffen TM, Hacker TA, Mollinger L. Age- and gender-related test performance in community dwelling elderly people: Six-Minute Walk Test, Berg Balance Scale, and Timed Up and Go Test and gait speeds. <i>Pediatr Phys Ther.</i> 2002;82(2):128–137.

These Standardized Balance Tests are simple and quick yet are good indicators of falls risk.

The first three test static and dynamic balance as well as leg strength. These also take less than 5 minutes to complete.

Fall Screening Tests

Timed Up and GO Test	Measures time it takes for an individual to get up from a seat, walk 3 m, turn around, and walk back to sit down on the same seat.	Steffen TM, Hacker TA, Mollinger L. Age and gender-related test performance in community dwelling elderly people: Six-Minute Walk Test, Berg Balance Scale, and Timed Up & Go TEST and gait speeds. <i>Pediatr Phys Ther.</i> 2002;82(2):128–137.
Single Leg Stand	Measures static standing ability (balance with feet fixed).	Bohannon R, Larking P, Cook A, et al. Decrease in timed balance test score with aging. <i>Phys Ther.</i> 1984;64:1067–1070.
Single Chair Rise	Measures ability of person to rise from a chair.	Guralnik JM, Simonsick EM, Ferrucci L, et al. A short physical performance battery assessing lower extremity function: association with self-reported disability and prediction of mortality and nursing home submission. <i>J Gerontol.</i> 1994;49:M85–M94.

Other Balance Measures for Assessments and/or Outcomes

Timed Chair Rise ×5	Measures ability of person to rise from a chair repeated (five times).	Whitney SL, Wrisley DM, Marchetti GF, et al. Clinical measurement of sit-to-stand performance in people with balance disorders: validity of data for the Five-Times Sit-to-Stand Test. <i>Phys Ther.</i> 2005;85:1034–1045.
Chair rise in 30 s	Measures how many times a person can rise to stand from chair for 30 s.	Rikli R, Jones J. Development and validation of a functional fitness test for community-residing older adults. <i>J Aging Phys Act.</i> 1999;7:129–161

TABLE 11.3 Pediatric Tests and Measures and What They Measure—cont'd

Test and Measures	What It Measures	Reference
Tandem stand	Assesses static balance with narrow base of support. Person stands with one toes of foot touching the heel of another foot.	Gurlnik JM, Ferruci L, Simonsick EM, et al. Lower-extremity function in persons over the age of 70 years as a predictor of subsequent disability. <i>N Engl J Med</i> . 1995;332(9):556–561.
360 degrees turn protocol	A measure of dynamic balance. Person turns in a complete circle, 360 degrees.	Berg KO, Wood-Dauphinee SL, Williams JI, et al. Measuring balance in the elderly: validation of an instrument. <i>Can J Public Health</i> . 1992;83(suppl 2):S7–S11.
Four Square Step Test	Tests more advance dynamic balance.	Dite W, Temple VA. A clinical test of stepping and change of direction to identify multiple falling older adults. <i>Arch Phys Med Rehabil</i> . 2002;83:1566–1571.
Alternate Step Test	Modified version of Berg Balance stool stepping test.	Tiedemann A, Shimada H, Sherrington C, et al. The comparative ability of eight functional mobility tests for predicting falls in community-dwelling older people. <i>Age Ageing</i> . 2008;37:430–435.
Tandem Walk Test	Walk heel to toe along a 10-foot line as quickly as possible without losing balance.	Bickley LS, Szilagyi PG, Bates B. <i>Bates' Guide to Physical Examination and History Taking</i> . 11th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2013:717.
Walking/Ambulation Tests		
Tests (Listed Alphabetically)	What It Measures	References
Dynamic Gait Index	Evaluates the ability to walk while performing different tasks and/or responding to different gait demands.	Marchetti GF, Whitney SL. Construction and validation of the 4-item dynamic gait index. <i>Phys Ther</i> . 2006;86(12):1651–1660.
Energy Expenditure Index (EEI)	Measures the energy cost or efficiency of walking with a comfortable speed or a fast speed for 2 to 3 minutes.	Rose J, Gamble JG, Lee J, et al. The energy expenditure index: a method to quantitate and compare walking energy expenditure for children and adolescents. <i>J Pediatr Orthop</i> . 1991;11(5):571–578.
Functional Mobility Scale (FMS)	Qualifies use of assistive devices for three distances using a six-point ordinal scale; the three distances represent mobility at home (5 m), school (50 m), and in the community (500 m).	Graham HK, Harvey A, Rodda J, et al. The Functional Mobility Scale (FMS). <i>J Pediatr Orthop</i> . 2004;24(5):514–520.
50-Foot Walk Test	Provides two measures; the amount of time it takes to walk 30 feet and the maximum amount of time to walk 50 feet that is acceptable to the classroom teacher.	Unver B, Kalkan S, Yuksel E, et al. Reliability of the 50-Foot Walk Test and 30-s chair stand test in total knee arthroplasty. <i>Acta Ortop Bras</i> . 2015;23(4):184–187.
Perceived Exertion Scales	Pictorial scales that seek a person's self-perception of the effort he or she is putting in to complete a tasks, can be used in conjunction with the other tests listed in this walking document.	Borg GA. Perceived exertion: a note on "history" and methods. <i>Med Sci Sports</i> . 1973;5(2):90–93
6-Minute Walk Tests	An endurance test that measures the distance walked in 6 minutes.	McDonald C, Henrickson E, Han J, et al. The 6-minute Walk Test: a new outcome measure in Duchenne Muscular Dystrophy. <i>Muscle Nerve</i> . 2010; 41(4):500–510.
30-Second Walk Tests	A simple test that measures the distance walked in 30 seconds.	Van Brussel M, Helders P. The 30-second Walk test norms for children. <i>Ped Physical Therapy</i> . 2009;21(3):244
Timed Floor to Stand (TFTS)	Measures the time it takes to get up from the floor, walk 3 m, turn around, and walk back to sit down in the same spot on the floor.	Weingarten G, Kaplan S. Reliability and validity of the timed floor to stand test-natural in school-aged children. <i>Pediatr Phys Ther</i> . 2015;27(2): 113–118.
Timed Up and Down Stairs (TUDS)	Measures the time it takes to ascend one flight of stairs, turn around in the landing, and descent the same flight of stairs.	Zaino CA, Marchese VG, Wescott SL. Timed Up and Down Stairs Test: preliminary reliability and validity of a new measure of functional mobility. <i>Pediatr Phys Ther</i> . 2004;16(2): n90–98.
Timed Up and Go (TUG)	Measures time it takes for an individual to get up from the seat, walk 3 m, turn around, and walk back to sit down on the same seat.	Steffen TM, Hacker TA, Mollinger L. Age- and gender-related test performance in community dwelling elderly people: Six-Minute Walk Test, Berg Balance Scale, and Timed Up & Go Test, and gait speeds. <i>Phys Ther</i> . 2002;82(2):128–137.

and social cognition.³³⁵ The PEDI incorporates three measurement scales: (1) the capability to perform selected functional skills, (2) the level of caregiver assistance that is required, and (3) identification of environmental modifications or equipment needed to perform a particular activity. The PEDI has been standardized and normed and is intended for use with children whose abilities are in the range of a typical 6-month-old to 7-year-old child.

The final example of a functional assessment is the School Function Assessment (SFA).³³⁶ The SFA is designed to measure a student's performance in accomplishing functional tasks in the school environment. It is composed of three sections that focus on (1) the student's participation in major school activities, (2) the task supports needed by the student for participation, and (3) the student's activity performance. The SFA is standardized and was conceptually developed to be reflective of the functional requirements of a student in elementary school. See Case Study 11.1, Part 2.

Family-Driven Goals and Objectives

Therapy Goal Orientation

Goal orientation is a second fundamental feature of effective service. The earlier section on relation-based practice described how relationships between child, family, and therapists are fundamental in providing effective intervention. Goal orientation encompasses both joint goal setting by (1) parents, caregivers, and families and (2) therapists and other service providers³³⁷ and the pursuit of meaningful child-, parent-, and family-selected goals.³³⁸ Goals of parents and families are to create a supportive environment for their child, provide opportunities for growth and belonging, and help their child to live as adaptive and independent a life as possible.³⁰⁷ Family-centered care incorporates trusting relationships in which the therapist demonstrates respect for the family's values, beliefs, and goals rather than imposing a plan of care on the child and family that aims to correct "deficiencies."

After a child's strengths and needs have been evaluated and the family's objectives identified, therapy goals and objectives can be

developed. In the past, establishment of these goals has primarily been the responsibility of professionals and often did not incorporate the needs and desires of the family. More recently, however, professionals have recognized the value of having families guide the process of establishing intervention goals and objectives.^{339,340} This shift toward collaborative goal setting and family-centered care has occurred largely as a result of the belief that families should determine their vision of the future for their children and that professionals should act as consultants and resources to help families achieve that vision. The stress that caregivers experience with the everyday care of a child can reduce compliance with a home therapeutic program,³⁴¹ which further supports the notion that parents should be jointly involved with therapists to determine goals and the means by which to attain identified outcomes.³⁴² When parents and families contribute to the planning process, they are more likely to believe in goals that are set and to play a role in ensuring that relevant strategies are implemented.³⁰⁷ They gain a sense of control over their child's services, supports, and resources, and this contributes to their personal and family's well-being.³⁴³ For children living in the United States, these goals are developed within the context of individualized service plans.

Individualized Service Plans

In the United States, the Individuals with Disabilities Education Act (IDEA) requires public schools to develop an Individualized Education Plan (IEP) for every student with disability. An IEP is designed to meet the unique educational needs of a student with disabilities as defined by federal regulation 34 CFR 300.320.³⁴⁴ Under IDEA 2004, a free appropriate public education (FAPE) is provided that is individualized to a specific student with a disability and that emphasizes special education and related services to prepare the student for further education, employment, and independent living (20 U.S.C. 1400 et seq, 20 U.S.C. 1400 © [5][A][i]).

Beginning with the enactment of US Public Law 94-142 in 1975³⁴⁵ and several important legislative revisions in 1990 (IDEA),³⁴⁵⁻³⁴⁷ 1991

CASE STUDY 11.1, PART 2 Assessment Strategies

	Dylen: Contrasting Features	Danika: Contrasting Features	Features of Both Girls
9–13 Months of Age Tests and measures			Both girls have abnormal EEG findings. Alberta Infant Motor Scale score: below fifth percentile. PEDI: Composite independence in functional skills less than 12% with total caregiver assistance.
Development	Regression in motor skills: sitting, rolling, and fine motor Babbling vocalization Emergence of truncal and extremity ataxia	Sits alone at 11 months	Dylen demonstrates skill regression; Danika slowly attains motor skills.
Other objective findings	Cold feet with reddened appearance; normal BP and HR	Emergence of hand-flapping behaviors	Both girls have small head circumferences.

BP, Blood pressure; EEG, electroencephalogram; HR, heart rate; PEDI, Pediatric Evaluation of Disability Inventory.

Another role of the therapist is to use assessment instruments that will help establish a baseline of motor and self-help skills and to monitor for progress or regression; the Alberta Infant Motor Scale and the PEDI, respectively, were initially used for these purposes. Last, the results of these tests and outcomes of intervention are interpreted and conveyed to the family and the child's pediatricians. In the

case of both girls, delays in motor, language, and self-help skills persisted, and ultimately both girls and their families were referred for genetic evaluation. Both girls received 1 to 2 hours of physical therapy weekly in their natural environment. The Peabody Developmental Motor Scales were added to monitor progress, guide goal development, and justify the need for continued EI services.

TABLE 11.4 Comparison of Required Components of the Individualized Education Plan and Individualized Family Service Plan

Content	IFSP IDEA Part C (34CFR303.344)	IEP IDEA Part B (34CFR300.320 THROUGH 300.324)
Information about child's status	A statement of child's present levels of physical, cognitive, communication, social or emotional, and adaptive development (physical development includes vision, hearing, and health status)	A statement on child's present levels of academic and functional performance
Family information	Statement of family's resources, priorities, and concerns related to enhancing the child's development	Information regarding parent's concerns can be documented in the present information about the child's status
Outcomes	Statement of measurable outcomes expected to be achieved for child and family and the criteria, procedures, and time lines used to determine the degree of progress toward outcomes and whether modification or revisions of outcomes or services were necessary	Statement of measurable annual goals, including academic and functional goals Include a description of how child's progress toward annual goals will be measured and process to report child's progress to parents
Services	Statement of specific Early Intervention (EI) services necessary to meet child's needs; include frequency, intensity, method of service delivery, location of services and natural environments	Statement of specific special education and related services to be provided, modifications, and supplementary aids to be provided to child
Schedule of services	Projected dates for initiation of services, anticipated duration	Projected date for beginning and ending date of service; any modification needed; frequency, location, and duration of services
Service coordinator	Identification of the service coordinator	No comparable requirement
Transition plan	Procedures and steps for transition from EI to preschool services under Part B Establish transition plan: 90 days to 9 months before third birthday	Procedures needed for postsecondary goals related to training, education, employment, and, where appropriate, independent living skills To be in effect when child turns 16 years of age
Transfer of rights	N/A	Must include statement that child has been informed about reaching the age of majority
Other		Explanation of any time the child will not participate along with nondisabled children

IDEA, Individuals with Disabilities Education Act; IEP, Individualized Education Plan; IFSP, Individualized Family Service Plan.

(PL 102-119), 1997 (PL 105-17), and 2004 (PL 108-446, Individuals with Disabilities Education Improvement Act of 2004),³⁴⁸ physical and occupational therapists working in public school settings are required to establish long-term annual goals and short-term therapy objectives within the framework of each child's educational needs. The document that defines a child's educational needs, including therapy services, from preschool through 12th grade is the IEP. Similar requirements are in effect for infants and preschool-aged children, documented in the individualized family service plan (IFSP). An IFSP must be written after a multidisciplinary assessment of the strengths and needs of the child has been completed. This assessment must include a family-directed assessment of the supports and services necessary to enhance the family's capacity to meet the needs of their child with a disability.^{347,348} A comparative listing of the components of an IEP and IFSP is given in Table 11.4.

Functional Objectives

The development of behaviorally written, measurable therapy objectives is crucial for monitoring the effects of intervention in a child with a genetic disorder. Many of the clinical symptoms listed in the descriptions of genetic disorders given earlier in the chapter may be monitored through systematic, periodic data-keeping procedures. One example is the monitoring of functional hand skills in girls with RS (see Case Study 11.1, Part 2). Periodic vital capacity measures for a child with OI or a child with Werdnig-Hoffmann disease can reflect progress toward a goal of maintaining respiratory function.

In the past, therapy objectives typically focused on a child's deficits. For example, delays in achieving motor milestones are often used to identify gaps in development, and therapy objectives are written and programs established to address these deficits. When the child meets an objective, new deficits are identified and new objectives developed. A different model for goal development that is consistent with a family-centered intervention philosophy is the "top down" approach, described by Campbell³⁴⁹ and later by McEwen³⁵⁰ and Effgren.²¹⁶ In this model, the child and family identify a desired functional outcome that is the driving factor for the therapeutic intervention plan. An example of this approach is seen in goal attainment scales. Goal attainment scaling (GAS) is an individualized, criterion-referenced measure of small, clinically important changes in a child's functional performance over time.^{351,352} Similar to behavioral objectives, GAS requires (1) the identification of observable goals, (2) reproducibility of conditions under which performance is measured, (3) measurable criteria for success, and (4) a time frame for goal achievement. In contrast to behavioral objectives, however, GAS identifies five possible outcomes with accompanying score values. By using five possible levels of attainment, it can be determined whether a child has made progress despite not having achieved the expected outcome or whether progress has exceeded the expected outcome. Case Study 11.1, Part 3, is an example of use of a goal attainment scale to assess a parent and child functional objective of sitting up on the floor to play with toys.

CASE STUDY 11.1, PART 3 Family-Directed Goals and Objectives

Both girls had poor postural control with muscular weakness and hypotonia that limited the activity of sitting. The parents of both girls expressed a desire that their daughters would be able to sit up and play with toys on the family room floor. The table illustrates the use of GAS for the goal of seated play with toys. In the course

of care, Danika made good progress toward the goal depicted in this scale; however, Dylen did not, and in fact demonstrated regression. Dylen's poorer outcome was indicative of the diagnosis of Rett syndrome (RS), which was revealed later. The family's goals for Dylen were revised, and the GAS was still a suitable framework.

Score	Attainment Level in Time Frame (INSERT) _____	Criterion-Referenced Goals Within Each Range (Time Frame: 3 Months)
-2	Much less than expected outcome with therapy	(Child name) ring-sits on the floor supported on 1 or 2 hands plus 25% physical assistance for balance support and guided reach and grasp of toys placed near her lap.
-1	Less than expected outcome with therapy	(Child name) ring-sits on the floor with standby assistance and uses both hands to play with toys placed near her lap.
0	Expected outcome with therapy	(Child name) ring-sits on the floor with supervision, reaches, and retrieves toys placed in front of her at arm's length away.
+1	Greater than expected outcome with therapy	(Child name) sits on floor independently and plays with toys placed at arm's length in front and to sides of her.
+2	Much greater than expected outcome with therapy	(Child name) sits on floor independently and retrieves toys placed slightly out of reach in front, to sides, and 45 degrees behind her and returns to upright for play.

Rather than focusing on a child's deficits, such outcome-focused objectives provide a more positive and supportive context for therapy and at the same time address the family's needs and priorities. This approach to developing

therapy goals and objectives in ways that support positive family functioning is also an important aspect of delivering therapy services to children and their families.

General Intervention Principles

Several general treatment principles guide the delivery of therapy services to children with genetic disorders and are detailed in this section. Special considerations for treatment of a child with a specific genetic condition may be found in the preceding section. The reader is also referred to Chapter 8 for information on interventions in neurological rehabilitation.

Focus on Activities and Participation

The goal of any therapeutic program for children should be to improve the quality and quantity of their participation in society. Achievement of basic motor skills such as sitting, standing, and walking is an outcome that can be measured with commonly used clinical tools, but whether or not children actually apply new skills on a regular basis (participation) is more difficult to capture objectively.³⁵³ Therapists must possess knowledge, skills, and tools if they are to assess and treat children in all domains defined by the World Health Organization (see [Case Study 11.1, Part 1](#)). With the purpose of improving participation in the end, pediatric therapists employ a variety of intervention strategies to increase opportunities that can help children to achieve independence and enjoyment of activities at home and school and in the community.

Many of the classic therapeutic approaches for children with neurological disorders incorporate techniques targeting impairments of body structure and function, such as abnormal muscle tone or joint alignment, to improve movement quality.²⁴⁰ Motor learning science and task-oriented models of neurological rehabilitation are based on the rationale that control of movement arises from appropriate practice of skills within the context of functional activities and enriched environments.³⁵³⁻³⁵⁶ Intervention therefore is aimed at teaching motor problem solving (adaptability to varied contexts),³⁵⁷ developing

effective compensations that are maximally efficient, and providing practice of new motor skills in functional situations. Rather than teaching individuals to perform movement patterns in a controlled therapy setting, this approach focuses on the learning that must take place for an individual to function independently of a therapist's guidance.^{353,355} Environmental adaptations can take many forms and include assistive technology that aids in the attainment of functional outcomes such as independence in self-help skills, communication, and mobility.³⁵⁸ For example, children with Down syndrome commonly have hypotonia, joint laxity, and delayed walking. Orthotics such as supramalleolar orthoses may be used to improve underlying joint and postural instability,³⁵⁹ and treadmill training has been shown to diminish delays in walking.³⁶⁰

Modern neurophysiological approaches use hands-on physical guidance with the child during movement practice of functional skills and activities. The inhibition of certain movements and facilitation of others are based on the rationale that less used movements will be eliminated in the pruning process of the developing brain and frequently used movement patterns will be reinforced^{240,353,361}; therefore approaches of this nature may be beneficial for infants and very young children with movement disorders.

Learning and performance of an activity seldom require just one component of function (e.g., mobility, language, cognition); therefore it should be understood and expected that improvements in one domain may indirectly, but significantly, have a positive impact on another. For example, Damiano³⁶¹ stresses the benefits of a lifetime of regular movement activity, with or without adaptations, on the overall development of children. Regardless of treatment techniques, it is a widely accepted principle that children learn new skills best when they are taught and practiced within the context in which they will be used.³⁶²

Delivery of Services in Natural Environments

The term *natural environment* refers to places and settings in which infants and children typically spend their day.³⁴⁷ The movement toward integrating therapy into classroom settings is one example of providing services in a natural environment.^{363–365} In an integrated model of service delivery, therapists work in the classroom with teachers, rather than removing students to an isolated therapy room to provide services. Therapists work closely with the teacher to establish common goals for the student and to devise programs that will allow therapeutic activities to be interwoven into a variety of activities throughout the day in a natural manner.

Another example of providing therapy in a natural environment is providing home-based services for infants and young children. Home-based programs are “normal” options for young children because the natural environment for most infants and toddlers is the home—either their own home or that of a day care provider.^{363–365} For children who are medically fragile, it is the preferred option for therapy.^{366,367} For other families, transportation to a center-based program may be difficult because of the expense or length of travel required.

Incorporating Therapy Activities Into Daily Routines

Therapists must work collaboratively with families to develop sessions that incorporate therapeutic activities into the family’s daily routine (e.g., during play, dressing, bathing, meals). Rather than practicing narrowly defined tasks in a controlled clinic environment, therapy activities should be interwoven into a variety of activities throughout the day in a natural manner. Practicing skills in the context of daily routines allows the child to learn to adapt to the real-life contingencies that arise during a functional task.³⁵⁵ In addition, activities become more meaningful to both the child and the family (Fig. 11.10).

Use of Assistive Technology Devices

The Assistive Technology Act of 2004 defines an assistive technology device as any item, piece of equipment, or product system—whether acquired commercially, modified, or customized—that is used to increase, maintain, or improve functional capabilities of individuals with disabilities (29 U.S.C. Sec 2202[2]).³⁶⁸

As noted previously, an important aspect of providing developmental therapy services is the use of assistive technology devices to

Fig. 11.10 This child with Angelman syndrome enjoys riding her adaptive tricycle to the park with her family.

maximize a child’s functional abilities, level of independence, and inclusion in school and community activities with peers. Examples of assistive technology include mobility devices, augmentative communication devices, and adapted computer keyboards. Assistive technology also includes adaptive devices such as splints, bath chairs, prone standers, and other positioning equipment that can be used to provide optimal body alignment and minimize the risk for contractures or deformities while encouraging a greater variety of movement patterns. Such devices can be constructed from readily available materials or obtained commercially. The developmental physical or occupational therapist works with the family and other team members to select, construct, or order assistive devices and to assist caregivers in the use of the devices.

Case Study 11.1, Part 4, demonstrates how these general treatment principles are applied to a particular child receiving therapy services. The case example also shows how the family’s priorities and needs are considered and supported in the planning and delivery of services.

CASE STUDY 11.1, PART 4 Focus on Activities and Participation in Meaningful Environments and Routines

Both families were referred by their respective physicians for genetic counseling and evaluation on the suspicion of Angelman syndrome (AS) based on the cluster of developmental delay, features of blue eyes and blonde hair, head circumference, and abnormal EEG findings. Danika received an earlier referral to a geneticist at 14 months of age; subsequent test results confirmed the diagnosis of AS by the time she was 16 months old. The course of medical diagnosis for Dylen was confounded by her presenting signs of frequent, intense vomiting coinciding with suspicion of seizure activity. Dylen did not receive genetic testing until she was 30 months of age. In the cases of both girls, their documented response to therapy and course of motor development were weighed by their respective physicians in their course of care and referral for genetics evaluation. AS was ruled out first for Dylen, and subsequent testing confirmed a diagnosis of RS.

During the period immediately after their child’s diagnosis, the parents in each family shared many questions and new knowledge with the treating therapist. Both families accessed local and national family support groups and were encouraged to learn of activities that their children would likely enjoy. The partnership between the therapists and the families was strengthened by clarifying that “untreatable condition” means that neither condition could be remedied by medical intervention and by focusing on the families’ values and priorities.

Both girls had limited postural endurance in sitting and standing that was anticipated to persist for several months. Adaptive equipment for these activities was employed for both girls to allow them to participate in functional upright activities (see Fig. 11.7). Danika enjoyed aquatic activities and tricycling, whereas she merely tolerated hippotherapy. Dylen was found to enjoy movement activities more when music was played during treatment.

Continued

CASE STUDY 11.1, PART 4 Focus on Activities and Participation in Meaningful Environments and Routines—cont'd

	Dylen: Contrasting Features	Danika: Contrasting Features	Features of Both Girls
14–36 Months of Age			
Diagnosis; body organ or structure and function	Rett syndrome; gastroesophageal reflux	Angelman syndrome; sleep disorder	Global developmental delay, seizures, hypotonia
Activities, limitations, and development	Motor skills plateaued at 9 months' chronological age, followed by period of skills regression to 6 months' developmental level	Ambulatory with assistive devices Persistent absence of expressive language but learns to respond to her name Expresses pleasure with giggles and subtle, jerky motions Uses raking motion to pick up small foods	Attends special education preschool
Physical therapy interventions	Movement-oriented activities with music	Aquatic therapy	Postural strengthening, sensorimotor activities
Assistive and adaptive equipment	Adaptive seating provides best opportunities to interact with others in learning environment	Walks indoors and outdoors with a gait trainer (see Fig. 11.7B) and shorter distances with a conventional posterior four-wheeled walker	Gait trainer Adaptive tricycle Bilateral ankle-foot orthoses
Participation of child and family			Support group events: walk, ride, stroll

SUMMARY

This chapter has addressed several chromosomal abnormalities and specific gene defects that are most likely to be seen in children in a typical developmental therapy setting. The inclusion of family members in all aspects of therapy has been stressed, along with the need to consider family goals, priorities, and resources in the development and implementation of therapy services. The importance of developing functional goals

and delivering services in natural environments has also been emphasized. Finally, many diseases or conditions have a genetic component that must be considered in the course of medical management. Physical and occupational therapists should expand their working knowledge of genetics to appropriately refer patients for genetic services. Readers are encouraged to consult the companion references for knowledge resources.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the

reader to a Medline abstract for the article cited. There are 393 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Vocabulary

- Chromosomal microarray**-a first-tier, high-resolution, diagnostic test using probes or markers to analyze small portions of DNA from known location on each of 46 chromosomes. The markers will help detect very small imbalances of chromosomal material such as duplications and deletions of specific DNA segments and help determine the cause of a health condition.
- Clustered Regularly Interspace Short Palindromic Repeats (CRISPR)**-technological genomic editing tool acting as a molecular scalpel; applied to a strand of DNA at a specific site for the purpose of altering the protein product of the targeted section of nucleotides.
- De novo mutation**-a genetic alteration present for the first time in one family member as a result of a variant/mutation in a germ cell of either parent. Also called a *de novo variant*, *new mutation*, and *new variant*.
- Diploid**-cells having a inherited, paired chromosomes. All human somatic cell are diploid. Gametes are haploid cells.
- DNA sequencing**- The process of determining the order of nucleotides in DNA to identify genetic variants that cause disease.
- Epigenetics**-study of how genes are expressed phenotypically without a change in the original genetic code, due to influence on gene regulation and expression via the action of the “epigenome.”
- Epigenome**-derived from Greek work “epi” (above) the genome: the epigenome is not part of DNA itself, but rather is a chemical compound attached to the DNA that regulates the function of the gene: the what, when, and where. The epigenome can be passed on from cell to cell during cellular division, generationally.
- Gametes**-a mature haploid male (sperm) or female (egg/ova) germ cell.
- Gene-Environment Interaction** -a different effect of an environmental exposure on disease risk in persons with different genotypes. Gene-environment interaction explains in part the genetic disorders collectively called *multifactorial disorders*.
- Gene replacement therapy (GRT)**-experimental technique to use vectored genes to treat or prevent disease by replacing a mutated gene with a healthy copy, inactivating a mutated gene, or introducing a new gene into the body.
- Genome (Human)** complete set of nucleic acid sequences in a human’s DNA, organized into 23 chromosome pairs, within the human cell nuclei (nuclear genome) and in smaller DNA molecules (mitochondrial genome) found within mitochondria cells.
- Genetics**-the study of the structure, function, and heritability of a single gene.
- Genomics**-the study of the interrelationship between all genes of an individual’s genome and resultant impact on growth and development.
- Genome-wide Association Studies (GWAS)**-research method to identify genes involved in human disease. Method searches the genome for small variations called single nucleotide polymorphisms (SNPs) that occur more frequently in people with a particular disease than without.
- Germline DNA**-genetic information, genes, that exists in gametes/germ cell (sperm, ova). Germline DNA is the inherited source of DNA that exists in all other cells in the body. Mutation of a germ cell can be passed via human sexual reproduction to offspring.
- Germline mutation**-a genetic change occurring in the gamete of an individual and not the somatic cells of the same individual; therefore, germline mutations that may result in a genetic condition can be passed to offspring without it being present in either parent (circumstance for a *de novo* mutation).
- Haploid cell**-cell containing half the chromosomes required in human sexual reproduction to produce a new human *zygote/offspring*. Sperm and ova are haploid cells.
- Hyperkinetic movements**: excess movement including tics, stereotypies, dystonia, chorea, tremor, and myoclonus.
- Inborn errors of metabolism (IEM)**-inherited disorders in which the body cannot properly turn food into energy; a pediatric movement disorder may be the predominant symptom of an IEM.
- Monogenic disease aka single gene disorder**- Disease thought to be caused by a mutation in a single gene or one or both inherited chromosomes. Examples are cystic fibrosis (CF) and Duchenne muscular dystrophy (DMD). Even though caused by a single gene, the phenotype can vary (e.g. severity of the disease) due to differences in the patient’s environment and genetic variations elsewhere in the individual’s genome.
- Multifactorial genetic disorders**-disorders that do not follow a predictable pattern of inheritance or expression due to a combination of genetic factors and external factors such as diet, lifestyle, exposure to chemicals, and other toxins. Example conditions are certain forms of cancer, Alzheimer disease, and eczema.
- Next-generation (gene) sequencing (NGS)**-aka *massively parallel or deep sequencing*. This term is a catch-all phrase to describe the most modern methods to sequence nucleotides in DNA. Currently, advances in NGS allow an entire human genome to be sequenced in only a single day as opposed to the traditional and more expensive, time-consuming, Sanger sequencing method. There are three types of NGS: 1) whole-genome sequencing (WGS), 2) whole-exome sequencing (WES) and 3) targeted sequencing.
- Nucleotide**-building block of DNA and RNA. A nucleotide consists of a base plus molecule of sugar and one phosphoric acid. DNA contain four different nitrogenous bases: Thymine, Cytosine, Adenine, Guanine.
- “Pediatric movement disorders” (PMD) (field of medical study)**-a classification of movement disorders that appear in pediatric age. PMD includes movements that cannot be fully initiated, modulated, or interrupted voluntarily. Involuntary movements caused by epileptic, cerebellar, pyramidal, and neuromuscular disorders are

excluded. PMDs are divided into *primary disorders (movement is only symptom)* and *secondary (other predominate symptoms, e.g. developmental delay)*. Two classifications of PMD: hyperkinetic and hypokinetic. PMD are defined as one or more of the following: dysfunction in target and velocity of intended movement, abnormal posturing, presence of unintended excessive movement, normal movements occurring at unintended or inappropriate times.²²⁴

Phenomenology of movement-the interpretation of the appearance of an individual's movement. For example, classifying a child's movement as *hyperkinetic* based on the appearance of dystonia or tremor.

Phenotypic pleiotropy-the phenomenon of a single gene affecting multiple traits in a single individual.

Precision medicine/Personalized medicine- a model of customized treatments based on the individual patient's unique genetic make up, environment, and lifestyle.

Mechanotransduction-mechanism by which mechanical perturbation (e.g exercise) influences genetic expression and cellular behavior

Single nucleotide polymorphism (SNP)-a genetic variation in a nucleotide, occurring in a specific position in the genome that is identified to commonly occur people. *Polymorphism* refers to the fact that at the specific nucleotide position on a gene, there are "poly" or "many" variations, of A, C, T, or G at the site.

Somatic cell-diploid human cells other than gametes. Changes/mutations in somatic cells are not passed via human sexual reproduction to offspring.

Somatic cell genome editing-modification to genes in the cells of a living person, such as in medical practice of *gene therapy*.

Targeted next- generation gene sequencing-gene sequencing that focuses on specific regions of the genome based on relatively few

specific genes that are commonly linked by pathological mechanisms or known clinical phenotype. An example of targeted gene sequencing is a dystonia gene panel.

TaskForce on Childhood Movement Disorders –created by NIH in 2001, this taskforce of professionals worked to define consistent terminology across disciplines to describe and classify terms spasticity, dystonia, rigidity, and other pediatric movement disorders. The taskforce was comprised of professionals from developmental pediatrics, neuology, neurosurgery, orthopedic surgery, physical therapy, occupational therapy, physical medicine and rehabilitation, neurophysiology, muscle physiology, and biomechanics.^{222,223}

Tic-movement that is repeated, individually recognizable, intermittent. Often brief, suppressible, and may be associated with premonitory urge.

United Nations Educational, Scientific, and Cultural Organization (UNESCO)-agency of the United Nations (UN). UNESCO has 195 member states and in 2003 adopted the International Declaration on Human Genetic Data in response to concern over the use of human genetic data contrary to individual human rights and freedom. www.unesco.org/new/en/social-and-human-sciences/themes/bioethics/human-genetic-data

Variants of unknown significance (VOUS)-an genetic variant identified in genetic testing with unknown clinical significance.

Whole-exome sequencing-sequencing that evaluates only the protein-coding portions of a gene.

Whole-genome sequencing-sequencing that evaluates the entire genomic content of an individual.

Zygote-a human zygote is the fertilized egg cell resulting from union of female and male gametes (egg and sperm).

Abstract: This chapter focuses on genetic disorders in children that result in a wide variety of health conditions and associated movement limitations. The resultant impact of certain genetic conditions on the child may be evident before or immediately after birth, whereas other conditions may not be diagnosed until later in life when problems manifest. This chapter provides an overview of common neurological disorders of known genetic origin that pediatric physical and occupational therapists are likely to encounter. Tools such as vocabulary,

illustrations, and internet-accessible resources are provided to help clinicians recall basic principles of genetic inheritance and genomics. Case studies are given to provide examples of clinical decision making, including diagnosis, therapy assessment, and prognosis. Last, this chapter includes highlights of advancements in genetics research from the completion of the 2003 Human Genome Project to the present day. **Keywords:** evaluation, functional skills, genetic disorders, natural environments, occupational therapist, physical therapist

Learning Disabilities and Developmental Coordination Disorder

Lenin C. Grajo, Julia Guzman, Stacey E. Szklut, and Darbi Breath Philibert

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Define the characteristics that typically identify a child with learning disabilities.
2. Articulate accepted definitions and terminology used in the field of learning disabilities.
3. Describe the proposed causes of learning disabilities.
4. Describe the clinical presentation of subgroups within the learning-disabled population.
5. Identify members of the specialist team and service provision types for children with learning disabilities.
6. Describe the characteristics of the child with developmental coordination disorder.
7. Identify areas of evaluation to assess motor deficits effectively in the child with a learning disability.
8. Articulate theoretical development and intervention techniques applicable to children with learning disabilities and motor deficits.
9. Describe the lifelong ramifications for the individual with learning disabilities.

KEY TERMS

developmental coordination disorder
learning disabilities
life-span disability
model of disablement
motor learning

neurodevelopmental treatment
nonverbal learning disabilities
praxis
sensorimotor
verbal learning impairments

AN OVERVIEW OF LEARNING DISABILITIES

Clinical Presentation

Learning disabilities are not a singular disorder but a group of varied and often multidimensional disorders.¹ Difficulties in learning may manifest themselves in various combinations of impairments in language, memory, visual-spatial organization, motor function, and the control of attention and impulses.^{2,3} The characteristics of a child with a learning disability are often diverse and complex. Each child presents a different composite of system problems/impairments and functional deficits, preventing participation in activities and societal limitations. [Table 12.1](#) summarizes some of the clinical and behavioral manifestations in children with learning disabilities.

The most commonly recognized performance difficulties in learning are associated with academic success. Fletcher and colleagues¹¹ argued that learning disabilities should be characterized as “unexpected” because the child is not learning up to expectations despite adequate instruction. Typically, the areas of deficits are observed in verbal learning, including difficulties with reading, the acquisition of spoken and written language, and arithmetic. Impairments in nonverbal learning are equally important and more recently recognized. The three primary areas affected by nonverbal learning disorders include

visual-spatial organization, social-emotional development, and sensorimotor performance.¹² Accompanying behavioral manifestations may include problems with self-regulatory behaviors, such as lack of attention, hyperactivity, and poor impulse control. Difficulties in social perception and social interactions may also be observed.^{12,13} These learning and behavioral difficulties may be isolated (e.g., academic, motor, or behavioral), combined (e.g., academic and motor), or global (academic, motor, and behavioral).¹⁴ In addition to verbal and nonverbal disabilities, specific motor impairments also can be present and affect academic achievement or daily life tasks.^{15,16}

Definition

The heterogeneity of persons with learning disabilities has made consensus on a single definition difficult. Many disciplines describe learning disabilities according to their own frames of reference. Medical professionals tend to relate the deficit to its cause, particularly to cerebral dysfunction. Terms historically used include *brain injured*,¹⁷ *minimal brain dysfunction*,² and *psychoneurological disorder*,¹⁸ all implying a neurological cause for the deviation in development. However, educational professionals prefer to describe the child’s difficulties in behavioral or functional terms. Educators view children with learning disabilities as “children who fail to learn despite an apparently normal

TABLE 12.1 Common Clinical and Behavioral Manifestations of Learning Disability in Children

Clinical and Behavioral Manifestation	Description
Deficiencies in rapid automatized naming and reading difficulties ⁴	Language-based phonological deficits do not account for many of the reading difficulties in children with a learning disability (LD). Many children have slower speeds of processing information as seen in assessments of rapid automatized naming of common objects (e.g., letters, colors, numbers, pictures of objects).
Cognitive processing difficulties ⁵	Children with LD demonstrate deficiencies in the following cognitive areas related to learning and language acquisition: <ul style="list-style-type: none"> • Syntactic awareness—the ability to understand the basic grammatical structure of language used. • Working memory—the ability to retain information in short-term memory while processing new information. • Morphological awareness—Morphemes are the smallest units of meaning within words; they help to make word pronunciation predictable and preserve the semantic relationship between words.⁶ Morphological awareness is the conscious awareness of the morphemic structure of words and the ability to reflect on and manipulate this structure. • Orthographic processing—the awareness of the structure of the words in a language
Memory difficulties ⁷	Many children with learning disabilities may demonstrate difficulties in complex divided attention and inability to monitor activities making multitasking challenging; children with LD may demonstrate limited processing and storage demands often manifesting as carelessness, forgetfulness, or lack of attention to details.
Mathematical difficulties ⁸	Many children with LD may have slower acquisition of counting knowledge and arithmetical skills.
Language-learning difficulties ⁹	Many children with LD may demonstrate late acquisition of first word; may require more and multiple exposures to expand vocabulary; reliance of shorter and simple words to communicate; poor articulation and atypical speech patterns; and restricted range of communicative intent.
Social cognition deficits ¹⁰	Children with LD may demonstrate challenges with social adjustment, slower processing of social cues and information, challenges with social and emotional interpretation, problem-solving skills, role-taking abilities.

capacity for learning.”¹⁹ Current terminology within the academic environment includes *reading disorder*, *mathematics disorder*, *disorder of written expression*, and *intellectual disabilities*.^{20,21} The lack of consensus for one accepted definition continues to affect consistency in diagnosis, research, and intervention for persons with learning disabilities.

After multiple revisions, the National Joint Committee on Learning Disabilities (NJCLD), which represents several professional organizations, proposed the following definition:

Learning disability is a general term [for a condition] that:

- Is intrinsic to the individual . . . [the term] refers to a heterogeneous group. (Each individual with learning disabilities presents with a unique profile of strengths and weakness.)
- Results in significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or mathematical abilities. (These difficulties are evident when appropriate levels of effort by the student do not result in expected performance, even when provided with effective instruction.)
- Is presumed to be due to central nervous system dysfunction and may occur across the life-span. (They persist throughout life and may change in their presentation and severity at various stages of life.)
- May occur concomitantly with other impairments or other diagnoses. (For example, difficulties in self-regulation and social interaction may exist separately or result from the learning disability. Individuals with attention-deficit disorders, emotional disturbances, or intellectual disabilities may experience learning difficulties, but these diagnoses do not cause or constitute them.)
- Is not due to extrinsic factors. (Such as insufficient or inappropriate instruction, or cultural differences.)²²

This definition identifies a proposed cause but does not provide a clear exclusion statement regarding what learning disabilities may not result from. A positive component of this definition is the lifelong nature of the condition. In addition, by including the behavioral manifestations of regulatory and social difficulties, a more complete picture of functional problems for the individual with learning disabilities is presented. This could assist in the creation of more comprehensive and life-spanning programs of service and ultimately help in the recognition and remediation of functional and societal limitations.

The definition used in educational settings was initially passed in Public Law 94-142 and later incorporated into the Individuals with Disabilities Education Act (IDEA) (Section 602.26).

Children with learning disabilities are defined by IDEA as follows:

- Individuals with a disorder in one or more of the basic psychological processes involved in understanding or using spoken or written language. (This emphasizes the receptive and expressive difficulties a student may demonstrate.)
- Those who are experiencing difficulties in the ability to listen, think, speak, read, write, spell, or do mathematical calculations. (These highlight the academic difficulties the student may experience.)
- Those who may have conditions such as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia.
- Those who have a learning problem that does not result from other disabilities such as motor deficits, emotional disturbances, or environmental, cultural, or economic differences.

This description does not specifically address cause but does highlight psychological processes versus neurological impairments. The primary disability focus is on language, which may exclude difficulties

in learning that involve nonverbal reasoning. This definition does not mention regulatory, reasoning, and social perception difficulties that may contribute to understanding the student's complete profile. On a foundational level, this definition formed the basis for creating academic programs and delineating appropriate services for children with learning disabilities.

IDEA mandates that all children will have free and appropriate education and authorizes aid for special education and educationally relevant services for children with disabilities. IDEA influences how children with learning disabilities are identified and classified. The 1997 amendments of IDEA, by promoting the early identification and provision of services, redirected the focus of special education services by adding provisions that would enable children with disabilities to make greater progress and achieve higher levels of functional performance.²³

The IDEA 2004 amendments eliminate a previous requirement that students must exhibit a severe discrepancy between intellectual ability and achievement for eligibility. This "severe discrepancy" policy often mandated that children would have to experience failure for several years to demonstrate the requisite degree of discrepancy.²⁴ The current goal is to identify ways of serving students more quickly and efficiently once they begin to show signs of difficulty.²⁴ Congress also indicated specifically that (1) intelligent quotient (IQ) tests could not be required for the identification of students for special education in the learning disabilities category and (2) states had to allow districts to implement identification models that used Response to Instruction (RTI).²⁵ The RTI models suggest that the learning difficulty may be intrinsic to the child, inherent in the instruction, or a combination of both. The models propose systematically altering the quality of instruction and repeatedly measuring the child's response to that instruction. Inferences can then be made about the child's deficits contributing to learning difficulties.²⁶

IDEA 2004 also limits the schools from finding a student eligible for special education services if the learning problems are determined to be caused by a lack of appropriate instruction. The law currently encourages schools to use scientific, research-based interventions to maximize a student's opportunity for success in the general education setting (least restrictive environment [LRE]) before being placed in special education. IDEA encourages educators to stress the importance of identifying individual differences and patterns of ability within each child and adjust the educational methods accordingly. Academic achievement relies heavily on the effectiveness of the teacher and the instructional techniques. Studies indicate that learning disabilities do not fall evenly across racial and ethnic groups, with a higher incidence of special education services needed for black, non-Hispanic children.²⁷ The No Child Left Behind (NCLB) Act challenges states and school districts to become more accountable for improving educational standards by intensifying their efforts to close the achievement gap between underachieving students and their peers.

In 2015 the Every Student Succeed Act (ESSA) replaced the NCLB. By law, ESSA requires state plans to include a description of how the state will implement the following^{28,29}:

- Academic standards
- Annual testing
- Goals for academic achievement
- Ways that schools will be held responsible for student achievement
- Plans for supporting and improving struggling schools, including professional development for educators and support for English learners

Despite the ESSA mandate, a systematic analysis by the NCLD²⁹ has found that groups of students, including students with disabilities, low-income students, and students learning English, are frequently neglected.

Classifications

The two most widely used classification systems are those of the American Psychiatric Association (APA) (*Diagnostic and Statistical Manual of Mental Disorders* [DSM])³⁰ and the World Health Organization (WHO) (International Classification of Diseases [ICD]).³¹ Educational professionals prefer the DSM classification for its academic relevance. A variety of specific academically related disorders are outlined in the DSM. The latest edition, DSM-V,³² defines specific learning disorders (SLDs; often referred to as learning disorder or learning disability; see note on terminology) as a neurodevelopmental disorder that begins during school age, although may not be recognized until adulthood. Learning disabilities refers to ongoing problems in one of three areas, reading, writing, and math, which are foundational to one's ability to learn.

The classification system commonly used by therapists is the ICD. The ICD codes are state-mandated diagnostic codes used for billing and information purposes. In the recently revised ICD-11,³³ learning disability is categorized under a "Mental, Behavioral, and Neurodevelopmental disorder." Specifically, learning disability is labeled as a developmental learning disorder and is "characterized by significant and persistent difficulties in learning academic skills, which may include reading, writing, or arithmetic." In addition, ICD-11 describes developmental learning disorders as "not due to a disorder of intellectual development, sensory impairment (vision or hearing), neurological or motor disorder, lack of availability of education, lack of proficiency in the language of academic instruction, or psychosocial adversity."³⁴

Incidence and Prevalence

In the United States the National Center for Learning Disabilities³⁵ reported that 1 in 5 children has learning and attention issues and 1 in 16 children will have Individualized Educational Plans (IEPs) for specific learning disabilities. From this subset, it has been reported that in fourth grade, 27% without disabilities, 69% with disabilities, and 85% with specific learning disabilities fall below basic levels of literacy.³⁵ In 2015 to 2016, the number of students aged 3 to 21 receiving special education services was 6.7 million, or 13% of all public school students. Among students receiving special education services, 34% had specific learning disabilities.³⁶

Perspectives on the Causes of Learning Disabilities

Learning disability is a diverse diagnosis with varied manifestations; therefore searching for a single cause would be inadequate. Historically, researchers have studied causative factors including (1) brain damage or dysfunction caused by birth injury, perinatal anoxia, head injury, fetal malnutrition, encephalitis, and lead poisoning; (2) allergies; (3) biochemical abnormalities or metabolic disorders; (4) genetics; (5) maturational lag; and (6) environmental factors, such as neglect and abuse, a disorganized home, and inadequate stimulation.³⁷⁻³⁹

Current sources agree that possible causes of learning disabilities can include problems with pregnancy and birth (e.g., drug and alcohol use, low birth weight, anoxia, and premature or prolonged labor) and incidents occurring after birth (e.g., head injuries, nutritional deprivation, and exposure to toxic substances such as lead).⁴⁰⁻⁴² Genetic and hereditary links also have been observed, with learning difficulties often seen across generations within families.⁴² The emotional and social environment have also been considered as a contributing factor to learning disabilities.²¹

Children with learning disabilities frequently display a composite of neuropsychological symptoms that interfere with the ability to store, process, or produce information. These symptoms typically include disorders of speech, spatial orientation, perception, motor

coordination, and activity level. Researchers have attempted to identify areas of the brain that may be responsible for these functional limitations. Tools being used include empirical measures of physiological function such as electroencephalography, event-related potentials (ERPs), brain electrical activity mapping (BEAM), regional cerebral blood flow (rCBF), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). These measures expand the understanding of brain functioning but are best used in conjunction with data on functional and behavioral manifestations.

Research findings on brain structure have documented that certain functions are specialized within each hemisphere, and this specialization is optimal for efficient learning.^{43,44} The left hemisphere processes information in a sequential, linear fashion and is more proficient at analyzing details. Academically, this hemisphere is responsible for recognizing words and comprehending material read, performing mathematical calculations, and processing and producing language.

The right hemisphere processes input in a more holistic manner, grasping the overall organization or the “gestalt” of a pattern.^{45,46} This type of organization is advantageous for spatial processing and visual perception. Functionally, the right hemisphere synthesizes nonverbal stimuli, such as environmental sounds and voice intonation, recognizes and interprets facial expressions, and contributes to mathematical reasoning and judgment. Over time these differences in left and right brain processing have become accepted and are commonly labels of cognitive style (i.e., left-brained versus right-brained learner).

A strict left-right dichotomy is oversimplified because it does not take into account many aspects of functional brain organization.^{45,47} Both hemispheres must work together for a variety of specific academic outcomes such as reading and mathematical concepts. In addition to the communication that occurs between the hemispheres via the corpus callosum, essential communication within the hemispheres is also present. Intrahemispheric communication is critical for developing higher level cognitive functions such as memory, language, visual-spatial perception, and praxis.⁴⁸ Research suggests that children with learning disabilities show different patterns of cerebral organization than normal children.^{45,47} However, brain plasticity is the basis for designing and implementing a variety of intervention techniques aimed at improving processing.

Subgroups

In early attempts to classify learning disabilities, Denckla and Rudel⁴⁹ determined that approximately 30% of the 190 children they assessed by neurological examination could be classified into three recognizable subgroups. The other 70% exhibited an unclassifiable mixture of signs. Of the 30%, the first subgroup was classified as children having a *specific language disability*. These children, who were failing reading and spelling, showed a pattern of inadequacy in repetition, sequencing, memory, language, motor, and other tasks, all of which require rote functioning. The second group had a specific *visual-spatial disability*. These children had average performance in reading and spelling with delayed arithmetic, writing, and copying skills. The children in this subgroup all had social and/or emotional difficulties. The third group manifested a *dyscontrol syndrome*. These children had decreased motor and impulse control, were behaviorally immature, and were average in language and perceptual functioning.

Grouping children with learning disabilities based on patterns of academic strengths and weakness is as important as grouping them based on neuropsychological or cognitive measures. With an academic classification the heterogeneity of learning disabilities can be more clearly recognized and learning modalities can be adjusted to the individual child. For example, a child with a specific reading difficulty could be experiencing deficits in word recognition,

fluency, or comprehension. Through identification of the specific areas of weakness in reading, intervention can be individualized to improve academic performance.¹¹

Based on historical and current trends the following general subgroups will be explored: verbal learning impairments, nonverbal learning disabilities (NVLDs), motor coordination deficits, and social and emotional challenges.

Verbal Learning Impairments

Verbal learning impairments typically include dyslexia, dyscalculia, and dysgraphia. Harris²⁰ classifies these deficits in functional terms, with dyslexia including disorders of reading and spelling, dyscalculia denoting a mathematics disorder, and dysgraphia describing a disorder of written expression. These learning disorders may occur individually or concurrently. Each of these verbal learning impairments will significantly influence academic performance.

Dyslexia (developmental reading disorder). Dyslexia is a learning impairment in which the ability to read with accuracy and comprehension is substantially less than expected for age, intelligence, and education and that impairs academic achievement or daily living.³⁰ The International Dyslexia Association adopted the following definition in 2002: “Dyslexia is a specific learning disability that is neurological in origin. It is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede the growth of vocabulary and background knowledge.”⁵⁰ Table 12.2 summarizes a multidimensional perspective to common characteristics of dyslexia.

Dyslexia is the most common learning disorder, affecting as many as 80% of individuals identified as learning disabled.⁵¹ Prevalence rates range from 10% to 15% of the school-aged population,⁵⁰ with the highest noted estimate of 17.4%.⁵² Historically, dyslexia was considered more common in boys than in girls, but data indicate an equal distribution between the sexes.⁵³ Boys are more likely to act out as a result of having a reading difficulty and are therefore more likely to be identified early. On the other hand, girls are more likely to try to “hide” their difficulty, becoming quiet and reserved.²⁵

Causes of dyslexia can be both genetic and neurobiological.^{21,25,50} Genetic causation has been linked to chromosomes 1, 2, 3, 6, 11, 13, 15, and 18.⁵⁴ There is a strong inheritability of the genetic links for dyslexia. Statistics suggest that 30% to 50% of children with dyslexia have a parent with the disorder.⁵⁵ Neuroanatomical abnormalities, atypical brain symmetry, and disruptions in neural processing have been observed in children with reading disorders.^{21,25,53,56} Anatomically, the measurements that best discriminate between children with and without dyslexia are the right anterior lobe of the cerebellum and the area involving the inferior frontal gyrus of both hemispheres.²⁵ Dynamic investigations using functional brain imaging techniques (PET, fMRI, and the newer ultrafast echo planar imaging [EPI]) are providing significant information on brain functioning during cognitive tasks such as reading and picture naming.^{21,53}

Reading skills consist of a combination of visually perceiving whole words and phonetically decoding letters, morphemes, and words.⁵⁷ Individuals with reading disorders exhibit brain activation patterns that provide evidence of an imperfectly functioning system for segmenting words into phonological (language) parts and linking the visual representations of letters to the sounds they represent.⁵² These disruptions of the posterior reading system result in increased reliance on ancillary systems during reading tasks, including the frontal lobe

TABLE 12.2 Signs of Possible Reading Difficulties**Sensory and Behavioral Signs**

1. Has short attention span for semistructured and highly structured reading tasks.
2. Easily distracted by extraneous stimuli in the environment and zones out during reading performance.
3. Avoids and indicates dislike for structured reading and writing tasks.
4. Complains of fatigue; shows visible signs of increased arousal and stress during structured reading tasks.
5. Gives up easily, whines and cries when encountering challenging words and texts during reading.
6. Squirms/fidgets on seat during reading tasks.

Performance Skills

1. Does not track words in text with eyes.
2. Skips words and lines during reading.
3. Does not attempt to sound out letters and words.
4. Confuses /b/, /d/, /p/, /q/ during reading.
5. Reverses letters and numbers consistently during writing.
6. Performance of near and far point copying is usually slow and laborious. Copies only one or two letters at a time.
7. Complains that letters look the same or moving when reading.

Reading Participation

1. Does not initiate reading at home and school.
2. May like being read to but will hesitate reading to someone.
3. Prefers easier books or books with more pictures and less words.
4. Prefers silent reading on his or her own over reading with and to others.
5. Gives up easily on reading sheets and homework.
6. Dislike for school and will have multiple reasons to get excused from class (e.g., frequent need to go to the restroom; feeling sick all the time; aggressive behaviors and hostility; defiance).
7. Glances over pictures and does not seem to process words and sentences during silent reading.
8. Slow, effortful, dysprosodic reading.
9. Gets left behind or lost during group reading.

and right hemisphere posterior circuitry. This suggests that the child with dyslexia may be compensating for poor phonological skills with other perceptual processes, helping to explain why individuals with dyslexia can develop reading skills, although they often remain slow and nonautomatic.⁵³

Dyscalculia (mathematics disorder). Dyscalculia is a learning impairment in which mathematical ability is substantially less than expected for age, intelligence, and education and that impairs academic achievement or daily living.³⁰ Difficulties occur with comprehending a variety of math concepts, including number quantities, money, time, and measurement. This disorder also involves difficulties with computations and problem solving of specific math functions, which affects the ability to understand, remember, or manipulate numbers or number facts.²⁵ This heterogeneous disorder may involve both intrinsic and extrinsic factors.⁵⁸ Intrinsic factors are hypothesized to include deficits in visual-spatial skill, quantitative reasoning, sequencing, memory, or intelligence. Extrinsic factors can be a combination of poor instruction in the mastery of prerequisite skills as well as attitude, interest, and confidence in the subject.

Characteristics of dyscalculia include the following⁵⁹:

- Confusing numbers and math symbols (+, −, ×, ÷)
- Inconsistent ability in addition, subtraction, multiplication, and division

- Problems sequencing numbers, or transposing them when repeated
- Difficulty with abstract concepts of time and direction
- Poor mental math ability
- Difficulty with money, budgeting, balancing checkbooks, and financial thinking (e.g., checking change or estimating the cost of items in a shopping basket)
- Problem reading analog clocks
- Trouble keeping score during games and playing games with flexible rules of scoring such as poker

Prevalence of dyscalculia is 5% to 6% in the school-aged population, with a nearly equal male-to-female ratio.^{21,60} Geary⁶¹ concludes that individuals with arithmetic disabilities currently appear to constitute at least two subgroups: those with only mathematical disorders and those with concomitant reading disorders and/or attention-deficit disorder.

Although there is evidence that this disorder is familial and heritable, much less research on its cause is provided than on the causes of most other learning disorders. Dyscalculia shares genetic influences with reading and language measures. The association between dyslexia and dyscalculia seems to be largely genetically mediated.^{21,60} Other risk factors for development of dyscalculia include prematurity and low birth weight. In addition, environmental deprivation, poor teaching, classroom diversity, and untested curricula have been linked to cause.⁶⁰

The neurological cause of dyscalculia was initially hypothesized to be right hemisphere dysfunction because of the strong relation of visual-spatial skills to numerical computation.⁶² Additional research supports the involvement of both hemispheres because mathematics computation involves a complex relation of spatial problem solving, sequential analysis, language processing, and memory.⁶⁰ Specifically involved are portions of the parietal and frontal lobes.²¹ In an effort to compensate, individuals with dyscalculia can recruit alternate brain areas, but this substitution often results in inefficient cognitive functioning.⁶⁰

Dysgraphia (disorder of written expression). Dysgraphia is a learning impairment in which writing ability is substantially less than expected for age, intelligence, and education that impairs academic achievement or daily living.³⁰ The DSM, fourth edition (DSM-IV) diagnosis of “disorder of written expression” depends on recognition of “writing skills substantially below those expected given the person’s chronological age, measured intelligence, and age appropriate education” that “significantly interferes with academic achievement or activities of daily living (ADLs) that require composition of written texts.”³⁰ Children with dysgraphia have specific difficulties in the ability to write, regardless of the ability to read. This may include problems using words appropriately, putting thoughts into words, or mastering the mechanics of writing. Classifications of dysgraphia can include penmanship-related aspects of writing (e.g., motor control and execution), linguistic aspects of writing (e.g., spelling and composing), or a combination.⁶³ This heterogeneous disorder is frequently found in combination with other academic, learning, and attention disorders.^{20,25}

Characteristics of dysgraphia include the following⁶⁴:

- Poor legibility: irregular letter size and shapes, poor spacing
- Mixing uppercase and lowercase letters; unfinished letters
- Spelling difficulties
- Fatigues quickly or complains of pain when writing
- Decreased or increased speed of copying or writing
- Needs to say words out loud while writing
- Struggles with organizing thoughts on paper
- Difficulty writing grammatically correct sentences and organized paragraphs

- Large gap between knowledge base and ability to express ideas in writing
- Awkward pencil grip

Limited data are available on the prevalence of dysgraphia. Although 10% to 30% of school-aged children struggle with handwriting, we cannot assume they have been diagnosed with dysgraphia.⁶⁵ Difficulties in written expression are frequently underidentified and can be masked by reading disorders or considered to be attributable to poor motivation. Studies have suggested that dysgraphia may be as common as reading disorders and may occur in 3% to 4% of the population.^{20,63}

Dysgraphia has been suggested to be a neurological processing disorder that seldom occurs in isolation and can result from a number of other dysfunctions, including attention deficit, auditory or visual processing weakness, and sequencing problems.^{21,66} The complex nature of written expression makes finding the cause difficult. Writing involves integration of spatial and linguistic functions, planning, memory, and motor output. This suggests involvement of both the left and right hemispheres for skill in decoding, spelling, formulating, and sequencing ideas, and producing work in correct spatial orientation, all coupled with rules of punctuation and capitalization.

Nonverbal Learning Disability

NVLDs (or NLDs) are considered by some to be a neuropsychological disability. Although this condition has been identified for more than 30 years, it has not yet been included as a diagnostic category in the DSM.⁶⁷ The pioneer in the field, Dr. Byron P. Rourke, first identified in 1985 this separate and distinct learning disability. In 1995 he defined nonverbal disability as “a dysfunction of the brain’s right hemisphere—that part of the brain which processes nonverbal, performance-based information, including visual-spatial, intuitive, organizational and evaluative processing functions.”⁶⁸ Nonverbal learning disorders affect both academic performance and social interactions in children. Three primary areas affected by NVLDs include visual-spatial organization, sensory-motor integration, and social-emotional development. The social and emotional difficulties for individuals with nonverbal learning disorders are paramount, leading some researchers to label this a *social-emotional learning disability*.^{20,69} NVLDs are generally identified by a distinct pattern of strengths and deficits, with excellent verbal and rote memory skills and poorly developed sensory-motor and graphomotor ability, executive functioning, and social interactions.^{20,70,71}

Characteristics of NVLDs include the following^{21,67,72}:

- Higher verbal IQ compared with performance (nonverbal) on the Wechsler Intelligence Scale for Children (WISC)
- Develops speech, language, and reading skills early
- Strong vocabulary and spelling
- Ability to memorize and repeat a massive amount of information provided it is in spoken form
- Learns better and faster through hearing information rather than seeing it
- Difficulties with constructional and spatial planning tasks
- Fine and gross motor difficulties affecting printing and cursive writing, physical coordination, and balance
- May exhibit limited facial expression, flat affect, unchanging voice intonation, and robotic speech
- Poor interpretation of emotional responses made by others
- Trouble reading and understanding facial expressions, gestures, and voice intonations
- Nuances of spoken language, such as hidden meanings, figures of speech, jokes, and metaphors, are interpreted on a concrete level

- Struggles with conversation skills, dealing with new situations, and changing performance in response to interactional cues
- Difficulties in problem solving and understanding cause-effect relationships
- Poor awareness of social space
- Can be intrusive and disruptive

NVLDs make up 5% to 10% of all individuals with learning disabilities.⁷³ NVLD is frequently overlooked in the educational arena because children with this disorder are highly verbal and develop an extensive vocabulary at a young age. Well-developed memory for rote verbal information positively influences early academic learning of reading and spelling. Yet these students will have difficulty performing in situations where adaptability and speed are necessary, and their written output will be slow and laborious.⁷⁰ Nonverbal learning disorders are therefore challenging to identify at younger ages but become progressively more apparent and debilitating by adolescence and adulthood. The challenges in early identification, the absence from the DSM-V, and the different views held by psychological and educational disciplines often result in lack of awareness of, accurate diagnosis of, and appropriate service provision for these students.

Little is known about possible genetic or environmental causes of NVLD. There are no family, twin, adoption, segregation, or linkage studies available.²¹ Pennington²¹ proposes that both Turner syndrome and fragile X syndrome in females appear to be possible genetic causes of NVLD. Similarities include deficits in executive functions, increased difficulties in math versus reading and spelling, functional structural language but impaired pragmatic language, and social anxiety and shyness.²¹ Differential diagnosis is essential because NVLD can occur in conjunction with dyscalculia, attention deficit, adjustment disorder, anxiety and depression, emotional disturbances, and obsessive-compulsive tendencies.

Motor Coordination Deficits

Children with learning disabilities may or may not manifest motor coordination problems. Conversely, some children have motor and coordination problems but do not experience learning difficulties. Children with motor deficits typically have difficulty acquiring age-appropriate motor skills and move in an awkward and clumsy manner. Difficulties in daily functional tasks and performance areas (e.g., school and leisure skills) are common. Motor deficits can result from a wide variety of neurological, physiological, developmental, and environmental factors. These impairments can manifest in diverse ways depending on the severity of the disorder and the areas of motor and social performance affected. This will be discussed at length in the next section.

Social and Emotional Challenges

Behavioral patterns or disorders associated with learning disabilities include frustration, anxiety, depression, attention deficits, conduct problems, and global behavior problems. Ames⁷⁴ stressed that no single behavior pattern is prevalent in children with learning disabilities. Children with learning disabilities not only struggle in the classroom but experience difficulties in the social arena as well.⁷⁵ Issues in learning and related behaviors affect one another in a complex manner, leaving us to wonder which is the cause and which is the symptom.

Frustration, deflated self-esteem, and other social and emotional difficulties tend to emerge when instruction does not match learning styles.⁷⁶ This frustration mounts as the child notices classmates surpassing them, and this often results in exasperation with trying to keep up. The pressure then becomes for the child to “try harder,” when ironically most do not understand just how hard the child is trying. The dissatisfaction in not meeting the teacher’s expectations is often

overshadowed by the inability to succeed in personal goals and a lack of self-worth. This can result in the development of internal perfectionism to deal with the lack of competence, with the belief of the child that he or she should not make mistakes.⁷⁷

Anxiety is another response that may occur with persistent difficulties in understanding and successfully completing schoolwork. This occurs when the child feels out of control and lacks the ability to plan and execute strategies for success.⁷⁶ The mismatch between ability, expectations, and outcomes can cause frustration, disappointment, and stress, triggering a range of emotions and behaviors that interfere with everyday functioning in multiple environments.⁷⁶

Other emotional difficulties are noted in attention. When a lesson is taught in a manner that is too complex, the child may become inattentive. Attention problems can influence behavior, often relating to difficulties with impulse control, restlessness, and irritability, affecting learning and peer interactions. These issues frequently coincide with frustration, anger, and resentment, which may manifest as a conduct problem (e.g., verbal and nonverbal aggression, destructiveness, and significant difficulties interacting with peers). Children with learning disabilities often become discouraged and fearful, are less motivated, and develop negative and defensive attitudes. These patterns of behavior can worsen with age, contributing to juvenile delinquency.³ Low self-esteem and depression are common during school years and tend to escalate around age 10 years.⁷⁸

Poor academic progress, additional prompting needed from teachers, and negative attention for disruptive behaviors can cause children with learning disabilities to perceive themselves as being “different.”⁷⁹ Lack of success in school experiences can influence the development of positive self-perception and can have powerfully negative effects on self-esteem.⁷⁶ A self-defeating cycle may be established: the child experiences learning problems, school and home environments become increasingly tense, and disruptive behaviors become more pronounced. These responses, in turn, further affect the child’s ability to learn. Lack of success generates more failure until the child anticipates defeat in almost every situation.

Assessment and Intervention

Specialists

Evaluation and intervention for children with learning disabilities should involve an interdisciplinary team, owing to the varied nature of presenting problems. Most children with learning disabilities are seen by a group of professionals, the makeup of which depends on the purpose, location, philosophical orientation, or availability of resources of a particular program. **Box 12.1** lists the different professionals and specialists who might participate in assessment or remediation of children with learning disabilities. The types of professionals are grouped into the four categories of education, medicine and nursing, psychology, and special services; they have been listed only once, although some professions could be categorized in multiple ways.

Therapists should be familiar with the roles of the various medical specialists and of primary care physicians. Psychologists have two distinct and often separate roles in the care of children with learning disorders. The first role is in identification of learning strengths and weaknesses. Psychological testing is often essential in the recognition of specific learning problems and may be done by clinical psychologists, school psychologists, or clinical neuropsychologists who specialize in diagnosis of learning disorders. The second role of psychologists is to provide mental health services and support systems to address academic, social-emotional, and behavioral issues. Counseling and behavior management can also be provided by a psychiatrist, behavioral specialist, or social worker. School adjustment or guidance

BOX 12.1 Types of Specialists Working With Children With Learning Disabilities

Education

- Classroom teacher
- Special educator
- Guidance counselor
- Learning disability specialist
- Educational diagnostician
- Reading specialist
- Physical educator
- Adaptive physical educator

Medicine and Nursing

- Family physician
- Pediatrician
- Pediatric neurologist
- Psychiatrist
- School nurse
- Biochemist
- Geneticist
- Endocrinologist
- Nutritionist
- Ophthalmologist or optometrist
- Otologist or ear, nose, and throat specialist

Psychology

- Clinical psychologist
- Neuropsychologist
- School psychologist
- Child psychologist

Special Services

- Occupational therapist
- Physical therapist
- Speech and language pathologist
- Audiologist
- Vision specialist
- Social worker
- Recreational therapist
- Music therapist
- Vocational education specialist

counselors offer support and advice on specific academic difficulties, social conflicts, and affective issues.

Physical educators, adaptive physical educators, physical therapists (PTs), occupational therapists (OTs), and speech therapists also may be involved in the assessment of motor deficits and related areas. Overlap in the areas assessed may occur. The unique training of each professional influences both the selection of tests and the qualitative aspects of assessment based on observations of a child’s performance. Although the evaluations may appear similar, differences among professions are apparent in orientation and rationale when interpreting dysfunction.

Planning an assessment protocol can prevent unnecessary duplication of testing and provide comprehensive information related to the referral concerns. The referral concerns and the functional difficulties the child is experiencing drive the assessment. Communication of information between professionals and the parents will generate a comprehensive picture of the child’s areas of strength and weakness, necessary for effective intervention planning. Case Study 12.1 illustrates the concept of a comprehensive pediatric assessment.

CASE STUDY 12.1 Joan

History: Joan is a 5-year-old, female, kindergarten student who is undergoing a complete psychological, neurological, educational, social, occupational, physical, speech, and language therapy school reevaluation. Joan received outpatient services including OT 1× week for 60 min and PT 1× week for 60 min for remediation of severe motor coordination and planning problems, as well as concerns with her graphomotor (ability to write) and visual perceptual skills for a year, but she no longer receives outpatient services. Joan was noted to have strabismus of both eyes. As per school records, Joan failed a hearing screening on her left ear.

Family Concerns: Joan is the third child of an intact family. She has two older brothers who excelled in sports. Joan's mother is concerned about her daughter's gross motor development and stated that Joan was "slower to walk, run, and jump than her other children." She followed her pediatrician's advice for outpatient therapy until her insurance benefits ran out. Joan's mother expressed that because she is the youngest child and her only daughter, she did not enroll Joan in extracurricular sports because of fear that she would get hurt and because, unlike her other children, "Joan is clumsy and awkward—not a graceful child." Joan's mom reported that her daughter has difficulty completing everyday day tasks such as dressing, writing, using playground equipment, and participating in sports activities with her peers and has agreed to a complete battery of assessments. As per parent report, Joan does not like to rough-house with her brothers and only likes indoor, sedentary play activities.

Clinical Observations at School: Joan demonstrated left-hand dominance. Her upper extremity range of motion and muscle tone were in the low end of normal limits. Her sitting posture was functional; however, because of the height of the table, Joan slumped in the chair, could not reach the floor, and frequently shifted positions. Joan stabilized using her right hand when necessary. She was able to cross midline, use both hands simultaneously, and transfer objects from one hand to another. Joan was able to cut a circle but held the scissors with an immature thumb down (inverse) grasp. Joan initiated a coloring activity with a tight grasp of the crayon in her left hand. She demonstrated heavy pressure on a writing utensil and broke the tip of a mechanical pencil. Joan presented with fair motor planning skills; she had difficulty sustaining certain postures such as standing on her tiptoes with her arms overhead or standing on one foot for more than 2 s. She also had some difficulty imitating positions even after demonstration.

Written Work: Joan is able to spell her first and last name; however, she writes her first name in mirror writing (i.e., the writing runs in the opposite direction to normal with individual letters reversed). She can print uppercase and lowercase letters of the alphabet but does not have uniform top-to-bottom letter formation. She has difficulty writing on the writing line with letters floating above and below the writing line when copying the alphabet and words.

Standardized Examination

The Beery-Buktenica Development Test of Visual Motor Integration, Sixth Edition (VMI)

The VMI measures a student's ability to reproduce shapes of increasing complexity following a developmental sequence. It is designed to assess the extent a student can integrate his or her visual and motor abilities (visual-motor integration). Summary of Joan's scores and impressions:

	Raw Score	Standard Score	Percentile	Interpretation
Motor integration	15	89	23	Below average
Visual perception	14	88	21	Below average

Joan has decreased visual spatial awareness, which interferes with the spacing between her words, following lines, and the organization of her written work on

paper. She formed letters with incorrect directionality, skipped lines, and frequently lost her place when copying. Joan's visual perceptual limitations interfere with legibility of her writing. Joan has fine motor and visual perceptual deficits that impact the quality of her written work. She was referred to a developmental optometrist to assess her visual motor and visual perceptual skills.

Bruininks-Oseretsky Test of Motor Proficiency, Second Edition (BOT-2)

Bruininks-Oseretsky Test of Motor Proficiency, Second Edition (BOT-2) is used to measure motor performance in fine and gross motor functioning. The test assesses eight areas including fine motor precision, fine motor integration, manual dexterity, bilateral coordination, balance, running speed and agility, upper-limb coordination, and strength. For the purpose of this assessment, Joan was evaluated using the short form of the assessment in the areas of fine motor precision, fine motor integration, bilateral coordination, balance, and upper-limb coordination.

Listed as follows are raw score and point score totals of Joan's evaluation:

Subtest 1: Fine Motor Precision	11
Subtest 2: Fine Motor Integration	6
Subtest 3: Manual Dexterity	5
Subtest 4: Bilateral Coordination	12
Subtest 5: Balance	6
Subtest 6: Running Speed and Agility	6
Subtest 7: Upper Limb Coordination	10
Subtest 8: Strength	6
Total Point Score	62
Standard Score	40 Below Average
Percentile	16th Below Average
Standard Deviation	-2.0

Fine Manual Control: This motor-area composite measures control and coordination of the distal musculature of the hands and fingers, especially for grasping, drawing, and cutting.

The Fine Motor Precision subtest consists of activities that require precise control of finger and hand movement. The objective of the subtest is to measure ability to draw, fold, or cut within a specified boundary. The Fine Motor Integration subtest requires the examinee to reproduce drawings of various geometric shapes that range in complexity from a circle to overlapping pencils. Sample's score is consistent with individuals who, when copying from pictures, can accurately draw a variety of geometric shapes such as a triangle and a wavy line, as well as more complex designs such as a five-point star and overlapping pencils.

Manual Coordination: This motor-area composite measures control and coordination of the arms and hands, especially for object manipulation. The Manual Dexterity subtest uses goal-directed activities that involve reaching, grasping, and bimanual coordination with small objects. Emphasis is placed on accuracy; however, the items are timed to differentiate levels of dexterity more precisely. The Upper-Limb Coordination subtest consists of activities designed to measure visual tracking with coordinated arm and hand movement.

Body Coordination: This motor-area composite measures control and coordination of the large musculature that aids in posture and balance. The Bilateral Coordination subtest measures the motor skills involved in playing sports and many recreational games. The tasks require body control, and sequential and simultaneous coordination of the upper and lower limbs. The Balance subtest evaluates motor-control skills that are integral for maintaining posture when standing, walking, or reaching.

CASE STUDY 12.1 Joan—cont'd

Strength and Agility. This motor-area composite measures control and coordination of the large musculature involved in locomotion, especially in recreational and competitive sports.

Personal Strengths and Weaknesses: A personal strength or weakness is indicated when an examinee's motor-area composite standard score is either substantially higher or substantially lower than his or her other motor-area composite standard scores. For Joan, Fine Manual Control represents a relative strength and Body Coordination represents a personal weakness. Based on the information obtained through the chosen subtests, it can be concluded that Joan has overall below average fine and gross motor development for her age range.

The Sensory Processing Measure

The Sensory Processing Measure is an assessment tool used to gauge presence of sensory processing issues, praxis, and social participation in elementary school-aged children. This assessment tool provides a unique and all-encompassing perspective of a child's sensory functioning in the environments of the home, school, and community were used to evaluate fine motor skills. The assessment covers behaviors from the main sensory systems including visual, auditory, tactile, proprioceptive, and vestibular functioning. It is essential to look at these different environments because symptoms or behaviors may manifest in differently in different environments.

Subtest	Raw Score	T-Score	Interpretive Range
Social participation	30	71	Definite difference
Vision	18	64	Some problems
Hearing	14	64	Some problems
Touch	24	68	Some problems
Body awareness	30	75	Definite dysfunction
Balance/motion	17	60	Some problems
Planning and ideas	30	77	Definite dysfunction
Total	162	78	Definite dysfunction

SPM Description and T-Score (Teacher) Average = 40T–59T, Some Problems = 60T–69T, Definite Difference = 70T–80T NOTE: Additional observations are included (Parent and Occupational Therapist). As noted above, Joan has a definite sensory dysfunction in the areas of social participation, body awareness (difficulty grading the proper amount of force), and planning and ideas (frequently bobbles or drops items she is carrying and shows poor organization of materials in on or around her desk). These areas of dysfunction may be affecting her social participation and school performance.

School-Based Service Delivery Models

The model of service delivery for each individual child should be developed to facilitate the student's ability to be successful in the learning environment. A continuum of services exists to enable interventionists to be responsive to all children's needs. The continuum includes consultation, integrated or supervised therapy, and direct service.⁸⁰ Unfortunately, a lack of available resources can influence what type and frequency of services are provided. In creating a plan that truly addresses the issues hindering a child's learning within the academic setting, the team must work together to fabricate relevant and inclusive goals.

IDEA currently requires that all children in special education be educated in the LRE. The law requires that students with disabilities be educated to the extent appropriate with their peers, within the inclusion classroom. Removing the child from the classroom for special education and intervention is discouraged unless it is absolutely necessary for the student to learn effectively. Although the model of inclusion can be effective for many children, it requires members of the team to work closely together with the regular education teacher. This collaborative effort ensures an understanding of the child's special learning needs and incorporation of therapeutic procedures into the regular classroom to facilitate the best learning environment.

Bricker⁸¹ contends that adhering strictly to this model can be detrimental to certain students, and each case must be looked at individually. The LRE should be determined after assessing the specific needs of the child. If services in a regular classroom, coupled with supplemental aids and services, do not meet the needs of the child, an alternate environment should be considered. The first adaptation

might be to have the child participate for the majority of the day in the regular classroom and leave for special instruction for part of the day. In some educational settings, children with learning disabilities are given full-time instruction in a special classroom with a small group of other children with learning disabilities. A special education teacher or a learning disability specialist is in charge of the classroom. The most specialized environment would be a private school only for children with learning disabilities.

LEARNING DISABILITIES AND MOTOR DEFICITS OR DEVELOPMENTAL COORDINATION DISORDER

Developmental coordination disorder (DCD) is a term that was first introduced in the DSM in 1987 to define a condition that has affected children for more than a century.⁸² It is defined as a failure of acquisition of skills in both gross and fine movements, not based on impaired general learning or lack of opportunity to gain motor skills as peers.⁸³ The APA and the WHO both have inclusive and exclusive criteria in their definition. For APA, the inclusive criteria include "impairment in the development of motor coordination, which can be manifested in delays in milestones such as standing and walking; inferior performance in sports activities; and untidy handwriting."⁸⁴ Exclusive criteria include a motor deficit not due to another diagnosed condition. In addition, if a significant learning difficulty is present, the motor difficulties should supersede the cognitive limitations. The WHO definition overlaps with the APA definition by noting that a child would need to score two standard deviations below the mean on a standardized test of motor impairment and be accompanied by limitations of

academic performance and/or ADLs.⁸⁵ In addition, there should be no concurrent neurological disorders, and those with an IQ below 70 should be excluded from diagnosis. Studies in DCD have shown that children perceive themselves as less competent than their peers, not only in the domain of physical competence but also in self-esteem and social acceptance.⁸²

Approximately half of children with learning disabilities have motor coordination problems.⁸⁶ Motor deficits are often the most overt sign of difficulty for the child with learning disabilities. Lowered academic achievement within any or all areas of learning (reading, spelling, writing) is also seen in children with DCD.^{15,30} A study by Jongmans and colleagues⁸⁶ indicates that children with concomitant perceptual-motor and learning problems are more severely affected in motor difficulties than those with only DCD or who are only learning disabled. At times, extreme discrepancy in competence over a range of motor skills exists, with strengths in some motor areas and significant weaknesses in others. Presentation of difficulties may change over time depending on developmental maturation, environmental demands, and interventions received.

An International Consensus Meeting on Children and Clumsiness was held in 1994 with expert educators, kinesiologists, OTs, PTs, psychologists, and parents. These experts discussed a common name to identify “clumsy” children with movement, coordination, and motor planning difficulties. The term *DCD*, as first described in DSM-III,³⁰ was identified to distinguish these children from those with severe motor impairments (such as those with cerebral palsy or paraplegia) and children with normal motor movements. A child with DCD often exhibits difficulty with motoric academic tasks such as handwriting and gym class, self-care skills such as dressing and using utensils, and leisure activities including playground games and social interactions.⁸⁷

Definition

The DSM-5³² classifies DCD as a discrete motor disorder under the broader heading of neurodevelopmental disorders. The specific DSM-5 criteria for DCD are as follows:

- Acquisition and execution of coordinated motor skills are below what would be expected at a given chronological age and opportunity for skill learning and use; difficulties are manifested as clumsiness (e.g., dropping or bumping into objects) and as slowness and inaccuracy of performance of motor skills (e.g., catching an object, using scissors, handwriting, riding a bike, or participating in sports).
- The motor skills deficit significantly or persistently interferes with ADLs appropriate to the chronological age (e.g., self-care) and impacts academic or school productivity, prevocational and vocational activities, leisure, and play.
- The motor skills deficits cannot be better explained by intellectual disability or visual impairment and are not attributable to a neurological condition affecting movement (e.g., cerebral palsy, muscular dystrophy, or a degenerative disorder).

Clinical Presentation

DCD is a childhood disorder characterized by poor coordination and clumsiness. Typically, there is no easily identifiable neurological disorder accompanying this lack of motor skills required for everyday life.⁸⁸ Characteristics can be seen in developmental areas such as gross motor, fine motor, visual motor, self-care, and social-emotional areas. Children tend to develop at a slower rate and require more effort and practice to accomplish age-level tasks. The salient features are coordination difficulties that include decreased anticipation, speed, reaction time (RT), and quality and grading of movement.^{89,90} These children often have difficulties analyzing the task demands of an activity,

interpreting cues from the environment, using knowledge of past performance, and transferring and generalizing skills.⁹¹

Coordination difficulties are most apparent when complex motor activities are attempted. Physical education class often presents major problems. For example, a 9-year-old boy described his motor problems as follows: “When the gym teacher tells us to do something, I understand exactly what he means. I even know how to do it, I think. But my body never seems to do the job.”⁹²

Development of gross and fine motor skills, coupled with the child’s ability to master body movements, enhances feelings of self-esteem and confidence. Through persistence in mastering the varied challenges of motor exploration the child builds self-reliance. The frustrations and accomplishments enhance confidence and the ability to take risks. By engaging in group activities children develop essential social skills, including how to compromise, work as a team, and deal with conflicts and different personality styles.

Poor motor coordination often results in significant social and emotional consequences. When a child is poorly coordinated, she or he is often teased and shunned from group play. This may lead to anxiety and avoidance of participation in games, as children frequently judge themselves to be both physically and socially less competent.⁹³ Anxiety may be more prevalent in adolescence, most notably in boys.⁹⁴ Because they are often unsuccessful in group participation, difficulties with navigating the changing demands of cooperative play and negotiating with others and reluctance to advocate for themselves often result. Boys with learning and motor coordination problems have been found to demonstrate significantly less effective coping strategies in all domains of functioning compared with a normative sample.⁹⁵ Feelings of incompetence, depression, or frustration are common and can be life-long problems.^{96,97} The impact of motor coordination difficulties on social behavior is exemplified by this statement from a child with learning disabilities and motor deficits:

Gross motor characteristics of DCD include the following:

- Diminished core strength and postural control
- Delayed balance reactions
- Often falling, tripping, and bumping into things; acquiring more than the usual number of bruises
- Motor movements that are performed at a slower rate despite practice and repetition⁹⁰
- Motor milestones that may be achieved in the later range of normal development
- Poor anticipation (do not use knowledge of past performance to prepare)
- Notably different quality of running and ball skills from typical peers
- Difficulty learning bilateral tasks such as riding a bicycle, catching a ball, and jumping rope
- Possible hesitance with and avoidance of new or complex motor tasks (e.g., playground equipment, gym class)
- Possibly poor safety awareness
- Inability to smoothly turn and position body when going up ladder to a slide or to get into a chair
- Possible sedentary activity level; may prefer to engage in solitary play
- Tendency to not play games by the rules
- Often, avoidance of team sports such as T-ball and soccer

Fine motor characteristics of DCD include the following:

- Diminished wrist and hand strength
- Maladaptive or immature grasp patterns
- Possible use of excess or not enough pressure
- Poor refinement of small motor movements with hands (qualitatively, the child looks like he or she is wearing a pair of gloves when trying to manipulate small objects)

- Often dropping or breaking items
 - Delayed dressing skills (buttons, zippers, fasteners, shoelaces)
 - Trouble with eating utensils (scooping, piercing)
 - Difficulty with tool use (e.g., scissors, pencils, stapler, hole punches)
 - Writing that is laborious and often illegible
 - Impaired drawing ability characterized by poor motor control, with wobbly lines, inaccurate junctures, and difficulty coloring within the lines
 - Decreased ability with pasting, gluing, manipulating stickers and other art materials
 - Difficulty with constructive, manipulative play (e.g., block building, Tinkertoys, Legos)
 - Often the presence of associated articulation deficits, possibly because of the fine motor nature demanded for articulation
- Visual motor characteristics of DCD include the following:
- Difficulty with visually guided motor actions (i.e., eye-hand and eye-foot coordination)
 - Hesitancy or decreased safety on stairs
 - Trouble with timing needed for kicking, hitting, and catching ball
 - Difficulty with hopscotch and four squares
 - Poor judgment of spatial relationships (knowing where the body is in space)
 - Delayed development of prepositional and directional concepts
 - Difficulty with spatial planning tasks such as puzzles, building models, and constructional toys
 - Handwriting that is often labored, with spacing and sizing problems evident; letters may be irregular, illegible, and poorly organized on the page
- Self-care characteristics of DCD include the following:
- Slowness to develop independence in ADLs
 - Overreliance on parents to help with self-care skills
 - Clothes that are often on backward or crooked
 - Struggles with cutting fingernails, putting on makeup, tying necktie, using a hair dryer
 - Difficulty blowing nose with tissue, putting on Band-Aid
 - Trouble putting toothpaste on toothbrush
 - Messy eater, spills often, does not recognize food on face
 - Difficulty pouring from a container, opening lunch box, unwrapping sandwich, opening containers, peeling fruit
 - Trouble packing a bag, backpack, or suitcase
 - Difficulty sequencing daily routines
- Social and emotional characteristics of DCD include the following:
- Often emotionally immature
 - May exhibit behavioral difficulties such as acting out or becoming class clown
 - May be more introverted and anxious
 - Can appear fiercely competitive, hating to lose, complaining that rules are unfair
 - Can be self-deprecating, calls self “stupid”
 - Often easily frustrated
 - May experience depression and feelings of incompetence
 - Has difficulty making and maintaining friendships, plays alone
 - Has feelings of low self-worth, poor self-esteem⁹⁸
 - Perceived by others as lazy, overprotected, or immature⁹⁹
 - Adolescents may have fewer social pastimes and hobbies than peers

Prevalence

The prevalence fluctuates between 4% and 5% in mainstream primary schools^{83,85} to 6% of the population,¹⁰⁰ and more recently, up to 10% worldwide.¹⁰¹ Prevalence is directly related to the way the assessment is

used and the establishment of cut-off points. Gender differences have been examined on numerous occasions, and the consensus is that the condition is more prevalent in boys than girls, with a ratio of 2.⁸⁵

Perspectives on the Causes of Developmental Coordination Disorder

There is no single explanation for the cause of DCD. Neurological dysfunction, physiological factors, genetic predisposition, and prenatal and perinatal birth factors have been proposed to explain the basis of DCD.^{99,102} It is recognized that DCD is heritable and is genetically distinct from attention-deficit/hyperactivity disorder (ADHD), although the comorbidity rate is up to 50%.²¹ Comorbidity is high with other diagnoses, including autism spectrum disorders,⁸⁸ as well as a variety of developmental learning problems such as math disability, reading disability, specific language disabilities, spelling and writing disabilities, and so on. Correlation has also been noted between pre-term infancy and low birth weight with characteristics of DCD. The heterogeneity of DCD makes finding a unitary cause difficult. Children with DCD present wide variability in both locus of specific problems and functional disabilities. Further complicating an understanding of the cause is that the intervention for the child with DCD is driven by competing treatments.¹⁰³

Few studies have been conducted to look at brain images in children with DCD, with no particular patterns of abnormality observed.⁹⁹ Hadders-Algra¹⁰⁴ has suggested that DCD is a result of damage at the cellular level in the neurotransmitter and receptor systems, rather than a specific region of the brain. Resulting coordination difficulties can be from a combination of one or more impairments in proprioception, motor programming, timing, or sequencing of muscle activity.

Possible physiological origins of motor coordination deficits have highlighted multisensory processing. Ayres,¹⁰⁵ in her theory of sensory integration, suggested that the integration among sensory systems is imperative for refined motor performance in children. She proposed that normal development depends on intrasensory integration, particularly from the somatosensory and vestibular systems. Lane¹⁰⁶ outlines the role of vision, combined with vestibular and proprioceptive inputs, as a foundation to motor performance. In combination, these systems sustain postural tone and equilibrium, provide awareness and coordination of head movements, and stabilize the eyes during movement in space.

More recently, Piek and Dyck¹⁰⁷ found support for the correlations between DCD and deficits in kinesthetic perception, visual-spatial processing, and multisensory integration.¹⁰⁷ In general, it is thought that reduced rates of processing information and deficits in handling spatial information may underlie the deficits in motor control.⁸⁸ Obviously more work is needed on the cause of DCD.

Subtypes of Developmental Coordination Disorder

Various approaches have been used to investigate subtypes of DCD, including classification by underlying causes, clinical and descriptive approaches, and statistical clustering.¹⁰⁸ Initial attempts at classifying subtypes within DCD support the heterogeneity of this group of children.¹⁰⁹ Work by Dewey and Kaplan¹¹⁰ suggests that children with DCD may be classified into subgroups based on distinctions in motor planning and motor execution deficits. They identified three subgroups: children who exhibited deficits in motor execution alone, those whose primary deficits were in motor planning, and children who exhibited a generalized impairment in both areas.

Macnab and colleagues¹¹¹ identified five different profiles of children with DCD. They used measures of kinesthetic acuity, gross

motor skill, static balance, visual perception, and visual motor integration. Two distinct groups emerged, with children exhibiting generalized visual deficits and generalized dysfunction in all areas. Generalized gross motor deficits did not emerge as a distinct subgroup, because the third group demonstrated a discrepancy between static balance and complex gross motor tasks, and the fourth group had poor performance on running but performed well on kinesthetic acuity. Other groups included children with deficits in visual motor and fine motor problems. These results suggest that a subtype based on motor execution or planning problems alone may be too general.

Diagnosis

A two-step approach to assessment using the Movement Assessment Battery for Children (M-ABC)¹¹² is the preferred standardized measure for motor impairment. The M-ABC checklist is used as a guide to examine the effects on daily living.⁸⁵ The M-ABC is the most widely used instrument and contains a standardized normative referenced test, plus a criterion-referenced test. The diagnosis of DCD is made for those scoring at or below the fifth percentile checklist.⁸⁵ The M-ABC consists of three subtests: manual dexterity, ball skills, and static and dynamic balance. Each subtest is given a score and totaled for an overall impairment score. A higher numerical score is indicative of a higher level of impairment.⁸²

DCD may co-occur with other disorders such as ADHD, dyslexia, and autism spectrum disorders. There is also evidence suggesting that one-third of children with speech and language impairment are likely to have DCD as well.⁸³ Because of the heterogeneous nature of the disorder, it is often underrecognized by health care professionals. In a survey of the physicians from Canada, the United States, and the United Kingdom, only 41% of pediatricians and 23% of general practitioners had knowledge of the condition. Furthermore, only 23% of the pediatricians and 9% of the general practitioners surveyed had ever diagnosed DCD.¹¹³ A systematic review involving school-aged children showed significantly greater odds of developing DCD among children who had very low birth weights (<1500 g) or were very preterm (<32 weeks) than among age-matched controls born at term with normal birth weights.¹¹³

Neurophysiology

There is no clear etiology for DCD; however, it is recognized as a central processing disorder.^{101,114–116} Some early studies have considered the neural mechanisms potentially implicated in DCD. However, the underlying neural processes remain unclear and the heterogeneous nature of the disorder further confounds attempts to find an underlying cause. The cerebellum is believed to be more implicated than peripheral mechanisms in the pathophysiological mechanisms of DCD.¹¹⁵ The behavioral manifestations of lack of postural control and lack of coordination suggest involvement of cerebellum, basal ganglia, and frontal and parietal lobes.¹⁰¹ The cerebellum might also be involved in the pathophysiology of DCD, because a disruption of the cerebellocerebral network has been given as an explanation for DCD.¹¹⁵ In skilled action, cerebellar and parietal areas process information and their outputs are integrated into one smooth movement. The posterior parietal cortex appears to also be involved with a faulty “feedforward mechanism” where the person cannot create an efference copy of a motor plan and thus has an “efference copy deficit.”¹¹⁵ The use of visual information sources in the guidance of goal-directed behavior was studied by de Oliveira and Wann¹¹⁷ through visual pursuits. The DCD subjects showed an impaired internal model with inadequate forward or predictive model of movement and difficulties in skilled movement when near and far visual information were present; therefore it is possible that integration of cerebellar and parietal areas was inadequate.¹¹⁷

Assessment of Motor Impairments

A variety of professionals may be involved in a comprehensive assessment of motor deficits. Pediatric OTs and PTs are often the core team assessing functional motor concerns. Areas assessed by pediatric OTs and PTs often overlap, so communication is essential to ensure that testing is not replicated. Ideally, performance will be evaluated in multiple environments and include components of skill, functional performance areas, and social and societal participation. Specific recommendations should include activities to enhance performance in the environments in which the child functions.

Clinical judgment of the therapist is important in designing an assessment protocol and synthesizing information to create a complete profile of the child. A variety of standardized and nonstandardized evaluation tools should accompany structured clinical observations and caretaker interviews. Observations of the child can yield more readily usable information than a standardized score,¹¹⁸ enabling the therapist to view the child in natural routines, self-directed activities, and unstructured play. The interview process is essential to gather information about the child’s interactions and participation. This process paints a verbal picture of the child to help us to understand levels of functioning and participation in a variety of environments. Other crucial information obtained is how the child’s difficulties are affecting the ability to parent or teach the student.¹¹⁸

Before choosing an evaluation tool the therapist should be aware of the intended purpose of this measure. Tools used to assess children with DCD are used for distinct purposes: identify impairments, describe severity of impairments, or explore activity or participation limitations.⁹¹ The choice of evaluations may also be determined by the setting, frame of reference of the therapist, and functional concerns of the child. A therapist should be familiar with all aspects of test administration and scoring for evaluation tools and should comply with the training requirements described in the test manual. Test construction, reliability, and validity for assessing DCD should be considered. [Appendix 12.A](#) provides an overview of standardized tests available for the assessment of motor dysfunction in children with learning disabilities. Uses and limitations of the individual tests and test batteries are listed.

Identification of subtle motor difficulties is critical and challenging. These subtle motor difficulties initially can be undetected, leading to unrealistic expectations of age-level motor performance. The child’s difficulty with skilled, purposeful manipulative tasks or with finely tuned balance activities may not be readily apparent in the classroom or may be perceived as lack of effort. Children with DCD may be able to perform certain motor tasks with a level of strength, flexibility, and coordination that is qualitatively average but must use increased effort and cognitive control for sustained success.

Levels of performance in gross and fine motor testing may fall in the borderline range. Careful observations are of paramount importance because the child’s deficits are often qualitative rather than quantitative. A child might have age-appropriate balance on testing but lack ability in weight shifting and making quick directional changes, which affects the ability to participate in extracurricular activities such as soccer or baseball. When assessing children with subtle motor deficits, it is important to realize that many evaluation tools have been developed for children with moderate to severe neurological impairments.

Children with DCD do not exhibit obvious evidence of neuropathological disease (i.e., “hard” neurological signs such as a cerebral lesion). Subtle abnormalities of the central nervous system are frequently noted by the presence of “soft” neurological signs. Deficits associated with soft neurological signs include abnormal movements and reflexes, sensory deficits, and coordination difficulties. Evaluation of soft neurological signs is typically part of an examination by a

BOX 12.2 Common Soft Neurological Signs Used in Assessment of Children With Learning Disabilities and Motor Deficits

Minor Neurological Indicators

Left-right discrimination
Finger agnosia
Visual tracking
Extinction of simultaneous stimuli
Choreiform movement
Tremor
Exaggerated associated movements
Reflex asymmetries

Coordination

Finger-to-nose touching
Sequential thumb-finger touching
Diadochokinesia
Heel to shin
Slow controlled motions
Postural-motor measures
Muscle tone
Schilder's arm extension posture
Standing with eyes closed (Romberg test)
Walking a line
Tandem walking (forward and backward)
Hopping, jumping, skipping
Ball throw and catch

Stereognosis
Localization of touch input

pediatric neurologist, although therapists can assess these areas in conjunction with standardized testing. Box 12.2 lists soft neurological signs frequently used to assess this population.

Researchers suggest that a high percentage of children with learning disabilities exhibit certain soft neurological signs. An early study reported that 75% of 2300 children with positive total “neurological soft sign” ratings had the symptom of poor coordination.¹¹⁹ More recently, 169 children aged 8 to 13 years were assessed for a relation between soft neurological signs and cognitive functioning, motor skills, and behavior. Those children with a high index for soft neurological signs were found to have significantly worse scores in each domain.¹²⁰ The relationship between neurological soft signs and DCD is difficult to validate without more current systematic research; however, they are indicators that intervention may be needed.¹²¹

In general, a composite of soft neurological signs is more predictive of dysfunction than single signs. Children without notable motor difficulties can frequently exhibit one or more soft signs; therefore identification of a single sign must be interpreted cautiously. Neurological signs involving complex processes were found to be the most predictive. The clinician needs to be familiar with typical developmental patterns, as certain soft neurological signs such as motor overflow, right-left confusion, visual tracking difficulties, and articulatory substitution are expected at younger ages and mature in quality over time.

Compiling a complete picture of motor deficits in children with learning disabilities involves assessing the following complex skills: (1) postural control and gross motor performance, (2) fine motor and visual motor performance, (3) sensory integration and sensory processing, (4) praxis and motor planning, and (5) physical fitness. Each of these interrelated functions is described in this chapter as an area of clinical assessment.

Postural Control and Gross Motor Performance

Muscle tone and strength. Low muscle tone and poor joint stability have been identified as characteristic of some children with learning disabilities. On observation, the child with low tone may look “floppy” and may have an open-mouth posture, lordotic back, sagging belly, and knees positioned closely together; muscles may be poorly defined and feel “mushy” or soft on palpation, and joints may be hyperextensible. A common method for assessing muscle tone and proximal joint stability involves placing the child in a quadruped position and observing the ability to maintain the position without locking of the elbows, winging of the scapula, or sagging (lordosis) of the trunk. The therapist can determine joint stability by asking the child to “freeze like a statue.” The therapist then provides intermittent pushes to the trunk, assessing the child’s ability to remain in a static position.

Children with low tone may develop patterns of compensation called *fixing patterns*. These patterns often include elevated and internally rotated shoulders, internally rotated hips, and pronated feet. The child compensates for low tone by using the stable joint positions and holding himself or herself stiffly for increased stability. These patterns may resemble those of children with slightly increased tone. Careful observation and palpation of muscles will help to differentiate fixing patterns from increased muscle tone. Judgments of muscle tone are primarily made through clinical observations and felt in a hands-on assessment.

Manual muscle testing can provide detailed information about impairment in strength of individual muscles but is not regularly used in assessing children with learning disabilities, unless concerns of a possible degenerative disease exist. More appropriately, the child’s functional ability should assess strength to move against gravity during activities. Within developmental assessments, the therapist is observing range of motion against gravity in skills such as reaching, climbing, throwing, and kicking. The therapist also can have the child hold positions against gravity to assess strength and endurance (e.g., prone extension and supine flexion).

Early postural reflexes. Early reflexes are essential for the development of normal patterns of motor development. These reflexes facilitate movement patterns that become integrated into purposeful motions. If they are not fully integrated, qualitative differences in muscle tone, postural asymmetries, transitional movement patterns, bilateral coordination, and smooth timing and sequencing of motor tasks may be observed. Residual reactions (e.g., asymmetrical tonic neck reflex [ATNR] and symmetrical tonic neck reflex [STNR]) that might be noted in children with DCD are subtle and most often are seen in stressful, nonautomatic tasks. McPhillips and Sheehy looked at incidence of primitive reflex patterns and motor coordination difficulties in children with reading disorders.¹²² The group with the lowest reading scores had a significantly higher rate of ATNR and motor impairments when compared with good readers. Assessment for persistence of primitive reflex patterns in children with learning disabilities should emphasize impact on functional aspects of performance.

The effect of lack of integration can be observed during tasks such as writing at a table or gross motor activities such as using ball skills and jumping rope. Persistence of these primitive reflexes may be seen in the child’s inability to sit straight forward at the table. The ATNR

influence might be observed by a sideways position at the table with the arm on the face side used in extension. During ball games the child may have diminished ability to throw with directional control because head movements will influence extension of the face-side arm. If the STNR is not fully integrated the child is often unable to flex the legs while sitting at a desk looking down at his or her work (neck flexion). Although residual reflex involvement may affect performance of these tasks, many other components are involved that require consideration.

Righting, equilibrium, and balance. Righting and equilibrium are dynamic reactions essential for the development of upright posture and smooth transitional movements. Righting reactions help to maintain the head in an upright alignment during movement in all directions. Equilibrium reactions occur in response to a change in body position or surface support to maintain body alignment. In simpler terms, equilibrium reactions get us into a position, and righting reactions keep us in that position. Together these reactions provide continuous automatic adjustments that maintain the center of gravity over the base of support and keep the head in an upright position.

Righting and equilibrium reactions are best assessed on an unsteady surface such as a tilt board or large therapy ball. These reactions occur in all developmental positions, and complete assessment will consider a range of positions during functional performance in gross and fine motor activities. To test equilibrium, the child's center of gravity is quickly tipped off balance. The equilibrium response is one of phasic extension and abduction of the downhill limbs for protection and of flexion of the uphill body side for realignment. In daily actions, most of the righting reactions are subtle and occur continuously to slight changes in body position. Subtle shifts of the support surface can be made to assess the child's ability to maintain the head and trunk in a continuous upright position. Righting and equilibrium reactions are the basis for functional balance and postural control.

To balance effectively, we use visual information (about the body and external environment), proprioceptive information (about limb and body position), and vestibular information (about head position and movement) to initiate an appropriate corrective response.¹²³ Balance reactions occur as a response to changes in the center of gravity that stimulate the vestibular receptors (utricle and semicircular canals). This stimulation causes muscles to activate, allowing balance to be maintained in static and dynamic activities (e.g., sitting in a chair, walking, standing on a bus). When the vestibular system works in conjunction with vision and information from the muscles (proprioception), balance is easier and more refined. Considering the impact of these sensory systems working together is important during assessment. The therapist should test the child's balance with the child's eyes open and closed and observe differences in ease and quality of performance. Standing with eyes closed relies more on vestibular and proprioceptive input, and difficulty may indicate that the child depends heavily on the visual system for balance. To further assess this sensory interaction, balance should also be observed on steady and unsteady surfaces (e.g., dense foam or a tilt board) with and without visual orientation. Traditional tests of balance include (1) the Romberg position—standing with feet together and eyes closed, (2) Mann position—standing with feet in tandem with eyes closed, and (3) standing on one leg with eyes open and eyes closed.

Postural control. Postural control is dependent on muscle tone, strength, and endurance of the trunk musculature, as well as automatic postural reactions required to maintain a dynamic upright position. A child has adequate postural control when he or she can maintain upright positions, shift weight in all directions, rotate, and move smoothly between positions. These areas are often deficient in children with DCD, affecting both gross and fine motor performance.

The child may fatigue quickly and fall often during gross motor play. Other body parts may be used for additional support because of weak postural musculature—for example, placing the head on the ground when crawling up an incline or sticking out the tongue when climbing or pumping a swing. In sitting, a child with diminished postural control will fatigue quickly, either leaning on his or her hands for additional support or moving frequently in and out of the chair. These compensations affect the child's ability to perform fine motor tasks or maintain attention for cognitive learning because so much effort is exerted on sitting up. Observing the effects of fatigue is important because both sitting and standing postures may deteriorate over the course of a day. The problem stems from motor programming problems versus muscle power.

Gross motor skills. *Gross motor coordination* refers to motor behaviors related to posture and locomotion, from early developmental milestones to finely tuned balance. Children with learning disabilities and DCD may attain high degrees of motor skill in specific activities. Motor accomplishments frequently remain highly specific to motor sequences or tasks and do not necessarily generalize to other activities, regardless of their similarities. When variation in the motor response is required, the response often becomes inaccurate and disorganized.

Although children with DCD can sit, stand, and walk with apparent ease, they may be awkward or slow in rolling, transitioning to standing, running, hopping, and climbing. Skilled tasks such as skipping may be accomplished with increased effort, decreased sequencing and endurance, and associated movements.

Evaluation of gross motor skills should include both novel motor activities and age-appropriate skills. For example, the child can be asked to imitate a hopping sequence or maneuver around a variety of obstacles. Skills that have been accomplished can be varied slightly (e.g., hopping over a small box). Age-appropriate social participation tasks, such as tag and dodge ball, can be observed for qualitative difficulties in timing and spatial body awareness. Developmentally earlier skills also should be observed to assess the quality of performance. *Bruininks-Oseretsky Test of Motor Proficiency, Second Edition (BOT-2)*¹²⁴ and the *Peabody Developmental Motor Scales*¹²⁵ are examples of tools for standardized assessment of gross motor skills (see [Appendix 12.A](#)).

Coordination Deficits

Three subtypes of DCD have been identified: ideomotor, visual-spatial and constructional, and mixed dyspraxia.¹⁰¹ The principal areas of impairment of the three subtypes were digital perception, imitations of gestures, digital praxis, Lego blocks, visual spatial structuration, visual motor integration, and coordination between upper and lower limbs. The accuracy of goal-directed movements, motor organization, and control of motor actions has been studied.^{101,117} Individuals with and without DCD do not differ in their ability to engage in motor imagery, and evidence suggests both groups used motor imagery (as opposed to visual imagery) because performance was better in simple rotations.¹¹⁷

O'Brien and colleagues¹¹⁶ examined the mechanisms underlying motor coordination in children with DCD. The processing of visual, auditory, and vibrotactile information was explored in children 6 to 7 years and 9 to 10 years with and without DCD. Because motor deficits of children with DCD include poor balance and postural control, difficulty with eye-hand coordination, longer movement times, and problems with sequencing, the authors studied patterns of choice RT to analyze the speed in which children process input and initiate a response. Thirty-six children were matched in the study (20 control and 16 with DCD), and their RT was analyzed to see the differences between spatially compatible and spatially incompatible RTs using the anatomical

and spatiotemporal mapping hypotheses. Spatial compatibility refers to conditions in which the location of the stimulus corresponds with the location of the response (i.e., same side), and spatially incompatible conditions are those in which the stimulus and expected response are in opposite sides.¹¹⁶ According to the anatomical mapping theory, ipsilateral responses should be faster than contralateral responses because they do not require transfer of information to the opposite hemisphere. The spatiotemporal mapping refers to the spatial relationship between the stimulus and the response; thus the RT would be shorter when the stimulus is in spatial proximity to the response.¹¹⁶ In the experiment, the children were asked to depress a switch with the index finger of each hand to respond as soon as they saw, felt, or heard a visual, auditory, or vibrotactile stimulus presented in blocked schedules of 15 trials under each condition. The authors found no differences between the group of 8- to 10-year-old children (with and without DCD) under the compatible or incompatible conditions. However, the 6- to 7-year-old children with DCD had significantly longer RTs than their counterparts without DCD under incompatible conditions. Overall, RTs for children with DCD were slower than were those of their peers without DCD under all sensory conditions (visual, auditory, and vibrotactile). In this study, the spatiotemporal mapping theory gained support as the primary mechanism children use when responding to simple visual, auditory, and vibrotactile input.¹¹⁶

Visuospatial Deficits

Children with DCD tend to rely more on visual than on proprioceptive information in organizing responses and often fail to anticipate or use perceptual information in preparing responses.¹¹⁶ Because DCD is a prominent motor function and visuospatial disorder, several studies have adopted the hypothesis that the basal ganglia, the parietal lobe, and the cerebellum may be implicated in its pathogenesis.^{101,115,117} Children with DCD have been found to respond slower in visuospatial cueing tasks than children in control groups. Wang and colleagues¹²⁶ found that children with DCD, as compared with typically developing children, exhibited slower RTs when responding to spatially cued targets, suggesting that a dysfunctional corpus callosum may be the cause of DCD.

The mechanisms underlying the deficit in visuospatial working memory (VSWM), a higher-order skill related to the ability to allocate attentional resources despite distraction or interference, have been investigated. Electrophysiology was used to compare brain activity while performing a VSWM task in children with DCD and typically developing children, resulting in children with DCD exhibiting weaknesses in VSWM.¹⁰¹ These results suggest that the component associated with resource allocation for attention and memory tasks showed smaller amplitude in the children with DCD, thus possibly explaining the longer processing time for information.¹⁰¹

Fine Motor and Visual Motor Performance

Fine motor skills. Fine motor coordination involves motor behavior such as discrete finger movements, manipulation, and eye-hand coordination. A child with DCD often demonstrates multiple fine motor concerns. Areas of difficulty typically include grasp and manipulation of small objects and dexterous hand skills, such as buttoning or putting coins into a vending machine. Assessment should include both standardized assessments and structured observations of functional performance.

A complete fine motor assessment should include observations of proximal trunk control to distal finger movements. Trunk control and shoulder stability affect the accuracy and control of reaching patterns and create a stable base from which both hands can be used to perform bilateral skills. The assessment of distal control considers wrist stability, development of hand arches, and separation of the two sides of the

hand, all providing a foundation for the control of distal movement. Qualitative observations of distal fingertip control include finger motions to move objects into and out of the palm of the hand and rotate an object within the hand.

Although standardized assessments such as BOT-2¹²⁴ and the *Peabody Developmental Motor Scales*¹²⁵ have fine motor sections, they do not measure manipulative components described previously. Combining qualitative observations during a variety of fine motor tasks with knowledge of typical development is important. Soft neurological signs, including diadochokinesia (rapid alternation of forearm supination and pronation), sequential thumb-to-finger touching, and stereognosis (identifying objects and shapes without visual input) can provide further qualitative information.

Eye-hand coordination, visual motor integration. Eye-hand coordination is the ability to use the eyes and hands together to guide reaching, grasping, and release of objects. This can include larger motions such as catching and throwing a ball to more refined tasks such as putting pennies in a bank or buttoning a shirt. Coordination of the eyes and the feet (eye-foot coordination) is important for skills such as ascending and descending stairs and kicking a ball. Children with DCD often exhibit difficulties in one or more of these areas. Qualitatively, they demonstrate poor coordination in the timing and sequencing of their actions. Evaluations such as BOT-2¹²⁴ and the Movement ABC¹¹² have subtests that assess eye-hand coordination in a standardized way. Supplemental clinical observations include the assessment of ball skills, fine motor tasks such as stringing beads and building block towers, and written accuracy tasks of drawing or coloring within a boundary.

Visual motor tasks involve the ability to reproduce shapes, figures, or other visual stimuli in written form. This skill is multidimensional, involving perceiving a visual image, remembering it, and integrating it to a written response. Visual motor integration is the foundational skill needed for handwriting. In addition, handwriting involves combination of fine motor control, motor planning, and sensory feedback to be accurate and legible. Children who have difficulties with handwriting commonly produce sloppy work with incorrect letter formations or reversals, inconsistent size and height of letters, variable slant, and irregular spacing between words and letters.

Assessment of visual motor skills can be completed through standardized measures such as the *Developmental Test of Visual Motor Integration* (BEERY VMI, Sixth Revision) or the *Motor-Free Visual Perception Test*, fourth edition.

The production of handwritten work can be assessed by using the Evaluation Tool of Children's Handwriting (ETCH),¹²⁷ the *Minnesota Handwriting Assessment* (MHA), and Handwriting Without Tears: The Print Tool.¹²⁸ Handwriting and drawing samples provide valuable information regarding functional abilities in written production.

Sensory Processing

It has been proposed that the term *sensory processing* be used for the assessment and diagnosis of sensory challenges impairing daily routines.¹²⁹ The process begins with *registration* or recognition of incoming sensory input ("What is it?"). The incoming information is quickly scanned for relevance in a process called *sensory modulation* ("Is it important?"). Sensory modulation determines the appropriate action for a situation and regulates arousal. Our system needs to respond strongly and quickly if our hand moves near a hot stove but should not respond as strongly if we are unexpectedly bumped. *Discrimination* of sensory input involves discerning subtle differences in sensation to learn about the qualities of objects and refine body movements within space. When we are receiving clear information

from our sensory receptors, we can understand and label what is happening (e.g., sour-sweet, hot-cold, soft-firm, heavy-light, up-down, fast-slow). Efficient sensory registration, modulation, and discrimination result in organized social and motor behavior.

Children with DCD often experience sensory processing difficulties. Diminished registration of sensation can result in poor body and environmental awareness, low arousal levels, and delayed postural reactions and motor coordination. These children may be sedentary or seek out strong sensation. *Sensory modulation* difficulties manifest primarily in emotional and behavioral responses. Behaviors often include oversensitivity, with aversive or exaggerated responses to sensation. These children struggle to remain regulated during typical daily events and may avoid uncomfortable sensations, demonstrate behavioral disorganization, seek strong, potentially unsafe input, become aggressive, or have tantrums. They often have difficulty performing in situations involving integration of multiple inputs (e.g., cafeteria, gym class, playground, team sports). Sensitivity to movement input can also cause the child to avoid playground equipment or become nauseated during car rides. Delayed *sensory discrimination* typically results in poor body awareness that may underlie qualitative motor difficulties observed in children with DCD. They often exhibit poor motor coordination and planning, deficient safety awareness, and poor grading of force, as well as timing and sequencing difficulties. These children may avoid complex motor challenges, team sports, and playground activities. Discrimination difficulties can also affect the acquisition of prepositional concepts (up, down, left, right, in front of, behind, next to). The child who has difficulty discriminating information from the body typically exhibits deficits in skilled actions involving balance, timing movements in space, bilateral and eye-hand coordination, fine motor control, and handwriting.

Clinical observation of a child's responses to a variety of sensory inputs and the ability to organize multiple inputs provides essential information regarding the integration of sensory input. Sensory modulation dysfunction is not easily identified with standardized, skill-based measures because of its physiological basis. Caregiver questionnaires, such as the Sensory Processing Measure^{130,131} and the Sensory Profile,^{132,133} can provide valuable information on modulation and regulation. Other tests, such as BOT-2¹²⁴ and the Movement ABC-2,¹¹² can provide qualitative observations in addition to quantitative measures of motor skill.

Gross and fine motor tasks that involve postural and ocular responses, bilateral motor coordination, planning, and sequencing reflect efficient sensory processing. Soft neurological signs, coupled with observations of play (e.g., playground, gym class, recess), can provide qualitative information on sensory discrimination and planning. The *Clinical Observations of Motor and Postural Skills* (COMPS) assessment tool¹³⁴ is a set of six standardized clinical observations and soft signs that can be useful in identifying motor deficit with a postural component.

Praxis and Motor Planning

Praxis involves the ability to plan and carry out a new or unusual action when adequate cognitive and motor skills are present. The components of praxis include *ideation* or generating an idea of how one might act in the environment, *planning* or organizing a program of action, and *execution* of the action sequence. Motor planning involves the same components relative to a novel motor task.

Children with praxis difficulties, or dyspraxia, may exhibit a paucity of ideas. The child may enter a room filled with toys or equipment and have limited capacity to experiment and play. Other children with dyspraxia may move from one activity to the next without generating effective plans for participating in or completing tasks. Lack of

variation and adaptation in play can be another indication of planning problems. Observations of typically developing children show continuous modifications in play, with spontaneous adaptations to motor sequences, making explorations varied and increasingly successful. Children with dyspraxia often have difficulties in situations characterized by changing demands, such as unstructured group play. Transitions also may be difficult because they involve the creation or adaptation of a plan. Frustration and difficulties with peer interactions frequently are part of the composite.

Observations of motor planning deficits may include trouble figuring out new motor activities, disorganized approaches, resistance, or inability to vary performance when a task is not successful, and awkward motor execution. Poor planning abilities can lead to the child being adult dependent, hesitant, or resistant to trying new activities. At times, children with dyspraxia also may exhibit poor anticipation of their actions. They can quickly engage in play with the equipment but demonstrate little regard for safety (e.g., kicking a large ball across the room where other children are playing). Movements are often performed with an excessive expenditure of energy and with inaccurate judgment of the required force, tempo, and amplitude.¹³⁵ Such children typically require more practice and repetition to master more complex, sequential movements. Frequently, children with planning problems recognize the differences between their performance and that of other children the same age, which significantly affects their self-esteem.

Manifestations of poor motor planning ability are apparent in many daily tasks. Dressing is often difficult. Children are not able to plan where or how to move their limbs to put on clothes. Problems are often demonstrated in constructive manipulatory play, such as building with toys, cutting, and pasting. Similarly, learning how to use utensils, such as a knife, fork, pencil, or scissors, is difficult. The child with dyspraxia often also has problems with handwriting.

Clinical observations can add valuable information regarding the child's ability to see the potential for action, organize and sequence motor actions for success, and anticipate the outcome of an action.

Physical Fitness

Physical fitness involves a person's ability to perform physical activities that require aerobic fitness, endurance, strength, or flexibility. Factors influencing fitness include motor competency, frequency of exercise, physical health, and genetically inherited ability. Physical fitness can encompass health-related and skill-related fitness.¹³⁶ Cardiorespiratory endurance, muscular strength and endurance, flexibility, and body composition are components of health-related fitness and important to monitor. Agility, speed, and power are the skill-related fitness components and are needed for the acquisition of motor skills and sports and recreational activities.¹³⁷

Children with DCD often have performance difficulties in games and athletic activities. They are often less active than typical peers and withdraw from physical activity. As a result, the level of physical fitness, strength, muscular endurance, flexibility, and cardiorespiratory endurance may be poorly developed. Hands and Larkin¹³⁶ found that body mass index (BMI) in children with motor difficulties was higher than in a control group of typical peers.¹³⁶ The percentage of overweight and obese 10- to 12-year-olds was found to be significantly higher in a DCD group than in typically developing peers.¹³⁸ This increased weight may further increase their movement difficulties.

In a study of 52 children aged 5 to 8 years with DCD, Hands and Larkin¹³⁶ revealed significantly lower scores on tests for cardiorespiratory endurance, flexibility, abdominal strength, speed, and power than the age- and gender-matched controls. Another study of 261 children aged 4 to 12 years found similar disparities for children with DCD,

with poor performance in fitness tests, with the exception of flexibility.¹³⁸ These disparities in fitness were found to increase with age between the two groups.¹³⁸

One task of the PT is to differentiate between poor physical fitness resulting from low motor activity as opposed to problems of low muscle tone, joint limitations, decreased strength, and reduced endurance. The low motor activity is a neurological sign and leads to a developmental lag or deviation in motor function. Collaboration among the physical educator, the adaptive physical educator, and the PT is critical. The President's Challenge is a physical fitness test administered twice a year in schools across the country. Children complete five events that assess their level of physical fitness in strength, speed, endurance, and flexibility. The test was founded in 1956 by Dwight Eisenhower to encourage American children to be healthy and active, after a study indicating that American youths are less physically fit than European children.¹³⁹ Standardized assessments of gross motor functioning, such as BOT-2,¹²⁴ that assess strength, speed, and endurance can provide information related to a child's fitness level.

INTERVENTION FOR THE CHILD WITH LEARNING DISABILITIES AND MOTOR DEFICITS OR DEVELOPMENTAL COORDINATION DISORDER

Creating an Intervention Plan

Using the information gathered throughout the assessment process, the therapist synthesizes areas of strength and weakness to develop an intervention plan. If impairments, activity limitations, and participation restrictions exist that affect the child's successful performance, intervention may be warranted. For example, children with DCD might demonstrate impairments in coordination or balance that underlie activity limitations in catching or throwing a ball, which create participation restrictions in playing baseball with peers.¹⁴⁰ Determining the child's functional difficulties and identifying the severity of the impairment will be important to justify service and guide the service delivery model and type of intervention. For children with DCD who have greater impairment and activity limitations, individualized treatment may be more beneficial, whereas those with less involvement may thrive with group intervention.¹⁴¹

Interpreting test data, integrating findings, identifying functional limitations, and creating goals is a complex process. Initial impressions of the child's areas of difficulty may result in the recommendation for further examination before outlining refined goals relevant to functional performance. Collecting additional assessment information may involve observations in other environments or during functional daily tasks, and/or formal testing. The end product is the creation of statements that delineate the type and quality of behavior desired as a result of remediation. In other words, the therapist must set treatment goals to be achieved through intervention.

Setting goals for the child with learning disabilities with motor deficits must be done by considering a variety of factors:

1. Referral information and age of the child
2. Medical, developmental, and sensory processing history
3. Parents' and teachers' perception of the child's strengths and concerns about functional impairments
4. Educational information
 - a. Major difficulties experienced in school
 - b. How motor problems are interfering with the child's daily participation
 - c. Current services being received
5. Child's peer relationships, play and leisure activities, and self-esteem

6. Therapists' observations and assessment of the child through informal and formal evaluation, both standardized and nonstandardized

7. Functional expectations and abilities at home and school

Goals for the child should be stated in terms of long-term and short-term objectives. Goal setting ideally involves establishing specific, measurable, attainable, realistic, and time-targeted objectives. Short-term objectives are generally composed of three parts: (1) the *behavioral statement* is what will be accomplished by the child; (2) the *condition statement* provides details regarding how the skill or behavior will be accomplished; and (3) the *performance statement* denotes how the skill or behavior will be measured for success. The most important consideration is ensuring that the goals and objectives chosen are relevant to the child's functional daily performance and are meaningful to the team, including the family, working with the child. [Case Study 12.2](#) provides an example of functional objectives.

Models of Intervention

Improvements in motor deficits can be achieved through a variety of models of intervention, both indirect and direct. Indirect intervention involves working with key people in the child's life to help them facilitate the child's delineated goals. An indirect model can occur through consultation, specialized instruction, and coaching. Direct intervention involves the therapist working directly with the child on specific goal areas or skills.

Mild deficits, subtly affecting participation in activities, may be addressed through a consultative (indirect) approach. This model of service provision incorporates the use of another team member's expertise to be responsible for the outcome of the child.^{80,142} The therapist may suggest environmental or task adaptations to facilitate more successful participation. Consultation with parents would be appropriate for the goal of riding a bicycle without training wheels. Parents may not understand the complexity of the task and may be focused only on the end product, which can cause frustration for all involved. To facilitate confidence and success, the therapist might recommend environmental modifications such as beginning on an open stretch of grass or dirt, with no other people around to decrease the child's anxiety. Breaking the task down into incremental steps for the parent and child (i.e., practicing getting on and off bike, balancing on still bike, gliding, braking, steering, pedaling) can allow success at each step.

Within a school setting, environmental adaptations might include changing the height or position of the desk or decreasing extraneous visual and auditory distracters. Task accommodations could include using a special grip to facilitate more refined pencil grasp or allowing more time for written work. In these instances, the teacher would be responsible for carrying out the program and determining its effectiveness. Communication between the therapist and teacher encourages problem solving and changing action plans over time. Kemis and Dunn¹⁴³ demonstrated positive outcomes on a variety of functional classroom goals when an OT and teacher met weekly throughout the school year in what they called a "collaborative consultation approach." Using this model, they achieved 63% (134 of 213) of their outlined goals. This collaborative effort supports the shared responsibility for identifying the problem or weakness of the child, creating practical solutions, implementing the intervention as the solution, and altering the plan as necessary for increased effectiveness.⁸⁰

Another model of indirect therapy involves teaching members of the team to implement treatment strategies. Specialized instruction or coaching allows the therapist to support a child within the natural environment by working with care providers who are with the child every day. The aim is to educate key people in the child's life to coach the child within the context of teachable moments.¹⁴⁴ These moments,

CASE STUDY 12.2 Jaiden

History: Jaiden is an 8-year-old child who emigrated from Russia 2 years ago and receives English as second language and small group academic instruction. He currently attends the third grade in a regular education classroom. Jaiden has a diagnosis of attention-deficit/hyperactivity disorder (ADHD) and secondary diagnoses of specific developmental reading disorder, low muscle tone, mixed receptive/expressive language disorder, fine motor impairment, and lack of coordination. Jaiden expressed that his least favorite class is gym. He also refuses to participate in after-school sports, as per his classroom teacher.

Examination: During classroom observation, Jaiden was engaged in completing previously assigned coursework. He interacted with a peer sitting next to him and would frequently be inattentive to the work to be completed. He required significant prompting and constantly adjusted his posture or stood when asked to complete seated work. Jaiden is reported to be very active, miss oral directions, and appears not to hear when called by name. He also has difficulty functioning if there is noise nearby. In addition, Jaiden is reported to come too close to peers when talking and tends to touch people and objects around him. His behavioral observations indicate that he is inefficient in his approach to tasks, takes long to complete tasks, and makes tasks more complicated than needed. He also seems more curious than other students as per his classroom teacher.

The administration of the Children's Assessment of Participation and Enjoyment (CAPE) was attempted to assess Jaiden's interest in various activities, more specifically to guide instruction and intervention. Although he was presented with cards visually representing the various activities (alone and with others, indoors-outdoors), he was not able to complete the standardized assessment because he often changed topics and had difficulty returning to task. His habit of inadvertently changing his focus of attention and conversation is observed to sometimes interfere with every day activities and may contribute to his difficulties with learning, behavior, discipline, and sustaining positive social participation.

Body Awareness/Proprioceptive Processing: Jaiden displayed difficulty with symmetrical and asymmetrical upper extremity positioning even when given verbal cues and a demonstration. Jaiden also displayed poor task approach and motor sequencing.

Fine Motor Skills: Jaiden is right-hand dominant and used an atypical grasp with this index finger wrapped on the pencil and his thumb in hyperextension. Jaiden requires adaptations and a pencil grip for writing assignments. His upper extremity range of motion was within normal limits, and his muscle tone was low throughout his body. Jaiden's sitting posture was functional. Jaiden stabilized adequately using his left hand when necessary. As observed through activities, he was able to cross midline, use both hands simultaneously, and transfer objects from one hand to another. Typical development of grasp was observed, with intact and voluntary release, intact in-hand manipulation, and accurate reaching for objects. Proprioception, or the sense of body in space, was adequate for grasp and release. Tactile input, the sensation of touch, was observed within normal limits.

Visual Perceptual Skills: Jaiden's skills of visual tracking, visual regard, spatial relations, and figure ground are intact. Jaiden is able to distinguish right

from left on body and understand basic directional terms. Jaiden had difficulty copying complex forms/shapes such as a star or overlapping forms. He also wrote his letters of his name out of sequence, J A I D N E.

Written Work: Jaiden was able to identify starting and stopping points on paper. He was able to print in designated spaces and work from left to right. Jaiden's writing is legible, but he has difficulty adhering to the writing line, his letters rest above the line, or he does not form descending letters below the line. Jaiden has difficulty with letter formation especially letters that involve diagonal strokes such as "x" or "y." He also reversed letter "q" and wrote his name out of sequence. Jaiden had difficulty reading the sentence he was asked to copy. As per school records, his reading level is below the first grade level.

When determining appropriate behavioral objectives for Jaiden, looking at the areas of functional relevance such as pleasure and safety in gross motor play, peer interactions, and independence in age-appropriate activities of daily living is critical. These areas of concern for Jaiden were consistent with those of his parents. His parents wanted him to feel more competent and less frustrated in play, at home, and at school.

One of the long-term goals was *improve Jaiden's planning and coordination abilities to increase his confidence and success in gross motor activities*

Jaiden was interested in learning to ride a bicycle, and his parents were hopeful that he could become more confident at the neighborhood playground. These objectives would measure the development of improved proficiency in discrimination of his body in space, postural control balance reactions, and motor planning. The following objectives were written:

1. Jaiden will independently climb the ladder and come down the slide without exhibiting fear, bumping into other children, or falling.
2. Jaiden will develop the ability to ride his bicycle without training wheels in straight lines and will learn to turn corners.

To address improvement in independence for self-care:

1. Jaiden will put on his coat independently in correct orientation and successfully zip it 4 out of 5 times.
2. Jaiden will successfully tie his shoes without assistance in a timely manner.

To address greater success in peer interactions:

1. Jaiden will participate in a structured game, following the rules, for 10 min.
2. Jaiden will play outside with the children in the neighborhood without conflict for at least 1 hour.

The OT believed that through remediation of sensory discrimination and motor deficits Jaiden could develop improved motor competence and planning abilities. This would lead to greater success in peer interactions and improved feelings of self-confidence.

If the OT or PT is working as a member of a team within the school, behavioral objectives will have implications for the child's performance in the school environment. Within the school system, statements of goals and specific objectives are included in the Individualized Educational Plan (IEP). Other areas related to gross and fine motor skills and peer interactions also were influential to Jaiden's success at school. Specific objectives written pertaining to school would have functional outcome measures chosen from tasks within the school environment such as gym class, playground interactions, and classroom expectations.

when a child is interested and working on acquiring a new skill, occur throughout the day and in many different environments.¹⁴⁵ This allows for therapeutic consistency and repeated practice, thereby increasing the chances for skill acquisition within the context of daily routines.

With this model, the therapist observes children and adults doing familiar routines and collaborates with the adults to enhance those routines in varied environments.¹⁴⁶ When implementing an intervention

strategy, the therapist might teach another adult to guide specific, developmentally appropriate skill sets with the child or problem solve to create strategies for greater success. Over time, parents and other caregivers are empowered to look at a toy, an activity, or an experience and find ways to adapt it to increase successful involvement and skill development. Successful coaching can enhance parent-child relationships indirectly by helping parents to feel more comfortable and competent in their abilities to meet their child's needs.¹⁴⁷

Direct intervention involves designing individualized treatment plans and carrying them out with the child individually or in a small group. This approach can focus on developing the foundations that underlie motor performance such as sensory processing, postural control, and motor planning. Specific skills, such as shoe tying or bike riding, can be practiced with the therapist as well, breaking these tasks down into component skills. Through combining approaches, adapting methods over the course of therapy, and responding to the changing needs of the child over time, progress is achieved more effectively.¹⁰³ Best practice dictates that direct therapy should always be provided in conjunction with one of the other service models to ensure generalization of skills to natural settings.⁸⁰ Without the use of other models, therapists cannot be confident that changes observed in the isolated setting are affecting the child's overall performance.

Intervention Approaches

According to the *International Classification of Functioning, Disability and Health* (ICF),¹⁴⁸ interventions should be directed toward several distinct goals:

- To remediate impairment
- To reduce activity limitations
- To improve participation

Two intervention approaches—bottom up and top down—have been developed. When using a bottom-up approach, therapy focuses on the missing or faulty underlying performance skills and client factors that prevent movement skills such as sensory-motor or perceptual motor techniques relying on the visual system. In contrast, a top-down approach focuses on specific performance by providing practice or problem-solving conditions in a variety of contexts. Cognitive motor refers to conditions where the child must identify a specific motor problem or problem solving where the child must evaluate the feasibility of the task.¹¹⁴ The top-down approach or functional skill training based on the dynamical systems theory has gained acceptance as more successful when taking into account contextual and environmental factors and use a motor learning approach at the level of the task. Task specific in a meaningful environment. Interventions should directly target the person's ability to transfer and generalize new skills. Some key elements of the top-down approach include practice of the skills, practice in variable environments and contexts, and consistent provision of feedback.¹⁴⁹

Interventions focused on treating at the ICF level of remediating impairments generally target the improvement of processing abilities (e.g., visual, proprioceptive, and vestibular) or performance components (e.g., balance and strength). The tenet is that by strengthening these foundational skills the child will develop greater success in appropriate activities and participation. This type of intervention is referred to as a “bottom-up” approach and is based on neuromaturation or hierarchical theories.

Intervention focuses on increasing the child's ability to take part in the typical activities of childhood.⁹¹ These treatment methods assume that skill acquisition emerges from interaction among the child, the task, and the environment.¹⁰³ Intervention is contextually based, occurring in everyday situations and focusing on the activities and tasks inherent to that situation. Problem solving, preparatory activities, and skill training may be used together to increase successful participation. This type of approach may minimize the challenges of learning new skills for a child who cannot easily generalize learning to new situations.

The intervention methods presented in this chapter for remediation of motor deficits in the child with learning disabilities include motor learning approaches (e.g., cognitive orientation to daily occupational performance [CO-OP])¹⁵⁰; sensorimotor treatment techniques; motor skill training approaches (e.g., ecological intervention¹⁵¹); and

physical fitness. None are mutually exclusive, and each requires a level of training and practice for competence, as well as experience in normal development. Most therapists synthesize information from different intervention techniques and use an eclectic approach, pulling relevant pieces from a variety of intervention modalities to best meet the needs of each child.

Therapeutic interventions to improve general coordination usually result in small gains. The main reason is because therapy lacks scientific foundation as the etiology of DCD is unknown.^{85,114} The relevance of research into the underlying causes of DCD is important for designing therapeutic treatment and to advance current knowledge about movement coordination. Most ADLs involve the coordinated use of visual information that is gathered before and during the execution of actions.

Children with DCD experience motor difficulties in a broad range of ADLs, such as mobility, personal hygiene, feeding, and dressing; handwriting and crafting; ball skills; and riding a bike.¹⁵² The five most common interventions cited in the literature are those designed to facilitate self-care tasks, task-specific approaches, interventions aimed at facilitating play, the CO-OP, and motor learning theories.¹⁵³ The ICF, the universal framework for health-related conditions, defines ADL as functional motor activities that are performed during daily life, “self-care and self-maintenance,” “productivity and schoolwork,” and “leisure and play.”¹⁵² A systematic review divided intervention into four categories: task-oriented intervention; traditional occupational therapy or physical therapy; process-oriented therapies; and chemical supplements.⁸³ The task-oriented interventions were aimed at learning specific motor skills that are particularly difficult for the child, and the process-oriented therapies focused on more global functions (e.g., sensory integration or visual-motor perception).¹⁵⁴ The largest effect sizes were shown for task-oriented interventions and for occupational or physical therapy with only a weak effect for process-oriented approaches. Therefore a referral to an OT or a PT to focus treatment on performing everyday tasks is recommended.⁸⁵ Although there is no conclusive evidence of which intervention is better, a metaanalysis¹⁵⁵ found that top-down approaches seem more efficacious than bottom-up and that home programs are superior to one-one interventions. Lastly, interventions that allow for more practice, occurring 3 to 5 times per week, yield better outcomes than intervention occurring less often. From motor learning research, there are three principles arise: practice distribution, feedback, and goal setting. Practice is the most important principle, and massed practice is best during initial stage of learning. Children should receive extensive repetition and practice of the same skill until achieving a rudimentary level of mastery and followed by a varied practice schedule knowing that mastery of skill may take longer in children with DCD. Positive feedback should be specific to allow the child to correct errors and encourage practice. Feedback should be immediate at first attempts of the skill and gradually faded to encourage the child's independence. Finally, goals must be small, progressive, and achievable to provide the child a sense of competency.¹¹⁴

The CO-OP measure is a client-centered approach that focuses on (1) skill acquisition, (2) cognitive strategy development and discovery of domain-specific strategies for problem solving, and (3) generalization and transfer where the child can use the skills and strategies for other daily tasks.¹⁵⁵ The CO-OP is a four-step self-talk strategy where the child must verbalize his or her own goals. A therapist helps the child to talk himself or herself through a solution to a motor problem and the child is active and cognitively involved in both problem solving and the learning of the skill.¹¹⁴

Motor Learning Theories

Motor learning refers to the process of acquiring, expanding, and improving skilled motor actions. The basic treatment premise of motor

learning theories is that improvement in movement skills is elicited through appropriate practice and timely feedback. Motor learning has taken place when a permanent change in the child's ability to respond to a movement problem or achieve a movement goal has occurred, regardless of the environment.¹⁵⁶ Therefore therapists measure learning through tests that measure retention and transfer of skills.¹⁵⁷

The closed-loop theory of Adams¹⁵⁸ is recognized as the first comprehensive explanation for motor learning. Adams believed that the central nervous system, based on sensory feedback, controls the execution of movement. He proposed that once a movement has occurred, errors are detected and compared with existing "memory traces." With practice, these memory traces become stronger and the accuracy of the movement increases, thus emphasizing learning through feedback.

In 1975 Schmidt contributed the idea of "open-loop" motor learning, which emphasized the ability to produce rapid action sequences in the absence of sensory feedback (e.g., hitting a baseball). He proposed that new movements were created from previously stored motor programs (schemas) of similar movements, as opposed to feedback from individual motor actions.¹⁵⁹ Schemas comprise general rules for a specific group of actions that can be applied to a variety of situations.¹⁶⁰ When a motor action occurs, the initial movement conditions, parameters used, outcomes, and sensory consequences of the action are stored in memory. With each goal-directed movement, specific parameters are used (e.g., force needed to pour juice into a glass) and consequences occur (e.g., spillage or not). Repeated actions using different parameters and creating different outcomes create data sets that help to refine the motor program, reducing errors and improving anticipation or feedforward information.¹⁶⁰ Schmidt's¹⁵⁹ schema theory contributed to current theories of motor learning principles regarding practice schedules and feedback about outcome of movements, known as *knowledge of results* (KR).

Based on the knowledge of motor skill development in children with DCD, four key variables are important to consider in targeted intervention. They include stage of the learner, type of task, scheduling of practice, and type of feedback.

Three stages of the learner have been proposed^{161,162}: the *cognitive stage*, *associative stage*, and *autonomous stage*. As a child learns and develops new motor actions, he or she progresses through the various stages at different rates, depending on the complexity of the skill. The *cognitive stage* is the initial phase of learning in which there is large variability as the child gets the general idea of the movement.¹⁴⁰ Awkward body postures are observed, errors are often made, and awareness of what needs to be improved or changed does not exist. (Consider when a young child attempts to throw a ball; the throw is a gross movement, the projection of the ball varies, and the movement appears uncoordinated.) As practice continues, the degree of accuracy increases, which is characteristic of the *associative stage*. Fewer errors are made, and error information is used to correct the movement patterns. (As the child continues to throw the ball, the ball may get closer to the target, with improved coordination observed.) During the *autonomous stage*, the skill is performed fluently and automatically, without as much effort or thought. Improvements in accuracy continue and errors are detected, with corrections made automatically. (The child can now throw a ball at a target and hit the target with coordinated, accurate movements, such as pitching; however, if a child were introduced to throwing a curve ball, the stages would start over.)

The type of task is a mechanism to classify motor skills in a dimensional fashion. Task components contribute to intervention decisions. The types of tasks are *gross motor* or *fine motor*; *simple* or *complex*; *discrete*, *serial*, or *continuous*; and *environment changing* or *stationary*. Gross and fine motor tasks are classified according to the type of muscle groups required.¹⁶³ *Gross motor skills* use large muscles and

tend to be fundamental skills (e.g., walking and running). *Fine motor skills* tend to require greater control of small muscles and usually have to be taught (e.g., handwriting, cutting). Task complexity refers to the level of difficulty and amount of feedback required. *Simple* tasks, such as reaching, require a decision followed by a response. A *complex* task, such as cutting out a picture, requires continual monitoring and feedback until completion. Tasks can require simple single actions or the coordination of sequential motions for completion. A single *discrete* movement has a clear beginning and ending, such as activating a button. *Serial* movements require a series of distinct movements combined to achieve the outcome, such as writing a sentence. *Continuous* movements, such as running, contain movements that are repetitive. Tasks that are discrete or serial can be practiced in parts, but continuous tasks usually need to be practiced as a continuous segment.

Environmental variations can greatly increase the complexity of the task, requiring higher levels of feedforward information and feedback. In an unstable or *changing* environment, the child has to learn the movement and monitor the environment to adapt to changes—for example, running on an uneven surface. The more predictable and stable the task and environments are, the easier it is to learn and replicate motor skills. Tooth brushing is an example of a task that generally occurs in a *stationary* environment. Home and classrooms can be stable, in that many elements within these settings are fixed and do not change. The size and shape of chairs, location of toys on the floor, and movements of other children are considered "variable features" within these stable environments. These variable features require a greater amount of motor control because the child must adjust movements and actions to the changing demands. Therapists generally practice in stable environments and therefore must ensure that the children are able to function under varied circumstances encountered in daily life situations.

Practice is believed to increase learning of a skill or movement. Variations in practice can occur in the order tasks are performed, in the environment where the tasks are practiced, and by changing aspects of the task. Practice schedules can be developed based on the practice techniques (*blocked* or *random*) or how task learning is approached (*component* or *whole task*). *Blocked* practice means the task is repeatedly rehearsed, sometimes focusing on one aspect of a technique or a specific motor sequence (e.g., hitting a golf ball off a tee with the same club). Repetitive, blocked practice often leads to improved immediate performance, particularly in situations that are stable. *Random* practice involves performing a number of different tasks in varied order or using several different aspects of technique (e.g., hitting golf balls from a tee, sand trap, and rough with the appropriate club). Random practice encourages learners to compare and contrast strategies used in performing the task, which positively influences performance in changeable environments.

If a task is discrete or contains multiple parts, breaking it down into *components* for blocked practice may be beneficial. For success in changeable situations in which the task component is integrated into skilled action, *whole-task* practice is essential—for example, practicing shooting basketballs, then practicing while moving or running toward the basket. When generalization is the goal, practice sessions can progress from stable (shooting from specific positions on the court) to a changeable environment (such as shooting basketballs with a person trying to block the shot). Opportunity and variety in practice appear to improve motor learning, particularly when skills are practiced in a random manner. Practice should therefore be varied and occur in multiple environments (e.g., home and school) to maximize motor learning.

Different types of feedback also affect the process of learning. *Intrinsic* feedback is received from any of the child's internal sensory

systems and is usually not perceived consciously unless external direction draws attention to it (e.g., when a child performs a task with his or her tongue sticking out). *Extrinsic* feedback is received from an outside source observing the results of an action and can be provided in the form of knowledge of performance (KP) or KR. KP focuses on movements used to achieve the goal, whereas KR focuses on the outcome.

Therapists tend to provide excessive feedback, especially when task performance is below what is expected. Low frequency and fading feedback, progressively decreasing the rate at which feedback is provided, appear to be most effective in facilitating learning.¹³⁵ One proposed reason is that with less feedback the individual can more readily engage in the processes that enable learning versus focusing on external cues. During intervention, feedback should not be provided for every movement or task execution. It is more beneficial to offer children the opportunity to self-evaluate and correct their own performance. The therapist can provide feedback as necessary to encourage successful task completion and reduce frustration. Verbal feedback can be general or specific. Children with DCD often lack the skills required to analyze task demands, interpret environmental cues, use KP to alter movements, or adapt to situational demands.¹⁶⁴ They therefore do not interpret and use sensory or performance feedback as well as children who are developing typically.¹⁵⁷ Motor observations of the child with DCD often reveal clumsiness, difficulty judging force, timing, and amplitude of motions, and deficits in anticipating the results of a motor action. Reactions, movements, and response times are typically slower,¹⁶⁵ thus the type of task and the method of teaching should be considered when recommending participation in sports and leisure activities.¹⁴⁰ Children with DCD can become successful in repetitive sports, such as swimming, skating, skiing, and bicycling. However, ball-related sports, such as hockey, baseball, tennis, football, and basketball, tend to be more difficult and frustrating owing to the high level of unpredictability and frequent changes in the direction, force, speed, and distance of the movement.¹⁴⁰

When using the motor learning model of practice, the therapist should incorporate a variety of teaching techniques, including verbal instructions, positioning, and handling, as well as observational learning (demonstrations).¹⁵⁷ The task and environment should be structured with extrinsic and intrinsic feedback provided, using a practice schedule that is optimal for the type of task.¹⁶⁶ Children with DCD benefit from experiential and guided learning when practice is performed so that each repetition of the action becomes a new problem-solving experience. To test whether motor learning has occurred, the therapist must create opportunities for demonstration of retention (repeating what was learned in a previous session), transfer (perform a different but closely related task), and generalization (perform a learned task in a new environment).

One method of intervention based on the principles of motor learning is the CO-OP, a frame of reference developed as a treatment approach specifically for children with DCD.¹⁵⁰ In this cognitive-based approach, the therapist focuses on the movement goal and facilitates the child's identification of the important aspects of the task, examines the child's performance during the task, identifies where the child is having the most difficulty, and problem solves alternative solutions.¹⁶⁶ Rather than using verbal instructions, this approach uses guided questions to help the child discover the problems, generate solutions, and evaluate his or her attempts in a supportive environment. Furthermore, the therapist solicits verbal strategies from the child that can help to guide the motor behavior, such as typical verbal cues that the therapist tends to provide during intervention.

To benefit from the CO-OP approach, the child must have sufficient cognitive and language ability to rate the level of his or her

performance and satisfaction of self-identified goals using the *Canadian Occupational Performance Measure* (COPM).¹⁶⁷ The basic objectives of this approach include skill acquisition, cognitive strategy development, and generalization or transfer of skills into daily performance. CO-OP is delivered over 12 one-on-one sessions, each lasting approximately 1 hour. The therapy process is divided into five phases: preparation, assessment, introduction, acquisition, and consolidation. Children are taught to talk themselves through performance issues using an approach of Goal-Plan-Do-Check. Domain-specific strategies are used to enhance performance, with the purpose of helping the child to see how he or she can set goals, plan actions, talk through doing, and check outcomes. Using this frame of reference, therapists help the child to acquire occupational performance skills using a metacognitive problem-solving process.¹⁵⁰

Research on the CO-OP model of motor learning. Current beliefs regarding the nature of motor learning for children with DCD suggest that assessment of participation, versus impairments, should be used to determine change over time.¹⁵⁷ By increasing the child's ability to participate in childhood activities, secondary deficits such as loss of strength and endurance might be prevented. Relatively new intervention strategies that use contemporary motor learning principles emphasize the role of cognitive processes (top down) in development of specific skills. The CO-OP model uses this approach to help children achieve their functional goals.¹⁵⁰

Research on the effectiveness of this approach to improve motor skills and functional performance is limited but shows promise. Polatajko and Cantin¹⁶⁸ reviewed three articles describing four studies and concluded that there was convergent evidence for the effectiveness of the CO-OP approach for children with DCD.

An exploratory study completed in 1994 by Wilcox as part of his graduate work was discussed by Polatajko and colleagues.¹⁶⁹ This initial single case study included 10 children aged 7 to 12 years who were referred to occupational therapy for motor problems. Using a global problem-solving approach to intervention, this study sought to identify whether children with DCD could use these strategies to acquire skills of their choice, and, once learned, whether the skills were maintained and performance in other areas enhanced. Children selected skills that were challenging and meaningful for them, such as shuffling playing cards, applying nail polish, making a bed, and writing legibly. Each of the 10 children made gains in the chosen activity, with 29 of the 30 targeted skills showing improvement.

A pilot study compared the CO-OP model to a traditional treatment approach with a group of 20 children aged 7 to 12 years. Findings indicated that the CO-OP model of intervention produced larger gains on client-selected goals. Improvements in self-ratings of performance and satisfaction were greater than in the comparative group. Although informal, the follow-up data suggested that children maintained their acquired skills and applied strategies to other motor goals.

Limitations in making conclusions regarding the effectiveness of this treatment are mandated by the small number of research studies, primarily carried out by the same research group. Mandich and colleagues¹⁰³ suggest that larger studies with control groups are needed. Suggestions for future research include identification of the salient features of this treatment approach, as well as determining the generalization and skill transfer to other settings.

Sensorimotor Intervention

Sensorimotor activities provide the foundation for the development of play in children.¹⁷⁰ The first level of play (i.e., sensorimotor) is pleasurable, intrinsically motivated activity that involves the exploration of sensation and movement.¹⁷⁰ As children react with adaptive motor responses to the array of sensations from their bodies and the

environment, central nervous system organization occurs. The assumption that the organization of sensory and motor experiences is essential to effective motor performance is the premise of sensorimotor intervention.¹⁷¹ Treatment encourages the child to actively engage in a variety of sensory-rich, motor-based activities, to enhance functional motor performance.¹⁶⁹ Evolution of sensorimotor intervention has not revolved around a single, unified theory but has incorporated a variety of theoretical foundations.¹⁷²

The goals of sensorimotor intervention are outcome based, with emphasis on the development of age-appropriate perceptual-motor and gross motor skills. The therapist chooses activities that meet the child's developmental levels, promote sensory and motor foundations, and encourage practice of appropriate motor skills. For the child having difficulty keeping up with the skilled activities in gym class such as rope jumping, components of these activities will be encouraged, with emphasis on sequencing and timing. The therapist may use a heavier jump rope or wrist and ankle weights to provide more sensory information for improved task performance.

In sensorimotor intervention, tasks are chosen for their innate sensory and motor components. The child is directed to activities that encourage the use of the body in space to complete a structured motor sequence. Activities incorporate sensory components such as movement (vestibular), touch (tactile), and heavy work for the muscles and joints (proprioception). Play interactions are considered important to encourage sensorimotor integration within the context of meaningful interactions with persons and objects.¹⁷⁰ Children may propel themselves prone on a scooter board through an "obstacle maze" while looking for matching shapes, for example. This activity provides tactile, proprioceptive, and vestibular sensory input and encourages the development of postural strength and endurance while addressing perceptual skill development.

Research on sensorimotor intervention. Sensorimotor intervention is a widely accepted modality, used by 92% of school-based therapists as a foundation for improving handwriting.¹⁷³ The activities used and goals addressed in treatment are extremely varied, because all functional motor skills involve some level of sensory and motor organization. Activities can range from horseback riding to using a vibrating pen when learning how to write letters. Owing to the enormous variation in intervention strategies and outcome measures, operationalizing treatment to make comparisons between research studies can be difficult. In a recent systematic review, Polatajko and Cantin¹⁶⁸ found five studies that met their criteria for using sensorimotor intervention. In those five studies, both the techniques used (e.g., therapeutic riding, movement therapy, educational kinesiology) and the populations addressed (autism, sensory modulation disorder, DCD) varied greatly. This review suggested that evidence for the effectiveness of sensorimotor intervention was "inconclusive," with the heterogeneity of diagnoses and functional problems limiting the ability to interpret efficacy.¹⁶⁸

Overall, relatively few studies have investigated the efficacy of sensorimotor integration. In an early comparison study, DeGangi and colleagues¹⁷⁴ found that children provided with structured sensorimotor therapy made greater gains in sensory integrative foundations, gross motor skills, and performance areas such as self-care than children who engaged in child-centered activity. More recently, Chia and Chua¹⁷⁵ used sensorimotor intervention in a random controlled study of 14 children with learning disabilities and DCD. Intervention consisted of providing sensory stimuli and facilitating a normal motor response while remediating impairments in posture and muscle weakness. Positive results in neuromotor functioning were noted. In a second study, Inder and Sullivan¹⁷⁶ used educational kinesiology techniques in four single-subject design experiments. Positive gains were

documented in some aspects of sensory organization and in an overall decrease in the number of falls children had.

Four studies have explored the effects of sensorimotor remediation on handwriting. Those programs that used sensorimotor interventions over only a short period of time did not yield positive results. Sudsawad and colleagues¹⁷⁷ compared the effects of kinesthetic-based intervention with handwriting practice with 45 first graders over a 4-week period. They found neither group to make significant improvements in handwriting and suggest that there is no support that kinesthetic training improves handwriting legibility for this age. In 2006, Denton and colleagues¹⁷⁸ compared sensorimotor intervention with therapeutic practice in 38 school-aged children with handwriting difficulties over 5 weeks. These authors noted moderate improvements in handwriting with therapeutic practice and a decline in ability in the sensorimotor group. They suggest that, although sensorimotor foundations did improve with sensorimotor intervention, there is no indication that these foundations affect the development of handwriting. Their findings suggest that structured therapeutic practice using motor learning principles has a much stronger impact on the development of handwriting.

Two studies that investigated the combined effects of sensorimotor intervention and higher-level teaching strategies did demonstrate a positive impact on handwriting.^{179,180} Peterson and Nelson¹⁷⁹ found that low socioeconomic first graders who received 20 sessions of occupational therapy combining sensorimotor, biomechanical, and teaching-learning strategies made significant gains over those receiving academic instruction alone. Weintraub and colleagues¹⁸⁰ compared a control group with two treatment conditions (task-oriented approach versus combination of sensorimotor and task orientation). Immediately after treatment and at a 4-month follow-up, significant gains in handwriting were observed in both treatment groups compared with the control group. The authors support the use of "higher-level" teaching strategies to improve the skill of handwriting.

Motor Skill Training

Motor skill training involves learning skills and subskills functionally relevant to the child's daily performance. Tasks are taught in a sequential manner by developmental ages or by steps from simple to complex. Skill training can occur for a wide variety of gross, fine, and visual motor tasks, as well as ADLs. An assortment of theoretical models and techniques may be used based on the child's impairment and activity and participation deficits.

Motor skill training can involve both indirect and direct facilitation of specific motor tasks. Activities that include balance, locomotion, body awareness, and eye-hand coordination can improve functional skills such as being able to sit at a desk within the classroom and complete written work, as well as success in recess games such as basketball. Specific skills such as dribbling and foul shooting can also be specifically taught and practiced. The goal is to provide a great variety of motor activities at the child's developmental motor level to promote motor generalizations for more successful participation.

An example of this approach is Sugden and Henderson's¹⁵¹ "ecological intervention," which is a method of skill training for children with DCD. In this model the therapist, called a *movement coach*, provides instruction to many individuals who interact with the child on how to develop specific targeted skills. All caregivers are actively involved in goal development and achievement. By having a variety of individuals work together across daily life environments, children more quickly become skilled.¹⁵¹ This approach also develops the caregivers' ability to understand the demands of specific tasks and to help facilitate the child's performance in all settings.

Physical Fitness Training

As previously reviewed, children with DCD are at great risk of low levels of physical fitness. The benefits of fitness and physical activity in minimizing disease and maximizing overall wellness are well documented. Deleterious effects resulting from DCD or factors associated with it include but are not limited to fatigue, hypoactivity, poor muscle strength and endurance, decreased flexibility, poor speed and agility, and diminished power.

Specific muscular training may be needed to undo the effects of reduced activity.¹⁸¹ Poor muscle strength, especially in the abdominal area, can lead to musculoskeletal issues such as back pain because posture and pelvic alignment require adequate muscle strength. Children with DCD often require specific instruction to perform muscle strengthening activities (e.g., sit-ups, push-ups) with appropriate form. Decreased flexibility and muscle tightness in the lower extremities can contribute to difficulties in running, jumping, and hopping. Flexibility can be encouraged with a regimen of stretches specific to the areas of tightness. Gentle and regular stretching can be incorporated into warmups during sessions or physical activities.

Fitness can improve and be maintained when children participate in regular, preferably daily, physical activity. These activities often require more structure and direction for children with movement difficulties. As therapists, our overall goal should be to educate children about the value and enjoyment of regular activity.¹⁸¹ Hands and Larkin¹⁸¹ suggest the following plan to ensure children with DCD learn or rediscover the joy of movement:

- Educate children to understand and monitor their bodies' responses to exercising (e.g., heart rate increases when they run).
- Assist them in finding developmentally appropriate activities they will enjoy with some success.
- Encourage them to maintain a healthy, active lifestyle by encouraging participation in lifelong activities such as swimming, cycling, golf, sailing, yoga, or weight training.

In sports and leisure activities, the emphasis should be on participation and fitness rather than competition. Encourage activities that do not require constant adaptation, because children with DCD tend to be more successful in sports that have a repetitive nature to the movements (e.g., swimming, running, skating, skiing).^{142,183} Sports that have a high degree of spatial challenge or unpredictability, such as baseball, hockey, football, and basketball, are less likely to be successful for children with DCD.¹⁸² Activities that are taught through sequential verbal guidance, such as karate, may be easier to learn.¹⁴⁰

PTs and OTs can have a positive impact on participation in fitness activities for children with DCD. A summary of key suggestions,⁹¹ including the following, can assist with encouraging involvement in community sports and leisure activities:

- Provide frequent encouragement and reward effort.
- Encourage participation, rather than competition; emphasize fun, fitness, and skill building.
- Use a variety of teaching methods to demonstrate new skills (one-on-one instruction, verbal cues, demonstration).
- Provide hand-over-hand instruction during the early acquisition phase.
- Break down skills into smaller, meaningful parts.
- Keep the environment as predictable as possible.
- Modify or adapt equipment for safety (e.g., use foam balls instead of hard balls).
- Focus on the enjoyment, not the product.
- Encourage multiple roles in some activities (e.g., referee, scorekeeper, time keeper).
- Recognize the child's strengths and reinforce social interaction.

Encouraging and facilitating participation in a healthy lifestyle can aid in ending the vicious cycle of withdrawal, diminished opportunities

for physical development, and decreased fitness and strength over time, a pattern very commonly seen in children with DCD.⁹¹

LEARNING DISABILITIES AND DEVELOPMENTAL COORDINATION DISORDER ACROSS THE LIFE-SPAN

Learning disabilities persist into adulthood and present lifelong challenges. Continuing issues with attention, cognition, emotional adjustment, and interpersonal skills can affect education, employment, family life, and daily routines. Adolescents and adults with learning disabilities frequently struggle with the concentration and organization needed to effectively manage daily routines and finances, vocational education or training, job procurement and retention, and finances.^{183,184}

A recent longitudinal study¹⁸⁵ demonstrated that IQ scores remain stable from childhood to adulthood, as do deficit areas. Therefore poor readers remain poor readers, poor spellers remain poor spellers, and delayed math skills persist. In addition, adults who had affective illness or mood disorders as children have a significant risk of recurrent episodes (e.g., depression, bipolar disorder). An early 20-year longitudinal study of individuals with learning disabilities cited a rate of 42% for adult psychological disturbance (e.g., depression, alcohol abuse, anxiety disorders), compared with 10% in the general population.¹⁸⁶

More recently, Seo and colleagues¹⁸⁷ found more optimistic results in their comparison of outcomes for individuals age 21 and 24 with and without documented learning disabilities. No significant differences were found in postsecondary school achievement or employment rates and earned income, although the 21 year olds with learning disabilities did receive significantly more public aid, such as food stamps, social security, and unemployment. The learning-disabled group did not have increased incidence of committing crimes or feeling victimized as young adults. Emotional health¹⁸⁵ and strong social relationships¹⁸⁸ are crucial for success; therefore children should be supported to develop healthy social connections and personal talents.

Several attributes have been identified as predictors of success for adults with learning disabilities.^{188,191} A combination of internal and external factors supports the individual in the belief that he or she can take control, evaluate needs, and develop appropriate coping strategies, while knowing when to seek additional help.¹⁸⁹ The ability to be proactive, set goals, and persevere is a key internal element to attaining success. Understanding one's learning disability, with recognition of strengths and limitations, affords more thoughtful choices in life roles. Self-esteem and confidence are promoted with external emotional support and positive feedback from family, friends, teachers, work colleagues, and employers.

The persistent motor coordination difficulties attributed to DCD further affect perceptions of competence^{97,190} and successful accomplishment of daily life skills.¹⁹¹ Raskind and colleagues¹⁸⁶ found that physical status, including motor impairment, was an important variable in determining success in adulthood. Slowness and variability in movement continue to be a pervasive feature, causing difficulties in tasks that require sequencing and dual-task performance, such as driving a car.¹⁹¹ Adults with DCD report higher levels of difficulty with motor-related tasks such as self-care and handwriting.¹⁹² Compared with adults with dyslexia, a greater number of adults with DCD continue to live at home with their parents, have fewer spare-time activities, and are more socially isolated.^{192,193}

Learning disabilities with motor impairments appear to have a persistent effect on a sense of competence and self-concept.^{15,193} Many individuals develop negative perceptions of themselves as they

experience frustration and ineffectiveness. They set lower aspirations, further reinforcing the cycle of failure. A combination of ADHD and DCD was found to be the most important predictor of poor psychosocial functioning in early adulthood.¹⁹⁴ Higher incidence of drug and alcohol abuse, affective disorders, crime conviction, and unemployment have been documented. Without adequate support, adults with

DCD have difficulties reaching their potential. They may benefit from counseling about their condition, vocational assessment, and guidance to assist with finding a suitable work environment, time management and organizational strategies, workplace and academic accommodations, and behavioral management.

SUMMARY

Learning disabilities are heterogeneous and multidimensional in their presentation. Research continues to work on identifying the causes and the associated functional deficits of learning disabilities, as well as developing effective intervention techniques. The variability of the group suggests a spectrum of neurological processing difficulties. As physiological measures of brain function improve, our theoretical understanding increases.

Assessment and teaching methods continue to be refined to identify underlying deficits and effective remediation strategies. The current trend is to recognize issues inherent in the child (i.e., a true learning disability) versus issues from inadequate or ineffective instruction. Early identification of difficulties and systematic alteration of instruction methods are advocated to serve students more quickly and efficiently. The challenge for the clinician is to recognize the multitude of components that interact to impede functional abilities and social participation for the child with learning disabilities.

Children with learning disabilities frequently manifest motor coordination problems. These motor deficits may be subtle and difficult to identify in a neurological evaluation or standardized testing. With better awareness and assessment measures, more children are being identified and diagnosed with DCD. Many theoretical models have been developed in an attempt to explain the qualitative motor deficits observed in

children with learning disabilities and to provide constructs to develop intervention programs. Continued formal research and careful documentation of clinical outcomes are needed to synthesize therapeutic approaches that best meet the individual needs of the child.

Identification, advocacy, teaching, and remediation are important aspects of the OT's and PT's roles. The goal is to formulate an intervention program that best addresses the underlying deficits in foundation skills and the functional weaknesses in daily life tasks. The experienced interventionist will combine knowledge from many areas of theoretical development and remediation to facilitate the best performance in each child.

It is clear that learning disabilities and DCD both persist across the life-span and can have a multitude of detrimental effects. All areas of daily life performance can be affected, including social and emotional functioning, self-care, education, vocation, and interpersonal relationships. Both intrinsic factors (perseverance, insight, sense of control) and extrinsic factors (emotional support, mentoring, positive feedback) play a role in the ultimate success of the individual with learning and motor challenges. Our role as a pediatric therapist is to provide the necessary extrinsic support and effective intervention to alleviate the deleterious effects of living with a disability.

A Summary of Standardized Motor Tests

BRUININKS-OSERETSKY TEST OF MOTOR PROFICIENCY, SECOND EDITION (2005)¹²⁴

Authors

Robert H. Bruininks, PhD, and Brett D. Bruininks, PhD

Source

American Guidance Service, Inc., Circle Pines, MN 55014

Ages

4 to 21 years

Administration

Individual. Complete form: 45 minutes to 1 hour. Short form: 15 to 20 minutes.

Equipment

Test kit needed

Description

The *Bruininks-Oseretsky Test of Motor Proficiency, Second Edition* (BOT-2) is the most recent revision of the Oseretsky Test of Motor Proficiency, first published in Russia in 1923. The Bruininks-Oseretsky Test is designed to provide information on a wide range of motor skills and is sensitive enough to identify mild to moderate motor control problems. In this revision the authors worked to improve the test item presentation, quality of the test kit, and functional relevance of test content. They also expanded the norms through age 21 and improved the test items for 4- to 5-year-olds. The BOT-2 yields standard scores, scaled scores, and percentile ranks, separately for males and females, and combined. Age equivalency scores are also available. The test assesses motor functioning in eight areas:

1. **Fine Motor Precision:** Functionally relevant drawing, paper folding, and cutting item that focuses on assessment of precise finger control. These items are untimed, and they focus on qualitative refinement.
2. **Fine Motor Integration:** Copying geometric shapes of increasing complexity as accurately as possible. These items are untimed, as they focus on precision.
3. **Manual Dexterity:** Goal-directed activities that involve reaching, grasping, and bimanual coordination with small objects (pennies, pegboard, card sorting, and stringing beads). Emphasis is placed on speed and accuracy (dexterity), and all items are timed.
4. **Bilateral Coordination:** Items that measure skill in sequential and simultaneous coordination of the upper and lower extremities. Includes both familiar tasks (e.g., jumping jacks and finger pivots

[“itsy-bitsy spider”]), as well as novel tasks (e.g., tapping feet and fingers with opposite sides of the body).

5. **Balance:** Static and dynamic balance items measure motor control for maintaining posture when standing, walking, and making transitional movements in space (e.g., reaching for a plate on a shelf). Assesses three areas that affect balance: trunk stability, static and dynamic postural control, and use of visual cues.
6. **Running Speed and Agility:** Four activities to assess speed and agility (shuttle run, hopping on one and both feet, stepping over balance beam).
7. **Upper-Limb Coordination:** Items that involve visual tracking and coordinated hand and arm movements (eye-hand coordination). Tasks include catching, throwing, and dribbling, with one or both hands together.
8. **Strength:** Assesses trunk and upper and lower extremity strength necessary for effective gross motor performance in daily activities.

CONSTRUCTION AND RELIABILITY

The Bruininks-Oseretsky Test has been carefully standardized on 1520 subjects from 38 states, stratified across sex, ethnicity, socioeconomic, and disability status. Sample sizes were larger in the younger age ranges because children develop more rapidly than adolescents. Three measures of reliability were determined for subtests, composites, short form, and complete form: internal consistency, test-retest, and interrater. In general, all were high, with best reliability shown when the complete form was used.

Comment

The BOT-2 appears to be one of the better standardized tests of motor performance. The 1978 version has been one of the most widely used tests to assess motor proficiency and has been used in research to identify motor deficits in individuals with DCD.^{195,196} It offers various levels of testing and screening with a comprehensive “complete form” that provides the most reliable measure of overall motor proficiency. The short form can be used for screening, to determine if further evaluation is necessary. In addition, only those single subtests or composites that are relevant to the child’s areas of difficulty can be administered. When qualifying a student for special education, it is suggested that this thorough assessment be used. In this revision the authors focused on including a variety of tasks that are engaging and goal directed, assessing both quantitative and qualitative aspects of motor performance. When testing children with motor dysfunction, careful attention must be paid to qualitative performance on individual items. A child may demonstrate the ability to complete a test item, but qualitatively it is accomplished with increased effort, decreased refinement, and speed.

MOVEMENT ASSESSMENT BATTERY FOR CHILDREN, SECOND EDITION (2007)¹¹²

Authors

Sheila E. Henderson, David A. Sugden, and Anna L. Barnett

Source

Harcourt Assessment, Proctor House, 1 Proctor Street, London, WC1V6EU

Ages

3 to 16 years

Administration

Individual; 20 to 30 minutes

Equipment

Test kit required

Description

The *Movement Assessment Battery for Children, Second Edition* (Movement ABC-2) is a recent revision of the M-ABC, which was originally developed from the Test of Motor Impairment (TOMI)–Henderson Revision. The Movement ABC-2 is a norm-based assessment of gross and fine motor performance whose main intent is to identify and describe children with movement difficulties. The test was also designed for intervention planning, program evaluation, and research. There are three components of the Movement ABC-2: the standardized evaluation, a checklist of competency in specific daily motor behaviors, and a companion manual for program planning (Ecological Approach to Intervention).¹⁵¹ The evaluation tool yields standard and percentile scores, with two determined cut-off points delineating definite movement difficulties and children at risk. The age ranges have been expanded, and the test is divided into three age brackets: children aged 3 to 6 years, 7 to 10 years, and 11 to 16 years. The test items vary in each age range, with increased complexity and skill required in the older age bands. There are eight tasks assessing three areas of coordination: manual dexterity, ball skills, and static and dynamic balance.

1. **Manual Dexterity:** Speed and dexterity with the preferred hand. Includes two manipulative tasks such as coins in a bank, stringing beads, pegs in a pegboard, threading lace, and turning pegs and nuts and bolts, as well as a written maze.
2. **Ball Skills:** Eye-hand coordination is assessed with two beanbag and ball tasks emphasizing aiming at a target and catching.
3. **Static and Dynamic Balance:** One task of static balance with eyes open, and two tasks of dynamic balance that emphasize spatial precision and control of momentum.

Construction and Reliability

The standardization sample included 1172 children in the United Kingdom. A stratified sampling was done to ensure that representative proportions of age, gender, race, and ethnicity, and parent educational level were included. Before the main study, testing was done around the world and revealed no culture-specific problems. The researchers consider this revision to be similar enough to the M-ABC that the studies used with that test remain relevant. Test-retest reliability for consistency of individual item scores fell within a range deemed acceptable, from 0.64 to 0.86. The mean of 0.77 was achieved for the test as a whole. Interrater reliability was excellent, exceeding 0.95.

Comment

This revision is the culmination of a lengthy program of research and development begun in 1966 by two groups of researchers. The Movement ABC-2 offers some additional advantages: (1) the checklist helps teachers to identify children with movement problems, and (2) information is provided for a cognitive-motor approach to intervention across environments. The test items are easy to administer and score. Although the manual provides a clear picture of what the task looks like, there are no standardized verbal instructions given in this revision. Scoring is based on a traffic light system, with the red zone (at or below 5th percentile) indicating significant movement difficulty, amber zone (6th to 15th percentile) delineating children at risk, and the green zone (above 15th percentile) indicating the absence of movement difficulties. Percentile scores are useful for parents and teachers because they are easily understood, but therapists should recognize that they do not form an equal interval scale, tending to cluster near the median of the normal curve. Therefore, for subtest raw scores near the median, a change of 1 point to the raw score could result in an increase of 8 percentile points, whereas at either end of the normal curve this might only translate to 2 percentile points.

PEABODY DEVELOPMENTAL MOTOR SCALES, SECOND EDITION (2000)¹²⁵

Authors

M. Rhonda Folio and Rebecca R. Fewell

Source

Pro-Ed, 8700 Shoal Creek Boulevard, Austin, TX 78757

Ages

Birth to 5 years

Administration

40 to 60 minutes (test items may be scored by direct observation or by parent or teacher report)

Description

An early childhood motor development program that provides, in one package, both in-depth assessment and training or remediation of gross and fine motor skills. The assessment is composed of six subtests that measure interrelated motor abilities that develop early in life. The *Peabody Developmental Motor Scales, Second Edition* (PDMS-2) can be used by OTs, PTs, diagnosticians, early intervention specialists, adapted physical education teachers, psychologists, and others who are interested in examining the motor abilities of young children. The PDMS was designed for use with children who show delay or disability in fine and gross motor skills. Test items are similar to those on other developmental scales, but only motor items are included. Items are scored on a 3-point scale: 0 for unsuccessful, 1 for partial, and 2 for successful performance. Age-equivalent scores, motor quotients, percentile rankings, and standard scores are provided. Scoring software for the PDMS-2 is available to convert the PDMS-2 scores into standard scores, percentile ranks, and age equivalents and generate composite quotients. The software also can be used to compare PDMS-2 subtest performances and composite performances to identify intraindividual differences and provide a printed report of the student information, including treatment goals and objectives.

Subtests

1. **Reflexes:** This eight-item subtest measures a child's ability to automatically react to environmental events. Because reflexes typically

become integrated by the time a child is 12 months old, this subtest is given only to children from birth through 11 months.

2. Stationary: This 30-item subtest measures a child's ability to sustain control of his or her body within its center of gravity and retain equilibrium.
3. Locomotion: This 89-item subtest measures a child's ability to move from one place to another. The actions measured include crawling, walking, running, hopping, and jumping forward.
4. Object Manipulation: This 24-item subtest measures a child's ability to manipulate balls. Examples of the actions measured include catching, throwing, and kicking. Because these skills are not apparent until a child has reached the age of 11 months, this subtest is given only to children aged 12 months and older.
5. Grasping: This 26-item subtest measures a child's ability to use his or her hands. It begins with the ability to hold an object with one hand and progresses up to actions involving the controlled use of the fingers of both hands.
6. Visual-Motor Integration: This 72-item subtest measures a child's ability to use his or her visual perceptual skills to perform complex eye-hand coordination tasks such as reaching and grasping for an object, building with blocks, and copying designs.

Composites

1. Gross Motor Quotient: This composite is a combination of results on the subtests that measure the use of the large muscle systems:
 - Reflexes (birth to 11 months only)
 - Stationary (all ages)
 - Locomotion (all ages)
 - Object manipulation (12 months and older)
2. Fine Motor Quotient: This composite is a combination of results on the subtests that measure the use of the small muscle systems:
 - Grasping (all ages)
 - Visual-motor integration (all ages)
3. Total Motor Quotient: This composite is formed by a combination of results on the gross and fine motor subtests. Because of this, it is the best estimate of overall motor abilities.

Construction and Reliability

Reliability coefficients were computed for subgroups of the normative sample (e.g., individuals with motor disabilities, African Americans, Hispanic Americans, girls, and boys), as well as for the entire normative sample. The normative sample consisted of 2003 persons residing in 46 states and was collected in the winter of 1997 and spring of 1998. Normative samples relative to geography, sex, race, and other critical variables are therefore representative of the current US population.

A test-retest reliability of 0.84 for the Gross Motor Scale and of 0.73 for the Fine Motor Scale (0.89 Total Motor) was reported based on a sample of 30 children from Austin, Texas, in the age range of 2 to 11 months. A second group of 30 children from Nacogdoches, Texas, aged 12 to 17 months, was tested with a test-retest reliability of 0.93 for the Gross Motor Scale and 0.94 for the Fine Motor Scale (0.96 Total Motor). These values are of sufficient magnitude for a tester's confidence in the test scores' stability over a period of time. The correlation coefficients between the PDMS and the PDMS-2 for criterion-prediction validity in the Gross and Fine Motor Quotients exceed 0.80, which supports the equivalency of the tests.

The PDMS-2 scores were correlated with those of the *Mullen Scales of Early Learning: AGS Edition* (MSEL:A) when both tests were administered on the same day to 29 children, aged 2 months to 66 months, in Evansville, Indiana. The relations of the PDMS-2 and MSEL:A demonstrated that Gross and Fine Motor Quotients exceed 0.80, high enough

to support the equivalency of the tests. When the concurrent validity of the age equivalent and standard scores of the Bayley Scales of Infant Development II (BSID-II) Motor Scale and PDMS-2 were calculated, the standard scores show poor agreement and had low concurrent validity, particularly the BSID-II Motor Scale and the PDMS-2 Locomotion Subscale.¹⁹⁷ The differences in the scores of these two tests warrant concern when using one test to make clinical decisions for service eligibility.

Comment

The PDMS-2 is primarily useful for children with mild to moderate motor deficits, such as a child with learning disabilities or a child with developmental delay. The test does not discriminate among children with moderate to severe motor disability because they fall far below the standard scores given. The skill categories are unevenly distributed and have too few items at some age levels to be meaningful. Despite the drawbacks, the PDMS-2 is probably the most valuable motor scale test currently available for preschool children.

CLINICAL OBSERVATIONS OF MOTOR AND POSTURAL SKILLS, SECOND EDITION (2000)¹³⁴

Authors

Brenda N. Wilson, MS, OT(C), Nancy Pollock, MSc, OT(C), Brenda Kaplan, PhD, and Mary Law, PhD, OT(C)

Source

Therapro Inc., 225 Arlington Street, Framingham, MA 01702

Ages

5 to 11 years

Administration

Individual; 15 to 20 minutes

Equipment

Test kit required for ATNR measurement tools. Stopwatch and mat needed for certain items.

Description

The *Clinical Observations of Motor and Postural Skills* (COMPS) is a standardized screening tool using six clinical observations suggested by Ayres^{105,198} of "soft neurological signs" to identify motor problems with a postural component. Historically, the clinical observations used by therapists have not had standardized administration or objective scoring and they have not taken into account the child's age and changes in abilities as the child matures. The authors felt it was important to objectify these observations and relate performance to age, as neuromotor maturation is very rapid in this age group. The test is designed to measure cerebellar function, postural control (stability), and motor coordination (mobility). Motor planning and sequencing are not intended to be measured directly, and repetition of directions, therapist prompting, and item practice are meant to separate motor performance from the cognitive aspects of planning. The test has six test items:

1. Slow Movements: Assesses the ability to move arms in a slow and symmetrical manner. Scoring is based on quality of performance, speed, and symmetry.
2. Rapid Forearm Rotation: A test of diadochokinesis; score is based on the number of forearm rotations accurately completed in 10 seconds.

3. Finger-Nose Touching: Measures proprioceptive mechanisms of motor control by switching midtask from eyes open to eyes closed. Scoring is based on accuracy, fluidity of motion, and force of touch.
4. Prone Extension Posture: The child holds a position of extension against gravity. Scoring is based on the duration of ability to hold position, quality of extension, and effort.
5. Asymmetrical Tonic Neck Reflex: The degree of inhibition of this reflex is looked at by measuring elbow flexion with manual head turn in a quadruped position. This test is also useful for identifying poor postural stability through observations including needing a wide base of support to sustain the position and locking elbows for stability.
6. Supine Flexion Posture: The child holds a position of flexion against gravity. Scoring is based on the duration of ability to hold position, quality of extension, and effort.

Construction and Reliability

Standardization of the test was done in two cities (Calgary and Hamilton) on a sample of 123 children, 67 who demonstrated DCD and 56 with no known motor problem. Test-retest reliability, interrater reliability, internal consistency, and construct validity were completed with a sample of 132 children with and without DCD. Test-retest reliability over 2 weeks was 0.98, and interrater reliability for pediatric OTs was 0.87. The internal consistency was high, indicating that the test discriminates well between children with and without motor problems, although the sample size was small.

Comment

The COMPS is a useful standardized tool for identifying subtle motor problems in children and was designed for and tested on children with DCD. The COMPS was not designed for children with known neurological or neuromotor problems such as intellectual delay, cerebral palsy, or epilepsy. It can be used as a screening tool for motor dysfunction, to assist in determining intervention approaches that would be beneficial for the child, and possibly to measure change over time. Children with motor performance problems can score within normal limits on the COMPS, and children who demonstrate low scores may not be exhibiting functional difficulties. The association between these clinical observations and functional performance is not always clear; therefore it is essential to gather information regarding the child's current functioning from observation and interview.

SCHOOL FUNCTION ASSESSMENT (1998)¹⁹⁹

Equipment

Record form; rating scale guides

Description

The *School Function Assessment* (SFA) is a judgment-based, criterion-referenced assessment to evaluate and monitor a student's performance on functional tasks that support school participation. This measure was designed to facilitate collaborative program planning for students with a variety of physical and cognitive disabilities. The SFA measures a student's ability to perform activities within the school setting that support participation in the academic and social aspects of an elementary program (grades K-6). Functional skills such as moving around the school, using classroom materials, interacting with peers, and caring for personal needs are included. The instrument is best completed by school professionals who are familiar with the student's typical performance. Task items are written in measurable, behavioral terms that can be used directly in the student's IEP. Criterion cut-off scores are provided for use in determining eligibility for special services. The SFA contains three parts:

1. Participation: Rates the student's involvement in six major school activity settings: regular or special education classroom, playground or recess, transportation, bathroom and toileting activities, transitions to and from class, and mealtime or snack time.
2. Task Supports: Identifies and rates the assistance and adaptations currently provided to the student for both physical and cognitive and behavioral tasks. Two types of task supports are examined separately: assistance (adult help) and adaptations (modifications to the environment or program, such as specialized equipment or adapted materials).
3. Activity Performance: Examines the student's performance of specific school-related functional activities. Physical tasks include travel, maintaining and changing positions, recreational movement, manipulation with movement, using materials, setup and cleanup, eating and drinking, hygiene, clothing management, going up and down stairs, written work, and computer and equipment use. Cognitive/behavioral tasks include functional communication, memory and understanding, following social conventions, compliance with adult directives and school rules, task behavior and completion, positive interaction, behavior regulation, personal care awareness, and safety.

Construction and Reliability

A sample of 678 students in two groups participated in the standardization of SFA. One group included children with special needs (363 students). These students had a variety of disabilities, including motor impairment, communication impairment, emotional or behavioral difficulties, and cognitive limitations. The second group included 315 students in regular education programs. Internal consistency was excellent at 0.92 to 0.98, indicating that items in a scale relate to one another and measure the same construct. Test-retest reliability was 0.82 to 0.98.

Comment

This assessment is unique in its focus on activity and participation levels, versus identifying impairments. It helps school personnel to recognize and ameliorate functional limitations that are affecting successful school participation. The comprehensiveness of assessment and functional IEP-ready goals makes it a useful tool to qualify and develop programs for children in need of special education services. Complete instructions are contained in the assessment booklet. Therefore the respondent does not need to refer to a manual to complete items, easing data collection. The manual is then used to compute transformed scores and interpret results.

BEERY-BUKTENICA DEVELOPMENTAL TEST OF VISUAL-MOTOR INTEGRATION, SIX REVISION (2010)²⁰⁰

Authors

Keith E. Beery, PhD, Norman A. Buktenica, and Natasha A. Beery

Pearson Clinical Assessments, 19500 Bulverde Rd #201, San Antonio, TX 78259

Ages

2 to 99 years

Administration

Individual or group; 5 to 15 minutes

Equipment

Protocol booklets (test forms), No. 2 pencil

Description

The *Beery-Buktenica Developmental Test of Visual-Motor Integration* (BEERY VMI) was developed for early screening and intervention of visual-motor deficits. It tests the ability to integrate visual and motor abilities by presenting 30 geometric forms of increasing difficulty to copy. A booklet is provided; below the design is a blank space in which the child replicates the form. A shorter format including the first 21 items is best suited for children aged 2 to 7 years. Items are judged pass or fail on criteria given in the manual, and scores are reported in standard scores and percentiles. Age equivalents are also available. If the child has significant difficulty completing the test or scores below the average range, this may be indicative of a visual-motor integration delay. To further assess where the difficulties lie, two additional tests are available to assess visual perception and motor coordination separately.

1. Visual Perception: Visual perception is assessed by limiting the motor response to pointing. The child matches geometric forms to a stimulus. Administration takes approximately 3 minutes.
2. Motor Coordination: Motor accuracy is assessed on a task of drawing within a double-lined path. Administration takes approximately 5 minutes.

Construction and Reliability

The BEERY VMI is based on a significant amount of research on visual-motor integration, coordination, and development. The test has been normed five times between 1964 and 2003, with a total of more than 11,000 children. For this revision the Visual Perception and Motor tests were standardized on the same sample of 2512 children. This test has an extensive range of age-specific norms, with 600 children for the age range of 2 to 6 years. Test-retest reliability is high for the three test components, ranging from 0.90 to 0.92. Various studies of interrater reliability, internal consistency, and concurrent and construct validity are reported in the manual. Comparisons to other tests assessing visual-motor integration supported the validity of the BEERY VMI.

Comment

The VMI provides a quick and easy method to assess the development of a child's ability to copy geometric forms. The uses are varied, including identification of significant difficulties with visual-motor integration and determination of an effective intervention program, as well as use as a research tool. For complete assessment of the child with

learning disabilities and DCD, it is best used in conjunction with other tests of gross motor, fine motor, visual perception, and eye-hand coordination. This culture-free, nonverbal assessment is suitable for children with diverse educational, environmental, and language backgrounds. New to this addition are teaching materials to promote visual-motor integration for children from birth through elementary school. These include *My Book of Letters and Numbers*; *My Book of Shapes*; a laminated wall chart of basic gross motor, fine motor, and visual developmental milestones; and a checklist for parents of over 200 developmental "stepping stones" to help parents observe skill development and track progress.

MOTOR-FREE VISUAL PERCEPTION TEST, FOURTH EDITION

Authors

Ronald P. Colarusso, EdD, and Donald D. Hammill, EdD

Source

Western Psychological Services. 625 Alaska Avenue, Torrance, CA 90503

Website: <https://www.wpspublish.com>

Ages

4 to 80+ years

Administration

Individual; 20 to 25 minutes

Equipment

Protocol booklets (test forms), manual

Description

The *Motor-Free Visual Perception Test, Fourth Edition* (MVPT-4) is an assessment tool that seeks to evaluate visual-perceptual skills and identify potential deficits in children and adults aged four and older. This assessment provides an overall picture of an individual's visual perception skills and does not offer detailed information in regard to specific areas that may be lacking. The five areas of visual perception included in the test items are spatial relationships, visual discrimination, figure-ground, visual closure, and visual memory.²⁰¹ During administration, the evaluator reads the instructions for the test plate, and the child either points to the response that they choose or recites the corresponding letter.

Construction and Reliability

Data was collected from 2012 to 2014 on a nationally stratified sample of more than 2700 individuals. This assessment is internally consistent with the average Cronbach's alpha value of 0.80. A value of 0.80 indicates that the assessment is internally consistent. Significant positive relationships between test and retest standard scores also verify the reliability of the MVPT-4.²⁰¹ It has been concluded that the MVPT-4 measures all aspects of visual-perceptual skills in which it intends to measure, therefore confirming validity.²⁰¹

Visual Perceptual Abilities Assessed

- Visual discrimination—discriminates dominant features of objects, including position, shape, and form.
- Spatial relationships—perceive the positions of objects in relation to oneself and other objects, including perception of pictures, figures, and patterns that are disoriented in relation to each other, such as figure reversals and rotations.

- Visual memory—recognize a previously presented stimulus item after a brief interval.
- Figure-ground—distinguish an object from background or surrounding objects.
- Visual closure—perceive a whole figure when only fragments are presented.

Comment

Before administering the MVPT-4, the chronological age of the client and reason for the selection of this specific assessment should be recorded. The client should feel like he or she is in a safe and comfortable environment. All directions and expectations should be explained in simple terms, and there should be an opportunity for the client to ask questions. The assessment may begin when the examiner feels that the client understands the procedure and expectations. If another person needs to be in the room to make the client feel comfortable, this is appropriate as long as they sit out of sight and do not engage in conversation. During this test, the examiner can observe the client's behaviors including their ability to focus, attend to the task, and stay seated. Notes about the client's behavior can be documented on the score sheets comments section. If lack of attention and other behaviors are preventing the client from successfully completing the assessment, the assessment should be discontinued and resumed at a later time.²⁰¹

EVALUATION TOOL OF CHILDREN'S HANDWRITING (1995)¹²⁷

Author

Description

The Evaluation Tool of Children's Handwriting (ETCH) is designed to evaluate manuscript and cursive writing for components of legibility and speed. Specific components of the child's handwriting, including letter formation, spacing, size, and alignment, are included for assessment. The following tasks are presented in order:

1. Lowercase alphabet letters (from memory)
2. Uppercase alphabet letters (from memory)
3. Numeral writing (from memory)
4. Near point copying (visual model)
5. Far point copying (visual model)
6. Dictation (verbal)
7. Sentence composition (independent)

A quick reference card is included with standardized directions and timing criteria. Written and illustrated scoring criteria have been designed to assist the evaluator in determining the legibility of letters and numbers. The primary focus of scoring is whether the written material is readable.

Construction and Reliability

Based on the efforts of numerous occupational therapy practitioners, students, and professors, the ETCH itself has evolved through scientific investigation. Pilots of the ETCH were designed by using adaptations of written tasks from existing tools. Three editions of the ETCH have been sampled by practitioners working in school systems, with feedback given on the examiner's manual, ease of administration and scoring, item selection, scoring procedures, and face validity of the instrument. When the ETCH was published, it lacked normative and psychometric information. Since that time, test reliability, validity, and normative data of the ETCH are being compiled through various research studies. Eight studies of handwriting speed are included for reference in the manual. The most recent examination of test-retest reliability studies²⁰² identified adequate stability of total word (0.95), letter (0.88), and number (0.84) scores. Individual letter, word, and number subtests were not as stable and should be used cautiously in interpretation of problems. Interrater reliability ranged from 0.63 to 0.94 for individual manuscript items and 0.64 to 0.97 for cursive. Overall, the total word reliability is more stable than task scores, ranging from 0.90 to 0.98.

Comment

The ETCH assesses functional writing skills that are relevant to academic performance. The varied tasks allow the examiner to identify areas of strength and weakness in written performance, including legibility components, speed, and composition models (visual, verbal, and memory). Information received from the ETCH is qualitative at this point because of the lack of normative samples. The author suggests that the ETCH be used in conjunction with observations of the child's writing activity in natural environments, such as classroom and home, as a determination of difficulties in functional written performance.

MINNESOTA HANDWRITING ASSESSMENT (MHA)

Author

Judith Reisman, PhD, OTR, FAOTA

Source

Pearson Clinical Assessments, 19500 Bulverde Rd #201, San Antonio, TX 78259

Ages

6 to 8 years

Administration

Individual or group; Initial Timed Portion: 2.5 minutes to establish rate score. Additional time given if test not completed in 2.5 minutes.

Total: 7 to 10 minutes (scoring time dependent on administrator's familiarity with scoring procedures)

Equipment

Test sheets, pencil, manual, stop-watch, ruler, red pen

Description

The *Minnesota Handwriting Assessment* (MHA) is a near-point copy test. Students are asked to copy words onto a marked lined paper. This assessment helps to identify students with handwriting difficulties through an objective analysis and normative rating system. It can also provide baseline data to document treatment effectiveness by specifically focusing on the students' rate of completing the writing task legibility (speed), alignment, size, and spacing.

Construction and Reliability

Normative data was provided for a large sample ($n = 2186$) of typically developing children in grades one and two (aged 6 to 8 years; 78 to 103 months).²⁰³ The sample of students was from 11 US states. An effort was made to obtain an ethnically diverse sample by soliciting a mix of students from both urban and rural school districts across several states. However, the sample does not reflect the ethnic composition of students in the general population. Special education students, mainstreamed into the regular classroom, were included (4% of the total sample). Diagnostic information for special education students was not provided. Sample by gender was on average 49% female and 51% male. Interrater and intrarater reliability for total MHA scores are reported to be excellent (Pearson correlation .77 to .88). Test-retest reliability was assessed in a sample of 99 grade two students with testing readministered after 5 to 7 days and found to range from poor to adequate (legibility, 64%-alignment, 86%) for total rate scores. Adequate intraclass correlation coefficients of test-retest reliability were also reported.²⁰³

Comment

Time efficient to use in classroom—children do not have to miss significant class time to take it.

It is a fairly objective assessment with a detailed manual with samples for guidance. The MHA is based on normative data and can measure treatment effectiveness with pretesting and posttesting. The limitations are the long and detailed scoring and some components subject to interpretation.

THE PRINT TOOL¹²⁸

Authors

Jan Olsen, OTR, and Emily Knapton, OTR/L

Source

Handwriting Without Tears, 8001 Mac Arthur Boulevard, Cabin John, MD 20818

Email: janolson@hwtears.com; website: <https://www.hwtears.com>

Ages

6 years old and older

Administration

Individual; administration for handwriting sample takes 15 minutes, scoring approximately 30 minutes

Equipment

Student booklet and pencil, or a writing sample can be collected from school; evaluation score sheet; transparent measuring tool for accurate scoring; comprehensive scoring overview; handwriting remediation plan forms to develop goals; and strategies for remediation

Description

The Print Tool is a formal printing assessment to use in evidence-based remediation programs. The Print Tool is used to evaluate handwriting skills, plan intervention, and measure progress in students experiencing handwriting difficulty. A student's ability to print dictated letters and numbers is assessed. Evaluation scores for each specific skill area assessed help identify the student's strengths and needs. The Print Tool provides general remediation suggestions and specific strategies to be carried out with the author's remedial Handwriting Without Tears curriculum. This tool can be used in all school and therapy settings and with all curricula. Eight handwriting components for capitals, lowercase letters, and numbers are considered:

1. Memory: remembering and writing dictated letters and numbers
2. Orientation: Facing letters and numbers in the correct direction
3. Placement: Putting letters and numbers on the baseline
4. Size: How big or small a child chooses to write
5. Start: Where each letter or number begins
6. Sequence: Order and stroke direction of the letter or number parts
7. Control: Neatness and proportion of letters and numbers
8. Spacing: Amount of space between letters in words and between words in sentences

Construction and Reliability

The Print Tool has been recently released. Standardization has not been completed; however, suggested age-related expectations are provided in the manual. Data collection is in process for standardization in the future.

Continuing education is recommended to understand the complete process of observing, scoring, and compiling a remediation plan with The Print Tool. A Level 1 Certification is offered by the Handwriting Without Tears organization. Both the assessment and the award-winning Handwriting Without Tears curriculum were developed based on the authors' many years of successful practice in evaluating and remediating handwriting problems. The Handwriting Without Tears program is a structured remedial program geared toward different age and skill levels. It is multisensory, developmentally based, and easy to implement. Support is provided via the Handwriting Without Tears website.

Abstract: This chapter provides an in-depth discussion of learning disabilities and developmental coordination disorders, and the role of rehabilitation clinicians on the evaluation and management of these conditions.

Keywords: developmental coordination disorder, learning disabilities, life-span disability, model of disablement, motor learning, neurodevelopmental treatment, nonverbal learning disabilities, praxis, sensorimotor, verbal learning impairments

Spina Bifida: A Neural Tube Defect*

Yasser Salem and Ellen M. Godwin

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the various types of spina bifida.
2. Recognize the incidence and etiology of spina bifida.
3. Identify the clinical manifestations of myelomeningocele, including neurological, orthopedic, and urological sequelae.
4. Understand medical management in the newborn period and beyond.
5. Determine physical and occupational therapy evaluations, including manual muscle testing, range of motion, sensory testing, reflex testing, muscle tone assessment, developmental and functional and mobility assessments, and perceptual and cognitive evaluations.
6. Determine the major physical and occupational therapy goals and appropriate therapeutic management for each of the following stages: (a) before surgical closure of sac, (b) after surgery during hospitalization, (c) early infancy, (d) preambulatory, (e) toddler through preschool age, (f) primary school age through adolescence, and (g) transition to adulthood.
7. Identify psychological adjustment to spina bifida.

KEY TERMS

Chiari malformation
crouch-control ankle-foot orthosis
diastematomyelia
hydrocephalus
lipomeningocele

myelodysplasia
myelomeningocele
neural tube defects
reciprocating gait orthosis
sacral agenesis

spina bifida
spina bifida cystica
spina bifida occulta
standing A-frame
tethered spinal cord

INTRODUCTION

Spina bifida, a congenital spinal cord injury, is a complex disability that results from a failure of the caudal neural tube to fuse early in embryonic development. This congenital condition predisposes many areas of the central nervous system (CNS) to not develop or function adequately. In addition, all areas of development (physical, cognitive, and psychosocial) that depend heavily on central functioning will likely be impaired. The clinician must therefore be aware of the significant impact this neurological defect has on motor function as well as on a variety of related human capacities.

A developmental framework, the *Guide to Physical Therapist Practice*,¹ and the International Classification of Functioning, Disability and Health (ICF) have been used to aid in understanding the sequential problems of the child with spina bifida. The developmental model, however, must always stay in line with the functional model for adult trauma because the problems of the congenitally involved child rapidly evolve into limitations in the functional activities and participation in the life of the injured adult. By concentrating on the present while keeping an eye on the future, appropriate management goals can be achieved.

OVERVIEW AND PATHOGENESIS

Spina bifida occurs in utero and is present at the time of birth. Understanding how this malformation develops requires an appreciation of normal nervous system maturation.

Overview of Neural Tube Formation

The nervous system develops from the external layer of the zygotic disc called the ectoderm in a process called neurulation. During embryonic development, a longitudinal thickening of the ectoderm, which is called the neural plate, will differentiate into the brain and spinal cord to form the CNS. The neural plate is a trough-shaped differentiation of the ectodermal layer of the embryonic disc. The neural plate is a vertically oriented, topographically flat sheet of cells; its wide end lies rostrally and becomes the brain, whereas the slim end lies caudally and becomes the spinal cord. A midline groove (central or ventricular zone) divides the neural plate into right and left halves (marginal zones). The central zone contains cells, neuroblasts, and glioblasts and the marginal zone contains the processes of cells of the ventricular zone. The edges of the neural plate (neural folds) fold gradually, creating and deepening the neural groove. By the 20th day of gestation, the neural plate is an oblong structure that is wide at its rostral area (future brain) and slim caudally (future spinal cord). On day 21 of gestation, the edges continue to grow dorsally toward each other until they meet, fusing to create a hollow cylinder called the neural tube. Along the site of fusion, cell surface coats consisting of glycoproteins are deposited

*Videos for this chapter are available at studentconsult.com.

Fig. 13.1 Neural Tube Formation. (From Lundy-Ekman L. *Neuroscience: Fundamentals for Rehabilitation*. 4th ed. Elsevier.)

as a glue to hold the folds in place until more permanent cell-to-cell contacts can be established.

The neural tube closes first in the future cervical region. The closure proceeds rostrally and caudally, like zippering, leaving an opening at the rostral (cranial) end called the anterior neuropore and an opening at the caudal end called the posterior neuropore. The anterior and posterior neuropores close on days 24 and 27 of gestation, respectively (Fig. 13.1).

By day 26, the neural tube differentiates into two concentric circles. The mantle layer (inner wall) contains cell bodies and will become gray matter. The marginal layer (outer wall) contains processes of cells, whose bodies are located in the mantle layer. The marginal layer develops into white matter, consisting of axons and glial cells.

At the junction between the neural plate and remaining ectoderm lies a narrow strip of cells that develop from the ectoderm, called the neural crest, that will generate a variety of adult structures, including most neurons of the peripheral nervous system (PNS). When the neural crest has developed, the neural tube and the neural crest move inside the embryo. The neural crest detaches from the lateral edge of the neural plate and assumes a location anterolateral to the neural tube. The overlying ectoderm is destined to become the epidermal layer of skin and closes over the tube and neural crest.

As the nervous system continues to develop, the rostral end of the neural tube differentiates into a series of vesicles that constitute the major brain regions and the caudal end of the neural tube forms the spinal cord. The neural crest differentiates to form most of the PNS neurons, with the rest arising from nearby ectoderm.

Neural Tube Defects

It is generally accepted that neural tube defects (NTDs) are caused by the failure of the neural tube to close, although it has also been suggested that a closed tube may reopen in some cases.^{2,3} A variety of defects results from the failure of the neural tube to properly close. Failure of closure of the neural tube may occur at several sites and the clinical types of NTDs differ depending on the site at which closure fails.³

The types of NTDs include anencephaly, spina bifida, encephalocele, craniorachischisis, and iniencephaly. The latter two types are rare, but they tend to occur with disproportionate frequency in areas that

have a high rate of NTDs, such as northern China.⁴ The most dysraphic disorders occur at the location of the anterior or posterior neuropores, resulting in anencephaly, encephalocele, or spina bifida.

Craniorachischisis is the most severe type of NTD in which the neural tube does not fuse. In this condition, either the none of neural tube closes, which leaves the entire spinal cord open, or the tube is partially closed, which leaves the spinal cord partially open. Craniorachischisis comprises 10% of NTDs, in which the entire neural tube remains open from midbrain to low spine.³

Iniencephaly is an uncommon but severe form of NTDs with severe defect of the cervical spine. Iniencephaly involves bifid neural arches, with retroflexion of the skull and an extremely short neck. Most cases involve occipital encephalocele. It seems to be more common in females.³

Failure of fusion of the cranial end of the neural tube results in a condition known as *anencephaly*. In this defect, there is minimal development of the brain, including an absence of development of the forebrain.⁵ In most cases, the brain stem may be fairly intact, but the cerebellum may be absent. A failure of the anterior neuropore to close results in a failure of development of the surrounding meninges and skull to form over the incomplete brain, leaving the brain and brain stem exposed (Fig. 13.2). Considerable facial abnormalities are commonly seen in these children. This NTD is not compatible with life. Most fetuses with this condition die before or shortly after birth, and almost none survive for more than few days.

Failure of the neural tube to close completely at the cranial level results in crania bifidum, a defect in the cranium. An encephalocele is a herniation of intracranial contents through a defect in the cranium. The cystic structure may contain only meninges (meningocele), meninges and brain structures (meningoencephalocele), or meninges, brain structures, and a part of the ventricular system (meningohydroencephalocele) (Fig. 13.3). Encephaloceles may occur anywhere along the center of the skull from the nose to the back of the neck. Encephaloceles are most common in the occipital region, but they may also occur between the forehead and the nose or at the top of the head. Encephalocele can be asymptomatic but can also be fatal, depending on the extent of brain damage.³

Defects in the closure of the posterior neuropore cause a range of malformations known collectively as spina bifida (Fig. 13.4). The

Fig. 13.2 (A) Spina bifida in a newborn. (B and C) Anencephaly showing absence of the cranial vault. (From *Pathophysiology: The Biologic Basis for Disease in Adults and Children*, 6th ed. McCance – Elsevier.)

Fig. 13.3 Encephalocele. (From *Neurologic Rehabilitation: Neuroscience and Neuroplasticity in Physical Therapy Practice*, Nichols Larsen – McGraw Hill.)

defect always involves a failure of the vertebral arches at the affected levels to form completely and fuse to cover the spinal cord. In most cases, the malformation is covered with skin, but the site may be marked by unusual pigmentation, hair growth, telangiectases (large superficial capillaries), or a prominent dimple. The defect can be open myelomeningocele and is considered the most severe form of spina bifida. Spina bifida is the most common of the NTDs.

TYPES OF SPINA BIFIDA

Spina bifida results from a failure in neural tube closure and closure of the overlying posterior vertebral arches (dysraphism). The extent of the defect may result in one of two types of spina bifida: occulta or cystica. The terms *spina bifida*, *myelodysplasia*, and *myelomeningocele* are frequently used interchangeably.

Spina bifida occulta is characterized by a failure of one or more of the vertebral arches to meet and fuse in the third month of gestation. The spinal cord and meninges are unharmed and remain within the vertebral canal (Fig. 13.5A). The bony defect is covered with skin that

Fig. 13.4 Meningomyelocele in an Infant. (From *Neuroscience Fundamentals for Rehabilitation*. 4th ed. Lundy-Ekman.)

may be marked by a dimple, pigmentation, or patch of hair.⁶ The most common site for this defect is the lumbosacral area, and it is usually associated with no disturbance of neurological or musculoskeletal functioning. Most individuals with spina bifida occulta are unaware that they have this defect.

Spina bifida cystica results when the neural tube and overlying vertebral arches fail to close appropriately. Cystic protrusion of the meninges or the spinal cord and meninges occurs through the defective vertebral arches and produces a cystic sac.

The milder form of spina bifida cystica, called *meningocele*, involves protrusion of the meninges and cerebrospinal fluid (CSF) only into the cystic sac (see Fig. 13.5B). The spinal cord remains within the vertebral canal, but it may exhibit structural abnormalities.⁷ Clinical signs vary (according to the extent of spinal cord anomalies) or may not be apparent. This is a relatively uncommon form of spina bifida cystica.

A rare but more severe form of spina bifida cystica, called *myelocele* or *myelocystocele*, or *terminal myelocystocele*, is present when the central canal of the spinal cord is dilated (syringocele) and surrounded by an expanded dural sheath, producing a large, skin-covered cyst. The neural tube appears to close normally but is distended from the cystic swelling. The CSF may ceaselessly expand the neural canal. Most born with myelocystocele have no neurological deficit; however, prompt medical attention is mandatory for repair of the cyst.^{8,9}

The more common and severe form of the spinal bifida is known as *myelomeningocele*, in which both spinal cord and meninges are

Fig. 13.5 Types of Spina Bifida. (A) Normal anatomical structures. (B) Spina bifida occulta. (C) Meningocele. (D) Myelomeningocele. (From *Pathology Implications for the Physical Therapist*. 4th ed. Goodman. Elsevier.)

contained in the cystic sac (see Fig. 13.5C). Within the sac, the spinal cord and associated neural tissue show extensive abnormalities. In incomplete closure of the neural tube (dysraphism), abnormal growth of the cord and a convoluted pathway of neural elements interrupt the normal transmission of neural impulses. The result is a variable sensory and motor impairment at the level of the lesion and below.⁶ In an open myelomeningocele, nerve roots and spinal cord may be exposed, with dura and skin evident at the margin of the lesion. Exposure of the open neural tube to the amniotic fluid environment leads to neuroepithelial degeneration, with massive loss of neural tissue by the end of pregnancy.¹⁰

Although spina bifida cystica can occur at any level of the spinal cord, myelomeningoceles are most common in the thoracic and lumbosacral regions. Myelomeningocele occurs in 94% of the cases of spina bifida cystica, and two-thirds of open lesions involve the thoracolumbar junction.⁶

Other forms of spinal dysraphism include diastematomyelia, lipomeningocele, and sacral agenesis. Diastematomyelia is present in 30% to 40% of patients with myelomeningocele and is secondary to partial or complete clefting of the spinal cord.¹¹ Lipomeningocele, another

form of spina bifida cystica, is usually caused by a vertebral defect associated with a superficial fatty mass (lipoma or fatty tumor) that merges with the lower level of the spinal cord. No associated hydrocephalus is present, and neurological deficit is generally minimal; however, problems with urinary control and motor control of the lower extremities may be noted.¹² Neurological tissue compromise may be caused by a tethered spinal cord; therefore early lipoma resection is indicated for cosmesis and to minimize neurological sequelae.

Lumbosacral or sacral agenesis may occur and is caused by an absence of the caudal part of the spine and sacrum. Children with this form of dysraphism may have narrow, flattened buttocks, weak gluteal muscles, and a shortened intergluteal cleft. The normal lumbar lordosis is absent, although the lower lumbar spine may be prominent. Calf muscles may be atrophic or absent. The pelvic ring is completed with either direct opposition of the iliac bones or with interposition of the lumbar spine replacing the absent sacrum. These children may have scoliosis, motor and sensory loss, and visceral abnormalities, including anal atresia, fused kidneys, and congenital heart malformations. Management is started early and is symptomatic for each system.¹³

INCIDENCE, ETIOLOGY, PREVENTION, AND ECONOMIC IMPACT

Incidence

Statistics about the incidence of spina bifida vary considerably in different parts of the world. Spina bifida and anencephaly, the most common forms of NTDs, affect about 300,000 newborns each year worldwide.¹⁴ In the United States, the most recent annual prevalence estimates that 1460 babies are born with spina bifida, and¹⁵ the incidence is currently 2.48 per 10,000, down from approximately 7.23 per 10,000 births from 1974 through 1979 (before the folic acid mandate^{16–18}). Current worldwide folic acid fortification programs have resulted in a decreased incidence of spina bifida,^{19,20} with annual decreases of 6600 folic acid–preventable spina bifida and anencephaly births reported since 2006.²¹ There was a 31% decline in spina bifida prevalence rates in the immediate postfortification period (October 1998 through December 1999^{17,19}). Additionally, there was a continued decline in spina bifida prevalence rates from 1999 to 2004 of 10%.²² Studies have also demonstrated that decline has varied by ethnicity and race from prefortification to optional fortification to mandatory fortification in the United States.^{17,22} Initially after fortification, the largest decline in prevalence was noted in Hispanic and non-Hispanic white races or ethnicities. Despite this initial decline, postfortification prevalence rates remain the highest in infants born to Hispanic mothers and less in infants born to non-Hispanic white and non-Hispanic black mothers.²² In addition to periconceptual folate supplementation, it is thought that incidence has decreased subsequent to food fortification in several countries, decreased exposure to environmental teratogens, and increased and more accurate prenatal screening for fetal anomalies.¹⁴

The incidence of spina bifida has declined since the advent of amniocentesis and the use of ultrasonography for prenatal screening. The diagnosis of spina bifida is one of the common indications for birth termination.

Spina bifida is thought to be more common in females than in males,²³ although some studies suggest no real sex difference.⁷ A study of the association of race and sex with different neurological levels of myelomeningocele found the proportions of whites and females to be significantly higher in patients with thoracic-level spina bifida.⁸ A significant relation has also been noted between social class and spina bifida: the lower the social class, the higher the incidence.^{24,25}

Etiology

A multifactorial genetic inheritance has been proposed as the cause of spina bifida, coupled with environmental factors of which nutrition, including folic acid intake, is key. Genetic factors seem to influence the occurrence of spina bifida. Cytoplasmic factors, polygenic or oligogenic inheritance, chromosomal aberrations, and environmental influences (e.g., teratogens) have all been considered possible causes.^{10,21} Many studies identified an increased risk of NTD-affected pregnancy to be associated with epidemiological findings such as maternal and paternal ages and occupations, maternal reproductive history, including maternal country of birth and country of conception, nutrition, including folic acid and vitamin B12 deficiency, hyperthermia during early pregnancy, hyperglycemia or diabetes or obesity, and maternal use of medications during early pregnancy.²⁶

Genetic considerations, such as an Rh blood type, a specific gene type (HLA-B27), an X-linked gene, and variations in the many folate pathway genes have been implicated, but not conclusively.^{27,28} Malformations are attributed to abnormal interactions of several regulating and modifying genes in early fetal development.²⁹ Disturbance of any of the sequential events of embryonic neurulation produces NTDs, with the phenotype (i.e., spina bifida, anencephaly) varying depending on the region of the neural tube that remains exposed.¹⁰ Environmental factors combined with genetic predisposition appear to trigger the development of spina bifida, although definitive evidence is not available to support this claim.³⁰

A family history of spina bifida is one of the strongest risk factors.²³ The chances of having a second affected child are between 1% and 2%, whereas in the general population, the percentage drops to one-fifth of 1%.^{31,32} Although these factors are related to the incidence of spina bifida, the cause of this defect remains in question.

It is generally accepted that inadequate maternal intake of natural folate, or its synthetic form, folic acid, before and during early pregnancy, is associated with an increased risk of spina bifida.^{23,26} Several studies have shown that the failure to consume folic acid supplements or folic acid-containing multivitamins increases the risk of having an affected child by two- to eightfold.³³ The risk of having a child affected by an NTD is indirectly related to both maternal folate and folic acid intake as well as to maternal folate status. Folate is important in nucleic acid synthesis and in the biosynthesis of methionine through the conversion of homocysteine to methionine. Disruptions in folate metabolism can result in increased homocysteine concentrations, which are teratogenic to the neural tube. The precise mechanism underlying the association between NTDs and folate has not been established.

Vitamin B12, which is metabolically related to folate, might also be associated with NTDs. Studies have shown that deficient or inadequate maternal vitamin B₁₂ status is associated with a significantly increased risk for NTDs.^{34–36}

Environmental conditions such as hyperthermia in the first weeks of pregnancy or dietary factors such as maternal consumption of canned meats, blighted potatoes, or tea have been implicated but not substantiated.^{37,38}

Maternal diabetes is another factor related to the incidence of spina bifida.³⁹ Women with pregestational diabetes are at increased risk of having a child with spina bifida and other types of birth defects.²³ In these women, the risk of nervous system malformation including spina bifida is two- to tenfold higher than the risk in the general population. The mechanism underlying this teratogenic effect has not been established, but it is clearly related to the degree of maternal metabolic control.⁴⁰

Other factors associated with NTDs include maternal exposure to anticonvulsant drugs during early pregnancy. Many anticonvulsant drugs such as valproic acid are known teratogens. An increased risk of spina bifida is associated with exposure to valproic acid or carbamazepine alone, or in combination with each other or other

anticonvulsants.^{41,42} This risk is increased for women who are taking more than one anticonvulsant.

Women who use these drugs for indications other than epilepsy (e.g., bipolar disease, migraine, chronic pain) are also at higher risk of having a child with spina bifida if they become pregnant while taking these drugs.^{23,41,42} The mechanism by which valproic acid and carbamazepine increase the risk of spina bifida has not been established.

Prevention

Historically, nutritional deficiencies, such as of folic acid and vitamin A, have been implicated as a cause of primary NTDs.^{43–46} Fifty to 70% of NTDs can be prevented if a woman of childbearing age consumes sufficient folic acid daily before conception and throughout the first trimester of pregnancy. As a result of research findings in support of folic acid implementation, the US Public Health Service has mandated folic acid fortification since 1998 as a public health strategy. Prenatal vitamins, especially folic acid, are recommended to discourage the condition's development. Current fortification programs are preventing about 22,000 cases, or 9% of the estimated folic acid–preventable spina bifida and anencephaly cases.²¹ At this time, folic acid supplementation and fortification provide the only means of primary prevention for spina bifida and other NTDs.²³

Economic Impact

Health care use and costs for children with spina bifida are significantly greater than those of unaffected children.⁴⁷ The lifetime cost to society per affected person with spina bifida is estimated to be over \$600,000.^{48–50} One-third of this amount comprises direct medical costs with the remainder being indirect costs, including special educational and caregiver needs and the loss of employment potential.⁴⁸ In addition to medical management costs per child, there are additional costs that affect both the family and society across the life-span and are variable and often related to differential market forces and social welfare policies.⁵⁰

A study published in 2012 that examined the associated costs during the first year of life among children with spina bifida indicated that the estimated hospital cost per infant is \$39,059⁴⁷ and the total medical expenditures during the first year is more than \$50,000.⁵¹ The majority of expenditures during infancy were from inpatient admissions secondary to surgeries concentrated during this time period for those with spina bifida.⁵¹ After infancy, average medical care expenditures during 2003 ranged from \$15,000 to \$16,000 per year among different age groups of persons with spina bifida. Incremental expenditures associated with medical care were not stable, but decreased with increasing age, from \$14,000 per year for children to \$10,000 per year for adults aged 45 to 64 years.⁵¹ These data were published in 2007 and reflect costs collected during 2002–2003. With a dynamic economy, it is likely that these values underestimate the cost to society today. Infants born with spina bifida who developed hydrocephalus had Medicaid health care expenditures 2.6 times higher than infants born with spina bifida who did not develop hydrocephalus.⁵²

A study examining hospitalizations during the first year of life among children with spina bifida reported that the average number of hospitalizations per infant is 2.4, while the average total days of hospitalization is 25.2, and approximately 18% of the infants were hospitalized more than three times during the first year of life.⁴⁷

CLINICAL MANIFESTATIONS

Weakness and Paralysis

Determining the extent of neurological impairment is not as straightforward as assumed and requires thorough and careful examination and evaluation of the infant. At birth, two main types of motor dysfunction

in the lower extremities have been identified. The first type involves a complete loss of function below the level of the lesion, resulting in a flaccid paralysis, loss of sensation, and absent reflexes. The extent of involvement can be determined by comparing the level of the lesion with a chart delineating the segmental innervation of the lower limb muscles and the examination findings. Orthopedic deformities may result from the unopposed action of muscles above the level of the lesion. This unopposed pull may lead to hip flexion, knee extension, and ankle dorsiflexion contractures, depending on the level of the lesion.

When the spinal cord remains intact below the level of the lesion, the effect is an area of flaccid paralysis immediately below the lesion and possible hyperactive spinal reflexes distal to that area. This condition is quite similar to the neurological state of the severed cord seen in traumatic injury. This second type of neurological involvement again results in orthopedic deformities, depending on the level of the lesion, the spasticity present, and the muscle groups involved.

Muscle Tone Abnormalities

Abnormality in muscle tone is a common feature observed in children with spina bifida. In these children, muscle tone can range from flaccidity to normal tone to spasticity. A mixture of spasticity and hypotonia may be observed in some children with spina bifida. Normal muscle tone has been reported in a small number of children with spina bifida. The majority of children with spina bifida will have lower motor neuron lesions. Children with lower level spina bifida present with signs and symptoms of lower motor neuron lesions including areflexia, hyporeflexia, flaccidity, or hypotonia. Children with higher level spina bifida present with signs and symptoms of upper motor neuron (UMN) lesions including spasticity. Children with Chiari II malformation, hydrocephalus, tethered cord syndrome (TCS), or cervical hydromyelia may present with spasticity, which has also been reported to occur in the upper extremities of many children with shunting. The relationship between muscle tone and function is not clearly understood and is controversial. Problems related to spasticity may include the potential for contractures, difficulty maintaining or changing positions, and the presence of exaggerated primitive reflexes. Difficulties associated with flaccidity may include inability to generate muscle force, inability to bear weight on the flaccid limb, deformities, poor limb posture, and other secondary disorders such as decreased bone strength. Determining the type of muscle tone abnormality and severity may help in decision making regarding treatment, such as braces, and teaching compensatory strategies for functional skills.

Sensory Impairment

Children with spina bifida have impaired sensation below the level of the lesion. The sensory loss often does not match exactly the lesion and radiological levels and needs to be carefully assessed. Sensory loss includes pain, temperature, kinesthetic, proprioceptive, and somatosensory information. Sensory deficits manifest in several ways. The child may be hyposensitive or not sensitive to sensory input, startling or withdrawing from light touch or painful stimuli. Because of sensory deficits, children will often have to rely heavily on vision and other sensory systems to substitute for this loss.

Sensory loss (level) correlates with outcomes in terms of mobility, continence, major complications, and overall disability as well as with deaths caused by renal failure. Sensory deficits may produce serious functional consequences. Impairment in sensation may result in significant motor deficits such as impaired balance and coordination. Sensory deficits can compromise safety and make the child vulnerable to injury if their response to painful or damaging stimuli is impaired. It is important that the child and parents be aware of these deficits and of possible ways to compensate or substitute for them, such as relying

on vision. Sensory deficits should be considered when creating awareness about safety and prevention of associated disorders such as skin breakdown and pressure ulcers.

Hydrocephalus

Hydrocephalus is common in children with spina bifida, developing in 80% to 90% of children with myelomeningocele.^{32,53} Hydrocephalus is a pathological enlargement of the brain ventricles as a result of increased amounts of CSF. CSF is produced by the choroid plexus in each brain ventricle. CSF passes through the ventricular system, exiting the fourth ventricle and entering the subarachnoid space, which is continuous around the brain and spinal cord. After passing through the subarachnoid space, the CSF reaches the arachnoid villi in the superior sagittal sinus and flows into the venous system. Absorption of CSF is via the arachnoid villi that are associated with venous sinuses as well as lymphatics that are associated with cranial and spinal nerves.

Hydrocephalus in patients with spina bifida results from a blockage of the normal flow of CSF between the ventricles and spinal canal. Excessive pressure in the ventricles exerted by CSF compresses the nervous tissue, which causes brain damage and may result in disproportionately large head size in newborns or infants. The pressure may interfere with the function of the adjacent structures and can cause a range of impairments in brain function.

In newborns and infants, the most obvious effect of the buildup of CSF is an abnormal increase in head size, which may be present at birth because of the great compliance of the cranial sutures in the fetus, or may develop postnatally.⁵⁴ Other signs of hydrocephalus include bulging fontanel or a tense soft spot (fontanel) on top of the head. Frontal lobe functions are also involved in causing disorders in emotion, planning, spatial awareness, and intellectual function. Hydrocephalus may result in a downward gaze of the eyes (sunsetting of the eyes) from compression of the oculomotor nerve. Symptoms may also include vomiting, sleepiness, irritability, seizures, abnormal muscle tone, weakness, sensory deficits, and poor feeding and growth.

In older children and adults, signs and symptoms may include abnormal enlargement of the head, headache, seizures, nausea and vomiting, blurred or double vision, sleepiness, lack of sleep, lethargy, poor appetite, weakness, sensory deficits, abnormalities in muscle tone, poor balance and coordination, and urinary incontinence.

Internally, a concomitant dilation of the lateral ventricles and thinning of the cerebral white matter are usually present. Without reduction of the buildup of CSF, increased brain damage and death may result. Surgical treatment for hydrocephalus can restore and maintain normal CSF levels in the brain. It is very important for all individuals (doctors, nurses, therapists, teachers, etc.) working with children with spina bifida to watch for any signs and symptoms of hydrocephalus, particularly in children with shunts due to shunt malfunction. These signs and symptoms include a high-pitched cry, sudden changes in appetite/sucking or feeding, unexplained and recurrent vomiting, unwillingness to move the head or lay down, breathing difficulties, seizures, unexplained weakness, changes in muscle tone, difficulty walking, decreased balance, or unexplained poor school performance.

Chiari Malformation

Chiari II, also known as Arnold-Chiari II malformation, is a common presentation in children with myelomeningocele, with a 99% chance of having an associated Chiari II (Fig. 13.6).¹¹ This malformation is a congenital anomaly of the hindbrain that arises in the fifth week of gestation as a consequence of abnormal neurulation.⁵⁵ This complex anomaly involves downward displacement of the cerebellum and herniation of the medulla, and at times the pons, fourth ventricle, and inferior aspect of the cerebellum, through the foramen magnum into the upper cervical canal. The herniation usually occurs between C1

Fig. 13.6 Myelomeningocele and Arnold-Chiari II Malformation. (From *Neurologic Rehabilitation: Neuroscience and Neuroplasticity in Physical Therapy Practice*, Nichols-Larsen – McGraw Hill.)

and C4, but may extend down to T1.^{11,56,57} In those with Chiari II malformations and spina bifida, there is a significant reduction in cerebellar volume while, within the cerebellum, the anterior lobe is enlarged and the posterior lobe is reduced.⁵⁸ Cardinal features of the Chiari II malformation include myelomeningocele in the thoracolumbar spine, venting of the intracranial CSF through the central canal, dysgenesis of the corpus callosum, hypoplasia of the posterior fossa, herniation of the hindbrain into the cervical spinal canal, and compressive damage to cranial nerves.⁵⁵ The abnormal configuration of the brain in Chiari II malformation often results in hydrocephalus, a blockage of the normal flow of the CSF in the ventricular system. Hydromyelia and syringomyelia are seen in patients with Chiari II malformation (Fig. 13.7).

Not all Chiari II malformations are symptomatic. The severity can vary dramatically, and signs and symptoms can vary from no symptoms to severe, potentially debilitating, or life-threatening symptoms. Chiari II malformations may present with a spectrum of signs and symptoms related to brain stem compression and lower cranial nerve dysfunction. As a result of a symptomatic Chiari II malformation, problems with respiratory and bulbar function may be evident in a child with spina bifida.⁶ Paralysis of the vocal cords occurs in a small percentage of patients and is associated with respiratory stridor. Apneic episodes also may be evident, although their direct cause remains in question. Children with spina bifida may also exhibit difficulty in swallowing and have an abnormal gag reflex.⁶ Problems with aspiration, weakness and cry, and upper-extremity weakness may also be present in children with a symptomatic Chiari II malformation.^{59,60} Thus depending on the orthopedic deformities present and the neurological involvement, severe respiratory involvement is possible in the affected child. These symptoms may be caused by significant compression of the hindbrain structures or dysplasia of posterior fossa contents, which can also occur in patients with Chiari II malformation.^{11,61} This complex hindbrain malformation is a common cause of death in children with myelomeningocele, despite surgical intervention and aggressive medical management.⁶²

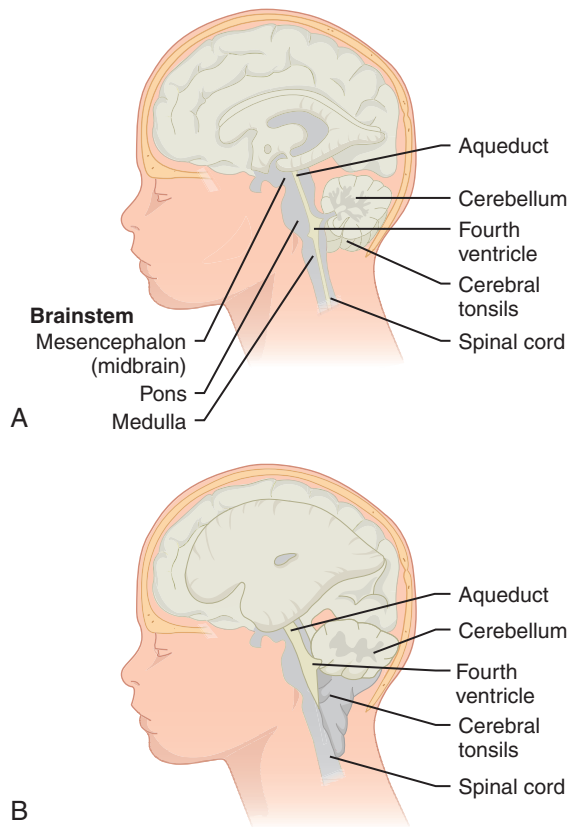

Fig. 13.7 (A) Normal Brain with Patent cerebrospinal fluid (CSF). **(B)** Arnold-Chiari malformation type II with enlarged ventricles. (From *Pathology: Implications for the Physical Therapist*. 4th ed. Goodman, Elsevier.)

Occipital headaches felt near the base of the skull radiating to the neck and shoulders are a common symptom in older children, which can be brought on or worsened by coughing, straining, or sneezing. Signs and symptoms may include abnormalities affecting the eyes, including blurred vision, double vision, abnormal sensitivity to light, nystagmus, and pain behind the eyes. Vertigo, dizziness, ringing in the ears (tinnitus), and bilateral hearing impairments can also develop. Additional symptoms associated with a Chiari malformation may include muscle weakness, balance deficits, poor coordination and paresis, and tingling or burning sensations in the fingers, toes, or lips.

Some children never require treatment for a Chiari malformation. Severe brain stem Chiari II malformation may be reversed after repair and lower rates of hydrocephalus are noted after fetal closure.

Association Pathways

Diffusion tensor tractography studies of association pathways in children with spina bifida have revealed characteristics of abnormal development, impairment in myelination, and abnormalities in intrinsic axonal characteristics and extraaxonal or extracellular space. An imaging study in children with spina bifida indicated that there is a pattern of thinning associated with hydrocephalus with an overall reduction in white matter and increased neocortical thickness in the frontal regions, suggesting long-term disruption of brain development in children with spina bifida that extends far beyond the NTD in the first weeks of gestation.⁶³ Other studies indicated changes or abnormalities in the tectum.^{64–66} These changes in diffusion metrics observed in children with spina bifida are suggestive of abnormal white matter development and persistent degeneration with increased age.⁶⁷

Hydromyelia

Hydromyelia is sometimes used interchangeably with syringomyelia, the name for a condition that also involves the development of syrinx, or a fluid-filled cavity within the spinal cord. Hydromyelia is commonly seen in patients with myelomeningocele, and studies have reported that 17% to 80% of patients with myelomeningocele have hydromyelia.^{11,68,69} Hydromyelia is usually defined as an abnormal widening (dilatation) of the central canal of the spinal cord, with an accumulation of CSF within the central spinal canal. Hydromyelia signifies dilation of the center canal of the spinal cord, whereas hydrocephalus signifies dilation of the ventricles of the brain. This can progress with increased pressure to the surrounding tissues. The area of hydromyelia may be focal, multiple, or diffuse, extending throughout the spinal cord. Hydromyelia does not seem to be present at birth or in early infancy, rather, it appears later on.⁷⁰ Adults with SB remain at risk for developing a syrinx anywhere along the spinal cord.⁷¹ The hydromyelia may be a consequence of untreated or inadequately treated hydrocephalus with resultant transmission of CSF through the obex into the central canal, with distention as a result of increased hydrostatic pressure from above.^{11,72} The increased collection of fluid causes the fluid cavity to expand. It may displace or cause pressure necrosis of the nerve fibers inside the spinal cord leading to muscle weakness and scoliosis, resulting from loss of input to the paraspinals.

In a majority of patients, syringomyelia or hydromyelia are asymptomatic,^{71,72} but in other cases, symptoms may be fatal.⁷¹ Syringobulbia is of particular concern and may contribute to sleep disordered breathing and sudden death.⁷¹ A wide variety of symptoms can occur, depending upon the size and location of the fluid cavity. Common symptoms of hydromyelia include rapidly progressive scoliosis, upper-extremity weakness, spasticity, ascending motor loss in the lower extremities, dissociated segmental sensory disturbances, bladder dysfunction, and pain.^{11,72,73}

Magnetic resonance imaging (MRI) with contrast (gadolinium) is a key tool for the diagnosis of hydromyelia. Not all children develop symptoms from hydromyelia that require treatment.⁷⁴ Aggressive treatment of hydromyelia at the onset of clinical signs of increasing scoliosis is mandatory and may lead to improvement in or stabilization of the spinal curve in 80% of cases. In cases where hydrocephalus or Chiari malformation are causing the hydromyelia, the surgeon will treat the underlying cause and the syrinx will usually shrink or disappear. Surgical interventions may include revision of a CSF shunt, posterior cervical decompression, or a central canal to pleural cavity shunt with a flushing device.^{11,61} Surgical treatment of hydromyelia has a very good outcome.

Tethered Cord

Tethered spinal cord is defined as a pathological fixation of the spinal cord in an abnormal caudal location (Figs. 13.8 and 13.9). This fixation

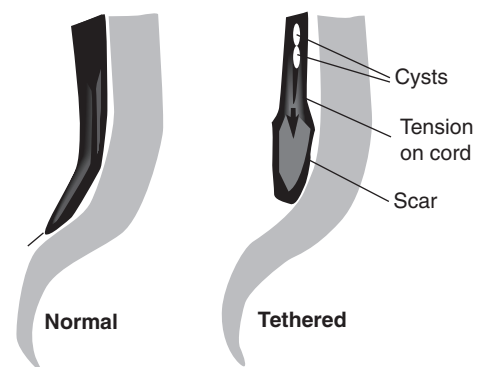

Fig. 13.8 Tethered Cord in Myelodysplasia. (From Staheli LT. *Practice of Pediatric Orthopedics*. Philadelphia: Lippincott Williams & Wilkins; 2001.)

Fig. 13.9 Magnetic resonance image showing a tethered spinal cord at L3. (From Lundy-Ekman L. *Neuroscience: Fundamentals for Rehabilitation*. 4th ed. Elsevier.)

produces mechanical stretch, distortion, and ischemia with daily activities, growth, and development.⁷⁵ Ischemic injury from traction of the conus directly correlates with degree of oxidative metabolism and degree of neurological compromise. In addition to ischemic injury, traction of the conus by the filum may also mechanically alter the neuronal membranes, resulting in altered electrical activity.^{76–80} The abnormal attachments cause an abnormal stretching of the spinal cord that limits its movement within the spinal column and may cause strain on the spinal cord during normal movements. This abnormal attachment is associated with progressive stretching and increased tension of the spinal cord as a child ages, potentially resulting in a variety of symptoms. The progression of neurological signs and symptoms is highly variable due to variation in growth rate of the spinal cord and the spinal column. In some individuals, symptoms can develop at birth, infancy, or early childhood (EC). Some patients may not develop symptoms until adulthood. The most commonly reported triggers in adult patients with repaired SB myelomeningocele are falls, back trauma, heavy lifting, and vaginal childbirth.⁷¹ The presence of TCS should be suspected in any patient with abnormal neurulation (including patients with myelomeningocele, lipomeningocele, dermal sinus, diastematomyelia, myelocystocele, tight filum terminale, and lumbosacral agenesis).

The specific symptoms, severity, and progression vary from one individual to another. Presenting symptoms may include decreased strength (often asymmetrical), development of lower-extremity spasticity, back pain at the site of sac closure, early development or an increasing degree of scoliosis (especially in the low lumbar or sacral level^{81–83}), or a change in urological function.^{62,84,85} Ten to 30% of children will develop TCS after repair of a myelomeningocele. Essentially all children with a repaired myelomeningocele will have a tethered spinal cord, as demonstrated on MRI. Diagnosis of TCS is made based on clinical criteria. The six common clinical presentations of TCS are increased weakness (55%), worsening gait (54%), scoliosis (51%), pain (32%), orthopedic deformity (11%), and urological dysfunction (6%).⁸⁶ This clinical spectrum may be primarily associated with these dysraphic lesions or may be caused by spinal surgical procedures.⁷⁵ The cord may be tethered by scar tissue or by an inclusion epidermoid or lipoma at the repair site.¹¹ In individuals with no or minimal symptoms, surgery may not be indicated, and the symptoms should be monitored for progression. Surgery soon after symptoms emerge

appears to improve chances for recovery and can prevent further functional decline. Surgery is recommended to prevent or reverse progressive neurological symptoms. The primary goal of surgery is to detach the spinal cord where it is adherent to the thecal sac, relieving the stretch on the terminal portion of the cord. Surgery to untether the spinal cord (tethered cord release [TCR]) is performed to prevent further loss of muscle function, decrease the spasticity, help control the scoliosis,^{82,87} or relieve back pain.^{88,89}

The responses to treatment for TCS vary from one person to another. The effectiveness of a TCR may be demonstrated by an increase in muscle function, relief of back pain, and stabilization or reversal of scoliosis.^{82,87,89} It has been reported that scoliosis response to untethering and progression of scoliosis after untethering vary with the location of tethering,^{82,89} as well as Risser grade⁹⁰ and Cobb angle.⁹¹ Those with Risser grades 3 to 5 and Cobb angle less than 40 degrees are less likely to experience curve progression after untethering. Those with Risser grades 0 to 2 and Cobb angle greater than 40 degrees are at a higher risk of recurrence.^{76,91} Spasticity, however, is not always alleviated in all patients.⁹² Selective posterior rhizotomy has been advocated for patients whose persistent or progressive spastic status after tethered cord repair continues to interfere with their mobility and functional independence.^{62,68}

Orthopedic Deformities

There are both congenital and acquired orthopedic deformities seen in patients with spina bifida. The orthopedic problems that occur with myelomeningocele may be the result of (1) the imbalance between muscle groups; (2) the effects of posture, positioning, and gravity; and (3) associated congenital malformations. Decreased sensation and neurological complications also may lead to orthopedic abnormalities.⁹³

Besides the malformation of vertebrae at the site of the lesion, various spinal deformities may be present including hemivertebrae; deformities of other vertebral bodies and their corresponding ribs may also be present.^{93,94} Lumbar kyphosis may be present as a result of the original deformity (congenital). In addition, as a result of the bifid vertebral bodies, the misaligned pull of the extensor muscles surrounding the deformity, as well as the unopposed flexor muscles, contributes further to the lumbar kyphosis. As the child grows, the weight of the trunk in the upright position may also be a contributing factor.⁹⁴ Scoliosis may be present at birth because of vertebral abnormalities or may become evident as the child grows older. The incidence of scoliosis is lower in low lumbar or sacral level deformities.^{94,95} Scoliosis may also be neurogenic, secondary to weakness or asymmetrical spasticity of paraspinal muscles, TCS, or hydromyelia.⁹⁵ Lordosis or lordoscoliosis is often found in the adolescent and is usually associated with hip flexion deformities and a large spinal defect.^{7,94} Many of these trunk and postural deformities exist at birth but are exacerbated by the effects of gravity as the child grows. They can compromise vital functions (cardiac and respiratory) and should therefore be closely monitored by the therapist and family.

The type and extent of deformity in the lower extremities depend on the muscles that are active or inactive. In total flaccid paralysis, in utero deformities may be present at birth, resulting from passive positioning within the womb. Talipes equinovarus (clubfoot) and vertical talus (which produces a “rocker-bottom” deformity) are two of the most common foot abnormalities. Knee flexion and extension contractures also may be present at birth. Other common deformities are hip flexion, adduction, and internal rotation, usually leading to a subluxed or dislocated hip. Although many of these problems may be present at birth, preventing positional deformity (such as the frog-leg position), which may result from improper positioning of flaccid extremities, is of the utmost importance. Orthopedic care varies throughout the course of the child’s life. One of the main goals of orthopedic

care of a patient with spina bifida is to correct deformities that may prevent the patient from using orthoses to ambulate in childhood. Additionally, monitoring of spinal balance and the status of the hips is required. Changes in clinical orthopedic management have evolved to establish evidence-based interventions.⁹⁶

Osteoporosis

Osteoporosis and osteopenia are often present in patients with spina bifida mostly related to the limited opportunities for weight bearing and upright mobility. The higher the level of neurological involvement, the greater the risk. Early mobilization and weight bearing can aid in decreasing osteoporosis.^{94,97} Because the paralyzed limbs of the child with spina bifida have increased amounts of unmineralized osteoid tissue, they are prone to fractures, particularly after periods of immobilization, especially spica casting.^{98–100}

Bowel and Bladder Dysfunction

Myelomeningocele is likely the most common congenital diagnosis for the development of a neurogenic bladder in children.¹⁰¹ Because of the usual involvement of the sacral plexus, nearly all patients with myelomeningocele have some degree of neurogenic bladder, and children with spina bifida commonly deal with some form of bowel and bladder dysfunction.

Spinal control of bladder, bowel, and sexual functions originates in the sacral spinal cord levels S2 to S4. When the bladder is empty, efferent sympathetic signals from spinal levels T11 to L1 inhibit contraction of the bladder wall and maintain contraction of the internal sphincter. When the bladder fills, the fullness of the bladder stretches the bladder wall and afferent fibers send signals to the reflex center in the sacral spinal cord about the fullness status. This information is then conveyed to the brain. When the condition is appropriate, the higher brain centers initiate emptying the bladder by sending signals to the urination center in the sacral spinal cord, which send signals to the parasympathetic neurons to stimulate contraction of the bladder wall and relaxation of the internal sphincter. Simultaneously, the pontine center sends signals to the spinal cord to facilitate neurons that inhibit the external sphincter and inhibit pelvic floor muscles. Bowel control is similar to bladder control. Stimulation of stretch receptors in the wall of the rectum stimulates emptying of the bowels by sending signals to the bowel center in the sacral spinal cord, which sends signals to alert the higher brain centers about the fullness status. If appropriate, the higher brain centers send signals to the bowel control centers in the sacral spinal cord to relax the sphincter and empty the bowels.

The level of spinal level lesion determines the type of bladder and bowel dysfunction. Lesions above the sacral spinal cord (the control center of the bladder and bowel) result in UMN bladder or bowel. The lesion interrupts descending efferent signals to the bladder and bowel centers but does not interrupt the sacral level reflexive control of the bladder and bowel. Disruption of the higher center control results in lack of inhibition of the bladder and bowel reflexive action, leading to hyperactive bladder and bowel. In this lesion, the bladder and bowel will not receive the signals from the higher center to empty. Reflexive emptying may occur automatically whenever the bladder and bowel are stretched by a certain volume. In this case, the bladder and bowel often expel or “squirt” small volumes at inconvenient times. The UMNL results in hypertonic, hyperreflexive bladder and bowel with reduced capacity. Failure to store or to empty the bladder with reduced capacity make those individuals prone to kidney damage.

Injuries at the sacral level are considered to be lower motor neuron lesions. This type of lesion results in damage to the reflexive bladder and bowel emptying and flaccid paralysis with the bladder and bowel being hypertonic. In this lesion, the reflexes are absent, so there is no

spontaneous emptying of the bladder or bowel. The bladder and bowel are flaccid. Urine or stool will fill the bladder or bowel without emptying. When the bladder or bowel overfill with urine or stool and cannot stretch any further, urine or stool leak or dribble out. This emptying is often incomplete. Individuals will often experience dampness from urine or smearing of stool. The continual filling without emptying leads to an overfilling of the bladder and bowel, which can cause infection.

The effects of bladder and bowel dysfunctions pose a serious medical condition with serious medical complications that require long-term management. Besides various forms of incontinence, incomplete emptying of the bladder remains a constant concern because infection of the urinary tract and possible kidney damage may result.¹⁰² Regulation of bowel evacuation must be established so that neither constipation nor diarrhea occurs. Negative social aspects of incontinence can be minimized by instituting intervention that emphasizes patient and family education and a regular, consistently timed, reflex-triggered bowel evacuation.¹⁰³

Bladder and bowel dysfunctions can have serious health complications, including death. They have negative influences on self-esteem, social activities, and quality of life, imposing significant limitations on a person's activity and participation in daily activities.¹⁰⁴ Urinary and fecal incontinence forms a major barrier to attending school, obtaining employment, and sustaining relationships.¹⁰⁵

Cognitive Impairment and Learning Issues

Children with spina bifida have a rather different cognitive profile than typically developing children.^{106,107} Impairments in the cognitive profile is related to both Arnold-Chiari II malformation and hydrocephaly. The Arnold-Chiari II malformation and hydrocephaly affect the development of brain structures of the hindbrain, midbrain, ventricular system, and subcortical gray matter. These deficits lead to impairments in the cognitive domains of executive functioning, visual-spatial working memory, intelligence, language, and learning.

Although children with spina bifida without hydrocephalus may have normal intellectual potential, children with hydrocephalus, particularly those who have shunt infections, are likely to have below-average intelligence.^{108–110} These children often demonstrate learning disabilities and poor academic achievement.¹¹¹ Even those with a normal IQ show moderate to severe visual-motor perceptual deficits.¹¹² The inability to coordinate eye and hand movements affects learning and may interfere with activities of daily living (ADLs), such as buttoning a shirt or opening a lunchbox.¹¹³ Difficulties with spatial relations, body image, and development of hand dominance may also be evident.^{6,113} Children with myelomeningocele demonstrate poorer hand function than age-matched peers. This decreased hand function appears to be caused by cerebellar and cervical cord abnormalities rather than hydrocephalus or a cortical pathological condition.¹¹⁴

Prenatal studies have shown that the CNS as a whole is abnormally developed in fetuses with myelomeningocele.^{115–118} The impairment of intellectual and perceptual abilities has been linked to damage to the white matter caused by ventricular enlargement.⁶ This damage to association tracts, particularly in the frontal, occipital, and parietal areas, could account for the often severe perceptual-cognitive deficits noted in children with spina bifida.^{67,119} Lesser involvement of the temporal areas may account for the preservation of speech, whereas the semantics of speech, which depends on association areas, is impaired. The “cocktail party speech” of children with spina bifida can be deceptive because they generally use well-constructed sentences and precocious vocabulary. A closer look, however, reveals a repetitive, inappropriate, and often meaningless use of language not associated with higher intellectual functioning. Research on learning difficulties in children

with spina bifida and hydrocephalus suggests that many of these children experience difficulties. Tasks and skills affected include memory, reasoning, math, handwriting, organization, problem solving, attention, sensory integration, auditory processing, visual perception, and sequencing.^{116–118}

Integumentary Impairment

Latex Allergy

Children with spina bifida have a higher risk of allergic reaction to latex. Latex allergy and sensitivity have been noted with increasing frequency in children with myelomeningocele, with frequent reports of intraoperative anaphylaxis.^{120–125} These children have also been reported to have a higher than expected prevalence of atopic disease.¹²⁶ A 1991 Food and Drug Administration Medical Bulletin estimated that 18% to 40% of patients with spina bifida demonstrate latex sensitivity,^{120,127} with others reporting an incidence of 20% to 67%.^{121,128,129} Within latex is 2% to 3% of a residual-free protein material that is thought to be the antigenic agent.¹²⁴ Frequent exposure to this material results in the development of the immunoglobulin E antibody. Children with spina bifida are more likely to develop the immunoglobulin E sensitivity because of repeated parental or mucosal exposure to the latex antigen.¹³⁰ Exposure to latex occurs when products containing rubber come in contact with a person's skin or mucous membranes such as the eyes, mouth, genitals, bladder, or rectum. Skin contact produces less severe reactions such as raised, pinkish, itchy bumps (welts), which develop suddenly and last a few days, but leave no visible trace. In addition, the powder from balloons or gloves can absorb particles and become airborne, causing reactions when breathed by a latex sensitive person. The most potent and life-threatening reaction is entry into the vascular system, which can lead to changes in blood pressure and circulation (anaphylactic shock). Latex-containing products include rubber gloves, therapy balls, some baby bottle nipples and pacifiers, spandex, dental dams, elastic or rubber bands, balloons, adhesive bandages, wheelchair tires, exercise bands, some urinary catheters, some enema tubing, art supplies, beach toys, and chewing gum. Because of the risk of an anaphylactic reaction, exposure to any latex-containing products should be avoided. Latex-free gloves, toys, therapy balls, treatment mats, and exercise bands are now widely available and should be considered for standard use in all clinics treating children with spina bifida. Spina bifida, even in the absence of multiple surgical interventions, may be an independent risk factor for latex sensitivity. Foods reported to be highly associated with latex allergy include avocado, banana, chestnut, and kiwi.¹³¹ Latex-free precautions from birth are more effective in preventing latex sensitization than are similar precautions instituted later in life.^{131–133} Latex sensitization decreased from 26.7% to 4.5% in children treated in a latex-free environment from birth.¹³²

Pressure Ulcers

Children with spina bifida are at high risk of developing skin injury. Various types of skin breakdown have occurred in 85% to 95% of all children with spina bifida by the time they reach young adulthood.¹³⁴ The most common causes of skin injury include lack of sensation and presence of paralysis that results in prolonged sitting in one position. Common areas at risk for pressure sores and decreased skin integrity include the heels, feet, buttocks, lower back, kyphotic or scoliotic prominences, and perineum. Deformities, particularly spinal deformity, may alter sitting balance and puts them at risk for uneven pressure loading on insensate skin with resultant skin ulcers.¹³⁵

A pressure ulcer develops when excessive and prolonged pressure is applied to the skin and soft tissues, usually over a bony prominence, and injures the skin and deep tissues. The pressure can result in reduced capillary flow, preventing oxygen from reaching tissues under the area of pressure. This may cause ischemia, cell death within the

deeper tissues, and eventually, tissue necrosis. Excessive pressure may manifest itself early as reactive hyperemia or sore, a blister, and later, as an open sore or overt necrosis. Chronic, untreated sores may lead to osteomyelitis and eventual sepsis.¹²⁶ The amount of pressure and length of time the pressure is in place will increase the severity of the lesion and ulcer. Persistent posture, such as sitting in one position, is a risk factor for skin breakdown and ulcers over the ischial tuberosity. Spinal deformity also alters their sitting balance and puts them at risk for uneven pressure loading on insensate skin and resultant skin ulcers.¹³⁵ Pressure sores often result in loss of time from school and work and can lead to financial hardship from medical treatment and hospitalizations. These negative consequences can largely be prevented with attention to education and instruction of the child and family. The goal of such education is to foster an understanding of the causes of skin breakdown and the necessary meticulous attention to skin care that must be carried out on a regular basis. Other common injuries include burns and trauma to insensate feet, emphasizing the importance of health education and guidance in prevention of secondary disability.⁵⁵

Growth Nutrition and Obesity

Children with spina bifida face multiple challenges throughout their life-span. Arnold-Chiari II malformation, hydrocephalus neurogenic bowel, neurogenic bladder, and lack of activities are common associated disorders that have implications for growth and nutrition.

Nutritional intake and weight gain and loss have been found to be problematic in children with myelomeningocele. Early on, infants with spina bifida may have feeding issues as a result of an impaired gag reflex, swallowing difficulties, and a high incidence of aspiration.^{6,60} Altered oral-motor function has been attributed to the Chiari II malformation.¹³⁶ These impairments may lead to nutritional issues and delayed growth and weight gain. Speech, physical, and occupational therapists (OTs) working as a team are often needed to address these issues.

Conversely, obesity can be a significant issue for children with spina bifida, particularly when the child gets older and moves into teenage years and adulthood. This problem is complex and multifactorial.¹³⁷ Mobility limitations and decreased energy expenditure result in lower physical activity levels. In addition, decreased lower limb mass diminishes the ability to burn calories, which leads to weight gain and makes it challenging for a child to achieve and maintain a healthy weight. Decreased caloric intake as well as a lifelong engagement in rewarding and physically challenging physical activities are necessary to enhance weight control and prevent obesity.

The presence of obesity may put the child at risk for additional associated problems such as high blood pressure, high blood sugars (diabetes), and high cholesterol.

Obesity may limit the child's ability to walk, transfer, and move, resulting in reduced mobility and decreased physical activity. This can limit the child's independence in self-care.

Being obese and overweight increases pressure on the skin. This may increase the risk of pressure ulcers for children in wheelchairs. Increased weight increases the amount of pressure on skin in the seating position and thus places the child at more risk for development of pressure ulcers.

Obesity may limit the child's ability to breathe and expand his chest, thereby increasing the risk for development of deformities, particularly scoliosis, as well as increasing the breathing difficulty associated with scoliosis.

Dysphagia and Swallowing

Chiari malformation and hydrocephaly may result in direct pressure upon cranial nuclei or cranial nerves by the herniated cerebellar tonsils

and/or cause traction on the cranial nerves as they pass around the herniated tissue to ascend to the neural foramina. This may affect coordination of the muscles involved in sucking, swallowing, and breathing patterns in infants and can result in neurogenic dysphagia. Additionally, hypotonicity and poor sitting posture, along with the Arnold-Chiari II malformation and hydrocephaly, may put infants with spina bifida at a higher risk for feeding issues.

Anthropometrics

Children with myelomeningocele are short in stature. Growth in these children may be influenced by growth-retarding factors as a result of a neurological deficit such as tethered cord.¹³⁸ Endocrine disorders and growth hormone deficiency have also been found to contribute to short stature in this population.¹³⁹ As a result of complex CNS anomalies (midline defects, hydrocephalus, and Arnold-Chiari malformation), these children are at risk for hypothalamopituitary dysfunction leading to growth hormone deficiency.^{140,141} Treatment with recombinant human growth hormone has proven successful in fostering growth acceleration in these children.^{140,142,143}

Obtaining an accurate length/height measurement in children with spina bifida may be challenging secondary to contractures, scoliosis, and body structure differences. In addition to the 2000 Centers for Disease Control and Prevention (CDC) growth charts, spina bifida growth charts may be used in conjunction with the CDC growth charts to evaluate growth in a child with spina bifida.¹⁴⁴ The disease-specific charts include growth data according to lesion level and ambulatory status.

Linear growth usually slows down around 2 years of age, but weight gain may continue trending or increase at a faster rate due to decreased activities. Children with spina bifida have earlier growth spurts and higher rates of precocious puberty; however, their final adult height is shorter in relation to their peers.¹⁴⁵

The lack of activity and ambulation results in a low level of total energy expenditure and needs, which can make it a challenge for a child to achieve and maintain a healthy weight. Children with spina bifida have been shown to maintain their weight with an energy intake meeting 80% of the Recommended Dietary Allowance (RDA).¹⁴⁶

Psychosocial and Emotional issues

Psychological and social issues in children with spina bifida seem to be affected by deficits in cognitive function and clinical manifestations such as neurological deficits, mobility deficits, and urological disorders. The consequences of the cognitive deficits seem to affect the social life of these individuals.^{147,148} Considering all the clinical manifestations resulting from this congenital neurological defect, social and emotional difficulties will arise for these children and their families. These will be considered appropriate when discussing the stages of recovery and rehabilitation from birth through adolescence.

MEDICAL MANAGEMENT

A patient with spina bifida requires a lifelong commitment by the patient, his or her family, and the health care personnel involved in the treatment. The medical goal is to maintain stable neurological functioning throughout the patient's lifetime.¹²¹ The wide range of extensive impairments and long-term disabilities in patients with spina bifida present a considerable challenge to the management of these patients. Patients with spina bifida require extensive and long-term medical needs due to medical conditions and neurological presentation, as well as the long-term aberrations of normal neurological, urological, and musculoskeletal function associated with the condition. Patients with spina bifida require interdisciplinary treatment. The medical treatment will vary based on the age, type, and severity of the

clinical presentations. Medical and surgical management may start prenatally, including fetal surgery, and will be important throughout the individual's life. Fetal or neonatal surgeries are followed by monitoring. Because of the neurological, orthopedic, and urological complications associated with spina bifida, some patients may require surgeries at a later age.

Prenatal Testing and Diagnosis

The majority of cases with spina bifida can be diagnosed during pregnancy. Ultrasonography can be used for early detection of spina bifida during pregnancy.¹⁴⁹ A common blood test, maternal serum alpha-fetoprotein (AFP), is offered during the second trimester (16th to 20th week of pregnancy) to screen for NTDs, including spina bifida and anencephaly. Positive findings of AFP in the amniotic fluid or a positive sonography can be followed by detailed sonography or amniocentesis to diagnose spina bifida. The presence of significant levels of AFP in the amniotic fluid has led to the detection of large numbers of affected fetuses,¹⁵⁰ and maternal serum AFP levels have been effective in detecting approximately 80% of NTDs.¹⁵¹ Prenatal screening can be most effective when a combination of serum levels, amniocentesis or amniography, and ultrasonography is used.¹⁵²⁻¹⁵⁴ Although this screening is not yet performed routinely, it is suggested for those at risk for the defect. Additionally, the fetal karyotype test can be used to identify or rule out chromosomal anomalies.

When a diagnosis of spina bifida confirmed, ultrasonography is used to detect any brain cranial abnormalities including the presence of Chiari II malformation. Ultrasonography can be used to assess spontaneous leg movements, spine and lower extremity deformities, and other physical defects.¹⁵⁵ Prenatal MRI, with ultrafast T2-weighted sequences, can also be used to characterize the Chiari II and other brain malformations.¹⁵⁶

Prenatal Care

NTDs, including spina bifida, are among the common indication for birth termination. Most fetuses with spina bifida that are not electively terminated receive no treatment until after birth.

If it is determined that the unborn baby has a confirmed diagnosis of spina bifida, both fetus and mother should be referred to a high-risk pregnancy specialist for further evaluation and follow up. A series of ultrasounds will be performed throughout pregnancy to monitor the fetus' progress and detect any other brain anomalies or lower limb deformities. A chromosomal analysis may be recommended to identify chromosomal abnormalities. Other tests, including a fetal MRI, may be recommended to detect cranial abnormalities and other associated disorders such as Chiari II malformation.

Knowledge of the defect allows for preparation for cesarean birth and immediate postnatal care. This includes mobilization of the interdisciplinary team that will continue to care for the child. For parents who decide to carry an involved fetus to term, adjustment to their child's disability can begin before birth, which includes mobilizing their own support system. Education from an integrated team regarding what will follow after delivery and neurosurgical closure is imperative to aid families in decision making and to allow families to assess and understand the child's disability and future care options.

Advances in the field of prenatal medicine that affect spina bifida management and outcome include in utero treatment of hydrocephalus and in utero surgical repair to close the myelomeningocele. This challenging surgical procedure is practiced in only a few specialty centers and so far has been shown to offer palliation of the defect, at best.¹⁵⁷ Treatment such as this, in conjunction with prenatal diagnosis, has been shown to have a positive impact on the incidence and severity of complications associated with spina bifida.¹⁵⁸⁻¹⁶⁵ Limitations of current postnatal treatment strategies and considerations of prenatal

treatment options continue to be explored. Ethics, timing of repair, and surgical procedures are all being investigated. In addition, continued assessment of outcomes from those who have undergone presurgical management requires continued exploration. The Management of Myelomeningocele Study (MOMS) was initiated in 2003 as a large randomized clinical trial designed to compare the two approaches to the treatment of infants with spina bifida (prenatal or fetal surgery versus postnatal surgery) to determine if one approach was better than the other. The primary end point of this trial was the need for a shunt at 1 year, and secondary end points included neurological function, cognitive outcome, and maternal morbidity after prenatal repair. Results demonstrated that prenatal surgery significantly reduced the need for shunting and improved mental and motor function at 30 months. Reduced incidence of hindbrain herniation at 12 months and successful ambulation by 30 months were also reported. While prenatal surgery was associated with improved function and reduced need for shunting, maternal and fetal risks, including preterm delivery and uterine dehiscence at delivery, were reported.¹⁶⁶

Neurosurgical Management

The key early priorities in the management of spina bifida are to repair the spinal cord and spinal nerves, to protect the exposed nerves and structures from additional trauma, and to prevent infection from developing in the exposed nerves and tissue through the spinal defect (Fig. 13.10). Timing of the surgical closure and repair is important and may occur prenatally or soon after birth to minimize the risk of neural damage and infection. The aim of either surgery is to replace the nervous tissue into the vertebral canal, cover the spinal defect, and achieve a watertight sac closure.¹⁶⁷ This early management has decreased the possibility of infection and further injury to the exposed neural cord.^{43,167,168}

Fetal surgery may be performed in utero, particularly for the child myelomeningocele, usually during weeks 19 to 25 of pregnancy. Postnatal surgery is usually recommended 24 to 48 hours after birth. Fetal surgery is performed within the uterus and involves opening the mother's abdomen and uterus and repairing the spinal cord of the fetus. The benefits of fetal surgery include less exposure of the vulnerable spinal nerve tissue to the intrauterine environment, thus reducing the damage to the spinal cord. Additionally, fetal surgery may decrease the risk of fetal hindbrain abnormalities, thus decreasing the severity

TABLE 13.1 Signs and Symptoms of Shunt Malfunction

Infants	Bulging fontanel Swelling along the shunt tract Prominent veins on scalp Downward eye deviation (“sunsetting”) Vomiting or change in appetite Irritability or drowsiness Seizures High-pitched cry
Toddler	Headache Vomiting or change in appetite Lethargy or irritability Swelling along the shunt tract Seizures Onset of or increased strabismus
Older child	All the above, plus: Deterioration in school performance Neck pain or pain over myelomeningocele site Personality change Decrease in sensory or motor functions Incontinence that begins or worsens Onset of or increased spasticity

of certain complications such as Chiari II and hydrocephalus, and in some cases may decrease the possibility of needing treatment for hydrocephalus and shunt implantation. The major risks to the fetus are those that might occur if the surgery stimulates premature delivery, such as brain hemorrhage, organ immaturity, or death. Delivery may need to occur at a high-risk pregnancy center. Cesarean section is the preferred method of deliver to avoid trauma to the spinal sac and minimize the amount of damage to the infant's exposed spinal nerves that may occur during vaginal delivery. A child born with meningocele or myelomeningocele usually requires care in the neonatal intensive care unit (NICU).

Progressive hydrocephalus may be evident at birth in a small percentage of children born with myelomeningocele. A greater majority, however, have hydrocephalus 5 to 10 days after the back lesion has been closed.^{167,169–171} With the advent of computed tomography (CT), early diagnosis of hydrocephalus can be made in the newborn without the need for clinical examination.

Although clinical signs are not always definitive, hydrocephalus may be suspected if (1) the fontanels become full, bulging, or tense; (2) the head circumference increases rapidly; (3) a separation of the coronal and sagittal sutures is palpable; (4) the infant's eyes appear to look downward only, with the cornea prominent over the iris (“sunsetting sign”); and (5) the infant becomes irritable or lethargic and has a high-pitched cry, persistent vomiting, difficult feeding, or seizures (Table 13.1).^{32,54,172}

If the results of CT confirm hydrocephalus, a ventricular shunt is indicated to control excessive CSF buildup and further brain damage. This procedure involves diverting the excess CSF from the ventricles to another site for absorption. In general, two types of procedures—the ventriculoatrial (VA) and ventriculoperitoneal (VP) shunt—are currently used, the latter being the most common (Fig. 13.11). The shunt apparatus is constructed from Silastic tubing and consists of three parts: a proximal catheter, a distal catheter, and a one-way valve. As CSF is pumped from the ventricles toward its final destination,

Fig. 13.11 Ventriculoatrial shunt. (From Goodman C, Fuller K. *Pathology Implications for the Physical Therapist*. 4th ed. Elsevier-Saunders; 2014.)

backflow is prevented by the valve system. In this manner, intracranial pressure is controlled, CSF is regulated, and hydrocephalus is prevented from causing damage to brain structures. An alternate means of controlling hydrocephalus may be the use of endoscopic third ventriculostomy (EVT). EVT is a procedure that, in selected patients with obstructive hydrocephalus, allows egress of CSF from the ventricles to the subarachnoid space. This can decompress the ventricles and allow normal intracranial pressures and brain growth. This procedure is typically reserved as a last resort.¹⁷³

Management strategies in the care of shunted hydrocephalus vary.¹⁷⁴ Shunt complications occur frequently and require an average of two revisions before age 10 years.⁵³ The most common causes of complications are shunt obstruction and infection.^{6,175} Revising the blocked end of the shunt can clear obstructions. Infections may be handled by external ventricular drainage and courses of antibiotic therapy followed by insertion of a new shunting system.⁶ The problem of separation of shunt components has been largely overcome by the use of a one-piece shunting system. The single-piece shunt decreases the complications of shunting procedures. Shunt revision is usually required as the child grows by installing a larger one.

Surgical treatment for hydromyelia usually has good outcomes; it may include treating the underlying cause such as revision of a CSF shunt, posterior cervical decompression, or a central canal to pleural cavity shunt with a flushing device.^{11,61}

Asymptomatic tethered spinal cord will require monitoring for any changes in the clinical signs and symptoms. Conservative treatments such as medications, alternative therapies, rest, and physical therapy may provide temporary relief from pain. The only successful intervention is untethering surgery. Surgery for tethered spinal cord is generally performed if there are clinical signs or symptoms of deterioration such as progressive or severe pain, loss of muscle function, deterioration in gait, or changes in bladder or bowel function. The surgery for

untethering the cord involves releasing the spinal cord and clearing it from the scarred tissues attached to it. Early surgery on a tethered spinal cord may allow the child to return to his or her baseline level of functioning and prevent further neurological deterioration.

Prophylactic antibiotic therapy 6 to 12 hours before surgery and 1 to 2 days postoperatively is effective in controlling infection for both sac repair and shunt insertion.⁶⁹ This brief course of antibiotics has not led to resistant organisms. Prophylactic antibiotic therapy has been prescribed since the introduction of clean intermittent catheterization (CIC) to minimize treatment and prevention of urinary tract infections in children with spina bifida. Long-term use of antimicrobial prophylaxis is associated with increased bacterial resistance. Recent studies indicated that routine antibiotic prophylaxis may not be necessary and discontinuation of antibiotic prophylaxis for urinary tract infections is associated with reduced bacterial resistance to antibiotics in children with spina bifida.^{176,177} The main cause of death in children with myelomeningocele remains increased intracranial pressure and infections of the CNS. With the use of antibiotics, shunting, and early sac closure, the survival rate has increased from 20% to 85%.^{54,110,121}

Urological Management

Initial newborn workup should include a urological assessment. The urology team aims to preserve renal function and promote efficient bladder management. An early start to therapy helps preserve renal function for children with spina bifida.¹⁷⁸ Initially, a renal and bladder ultrasound is performed to assess those structures.¹¹⁵ Urodynamic testing can be performed to determine any blockage in the lower urinary tract. Functioning of the bladder outlet and sphincters, as well as ureteric reflux, can also be evaluated. These tests, plus clinical observations of voiding patterns, help the urologist classify the infant's bladder function. If the bladder has neither sensory nor motor supply, a constant flow of urine is present. In this case, infection is rare because the bladder does not store urine and the sphincters are always open.¹⁷⁹

If no sensation but some involuntary muscle control of the sphincter exists, the bladder will fill, but emptying will not occur properly. Overflow or stress incontinence results in dribbling urine until the pressure is relieved. Because of constant residual urine, infection is a potential problem and kidney damage may result.¹⁷⁹ When some voluntary muscle control but no sensation is present, the bladder will fill and empty automatically. The child can eventually be taught to empty the bladder at regular intervals to avoid unnecessary accidents.

Regardless of the type of bladder functioning, urodynamics should be performed on a yearly basis in order to check for infection and bladder and kidney function. This is important as urine retention in the bladder can cause urine to backflow into the kidneys, thereby damaging them. Urodynamic tests can include urine tests, blood tests, and ultrasound of the bladder and kidneys. Cystogram and cystoscopy can be applied as needed. On the basis of clinical findings and urodynamic test results, the urologist will suggest the appropriate intervention.

The goals of an effective bladder program are to reduce common problems such as hydronephrosis, overfull bladder, urinary tract infection, bladder and kidney calculi, reflux, and bladder accidents.

A bladder retraining program may include establishing a routine, diet, and healthy life style. Establishing routines involve schedules for eating, drinking, and for emptying the bladder. It is best to limit or avoid caffeine, fizzy drinks, and alcohol, as these can irritate the bladder. Manual stimulation using Crede technique (pushing on bladder with your fingertips) can help voiding.

In principle, all newborn patients are put on CIC, oxybutynin, and chemoprophylaxis immediately after closure of the back.¹⁸⁰ CIC involves inserting a fine tube into the urethra to drain urine out of the bladder. This CIC program may start immediately after closure of the

back. Of course, it is still a matter of discussion whether it is necessary to perform CIC from birth onward in all children.¹⁸⁰ This program of CIC is typically done every 3 to 4 hours to prevent infection and maintain the urological system.^{181–184} Parents are taught this method and can then begin to take on this aspect of their child's care. At the age of 4 or 5 years, children with spina bifida can be taught CIC and can become independent in bladder care at a young age. Achieving this form of independence adds to the normal psychological development of these children. Early CIC helps eliminate overflow incontinence and maintaining safe pressures in the lower urinary tract has also reduced the need for bowel augmentation of the bladder from 90% to less than 5%.¹⁸⁰ Although CIC is not possible for all children with spina bifida, it remains the method of choice for bladder management.

Indwelling catheterization is a form of long-term catheterization that can be used if CIC is not successful. This involves inserting a fine tube through the urethra up into the bladder. This can be attached to either a valve or a drainage bag. The catheter will need to be replaced every few weeks. A suprapubic catheter is an alternative form of long-term catheterization and involves a small surgical procedure to place a tube directly into bladder through the abdomen. This can be attached to either a valve or a drainage bag.

Intravesical injection of botulinum toxin (Botox) into the detrusor muscle is performed as an outpatient procedure using a cystoscope under anesthesia. This injection can be repeated safely. This approach is a good temporary measure to enhance bladder capacity and decrease intravesical pressures.

Neuromodulation modifies the innervation of the bladder. Neuro-modulation includes nonoperative measures such as transurethral electrical bladder stimulation by providing consistent stimulation of the efferent fibers of the sacral nerve roots or by providing rhythmic contractions of the pelvic floor; minimally invasive procedures such as implantation of a sacral neuromodulation, which is a reversible implanted (pacemaker) device; as well as operative measures that reconfigure sacral nerve root anatomy.^{181,185} Xiao Procedure is a new procedure in which the proximal stump of the ventral root of L5 is anastomosed to the distal stump of the S3 ventral root. Early research studies about this procedure were promising, but recent studies showed that this procedure is ineffective.

The most common type of urinary diversion is the creation of a urostomy or Ileal Conduit. This involves creating a stoma using a piece of the small bowel (usually the small intestine) which will be repositioned to serve as a passage, or conduit, for urine from the ureters to a stoma. This stoma will come through the abdomen into an external pouch.^{186–188} A Mitrofanoff is a continent stoma created by using a small piece of the appendix or small bowel to form a conduit between the bladder and skin surface. An opening is created low on the abdomen or through the belly button, and a catheter is inserted into the opening when needed to empty the bladder.^{186–187} Traditional bladder reconstruction includes bladder augmentation by enlargement of the bladder with a piece of intestine to increase bladder capacity and lower intravesical pressures.

Most individuals with spina bifida will have common bowel problems including lack of control, constipation, impaction, diarrhea, and bowel accidents. Bowel management and training programs should be started early. Medications, digital stimulation, laxatives, stool softeners, suppositories, enemas and irrigation, and attention to fiber content in the diet are all of value in establishing a bowel management program. Similar to a bladder retraining program, a bowel retraining program may include establishing a routine, diet, and healthy lifestyle. Establishing routines involves maintaining schedules for eating, drinking, and for emptying the bowel. A balanced diet with plenty of fiber and

enough fluid consumption helps regulate the bowel and keep stools at the right consistency to avoid constipation.

If a bowel management program is not effective, surgical treatments may be needed. The Antegrade Colonic (Continence) Enema (ACE) can be used for patients with fecal incontinence, severe constipation, or lack of anal control. This procedure is an important adjunct in the case of adults and children with problems of fecal elimination in whom standard medical therapies have failed.^{189,190} This procedure involves creating a stoma, usually from the appendix or the small intestine. Similar to the bladder stoma, a connection is formed between the bowel and the skin. A small artificial opening is created in the umbilicus or lower abdominal wall. A catheter can be inserted into the stoma, and a washout solution is injected to carry out a controlled bowel movement. Colostomy involves diverting one end of the large bowel through an opening in the abdominal wall; a pouch is placed over the opening to collect stools. Colostomy is usually the last resort if other methods have not been successful.

ORTHOPEDIC MANAGEMENT

Children with spina bifida present with multiple orthopedic disorders. Some of these conditions are seen at birth or occur early in life, and some occur secondary to existing disorders. Careful evaluation and management of these patients should occur as part of a team approach given the variety and complexity of the medical conditions and comorbidities associated with spina bifida. The primary goals for orthopedic management should be to minimize deformity and maximize function and mobility, while limiting complications.⁹⁹

Orthopedic management of the newborn with a myelomeningocele will generally concentrate on the feet and hips. Soft tissue release of the feet may take place during surgery for sac closure. Casting the feet (Fig. 13.12) and performing early aggressive taping are also effective in the management of clubfoot deformities.^{191,192} Short-leg posterior splints (ankle-foot orthoses [AFOs]) may be used to maintain range of motion (ROM) and prevent foot deformities.

The orthopedist will also evaluate the stability of the hips. In children with lower-level lesions, attempts to prevent dislocation are made by using a hip abductor brace (Fig. 13.13A) or a total-body splint (see Fig. 13.13B) for a few months after birth. With higher-level lesions, dislocated hips are no longer treated because they do not appear to have an effect on later rehabilitation efforts.^{172,193–195}

Fig. 13.12 Plaster cast of the foot and ankle to reduce clubfoot deformities.

Fig. 13.13 (A) Hip abductor brace. (B) Total-body splint.

Orthopedic management needs to be ongoing throughout the child's lifetime, with continued assessment of orthopedic deformities and the need for surgical intervention. Important management issues relevant to function that the physical therapist (PT) should be aware of may include hip dislocation, knee valgus stress, scoliosis, foot deformities, fractures, osteoporosis, and postoperative management (Fig. 13.14).

Hip Dislocation

Hip dislocation is commonly seen in children with spina bifida. Dislocation is probably related to paralysis, muscle imbalance, lack of sensation, and joint development, as well as contractures in muscles and soft tissues around the hip joint.^{93,196} If not treated properly, contractures can lead to pelvic obliquity and compensatory spinal abnormality.⁹³ Hip dislocation in children with spina bifida can be paralytic or teratological. Paralytic hip dislocation is a common and complicated problem that may occur at any level of neurological deficit.¹⁹⁷

In the past, surgeries were aimed at the maintenance of hip reduction as indicated by radiographic realignment.⁹⁹ Transfer of the iliopsoas tendon along with open reduction and capsular plication was the most common surgery in children with spina bifida in order to achieve and maintain reduction of paralytic hip dislocations.⁹⁹

Concerns developed regarding whether the radiological success of hip reduction led to restricted ROM and pathological fractures, thereby compromising the functional result. Subsequent studies of functional results found that the presence of a concentric reduction did not lead to improved hip ROM or the ability to ambulate. Additionally, several studies reported a high rate of complications leading to decrease in ambulatory function, limited ROM, re-dislocation, and

pathological fractures in children treated surgically for the reduction of hip dislocation. Although hip reduction surgery may reduce the dislocated hip, the result must be weighed in terms of the potential for complications and functional decline.⁹⁹

Current treatment goals for those with hip dislocation focus on functional outcomes versus maintaining radiographical realignment. Thus current treatment focuses on maintaining level pelvis and free motion of the hips. Reports stressed that the preservation of muscle strength, specifically of the iliopsoas and quadriceps, is more relevant to determining potential for adult ambulation than the status of the hip joint.⁹⁹

The most important factor in determining ability to walk is the level of neural involvement and not the status of the hip.^{99,194,198–200} A level pelvis and good hip ROM are more important than hip relocation. In general, surgical hip procedures include surgical hip reduction, soft tissue procedures, or osseous procedures. Surgical hip reduction is used to stabilize the hip and prevent further subluxations. Soft tissue procedures seek to balance muscle forces and prevent contractures. These may include transfer of iliopsoas to greater trochanter, transfer of external oblique muscle combined with adductor tenotomy or transfer of adductors to the ischium, or tenotomy of iliopsoas and adductor muscles to relieve the muscle balance of the hip. Osseous procedures are aiming to correct deficiency of the acetabulum as well as to correctly center the femoral head in the acetabulum. These procedures may include Shelf procedure, Pemberton osteotomy, or Chiari osteotomy. Femoral osteotomy may be performed to correct rotational and angular deformity.

In those with a thoracic lesion with both hips unstable or who are unable to walk, surgeries to reduce hips are not indicated. Treatment

Fig. 13.14 Lower Limb Deformities. (A) Hip dislocation, (B) hip dysplasia and subluxation, (C) Genu varus, (D) Genu valgus, (E) Equinovarus, (F) Calcaneal valgus. (From *Campbell's Physical Therapy for Children Expert Consult*. 5th ed. Figure 14.)

should be directed at preventing or releasing the contractures. Similarly, in those with lumbar lesions and asymmetry caused by contracture, treatment will be directed at releasing the contracture and no attempts will be made to reduce the hip. This can be accomplished by exercises, positioning, or anterior hip release for hip flexion contractures. Muscle transfers alone usually are not effective in producing stability of the hip in these children. Hip dislocations in those with

lower lumbar (L4 or below) or sacral level lesions should be considered as lever-arm dysfunction, and surgical hip relocation is indicated.^{96,197-199} Reduction of the hip in these children is aimed at the prevention of progressive subluxation, which will ultimately interfere with walking. Osteotomy can be indicated to avoid future leg length discrepancy or pelvic obliquity. Immobilization after hip dislocation may lead to a frozen, immobile joint from an open reduction

procedure, re-dislocation from a lack of significant dynamic forces available for joint stability around the hip joint, and an increased fracture risk. Recently, a questionnaire called the Spina Bifida Hips Questionnaire (SBHQ), which was developed to evaluate the ADLs important to children with spina bifida and dislocated hips along with their families, has demonstrated construct validity as well as reliability.²⁰¹

Knee Valgus Stress

Many children with spina bifida who walk have excessive trunk and pelvic movement, knee flexion contractures, and rotational malalignment that may lead to excessive knee valgus stress. Valgus knee deformity is frequently seen in low-lumbar and sacral-level patients leading to instability, pain, and arthritis in adulthood. The most common deformities leading to this problem are rotational malalignment of the femur and femoral anteversion in association with excessive anterior tibial torsion. The knee valgus deformity is influenced by increased lateral trunk sway, weak hip abductor muscles, and internal hip rotation in combination with increased knee flexion and valgus foot deformity.²⁰²

These deformities should be addressed via surgical correction, as excessive knee valgus stress can lead to knee pain and arthritis in adulthood.^{96,99,202,203} Surgical correction of excessive rotational deformities has been shown to lead to a significant improvement in knee stress and pain and may prevent the onset of late degenerative changes.²⁰⁴ If knee valgus is associated with knee flexion contracture or hindfoot valgus, the surgical correction of these deformities is required at the same setting. In addition to physical therapy and exercises, the use of assistive aids, bracing, or a combination of both should be encouraged to increase stance-phase stability, decrease stress in the knee joint, and maintain long-term joint viability.^{203,205}

Rotational Deformities

Rotational deformities of the lower extremities are frequently seen in both ambulatory and nonambulatory patients with spina bifida. Femoral torsion may be present at birth in newborns and does not seem to decrease with growth due to abnormal gait and activity level; it may be secondary to foot deformities. Tibial torsion may be congenital secondary to clubfoot or other foot deformities; it may also be secondary to muscle imbalance or associated foot deformity.

For the nonambulatory children, torsional problems are largely cosmetic. For the ambulatory child, torsional deformities in the lower extremity can be addressed using Torsional Splints attached to an AFO, often referred to as a twister cable. In the long term, significant rotational deformities may be addressed surgically with de-rotational osteotomy.

Scoliosis

The prevalence of scoliosis in spina bifida is estimated to be as high as 50%.²⁰⁶ Increasing scoliosis can lead to the loss of trunk stability when curves are greater than 40 degrees and when associated pelvic obliquity becomes 25 degrees or more. Scoliosis can progress to affect sitting²⁰⁷ and standing balance. It may affect the ability to sit, stand, and walk and interferes with positioning in the wheelchair. Surgical intervention, often recommended to prevent further progression, may improve or further impair sitting balance, ambulation, and performance of ADLs.²⁰⁸ Various authors have reported that although surgery can improve curves by up to 50%, surgical morbidity must be considered, with complications possibly being as high as 40% to 50%. Functional benefits are largely unsubstantiated owing to poorly constructed studies.²⁰⁹ Wai^{210,211} suggests that spinal deformity may not affect overall physical function or self-perception. After surgical correction, it may take up to 18 months to appreciate functional improvement, and walking may be

difficult for those who were just exercise ambulators before correction. Although surgical repair of scoliosis does improve quality of life in patients with cerebral palsy and muscular dystrophy, this has not been demonstrated in those with spina bifida.²¹² Interventions such as chair modifications to shift the trunk to improve balance in the coronal plane and reduce pelvic obliquity and truncal asymmetry should be considered as a first option, before surgical correction.^{208,212}

Back Pain

Back pain needs to be efficaciously evaluated in those with spina bifida who report experiencing it. Knowing when the patient experiences pain, what increases pain, what positions exacerbate pain, and what region of the body is affected can help lead to appropriate referral, testing, and management. Knowing if your patient has a shunt, spinal rods, and/or a Chiari malformation will also be important to your assessment and management. Pain in the neck, shoulders, and upper back with associated weakness and/or abnormal sensory findings should be evaluated by the treating neurosurgeon to rule out shunt malfunction. Spinal rods that have broken or that are breaking through the skin may also be a source of pain in this area. Pain not caused by rods, a shunt, Chiari issues, or a syrinx may have a mechanical cause and could be a result of poor posture, tension, or weight gain. A patient who reports low back pain may have a symptomatic tethered cord if the patient is also reporting changes in gait, increased tripping or falling, bladder changes, and/or pain shooting down the legs. Manual muscle testing (MMT) and urodynamic testing are appropriate at this point and should be compared with baseline testing findings. Mechanical low back pain may be a result of abnormal gait mechanics, asymmetrical strength, and use of older orthotics that no longer fit. Assessment of seating and support systems, including cushions, and gait mechanics with the use of orthotics and ambulatory aids are mandatory to increase stability and redistribute balance over stressed joints, maximizing reduction of the patient's pain and discomfort. Strengthening, particularly of the gluteal muscles, for those who are ambulatory may also be indicated. In addition, programs aimed at weight reduction may be necessary to alleviate stress and pain to preserve long-term viability of tissues. In addition, for women, the chest may cause tension on the upper back, and breast reduction has been advocated for some to relieve this tension.^{213–215}

Foot Deformity

Almost all children with spina bifida will experience problems with foot deformity. Foot deformities are caused when muscle weakness leads to abnormal positioning in utero or may occur from ongoing muscle imbalance, postural effects of gravity, and growth. Foot deformities include calcaneus, equinus, varus, valgus, clubfoot, vertical talus, or a combination of deformities. A plantigrade foot in neutral position is essential for optimal walking, and a well-positioned foot may protect against skin breakdown. Foot deformity can cause difficulty with shoe wear and bracing.

The goal of treatment of the foot in spina bifida should be a flexible and supple foot. An insensate flail foot often becomes rigid over time, and foot management can become complicated by pressure sores. Up to 95% of patients will use an orthosis, and a supple flail foot will be easier to manage over time. Surgeries that are extraarticular with avoidance of arthrodesis, as well as simple tenotomies versus tendon releases and lengthenings, may best manage outcomes for bracing and ambulation.⁹⁶ Clubfoot or equinovarus deformities may be managed with early and intensive taping in the newborn period, known as the *French method*,^{216,217} as well as by stretching and casting and surgical intervention. The Ponseti method, advocated by some, has also been reported to have positive outcomes; however, the significant investment

in time and commitment by the family for frequent cast changes may affect the ability to carry out other ADLs without disruption.¹⁹⁷ Recurrent clubfeet are difficult to treat, but a talectomy with calcaneocuboid fusion may be used for recurrent clubfeet.²¹⁸ In those with lipomas, foot deformity that may be acquired over time is best managed in a similar manner as in equinovarus deformities. Maintaining a supple and plantigrade foot with adequate muscle balance and using soft tissue correction through tendon lengthening, tendon transfer, and plantar fascial release are recommended until 8 years of age. After that time, deformities may become more rigid and may necessitate more bony procedures.²¹⁹

Valgus deformity can also occur at the ankle joint and can be easily treated with guided growth principles in a growing child, which allows for gradual correction of the deformity by tethering the medial side of the growth plate.^{220,221} Severe hindfoot valgus can be treated by medial displacement osteotomy of the calcaneus in children with spina bifida. This allows preservation of motion with osteotomies opposed to arthrodesis of joints.

Calcaneus deformity is not very common but may occur in patients with unopposed anterior tibialis activity, leading to excessive pressure on the heel area with subsequent risk of skin breakdown. Tendon transfer or release do not seem to be successful. Long standing calcaneal deformity may be addressed with triple arthrodesis (fusing the three joints about the hindfoot).

Osteoporosis, Osteopenia, and Fracture

Osteoporosis (thinning of the bone) and osteopenia (low bone mineral density [BMD]) in the legs and spine have been described in children and teens with spina bifida. These conditions increase the risk of fracture, increase the time for healing after fracture, and may lead to back pain. A study by Valtonen and colleagues in 2006 documented the occurrence of osteoporosis in adults with spina bifida. This condition is often not recognized.²²² Medical factors may contribute to increase the risk of osteoporosis, osteopenia, and fracture, such as physical inactivity, lack of physical loading and weight bearing due to lack of ambulation or inability to ambulate, decreased vitamin D, diminished exposure to sunlight, urinary diversion, renal insufficiency, hypercalciuria, medication for epilepsy, and oral cortisone treatment for more than 3 months.^{97,223,224} It can be assumed that patients with meningocele are at potential risk for development of osteoporosis at a younger age because of flaccidity, impaired walking ability, and subsequent low physical loading of the lower limbs. Older age and higher levels have been associated with increased numbers of fractures in spina bifida.²²² The optimal strategies for prevention and treatment of osteoporosis in this population have not been established. Further research is required to see if the methods used to prevent and treat osteoporosis in individuals without spina bifida also work for teens and adults who have spina bifida. Considering the effects of prolonged immobilization on independence in daily activities and quality of life, there should be no disagreement that all efforts are necessary to prevent these fractures. Furthermore, osteoporotic fracture may lead to a vicious cycle of immobilization, decreased bone density, and repeated fractures.²²² Annual incidence of fracture is 0.029% in adolescents and 0.018% in adults.²²⁵

Management of bone fragility in children with disabilities has been limited to conservative measures such as standing program, loading and weight-bearing activities, and calcium and vitamin D intake. Those measures may not be enough to treat osteoporosis. The effects of standing programs on bone density are unclear,^{226,227} although standing with the use of a standing frame or vibration therapy appear to increase BMD in other children with disabilities.^{228,229} Studies have shown promising results of regular functional electric stimulation-assisted

training, but this is often nearly impossible to carry out in daily life.²³⁰ Additionally, the period of immobilization after a surgical intervention should be reduced, if possible, and weight bearing should be allowed as soon as possible. Management should include attention to nutritional factors, in particular, adequate intake of calcium and vitamin D.²³¹ However, constipation secondary to neuropathic bowel is a frequent problem in patients with spina bifida, and supplementation with calcium may exacerbate it.²²⁹ Antiresorptive drugs may be used for adults with low BMD. Parathyroid hormone therapy would be an alternative if the patient fails to gain adequate BMD. This therapy is not used in children and adolescents due to the risk of osteosarcoma. Bisphosphonates may be used to increase bone strength in children with osteoporosis, but its use should be weighted along with the serious side effects.²²⁹

The prevention of fractures should be among the major goals in the rehabilitation of people with meningocele. The assessment of BMD is worthwhile in nonambulatory children and patients with risk factors for osteoporosis, because low BMD is a known risk factor for fractures.²²³

Postoperative Management

Care should be taken to avoid postoperative complications such as skin breakdown and postimmobilization fractures in the postoperative period. To decrease the risk of nonunion and allow for early mobilization and weight bearing, one should consider rigid internal fixation versus Kirschner wire fixation. After surgery, immobilization in a custom-molded body splint rather than a hip spica cast is preferred. Postoperative physical therapy should begin as soon as wounds are stable and healing is occurring. Therapy should focus on ROM (active and passive) and early weight bearing. Crawling should be strictly forbidden for a minimum of 3 to 4 weeks postimmobilization to reduce the risk of fracture.⁹⁹

EVALUATION

Since assessment is important for guiding clinical management and for evaluating therapeutic outcomes, thorough assessment of patients with spina bifida is essential. Assessment allows for detailed identifications of impairments, functional limitations, and disability. Assessment identifies the patient's strength, challenges, and needs. Assessment is a guide to treatment and lays the foundations for planning of future management. In attempting to evaluate the child with spina bifida, a number of evaluations can be chosen, each designed to test specific yet perhaps unrelated components of function. The following section discusses those test procedures as well as the specific standardized tests that would best define the complexity of the problem.

Assessing Muscle Strength

Loss of muscle strength is one of the main impairments in children with spina bifida. Therefore assessment of muscle strength and timely detection of muscle weakness is critical and should be assessed regularly in the growing child to monitor any changes in strength. Accurate and reliable strength measures are essential in early and ongoing management of a child with spina bifida.²³²

Assessing the muscle strength of children, in general, and young children with spina bifida, in particular, can be a challenge. Several alternatives to MMT have been advocated to evaluate motor function in children. MMT is used worldwide with children with spina bifida. Alternate methods to MMT for strength assessment of children with spina bifida include hand-held dynamometry (HHD), isokinetic strength testing, somatosensory evoked potentials, and electromyography. Muscle contour and symmetry can be used as a subjective method

to assess muscle strength in some children. Observation of significant muscle atrophy and limb contour can be indicative of significant muscle strength.

In the newborn, infant, very young child, or a child who is not able to understand or follow directions, the traditional form of MMT is not appropriate or possible. Therefore alternate methods to assess muscle strength in this population are necessary. Observation of infant spontaneous movements, such as leg kicking and responses to stimuli, can be used to assess strength in the newborn or infant. Observation of the infant or young child performing typical movement activities or functional tasks can be used to assess strength. This may include observing the child moving their hand to reach for a toy, kicking their leg against gravity, or using the hip flexors during creeping.

In the newborn, testing may be done in the first 24 to 48 hours before the back is surgically closed. In this case, care must be taken not to injure the exposed neural tissue during testing. Prone and side lying to either side are the most convenient and safe positions for evaluation during this time. Subsequent testing is done soon after the back has been closed and as indicated throughout childhood.

In evaluating the newborn, the importance of alertness is essential. A sleeping or drowsy infant will not respond appropriately during the evaluation. The infant must be in the alert or crying state to elicit the appropriate movement responses. Testing hungry or crying infants provides an advantage because they are likely to demonstrate more spontaneous movements in these behavioral states. The cumulative effect of a variety of sensory stimuli may be more effective in bringing the infant to alertness than using one stimulus in isolation. For example, the infant may be picked up and rocked vertically to allow maximum stimulation to the vestibular system and to help bring the child to an alert state. In addition, the therapist may talk to the child to help him or her fixate visually on the therapist's face. Tactile stimuli above the level of the lesion further add to the child's level of arousal, thus contributing to more conclusive test results. In this way, the CNS receives an accumulation of information from a variety of sensory systems rather than relying on transmission from one system that may be weak or inefficient.

As the child is aroused, spontaneous movements can be observed and muscle groups palpated. Additional methods to stimulate movement may be necessary. For example, tickling the infant generally produces a variety of spontaneous movements in the upper and lower extremities. Passive positioning of children in adverse positions may stimulate them to move. For example, if the legs are held in marked hip and knee flexion, the infant may attempt to use extensor musculature to move out of that position. If the legs are held in adduction, the child may abduct to get free. Holding a limb in an antigravity position may elicit an automatic "holding" response from a muscle group when spontaneous movements cannot be obtained in any other way.

In grading muscle strength, differentiation between spontaneous, voluntary movement, and reflexive movement is important. After the severing of a spinal cord, distal segments of the cord may respond to stimuli in a reflexive manner. This results from the preservation of the spinal reflex arc and is known as *distal sparing*. If distal sparing of the spinal cord is present, the muscles may respond to stimulation or muscular stretch with reflexive, stereotypical movement patterns. The quality of this reflexive movement will be different from that of spontaneous movement and must be distinguished when testing for the level of voluntary muscle functioning.

Muscle strength is generally graded for groups of muscles and can be graded by using either a numerical scale (1 to 5), an alphabetical designation (Fig. 13.15), or simply by noting presence or absence of muscular contraction by a plus or a minus on the muscle test form. The last method may be sufficient initially, but as the child matures, a more definitive muscle grade should be determined.

By use of an MMT form that lists the spinal segmental level for each muscle group, an approximate level of lesion can be determined from the test results (see Fig. 13.15). Because the spinal cord is often damaged asymmetrically, MMT does not always accurately reflect the level of the lesion. If reflex activity is also noted on the form, the presence of distal sparing of the spinal cord can be determined. Muscle testing of the newborn gives the clinician an appreciation of muscle function and possible potential for later ambulation, as well as an awareness of possible deforming forces. For example, if hip extensors or abductors are not functioning, then the action of hip flexors and adductors must be countered to prevent future deformities.

Muscle testing of the toddler or young child may require some of the techniques previously described. In addition, developmental positions can be used to assess muscle strength in an uncooperative youngster. For example, strength of hip extensors and abductors can be assessed as a child attempts to creep up steps or onto a low mat table. With addition of resistance to movements, fairly accurate muscle grades can be determined. To elicit hip flexor action in sitting, it is useful to place an interesting toy or object on the child's ankle or between the toes, as the child will often lift the leg spontaneously to reach for it. Ingenuity and creativity are prerequisites for muscle testing in the young child. Reliability of MMT in children with spina bifida younger than 5 years is difficult, but has been demonstrated in a clinic setting where all therapists were trained in specific MMT techniques to ascertain consistency in testing.²³³ By the age of 4 or 5 years, muscle grades can generally be determined by traditional testing techniques, although the reliability of the test results will increase with the age of the child.²³⁴ In most clinics, MMT is used to assess strength and changes in strength over time. Reliability of MMT may be called into question when trying to assess meaningful, detectable changes in power against gravity. If that is the case, a HHD can be used to test muscles with a grade of 3 or greater. Excellent intertester reliability of HHD for children with spina bifida has been reported.²³²

Muscle testing is indicated before and after any surgical procedure and at periodic intervals of 6 months to 1 year to detect any change in muscle function. Timely detection of any loss in strength is critical, as the child may encounter increased weakness resulting from tethering of the spinal cord or shunt malfunction as they grow. The level of innervation should not decrease throughout the life of the child with spina bifida. In the growing child or adolescent, an increasing weakness resulting from shunt malfunction, tethering of the spinal cord, or hydromyelia frequently can be substantiated by a muscle test of the lower extremities. The MMT is also valuable in determining the motor level so that potential future functional level can be determined (Fig. 13.16).

Muscle Tone Assessment

Over recent years, a controversy has developed with regard to the clinical significance of assessing muscle tone. Determining the severity and type of muscle tone abnormality is important to determine the type of bracing as well as serve as a baseline to determine whether neurological deterioration from Chiari II or hydrocephaly is occurring.

Children with spina bifida may present with a mixture of hypotonia and hypertonia. Tone examination should consider the presence of reflexive movements. In older children, examination should consider the difference between spasticity and stiffness resulting from contractures.

The most common method for assessment of muscle tone is passive movement of the limb. The Ashworth scale, Modified Ashworth scale, and Tardieu scale are commonly used scales to rate the severity of spasticity. Pendulum test can be also used to assess the type and severity of muscle tone abnormality. The severity, type, and distribution of muscle tone abnormalities should be noted.

Sensory Testing

The primary aim of sensory testing is to determine the lowest level of normal sensation. Full sensory tests are not possible until the child has acquired sufficient cognitive and language abilities to respond appropriately to testing. Sensory testing of the infant and young child is simplified to determine the level of sensation as accurately as possible with a minimal amount of testing. As sensory level does not necessarily

correlate with the level of the lesion and radiological level, there may be a skip in sensory loss at some sensory level. Because of this skip of sensory loss, it is necessary to test all dermatomes and multiple areas within a given dermatome to ascertain an accurate dermatomal level.

In general, sensory testing is best carried out with the child in a quiet state. In newborns and infants, many aspects of sensory function

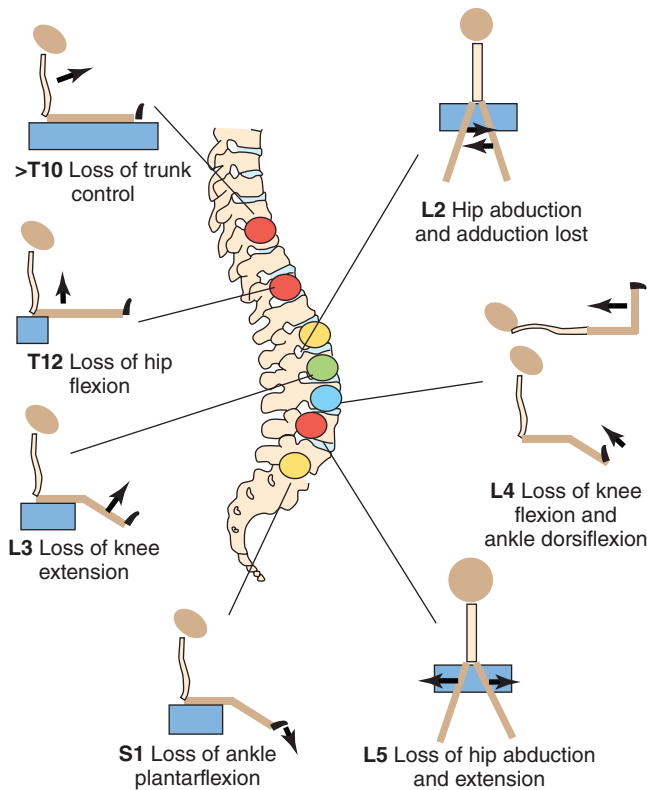

Fig. 13.16 Weakness Related to Level of Spinal Defect. (From Staheli LT. *Practice of Pediatric Orthopedics*. Philadelphia: Lippincott Williams & Wilkins; 2001.)

are observed simultaneously with motor function and during play. Sensory testing in newborns and infants is usually limited to basic testing while assessing for motor output as a potential response to a stimulus. Light touch or tickling usually precipitates a withdrawal of the foot. Response to touch can be determined by looking for a withdraw of the trunk or limb in response to a light tickle or pinch. Proprioception can be grossly assessed by moving the limb into an awkward position and watching the child's response to it. Vibration sense can be observed using a tuning fork, and the infant or newborn will usually withdraw a limb in response. Noxious stimuli such as nail bed pressure, pinching of the skin, or pinprick should also elicit a facial grimace, cry, or withdrawal.

In the newborn, beginning at the lowest level of sacral innervation, the skin is stroked with a pin or other sharp object until a reaction to pain is noted. Although none of these methods is fail-safe, they may be helpful in adapting a muscle test to a newborn or young infant. Repeated evaluation may be necessary to get an accurate picture of muscle function.

Because of dermatome innervation, the pin is usually drawn from the anal area across the buttocks, down the posterior thigh and leg, then to the anterior surface of the leg and thigh, and finally across the abdominal muscles. Reactions to be noted are a facial grimace or cry, which indicates that the painful sensation has reached a cortical level. Care must be taken to see that each sensory dermatome has been evaluated. Results can be recorded by shading in the dermatomes where sensation is present (Fig. 13.17).

A newborn sensory evaluation is usually done before surgical closure of the spinal meningocele. Although sensory and motor levels can be determined as previously described, the infant's general condition should be considered in interpreting test findings. Any medication

Fig. 13.17 Lower-limb Dermatomes. (From Brocklehurst G. Spina bifida for the clinician. *Clin Dev Med*. 1976;57:53.)

taken by the mother during labor and delivery may influence the neonate's performance and should therefore be noted. In addition, the physiological disorganization normally seen in all infants during the first few days after birth may also affect testing.²³⁵ At best, this presurgical evaluation establishes a tentative baseline, but significant changes in the infant's neurological status in the first few weeks of life should not be surprising to the clinician.

In the young child from 2 to 6 years of age, light touch sensation and position sense can be tested in addition to pain sensation. Again, to elicit an appropriate response and reliable test results, the ingenuity of the therapist will be required. Using games such as "Tell me when the puppet touches you" may be more effective for the young child than traditional testing methods. Sensory dermatome mapping using the chart in Fig. 13.17, or a similar form such as the WeeSTeP once the child with spina bifida gets older, can aid in establishing sensory level as well as insensate areas that may be at high risk of injury.²³⁶

From age 6 years through adolescence, formal and full sensory testing can be carried out and additional sensory tests of temperature and two-point discrimination may be added. Traditional methods are usually sufficient to ensure reliable testing, but a more behavioral approach may be indicated, depending on the individual's cognitive functioning.

After testing, a survey of the sensory dermatome chart should indicate whether sensation is normal, absent, or impaired. MMT, including myotome testing and sensory testing (dermatomes), can assist in determining the spinal level of function (Fig. 13.18).

Range of Motion Assessment

Assessment of joint ROM is a standard examination for children with spina bifida, since development of contractures is a common presentation in these children. ROM is an important component of functional tasks and a key determinant for function in children with spina bifida. Development of contracture may preclude the development of motor milestones. It is necessary to identify the available ROM, as it is necessary for developing the plan of care, such as establishing an exercise program to promote ROM and flexibility, and preventing or delaying development of contractures. ROM can help determine functional abilities and predict future functional abilities. It may also help determine the type and timing of assistive devices and surgical interventions that address contractures.

Several methods can be used to examine ROM, including goniometry, visual observation, still photographs, or computerized motion analysis systems. In clinical practice, the use of goniometry and structured visual observation are the most common methods to assess ROM. Accurate examination is typically assessed using universal

goniometer. Visual observation can be also used as screening for ROM or when a very quick assessment is needed. Moreover, ROM can be assessed using structured observation of functional motor skills and some handling/positioning. For example, squatting position is a good indication of passive ROM of hip and knee flexion. ROM examination should be performed with hands placed close to the joint being moved to prevent unnecessary stress to soft tissues and joint structure.

A complete ROM evaluation of the lower extremities is indicated for the newborn with spina bifida. Examination in newborns should take into consideration the normal physiological flexion that is greatest at the hips and knees. In the normal newborn, these apparent “contractures” of up to 35 degrees are eliminated as the child gains more control of extensor musculature and kicks more frequently into extension.

Hip adduction should not be tested beyond the neutral position because of the risk of hips dislocation, which are often unstable or dislocated. ROM should be done slowly and without excessive force to avoid fractures, so often experienced in paralytic lower extremities. ROM should be checked with the same frequency as MMT. Active ROM of the upper extremities can be assessed by observation and handling the infant. A formal ROM evaluation for the upper extremities is not usually indicated. A baseline ROM and tone assessment of the upper extremities should be completed.

In the child with spina bifida, contractures may be evident at multiple joints at birth because of unopposed musculature (Fig. 13.19). Common limitations in ROM in neonates with spina bifida include tightness of hip flexors, hip adductors, ankle dorsiflexors, and evertors (Tappit-Emas, 1999). These contractures are primarily due to lack of unopposed forces from weak or paralyzed antagonist muscles. For example, tightness and contractures of the hip flexors is common in children with L2 to L4 motor level. This can be due to unopposed forces from weak or paralyzed hip extensors. Hip flexion and knee flexion contractures are common in older children with spina bifida. In addition to the muscle imbalances, contractures and tightness can be due to poor positioning. Passive and active ROM continue to be monitored with documentation of changes that are noted over time.

Fig. 13.19 Infant With Myelomeningocele With Contractures. (From Molnar GE, Alexander MA. *Pediatric Rehabilitation*. Philadelphia: Hanley & Belfus; 1999.)

Reflex Testing

There are different type of reflexes that can be tested including deep tendon, neonatal, and developmental reflexes. The evaluation of deep tendon reflexes may be used to assess the function of the afferent (sensory) neurons and the efferent (motor) neurons, and to differentiate between children with UMN lesion and children with lower motor neuron lesion. A reflex hammer is used to measure deep tendon reflexes. Routinely evaluated reflexes include the patellar tendon reflex (L2 to L4), Achilles tendon reflex (S1 to S2), and anal reflex (pudendal nerve, S3 to S4). Deep tendon reflexes are evaluated bilaterally.

Neonatal and developmental reflexes testing is used to check for the presence of normal reflex activity and to check for the integration of primitive reflexes and the development of more mature reactions. In the newborn, for example, strong rooting and sucking reflexes are expected. In the child with spina bifida, because of possible involvement

of the CNS as previously described, these reflexes may be depressed or absent. Because these reflexes play an integral part in obtaining nutrients for the infant, their value is obvious. On the other hand, primitive reflexes that persist past their expected span may also indicate abnormality. For example, if the asymmetrical tonic neck reflex persists past 4 months, it will limit the infant's ability to bring the hands to midline for visual and tactile exploration.

As the primitive reflexes initially needed for survival and to experience movement become integrated, they are replaced by more mature and functional reactions. Righting and equilibrium reactions help the child attain the erect position and counteract changes in the center of gravity. Because these reactions depend on an intact CNS, as well as a certain level of postural control, they may be delayed, incomplete, or absent in the child with spina bifida. For example, a child with a low thoracic spinal cord lesion may show an incomplete equilibrium reaction in sitting. This may be caused by the lack of a stable postural base or by lack of initiation of the reaction centrally. Both the neurological and muscular components of these reactions must be considered. Reflex testing for the child with spina bifida may not be as intensive as that for a child with cerebral palsy. It may, however, provide a check on the progress of normal development, and as such, reflect the integrity of the CNS. In general, persistent presence of primitive reflexes beyond the age of 2 years and absent development of postural reflexes (righting and equilibrium reactions) may be negative indications for ambulation.

Development and Functional Assessment

Besides being aware of a child's sensory and motor levels, assessing the functional level is also important. Two important questions need to be asked: "Does the child demonstrate normal components of posture and movement synergies?" and "What is the child's level of function and mobility?" Several developmental and functional evaluations can be used with the child with spina bifida. The following are some suggestions for evaluation approaches and specifically designed tests to assist in assessment of this area.

Initially, a developmental sequence may be used to assess how a child is functioning. In each position used, both posture and movement are evaluated. The goals in using this type of assessment are to determine what a child can and cannot do, the quality of the action, and what is limiting the child. The progression begins in the supine position, rolling to prone, prone on elbows, prone on hands, up to sitting, on hands and knees, kneeling, half-kneeling, standing, and walking. Both the ability to attain and the ability to maintain the positions should be assessed.

The way in which a task is accomplished is as important to evaluate as the accomplishment itself. For example, in rolling, is head righting sufficient to keep the head off the supporting surface? From the hands-knees position, can reciprocal crawling be initiated without the lower extremities being held in wide abduction? Can the child pull to stand easily by using trunk rotation? Assessing the quality of the child's abilities will assist the clinician in determining where therapeutic measures should begin and what the goals of such intervention will be. Standardized assessments may provide the families with guidelines and a record of motor skills over time.

There are no standardized functional or motor assessments specific to those with spina bifida. Some assessments look at development relative to standardized norms and may guide the family and therapist in determining treatment goals and challenges. This information may be invaluable in determining bracing needs and other equipment needs as well as timing of various interventions. If a standardized assessment is desirable for the infant with spina bifida, the Alberta Infant Motor Scale (AIMS) might be appropriate. The AIMS²³⁷ is designed to

measure motor development from birth to 18 months of age. It is a 58-item observational test of infants in supine, prone, sitting, and standing positions. Each item includes detailed descriptions of the weight-bearing surface, the infant's posture, and antigravity movements expected of the infant in that position. The AIMS requires minimal handling of the infant and can be completed in 20 to 30 minutes. The test was normed on a cross-sectional sample of 2200 infants in Alberta, Canada. Interrater and test-retest reliability are high (0.95 to 0.99), as is concurrent validity with the Peabody Developmental Motor Scales (PDMS) (0.99) and the Bayley Scales of Infant Development (0.97).²³⁸ For the child with spina bifida, the AIMS could be used to assess current motor development and track progress in motor development over time. The AIMS is also useful in determining the percent of delay in motor development in an infant, which is often needed to determine eligibility for early intervention services under IDEA (Individuals with Disability Education Act).

The Milani-Comporetti Motor Development Screening Test for Infants and Young Children may also be useful in assessing the functional level of the child with spina bifida. This screening examination is designed to evaluate motor development from birth to 2 years of age (Fig. 13.20). It requires no special equipment and can be administered in 4 to 8 minutes. The test evaluates both spontaneous behavior and evoked responses. Spontaneous behavior includes postural control of the head and body in various positions as well as a sequence of active movement patterns. Primitive reflexes, righting, and equilibrium reactions constitute the evoked responses. The Milani-Comporetti test was normed on a sample of 312 children from Omaha, Nebraska. Interrater reliability percent of agreement was 89% to 95%. Test-retest reliability percent agreement was 82% to 100%. Predictive validity of the test has not been well established.²³⁹ The Milani-Comporetti test should assist the clinician in evaluating each child's underlying postural mechanisms and his or her ability to attain the erect position. The test manual provides information on special examination procedures and scoring. It should be noted that the Milani-Comporetti is a screening tool and a more detailed assessment of motor performance should also be performed.

The Ages and Stages Questionnaire (ASQ) is a screening assessment that assesses developmental and social-emotional delays during crucial early ages of life. This test is available in English and Spanish and can be completed in 10 to 15 minutes.²⁴⁰ It was developed and validated on 15,138 children in all 50 states and several US territories. The test-retest reliability (0.92), interrater reliability (0.93), validity (0.82 to 0.88), sensitivity (0.86), and specificity (0.85) have been well documented.²⁴⁰ This test provides parents and providers with a checklist to easily assess change over time.

The PDMS-2 is another standardized assessment that may prove helpful in evaluating a child with spina bifida.²⁴¹ The PDMS-2 consists of six gross and fine motor subtests for children from birth through 6 years of age. The test takes 45 to 60 minutes to complete or 20 to 30 minutes per subtest. The two scales allow a comparison of the child's motor performance with a normative sample of children at various age levels. A stratified sample of 2003 children from 46 states in the United States was used to develop PDMS-2 test norms. Test-retest and interrater reliability are high. Content, construct, and concurrent validity have been well established. Although the child with spina bifida and activity limitations would not be expected to succeed on many of the gross motor items at the later age levels, the scale still serves as a reminder of expected gross motor performance at each age. Children with higher levels of neurological impairment will have more difficulty completing the test items. The fine motor scale offers a chance to assess fine motor performance of children with congenital spinal cord injury. This area has been frequently overlooked in children with myelomeningocele. Fine motor

development, however, may be affected because of congenital abnormalities in brain development associated with myelomeningocele or related to tethering of the spinal cord that can result in fine motor paresis. In addition, the PDMS-2 offers guidelines for administering the test to children with various activity limitations.²⁴¹

The Bruininks-Oseretsky Test of Motor Proficiency, second edition (BOT-2), can be used to evaluate the higher functioning ambulatory child with lower lumbar or sacral level spina bifida.²⁴² Fine manual

control, manual coordination, body coordination, and strength and agility subtests can be used to assist in evaluating areas of fine motor control, balance, and coordination difficulties. This test has been standardized on a sample of 1520 subjects from age 4 through 21 years.²⁴²

The Movement Assessment Battery for Children, second edition (Movement ABC-2), can be used to identify children who are significantly behind their peers in motor development, assist in planning an intervention program in either a school or a clinical setting, and

measure change as a result of intervention or can serve as a measurement instrument in research involving motor development. This tool may be useful to assess children with lower lumbar and sacral level myelomeningocele, as well as children with lipomeningocele. The Movement ABC identifies and evaluates the movement problems that can determine a child's participation and social adjustment at home or school. The Movement ABC Checklist provides classroom assessment of movement difficulties, screening for "at risk" children (aged 5 to 12 years), and systematic monitoring of treatment programs. It provides a comprehensive assessment for those identified as "at risk" (3 to 16 years, 11 months), yielding both normative and qualitative measures of movement competence, manual dexterity, ball skills, and static and dynamic balance.²⁴³

The Pediatric Evaluation of Disability Inventory (PEDI) is a comprehensive assessment of function in children aged 6 months to 7 years.²⁴⁴ The PEDI measures both capability and performance of functional activities in three areas: self-care, mobility, and social function. Capability is a measure of the functional skills for which the child has demonstrated mastery. Functional performance is measured by the level of caregiver assistance needed to accomplish a task. A modifications scale provides a measure of environmental modifications and equipment needed in daily functioning. The PEDI has been standardized on a normative sample of 412 children from New England. Some data from clinical samples ($N = 102$) are also available. Interrater reliability of the PEDI is high as demonstrated by high intraclass correlation coefficients (ICCs = 0.96 to 0.99). Concurrent validity of the PEDI with the WeeFIM (child's version of the Functional Independence Measure) was also high ($r = 0.80$ to 0.97).²⁴⁴ The PEDI can be administered in approximately 45 minutes by clinicians or educators familiar with the child or by structured interview of the parent. The PEDI should provide a descriptive measure of the functional level of the child with myelomeningocele as well as a method for tracking change over time. The PEDI has had a rich tradition in helping to document functional development. Computer Adapted Test (PEDI-CAT) is a revised version of the PEDI. In addition to the original three domains, a responsibility domain has been added. The PEDI-CAT has been validated from the patient's birth through twenty years old.

Another assessment of motor performance that may be commonly used with the school-aged child with spina bifida is the School Function Assessment (SFA). The SFA is standardized and was conceptually developed to reflect the functional abilities and needs of a student in elementary school. The three areas assessed include the student's participation in school activities, task supports required by the student for participation, and the student's activity performance.^{245,246} It was designed to facilitate collaborative program planning for students with a variety of disabling conditions. The instrument is a judgment-based (questionnaire) assessment that is completed by one or more school professionals who know the student well and have observed his or her typical performance on the school-related tasks and activities being assessed. Items have been written in measurable, behavioral terms that can be used directly in the student's Individualized Educational Plan (IEP).²⁴⁵

Finally, the Functional Mobility Scale (FMS) was originally developed a tool to describe the functional mobility of children with cerebral palsy,²⁴⁷ and has recently been applied to children with spina bifida.²⁴⁸ The scale assesses a child's mobility at three distances: 5, 50, and 500 m. These distance are to represent, home, school, and community ambulation. The child is scored on a 6-point scale based on the ability to ambulate on level or unlevel surfaces and the type of assistive device needed at each distance. A score is given for each distance and has been found to distinguish groups of children with various levels of disability. The FMS was standardized on a group of 310 children in Australia and was found to have high levels of interrater and intrarater

reliability (ICC's of 9.0 to 9.5). Its construct, content, and concurrent validity was established with comparisons to the Pediatric Outcomes Data Collection Instrument (PODCI), Child Health Questionnaire, and mobility up timers ($r = 0.81$ to 0.89)

Gait Analysis

Instrumented three-dimensional computerized gait analysis (IGA) was initially used to evaluate children with cerebral palsy beginning in the 1980s. Since that time, the use of IGA has increasingly been used to evaluate children with spina bifida. The body of knowledge of the use of IGA in the management of children with spina bifida has steadily increased.

The use of gait analysis has helped physicians and other health care providers gain a better understanding of the impact of orthopedic impairments on function and has caused a shift in the focus of orthopedic management from focusing on radiological changes to functional outcomes.⁹⁹ IGA affords a better understanding of the complex gait patterns of children with spina bifida to determine factors leading to changes in gait, including changes in alignment, muscle length, muscle torque, and symmetry. Intervention strategies for orthopedic surgery, orthotics, and rehabilitation can be planned and assessed with more accuracy. This is especially important in the assessment of individuals with rotational deformities. Gait analyses have also been useful in establishing a database of trends in kinetics and kinematics for various levels of spina bifida and the development of classification schemes.²⁴⁹ Children with lumbar and sacral level lesions are most suitable for assessment with IGA due to their greater ambulation capabilities. Access to gait analysis laboratories and issues with insurance coverage have been a limitation in the use of IGA in the management of children with spina bifida and other disabilities, but is improving.

Perceptual and Cognitive Evaluations

When evaluating a child with spina bifida, some assessment of perceptual and cognitive status is important to include. The appropriate assessment depends largely on the age of the child. The assessment may be performed by the physical, occupational, or speech therapist, depending on the setting.

For the newborn from 3 to 30 days old, the Brazelton Neonatal Behavioral Assessment scale may be adapted to assess the infant's organization in terms of physiological response to stress, state control, motoric control, and social interaction.²³⁵ Ideally, the infant should be medically stable and free from CNS-depressant drugs before evaluation. Generally, this evaluation will occur after the back lesion has been closed and a shunt has been positioned to relieve the hydrocephalic condition.

Although test results may not have prognostic value because of the plasticity of the nervous system at this young age, they supply the clinician with information concerning the current status of the child. This information can be conveyed to the infant's caregivers—both medical personnel and parents—so that strengths can be appreciated and weaknesses anticipated and handled appropriately. Helping parents identify that their infant has their own unique characteristics and assisting them in dealing with these characteristics does a great deal to strengthen already precarious parent-infant bonding.

PHYSICAL THERAPY MANAGEMENT

Given the range of impairments seen in patients with spina bifida, there is a clear need for coordinated interdisciplinary approach. Intervention for the patients with spina bifida involves multiple systems, including neuromuscular, musculoskeletal, integumentary, and psychosocial systems. The goal of management of these children is to

achieve maximal independence in mobility and to maximize their function, quality of life, and community participation. Intervention should be unique for each patient and may vary based on the severity of the lesion, level of the lesion, presence of associated disorders, and patient's age. Intervention for patients with spina bifida needs to be individualized to fit the patient and family's needs. Intervention activities may focus on enhancing participation across immediate and expanded environments such as home, daycare, preschool, school, and community.

Before Closure of Myelomeningocele

Physical therapy management of the infant before Closure of Myelomeningocele is limited by his or her medical condition (Table 13.2). Therapists are called to the NICU or stepdown unit on a regular basis in large tertiary care centers to carry out preoperative MMT and help

ascertain functional motor level. Physicians (neurosurgeons and orthopedic surgeons) on the spina bifida care team rely on this assessment to guide their discussion with the families regarding care and prognosis. When carrying out the preoperative MMT, great care must be taken to avoid contaminating an open sac, which is usually covered with a Telfa nonadherent dressing or a wet sterile dressing that must be kept moist with a saline solution. PTs as part of the NICU team may also provide suggestions for the positioning and handling of the infant during the course of their NICU/nursery stay.

After Surgery, During Hospitalization, and Transitioning to Home

A major goal during this stage is to prevent contractures and maintain ROM while giving stimulation to provide as normal an environment as possible.

TABLE 13.2 Summary of Treatment Planning and Rehabilitation Related to Significant Stages of Development

Stage of Recovery	Major Physical Therapy Goals	Physical Therapy Management
Newborn to Toddler (Preambulatory Phase)		
Stage 1: Before surgical closure of myelomeningocele—newborn	Determine functional motor level	Preoperative manual muscle testing
Stage 2: After surgery, during hospitalization—newborn to infant	Confirm functional motor level Prevent contracture and deformity Encourage normal sensorimotor development	Postoperative manual muscle testing ROM exercises taught to hospital personnel and family Positioning in prone and side lying Provide toys of various colors, textures, and shapes Graded auditory and visual stimuli: music boxes, squeaky toys, brightly colored objects Therapeutic handling to encourage good head and trunk control
Stage 3: Condition stabilized—infant to toddler	Confirm functional motor level Encourage normal development sequence	Manual muscle testing once or twice per year Work in sitting on head righting and equilibrium reactions Eye-hand coordination activities Early weight bearing on lower extremities Encourage prone progression Weight shifting in standing frame Comprehensive home program
Toddler Through Adolescent (Ambulatory Phase)		
Stage 4: Toddler through preschool	Confirm functional motor level Begin ambulation Continue development in cognitive and psychosocial areas Collaborate on goals with other team members	Manual muscle testing once or twice per year Choose appropriate orthotic device Gait training Development and strengthening of righting and equilibrium reactions Consider referral to EI program Public preschool program Continue home program Open communication with other team members
Stage 5: Primary school through adolescence	Confirm functional motor level Reevaluate ambulation potential Maintain present level of functioning Prevent skin breakdown as child becomes more sedentary Promote independence in self-care skills Remediate any perceptual-motor problems Provide appropriate adaptive devices Promote self-esteem and social-sexual adjustment	Postoperative manual muscle testing Replace orthotic device as necessary Wheelchair prescriptions as necessary Teach locomotion activities Maintain strength in trunk and extremities Teach skin care Work with team members to teach dressing, feeding, hygiene, and bowel and bladder care Provide program and activities for sensorimotor integration Check for fit and proper use of adaptive devices Collaborate with other team members in counseling efforts

EI, Early intervention; ROM, range of motion.

Therapeutic intervention after surgical back closure during this stage is often limited by the infant's neurological and orthopedic status. Physical therapy in postoperative and intensive care units addresses infant positioning needs and provides parent and family education.

Handling and positioning procedures must avoid adding pressure on the operated site. The prone position helps prevent fluid around the spinal cord from leaking out through the incision and allows for optimal positioning of the leg without any pressure or tension on the operated site. Lying prone is also recommended for the child with hip dysplasia. Some neurosurgeons may permit partial side lying to allow for position changes and to facilitate feeding. Feeding can start when the child is stable and alert after surgery. Holding the child upright against the body may be introduced gradually to help with feeding, and cuddling the child in this position can provide comfort. Once the incision is healed, the child can be positioned normally. Positioning the head below the heart level should be avoided for children with hydrocephalus to avoid increased intracranial pressure.

ROM exercises, positioning, and handling should be taught to the nursing staff and to the family before discharge. ROM exercises should be performed slowly and carefully. Excessive hip flexion or adduction should be avoided to prevent hip subluxation or dislocation.

A normal sensory experience should be presented to the child in spite of the hospital setting. Because of their medical conditions, hospitalized infants often experience early separation from their parents. Teaching the family to handle the child as described may enhance parent-infant bonding. Adequate bonding is essential for normal psychosocial development to occur.

In treating the newborn after surgery, great care must be taken to avoid contaminating the surgical dressing, which usually consists of Xeroform Petrolatum Gauze (3% bismuth tribromophenate in a special petrolatum blend on fine mesh gauze) covered with Telfa. The Xeroform dressing is nonadherent but clings and conforms to all body contours. This postoperative dressing remains on for 2 weeks.

Newborn Through Early Infancy

After discharge, the child should be monitored closely by the spina bifida team, which may include a neurosurgeon, an orthopedist, a urologist, a nurse clinician, a PT, an OT, an orthotist, and a social worker. Before discharge, a definitive home program as well as referral to the local Early Intervention (EI) program should be given to the family because the child will most likely require ongoing therapy, including both PT and OT. Other professionals who may be involved in the child's EI program may include speech and language pathologists (SLPs), developmental therapists (DTs), social workers, and psychologists.

Range of Motion Exercises

ROM is a key determinant for function throughout rehabilitation. Adequate ROM is necessary for functional excursions of the muscle and joints, and for maintaining normal posture and alignment. Sufficient ROM is also necessary to prevent the development of contractures, deformities, and secondary disorders.

ROM exercises should be performed daily, with hands placed close to the joint being moved and holding briefly at the end of the range, thereby preventing unnecessary stress to soft tissues and joint structure. Exercises should be performed carefully for the child with hip instability or with very low muscle tone to avoid subluxation or dislocation. Positions beyond neutral or excessive hip flexion should be avoided, particularly for the child with hip instability. Range should be increased slowly and without excessive force to avoid fractures that are so often experienced in paralytic lower extremities.

Therapists should take into consideration that normal physiological flexion is greatest at the hips and knees, and that these apparent "contractures" do not require intervention. In children with spasticity, therapists should use special care when performing ROM exercises and stretching on the muscles that are spastic or tend to develop contractures, particularly hip flexors and adductors, knee flexors, and ankle plantar flexors. If clubfeet or other foot deformities are present, soft tissue stretching may be indicated. Stretching should begin distally on the soft tissue of the forefoot and proceed proximally toward the calcaneus. This is done to take advantage of the pliability of soft tissue structures and to minimize future fixed deformity. In addition, taping may be used to maintain optimal ROM and alignment between periods of stretching.

In the home, ROM exercises can be carried out while the child is being held over the adult's shoulder or prone in the adult's lap. These positions allow closeness between the caregiver and infant, thus encouraging maximal relaxation and interaction between them. ROM exercises can be incorporated into the child's routine alongside feeding and diaper changes. This approach makes it easy for the parents to remember to do them.

Handling and Positioning

Positioning should focus on normal alignment and facilitating normal development and social skills. Positioning and handling should encourage symmetry and avoid the effects of tonic reflexes such as asymmetrical tonic neck reflex. Handling should use a variety of movement and postures to facilitate functional activities and sensorimotor development. Positioning and handling should also be taught to the family.

When the child is not being handled, resting positions can be used to maintain ROM and enhance development. The prone position is the most advantageous because it prevents hip flexion contractures and encourages the development of extensor musculature as the child lifts his or her head. Side lying, which allows the hands to come to midline and generally encourages symmetrical posture, can be used for alternate positioning. As much as possible, the supine position should be avoided because the child is most dominated by primitive reflexes and the effects of gravity in this position. For example, for the child with spina bifida with CNS involvement, the effects of the tonic labyrinthine reflex combined with paralytic lower extremities may make movement from the supine position extremely difficult. Before initiating activities in the supine position, the therapist should obtain medical clearance.

Positioning of the lower extremities should consider the existing limitations in ROM, muscle tone, or deformities such as clubfoot or the common contractures and deformities seen in children with spina bifida. Forced leg swaddling should be avoided to minimize the risk of hip subluxation. The presence of hydrocephalus and the increased risk of developing pressure sores are other factors to consider when positioning and handling a child with spina bifida.

Sensorimotor Training

Developing normal sensorimotor experiences is one of the treatment goals for young infants. Sensorimotor activities facilitate the emergence of motor and developmental skills, mobility, play, and social skills. Sensorimotor activities encourage behaviors such as reaching, handling toys, rolling, and other developmental skills. Sensorimotor training involves activities that promote normal alignment, joint stability, trunk rotation, dissociation between body segments, spatial and perceptual awareness, weight bearing, and weight shifting and transition from one position to another.

A normal sensory experience should be presented to the child early in infancy, including while in the hospital setting. Toys of various

colors, textures, and shapes should be made available. Musical mobiles hung low enough for the child to reach provide a variety of sensory experiences. Stimuli such as squeaky toys or the human face and voice can be used to encourage visual and auditory tracking. Controlled stimulation relevant to the infant's neurological state, rather than overstimulation, should be the rule. Depending on the age of the child, appropriate learning situations must be presented to provide the child with as normal an environment as possible for perceptual and cognitive growth.

Facilitation of Normal Development

During the stage of early child development, the primary emphasis should be on attaining good head and trunk control, eliciting appropriate righting reactions, facilitating the ability to sit, and promoting early mobility. The normal developmental sequence may guide the progression of motor activities, ultimately preparing the child to assume the upright posture.

One of the first skills to develop is head control, including ability to hold the head upright and move and maintain head positions. Head control may be difficult if the head size is large due to hydrocephalus. Rolling may be difficult or delayed in some children with spina bifida due to large head size and weakness and paralysis in the trunk and lower extremity muscles. Creeping and crawling are also delayed due to weakness and paralysis of the trunk and lower extremities, which results in the lack of ability to stabilize and bear weight on the lower extremities.

Therapists may focus on the facilitation of developmental skills. For example, the child can be seated on the therapist's lap, facing the therapist, and alternately lowered slowly backward and side-to-side. This action helps stimulate head righting and to strengthen the neck and abdominal muscles. Weight shifting in various positions and through therapeutic handling is important to enhance the development of early head and trunk control. Developmental handling may be limited by surgical interventions that limit mobility.

Active movements such as reaching to toys in different directions from different developmental positions help stimulate head and trunk control and facilitate trunk elongation. Reaching activities from sitting (supported or unsupported) to toys in different directions may assist in head control, trunk elongation and rotation, and development of sitting control.

Infant to Toddler (Preambulatory)

In this stage of rehabilitation, the major emphasis is on preparing the child mentally and physically for upright standing and mobility. In addition, routine MMT should be performed every 6 to 12 months to reassess functional motor level and to ascertain that no change in status has occurred. Goals of preventing contractures and maintaining ROM will remain throughout the child's life. Standing and ambulation become more difficult and often impossible in the presence of contracture and deformities. If possible, prone positioning during play and sleeping assists greatly in stretching tight musculature, particularly hip flexors. Resting splints for the lower extremities or a total-body splint can be used as necessary to position and maintain ROM and alignment.

Developmental strategies should be aimed at facilitating movement and motor control. Assuming that the child has previously gained good head and trunk control, the next step is developing sitting equilibrium reactions. Independent sitting is typically delayed and may not occur until the age of 1 to 2 years old. This may be due to weakness and paralysis in the trunk and lower extremities, large head size, and lack of trunk mobility following surgery. Back surgery and a tendency to develop scoliosis may limit the child's ability to shift the pelvis in

response to equilibrium stimulation. This may contribute to delayed sitting and impact upright sitting posture. Reaching activities that involve weight bearing and weight shifts from a variety of sitting postures can be used to facilitate sitting. Activities that develop equilibrium reactions from sitting can be used to promote sitting. As the child learns to sit independently, the child will learn to reach in different directions, and this will facilitate accommodation to equilibrium shift. As sitting balance improves, fine motor and eye-hand coordination activities should be introduced. Upper-extremity functioning is often overlooked in the child with spina bifida, whose problems appear to be concentrated in the lower extremities. However, most children with spina bifida show decreased fine motor coordination, and this problem should be addressed when developmentally appropriate. The normal infant begins to reach and grasp by 6 months of age; therefore the child with spina bifida must be given ample opportunities to practice and perfect these same skills at an early age. Because many children with spina bifida may be receiving PT as their primary service through EI in these early months, referral to and consultation with an OT at this age are highly recommended.

Following a normal developmental sequence, the child with spina bifida will usually begin some form of prone progression as trunk and upper-extremity stability improve. This is a significant phase of development because it allows for the development of a sensorimotor base as the child expands environmental horizons. During this phase of high mobility, insensate skin must be checked for injury frequently and often must be protected by heavier clothing. This may help prevent any major skin breakdown, which could significantly delay the rehabilitation process. A scooter board may provide the child with spina bifida opportunities to explore the environment. "Soft tummy" versions of the scooter boards are available for the child with sensitive skin. For some children with high-level lesions in whom prone mobility is not safe or practical for long distances, a Star Car (Tash), Ready Racer (Tumble Forms), PlasmaCar, or similar mobility equipment may be used. These provide the child with a means of exploring the environment safely and independently.

Emphasis on head and trunk control and strengthening exercises in a variety of sitting postures is important in this early preambulatory phase. Development of adequate strength and motor control for trunk righting, equilibrium reactions, and protective reactions will ultimately lead to improved sitting balance. Hands-free sitting with good balance is the optimal goal in this stage to allow for independence and freedom in play skills. In addition, hands-free sitting is a necessary precursor to ambulation with lower-extremity bracing and often is the determinant in deciding if a child will use a standing frame or will become a functional ambulator.

Early weight bearing is also of utmost importance, both physiologically and psychologically. The upright position has beneficial effects on circulation and renal and bladder functioning as well as on the promotion of bone growth and density. Psychologically, weight bearing in an upright posture allows a normal view of the world and contributes to more normal perceptual, cognitive, and emotional growth. One way to achieve this weight bearing is in the kneeling position. This is developmentally appropriate because children 8 to 10 months old frequently use kneeling as a transition from all fours to standing.

Because young infants are frequently held in the standing position and bounced on their parents' laps, this form of weight bearing on the lower extremities is appropriate from birth onward. Failure to promote weight bearing in this manner may deprive the child with spina bifida of the normal experience of standing at a very early age. When standing these children, care must be taken to see that the lower extremities are in good alignment and that undue pressure is not exerted on them.

This way they experience normal weight bearing while minimizing the risk of fractures.

Also, in this phase of preambulation, transitions from one position to another should be assessed and facilitated. Teaching the child strategies for transitions will enhance his or her optimal functional independence. Compensations may be taught to substitute for weakened musculature. In addition, adaptive equipment and mobility devices may be recommended to enhance acquisition of age-appropriate milestones. Providing appropriate facilitation of mobility at a level similar to that of a child's peers is important for psychosocial growth and development.

Once the child is able to crawl, the child will attempt to pull to standing. This skill requires integration of many factors, including strength in the trunk and upper and lower extremities, and some level of standing balance and ability to bear weight on the lower extremities. The ability to pull to a standing position is typically delayed and may not occur until the child is 3 years of age. When the child attempts to pull to a standing position or would be expected to do so normally (at 10 to 12 months of age), the use of a standing device is indicated. Generally, a standing frame is the first orthosis chosen. This is a relatively inexpensive tubular frame to which adjustable parts are attached. Because it is not custom made, it can be fitted fairly quickly, although adjustments may be necessary to accommodate spinal deformities. This standing device offers support of the trunk, hips, and knees and leaves the hands free for other activities. Time spent in the standing frame should be increased gradually. This allows the child to adjust to the upright position in terms of muscle strength, endurance, blood pressure, and pressure on skin surfaces. Parents may assist in providing activities that focus on standing ability and tolerance. Parents can help facilitate the child's tolerance to standing using different activities, such as coloring while standing. Proper alignment should be taken into consideration while standing to avoid developing deformities.

In typical development, while standing, children will attempt to shift weight in preparation for cruising and walking. Cruising along an object such as a chair or sofa is the next step in development. Initial cruising is controlled by arm strength but also requires balance, strength, and the ability to shift and bear weight on the lower extremities. The control of cruising will shift gradually from the upper to lower extremities in preparation for independent ambulation. After children have built up a tolerance for standing, they may be taught to move in the device by shifting their weight from side to side. Initial shifting of weight onto one side of the body is necessary to allow the other side to move forward. This preliminary weight shift is also a prerequisite for developing equilibrium reactions in the standing position and will thus prepare the child for later ambulation. As the child shifts weight, the trunk musculature on the weight-bearing side should elongate and on the nonweight-bearing side should shorten as muscle strength allows. This normal reaction to weight shifting also includes righting of the head and should be closely monitored by the therapist for completeness. Activities may focus on standing tolerance and ability to shift weight. Parents can help facilitate cruising using different play skills such as reaching to toys in different standing postures.

A therapy program must be designed to meet the individual's needs in each area. Age alone does not determine the appropriateness of therapeutic goals. Goals that are not suited for the child's cognitive and emotional needs, in addition to physical needs, will not facilitate best outcomes. For example, an 18-month-old may have the physical capabilities to ambulate independently with crutches and braces. The child may not, however, have the cognitive skills necessary to learn a four-point gait or be ready emotionally to separate from his or her mother for intensive therapy sessions. A more realistic goal may be to let the child walk holding onto furniture (cruising) while a wheeled walker

for more independent ambulation is slowly introduced. Another alternative to using a conventional walker is to encourage the child to play with push toys such as grocery carts and baby buggies.

During this preambulatory stage, therapy goals may be accomplished through a comprehensive home program, with frequent checks to note progress or problems and to change the program accordingly. For the more involved child, increased frequency of direct intervention may be indicated to achieve optimal developmental progress. A telehealth program can assist in adherence to home program.

The program must be reevaluated often and have goals changed if conditions such as shunt malfunctions or fractures occur. The warning signs for shunt dysfunctions are generally those previously described for suspected hydrocephalus. In addition, swelling along the shunt site may indicate a malfunction. Swelling and local heat or redness of a limb are the usual signs of a fracture. The limb may also look misaligned, and the child may develop a fever. As previously mentioned, these fractures generally heal quickly with proper medical intervention and minimally interrupt rehabilitation efforts.

Toddler Through Preschool (Ambulatory Phase)

This period in development marks the end of infancy and the beginning of childhood. For the typically developing child who has developed a strong sensorimotor foundation, physical development is marked by increased coordination and refinement of movement patterns. In addition, a great variety of motor skills will be achieved as the typically developing child learns to throw, catch, run, hop, and jump. This is also a period of great cognitive growth, as children's use of mental imagery and physical knowledge of their environments expand. Concepts of size, number, color, form, and space are all developing. Emotionally, most children are becoming more independent and begin to break away from the sheltered environment of the home. They are now more interested in interacting with others and become social beings to a greater extent.

All these changes in physical, cognitive, and emotional development will be evident in the child with spina bifida, although the degree depends on the extent of the functional limitations and their effect on the child's ability to participate in life. The characteristics of normal development must be understood so that cognitive, emotional, and motor behaviors can be nurtured and enhanced in the child with spina bifida.

Goals for this stage, as for any other stage, must address physical, cognitive, and emotional development. The most obvious goal at this stage is to help the child who is already standing to progress to an ambulatory status. Even the child with a low thoracic lesion can usually manage some form of ambulation.

Thus far, the child has learned to shift weight in the standing frame. By rotating the trunk toward the weighted side, the non-weight-bearing side can be shifted forward (Fig. 13.21). By reversing the weight shift, the opposite side can be moved forward and a type of "pivoting forward" progression can be accomplished. To maintain balance while shifting, the child may initially use a two-wheeled walker. The therapist may help initiate weight shift and trunk rotation by alternately pulling the arms forward.²⁵⁰ Once the child has gained this form of mobility, the type of permanent bracing chosen will depend on the level of the lesion and a variety of other factors.

The overall goal for ambulatory training is to promote efficient, independent mobility with the least amount of bracing while maintaining optimal joint integrity. Ambulatory potential as well as choice of bracing depends on many factors, including neurosegmental level of the lesion, motor power at the neurosegmental level, stability in neurological condition, extent and degree of orthopedic deformity, balance, age, height, weight, sex, motivation, spasticity and tone abnormalities, type,

Fig. 13.21 Weight Shift and Forward Rotation in Standing Frame.

design and effectiveness of the orthosis, effectiveness of PT intervention, environmental factors, upper-extremity strength and control, and cognitive level.^{208,251} The best prognosis for ambulation is most often seen in the child who is not shunted and has good cognition, good quadriceps power, no deformity, a stable neurological condition, and hands-free sitting balance. Factors that may limit the potential for ambulation include hydrocephalus, high-level lesions, kyphosis or kyphoscoliosis, and unstable neurology.

Developmental progression preceding ambulation in spina bifida shows a high degree of variability.²⁵² A study on motor development and ambulation in children with spina bifida reported that those with greater muscle power of the lower limb muscles ambulated earlier and more frequently.²⁵² This study also reported that walking starts in some children during the first year of life and is seen increasingly more frequently until 6 years of age.²⁵² Those engaged in physical therapy programs aimed at achieving the specific goal of walking are also likely to make earlier strides toward ambulation, although this has not been formally studied. Those who have been enrolled in early body weight supported treadmill training (BWSTT) programs as infants have demonstrated early stepping responsiveness, and it has been suggested that BWSTT training intervention could promote muscle strengthening and take advantage of neural plasticity to promote development of the neuromuscular patterns necessary to support the onset of gait. There is also potential to improve bone density, cardiovascular function, and the integrity of lower spinal sensorimotor function. Infants with spina bifida demonstrate developmental delay as early as 3 months of age, and BWSTT intervention during the first postnatal year has the potential to reduce this delay and promote earlier onset of gait in the population with spina bifida.²⁵³ Efficacy of enhanced sensory inputs during treadmill stepping in children with spina bifida has also been examined. Increasing friction by using Dycem matting and enhancing visual flow by using a checkerboard pattern on the treadmill belt both appear to be more effective than the standard black treadmill belt in eliciting stepping.²⁵⁴ A study on stepping responses in infants with spina bifida reported a decrease in number of steps per minute compared with typically developing peers (14.4 vs. 40.8 steps per minute) and a decrease in frequency of alternating steps.²⁵⁵ In contrast to these interlimb coordination differences, the study reported that

within-limb step parameters in infants with spina bifida were quite similar to those in children who were typically developing.²⁵⁵

For thoracic and high-level lumbar lesions, a parapodium is often chosen. The parapodium was developed by the Ontario Crippled Children's Centre in 1970 and is similar to the standing frame except that hinges at the hips and knees allow for sitting and standing.²⁵⁰ It also can be adjusted for growth and can accommodate orthopedic deformities. As with the standing frame, proper alignment of the parapodium is critical. The therapist, in conjunction with the orthotist, should check for correct standing alignment. The prevention of additional orthopedic deformities, development of good muscular control, and normal body image depend on a well-fitting orthosis.

After a pivoting gait has been learned with the parapodium, a swing-to or swing-through gait can be attempted. By 4 to 5 years of age, a swing-through gait, with the child using Lofstrand crutches, can usually be accomplished. Variations of the parapodium allow for easier locking and unlocking of hip and knee joints. A swivel or pivot walker also may be attached to the footplate. Another type of orthosis for the child with a thoracic or high lumbar lesion is the Orthotic Research and Locomotion Assessment Unit (ORLAU) swivel walker. It consists of modular design similar to that of the standing frame, with a chest strap and knee blocks attached to swiveling footplates.²⁵⁶ Rather than the whole base moving forward, as when weight is shifted in the parapodium, in the swivel walker each footplate is spring-loaded and is able to swivel forward independently, thereby allowing for independent balance on one foot. The ORLAU swivel walker is manufactured in the United Kingdom, and assembly kits may be ordered; however, availability is limited.²⁵⁷ Another parapodium in use is the Rochester parapodium. Separate hip and knee joints allow a variety of free movement for sitting and bending down. The lower portion remains rigid and supportive when hips are flexed. Therefore a child can bend and pick up objects from the floor, and the unlockable hip and knee joints will relock automatically on extension.

There is a perception that although children with myelomeningocele use orthoses effectively, very few continue ambulation into adulthood. Two studies of patients with thoracic-level myelomeningocele²⁵⁸ demonstrated that the ORLAU can be used effectively into the adult years. Both studies noted a 58% to 59.4% compliance rate. Patients in the studies who started using the ORLAU after 11 years of age continued use for 3 to 24 years. Children who do not ambulate had a fivefold increase in pressure sores and twice the number of fractures compared with those who did ambulate.²⁵⁸ Vigorous walking programs should be considered to assist long-term health.²⁵⁸

Both the parapodium and swivel walker have had some problems with instability, ease of application, and cosmesis. New designs attempt to correct these problems.²⁵⁹ Nevertheless, existing limitations in the parapodium and swivel walker, particularly energy cost of walking, slow rate of locomotion, and cosmesis, have limited their use, primarily to the younger child. These devices, however, remain an effective means of preventing musculoskeletal deformities caused by long-term sitting, wheelchair positioning, and general immobility. They also enhance social-emotional development gained from the upright position.^{256,260}

Another option for the child with a higher-level lesion and good sitting balance is the reciprocating gait orthosis (RGO). This brace consists of bilateral long-leg braces with a pelvic band and thoracic extension, if necessary. The hip joints are connected by a cable system that can work in two ways: If the child has active hip flexors, he or she can activate the cable system by shifting weight and flexing the non-weight-bearing extremity. This brings the weight-bearing extremity into relative extension in preparation for the next step. Without hip flexors, the child extends his or her trunk over one extremity, thus

positioning it in relative extension. By virtue of the cable system, the non-weight-bearing extremity moves into flexion, thus initiating a step. Several types of the RGO are in use, including the dual-cable LSU²⁶¹ and the horizontal-cable type. Most recently, the Isocentric Reciprocating Gait Orthosis (I-RGO) (Center for Orthotics Design, Campbell, CA) has been used for children with high-level spina bifida. It has a more cosmetic and efficient design compared with the dual-cable LSU or horizontal cable-type RGO. This cableless brace has two to three times less friction and is therefore more energy efficient. The brace stabilizes the hip, knee, and ankle joints and balances the person, enabling him or her to stand hands free without the use of crutches or a walker (Fig. 13.22). Leg advancement for walking occurs through use of hip flexor or lower abdominal muscle contraction or through use of active or passive trunk extension. In a study of 15 patients with lesions from T10 to L3, use of the RGO produced favorable results. It was used effectively by 13 of the 15 patients. Initial use of the RGO was initiated at 5 years, and 8 of the 15 discontinued use at 10 years of age. During the period of use, four became community ambulators, nine were household ambulators, and two remained nonfunctional (standing only). Average daily use ranged from 6 hours for those ambulating in the community to 30 minutes for those who were nonfunctional ambulators. Six of the 15 had no quadriceps power yet were able to functionally use the RGO for ambulation. Strong motivation and realistic goals are important to successful use.²⁶²

A more common means of maintaining the upright position has been through the use of long- or short-leg braces. Polypropylene braces and carbon-reinforced braces are considerably lighter than metal bracing and therefore reduce the energy cost of walking for the child with spina bifida. They allow close contact and can be slipped

Fig. 13.22 Reciprocating Gait Orthosis.

into the shoe rather than worn externally, thus affording the patient a better-fitting, more cosmetic orthosis.

The type of orthosis chosen (long-leg, with or without pelvic band, or short-leg) depends on the level of the spina bifida and the muscle power within that level (Table 13.3). Because lesions are frequently incomplete, muscle strength must be accurately assessed before bracing is prescribed. Independent sitting balance with hands free also is a prerequisite for use of long- or short-leg braces. Even children with L3 to L4 lesions who demonstrate incomplete knee extension may be able to use a short-leg brace with an anterior shell rather than requiring long-leg bracing.²⁶³ This crouch-control AFO (CCAFO) will prevent a crouching gait pattern by improving knee extension during gait (Fig. 13.23).²⁶⁴ Another alternative to a standard solid ankle AFO may be the carbon fiber spring AFO. This brace provides dynamic assist, supports the patient through the entire stance phase, and increases energy return during the third rocker phase of push-off, simulating the natural push-off action.²⁶⁵ For children demonstrating excessive knee valgus caused by hip adduction, use of a Ferrari KAFO (FKAFO) may be considered.²⁶⁶ The PT must work in conjunction with the orthopedist and orthotist to have each child fitted with the minimal amount of bracing that allows for joint stability and a good gait pattern.

Children with lower-level lesions (L5 to S1) who use below-knee bracing often develop the ability to or choose to ambulate without assistive devices. However, recent studies have shown that crutch use may decrease excessive pelvic motion, which results in reducing abnormal joint forces.^{202,205} The use of crutches may prevent abnormal joint forces, maintain joint integrity, and decrease the risk of additional orthopedic complications.

The literature has suggested that the long-term use of crutch-assisted ambulation may result in long-term pathology. In patients with higher lumbar lesions (L3 to L4) who use Lofstrand crutches, the dynamics and kinematics of upper-extremity function were explored during swing-through and four-point reciprocal modes of gait. Although there were better joint kinematics in the shoulder and other upper-extremity joints during swing-through gait, kinetics were more problematic with increased force and torque in shoulder and wrist joints in those using a swing-through gait. Whereas the swing-through gait allows a potentially faster mode of ambulation, long-term use of this pattern may lead to increased upper-extremity pathology. Careful monitoring of all joints, including upper-extremity joints, during gait reassessment should be considered in order to deter and manage these potential issues that may compromise overall joint integrity and function.²⁶⁷

The excessive femoral torsion present in all newborns at birth does not decrease with growth and development in the child with spina bifida because of abnormal gait and activity.⁹⁹ Children ambulating with AFOs often show excessive rotation at the knee because of the lack of functioning lateral hamstrings. Rather than going to a higher level of bracing, a twister cable can be added, which often decreases the rotary component during gait.⁹⁹ Twister cables can be heavy-duty torsion or more flexible elastic webbing, depending on function. Typically, the young child who is just beginning to pull to stand and remains reliant on floor mobility as the primary means of mobility should have elastic twistors prescribed to allow for ease of creeping and transitions. The older and more active child will require heavy-duty torsion cables. Rotational stresses may eventually lead to the onset of late degenerative changes around the knee. A tibial derotation osteotomy may be indicated to prevent these changes from occurring.^{99,204,268}

For children with low lumbar or sacral lesions who have at least fair strength in their dorsiflexors and plantar flexors, a University of California Biomechanics Laboratory (UCBL) or polypropylene shoe insert to control foot position is often the only bracing needed. These

TABLE 13.3 Common Gait Patterns and Levels of Assistance Required in Myelomeningocele

Level of Lesion	Muscle Performance	Recommended Level of Assistance and Bracing	Ambulatory Progression
T8–L1 and above	Flaccid LEs with fair to poor trunk	Parapodium: ORLAU, Toronto, Rochester Assistive devices often unnecessary with ORLAU but may improve function with Toronto or Rochester braces	
L1–L2	Flaccid LEs with hip flexors present	Parapodium with progression to RGO RGO, ambulating with hips locked	Begin ambulating with a walker, progress to forearm crutches Four-point or swing-through gait
L3–L4	Fair quadriceps with weak or absent hamstrings	HKAFOs may be used with severe lordosis because of weak or absent gluteal musculature and decreased trunk control or to control rotation and abduction and adduction. If quadriceps are less than fair strength, KAFOs may be needed As the patient progresses he or she may be cut down from KAFOs to AFOs; AFOs may be used with or without twister cables	Begin ambulating with a walker, progress to forearm crutches Four-point gait Begin ambulating with a walker and progress to forearm crutches. In some rare cases the patient may progress to no assistive device at all depending on the gait pattern With increased use of trunk reversal, the patient should be returned to forearm crutches to allow for a pattern that is more cosmetic and energy efficient Four-point gait pattern
L5	Good hip flexors and quadriceps; fair anterior tibialis; weak gluteus medius and maximus, toe extensors and gastrocnemius	AFOs with or without twistors depending on gluteal strength AFO is used to prevent a crouch gait pattern from weak gastrocnemius	Forearm crutches or no assistive devices Four-point gait
S1	Good hip flexors, quadriceps, gluteus medius, and toe extensors; weak gluteus maximus and gastrocnemius	AFO	Generally, no assistive device is used unless decreased balance reactions or excessive lateral trunk flexion is present
S2–S3	Good hip flexors, quadriceps, gluteus medius and maximus, and gastrocnemius	Often no bracing needed	Often no assistive devices needed

AFO, Ankle-foot orthosis; HKAFO, hip-knee-ankle-foot orthosis; KAFO, knee-ankle-foot orthosis; LE, lower extremity; RGO, reciprocating gait orthosis.

Fig. 13.23 Crouch Control Ankle-foot Orthosis.

inserts fit snugly inside the shoe and help control calcaneal and forefoot instabilities. A supramalleolar orthosis (SMO) will also fit easily inside the shoe but will provide additional medial and lateral support and stability that an insert would not provide. Even though a child may be able to ambulate without an assistive device or bracing, consideration must be given to the stresses that occur at the joints that, over time, may lead to orthopedic deformity. The greatest risk of joint instability often occurs at the knee. Barefoot walking versus use of an AFO has shown increased instability, joint stress, and pain at the hip and knee as well as increased energy expenditure.^{269–271} Even though children may be able to ambulate without the use of crutches, comparison of gait kinetics and kinematics of walking with crutches has shown a significant decrease of valgus forces at the knee and better overall alignment of the lower extremities.²⁰⁵ Treatment aimed at strengthening the gluteus medius and maximus to aid in increasing pelvic stability and reducing kinematic compensations can also be important in the management of patients with lesions at this level to enhance their efficiency during ambulation.^{272,273}

Gait training, begun as the child first starts to stand, can now continue in a more formalized manner. By using the appropriate orthosis and assistive devices (walker, crutches, or cane), each child must be helped to achieve the most efficient and effective gait pattern possible (see Table 13.3). As a part of gait training, the child should be taken out of the bracing and “challenged” so that righting and equilibrium reactions can be developed to their maximum. For example, having a child

maintain balance while sitting on a ball or another movable surface (tilt board, trampoline) requires the participation of all available musculature, especially abdominal and trunk extensor muscles (Fig. 13.24). Strengthening available musculature is a primary objective in this phase of treatment. Slow gains in muscle strength are often the result of continued emphasis on strengthening during physical therapy. In addition to trunk muscles, the gluteus medius, gluteus maximus, and quadriceps are often targeted. Prone activities such as picking up toys while over a Swiss ball or moving around while prone on a scooter board require use of these muscles while providing an enjoyable exercise for the child. Therapists may use therapeutic equipment, such as the Lokomat, and LiteGait or robotic devices to assist in walking and gait training. Participation in hippotherapy and aquatic therapy programs at this age can also be beneficial. These treatment approaches can be used to improve muscle strength in general and the gait pattern when bracing is reapplied. Regardless of the strengthening activities chosen, the pediatric therapist has the special task of using creativity to involve the child in therapeutic play activities. The ideas for creative activities are limitless but essential for combining therapy with age-appropriate cognitive abilities.

Studies examining the effects of strength and endurance training in those with spina bifida²⁷⁴⁻²⁷⁶ have demonstrated enhanced functional outcomes. These studies included individuals in wheelchairs as well as ambulators. Interventions aimed at strengthening those with spina bifida, including electrical stimulation,^{277,278} behavioral treatment,^{279,280} and motor skills training,²⁷⁹ have been reported. The evidence supporting strengthening, using exercise, electrical stimulation, and motor

Fig. 13.24 Balance and Strengthening Exercises Done on a Movable Surface.

skills training, was recently examined in a systemic review.²⁸¹ This review synthesized six studies supporting interventions in strengthening.^{275,277-282} The level of evidence for the studies was determined using the American Academy of Cerebral Palsy and Developmental Medicine Levels of evidence.²⁸³ The total number of subjects in all of the six studies was 26 subjects. All six studies reported improvements in strength; however, only three noted statistically significant results. Although the evidence suggests the possibility of being able to increase muscle strength using these modalities, in this population one must interpret the results with caution owing to lack of rigor, small subject populations, and variability across studies.

Upper extremity strengthening exercises may be necessary for those with spina bifida. Upper extremity strength training can help maintain the ability to perform functional skills including transfer, pushing wheelchair, and use of assistive devices for walking such as walking and crutches. Upper extremity strength training can also help increase cardiovascular endurance and prevent injuries associated with overuse.

Spina bifida is a congenital-onset condition that requires intervention by the PT from infancy through adolescence. Most of the impairments and functional deficits described throughout this chapter last throughout a lifetime. Health providers familiar with the complexity of the secondary impairments should follow up with individuals with spina bifida on a regular basis. Physical therapy plays an important role in screening for potential problems and providing recommendations for maintenance of mobility and health-related fitness as well as promoting activity and participation for children with spina bifida. OTs within the school systems often provide interventions within the area of integration of perceptual function. However, additional research needs to be done to guide “best practice,” as there is little support for those interventions that expert clinicians deem beneficial in the habilitation of these patients.

Obesity affects the ability for interaction and participation at multiple levels across the life-span of those with spina bifida. Obesity may affect independence in transfers and ambulation, self-care and mobility, as well as in personal social interactions at all ages. Some children may lose the ability to ambulate if they have excessive weight gain without a comparable gain in muscle strength. Often, the child with spina bifida may be the last to be asked to participate and/or the child’s inability may affect his or her ability or willingness to participate in physical games and activities with peers. Obesity puts more pressure on skin, thereby increasing the already high risk of skin breakdown. It may make it difficult for the child to reach private areas of the body, thus interfering with hygiene. Equipment and orthotic needs can also be complicated by increases in weight gain and obesity as the child ages.

Studies using dual-emission x-ray absorptiometry (DEXA) have shown that those with spina bifida have significantly decreased lean body mass as compared with controls.²⁸⁴ Children with spina bifida likely have lower metabolic rates secondary to decreased muscle mass and decreased ability to burn calories. Those with higher-level lesions often have greater issues with obesity owing to decreased lower-extremity muscle activity, decreased physical activity, and decreased overall muscle mass. Adult wheelchair users have been shown to require 1500 fewer calories per day, and overall nutritional intake should be lower for those with spina bifida than their typically developing peers.²⁸⁵⁻²⁸⁷ A weight management program is recommended for both the ambulatory and wheelchair users. Interventions to address physical inactivity and obesity may include increased physical activity, regular exercise, behavioral modifications, nutrition education programs, and attention to weight control. Exercise programs targeting upper-extremity resistance combined with aerobic activities such as swimming and arm-cycling

using arm-ergometry can be helpful in addressing obesity in those with spina bifida. Adolescents with spina bifida who used an upper-extremity cycling program that was integrated with video gaming three times per week for 16 weeks improved oxygen uptake and maximum work capability.^{284,288,289}

Sensory limitations may impede progress during early ambulation training. Because of limited kinesthesia and proprioception, available sensory systems must be augmented, and the child must be taught to substitute with nonimpaired sensory systems. Impaired kinesthesia in children with spina bifida impedes their ability to anticipate changes in terrain and poses a safety problem. Vision may be the most relevant system that allows them to scan and preplan for changes in their walking environment. The parents and child should learn that the child is at risk of injuring a limb as the child cannot feel painful stimuli that might injure that limb. The parents and child should be educated to frequently check the position of the limb and observe the skin for any sign of irritation. They will also need to learn to check water temperature and use extra caution around extremely hot or cold objects. Tight or restrictive clothing and shoes should be avoided. Sensory deficits impact function and should be considered when teaching a child functional skills. Adding weight to the limb (ankles) or walker may supplement proprioceptive awareness and facilitate gait training.

Gait training and muscle strengthening are not the only consideration of the therapist. How cognitive and psychosocial development can be enhanced during this stage of the child's development is also important. One appropriate solution is to place the child in a center-based EI program. Although these programs may vary in the services they provide, most usually include age-appropriate play activities and some type of parental counseling. In addition, many offer therapeutic intervention from physical, occupational, and speech therapists. This intervention may occur in groups or individually and typically occurs in the child's natural environment.

In addition to the socialization that center-based EI programs provide for the child with spina bifida, they also teach the child age-appropriate ADLs, such as dressing and undressing. At this age, ADL skills are more appropriately taught in a group setting than individually. For many children the EI program, along with individualized therapy, is sufficient to enhance development in the physical, cognitive, and psychosocial realms.

Presently, when children reach the age of 3, public school education becomes available to them. The preschool or EC program continues to offer the same fundamental benefits as the EI program. It is the role of the EI therapist to communicate the specific needs of each child entering the public school system. In this way, continuity in the child's rehabilitation program is preserved.

The spina bifida team, usually headed by a pediatrician or clinical nurse specialist, continues to follow the child closely during this stage. The neurosurgeon checks shunt functioning and performs revisions as necessary. The orthopedist supervises bracing efforts to prevent and correct deformities in the spine and lower extremities. Well-child care and general medical treatment are the responsibility of the pediatrician on the team. The urologist continues to monitor renal functioning while keeping the child dry and free of infection. At this stage, the clinical nurse specialist will usually teach bowel and bladder training to the child and family. This clinician generally initiates this training according to age-appropriate developmental guidelines.

Bladder training usually consists of transferring the job of CIC from the parents to the child. Children as young as 3 years, but certainly by the age of 5 years, can learn CIC in a short period.²⁹⁰ Children may first practice on dolls with male and female genitalia. Next, using mirrors to understand their own genital anatomy, they are able to accomplish the technique on themselves. CIC in conjunction with

pharmacotherapy is useful in achieving continence in children with spina bifida.¹⁸¹ Another method of bladder training recently being used is intravesical transurethral bladder stimulation. This technique has allowed children with neurogenic bladder to rehabilitate their bladder function so that they can detect bladder fullness and generate effective detrusor contractions, leading to improved continence.^{115,291}

Bowel training can be achieved through proper diet, regular evacuation times, and appropriate use of stool softeners and suppositories.¹¹⁵ Constipation (and resulting bypass diarrhea) can be prevented by proper habit training and use of fiber supplements. Stool softeners (not laxatives and enemas) and suppositories should be used to keep the stools soft and help stimulate evacuation. Finally, toilet training, which amounts to scheduled toileting in time with the stool stimulants, usually achieves bowel continence. Surgical procedures, such as the Malone ACE procedure,¹⁰² may be necessary when other interventions have failed. The Malone ACE procedure, performed in conjunction with a Mitrofanoff procedure to gain urinary continence, can help these patients attain a better quality of life. Consistency at each step along the way is the key to successful bowel training. A therapist may be called on to assist the parents and child in achieving independence in this ADL.

Other members of the team, such as the psychologist, social worker, and dietician, continue to function in their appropriate roles, interacting with the child and family as necessary. PTs and OTs, as members of the team, must collaborate with the efforts of other team members in the creation of their treatment plans.

Mobility and bladder and bowel dysfunction in toddlers and school-aged children represent ongoing stressors for parents of children with spina bifida. It has been noted by many that spina bifida represents a considerable challenge to all family members, particularly mothers. Family climate, parents' partner relationships, and social support networks play a considerable role in balancing stress and psychological adjustment for parents. Awareness of available systems of support for the patient and family as well as resources to which parents and their children can be referred for psychological and social support as needed are important for all health care practitioners.^{292,293}

Primary School Through Adolescence

The primary school years and adolescence is a period when there is less rapid growth than earlier childhood and ends with a period of rapid physiological growth. Children in the 6- to 10-year age group are interested in a wider variety of physical activities as they challenge their bodies to perform. The adolescent, however, is going through a period of great sexual differentiation as primary and secondary sexual characteristics develop more fully.

Cognitively, children are able to solve problems in a more sophisticated manner, although they revert to illogical thinking with complex problems. As they reach adolescence, they become capable of hypothetical reasoning and their thought processes approach those of adults.

Emotionally, the 6- to 10-year-old is in a period of relative calm. Children are interested in schoolwork and are eager to produce. This is a period during which they are developing relationships outside of the family and beginning to assume an identity and autonomy. Problem-solving and decision making skills are at the crux of this time period. However, it is also challenging to promote independence and minimize self-reliant behaviors. Social passivity may ensue as "learned helplessness" behaviors emerge. Therefore professionals, including both PTs and OTs, should begin targeting independent function early and before adolescence.²⁹⁴ Relevant family education regarding this issue should be inherent in all care plans, and independent behaviors should be promoted from very early on. Engagement in family decision

making and opportunities for active problem solving have been linked to increased positive self-esteem and ego development.²⁹⁵ During this time period, children with spina bifida are at risk for developmental delays in social functioning.²⁹⁴

School-aged children and adolescents are building the skills of the future, preparing them for adult work. This is a prime time to introduce and teach new skills while fostering increased autonomy and independence. Autonomy is difficult for the youngster with spina bifida. Motor skills impeding progress toward autonomy vary for each child and are dependent on the level of spina bifida as well as on any cognitive impairment. However, it has been observed that the motor skills hardest to attain are those that involve motor planning and that the process skills hardest to attain are those related to adaptation of performance and initiation of new steps. Thus guidance to learn not only how to do things but how to get things done is important.²⁹⁶

Interventions targeting independence have been embedded into various settings, including after school, adapted sports, and summer camps. O'Mahar and colleagues²⁹⁷ report on one such camp program focused on campers 7 to 14 years of age the program emphasized individualized collaborative (i.e., parent and camper) goal setting, group sessions with psychoeducation and cognitive tools, and goal monitoring by the camp counselor. Campers reported significant gains in individual goals, management of spina bifida responsibilities, and independence.²⁹⁷

Children with spina bifida and disabilities, in general, do not participate in physical, recreational, and social activities to the same degree as typically developing children. Decreased participation in physical, recreational, and social activities is greater when children with spina bifida 6 to 12 years of age have medical issues such as a shunt for hydrocephalus and bowel and bladder issues. Participation for children with spinal bifida has been found to decline with age. School-aged children participate less than preschoolers, and adolescents participate less than school-aged children. Preschool is a time of intense learning in all domains—physical, intellectual, and social. As children get older, their physical participation declines. Thus the school-age years may be a time to encourage participation in physical and recreational activities. Participation in physical activities often foster social interaction, which is also needed at this age.²⁹⁸

Usually at this age, if it has not occurred previously, the evaluation of future ambulation potential occurs. The child whose larger size and limited abilities make ambulation more difficult each day frequently warrants this evaluation. Strength does not increase in the same proportion as body weight.²⁹⁹ Ambulation, although possible for the young child, may be impossible for that same person as a young adult.

As the energy cost of walking becomes too high, the use of a wheelchair for locomotion often becomes appropriate. To a teenager whose emotional needs include a strong peer identity, transitioning to a wheelchair may foster increased independence owing to improved ability to participate and engage with peers. Appropriate alternatives may be to delay the decision to use a wheelchair full time or limit ambulation to short distances or to those places most important to the child. Again, goals must be tailored to the child's needs and encompass his or her whole being.

Although no guidelines include every patient, children with thoracic-level lesions are rarely ambulators by the late teens.^{195,300,301} Those with upper lumbar lesions may be household ambulators with long-leg bracing but will require wheelchairs for quick and efficient mobility as adults. With low lumbar lesions, most adults can become community ambulators. Patients with sacral-level lesions are usually able to ambulate freely within the community. Many require minimal bracing and ambulate without assistive devices.^{99,195} It must be remembered that ambulatory status is not determined by level of the lesion

alone. The muscle power available; degree of orthopedic deformity; age, height, and weight of the patient; and, of course, motivation are also determining factors.^{85,99,193,302}

For children and adolescents who continue to ambulate with orthoses, in accordance with the child's growth spurts, frequent adjustment or reordering of bracing will be necessary. Continual reevaluation of orthotic needs may reveal that the level of bracing may decrease as the child grows and becomes stronger; the opposite development is also a possibility. Ambulatory children must be taught to assess their skin for pressure areas or abrasions from orthoses and shoes. Those with sacral level lesions must be cautious with their choice of shoes/footwear.

Because a large number of older children with spina bifida will become full-time wheelchair users, potential problems connected with a sedentary existence must be properly managed. Skin care, always a concern for the child with spina bifida, becomes a priority for the constant sitter. Well-constructed foam, gel, or air-cell seat cushions are essential for distributing pressure evenly. Children should be taught frequent weight shifting within the chair to relieve pressure area as well as to use mirrors for self-inspection of the skin twice daily. Clothing should not be constricting but should be heavy enough to protect sensitive skin from wheelchair parts. Children must also be taught to avoid extremes of temperature and environmental hazards, such as radiators, sharp objects, and abrasive surfaces. The therapist must reinforce the importance of skin care to prevent setbacks in the rehabilitation process that may result when skin breakdown develops.

Children with higher-level lesions may need spinal support to prevent deformities. A polyethylene body jacket or thoracolumbosacral orthosis (TLSO) can be used to provide this support and, hopefully, prevent the progression of any paralytic deformities. Whatever type of device or wheelchair padding is used, the therapist must check to see that weight is distributed equally through both buttocks and that the spine is supported as needed. Part of the therapeutic intervention is to provide strengthening exercises or activities to be done out of the supporting orthosis. This is necessary to maintain existing trunk strength and to preserve the child's present level of function.

Generally, in late childhood or early adolescence, orthopedic deformities that have been gradually developing may require surgical intervention. Progressive scoliosis or kyphosis may require internal fixation when conservative methods fail.³⁰³ Lengthening or release of tight or contracted muscles at the hip and knee is often required.¹⁹⁵ The iliopsoas, adductors, and hamstrings are frequently the offending muscles. These surgeries, followed by strengthening exercises and gait training, often add to the ambulatory life of the child with spina bifida. For example, in a child who displays an extreme lordotic posture, hip flexion contractures may be present and surgical lengthening of the tight muscles may be required to allow improved biomechanical alignment for standing and balance. A postoperative therapeutic program might include periods of prone lying to prevent future contractures and strengthen hip and pelvic musculature, core, and abdominals for stability and support to develop and maintain improved standing alignment. Gait training will be necessary to incorporate improved posture and alignment into the gait pattern.

Of primary importance during this stage is preparing the child for independence in ADLs, which may be broken down into self-care, locomotion-related, and social interaction activities. In conjunction with the nurse, PT, and OT, self-care skills of dressing, eating, and food preparation; general hygiene; and bowel and bladder care can be addressed. Because the adolescent is so concerned with achieving independence, he or she is more likely to comply with a regimen of strengthening exercises if shown how they relate to functional independence. A creative therapist may, for example, incorporate trunk

Fig. 13.25 Participation in Wheelchair Racing. (Courtesy Su Metzler.)

stability and upper-extremity strengthening work in activities such as making popcorn or getting ready for a dance. In addition, fostering social and recreational independence through adaptive sports and fitness programs and leisure activities should not be overlooked. Participation in adaptive sports can aid immensely in improving strength, endurance, and self-esteem. Community adaptive recreational programs may include T-ball, martial arts, swimming, tennis, basketball, skiing, bowling, and many other common sports and leisure activities (Figs. 13.25 through 13.27).

Fig. 13.27 Participation in Adaptive Tennis. (Courtesy Su Metzler.)

Locomotion activities should include all gait-related skills, such as falling down, getting up, and ambulation on various terrains and stairs. Transfers of all types should also be included in locomotion activities. Again, a creative therapeutic program helps make achievement of skills more palatable. For example, school-aged children may enjoy a competitive relay race situation in which each child falls, gets up, walks across the room, and sits down in a chair safely. This type of activity combines gait-training activities with group socialization and may meet a variety of goals (motor and psychosocial) at the same time.

The achievement of independence in ADLs for the child and adult with spina bifida does not depend solely on the level of paralysis. Also, important are psychosocial and environmental factors. Mean ages for the achievement of various ADL activities have been developed and may assist the therapist in establishing realistic therapeutic goals in this area.³⁰⁴

Often during this stage of rehabilitation, the therapist is asked to assist in assessing cognitive function. The perceptual and cognitive evaluations previously discussed may be administered and the results interpreted for parents and school personnel.

Also, as previously discussed, children with spina bifida have a general perceptual deficit that can manifest itself in a variety of ways. First, the child may have difficulty recognizing objects and the relations that they have to one another. He or she may therefore perceive the world in a distorted manner and have reactions that are unstable and unpredictable. These perceptual difficulties will most likely affect academic learning, and the child may associate failure with the learning process. At times, difficulties in attaining independence in ADLs may also be linked to perceptual problems. The perceptual difficulties of the child with spina bifida may result in emotional difficulties for the older child and adolescent, as they are not achieving independence to the same extent as their typically developing peers.¹¹³

Remedial programs that use a multisensory approach to developing perceptual skills, such as the Frostig Program for the Development of Visual Perception, have been effective in improving the visual perception of children with spina bifida.¹¹³ Programs of this type are most

Fig. 13.26 Participation in Wheelchair Basketball. (Courtesy Su Metzler.)

effective when remediation begins early—preferably at or before the time the child enters school. Developmental optometry examination and remediation programs focusing on vision training may also be of benefit.

Children with spina bifida may also have difficulties with tasks requiring sensorimotor integration. Children requiring sensory integration therapy should be referred to a therapist certified in this area, most often OTs. Many appropriate activities for sensorimotor integration may be adapted from Ayres³⁰⁵ or Montgomery and Richter, and are now being carried out in sensory gyms by certified therapists both physical and occupational.³⁰⁶

Regardless of the school setting chosen for the child, the therapist should be able to serve the classroom teacher as a consultant. Advice on adaptive seating and therapeutic goals appropriate for the classroom help ensure that the rehabilitation process will continue in the classroom as well as promote optimal conditions for learning.

When a child is moving from the preschool to the elementary school setting, the support of the therapeutic team is essential and invaluable. The teacher's expectations, as created by the therapist, regarding the child's special needs and abilities, often spell the difference between success and failure of complete academic and psychosocial integration within the school setting. Even though the child may no longer require direct therapeutic intervention, periodic consultation, including site classroom visits, is recommended to prevent minor problems from developing into major ones. For example, bowel and bladder accidents can be avoided by scheduling regular times for toileting. The teacher may be able to make minor adjustments in the teaching schedule to accommodate this scheduling. The PT should consult with and educate the teacher and classroom staff on how a child's braces and adaptive equipment operate to enable the teacher and staff to assist the child as needed.

The psychological perspective of the child colors therapeutic goals in this stage. As the child nears adolescence, these psychosocial aspects become of paramount importance. Although the therapist should not take on the role of the psychologist, collaborative efforts in the area of counseling will be necessary. Questions will arise many times during physical and occupational therapy sessions, requiring factual answers that the therapist can and should provide.

TRANSITIONS TO ADOLESCENCE

The consequences of the physical, medical, and cognitive effects of spina bifida extend into young adulthood and have an impact on quality of life.³⁰⁷ Adolescence is a stormy emotional period. Adolescents remain in turmoil as they seek their identities through sexual, social, and vocational activities. As their value systems develop, they feel less ambivalence between remaining children and striving for independence.

Adolescents with spinal bifida are often unable to perform everyday tasks in an efficient and independent manner due to both lower motor abilities as well as lower processing abilities. Difficulties with motor planning and how to adapt body position impede the ability to accomplish a task efficiently. Processing skills hardest to achieve include adapting performance to the situation and the initiation of new steps. Therefore for the child with myelomeningocele, adolescence may not be the optimal time to introduce new skills leading toward self-care and independence. This needs to be introduced at a much younger age and consistently as the child develops. Adolescents with spina bifida need the opportunity not only to learn skills but how do get things done. It is important to inform parents and caregivers of children with spina bifida from an early age to provide the opportunity to practice skills as well as autonomy in the performance of everyday activities.²⁹⁶

TRANSITION TO ADULTHOOD

The transition to adult health care has lagged behind the medical advancements that have increased the number of survivals into adulthood.³⁰⁸ As the individuals transition into adulthood, a unique set of challenges arise. Eighty-five percent of infants born with spina bifida will reach their adult years. Adults with spina bifida continue to present with unique long-term medical challenges. The health of adults with spina bifida can vary widely based on age, level of lesion, number and severity of comorbidities, functional skills achieved in childhood, degree of self-care skills, amount of family and community support, and access to medical care.⁷¹

Adults with spina bifida are at risk for the same secondary complications as children, but also have potential health concerns from the longitudinal effects of paralysis, weakness, sensory loss, hydrocephalus, immobility, neurogenic bowel and bladder, bone and joint deformity, and contractures and abnormal peripheral circulation.⁷¹ In addition, there are potential complications from the lingering effects of childhood procedures such as ventricular shunting, urinary and continence procedures, and orthopedic surgeries.⁷¹ A prospective study reported the 25-year outcomes and medical needs of an original cohort of patients with spina bifida in a multidisciplinary clinic. Eighty-six percent of those patients had CSF diversion, with 95% who had undergone at least one shunt revision. For those who underwent a TCR, 97% experienced an improvement or stabilization in their preoperative symptoms. Forty-nine percent had scoliosis, with 43% requiring a spinal fusion. More than 80% of the young adults had social bladder incontinence. Twenty-three percent had at least one seizure. Approximately 1/3 were allergic to latex, and six patients had experienced a life-threatening allergic reaction. Eighty-five percent of the individuals attended or had graduated from high school and/or college. The results of this study indicate that late deterioration is common in individuals with spina bifida. One of the greatest challenges today is establishing a network of care for these adults with spina bifida.¹²¹

For the adolescent with spina bifida, the transition to adulthood includes a new set of expectations. Independent mobility expands to driving or arranging public transportation and getting to the correct destination in unfamiliar surroundings for leisure and recreation, continued education, or job opportunities. Self-care includes performing ADLs but expands to household management and financial responsibilities. Social relationships expand to include long-term partnerships with friends and business contacts; encounters with equipment vendors, insurance professionals, and medical providers; and may include hiring, firing, and directing personal health care assistants.

For some adults with spina bifida, living independently in society is a difficult goal to reach. Approximately 50% to 70% of adults with spina bifida live with family or in an assisted-living arrangement. The individual with spina bifida continues to require assistance with management of and resources related to medical, rehabilitative, and social-emotional needs throughout adulthood.^{215,309–311} Secondary impairments span a wide range of domains, but management of secondary health conditions is a priority in reducing mortality, deterioration of general health, and further impairments throughout the adult years. Renal, respiratory, and cardiac complications have been identified as frequent causes of death.²¹⁵ Living with the long-term consequences of spina bifida places increased demands on the musculoskeletal system, and the effects of aging can appear earlier than usual. Osteoporosis, increased risk of fractures, risk of osteoarthritis, muscular pain from overuse of the upper extremities with use of crutches and longer-distance wheelchair propulsion over all terrains, increased transitions for self-care management and routines, and abnormal stresses placed on the knee from weak hip abductors and calf muscles can lead to

degenerative changes and joint pain. Obesity and weight gain resulting from a more sedentary lifestyle and hypertension, heart disease, and diabetes are common problems with aging.³¹² Thinner and less elastic skin that is susceptible to breakdown, insufficient pressure relief and poor tissue perfusion, incontinence and perspiration, wound infections after surgical procedures, burns and bumps that occur to insensate limbs, and long-term immobilization during hospitalizations have been major sources of decreased skin integrity.^{215,312,313}

Muscular strength, flexibility, balance, and endurance decrease during the aging process. Changes in the CNS affect memory, reaction time, and attention span. An increased risk of depression and anxiety has been documented in several studies that measure quality of life in the adult with spina bifida.^{215,309,314} Secondary conditions in adults with spina bifida have been linked to admission rates to hospitals that are nine times higher than in the nondisabled population. Adults with spina bifida also have medical expenditures that are three to six times greater than those of adults without spina bifida.²¹⁵

Additional unmet needs reported by adults with spina bifida are related to functional mobility, household management, and active recreation. Being independent with regard to mobility has been the most important determinant in quality-of-life surveys.^{22,314} A review of the literature over the past few years has indicated high unemployment rates for people with disabilities. For those with spina bifida, 47% of adults were in competitive employment, 15% were in sheltered or supported employment, and 38% were unemployed or had never been employed.³¹⁵ Limited mobility accounts for only part of the high unemployment rate. Accessibility into public buildings is another factor that limits employment opportunities. Tight doorways, steep ramped entrances and exits, inefficient workstations, and unreliable public transportation all play a role in a lower employment rate. Universal design (broad-spectrum solutions that produce products and environments that are usable and effective for everyone), construction of newer buildings with attention to adjustable work tables for computers and equipment access for people with different body proportions, as well as wider doorways, lower counters, doors that open electrically, and bathroom modifications (for both manual and power wheelchair users) with Americans with Disabilities Act (ADA) specifications for building modifications will improve universal access for all people with and without disabilities. Modifications of bathrooms that accommodate wheelchair and crutch users, including different height grab bars and roll-in shower arrangements, sloping landscape for entrances and exits, and room modifications with lower counters and closet access, to name a few considerations, may enhance travel and leisure time and recreational opportunities. A study that reviewed life-span issues of people with childhood-onset disabilities reported that more than 50% requested more information on their specific medical condition and the consequences of this condition on adulthood recreation.³¹⁴

Most adults with spina bifida use some form of assistive technology (AT) that plays a significant role in increasing independence at home and in the community.³⁰⁹ A study on the use of AT among individuals with spina bifida indicated that 35% use bracing, 23% use walking devices, and 57% to 65% use lightweight wheelchairs (both manual and power assisted³⁰⁹). Mobility equipment needs change as people age. Therapists have expertise in adaptation and modification and can recommend solutions for decreased mobility. Physical changes in the workplace and home to decrease excessive stress on joints while maintaining flexibility and musculoskeletal alignment for efficiency without pain may also be required. Evaluating the individual needs of the patient and locating and selecting the types of technology that may enhance the adult's personal care management and improve efficiency in household tasks may make the difference in helping the patient have a more satisfying quality of life. Cell phones, computer access, and watch

timers for pressure relief and personal care routines can all assist memory and organizational skills.³⁰⁹

AFO is the most frequent used orthosis for children with spina bifida. AFOs often help improve alignment and walking and prevent contractures and deformities dependent on the level of lesion. Some AFOs are made with carbon springs that store energy. Other leg and feet braces can be used to stabilize weak muscles and prevent malalignments. Crutches can be used to minimize the amount of weight bearing on the legs and hips. Crutch tips that can be changed to accommodate different surfaces (e.g., with spikes attached for snow and ice), forearm crutches with hand grips and forearm cuffs that distribute weight and reduce joint stress to shoulders and wrists, powered add-on devices for manual wheelchairs to reduce stress on painful shoulders, adjustable furniture, wrist rests, footrests, and arm supports to ensure correct posture and reduce cervical and lumbar strain are examples of current and experimental AT that may promote greater independence. Specific devices are supported by the individual needs assessment of the patient by the therapist and education in the device's maintenance for appropriate use and durability. It is beyond the scope of this chapter to discuss specific equipment items in detail.

The transition to adult health care has lagged behind the medical advancements that have increased the rate of survival into adulthood.³⁰⁸ As individuals transition into adulthood, a unique set of challenges arise. Transitioning to health care providers can be challenging due to reduced family support, concerns with executive skills, and lack of access to knowledgeable adult care providers. Although some pediatric spina bifida clinics provide services to the adult population, many other clinics have age limits. Additionally, changes in insurance policies as the patient reaches certain age may require that the patient move to different providers or hospitals. One of the challenges to health care is finding access to health care providers who provide services for adults with special needs, in both the primary care setting and medical subspecialties.^{38,308}

Resistance to health care transitioning is multifaceted and may come from the patient, family, or both. Transitioning to adult health care may involve leaving multidisciplinary care clinics to care from multiple specialists with less multidisciplinary or coordinated care. Lack of coordinated medical care is a significant issue as the adolescent transitions into adulthood. This may result in a lack of follow-up and missing treatment visits. Transition may be delayed due to lack of initiatives or motivation or anxiety about the change in providers. Decreased intellectual functions in some individuals with spina bifida may affect provider, parent, and patient readiness to transfer responsibility of important health care activities and decisions.³¹⁶ Resistance may also come from parents who may feel that a transition to adult care would begin to exclude them from the dynamics of care and decision making processes.

Lack of clinical guidance on how to transition from long-term pediatric providers to adult care may cause patients to miss routine primary care or subspecialty appointments.³¹⁶ A study on adult with spina bifida from 19 to 64 years of age reported that that 75% of the participants could not name their primary care physician and had not seen a medical professional in over a year.²¹⁵ In adulthood, lack of regular care or experiences care in adult care individuals with spina bifida may result in increased preventable secondary complications and higher rate of emergency department admission.

Transitioning from adolescence to adulthood involves acquiring adult life skills and experiences to manage health care tasks and decisions, as well as developing and learning a new role as a recipient of care in an adult setting.³¹⁶ It is possible that transitioning to adult care may provide patients with feelings of autonomy and independence in their abilities to manage care.

The transition to adulthood should be gradual and should include a coordinated approach involving the patient, family, and significant individuals involved in the patient's care.³¹⁶ The recommended age for starting the discussion on transition is 14 years but may occur earlier.³⁰⁸ Discussions about the timing of the transfer of care should take place early among the patient, family, and pediatric provider and not during an acute medical crisis. A good support system including family support and motivation can facilitate the transition to adult health care.

Although some pediatric spina bifida clinics provide services to the adult population, many other clinics have age limits. Additionally, changes in the insurance policy as the patient reaches a certain age may require the patient to move to different providers or hospitals. Transitioning health care providers can be challenging due to reduced family support, concerns with executive skills, and lack of access to knowledgeable adult care providers.

Transitioning to adult health care may involve leaving multidisciplinary care clinics to care from multiple specialists with less multidisciplinary or coordinated care. One of the many challenges to adults with spina bifida is finding access to health care providers who provide services for adults with special needs, in both the primary care setting and medical subspecialties.^{38,308} Lack of coordinated medical care and clinical guidance on how to transition from long-term pediatric providers to adult care may cause patients to miss routine primary care or subspecialty appointments.³¹⁶ A study on adult with spina bifida from 19 to 64 years of age reported that that 75% of the participants could not name their primary care physician and had not seen a medical professional in over a year.²¹⁵ In adulthood, lack of regular care may result in increased preventable secondary complications and higher rate of emergency department admission.

Five key elements have been identified as necessary elements for the successful transition from pediatric to adult medical care.²¹⁵ These include (1) early preparation and education of the individual and family, (2) flexible timing of the transition, (3) introduction to the transition clinic, (4) interested adult center providers, and (5) a coordinated transfer of care approach among the individual, family, pediatric primary care providers, and adult specialists. The barriers include child health care providers refusing to "let go," reluctance to leave a family-centered care program, and adult care providers having limited knowledge about or interest in caring for these individuals. Finding a primary care physician or physiatrist who can assist with identifying a team of health care specialists for referrals as needed is a major concern for this adult population. The Spina Bifida Association of America publishes a health guide for adults living with spina bifida, based on feedback from adults across the United States. The *Health Guide* was sponsored by a grant from the National Center for Birth Defects and Developmental Disabilities and the Centers for Disease Control and Prevention.

Spina bifida is a congenital-onset condition that requires intervention by the therapists from infancy through adolescence. Most of the impairments and functional deficits described throughout this chapter last throughout the patient's lifetime. Health providers familiar with the complexity of the secondary impairments should follow individuals with spina bifida on a regular basis. Both PTs and OTs play an important role in screening for potential problems and providing recommendations for the maintenance of mobility and health-related fitness. Optimal management of the adult with spina bifida involves more than the sum of the subspecialties. This requires interdisciplinary, coordinated care among all of the providers and health professionals. Optimal management involves assessing individual's strengths, weaknesses, and needs to anticipate future challenges and opportunities.

Sexuality and Reproductive Issues

There are limited studies of gynecological and sexual issues in patients with spina bifida. Generally managing the bladder and bowel is very important for sexual function and good hygiene.

Women with spina bifida and hydrocephalus may have early onset puberty and menarche.⁷¹ Hydrocephalus may impact neuroendocrine function and the abnormal fetal development of the neurological system in spina bifida. Generally, the sexual capacity of the female with spina bifida is near normal. A woman with spina bifida has potential for a normal orgasmic response, is fertile, and can bear children.³¹⁷ High-dose folic acid supplementation is recommended prior to conception and during early gestation. The pregnancy, however, may be considered high risk, depending on existing orthopedic abnormalities. There have been some reports of congenital anomalies, but pregnancy outcomes are generally good.³¹⁸ Cesarean sections are common due to the neuromuscular and musculoskeletal changes of the perineum and contractures and deformities of the hips and lower extremities. The challenges of neuromuscular impairments, immobility, contractures, and deformities may impact menstrual hygiene. Several factors may impact sexual activity, especially positioning and sensation such as bladder and bowel function and hygiene, urinary or colon conduit and stoma, skin integrity, neuromuscular impairments, immobility, contractures, and deformities.

Affected males are frequently sterile and have small testicles and penises. The majority may have issues with erectile dysfunction. Their potential for erection and ejaculation depends on the level of the lesion. In general, the higher the neurological lesion level, the less likely the individual is to have typical function. Erection may be preserved in males with higher lesion level compared to individuals with lower motor neuron lesion. In many cases psychological problems may be a primary cause of sexual failure. Sexuality is not merely a process involving the genitalia; it also depends on a positive body image and a feeling of self-esteem that is nurtured from birth.³¹⁹

Although great advances in medical management of children with myelomeningocele have been made, a contrasting lack of improvement related to sexual function and reproductive issues exists. Five factors have contributed to delayed social and sexual growth in these adolescents: (1) severity of the mental impairment, (2) poor manual dexterity, (3) lack of education, (4) overprotective parents, and (5) limitations in health care personnel's ability to address sexuality with individuals with physical disabilities and their families.³²⁰ Either the parents or the child/patient may bring up questions about sexuality. Parents of children with spina bifida realize the need to teach their children about sexuality, but they often feel inadequate about doing so and are reluctant to bring up questions to health care professionals.³²¹ The therapist must be open, informed, and able to provide resources to both parents and children.

Adolescents and adults with spina bifida show great concern with regard to self-esteem and sexual function.³²² Some of these concerns appear directly related to efficient bowel and bladder management.³²³ Strategies to cope with bowel and bladder difficulties, as previously outlined, combined with appropriate emotional support from family and medical personnel help alleviate this concern.

PSYCHOSOCIAL ADJUSTMENT TO SPINA BIFIDA

Because of the congenital nature of spina bifida, psychological adjustment is somewhat different from adjustment to a traumatic spinal cord injury or other disabilities that occur later in life. The psychological adjustment to this congenital disability must be considered from the perspective of the parents, the family, and, of course, the child.³²⁴

Although there is considerable variability in the degree to which children with spina bifida, their parents, and their siblings experience stress and adjustment difficulties, children with spina bifida are at risk for higher rates of stress and adjustment problems.³²⁵ Parents of children with spina bifida may appear resilient, although they experience more stress than the parents of typically developing children.³²⁵

A longitudinal study concerning the psychological aspects of spina bifida showed that the parents go through a series of steps in the adjustment process. From birth to approximately 6 months of age, parents experience shock and bewilderment. Information given during this time may be disregarded, rejected, or misinterpreted. Health care professionals must therefore be prepared to repeat the same information to parents on several occasions during the first few years of the rehabilitation process. The period of the first 6 to 18 months of the child's life may be the most stressful for parents. Frequent hospitalizations during this time place increased pressure on the whole family. Parents are now able to fully comprehend the implications of their child's functional limitations and inability to participate in life. They begin to worry about the future and the impact of the disability on the rest of the family structure. The period from the age of 2 years through the preschool years is relatively peaceful. The parents are more concerned with toilet training, social acceptability, and general information on child rearing. They seem less aware of their child's cognitive limitations as he or she continues to develop into a relatively happy, well-adjusted child.

By the age of 6 years, children are becoming more aware of their limitations and parents are concerned about problems that may arise as their children enter elementary school. The child's psychological adjustment depends partly on the severity of his or her motor problems but primarily on the attitude of the parents and family and on the environmental conditions to which the child is exposed.^{326,327}

Because of their disabilities, children with spina bifida are often denied small tasks or chores that promote a sense of responsibility. To promote emotional growth and psychological well-being, caregivers must be persuaded to let go. Children with spina bifida must develop responsibility and independence by being given the chance to interact

and even compete with their peers. During adolescence, concerns regarding independent living situations and vocational placement must be addressed. With a foundation of strong support systems fostering emotional maturity, the future can be bright for the child with a congenital spinal cord injury.

Adults with spina bifida, like their younger counterparts, have difficulties in psychological adjustment and in fully engaging in the community. Depression and increased anxiety are common symptoms in those individuals. These symptoms may contribute to spending more time at home and less time outside and in social and community participation. The lesion level, functional abilities and skills, shunting, urinary and continence procedures, orthopedic surgeries, associated disorders and complications, and family support are among the key factors that contribute to psychological adjustment difficulties. In addition, there are other factors that may impose challenges to psychological adjustment in adults with spina bifida; The transition from pediatric health care to adult health care may be challenging. Individuals with spina bifida are less likely to attend college. They have less vocational opportunities and a lower employment rate compared with typically developing individuals. They form romantic relations at a lower rate and report a lower quality of life that tends to decline from adolescence to young adulthood. The participation in leisure and recreational activities tends to be low in adults with spina bifida. Appropriate emotional family support and psychological support, activities that provide social supports such as group exercises, and physical activities may assist in alleviating the psychological symptoms of depression and anxiety and may increase community engagement and participation.

Abstract: Spina bifida, a congenital spinal cord injury, is a complex disability that results from a failure of the caudal neural tube to fuse early in embryonic development. This congenital condition predisposes many areas of the central nervous system (CNS) to not develop or function adequately. In addition, all areas of development (physical, cognitive, and psychosocial) that depend heavily on central functioning will likely be impaired. The clinician must therefore be aware of the significant impact this neurological defect has on motor function as well as on a variety of related human capacities. A developmental framework, the Guide to Physical Therapist Practice and the International Classification of Functioning, Disability and Health (ICF) have been used to aid in understanding the sequential problems

of the child with spina bifida. The developmental model, however, must always stay in line with the functional model for adult trauma because the problems of the congenitally involved child quickly evolve into limitations in the functional activities and participation in the life of the injured adult. By concentrating on the present while keeping an eye on the future, appropriate management goals can be achieved.

Traumatic Spinal Cord Injury*

Myrtice B. Atrice, Paula M. Ackerman, Kristen Webber, Elizabeth Pharo, Elizabeth Sasso-Lance, and Rebecca Hammad

OBJECTIVES

After reading this chapter the reader will be able to:

1. Describe the demographics, etiology, and mechanism of injury of spinal cord injury.
2. Discuss the acute medical management of people with spinal cord injury.
3. Describe the secondary conditions of spinal cord injury, the appropriate interventions, and the impact of complications on the rehabilitation process.
4. Identify the basic components of the examination process.
5. Identify patient problems based on the examination, establish appropriate goals, and plan individualized treatment programs for patients with a spinal cord injury.
6. Describe adaptive equipment available to increase function.
7. Discuss progression of each individual and the process of discharge planning throughout the rehabilitation process.
8. Describe functional expectations for individuals with complete spinal cord injuries.
9. Identify equipment needs for a given spinal cord injury lesion.
10. Describe various principles of neuroplasticity to promote recovery after spinal cord injury.

venous thromboembolism (VTE)

Spinal cord injury (SCI) is a catastrophic condition that, depending on its severity, may cause dramatic changes in a person's life. SCI usually happens to active and independent people who at one moment are in control of their lives and in the next moment are paralyzed. Loss of sensation and loss of bodily functions can lead to dependence on others for even the most basic needs. To reduce negative impact, individuals with SCI need a well-coordinated, specialized rehabilitation program to assist them in maximizing the development of skills necessary to live a satisfying and productive postinjury life.¹⁻²

A successful rehabilitation program requires a team of health care professionals who work in collaboration to address alterations in body function, increase the individual's independence in all daily activities, ensure long-term health and wellness, and return the individual to the highest level of community participation specific to that individual's life situation. Ideally, the team should include a physician, a case manager, an occupational therapist, a physical therapist, a recreational therapist, a prosthetist or orthotist, a nurse, a speech-language pathologist, a dietician, an assistive technologist, a respiratory care practitioner, a psychologist, a social worker, a vocational counselor, a rehabilitation engineer, and a chaplain.³⁻⁵ The most important element determining success in any rehabilitation program is

*Videos for this chapter are available at studentconsult.com.

the patient's and caregiver's active participation throughout the rehabilitation process.

This chapter provides a general overview for the management of individuals with SCI throughout inpatient and postacute phases of the rehabilitation continuum. The information is intended to aid health care professionals in the treatment of individuals with SCI by providing guidelines to maximize each individual's return to their preinjury lifestyle.

SPINAL CORD LESIONS

SCI occurs when the spinal cord is damaged as a result of trauma, disease processes, vascular compromise, or congenital neural tube defect. The clinical manifestations of the injury vary depending on the extent and location of the damage to the spinal cord.

Tetraplegia

Tetraplegia (preferred to *quadriplegia*) refers to impairment or loss of motor and/or sensory function as a result of damage to the cervical segments of the spinal cord. Function in the upper extremities (UEs), lower extremities, and trunk is affected. It does not include brachial plexus lesions or injury to peripheral nerves outside the neural canal.⁶

Paraplegia

Paraplegia refers to impairment or loss of motor or sensory function as a result of damage to the thoracic, lumbar, or sacral segments of the spinal cord. Depending on the level of the damage, function may be impaired in the trunk and/or lower extremities. Also, the term paraplegia can be used to refer to cauda equina and conus medullaris injuries but not to lumbosacral plexus lesions or injury to peripheral nerves, which are considered outside of the central nervous system.⁶

Complete, Discomplete, and Incomplete Lesions

In a complete lesion, sensory and motor function in the lowest sacral segments (S4-S5) is absent postinjury.⁷ The American Spinal Injury Association (ASIA) classification for this type of injury is the ASIA Impairment Scale (AIS) A. The ASIA Impairment Scale is determined by completion of the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) assessment.⁶

Discomplete injury is a relatively new term in SCI research and practice. It is defined as a lesion that is "clinically complete but which is accompanied by neurophysiological evidence of residual brain influence on spinal cord function below the level of the lesion."⁸ Studies of people whose spinal cord injuries were considered complete under ASIA standards have shown that in a large percentage (84%), there was residual brain influence on the spinal cord below the level of the lesion.⁸ The current gold standard for testing, the ISNCSCI, does not examine this aspect of SCI.

With incomplete lesions, there is detectable residual sensory or motor function below the neurological level and specifically in the lowest sacral segment. According to ASIA standards, any sensation in the anal mucocutaneous junction or deep anal pressure⁶ indicates that the lesion is incomplete. If only sensation is preserved, the injury is classified as AIS B. If motor function in key muscles is maintained to some degree, patients may achieve level AIS C, D, or E classification. This testing will be reviewed further in this chapter.^{6,9}

DEMOGRAPHICS

The number of people living in the United States today with SCI is between 247,000 and 358,000.¹⁰ The incidence of SCI in the United States is approximately 17,700 new cases per year, 78% of which are

TABLE 14.1 Spinal Cord Injury Demographics

Data from National Spinal Cord Injury Statistical Center. *Spinal Cord Injury: Facts and Figures at a Glance*. February 2018, Birmingham, AL, 2018, University of Alabama, National Spinal Cord Injury Statistical Center. Available at <https://www.nscisc.uab.edu/Public/Facts%20and%20Figures%20-%202018.pdf>

males.¹⁰ The average age at the time of SCI has increased steadily from 29 years to 43 years since the mid-1970s.¹⁰ Vehicle crashes and falls are the top two causes of SCI and account for close to 70% of new cases each year. Table 14.1 lists additional demographics.

In 2015, the average length of inpatient stay was 45 days (11 days in an acute care facility and 34 days in rehabilitation). This was a slight decline from 2005, where the average length of inpatient stay was 50 days (12 days in an acute care facility and 38 days in rehabilitation), and a substantial decline from the 1970s when the average length of inpatient stay was 122 days (24 days in an acute care facility and 98 days in rehabilitation). The average yearly health care and living expenses vary according to severity of injury. In the first year, individuals with high tetraplegia spend an average of \$1,102,403 (up from \$829,843 in 2005), whereas individuals with paraplegia spend an average of \$537,271 (up from \$303,220 in 2005).¹⁰ Approximately 30% of individuals living with SCI are rehospitalized, with the average rehospitalization lasting 22 days. Genitourinary disease is the leading cause of hospitalization, followed by skin, respiratory diseases, digestive, circulatory, and musculoskeletal issues as other leading causes. Additionally, the life expectancy for patients with SCI continues to increase but is still below the national average of persons without SCI. Mortality rates are significantly higher during the first year after injury, especially for severely injured persons. According to the National SCI Database, the leading causes of death after an SCI are pneumonia, pulmonary emboli, and septicemia.

SEQUELAE OF TRAUMATIC SPINAL CORD INJURY

As stated previously, most spinal cord injuries occur as a result of trauma, be it motor vehicle accidents, falls, violence, or sports-related injury. The degree and type of forces that are exerted on the spine at the time of the trauma determine the location and severity of damage to the spinal cord.¹¹ Injuries to the vertebral column can be classified biomechanically as flexion or flexion-rotation injuries, hyperextension injuries, and compression injuries.¹² Penetrating injuries to the cord are usually the result of gunshot or knife wounds.¹²

Spinal cord damage can also be caused by nontraumatic mechanisms. Circulatory compromise to the spinal cord resulting in ischemia causes neurological damage at and below the involved cord level. This can be caused by a thrombus, swelling, compression, or vascular malformations and dysfunction. Degenerative bone diseases can cause compression of the spinal cord by creating a stenosis of the spinal canal and intervertebral foramina. Stenosis can also result from the prolapse of the intervertebral disc into the neural canal. The encroachment of tumors or abscesses within the spinal cord, the spinal canal, or the surrounding tissues also can lead to SCI. Congenital malformation of the spinal structures, as in spina bifida, can compromise the spinal cord and its protective layers of connective tissue. Some of the more common diseases and conditions that result in compromise of the spinal cord include Guillain-Barré syndrome, transverse myelitis, amyotrophic lateral sclerosis, and multiple sclerosis.⁹

After the spinal cord has sustained trauma, cellular events occur in response to the injury and are classified in three phases of progression: acute, secondary, and chronic responses. The acute process begins on occurrence of an injury and continues for 3 to 5 days.¹³ Abrupt necrosis or cell death can result from both mechanical and ischemic events. The impact of an SCI often causes direct mechanical damage to neural and other soft tissues as well as severe hemorrhaging in the surrounding gray and white matter, resulting in immediate cell death.^{14–15} In the next few minutes after the insult, injured nerve cells respond with trauma-induced action potentials, which lead to increased levels of intracellular sodium. The result of this influx is an increase in osmotic pressure, or movement of water into the area. Edema generally develops in as many as three levels above and below the original insult and leads to further tissue deconstruction.^{13,15,16} Increased levels of extracellular potassium and intracellular concentrations of calcium also result in an electrolyte imbalance that contributes to a toxic environment.^{17–19} Abnormal concentrations of calcium within the damaged cells disrupt their functioning and cause breakdown of protein and phospholipids, leading to demyelination and destruction of the cell membrane.¹⁸ The cascade of these events consequently contribute to a dysfunctional nervous system.

During this acute phase, evidence of spinal shock and neurogenic shock may be present. Spinal shock may begin 30 to 60 minutes after spinal trauma and is characterized by flaccid paralysis and absence of all spinal cord reflex activity below the level of the spinal cord lesion.²⁰ The length of time this condition lasts can range from about 24 hours after injury to several weeks.^{21–22} Spinal shock represents a generalized failure of circuitry in the spinal neural network and is thought to be directly related to a conduction block resulting from leakage of potassium into the extracellular matrix.²³ Accurately determining the completeness of the lesion may be difficult until spinal shock is resolved. The signs of spinal shock resolution are controversial; however, the return of reflexes may be a good indication.²¹ Neurogenic shock, on the other hand, refers to a life-threatening condition. It consists of hypotension, bradycardia, and peripheral vasodilatation caused by severe central nervous system damage resulting in loss of sympathetic stimulation to the blood vessels and unopposed vagal activity. This is

common in patients with a SCI at the level of T6 or higher. An important goal of treatment in the first week after sustaining an SCI is to maintain a mean arterial pressure (MAP) of 85 to 90 mm Hg.^{2,24–26}

The secondary phase of the injury occurs within the course of minutes to weeks after the acute process and is characterized by the continuation of ischemic cellular death, electrolytic shifts, and edema. Extracellular concentrations of glutamate and other excitatory amino acids reach concentrations that are six to eight times greater than normal within the first 15 minutes after an injury.¹⁹ In addition, lipid peroxidation and free radical production also occur.²⁷ Apoptosis (a secondary programmable cell death) occurs and involves reactive gliosis. There is also an important immune response that adds to the secondary damage that may be a result of a damaged blood-brain barrier, microglial activation, and increased local concentrations of cytokines and chemokines.²⁸ The lesion enlarges from the initial core of cell death, expanding from the perilesional region to a larger region of cell loss.

In the chronic phase, which occurs over a period of days to years, apoptosis continues both rostrally and caudally. Receptors and ion channels are altered, and with penetrating injuries, scarring and tethering of the cord occurs. Conduction deficits persist due to demyelination, and permanent hyperexcitability develops with consequential chronic pain syndromes and spasticity in many individuals with SCI.²⁹ Changes in neural circuits result from alterations in excitatory and inhibitory inputs, and axons may exhibit some limited regenerative and sprouting responses.¹⁹

CLINICAL SYNDROMES

Some incomplete lesions have a distinct clinical picture with specific signs and symptoms. An understanding of the various syndromes can be helpful to the patient's team in planning the rehabilitation program. However, using a syndrome for classification is not recommended due to the fact that many clinical cases present as a variation of a syndrome versus presenting as a true syndrome. Additionally, there are no clear objective guidelines by which to define an incomplete injury from a syndrome.³⁰ Fig. 14.1 depicts the anatomy of the spinal cord,⁹ which can be referred to as the various syndromes are described.

Central Cord Syndrome

Central cord syndrome is the most common of the SCI syndromes and accounts for about 9% of traumatic SCIs in adults.^{31–32} In adults 45 to 50 years of age, hyperextension injuries in the presence of cervical spondylosis or spinal stenosis is the most common cause during a low impact accident or injury. Younger patients are more likely to have a flexion-compression injury during a high impact accident or injury, causing fracture or disc herniation.⁹ However, it is suggested that injury occurs in the white matter of the lateral corticospinal tracts with diffuse axonal injury, and there is sparing of the central gray matter. Additionally, Wallerian degeneration may occur in axons nearby the injury site causing neurological impairment.³¹

Fig. 14.1 Cross-Sectional Anatomy of the Spinal Cord.

Although the prognosis for functional recovery is good for individuals with central cord syndrome, the pattern of recovery is such that intrinsic hand function is the last thing to return. Most people with central cord syndrome will recover some level of ambulatory function, and over half will experience spontaneous voiding and bladder emptying. Slightly under half may gain some form of hand function.^{9,31}

Brown–Séguard Syndrome

Occasionally, as a result of penetrating injuries (gunshot or stab wounds), only the lateral half of the spinal cord is damaged. Brown–Séguard syndrome occurs in 1% to 4% of traumatic SCIs and is characterized by ipsilateral loss of motor function and position sense and contralateral loss of pain and temperature sensation several levels below the lesion.^{9,31} The prognosis for recovery is good. Nearly all patients attain some level of ambulatory function, 80% regain hand function, 100% have bladder control, and 80% have bowel control.⁹ While rare in its pure form, this syndrome more commonly presents with features of central cord syndrome, sometimes called Brown–Séguard-plus syndrome.⁶

Anterior Cord Syndrome

Anterior cord syndrome, also known as anterior spinal artery syndrome, occurs in 2.7% of traumatic SCIs, and is often caused by flexion injuries in which bone or cartilage spicules compromise the anterior spinal artery, thereby impairing the blood supply to the anterior two-thirds of the spinal cord. Motor function and pain and temperature sensation are lost bilaterally below the injured segment, whereas light touch and proprioception are preserved. The prognosis is extremely poor for return of bowel and bladder function, hand function, and ambulation.^{6,9}

Posterior Cord Syndrome

Posterior cord syndrome is rare, with an incidence of less than 1%. This results from compression by disc or tumor, infarction of the posterior spinal artery, or vitamin B12 deficiency.³² Clinically, proprioception, stereognosis, two-point discrimination, and vibration sense are lost below the level of the lesion; and motor function and pain and temperature sensation are preserved.^{9,32} Additionally, patients presenting with posterior cord syndrome may have bowel and bladder continence, allowing for increased functional return home.³³

Cauda Equina Syndrome

Damage to the cauda equina involves the lumbosacral nerve roots, often sparing the cord itself. This syndrome is commonly caused by a burst fracture of a lumbar vertebrae or a centrally herniated disc and results in a lower motor neuron lesion that is usually incomplete. This lesion results in flaccid paralysis with no spinal reflex activity present. Sensation may be partially or completely lost, and sacral reflexes will be absent, affecting the lower urinary tract, distal bowel, and sexual function.^{9,34} Bladder outcomes worsen the longer the cauda equina is compressed.³⁵ Due to the potential of lumbosacral nerve roots to regenerate, there is a more favorable prognosis for recovery.³²

Conus Medullaris Syndrome

Typically caused by trauma and tumors, this syndrome is similar to cauda equina syndrome; however, the injury is more rostral and may involve the cord and be related to an L1-L2 bony injury. Clinically the presentation may appear mixed with characteristics of both upper and lower motor neuron lesions due to possible involvement of both the conus and the nerve roots. Sacral reflexes may be preserved depending on the level of the lesion and therefore may be overactive or acontractile.^{6,9,34}

DUAL DIAGNOSIS: CO-OCCURRING BRAIN AND SPINAL CORD INJURY

Incidence reports of co-occurring brain and SCI range from 15% to 70%.^{36–37} The significant variation in reporting of this co-occurrence is due to the diagnostic factors utilized by physicians immediately following injury. When imaging is the primary resource used to determine co-occurrence of brain injury with SCI, rates range from 16% to 24%. When posttraumatic amnesia is added as a diagnostic factor, rates increase to 42% to 50%.^{38–40} According to the International Classification of Diseases, codes to classify brain injury are based on loss of consciousness and posttraumatic amnesia. Despite the frequency of co-occurring brain and SCI, this dual diagnosis tends to be undiagnosed or undocumented and therefore is often not adequately addressed during SCI rehabilitation.^{38–41}

Co-occurring traumatic brain injuries are missed when the SCI or any other injury is prioritized for lifesaving needs.³⁸ Frequently, the initial paramedic and emergency department reports do not include information regarding the loss of consciousness and duration of post-traumatic amnesia. This lack of reporting leads to an underdiagnosis of brain injury. Unless significant cognitive deficits or a medical status change indicate the need for further diagnostic testing, the patient progresses through the continuum of care without a formal diagnosis of brain injury.

The rehabilitation team often notes signs, symptoms, and behaviors of brain injury in their documentation and team meetings. The rehabilitation process involves working with a team over an extended period of time, novel task training, and a holistic approach, which increases the likelihood that the patient will endorse behaviors, signs, and symptoms of brain injury. If the patient with a co-occurring brain and SCI is not managed and identified properly, they are commonly misperceived as being noncompliant, unable to learn, and/or having poor coping abilities, poor motivation, or a bad attitude.^{41–42}

Patients with co-occurring brain and SCI require a longer inpatient rehabilitation length of stay to reach expected outcomes based on their SCI level. This allows for the opportunity to learn adaptive and compensatory techniques, which are typically acquired by their non brain-injured peers. If length of stay is not adjusted, evidence indicates that this population will experience a significant reduction in short- and long-term functional outcomes.^{41–44} This population will endorse difficulties in functional motor tasks such as transfers, bed mobility, dressing, etc., due to poor motor planning, spatial awareness, and decreased executive functioning.^{41,43–44} The therapy team should utilize the Rancho Los Amigos Brain Injury Severity Scale (Rancho Level) to guide the introduction of errorless learning versus erred learning.

Successful progression of the patient with a co-occurring brain and SCI requires the rehabilitation team to understand how the patient's cognitive status (Rancho Level) influences their stage of motor learning. Refer to the [Box 14.1](#) for more information on the Rancho Los Amigos Brain Injury Severity Scale. Correctly identifying the stage of motor learning and crafting therapy to meet the patient's stage maximizes long-term functional gains ([Box 14.2](#)). Errorless learning is the ideal method for patients who meet criteria suggesting Rancho VII or less, because they are in the cognitive stage and just emerging to the associative phases of learning. Error-based learning (also known as trial and error learning) should occur later in the rehabilitation process, with individuals who are categorized as Rancho VIII or greater. It is important to note that continuing with errorless learning with patients who have the capacity to progress through the associative and autonomous stages of motor learning will result in reduced functional gains.^{43–46}

BOX 14.1 Rancho Los Amigos Brain Injury Severity Scale

I	No Response	Completely unresponsive to stimuli
II	Generalized Response	Inconsistent and nonpurposeful response to stimuli
III	Localized Response	Specifically, but inconsistently to stimuli
IV	Confused-Agitated	Behavior is bizarre and nonpurposeful relative to immediate environment
V	Confused-Inappropriate	Responds to simple commands fairly consistently
VI	Confused-Appropriate	Goal directed behavior but is dependent on external input or direction
VII	Automatic-Appropriate	Appears oriented and appropriate within hospital and home setting, goes through routine automatically
VIII	Purposeful-Appropriate	Recalls and integrates past and recent events, responsive to environment

Fulk GD. Traumatic brain injury. In: O'Sullivan SB, Schmitz TJ, eds. *Physical Rehabilitation*. 5th ed. Philadelphia, PA: F. A. Davis Company; 2007:895–935).

BOX 14.2 Stages of Motor Learning

Stage	Patient Presentation	Ideal Environment for Patients in Stage
Cognitive Stage	Understanding the task is compromised and task performance has lots of variability	Quiet environment, extra time, and external cues
Associative Stage	Performance is refined but some errors or variability persist, internal cues from the learner are present	Environment can be distracting
Autonomous Stage	Performance of tasks achieved with few errors	Learning can be assessed formally with standardized measures

From Pohl PS. *Motor Learning. Topics in Physical Therapy: Neurology. An APTA Professional Development Home Study Course*. APTA; January 2002.

Proper management of patient with co-occurring brain and SCI requires a holistic approach, increased length of stay, and carefully crafted approach to learning. Establishing a patient-centered approach to care, adapting the environment, and the activity based on the patient's presentation are essential. In addition to these basic alterations, individuals working with an adult population with co-occurring brain and SCI need to be mindful to avoid language that may be perceived as patronizing, such as pet names, slowed speech, overly simplistic sentence structure, etc., to maintain the dignity of the patient and their family. With a comprehensive approach, patients with co-occurring brain and spinal cord injuries can make significant progress toward independence postinjury.

MEDICAL MANAGEMENT

Medical treatment for the acute SCI includes anatomical realignment and stabilization interventions, pharmacological management to

BOX 14.3 Principal Elements for Initial Medical Management of the Patient With Acute Traumatic Spinal Cord Injury^{1,47–48,50–52}

- Resuscitate (maintain the airway)
- Immobilize at the scene—Emergency Medical Services (EMS)
- Rapid transport to the nearest spinal cord injury care facility
- Maintain airway and maintain mean arterial pressure (MAP)
- Steroids not recommended—consider steroids ONLY within the first 8 h post injury
- Radiographical assessment (computed tomography is initial study of choice)
- Immediate realignment of the spine; closed vs. open reduction
- Immobilize-external or internal orthosis
- Maintain MAP perfusion
- Magnetic resonance imaging for mass lesion, extent of cord injury
- Operative decompression early. Delay only for medical stabilization

lessen/prevent further neurological trauma and enhance neural recovery,^{47–49} as well as to support all organ systems affected by this potentially catastrophic event (Box 14.3).

Immobilization/Transportation

The injured person should be triaged and immobilized at the accident scene by trained emergency medical personnel and transported to a level one trauma center. Immobilization is recommended for all trauma patients with a cervical spine or SCI or with a mechanism of injury having the potential to cause further damage. Immobilization for persons with penetrating injuries is not recommended due to increased mortality from delays in resuscitation. Additionally, immobilization is not recommended for trauma patients who are awake, alert, not intoxicated, without neck pain, without any abnormal sensory or motor changes, and are without any additional significant associated injuries. Once stabilized, transportation to a specialized SCI treatment center is recommended.^{1,51–52}

Surgical Stabilization

In the emergency department, definitive radiological assessment and neurological assessment are the key factors to determine the medical course. Specific diagnostic studies are used to determine the severity, type, and degree of spine instability. Indications for surgical intervention include, but are not limited to, signs of progressive neurological involvement, type and extent of bony lesions, and degree of spinal cord damage.⁵³

Cervical Spine

In the presence of instability and neurological compromise, surgical stabilization is usually indicated after a thorough radiological and neurological assessment. High-quality computerized tomography (CT) imaging is the recommended radiological assessment. The ISNCSCI examination is the preferred neurological assessment tool.⁶ If high-quality CT is not available, routine 3-view cervical spine series (anteroposterior, lateral, and odontoid views) is recommended. Common surgical procedures include posterior and anterior approaches or a combination of both.⁵⁴ Fig. 14.2 shows radiographs of a person who had an anterior cervical fusion at C3–C4. Unstable compression injuries are usually managed by a posterior procedure except when there is a deficient anterior column. Anterior approaches are indicated for patients with evidence of residual anterior spinal cord or nerve root compression and persistent neurological deficits.

Fig. 14.2 (A) Radiograph of a person who had an anterior cervical fusion at C3-C4. **(B)** Lateral radiological view of anterior fusion C3-C4.

After cervical surgical stabilization, the use of a cervical orthosis is recommended. Examples of these orthotic devices are Philadelphia collar (Fig. 14.3), Miami collar, sternal-occipital-mandibular immobilizer (SOMI) brace (not pictured), and Aspen collar (Fig. 14.4). These orthotic devices are used until there is radiographical evidence of solid bony fusion, which usually takes 6 to 8 weeks, and/or at the physician's discretion.⁵⁵ When surgery is not indicated but external stabilization is needed to provide immobilization, halo vest immobilization may be used for closed reduction of the cervical spine.^{1,56} The halo orthotic device restricts more movement in the upper cervical spine compared with the lower cervical spine. The halo device consists of three parts: the ring, the uprights, and the jacket (Fig. 14.5). The ring fits around the skull, just above the ears. It is held in place by four pins that are inserted into the skull. The uprights are attached to the ring and jacket by bolts.¹ The jacket is usually made of polypropylene and lined with sheepskin. This equipment is left in place for up to 12 weeks until bony healing is satisfactory.⁵⁵ The advantage of using the halo device is the ability to mobilize the patient as soon as the device has been applied without compromising spinal alignment. This allows the rehabilitation program to commence more rapidly. It also allows for delayed decision making regarding the need for surgery.

The disadvantage of the halo device is that pressure and friction from the vest or jacket may lead to altered skin integrity.⁵⁵ Special attention must be given to ensure the skin remains intact. During more active phases of the rehabilitation process, the halo device may slow functional progress because of added weight and interference with the middle-to-end range of upper-extremity movement. In a small percentage of patients, there are complications of dysphagia and temporomandibular joint dysfunctions associated with wearing the halo device.⁵⁵

It should be noted that cervical traction using Gardner Well Tongs (not pictured) has been used much less in the last 25 to 30 years due to

Fig. 14.3 Philadelphia Collar. It is fabricated of polyethylene foam with rigid anterior and posterior plastic strips; it is easily applied via Velcro closures, and it limits flexion, extension, and rotary movements of the cervical spine.

Fig. 14.4 The Aspen collar (formerly known as the Newport collar) encircles the neck, is somewhat open, and provides cervical motion restriction. It is rigid yet flexible at its edges to conform to each patient's anatomy. Pads and shells are removable and washable.

Fig. 14.5 Halo Orthosis. Basic components are the halo ring, distraction rods, and jacket (jacket not pictured).

improved surgical techniques but may be indicated when surgery is delayed due to life-threatening trauma in other areas of the body. The reader should be aware that the management of the pediatric SCI patient is more specialized and will not be addressed in this chapter.

Thoracolumbar Spine

Thoracic level SCIs account for approximately 35% of all SCI.⁵⁷ Internal fixation of the thoracolumbar region is necessary when stability and distraction cannot be maintained by other means. The timing of surgery has been a topic of debate. However, the consensus is that surgery should occur as soon as the patient is hemodynamically and respiratorily stable within the first 24 to 48 hours after the injury.⁵⁸⁻⁵⁹ The surgical approach may be either anterior, posterior, or a combination of both based on the patient's radiological and neurological assessments. A commonly used thoracic stabilization procedure is transpedicular screws (Fig. 14.6). Surgeons may use the Thoracolumbar Injury Classification and Severity Score (TLICS) as well as the American Orthopedic Spine Group recommendations in the decision making process for surgical intervention.^{48,60}

The goals of the operative procedures at any spinal level are to reverse the deforming forces by decompression, restore proper spinal alignment, and stabilize the spine.^{54,61} All these procedures have advantages and disadvantages. The surgeon, patient, and family must be involved in the decision making process to select the most appropriate method of treatment. Assuring spinal stability sets the stage for a successful therapeutic rehabilitation process.⁶²

Fig. 14.6 Radiograph of Transpedicular Screws. (Courtesy Dr. H. Herndon Murray, Assistant Medical Director, Shepherd Spinal Center, Atlanta, Georgia.)

Fig. 14.7 Custom Thoracolumbosacral Orthosis. This molded plastic body orthosis has a soft lining. It controls flexion, extension, and rotary movements until healing of the bone has occurred.

Postoperatively, an external trunk support may be necessary to limit excessive vertebral motion and to maintain proper thoracic and lumbar alignment. This may be achieved by a custom thoracolumbosacral orthosis (Fig. 14.7),⁶³ Jewett brace (Fig. 14.8), or other appropriate orthotic device at the discretion of the surgeon. Spine precautions may be warranted following surgical intervention to allow for a complete fusion to take place and to minimize the possibility of surgical failure. The use of and specificity of postoperative precautions vary and are surgeon specific.

Clinical Trials and Ongoing Research

Much scientific work has been done in an effort to manage the cascade of cellular events following the primary SCI injury. The results of previous large phase II and III landmark investigations^{47,50,52} aimed at neuroprotection^{47,50,52} have been discredited through several meta analyses over the past decade. However, there is some consensus that the use of corticosteroids within the first 8 hours of injury is supported by level III scientific evidence and should be considered in appropriate instances. Knowledge⁵⁰ gained from past research has laid the foundation for ongoing investigations. Present research includes but are not limited to studies aimed at neuroprotection, neuroregeneration, spinal

Fig. 14.8 Jewett Hyperextension Brace. A single three-point force system is provided by sternal pad, suprapubic pad, and thoracolumbar pad. Forward flexion is restricted in the thoracolumbar area.

cord stimulation, cell-based therapies, and the use of biomaterials (Table 14.2).^{51,64}

THERAPEUTIC REHABILITATION CONTINUUM OF CARE

Therapeutic rehabilitation can be effectively delivered beginning in an acute-care setting at the time of injury and continuing on through a lifetime of care. Rehabilitation teams may use one of three models: multidisciplinary, interdisciplinary, and transdisciplinary.⁶⁶ The standards set forth by the Commission on Accreditation of Rehabilitation Facilities (CARF) suggest that the interdisciplinary model of team structure is optimal in the rehabilitation setting.

The continuum of care may be divided into several phases that include medical management (previously described), acute care (including the intensive care unit), inpatient rehabilitation, and post-acute services (including day program rehabilitation, outpatient rehabilitation, and home health). The continuum also includes returning the patient into wellness programs and community reentry outreach programs. The progression of a patient through the rehabilitation process will vary greatly from one person to the next. The patient may also move back and forth throughout the continuum of care.

Inpatient (Acute Care and Rehabilitation)

Inpatient rehabilitation begins during the critical and acute-care stages after an SCI. The primary emphasis of early rehabilitation is to lessen

TABLE 14.2 Summary of Current Topics in Spinal Cord Injury Research Related to Regeneration, Restoration, Recovery, and Neuroprotection (USA)⁶⁵

Category	Intervention	Goal	Description	Example/Location
Regeneration	Biological: autologous human Schwann cells ^{65a}	Safety; repair myelin to improve axon function and improve neural plasticity	Schwann cells harvested from the sural nerve of the participant will be autologously transplanted into the epicenter of the participant's spinal cord injury	Miami project: Safety of Autologous Human Schwann Cells (ahSC)
	Biological: human embryonic stem cells ^{65b}	Safety; neurological recovery	Use stem cells to promote partial repair of spinal cord tissue	Asterias Biotherapeutics: Biological AST-OPC1
	Device: neural-spinal scaffold ^{65c}	Safety; facilitate repair of the spinal cord	An investigational bioresorbable polymer scaffold that is designed for implantation at the site of injury within a spinal cord contusion to provide structural support to the spared spinal tissue and a matrix to facilitate endogenous repair	InVivo Therapeutics: Inspire Study for Neuro-Spinal Scaffold
Restoration	Device: brain-machine interface ^{65d-f}	Safety of individual and efficacy of electrodes, improve function and restore movement	Brain-machine interface (BMI) technology is based on the finding that with intact brain function, neural signals are generated even though they are not sent to the arms, hands, and legs. By implanting electrodes in the brain, individuals can be trained to send neural signals, which are interpreted by a computer and translated to movement	University of Pittsburgh, University of Miami
	Device: implantable neuroprosthetic ^{65g}	Restore grasp and trunk function	Network of implantable systems to help increase functional independence	Cleveland, Ohio
	Drug and device ^{65h}	Develop new approaches to restore upper limb function	Paired pulse induced spike-timing dependent plasticity (STDP) enhances synaptic strength between residual corticospinal tract (CST) axons and spinal motoneurons (SMNs) resulting in temporary improvements in upper-limb function in humans with incomplete cervical SCI. Motor training will be combined with paired-pulse STDP stimulation to further enhance plasticity and behavioral recovery	Veterans Administration Office of Research Drug: Seromycin, Dextromethorphan; Device STDP
Recovery	Noninvasive brain stimulation: ^{65i-l} (electrical)	Restoration of upper-extremity (UE) function	Transcranial direct current stimulation (tDCS) or transcranial pulsed current stimulation (tPCS) provides regional brain polarization for neuromodulation; low voltage to increase brain excitability in order to make brain and nervous system respond to training or with activity	Shepherd Center, Burke Medical Research Institute: transcranial pulsed and direct current stimulation (tPCS and tDCS)
	Transcutaneous spinal cord stimulation (TSCS) ^{65m}	Improve muscle activity and function	Transcutaneous electrical stimulation applied over the cervical or thoracic spinal cord to target upper or lower extremities	Kennedy Krieger, University of Washington (UE), Shepherd Center (LE)
	Epidural spinal cord stimulation ^{65n,o}	Facilitate volitional movement, stepping	Establish the disinhibitory effect of spinal cord stimulation	University of Minnesota, University of Louisville
	Acute intermittent hypoxia (AIH) ^{65p}	Improve lower-extremity (LE) function and walking	Subjects breath lower levels of oxygen to trigger a cascade of events in the SC, which improve sensitivity and circuitry necessary for breathing and walking	Spaulding Rehabilitation Hospital; AIH

the adverse effects of neurotrauma and immobilization. This focus may last from a few days to several weeks, depending on the severity and level of injury and other associated injuries. Although therapeutic intensity may be limited, patients may begin participating in early therapy, which should include—but should not be limited to—out-of-bed activities, gaining upright tolerance, range-of-motion (ROM) exercises, early strength training, skin management, and education. Goals during this phase should focus on the prevention of secondary conditions and preparation of the patient for full rehabilitation participation. Discharge planning and caregiver training is initiated by the treatment team in this phase in order to ensure a smooth transition back into the community. Comprehensive discharge planning typically looks at discharge location, supervision or care needs, community resources, circle of support, advocacy, and insurance benefits for postacute referrals.

As the acute phase progresses, out-of-bed activities are tolerated for longer periods of time and the patient begins to work toward specific long-term goals. In accordance with Medicare guidelines for inpatient rehabilitation, the patient is able to participate in therapeutic programs a minimum of 3 hours a day.^{67–68} The intensity of therapy may continue to be limited according to unresolved medical issues. As medical issues resolve and endurance improves, the patient will progress to a higher and more active level of participation. During inpatient rehabilitation, the patient gains varying levels of independence in activities of daily living (ADLs) and functional mobility. Community outings are used to refine advanced skills, identify further needs, and foster community reintegration and participation. Other aspects of rehabilitation during this phase are continuation of caregiver training, home exercise programs, assistive technology (AT) referrals, home and school or work evaluation, driving and dependent passenger evaluations, delivery and fitting of discharge equipment, and referrals for continued services.

Postacute Rehabilitation

Postacute rehabilitation and discharge from an inpatient rehabilitation program mark only the beginning of the lifelong process of adjustment to changes in physical abilities, community reintegration, and participation in life activities. Due to the shortened lengths of hospitalization and the reduction of inpatient and outpatient insurance benefits, services provided after discharge are becoming increasingly important. A direct consequence of shorter hospitalization results in patients who have more acuity, greater care needs, and fewer skills attained in the inpatient rehabilitation program before entry into

the postacute arena. Services provided after inpatient discharge may include home health services, day program, single-service outpatient therapy visits, wellness programs, and routine follow-up visits and services.

Home health referrals are often selected when home services are needed or when the medical acuity requires ongoing nursing assessment. The benefits of receiving care in the home allow for ADL and mobility training in that specific environment, whereas day program or outpatient therapy typically has more equipment and tools for skill progression. Common day program or outpatient therapy treatment programs have included advanced transfer training, advanced wheelchair skills, locomotor training, progression of ADL, home exercise programs, and finalization of durable medical equipment (DME).

There are a variety of outpatient rehabilitation options for individuals, and depending on the facility, the programs may be described as day program, outpatient therapy, or single-service outpatient therapy visits. One common thread for virtually all outpatient settings is that the patients are medically stable and do not require skilled nursing services during the night. The “day program” concept has emerged to meet the demand for more comprehensive rehabilitation services. The primary purpose of these services is to provide a coordinated effort for the patient to return to full reintegration into the community, with the focus on performance of functional skills, and on the transference of these skills into the community. Other outpatient rehabilitation options are “single-service,” which indicates the patient has goals specific to a single discipline, such as physical therapy, occupational therapy, or speech therapy. Goals within each discipline are met, and there is a lesser degree of coordination of services. Wellness programs have emerged as an option for promotion of lifelong health. Typically, these programs are offered as a self-payment option and may not be tied directly to functional goals related to ADLs or mobility performance.

Regardless of what services the patient is referred for after the inpatient discharge, patients may progress from one option to another or may be appropriate to move in and out of services in a less linear fashion. Each stage of rehabilitation requires an examination of the patient’s body function and structure, activity, participation levels, and personal and environmental factors. This is known as the International Classification of Functioning, Disability and Health (ICF), which is a framework from the World Health Organization.⁶⁹

EXAMINATION AND EVALUATION OF BODY FUNCTION AND STRUCTURE

Regardless of where the patient begins the rehabilitation process, an examination is completed on admission. The examination and evaluation will assist in establishing the diagnosis and the prognosis of each patient as well as determining the appropriate therapeutic interventions. The patient and caregivers participate by reporting activity performance and functional ability.^{55,70} Any pertinent additions to the history stated by the patient should be described. The patient's statement of goals, problems, and concerns should be included. The main areas of the examination are outlined here.

History

The history should include general demographics, social history, occupation and employment status, pertinent growth and development, living environment, health history and history of current condition, functional status and activity level, completed tests and measures, medications, family history, reported patient and family health status, and social habits.⁷¹ Reviewing the medical chart is a vital step and should be conducted prior to hands on examination. If the history suggests a loss of consciousness or brain injury, the clinician should consider the possibility of compromised cognition and should include appropriate tests and measures during the examination.

Systems Review

The physiological and anatomical status should be reviewed for the cardiopulmonary, integumentary, musculoskeletal, and neuromuscular systems. In addition, communication, affect, cognition, language, and learning style should be reviewed.⁷¹

Tests and Measures

Depending on the data generated during the history and systems review, the clinician performs tests and measures to help identify impairments, activity limitations, and participation restrictions as well as to establish the diagnosis and prognosis of each patient. Tests and measures that are often used for persons with SCI are included in [Box 14.4](#). For more detail related to specific tools, refer to the *Guide to Physical Therapist Practice* (<http://www.apta.org/Guide/>),⁷² *ANPT Outcome Measures Recommendations (EDGE)*, *Rehab Measures Database*, or *Spinal Cord Injury Rehab Evidence (SCIRE)*.^{73–74}

Neurological Examination

American Spinal Cord Injury Association Examination

It is recommended that the ISNCSI be used for the specific neurological examination after an SCI.⁶ See [Fig. 14.9](#) for the ASIA motor and sensory examination form. Assessment of muscle performance allows for specific diagnosis of the level and completeness of injury. The examination of muscle performance includes each specific muscle and identifies substitutions from other muscles.

Along with the strength of each muscle, the presence, absence, and location of muscle tone should be described. The Modified Ashworth Scale is a common tool used to describe hypertonicity.^{61,75} The patient's sensation is described by dermatome. The recommended tests include (1) sharp-dull discrimination or temperature sensitivity to test the lateral spinothalamic tract, (2) light touch to test the anterior spinothalamic tract, and (3) proprioception or vibration to test the posterior columns of the spinal cord. Sensation is indicated as intact, impaired, or absent per dermatome. A dermatomal map is helpful and recommended for ease of documentation.

BOX 14.4 Tests and Measures

Body System and Structure

- Aerobic capacity and endurance
- Anthropometric characteristics
- Circulation (arterial, venous, lymphatic)
- Cognitive functioning
- Integumentary integrity
- Joint integrity and mobility
- Motor function
- Muscle performance, including abnormal muscle tone
- Neurological examination, including cranial and peripheral nerve integrity
- Orthotic, protective, and supportive devices
- Pain
- Skeletal integrity and posture
- Range of motion
- Reflex integrity
- Sensory integrity
- Ventilation and respiration
- Diagnosis of impairment and disabilities

Activity or Participation

- Assistive and adaptive devices assessment
- Community, social, and civic life (including educational level and work/school status)
- Environmental barriers
- Gait, locomotion, and balance
- Self-care, domestic life, and home management

FUNCTIONAL EXAMINATION FOR ACTIVITY

It is recommended that a complete functional assessment is performed on initial examination and thereafter, in order to document progress. A myriad of standardized tools exists to assess functional skills that address home, community, and institutional mobility and ADL functional skills. The Functional Independence Measure (FIM) is one of the more commonly used tools that is currently applied for many impairment diagnostic groups, including SCI.⁷⁶ Another tool that is recognized as a primary outcome measure to assess functional recovery for the patient with SCI is the Spinal Cord Injury Independence Measure III (SCIM III).⁷⁷ This tool was specifically designed for the functional assessment of individuals with SCI. The SCIM III has been shown to be valid, reliable, and easily administered.^{78–80} Other tools, such as the Quadriplegia Index of Function (QIF)⁸¹ and the Craig Handicap Assessment and Reporting Technique (CHART),⁸² are options. Additional assessments for patients with SCI are described in [Table 14.3](#).

GOAL SETTING FOR ACTIVITY AND PARTICIPATION SKILLS

Goal setting is a dynamic process that directly follows the examination. Each activity limitation identified should be addressed with specific short- and long-term goals. The clinician must interpret new information continuously, which leads to continuing reevaluation and revision of goals.⁷¹ Goals should always be individualized and directed by the patient and should be established in collaboration with the treatment team, the patient, and the caregiver, along with realistic consideration of anticipated needs on return to the home environment. Factors to consider in the goal-setting process include age, body type, associated

Muscle Function Grading

0 = Total paralysis
1 = Palpable or visible contraction
2 = Active movement, full range of motion (ROM) with gravity eliminated
3 = Active movement, full ROM against gravity
4 = Active movement, full ROM against gravity and moderate resistance in a muscle specific position
5 = (Normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person

NT = Not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of >50% of the normal ROM)
0*, 1*, 2*, 3*, 4*, NT* = Non-SCI condition present *

Sensory Grading

0 = Absent 1 = Altered, either decreased/impaired sensation or hypersensitivity
2 = Normal NT = Not testable
0*, 1*, NT* = Non-SCI condition present *

Note: Abnormal motor and sensory scores should be tagged with a "" to indicate an impairment due to a non-SCI condition. The non-SCI condition should be explained in the comments box together with information about how the score is rated for classification purposes (at least normal / not normal for classification).

When to Test Non-Key Muscles:

In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, abduction, adduction, internal and external rotation	C5
Elbow: Supination	
Elbow: Pronation	
Wrist: Flexion	C6
Finger: Flexion at proximal joint, extension	
Thumb: Flexion, extension and abduction in plane of thumb	C7
Finger: Flexion at MCP joint	
Thumb: Opposition, adduction and abduction perpendicular to palm	C8
Finger: Abduction of the index finger	T1
Hip: Adduction	L2
Hip: External rotation	L3
Hip: Extension, abduction, internal rotation	
Knee: Flexion	
Ankle: Inversion and eversion	L4
Toe: MP and IP extension	
Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments S4-5 by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body. (This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3 .

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3 .

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

- Determine sensory levels for right and left sides.**
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.
- Determine motor levels for right and left sides.**
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: In regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.
- Determine the neurological level of injury (NLI).**
This refers to the most caudal segment of the cord with intact sensation and sensory motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
- Determine whether the injury is Complete or Incomplete.**
(i.e. absence or presence of sacral sparing)
If voluntary anal contraction = No AND all S4-5 sensory scores = 0 AND deep anal pressure = No, then injury is Complete.
Otherwise, injury is Incomplete.
- Determine ASIA Impairment Scale (AIS) Grade.**
Is injury Complete? If YES, AIS=A
NO
Is injury Motor Complete? If YES, AIS=B
NO (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)
Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?
NO
YES
AIS=C AIS=D
- Determine the zone of partial preservation (ZPP).**
The ZPP is used only in injuries with absent motor (no VAC) OR sensory function (no DAP, no LT and no PP sensation) in the lowest sacral segments S4-5, and refers to those dermatomes and myotomes caudal to the sensory and motor levels that remain partially innervated. With sacral sparing of sensory function, the sensory ZPP is not applicable and therefore "NA" is recorded in the block of the worksheet. Accordingly, if VAC is present, the motor ZPP is not applicable and is noted as "NA".

TABLE 14.3 Assessment of Function Summary

Overall Functional Assessments	Description
Spinal Cord Injury (SCI) Functional Assessments	
Spinal Cord Injury Independence Measure (SCIM) ⁸³	Designed for the functional assessment of individuals with spinal cord injury in the categories of self-care, respiratory, sphincter management, and mobility skills
Quadriplegia Index of Function (QIF) ^{84–85}	Assesses function for individuals with tetraplegia in the categories of transfers, grooming, bathing, feeding, dressing, wheelchair mobility, bed activities, bowel, bladder, and knowledge of personal care
Capabilities of upper extremity (CUE) instrument ⁸⁶	Assesses the action of grasp, release, and reaching in individuals with tetraplegia by measuring reaching and lifting, pulling and pushing, wrist action, hand and finger actions, and bilateral action
Walking Function Assessments	
Spinal cord injury functional ambulation inventory (SCI-FAI) ⁸⁷	Observational gait assessment that assesses gait, assistive device use, and walking mobility
Walking Index for Spinal Cord Injury (WISCI) ⁸⁸	An ordinal scale describing walking function that takes into consideration level of independence, assistive device use, and lower-extremity orthotic use
Six-minute walk test ⁸⁹	An endurance walking test that measures the distance walked over a 6-min period of time
Ten-meter walk test ⁹⁰	Measures walking speed by measuring how fast an individual walks a distance of 10 m
Timed Up-and-Go Test ⁹⁰	Assesses standing, walking, turning, and sitting
Wheelchair Function Assessments	
Wheelchair circuit ⁹¹	Assesses the performance of various wheelchair propulsion skills by measuring ability, performance time, and physical strain for eight standardized skills
Wheelchair assessment tool ⁹²	Measures the ability and time to perform 6 mobility and wheelchair skills for individuals with paraplegia
Wheelchair skills test ⁹³	Assesses the ability to perform 50 separate skills in the areas of wheelchair handling, transfers, maneuvering the wheelchair, and negotiating obstacles
Obstacle course assessment of wheelchair user performance ⁹⁴	Assesses the wheelchair user's performance in 10 difficult environmental situations
Wheelchair users functional assessment (WUFA) ⁹⁵	A 13-item assessment of wheelchair skills in individuals who primarily use a manual wheelchair for their mobility
Wheelchair physical functional performance (WC-PFP) ⁹⁶	Assesses the ability to complete various tasks from the wheelchair by measuring upper body strength, upper body flexibility, balance, coordination, and endurance
Functional evaluation in a wheelchair ⁹⁷	Assesses functional performance from a manual and/or power wheelchair via a self-administered questionnaire

injuries, premorbid medical conditions, additional orthopedic injury, cognitive ability, psychosocial issues, spasticity, endurance, strength, ROM, funding sources, family and social roles, work and school status, and level of participation or motivation.

Long-term goals for the rehabilitation of patients with SCI reflect functional outcomes and are based on the strength of the remaining innervated or partially innervated musculature. Short-term goals identify components that interfere with functional ability and are designed to “address these limiting factors while building component skills”⁵⁵ of the desired long-term goals.

Functionally based goals are established in the following areas: bathing, bed mobility, bladder and bowel control, communication, environmental control and access, feeding, dressing, gait, grooming, home management, ROM and positioning, skin care management, transfers, transportation and driving, wheelchair management, and wheelchair mobility. Refer to [Table 14.4](#) for anticipated goals for each level of injury. Information presented in this table should be

recognized as general guidelines because variability exists. These guidelines are most usefully applied to patients with complete SCI. Goal setting for individuals with incomplete SCI is often more challenging, given the greater variability of patient presentations and the uncertainty of neurological recovery. As with any patient, continual reevaluations provide additional insight into functional limitations, progression, and potential, thereby directing the goal-setting process. In addition to specific functional goals and expectations, other factors impacting goals should be considered, such as caregiver training, home, work, or school modifications, and community reentry.

Rehabilitation teams may elect to hold a goal-setting or interim conference for each patient, during which team members, including the patient, have the opportunity to discuss the long-term goals that have been established. It may be useful to request that the patient sign a statement acknowledging his or her understanding of, and agreement to, all long-term goals.

TABLE 14.4 Functional Expectations for Complete Spinal Cord Injury Lesions

Functional Component	Outcome Potential	Anticipated Equipment to Achieve Outcomes
C1-4		
Sitting tolerance	80–90 degrees for 10–12 h per day	Power wheelchair with power tilt, recline Wheelchair cushion
Communication		
Mouth stick writing	Minimal assistance	Mouth sticks and docking station
ECU	Setup	ECU
Page turning	Minimal assistance to setup	Book holder
Computer operation	Minimal assistance to setup	Computer
Call-system use	Setup	Call system or speaker phone
Cuff-leak speech (ventilator dependent)	Up to 6 h	
Feeding	Dependent, but verbalizes care	
Grooming	Dependent, but verbalizes care	
Bathing	Dependent, but verbalizes care	Reclining shower chair
Dressing	Dependent, but verbalizes care	
Bowel management	Dependent, but verbalizes care	
Bladder management	Dependent, but verbalizes care	
Bed mobility		
Rolling side to side	Dependent, but verbalizes care	Four-way adjustable hospital bed to assist caregiver with task
Rolling		
Supine, prone		
Supine to and from sitting		
Scotching		
Leg management		
Transfers		
Bed	Dependent, but verbalizes care	Overhead lift system
Tub, toilet		Hydraulic lift
Car		Slings
Floor		
Power wheelchair mobility		
Smooth surfaces	Modified independent	Power wheelchair with power recline or tilt system
Ramps	Modified independent	
Rough terrain	Modified independent	Lap tray
Curbs	Dependent, but verbalizes	Armrests, shoulder supports, and lateral trunk supports
Manual wheelchair mobility		
Smooth surfaces	Dependent, but verbalizes	Manual reclining or tilt wheelchair with same options as power wheelchair
Ramps		
Rough terrain		
Curbs		
Stairs		
Skin		
Weight shift	Modified independent with power wheelchair	Recline or tilt wheelchair
Padding, positioning	Dependent, but verbalizes	Wheelchair cushion
Skin checks	Dependent, but verbalizes	Pillow splints, resting splints Mirror
Community: ADL-dependent passenger evaluation	Dependent, but verbalizes	Modified van
ROM exercises to scapula, upper extremity, lower extremity, and trunk	Dependent, but verbalizes	
Exercise program	Independent for respiratory and neck exercises	Portable or bedside ventilator (C1-3 only)

TABLE 14.4 Functional Expectations for Complete Spinal Cord Injury Lesions—cont'd

Functional Component	Outcome Potential	Anticipated Equipment to Achieve Outcomes
C5		
Sitting tolerance	90 degrees for 10–12 h per day	Power recline or tilt wheelchair Wheelchair cushion
Communication		
Telephone use	Modified independent	Telephone adaptations
ECU	Setup	ECU
Page turning	Setup	Book holder, wrist support with cuff
Computer operation	Supervision	Computer
Writing, typing	Setup	Long Wanchik brace
Feeding	Minimal assist to setup	Mobile arm support Adaptive ADL equipment
Grooming		
Wash face	Minimal assistance to setup	Mobile arm support
Comb or brush hair	Minimal assistance	Wrist support with adapted cuff
Oral care	Minimal assistance to setup	Adaptive ADL equipment
Bathing	Dependent, but verbalizes care	Upright or tilt shower chair
Dressing	Dependent, but verbalizes care	
Bowel management	Dependent, but verbalizes care	
Bladder management	Dependent, but verbalizes care	Automatic leg bag emptier
Bed mobility		
Rolling side to side	Dependent to maximal assistance	Four-way adjustable hospital bed to assist caregiver with care
Rolling		
Supine, prone		
Supine to and from sitting		
Scooting		
Leg management		
Transfers		
Bed	Dependent to maximal assistance for level transfers,	Overhead or hydraulic lift and slings
Tub, toilet	verbalizes unlevel transfers	Possible transfer board
Car		
Floor		
Power wheelchair mobility	Recommended mode of locomotion	Power wheelchair with power recline or tilt system
Smooth surfaces	Modified independent	
Ramps	Modified independent	Recommend lap tray
Rough terrain	Modified independent	Armrests, shoulder supports, and lateral trunk supports
Curbs	Dependent, but verbalizes	
Manual wheelchair mobility		
Smooth surfaces	Dependent to minimal assistance for short distances on smooth surface	Upright or reclining wheelchair with special back and trunk supports
Ramps	Dependent, but verbalizes care	Consider manual wheelchair with power assist pushrims
Rough terrain	Dependent, but verbalizes care	
Curbs	Dependent, but verbalizes care	
Stairs	Dependent, but verbalizes care	
Skin		
Weight shift	Modified independent with power wheelchair Maximal assistance to dependent with manual wheelchair	Recline or tilt wheelchair and wheelchair cushion
Padding, positioning	Dependent, but verbalizes	Pillow splints or resting splints
Skin checks	Dependent, but verbalizes	Mirror
Home management		
Prepare snack	Maximal to moderate assistance	Wrist support with cuffs Adaptive ADL equipment

Continued

TABLE 14.4 Functional Expectations for Complete Spinal Cord Injury Lesions—cont'd

Functional Component	Outcome Potential	Anticipated Equipment to Achieve Outcomes
Community ADL		
Drive van	Independent	Highly adapted vehicle
Dependent passenger evaluation	Dependent	Modified van
ROM exercises to scapula, upper extremity, lower extremity, and trunk	Dependent, but verbalizes	
Exercise program		Airsplints or light cuff weights
Upper extremity and neck	Minimal assistance	E-stim unit
C6		
Sitting tolerance	90 degrees for 10–12 h per day	
Communication		
Telephone use	Modified independent	Adaptive ADL equipment
Page turning		Tenodesis splint
Writing, typing, keyboard		Short opponens splint
Feeding	Modified independent	Adaptive ADL equipment
Grooming	Minimum assistance to modified independent	Adaptive ADL equipment Tenodesis splint
Bathing		
Upper body	Minimal to modified independent assistance	Upright shower chair
Lower body	Moderate assistance	Various bathing equipment
Dressing		
Upper body	Modified independent	Adaptive ADL equipment
Lower body (bed)	Maximum to minimal assistance	
Bowel management	Maximum to modified independent	Dil stick Adaptive ADL equipment
Bladder management	Male: moderate assistance to modified independent Female: moderate assistance to dependent	Tenodesis Adaptive ADL equipment
Bed mobility		
Rolling side to side	Independent to minimal assistance	Four-way adjustable hospital bed or regular bed with loops or straps; or no equipment
Rolling		
Supine, prone		
Supine to and from sitting		
Scotting		
Leg management	Minimum assistance to dependent	
Transfers		
Bed	Minimal assistance	Transfer board
Tub, toilet	Moderate assistance	
Car	Maximal to moderate assistance	
Floor	Dependent, but verbalizes procedure	
Power wheelchair mobility	Recommended mode of locomotion	Power upright wheelchair for weak C6
Smooth surfaces	Modified independent	
Ramps	Modified independent	
Rough terrain	Modified independent	
Curbs	Dependent, but verbalizes	
Manual wheelchair mobility		
Smooth surfaces	Modified independent	Ultralight upright wheelchair (recommended as primary only if scapulae grades are 3 or better)
Ramps	Modified independent	May need adaptations to facilitate more efficient propulsion (i.e., push pegs and plastic-coated handrims)
Rough terrain	Moderate to minimal assistance	
Curbs	Dependent, but verbalizes procedure	Consider manual wheelchair with power assist pushrims
Stairs	Dependent, but verbalizes procedure	

TABLE 14.4 Functional Expectations for Complete Spinal Cord Injury Lesions—cont'd

Functional Component	Outcome Potential	Anticipated Equipment to Achieve Outcomes
Skin		
Weight shift	Modified independent	Upright wheelchair with push handles
Pad, positioning	Moderate to minimal assistance	Mirror
Skin checks	Moderate to minimal assistance	
Home management		
Light home management	Minimal assistance	Various adaptive ADL equipment
Heavy home management	Dependent to moderate assistance	
Community ADL		
Driving vehicle	Modified independent	Modified vehicle
ROM exercises to scapula, upper extremity, lower extremity, and trunk	Minimal assistance	Leg lifter to assist with lower-extremity ROM
Exercise program	Minimal assistance	Cuff weights Air splints E-stim unit
C7-8		
Sitting tolerance	90 degrees for 10–12 h per day	
Communication		
Telephone use	Modified independent	Adaptive ADL equipment
Page turning		
Writing, typing, keyboard		
Feeding	Modified independent	Adaptive ADL equipment
Grooming	Modified independent	Adaptive ADL equipment
Bathing		
Upper body	Modified independent	Upright shower chair
Lower body	Modified independent	Various bathing equipment
Dressing (upper and lower body)	Modified independent for upper-body dressing	Adaptive ADL equipment
In bed	Minimal assistance to modified independent	
In wheelchair	for lower-body dressing	
Bowel management	Modified independent	Dil stick
Bladder management		
Bed	Male: modified independent	Various bladder management or adaptive ADL equipment
Wheelchair	Female: moderate assistance to modified independent Male: modified independent	
Bed mobility		
Rolling side to side	Modified independent	Leg lifter
Rolling		
Supine, prone		
Supine to and from sitting		
Scotting		
Leg management		
Transfers		
Bed	Modified independent	Transfer board
Tub, toilet	Modified independent	May not need transfer board for even surfaces
Car	Minimal assistance for loading wheelchair	
Floor	Maximal assistance	
Power wheelchair mobility		
Smooth surfaces	Modified independent	Power upright wheelchair
Ramps	Modified independent	
Rough terrain	Modified independent	
Curbs	Dependent, but verbalizes

Driving vehicle	Modified independent	Hand controls for vehicle
ROM exercises to left extremity and trunk	Modified independent	Leg lifter to assist with lower-extremity ROM
Exercise program	Modified independent	Cuff weights and e-stim if any weakened lower-extremity muscles

ADL, Activity of daily living; ECU, environmental control unit; ROM, range of motion.

EARLY REHABILITATION AND COMPLICATION PREVENTION

Early rehabilitation of the patient with SCI begins with prevention. Of individuals living with SCI, 70% will have at least one complication or secondary condition (nonneurological) during their inpatient rehab stay; those with high cervical injuries (C1-4) are 2.2-times more likely to have at least one.⁹⁸ Preventing secondary conditions speeds entry into the rehabilitation phase and improves the possibility that the patient will become a productive member of society.

Table 14.5 describes an overview of the primary complications that can arise after an SCI. In this table, known causes and common management activities are reviewed. Tests and measures commonly used to determine the complication and the recommended medical and/or therapeutic interventions are listed in the table. Although various reports of incidences are published, the largest database is the Model Spinal Cord Injury Care Systems report.⁹⁹ Because of their high incidence and potential effect on long-term outcomes, the following conditions⁹⁸ require further discussion: skin compromise, loss of ROM or joint contractures, respiratory compromise after SCI, and urinary tract infections (UTIs).

Preventing and Managing Pressure Injury and Skin Compromise

After SCI and during the period of spinal shock, patients are at greater risk for the development of pressure injury.¹¹⁵ The use of backboards at the emergency scene and during radiographic procedures contributes to potential skin compromise; therefore immediate concern for tissue death, especially at the sacrum, should be taken into account. Recently, padded spine boards have become available and are recommended to reduce the risk of skin complications. In addition to this immediate risk factor of immobility associated with severe injury, completeness of injury and age can increase the risk of pressure

injury^{116,117}; some studies show a relationship between pneumonia and the incidence of skin compromise.¹¹⁶

Preventive skin care begins with careful inspection and a risk assessment.^{101,115} Soft tissue areas over a bony prominence are at greatest risk for acquiring a pressure sore.^{101,115} Key areas to evaluate include the sacrum, ischia, greater trochanters, heels, malleoli, knees, occiput, scapulae, elbows, and prominent spinous processes. A turning schedule should be initiated immediately. Even if the patient has unstable fractures or is in traction, he or she can be turned and positioned with flat pillows using the logroll technique. Even small changes off the sacrum and coccyx are helpful. The patient's position in bed should be initially established for turns to occur at least every 2 hours.¹⁰¹ This interval can be gradually increased to 6 hours with careful monitoring for evidence of skin compromise. A reddened round area over the bone that does not disappear after 15 to 30 minutes is the hallmark start of a pressure sore, and action to avoid or minimize pressure in the area must be taken immediately to avoid progression. Turning positions include prone, supine, right and left side-lying, semi prone, and semi supine positions.¹¹⁸ Secondary injuries such as fractures and the presence of vital equipment, such as ventilator tubing, chest tubes, and arterial lines, should be considered when choosing turning positions. The prone position is the safest position for maintaining skin integrity but may not always be feasible. Additionally, skin integrity and body type should be considered. Someone with fragile skin may require more frequent turns or weight shifts; an obese individual with excess skin folds may be at risk for moisture buildup, whereas someone with little soft tissue may have increased pressure on bony areas. A history of smoking or diabetes are other examples that impact skin health.^{101,115}

Pillows or rectangular foam pads may be used to bridge off the bony prominences and relieve potential pressure. This is especially helpful above the heels. Padding directly over a prominent area with a firm pillow or pad may only increase pressure and should be avoided. Great care should be taken for regular checks if this bridging technique is used in the trunk or buttocks region while the patient is in bed,

TABLE 14.5 Complications After Spinal Cord Injury

Complication	Cause	Diagnostic Tests and Measures	Medical Treatment or Intervention	Therapeutic Intervention
Cardiopulmonary				
Pneumonia Atelectasis	Bacterial or viral infection, prolonged immobilization, prolonged artificial ventilation, and general anesthesia	Radiographical studies and diagnostic bronchoscopy	Antibiotics, bronchodilator therapy, therapeutic bronchoscopy, suctioning	Chest physical therapy: percussion, vibration, postural drainage, mobilization, and inspiratory breathing exercises
Ventilatory failure	Weakness or paralysis of the inspiratory muscles and unchecked broncho-spasm	Pulmonary function tests (PFTs), arterial blood gases (ABGs), end-tidal CO ₂ monitoring, and pulse oximetry	Artificial ventilation and supportive therapy, management of underlying cause (e.g., pneumonia), and oxygen therapy	Airway and secretion management treatment as above, early mobilization once stabilized, and biofeedback to assist with ventilator weaning as appropriate
Venous thrombo-embolism, including deep vein thrombosis (DVT) ^a	Venous stasis, activation of blood coagulation, pressure on immobilized lower extremity, and endothelial damage ^{61,100}	Doppler studies, leg measurements, extremity visual observation and palpation, and low-grade fever of unknown origin	Subcutaneous heparin ^{61,100} Prophylactic anticoagulation can decrease incidence to 1.3% ^{61,100} Vena cava filter for failed anti-coagulant prophylaxis	Early mobilization and range of motion (ROM) for prevention, centripetal massage for prevention, compression garments, education about smoking cessation, weight loss, and exercise; avoid constricting garments and monitor overly tight leg bag straps and pressure garments (PVA 2016)
Pulmonary embolus	Dislodging of DVT	Ventilation-perfusion lung scan, signs and symptoms, including chest pain, breathlessness, apprehension, fever, and cough	Vena cava filter Anticoagulation therapy	None
Orthostatic hypotension	Vasodilation and decreased venous return and loss of muscle pump action in dependent lower extremities and trunk ⁶¹	Monitor blood pressure with activity and changes in position and observation for signs and symptoms	Medications to increase blood pressure and fluids in the presence of hypovolemia	Gradient compression garments: Ace wraps, abdominal binders, and appropriate wheelchair selection to prevent rapid changes in position early in rehabilitation
Apneic bradycardia	True origin unknown; believed to be caused by sympathetic disruption resulting in vagal dominance in response to a noxious stimulus or hypoxia ^{61,100}	Electrocardiogram Heart rate Respiratory rate	Hyperventilation	Remove noxious stimulus
Integumentary System				
Pressure injury	Prolonged external skin pressure exceeding the average arterial or capillary pressure ¹⁰¹	Wound measurements, staging classification, and nutritional assessment ¹⁰¹	Nutritional support as needed, surgical or enzymatic debridement, surgical closure, muscle flap, skin flap or graft, and antibiotics as appropriate	Irrigation and hydrotherapy, dressing management, and electrotherapy ¹⁰¹
Shearing	Stretching and tearing of the blood vessels that pass between the layers of the skin ¹⁰¹	See pressure injury	See pressure injury	Add protective padding during functional activities, skill perfection, and correct handling techniques
Moisture	Excessive sweating below the level of injury, urinary and bowel incontinence, and poor hygiene	See pressure injury	See pressure injury, treat possible urinary tract infection, and medications for bladder incontinence	Protective barrier ointments and powders establish effective bowel and bladder programs, educate for improved hygiene, and refine activity of daily living (ADL) skills

TABLE 14.5 Complications After Spinal Cord Injury—cont'd

Complication	Cause	Diagnostic Tests and Measures	Medical Treatment or Intervention	Therapeutic Intervention
Neuromuscular and Musculoskeletal				
Spasticity	Upper motor neuron lesion ⁶¹ Deep tendon reflex spasticity scale evaluation	Ashworth or Modified Ashworth Scale Baclofen pump insertion ¹⁰²	Antispastic pharmacological agents: baclofen, diazepam (Valium), dantrolene Surgical intervention: myelotomy, rhizotomy, peripheral neurotomy ⁶¹ Botox injection	Prolonged stretching; inhibitive positioning or casting Cryotherapy, weight-bearing exercise, and aquatic therapy
Flaccidity	Lower motor neuron lesion. Most often in injuries at L1 level and below	Deep tendon reflexes (would be absent)	None	None for treating flaccidity; however, secondary treatments that need to be considered include positioning to improve postural support, education for skin protection, and bracing and splinting to maintain joint integrity
Autonomic dysreflexia	Triggering of an uncontrolled hyperactive response from the sympathetic nervous system by a noxious stimulus; noxious stimuli may include bowel or bladder distention, urinary tract infection, ingrown toenail, tight clothing, and pressure sore	Sudden rise in systolic blood pressure of 20-40 mm Hg above baseline observation of signs and symptoms: Sweating above level of injury Goosebumps Severe headache Flushing of skin from vasodilation above level of injury ^{61,103}	Catheterization of the bladder, irrigation of indwelling catheter, pharmacological management if systolic blood pressure is greater than 150 mm Hg Remove ingrown toenail if present	Immediately position the patient in upright position, identify and remove noxious stimuli, check clothing and catheter tubing for constriction, and perform bowel program if fecal impaction is suspected
Contractures	Muscle imbalance around joint; prolonged immobilization, unchecked spasticity, pain	Goniometric measurements	Tendon release; Botox injection for isolated spasticity	ROM functional use of extremity, casting or splinting, achieving and maintaining optimal postural alignment
Heterotopic ossification (HO)	Unknown	Alkaline phosphatase levels (increase after 6 weeks) ^{104,105} ; observation ¹⁰⁶ for sudden loss of ROM, local edema, heat, erythema, and nonseptic fever	Etidronate disodium (Didronel): use prophylactically or during inflammatory stage Surgical resection	Maintain available ROM; avoid vigorous stretching during inflammatory stage; and achieve and maintain optimal wheelchair positioning
Osteoporosis and joint changes degenerative	Bone demineralization	Bone scan	None; calcium supplement for prevention	Weight-bearing techniques: amount and type unknown, specific to spinal cord injury
Spinal deformities	Muscle imbalance or weakness around spinal column; poor postural support; and asymmetrical functional activities	Posture evaluation and seating evaluation	If severe: surgical fixation and thoracic orthosis	Restore postural alignment, avoid repetitive asymmetrical activities, and control spasticity
Genitourinary and Gastrointestinal				
Urinary tract infections	Presence of excessive bacteria in urine	Urinalysis, urine culture and sensitivity, temperature	Antibiotics	Monitor fluid intake and educate for proper technique during bladder care
Gastroduodenal ulcers, gastrointestinal bleeding	Acute: disruption of central nervous system, abdominal trauma or stress response to neuroendocrine system ¹⁰⁷ Chronic: impairment of autonomic nervous system ¹⁰³	Hematocrit and hemoglobin; observation of gastrointestinal fluids	Surgical intervention; restore normal gastrointestinal function	Establish effective bowel program, establish high-fiber diet, and provide education and stress management

Continued

TABLE 14.5 Complications After Spinal Cord Injury—cont'd

Complication	Cause	Diagnostic Tests and Measures	Medical Treatment or Intervention	Therapeutic Intervention
Neurogenic bowel ¹⁰⁸	Refer to bowel management section	Positive bulbocavernosus reflex: indicates reflexic bowel	Oral laxative, suppositories, and enemas	Establish comprehensive bowel program
Other				
Thermoregulation problems	Interruption between communication with autonomic nervous system and hypothalamus Lack of vasoconstriction and inability to shiver or perspire ⁶¹	Body temperature	Cooling or warming blanket if extreme	Education about risk and proper protection from elements; behavior modification, and education for proper hydration and appropriate clothing
Pain	Radicular pain originating from the injury, ¹⁰⁹ kinematic or mechanical pain, direct trauma, and referred pain ^{61,111}	Pain scales, functional assessment, ¹¹⁰ and taxonomy	Immobilization and rest, pain medications, injections for pain, or antiinflammatory measures	Restore ideal alignment and posture, thermal modalities and electromodalities, manual therapy as well as improve movement patterns
Edema	Dependent position of extremity with loss of muscle pump; venous insufficiency; IV infiltrate; lymphatic system overload; trauma i.e., fracture; and systemic edema i.e., organ failure	Rule out VTE; circumferential measurements; volumeter; pitting scale	Medications to increase fluid return; review of medications contributing to edema	Elevation of extremity above heart; gradient compression garments; and complete decongestive therapy (CDT) with certified lymphedema therapist
Cardiometabolic Syndrome (exists when 3 of the following risk factors present): central obesity, hypertriglyceridemia, low-plasma high-density lipoprotein cholesterol (HDL-C), hypertension, and fasting hyperglycemia ¹¹²	Decrease in physical activity, hypercaloric diet, and changes in metabolism ¹¹²	Screen for metabolic syndrome: <ul style="list-style-type: none"> • Waist circumference • Lipid profile • Plasma glucose • Blood pressure¹¹³ 	Prescription medications exist to treat hyperglycemia, hypertension, dyslipidemia, and obesity	Lifestyle interventions including diet, exercise, behavioral modifications, smoking cessation, and nutritional counseling ^{112–114}

^bConsortium for Spinal Cord Medicine Clinical Practice Guidelines. *Neurogenic Bowel Management in Adults with Spinal Cord Injury*. Washington, D.C., March 1998, Paralyzed Veterans of America.

owing to eventual shifting of the foam. In the presence of an open wound cutouts and donut-type cushions should be avoided, as the edges of the cushion would increase pressure on the already compromised area.¹⁰¹

Keeping the head of the bed as low as tolerated minimizes the risk for shearing and excessive sacral pressure. For individuals not able to turn themselves, or who are not appropriate for rigorous turning schedules (e.g., patients with unstable fractures), an active support surface such as an alternating pressure mattress is recommended. Low air loss, alternating pressure, or even air-fluidized mattresses are

available for those who require the head of the bed to be elevated more than 30 degrees for prolonged periods and have other extenuating conditions such as multiple wounds, recent skin flap surgery, respiratory distress, diabetes, and/or low prealbumin.¹⁰¹

While the patient is sitting, a customized seating system with appropriate pressure redistribution (relief) cushion is ideal to provide optimal postural support while preventing increased areas of pressure.¹⁰¹ Wheelchair footrest height should be assessed, as increased footrest height can lead to increased pressure under the ischial tuberosities¹¹⁹; a pressure relief (weight shift) schedule should be established

and strictly enforced. Bathroom equipment also should be appropriately padded, and the patient should be able to perform weight shifts. To encourage compliance with weight shifts, options such as using timers, personal technology devices, and patient education on the need for weight shift schedules are utilized.¹¹⁹

Although pressure is one of the most prevalent causes of skin compromise, other forces may lead to problems, including friction, shearing, excessive moisture or dryness, infection, and bruising or bumping during activities. This is especially true of patients with SCI because of altered thermoregulation, changes in mobility, decreased or absent sensation, and incontinence of bowel and bladder. In addition, as patients begin to learn functional skills, they may have poor motor control and impaired balance, and must be carefully monitored to avoid injury. Other SCI-related considerations for risk are incontinence, as it may cause moisture buildup on the skin; nutrition, as adequate fluid and nutrition is needed to maintain skin health; and vascular integrity, as blood flow also impacts skin health. When making recommendations for equipment that a spinal cord injured individual needs, skin integrity, appropriate pressure relief, and reduction of heat and moisture should always be considered.^{101,115}

Should skin compromise occur, the first intervention is to identify and remove the source of the compromise. Modifications to the seating system or changing to a more pressure-reducing mattress system or cushion may be necessary. Examination and treatment will then need to focus on healing the wound and preventing other secondary conditions that may occur as a result of potential immobility and delayed physical rehabilitation. The reader is encouraged to refer to The National Pressure Ulcer Advisory Panel for educational and clinical resources.¹¹⁵

Treatment interventions may include hydrotherapy, specialty wound dressings, electro-modalities, and thermal modalities to increase circulation.^{55,101} Mechanical, autolytic, enzymatic, or surgical debridement may be necessary to obtain and maintain a viable wound bed. If the wound does not heal, surgical interventions with myocutaneous or muscle flaps may be necessary for closure. Coordinated return-to-sit programs or protocols after such medical interventions are necessary to prevent opening of the surgical site. Such surgical procedures are costly and significantly delay functional rehabilitation.

After closure and healing of the wound, education becomes a priority to maintain skin integrity. The patient must adhere to a more rigorous skin check program as rehabilitation continues, giving special attention to the affected area. Education for a nutritious diet and teaching patients to advocate for themselves is critical. Problem-solving equipment and lifestyle issues that may affect their skin condition will reduce the recurrence rate. Alcohol, tobacco, and drug use (both recreational and prescription) should be managed for long-term success. Prevention of skin compromise is critical and cannot be stressed enough to health care providers, patients, and caregivers.¹⁰¹

Prevention and Management of Joint Contractures

The development of a contracture may result in postural misalignment or impede potential function. Daily ROM exercises, proper positioning, and adequate spasticity management may help prevent contractures. Contracture prevention includes the use of splints (Fig. 14.64) for proper joint alignment, techniques such as weight bearing, ADLs, and functional exercises. Patients exhibiting spasticity may require more frequent ROM intervention.¹¹⁸

Adaptive Shortening or Adaptive Lengthening of Muscles

Although isolated joint ROM should be normal for all patients, allowing adaptive shortening or adaptive lengthening of particular muscles is recommended to enhance the achievement of certain functional

Fig. 14.10 Tenodesis Grasp Utilizing a Short Opponens Splint.

skills.¹¹⁸ Likewise, unwanted shortening or lengthening of muscles should be prevented. The following section reviews a few examples of these concepts as they relate to SCI.

Tenodesis is described as the passive shortening of the two-joint finger flexors as the wrist is extended. This action creates a grasp, which assists performance of ADLs (Fig. 14.10).^{102,118} A patient with mid to low tetraplegia may rely on adaptive shortening of these long finger flexors to replace active grip.¹¹⁸ If the finger flexors are stretched across all joints during ROM exercises, the achievement of some functional goals may be limited as their tenodesis may be ineffective if they become overstretched. ROM to the finger flexors should be applied only while the wrist is in a neutral position. There is controversy over shortening of the flexor tendons. Some clinicians argue that the patient can develop a fixed flexion contracture of the proximal interphalangeal joints (IP), interfering with future surgical attempts to restore finger function. It is recommended to promote tenodesis functioning via adaptive shortening while maintaining joint suppleness.

In the presence of weakened or paralyzed elbow extensors, patients are at risk of flexion-supination contracture due to the unopposed strength of the elbow flexors. The shortening of the elbow flexors in a supinated position will limit participation in ADL function and transfer skills (Fig. 14.11). Contracted elbow flexors (which contribute to supination) in a patient with an SCI level of C6 can cost this patient his or her independence. Likewise, the rotator cuff and the other scapular muscles should be assessed for their length-tension relationships and their ability to generate force. Normal length of these muscles should be maintained. For example, achieving external rotation of the shoulder (active and passive) is critical for patients with low-level tetraplegia. Shortening of the subscapularis, an internal rotator, and other structures can quickly result in a decrease in motion, limiting bed mobility, transfers, feeding, and grooming skills.

Appropriate length of lower extremity (LE) and trunk muscles are also important for function. Hamstrings should be lengthened to allow 110 to 120 degrees of a straight leg raise. If adequate hamstring length does not exist, it is important to make modifications to prevent overstretching of the low back muscles during functional activities. The combination of lengthened hamstrings and adaptive shortening of the back-extensor muscles provides stability for balance in the short- and long-sitting positions. Balance in short sitting aids in the efficiency of transfers and bowel and bladder management while balance in long sitting assists with lower-extremity dressing and other ADLs. It is also

Fig. 14.11. Supination Contraction of a Patient With C5 Level of Injury.

important to maintain functional ROM in hips, knees, and ankles as limited ROM in any of these joints can impact the ability to achieve standing and ambulation goals.

Splinting to Prevent Joint Deformity

Deformity prevention is the first goal of splinting.¹²⁰ Patients with cervical spinal cord injuries may have lost normal neural input to musculature in their wrists and hands. Other patients may have partial motor control, which may lead to muscle imbalances and loss of ROM. In the absence or weakness of elbow extensors, a bivalve cast or an elbow extension splint at night may be beneficial to prevent joint contractures. At the wrists, a volar wrist support is commonly used initially and may be progressed to a longer-term option of a definitive wrist orthosis or custom wrist orthosis fabricated by an orthotist. Other splints often used for deformity prevention of the hands include resting hand splints with proper positioning to maintain the support of the wrist and web space (Fig. 14.12A).¹²¹ Another hand-based option is the intrinsic plus splint (see Fig. 14.12B), which places the metacarpophalangeal (MP) joints between 70 and 90 degrees of flexion and decreases intrinsic hand muscle tightness. The intrinsic plus splint position promotes joint motility for tenodesis and is the preferred position.

Another goal of splinting in the SCI population is to increase function. Patients with tetraplegia at the C5 level rely on an orthosis to be independent with communication, feeding, and hygiene. They must have joint stability and support at the wrist and the hand to perform these skills. The splint is often adapted with a utensil slot or cuff so the patient can effectively perform the skills mentioned previously.

Patients who are not strong enough to use their wrists for tenodesis may require splinting to support their wrists until they can perform wrist extension against gravity. Long opponens splints can be used to position the thumb for function and support the weak wrist (Fig. 14.13). Once the wrist muscles strengthen, the long opponens splint can be cut down to a hand-based short opponens to maintain proper web space and thumb positioning while maximizing tenodesis.

As mentioned previously, patients with injuries at the C6 level can use their wrists for a tenodesis grasp.^{102,122,123} Critical components of the splint assessment for these patients are the positioning of the thumb, web space, and index finger observed during the grasp. It is recommended that the patient's hand be positioned with the thumb in

Fig. 14.12 (A) Resting hand splint. **(B)** Volar intrinsic plus splint maintains alignment of the wrist and fingers to promote metacarpophalangeal flexion for tenodesis grasp.

Fig. 14.13 Long Opponens Splint.

a lateral pinch position because this is the most commonly used prehension pattern to pick up objects. Patients who are not splinted may not have the proper positioning to pick up objects because their tenodesis is “too tight” or “too loose.”

Patients with C8 to T1 injuries or patients who have incomplete injuries may have “clawing” or hyperextension of the metacarpophalangeal joints. This is caused by finger extensor musculature that is stronger than finger flexor musculature.¹⁰² To prevent this, a splint can be made to block the metacarpophalangeal joints and promote weak intrinsic muscle function. Depending on the extent of the imbalance, these splints can be used during function or worn only at night. Alternatively, the splinting position of composite finger extension (MPs and IPs simultaneously) with wrist extension may be considered for a prolonged stretch.

Cost, time, material, and clinician experience are important considerations when deciding between custom and prefabricated splints. A well-fitting, prefabricated splint can be as effective as a custom-fabricated splint in certain situations. Custom splints require additional resources and clinician expertise. One way to minimize time spent in the fabrication of splints is to use a good pattern and premade straps. Finally, educating the patient on the splint-wearing schedule, skin checks, and splint care is important for preventing skin breakdown.

Treatment for Joint Deformity

If a joint contracture occurs despite preventive measures, more aggressive treatments are necessary. This may include more aggressive use of splinting, plaster or fiberglass casting techniques, or injections of neurolytics, such as botulinum toxin type A (Botox).^{124–126} When splinting is not effective, casting may be indicated. The patient with minimal ROM limitations may require only one cast. The patient with significant limitations may require multiple casts, called serial casting. This process involves the application of several casts that are removed and reapplied over a period of weeks to increase extensibility in the soft tissues surrounding the casted joint.¹²⁷ With each cast, the involved joint is placed at submaximal ROM.¹²⁸ Once the cast is removed, the joint should have an increase of approximately 7 degrees of ROM.¹²⁸ This process continues until the deformity is minimized or resolved. The final cast is fabricated into a bivalve splint by cutting the cast into a top half and bottom half and adding strapping. The bivalve splint acts as a positioning device to promote ROM gains made during serial casting. It can be easily applied and removed (Fig. 14.14). Casting contraindications include the following: skin compromise over the area to

Fig. 14.14. Bivalve Splint.

Fig. 14.15. Dropout Cast.

be casted, heterotopic ossification, edema, decreased circulation, severe fluctuating hypertonicity, and inconsistent monitoring systems.

The elbow, wrist and hand, and finger joints are the most common joints casted for patients with SCI. Long-arm casts are used when elbow and wrist contractures must be managed simultaneously. In the case of a pronation or supination contracture, a long-arm cast would also be the cast of choice as the elbow and wrist joint must be included to impact forearm rotation. Dropout casts are used with severe elbow flexor or extensor contractures, but the patient should be in a position in which gravity can assist (Fig. 14.15). Forearm based wrist-hand and individual finger casts are indicated for contractures that prevent distal upper-extremity function. Most commonly, a patient will have a wrist flexion-extension contracture or have finger flexor-extensor tone and will require a cast to use the tenodesis or individual fingers for fine motor skills. Casting is an expensive and labor-intensive treatment modality, but if indicated and used appropriately it can assist a patient in regaining lost joint ROM needed for increased independence and function.

Botox may be used in conjunction with casting. In a study conducted by Corry and colleagues¹²⁵ tone reduction was evident when botulinum toxin type A was used; however, ROM and functional improvement varied among subjects. Pierson and co-workers¹²⁶ found that, with careful selection, subjects who received Botox had significant improvements in active and passive ROM. Research indicates that patients who have flexor spasticity without fixed contracture will benefit the most.

Surgical intervention may be recommended by an orthopedic physician in severe cases of joint contracture.¹²⁹ Some of the more commonly used surgical options include joint manipulation under anesthesia, arthroscopic surgical releases, open surgical releases, and rotational osteotomy.

Prevention and Management of Respiratory Complications

Individuals with a SCI are susceptible to respiratory complications. While level of injury, age, and trauma are leading variables, those with high cervical injuries will be 3.3-times more likely to develop a respiratory condition.⁹⁸ This population is more likely to have pneumonia, atelectasis, or some other respiratory condition. Pneumonia frequently leads to death in this population (National Spinal Cord

Injury Statistical Center). Atelectasis can occur in the presence of diaphragmatic paralysis, and the most common location is in the left lower lobe.¹³⁰ Early management must focus heavily on preventing pulmonary complications and maximizing pulmonary function so the patient may perform physical activities. The clinician should first determine which ventilatory muscles are impaired. The primary ventilatory muscles of inspiration are the diaphragm and the intercostals. The diaphragm is innervated by the phrenic nerve at C3 through C5. The intercostals are innervated by the intercostal nerves positioned between the ribs. If the diaphragm is weak or paralyzed, its descent will be lessened, reducing the patient's ability to ventilate. Overall dysfunction of these muscles will lead to respiratory insufficiency, increased airway resistance, and impaired secretion clearance. Additionally, if dysphagia is present in someone who has an SCI, it can lead to increased risk of infection.⁹⁸

Accessory muscles of ventilation are primarily located in the cervical region. The accessory muscles are used to augment ventilation when the demand for oxygen increases, as during exercise. Accessory muscles may also be recruited to generate an improved cough effort.¹³⁰ The most commonly cited accessory muscles are the sternocleidomastoids, the scalenes, the levator scapulae, and the trapezius muscles. The erector spinae group may also assist by extending the spine, thus improving the potential depth of inspiration.

The abdominals are the primary muscles used for forced expiration in such maneuvers as coughing or sneezing. The latissimus dorsi, the teres major, and the clavicular portion of the pectoralis major are also active during forced expiration and cough in the patient with tetraplegia.¹³¹ Alterations in the function of these muscles will have an impact on the patient's ability to clear secretions and produce loud vocalization. Gravity plays a crucial role in the function of all ventilatory muscles. Neural input to the diaphragm increases in the upright position in persons with intact nervous systems. As one moves into an upright position, the resting position of the diaphragm drops as the abdominal contents fall. The diaphragm is effectively shortened, which makes generating a strong contraction more difficult. However, with intact abdominal musculature, a counter pressure is produced and adequate intraabdominal pressure is maintained, allowing the diaphragm to perform work. If weakness or paralysis of the abdominal wall is present, the patient may need a binder or corset to maintain the normal pressure relationship.^{118,130,132} Unless the SCI has affected only the lowest sacral and lumbar areas, some degree of ventilatory impairment is present and should be addressed in therapeutic sessions.

Many treatment techniques are available to address the myriad causes of ventilatory impairment. Decreased chest wall mobility and the inability to clear secretions should always be addressed. Maintaining chest wall mobility is needed to prevent contractures and lung restrictions. With high cervical injuries, the risk of bulbar involvement increases—this impacts secretion clearance. Interventions may include inspiratory muscle training, chest wall mobility exercises, and chest physical therapy.^{118,133–135}

Inspiratory Muscle Training

Inspiratory muscle training may be used to train the diaphragm and the accessory muscles that are weakened by partial paralysis, disuse from prolonged artificial ventilation, or prolonged bed rest. In the presence of significant impairments, it is generally recommended that training be initiated in the supine or side-lying position and progressed to the sitting position when tolerated. When training a moderately weak diaphragm, gentle pressure during inspiration may be used to facilitate the muscle (Fig. 14.16). Accessory muscle training may be facilitated with the patient in the supine position while a slight stretch is placed on these muscles.^{132–135} The stretch is accomplished by shoulder abduction and external rotation, elbow extension, forearm supination, and neutral alignment of the head and neck.^{133–135} A more challenging position incorporates upper thoracic extension. The clinician's hands are placed directly over the muscle to be facilitated. The patient is instructed to breathe into the upper chest (Fig. 14.17). As the treatment progresses, the diaphragm may be inhibited for short training periods by applying pressure over the abdomen in an upward direction. Care must be taken to avoid excessive pressure to prevent occlusion of vital arteries.

As the inspiratory muscles strengthen, resistive inspiratory devices may be used. Inspiratory devices are relatively inexpensive and most function similarly. Most devices have a one-way valve that closes when the patient inspires, forcing him or her to breathe either through a small aperture or against a spring-loaded resistance. Although evidence fully supporting this intervention remains inconclusive,¹³⁶ some researchers have shown improvements in total lung capacity¹³⁷ and improved endurance measures.¹³⁸ The diaphragm may also be trained by using weights on the abdominal wall with the patient in the supine position. However, muscle trainers appear to promote more of an endurance effect than the use of abdominal weights.

Fig. 14.16 Diaphragm Facilitation. (A) Hand placement and patient positioning to facilitate the diaphragm and inhibit accessory muscle activity. (B) Firm contact is maintained throughout inspiration. The lower extremities are placed over a pillow in flexion to prevent stretching of the abdominal wall.

Fig. 14.17 Accessory Muscle Facilitation. Hand placement and patient positioning.

Diaphragm and Phrenic Nerve Pacing

When the primary inspiratory muscles are no longer volitionally active as a result of SCI, the diaphragm can be stimulated directly or by phrenic nerve pacing. These interventions are most commonly indicated when the lesion is at or above the C3 level.^{139–142} Assessing the viability of the phrenic nerve will indicate whether stimulation will produce an optimal contraction of the diaphragm and whether it will be painful to the patient.^{130,142} Transdiaphragmatic pacing, in which electrodes are placed laparoscopically on the diaphragm, is also an option.¹⁴³ Transdiaphragmatic pacing is less invasive than direct phrenic nerve pacing, may be implanted and initiated on an outpatient basis, and may result in improved outcomes. Both of these procedures require a reconditioning program that involves extensive caregiver and patient training. Complications could include myopathic changes of the diaphragm, phrenic nerve compression, or infection.¹⁴⁰ Many patients require some residual use of mechanical ventilation even after maximal tolerance has been achieved so as not to over fatigue the phrenic nerve. Other researchers are also considering pacing intercostal muscles¹⁴⁴ or using a combination of diaphragmatic and intercostal pacing. There is limited evidence comparing the outcomes associated with these devices in isolation or in combination therapies.

Glossopharyngeal Breathing

Glossopharyngeal breathing is another way of increasing vital capacity in the presence of weak inspiratory muscles. Moving the jaw forward and upward in a circular opening and closing manner traps air in the buccal cavity. A series of swallowing-like maneuvers forces air into the lungs, increasing the vital capacity. This technique has been reported to increase vital capacity by as much as 1 L.^{134,145} Additionally it may improve voice volume.¹³⁰ Although this technique is rarely used to sustain ventilation for long periods of time,¹⁴⁵ it may be used in emergency situations and to enhance cough function. The patient with high tetraplegia should attempt to master this skill.

Secretion Clearance

Ventilatory impairment, the leading cause of rehospitalization in people with tetraplegia, occurs when the patient cannot produce an effective cough to clear secretions.¹⁴⁶ Factors such as artificial ventilation and general anesthesia hamper secretion mobilization. With artificial ventilation, patients may require an artificial airway.¹³⁰ The presence of this airway in the trachea is an irritant, and the patient subsequently produces more secretions. A description of various types

and parameters of ventilation is beyond the scope of this chapter. Clinicians working with patients requiring artificial ventilation are referred to other publications.

Secretions are most commonly removed by tracheal suctioning, unassisted coughing, assisted coughing, or mechanical insufflation–exsufflation. Insufflation–exsufflation utilizes rapidly alternating pressures to deliver a breath followed by an exhalation that sucks the air out, and is believed to be the most effective method of clearing secretions.^{130,147} A recent case study investigated the use of abdominal electrical stimulation to assist with insufflation–exsufflation and found it may be more effective than insufflation–exsufflation alone in clearing secretions. To date, conclusive research determining which single technique or combination of techniques achieves the best outcome is not available. Insufflation–exsufflation may result in fewer complications and is reported to be more comfortable to the patient. Postural drainage, percussion or clapping, and shaking or vibration are used to assist with moving secretions toward larger airways for expectoration.^{11,118}

Assisted coughing is typically used with people who are unable to generate sufficient effort to clear secretions independently. It also helps with basic postural drainage.¹³⁰ The assistant places both hands firmly on the abdominal wall. After a maximal inspiratory effort, the patient coughs and the assistant simply supports the weakened wall. A gentle upward and inward force may be used to increase the intraabdominal pressure, yielding a more forceful cough (Fig. 14.18).¹²⁷ Excessive pressure over the xiphoid process should be avoided to prevent severe injury.

Patients may learn independent coughing techniques. In preparation for a cough, the patient positions an arm around the push handle of the wheelchair, opening the chest wall to enhance inspiratory effort. The other arm is raised over the head and chest during inspiration. This procedure is followed by a breath hold, strong trunk flexion, and then a cough (Fig. 14.19). Another technique for independent coughing is accomplished by placing the forearms over the abdomen and delivering a manual thrust during cough. This technique is more difficult and may not provide an inspiratory advantage.

Urinary Tract Infection

UTIs are one of the most prevalent complications associated with spinal cord injuries, with an overall incidence of 62% within the first year of injury.¹⁴⁸ Since individuals with SCI often need some form of catheterization—indwelling or intermittent—it is often catheter insertion that introduces bacteria into the bladder, and it is the indwelling catheters that are associated with higher risk compared to intermittent ones.^{149,150} A type of external catheter—a condom catheter frequently used with males—can be associated with increased incidence of a UTI if not changed at least every other day.¹⁵⁰ Once in the urinary system bacteria multiply in a short period of time.¹⁴⁹

Important factors leading to UTI in the SCI population is method of voiding, vesicoureteral reflux, high pressure voiding, large postvoid residuals, presence of stones, outlet obstruction, and the ability to fully empty the bladder. Indwelling catheters lead to a decrease in the mucosal lining, thereby interfering with the function of the mucus, which leads to increased bacteria adhering to the bladder wall. If the bladder is not fully emptied and becomes distended, ischemia can occur in the bladder wall, which impairs its natural defense mechanisms against bacteria.¹⁴⁹ Additionally, high bladder volumes (over 500 mL) can lead to distention and therefore monitoring fluid intake and frequency of emptying is crucial.¹⁵¹ For these reasons it is important to choose the least invasive method of draining the bladder that is most feasible for the level of injury and functional status of the patient.^{149,150}

Fig. 14.18 Assisted Coughing. (A) Hand placement for the Heimlich-like technique. (B) Anterior chest wall assisted coughing. The inferior forearm supination promotes an upward and inward force during the cough.

Fig. 14.19 Self-Produced Assisted Coughing. (A) Full inspiratory position. (B) Expiratory or cough position.

Early Mobilization

Getting the patient upright as soon as possible promotes self-mobility and should be planned carefully. An appropriate seating system for pressure relief and support should be chosen. Most patients require a reclining wheelchair with elevating footrests or tilt-in-space wheelchairs when they are first acclimating to the upright position.¹¹⁸ The patient is transferred initially to a reclining or tilting back position and progressed to an upright position as signs and symptoms of medical stability allow. The patient should be monitored for evidence of orthostatic hypotension. Dizziness or lightheadedness is most common. Ringing in the ears and visual changes also may occur. Changes in mental function may indicate more serious hypotension, and the

patient should be reclined immediately. Assessing blood pressure before and during activities provides an objective measurement of the patient's status.

Because of paralysis, the abdominal wall may not support the internal organs and viscera. In these cases, an abdominal binder or corset should be applied to all patients with lesions above T12 to assist in venous return^{55,133}; as discussed, this will enhance ventilatory function. If the patient has a history of vascular insufficiency or prolonged bed rest, wrapping the lower extremities with elastic bandages while applying the greatest pressure distally may be beneficial.

Abdominal binders and corsets are fitted so that the top of the corset lies just over the lower two ribs. The bottom portion is placed

Fig. 14.20 Abdominal Binder. Correct placement is over the anterior-superior iliac spine and at the level of lower rib cage. Custom corsets may be used if an elastic binder does not provide adequate support to enhance vital capacity.

over the anterior iliac spine and iliac crest (Fig. 14.20). The corset or binder should be adjusted slightly more tightly at the bottom to assist in elevating the abdominal contents.¹¹⁸ Properly fitting the abdominal binder is essential. If it is placed too high or allowed to ride up, ventilation may be impaired by restriction of chest wall excursion. If placed too low, it will not provide the necessary abdominal support.^{55,134}

The patient can be transferred initially with a manual or mechanical lift. Lift systems may be advantageous because they allow total control of the patient and give the assistant more time to ensure that monitoring devices, lines, or tubes attached to the patient remain intact. Lift systems may be freestanding hydraulic lifts or electronic devices, or may be mounted on the ceiling.

Once the patient is out of bed, a weight shift or pressure relief schedule is immediately established. Initially, weight shifts are performed at 30-minute intervals and modified according to skin tolerance. A timer may be issued to ensure reminders for weight shifts. This is particularly important if the patient has cognitive deficits. The skin is inspected thoroughly before and immediately after out-of-bed activities. Total sitting time is progressed according to tolerance.

REHABILITATION: ACHIEVING FUNCTIONAL OUTCOMES

Once secondary conditions are managed and the patient is able to tolerate out-of-bed activities, more aggressive functional training begins. The following information will address special considerations for functional progression related to SCI.

Optimal neck, shoulder, and upper-extremity strength and ROM are important factors to consider in order to maximize functional outcomes. Neck musculature is typically painful and restricted in cervical injuries, especially after surgical procedures. Most patients will have a cervical orthosis in place postoperatively to prevent rotation and flexion and extension. Cervical spine mobility may be so limited that correcting a forward head posture is the first goal. Soft tissue massage, manual therapy, and other modalities may be beneficial. When cleared by the physician, the patient can begin more aggressive neck exercises.

The key muscle groups to consider include the musculature of the shoulder, scapula, and thoracohumeral muscles, which allow for humeral flexion, adduction and abduction, shoulder internal and

external rotation, and scapular movements. Patients with high cervical injuries have the potential for the development of tight upper trapezius muscles, shoulder subluxations, capsule tightness, nerve root injury, or radicular pain.¹⁵² Upper trapezius inhibitory taping or scapular taping to relax the tight muscles and facilitate the weak scapular musculature is often beneficial. If the injury level is above C7, the scapular musculature may not be fully innervated, and thus positioning in the proper alignment and strengthening the innervated musculature are essential. Some individuals require positional aides, such as slings or custom orthosis, to avoid humeral displacement or subluxation. The clinician will use findings from manual muscle testing and the goniometric examination to determine the appropriate stretching, strengthening, and positional interventions. Patients may need to begin with gravity-eliminated exercises using air splints, bilateral slings, skateboards, and functional electrical stimulation (FES).^{152,153}

Activities of Daily Living and Instrumental Activities of Daily Living

ADLs include skills such as communication, feeding, grooming, bathing, dressing, bladder and bowel management, sexual health, home management, and community reentry. Instrumental activities of daily living (IADLs) encompass multistep activities to care for self and others,¹⁵⁴ such as parenting, household management, and financial management. Depending on the level and severity of the SCI, patients will achieve varying levels of independence. Most of the ADL areas discussed in this section will address skill levels with a complete injury. Activities should be graded differently for an incomplete injury after completion of ISNCSCI examination and manual muscle testing. For purposes of this discussion we will use terms used in the FIM.

Patients with complete high-level tetraplegia (C1 to C4) will be dependent in most ADLs and IADLs; therefore the focus of ADL training is to verbalize how to safely perform all skills. Patients with low-level tetraplegia (C5 to C8) may achieve some level of independence, but this will vary according to the amount of intact musculature and the patient's body shape and weight, age, and motivation level. The ability of these patients to achieve maximum independence in all areas of ADLs may be accomplished with appropriate orthoses or adaptive equipment.¹⁵⁵ See Table 14.4 for functional expectations and Table 14.6 for orthotic indications.

Patients with complete injuries at the C5 or C6 level have unique challenges regarding return to ADL participation. These patients must have biceps function and adequate elbow ROM before any ADL goals can be achieved. To achieve these goals, patients need to work toward supporting their body weight with simultaneous extension of the shoulder, elbow, and wrist (otherwise known as propping; Fig. 14.21A to C). Elbow positioning devices such as pillow splints, casts, or resting splints enhance alignment. Other orthotics to consider for maximizing function include definitive wrist supports and mobile arm supports (MASs)¹⁵⁶ or short opponens splints if the patient has wrist extension. Appropriate wheelchair positioning with lap trays, armrests, wedges, or lateral trunk support is important to maximize function for persons with C5 or C6 injuries.¹⁵⁵

Patients with a complete C7 or C8 level of injury generally achieve ADL goals with less adaptive equipment and task-specific training. With the presence of triceps, ADL skills are easier to achieve. Most patients, given the right body type, will be able to achieve these goals with only minimal assistance from a caregiver.¹⁵⁵

Patients with complete paraplegia usually achieve total independence with communication, feeding, and grooming. These patients may need adaptive equipment to perform some of these IADL and

TABLE 14.6 Upper-Extremity Orthotics

Splint	Level of Spinal Cord Injury	Rationale
Dynamic Orthotics		
Mobile arm support (ball-bearing feeder)	Weak C5 Incomplete injuries Also indicated with shoulder weakness (internal-external rotator muscle grades 2- to 3/5; bicep-supinator muscle grades 2-5)	Function Assists in reaching in horizontal and vertical planes Increases functional ROM and strength Independence with feeding and hygiene after setup Provides support to allow correct movement patterns
Overhead rod and sling	Weak C5 Incomplete injuries Also indicated with shoulder weakness (internal-external rotator muscle grades 3 to 3+/5; bicep/supinator muscle grades 3/5)	Function Increases functional ROM and strength Independence with wheelchair driving after setup Independence with feeding and hygiene after setup Provides support to allow correct movement patterns
Static Splints, Casts, and Orthotics		
Resting hand splint ¹²¹	C1-C7	Position Prevent joint deformity Preserves web space Preserves balance with intrinsic and extrinsic musculature
Intrinsic plus splint ¹²¹	C1-C7	Position Same as resting hand splint but places finger MP joint in more flexion Long term, allows better tenodesis alignment of first digit and thumb
Elbow extension splints, bivalve cast	C5-C6	Position Prevents elbow contracture from muscle imbalance and/or hypertonicity
Rolyan Tone and Positioning (TAP) splint (prefabricated)	C5-C6	Position Provides constant low stretch Use with muscle imbalance and/or mild hypertonicity
Dorsal wrist support splints	C5	Function (e.g., slot for utensils) and position Prevents severe wrist drop and ulnar deviation If positioning is needed long term, may consider permanent splint fabricated by orthotist
Long opponens splint	C5	Position and function Can be dorsal or volar Prevents wrist drop and ulnar deviation Preserves web space and supports thumb, reducing subluxation Slot may be fabricated for function
Wrist cock-up splint	C5 Incomplete injuries	Position and function Supports wrist in slight extension Allows finger movement for incomplete injuries
Short opponens splint	C6-C7	Position and function Supports thumb to prevent subluxation Improves tenodesis and prehension
Tenodesis brace or splint ^{102,122,123}	C6-C7	Function Enhances natural tenodesis in either tip-pinch or lateral pinch May consider permanent splint fabricated by orthotist
MP block splint ¹⁰²	C8-T1	Position Prevents “claw hand” or hyperextension of the MP joints Protects weak intrinsic musculature

MP, Metacarpophalangeal; ROM, range of motion.

ADL skills; however, they should be able to be performed without assistance from another person. Endurance is a major concern for the patient's independence while performing ADLs. Some skills require a considerable amount of time and effort. If endurance becomes a factor, patients should choose to perform some activities while receiving assistance for other skills that are too challenging or time-consuming.¹⁵⁵

Feeding

Patients with complete C1 to C4 tetraplegia are dependent in feeding; therefore verbalization of this skill is essential. Patients with complete C5 SCI with weak shoulders and biceps musculature require a dynamic orthosis to support the UE during feeding. The most common orthoses used are the MAS^{156,157} (Fig. 14.22) and the deltoid aid. Patients

Fig. 14.21 Bed Mobility and Coming to Sit. **(A)** The patient rolls from supine to side-lying position. **(B)** He progresses to supporting his weight through the downside elbow and shoulder. **(C)** He pushes up onto extended arms. **(D)** While shifting his weight onto the left arm, he unweights the right arm and hooks his right hand behind his right knee, gaining enough leverage to push and pull himself toward upright in a long sitting position. **(E)** He continues to shift his weight to the right until he gains a balanced sitting position with his weight forward over his extended legs. **(F)** and **(G)** Starting from a supine position on a bed or a mat, the arms are extended and the hands positioned under the buttock or in the curve of the back (lumbar spine); the head is lifted, and leverage is used to pull up until the upper body weight is supported on bilateral elbows. **(H)** The weight is shifted from right to left or vice versa, and the elbows are extended to support the upper body weight. **(I)** While the elbows are kept extended, the hands are carefully walked forward until balanced long sitting has been achieved.

Fig. 14.22 Mobile Arm Support Used During Feeding.

with low-level tetraplegia may not have weakness in the shoulder impacting feeding, but they may have weak wrist function. This weakness can be addressed with dorsal wrist supports with a built-in functional cuff, whereas the patient with no finger function can use a tenodesis grasp for managing objects or to hold a feeding utensil. A universal grasp can be worn on the hand to hold feeding utensils (Fig. 14.23A). The patient with weak finger function can use built-up handles on the utensils. There are also commercially available utensils such as those in Fig. 14.23B. Cutting with decreased hand function is addressed with adapted equipment such as rocker knives.

Grooming

The basic components of grooming are washing the face, combing or brushing the hair, performing oral care, shaving, and applying makeup. More advanced grooming activities may include nail care, donning and doffing of contact lenses, or other hygiene tasks specific to the individual. Individuals with complete C1 to C4 tetraplegia are dependent; therefore verbalization of this skill is essential. Patients with

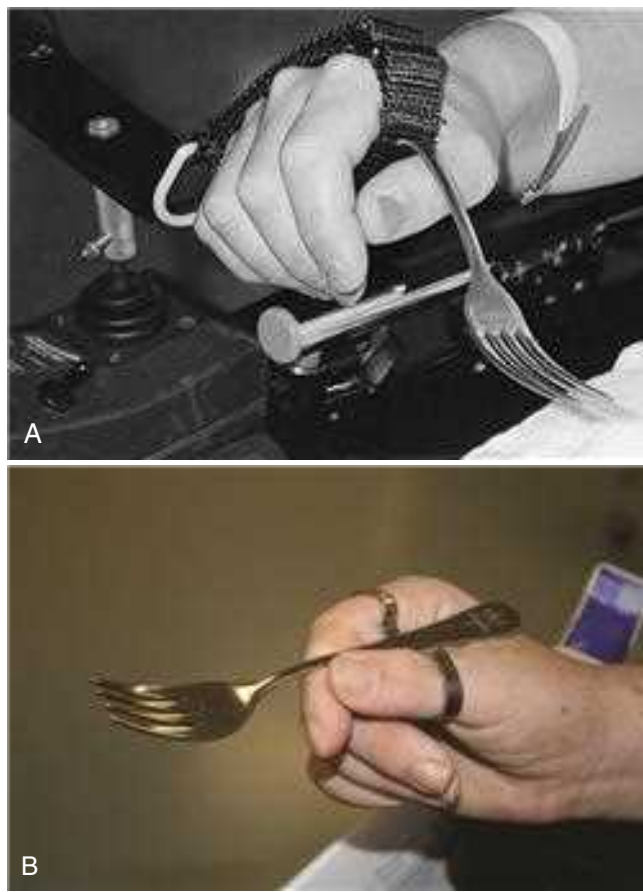

Fig. 14.23 (A) Universal cuff used for feeding. **(B)** Dining with Dignity is one commercially available type of flatware for individuals with impaired grip.

complete C5 injuries perform these skills with some assistance but may require orthotic devices, such as a mobile arm support (MAS) and a splint for wrist support. Patients with complete low-level tetraplegia may need cuffs or built-up grips on razors, brushes, and toothpaste to be independent (Fig. 14.24). All patients require a bathroom that is carefully designed and set up to allow for wheelchair access and chair-level functioning. Patients with tetraplegia often rely on the support of the elbows as an assist, so sink height and durability should be considered. The proper positioning and adaptive equipment will be the difference between independence and dependence in these skills (Figs. 14.25 and 14.26).

Bathing

Bathing includes washing and rinsing the UEs, LEs, and the trunk. Patients with complete C1 to C4 tetraplegia are dependent in bathing; therefore verbalization of this skill is essential. Patients with complete C5 injury can range from requiring maximal assistance to being dependent in bathing. Arm support and positioning for C1-5 tetraplegia is essential to ensure that shoulder integrity is maintained.¹⁵⁵ Prolonged poor positioning in shower chairs or bathing equipment can result in humeral displacement, capsule tightness, nerve root injury, or radicular pain.¹⁵² Patients with complete low-level tetraplegia bathe with moderate assistance to total independence with use of adaptive devices. Patients with paraplegia are typically independent in bathing but may need adaptive devices. After examination of the patient's upper-extremity strength, balance, spasticity, body type, skin integrity, endurance, and home accessibility; the therapy team can determine the appropriate bathing equipment and setup for the patient (Fig. 14.27).

Fig. 14.24 Simple Razor Adaptation That Helps Turn Razor On and Off With a Grosser Motor Movement.

Patients with limited upper-extremity and trunk strength may need straps to assist with trunk support and adaptive cuffs to control the hand-held shower head. Basic bathing safety should be taught to all patients. Bathing safety includes checking the water temperature with a known area of intact sensation; skin checks before and after bathing; weight shifts throughout the routine; and skin protection during the transfers. These precautions are necessary to prevent burns and skin breakdown during the bathing process.¹⁵⁵

Dressing

Dressing includes dressing and undressing the UEs and LEs with clothing that fits the patient's premorbid lifestyle. Patients with complete C1 to C5 tetraplegia are dependent; therefore verbalization of this skill is essential. This verbalization should focus on how to direct the caregiver in shoulder protection techniques. Independence in this skill for patients with low tetraplegic and paraplegic injuries may depend on where the skill is performed (e.g., mat, bed, or wheelchair). Patients with low-level tetraplegia can perform upper body dressing and undressing independently with equipment such as a button hook, hook and loop fasteners (Velcro), or adapted loops. Initially, lower-body dressing is performed in bed (Fig. 14.28) versus the wheelchair because of endurance, strength, and body type issues. Patients with paraplegia are expected to dress with total independence in the bed, but they may need equipment such as a leg lifter or a long-handled shoe horn for dressing in the wheelchair (Fig. 14.29). Mastering dressing in the wheelchair is ideal for independence in the community.¹⁵⁵

Bladder Management

Bladder management includes selecting and performing the bladder program, clothing management, body positioning, setup and equipment cleanup, urine disposal, and body cleanup. Patients often enter the rehabilitation program with an indwelling catheter as their bladder management program. The indwelling catheter should be removed as soon as possible to reduce the risk for chronic UTIs.¹⁴⁹ Following removal of the indwelling catheter, the rehabilitation team implements dependent intermittent catheterizations until the patient gradually takes over their bladder routine. Some patients require more extensive review of their bladder function prior to establishing successful bladder management. In these cases, physicians utilize water or video urodynamic studies to determine the patient's bladder status and to determine optimal bladder training programs.

The neurologically intact individual manages bladder function through the use of sensory messages sent via S2-S4 nerve roots, which triggers a reflex starting a cascade allowing for bladder control. Following an SCI, this communication between the bladder, spinal cord, and

Fig. 14.25 (A) A patient with a C5 spinal cord injury is able to brush his teeth with use of a cuff, adapted long straw, and proper wheelchair positioning at the sink. (B) Patient with C6 spinal cord injury uses bilateral tenodesis to support toothpaste while holding a toothbrush in his mouth.

Fig. 14.26 Sink height can be important in assisting this patient with C6 spinal cord injury to brush his hair.

Fig. 14.28 Patient with low-level tetraplegia maintains balance while performing lower-extremity dressing in bed.

Fig. 14.27 Adjustable height shower and commode chair with 2-inch padded watercrest seat with optional armrest, backrest, and transfer arm.

Fig. 14.29 Early practice when dressing in the wheelchair may involve leaning on a surface to assist with this skill.

brain is disrupted, resulting in one of two different possible bladder presentations based on the level of SCI.

On the basis of injury level, patients have either a reflexive bladder (upper motor neuron lesions) or an areflexive bladder (lower motor neuron lesions).¹¹⁸ The reflexive bladder reflexively empties when the bladder is full. The therapeutic goals for managing the reflexive bladder include low-pressure voiding and low residual urine volumes. The nonreflexive bladder will not empty reflexively and needs to be manually emptied at regular intervals. The goals for managing the areflexive bladder include establishing a regular emptying schedule and continence between emptying. Management of an areflexive bladder includes performance of intermittent catheterizations.¹⁵⁸

Typically, patients with complete C1 to C5 tetraplegia are dependent in their bladder programs. An automatic leg-bag emptier can assist with the elimination component of the bladder skill. The patient will be dependent in the other components of bladder management; therefore verbalization of this skill is essential. Male patients with injuries at C6 level and below have the potential to complete the majority of bladder management. Several factors influence the patient's potential for independence including catheter selection, hand function, body habitus, urethral integrity, and adaptive equipment. Patients with limited hand function often utilize adaptive devices, such as orthoses, to assist with catheter insertion, adaptive scissors to open bladder packages, flip-top openers, and leg bag loops (Fig. 14.30).^{155,159}

Among patients with a paraplegic level of injury, intermittent catheterization is the most commonly used modality. A 2016 study found that patients who were determining how to transition from indwelling catheters to intermittent catheterizations primarily relied on their clinical team to determine the type of catheter and devices for performance.¹⁶⁰ Female patients with paraplegia will most likely need to begin their training in bed with a mirror to obtain the most ideal position. If finger sensation is intact, touch technique can be taught to eliminate reliance on a mirror. The majority of male patients with paraplegia require minimal use of adaptive equipment during bladder management at bed or wheelchair level. Some people with SCI may decide to have a suprapubic catheter placed or a bladder augmentation procedure as a lifestyle choice. Each method of bladder management has advantages and disadvantages requiring patients to balance factors such as the potential for secondary complications from renal and urinary health, convenience, comfort, expense, and quality of life.¹⁶¹

Fig. 14.30 Bladder management supplies may include knee spreader with mirror, sterile catheter kit, catheter inserter, leg bag with tubing and adapter, catheter, “HouseHold” for positioning, bungee cord to hold pants, pants holder, small prelubricated female catheter.

Bowel Management

The goal of bowel management is to have the patient able to predictably induce regular elimination. As described under bladder management, the level of injury will assist in telling if the patient will have either a reflexive bowel or a nonreflexive bowel.¹¹⁸ The bulbocavernosus reflex (BCR) is elicited by pinching the dorsal glans penis or by pressing the clitoris and palpating for bulbocavernosus and external anal sphincter contraction.¹⁶² If the patient has a positive BCR, this is indicative of a reflexive bowel. With a reflexive bowel, tone of the internal and external anal sphincter is present although the patient will not feel the need to have a bowel movement. Voluntary anal contraction and relaxation are not possible, but the nerve connection between the colon and the spinal cord are still intact, allowing the patient to reflexively eliminate stool. This can be done with chemical or mechanical stimulation.¹⁶²

Flaccid bowel programs are much more difficult to regulate because there is no internal or external anal sphincter tone. Timing and diet are critical for the success of this program. A suppository may be required to assist with the process, and in this situation the rectum should be emptied before suppository insertion.¹⁶³ If the established bowel program is not followed consistently, involuntary bowel movements or impaction may occur.

Bowel management training must begin as soon as the patient is medically stable. The components of bowel management include clothing management, body positioning, setup and cleanup of equipment, performance of the bowel program, disposal of feces, and cleanup of self. To establish the most effective bowel training program, the interdisciplinary team must work together. The team will need to discuss patient medications that may affect the bowels, the time of day when the patient plans to perform the program, the physical appropriateness related to scapular strength and endurance, and all equipment that will be used.

Patients with injury above the C6 level will be dependent in performing the bowel program; however, they should be independent in the verbalization of the technique. Patients with limited hand function (C6 to C7) may require a digital bowel stimulator and a suppository inserter with an adapted cuff or splint (Fig. 14.31). In addition, a roll-in shower chair or upright shower or commode chair with a padded cut out in the seat will allow the patient to reach the buttock area to perform the stimulation. For this level of injury, it may be advantageous to perform the bowel program in conjunction with the shower to conserve energy with transfers. For individuals with paraplegia, full independence is expected for completion of all bowel management skills. These programs are typically performed on appropriate

Fig. 14.31 Dil Stick and Suppository Inserter With Adaptive Cuffs.

BOX 14.5 Guidelines for Bowel Program

1. Perform the bowel program at the same time each day.
2. Follow a diet high in fiber (25–35 g recommended).
3. Drink at least 8 glasses of water per day.
4. Drink a hot liquid 30 min before initiating the bowel program.
5. Perform the bowel program in an upright position.
6. Consider premorbid bowel schedule.

bathroom equipment or the bed. Weight shifts and body positioning are essential during the patient's bowel routine to prevent skin breakdown from occurring.¹⁵⁵

To increase the effectiveness of the bowel program the patient should follow the guidelines identified in [Box 14.5](#).

Sexual Health

Sexuality is how people experience and express themselves as sexual beings and is a normal part of being human,¹⁶⁴ so it is not surprising that people with SCI place a high priority on resuming sexual functions after their injury.¹⁶⁵ After SCI, men may experience impairments in penile erection, ejaculation, orgasm, and fertility. Women with SCI may experience impairments in the ability to become aroused or achieve orgasm and/or may have decreased vaginal lubrication.¹⁶⁴ Addressing sexual functions is a high priority for both men and women after SCI.¹⁶⁵ [Table 14.7](#) lists the relationship of the level of spinal injury to sexual function. Treatment of sexual dysfunction should be a coordinated effort among the patient, appropriate health care professionals, and the identified significant other. Sexual counseling, educational programs, and medical management provide opportunities to address the areas of sexual dysfunction, alternative behaviors, precautions, and other related areas.¹⁶⁶

Depending on the level and completeness of the SCI, most men can attain an erection either through psychogenic (via T11 to L2 pathways) or reflexogenic pathways (S2 to S4)¹⁶⁷; however, these erections are often not reliable or adequate for sexual intercourse. The first-line treatment for erectile dysfunction after SCI is the use of phosphodiesterase type V inhibitors such as sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra). Other treatments include intracavernosal

(penile injectable) medications, mechanical methods (e.g., vacuum devices and penile rings), and, as a last resort, surgical penile implants.¹⁶⁴

Male orgasm and ejaculation are likely to occur together; however, after SCI an orgasm may not always lead to ejaculation, or there may be retrograde ejaculation into the bladder.¹⁶⁸ A study by Sipski and colleagues showed that 78.9% of men with incomplete upper motor neuron SCI achieved orgasm as compared with 28% of men with complete upper motor neuron injuries ($P < .001$), whereas 0% of men with lower motor neuron injuries affecting their sacral cord achieved orgasm.¹⁶⁸

“Will I ever be able to become a father?” is a common question of men after SCI. Pregnancy rates in partners of men with SCI are lower than in the general population, but there is a good chance (greater than 50%) that men with SCI can become biological fathers with advances in reproductive assisted technology. Roughly 2 weeks after an SCI, semen quality declines¹⁶⁹ to levels approaching those observed in males with chronic SCI.¹⁷⁰ There is evidence that bladder management with clean intermittent catheterization may improve semen quality over other methods of bladder management.¹⁷¹ The two most common methods of sperm retrieval are vibrostimulation (less invasive) and electroejaculation. These methods are successful for persons with lesions above T10. If these methods are not successful, there is an option of surgical aspiration. Depending on the semen quality, a progression from intravaginal insemination, intrauterine insemination, in vitro fertilization (IVF), to IVF plus intracytoplasmic sperm injection is recommended.¹⁶⁴

Women with SCI require access to integrated care starting with sexual wellness visits, child planning classes, and preconception through postpartum care.¹⁷² Research is currently lacking regarding reproductive aging in women with SCI; what is clear from the literature thus far is the need for women with SCI to receive education regarding the importance of accessing care following injury.¹⁷³ Timing of sexual health education following injury should begin during the rehabilitation process and continue throughout the patient's life. Health care providers need to be mindful to ensure all females receive information on sexual health regardless of age, marital status, and level of disablement following spinal injury or dysfunction.¹⁷⁴

Women need to be educated on how to screen the health care provider for wheelchair access into the clinic, treatment room, and transfer status onto the exam table.^{174–176} A 2013 study found that the subspecialty of gynecology had the highest rate of inaccessible practices.¹⁷⁷ It is up to the rehabilitation team to ensure female patients receive the knowledge necessary to access quality care. For example, pelvic exams following injury should not be performed in the patient's wheelchair since pelvic positioning significantly impacts the quality of a pelvic exam.¹⁷⁸ The therapy team should work with female patients to determine transfer techniques and options, altered positioning for exams, and topics to cover with their health care providers throughout their life-span.

Immediately following injury, amenorrhea may last up to 4 to 5 months. This delay allows health care providers to review menses management techniques without the challenge of discharge. Some women choose to limit menses via pharmacological interventions; others manage with tampons, menstrual cups, pads, or period panties. Careful consideration should be placed on the likelihood of eliciting autonomic dysreflexia, caregiver burden, and skin integrity when determining interventions. Following injury, the women's hand function, lifestyle, comfort, and personal preferences need to be considered to maximize quality of life.

Despite delay in return to menstruation, it is believed that fertility in women is unaffected by SCI.¹⁷⁹ Women need to be educated

TABLE 14.7 Relation of Level of Spinal Injury to Sexual Function

Injury Level	Sexual Function
Cauda equina/conus	Males
	Usually no reflex erections Rare psychogenic erection Ejaculation occasionally occurs
	Females
	Vaginal secretions often absent Patients generally fertile
Thoracic/cervical	Males
	Reflex erections predominate (usually short duration) Psychogenic erections generally absent Ejaculation occasional
	Females
	Vaginal secretions present as part of genital reflex Fertility preserved Sensation of labor pain absent

regarding contraceptive options following injury. Women are able to conceive; however, there are increased risks to pregnancy, which may include bladder problems, spasticity, pressure sores, autonomic dysreflexia, and problems with mobility.^{172,180} As noted previously, women need close collaboration with their health care providers prior to and throughout pregnancy to ensure safety.

In addition to addressing wellness visits following injury, women need specific education regarding intimacy and relationships. Women with SCI may have impairment in arousal and orgasm. The vagus nerves are thought to facilitate the presence of vaginal–cervical perception of orgasm. Preservation of T11 to L2 sensory dermatomes is associated with psychogenically mediated genital vasocongestion and lubrication.¹⁸¹ There is some evidence that supports the use of sildenafil in women to partially reverse subjective sexual arousal difficulties.¹⁶⁴ For women who have a lower motor neuron lesion, vaginal secretions are often absent, and an artificial lubricant is recommended. Safe transfers, positioning, and devices should be reviewed to ensure sexual function, responsiveness, and expression needs are met. It is important that health care providers maintain professional boundaries when addressing sexual issues and consider the age of injury onset, previous sexual experiences, and baseline sexual knowledge. Sexual education and counseling should occur in accordance with patient-centered care.¹⁸²

Home Management

Home management may be divided into two components: light home management and heavy home management. Light home management includes managing money, preparing a snack in the kitchen, doing laundry, and making the bed. Heavy home management includes shopping for groceries, preparing a complex meal in the kitchen, dusting, and vacuuming. The clinician should discuss the role the patient would like to assume at home. The patient may want to resume previous home management roles or may want to discuss changing roles with a family member or caregiver to have energy for other skills.

Patients with C1 to C5 tetraplegia will be dependent in home management. Patients with limited or no hand function will need adaptive kitchen devices, adapted utensils, and adapted cleaning equipment. Preplanning activities may be essential for independent function with patients at all levels of injury. Patients with hand function may require extended handles on equipment and must incorporate energy conservation techniques.

Parenting

Research has shown the importance of parenting behavior and attitude on children's ability to adjust to various circumstances. However, this adjustment is not affected by the disability status of a parent.^{183,184} Patients with C1 to C5 tetraplegia may be dependent in the physical aspects of parenting. Patients with low-level tetraplegia are able to participate in the more physical aspects of parenting with some level of adaptations, such as a wheelchair-accessible table with sides to change an infant.¹⁸⁵ Parenting skills for a patient with paraplegia depend on the environment and the specific activity being performed as well as the mobility of the individual. Therapists can provide advice and ideas to assist with the selection of parenting and baby equipment as well as being a resource in discussing and adapting equipment options such as slide-down cribs, adjustable-height high chairs, carrying slings or supports, and baby strollers that can be more easily pushed with one hand.^{185,186}

Assistive Technology

AT can be helpful in letting people resume more independent lives in areas of self-care, work, and recreation. AT is defined by the 1998 Technology-Related Assistance for Individuals with Disabilities Act

(Public Law 105-394). It defines AT devices as “any item, piece of equipment, or product system, whether acquired commercially, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities.” Hedrick and colleagues¹⁸⁷ found that in both civilians and veterans the most frequently used AT devices were (1) manual mobility and independent living devices (e.g., manual wheelchairs, manual exercise equipment, manual motor vehicle control devices, such as a steering knob, walkers, and reachers); (2) powered mobility and independent living devices (e.g., power lifts, power doors, motorized wheelchairs, power-assisted motor vehicle operation devices); (3) prosthetics and orthotics (static and dynamic, e.g., splints, mentioned earlier); (4) alternative computer access devices, which may be as simple as a typing splint to as complex as brain control; and (5) speech-generating devices, formerly known as *augmentative and alternative communication devices*.

Many specialty facilities that treat large numbers of SCI patients will have specialized therapists called Assistive Technology Practitioners (ATPs), Seating and Mobility Specialists (SMS), Certified Driver Rehabilitation Specialist (CDRS), and/or AT departments to specifically assess, select, and train in the use of device(s)—specifically seating, driving, and electronic access.¹⁸⁸ ATPs have a broad scope of practice regarding technology implementation for consumers with disabilities. ATPs, SMS, and CDRS demonstrate extensive experience in each specialty field, pass certification exams, and may come from many backgrounds including rehabilitation, education, and engineering.

Not every team has access to someone with a specialized certification; thus consideration should be given by the primary therapist in the evaluation phase to include what are the patient's primary needs at this time and moving forward for safety, quality of life, and independence. For example, when considering the wheelchair, a therapist must first consider the physical needs of the patient and then look at the environmental context. Considering where the patient will use the chair and how it will get there, looking at the “big picture” rather than only the mobility device is essential for success. How will the wheelchair be transported? Can the wheelchair be locked down so the patient may drive in a van or be a dependent passenger? Can the patient load the manual chair into his or her car (Fig. 14.32)? All of these details need to be considered as the patient makes a final decision on chair type and specialization.

There are specially trained practitioners called *driving rehabilitation specialists* who specialize in recommending equipment and transportation of the patient as a passenger in addition to providing driver education and driver training. They help to evaluate and to assist with making correct vehicle modifications and adaptive equipment choices for the patient as a driver. There are over 700 specialists who identify as driving rehabilitation specialists represented in the United States and Canada. Certified Driver Rehabilitation Specialist Certification (CDRS) is a credential offered by the Association of Driver Rehabilitation Specialist (ADED) representing advanced experience and expertise in diverse areas within the field. Those that hold a CDRS credential have passed a formal certification exam, have proven their capacity for providing the full spectrum of driver rehabilitation services, are held to the ADED Best Practice Guideline and Code of Ethics, and recertify every 3 years. Currently there are 370 active CDRS in the United States and Canada. A professional can be found on the Association for Driver Rehabilitation Specialists.^{189,190}

When considering a sedan, these specialists will evaluate the patient to see how he or she operates primary and secondary vehicle controls, opens and closes the door, transfers into the vehicle, and stores, secures, and retrieves the wheelchair. If the patient is unable to perform any of those tasks, then a van may be an option. Modifications

Fig. 14.32 Car Transfer. Most patients with a paraplegic level of injury are modified independent (FIM level 6) in the performance of a car transfer. The patient approaches the car on the driver's side and opens the door. **(A)** After stabilizing the wheelchair, he may place his foot or feet into the car or leave them on the footrest or the ground. **(B)** He performs a depression-style transfer onto the seat of the car; **(C)** positions his lower extremities appropriately inside the car; and **(D)** prepares to get the wheelchair into the car by removing the wheels (quick release) and cushion and placing these on the floor in the front passenger area or in the back seat. **(E to G)** The rigid model of the wheelchair is folded and transferred across the patient onto the passenger seat. Transferring out of the car is the reverse process, beginning with getting the wheelchair out of the car and reassembling it.

can allow a person to transfer to the van's driver seat or to drive from the wheelchair. The driving control technology that is available to compensate for reduced strength or ROM includes steering systems, hand controls, and reduced effort and zero effort steering and braking. The rehabilitation specialist will provide a comprehensive evaluation to determine the patient's ability to drive. That evaluation will consider visual, perceptual, and functional abilities as well as reaction time and behind-the-wheel assessment. In both sedan and van selection, it is always best to recommend that the patient consult the driving rehabilitation specialist before purchasing and modifying the vehicle.

Technology is ever changing; therefore the patient may need assistance to access many electronic devices, such as computers, digital readers, televisions, lights, call systems, cell phones, music systems, and smart home systems. Many patients require extensive assistance to understand and integrate their task-specific products into their smart

home devices. Smart home devices fall under the blanketed domain of home automation or domotics.¹⁹¹ From 2011 to 2016 the market experienced rapid growth in the domain of home automation with the first devices with full voice activation hitting the market. Both phone and home speaker systems allow for one touch or voice activation for device use following set up. Despite significant improvements in access with these advances, patients with diaphragmatic compromise, dysarthric speech, poor dentition, and/or consonant deletion due to a regional accent struggle with voice activation and commands. As smart home systems progress for the general population, the cost of device and versatility of the products improve for individuals with disabilities. Although working toward home automation can be the goal for those with disabilities, the professionals assisting with device set up and maintenance need to consider the unique challenge of integrating devices across platforms. Patients need to be educated regarding how to

troubleshoot their home automation systems, who to contact if issues occur, and vulnerabilities that may result from one device updating when others do not.

The most popular and inexpensive way to access a computer is speech recognition software. For patients who are unable to utilize voice activation with a computer, dexterity is required to operate many standard devices. There are off-the-shelf adaptations using universal designs to enable persons with limited dexterity to use technology, including touch screen or keyboard on screen allowing for pointer and mouth-stick use. A person with a higher tetraplegic level of injury can use alternative methods to access a computer, such as pneumatic controls (sip-and-puff devices), eye gaze system, or bite-switch options.¹⁹² Shortcut keystrokes are a way for most users to limit the burden of keyboard use while also eliminating the need for a mouse.

Often considered a “last-choice communication system” it is important to note that Brain-Computer Interfaces (BCIs) have advanced significantly in since 2014. BCIs translate brain signals into computer commands in real-time via electroencephalographic signals, magnetoencephalography, electrocorticography, intracortical microelectrode recording of action potentials, or through imaging such as functional magnetic resonance imaging, or functional near-infrared spectroscopy.¹⁹³ The *Journal of Brain-Computer Interface* published its first issue in 2014, and the journal continues to report on a broad range of BCIs that replace, restore, enhance, supplement, or improve brain output.¹⁹³ At this time, the majority of BCI studies have focused on proof-of-principle; whereas actual BCI use has been limited to a handful of case studies. Investigators note that the most promising area of BCI use is not in-home computer access or home automation, but instead it is part of neurorehabilitation.

It is easy for therapists to become swept up in the latest technology when determining how to improve their patients’ access and quality of life. When introducing AT and adaptive equipment to the patient, therapists should focus on utilizing the most basic form of technology with the shortest learning period. Often, patients are introduced to and utilize technology for a limited time before moving into different equipment or attempting to complete a task in a new way. For example, patients with C3 to C4 injuries, depending on neck strength and ROM, can use equipment such as mouth sticks for pushing cell phone buttons from the wheelchair in addition to the head rest buttons or a sip-and-puff switch (Fig. 14.33). Patients with C5 injuries begin to use their biceps, deltoids, and internal and

Fig. 14.33 Mouth stick writing can be accomplished with the patient upright in the wheelchair and with the support of a bedside table and bookstand.

external rotator strength to interact with their environment. Positioning of the buttons, devices, or mounts for devices is important for these patients, who may or may not be using an MAS. Adaptive splinting for support at the wrist can allow these patients to use their upper arms in writing, typing, turning pages, and using computers (see Fig. 14.13). Patients with wrist function but no finger function can use utensil holders with a pointer to “dial” a phone number, for example, or can use their natural tenodesis to grasp and manipulate objects. For injuries at the T1 level and below, interaction with the environment in all areas should be independent.

Additive Manufacturing

Commonly referred to as 3D printing, additive manufacturing (AM) is the creation of an object by building it layer by layer. AM printers have become more accessible in hospitals and clinics as AM printer price decreases, size varies, and production quality improves.¹⁹⁴ AM allows for complete freedom in design through the use of computer aided design (CAD) software that works by scanning the patient to allow for device creation based on their unique characteristics.¹⁹⁴ The CAD software divides the computer generated object into layers. The AM machine then prints out each layer of the device in the material selected by the creator. AM is currently used in rehabilitation for individuals following SCI for orthoses, prostheses, and AT fabrication.

Preliminary studies of AM fabrication devices in rehabilitation highlight the use of this technology for complete customization, rapid manufacturing time, and an inexpensive durable material. A 2014 feasibility study revealed that an AM created prosthetic hand cost \$50 to fabricate, compared to the traditionally obtained device, which cost over \$4,000.¹⁹⁵

It is important to note that AM does not have a developed reimbursement model at this time, due to perceived issues in quality control between products, risk management, and liability. All of these topics require investigation before insurance authorization standards are established. Despite the lack of funding, AM is beginning to be widely used in the rehabilitation model as a cost effective and personalized solution to orthoses, prostheses, and AT fabrication.

Mobility

Bed Mobility and Coming to Sit

The components of bed mobility include rolling side to side, rolling supine to prone, coming to sit, and scooting in all directions while either long or short sitting. Initial training for bed mobility is usually conducted on the mat, as it is easier to learn on the firmer surface. When skills on the mat are mastered, the patient can be progressed to a less firm surface, such as the bed. Bed mobility is a challenging skill for patients with tetraplegia to learn because of their limited upper-extremity strength (see Fig. 14.21A to C).^{55,118,196} To accommodate the loss of upper-extremity musculature, compensatory strategies and assistive devices, such as bed loops, may be used (see Fig. 14.21F to I). Patients with paraplegia often master bed mobility skills quickly and much more easily than patients with tetraplegia because of their intact upper-extremity musculature.^{55,118}

Pressure Relief in the Upright Position

The patient with high tetraplegia achieves independent pressure relief in the wheelchair through appropriately prescribed specialty controls. For example, a pneumatic control switch may be used to activate the tilt mode of a power wheelchair (Fig. 14.34). When the patient is unable to operate a specialty switch, an attendant control may be used. When powered options are not feasible because of cognitive deficits, financial limitations, or other reasons, a manual recliner (Fig. 14.35A)

Fig. 14.34 The pneumatic control (sip-and-puff straw) is usually ordered on a power reclining or tilt-in-space wheelchair for patients with injury levels above C6. The straw is removable, and several are supplied with the wheelchair. The straw is attached to a flexible arm, and it is adjustable to different heights and angles to fit the needs of the patient.

or tilt wheelchair (see Fig. 14.35B) is recommended. When patients are dependent in performing pressure relief, they can be taught to instruct others in this skill. Patients with mid- and low-level tetraplegia are taught to perform a side or forward lean technique for pressure relief if the strength of the shoulder musculature is appropriate (Fig. 14.36). Traditionally, patients with paraplegia are often taught to perform pressure relief by performing and maintaining a pushup (depression) (Fig. 14.37). However, evidence suggests that the use of alternative methods should also be encouraged for these individuals because they may considerably reduce upper limb (UL) mechanical loads while being just as effective.^{197,198} It is important for individuals with SCI to reduce UL loads whenever possible in order to preserve UL function and prevent overuse injury. The forward lean and side to side methods of performing a weight shift have been proven to be effective alternatives to a depression pressure relief in order to preserve skin and soft-tissue integrity among individuals with SCI.^{197,198}

The appropriate time to maintain the change in position is usually 60 seconds at intervals of 30 to 60 minutes. The treatment plan should include instructing the patient in ways to ensure that the schedule for pressure relief is maintained in all settings. The use of watches, clocks, timers, and attendant care may be necessary.

Wheelchair Transfers

The physical act of moving oneself from one surface to another is described as a *transfer*. Wheelchair transfers may be accomplished in many different ways. The type of transfer used by a patient is determined by the injury level, residual limb function, assistance needed, patient preference, and safety of the transfer. When performing transfers, both the patient and the person assisting must give attention to the use of appropriate body mechanics.

Dependent transfers may be accomplished with an electric (power) patient lift, manual hydraulic patient lift, manual pivot, transfer board, or manual dependent lift, which may require two or three people. A transfer using an overhead power patient lift is the least physically challenging for the caregiver; however, these lifts are costly and are not

A

B

Fig. 14.35 (A) The manual reclining wheelchair is a piece of durable medical equipment that is prescribed on a temporary or a permanent basis. The back of the wheelchair fully reclines, and the legrests elevate to allow for effective pressure relief while the patient is out of bed. Other features of the wheelchair are desk armrests, which may be adjustable in height; a removable headrest; and removable legrests. The wheelchair folds and may be transported in a vehicle. (B) The manual tilt in space wheelchair is an alternative to the manual reclining wheelchair and may be preferred especially in cases where increased muscle tone in hip extensors is present. The 90/90 hip position is better maintained in this wheelchair, which can decrease the need for repositioning.

A

B

Fig. 14.36 (A) Pressure Relief: Side Lean. The tetraplegic patient with a C6- to C7-level injury may use a side lean to achieve pressure relief over the ischial tuberosities. The patient hooks one upper extremity around the push handle or back post of the wheelchair on one side and leans away from the hooked upper extremity until the ischium on the hooked side is clear of the wheelchair cushion. The position is maintained for 1 minute and repeated on the other side. **(B) Pressure Relief: Forward Lean.** The forward lean method of pressure relief is used for many different injury levels. The subject must have adequate range of motion at the hips and in the lumbosacral spine to allow the ischia to clear the wheelchair cushion at the end range position.

easily transportable. The use of a manual hydraulic patient lift may be desirable if funding is not available for a power lift or the transfer needs to be done in an outdoor environment (i.e., car transfer). However, the hydraulic patient lift may not be the method of choice due to bulkiness, difficult storage, and transport. Pivot transfers or manual lifts may be used based on patient/caregiver preference or when

Fig. 14.37 Pressure Relief: Depression. This method of pressure relief is consistent with a full pushup in the wheelchair. Most patients with a paraplegic level of injury and some patients with a low tetraplegic injury level are able to perform this method of pressure relief.

patients are smaller in stature and other, more costly, lift systems are not available to the individuals.

Transfers can be performed with the use of a transfer board, depression style, or via the stand or squat-pivot method. The mechanics of teaching an assisted transfer to a patient with C7 tetraplegia is depicted in Fig. 14.38. To use compensation for movements such as transfer, momentum forces create movement by teaching patients to swing their head in the opposite direction from where they want the hips to go. Also, head and eye gaze relationships are important for balance and rolling whereby arm swing creates momentum and the body will follow the eyes and head when learning this skill. The patient is taught to position the wheelchair, position the transfer board, use correct body mechanics to get the best leverage to effect movement in the desired direction, remove the board, and position his or her body appropriately.^{55,199}

Wheelchair transfers are performed on many different surfaces. The training procedure begins with the easiest transfer and progresses to the more difficult transfer. Instructions for wheelchair transfers usually begin on level surfaces and progress to uneven surfaces as individual strength and skill allow.⁵⁵ Given these two principles, the following list is an example of how one might proceed with transfer training:

1. Mat transfer (see Fig. 14.38)
2. Bed transfer

Fig. 14.38 Wheelchair to Mat Transfer Using a Transfer Board. **(A)** The patient positions the wheelchair at a 20- to 30-degree angle to the surface to which he is transferring and positions the board with or without assistance. **(B)** The patient moves forward in the wheelchair to clear the tire in preparation for lateral movement on the transfer board. **(C)** To achieve the appropriate mechanical leverage, the patient is instructed to twist the upper body and look over the trailing shoulder **(D)**. He pushes and lifts to affect movement across the board. **(E)** When the patient has achieved a safe position on the transferring surface, the transfer board is removed. **(F and G)** The patient is helped to get his feet onto the surface.

3. Toilet transfer
4. Bath transfer
5. Car transfer (see Fig. 14.32)
6. Floor transfer (Figs. 14.39 to 14.41)
7. Other surfaces (e.g., armchair, sofa, theater seat, and pool)

Wheelchair Mobility Skills

Instructions in the safe and appropriate use of the wheelchair may begin before getting the patient out of bed by orienting the patient to the wheelchair and its component parts.

Ideally, a power reclining or tilt wheelchair is supplied for patients with C1 to C5 tetraplegia to promote maximal independence. The most common drive-system options available for these patients include, but are not limited to, chin drive, pneumatic systems (see Fig. 14.34), and head control (Fig. 14.42). A patient with mid- to low-level tetraplegia may be instructed in the use of both power and manual upright wheelchairs. The patient with paraplegia is instructed in the use of a manual upright wheelchair unless there are extenuating

circumstances. For example, a power wheelchair is appropriate for a patient who is 50 years old and has severe rheumatoid arthritis.

There are wheelchair options that combine the benefits of a manual wheelchair with a power-assist component (Fig. 14.43).²⁰⁰⁻²⁰² This option may be best suited for patients who have some upper-extremity weakness, joint degeneration, upper-extremity pain from propelling a manual wheelchair, or reduced exercise capacity or endurance. This type of wheelchair could potentially delay secondary injuries of manual wheelchair users. Both power and manual wheelchair mobility training begins on level surfaces. When a patient is instructed on how to propel a manual wheelchair, it is suggested that a semicircular pattern be used to reduce the trauma to the UEs. Wheelchair gloves are beneficial in reducing friction over the palms of the hands during propulsion (Fig. 14.44). Research evidence is available that demonstrates the safety and superior efficacy of a formal approach to wheelchair skills training of wheelchair users and their caregivers. The Wheelchair Skills Program is one example of such a program and is available free on the Internet.²⁰³ This program includes useful evaluation

Fig. 14.39 Floor Transfer. The independent performance of a floor transfer is a goal for most patients who have a paraplegic level of injury. The patient may use different techniques to get onto the floor. Forward floor transfer: **(A)** The patient positions his feet off the footrest and moves forward onto the front edge of his cushion. **(B)** He reaches for the floor, first with one hand then with both, and **(C)** lowers his knees to the floor. **(D)** He advances his hands forward until his body is clear of the wheelchair.

Fig. 14.40 Floor Transfer Sideways. After moving to the front of the wheelchair seat, **(A)** the patient leans to the left and reaches for the floor and **(B)** shifts his weight toward the left arm. **(C and D)** He balances his weight between both arms and in a very controlled manner lowers his body to the floor.

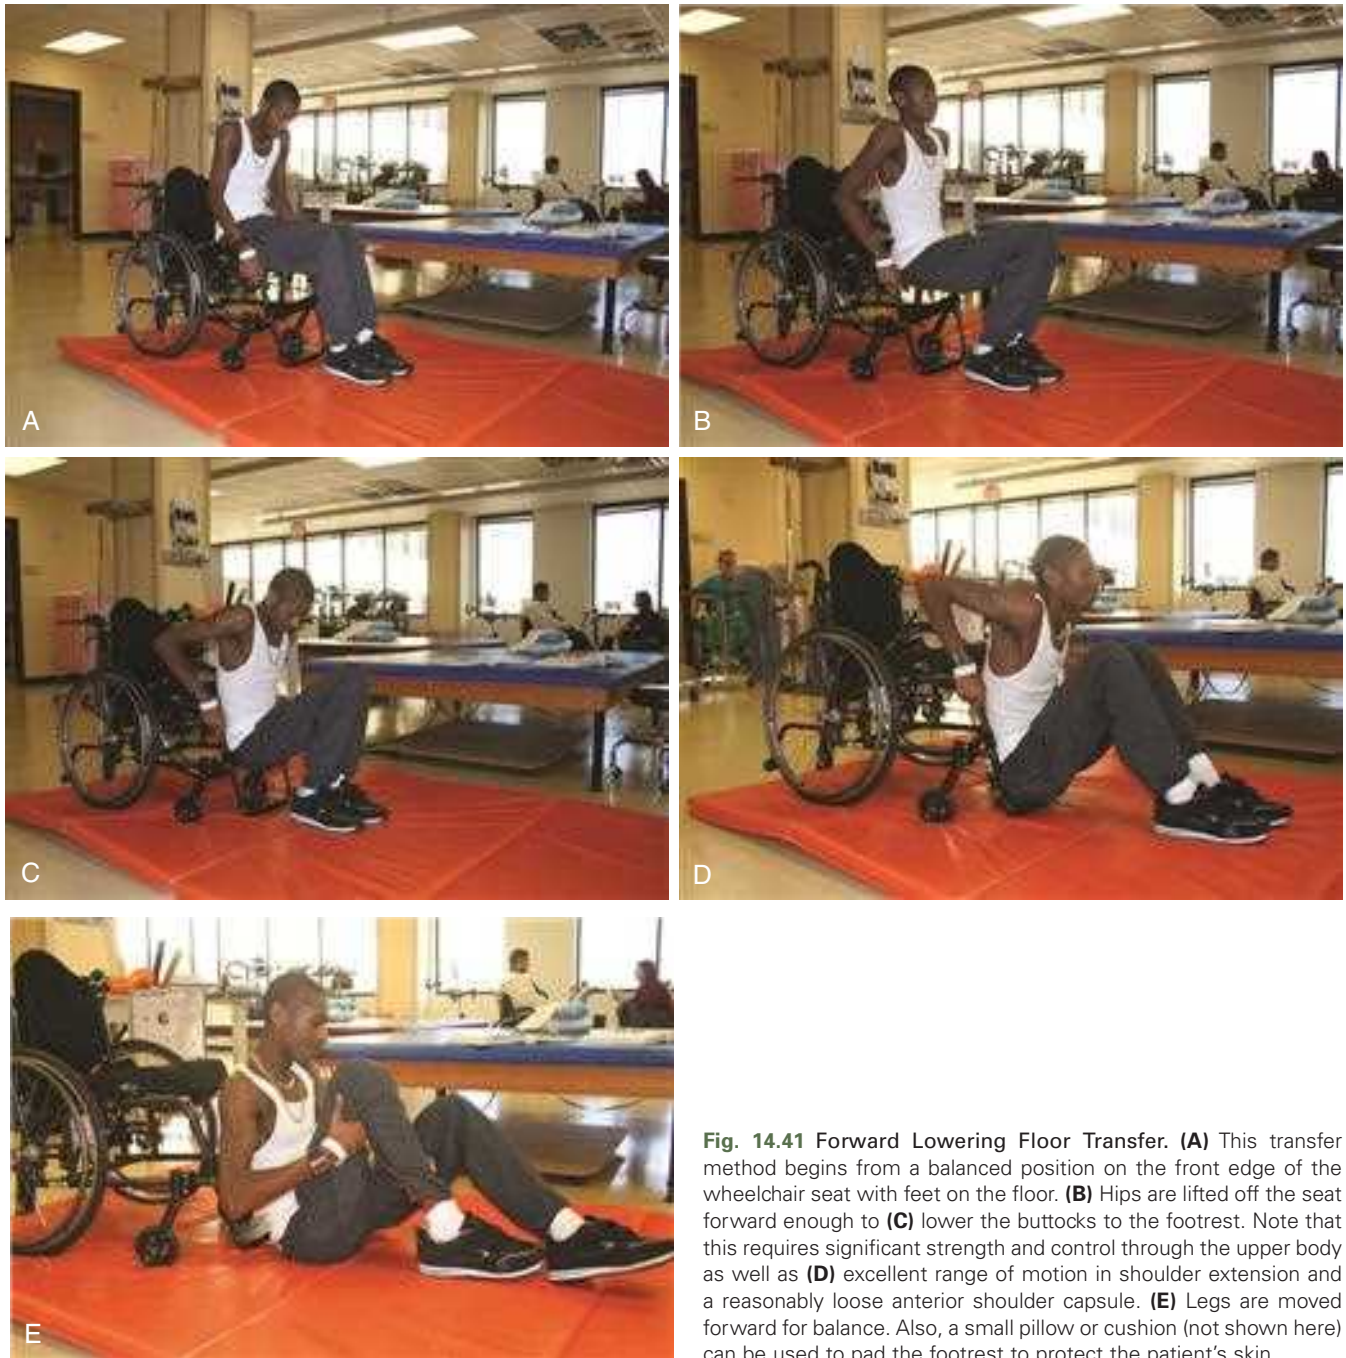

Fig. 14.41 Forward Lowering Floor Transfer. (A) This transfer method begins from a balanced position on the front edge of the wheelchair seat with feet on the floor. (B) Hips are lifted off the seat forward enough to (C) lower the buttocks to the footrest. Note that this requires significant strength and control through the upper body as well as (D) excellent range of motion in shoulder extension and a reasonably loose anterior shoulder capsule. (E) Legs are moved forward for balance. Also, a small pillow or cushion (not shown here) can be used to pad the footrest to protect the patient's skin.

and training tools to help practitioners translate this research evidence into clinical practice.^{204,205}

Wheelchair mobility training may progress toward more difficult skills as follows:

1. Mobility on level surfaces in open areas
2. Setup for transfers
3. Mobility in tight spaces
4. Mobility in crowded areas
5. On and off elevators
6. Up and down ramps
7. Through doors
8. Wheelies (Fig. 14.45)

9. Negotiation of rough terrain

10. Up and down curbs and steps (Figs. 14.46 and 14.47)

Equipment

In SCI rehabilitation, the use of equipment is necessary to achieve the expected outcomes. Clinicians work closely with the physician and other team members, including the rehabilitation technology supplier, to determine the most appropriate equipment to meet individual needs. It is important to have access to trial equipment so the patient has the opportunity to practice with equipment similar to what will be prescribed. Ideally the rehabilitation technology supplier should be accessible to the rehabilitation team to allow for necessary adjustments

Fig. 14.42 Head array is a headrest and head control for driving wherein the position of the head activates the drive control of the wheelchair. It is appropriate for persons with high cervical injuries. The head array switches can be adjusted to the individual's specific needs relative to their active range of motion and control of their head. The switches are embedded in the headrest panels and not only control driving but can also control the activation of other devices for environmental control. The side panels of the headrest can be straight or curbed depending on the needs of the patient. Additionally, the head array can be sized for either adult or pediatric patient.

Fig. 14.43 Smartdrive. Courtesy of Permobil.

to the equipment. In addition, rehabilitation technology suppliers should be knowledgeable and responsible for educating rehabilitation professionals regarding new products. When possible, all equipment should be ordered from a single supplier to reduce confusion when the need for repairs arise. To ensure that the most appropriate piece of equipment is prescribed, the following must be considered: durability, function, transportability, comfort, cost, safety, cosmesis, and acceptance by the user.²⁰⁶ Generally, the higher the injury level, the more costly the equipment based on the technology involved. [Table 14.8](#) lists equipment according to injury level.

Fig. 14.44 Para Push Gloves. Wheelchair gloves, mesh back, open fingers, and leather-padded palm. Usually appropriate for patients with paraplegia-level injuries. Available from multiple suppliers.

Fig. 14.45 A wheelie is a functional mobility skill that enhances functional independence. The performance of a wheelie is a precursor to negotiating steep ramps, curbs, steps, and rough terrain.

Equipment should be ordered as soon as possible so the patient can be fitted before discharge. Shorter lengths of stay make early equipment ordering difficult. For example, a patient may not have 3/5 wrist extension to be fitted with a tenodesis brace but with strengthening over time would be an excellent candidate. Clinicians need to negotiate

Fig. 14.46 (A) Descending a curb is an advanced wheelchair mobility skill. This man with AIS A, T12 paraplegia assumes the balanced wheelie position and approaches the curb in a forward position. The wheelie position is maintained as he rolls off the curb. **(B)** Climbing a curb with assistance is also an advanced skill. This is the same man as in A. He “pops” into a wheelie and advances his wheelchair to move his casters up onto the curb. He then reaches back to his wheel, leans forward, and pushes as the helper assists by lifting the back of the chair. A more advanced skill would be to perform this activity by approaching the curb with speeds fast enough to gain momentum, “pop” a wheelie, and advance up and over the curb in one continuous movement (not shown). The curb height, strength, level of injury, and body composition of the patient are determining factors for speed requirements.

Fig. 14.47 Descending Steps Using One Handrail. This patient with AIS A, level T12 approaches the steps backward, using the handrail on his right with both hands, and lowers himself down three steps. This is one of several methods that may be used to negotiate steps.

with the funding source so that equipment may be ordered in the outpatient setting. Equipment required for the SCI population is costly and requires extensive review by third-party payers before funding is approved or denied. Many health care policies do not cover the funding of needed equipment. As a result of these factors, many patients are discharged without the equipment they need. Lack of appropriate equipment may result in (1) a feeling of loss of control, (2) contractures and postural deformities, (3) skin breakdown, (4) a loss of skills learned in rehabilitation, (5) poor self-image, and (6) increased dependence on others.^{55,207}

Seating Principles

Many individuals spend 8 to 12 hours or more per day in their wheelchairs after an SCI. Consequently, proper seating of these patients may be the most important intervention clinicians provide. The seating process should be addressed on admission, continually throughout the rehabilitation program, and regularly after discharge to help prevent and minimize complications. The wheelchair is an integral part of the patient’s self-image and in many ways will help define personal

TABLE 14.8 Equipment Needs Correlated to Injury Level

Injury Level	Equipment	Cost (in \$)	Injury Level	Equipment	Cost (in \$)
C1–C3	Ventilator (bedside)	8,000–12,000		Mobile arm support	500–1,000
	Ventilator (portable for wheelchair)	8,000–12,000		Upper-extremity orthotics	700–1,200
	Power tilt or recline wheelchair	17,000–26,000	C6	Power upright wheelchair	7500–20,000
	Manual recline wheelchair for transport	2,000–3,000		Manual wheelchair	2,000–6,000
	Wheelchair cushion	450–600		Power assist wheels (Fig. 14.63)	6,000
	Reclining commode or shower chair	2,500–4,000		Wheelchair cushion	450–600
	eADL control devices (TV, lights, fans)	400–1,000 (less if you have voice)		Bedside table	225
	eADL (thermostat, door locks, and openers)	200–7,000		ECU	6,000–1,0000
	ECU	6,000–10,000		eADL as listed above	
	Call system	100–500		Electric hospital bed	2,000–4,000
	Bedside table	225		Specialized mattress	800–10,000
	Fully electric hospital bed	2,000–4,000		Commode or shower chair	500–1,500
	Specialized mattress	3,500–4,0000		ADL equipment	900–1,500
	Access to a computer–accessories	1,000–2,000		Tenodesis splint	1,700
	Computer and accessories	1,500–3,000		Transfer board	100–200
	Communication devices	5,000–20,000	Hand control for car	500–2,500	
	Overhead power lift	6,000–15,000	Bowel-bladder equipment	125–250	
	Hydraulic lift for transfers	1,200–2,000	C7–C8	Power upright wheelchair	7,500–15,000
	C4–C5	Power tilt or recline wheelchair		17,000–26,000	Manual wheelchair
Manual wheelchair for transport, i.e., K-4		1,500–2,000		Wheelchair cushion	450–600
Lap tray		500–1,000		Bedside table	225
Wheelchair cushion		450–600		ECU	250–1,000
Bedside table		225		Electric hospital bed	2,000–3,000
ECU		6,000–10,000		Specialized mattress	600–10,000
eADL control devices (TV, lights, and fans)		75–1,000		Commode or shower chair	1,500
eADL (thermostat, door locks, and openers)		200–7,000	Hand controls for car	300–1,500	
Call system		100–500	ADL equipment	300–1,000	
Fully electric hospital bed		2,000–4,000	Transfer board	100–200	
Specialized mattress		3,500–40,000	Bowel and bladder equipment	125–250	
Commode or shower chair		1,500–3,000	Paraplegia	Manual upright wheelchair	3,500–4,000
Communication devices		5,000–20,000		Wheelchair cushion	450–600
Access to computer (accessories only)		1,000–2,000		Raised or padded commode seat (cutout)	200–400
Access to computer (computer and accessories)		1,500–3,000		Tub bench	220
Call system		100–500		Hand controls for car	500–1,000
ADL equipment		400–1,400		ADL equipment	100–300
Hydraulic lift for transfers		1,400–2,000		Bowel and bladder equipment	50–250
Overhead power lift		4,000–15,000	Lower-extremity orthotics (if ambulation is a goal)	4,000–6,000	
Overhead power lift (not in ceiling)	4000–5000

lifestyle.²⁰⁸ Goals for seating the patient with an SCI are identified in Box 14.6.

Every seating session begins with a thorough examination, as described earlier. Trial simulations are essential to determine how the patient will function and maintain posture over time in the seating system. Simulations help to avoid costly mistakes. The patient must be involved in the decision making process to ensure that the seating system will work.

Individuals with SCI are at high risk of pressure injury due to lack of mobility and impaired sensation. Great care should be taken to reduce pressure over bony prominences and to distribute pressure over as large an area as possible or to offload the pressure from the bony prominences.²⁰⁹ Pressure-distributing or off-loading cushions should be evaluated clinically and with pressure-sensing devices to determine the optimal wheelchair cushion for each individual.

BOX 14.6 Goals for Seating the Patient With Spinal Cord Injury

1. Maximize functional independence
2. Improve pressure distribution and relief of pressure
3. Optimize comfort
4. Enhance the quality of life
5. Optimize good postural alignment and sitting balance
6. Compensate for fixed deformities
7. Allow for transportation of the mobility system

The following are basic seating concepts of proper postural alignment:

- Neutral pelvic alignment
- Symmetrical alignment of the trunk and neck
- Neutral head positioning over the pelvis
- Maintenance of a horizontal gaze
- Maintenance of ankle in neutral alignment with full support of the foot
- Maintenance of the thighs in neutral abduction and adduction with full contact with the cushion
 - Neutral shoulder positioning to avoid shoulder elevation, protraction, or retraction and to provide adequate upper-extremity support.²⁰⁸ Elbow angle that approximates 100–120 degrees when the hand is resting at the top of the wheel or pushrim.²⁰²

Many patients with muscle paralysis of the trunk find that the effects of gravity in a sitting position pull the head and upper torso forward and over the pelvis, resulting in a long kyphosis or a C-curved posture (Fig. 14.48).²¹⁰ Two resulting problems are increased weight bearing on the sacrum and development of a thoracic kyphosis, leading to neck hyperextension in an effort to maintain a horizontal gaze.^{208,210} This position is also assumed by patients to improve their balance. This occurs when the seat-to-back angle is closed and the patient feels as if he or she is falling forward. Unfortunately, this poor sitting posture is quickly learned and difficult to correct. This posture can often be prevented by tilting the wheelchair slightly backward while maintaining a fixed seat-to-back angle (Fig. 14.49). In this position, the effects of gravity augment sitting balance and facilitate good spinal alignment. Education regarding proper positioning, the use of a sacral block, a firm wheelchair seat and back, and properly applied pelvic positioning devices also aid in preventing the kyphotic posture.

Asymmetrical muscle strength, asymmetrical spasticity, and preferential use of one UE over another often result in poor trunk alignment. The use of lateral trunk supports, lateral pelvic supports, and properly applied seat belts may aid in maintaining a symmetrical trunk posture.²⁰⁸

Strong muscle spasms, combined with the effects of gravity, may cause the person with severely impaired mobility to slide down in the wheelchair, resulting in increased pressure on the sacrum and shearing of the skin. For these patients, a manual wheelchair with adjustable seat and back angles can be used to improve stability. Power wheelchairs with power tilt systems allow users to reposition themselves and use the power tilt for improved stability.

Optimal pressure distribution is achieved by maximizing the surface area, allowing immersion into the seat cushion, and promoting a symmetrical posture. The width of the seat should be equal to or slightly more than that of the widest body part, with recent weight changes, body type, and other factors taken into consideration. The seat depth should come within 1 to 2 inches of the popliteal fossae, except when it interferes with LE management of the wheelchair; that is, foot propulsion. The height of the back should reflect the patient's motor function and seated stability. If the back is too high, it can create postural instability and restrict functional activities such as wheelchair

Fig. 14.48 Example of Typical Kyphotic C-Curve Posture in the Patient With Tetraplegia.

propulsion and wheelies. Patients with tetraplegia who use the push handles of the wheelchair to hook while performing functional activities may require custom modification of the wheelchair back (Fig. 14.50).

The size, weight, and portability of the wheelchair seating system affect the individual's lifestyle. The patient's home or work environment must be evaluated closely for accessibility so the wheelchair seating system can be used effectively in those environments. The buildings must be structurally sound and spacious to accommodate heavy-power wheelchair systems. The means of transportation of the wheelchair (car vs. van) may determine whether a rigid or folding wheelchair frame is indicated. Transit options and tie-down systems must be considered for safe transportation. The manual wheelchair must be adjusted to make it as efficient as possible to propel to reduce stress on upper-extremity joints. Many manual wheelchairs are lightweight (less than 35 pounds) and have multiple adjustments and choices of tires and casters, which make manual wheelchair propulsion more efficient. Reducing rolling resistance, positioning the rear axle for maximum propulsion stroke efficiency, and teaching efficient propulsion techniques reduce shoulder musculature fatigue and upper-extremity injury. Rear wheel size and rear seat to floor height should be selected so that when the wheelchair user is seated, he or she is able to touch the rear axle with the middle finger. This position increases the range of contact during propulsion. In addition, shifting the distribution of the user's weight back over the rear axle (usually accomplished by moving the rear wheel axle forward) reduces the percentage of weight on the front casters, making propulsion more efficient.^{204,211} This adjustment reduces the rear stability of the wheelchair, so the use of anti-tip bars and/or training in wheelie maneuvers is essential.

Fig. 14.49 Example of Corrected C-Curve Posture.

Fig. 14.50 Example of custom modification of a wheelchair back to allow a patient with tetraplegia to hook the push handle with one upper extremity.

Finally, along with wheelchair fit, the esthetics of the wheelchair can affect the individual's self-image and therefore the reentry into the community. This should be considered when assisting the patient to make wheelchair seating decisions.

Return to Walking

“Will I ever walk again?” is a question often asked during SCI rehabilitation. The team must be empathetic toward and acknowledge the patient's goals for ambulation, and the topic should be discussed openly. The professionals involved in the care of the patient must be careful not to take hope away from the patient as hope is important to maintain positive outcomes and coping skills during the rehab phase. It is also important for clinicians to consider the potential for continued recovery of function when addressing ambulation with people with SCI, especially with those newly injured. Varying amounts of recovery are possible after an SCI due to the potential for neuroplastic and activity-dependent changes to occur.²¹² These concepts will be discussed later in the chapter.

When ambulation is an appropriate goal, the treatment program may be short and relatively uncomplicated for some and extremely laborious for others. Treatment techniques may include therapeutic exercise, biofeedback, neuromuscular stimulation, locomotor training, balance training, standing, and various other pre-gait and gait activities. The walking disposition of patients with incomplete SCI is challenging due to the complexity of problems and the varying degree of impairments. These patients may have pain, ROM limitations, ventilator pump dysfunction, weakness, spasticity, as well as sensory and balance dysfunction. In addition, their premorbid physical condition and body type must also be considered. Musculoskeletal asymmetries, such as muscle shortening on the stronger side and lengthening on the weaker side, may be present and may lead to pelvic obliquity and scoliosis.

Locomotor and Gait Training

The term locomotor training has been widely used over the years to refer to interventions directed at walking function and gait. Although the terms are often used interchangeably, it is important to differentiate between locomotor training and traditional gait training.²¹³

Locomotor training is based on the principles derived from basic science using spinalized cats and body weight support treadmill training (BWSTT) systems in the 1980s.^{214–218} It is then progressed to human subjects with increasing popularity in the 1990s and 2000s (Fig. 14.51A).^{219–224} Much of the theory behind this rehabilitation approach is based on activating intrinsic connections of spinal cord circuitry to elicit the appropriate patterns of muscle activation for walking called central pattern generators (CPGs).²²⁵ Research involving the cat model has provided the most conclusive and descriptive evidence for the presence and activity of CPGs,²²⁶ including the ability to produce locomotor output in spinalized animals.²²⁷

Locomotor training requires repetition and adherence to specific training principles and sensory cues with the goal of generating locomotor output by activating the neural circuits. The principles include (1) maximizing LE weight bearing, (2) optimizing sensory cues appropriate for task, (3) optimizing posture and kinematics for each motor task, and (4) maximizing recovery and minimizing compensation.²²⁸

In contrast, gait training specifically addresses learning to walk again, and often uses orthotics and or assistive devices to help compensate for strength impairments due to paresis or paralysis.²¹³

Although locomotor training started with BWSTT, there have been several other equipment options that have recently been developed to help assist with the delivery of locomotor training. Some of the other

Fig. 14.51 (A) Manual treadmill. Treadmill training with body-weight-supported and manual assistance is being completed on the TheraStride Innoventor, which combines a treadmill and support harness system with software that measures variables of gait training, including speed, weight supported, and amount of time walked. Two or three therapists are needed to provide assistance at the trunk and lower limbs to facilitate an appropriate gait pattern. **(B)** Robotic treadmill. The Lokomat by Hocoma is a robotic-assisted treadmill that provides adjustable body-weight support and gives clinicians the ability to adjust gait-specific parameters when completing training with patients who have mobility deficits.

interventions may include body weight support overground systems, robotic body weight support treadmill systems, and exoskeletons. Many of these devices offer a less burdensome alternative to facilitate walking in people with SCI while reducing therapist strain.^{222,229} Over the last several years, much research has been done looking at the effectiveness of these various types of locomotor training for people with SCI. However, many questions remain regarding the efficacy of specific intervention choices and timing for this population. In a randomized controlled trial, Dobkin and colleagues reported that after 12 weeks of equal administration of locomotor training using treadmill training with manual assistance and conventional overground gait training, no differences in walking abilities were reported in patients with incomplete SCIs with either intervention.²²³ Field-Fote and Roach²³⁰ conducted a randomized controlled trial (RCT) evaluating walking speed. Sixty-four participants with chronic incomplete SCI and minimal walking function were randomly assigned into one of four different stepping groups using bodyweight support including treadmill training with manual assistance, treadmill training with electrical stimulation, overground training with stimulation, and treadmill training with robotic assistance. After 12 weeks of training, the effect size for speed and distance was greatest with overground training, but differences among the four groups were not statistically significant.²²² Finally, a Cochrane Review published in 2012 that reviewed five RCTs and looked at the effects of locomotor training on improvement in walking function for people with traumatic SCI concluded that there is insufficient evidence that any one locomotor training strategy improves walking function more than another for people with SCI.²³¹

Although these studies demonstrate that no conclusive results have been found determining that one method of locomotor training is

superior to another, it is important not to dismiss the potential benefits that each type of locomotor training may offer in certain situations. Determining the best method must be based on several different factors including the patient's available resources, spasticity level, general health conditions, body anthropometry, strength, ability to initiate movement, tolerance to upright posture, skin condition, and ROM. These considerations may make one type of locomotor training or training device more beneficial and or more feasible than another. Many clinicians and centers choose to use a multifaceted treatment approach offering a variety of types of locomotor training when available and appropriate. If various types of locomotor equipment are not available, the clinician can still utilize the principles and theories of locomotor training to capitalize on activity-dependent neuroplasticity and attain favorable results.²³⁰

It is also important to acknowledge that most of the large studies evaluating the benefits of locomotor training have studied individuals with chronic injuries that have some degree of walking function. In many instances, locomotor training equipment, including robotic, manual treadmill, and overground bodyweight support systems, enable newly injured individuals with minimal ability to stand, weight bear, or walk very early on after injury. Clinicians must acknowledge the current evidence, but then use clinical judgment and an understanding of the resources available to determine the best treatment approach for recovery of walking. This should be done on an individualized basis making sure to address patient's specific goals and postdischarge environment.

Regardless of what type of training is used, or what tools or technology may or may not be available to help administer it, recovery of walking function can and should be considered with patients with

SCI. Prior to initiating locomotor training, an individual should be able to tolerate being vertical with a stable blood pressure. Also, skin should be intact for any locomotor device that contacts the skin (i.e., a harness or a robotic device). If skin is not intact, an alternate locomotor training device should be used.

Orthotics: Traditional and Powered

Ideally, each patient's neurological recovery potential is maximized before or while brace prescription takes place. It is imperative that advanced rehabilitation strategies that facilitate neural plasticity and recovery of function (i.e., walking and or task specificity training) are utilized throughout the rehabilitation process. However, if it is determined that an orthotic (compensatory approach) is necessary to maximize safety and function with discharge to home and the community, a team approach to orthotic prescription is desirable to meet the needs of patients with SCI. Even if orthotic devices enable these patients to become independent with standing or walking, the energy costs, joint deterioration, and muscle stresses over the life expectancy of each individual need to be considered. Orthotic prescription should be approached systematically. The patient's goals, funding, premorbid and current health status, social support, and the environment to which they are returning should be considered. A basic clinical algorithm for the selection of orthoses for persons with neurological impairment has been proposed by researchers at Rancho Los Amigos Medical Center. This algorithm is referred to as the Rancho ROAD-MAP (Recommendations for Orthotic Assessment, Decision Making, and Prescription).²³² Successful brace prescription uses the minimum amount of bracing to achieve the maximum amount of function. It also anticipates changes in each patient's clinical picture. For example, braces may be manufactured with joints built into the plastic, or joints that begin as fixed, and are later cut to allow articulation. Some models of knee-ankle-foot orthoses (KAFOs) can be altered to become ankle-foot orthoses (AFOs).⁵⁵

Factors that affect orthotic selection are cost, injury level, residual motor function, experience bias of the clinician, patient's medical status, skin and cardiovascular integrity, and patient's acceptance. Generally, the hip-knee-ankle-foot orthosis (HKAFO) is used when selected motions of the hip need control or the benefits of the reciprocating gait orthosis are desired, as is the case with the pediatric population or with adults with SCI higher than T10. In the absence of gluteal muscles, use of a KAFO is typically indicated when the quadriceps muscle strength is less than 3/5. AFOs are indicated in the presence of knee and or ankle instability and weakness and to control the joints.²³³

With traditional orthoses, the energy cost for ambulation is highest for persons with complete paraplegia who use a swing-through gait pattern with spreader bar, and lowest for persons who use bilateral AFOs or a combination of an AFO and a KAFO. Even individuals requiring only bilateral AFOs have a gait efficiency of less than 50% of normal, underscoring the importance of the hip extensor and abductor muscles required for functional ambulation. These gluteal muscles are often severely or completely paralyzed in this population.^{234,235}

The energy cost of ambulation for a person with paraplegia is progressively reduced when more residual motor function is present in the lower extremities. Conversely, the individual with incomplete tetraplegia has higher energy costs for ambulation despite spared lower-extremity function because of upper- and lower-extremity weakness (Boxes 14.7 and 14.8 and Figs. 14.52 to 14.56).^{234–238a}

Materials and components of bracing continue to evolve. Carbon fiber is becoming more common in bracing due to being lightweight and flexible but also supportive. However, the trade-off is that carbon fiber is not easily modified/customized.⁵⁵

BOX 14.7 Categories of Ambulation and Average Walking Speed (Perry 1995)

1. Standing only
2. Exercise—ambulates short distances
3. Household—ambulates inside home or work, uses wheelchair much of the time (<0.4 m/s)
4. Limited community-independent on all surfaces; does not use wheelchair (0.4–0.8 m/s)
5. Full community ambulation (>0.8 m/s)

BOX 14.8 Lower-Extremity Orthoses²³³

Hip-Knee-Ankle-Foot Orthoses

Reciprocating gait orthosis (RGO) (see Fig. 16.50)

Hybrid KAFOs (see Fig. 14.54)

Ankle-Foot Orthoses

Conventional ankle-foot orthoses (AFOs) (metal)

Custom polypropylene AFOs

Carbon-fiber AFO (see Fig. 14.56)

Solid ankle AFO (see Fig. 14.55A)

Custom polypropylene AFOs, articulated ankle (see Fig. 14.55B)

Fig. 14.52 The reciprocating gait orthosis (RGO), although generally used with children, is also used with adults. Its main components are a molded pelvic band, thoracic extensions, bilateral hip and knee joints, and lower limb segments that may be of polypropylene construction with a solid ankle. The RGO uses a dual cable system to couple flexion of one hip with extension of the other.

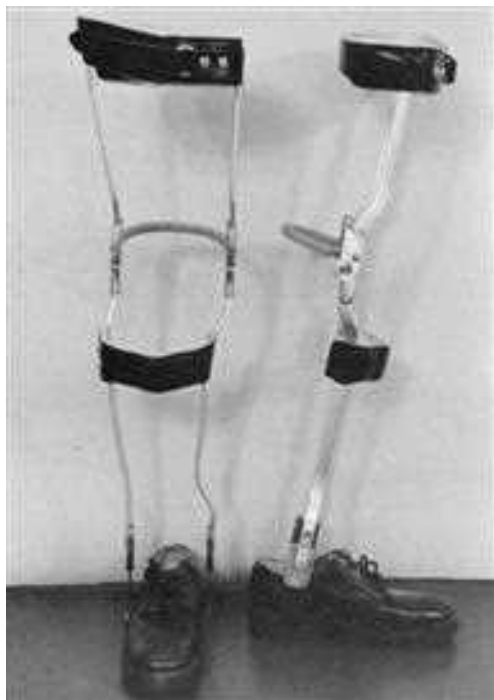

Fig. 14.53 Scott-Craig knee-ankle-foot orthosis is a special design for spinal cord injury. The orthosis consists of double uprights, offset knee joints with pawl locks and bail control, one posterior thigh band, a hinged anterior tibial band, an ankle joint with anterior and posterior adjustable pin stops, a cushion heel, and specially designed longitudinal and transverse foot plates made of steel.

As technology continues to advance, so do the components manufactured for orthotics. One example is the development of stance control knee joints for KAFOs. Traditionally, KAFOs kept the knee locked into full extension throughout swing and stance phase of the gait cycle, thus restricting normal hip/knee flexion during swing phase. However, stance control knee joints allow the knee to unlock during the swing phase and lock during the stance phase, thus functioning in a more normal reciprocal pattern. Research indicates that there are clear indications of the benefits to stance control orthosis systems including greater knee flexion and greater ground clearance in swing, relief of joints on the sound limb, reduction in compensatory movements and energy consumption, as well as improved patient satisfaction.²³⁹

The philosophy regarding the use of orthoses for ambulation for individuals with complete paraplegia varies greatly among clinicians. In the past, some clinicians have encouraged ambulation for these individuals, whereas others strongly discourage it, given that only a small percentage of persons with complete paraplegia continue to use bilateral KAFOs after training has been completed.^{236,238} However, with the evolution and development of LE robotic exoskeletons or powered orthoses (discussed later in section), individuals with little or no LE movement may now safely ambulate in a more energy efficient capacity.^{240,241} When the philosophy of the clinician is to use a traditional nonpowered orthosis for patients who do not have functional motor control below their level of injury, criteria should be established so that both the patient and the clinical staff are consistent in their expectations and approach to ambulation.

If the decision is made to order braces after a trial period training with BKAFOs and stability aids (a walker or forearm crutches), specific goals should be discussed and established. Goals range from standing and exercise ambulation to community ambulation. Most persons

Fig. 14.54 (A) Polypropylene knee-ankle-foot orthosis (KAFO) and combination plastic and metal KAFO. (B) Stance-control KAFO knee joint. This joint combines the stability of a locked knee during the stance phase of walking but allows flexion of the limb for the swing phase of gait. A locked knee makes it much harder to clear the leg over the ground. Some long-leg brace users are perfect candidates for the stance-control KAFOs. These devices, through a few different types of joint mechanisms, create a locked knee when the leg is supporting the weight of the body but unlock when the leg is lifted to allow for easy advancement of the leg as it is allowed to bend. For the right patients, this allows them as much mobility to get around as it does stability.

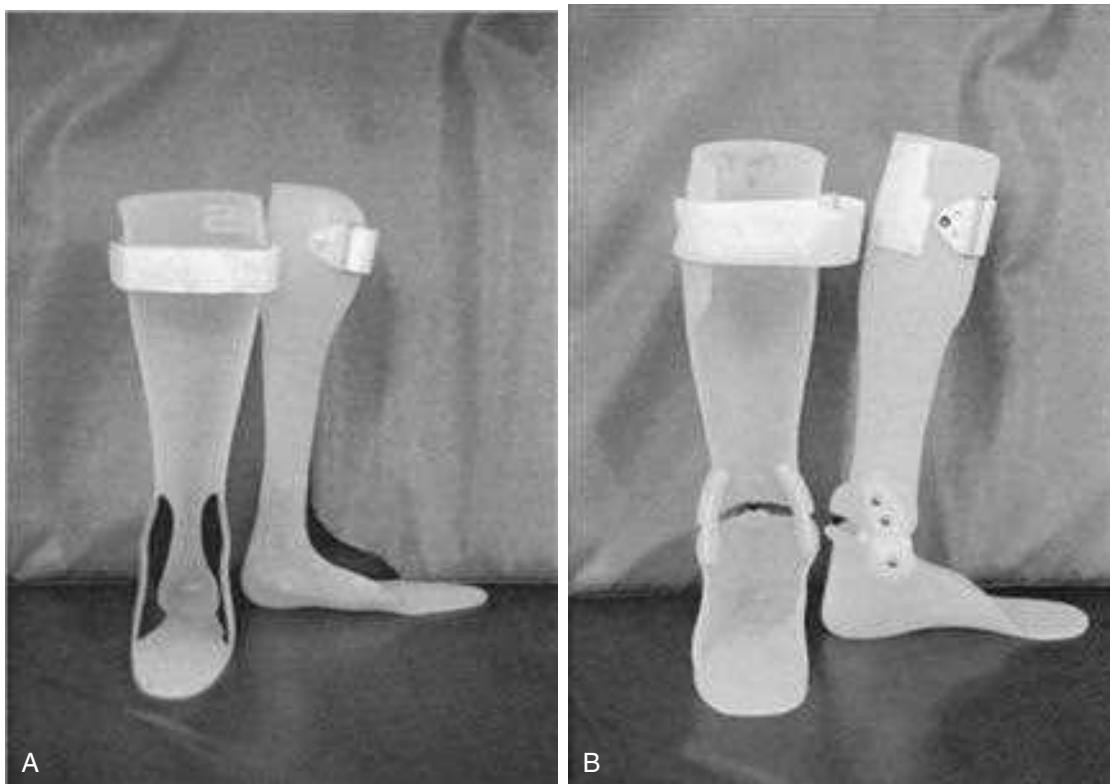

Fig. 14.55 (A) Custom-made solid ankle-foot orthoses (AFOs) in 5 degrees of dorsiflexion with full footplates. (B) Custom-articulated AFOs with adjustable Oklahoma ankle joints.

with complete injuries L2 or higher achieve only exercise ambulation because of the energy expenditure required for functional community ambulation.

Current research indicates that the energy cost of ambulation for individuals with complete lesions at T12 or higher is above standard anaerobic thresholds and cannot be maintained over time. This study also concluded that ambulation for these individuals using a swing-through gait pattern is equivalent to “heavy work.”^{234–238} Consequently, it is understandable why BKAFOs often end up unused after a short time as they may be too tiring to use regularly. A functional alternative to BKAFO walking for persons with complete paraplegia are robotic exoskeletons. Evans and colleagues demonstrated that persons with paraplegia can alter the amount of exertion to walk with a robotic exoskeleton for either mobility or exercise.²⁴²

Robotic exoskeletons are becoming more widespread as an option for personal use (to take home) and for use in rehabilitation settings as an option for gait retraining. There are currently four different exoskeletons that are US Food and Drug Administration (FDA) approved for clinical use (exercise) in the United States (Ekso, Indego, ReWalk, and Rex), three of which may be used for gait or locomotor training. See Table 14.9 for details. Each inclusion criteria, diagnosis for use, and device operation are very different.

Exoskeletons for Rehabilitation

Initially exoskeleton use was only for people with paraplegia. However, recent expansion of FDA approval now allows for people with low cervical (C7) injuries and stroke to use exoskeletons in clinical settings. An Institutional Review Board (IRB) approved research settings, people with levels of injury as high as C5 have successfully stood and walked with exoskeletons using an appropriate stability aid and physical assistance.²⁴³ Exoskeletons can be used on a variety of indoor and

outdoor surfaces, and some even have capabilities for stair climbing.²⁴⁴ Exoskeletons may be used as a mobility device, for exercise, or as a gait retraining intervention to help promote recovery and facilitate neuroplasticity.^{242,245–247}

Exoskeletons for Personal Use

There are currently two FDA-approved exoskeletons (Indego and ReWalk) approved for personal use in one’s home and community in the United States. For safety reasons, current FDA guidelines require a trained support person (companion) to be present with the user at all times while in the device. People with SCI may choose to use exoskeletons for personal use for exercise and/or mobility. From a health and wellness standpoint, there are several benefits supported in the literature to standing and walking to include, but not limited to, pain reduction, improvements in bowel and bladder function, improved spasticity, and potential benefits in bone health.²⁴⁸ Exoskeletons are not covered by Centers for Medicaid and Medicare Services (CMS) or most private insurance companies. A few workers compensation companies have covered the cost of the device and training. The Veterans Administration is covering the cost of the device and training for those who qualify to use (meet manufacturer qualifications) either the Indego or the ReWalk system. Prior to coverage of exoskeleton home use for the private sector, much more evidence supporting medically necessary versus medically beneficial will have to be substantiated.

It is important that users and clinicians realize that exoskeletons are not intended to replace wheelchairs, but rather to provide users with an alternate means of mobility. One main reason for this is that the wheelchair is more efficient due to speed. The average walking speed for someone using an exoskeleton is 0.26 m/s.^{249–251} This can vary significantly based on the exoskeleton used; the user’s physical presentation, level, and completeness of injury; and the user’s proficiency

TABLE 14.9 Exoskeleton Chart

			
Company	Parker Hannifin	ReWalk Robotics Inc.	Ekso Bionics Inc.
FDA approval (US)	Rehab and Personal	Rehab and Personal	Rehab
Device weight	26 lbs (12 kg)/30 lbs (13.5 kg)	51 lbs (23 kg)/66 lbs (30 kg)	55 lbs (25 kg)
Indication for use	SCI Rehab C7 (AIS A-D) and below, SCI Personal T3 (AIS A-D) and below, Stroke Rehab	SCI Rehab T4 (AIS A-D) and below, SCI Personal T7 (AIS A-D) and below	SCI Rehab C7 (AIS D) and below SCI, T4 (AIS A-D) and below SCI; Stroke Rehab
Variable power assist	0%–100% support at each right and left lower extremity as well as to separate out hip or knee joint	Walking current able to be modified dependent on the weight and spasm of the patient	0%–100% support for either the right or left lower extremity. Does not isolate hip or knee
Walking surfaces	Level and unlevelled surfaces; 8 degrees incline	Level and unlevelled surfaces; 8 degrees incline	2 degrees incline

using the exoskeleton. To be considered a limited community ambulator for someone with SCI, walking speeds need to be approximately 0.40 m/s to 0.8 m/s, and greater than 0.8 m/s to ambulate without an assistive device or to be considered a full community ambulator.^{252,253} Walking speeds necessary to cross a street is range from 0.44 m/s to 1.32 m/s.^{254,255} Until recently, exoskeleton-enabled gait speeds were not fast enough to support community ambulation. However, the development of a new controller for one of the exoskeleton devices enables users to accomplish faster speeds. With only a few training sessions, all subjects achieved walking speeds above limited community thresholds, and some of the subjects achieved within 1 standard deviation of full community ambulation.²⁵⁶ With additional training sessions, it is reasonable to assume that the appropriate patients could achieve walking speeds approaching 1.2 m/s or greater.

RECOVERY AND RESTORATION

For many years SCI rehabilitation focused on compensatory strategies; however, clinicians and researchers have made the case for recovery more popular for nearly 20 years. When considering restoration and recovery versus compensation it is important to understand the science that supports the clinical interventions seen today. This section will focus on applying the science of neuroplasticity to clinical interventions.

PRINCIPLES OF NEUROPLASTICITY

For recovery to occur, the nervous system needs to adapt. Evidence shows that the nervous system is plastic,^{257,258} and that neurons can rearrange their anatomical and functional connectivity in response to environmental input, thereby achieving new or modified outputs. Possible mechanisms are the balance between inhibitory and excitatory synaptic connections are improved, silent connections are aroused, new dendrites sprout, the number or size of synapses increases, or new neurons are “born” (neurogenesis). Regardless of which occurs, clinicians need to capitalize on it—and how they train these new connections is the art of the clinician applying the science. There are 10 *Principles of Neuroplasticity* (see Box 14.9) that can guide the clinician on treatment planning.²⁵⁷

Clinicians and researchers use various terms to describe high-volume and high-intensity approaches for treating deficits induced by neurological paralysis^{257,259}: *use-dependent plasticity*, *experience-dependent plasticity*, *activity-dependent plasticity*, *activity-based restorative therapies (ABRT)*, *activity-based therapies*, and *activity-based rehabilitation*. Regardless of the term used, the goal is to use rehabilitation therapies to facilitate recovery. This can be done by applying the principles of neuroplasticity in order to achieve activation of the spinal circuitry located above and below the level of injury.²⁶⁰ Those who

BOX 14.9 Principles of Experience-Dependent Plasticity²⁵⁷

Principle	Description
Use it or lose it.	Failure to drive specific brain functions can lead to functional degradation.
Use it and improve it.	Training that drives a specific brain function can lead to an enhancement of that function.
Specificity.	The nature of the training experience.
Repetition Matters.	Induction of plasticity requires sufficient repetition.
Intensity Matters.	Induction of plasticity requires sufficient training intensity.
Time Matters.	Different forms of plasticity occur at different times during training.
Salience Matters.	The training experience must be sufficiently salient to induce plasticity.
Age Matters.	Training-induced plasticity occurs more readily in younger brains.
Transference.	Plasticity in response to one training experience can enhance the acquisition of similar behaviors.
Interference.	Plasticity in response to one experience can interfere with the acquisition of other behaviors.

Kleim JA, Jones TA. Principles of experience-dependent neural plasticity: implications for rehabilitation after brain damage. *J Speech Lang Hear Res.* 2008;51:S225-S239.

subscribe to this type of intervention may follow the five key components to ABRT: weight-bearing activities, FES, task-specific practice, massed practice, and locomotor training.²⁵⁹ There is some overlap between these key components and the 10 *Principles of Neuroplasticity*; however, not all components can be extrapolated to *all* activities. For instance, when needing to accomplish UE tasks, locomotor training

may not be the intervention of choice. However, repeated reaching activities may utilize these principles and be key to helping a patient reach a functional goal.²⁶¹ Clinicians should keep activities specific and purposeful to the end goal.

The use of technology can facilitate training by applying these principles and/or key concepts. For example, a device may allow longer training time (repetition) or maintain an intensity level that would otherwise be a physical burden on a clinician. There are many types of rehab technologies to choose from with the goal of promoting the positive effects gained in training (Table 14.10).^{55,262} When implementing these devices, the therapist must have knowledge of the impairment being treated, how to safely use the device while capitalizing on its benefits, and how to coach the patient to be an active participant in the training.²⁶³ Maintaining active participation provides afferent stimulation, which is key for harnessing neuroplasticity.²⁶¹ It is important for the clinician to be mindful that the use of technology alone will not cause neuroplastic changes to occur. The technology must be thoughtfully and skillfully applied throughout the treatment session. Additionally, one should consider the desired output and what other modes of afferent input are needed. For example, with locomotor training the stance limb requires adequate loading to elicit hip flexion on the contralateral limb for stepping needs.^{259,263,264}

While positive outcomes are always the goal, one must recognize the potential for maladaptive changes.^{257,258,263,305} For instance, increased recruitment of excitatory spinal interneurons may enhance spasticity, which in turn may potentially have a negative effect on function.²⁵⁸ Undirected synaptic plasticity could lead to an imbalance of inhibitory and excitatory activity.²⁶³ Again, careful and thoughtful application of neuroplastic principles and interventions can help avoid these maladaptive changes and lead to positive outcomes.

TABLE 14.10 Summary of Rehabilitation Technologies for Spinal Cord Injury

Types of Devices (Examples)	General Info	Indications	Options	Potential Benefits
Multichannel ^{265–269} FES, ^{270,271} Cycles ^{260,272} Sadowsky, Johnson <ul style="list-style-type: none"> Restorative Therapies (RT 300 series) (Fig. 14.57) MyoLyn MyoCycle Hasomed RehaMove^{273,274} 	Muscle groups assigned to specific channels; e-stim delivered with timed and sequenced revolutions with or without motor support; and frequency, pulse duration, and amplitude adjustable	Strengthening, endurance training, muscle conditioning, and reciprocal patterning	Upper and lower extremity cycling; options to include trunk musculature; active or passive cycling; some devices are designed for supine bed use; and able to use channels for other activities	Maintenance or increase in muscle bulk, increase in blood flow, reduction in muscle spasms, maintenance of ROM, and maintenance of bone density
Other multichannel FES devices ^{274,275} : <ul style="list-style-type: none"> RT 200 seated elliptical, RT 600 stepper, RT Xcite Hasomed RehaMove Cycle 	Device has more than 2 channels; able to assign channels to multiple muscle groups at once	Strengthening of multiple muscle groups at once, repeated mass practice, and task specificity to increase endurance with an activity	FES to extremities and trunk; some are portable; may have preprogrammed settings for specific activities; and different devices offer different	Task specific muscle retraining in conjunction with functional activity or ADL and enables increased muscle fibers to be used during activity
Neuroprosthetics/Neuromuscular Reeducation devices ^{276–279} <ul style="list-style-type: none"> Bioness H200 (Fig. 14.61) and L300 (Fig. 14.58) Walk-aide (Fig. 14.59) MyoPro^{280–282} 	Wearable device in the form of prosthetic that delivers e-stim or power to provide assistance and used primarily for gait training, functional activities, and/or ADLs	Muscle retraining, foot drop, repeated mass practice, and task specificity to increase endurance with an activity	Reaching and/or grasping, gait; exercise modes; wireless; and clinic or personal use	Task specificity; repetition; muscle strengthening; and structural support or joint protection
Body Weight Support Tracking Systems ^{283,284} <ul style="list-style-type: none"> Aretech Zero-G Bioness Vector 	Overhead harness system; reduces percentage of weight bearing through patient's LEs while supporting trunk	Gradual introduction to weight bearing, standing, or ambulating; basic or dynamic balance training	Computer interface; static or dynamic systems; able to use over ground or over treadmill; prevent falls; and track progress	Initiate weight bearing, balance, and upright earlier; reduced effort to patient, therapist/team; increased safety; and low fear of falling

TABLE 14.10 Summary of Rehabilitation Technologies for Spinal Cord Injury—cont'd

Types of Devices (Examples)	General Info	Indications	Options	Potential Benefits
Body Weight Support Treadmill Systems ²⁸⁵ (Robotic, Manual ^{286–289}) <ul style="list-style-type: none"> • Hocoma Lokomat^{285–287} • Aretech Zero-G Lite • Motorika Optimal G • P&S Walkbot • Healthsouth Auto-ambulator 	Patient is suspended by harness over treadmill; robotic system includes exoskeleton that attaches to patient's LEs and can assist or guide stepping pattern; manual system utilizes team of trained staff to guide pelvis in weight shifts and LEs in stepping pattern	Impaired gait, proprioception or motor control; decreased standing endurance; weight bearing restrictions; weakness; spasticity; and weight bearing	Robotic—computer interface; adjustability of gait pattern; stability vs. motion at pelvis; manual feature; interactive programs or virtual reality; track progress/outcomes; decreased number of staff needed. Manual—computer interface assists therapist with setting amount of body weight support and tracking speed and endurance parameters	Assist in providing locomotor training: repeated mass practice; task specificity; increase endurance and/or speed with stepping; decrease level of assistance with stepping; improved trunk/postural training in upright position; increased circulation of LEs; improved bowel/bladder function; and improved respiratory function
Gaming & Computer Interface Devices <ul style="list-style-type: none"> • Virtual Reality Headsets • Wii • PlayStation • Xbox • Hocoma Armeo^{290,291} 	Gaming device used in the home; has various activities from sports to first person action	Balance, activity specific intervention, gross and fine motor options	Can add games/activities; and various controller options dependent on device (ex: motion sensor, head control, and multiplayer w/single controller)	Able to track changes; patient can visibly see progress; inexpensive and easy to use in the home
Whole Body Vibration (Fig. 14.62) ^{292–295} <ul style="list-style-type: none"> • Wave • Powerplate • Vibeplate 	Vibration is delivered through a plate the patient can utilize at various positions (standing, sitting w/feet on plate, prone w/UEs on plate, etc.); evokes reflex contractions; can mimic resistance or aerobic training; can also be fatiguing to muscles; can reduce H-reflex depending on frequency	Stimulate motor unit recruitment; increase strength output; modulation of spasticity	Ideal devices allow adjustable amplitude and frequency to suit therapeutic goal; various sizes available for portability and to meet patient needs	Priming of neural circuits to enhance training (i.e., in prep for repeated tasks); decrease spasticity, which negatively impacts function or the ability to participate in tasks designed to capitalize on neuroplasticity
Robotics <ul style="list-style-type: none"> • AMES^{296–297} • Alter G Bionic Leg²⁹⁸ • Erigo^{299–300} • LE Exoskeleton²⁴⁸ (Ekso, Indego, ReWalk) 	<i>Motorized</i> device attaching to a limb with the purpose of guiding and/or assisting movement	Passive or assisted limb movement; repetition of movement; afferent input for a desired output; decrease pain or spasticity; strength training; and functional training	May have e-stim or vibration associated with device; sensor driven movement; vary degree of assist. Various types: somatosensory augmentation, intention-based robotic limb, passive or active-assist devices, exoskeletal walking devices designed to be used with assistive device for overground walking ^{296–297}	Increased independence with ADLs or mobility; exercise; repetition; and general and/or early mobility
Manipulandum <ul style="list-style-type: none"> • ReJoyce^{301–302} 	Hand strengthening and training disguised as games—functional ROM, functional tasks, and placement tasks	For hand strength and fine motor training, endurance, and task specificity training	Difficulty modulated based on performance; computer contains outcome measure and progress tracking; can be used in conjunction with other interventions (i.e., e-stim), can be used in the home; and therapist can supervise and track remotely	Continued training in the home; functional and neuroplastic improvements in ARAT and GRT (—Action Research Arm Test and Grasp Release Test) ^{302–304}

ADL, Activities of daily living; FES, functional electrical stimulation; LE, Lower extremity; ROM, range of motion.

Fig. 14.56 Allard Braces. The Allard family of ankle-foot orthoses (AFOs) include a prefabricated shell that can be customized by the trained orthotist to the specific needs of the patients. These dynamic orthoses are constructed of carbon composites, which accounts for their strength as well as their light weight. There are three different AFOs in the series: Ypsilon, ToeOFF, and BlueRocker. The AFOs are intended to be used with a custom foot orthotic.^{238a}

Fig. 14.57 RT300-SL leg functional electrical stimulation (FES) system is a portable FES cycle that can be easily accessed from the patient's wheelchair. Adhesive electrodes can be applied to a variety of lower-extremity muscles including the quadriceps, hamstrings, gluteals, tibialis anterior, and gastrocnemius. These muscles are stimulated at the appropriate time to facilitate a cycling motion using a lower-extremity ergometer. FES bike software has the capability to store patient-specific parameters between sessions and patients. Courtesy of Restorative Therapies.

UPPER-EXTREMITY RESTORATION

Improving hand and upper-extremity function plays a critical role in achieving independence with ADLs. Surgical restoration of hand grasp, lateral pinch, or elbow extension in a patient with tetraplegia can be an option through tendon transfers.^{306,307} Typically, before individuals are considered for surgery, their neurological function has reached a plateau, they are psychologically stable, and they have functional goals.³⁰⁷ Individuals seeking restorative surgery to the UE, to provide another function lost from paralysis, undergo a

Fig. 14.58 Bioness L300 system is a neuroprosthetic device that contains an orthotic cuff and electrodes. It fits just below the knee to supply FES to the lower leg, targeting the peroneal nerve to cause dorsiflexion. An additional thigh cuff (L300 Plus) can be added to help assist with knee flexion and extension and provide additional support. Courtesy of Bioness, Inc.

Fig. 14.59 The WalkAide System is a neuroprosthetic device that contains an orthotic cuff and electrodes. It fits just below the knee to supply functional electrical stimulation (FES) to the lower leg, stimulating the appropriate muscles and causing dorsiflexion. It is activated by a tilt sensor mechanism and relies on the angle of the tibia for appropriate timing of the FES to assist with foot drop. Courtesy of Hanger, Inc.

preoperative evaluation using the International Classification for Surgery of the Hand in Tetraplegia (ICSHT).³⁰⁸ This classification provides information about the number of voluntary muscles available for surgical transfer and whether the person has cutaneous sensation in the thumb. A physical assessment is included to evaluate UE active range of motion, passive range of motion, and strength. The presence of UE contractures and/or poorly managed spasticity may limit an

individual's candidacy.³⁰⁹ Before any surgical interventions, therapy may be recommended to ensure that the individual is a candidate for tendon transfer procedures.³⁰⁷ Postoperative rehabilitation varies on the basis of specific procedures and may consist of 2 months or more, with strength improvements continuing for up to 1 year postoperatively.³¹⁰ Tendon transfer procedures may be an option to improve UE function.

Regardless of the procedure, the therapist can tap into neuroplasticity principles and interventions mentioned above to assist with what might be considered a transition to potential recovery. Retraining the nervous system along with the musculoskeletal system helps patients reach their goals for independence.

HEALTH PROMOTION AND WELLNESS

Health promotion and wellness are something that should be introduced and presented throughout the continuum of care and do not necessarily require someone to be enrolled in a specific health and wellness program. Education on wellness should include:

- Prevention of chronic diseases and secondary conditions
- Physical activity
- Nutrition
- Injury prevention
- Psychological support

Individuals with spinal cord injuries are living longer due to improvements in medical management, but this has also led to increased incidence of chronic diseases, such as cardiovascular disease (CVD) and comorbid endocrine disorders in persons with SCI.^{112,311,312} CVDs are a major cause of morbidity and mortality among aging people with SCI (C),¹¹³ with the prevalence of heart disease being 17.1% for people with SCI compared to 4.9% for individuals without SCI.³¹³ Heart disease is the fourth leading cause of death among people with SCI aged 40 to 70 years.³¹⁴

The terms cardiometabolic syndrome (CMS) or metabolic syndrome are terms widely reported to describe a clustering of risk factors that are often reported after SCI and worsen the risk of cardiovascular disease (CVD) prognosis. Cardiometabolic syndrome is said to exist if three of the five following risk factors are present: central obesity, dyslipidemia (specifically low high-density lipoprotein cholesterol), elevated triglycerides, hypertension, and insulin resistance.¹¹² Although there is no single definitive cause for the development of CMS after SCI, there is a high likelihood that physical deconditioning along with a hypercaloric diet are major contributors.¹¹²

Physical deconditioning and a sedentary lifestyle after SCI has ranked individuals with SCI at the lowest end of the human fitness spectrum,³¹⁵ and recent reports find that 50% of people with SCI have no leisure-time physical activity, and 15% of those that do report physical activity do not meet the minimal threshold for meaningful health benefits.^{114,316} There are many reasons why someone with an SCI may find it difficult to engage in physical activity including muscle paralysis, physical, financial, and transportation barriers.^{114,317} However, there are a variety of exercise interventions (to be discussed later in this section) that are available to people with SCI and can promote clinically relevant improvements in health, fitness, and overall function.¹¹⁴ It is also important to note that as a health professional, encouraging and educating patients on the importance of exercise and prescribing appropriate exercise programs that minimize barriers is critical to the patient engaging in exercise. Research has demonstrated that a health professional's recommendation to exercise is the single most important determinant for the adoption of an active lifestyle.³¹⁸

Although critical, exercise is only one piece of the healthy lifestyle puzzle. There are physical, nutritional, and behavioral modifications that need to be made for someone to lead a healthy lifestyle. Research has shown that physical activity alone does not offset the caloric excess

of someone who is not eating a health-conscious diet,^{319,320} and caloric restriction may be the most important of all three components in preventing diabetes or prediabetes.^{319,320} People with SCI require a reduction in calories to prevent weight gain due to decreases in muscle mass with an associated increase in fat mass as well as lower levels of physical activity.^{113,321} As a result, obesity is extremely prevalent among people with chronic SCI with prevalence rates for overweight and obesity ranging from 55.0% to 95.7% of the population.³²² This is why appropriate nutrition and caloric levels to maintain stable body mass as well as behavioral support to assist with following a healthy diet are so important in helping someone consistently engage in a healthy lifestyle.¹¹²

Recent evidence resulting from a National Institute of Health multisite RCT demonstrated significant weight reduction (58%) and decreased incidence of type 2 diabetes from a 1 year structured lifestyle intervention as part of a diabetes prevention program consisting of moderate-intensity physical activity, an energy restricted Mediterranean-style diet, and behavioral approaches.³¹⁹ This lifestyle intervention program was also applied to people with SCI, further demonstrating the importance of all three components of a healthy lifestyle.^{112,319}

Physical Activity and Exercise Interventions

Physical activity after SCI has been shown to improve muscle strength, endurance, mobility, the ability to fall asleep, self-image, and blood lipid profiles, as well as decrease the risk of premature death. In addition, exercise has been shown to decrease anxiety, loneliness, depression, stress, heart disease, blood pressure, respiratory illness, diabetes, obesity, and other medical complications.³²³ Current evidence has established two guidelines for physical activity for adults with SCI: (1) for cardiorespiratory fitness and muscle strength and (2) for cardiometabolic health benefits. See [Box 14.10](#) on physical activity guidelines. It is important to note that both guidelines recommend a lower frequency and duration than the 150 min/wk advised for the general population.³²⁴

Exercise programs for individuals with SCI must take into consideration the musculoskeletal, respiratory, cardiovascular, and autonomic nervous system changes that occur after SCI. Components of an exercise program should include flexibility, muscular strength, and cardiovascular endurance; and an appropriate exercise prescription should address exercise mode, intensity, duration, and frequency. It is important to find a type of exercise that is enjoyable for each individual so that it can be easily integrated into his or her lifestyle, as a variety of exercise interventions exist that may lead to improvements in health, fitness, and overall function.¹¹⁴

Exercise programs, both in the clinic and home, may or may not incorporate specialized equipment. The types of equipment available for exercise testing or training in persons with SCI are well documented in the literature. Arm crank ergometers, wheelchair ergometers, circuit resistance training (CRT), wheelchair treadmills,

BOX 14.10 Physical Activity Guidelines for Adults With Spinal Cord Injury³²⁴

Fitness guideline for cardiorespiratory fitness and muscle strength benefits

- 20 min of moderate to vigorous intensity aerobic exercise 2×/wk
- 3 sets of strength exercises 2×/wk for each major functioning muscle group, at a moderate to vigorous intensity

Cardiometabolic health guideline—for cardiometabolic health benefits

- 30 min 3×/wk of moderate to vigorous intensity aerobic exercise

Martin Ginis KA, van der Scheer JW, Latimer-Cheung AE, et al. Evidence-based scientific exercise guidelines for adults with spinal cord injury: an update and a new guideline. *Spinal Cord*. 2018; 56(4):308-321. doi:10.1038/s41393-017-0017-3.

lower-extremity cycling with FES, overhead bodyweight support systems, as well as field test protocols are among the more widely used equipment in the clinic.³²⁵

When volitional extremity movement exists, exercise utilizing those available muscles should be used to improve cardiovascular and metabolic health in individuals with SCI. Specifically, there is evidence that arm-crank ergometry, wheelchair propulsion, hand cycling, and CRT can improve cardiovascular fitness, metabolic health, and physical capacity measures in individuals with SCI.¹¹⁴ Exercise equipment varies in expense, and each clinic must choose the method that best fits its treatment setting and budget. Home exercise programs may be established with equipment such as weights and cuff weights, elastic bands and tubing, and hand cycles. However, regardless of what equipment is being used, careful consideration and individualized attention to available muscle strength and proper kinematics is required prior to prescribing exercise. One type of exercise does not fit all people with SCI, and therefore modifications often need to be made in order to accommodate various types of injuries, presentations, and postural deformities in order to maximize benefit and minimize injury, especially an overuse injury.

Overuse syndromes are common among long-term wheelchair users. When any type of exercise program is established, factors that are specific to SCI should be considered.³²⁶ Long-term wheelchair use can lead to an increased incidence of carpal tunnel syndrome, elbow or shoulder tendonitis, early onset of osteoarthritis, and rotator cuff injuries. The motion and resistance of the upper-extremity muscles during wheelchair propulsion can lead to an overdevelopment of anterior shoulder muscles, scapular protraction, and posterior shoulder weakness. This musculature imbalance may lead to elevation and internal rotation of the humeral head that may cause pain as a result of impingement. Injuries can be prevented or slowed if individuals perform a proper warm-up with stretching and flexibility exercises, wear protective equipment (e.g., helmet and padded gloves), alternate modes of exercise, get proper rest between exercise sessions, and establish exercise programs to help prevent or correct muscle imbalances.

CRT is one type of exercise program that is specifically designed to help strengthen weak muscles that are critical to function in people with SCI (upper trunk and shoulder complex) while stretching the muscles that tend to be tight (chest and back).³²⁷ In addition to the strengthening and stretching components, it also incorporates cardiovascular endurance exercise. The cardio components can be accomplished using low-resistance, high-speed arm cranking, or simply spinning arms in the air with no equipment.^{327,328} As a result, CRT is one simple method of exercise for people with SCI that can address several fitness goals at once. It can be used performed in a rehab setting, in a more traditional gym, or even in a home setting.³²⁹ Research has shown that a CRT program, using alternating strengthening exercises and low-resistance, high-speed arm exercise can be beneficial in improving muscle strength, endurance, and anaerobic power of middle-aged men with paraplegia while also significantly reducing their shoulder pain.³²⁶ CRT has also been shown to increase peak oxygen consumption and cardiorespiratory endurance in patients with chronic paraplegia.^{327,330} (See **Box 14.11** for description of the program.)

Whether it is through an established health and wellness program or an individualized health and wellness plan, a person living with an SCI has the potential to increase quality of life, improve ADLs, decrease secondary conditions, decrease depression, and decrease the number of related hospitalizations. It is a goal that integration to wellness programs for individuals with SCI will become a standard in all facilities, and individual health professionals will address health and wellness as part of routine care.

BOX 14.11 Circuit Resistance Training Program^{114,328,330}

Exercises	Instructions
Arm ergometer/arm spinning Military press Horizontal rows Chest fly Preacher curls Latissimus pull-down Seated dips	<ul style="list-style-type: none"> • Sets of resistance exercises will be performed in pairs • 10 repetitions of each exercise (6 s movement each rep) • 2 min of endurance exercise (arm ergometer or spinning); cadence of 50 rpm (no resistance) interposed between pairs • 2 more sets resistance exercises performed. • Resistance and endurance exercises are alternated until subjects have rotated through each resistance station 3 times for a total of 3 sets • ≤15 s rest between stations
Perform CRT 3× week on nonconsecutive days. Each session lasts about 40–45 min. Start with warm-up and end with cool down of approximately 4 min of arm ergometer or arm spinning.	

EDUCATION

Education of the patient and caregivers is an integral part of the rehabilitation process. Formal education includes group and individual instruction and family and caregiver training. Patients and caregivers are taught the following: preventive skin care, bowel and bladder programs, safe ways to perform all ADL tasks, nutritional guidelines, thermoregulation precautions, pulmonary management, cardiopulmonary resuscitation, management of autonomic dysreflexia, equipment management and maintenance, transfer techniques, wheelchair mobility, ambulation, proper body positioning, ROM exercises, ADL basics, and leisure skills. Home programs are taught to maintain or increase strength, endurance, ROM, and function. Energy conservation techniques and proper body mechanics are incorporated into all aspects of training.

Patients are formally tested on their knowledge, and remedial instruction should be provided in deficient areas. Caregivers should be formally evaluated on their abilities to safely provide care to the patient. Supervised therapeutic outings and passes allow the patient, caregivers, and the team to identify problem areas and provide additional education in those areas.

PSYCHOSOCIAL ISSUES

The immediate reaction to the onset of SCI is physical shock accompanied by anxiety, pain, and fear of dying. The response to such an injury varies greatly and depends on the extent of the injury, the pre-morbid activity level, the style of coping with stress, and family and financial resources. There may be great sensory deprivation from immobilization, neurological impairment, and the monotony of the hospital routine. Several psychological theories have been proposed to describe responses and coping mechanisms. The process of coping with these changes is referred to as *adjustment* (see Chapter 5).

Rehabilitation personnel are becoming more aware of the need to teach not only functional skills but also psychosocial and coping skills to the patient and significant others. Education in the following areas facilitates the adjustment process: creative recreation, financial planning, negotiating community barriers, social skills, managing an attendant, creative problem solving, accessing community resources, fertility and child care options, assertiveness,

sexual expression, vocational planning and training, and the use of community transportation. These skills may be introduced in the inpatient rehabilitation setting but will be developed further in the home and community environments. True adjustment and adaptation begin after discharge from rehabilitation.^{331,332}

DISCHARGE PLANNING

Discharge planning begins from the time the patient is being considered for admission and continues through the rehabilitation program. It is a continuous process that includes the patient, family, treatment team, and community resources, with the goal being successful community reintegration and a perceived good quality of life. The rehabilitation team must identify the specific needs of the patient and must structure the program to enhance the chance of success. Lengths of stay are getting shorter in response to pressure from third-party payers to contain costs. This requires the discharge planning process to be expedited so that procurement of needed equipment, completion of architectural modifications, and referrals to postacute services and community resources occur in a timely manner.

ARCHITECTURAL MODIFICATIONS

Architectural barriers in the home, transportation system, workplace, or school may prevent access to opportunities. The architectural changes required by the person with SCI for independence in the home and community depend on the degree of impairment, financial resources, and patient and family acceptance of modifications or equipment. The clinician should discuss equipment options with the patient and family on the basis of the degree of modification they plan to make to their home. Thinking creatively about low-tech adaptations should be considered part of the therapist's role. Problem solving with and by the patient is vital to the process of identifying alternatives as ideas for the future (Fig. 14.60).

Many available resources describe the dimensions of the basic wheelchair and specifications for making homes and facilities accessible to wheelchair users. See Appendix 14.A at the end of this chapter for resources on architectural modification. When architectural modification recommendations exceed the scope of the clinician, referral to an AT Practitioner may be necessary. If families are considering building a home to meet their needs, universal design principles should be integrated into the plans to ensure access and aging in place for the patient and their family.

COMMUNITY REINTEGRATION

Successful community reintegration after SCI includes returning to preinjury social roles and, more specifically, returning to work, school, and/or leisure interests. Public school systems have a legal obligation to provide an appropriate school setting for a child with a disability. Rehabilitation teams may assist with school reentry by adding school visitations and education for faculty or peers. School accessibility can be assessed, and the patient and therapists can have an opportunity to share appropriate information about the new impairments before reentry into the school system. Also, rehabilitation programs that are CARF accredited must offer academic programs. School reentry programs may enhance communication between academic rehabilitation faculty and school, bridging the gap for return. Students returning to college may need assistance developing problem-solving skills related to campus accessibility, Americans with Disabilities Act (ADA) rights, campus transportation options, and self-advocacy for sports adaptations. Figs. 14.60 to 14.64 represent the range of solutions utilized by clinicians to address patient needs. Solutions to address patient needs can range from functional electrical stimulation, power assisted mobility, vibration therapy to address tone and muscle recruitment, and positioning devices.

Rehabilitation programs must also emphasize returning to work throughout the process. For patients who have sustained a traumatic SCI and are included in SCI model systems data, 57.7% report being employed at the time of the accident. Only 12.4% are employed at the 1-year anniversary, but by the 20-year anniversary, 33.1% are

Fig. 14.61 The Bioness H200 system is a neuroprosthetic device that contains an orthosis for the upper extremity and electrodes. It fits to the wrist and forearm and targets opening and closing of the hand and fingers. The device can be used in an exercise mode or to perform functional tasks. Courtesy of Bioness, Inc.

Fig. 14.63 Power assist wheels added to a manual wheelchair meet the needs of users who may need supplemental support in the community while also requiring the ease of transportation that a manual chair provides. Power assist wheels help users with energy conservation and shoulder maintenance long term.

employed. Many individuals can return to their previous jobs after SCI.³³⁸ The ADA of 1990 (PL 101-336) prohibits businesses with 15 or more employees from discrimination against “qualified individuals with disabilities” with respect to the terms, conditions, or privileges of employment.³³⁹ Job site and job responsibilities may need to change to accommodate the new impairments, allowing the patient to fully participate. For those who are unable to perform previous jobs or who

Fig. 14.64 A volar based forearm thumb spica splint can help maintain soft-tissue length and thumb integrity while providing the user with the ability to complete fine motor tasks with digits II-IV.

were unemployed before injury, many programs exist for training in vocational skills. The Department of Rehabilitation Services (DRS) evaluates patients for skills and functional abilities and provides funding for those qualifying for job training, job site modification, and the purchase of essential equipment that may include transportation. Services offered by the DRS vary from state to state. Each state agency has a list of resources available in the community, such as rehabilitation technology, independent living centers, and job training and placement programs. Individuals should refer to their state DRS for assistance with employment.

Engaging in sports and other leisure skills can open doors for patients returning to the community. Participating in sports and leisure, whether learning a new skill or adapting something previously enjoyed, may boost physical capacity and enhance self-worth. Adapted sporting activities found in the United States include power soccer, quad rugby, wheelchair basketball, tennis, swimming, and snow skiing, to name a few. The Paralympics provide competitive venues for elite athletes, and many road races across the United States have opened the doors for wheelchair athletes to compete alongside able-bodied runners. A handful of colleges and universities have developed adapted sports teams and are beginning to offer student scholarships.

CONCLUSION

Comprehensive treatment of the individual with SCI can be very challenging. Health care reform issues force the rehabilitation team to explore new cost-efficient options to continue to provide high-quality rehabilitation. New medical and rehabilitation interventions provide the clinician with a plethora of interventions to improve functional recovery and to promote neurological recovery after SCI (see Table 14.9). Scientists continue to research ways to prevent and/or cure paralysis and loss of function after SCI; however, until those goals have

been achieved the best defense against SCI is to prevent the injury from occurring. Programs that target the top mechanisms for traumatic SCI, such as ThinkFirst, are aimed at helping individuals of all ages learn to reduce their risk of SCI by educating them to make safe choices. Creation of innovative apps called AutoCoach that teach parents how to teach their teens to drive, Distracted Driving programs and laws, and continued efforts to educate the community through mass media campaign on key concepts such as “Buckle up, Drive safe and sober, Arrive alive, Wear a helmet, Check the water before you dive,” are important elements in the effort to reduce the number of new spinal cord injuries.^{340,341}

CASE STUDY 14.1 C5-C6 Fracture

The patient, a 23-year-old man, was injured when he dove into the shallow end of a swimming pool while at a party. He had hit his head on the bottom of the pool but never lost consciousness. His friends noticed he did not come to the surface, and they dove in and brought him to the surface so he could breathe. When the emergency medical services personnel arrived at the scene, the patient was complaining of neck pain and was unable to move his trunk and legs. A cervical collar was applied, and he was placed on a spine board for transportation to the closest emergency medical center.

On arrival, the physician ordered radiographs of the spine, skull, and chest, which revealed a C5-C6 fracture and subluxation. Physical examination revealed the following: patient awake and alert, absent deep tendon reflexes below the C5 level (indicative of spinal shock), absent sensation below the nipple line, and no volitional movement in the upper or lower extremities except for shoulder shrugs, elbow flexion, and trace wrist extension.

Within 2 hours of the initial injury, 30 mg/kg of methylprednisolone, was administered intravenously. Additional emergency department treatment consisted of starting an intravenous catheter, inserting a Foley catheter, administering oxygen by means of a nasal cannula, and continuing immobilization in the cervical collar. CT scans of the cervical spine confirmed the initial diagnosis of fractures. The patient was admitted to the intensive care unit. Approximately 36 h after his accident, the patient underwent a wiring and fusion internal fixation from C5-C7 using an anterior approach. The patient was placed on deep vein thrombosis prophylaxis. Arrangements were made for transfer to a model SCI center on day 5.

On admission to the SCI center, the patient was taken to the rehabilitation unit and evaluated by the attending physician. Referrals were made to the rehabilitation team, including dietary services, occupational therapy, physical therapy, psychological services, respiratory therapy, social services, speech therapy, therapeutic recreation, and vocational counseling. The nursing staff initiated strict turning times with appropriate padding and positioning to prevent pressure ulcers and pulmonary complications.

The therapy evaluations, including the ISNSCI exam, were completed within 24 hours of admission and revealed the following neurological findings: the biceps were 5/5 and wrist extensors were 3/5. All other key muscles of the UE were absent. The motor neurological level was C6 bilaterally, and the AIS was an A. There was no sensory sparing below the C6 level of injury.

The patient's physical therapy (PT) sessions focused heavily on bed and mat mobility activities, balance activities in long sitting and short sitting and in supported and unsupported positions, w/c skills, and transfer activities. He also focused on strengthening his shoulder, neck, and biceps muscles. The patient was prescribed a manual wheelchair with power assist wheels in the seating clinic and was modified independent with propulsion on smooth surfaces and over rough terrain. He was dependent with bed transfers. During all PT sessions, care was taken to preserve functional tenodesis.

Because he had a complete SCI, most skill acquisition strategies focused on teaching compensatory movements, using momentum and a “head-hip” relationship to learn new movement. The foundation is that movement

strategies are often opposite from able bodied movement where the head commonly leads the movement and the body *generally* follows in the same direction. To use compensation for movements such as transfer, momentum forces create movement by teaching patients to swing their head in the opposite direction to where they want the hips to go. Also, head and eye gaze relationships are important for balance and rolling, whereby arm swing creates momentum and the body will follow the eyes and head when learning this skill.

The patient required minimal assistance in meal preparation and was able to eat with modified independence using utensils with built-up handles. He was able to dress his upper body with the use of a button hook and zipper pull. He was modified independent in all grooming skills and could bath his UE and trunk. He required maximum assistance to bathe his lower extremities, but he used a long-handled sponge to help to access hard-to-reach areas. The patient was modified independent in written communication skills with adapted writing equipment (built up pens/pencils or short splint). His occupational therapy (OT) sessions use similar strategies, teaching compensation techniques for movement and using adaptive equipment.

Questions

Would you describe the movement strategies the patient uses to perform mobility skills as using compensation or using recovery focused movement patterns?

Compensation—the patient has a complete C6 SCI. He is many years status post (s/p) injury, and his neurological recovery has reached a plateau. He currently is using compensatory movement patterns using substitutions, momentum, and residual strength to complete mobility tasks.

When performing mobility skills, such as scooting and transfers, why is it important to preserve tenodesis?

Tenodesis preserves compensatory grasp, which is important for other ADL skills, such as dressing, grooming, and eating, and allows functional grasp for other mobility skills.

Question

What compensatory strategy(s) is the patient using to accommodate for UE paralysis during (a) rolling; (b) coming to sit; and (c) long sitting?

- External rotation of the shoulder and supination of the forearm to accommodate for loss of triceps function; also, patient used neck flexion to reduce the amount of weight on the bed surface during rolling*
- Flexion of the trunk; external rotation of the shoulder and scapular depression; use of the head to allow momentum simultaneously with the arm movements*
- For prop sitting, the patient used external rotation of the shoulder to allow the elbow to be in a locked position, wrist in extension with fingers flexed to preserve tenodesis*

Question

Describe forward chaining techniques and how they may be used as a training technique during dressing.

Forward chaining training includes taking a task, breaking that task into steps, and training the patient one step at a time beginning with step 1, then 2,

CASE STUDY 14.1 C5-C6 Fracture—cont'd

then 3.... Once the patient has mastered each individual step, then the final goal is to have the patient complete all steps together in a single instance for task success.

With dressing, first have the patient learn to handle the pants, especially if they do not have all muscles of the UE innervated. Second, work on managing pants over one foot and then the other foot utilizing different techniques to un-weight the ankles for success of the task. Third, pull the pants to upper thighs and then get the pants over the hips by shifting weight back and forth to accomplish this task. Finally work with fasteners. Successful completion of the task is indicated when all steps of lower body dressing can be accomplished at one time.

Question

Based on the technology chart you reviewed, what devices would you consider incorporating into this patient's plan of care and why?

A UE neuroprosthetic such as the Bioness H200—to provide electrical stimulation to the muscles of the hand to maintain intrinsic muscle mass and to work on opening/closing of the hand. This would hopefully assist in the long-term use of the hand for functional activities and to improve use of tenodesis grip.

FES cycling for UE and LE—to provide reciprocal extremity motion, afferent input below the level of injury, provide muscle pumping (especially to the legs) to assist with circulation. Including the trunk muscles will help with sustaining muscle tone for postural maintenance.

Abstract: This chapter provides a general overview for the management of individuals with spinal cord injury (SCI) throughout inpatient and postacute phases of the rehabilitation continuum. The information is intended to aid health care professionals in the treatment of individuals with SCI by providing guidelines to maximize each individual's return to their pre-injury lifestyle.

Keywords: American Spinal Injury Association (ASIA), autonomic dysfunction, autonomic dysreflexia, body-weight-supported treadmill

(BWST), bulbocavernosus reflex, complete lesion, deep vein thrombosis (DVT), dual diagnosis, Venous thromboembolism (VTE), discomplete, Functional Independence Measure (FIM), incomplete lesion, intermittent catheterization, locomotor training, lower motor neuron, mobile arm support (MAS), paraplegia, pressure injury, pulmonary embolism (PE), robotic exoskeleton, spinal cord injury (SCI), spinal shock, tenodesis, tetraplegia, upper motor neuron

Neuromuscular Diseases

Diane D. Allen

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the basic pathology, clinical course, and medical treatment of amyotrophic lateral sclerosis and Guillain-Barré syndrome.
2. Describe the current rehabilitative goals and interventions for each condition.
3. Describe the “safe” parameters for exercise related to disuse atrophy and overwork damage.
4. Apply intervention concepts discussed in this chapter to other neuromuscular diseases.

KEY TERMS

amyotrophic lateral sclerosis (ALS)
disuse atrophy
dysarthria
dysphagia

Guillain-Barré syndrome (GBS)
noninvasive (positive-pressure)
ventilation (NIV)
overwork damage

percutaneous endoscopic
gastrostomy (PEG)
polyradiculoneuropathy

Neuromuscular diseases encompass disorders of *upper or lower motor neurons* (UMNs, LMNs) or the muscles they innervate. This chapter traces the connections among the central nervous system (CNS), peripheral nervous system (PNS), and musculoskeletal system through the disordered functioning associated with two neuromuscular diseases: amyotrophic lateral sclerosis (ALS), which damages UMNs and LMNs including cranial nerves; and Guillain-Barré syndrome (GBS), which compromises LMNs and sensory neurons of the PNS, including the autonomic nervous system (ANS).

To review the normal connections, UMNs originate in the motor cortex of the brain as cells also known as *Betz or pyramidal cells*. Axons from these UMNs collect together and descend as the *corticobulbar* and *corticospinal* tracts to synapse with LMNs located in the *bulbar* area of the brain stem (pons and medulla: signaling motor functions through cranial nerves [V and] VII-XII) and *ventral horn* of the spinal cord (anterior portion of the spinal gray matter: signaling motor functions of the neck, trunk, and limbs; Fig. 15.1). Axons from the LMNs collect together and exit the CNS as nerve roots from the brain stem or spinal cord. In the spinal canal, the motor or *ventral* nerve roots join with incoming sensory fibers forming the *dorsal* roots; when bundled together, the motor and sensory fibers become *spinal nerves* exiting the spinal canal. Spinal nerves collect together to form *peripheral nerves*, bundles of fibers traveling to muscles or sensory receptors. The axons of the LMNs in these peripheral nerves then synapse with muscle fibers. LMNs are also known as *α motor neurons* because they have relatively large diameter axons. One axon of a lower (α) motor neuron plus all the muscle fibers it innervates equals a *motor unit* (Fig. 15.2). The motor unit responds to excitation by propagating

a signal along the axon and contracting all of the muscle fibers associated with it. Muscle contraction stimulates sensory receptors in the muscles, tendons, joints, and skin, depending on the type and force of contraction. These receptors send signals through sensory fibers of the peripheral nerves (running in the same nerve bundle as the axons of the LMNs) to communicate the result of muscle contraction and movement to the CNS, both locally within the spinal cord and to higher neural levels for processing. Depending on the site of the pathology, neuromuscular diseases can be classified as neurogenic or myopathic. ALS and GBS are neurogenic disorders: they affect the neurons, not the muscles directly.

With motor neurons involved in both disorders, movement abilities can show several types of deficits. Using the conceptual model of the six dimensions of movement,² *strength* and *endurance* are primary losses, with *flexibility* and *speed* deficits secondarily resulting from these. The movement dimensions of *adaptability* and *accuracy* may be affected to a greater or lesser extent. See Fig. 15.3 for a movement ability plot or MAP showing the relationship of possible deficits in the six dimensions of movement with ALS or GBS.³ Changes in movement ability can make themselves apparent in limbs, trunk, neck, face, eyes, or oral cavity.

Weakness is a primary symptom in both disorders (with loss of *strength*), with decreases in the individual's ability to generate force in the affected muscles. Loss of muscle strength can result in not only limb and trunk dysfunction but also speech, swallowing, and respiratory difficulties. Fatigue is another primary deficit (with loss of *endurance*); neurogenic disorders tend to result in *central fatigue* (deficit in ability to recruit and activate motor units) in contrast with myopathic

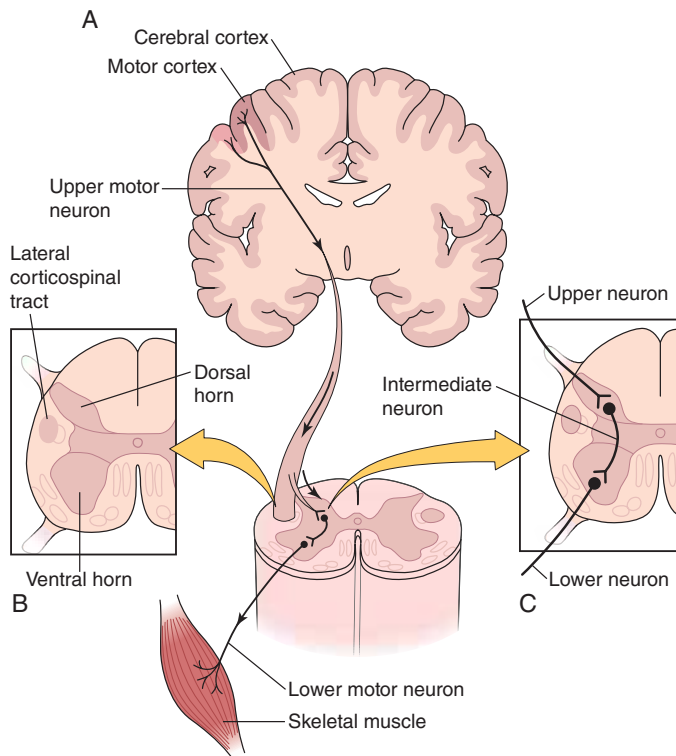

Fig. 15.1 Upper and Lower Motor Neurons. (A) The origin of the upper motor neurons in the motor cortex, showing an uncrossed portion of their pathway to the lateral corticospinal tract and spinal cord to synapse with lower motor neurons. Lower motor neurons originate in the nuclei of the motor cranial nerves (not depicted) and ventral horn of the spinal cord, and carry the neural signal to skeletal muscles. (B) Cross-section of the spinal cord showing the location of the lateral corticospinal tract on one side of the body. (C) Pathway of an upper motor neuron showing the connection with lower motor neurons in the ventral horn. (Modified from Blatzheim K. Interdisciplinary palliative care, including massage, in treatment of amyotrophic lateral sclerosis. *J Bodyw Mov Ther.* 2009;13:328–335.)¹

disorders that tend to induce *peripheral fatigue* (deficit in ability of muscle fibers to contract forcefully).⁴

Secondary movement problems include loss of flexibility and speed of movement. *Flexibility* may be affected if muscles develop *spasticity* (with UMN involvement in ALS) and show resistance to quick stretch. Other flexibility issues or loss of range of motion (ROM) arise secondarily if resistance to movement, painful muscle spasms, or immobility because of weakness and fatigue result in stiff muscles and joints. *Speed* is affected as force production diminishes and stiffness impedes movement; individuals will have more difficulty putting on a burst of speed. Muscles may also adapt to weakness and disuse by changing the ratio of slow- and fast-twitch muscle fibers (with fewer fast-twitch fibers), further affecting the ability to move fast at will.

Adaptability, the ability to sense obstacles or changes in the environment and change the course of a movement in response,² may be affected with primary sensory loss in GBS. Adaptability may be secondarily affected when the strength dimension is so dysfunctional (ALS or GBS) that the muscles cannot change the course of a movement (to keep a body upright), even if sensory information (about a perturbation) reveals a need for it. *Accuracy*, the ability to move in a coordinated fashion with the right timing and direction for the task, may also show secondary deficits related to weakness (ALS and GBS). Accuracy shows primary deficits as ataxia in some forms of GBS (Miller-Fisher syndrome) that are more likely to have dysfunction of the neurons carrying proprioceptive information from the muscle spindles.

The International Classification of Functioning, Disability and Health (ICF) model⁵ provides a framework for understanding the effects of devastating diseases such as ALS and GBS (Fig. 15.4). Movement disorders with neuromuscular diseases (*health condition*) affect not only the *body structures* of motor nerves and muscles and *body functions* commensurate with the movement dimensions of strength, endurance, and flexibility, but also the *activities* and *participatory* roles that an individual has in life. Activities such as walking may undergo limitations when the lower extremity muscles are weak; participation in work or leisure activities may undergo restrictions when walking

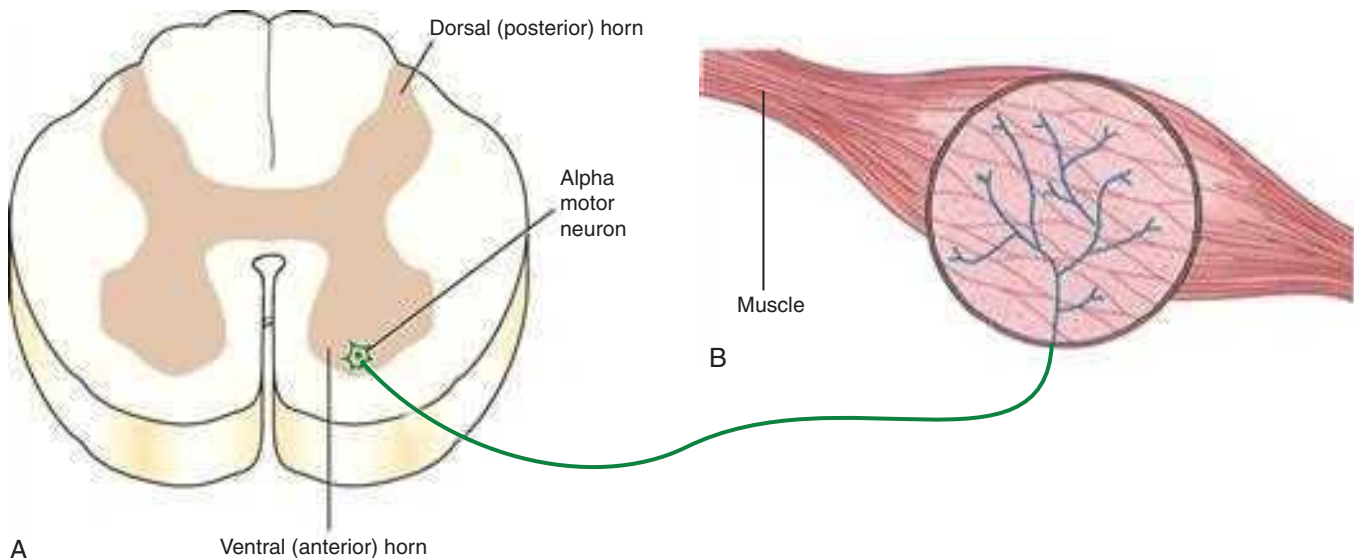

Fig. 15.2 One Motor Unit: α motor neuron (A) and muscle fibers innervated by it (B). (Modified from Allen DD, Widener GL. Tone abnormalities. In: Cameron MH, ed. *Physical Agents in Rehabilitation*. 5th ed. St. Louis, MO: Elsevier; 2018.)

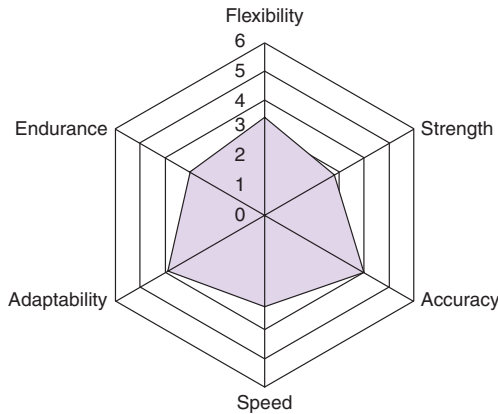

Fig. 15.3 Movement Ability Plot (MAP)³ depicting movement dimensions² likely to be most affected by amyotrophic lateral sclerosis (ALS) or Guillain-Barré syndrome (GBS) when a patient is moderately impaired: strength and endurance are primary, but other movement dimensions will also be affected. Scale from logits is transformed to 0 (cannot do even with assistance—may be the case with severe impairment in ALS or GBS) to 6 (moves competitively, as in a professional athlete).

deteriorates. *Environmental* and *personal* factors will influence how the individual responds to the impairments of body structure and function within the activities and participatory roles that individual engages in. As the medical and rehabilitative management of these disorders proceeds, patients' individual needs will require assessment to ensure that, together with the patient (and family), the rehabilitative team can help optimize quality of life at whatever stage of the disease process the patient presents.

AMYOTROPHIC LATERAL SCLEROSIS

Etiology, Incidence, and Medical Diagnosis

ALS, the most common form of *motor neuron disease* in adults and frequently called *Lou Gehrig disease* in the United States, is a relentless, degenerative, terminal disease affecting both UMN and LMNs. The name comes from two concurrent events. "Amyotrophy" indicates the muscle atrophy and weakness resulting from massive loss of lower (α) motor neurons originating in the spinal cord and motor cranial nerve nuclei in the lower brain stem. "Lateral sclerosis" indicates the demyelination and gliosis (i.e., "scarring" with hypertrophy and a dense

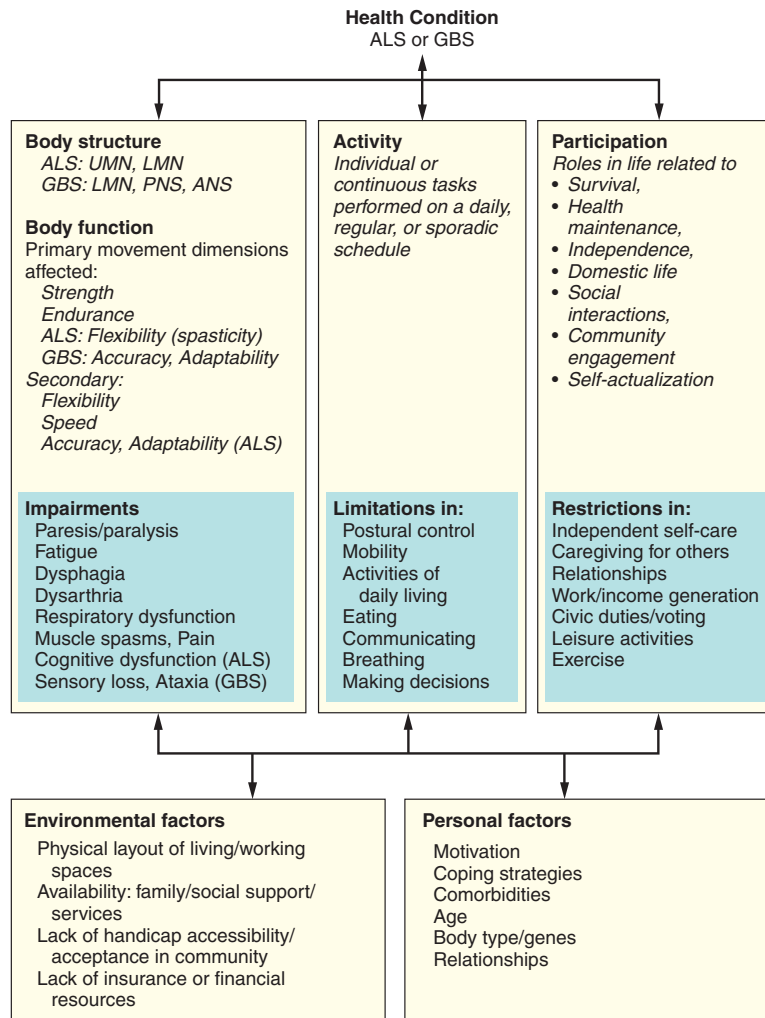

Fig. 15.4 Framework for relating the effects of ALS or GBS to function based on the International Classification of Functioning, Disability and Health⁵ and the Six Dimensions of Movement.² ALS, Amyotrophic lateral sclerosis; GBS, Guillain Barré Syndrome; PNS/ANS, peripheral/autonomic nervous system; UMN/LMN, upper/lower motor neurons. (Adapted from *International Classification of Functioning, Disability and Health: ICF*. Geneva, Switzerland: World Health Organization; 2001.)

fibrous network of neuroglia) of the corticospinal tracts (that run laterally in the spinal cord) and corticobulbar tracts resulting from degeneration of the *Betz cells* (also known as *pyramidal cells*) in the motor cortex, the cell bodies of the UMN. With both UMNs and LMNs affected, people typically experience rapid degeneration, become dependent for all care, and (without mechanical ventilation) die of respiratory failure within 3 to 5 years after symptom onset. A notable exception to this rule was Dr. Stephen Hawking, who lived with ALS for over 50 years before his death in 2018, working and contributing to society even while dependent on mechanical ventilation and assistance for all motor functions.

The cause of ALS is unknown. Numerous theories have proposed genetic, infectious,⁶ environmental, and autoimmune etiologies. Some authors suggest that ALS and other neurodegenerative disorders are related to TDP-43 proteinopathy, which links ALS to frontotemporal lobar degeneration (FTD), a disease that affects cognitive function but typically spares memory.⁷ Ninety percent of cases of ALS are sporadic without a known genetic component; however, approximately 5% to 10% seem to have a complex genetic basis coded on *ALS1* through *ALS8* and other mutations that are associated with frontal lobe dementias. Twenty percent of genetic causes of ALS are considered to be related to mendelian mutations in the superoxide dismutase-1 (SOD1) gene (*ALS1*). Other factors considered in the genesis of ALS are vascular endothelial growth factors, toxicity (e.g., from heavy metals such as lead, selenium, and mercury) leading to motor neuron death, oxidative stress, and mitochondrial dysfunction related to microglial inflammation^{8,9} and environmental factors.¹⁰ Controversy regarding the role of physical activity as a risk factor¹¹ or a factor associated with earlier onset of ALS versus neuroprotection against ALS¹² has evidence on both sides.¹³ Factors such as trauma and multiple traumatic brain injuries, associated with greater risk for ALS,¹² confound the evidence regarding the association of ALS with vigorous sport activity. Some evidence indicates that ALS is the consequence of multiple interactions among these factors, and that none of them alone is the direct cause.^{14,15}

Because ALS has no specific biomarkers identified, the differential diagnosis requires extensive work up, ruling out other possibilities and allowing time to monitor progression. Cervical or lumbar myelopathy, syringomyelia, multiple sclerosis, primary lateral sclerosis, diseases associated with LMN pathology, heavy metal toxicity, paraneoplastic syndromes, myopathies, and Lyme disease must be excluded before the diagnosis of ALS is made.¹⁶ Creatine phosphokinase levels are elevated in approximately 70% of patients and tend to be higher in patients with limb onset ALS rather than bulbar onset.¹⁷ Genetic testing to identify the mutations in the copper/zinc (Cu/Zn) SOD1 gene is available when a family history of ALS is present. Other laboratory tests, such as identification of biochemical markers in the blood and cerebrospinal fluid (CSF), are used to exclude other neurological diseases. Testing CSF may have an additional benefit. A meta-analysis of 10 articles examining elevated levels of neurofilaments (reflective of ongoing destruction of axons) in the CSF revealed a pooled sensitivity and specificity at 81% and 85%, respectively, for association with motor neuron disease (9 out of 10 articles specified ALS), indicating potential diagnostic accuracy in people already showing symptoms.¹⁸ Electromyography (EMG) and nerve conduction studies can be helpful to confirm the presence of widespread LMN disease (with neurogenic and fibrillation potentials and/or sharp waves) without peripheral neuropathy or polyradiculopathy. Neuroimaging studies can rule out conditions such as cervical myelopathy and myelitis¹⁹ that may have clinical signs similar to those of ALS.²⁰ To date, while multiple laboratory tests, genetic testing, and imaging studies are performed, they are used more to rule out other possibilities than to rule in ALS.

Clinical diagnosis of ALS requires a pattern of observed and reported symptoms of both UMN and LMN disease and persistent declines in physical functions that cannot be attributed to other disorders. Because of the overlap of symptoms with other neuromuscular disorders, misdiagnosis is not uncommon.²¹ The World Federation of Neurology (WFN) has developed suggested diagnostic criteria (the El Escorial criteria, refined by the Awaji²² criteria to identify specific EMG interpretations), indicating suspected, possible, laboratory-supported-probable, probable, and definite ALS for patients with ALS entering clinical research trials.²³ The categories have sometimes been simplified, labeling just three: possible, probable, and definite ALS. (The WFN ALS website [www.wfnals.org] provides up-to-date criteria used for clinical studies.) Essentially, a patient with “definite” ALS must show concomitant UMN and LMN signs in multiple spinal regions (regions designated as cervical, thoracic, lumbosacral) or in two spinal regions plus bulbar signs and show evidence of progression over a 12 month period.^{19,23} The category of “possible” ALS can be interpreted as a diagnosis of ALS if progressing LMN signs are present in two or more body regions, even without UMN signs, yet apparent as long as other diseases have been ruled out; the literature suggests that UMN pathology is present before clinical signs become apparent.¹⁹

ALS has an incidence of approximately 2 to 3 cases per 100,000 Caucasians, with somewhat lower incidence in Asians and African Americans.¹⁴ Mean age at onset is 57 years, with two-thirds of patients aged 50 to 70 years old at time of onset.²⁴ Men are affected approximately 1.3 to 1.5 times more frequently than are women, although gender differences decrease with late onset of disease (aged 70+).

Clinical Presentation

For an overall view of the clinical presentation of a person with ALS as categorized by the ICF model, review Fig. 15.4. The predominant body function impairments of ALS are weakness and fatigue (affecting movement dimensions of strength and endurance²), with muscle atrophy and fasciculation indicating body structure effects on LMNs and spasticity indicating body structure effects on UMNs (see Fig. 15.1). Activity limitations and participation restrictions progress as the impairments of weakness and fatigue become more severe, but an individual's clinical presentation will depend on environmental and personal factors as well, such as economic resources and coping mechanisms (see Fig. 15.4).

Some less prominent or prevalent body function impairments were originally thought to be exclusionary criteria for ALS: ocular motor abnormalities, deficits in sphincter control (especially bladder), sensory loss, or cognitive involvement. With longer survival facilitated by mechanical ventilation and better tools to examine pathology, these signs and symptoms are no longer considered spared, but merely resistant or delayed.²⁵ For example, in a review of literature on ocular motor pathology in ALS, Sharma and colleagues²⁵ speculate that the ontogenetically older and more complex pathways of the ocular motor system protect it somewhat from ALS pathology. The nuclei for cranial nerves III, IV, and VI do not receive direct monosynaptic connections from the motor region of the cortex like other motor neuron pools in the brain stem or spinal cord. Also, the predominant neurotransmitters are different (fewer glycinergic and muscarinic cholinergic receptors in the ocular motor nuclei) and the oculomotor neurons contain a higher ratio of calcium-binding proteins (important for maintaining lowering levels of intracellular calcium, thought to be a source of excitotoxicity in ALS) than in motor neuron pools typically affected in ALS.²⁵ In addition to ocular motility, signs of neurogenic bladder have been reported in about 40% of patients,²⁶ and progressive functional deficit in sensation have been recorded in ALS, perhaps related to ongoing immobility.²⁷

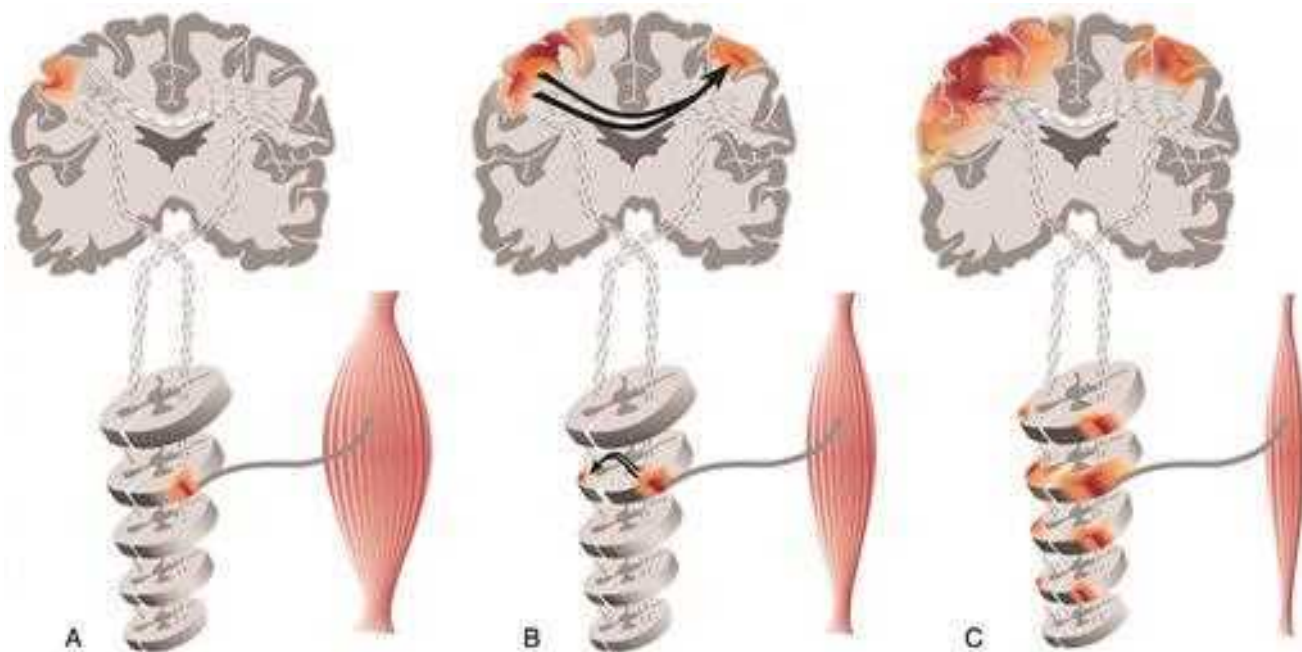

Fig. 15.5 Possible Pattern of Degeneration in Amyotrophic Lateral Sclerosis. (A) Onset in cortex or spinal cord; (B) interhemispheric and interneuronal connections in the cortex and spinal cord spread the disease from the site of onset to contralateral motor neurons; (C) degeneration continues in areas adjacent to sites of onset, affecting additional muscles in the same limbs and in additional regions. (Figure from Walhout R, Verstraete E, van den Heuvel MP, et al. Patterns of symptom development in patients with motor neuron disease. *Amyotroph Lateral Scler Frontotemporal Degener.* 2018;19:21–28.)

Similarly, cognitive deficits have been noted in ALS. A small subgroup of patients with both familial and sporadic forms of ALS has been identified as having concomitant evidence of FTD, with pathology in cortical areas outside of the cortical motor regions. These patients show lower scores on executive cognitive functions, word finding, and phrase length.²⁸ As people can exhibit a combination of ALS and FTD, the evidence suggests that a common cause may be possible.²⁹ Because of these findings, therapists should be aware of the possibility of cognitive deficits in their patients with ALS, manifested as a decrement in planning, organization, and language problems.³⁰ Such patients may have more difficulty following through on medication and therapeutic recommendations, and their families may need more support. Unassociated with overall cognitive impairment, some deficits in action knowledge as opposed to object knowledge have been noted in patients with ALS, correlating with atrophy in the motor and premotor cortex.³¹

Although impaired strength and endurance predominate in ALS, the appearance of weakness (paresis to paralysis) and fatigue are heterogeneous. Some people have limb (spinal) onset; others have cranial nerve (bulbar) onset.³² Many start with a single limb involved (flail arm or flail leg) at first, with different neural roots and nerves affected within that limb. Some may present with progressive muscular atrophy (LMN predominant); others present with primary lateral sclerosis (UMN predominant). During initial diagnostic visits, patients frequently report to their physicians a profound sense of fatigue or the loss of exercise tolerance. Because the onset of ALS is insidious, most patients are not aware of the strength changes, or they have adjusted to the changes until they have difficulty with a functional activity such as tying shoes, climbing stairs, or stumbling with a fall. Physical examination usually demonstrates more widespread and extensive weakness and atrophy than reported by the patient. By the time most patients report weakness, they have lost approximately 80% of their motor

neurons in the areas of weakness. Relative preservation of function despite so much tissue damage demonstrates both the reserve and the plasticity of the nervous system (or the mindset of the individual patient who delays reporting changes) in the drive to adapt to meet functional goals. As the disease progresses, weakness spreads to include musculature throughout the body.

ALS progression varies with several distinct patterns according to the primary area of onset.³³ Lower-extremity onset is slightly more common than upper-extremity onset, which is more common than bulbar onset. With leg onset, the next area of symptoms tends to be the contralateral leg, then the ipsilateral and contralateral arm before bulbar symptoms appear, especially if a distinct indication of both UMN and LMN disease is present (Fig. 15.5). A significant diagnostic feature of the pattern of disease is the asymmetry of the weakness and the sparing of some muscle fibers, even in highly atrophied muscles. For example, a patient may have weakness of the right intrinsic and shoulder musculature or weakness of the left anterior tibial muscles. Bulbar symptoms are presaged by tongue fasciculations and weakness, facial and palatal weakness, and swallowing difficulties, which result in dysphagia and dysarthria. Table 15.1 lists bulbar and respiratory impairments and activity limitations in ALS. Pseudobulbar signs (sometimes referred to as pseudobulbar palsy or affect) are sometimes present in ALS, manifested by exaggerated laughing or crying beyond what seems to be appropriate to the situation.³⁴ Despite the pattern of onset, the eventual course of the illness is similar (with variations in timing) in most patients, with an unremitting spread of weakness to other muscle groups leading to total paralysis of limb, trunk, and diaphragm musculature and muscles innervated by the cranial nerves. Death is usually related to respiratory failure, occurring within 3 years of symptom onset in approximately 50% of patients.³⁵ With mechanical ventilation, up to 10% of people with ALS live longer than 10 years.³⁶

TABLE 15.1 Common Physical Findings with Bulbar Palsy

Body Structure— Innervation	Observation	Body Function Impairment	Activity Limitation
Tongue—Cranial Nerve (CN) XII	Fasciculations at rest; atrophy; difficulty articulating during speech	Strength: paresis to paralysis affecting range of motion and force in the anterior-posterior (protrusion-retraction), superior-inferior (touch palate), and lateral directions Speed: impaired ability to perform rapid motion Endurance: fatigues quickly	Dysarthria (spastic/flaccid/mixed): imprecise consonants <i>t</i> , <i>d</i> , <i>l</i> , <i>k</i> , <i>sh</i> , <i>soft g</i> ; slowed lateral motion, “ta-ta-ta” or “la-la-la” Inability to manipulate food bolus or avoid pocketing of food in cheeks Inability to lick lips or popsicle Unable to sustain effort to continue a conversation or complete a regular meal
Lips—CN VII	Lips slack Smile uneven, partial or absent Leakage of food or saliva	Strength: impaired to absent lip closure, pursing, suction action Endurance: if lip closure successful with effort, fatigues quickly	Dysarthria (imprecise consonants <i>p</i> and <i>b</i> ; <i>f</i> , <i>v</i>) Inability to whistle or kiss Inability to use a straw or fully clear a spoon or fork Drooling
Palate—CN V, X, IX	Uvula movement impaired during phonation (say “ahhhh”); changes in resonance of speech	Strength: unsustained or slow palatal elevation Endurance: fatigues with effort	Dysarthria (hypernasal speech; imprecise <i>k</i> and hard <i>g</i>) Impaired nasopharyngeal reflex on swallowing Choking; aspiration
Muscles of mastication, Masseter, temporalis—CN V	Atrophy; mouth hangs open	Strength: weak or no-longer-palpable contraction Endurance: chewing fatigue	Elimination of foods that require chewing Mouth breathing with drying of secretions
Pterygoids—CN V	Jaw does not move side to side or protrude	Strength: weak or absent	Cannot stick chin out
Tongue, lips, jaws combined	Slowed speaking rate Speech intelligibility drops	Strength: impaired Endurance: highly fatigable	Speaking rate over 160 words per minute (wpm) = Normal, presymptomatic* 120–160 wpm = Early changes in speech intelligibility <120 wpm = Rapid decline in speech intelligibility
Trapezius—CN XI Sternocleido-mastoid—CN XI	Cannot shrug shoulders Cannot lift head from supine	Strength: progressive weakness Endurance: highly fatigable	Inability to comb hair Inability to perform facial grooming May need neck collar to help support head when upright
Vocal cords, CN X	Breathy voice (if flaccid); strained or tense voice (if spasticity present), other changes in phonation during speech	Strength: progressive loss of vocal cord closure (weak—> flaccid) Flexibility: tight (if spasticity present) vocal cords Endurance: highly fatigable (if weak)	Impaired oral communication Impaired singing Impaired inspiration (if spasticity present)
Extraocular muscles—CN III, IV, VI	Fixed gaze or nonconvergent eye movement	Strength: progressive weakness to paralysis	Generally occurs after other bulbar and head/neck muscle loss so no compensatory head movement available: limitation of gaze Diplopia if strength loss is asymmetrical
Respiratory Group			
Diaphragm—C3-C5	Shortness of breath Low voice volume	Strength: progressive weakness Endurance: highly fatigable	Diminished vital capacity Poor breath control; impaired ability to sniff or blow Difficulty sustaining a vowel
Intercostal and abdominal muscles—T1-T11 Accessory muscles of respiration—CN VII, XI, XII, C5-C8	Weak cough	Strength: progressive weakness Endurance: highly fatigable	With vital capacity moderately impaired, change in speech phrasing; at severely impaired, one syllable per breath, short of breath when swallowing

*Bandini A, Green JR, Wang J, Campbell TF, Zinman L, Yunusova Y. Kinematic features of jaw and lips distinguish symptomatic from presymptomatic stages of bulbar decline in amyotrophic lateral sclerosis. *J Speech Lang Hear Res.* 2018;61:1118-1129.

Once ALS has been diagnosed, knowing the natural history of the progression of ALS should help in the institution of medical and supportive treatment planning and interventions. Disease-specific standardized scales have been developed that help chart the course of ALS. Hillel and colleagues³⁷ developed the ALS

Severity Scale (ALSSS) for rapid functional assessment of disease stage. Their ordinal scale allows clinicians and therapists to score patients in four categories, with 10 points possible for each: speech, swallowing, and lower-extremity and upper-extremity function (Box 15.1). A multistage scale of severity

BOX 15.1 Amyotrophic Lateral Sclerosis Severity Scale**Lower Extremities, Upper Extremities, Speech, Swallowing****Lower Extremities (Walking)***Normal*

10	Normal ambulation	Patient denies any weakness or fatigue; examination reveals no abnormality
9	Fatigue suspected	Patient experiences sense of weakness or fatigue in lower extremities during exertion

Early Ambulation Difficulties

8	Difficulty with uneven terrain	Difficulty and fatigue when walking long distances, climbing stairs, and walking over uneven ground (even thick carpet)
7	Observed changes in gait	Noticeable change in gait; pulls on railings when climbing stairs; may use leg brace

Walks With Assistance

6	Walks with mechanical device	Needs or uses cane, walker, or assistant to walk; probably uses wheelchair away from home
5	Walks with mechanical device and assistant	Does not attempt to walk without attendant; ambulation limited to less than 50 ft; avoids stairs

Functional Movement Only

4	Able to support	At best, can shuffle a few steps with the help of an attendant for transfers
3	Purposeful leg movements	Unable to take steps but can position legs to assist attendant in transfers; moves legs purposefully to maintain mobility in bed

No Purposeful Leg Movement

2	Minimal movement	Minimal movement of one or both legs; cannot reposition legs independently
1	Paralysis	Flaccid paralysis; cannot move lower extremities (except, perhaps, to close inspection)

Upper Extremities (Dressing and Hygiene)*Normal Function*

10	Normal function	Patient denies any weakness or unusual fatigue of upper extremities; examination demonstrates no abnormality
9	Suspected fatigue	Patient experiences sense of fatigue in upper extremities during exertion; cannot sustain work for as long as normal; atrophy not evident on examination

Independent and Complete Self-Care

8	Slow self-care	Dressing and hygiene performed more slowly than usual
7	Effortful self-care performance	Requires significantly more time (usually double or more) and effort to accomplish self-care; weakness is apparent on examination

Intermittent Assistance

6	Mostly independent	Handles most aspects of dressing and hygiene alone; adapts by resting, modifying (e.g., use of electric razor), or avoiding some tasks; requires assistance for fine motor tasks (e.g., buttons and ties)
5	Partial independence	Handles some aspects of dressing and hygiene alone; however, routinely requires assistance for many tasks such as applying makeup, combing, and shaving

Needs Attendant for Self-Care

4	Attendant assists patient	Attendant must be present for dressing and hygiene; patient performs the majority of each task with the assistance of the attendant
3	Patient assists attendant	The attendant directs the patient for almost all tasks; the patient moves in a purposeful manner to assist the attendant; does not initiate self-care

Total Dependence

2	Minimal movement	Minimal movement of one or both arms; cannot reposition arms
1	Paralysis	Flaccid paralysis; unable to move upper extremities (except, perhaps, to close inspection)

Speech*Normal Speech Processes*

10	Normal speech	Patient denies any difficulty speaking; examination demonstrates no abnormality
9	Nominal speech abnormalities	Only the patient or spouse notices speech has changed; maintains normal rate and volume

Detectable Speech Disturbance

8	Perceived speech changes	Speech changes are noted by others, especially during fatigue or stress; rate of speech remains essentially normal
7	Obvious speech abnormalities	Speech is consistently impaired; rate, articulation, and resonance are affected; remains easily understood

Intelligible With Repeating

6	Repeats message on occasion	Rate is much slower, repeats specific words in adverse listening situation; does not limit complexity or length of messages
5	Frequent repeating required	Speech is slow and labored; extensive repetition or a "translator" is commonly used; patient probably limits the complexity or length of messages

Speech Combined with Nonvocal Communication

4	Speech plus nonverbal communication	Speech is used in response to questions; intelligibility problems need to be resolved by writing or a spokesperson
3	Limits speech to one-word responses	Vocalizes one-word responses beyond yes and no; otherwise writes or uses a spokesperson; initiates communication nonvocally

Continued

BOX 15.1 Amyotrophic Lateral Sclerosis Severity Scale—cont'd**Loss of Useful Speech**

2	Vocalizes for emotional expression	Uses vocal inflection to express emotion, affirmation, and negation
1	Nonvocal	Vocalization is effortful, limited in duration, and rarely attempted; may vocalize for crying or pain
X	Tracheostomy	

Swallowing**Normal Eating Habits**

10	Normal swallowing	Patient denies any difficulty chewing or swallowing; examination demonstrates no abnormality
9	Nominal abnormality	Only patient notices slight indicators such as food lodging in the recesses of the mouth or sticking in the throat

Early Eating Problems

8	Minor swallowing problems	Reports some swallowing difficulties; maintains essentially a regular diet; isolated choking episodes
7	Prolonged times, smaller bite size	Mealtime has significantly increased and smaller bite sizes are necessary; must concentrate on swallowing thin liquids

Dietary Consistency Changes

6	Soft diet	Diet is limited primarily to soft foods; requires some special meal preparation
5	Liquefied diet	Oral intake adequate; nutrition limited primarily to liquefied diet; adequate thin liquid intake usually a problem; may force self to eat

Needs Tube Feeding

4	Supplemental tube feedings	Oral intake alone no longer adequate; patient uses or needs a tube to supplement intake; patient continues to take significant (>50%) nutrition orally
3	Tube feeding with occasional oral nutrition	Primary nutrition and hydration accomplished by tube; receives less than 50% of nutrition orally

No Oral Feeding

2	Secretions managed with aspirator and/or medications	Cannot safely manage any oral intake; secretions managed with aspirator and/or medications; swallows reflexively
1	Aspiration of secretions	Secretions cannot be managed noninvasively; rarely swallows

has also been proposed based on milestones common among 1471 patients with ALS in one treatment center.³⁸ Patients in stage 1 (mild disease) have symptom onset, with noticeable or functional involvement in one region (bulbar, upper limb, lower limb, or diaphragmatic); at stage 1, individuals are functionally independent in ambulation, activities of daily living (ADLs), and speech. Stage 2a is when most people get diagnosed; stage 2B is when a second region shows clinical involvement. Stage 3 is when a third region is involved; the patient has (moderate) deficits in function in three regions or a moderate to severe deficit in one region and mild functional loss in two other regions. Stage 4A indicates need for gastrostomy because of eating difficulties; 4B indicates need for respiratory support (usually noninvasive ventilation).³⁸ The ALS Functional Rating Scale (ALS FRS) and the ALSFRS-Revised consist of 13 items with response options of 0 (unable) to 4 (normal performance) that assess how well people are functioning across various systems; this scale is frequently used clinically and in clinical trials to document status and changes (Box 15.2).³⁹ Mitchell and Borasio provide more information on the natural history of ALS.³⁴

Along with the primary impairments of weakness and fatigue affecting body structure and function in ALS, patients also have progressive limitations in activity and participation.⁴⁰ Activity limitations result in gradual loss of independence in community and then household tasks. Mechanical and electronic adaptive devices can help extend independence in some ADLs past the initial strength losses. Participation limitations result in progressive isolation from the community and family unless extraordinary efforts are made to implement an evolving communication system, usually using electronic interfaces.

Medical Prognosis

In almost all cases ALS progresses relentlessly and leads to death from respiratory failure. The rate of progression seems to be consistent within each patient but varies considerably among patients. Patients with an initial onset of bulbar weakness (dysarthria and dysphagia) and respiratory weakness (dyspnea) tend to have a more rapid progression to death than patients whose weakness begins in the distal extremities.³⁴ Reports vary in terms of long-term prognosis, depending on medical care and choices regarding mechanical ventilation, but death usually follows within 2 to 4 years after diagnosis. Diagnosis is often delayed 1 to 2 years after the onset of symptoms when the clinical presentation of symptom progression is recognized by a physician. A small number of patients live for 15 to 20 years.²¹

Years of survival after diagnosis may change as drug therapies are developed.⁴¹ In addition, increasing numbers of patients are electing to prolong life with home-based mechanical ventilation as opposed to palliative or comfort care only.

Medical Management

ALS has no known cure and few effective disease-slowing treatments. Mitchell and Borasio³⁴ summarize the results of trials of many putative ALS-modifying pharmaceuticals. Riluzole has the longest history as an approved treatment of ALS. Riluzole, a glutamate inhibitor, provides very modest improvement over a placebo in both bulbar and limb function, but not in actual strength of muscles.⁴² According to meta-analyses of randomized controlled trials (RCTs), riluzole extends lifespan an average of 2 to 3 months.⁴² The side effects were minimal in some studies, but fatigue and weakness have been noted in 26% and 18% of patients taking riluzole compared with a placebo.⁴³ In 2017, the

BOX 15.2 Amyotrophic Lateral Sclerosis Functional Rating Scale Revised

Date:..... Name Patient:..... Date of Birth:.....

Patient's number Right-/left-handed

Item 1: SPEECH

- 4 Normal speech process
 3 Detectable speech disturbance
 2 Intelligible with repeating
 1 Speech combined with nonvocal communication
 0 Loss of useful speech

Item 2: SALIVATION

- 4 Normal
 3 Slight but definite excess of saliva in mouth; may have nighttime drooling
 2 Moderately excessive saliva; may have minimal drooling (during the day)
 1 Marked excess of saliva with some drooling
 0 Marked drooling; requires constant tissue or handkerchief

Item 3: SWALLOWING

- 4 Normal eating habits
 3 Early eating problems—occasional choking
 2 Dietary consistency changes
 1 Needs supplement tube feeding
 0 NPO (exclusively parenteral or enteral feeding)

Item 4: HANDWRITING

- 4 Normal
 3 Slow or sloppy: all words are legible
 2 Not all words are legible
 1 Able to grip pen, but unable to write
 0 Unable to grip pen

Item 5a: CUTTING FOOD AND HANDLING UTENSILS

Patients *without* gastrostomy → Use 5b if >50% is through g-tube

- 4 Normal
 3 Somewhat slow and clumsy, but no help needed
 2 Can cut most foods (>50%), although slow and clumsy; some help needed
 1 Food must be cut by someone, but can still feed slowly
 0 Needs to be fed

Item 5b: CUTTING FOOD AND HANDLING UTENSILS

Patients with gastrostomy → 5b option is used if the patient has a gastrostomy and only if it is the primary method (more than 50%) of eating.

- 4 Normal
 3 Clumsy, but able to perform all manipulation independently
 2 Some help needed with closures and fasteners
 1 Provides minimal assistance to caregiver
 0 Unable to perform any aspect of task

Item 6: DRESSING AND HYGIENE

- 4 Normal function
 3 Independent and complete self-care with effort or decreased efficiency
 2 Intermittent assistance or substitute methods
 1 Needs attendant for self-care
 0 Total dependence

Item 7: TURNING IN BED AND ADJUSTING BED CLOTHES

- 4 Normal function
 3 Somewhat slow and clumsy, but no help needed
 2 Can turn alone, or adjust sheets, but with great difficulty
 1 Can initiate, but not turn or adjust sheets alone
 0 Helpless

Item 8: WALKING

- 4 Normal
 3 Early ambulation difficulties
 2 Walks with assistance
 1 Nonambulatory functional movement
 0 No purposeful leg movement

Item 9: CLIMBING STAIRS

- 4 Normal
 3 Slow
 2 Mild unsteadiness or fatigue
 1 Needs assistance
 0 Cannot do

Item 10: DYSPNEA

- 4 None
 3 Occurs when walking
 2 Occurs with one or more of the following: eating, bathing, dressing (ADL)
 1 Occurs at rest: difficulty breathing when either sitting or lying
 0 Significant difficulty: considering using mechanical respiratory support

Item 11: ORTHOPNEA

- 4 None
 3 Some difficulty sleeping at night due to shortness of breath, does not routinely use more than two pillows
 2 Needs extra pillows in order to sleep (more than two)
 1 Can only sleep sitting up
 0 Unable to sleep without mechanical assistance

Item 12: RESPIRATORY INSUFFICIENCY

- 4 None
 3 Intermittent use of BiPAP
 2 Continuous use of BiPAP during the night
 1 Continuous use of BiPAP during day & night
 0 Invasive mechanical ventilation by intubation or tracheostomy

Interviewer's name

ALS Functional Rating Scale Revised (ALS-FRS-R). Version: May 2015

Amyotrophic Lateral Sclerosis Functional Rating Scale—Revised; Form adapted from Cedarbaum JM, Stambler N, Malta E, et al. The ALSFRS-R: a revised ALS functional rating scale that incorporates assessments of respiratory function. BDNF ALS Study Group (Phase III). *J Neurol Sci*. 1999;169:13–21. Form available online: <https://www.encals.eu/wp-content/uploads/2016/09/ALS-Functional-Rating-Scale-Revised-fill-in-form.pdf>.

Federal Drug Administration (FDA) approved the use of edaravone, a free radical scavenger, in the early disease stages of ALS; further research is needed to determine whether this drug is associated with improvement in quality of life.⁴⁴

Animal studies reveal some promise. In a mouse model of ALS, cell-therapy researchers targeted both the motor neurons and

astrocytes and the microglia that surround them, noting an additive effect on life-span and motor function.⁴⁵ This study confirms that the pathology in the genetic strains of ALS stems from both the mutant gene expression in motor neurons and in the hostile cellular environment provided by the microglia. Unfortunately, the study of animal models may relate to the genetic forms of ALS (about 10% of cases)

but does not translate well to the sporadic forms. A 2016 Cochrane review of cellular treatments in humans with ALS found no completed RCTs, although several trials were under way.³⁶ Jaiswal in 2017¹⁵ highlighted the promise of stem cell research for humans: induced pluripotent stem cells can be prepared in vitro to differentiate as motor neurons with ALS, to create “disease in a dish.” Microglia and astrocytes can also be created. With substantial amounts of human cells to work on, promising replacement cellular therapies can be tried, repeated, and modified before in vivo trials begin.

The popular press has reported on nutritional cures for ALS, including regular use of vitamin E. However, Orrell and colleagues⁴⁶ found insufficient evidence to support clinical use of vitamin E supplements in ALS as an additive to riluzole treatment or as adjunctive therapy, although no apparent contraindication was found to taking the supplement. Vitamin D supplementation was associated with a reduction in functional decline in preliminary studies.⁴⁷ Other nutritional and non-pharmaceutical supplements have had some success in animal models of ALS, but this has not yet been confirmed in humans.⁴⁸

Cannabis has been studied for its effect on spasticity in patients with multiple sclerosis and spinal cord injury, but evidence in ALS is limited. In a study of 131 people with ALS, 13 used cannabis, with reports of reduction in spasticity, pain, and depression.⁴⁹ A systematic review cites moderate-quality evidence indicating that tetrahydrocannabinol (THC) is probably ineffective in reducing muscle cramps in ALS.⁵⁰ As with many other approaches, more high-quality research is needed.

Because of the apparent hopelessness of the diagnosis, many physicians, especially those not associated with major medical centers having neuromuscular disease units, do not refer patients with ALS for rehabilitative or support services. However, few primary care physicians or neurologists have extensive experience in the care of patients and families coping with ALS because of the low incidence of the disease. Referral of patients with ALS to a multidisciplinary clinic typically extends the patient's life-span, especially patients with bulbar onset of ALS.^{35,42,51}

Although the overall disease course has not been halted, several specific impairments have been addressed through medical and pharmaceutical interventions. The following subsections discuss medical management of muscle spasms and pain, dysphagia, dysarthria, and respiratory dysfunction.

Muscle Spasms and Pain

Some patients experience muscle cramps and spasms related to UMN pathology, and up to 73% of patients complain of pain, typically in the later stages.³⁴ Muscle soreness and nonspecific aching are common, perhaps resulting from immobility or small traumas to paralyzed muscles during caregiving procedures or injudicious overexertion. A Cochrane systematic review in 2013 found no randomized or quasi-RCTs of drug therapy for pain in ALS, although the authors noted several case series reporting the use of acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), or opioids.⁵² In a more recent study, 46% of 80 patients with motor neuron disease (71 with ALS) reported chronic pain (daily for over 3 months), with muscular origins being the most frequent source.⁵³ Neuropathic pain was absent. In this study, analgesics or antiinflammatories usually resulted in good relief of pain.⁵³ Because many patients have compromised respiratory function, the physician must take great care when prescribing pain medication that depresses respiratory drive, especially opiates, which are often used when antispasmodics or antiinflammatory pain medications no longer work.³⁵ Patients should be instructed to keep a daily reporting log of the effectiveness of prescribed medication so that the dosage can be adjusted if necessary.

Stretching and massage may prove helpful for nocturnal muscle cramps.³⁵ Some patients may respond to medications such as quinine or baclofen to relieve symptoms, but evidence of effectiveness is currently low quality in ALS.⁵⁰

In addition to muscle spasms, spasticity may affect function in many patients. In a review of studies on the treatment of spasticity in ALS, Ashworth and colleagues⁵⁴ found only one randomized study addressing spasticity: a moderate-endurance exercise regimen decreased spasticity at 3 months after initiation of the program. Kesiktas and colleagues⁵⁵ report that in a controlled study of spasticity in patients after *spinal cord injury*, adding hydrotherapy to a program of medication and exercise decreased severity of spasticity-related spasms and decreased the amount of medication required. A similar response could be hypothesized in patients with ALS. Medications such as baclofen (sometimes administered via implanted intrathecal baclofen pump), tizanidine, dantrolene sodium, and diazepam are useful for some patients with spasticity. Because each has a different action and side effects, the medications may have to be adjusted to find the right dosage and combination for the individual. In some patients with severe cramping, botulinum toxin injections might be helpful, but they must be carefully administered to prevent further weakness and loss of function. Note that spasticity, as a sign of UMN loss, may appear in some patients, but then may diminish or disappear as LMN disease in ALS eventually stymies the ability of the nervous system to increase tone in the muscles.

Dysphagia

Dysphagia, defined as difficulty swallowing liquids, foods, or saliva, contributes to deficits in nutrient intake in the patient with advancing ALS,⁵⁶ and must be dealt with aggressively. Dysfunction with chewing, manipulation of food, and swallowing is associated with weakness of the lips, tongue, palate, and mastication muscles.⁵⁷ One study of 86 consecutive patients with ALS determined that 79% had dysphagia; they tended to be underweight, with dysfunction of both oral and pharyngeal phases of swallowing and more difficulty with thin liquids.⁵⁸ This means that most patients with dysphagia also have severe problems with management of their saliva (sialorrhea). If a patient has difficulty transporting saliva back to the oropharynx for swallowing, choking and drooling are common. Drooling, in particular, is disconcerting to the affected person, who must constantly wipe the mouth or have someone do it for him or her. Embarrassment associated with lack of control of saliva or management of food intake can result in social isolation.⁵⁷ As the progressive loss of swallowing develops, patients are at extreme risk for aspiration. Combined with dysfunction of the respiratory muscles, aspiration can be deadly.

Direct rehabilitation to address the action of eating and swallowing is rarely described in the literature, and little has been reported regarding objective measures of its benefit.⁵⁹ General techniques include attention to head position and posture when eating, changing bolus size and swallowing frequency, using sensory augmentation, and changing the consistency or texture of foods and drinks. Tongue strengthening has been piloted, with direct changes in tongue strength and endurance, but little effect on swallowing safety.⁵⁹

When swallowing becomes a burden, secretions are often thickened because of dehydration. Viscosity of saliva can best be treated by hydration and, in some cases, pharmaceuticals. Medications such as decongestants, tricyclic antidepressants, and anticholinergic agents can help control the amount of saliva, provided the patient is well-hydrated.⁶⁰ A randomized pilot study compared radiotherapy and botulinum A toxin injections into salivary glands to control drooling and found little difference between them; neither works well when the patient has severe dysphagia.⁶¹

Although dietary treatment is not known to be effective in changing the course of ALS, rapid weight loss in ALS (>10% original body mass index) has been linked to more rapid loss of function; thus a nutritious diet must be maintained to meet caloric, fluid, vitamin, and mineral needs. Seventy-three percent of patients with ALS in mid stages have difficulty bringing food to the mouth, making them dependent on others for their dietary needs. Because of the time it takes to be fed, many patients decrease their intake. In a study of 370 patients with ALS at clinical stages 2, 3, and 4, Lee and colleagues⁵⁶ found that energy intake was less than total daily energy expenditure at all stages, but especially at stage 3. The authors conclude that nutrition support should be started at least before stage 3.⁵⁶ Nutrition support should include a dietary consultation to determine the choice and progression of solid and liquid foods and supplements.⁶² Appel and colleagues⁶² describe nutritional plans to maintain nutrient intake and hydration in patients with motor neuron diseases.

Patients who are no longer able to consume nutrients orally because of motor control problems and recurrent aspiration may need a percutaneous endoscopic gastrostomy (PEG) for feeding, depending on the patient's wishes for long-term care.⁶³ Some evidence exists that the PEG should be performed early in the disease process to prevent severe weight loss and aspiration.⁶⁴ Plus, a PEG must be placed (if at all) before the forced vital capacity (FVC) drops below 50%, because the PEG placement procedure generally includes intubation; if the FVC is too low, clinicians may not be successful at weaning the patient off the ventilator once the PEG is placed. Mixing nutritional issues with respiratory life support complicates the decision making process for the patient and family. Although a PEG may not appreciably lengthen survival time,⁶⁵ quality of life may improve if patients have less fear of choking or aspiration and further weight loss is inhibited. Receiving nourishment from a PEG does not prevent the person from taking food orally if desired.

Dysarthria

Dysarthria, defined as impairment in speech production, is the result of abnormal function of the muscles and nerves involved in talking. It is manifested by dyscoordination of the tongue and lips, larynx, soft palate, and respiratory system. Speech impairments are the initial symptom in most patients with bulbar involvement; however, a survey of 38 ALS clinics in the northeast region of the United States indicated that formal speech testing is performed at only 18% of sites.⁶⁶ Evaluation of speaking rate and sentence intelligibility have been particularly advocated; speaking rates less than 120 words per minute are associated with a more rapid decline in intelligibility.⁶⁶ Speech intelligibility is compromised by hypernasality, imprecise consonants and vowels, abnormalities of speed and cadence of speech, and reduced vocal volume.⁶⁷ Speech is further compromised by inadequate breath control for normal phrasing. A possible option to help patients with severe hypernasality is a palatal lift prosthesis to augment velopharyngeal function.^{68,69} Because little can be done medically to delay the loss of speech control, early referral to a speech therapist is essential. Numerous augmentative and alternative communication systems are now available, the simplest being voice amplifiers, dry erase boards, communication boards, and text to speech apps on devices such as tablets or phones. More complex (and costly) systems include computer-based head or eye tracking text-to-speech systems that can be modified as patient status changes. The type of communication system should be chosen upon consultation among the patient-caregiver and rehabilitation team.⁷⁰

Up to 95% of people with ALS eventually lose their speech function, with devastating effects on quality of life.⁶⁷ In the advanced stages of ALS, if a patient has a tracheostomy for respiration and has lost all

motion in bulbar muscles as well as limb and trunk musculature, communication may rely on eye movements. This is called "locked-in state" because cognition and emotion are assumed to be relatively intact. Some brain-computer interface technologies have assisted with communication in this state. If eye movement is also lost, the condition is called "completely locked-in state." Functional near-infrared spectroscopy (recording changes in oxygenation of the brain) as the entry point for brain-computer interface has been tried in people with ALS to at least give capability for automatic yes/no responses to questions.⁷¹ Future research may continue to expand on the technology currently under investigation.

Respiratory Management

Respiratory failure is the primary cause of death in patients with ALS. Progressive respiratory failure is related to primary diaphragmatic, intercostal, abdominal, and accessory respiratory muscle weakness (see Table 15.1).⁷² Respiratory failure should be anticipated and discussed early following the diagnosis of ALS (as patients and families are ready), so that patients and their caregivers can express their wishes and develop an advanced directive for care in the terminal phase of the disease.⁷³

Physiological tests used to indicate respiratory dysfunction include vital capacity (VC), sniff nasal pressure, *maximal inspiratory pressure* (MIP), and nocturnal oximetry.²¹ VC (commonly reported as percentage predicted) has been measured in various ways; measuring *slow vital capacity* (SVC, recording volume upon slow exhalation after maximal inspiration as opposed to *forced vital capacity* [FVC] that requires fast and effortful exhalation) has been advocated in ALS because it requires less effort and thus can continue to be assessed through more of the disease process.⁷⁴ However, FVC remains the usual indicator of the need for ventilation: when the measure drops below 75% (of normal expected) FVC, the individual should be monitored for respiratory failure; 50% (of normal expected) FVC indicates need for ventilatory assistance.⁷⁵ Some researchers have explored instituting assisted respiration intermittently at earlier stages (77% FVC).⁷⁶ Clinical signs of increased respiratory dysfunction are dyspnea with exertion or lying supine, hypoventilation, weak or ineffective cough, increased use of auxiliary respiratory muscles, tachycardia (also a sign of pulmonary infection with fever and tachypnea), changes in sleep pattern, daytime sleepiness and concentration problems, mood changes, and morning headaches.⁷⁷

In early stages of patient care, physical therapists (PTs) may help manage respiratory dysfunction by providing postural drainage with cough facilitation (suctioning if necessary), especially during acute respiratory illnesses. The patient and care providers should also be taught breathing exercises, chest stretching, and incentive spirometry techniques, as well as postural drainage techniques if the caregivers are prepared to provide such support. Although breathing exercises consisting of resisted inspiratory muscle training can facilitate functional respiration, even practicing unresisted breathing for 10 minutes three times a day has been shown to result in improved function.⁷⁸ Breathing techniques such as diaphragm training have shown little benefit, perhaps because patients have difficulty changing their pattern of breathing even with the training. Overall, inspiratory muscle training in ALS, although showing some effect on survival time in one out of the four studies reviewed, requires further research with standardized protocols and timing.⁷⁹ An assessment of the home environment is imperative to identify sleeping positions and energy conservation techniques that can make breathing easier and be incorporated into the patient's daily life.

As respiratory symptoms increase, some advocate the intermittent use of oxygen at 2 L/min or less; the down side of supplemental oxygen

Fig. 15.6 Example of Mouthpiece Ventilation Interface for Noninvasive Ventilation. **(A)** Mouthpiece, flexible tubing, mechanical ventilation unit; **(B)** patient with amyotrophic lateral sclerosis using mouthpiece interface for noninvasive ventilation (NIV) during the day. This patient requires NIV 24 hours a day. He uses a nasal interface at night. (From Garuti G, Nicolini A, Grecchi B, et al. Open circuit mouth-piece ventilation: concise clinical review. *Rev Port Pneumol.* 2014;20:211–218.)

is possible suppression of the respiratory drive with potentially poorer outcomes. When hypoventilation with a decline in oxygen saturation becomes common during sleep, resulting in morning confusion and irritability, patients have the option to initiate use of noninvasive, intermittent positive-pressure ventilation (abbreviated NIV or NIPPV). NIV provides greater inspiratory than expiratory pressure to decrease the effort of breathing, and can be administered by mask, contoured nasal delivery systems, or a mouthpiece⁸⁰ interface (Fig. 15.6). Some evidence indicates that early use of NIV can increase survival time by several months and increase quality of life.⁸¹ Moderate-quality evidence indicates that the length of survival with NIV depends on bulbar function: if bulbar function is less than moderately impaired, median additional days was 205; if bulbar function is poor, NIV neither prolongs survival nor improves quality of life, although sleep function may improve.⁷⁶ When a patient can no longer benefit from NIV, a decision must be made about initiating invasive ventilation by tracheostomy⁸² or to switch to palliative care.⁸³ (See also Miller and colleagues⁸⁴ for a discussion of practice parameters in the decision making process related to ventilatory support.) Although in the initial stages of ALS most patients indicate they would not want prolonged ventilator dependence at home, patients may change their minds as they adapt to the disease restrictions or they and family members may retain hope for the future despite functional losses.⁸⁵ A small study of patients who started tracheostomy intermittent positive-pressure ventilation (TIPPV or TIV) demonstrated increased long-term survival (2 to 64 months).⁷³ In another series of 70 patients on long-term TIPPV, 50% of the patients were living after 5 years; however, 11.4% of these patients had entered a “locked-in” state.⁸⁶ Decisions about long-term ventilator use should be made by the patient and involved family

members or partners, with input from the interdisciplinary team caring for the patient. Discussions of preferred long-term care options should be revisited as the patient’s condition changes.

If a patient decides that home ventilation is a reasonable option, those involved in the decision might benefit from visiting another patient who is using in-home mechanical ventilation (HMV). Because the decision for home mechanical ventilation (HMV: NIV or TIPPV) also affects the life of the patient’s spouse, children, and extended family, who may be responsible for some aspects of home care or whose lives may be affected by the presence of in-home nurses or attendants, the decision for HMV should not be taken lightly. Extensive preparation, ongoing support, and respite options for caregivers are necessary if HMV is to be successful. Success of HMV also depends on such variables as third-party payment for home care equipment and nurse or attendant staffing, working status of the partner or spouse, age and physical fitness of the spouse and children, pre-ALS family psychosocial interactions, and financial factors. HMV should be viewed as long term, often extending for more than 1 year. Initiation of HMV results in a reasonable perceived quality of life for the patient, yet caregivers report that their quality of life may be lower than the patient’s because of the burden of care that must be provided.⁸⁷

With chronic respiratory insufficiency, the patient and family must be involved in the long-term care decisions related to instituting mechanical assistance (invasive ventilation) under either emergency situations or in response to gradual deterioration. This discussion should occur before respiratory failure develops in patients. Acute respiratory failure can happen quickly and is generally frightening; few patients or family members are prepared to forego intubation and artificial ventilation during the emergency unless they have settled the issue early.

Patients and caregivers should understand that not making a decision about mechanical ventilation, noninvasive or invasive, is a decision to support mechanical ventilation.⁸⁸

Physicians and health care workers who work with the patient and family must be aware of their own feelings and beliefs about prolonging life and the value of quality of life. For example, a healthy physician or therapist who values control and an active lifestyle may envision a life on a ventilator as intolerable and pass that value on to the patient, who may or may not have the same needs. The patient's decision, or change in decision, must be respected by the medical team involved in care. In medical centers that use a team approach, patients and families may find support by meeting with counselors or peers with ALS who are making or have made decisions about long-term ventilator care.

Therapeutic Management of Movement Dysfunction Associated With Amyotrophic Lateral Sclerosis

Perhaps because of the multitude of issues to consider when managing the impairments and limitations associated with ALS, evidence suggests that patients treated by a specialized ALS multidisciplinary team (typically including physician, PT, occupational therapist, speech language pathologist, respiratory therapist, nurse coordinator, and social worker)⁸⁹ fare better than do those treated by single-source providers,⁹⁰ or general neurology clinics.⁴³ One study reported a 2-year post-diagnosis mortality rate of 24% with multidisciplinary care compared to about 50% after 18 months in historical controls.⁹¹ However, a systematic review of the evidence for multidisciplinary care advantages in this population concluded that the evidence is of low quality, so far,⁹² with no controlled trials identified as of 2017.⁵⁰ Whether administered through an ALS-specific multidisciplinary team or not, therapeutic management will necessitate examination of the patient's current status, evaluation of the deficits in relation to patient preferences and needs, and establishment of a plan based on mutually determined and realistic goals. In addition to the team members listed previously, the plan may eventually involve nutritionists, orthotists, pulmonologists, gastroenterologists, assistive technology experts, home modification/designer experts, psychologists, and palliative-care providers.⁸⁹

The rate of the patient's disease progression, the areas and extent of involvement, and the stage of illness must be considered. A patient at the initial stages (independent) will have different needs than a patient at later stages (dependent) whether or not the patient has chosen to have assisted ventilation. NIV or tracheostomy ventilation may extend life-span, but typically individuals have a markedly reduced mobility level. The goal at all stages is to focus on what the patient needs to optimize health and increase quality of life. With guidance and environmental adaptations, patients with slowly progressing weakness may be able to continue many of their ADLs for an extended number of months or years. In the final stages of the disease, when the patient is bedridden, programs to increase long-term strength or endurance evolve into programs to improve patient-caregiver communication and handling for daily tasks. At this stage, interventions such as stretching may not effectively control contracture development. However, patients who are dependent on all mobility may still benefit from positioning and ROM exercises to decrease muscle and joint pain related to immobility. The prescription of assistive devices and training of caregivers will be needed through much of the final stage. The efficacy of therapeutic interventions will be related to the timing of interventions, the motivation and persistence of the patient in carrying out the program, and support from family members or caregivers. Objective documentation using standardized outcome measures will help justify the usefulness of therapeutic interventions at each stage of this disease. For examples of rehabilitation team roles at three different stages of ALS, see the review with case studies by Majmudar and colleagues.⁸⁹

Assessment

Rehabilitation professionals specifically address body function impairments, activity limitations, and participation restrictions related to ALS (see Fig. 15.4), along with environmental and personal factors, using standardized measures where possible.⁹³

The extent of the therapeutic assessment by any one rehabilitation professional will depend on whether the clinician is working as a member of a rehabilitative team or as an independent or clinic-based therapist receiving a referral to evaluate and treat. PTs and OTs working as team members may have a more circumscribed role related to gross motor function and ADLs, with other consultants focusing on bulbar, respiratory, and environmental adjustments. The therapist working in a facility without a neuromuscular disease clinic or in a community or rural environment, however, should be aware of the need to carry out a broad-based assessment. In addition to standard neuromuscular, musculoskeletal, and functional-level examinations within the specific discipline of PT or OT, the therapist should also evaluate the patient's stated or observed functional problems relative to bulbar and respiratory impairments, environmental barriers to independence, and caregiver education.

If possible, before the patient's initial visit, the therapist would benefit from contacting the patient and requesting that he or she keep an activity log for several days. If an early contact is not possible, the therapist can assign that task during the initial session. The log should include 15-minute time increments in which the patient or caregiver can record what she or he was doing during a specific period. The log should also indicate whether the patient was experiencing fatigue or pain during the activity and how the patient perceived her or his respiratory status. An example of a completed activity log is shown in Fig. 15.7. The patient's sense of fatigue with repetitive muscle activity or functional tasks should be specifically tracked.

Primary deficits. Weakness and fatigue will be the primary deficits (see Fig. 15.3), with spasticity or other problems following depending on the location of strength loss. Muscle weakness and the experience of fatigue will require separate measures.⁹⁴ In the literature, strength has been assessed with manual muscle testing (MMT) or maximal voluntary isometric contract (MVIC) against a strain gauge or dynamometer. Multiple muscles may be tested by uniformly trained therapists and averaged together using MMT numbers along with minus and plus scores (e.g., 4-, 4, 4+) to convert scores to a 0 to 10 scale; the result is both reproducible and sensitive to change in ALS. Equally reproducible is the Tufts Quantitative Neuromuscular Evaluation (TQNE) that measures muscle strength of 10 muscle groups bilaterally using standardized positions and a strain gauge or dynamometer, along with pulmonary function and timed motor tasks. The TQNE provides reliable measurement but requires large equipment space and frequent position changes, which can be very resource intensive and fatiguing for patients.⁹⁵ For testing of single muscles or a few muscles to determine change with intervention, a quantitative measure is recommended, such as hand-held dynamometry testing or grip or pincher strength testing, with standardized protocols to maximize reliability.

Fatigue may occur at any stage, whatever the patient's strength or physical capabilities.⁹⁶ Fatigability is typically greater in people with ALS than without ALS, and can be assessed with a Rate of Perceived Exertion (RPE) scale following activity, the change in maximal strength produced (dynamometer recording or MVIC) after strenuous activity, or the deficit in number of meters walked in minute 6 versus minute 1 of a 6-Minute-Walk-Test (6MWT). Perception of fatigue can be assessed using self-report measures such as a visual analogue scale for fatigue (VAS-F) or questionnaires covering different dimensions of fatigue such as the Fatigue Severity Scale (FSS).⁹⁷

Name: C.J.DATE: 5-10-00
DAY: Saturday**DAILY ACTIVITY LOG**

- Instructions:
- 1) In column I write in what you are doing during the 24 hour period. You may draw a line or an arrow to indicate when the activity occurs for more than one 15 minute time period.
 - 2) In column II indicate whether you are lying down, sitting, standing, or moving actively (walking, etc.) during the activity.
 - 3) In column III on a 10 point scale, indicate how fatigued you feel while performing the activity (No fatigue = 0, extreme fatigue = 10.)
 - 4) In column IV indicate where you feel pain if any and score the intensity on a 10 point scale (No pain = 0, extreme pain = 10.)

Try to fill out your log three or four times a day so you don't forget what you have been doing. An example is shown below.

	I	II	III	IV	
	What are you doing? Type of activity	What position are you in (lying, sitting, standing, moving)	Fatigue level 0 - 10	Location	Intensity 0 - 10
5:30 AM	sleep	lying	0		
45					
6:00					
15					
30	Bathroom shart, etc	standing	2	neck	3
45					
7:00	Breakfast	sitting	3	neck	3
15					
30					
45					
8:00	Reading	sitting	3	neck shoulder	3
15					
30					
45	walk	standing, walking	4	neck	2
9:00					
15	nap	lying	2	neck hips	4
30

30					
45	walk	standing, walking	5	hips	3
11:00					

Fig. 15.7 Example of a Log for Monitoring Activity Level of Patients With Amyotrophic Lateral Sclerosis.

Initial examination. A typical initial examination of a patient's movement and function includes the following components. Different rehabilitation personnel will target this list depending on the standards of their discipline, such as the comprehensive list of examination components in the Guide to Physical Therapist Practice.⁹⁸ Considerations specific to an examination in ALS are shown in Box 15.3. The extent of the examination in any one session depends on the patient's condition and the patient's or caregiver's ability to participate.

- **Patient History.** The chart review or history should extract the patient's medical and activity records, especially time since diagnosis, time course, and rate of disease progression to date, current

BOX 15.3 Considerations Specific to the Examination of Patients With Amyotrophic Lateral Sclerosis

Chart Review, Patient History

Time since onset, time since diagnosis
 Initial symptoms
 Disease progression rate
 Comorbidities
 Current medications and medical management
 Lifestyle, activities, participation, preferences
 Support system, caregivers available
 Living environment
 Current concerns and goals

Systems Review

Skin integrity (for redness or decubitus ulcers in patients who are immobile): visually inspect pressure points (bony prominences that might develop pressure sores) in supine, side-lying and sitting positions
 Communication (augmentation required?)
 Cognition (in case of overlapping frontotemporal degeneration)
 Vital signs
 Sensation

Tests and Measures

Visual inspection to identify symmetry of muscle bulk, fasciculations, function
 Movement ability of body region(s) with deficits
 Flexibility: Range of motion, muscle tone (spasticity)
 Strength: Identify patterns/progression of weakness/paralysis
 Accuracy: Observe/record ataxia/dysmetria in upper and lower extremities; perform rapid alternating movements as appropriate
 Speed: Timed tasks in motions where primary movers have against-gravity capability.
 Adaptability: Ability to change movement as obstacles or the environment changes
 Endurance: Questionnaires for experienced fatigue, circumstances; test fatigability
 Cranial nerves (bulbar vs. ocular-motor; motor and sensory)
 Balance, static and dynamic, sitting and standing (if testable)
 Functional status (activities of daily living, participation in life, eating, bowel and bladder function, ambulation) in the patient's natural environment or simulated circumstances
 Pain: Intensity, type, and location (use body chart); what aggravates/eases?
 Dysarthria, dysphagia, and respiration (screen for changes, refer to specialists)
 Environmental adaptations and equipment relevant to current and projected status
 Quality of life, including subdimensions such as sleep, well-being
 Psychosocial systems: Identify patient and family concerns, self-efficacy. Refer for social worker evaluation of financial resources, day-to-day living problems (e.g., transportation and child care), support systems, and coping strategies

medications, concurrent medical issues, current activities and participation, and any symptoms related to them. The history should focus on current and recent activities and participation signifying patient's lifestyle, ADL tasks, hobbies or interests, and work focus; primary complaints, including weakness, fatigue, muscle spasms, pain, respiratory status, safety, or speech and swallowing issues; psychosocial support issues (family, caregivers, and agencies); the patient's and family members' understanding of ALS and the likely progression and prognosis; and the patient's current concerns and goals. This last item is critically important: the focus of attention should be on the patient's and family's current concerns and goals, rather than on the therapist's knowledge of issues expected in the future.

- **Systems Review.** Screening for multisystem involvement should include checking vital signs at rest, skin integrity, bony abnormalities, sensory integrity, communication ability, and the ability to follow multistep commands. Cognitive screening may include measures such as the Mini-Mental Status Exam (MMSE) because of the possibility of ALS-FTD. When gross screening shows systems with deficits, more extensive examination may be indicated, or the patient may be referred to appropriate health care professionals.
- **Tests and Measures.** Body functions to be tested include movement ability (with attention to the six dimensions of movement² appropriate to the region of the body with deficits), pain, cognitive function (if needed), and specific impairments such as dysarthria, dysphagia, and respiratory function. Measures should also be used to document relevant activity limitations, participation restrictions, and environmental and personal factors affecting function at the current stage of the disease process. Any Clinical Practice Guidelines regarding core sets of outcome measures should be followed as appropriate.⁹⁹ Tests and measures generally include:
 - Baseline testing of muscle strength (MMT or hand-held dynamometer testing, grip strength, 5 times sit-to-stand test—also used to assess transfers),⁹⁹ endurance (6MWT, time tolerating activity, self-report questionnaires for fatigue), flexibility (ROM, muscle tone), speed (timed tasks), and accuracy and adaptability as needed. Therapists may observe and document any areas of atrophy or fasciculations.
 - Assessment of functional activity level (using a standardized test or assessment tool whenever possible) to include, as appropriate: transfers, gait, upper-extremity function, postural control, eating, toileting, and assistive devices. Suggested tools include the ALSFRS-R,⁹⁹ the ALSSS,³⁷ timed walk test (25-foot walk test or 10-m walk test), Timed Up and Go test,¹⁰⁰ 6MWT,¹⁰¹ and 9-Hole Peg Test. Of the generic walking measures, the 6MWT has been validated in ALS.¹⁰¹ Although weakness may affect balance during gait, patients with ALS have not shown deficits in postural control during quiet stance despite significant paresis or tone changes, possibly because sensation is relatively preserved.¹⁰² However, generic postural control tools may be useful, such as the Berg Balance Test (when the patient can stand dynamically) or the Function in Sitting Test (when standing is no longer possible but unsupported sitting is available). The Barthel Index or Functional Independence Measure (FIM) could be used for testing of independence in ADLs.
 - Documentation of pain (onset, type, site, and intensity; use body chart and subjective pain scale); identify what makes pain worse or better. Sensory testing may also be required.
 - Assessment of bulbar and respiratory function (review Table 15.1). Perform cranial nerve screening tests; observe facial, lip, tongue, and jaw movements; look for atrophy or fasciculations in the tongue; and palpate muscles of mastication.

Document breathing patterns at rest and with exertion; listen to breath control during speech. For an in-depth evaluation of bulbar function, the patient should be referred to an ear, nose, and throat clinic, speech-language pathologist, or communications disorders clinic, unless full evaluation is available in a comprehensive ALS clinic.

- Assessment of quality of life or subdimensions such as sleep, well-being, and life satisfaction using generic measures that have been validated in other neuromuscular populations. The Nottingham Health Profile and SF-36 have been recommended in this population.⁹⁶
- Assessment of the patients' environment with a focus on energy conservation and safety at current and future functional capabilities. Assessment of adaptive equipment needs and modifications. Documentation of personal factors (motivation and coping skills) affecting function and availability of psychosocial support is especially necessary as the disease progresses.

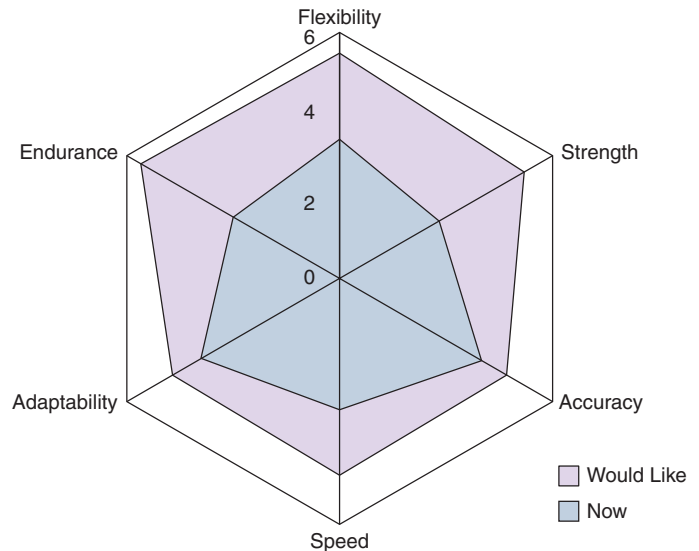

In evaluating the results of the examination, the therapist should synthesize data to define the following, all of which are necessary for developing goals with the patient:

- Rate of the patient's disease progression to date
- Distribution of weakness, atrophy, and spasticity; respiratory factors leading to hypoxemia; ease of fatigability; and bulbar involvement
- Stage of the disease
- Any preexisting impairments and/or activity limitations

Goals of Therapeutic Intervention

Intervention goals and the recommended exercise and activity program designed by PTs or OTs must be based on the patient's personal goals. Goals are often a difficult area for therapists to discuss with the patient because the disease is progressive despite intervention. Patients, therapists, and physicians may tend to assume that because nothing can be done to "cure" the disease, not making additional demands on a patient who is already coping with daily loss is somehow kinder. Some believe that exercise programs may create false hopes that exercise will delay progression. Others believe (mistakenly) that exercise will hasten progression.¹⁰³ The literature on rehabilitation in neuromuscular disorders, however, suggests that patients with ALS can benefit from carefully designed exercise and activity programs. Active participation in determining goals for therapy can provide the patient and the family with some sense of control over a difficult situation.¹⁶ A standardized tool such as the Movement Ability Measure^{104,105} (MAM or MAM-CAT,¹⁰⁶ validated in musculoskeletal and neuromuscular populations and recommended as a scale of patient-reported mobility¹⁰⁷) can assist the patient and therapist to identify together the movement dimensions the patient prioritizes, so that therapy and home exercises can emphasize what the patient values most¹⁰⁶ (Fig. 15.8). Other tools that help engage the patient in treatment planning include Goal Attainment Scaling¹⁰⁸ (used in diverse populations, including neurological), Canadian Occupational Performance Measure,¹⁰⁹ and the Patient-Specific Functional¹¹⁰ Scale (used more in musculoskeletal populations).

The broad general goals for both patient and therapist are related to maintaining maximal independence in daily living and a positive quality of life for as long as possible. More specific therapeutic goals are (1) maintenance of mobility and independent functioning (sometimes with training in new strategies and motions to perform locomotion and other functional tasks given current status), including safe mobility for patient and caregiver; (2) maintenance of maximal muscle strength and endurance within limits imposed by ALS; (3) prevention and minimization of secondary consequences of the disease, such as contractures, adhesive capsulitis, thrombophlebitis, deep vein

	Now	Would Like	Gap
Flexibility	3.4	5.5	-2.1
Strength	2.8	5.2	-2.4
Accuracy	4.0	4.7	-0.7
Speed	3.2	4.8	-1.6
Adaptability	3.9	4.7	-0.8
Endurance	3.0	5.6	-2.6
Total	20.3	30.5	-10.2

Fig. 15.8 Movement ability plot from the self-report Movement Ability Measure (MAM)-CAT¹⁰⁶ tool depicting the gaps between the movement ability an individual has *now* and the ability the individual *would like* to have. Dimensions with the largest gap (endurance at -2.6, with strength and flexibility closely following) should be the focus of the episode of care. Scale from logits is transformed to 0 (cannot do even with assistance) to 6 (moves competitively).

thrombosis (DVT), decubitus ulcers, and respiratory infections¹⁶; (4) management of energy conservation techniques and respiratory comfort; (5) determination of adaptive equipment needs to include mobility, self-help and feeding devices, augmentative communication units, and hygiene equipment that supports both patient and caregiver¹⁶; and (6) minimizing or preventing pain.¹¹¹

Therapeutic Considerations

To prevent more rapid functional loss than expected from the natural history of the disease, both the patient and therapist must delicately balance the level of activity between the extremes of inadequate and excessive exercise. Exercise has been recommended for the general public for its many benefits.¹¹² Inadequate exercise may result in loss of strength and endurance from disuse, as well as secondary problems such as loss of ROM, muscle cramping, and pain. Excessive exercise may result in excessive fatigue and consequent inability to perform ADLs during recovery periods. Overuse injury with excessive volume and/or intensity of exercise may also lead to unnecessary pain, fatigue, and loss of strength. The next two sections review the evidence for the optimal amount of activity or exercise.

Disuse atrophy. Because ALS is typically diagnosed in older adults, patients may not have maintained their aerobic fitness or muscle strength before the onset of this disorder. Newly diagnosed patients also commonly report that they had markedly decreased their

activity level in the months before diagnosis because of a sense of fatigue or increasing clumsiness from progressive weakness. If the patient led a sedentary lifestyle before diagnosis, the additional decrease in activity level after the onset of ALS can lead quickly to marked cardiovascular deconditioning and disuse weakness. The disuse weakness lowers muscle force production and reduces muscle endurance.

Exercise intolerance or overwork damage. Observers during the poliomyelitis epidemic of the 1940s and 1950s reported that muscle activity or overwork exercise led to a loss of muscle strength.¹¹³ During that epidemic, physicians and therapists noted that patients with poor- and fair-grade muscles who exercised repeatedly or with heavy resistance after reinnervation often lost the ability to contract the muscle at all.¹¹⁴ However, controlled testing of this observation suggests that overwork damage occurs in mostly denervated muscles, not in all muscles. In a seminal study in rats, Reitsma¹¹⁵ noted that *vigorous exercise* damaged muscles if less than one-third of motor units were functional. If more than one-third of the motor units remained, exercise led to hypertrophy, a beneficial result. One mechanism of potential overwork damage is inhibition of the collateral sprouting of intact axons to re-innervate “orphaned” muscle fibers when other axons degenerate (Fig. 15.9). Yuen and Olney¹¹⁶ provided evidence that collateral sprouting of intact axons can partially reinnervate orphaned muscle fibers in ALS. This reinnervation process creates macromotor units (more motor fibers innervated per motor neuron) and is sensitive to overload: in a rat model of partially denervated muscles, highly intensive activity reduced the ability of adjacent axons to sprout when fewer than 20% of intact motor units remained.¹¹⁷ Reduction in sprouting does not occur when denervation is more moderate.¹¹⁷ In a mouse model, vigorous exercise had no adverse effect on the course of ALS.¹¹⁸ Lui and Byl¹¹⁹ systematically reviewed the literature reporting exercise effects in animal models of ALS and calculated an effect size of 1.39 (where numbers over 0.8 are considered large) in favor of exercise. The few negative effects they noted were associated with either very high-intensity exercise or a

slow rate of exercise (slower than usual activity for animals when unrestricted in activity). These results reflect the responses of animal models of disease rather than humans, so would need to be interpreted with caution.¹¹⁹

Normal functional reserve in healthy adult ventilation means that only 70% of maximal voluntary ventilation is used during exercise testing.⁷⁷ Adequate reserves likely allow patients with ALS to maintain a normal ventilatory response, but may mask early losses of respiratory function. Close monitoring is warranted even with moderate exercise. Some of the specific mechanisms of exercise intolerance in neuromuscular diseases include inspiratory muscle weakness, expiratory insufficiency from diminished elasticity, disrupted sleep (frequently from respiratory impairment), vocal cords that go into spasm with forceful exhalation, inadequate muscle activation, and central fatigue.⁷⁷

Researchers have expressed concern about the possible relation between high-resistance exercise and muscle fiber degeneration in humans with motor neuron disease.¹²⁰ Because of early concerns about stressing substantially denervated muscles, Sinaki and Mulder¹²¹ published recommendations in 1978 that patients with ALS not engage in any vigorous exercise and focus instead on exercise associated with walking and daily activities. On the other hand, McCrate and Kaspar¹²² reviewed the possible mechanisms by which exercise protects nerves from more rapid degeneration. Thus the controversy continues. Evidence regarding the positive benefits of exercise in ALS has been accumulating, with fewer adverse effects than some expected.

Evidence of the benefits of exercise. Few controlled trials have been published regarding exercise in ALS, and most enroll small sample sizes because the disease is relatively rare.¹²³ However, an examination of the protocols and inclusion criteria of their subjects may still provide useful information for the clinician.

Resistive exercises are necessary for improving strength. Aksu and colleagues¹²⁴ compared a supervised versus home exercise protocol in 26 ambulatory ALS patients. They noted that supervised breathing exercises, stretching, manually applied resistance exercise with PNF,

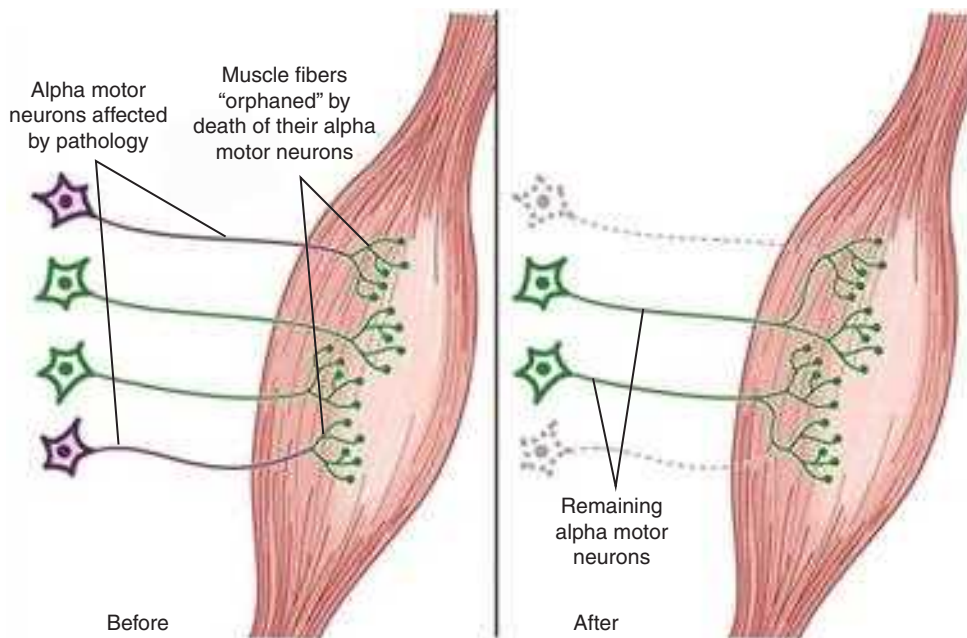

Fig. 15.9 After degeneration of some α motor neurons, adjacent α motor neurons may undergo collateral sprouting to re-innervate orphaned muscle fibers, creating macromotor units. (Adapted from Allen DD, Widener GL. Tone abnormalities. In: Cameron MH, ed. *Physical Agents in Rehabilitation: An Evidence-Based Approach to Practice*. 5th ed. St. Louis, MO: Elsevier; 2018.)

and functional mobility training 3 days a week for 8 weeks resulted in small gains in function in the first 4 weeks and a slower decline over the subsequent 10 months compared with home-based breathing, stretching, and active ROM exercises. The groups were not randomly allocated but were not significantly different in the measured variables at baseline.¹²⁴ In an RCT, Drory and colleagues¹²⁵ assigned 25 patients with ALS to a group continuing their normal daily activities or a group participating in a daily program of moderate exercise individualized for each patient. The primary exercise focus was to have muscles of the trunk and limbs work against “modest” loads while undergoing significant shortening (not lengthening or eccentric contractions). The exercises were completed twice daily for 15 minutes at home with phone contact by the treating therapist every 14 days. Data were evaluated for 3 and 6 months after initial assessment. All patients showed continued disease progression; however, in all cases, at the 6-month assessment patients who exercised showed positive effects in maintenance of muscle strength, less fatigue, less spasticity, less pain, and higher functional ratings.¹²⁵ In another RCT, Dal Bello-Haas and colleagues¹²⁶ prescribed moderate load and moderate-intensity resistance exercises individually to patients in the early stages of ALS. The exercise group had significantly less decline in function, small improvements in strength, and no reported adverse effects, compared with patients who performed stretching exercises alone.¹²⁶ A Cochrane review designated the quality of these two RCTs as “fair” to “adequate,” and class II level evidence.¹²⁷

In a more recent RCT, Lunetta and colleagues¹²⁸ found that supervised exercise, especially those who had resistive plus aerobic exercise at 60% power daily for 2 weeks each month over 6 months, resulted in better ALSFRS-R scores than the 30 people with ALS who had twice weekly home care. Merico and colleagues¹²⁹ conducted a pilot RCT of endurance and resistance training in 38 ambulatory individuals with ALS. Fifteen received standard neuromotor rehabilitation that specifically

excluded eccentric and concentric muscle contractions. Twenty-three participants received individualized, progressive programs of submaximal, time-based isometric contraction of muscles testing 3, 4-, or 4 on the MMT scale, and moderate aerobic exercise using ergometer or treadmill according to the subject’s level of disability. Both groups received intervention 1 h/day, 5 days/week, for 5 weeks. The specific exercise group had improved strength, oxygen consumption, and function compared to the other group.¹²⁹ Jensen and colleagues¹³⁰ conducted a study in which five ambulatory subjects with ALS were their own controls, with 12-week lead in period followed by 12 weeks of resistance training two to three times per week. The resistance was increased progressively for 10 major muscle groups (six per session), from 3 sets of 12 repetitions at a load of 15-repetition maximum (RM) to conclude at 2 sets of 5 repetitions at 6 RM. For these five subjects, strength decline did not slow during training; at biopsy, some type II muscle fibers hypertrophied, but others atrophied.¹³⁰ The subjects mostly had shorter disease duration prior to study involvement (4 at less than 12 months) and higher ALSFRS-R function scores (average 40 points) than in other studies, which may have affected response to this treatment. Table 15.2 summarizes the studies of exercise published since 2000 in ALS. As a side note, preliminary evidence suggests that creatine supplementation may increase isometric power in patients with ALS over the short term.¹³¹

Few researchers have considered rehabilitation to increase endurance in neuromuscular disorders.^{112,134} Endurance training for longer than 10 to 15 minutes in patients with ALS may be restricted by central fatigue, the decreased ability to recruit all motor units or develop high discharge rates,¹³⁵ and not merely alterations in oxygen supply or muscle metabolism. In healthy individuals, exercise has the potential to improve motor unit activation, blood supply, muscle metabolism, and chemical imbalances and thus has promise in ALS. In addition to studies of strengthening or combined exercises, studies focusing on aerobic exercise have reported positive results. Braga and colleagues¹³³

TABLE 15.2 Summary of Exercise Studies Since the Year 2000 in Amyotrophic Lateral Sclerosis

Author	Study Population (Sample Size): Research Design	Duration of Training	Training Modality	Training Protocol	Response(s)
Drory et al., 2001 ¹²⁵	ALS disease duration 20 months (25): RCT assigned to treatment or control groups	24 weeks	Moderate load, trunk and limbs, concentric contractions	Twice daily, 15 min per session	Treatment group: Maintenance of strength, less fatigue, less spasticity, less pain, higher function
Aksu et al., 2002 ¹²⁴	ALS (26): Convenience assignment to treatment and control groups	8 weeks	Breathing exercises, PNF, stretching vs. stretching, ROM, and breathing exercises	3 days/week supervised vs. home	Treatment group: Increased ROM, strength; function sustained better
Dal Bello-Haas et al., 2007 ¹²⁶	Early stage ALS (27): RCT, allocated to resistance exercises plus stretch or just stretch groups	24 weeks	PT-prescribed resistance exercises performed at home to patient tolerance	3 days/week resisted exercise plus stretch vs. just stretch group	Treatment group: Slowed decline and small strength gains
Sanjak et al., 2010 ¹³²	ALS (9; 6 completed study): Pilot study	8 weeks	Repetitive rhythmic exercise performed for 30 min total, 5 min ex followed by 5 min rest	3 times per week, 60-min session with 6 intervals of 5 min	Improved Rating of Perceived Exertion, ALSFRS-R; gait variables improved
Lunetta et al., 2016 ¹²⁸	ALS disease duration <24 months, ALSFRS-R average 38 (60): RCT, monitored ex vs. usual care group	6 months with a 1 year follow up	Ex group divided into 3 groups: (a) resisted ex 3 sets of 3 repetitions at 60% power plus cycloergometer; (b) resisted ex; (c) passive ex; usual care received passive ex and stretching	Ex: daily 20-min sessions for 2 weeks each month; usual care: 20 min 2 days per week at home	Treatment group: ALSFRS-R (especially motor portion) was better, especially ex group (a) at end of treatment and at 1 year; survival and respiratory support did not differ

TABLE 15.2 Summary of Exercise Studies Since the Year 2000 in Amyotrophic Lateral Sclerosis—cont'd

Author	Study Population (Sample Size): Research Design	Duration of Training	Training Modality	Training Protocol	Response(s)
Jensen et al., 2017 ¹³⁰	ALS, ambulatory without assistance, ALSFRS-R average 40, disease duration <12 months (4/5): case series	12 weeks lead in; 12 weeks training	Progressive resistance for 10 major muscle groups: 3 sets of 12 repetitions at 15 RM to 2 sets 5 repetitions 6 RM	Training: 2–3 times per week, 6 muscle groups each session	Training period: No attenuation of strength loss; mixed increase in hypertrophied and atrophied type II fibers
Braga et al., 2018 ¹³³	ALS disease duration <12 months, ALSFRS-R = 39 (48): controlled trial, allocation to groups based on geographical residence	6 months	Both groups had standard care exercises daily, with ROM, limb relaxation, trunk balance, gait training. Group 1: Also had treadmill exercise with training intensity (moderate) defined by cardiopulmonary exercise testing (CPET)	Daily standard exercises to perceived fatigue. Group 1 added twice weekly CPET regulated moderate intensity ex	Group 1 had better respiratory measures at peak effort: Oxygen uptake peak, metabolic equivalent, carbon dioxide output, and minute ventilation
Merico et al., 2018 ¹²⁹	ALS disease duration 30 months, ALSFRS-R = 35 (38): RCT, 23 completed ex group; 15 completed standard rehabilitation	5 weeks	Ex group: 3 repetitions isometric contraction held for 80% of time of max contraction plus aerobic ex at 65% max heart rate adjusted for age; standard group: stretching, active mobilization, muscle reinforcement	5 days/week, 1 h each day	Treatment group: Improved in strength, oxygen consumption, FIM test; standard group improved in FIM test but not as much

ALS, Amyotrophic lateral sclerosis; ALSFRS-R, ALS Functional Rating Scale-Revised; ex, exercise; FIM, Functional Independence Measure; max, maximum; PNF, proprioceptive neuromuscular facilitation; PT, physical therapist; RCT, randomized controlled trial; RM, repetitions maximum; ROM, range of motion.

provided standard care exercises to two groups of patients with ALS with disease duration averaging less than 9 months, adding moderate intensity (level determined by cardiopulmonary exercise testing) treadmill walking two times per week to group 1. Group 1 showed better ALSFRS-R scores than Group 2 at 6 months, and slope of functional decay was not as steep. Sanjak and colleagues¹³² conducted a treadmill study of nine patients with ALS who already required assistive devices to walk, six of whom completed the study. The frequency was three times a week for 8 weeks, with 30 minutes of walking split up into 5-minute intervals of exercise and rest. Improvements in ALSFRS-R score, FSS, and gait measures were noted in the first 4 weeks and retained at 8 weeks. A systematic review of studies focusing on reducing fatigue (perception of tiredness or decreased ability to contract muscles at maximum force) describe three studies in ALS indicating possible improvements with modafinil (a drug that reduces sleepiness),¹³⁶ respiratory exercise versus sham intervention, and repetitive transcranial magnetic stimulation (rTMS).¹³⁷ Signs of fatigue after any exercise must be monitored carefully. If a patient shows evidence of significant, persistent weakness after institution of an exercise program or persistent morning fatigue after exercise on the previous day, the therapist must carefully redesign the patient's exercise program and activity level and increase the frequency of monitoring the patient's program.

In addition to strength and endurance benefits from exercise, ongoing moderate exercise programs may also help decrease persistent pain and muscle stiffness that often accompany weakened, overtaxed muscle groups.¹³⁸ Factors such as spasticity, age at onset of ALS, prior levels of fitness and activity, and psychological factors, including past responses to extremely challenging situations and satisfaction with social support, must also be considered when prescribing rehabilitation for this population. See [Box 15.4](#) for factors to consider when prescribing exercise in the early stages of ALS.

BOX 15.4 Considerations for Exercise Prescription

Based on evidence and current practice, exercise prescription in the early stages of ALS (and recovery stages of GBS) should address the following¹¹¹:

1. Include both a formal exercise program and enjoyable physical activities to improve compliance.
2. Include activities with opportunities for social development and personal accomplishment.
3. Strengthening programs should use moderate resistance rather than high resistance, and focus on muscles that have at least antigravity strength (3/5 on MMT).
4. Endurance programs should be monitored for signs of fatigue, more so when continuous activity lasts longer than about 15 min. Activity programs should include rest periods.
5. Patients should ensure that they have adequate oxygenation and carbohydrate loads¹¹² as well as adequate fluids before exercising.
6. Muscle strength must be monitored to assess for possible overwork weakness; in unsupervised programs, patients must watch for signs and symptoms that indicate overwork, including postexercise fatigue that interferes with daily activities, feeling weaker or pain beyond 30 min after exercise, having excessive soreness 24–48 h after exercise, and experiencing severe muscle cramping, heaviness in the extremities, or prolonged shortness of breath.¹³⁹ Therapists should check with an independently exercising patient regularly to assess whether any deterioration in strength may be from progression of the disease or overwork weakness.
7. The program must be adjusted as the disease progresses.

ALS, Amyotrophic lateral sclerosis; GBS, Guillain-Barre syndrome; MMT, manual muscle testing.

Therapeutic Interventions

Sinaki¹⁴⁰ has described three phases and six substages of ALS with recommended exercise levels (Box 15.5). These phases and stages provide an orderly structure for describing therapeutic interventions, although patients may not fit precisely within the stages. Bulbar signs may have progressed to a different stage than motor ability in the limbs, for example, and respiratory dysfunction can occur on its own

time schedule. However, recommending a progression of interventions from independence to partial independence to dependence may be particularly helpful to therapists who do not have the opportunity to work with large numbers of patients with ALS.

Most patients need specific guidance about what types of activities and exercises they should do.⁸⁶ Although many physicians may suggest to patients that they increase their activity level, their suggestions are

BOX 15.5 Exercise and Rehabilitation Programs for Patients With Amyotrophic Lateral Sclerosis According to Stage of Disease

Independent (Phase I)

Stage 1

Patient Characteristics

Mild weakness
Clumsiness
Ambulatory
Independent in activities of daily living (ADLs)

Treatment

Continue normal activities or increase activities if sedentary to prevent disuse atrophy
Begin program of range-of-motion (ROM) exercises (stretching, yoga, tai chi)
Add strengthening program of gentle resistance exercises to all musculature with caution not to cause overwork fatigue
Provide psychological support as needed

Stage 2

Patient Characteristics

Moderate, selective weakness
Slightly decreased independence in ADLs, such as:

- difficulty climbing stairs
- difficulty raising arms
- difficulty buttoning clothing

Ambulatory

Treatment

Continue stretching to avoid contractures
Continue cautious strengthening of muscles with manual muscle testing (MMT) grades above F+ (3+); monitor for overwork fatigue
Consider orthotic support (e.g., ankle-foot, wrist, thumb splints)
Use adaptive equipment to facilitate ADLs

Stage 3

Patient Characteristics

Severe selective weakness in ankles, wrists, and hands
Moderately decreased independence in ADLs
Easy fatigability with long-distance ambulation
Ambulatory
Slightly increased respiratory effort

Treatment

Continue stage 2 program as tolerated; use caution not to fatigue to point of decreasing patient's ADL independence
Keep patient physically independent as long as possible through pleasurable activities such as walking
Encourage deep breathing exercises, chest stretching, postural drainage if needed
Prescribe wheelchair, standard or motorized, with modifications to allow eventual reclining back with head rest, elevating legs

Partially Independent (Phase II)

Stage 4

Patient Characteristics

Hanging-arm syndrome with shoulder pain and sometimes edema in the hand
Wheelchair dependent
Severe lower-extremity weakness (with or without spasticity)
Able to perform ADLs but fatigues easily

Treatment

Heat, massage as indicated to control spasm
Preventive antiedema measures
Active assisted passive ROM exercises to the weakly supported joints; caution to support, rotate shoulder during abduction and joint accessory motions
Encourage isometric contractions of all musculature to tolerance
Try arm slings, overhead slings, or wheelchair arm supports
Motorized chair if patient wants to be independently mobile; adapt controls as needed

Stage 5

Patient Characteristics

Severe lower-extremity weakness
Moderate to severe upper-extremity weakness
Wheelchair dependent
Increasingly dependent in ADLs
Possible skin breakdown as a result of poor mobility

Treatment

Encourage family to learn proper transfer, positioning principles, and turning techniques
Encourage modifications at home to aid patient's mobility and independence
Electric hospital bed with antipressure mattress
If patient elects home mechanical ventilation (HMV), adapt chair to hold ventilator unit

Dependent (Phase III)

Stage 6

Patient Characteristics

Bedridden
Completely dependent in ADLs

Treatment

For dysphagia: soft diet, long spoons, tube feeding, and percutaneous gastrostomy
To decrease flow of accumulated saliva: medication, suction, and surgery
For dysarthria: palatal lifts, electronic speech amplification, and eye-pointing electronics
For breathing difficulty: clear airway, tracheostomy, and ventilator if patient elects HMV
Medications to decrease impact of dyspnea

seldom specific. Examples of exercise advice that patients have recalled are “Try to move around as much as possible,” “Walk some more,” and “Be active, but don’t overdo it.” Because changing their typical exercise pattern is difficult for most patients, even when they know doing so is important, referral for a physical therapy consultation can be helpful for movement-related issues.¹⁴¹

Independent: Phase I, Stages 1 to 3. A program to increase activity must be specifically designed, with input from the patient about willingness to participate and knowledge of the patient’s environmental situations and social support systems. In the early stages of the disease, patients should be encouraged to continue as many of their usual and valued prediagnosis activities as tolerated. For example, a golfer should continue to golf for as long as possible. Walking the course should be encouraged if it is not too fatiguing. When walking or balance becomes difficult on uneven terrain, the golfer can use a golf cart, decrease the number of holes played, move to a par three course, or hit balls at a driving range. If upper-extremity weakness is a major problem that interferes with swinging the club for distance shots, the player can continue playing the greens or on putting courses. Some people who play golf may need adaptations to club handles with nonskid material such as Dycem (Dycem Non-Slip products, <http://www.dycem.com>) or Scoot-Gard (Vantage Industries Product) to prevent the club from rotating on impact. Similar progressions could be imagined for patients with other activity interests.

Patients with newly diagnosed ALS who had a sedentary lifestyle before diagnosis should be encouraged to increase their activity level as fatigue status and rate of disease progression allow. This may include activities that require muscular effort within or around the home, such as sharing household and gardening tasks or beginning a walking program around the neighborhood. After diagnosis, some patients begin searching for in-home exercise devices such as bicycles and rowing machines. As with healthy persons who plan to start an exercise program after the purchase of exercise equipment, patients with ALS often do not use the new equipment consistently if they did not do so before a diagnosis. The search for a “perfect” exercise machine may reflect the patient’s desperation to do something tangible. Without taking away the patient’s motivation to exercise, therapists can encourage participation in physical activity and/or exercise programs that do not require expensive equipment, such as walking or working out using video-guided exercise routines. A media-savvy therapist can make a video for each patient that includes stretching and gentle exercise programs that elicit muscle contractions from all functional muscle groups (by using inexpensive elastic bands or small weights) with follow-up breathing, “warm down,” and relaxation exercises. Patients could follow a program of isometric contractions of the major muscle groups held for 6 seconds each and isotonic elastic band exercises at submaximal levels to maintain and improve muscle strength, with progression established by the therapist. Patients who are limited by fatigue should exercise for short periods several times a day rather than attempting to exercise all muscle groups in one session.

For most patients in the early stages of ALS, pleasurable, natural activities such as swimming, bowling (using a lighter ball if shoulder strength is a problem), walking, bicycling (three-wheeler may be needed or in-home stationary bicycle, either of which must be evaluated for easy mounting and dismounting), or tai chi can be recommended. Some patients prefer to exercise alone, whereas others will gain confidence and companionship by joining a group activity. Listening to the patient’s desires related to group activities is important. The dropout rate is high among those who have been pressured to participate. Some spouses or family members are supportive of the patient’s activity needs and will join the patient in his or her regimen.

If possible, the spouse and family members should be engaged in the treatment planning process.

The therapist must observe patients completing their entire recommended activity program. The patient’s response to the program must be monitored because fatigue from exercise sessions can interfere with the ability to carry out other normal daily activities. If patients become too exhausted at the end of a session, they may learn to fear exercise and may become depressed about the decreased activity status. This depression may lead to decreased activity and further deconditioning.

Partially independent: Phase II, Stages 4 and 5. When the patient is partially independent, the goal of physical and occupational therapy intervention should be to help the patient adapt to limitations imposed by weakness, fatigue, or spasticity, an increasingly compromised cardiorespiratory status, and possible musculoskeletal pain secondary to weakness or muscle imbalance. This transition stage is often disturbing for patients because the decrease in function and independence becomes clear; therapists should accentuate what the person can do and how accommodations can be made to help maintain independence. After a full physical assessment of the patient’s motor status similar to the initial evaluation, the patient, family members, and therapists (including a PT, OT, and speech-language pathologist if a team approach is possible) should discuss treatment options and adaptive devices that can help the patient remain as independent as possible. Majmudar and colleagues⁸⁹ and Connors and colleagues¹⁴² provide lists of commonly used adaptive equipment that might provide helpful ideas.

During the transition from independence to partial independence, many patients show significant weakness of both upper- and lower-extremity musculature, but they each have their own pattern and rate of progression of weakness and onset of spasticity, bulbar, and respiratory symptoms. A typical patient at this time may have marked weakness of the intrinsic muscles, shoulder muscle weakness (in some cases “hanging arm” syndrome) with shoulder pain, and generalized lower-extremity weakness (in some cases more severe distally). Patients may be able to walk within the home environment, but many patients have precarious balance; they may fall easily because of muscle weakness. Getting up from a fall will be more difficult when the weakness affects antigravity muscles such as the gluteus maximus, quadriceps, and plantarflexors. At this stage, most patients report fatigue with minimal work and have to rest frequently when carrying out ADLs. ROM can deteriorate quickly in this phase of the disease, requiring daily stretching for the calf, quadriceps, hip adductors, trunk lateral flexors, shoulder (to prevent adhesive capsulitis), and long finger flexors.⁴⁰ Moderate resistive exercise as described by Drory and colleagues¹²⁵ (see [Table 15.2](#)) can have a modest effect in reducing spasticity.

Patients at this point, even if ambulatory, may consider using a wheelchair outside the home to conserve energy.¹¹¹ Factors to consider in choosing a wheelchair include extent of insurance coverage or financial assistance programs for purchase of wheelchair (some policies or programs may provide only one type of wheelchair or only one wheelchair, either motorized or manual); transportability of the wheelchair from home to community and work (few motorized wheelchair brands fold for stowing in a car trunk, and few families can afford to purchase a van with a ramp or lift that will allow the patient to drive or be driven while in a motor chair); reclining potential of chair back, tilt of the seat, and headrest (preferably electric) to allow the patient to shift weight and rest while in the chair during later stages of the disease; seat elevator; elevating leg rests to avoid prolonged sitting with the legs in a dependent position; for power w/c, adaptable electronic controls that can be modified for changes in hand function; removable arm rests for ease of transfer; headrest or extension; potential

mounting area for portable ventilator equipment if needed; and ease with which caregiver can help patient with chair mobility transfers.¹¹¹ Chairs should have lumbar support and appropriate cushioning to prevent pressure ulcers.¹³⁹

At this stage, patients with more advanced bulbar symptoms begin to experience dysarthria and may need guidance in dealing with communication issues. In a study of communication strategies in ALS, Murphy¹⁴³ indicated four major reasons for communication: to identify needs or request help, share information, respond politely in social situations, and maintain social closeness. The primary focus of communication for the study participants was to maintain social closeness. Although few patients had any instruction in ways to deal with communication problems, most patients and caregivers created ways to make themselves understood, such as giving cues about the topic and context, creating a “shorthand” language, and checking with the dysarthric speaker to ensure that the listener understands the patient correctly. A number of patients in the study who had significant dysarthria commented that attempting to communicate socially was extremely tiring. Therapists who are guiding patients with energy conservation techniques should be aware of the exhaustion that can be associated with communication. See **Box 15.6** for a number of strategies recommended by the American Speech-Language-Hearing Association¹⁴⁴ that can be used by the person with ALS to deal with the effects of dysarthria. Also in this stage, some patients and families may need support to identify adapted feeding systems (special utensils, adapted plates, adjustable tables) and hygiene equipment if transfers in the family bathroom are problematic.¹⁴²

BOX 15.6 Recommended Strategies for the Individual With Dysarthria

- Reduce background noise in the room
- Face the person while talking
- Use short, simple phrases rather than long, complicated ones
- Take the time to say what needs to be said; do not allow people to rush conversation
- Make extra use of body language, such as gestures and facial expressions, and use writing to supplement speech, if possible
- Do not worry about saying things correctly; if the basic message being conveyed is understood, then that is enough

American Speech-Language-Hearing Association. Dysarthria. Available at: www.asha.org/public/speech/disorders/dysarthria.htm. Accessed November 23, 2018.

Mr. Turner in **Case Study 15.1** was cared for in a neuromuscular disease clinic, so he benefited from input from multiple specialists working as a team to help him maintain his independence. Unfortunately, many patients do not have the benefit of such a coordinated treatment environment. Therefore when necessary, the therapist must be in a position to provide input on adaptive and safety devices and bulbar issues if other specialist input is not available. Therapists working in smaller communities and rural areas most likely need to be chameleon-like to play many therapeutic roles when working with the patient with ALS.

CASE STUDY 15.1 Mr. Turner

Transitioning to Partial Independence

Mr. Turner is a 45-year-old man who first noticed symptoms about 15 months ago. As progression continued and medical testing ruled out other possibilities, he was diagnosed 7 months ago with ALS. He was started on a schedule of visiting a regional ALS clinic every 3–4 months. This is his second visit.

Mr. Turner lives at home with his wife, who works full-time, and two teenage children. Mr. Turner is a computer programmer for an engineering firm. Since his diagnosis, Mr. Turner has been able to continue his full-time work schedule, although he states that he is no longer able to touch type and can type with the index fingers only. He has noticed that his shoulders and neck hurt (4 out of 10 on a numeric pain rating scale) after an hour at the computer. In the last 2 weeks he has found it fatiguing to walk to the office dining area for lunch (approximately 100 m), and he fears that he will be knocked down when walking in crowds. He dropped his lunch tray last week, which was embarrassing, so he decided to eat in his office, even though he misses the socialization and opportunity to discuss work issues with his colleagues.

Mr. Turner has been able to continue most of his nonwork activities, although he is no longer able to operate his sailboat independently and is having trouble maintaining his balance when playing golf. He now uses a cart and plays only nine holes. He states that his wife and children are supportive and that they have made some changes in the home environment to accommodate his increasing weakness. He also revealed, however, that his children seem frustrated with him because he is so much slower than he was before the illness.

On assessment, Mr. Turner showed marked wasting of hand intrinsic muscles. He was unable to abduct or flex either shoulder past 90 degrees. His right shoulder showed considerable atrophy, especially of the deltoid and supraspinatus muscles. All other upper-extremity movements were weakened but in the G– (4–/5 MMT) range. His neck posture was forward: neck extension

was F+ (3+) and neck flexion was G– (4–/5). Scapular winging was noted bilaterally. No spasticity or loss of passive ROM was evident in the upper extremities. Lower-extremity musculature showed generalized weakness at the F (3/5) to F+ (3+/5) range, with left musculature weaker than right, marked wasting of the anterior and posterior compartment muscles of the lower legs, and a cavus foot position bilaterally. Spasticity of the hip adductors and hamstrings was noted (Modified Ashworth Scale grade 2), but no passive ROM loss was detected in the lower extremities. Most obvious during gait was inadequate dorsiflexion for heel strike and no propulsion during heel-off. He showed a bilateral corrected gluteus medius pattern on weight bearing. He showed uncontrolled genu recurvatum in mid- to terminal stance during gait, using gluteus maximus thrust to lock the knee for stability. He had great difficulty ascending and descending the four steps to enter his home. There were no stairs to negotiate at work.

Until this appointment, Mr. Turner had not been willing to discuss the use of adaptive equipment or a wheelchair. During prior clinic visits his decisions were supported and he was told that when he was ready, therapists would work with him and his family to help with equipment decisions.

Mr. Turner also showed some early bulbar signs. He noted that he sometimes had to catch drool when working intensely, and that his pillow was moist in the morning. Tougher and bulkier food sometimes got stuck in his throat; he pocketed some food in the cheek area that he had to make a conscious effort to move out with his tongue. Swallowing was still adequate for eating all foods; however, he had had a few coughing episodes when drinking coffee and wine. He showed no increased use of accessory musculature when breathing and had no reports of respiratory distress. His cough was adequate to clear secretions. His FVC was 90% and ALSFRS-R score was 36 (out of 48). Body weight has remained steady over the last 7 months despite decreasing activity.

CASE STUDY 15.1 Mr. Turner—cont'd

Goals

With input from the therapist, Mr. Turner and his wife identified the following general goals:

1. Increase mobility while conserving energy.
2. Control fatigue and pain of upper extremities and neck during computer work.
3. Maintain maximal muscle strength and ROM (patient reported that he felt stiff).
4. Identify safety issues within the home and work environment and adjust household and work environment to prepare for the time when Mr. Turner could not ascend and descend stairs safely.

Treatment Plan

A treatment plan was developed to achieve the following:

1. Increase mobility. Because of his increased walking difficulties, Mr. Turner decided to use a four-wheeled walker with a seat attachment at home. He had hand grip weakness, but elected against using forearm troughs because of their bulk. He used bicycle type (hand) brakes on the walker. For his worksite, he selected a motorized wheelchair so that he could maintain his independence at work. Although he found that he could push an ultralight manual chair, his upper-extremity strength was clearly decreasing. Mr. Turner decided that he preferred a lightweight foldable power wheelchair to an electric scooter because of the financial cost of switching devices when the scooter no longer provided adequate postural support. As Mr. Turner was still ambulatory in the community and at home, insurance would not pay for the power wheelchair at this time; the therapist was able to connect him with the regional ALS group, and he was able to borrow one from the ALS loan closet to keep at work.

Because Mr. Turner's family had no vehicles to transport the electric wheelchair easily, the ALS Society also loaned the family a manual wheelchair for home use. Although not ideal, it was functional. Mr. Turner's teenagers made some inexpensive adjustments to adapt the chair for a headrest, and repainted the chair to his specifications.

Because Mr. Turner wanted to keep as active as possible and use his walker within the home, he was fitted with light-weight bilateral ankle-foot orthoses (AFOs) to assist with ankle dorsiflexion during swing phase of gait. Straps were simple overlap style because Mr. Turner had poor thumb and grasp control.

2. Decrease fatigue and pain of neck and upper extremities. Mr. Turner was taught some simple ROM exercises of the neck and arms to perform every half hour while working at the computer. In a simulated work environment, the therapist noted that Mr. Turner had a forward head position when working at a computer similar to his workstation. The height of the computer was adjusted to decrease his neck strain, and the desk height was adjusted to allow his wheelchair to fit under the desk so that his arms could rest fully on the surface. He felt immediate relief with the adaptations. He was also fitted for a soft neck collar to wear when he felt he needed more neck support. (As his condition worsened, he learned to rest his head on the headrest of his chair and recline slightly for a few minutes every 15 min.)
3. Maintain maximal muscle strength and ROM. Mr. Turner was taught as many self-ranging maneuvers as possible, which he was encouraged to do in small segments frequently throughout the day. For example, his series of motions included neck rotations, side bends, and flexion and extension within strength limits; upper-extremity motions including shoulder flexion and abduction to maintain or improve the 90 degrees he had at assessment; hip flexion, abduction, and rotation; full knee extension; and all ankle motions. When using the walker, Mr. Turner was encouraged to extend each hip fully and to stretch his heel cords. Mrs. Turner and their children were taught to administer full ROM exercises, including trunk rotations, with special attention to ranging of the shoulders to prevent impingement. Simple massage techniques were also taught to all family members who felt comfortable with the task.

Mr. Turner had been active before the onset of ALS, and he liked to exercise. He rented a portable pedaling unit to attach to a chair at home. He pedaled two to four times a day, with no additional resistance, to the point at which he felt fatigue (usually 3 to 5 min at this stage). He carefully monitored his soreness and fatigue level after exercise and increased and decreased his pedaling depending on how he felt immediately and 2 days after exercise. Mr. Turner felt invigorated by this exercise, which he usually did while watching television. He was also taught a series of simple elastic band exercises for his upper extremities, with tensile strength adjusted according to his ability to contract his muscles without severe fatigue. Mr. Turner was also shown a series of isometric exercises for all major muscle groups to do at least once during the work day. Because he had some foot and ankle edema, he was encouraged to wear lightweight pressure stockings while sitting. Mr. Turner also had access to a swimming pool, and he was encouraged to carry out walking and upper-extremity exercises in the pool as long as another adult was with him in the water at all times.

4. Assess environment of home and work. Occupational therapy input was requested to help with work efficiency and placement of tools for ADLs to avoid wasting energy. Mr. Turner's OT made several visits to his worksite and home to identify adaptations of the environment for safety and independence. His wheelchair was eventually adapted with universal joint arm troughs to decrease his effort during self-feeding and basic upper-body hygiene. Ramps were recommended for home entry, and safety rails were placed in the bathroom. Mr. Turner was able to transfer to a shower chair, and the shower head was replaced with a hand-held unit.

A speech pathology consultation was also requested. Using information from the PT's MMT, the speech pathologist carried out a thorough bulbar evaluation and provided information about swallowing techniques. The speech therapist focused on ways to decrease drooling and instructed Mr. Turner and his wife how to prepare foods with textures that were easily swallowed and manipulated.

Transitioning to Dependence

Within 7 months (to 14 months post diagnosis), Mr. Turner was no longer able to continue working despite workplace adaptations. The electric wheelchair was brought home for regular use when sitting or "strolling" around the neighborhood; the manual wheelchair was only used for brief excursions to a store or community event when a family member could push it. He could still walk short distances in the house with his walker and get dressed on his own, but he got breathless with dressing. His speech was beginning to be affected with slowing and effort to attain normal volume. He lost 10 pounds, so he was referred to the dietician for information about how to maintain nutritious calorie intake. The speech pathology consultant recommended ways to conserve energy when speaking, and to make eating more enjoyable and efficient—for example, advising him on ways to cope with food pocketing (tongue mobility was beginning to be impaired) by using techniques such as hand pressure on the cheek to push food back to the center of the mouth. At home, he became more dependent for household tasks, using a knife and fork, and managing saliva. OT recommended aids such as reachers, utensil adaptors to facilitate grip, rubber pen grippers, key adaptors to permit turning, and thumb abduction splints to assist in pincer grasp. At this point, his ALSFRS-R was 30 (63% of normal) and FVC was 70%.

As his ALS continued to progress over the next 7 months (to 21 months post diagnosis), Mr. Turner was able to use ADL tools for a while but gradually gave them up as he lost more hand strength. He also lost functional ambulation. He had to rely on others for more of his daily self-care although he could still assist if given time. Transfers required moderate assistance using a stand and pivot technique. Despite nutritional support, Mr. Turner lost another 15 pounds because of frustration with the length of time it took to eat. His ALS FRS-R had dropped to 23, and FVC was at 60%.

Continued

CASE STUDY 15.1 Mr. Turner—cont'd

Mr. Turner had great difficulty adjusting to physical dependence. Initially Mr. Turner angrily resisted his wife's attempts to help him with eating and dressing tasks. This began to alienate her and the children until a family meeting was held with their medical social worker and PTs and OTs. All family members had the opportunity to express their frustrations. A major irritation to the children was what they perceived to be their constant waiting for their father to complete a task. Mrs. Turner was most irritated when Mr. Turner yelled at her when she attempted to help, even though he frequently expressed anger about his clumsiness. Mr. Turner sadly admitted that he was having increasing difficulty with his ADLs and was sometimes too tired after dressing to participate in family activities. At the end of the meeting, the family had worked out a compromise plan. Mr. Turner would continue to do as much as possible for himself. He would specifically ask for help from Mrs. Turner when he wanted it so she did not get caught in his anger about needing help. He preferred that the children not have to take any role in his personal care and hygiene at this point but realized that he might need their help later. Visiting nurse support was requested twice a week to help with bathing, and the OT was requested to make another home visit to develop strategies to help with toileting needs. Mr. Turner felt comfortable with his wife and children carrying out ROM exercises. A PT home episode of care (4 visits spread out over 3 weeks) was arranged to review the ROM exercise and positioning program, as well as respiratory exercises, postural drainage techniques, and family review of body mechanics.

By 28 months post diagnosis, Mr. Turner required assistance for feeding, all self-care, and turning in bed. With an augmented communication system, Mr. Turner was able to continue control over his expressive, cognitive, and emotional life. He could read and text (slowly) on a computer/tablet once set up so his minimal hand power could be facilitated to tap for page turning and cursor movement. Mr. Turner was dependent for all physical needs but could help direct his care, instructing caregivers in the best ways to position him for comfort. Nursing assistants were provided through his insurance 14 h a day from 6:30 a.m. to 8:30 p.m. He had a condom catheter and was assisted onto a bed pan for bowel movements. His weight stabilized because the nursing assistants could feed him at short intervals throughout the day. He could be assisted (using a Hoyer lift) into his powered wheelchair for a couple of hours at a time, two to three times a day, but spent more of his day in bed because of fatigue. He had a hospital bed with a special mattress for comfort; the head and knees could be elevated and he could be propped on pillows to change his position. Family members provided

care from 8:30 p.m. until midnight. Mr. Turner was able to activate a bell after midnight to call for help if needed. In addition, his wife and children followed a schedule to turn him every 3 h throughout the night. Nighttime responsibilities were taking a heavy toll on his wife, who worked full time, and the children, who were in high school and community college. His ALSFRS-R was 17, and FVC had dropped to 50%. Although he had mechanical cough assistance when needed, Mr. Turner had resisted starting respiratory assistance with NIV. However, in the following months he began NIV for longer periods of time and finally progressed to tracheostomy intubation.

When Mr. Turner became ventilator dependent at 35 months post diagnosis, he required attendance 24 h daily. Fortunately the family was able to pay for an attendant to remain at Mr. Turner's bedside throughout the night, although the family members all felt that they had no privacy. The family was committed to having Mr. Turner remain at home until his death, but all agreed that they needed occasional respite. Thus several week-long hospitalizations were made to give the family a break in the constant care needs.

Although Mr. Turner had elected HMV with a tracheostomy, he also had signed a durable power of attorney for health care, indicating that he did not want treatment for infections and that palliative care for comfort should direct his treatment. He had a strong lust for life, but he had come to accept his impending death. He did not have strong religious views, but he had talked with all his caregivers and therapists about his concerns related to death. He freely expressed his fear of "nonbeing." Because his caregivers and therapists were willing to talk about his and their own feelings, Mr. Turner came to believe that he would live on in the minds, hearts, and behaviors of those he had known. This idea seemed to give him great comfort. He particularly liked to talk to others about special times they had had together and how their interactions had affected each other. To help Mr. Turner process his death, his family, friends, and medical team put together an album of pictures and statements about their time together. Mr. Turner frequently liked to have his wife read through the book with him. His family continued to carry out his ROM exercises and massage because Mr. Turner had indicated that the treatments provided him physical comfort and the spiritual closeness he needed with his family. His primary treatment during the last few days consisted of morphine to decrease his respiratory discomfort. At about 36 months post diagnosis with ALS (about 3.6 years post symptom onset), Mr. Turner died at home in his sleep from a respiratory illness.

Dependent: Phase III, Stage 6. PTs and OTs are usually less involved in care when the patient becomes dependent; nursing personnel become more active. During this phase, therapists make home visits to support caregivers and respond to questions about pain control, bed mobility, positioning to prevent pressure ulcers, ROM, and equipment adaptations.^{40,111,139} Therapists should be sure to teach all caregivers some basic body mechanics to use during lifting and patient care activities. If possible, caregivers should be taught how to safely move the person with ALS from the bed to a reclining wheelchair or other reclining chair, perhaps with a Hoyer lift or other assistive devices, during specific times of the day so that the person can continue to be part of the family activities. However, the ease of caregivers in transferring and caring for the person in the wheelchair must also be considered. Although some patients want to be in the midst of family activities even when dependent on HMV, other patients feel uncomfortable with their dependency and appearance and are reasonably content to stay in their room with television and visits from family members. This highly personal decision by patients must be respected. The therapist should review ROM procedures with family and professional caregivers and provide splinting or positioning devices if spasticity or paralysis leads

to caregiving difficulties (e.g., excessive adductor tone and contractures interfering with hygiene and bowel care) or tissue damage and pain. If nursing care providers do not give advice on pressure relief beds or mattresses of air or foam,¹³⁹ therapists should be prepared to do so. Unfortunately, many insurance providers and Medicare may not fund special mattresses, and they can be costly. Therapists may also need to review postural drainage techniques with caregivers.

Of greatest importance in the dependent stage, and sometimes in earlier stages, is the patient's ability to communicate. In the earliest manifestation of dysarthria, therapists train patients to slow the speech rate and cadence, exaggerate lip and tongue movements, and manage phrasing through breath control. Although spouses and caregivers can often interpret their partner's or patient's severely dysarthric speech (see earlier discussion of partial independence), most patients who use NIV or invasive ventilation for a prolonged period need to find nonverbal methods to communicate. If severe bulbar impairments precede extremity paralysis, paper and pencil, alphabet and word boards, and adapted computer keyboards can be used with minimal upper-extremity or finger strength for pointing. The American Speech-Language-Hearing Association provides suggestions for

developing communication boards with the specific language most appropriate for the patient's situation.¹⁴⁴ For example, the board may be designed with commonly needed sentences, words used in the person's daily life, and the alphabet. As the person's ability to finger point decreases, the language board can be redesigned. A laser pointer strapped to the head may assist a patient in continuing to use a communication board using head/neck movements. When no extremity movement is possible, subtle neck movements or pressures, eye gaze, eye blink, upper facial movements, and electroencephalographic activity can be harnessed to operate communication devices. Learning to use more intensive brain-computer interfaces, however, takes months of intense training and may not provide a reasonable system for communication for most patients with ALS.^{71,145}

Some patients with hypernasality benefit from using an orthodontic palatal appliance. Patients with a tracheostomy may benefit from use of a Passy-Muir (Irvine, CA) speaking valve tracheostomy tube. These devices require recommendation by communication specialists. As speech quality deteriorates and sound projection wanes, the spouse or caregiver can use an electronic speech amplifier to magnify the patient's speech. Speech pathologists and therapists have information on commercially available amplifying devices that are often used by persons with hearing problems but can be used by hearing people to amplify the speech of a person with severe weakness of phonation.

When selecting a communication device, therapists must work closely with the patient and family members to ensure that the system is compatible with patient skills and communication needs and preferences. Expensive systems commonly lie unused because of simple factors such as lack of proximity to the patient, interference of the unit with personal care, increased caregiver workload to manage the unit, and slowness of communication processing. The best systems are tailored to the precise needs of the patient; however, many patients do not have the financial or insurance support to purchase the device, and many patients in the end stages of ALS do not have the time to wait for systems designed for their specific needs. In such cases, commercially manufactured systems may be most appropriate.

Some patients and caregivers learn to communicate effectively with simple eye gaze, eye blinking, and clicking techniques with Morse code or self-developed codes. At minimum, patients with no ability to communicate or move must have some system to communicate emergency needs with their caregivers; for example, looking to the right means "help" and looking to the left means "pain." Therapists should help patients develop alternative modes of communication before intelligible speech becomes impossible.

In addition to communication systems, environmental control systems can be programmed to turn on and off television, lights, and other electronic units with the same type of switching units used for communication (e.g., eye blink, infrared beam, and head movement pressure). Unfortunately, these devices are often expensive and may not be available to all patients. Financial support is often not extended for high-tech equipment by third-party payers because of the patient's limited life expectancy. The ability to communicate and call for help, however, is of paramount importance with completely dependent patients.

By the dependent stage, most patients have significant problems eating and maintaining nutrition, although these problems may manifest in earlier stages. Patients often report choking or coughing after swallowing liquids or problems moving food around in the mouth or to the back of the throat for swallowing. These problems are best handled medically and can be assessed with videofluoroscopy or videoendoscopy. The aggressiveness of treatment intervention depends on the patient's preference and whether she or he still wants to attempt any oral feeding (e.g., syringe feeding and oral gastric tubes) or wishes

to have a PEG or another alternative to oral feedings implemented. Therapists, however, can help patients and caregivers develop strategies that improve eating and nutrition, such as adjusting eating position, changing head and neck alignments, adding thickeners to liquids, and adjusting portion sizes and texture of foods.¹⁶

Psychosocial Issues in Amyotrophic Lateral Sclerosis From the Clinicians' Perspective

Giving the bad news of a terminal diagnosis is difficult for even the most experienced clinician. In dealing with the diagnosis of ALS, most physicians now believe that the diagnosis, prognosis, and possible patterns of progression should be shared with the patient and family or partners and caregiving friends. Only by knowing the truth can patients and families deal openly with one another and make plans for the future. McCluskey and colleagues¹⁴⁶ suggest that those giving the medical or therapeutic diagnosis should attend to best practice parameters when giving bad news, such as creating the appropriate setting, identifying patient and caregiver needs, asking what patients and caregivers want to know, providing knowledge, exploring feelings of the patients and caregivers, and formulating a strategy for dealing with the situation. Patients and family members seldom remember what they are told when first given a terminal diagnosis. They do, however, remember how the information was given. Therefore information should be given honestly but with a sense of hope.

All information need not be given at the time of diagnosis. Rather, the patient and family can be exposed to more in-depth information over a number of sessions when they have the opportunity to ask questions that occur during the assimilation process. Therapists, especially those working in isolation from a comprehensive clinic, should also follow these guidelines by providing information, helping the patient and family to identify goals, and establishing a plan for intervention. Patients should know that the goals will have to be adjusted and plans reset as the disease process continues. If patients and families know that they can contact the therapist for support and advice, many of the negative aspects of the illness can be confronted in a positive manner. Preferably, an appointment for a follow-up visit will be set so patients and family members feel that contact with the care provider is expected.

Information about transitions related to nutrition, communication, and respiratory functions should be delivered to patients and families in time to make thoughtful decisions rather than just before or during a time of crisis, such as after a choking episode or during respiratory arrest. Care should also be taken to respect the cultural and spiritual views of the patient and family.⁸³ Preferably, patients and family members will prepare an advance medical directive that should be reviewed with the physician at least every 6 months.

Therapists treating patients who do not have access to a multidisciplinary ALS clinic should remember that they are often the person who works most closely with the patient, and they should plan on spending enough time with the patient and family to respond to concerns and help with problem solving. Patients and families will progress through the adjustment process with different responses and at different rates; they may move through a continuum of coping strategies, ranging from cognitive approaches, characterized by asking many questions and reviewing the most current research, to the extreme of marked denial and disinterest in participating in any medical or therapeutic recommendations.

Therapists should be aware of their own biases and knowledge base as they communicate with patients and families about consequential decisions like PEG and NIV use; physicians and allied health professionals can differ in their attitudes regarding these interventions.¹⁴⁷ Therapists may need to consult with specialists on an ALS team

Categories	Focused codes
Being yourself in the care	Defending autonomy, continuing life as before, doing what you need, changing habits
Growing and changing	Nurturing the mind, growing with the disease, inquiring about the disease, accepting the illness
Thinking about the future	Spending time for yourself, life beyond tracheostomy, being aware of death, controlling the disease, the meaning of time
You and who helps you	Deciding, controlling the care, depending physically, finding the right person, being a burden
Family role	Being grateful, distinguishing roles, discovering parents, adjustment in couple dynamics

Fig. 15.10 Themes generated regarding self-care from patients with motor neuron disease. (From Bassola B, Sansone VA, Lusignani M. Being yourself and thinking about the future in people with motor neuron disease: a grounded theory of self-care processes. *J Neurosci Nurs.* 2018;50:138–143.)

regarding guidelines for decision making and potential benefits to patients of these interventions, but may also need to share with the physicians what they have heard regarding the patient's perspective during their more extensive interaction with the individual patient/caregiver or family in the home.

Patients' Attitudes and Fears

To investigate ways that patients take care of themselves psychologically, Bassola and colleagues¹⁴⁸ used a grounded theory approach to examine interview responses from 21 patients with motor neuron disease (9 had ALS). Common themes included control of decision making related to present and future adherence to medical recommendations, and acknowledgement of the need to change as the disease progresses (Fig. 15.10).¹⁴⁸ Patients wanted to process and respond in their own way, in their own time. Patients cite the importance of both family and caregivers; a healthy relationship with each is critical,¹⁴⁸ especially when family relationships and caregiving roles overlap.

Purtilo and Haddad¹⁴⁹ identified four major fears of the patient who has a terminal condition: fear of isolation, fear of pain, fear of dependence, and fear of death itself. Such fears add stress for the patient and family. Patients with progressive diseases often see their social contacts decrease. Mr. Turner in Case Study 15.1 was concerned when he was no longer able to join his colleagues in the company cafeteria. After he received his motorized wheelchair, he was able to continue his social contacts until his bulbar symptoms progressed to a point that he chose not to eat in public. When Mr. Turner lost the ability to speak and had to use his computerized speech system, he noticed that fewer colleagues stopped by his office to talk because of the slowness of the communication process. Although he understood the problem, Mr. Turner mourned the loss of friendship and his loss of standing as a competent computer expert. Because of his need for social contact, Mr. Turner continued to work until he could no longer tolerate the sitting position. His fear of isolation increased when he became homebound. Although colleagues came for visits regularly at first, as Mr. Turner progressed to a near locked-in state, only a few close friends came by for brief visits. Mr. Turner's greatest fear was being separated

from his family and abandoned to hospital care with inconsistent staffing patterns. Fortunately, in his community, Mrs. Turner was able to set up visitations from several church members, clerics, and hospice volunteers.

Fear of uncontrolled *pain* is common among people with terminal diseases. Patients need assurance that their pain will be controlled. Fortunately, today pain medications can be administered in many forms, dosages, and frequencies that can be tailored to the patient's specific needs. In a study of the final month of life with ALS, caregivers reported that a major emphasis of care was to eliminate as much pain and discomfort as possible, even if it shortened the patient's life.¹⁵⁰ Keeping a pain log of intensity, type, location, and time of pain may provide the physician with information necessary to best prescribe dosages. Many patients with ALS do experience significant pain from musculoskeletal sources, persistent spasms or spasticity, and pressure sores. Most of these problems can be handled with appropriate pain medications, muscle relaxants, careful positioning, frequent ROM exercises, and tissue massage. Massage may help decrease cortisol levels, decreasing anxiety and increasing mental relaxation along with any local musculoskeletal effects.¹ Undertreated and uncontrolled pain is associated with a patient's seeking information on assisted suicide.¹⁵¹ Some patients who expressed interest in assisted suicide options did not follow up because of religious beliefs and concerns about possible loss of life insurance coverage for surviving family members.¹⁵²

A major concern of patients with ALS is the *dependence* necessary, with increasing reliance on the help of others as the patient loses functional ability. Because the process is gradual, most patients have the opportunity to make adjustments. Increasing reliance on others and resulting privacy issues tend to be uncomfortable for patients who have always valued self-control and independence. Some patients are also concerned about their increasing dependence on others because of increased burden of care on spouses or other caregivers.¹⁵³ Concern for others sometimes prompts patients to choose hospital, nursing home, or in-patient hospice care over home care during the terminal stage of the disease. Not all patients with terminal illness react the same way during the dying process. Throughout the process, patients and

family members may cycle back and forth through a range of different emotional and coping reactions: depression, anger, hostility, bargaining, and acceptance and adaptation (order is not implied).¹⁴⁹

How the patient coped with life's difficulties before the illness and her or his prior relationship patterns often direct how the patient will deal with the terminal illness. One man and his family who decided early in life to "try for happiness" relate the continued vibrancy of life despite his ALS and near total dependence for all physical needs (watch the video: https://www.youtube.com/watch?time_continue=2&v=2OVUFqgvm_Q; read the story: <https://paloaltoonline.atavist.com/a-vibrant-life>).¹⁵⁴ This individual has written a book using an eye-gaze device, in which an infrared reader scans the movement of his pupils. The patient can track a digital keyboard on his computer monitor and click with an on-screen mouse (read the story: <https://paloaltoonline.atavist.com/powerd-by-passion>).¹⁵⁵ Other patients and the significant others in their lives may choose a different coping response, or cycle through multiple responses as each functional loss forces additional changes.

Depression. Health care providers and family members often have great difficulty coping with a patient who is depressed; they may make repeated efforts to "talk the person out of" their sadness or hopelessness. Medical professions must be able to distinguish between depression that can be destructive and the mourning or grieving process that is a necessary and vital response to dealing with loss. In both states the person may feel a level of withdrawal, sadness, apathy, loss of interest in activities, and cognitive distortions. In a clinically depressed state, however, the patient experiences an accompanying loss of self-esteem.

A person in mourning rarely experiences the loss of self-esteem essential to a diagnosis of clinical depression. A person who grieves for what is lost but who has retained agency (ability to make decisions for themselves) may make plans for the impending death. Such behaviors are positive coping strategies. On the other hand, depressive symptoms expressed as hopelessness, uncontrolled suffering, and perceived burden on caregivers may lead to feelings of worthlessness; such feelings are more closely related to a choice for treatment discontinuance of feeding or ventilatory support.¹⁵²

Diagnosis of depression is complicated by pseudobulbar affect (emotional lability with exaggerated laughing and crying), which is manifested by approximately 50% of patients with ALS. This emotional lability is not under complete control of the patient and is often misunderstood by family members and caregivers. Although current treatment is antidepressant medications, underlying clinical depression may or may not be present that would respond to higher doses of antidepressant medication and counseling.⁴³

Pressuring a patient who appears depressed to see a mental health clinician can lead to loss of trust if the patient is not comfortable talking about feelings or confiding in a counselor. OTs and PTs and other persons involved in the direct care of a patient who is dying may find that their patients feel safer talking with nonprofessional counselors or psychotherapists about the burden of their care on family members or their own impending death. Rehabilitation personnel should therefore be aware of local options for in-home support services, palliative care, and end-of-life options and services and be prepared to listen to the patient's concerns if the patient expresses the need for emotional support.

The existence of depression and potential associated cognitive impairment has been discussed as a factor reducing a patient's decision making capability in the right-to-die debate.¹⁵⁶ In ALS, however, a patient's wish to die may not be directly related to depression and may not be related to cognitive or behavioral impairments. In a study of 247 patients with ALS, average disease duration of 1 year, 62 expressed

a wish to die (25%), and only 37% of those 62 patients (i.e., 23 patients out of 247) had clinical depression.¹⁵⁶ Such evidence must be considered, along with individual circumstances, in any discussion regarding life-saving interventions or physician-assisted death participation (where legal).

Family Members as Caregivers in Amyotrophic Lateral Sclerosis

Often in the concern for the patient's needs, health care professionals pay little attention to the effect a person's degenerative illness has on other members of the family. ALS significantly affects the person's extended family because the patient gradually becomes increasingly dependent on family members, partners, or caregiving friends for physical care, social arrangements, cognitive stimulation, and emotional support. For some families, the spouse may have to take on additional work, return to work, or, in the case of some older homemakers, join the workforce for the first time to deal with the financial stresses that occur when chronic illness invades the family unit. Family members must also absorb the former family duties of the dependent person. For example, a spouse or child may have to handle all the cooking, cleaning, or other household chores or work to help support the family. Once the patient becomes dependent, the caregiver may need to reduce or discontinue employment to take care of the patient. All family members may need to become involved in the physical care of the increasingly dependent person with ALS. Caregivers frequently influence the decision making process throughout management of ALS, but especially when considering the use of tracheostomy and invasive ventilation (TIV).⁸⁵ A study comparing ALS caregivers in Japan and America noted that caregivers in both countries were more likely to say yes to TIV than the patients they cared for.⁸⁵

Children of patients with ALS also have to deal with major changes in their lifestyle. Although they may love their parent who is sick, at some level most can become frustrated with factors such as the need to provide physical care to parents. This is a difficult problem especially for children who have not had a positive relationship with that parent. Children living in the home of a parent who is dying of ALS also express frustration about the lack of privacy in their home when nursing personnel and attendants are present, interruptions in family and personal life plans, embarrassment because of the parent's appearance and dependency, lack of attention from the caregiving and working parent, and fear of financial crises (e.g., possible loss of home and no financial support for college).

The entire family is affected by the sick person's increasing dependency, behavioral or cognitive changes, and impending death. In a small study of 11 family caregivers, many caregivers felt frustrated and resentful because their lives were consumed with the caregiving responsibilities. Most caregivers had adjusted to some degree after 2 to 4 years. Caregivers who adjusted most successfully learned to take time for themselves without guilt and to tap their social support systems for help.¹⁵⁷ Fortunately, most families manage to cope with the process—the major contributing factor being the coping ability of families before the illness.

To be really effective, the therapist working with the patient with ALS must be prepared to help families and caregivers find appropriate ways of coping with the emotional, social, and physical stress of caregiving. For example, therapists should present, without pressing, adaptive equipment options to patients when they first start to show impairment in functional ability. If shown how the equipment will help them maintain independence, most patients are receptive to its use. Even when presented in a positive way, however, a wheelchair or adaptive devices may be resisted long after the adaptations would facilitate mobility and ADLs. Therapists must be attentive to patients'

feelings and fears at this time because use of a wheelchair (or other specific equipment) heralds to many patients the “beginning of the end.”

Other factors that affect the family of a patient with ALS include medical insurance and differing levels of long-term care coverage. Some families are fortunate to have excellent coverage that provides extensive home nursing support, whereas other families are unable to cope with the financial stresses and must accept public assistance during the final stages of the disease. As opposed to Germany and Japan, which provide long-term nursing care insurance, in the United States financial stress on patients with ALS can reach more than \$150,000 per year for ventilation support at home.⁸⁸ Financial burden significantly impacts patient and caregiver decisions. (Resources are available for end-of-life issues e.g., www.nlm.nih.gov/medlineplus/endoflifeissues.html#cat1.)

GUILLAIN-BARRÉ SYNDROME

Pathology, Incidence, and Medical Diagnosis

GBS, also known as acute inflammatory demyelinating polyradiculoneuropathy (AIDP), is the most common form of the broad spectrum of acute or subacute conditions causing generalized paralysis. GBS is an immune-mediated disease that affects nerve roots and peripheral nerves, leading to motor neuropathy and flaccid paralysis with possible sensory and ANS effects.¹⁵⁸ Unlike ALS, GBS makes itself apparent very quickly, progressing to complete paralysis (in some cases) within days to weeks instead of years. Fortunately, GBS usually has a good prognosis, with most patients returning to their prior functional status by 1 to 2 years after onset. Note, however, that “prior functional status” does not mean that no impairments remain; prognosis will be discussed in a later subsection.

Purely motor forms and mixed motor and sensory forms of GBS have been identified.¹⁵⁹ The motor subtype, *acute motor axonal neuropathy* (AMAN), has a good prognosis, although recovery of ambulation may take longer than in AIDP¹⁶⁰; this subtype is more common in Asia and South America. Less common subtypes include *acute motor and sensory axonal neuropathy* (AMSAN), which has a less positive prognosis (and may be a severe variant of AMAN)¹⁶¹; *Miller-Fisher syndrome*, with primarily cranial nerve (especially oculomotor) symptoms, ataxia, and areflexia¹⁶²; and *chronic inflammatory demyelinating polyradiculoneuropathy* (CIDP), which causes progressive or relapsing and remitting numbness and weakness.¹⁶³ AIDP may be relabeled as *acute onset CIDP* in about 5% of individuals¹⁶⁴ who experience a new *relapse* (episode of deterioration) after 8 weeks from onset of weakness, or if three or more relapses occur within that first 8 weeks. Most references to GBS can be assumed to describe the AIDP and AMAN varieties; Miller-Fisher syndrome, AMSAN, and CIDP are typically called out specifically if research findings include or address them.

The incidence of GBS is approximately 1 to 4 cases per 100,000 persons. Lower incidence is noted in younger ages (0.62 cases per 100,000 person-years for 0- to 9-year-olds, increasing by a highly variable 20% with every 10-year increase in age)¹⁶⁵ and in Western countries compared with Asia. AIDP is one subtype of the disease, accounting for 90% of the cases in North America and Europe.¹⁶⁶ Epidemiological studies show that males are affected by GBS up to twice as often as are females¹⁶⁷; a meta-analysis of incidence studies in North America and Europe showed an incidence in males that was 1.6 that of females.¹⁶⁵

Approximately 27% of patients with GBS have no identified preceding illness; however, more than two-thirds had symptoms of an infectious disease approximately 2 weeks before the onset of GBS symptoms. In the motor form (AMAN) and in Miller-Fisher syndrome, serum antibodies have been found against specific *gangliosides*,

Fig. 15.11 Myelin Formed by Schwann Cells on the Axon of an α Motor Neuron. (Reproduced from Allen DD, Widener GL. *Tone abnormalities*. In: Cameron MH, ed. *Physical Agents in Rehabilitation: An Evidence-Based Approach to Practice*. 5th ed. St. Louis, MO: Elsevier; 2018.)

lipids that reside on neuronal membranes and assist with cell function.¹⁶² Research has identified a specific lipid in *Campylobacter jejuni* that mimics normal human gangliosides in AMAN; following this infection, the antibodies developed to attack the bacterial lipid also bind to normal gangliosides. The new compounds activate axon-destroying complement,¹⁶⁸ the cascade of immune system events that triggers macrophage proliferation and inflammation. Associations with additional infectious agents have been recorded, with differing propensities to activate myelin- or axon-destroying complement (e.g., *Mycoplasma pneumoniae*, influenza A, cytomegalovirus, Epstein-Barr, and *flavivirus*).¹⁶⁹ The flaviviruses include both Dengue and Zika; a meta-analysis of the incidence of GBS in confirmed cases of Zika virus reveals an incidence of 1.23%, much more prevalent than in the noninfected population, although still somewhat rare.¹⁶⁹

GBS pathology may be easier to grasp after a brief review of normal anatomy. In healthy peripheral nerves, a myelin sheath formed by Schwann cells wraps around the axon of α motor neurons to insulate the axon (Fig. 15.11). This insulation speeds electrochemical conduction of the neural signal using a process known as “saltatory conduction” because transmission jumps past insulated sections, from node to node (*nodes of Ranvier*), the spaces between myelin sheathing (Fig. 15.12). In GBS, an infection or triggering event activates the immune system’s complement cascade. The cascade of events in the complement (a specific series of molecules and actions that complement other immune system responses to identified threats) breaks up

Fig. 15.12 Saltatory Conduction Along a Myelin-Wrapped Axon. (Reproduced from Allen DD, Widener GL. *Tone abnormalities*. In: Cameron MH, ed. *Physical Agents in Rehabilitation: An Evidence-Based Approach to Practice*. 5th ed. St. Louis, MO: Elsevier; 2018.)

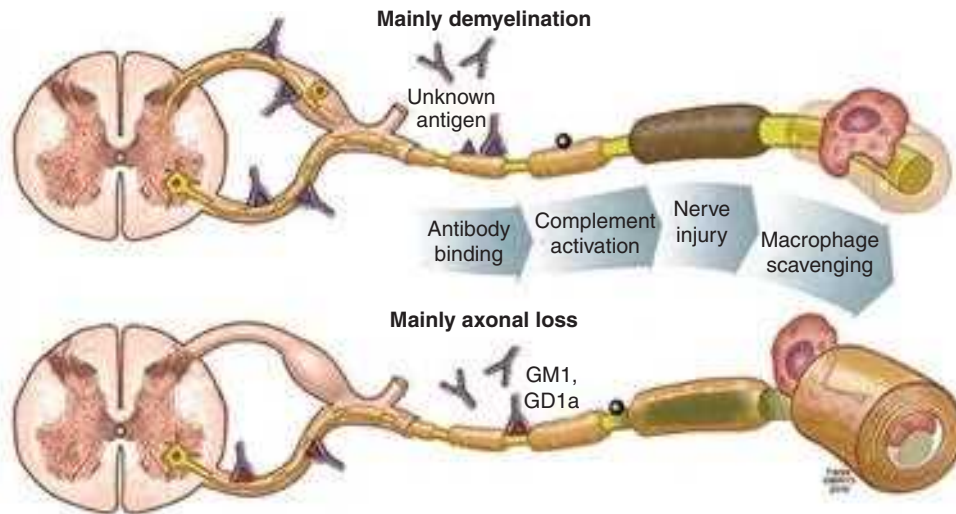

Fig. 15.13 Guillain-Barré Pathogenesis. In the demyelinating subtype, no specific antigen has been identified, but complement activation destroys myelin and macrophages proliferate to clean up myelin debris. In the axonal subtype, gangliosides GM1 and GD1a on the neuronal membrane have been identified as the normally occurring molecules that various bacterial and viral antigens mimic. Antibodies bind to these molecules at the nodes of Ranvier (between myelin sheathing) and activate the complement sequence from there. Macrophages clean up debris from membrane and axon destruction, leaving the myelin relatively intact. (Reproduced¹⁶⁸ from Wijdicks EFM, Klein CJ. Guillain-Barré syndrome. *Mayo Clin Proc.* 2017;92:467–479.)

myelin (in AIDP) or damages axons in spinal roots and peripheral nerves (in AMAN) by attacking the neuronal membrane (resulting in disruption of voltage-gated sodium channels)¹⁶¹ at the nodes of Ranvier or axon terminals close to the muscle fibers. The cascade promotes inflammation and attracts macrophages to come in and clean up the fragments (Fig. 15.13).

In AIDP, damage to the myelin sheath disturbs saltatory propagation of the action potential, resulting in slowed conduction velocity or complete *conduction block* (difference in amplitude of signal when

comparing proximal versus distal stimulation along a peripheral nerve). Partial conduction block is most often seen in the early stages of GBS, and the conduction block increases through the *progressive stage* of the disease (usually about 4 weeks). The most common conduction block findings are in the peroneal nerve, followed by the tibial nerve. Proximal conduction block is evident more often than distal conduction block. In axonal neuropathy (AMAN), conduction block can be more severe, and the number of functional motor units is decreased (Fig. 15.14).¹⁷⁰

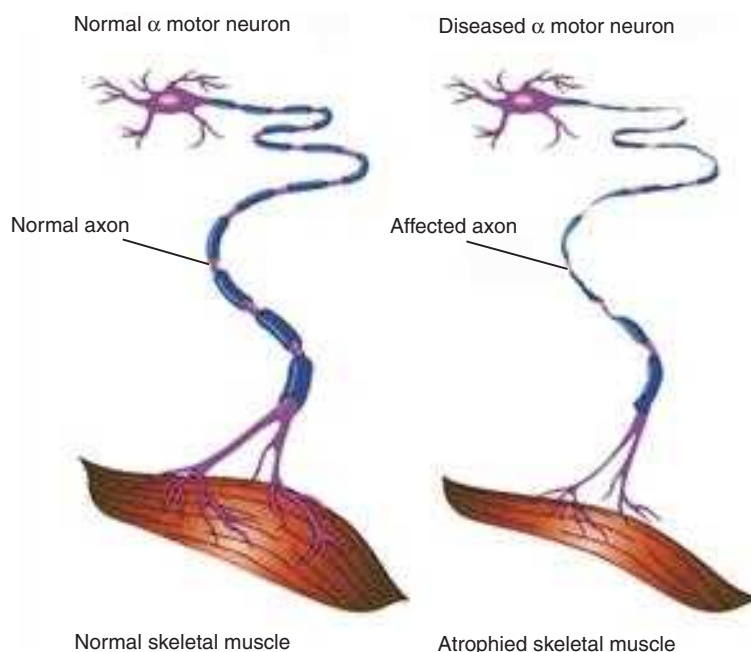

Fig. 15.14 Normal Neuron and Degenerated α Motor Neuron in Pathological Conditions. (Adapted from <http://www.brainstorm-cell.com/assets/ALS-Neurons.jpg>.)

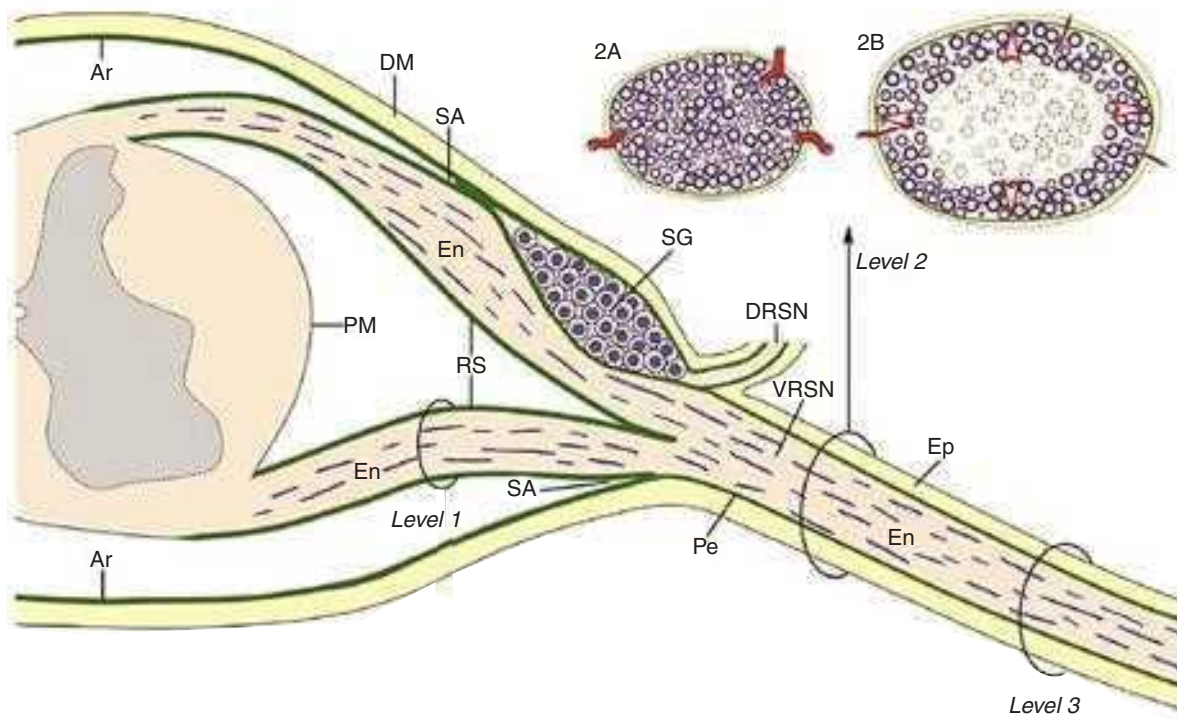

Fig. 15.15 Membranes and anatomy of spinal nerves (including the ventral ramus [VRSN] and dorsal ramus [DRSN]) and nerve roots (including the spinal ganglion [SG], also known as the dorsal root ganglion). The nerve membranes, in order, are endoneurium (En), perineurium (Pe), and epineurium (Ep). The En persists along spinal nerves and nerve roots to their junction with the spinal cord. The Ep is continuous with the dura mater (DM) beginning at the subarachnoid angle (SA). The Pe continues past the SA, mostly between the DM and arachnoid (Ar) membranes, but part of it becomes an inner layer of the root sheath (RS). The external layer of the RS is formed by the arachnoid membrane turning back on itself at the SA. Where the roots join with the spinal cord, the RS becomes part of the pia mater (PM). Inflammation, edema, and demyelination or axonal injury in early Guillain-Barré can occur at levels 1, 2, or 3: nerve root, spinal nerve (including ventral and dorsal rami), or peripheral nerve, respectively. In axonal subtypes, Figs. (2A) and (2B) show the spinal nerve (level 2) with transperineural blood vessels in the normal cross-section (2A), and with edema that pushes axons away from each other, constricting vessels against the compliance limits of a relatively inelastic Pe (arrows, 2B), resulting in ischemia and further injury. Edema can also constrict the passage of the spinal nerve as it emerges through the intervertebral foramen (proximal to the DRSN). (Figure modified from Berciano J. Spinal nerve involvement in early Guillain-Barré syndrome; the Haymaker and Kernohan's Legacy. *J Neurol Sci.* 2017;382:1–9.)

Some researchers have noted in early GBS (the *acute stage*, within 10 days of onset) that inflammatory edema in the *endoneurium* and *epi-perineurium* (membrane layers that cover the nerve) may cause compression and constriction of transperineural blood vessels, resulting in ischemia of the axons (Fig. 15.15). When axons are compressed or deprived of blood flow, they show *Wallerian-like degeneration* (the portion of the axon distal to the lesion degenerates—away from the cell body) and the surrounding myelin of degenerating axons can collapse. When complement activation only affects myelin (in AIDP), the axons are left intact and can remyelinate, typically in a matter of weeks.¹⁷¹ However, when axons degenerate, recovery depends on axonal regeneration from intact elements of the neurons, which takes months and may be incomplete.¹³⁵ In acute axonal

motor neuropathy, the immune system and complement affect the axon directly, leaving the myelin intact.¹⁷² Some evidence indicates that axonal loss is related to longer-lasting or permanent muscle weakness.¹⁷³

The diagnosis of GBS requires both clinical and supportive medical tests. Progressive weakness involving multiple nerve root and nerve distributions (*polyradiculoneuropathy*), usually symmetrical, developing over a couple of days or weeks, accompanied by hypo- or areflexia, generally triggers medical tests such as examination of CSF and electrodiagnostic tests of neural conduction.¹⁶⁶ Characteristic CSF will show *albumino-cytological dissociation*: increased protein (from the fragments of axons and myelin) with no elevation of white blood cells. Motor and sensory neural conduction tests are generally performed at

BOX 15.7 Common Diagnostic Features of Guillain-Barré Syndrome

A. Motor weakness

1. Progressive symptoms and signs of motor weakness that develop rapidly (1–2 weeks)
 - a. Relative symmetry of motor involvement
 - b. Typical progression of weakness from legs to arms; may start in proximal leg muscles, limiting stair climbing or rising from sitting position; may self-limit to upper and/or lower extremities or may extend to full tetraplegia with respiratory and cranial nerve involvement. Facial and oropharyngeal muscle involvement noted in about 50% of cases
 2. Muscle stretch reflexes depressed or absent in at least distal tendon responses
 3. In Miller-Fisher syndrome, diplopia and ataxia may be present
- B. Mild sensory symptoms or signs, particularly paresthesias and hypoesthesias in stocking/glove patterns; these may precede motor signs by 1–2 days
- C. Autonomic dysfunction such as tachycardia and arrhythmias, vasomotor symptoms: extreme blood pressure fluctuations and response to drug therapy may be the presenting signs. Acute autonomic dysfunction typically resolves during the plateau phase
- D. Absence of fever at onset of symptoms; recent history of flulike illness common
- E. Laboratory test results characteristically show elevation of cerebrospinal fluid protein with normal white blood cell counts (cerebrospinal fluid cells at 10 or fewer mononuclear leukocytes per cubic millimeter of cerebrospinal fluid)
- F. Electrodiagnostic testing, nerve conduction velocities of motor nerves usually slower and may reveal a conduction block, but may take 2 weeks to develop. Electromyography in paralyzed muscles may show fibrillation
- G. Serum testing may reveal antibodies to specific gangliosides, specific viral or bacterial infection; may rule out drug or toxins in the blood
- H. Recovery usually begins 2–4 weeks after plateau of disease process

From references 161, 162, and 168.

multiple motor and sensory sites, frequently including the median, ulnar, tibial, peroneal, and sural nerves; abnormalities indicating potential GBS include slowed velocity, lower amplitude of signal, longer latency distally or in the F response, and decrease in compound motor action potential.¹⁶⁰ No test is completely definitive: CSF abnormalities may take up to 2 weeks to develop,¹⁷⁴ and electrodiagnostic tests may continue to be normal for several weeks after onset; up to 20% of patients never have abnormalities apparent on nerve conduction testing.¹⁶⁶ CSF may rule out other diagnoses if cytology suggests carcinomatous origins or active infection. Serum samples may be tested for recent infection with *Campylobacter jejuni*, cytomegalovirus, or other viruses, especially if patients report having had a course of febrile diarrhea, sore throat with headaches, or upper respiratory infection in the 4 weeks preceding symptoms. The diagnostic criteria for GBS were developed and modified by the US National Institute of Neurological Disorders and Stroke and are provided in [Box 15.7](#).¹⁶¹

Clinical Presentation

For an overall view of the clinical presentation of a person with GBS as categorized by the ICF model, review [Fig. 15.4](#). The predominant body function impairments of GBS are weakness and fatigue (affecting movement dimensions of strength and endurance²), with muscle atrophy and fasciculation indicating body structure effects on LMNs with their motor units (review [Figs. 15.1](#) and [15.2](#)).¹⁷⁵ Because the affected body structures include nerve roots, spinal nerves, and peripheral nerves (review [Fig. 15.15](#)), sensory neurons and neurons transmitting information to and from the ANS can also show deficits. Sensory

dysesthesias and autonomic malfunction (*dysautonomia*) can range in severity from annoying pins and needles to life-threatening cardiac arrest. Activity limitations and participation restrictions occur at onset, worsening through the acute stage (about 10 days) and any further progression to the *nadir* (peak) of motor impairment (2 to 8 weeks after onset), depending on the severity of weakness and fatigue, stabilizing during the plateau (2 to 4 weeks), and improving from the beginning of recovery (2 to 3 months post onset to several years). As with ALS, an individual's clinical presentation will depend partly on environmental and personal factors, such as economic resources and coping mechanisms.

Onset

The initial symptoms of GBS may be acute onset of severe midline back pain or sensory paresthesias with tingling progressing from the distal limbs more proximally. Individuals may also complain of a “tight band” feeling.¹⁶⁸ Weakness develops, either as the initial symptom or within 1 or 2 days of sensory signs, frequently in proximal muscles first. Individuals may notice trouble climbing stairs or rising from a chair. Motor signs drive the course of the disease in both children and adults: rapidly evolving, relatively symmetrical ascending (legs to arms) weakness or flaccid paralysis. Motor impairment at the nadir may vary from mild weakness (may be worse in distal lower-extremity musculature)¹⁶⁶ to total paralysis of the peripheral, axial, facial, and extraocular musculature. Tendon reflexes are usually diminished or absent. Because development of motor signs can be rapid and ANS symptoms can develop without warning, cardiac arrest or respiratory failure can occur fairly suddenly. Most patients are hospitalized with monitoring of cardiorespiratory function through the nadir in case cardiac pacemaker, intubation, or less invasive mechanical ventilation becomes necessary.

Respiration

One-third of patients may require assisted ventilation because of paralysis or weakness of the diaphragm, intercostals, and accessory respiratory musculature, or weakness of abdominal musculature (affecting forceful cough) and diminished recoil of the thorax with stiffness developing over a period of time.¹⁶⁸ Impaired respiratory muscle strength may lead to an inability to manage aspiration and to decreased VC, tidal volume, and oxygen saturation. Secondary complications such as infections or organ system failure lead to death in 3% to 6% of patients with GBS, with higher rates of 10% or 20% when individuals have severe comorbidities.¹⁶⁸

Guillain-Barré Syndrome Disability Scale

The GBS disability scale (also referred to as the Hughes scale)¹⁶⁰ is commonly used to track the clinical course of GBS although authors differ slightly in the descriptors they use for different grades¹⁶⁶ ([Box 15.8](#)). A grade of 2 on the GBS disability scale (walks without device) is frequently the target of acute care therapies. Therapy is considered more effective than the alternative if individuals take less time from the onset of symptoms to reach the level of walking without assistance (grade 2), or if a higher proportion of patients walk without assistance by 4 weeks. The GBS disability scale focuses on activity limitations resulting from weakness, especially related to respiration and walking. While used frequently to record status of a patient, the psychometrics of this scale have not been reported, and it has low sensitivity to small changes in impairments or activities.¹⁷⁶

Weakness

The primary deficit driving the course of GBS is *loss of muscle strength*. Strength is typically tested at individual muscles with a manual muscle

BOX 15.8 Guillain-Barré Syndrome Disability Scale^{160,166}

- 0 = Normal (healthy)
- 1 = Minimal signs and symptoms, able to run (minor symptoms or signs of neuropathy but capable of manual work)
- 2 = Ambulates independently (at least 5 m across an open space but incapable of manual work/running)
- 3 = Able to walk 5 m with aid (stick, appliance, or support)
- 4 = Bed bound (or wheelchair)
- 5 = Requires assisted respiration (for any part of the day or night)
- 6 = Death

test (MMT: 0 to 5, with 5 being normal and 0 meaning unable to contract). However, the clinical course of strength loss and recovery does not show random deficits in individual muscles but is fairly symmetrical and related to distal versus proximal musculature. In many studies, strength testing has been standardized for recording the clinical course in GBS based on MMT scores across multiple muscle groups. MMT scores across specific distal and proximal muscle groups of the bilateral upper and lower extremities are summed to form the Medical Research Council (MRC) strength assessment.¹⁶⁶ MRC for GBS designates six pairs of muscles¹⁷⁷ (although some authors report assessment across four pairs of proximal and distal muscles)¹⁶⁶: shoulder abductors, elbow flexors, wrist extensors, hip flexors, knee extensors, and ankle dorsiflexors.¹⁷⁸ Each of 12 (or 8) muscles is scored from 0 to 5 using the MMT definitions, with 60 (or 40) indicating the top score for normal strength across the tested muscle groups. Using 40 as the top score (for the sum across eight muscles), authors have categorized motor deficit as mild (MRC 31 to 40), moderate (MRC 11 to 30), and severe (MRC 0 to 10).¹⁶⁶ Mild motor deficit may be translated as most muscles testing as 4 to 5/5 on MMT; moderate indicates that most muscles test as a 2 to 3/5, and severe indicates that muscles test as 0 to 1/5. Others divide the MRC (60) into “decade” groups¹⁷⁷ of scores: 51 to 60, 41 to 50, 31 to 40, 21 to 30, and less than 21. A modification of the MRC proposes a new scoring system of 0 to 3 for each muscle to improve reliability among physicians (who performed the MRC in the data used) who were shown to be inconsistent in their use of the 0 to 5 MMT scale.¹⁷⁸ In the new scoring system, the scores would indicate normal strength (3), slight weakness (2), severe weakness (1), and paralysis (0). The modified scoring has not yet become the standard practice.

Note that the MRC scores include the upper and lower extremities, but do not assess axial muscles or cranial nerve weakness. Axial muscles typically have deficits that align with limb muscle weakness; muscles innervated by cranial nerves may be more or less affected than limb musculature in patients with GBS.

Approximately 50% of patients develop some *cranial nerve involvement*, primarily facial muscle weakness, although patients may also develop paresis or paralysis in oropharyngeal (bulbar involvement in AIDP or AMAN) and oculomotor (most frequently in Miller-Fisher syndrome) muscles.¹⁶⁸ Bulbar signs are occasionally the presenting motor symptoms. When bulbar signs are present, dysarthria and dysphagia are likely, which is similar to that seen in ALS but without spasticity in the tongue or larynx (see [Table 15.1](#)).

Fatigue

Fatigue is common in GBS and can be both a primary and secondary effect. Primary fatigue may result from increased central effort

required to activate partially denervated muscles and diminished ability to recruit sufficient motor units to maintain peripheral contractions.⁹⁶ Fatigue is inevitable when muscles weakened through the disease process must work at a higher percent of their maximal strength for ordinary daily tasks. However, in a consensus statement combining literature review and expert opinion, authors agree that at least part of the cause of fatigue in GBS is the forced inactivity¹⁷⁹ consequent to muscle weakness. Thus secondary fatigue may occur with deconditioning. Most measures of fatigue do not distinguish between these sources, but management differs so distinction is useful. Fatigue experienced in the early stages of the disease is assumed to be primary fatigue: it is related to the severity of weakness, and intervention usually requires reduced activity to minimize overuse of partially denervated muscles. Fatigue experienced after reinnervation of muscles is assumed to be secondary fatigue: it is not related to severity of the initial illness, and intervention can utilize the overload principle or progressively challenging activities.

Severe fatigue (undifferentiated as to primary or secondary fatigue) is present in 38% to 86% of patients with GBS, depending on the cutoff point used to define severity and the age of the sample, with a positive correlation between severe fatigue and greater age.¹⁸⁰ Fatigue tends to be long-lasting: up to 42% claim they still have severe fatigue after 20 years¹⁸¹ post onset of GBS. In a study comparing people “well-recovered” from GBS and healthy controls, maximal voluntary contraction was only slightly less than healthy controls, but a sustained contraction showed less peripheral fatigue and more central activation failure (indicating inability to maintain recruitment at MVC level even though the muscles had not yet fatigued) in the first minute in GBS.¹⁸² The people with GBS also rated their experience of fatigue as significantly higher before the exercise, and tended to increase after the exercise, while the fatigue of healthy controls did not. The authors interpreted these findings as indicative of a possible change in muscle fiber type, and the loss of some motor units compared to pre-GBS status. A limited number of recovered motor axons in GBS would mean that the dropout of only a few motor units during sustained contraction would signal a relatively large central activation failure.¹⁸²

Other Signs and Symptoms

ANS involvement, sensory deficits, and pain are also frequently seen to a greater or lesser extent in the clinical course of GBS.¹⁸³

ANS symptoms are noted in about 50% of patients; both motor and sensory autonomic neurons may be affected. *Dysautonomia* may manifest as orthostatic hypotension, blood pressure instability, cardiac arrhythmias, and sometimes bowel and bladder dysfunction. It is relatively common in patients with GBS requiring ventilatory support and can compromise management of respiratory function or result in cardiac arrest (an emergency situation). Blood pressure fluctuation may result from demyelination of the vagus cranial nerve.¹⁶⁸ One study of 34 patients with GBS still showed some abnormal drop in blood pressure upon standing several years after GBS onset, although none of them complained of orthostatic problems.¹⁸⁴ Other typical ANS symptoms may result in peripheral pooling of blood (with consequent orthostatic hypotension), poor venous return, *ileus* (absence of contractile activity in the intestines), and urinary retention. In patients with paraplegia or tetraplegia at the nadir of GBS, approximately one-fourth had problems with urinary retention caused by detrusor areflexia or overactivity, overactive urethral sphincter, and disturbed bladder sensation.¹⁶⁷ However, bladder symptoms are generally slower to develop than other motor symptoms and tend to resolve more quickly. In fact, severe bowel or bladder dysfunction at initiation of symptom onset reduces the possibility that the diagnosis is GBS.¹⁶⁶

One author states that other dysautonomic symptoms such as residual impotence¹⁷⁶ “settle with time.”

Sensory symptoms such as distal hyperesthesias, paresthesias (tingling, burning), numbness, and decreased vibratory or position sense are common. The sensory disturbances often have a stocking-and-glove pattern rather than a dermatomal distribution of loss. Although the sensory problems are seldom disabling,¹⁶⁸ they can be disconcerting and upsetting to patients, especially when interpreted as pain during the acute stage. Uncomfortable *dysesthesias* are thought to result from the imbalance of sensory input from intact smaller, unmyelinated sensory fibers versus input from impaired larger, myelinated fibers. In some cases, response to pinprick, light touch, and vibration and proprioception may remain fairly normal or only mildly impaired (especially in GBS designated as the motor neuronal type, or AMAN) despite other sensory symptoms.

Pain associated with GBS can have heterogeneous origins, both *nociceptive* and *neuropathic*, and a careful evaluation is needed to treat it effectively. For example, nociceptive pain may stem from inflammation at the nerve roots and peripheral nerves or entrapment when the spinal nerve develops edema at the exit through the intervertebral foramen (review Fig. 15.15).¹⁸⁵ Neuropathic pain can arise from either central or peripheral sensitization in GBS, having been identified in the animal model of experimental autoimmune neuritis (EAN), which shows symptoms of polyradiculoneuropathy similar to GBS in humans.¹⁷⁴

Pain was identified as a significant presenting symptom in the historical articles describing GBS¹⁶⁸; in a more current study, pain reached its peak in the 2 weeks preceding the onset of weakness in about one-third of cases.¹⁷⁴ When pain presents as the first symptom of GBS, it is typically symmetrical, and at the midline of the back or in the gluteals, quadriceps, and hamstrings; lower leg and upper-extremity muscle pains are less common initially. This pain has been described as acute and worsening with activity or strenuous exercise; it is thought to reflect inflammation and entrapment of nerve roots. Because acute low back pain may have similarities to this initial pain, therapists who work with patients presenting with acute severe back pain must be alert to differentiating signs and symptoms: GBS initial pain develops quickly (over a few days) but is not associated with known injury or stress (which are frequently identifiable in low back pain); patients may also have paresthesias (pins and needles) in stocking and glove patterns rather than following nerve roots; patients with GBS may have vibratory perception loss, or multiple decreased tendon reflexes. Further, GBS will rapidly evolve with an onset of weakness either prior to pain or within days of its onset.

Pain experienced beyond the initial presentation is also common. A majority of patients with GBS (54% to 89%) report having significant pain during the acute stage of the disease, and 38% still report pain after 1 year post onset of weakness.¹⁷⁴

Multiple pain types can occur simultaneously or sequentially in GBS.¹⁸⁵ Pain may manifest as paraesthesia or causalgia, with acute *hyperesthesias* or sensitivity to touch or air movement¹⁸⁶; unless controlled pharmacologically, hyperesthesias can interfere with nursing care and limit therapy interventions. Muscle aching or cramping pain can last for days in weakened muscles (<3/5 MMT score) that have been overworked beyond capacity. Joint pains can occur as a result of lack of movement or overstretching when muscles are flaccid on one side of an unsupported joint. Some pain reported during convalescent stages has been described as “stiffness.”

Secondary complications and residual deficits. Secondary problems can develop from severe weakness, pain, and the corresponding lack of activity. The possibility of DVT and pulmonary embolus must be monitored, especially in people who are not moving around

as much as they did before disease onset; prophylactic treatment is sometimes used.¹⁸⁷ Pressure ulcers and pulmonary infections are also common secondary complications in GBS although most can be prevented with careful medical management.¹⁶⁴ Other complications can occur related to the severity of symptoms, side effects of mechanical ventilation or immunotherapy, autonomic dysfunction, or postinfection disorders.¹⁸⁸

In 8% to 16% of those with GBS, individuals may show a reversal of direction of recovery, with relapse after a plateau or after movement starts to recover¹⁸³ in the first 8 weeks. This relapse may be called *treatment-related fluctuation*; some authors advise a second course of immunotherapy treatment, but the research regarding its effectiveness in such cases is lacking.¹⁸⁹

Residual deficits in about 20% of people 1 year and more after onset of GBS can range from minimal impairments to impairments that limit activity and participation and prohibit return to prior levels of function. Many former GBS patients may prefer to avoid further medical scrutiny after a year plus of intense focus on their impairments. However, some residual deficits years post GBS onset may be successfully addressed with an intensive episode of rehabilitation.¹⁹⁰

Medical Prognosis

Most patients have a *fulminating* course of GBS, in which the *disease develops suddenly and severely*. Many progress to maximal paralysis within 1 to 2 days of onset, 50% of patients reach the *nadir* (the point of greatest severity) within 1 week, 70% by 2 weeks, and 80% by 3 weeks. In some cases the process of increasing weakness continues for 1 to 2 months. If function continues to deteriorate, or if deterioration begins again after 8 weeks, the condition may be rediagnosed as acute onset of the chronic form of GBS, or CIDP. The acute and progressive stages of the acute forms of GBS are generally followed by a *plateau*, during which no further deterioration is evident, but no motor recovery has yet begun.

The *onset of recovery* varies, with most patients showing gradual recovery of muscle strength starting 2 to 4 weeks after the condition has plateaued. Once begun, recovery is typically protracted, with the most gains in the first year, but additional gains possible several years after the onset of symptoms.

The *extent of recovery* also varies, with about 33% claiming they are completely cured within a mean of 230 days (about 8 months) after onset of GBS.¹⁹¹ Approximately 80% become ambulatory within 6 months of onset of symptoms. However, 50% to 67% of patients may show neurological deficits remaining at 1 year (e.g., loss of power,¹⁹¹ diminished or absent tendon reflexes), but only about 15% have residual loss of function.¹⁷⁶ The most common long-term deficits are weakness of the anterior tibial musculature and, less often, weakness of the foot and hand intrinsic, quadriceps, and gluteal musculature. Motor and sensory disturbances may still affect work, home functioning, and leisure activities 1 to 5 years after onset. Fatigue or poor endurance is also noted as a long-term consequence of GBS, possibly attributable to deconditioning and muscular fatigue during the recuperative process.¹⁸⁰ Vajsar and colleagues¹⁹² report that fatigue and poor exercise tolerance were common persisting symptoms in children who otherwise appeared to have fully recovered from acute GBS. Different studies show significant proportions of patients with continuing symptoms at 1, 2, 10, and 20 years: 43% were still affected psychologically¹⁹¹ (mood changes, anxiety, and depression), and 14% were dependent in ADLs at 1 year, 17% were unable to work at 2 years,¹⁹³ 52% had some limitation in walking at 10 years,¹⁹⁴ and 10 out of 24 individuals noted severe fatigue 20 years¹⁸¹ after GBS onset. Three percent to 5% of patients die of secondary cardiac, respiratory, or other systemic organ failure.¹⁶⁷

Note that the chronicity of remaining impairments following acute GBS does not change the diagnosis to the chronic form of GBS or CIDP; CIDP depends on a relapsing course, where renewed deterioration results in worsening of symptoms after recovery begins.

Although not the focus of most studies on the long-term impact of GBS, *sensory deficits* (impaired response to pinprick, light touch, and vibration and proprioception in combination with other sensory losses) are an ongoing problem for some patients 1, 3, and 6 years after recovery from acute GBS. In a study of 90 patients who completed a survey at homecoming and 12 months after initiation of the disease process, 36% still had disturbed sensation in the arms and 60% had disturbed sensation in the legs¹⁹¹ at 1 year. Similar percentages were noted in a different study of 122 individuals at 3 and 6 years after GBS onset.¹⁹⁵ The muscle aches and cramps experienced by some of these patients appeared to be related to sensory rather than persistent motor dysfunctions as usually thought. Sensory and persistent nociceptive abnormalities may be related to the smaller size of the neuronal fibers carrying information from the periphery to the spinal cord: one study in GBS showed that small myelinated fibers (A- δ fibers) are more likely than larger myelinated fibers to have myelin and axon impaired simultaneously,¹⁹⁶ potentially leading to prolonged recovery times.

Factors associated with a poor prognosis include severity of muscle weakness (especially tetraplegia), the need for respiratory support, cranial nerve involvement associated with loss of eye movement and swallowing, rapid rate of progression from onset, length of time to nadir, older age at onset, history of gastrointestinal illness, and recent cytomegalovirus infections.¹⁶⁷ In a study of 76 patients with GBS who had been in the intensive care unit (ICU), mechanical ventilation was associated with more morbidities and fatalities, although one of those who had been ventilated for over a year was eventually able to ambulate independently.¹⁹⁷ In a derivation cohort of 397 patients with GBS in Europe, the factors associated with slower recovery (inability to walk unaided 10 m at 1, 3, and 6 months after hospital admission) were increased age, lower combined strength score, and previous course of diarrhea.¹⁹⁸ In separate research, the Erasmus GBS Outcome Score¹⁹⁹ was developed that predicts whether a person will be able to walk independently at 6 months; the prognostic variables include age, preceding diarrhea, and the GBS disability score at 2 weeks. Individuals who have the Miller-Fisher type of GBS have a better prognosis, with complete recovery from eye muscle weakness, areflexia, and ataxia in 60% to 100% of patients after 6 months¹⁸³ with no more than supportive care.²⁰⁰ A varying percentage (25% to 50%) of individuals with Miller-Fisher syndrome progress to developing limb weakness or bulbar symptoms that overlap with the more typical GBS presentation; in these cases, individuals may benefit from the addition of immunotherapy as part of their medical management although specific research in this subgroup is sparse.¹⁸³

Medical Management

Medical treatment depends on the rate of progression and degree of paralysis and other symptoms. In mild cases of GBS showing limited weakness and sensory dysfunction, spontaneous recovery may occur with only monitoring over time. In moderate to severe cases, medical management is critical: early institution of immunotherapy can limit the progression of neural damage, and excellent supportive care can prevent secondary problems.¹⁶⁴ If an individual has rapid onset of pulmonary and cardiac manifestations of dysautonomia¹⁸⁷ or acute respiratory compromise, medical management can save a life.

Life Support

When an individual presents with rapid progression of severe weakness, hospitalization is the likely choice to provide supportive care and

Measure	Categories	Score
Days between onset of weakness and hospital admission	>7 days	0
	4–7 days	1
	≤3 days	2
Facial and/or bulbar weakness at hospital admission	Absence	0
	Presence	1
MRC sum score at hospital admission	60–51	0
	50–41	1
	40–31	2
	30–21	3
	≤20	4
EGRIS		0–7

Fig. 15.16 Erasmus Guillain-Barré Respiratory Insufficiency Score Model. Elements of the Erasmus Guillain-Barre Respiratory Insufficiency Score (EGRIS) predicting the need for mechanical ventilation in the first week of hospitalization. An EGRIS of 2 is associated with a probability of .08 of requiring mechanical ventilation in the first week; an EGRIS of 7 is associated with a .91 probability. *MRC*, Medical Research Council, the summed manual muscle test scores of a designated six pairs of limb muscles, each muscle scored 0 to 5, with 5 being normal. (Reproduced from Walgaard C, Lingsma HF, Ruts L, et al. Prediction of respiratory insufficiency in Guillain-Barré syndrome. *Ann Neurol*. 2010;67:781–787.)

monitoring. The individual may be monitored every 1 to 3 hours¹⁶⁴ for onset of respiratory insufficiency and continuously for cardiac arrhythmias and extreme BP fluctuations (exceeding 85 mm Hg). Monitoring for dysautonomia generally continues until the patient has discontinued ventilatory support, had tracheostomy removed, or begun to recover without needing either intervention.¹⁷⁹ Walgaard and colleagues¹⁷⁷ developed a model (Erasmus Guillain-Barré Respiratory Insufficiency Score [EGRIS]) to predict those who are more likely to require ventilatory assistance based on measures typically gathered upon hospital admission. EGRIS was developed on a cohort of 397 patients in Europe: 20 (5%) were intubated prior to hospitalization, 83 (22%) during the first week, and 16 (4%) during the second week of hospitalization. EGRIS included MRC (summed score from MMT of six pairs of bilateral muscles), rate of initial disease progression (by the number of days between weakness onset and hospitalization), and facial/bulbar weakness (Fig. 15.16).¹⁷⁷

Patients who progress to respiratory deficiency must be treated in an intensive care environment where adequate respiratory function can be maintained, secondary infections can be prevented or limited, and metabolic functions can be carefully monitored. The patient is typically intubated for mechanical ventilation if functional VC falls below 20 mL/kg (or <60% of predicted value^{161,201}) or PO₂ value falls below 75 mm Hg²⁰²; if VC, inspiratory, or expiratory pressures fall by more than 30% from baseline; if the patient has bulbar dysfunction (especially with aspiration); or if the patient is increasingly dyspneic even if VC is above the cutoff level.²⁰² Intubation is considered invasive ventilation and may be performed with an endotracheal tube or via tracheostomy.⁸² One consensus document noted that tracheostomy can be delayed for 2 weeks to see if pulmonary function tests improve with just the endotracheal tube. If function does not improve in that time,

transition to tracheostomy intubation may be performed to increase patient comfort and airway safety, and make weaning easier.^{179,203} Twenty-five percent of patients who experience respiratory failure will develop pneumonia. Even if daytime respiration seems adequate, nighttime respiratory insufficiency (sleep-disordered breathing) should be suspected if patients have persistent sleepiness or fatigue.¹⁸⁰

Psychological Support

Patients with GBS who are in the ICU on ventilation, with varying levels of paralysis and sensory dysfunction, will require management to address psychological and communicative concerns. Patients may feel trapped and out of control if severe paralysis and respiratory equipment hinder them from expressing their needs. These patients can usually hear well, and most can see what is happening around them. They benefit from being oriented to time, having the health care personnel explain all procedures, and having some means of obtaining help. In one study, patients without vocal communication or means of activating a call light were trained to hold their breath for 12 seconds to trigger the apnea alarm of the ventilator, set at 12 seconds, to indicate when they needed additional pain medication.¹⁸⁶ Therapists can work with the ICU staff to provide the patient with other forms of communication, such as eye blink, clicking, and communication boards designed for their needs. Having some form of communication and knowing that they will not be left alone will help prevent traumatic stress reactions.¹⁸⁷

Immunotherapy

As monitoring and supportive care get underway, one of two specific immunotherapy-based treatments will usually begin. Both have good evidence-based support to decrease the duration of ventilator dependence and time to the beginning of recovery if initiated within 2 weeks of symptom onset. In *plasma exchange* (also known as *plasmapheresis*), the blood plasma is purified (to decrease the concentration of pathological autoantibodies)²⁰⁰ by extracting the blood and processing it outside of the body, and then reinjecting it.¹⁸⁸ In essence, blood is extracted through a vein, the blood plasma is separated from cells using membrane filtration or centrifugation and removed; the cellular component is reinfused along with a replacement solution consisting of fresh frozen plasma, albumin or saline, or doubly-filtrated auto-plasma to maintain the individual's blood volume during the process. One plasma volume is exchanged on five separate occasions, usually every 2 days.¹⁸⁸ In *intravenous immunoglobulin* (IVIg), human plasma from over 1000 donors is purified, marketed, and injected into a vein of the patient. The injected immunoglobulin seems to neutralize pathogenic antibodies, inhibit complement activation, and modify macrophage activity.²⁰⁰

Moderate evidence supports plasma exchange as decreasing recovery time and improving outcome at 1 year compared to supportive care alone.²⁰⁴ Plasma exchange is most beneficial if begun within the first week of diagnosis and can be beneficial up to 30 days after diagnosis.²⁰⁴ Plasma exchange is also cost-effective as used in patients with mild, moderate, or severe courses of GBS.^{166,205} IVIg is somewhat safer and easier to administer than plasma exchange: IVIg requires only one peripheral vein for injection (plasma exchange requires two, one of which must accept a high flow volume, and possibly insertion of a central venous line), no special equipment for plasma separation or purification, and no specifically trained personnel to complete the procedure. IVIg speeds recovery by the same amount of time as plasma exchange in adults and is more effective than supportive care in children.²⁰⁶ High-quality evidence supports IVIg use in adults with GBS; the quality of evidence is slightly less high to support its use in children with GBS.¹⁸⁹ Evidence comparing IVIg with plasma exchange is mixed. In one randomized comparison, plasma exchange resulted in better muscle strength, disability levels, and biochemical indicators

at 2 weeks after intervention.²⁰⁷ In a trial in which treatment was applied according to economic level of the patient, the group receiving IVIg (the more costly alternative in many health care settings perhaps because of the need for processing plasma from 1000s of human donors) outperformed the group receiving plasma exchange in length of ICU stay, time to beginning of recovery, and weaning off of mechanical ventilation.²⁰⁸ In a retrospective study comparing outcomes of 1166 patients with GBS, disability outcomes were equivalent at 2, 6, and 12 months, although those with IVIg (with a relatively higher economic status) had a shorter hospital stay on average.¹⁶⁶ Adding IVIg to plasma exchange does not improve time to recovery any more than either treatment alone.²⁰⁶ Thus the standard therapy for any patient with GBS having a 2 or higher disability score (walking is impaired) is to treat with *either* plasma exchange *or* IVIg, but not both. The American Academy of Neurology has published practice parameters guiding the dosage of these immunological interventions.²⁰⁹

Pharmacotherapy for Pain

Gabapentin and carbamazepine, both anticonvulsant drugs, have each been used successfully to decrease neuropathic pain in people with GBS in the ICU, with advantages for those taking gabapentin in decreasing pain and minimizing demand for fentanyl (used as a supplementary analgesic).¹⁸⁶ Although corticosteroids have been used to decrease the inflammatory process in GBS since the 1960s, an RCT showed no significant reduction in pain with methylprednisolone,¹⁷⁴ and a review of studies showed that corticosteroid treatment alone does not hasten recovery from GBS.²¹⁰ If pain is more related to muscle and joint aching, acetaminophen or other simple analgesics and NSAIDs may suffice¹⁷⁹ for short-term relief.

Other Supportive Management

Additional supportive treatment generally includes enteral nutrition for those with dysphagia, bladder catheterization for severely affected patients along with pharmacological agents for ileus, antibiotics for pulmonary infections, and heparin or other medications as prophylaxis against DVT. Although no studies have been published in GBS, heparin and support stockings have evidence supporting their effectiveness at reducing risk of DVT in other populations of nonambulatory acutely ill or postoperative patients¹⁷⁹ and are recommended by consensus. Pressure ulcers can usually be prevented with air mattresses, regularly scheduled turning and repositioning of the patient, and use of padding over pressure points¹⁸⁶ such as elbows, knees, and heels.

So far, no pharmaceutical agents have been helpful in alleviating fatigue in this population. In a study of the use of amantadine to relieve severe fatigue in 74 patients with GBS randomly allocated to treatment or placebo groups, the groups showed no difference in any of the primary or secondary measures recorded.²¹¹

Medical management for CIDP, the chronic form of GBS, has its foundation in the management choices for the acute onset of GBS, with IVIg as a first line medication. Because of the long-term nature of the relapsing and chronic impairments, corticosteroids have also been used successfully in many patients.²¹² Articles that focus specifically on CIDP provide information about other differences in medical management for this relapsing form of the disease^{213,214} but were not reviewed for this chapter. A case report of a patient with CIDP from the perspective of the PT has also been published.²¹⁵

Therapeutic Management of Movement Dysfunction Associated With Guillain-Barré Syndrome

Therapeutic management of the movement deficits associated with GBS includes supportive management during the acute and progressive

phases, prevention of long-term medical comorbidities during the plateau, and staged rehabilitation throughout recovery.²⁰¹ Unfortunately, direct evidence and controlled trials to support rehabilitation is sparse in GBS,¹⁷⁹ and clinicians must make assumptions based on similarities with other populations (e.g., poliomyelitis and peripheral neuropathies) at various stages. With the assumption that the patient will have significant return of function within months, rehabilitation professionals must help maintain the integrity of functioning systems, address pain and other complaints, teach compensatory strategies, and appropriately promote increasing activity as patients regain mobility. The immediate needs of the patient will change as the patient moves through the acute stage, the plateau at the nadir, the beginning of recovery, and later recovery stages of GBS before and after muscles attain antigravity (3/5 MMT) strength. Transitioning between the therapeutic goals required at each stage necessitates careful examination of the current status, progression of the disease, and needs of the patient.

In direct contrast to ALS, the stages of GBS frequently start with hospitalization and progress through to clinical and outpatient care. Hospitals and ICUs are where a multidisciplinary team is typically most available. If a patient moves to an inpatient rehabilitation unit, multidisciplinary care hopefully continues, with team planning and common goal setting with the patient as the prime decision maker. In this setting, functional improvement can occur, as recorded using Functional Independence Measure (FIM) scores, and this improvement is retained 6 months later.^{216,217} Unfortunately, as patients transition to home care and independence, they may have less access to some of the disciplines they need to address lingering impairments. Research assessing the effects of a multidisciplinary team in GBS is lacking,²¹⁸ with only one controlled trial identified.¹⁹⁰ Low-quality studies show that inpatient rehabilitation is effective in improving function and

decreasing disability, but the data are only available from the beginning recovery stages, not in the protracted time frames in which many people with GBS experience impairments. When multidisciplinary resources are not available, each clinician must be prepared to screen for important components of patients' needs and intervene and refer appropriately. Clinicians must also advocate for patients who have not received an order for physical therapy, for example, either as an inpatient or after discharge, because of the disability that remains for some who are independent in basic functions.²¹⁹

Examination

Rehabilitation professionals will specifically address body function impairments, activity limitations, and participation restrictions related to GBS (see Fig. 15.4), along with environmental and personal factors, using standardized measures where possible. A typical examination of a patient's movement and function includes the following components. As in ALS, different rehabilitation specialists will target assessment depending on the standards of their discipline, modifying from comprehensive lists such as that found in the Guide to Physical Therapist Practice.⁹⁸ Considerations specific to GBS are shown in Box 15.9. The extent of the examination in any one session depends on the patient's condition and ability to participate.

- **Patient History.** Chart review and history taking should extract the course of the disease across what time period, along with any recent illness (especially gastrointestinal or respiratory tract infection in the 4 weeks preceding symptom onset), recent vaccinations, pre-existing neuromotor or other medical conditions, current concerns, and the patient's immediate goals.
- **Systems Review.** Screening tests can help determine whether cranial nerves or sensory and autonomic systems are involved along

BOX 15.9 Considerations Specific to the Examination of Patients With Guillain-Barré Syndrome

Chart Review, Patient History

Patterns and sequence of symptom onset
Recent illness, vaccination, or injury
Prior episodes of sensorimotor problems
Comorbidities
Current medical management
Patient complaints and preferences

Systems Review

Vital signs critical: Blood pressure resting and immediately after activity (prone, sitting, standing, if possible); heart rate resting and immediately after activity, dysrhythmias
Body temperature stability; respiration stability
Skin integrity (for redness or decubitus ulcers in patients who are immobile): visually inspect pressure points (bony prominences that might develop pressure sores) in supine, side-lying, and sitting positions
Communication (augmentation required?)
Comorbidities

Tests and Measures

Visual inspection to identify symmetry of muscle bulk, fasciculations, and function
Stretch reflexes
Movement ability of body region(s) with deficits
Flexibility: Range of Motion (use a form for serial recording)
Strength: Manual muscle testing, carefully identifying pattern of weakness (testing should be muscle specific as possible rather than assessing muscle groups only; recommend use of a standardized form for serial recording of muscle testing)

Accuracy: Observe/record ataxia/dysmetria in upper and lower extremities, trunk, neck, bulbar areas; perform rapid alternating movements as appropriate
Speed: Timed tasks in motions where primary movers have against-gravity capability
Adaptability: Ability to change movement as obstacles or the environment changes
Endurance: Questionnaires for experienced fatigue, circumstances; test fatigability
Cranial nerve testing/screening, especially oculomotor
Balance, static and dynamic, sitting and standing (if testable)
Functional status (activities of daily living, participation in life, eating, bowel and bladder function, and ambulation) in the patient's natural environment or simulated circumstances
Sensation: Pattern and type of sensory loss or changes (e.g., paresthesias, anesthesia, and hypoesthesias)
Pain: Intensity, type, and location (use body chart); what aggravates/eases?
Psychosocial systems: Identify patient and family concerns in acute circumstances and projections about long-term issues. Refer for social worker evaluation of financial resources, day-to-day living problems (e.g., transportation and child care), support systems, and coping strategies
Quality of life, including sleep, well-being
Environmental adaptations and equipment relevant to current and projected status
Electrodiagnostic testing: Nerve conduction velocity; electromyography. (These studies to be performed by a clinician skilled in the procedures. This may be a physical therapist, physician, or technician depending on facility.)

with motor systems in the trunk and limbs. Checking vital signs (heart rate, blood pressure, respiratory rate, and ease of breathing) at rest and immediately after activity, assessing skin integrity especially in immobile patients, screening cranial nerve performance, and noting communication ability are all important components. Additional testing of sensation (and documentation on a body chart, for example) or autonomic systems may be required if the screening tests indicate a potential problem. Cognition may be screened. Referral to appropriate health care professionals may be indicated.

- **Tests and Measures.** Body functions to be tested include the six dimensions of movement,² pain, sensation, and specific impairments such as dysarthria, dysphagia, and respiratory function. Both primary and secondary effects should be recorded, along with relevant activity limitations, participation restrictions, and environmental and personal factors affecting function. Any Clinical Practice Guidelines regarding core sets of outcome measures should be followed as appropriate.⁹⁹
 - Strength (a primary target of GBS) and flexibility (a secondary effect of loss of movement) require serial documentation to track the patient's course of progression or improvement. MMT, dynamometry, grip strength, or isokinetic testing may be useful in various stages to test strength; goniometry is typically used for ROM testing and flexibility. Patterns of weakness associated with contractures (such as significantly decreased voluntary movement or asymmetries of strength on the two sides of a joint) may be noted, and the appropriate level of passive or active stretching can be planned. Full MMT and joint ROM assessment may require several sessions in the initial stages. Following the initial assessment or after the recovery stage begins, a few specific muscles and joints may be selected to test for changes weekly (e.g., the muscles designated for the MRC summed score; grip strength; sternocleidomastoids, deltoids, triceps, flexor carpi ulnaris, lumbricals, iliopsoas, gluteus medius, anterior tibialis, and flexor hallucis longus; and shoulders, fingers, and ankles).
 - Endurance can be recorded using amount of activity tolerated (with specific symptoms noted before rest is required), time on a task (e.g., "tolerated 6 minutes of sitting before requiring rest in a reclining position," or "able to sustain a muscular force for 15 seconds before strength deficit"), perceived exertion (RPE scale), or work performed in a designated time period (meters walked in 6 minutes). Physical measures of endurance may be called fatigability measures. Self-report measures of fatigue include questionnaires such as the FSS, Fatigue Impact Scale (FIS), Modified Fatigue Impact Scale (MFIS),¹⁷⁶ or the VAS-F.¹⁸⁰

Note that several factors may interfere with complete assessment of strength, flexibility, and endurance in the acute and progressive stages. Patients who report considerable pain during handling or active movement may not tolerate standard procedures, or may be unwilling or unable to cooperate with testing. Fatigue and respiratory difficulties may also preclude complete strength assessment in a single session. Fatigue in the initial stages may result from increased effort to activate weakened muscles and inability to maintain force generation for function.⁹⁶ As recovery begins, fatigue can also be related to deconditioning.

- Pain may be tracked by level and type on a visual analogue scale (VAS-pain), numeric rating scale (NRS-pain), and body chart, or the Dallas Pain Questionnaire.¹⁷⁶ Tracking pain can help distinguish between weakness and loss of ROM related to pathological condition, immobility, or pain. Pain should also be tracked to observe response to intervention.

- Sensation should be assessed using proprioception tests (e.g., through passive movement at index finger and big toe)¹⁸⁴ as well as light touch (e.g., Semmes-Weinstein monofilaments) and vibratory (e.g., biothesiometry; 128 Hz tuning fork at base of finger and thumb)¹⁸⁴ measures.
- Other dimensions of movement may be assessed. *Accuracy* should be assessed if signs of ataxia are observed, such as when the individual has the Miller-Fisher type of GBS. Rapid alternating movements of the hands or feet are common tasks that are timed for 10 repetitions, or counted for number of repetitions in a 10 second period. Ataxia can also be assessed using a standardized tool such as the Scale for the Assessment and Rating of Ataxia (SARA), which contains eight performance-based items rated on an ordinal scale, with higher numbers indicating more severe ataxia.²²⁰ The SARA has positive psychometric features when used in other neurological populations such as multiple sclerosis.²²¹ *Adaptability* may be observed as the ability to resume a task when a trajectory is perturbed; if the individual is ambulatory, the Functional Gait Assessment⁹⁹ standardizes assessment of adaptability. *Speed* of movement can be recorded by timing the completion of functional tasks.
- Functional tests (at the activity level of the ICF model) may include standardized scales of independence in ADLs or balance, tests of manual dexterity, and temporal measures of gait, although few standardized measures are specifically validated in GBS. Chehebar and colleagues²⁰¹ compared three standardized functional scales: the GBS disability scale, Barthel Index, and the FIM. The GBS disability scale is specific to this population and is widely used in research, but with scores only ranging from 0 to 6, it does not have the granularity to reflect small changes. The Barthel Index and FIM are able to document change in other neurological populations; while the Barthel Index is more economic and practical, neither is detailed enough to direct clinical decision making for individual patients.²⁰¹ The FIM has reflected improved independence in patients with GBS following inpatient rehabilitation²¹⁶: in 1079 older adult patients with GBS, the average improvement in mobility was 144%; in self-care it was 84.1%; and in cognition it was 51.7%. The FIM has shown sensitivity in detecting disability in people with GBS and improvement correlates with decreased requirement for mechanical ventilation.¹⁷⁶ Other functional tests recommended in GBS include the Canadian Occupational Performance Measure and the Modified Rankin Scale.¹⁷⁶ Balance tests may include the Function in Sitting Test (standardized for low-level patients post-stroke), the Berg Balance Scale¹⁷⁶ (for those able to stand upright), Tinetti Assessment Tools, or the more advanced Functional Gait Assessment⁹⁹ that uniquely documents adaptability while walking. Tests of manual dexterity could include the Box and Block Test of Manual Dexterity¹⁷⁶ and the 9-Hole-Peg Test. Measures of gait could include the 10 m or 25-foot walk test (25FWT), Timed-Up-and-Go (TUG), 6MWT, digital gait analysis,²²² or measures of stride length and cadence.
- *Dysarthria, dysphagia, and respiration* should be tested in the acute and progressive stages and thereafter if the individual had these impairments acutely. Review [Table 15.1](#) for items to consider; unlike ALS, patients with GBS rarely show spasticity and may have sensory loss in the face in addition to motor losses. A simple estimate of VC can be done at bedside. If, after taking a large breath, the patient can count out loud only to 10, the total VC is approximately 1 L and intubation may be considered.²²³ Some clinicians recommend cervical auscultation to listen to swallowing sounds during the acute phase of GBS, and listening

to breath sounds for indications of aspiration. With evidence of swallowing difficulties and possible aspiration, the patient should be referred for comprehensive testing with videofluoroscopy. Other referrals for bulbar evaluation may be considered to an ear, nose, and throat specialist, speech-language pathologist, or communication disorders clinic unless full evaluation is available in the facility or at a comprehensive neurology clinic.

- Quality-of-life measures (at the participation level of the ICF model) have not been generated that are specific to people with GBS. Health-related quality-of-life measures used in related populations (neuromuscular diseases) include the Nottingham Health Profile and the SF-36, which have the advantage of including a fatigue component labeled as “energy” and “vitality,” respectively.⁹⁶ Recommended measures may also include the Sickness Impact Profile,²²⁴ Rotterdam 9-item scale (regarding disadvantages during specific tasks), and the Handicap Assessment Scale.¹⁷⁶ A new measure has been developed for inflammatory neuropathies, the IN-QoL,²²⁵ that was shown to be responsive to change in GBS. It may be useful in future trials. Assessment of environmental factors might include the Environmental Status Scale, which assesses restriction in participation.¹⁷⁶

Forsberg and colleagues²²⁶ provide a comprehensive list of tests they administered in a prospective study of 42 patients followed for 2 years after the onset of GBS. At 2 weeks post onset, 40 of 42 patients had submaximal scores on total muscle strength, grip strength, balance, and gait speed testing. At 2 months, total muscle strength was still most affected, whereas 25% of the patients had regained maximal grip strength, balance, and gait speed (designated as 1.4 to 1.5 m/s). By 2 years, more than half of the subjects still lacked the maximum total muscle score, and 40% claimed fatigue. Sensory deficits were claimed by up to 36% of patients at 2 years.²²⁶ Thus tests of strength, balance, gait speed, fatigue, and perception of sensory deficits remain relevant 2 years post diagnosis of GBS.

Changes in the patient’s condition should be monitored with serial MMT, ROM assessments, sensory testing, and functional status examinations. Before the patient is discharged from the hospital or rehabilitation unit, therapists should complete an assessment of the patient’s home environment so that appropriate safety and adaptive equipment can be in place in time for the patient’s return home.

Intervention Goals

General goals for the care of the patient with GBS, to be specified with reference to the patient’s status and preferences, include the following:

- Facilitate resolution of respiratory problems, communication difficulties, and dysphagia.
- Minimize pain and desensitize dysesthesias.
- Prevent contractures, decubitus ulcers, and injury to weakened or denervated muscles.
- Optimize strength and endurance through judiciously progressive resistance and aerobic exercise while monitoring overuse and fatigue.
- Prescribe and update as necessary appropriate adaptive equipment, wheelchairs, and orthoses to optimize function.
- Resume psychosocial roles at optimal level and improve quality of life.

Therapeutic Interventions

In a Cochrane review focused on people with peripheral neuropathies, no randomized or quasi-RCTs of exercise or rehabilitation were identified for patients with GBS as of September 2009.¹⁷¹ Since then, one RCT has been conducted.¹⁹⁰ In addition several intervention studies have been reported that do not have randomization and may only compare to healthy controls (Table 15.3). Many of the therapeutic recommendations therefore come from consensus of experts based on clinical experience with GBS and disorders that result in similar impairments and activity limitations.

TABLE 15.3 Summary of Exercise Studies Since the Year 2000 in Guillain-Barré Syndrome

Author	Study Population (Sample Size): Research Design	Duration of Training	Training Modality	Training Protocol	Response(s)
El Mhandi et al., 2007 ²²⁷	GBS first week of recovery stage (6); Pragmatic cohort study; healthy controls (6)	3–4 weeks inpatient, 4–10 weeks outpatient and home exercise program	Individualized inpatient and outpatient rehabilitation: muscular reinforcement and active mobilizations	Outpatient consisted of 2–3 physical therapy sessions per week	Outcomes assessed at 6, 12, and 18 months after recovery began: increase in MVIC and isokinetic strength noted at all time periods in knee, elbow, shoulder, and ankle muscles
Graham et al., 2007 ²²⁸	GBS >1 year after nadir (10), CIDP stable for 6 months, (4); healthy controls (8): case-control intervention study	12 weeks	10 min warm up at below 60% of peak heart rate, 20 min of aerobic ex at 65%–85% of peak heart rate, isometric strengthening exercises sustained 10-s maximal isometric contractions, functional activity practice, major muscle group stretches	3 times a week for 36 sessions, unsupervised, community-based strengthening, aerobic, functional exercise program	Improvements at end of program were retained at 6-month follow-up: Overall Disability Sum Score improvement, physical function score of SF-36, Fatigue Severity Score, Anxiety, Depression; both patients and healthy controls showed moderate increases at end of program in isometric muscle strength of trained muscles, able to exercise at peak load for longer duration

TABLE 15.3 Summary of Exercise Studies Since the Year 2000 in Guillain-Barré Syndrome—cont'd

Author	Study Population (Sample Size): Research Design	Duration of Training	Training Modality	Training Protocol	Response(s)
Garssen et al., 2004 ¹⁸² ; Bussman et al., 2007 ²²⁹	GBS with fatigue, stable for 3 months (16); CIDP with fatigue, stable (4); healthy controls (10): case control intervention study	12 weeks	Bicycle exercise training for patients but not controls	3 times per week, supervised; 5 min of warm up (65% of maximum heart rate) and 30 min of cycling (70%–90% max heart rate); 5–10 min of cool down	20% fatigue severity reduction, improvement in fatigue impact, anxiety, depression, physical component of SF-36, isokinetic muscle strength elbow and knee
Khan et al., 2011 ¹⁹⁰	GBS, chronic phase (79): RCT, individuals assigned to high intensity or lower intensity treatment groups	Up to 12 weeks	Experimental group: multidisciplinary training, three 1-h sessions consisting of half-hour blocks of PT, OT, psych, speech, social; control: home based program of maintenance ex and education for self management plus 30 min activity (walking, stretching)	Experimental group: 2–3 times per week for 12 weeks; control: 2 times a week	Assessment at 12 months: Treatment group had significantly higher scores on FIM (mobility, self-care, continence) and relationships than controls

CIDP, Chronic inflammatory demyelinating polyradiculoneuropathy; *ex*, exercise; *FIM*, Functional Independence Measure; *GBS*, Guillain-Barré syndrome; *max*, maximum; *MVIC*, maximal voluntary isometric contract; *OT*, Occupational Therapist; *PT*, physical therapist; *RCT*, randomized controlled trial; *ROM*, range of motion.

Respiratory dysfunction, communication difficulties, dysphagia.

Depending on the facility, PTs may be involved in the respiratory care of patients with GBS. PTs may conduct chest percussion, breathing exercises, resistive inspiratory training, or strict protocols to prevent overfatigue of respiratory muscles while weaning patients from mechanical ventilation.¹⁷⁶ A therapist working in a clinic or small community hospital may be the first person to note a patient's changing respiratory status during an evaluation and treatment session for muscle weakness or acute back pain. That therapist must be prepared to alert medical staff about the need to test oxygen saturation levels and VC. Likewise, if the patient has mild symptoms at admission, the patient may not seem to require intensive care. If the patient is not continuously monitored for autonomic function, the therapist should be on the lookout for rapid onset or life-endangering symptoms requiring emergent intervention.²³⁰

Goals of treatment for respiratory impairment are related to increasing ventilation or oxygenation, decreasing oxygen consumption, controlling secretions, and improving exercise tolerance. See Irwin and Tecklin²²³ for coverage of treatment programs and techniques appropriate for the GBS patient with acute or residual respiratory dysfunction.

When patients have endotracheal intubation, communication can be difficult and frustrating, especially if general paralysis also hinders writing or pointing to a communication board. The rehabilitation team can help develop and execute alternative means of communication. If phonation is effortful, supported posture in an upright and aligned position may help coordinate breathing and speech. Readers are also referred to [Box 15.6](#) for recommended strategies to manage dysarthria and effortful speaking.

In the more severe cases of GBS, cranial nerve involvement can lead to dysphagia and vocal cord paralysis. Therapeutic goals are the prevention of choking and aspiration and the stimulation of effective swallowing, eating, and oral speech.

In many facilities, speech pathologists, or OTs are responsible for establishing a dysphagia treatment program. However, all health care personnel may need to participate in preventing aspiration, by helping patients maintain an upright position for 30 to 60 minutes after feeding through a tube or promoting effective swallowing and eating with upright positioning and head tilted slightly forward. The act of chewing and swallowing is complex and requires coordinated reflexive and conscious action. Intervention is focused on positioning, head control, and oral-motor coordination (e.g., sucking an ice cube, stimulating the gag response, facilitating swallowing with quick pressure on the neck and thyroid notch timed with intent to swallow). A conscious swallowing technique is introduced with thick liquids and progressed to thinner liquids after the patient's oral-motor coordination response is enough to control movement of fluids. Once the patient has good lip closure, fluids should be introduced one sip at a time from a straw cut to a short length to minimize effort. Semisoft, moist foods are gradually introduced (pasta, mashed potatoes, squash, gelatin). Any crumbly or stringy foods (coffee cakes, cookies, snack chips, celery, and cheeses) should be avoided, and the patient should not attempt to talk or be interrupted during eating until choking episodes no longer occur and swallowing is comfortable and consistent. Feeding training should occur during frequent, short sessions to prevent fatigue. Therapists should be prepared to use the Heimlich maneuver if choking occurs or have a suction machine available at bedside. Readers are referred to the section on medical management of ALS for additional suggestions on dysphagia management.

Pain. Pain may be a major factor limiting the patient's passive or active motion, and the treatment team should determine the best approach to alleviate pain. Medical management alone may not reduce pain to 0, and many studies examine the effects of pharmacological agents only in the acute and active rehabilitation stage. No studies have examined interventions for pain in the later recovery stage (3 months and following). A combination of positioning and

passive to active movement may be helpful, but no controlled trials have provided evidence to support nonpharmacological treatments for pain in GBS.

Sensory treatments may be of benefit to reduce the experience of pain. Transcutaneous electrical nerve stimulation (TENS) might be an adjuvant treatment option to help with desensitization in patients whose pain is not controlled with passive movement or pain medications.¹⁷⁶ Another option is capsaicin,²³¹ the active ingredient in chili peppers, which when applied topically interacts with the sensory neurons to relieve pain from peripheral neuropathies. Therapists, wearing gloves, may apply a topical anesthetic until the area is numb. The capsaicin is then applied topically. The capsaicin remains on the skin until the patient starts to feel the heat, at which point it is promptly removed using soap and water. Because the nerves are overstimulated by the burning sensation, the sensory gateway is unable to report pain for an extended period.²³¹ A high-concentration capsaicin patch has been studied with good results in people with peripheral neuropathies with other etiologies, but not in GBS.²³²

Some patients who experience extreme sensitivity to light touch, such as from movement of sheets, air flow, and intermittent touch contact, benefit from a “cradle” that holds sheets away from the body. Some find relief if the limbs are wrapped snugly with elastic bandages, which provide continuous low pressure while warding off light and intermittent stimuli. Alternatively, the patient’s pain response can be desensitized through methodical stimulation with frequent, consistent stimuli to the affected area for short durations to allow acclimatization.¹⁷⁶

A randomized pilot study of yoga using meditation, relaxation, and breathing techniques 5 days a week for 3 weeks resulted in improved self-reported sleep in patients with GBS, but no difference in pain, anxiety, depression, or functional scales compared with a group that had the same inpatient rehabilitation without the yoga.²³³ In fact, both groups had significant reduction in average pain on a numeric pain rating scale. Thus it may be that usual multidisciplinary rehabilitation itself is partly responsible. The authors reported that both groups received pharmacotherapy, physiotherapy (ROM, stretching, strengthening with weights, breathing exercises, and gait training), and occupational therapy (ADL training, hand function training, trunk stability training, and education about transfer techniques).²³³

Contractures, decubitus ulcers, and injury to weakened or denervated muscles

Positioning. A consensus statement arising from a review of the literature plus expert opinion for a group of scientists and clinicians specializing in GBS recommended that rehabilitation should focus on proper limb positioning, posture, orthotics, and nutrition.¹⁷⁹ Positioning and passive ROM to prevent contractures and decubitus ulcers is particularly important in the acute stage.²³⁴

Positioning to prevent pressure sores starts within the first few days of hospitalization, especially for the patient who has complete or nearly complete paralysis along with loss of sensation. A positioning program for the dependent patient is the first line of defense against decubitus ulcers and pulmonary infection, with turning at least every 2 hours for both pressure relief and lung drainage. The rehabilitation team may assist nursing personnel in determining positions that do not excessively stress vulnerable (flaccid) joints and create pictures to place by the bed to assist persons on each shift to follow the prescribed schedule and positions. In addition, the patient may have a special mattress or mattress unit that constantly changes the pressure within the mattress to shift the patient’s position or is designed to spread pressure over wide surfaces. Patients who are slender or who have lost

significant muscle mass from GBS-induced atrophy will have prominent bony surfaces; the therapist may need to fashion foam “doughnuts” or pads or use sheepskin-type protection for pressure relief. Nerves are especially vulnerable to pressure in this state; the ulnar, peroneal, and cutaneous femoral nerves should all be protected with padding and positioning to avoid compression.¹⁷⁶ Patients who have muscle pain may prefer to have their hips and knees flexed. If so, the patient must be taken out of the flexed position for part of each hour to avoid muscle shortening.

As part of a complete positioning program, therapists should consider how best to maintain the physiological position of the hands and feet. Research has shown that mild continuous stretch maintained for at least 20 minutes is more beneficial than stronger, brief stretching exercises. Thus the use of splints for prolonged positioning is superior to the use of short bursts of intermittent, manually applied passive stretching to attain functional range. Although some facilities still use a footboard to control passive ankle plantarflexion, most therapists now use moldable plastic splints that can be worn when the patient is in any position. Because ankle-foot splints often prevent visual inspection of the heel position, care must be taken to ensure that the heel is firmly down in the orthosis and that the strapping pattern is adequate to secure the foot. The strap system must be simple enough to be positioned properly by all staff and family members caring for the patient. The ankle-foot splint should extend slightly beyond the end of the toes to prevent toe flexion and skin breakdown from the toes rubbing on sheets. Care should be taken not to compress the peroneal nerve with the splint as it crosses the fibula, a particularly vulnerable area after the loss of muscle mass in the lower legs from the GBS. Wrist and hand splints may be prefabricated, resting-style splints, or molded to meet the patient’s specific needs. Because spasticity is not typically a problem in the patient with GBS, a simple cone or rolled cloth may be adequate to maintain good wrist, thumb, and finger alignment for short-term immobility.

Range of motion. With paralysis in GBS comes the risk of muscle shortening and joint contractures.¹⁷⁹ ROM is the best defense against such impairments. To be effective, the ROM program must start within the first couple of days of hospitalization and include both accessory and physiological motions to increase circulation; provide lubrication of the joints; and maintain extensibility of capsular, muscle, and tendon tissue. Special attention should be paid to 2-joint muscles (hamstrings and gastrocnemius), which are at greater risk for shortening.¹⁷⁶ Passive ROM exercises to the ends of normal range for all extremity joints, fingers and toes, neck, and trunk should be performed twice daily—more frequently if the patient has no active movement. Patients can be instructed to perform the ROM exercises themselves if they can move actively without pain or fatigue; during the acute stage of declining strength, they should be observed during ROM activities to ensure adequacy of the range and any changes in quality of movement. If the patient cannot complete movement through full range independently, a therapist or well-instructed and monitored caregiver can assist the patient in moving to the end of range. This may not be easy if the patient has pain with touch or motion. Knowing whether to “push through the pain” or stay within the limits of pain is often a great dilemma for the therapist. The therapist needs to find a balance between working for full joint range and reacting to the patient’s reports of pain. If the ends of ranges become stiff, stretch should be slow and sustained at the endpoint for 10 to 30 seconds. Orthotic devices might assist in maintaining prolonged stretch at the end ranges of some joints.

Some patients will prefer to position their limbs so muscle and tendons are in the shortened range in an attempt to decrease muscle pain. This may lead to capsular contractures. The therapist should note

changes in “end feel” over time when testing ROM of each joint to determine if capsular and ligamentous structures are also becoming more restricted as the muscle and tendon tissue shortens. Patients who have intact sensation of pain and temperature may respond positively to the use of heat (up to approximately 45°C or 113°F) before stretching to decrease muscle pain and facilitate tissue elongation before stretching. For safety reasons, heat should not be used on a patient with a sensory deficit that inhibits ability to distinguish differences in temperature.

Injury prevention. Denervated and weakened muscles can be injured easily; the therapist is responsible for ensuring that ROM activities are done with appropriate support of the limb to prevent sudden overstretching and possible damage of joint structures. Instruction to caregivers regarding passive ROM activities must include details such as externally rotating the shoulder during abduction to prevent impingement and ensuring that the subtalar joint is in the neutral position during dorsiflexion to avoid overstretching of the midfoot. In inpatient settings where the patient is treated by a changing staff of therapists or nurses or by family members, a positioning schedule with diagrams, a splinting plan, and ROM recommendations should be presented in poster format at the patient’s bedside to facilitate consistent treatment.

ROM can usually be maintained with standard positioning and ROM programs. Nevertheless, some patients, especially those who have severe extremity and axial pain early during the disease process and those who have been quadriplegic and ventilator dependent for prolonged periods, may develop significant joint contractures despite preventive interventions. As with patients with spinal cord or severe head injuries, heterotopic ossification can occur with immobility-related hypercalcemia.¹⁷⁹ Early mobilization was associated with therapeutic decreases in serum calcium levels in one study.¹⁷⁹ Aggressive ROM (but not hard or abrupt movements that may injure the muscle) may impede the effects of heterotopic bone overgrowth that can have a severe impact on ROM. Once heterotopic ossification has been identified, treatment includes modification of ROM exercise to use only the pain-free arc for active and passive motion.¹⁷⁶

Massage may play a positive role in maintaining muscle tissue mobility and tissue nutrition while limiting the amount of intramuscular fibrosis development. The use of massage in patients with GBS has not been reported; however, it may be a useful adjunct to ROM exercises in patients who do not have marked hypersensitivity to touch, significant muscle pain, or a history of DVT. Patients with or without a history of DVT who are immobile for long periods or who have concomitant cardiac illnesses may have marked pooling of fluids with swelling of the distal limbs and orthostatic hypotension.¹⁷⁹ After medical clearance, edema-specific massage and limb-elevation techniques may be useful if tolerated by the patient. Early active ROM exercises creating “muscle pumping” contractions in muscles with at least fair strength (3/5 MMT) can help prevent uncomfortable edema.

Optimizing Strength and Endurance While Monitoring for Overuse and Fatigue

Although most patients with GBS recover from the paralysis, the course and rate of recovery may vary significantly among patients. With such a variable natural course, it is difficult to tell whether any particular exercise program has a positive effect unless compared against a control group. However, few controlled studies have been conducted to examine exercise in GBS. No controlled evidence exists to indicate that active exercise can change the rate of progression of the disease or regrowth of myelin or axons, although it may improve function through increased strength and aerobic capacity once muscles are reinnervated (see Table 15.3). Despite the lack of evidence, consensus recommendations¹⁹⁷ and “usual care” as described for the control

groups for GBS medical intervention trials support rehabilitation. In addition, several case reports have described improvements with various rehabilitation programs.^{235–237} Individualized programs have been advocated consisting of gentle strengthening, isometric, isotonic, isokinetic, manual resistive, and progressive resistive exercises.¹⁷⁹ The major goal of exercise and physical activity throughout the course of GBS must be to maintain the patient’s musculoskeletal system in an optimal ready state, prevent overwork, enhance circulation and cardiorespiratory endurance within the limits of active movement, and pace the recovery process to obtain maximal function as reinnervation occurs. Once reinnervation occurs (generally after a muscle exceeds 3/5 on a MMT), progressive resistance exercises at moderate intensities (50% to 70% of 1 repetition maximum [1RM]), use of the overload principle, and progressive challenge can be built in to the rehabilitation program as tolerated.

As was discussed in the section on therapeutic considerations for patients with ALS, a muscle that has significant denervation is more likely to respond to exercise with overwork fatigue. Strenuous exercise and fatigue during this early period have been associated with recurring episodes of a temporary loss of function. Thus the current opinion for patients with GBS is that excessive exercise during denervation and early reinnervation (when only a few functioning motor units are present) can lead to further damage rather than to the expected exercise-induced hypertrophy of muscle.

Exercise from onset through the plateau. When motor function is still deteriorating, and cardiovascular variables fluctuate with dysautonomia, resisted and aerobic exercise cannot be well monitored for their effects. Negative response (overwork damage) may be confused with progression of the disease. Thus, exercise in the acute and progressive stages may be limited to ROM (of all joints, including back and neck) performed actively by the patient (with mild deficits) or with assistance by the therapist (for patients with moderate or severe deficits). As the disease reaches its nadir, activity remains limited. Once weakness stops progressing, passive maintenance of ROM remains important for all muscles and joints not moving actively.

Once the plateau is reached (no further deterioration noted for several days and medical issues stabilized), tentative progression can be tried. The therapist might start by asking for a voluntary contraction of a muscle or muscle group during breathing (e.g., diaphragm), positioning, or ROM, and increasing experience of upright positioning. During the plateau, patients can move with appropriate assistance as long as it is without pain or excessive fatigue.¹⁷⁶ Slings or adaptive devices may help support the weight of a limb to continue active movement in a gravity-eliminated plane for those muscles that have lost antigravity strength (<3/5 MMT).

Beginning of recovery. As strength begins to return after the plateau, therapists must prescribe limited repetitions of low-resistance activities, with strict avoidance of antigravity strain on the muscles until strength reaches the 3/5 (Fair) range of MMT. In the beginning of recovery, short periods of exercise should be frequent. As reinnervation occurs and denervated motor units become responsive, the early process of muscle reeducation may follow progressions used in recovery stages after poliomyelitis or in the technique called “rhythmic initiation” described in proprioceptive neuromuscular facilitation (PNF). Using this technique to encourage active contraction of the muscle the therapist should demonstrate the expected movement to the patient. The therapist then passively moves the patient’s limb while the patient observes. After gaining a clear picture of what movement is expected, the patient is encouraged to contract muscles, first “helping” with the movement, then taking over as able. Once the patient can move smoothly through the entire motion independently, the therapist may apply gradually stronger resistance; the therapist can determine when resistance

is too strong if the patient's movement becomes less smooth through the whole motion or stops on the way. If the sensory and pain status of the patient permits, facilitation techniques such as skin stroking, brushing, vibration, icing, tapping, and verbal and visual cueing may be used in conjunction with the muscle reeducation process. The patient is taught to reassess his or her movements and make corrective responses.

Functional activities should be appropriate for the muscle grade of the active muscle or muscle group. For example, if the patient's deltoid muscle has a poor (2/5) grade on MMT (full ROM with gravity eliminated), the patient should be cautioned not to attempt to elevate her or his arm against gravity (e.g., to shave or comb one's hair). Patients may exercise when the limb weight is supported (using overhead slings, powder boards, pool exercises) to allow the patient to move actively through a full range in the gravity-eliminated position until he or she can take slight resistance in that plane of movement. Children, teenagers, or adults with impaired judgment often need a strict schedule of rest and activity. Work simplification and energy conservation strategies may be useful to improve function in the beginning recovery stages of GBS.¹⁷⁶

Active repetitions can be added very slowly, with frequent rest periods and monitoring to avoid fatigue. Activity should be halted at the first point of fatigue or muscle ache; abnormal sensations (tingling, paresthesias) that persist for prolonged periods after exercise may also indicate that the exercise or activity level was excessive. Any progression of resistance or repetitions of strengthening exercises at the below 3/5 level should be instituted in one session, and the results monitored for 30 minutes (for fatigue that prevents daily activities) and for 3 to 5 days for overwork weakness, muscle spasms, or soreness; if adverse response is minimal, exercises may remain at that level until additional assessment reveals that exercises may be progressed further.¹⁷⁶ If additional weakness or soreness ensues, the additional activity should be regressed to a prior level for several days, with reinitiation at a lower level of resistance or number of repetitions, followed by a more gradual increase.

Patients and staff need to be reminded that prolonged sitting in bed or in a wheelchair, even when supported, may tax the axial musculature, including the neck. A program of gradual sitting should be instituted, with the final goal being independent, unsupported sitting with functional equilibrium reactions. In busy hospitals, a schedule of sitting, resting, and specific activity should be posted in clear view at the patient's bedside.

In the initial stages of *upright activity* after any period of bed rest, therapists must progress upright tolerance very carefully because 19% to 50% of people with GBS show orthostatic hypotension along with dysautonomia. A program to improve tolerance to upright position can be started in the ICU if the patient is on a type of standing bed. If a standing bed is not available, a sitting program can be initiated as soon as it is tolerated. A progressive standing program can be instituted when the patient's respiratory system and ANS are no longer unstable and the patient can be moved to a tilt table or standing frame. Caution should be taken to stabilize the patient's limbs fully to maintain alignment and to limit activity in muscles that have strength below the fair range (3/5 MMT). When beginning training, some patients benefit from using an abdominal binder or foot-to-thigh compression stockings (if tolerated without provoking dysesthesia) to counter the pooling of fluids. Because of the relation between poor hydration and hypotension, therapists must ensure the patient is well hydrated before beginning upright or standing tolerance programs.¹⁷⁶

In patients with Miller-Fisher syndrome, *ataxia* may be a significant feature hindering movement as recovery begins. No specific rehabilitation literature has yet been published in this variant of GBS, but progressions for ataxia in multiple sclerosis or cerebellar disease²³⁸ may

be useful. Therapeutic management may address dysmetria of the limbs, trunk, or neck or stabilize the trunk during gait training. Providing augmented sensation through vibratory stimulation, the wearing of substantial limb weights or small torso weights may be effective in helping to stabilize the core for more controlled movement of distal musculature.²³⁸ Diplopia resulting from oculomotor deficits may be addressed with variable use of an eye patch, at first to minimize annoyance and balance disturbance, but also to practice eye movement in each eye separately before practicing convergent movements.

Activity progression during active recovery. As strength increases, additional resistance may be applied to muscles showing good recovery (4/5 MMT) while avoiding strain on muscles that have not yet reached the same level, frequently the most distal musculature. Functional tasks may be practiced specifically. For example, a patient may score full independence on a Barthel Index and have minimal disability remaining at 10 months post onset, but have pain on heel contact during gait that limits his activity. In a case report describing such a patient, part-practice of components of gait with closed chain and eccentric lower extremity exercise progressing to lunging, jumping, running, and practice of throwing from a wobble board were useful in improving gait performance and participation according to digital and subjective measures.²²² Even when strength has returned throughout, rehabilitation and exercise may need to continue to address fatigue that may persistently affect each of the ICF levels: body function and structure, activity, and participation.¹⁸⁰ For an outline of treatment progression for a patient with severe GBS during the acute stage from week 1 through week 12, see [Table 15.4](#).

As the patient gains strength, clinicians should direct isolated movements into functional activities to add salience and provide more normal distractions to encourage automaticity of function. For those patients who experience significant losses in proprioception after GBS, sensory reintegration activities and high repetitions of task practice may help redevelop motor engrams that are based on the altered sensory perception. Aerobic training may be instituted to improve physical fitness, functional outcome, and quality of life, and decrease fatigue.¹⁷⁶

As reinnervation progresses and strength and exercise tolerance increases, the therapist may choose to use facilitative exercise techniques. In a case report following 2 months of inpatient rehabilitation for a man with GBS, home physical therapy 3 days per week successfully promoted proximal muscle stability for function using neurodevelopmental sequencing; practiced activities progressed from supine and prone to function in quadruped and kneeling.²³⁷ PNF²³⁹ with manual resistance of prescribed patterns could also be useful to promote recruitment of maximal desired contraction in specific muscle groups. Although PNF techniques are excellent for eliciting maximal contraction, care must be taken not to overwork the weaker components of PNF movement patterns. A positive aspect of PNF techniques is that they can be tied in with functional patterns such as rolling, which is necessary for bed mobility; transitions to quadruped, kneeling, sitting, and standing; and gait.

As muscles regain antigravity strength, independent function becomes possible, although movement may still be slow and function may require assistive devices. Patients will likely progress from inpatient to home to outpatient services, with necessarily less frequent therapy sessions. More of their exercise and physical activity will need to be performed unsupervised, under their own initiative or in community programs or gyms. A successful "home" program is one in which the patient knows the purpose of each exercise and understands the reason for the level of intensity; the patient must value the activity's end goal and be able to perform each exercise effectively in their own environmental context. Standardized tools that engage the patient in

TABLE 15.4 Outline of First 12 Weeks for Patients With Moderate to Severe Guillain-Barré Syndrome: Medical Status and Treatment

Timing	Medical Status	Treatment ^a
Week 1	Intubation with endotracheal tube Ventilator dependent Complete cranial nerve paralysis Tetraplegia	Postural drainage every 3 h around the clock Passive ROM exercises to all joints; communication and nutrition programs instituted; other support as needed Splinting (molded plastic) of hands and feet to maintain functional position Positioning, splinting, and ROM program schedule posted at bedside
Weeks 2–5	At 2 weeks, transition to tracheostomy if pulmonary function no better than when intubated	Postural drainage decreased to two times each shift (every 8 h) Passive ROM exercises, physiological and accessory motions, gentle stretching of intercostal musculature, trunk rotations Continue splinting and positioning program; continue communication and nutrition programs, modifying as needed Family education: family members taught gentle physiological ROM techniques, with attention to correct shoulder patterns and simple massage techniques
Weeks 6–7	Ventilator set on intermittent ventilation Weaning to use ventilator only at night by end of week 7 No active muscle contractions except eye opening and lip movements Dysphagia	Postural drainage two times each shift (every 8 h) Continue ROM program, splinting, and positioning Begin to build tolerance of upright sitting with good trunk alignment Begin facilitation of active facial and tongue muscle activity in patterns necessary for swallowing, eating, and speaking; speech pathology, occupational therapy for oral training Family members active in care as they choose, helping with ROM, splinting, and positioning schedule
Weeks 8–12	Palpable muscle activity in neck, trunk, proximal musculature of upper and lower extremities	Postural drainage one time each shift Chest stretching, breathing exercises Dysphagia program in collaboration with speech consultant Muscle reeducation program with electromyographic biofeedback (if MMT 3/5 or better); gravity-eliminated exercises using suspension slings attached to bed Tilt-table standing program to increase tolerance to upright (wearing positioning splints if necessary) Collaborate with occupational therapist for treatment in wheelchair with suspension slings to facilitate active arm motion in gravity-limited position Exercise, rest, positioning schedule posted Family, patient educated about stimulating activity level to prevent fatigue, overuse of reinnervating muscles

^aTreatment depends on rate of recovery.
MMT, Manual muscle testing; ROM, range of motion.

goal setting may be useful: the MAM^{104,105} (or MAM-CAT,¹⁰⁶ validated in musculoskeletal and neuromuscular populations and recommended as a scale of patient-reported mobility),¹⁰⁷ Goal Attainment Scaling¹⁰⁸ (used in diverse populations, including neurological), Canadian Occupational Performance Measure¹⁰⁹ (known in the OT literature), or the Patient-Specific Functional¹¹⁰ Scale (used more in musculoskeletal populations). A tool such as the MAM-CAT may assist the patient and therapist to identify together the movement dimensions the patient prioritizes so that therapy and home exercises can emphasize what the patient values most (see Fig. 15.8).¹⁰⁶

In the months (and years) that follow inpatient rehabilitation, the course of therapy may be intermittent as long as any GBS-related deficits continue, with episodes of care interspersed with periods of independent activity progression. Episodes of care might include examining current status, updating exercise prescription, reviewing use of orthotic and assistive devices, suggesting strategies for optimizing function, supervising any new exercises or activities to ensure competence, and encouraging the patient or client in maintaining health and fitness. The main goal of each episode of care will depend on the patient's own preferences for activity and participation, with consideration of age-appropriate norms, any comorbidities, and the pre-GBS level of function.

Documenting relapses. Throughout the recovery period, therapists should carefully document any serial negative changes or plateaus in motor, sensory, or respiratory impairments or functional status that may herald a relapse. Documentation is critical so that new personnel in each new setting do not miss a change that has been ongoing prior to transfer or discharge. Although 65% to 75% or more of patients with GBS show a return to clinically normal motor function, 2% to 5% of patients have a recurrence of symptoms similar in onset and pattern to the original illness. Recurrence of symptoms should trigger immediate reassessment of physical status, potential medical referral, and monitoring for worsening cardiorespiratory signs.

Addressing residual deficits in later stages of recovery. The possibility of lingering endurance deficits should be considered as patients and therapists address long-term plans. Patients may appear to have reached full recovery of strength but still report fatigue that limits return to work or activities that require sustained maximal effort.²⁴⁰

Determining the source of fatigue in a late stage of GBS may be complicated by differences in measures of experienced fatigue (subjectively reported) versus physiological fatigue (central or peripheral reduction in voluntary muscle force production) and the weak relationship between these in many neuromuscular disorders.²⁴¹ In

addition, cardiovascular fitness may continue to be compromised after recovery from GBS weakness. Fitness compromise may be caused by altered muscle function, but may also be related to cardiovascular deconditioning from an imposed sedentary lifestyle.¹⁹² Several researchers have discussed the effect of endurance exercise training in the later recovery stage of GBS. Fehlings and colleagues²⁴² tested muscle strength and endurance in a group of children at least 2 years after acute onset of GBS. Although the children appeared essentially recovered, endurance of the arm muscles was lower than that of the lower extremities. They hypothesized that the typical walking, running, and cycling activities that the children participated in were sufficient to improve strength and endurance of lower-extremity muscles, but that upper extremities were not challenged to the same degree. The authors recommended that children be encouraged to participate in activities such as swimming to improve upper-extremity endurance. Controlled tetherball and volleyball activities are also appropriate to engage upper-extremity endurance.²⁴² Tuckey and Greenwood²³⁶ reported positive results of aerobic treatment with partial body-weight support (PBWS) treadmill exercise for a patient with severe GBS. Garssen and colleagues²⁴³ reported a 20% reduction in fatigue levels, along with improved physical condition and strength, after a 12-week intensive bicycling exercise program for patients several years after the onset of GBS. On the other hand, Bussman and colleagues²²⁹ showed that the change in physical fitness (as assessed using measures of oxygen uptake and peak power output) with a 12-week exercise program was only weakly associated with changes in activity (recorded with an activity monitor) or perceived physical functioning (coefficients <.30). Associations with perceived mental function, however, were much stronger (coefficients of change scores were .54 to .57). Thus exercise programs may have a significant effect on psychological variables along with physical measures; clinicians and patients should be sure to document these outcomes of a course of exercise. Tools used in the Bussman and colleagues²²⁹ study included self-report questionnaires such as the cognitive portion of the FIS and the Hospital Anxiety and Depression Scale.

Improvements in strength and endurance after GBS may continue for months to years. A prospective study following six patients for 18 months after onset of GBS recorded continuing improvement of muscle strength on average throughout the assessment period, and yet the average strength of major muscle groups had not yet reached that of healthy controls.²²⁷ Although the traditional thought has been that little clinical improvement occurs after 2 to 3 years, Bernsen and colleagues²⁴⁴ found that 21% of the patients in a study of 150 patients after recovery from acute GBS reported improvement after 2.5 to 6.5 years, although the authors thought the perception of improvement was related to improved sensory function. Of interest for future research and clinical decision making are the long-term consequences of GBS and how the normal aging process will affect patients who have some mild residual effects—for example, whether some patients will develop increasing weakness over time similar to persons with postpolio syndrome.

Adaptive Equipment and Orthoses

Judicious use of orthotic devices and adaptive equipment should be considered an integral part of the rehabilitation process. The purpose of the orthotic and adaptive devices is twofold: (1) to protect weakened structures from overstretch and overuse and (2) to facilitate ADLs within the limits of the patient's current ability. The purpose of adaptive equipment and orthotics is similar in ALS; thus articles that have discussed these devices could be helpful in GBS as well.^{89,142} Orthotic devices and adaptive equipment should be introduced and

discontinued on the basis of serial evaluations of strength, ROM, and functional needs. For example, a hospitalized patient who has poor (2/5) middle deltoid strength may practice upper-extremity activities such as eating while using suspension slings. A thumb position splint may be used temporarily to aid thumb control in grasping tasks.

Most patients will need a wheelchair for several months until strength and endurance improve. As strength returns, patients recovering from severe paralysis may need to change from use of a wheelchair with a high, reclining back with a headrest to use of a lightweight, easily maneuverable chair. A quandary for the therapist is to predict how long a wheelchair will be necessary and whether it should be rented or purchased as the patient progresses through different stages of recovery. While moving from wheelchair mobility to independent ambulation, patients will usually progress from parallel bars to a walker with a seat to allow frequent resting, and then to crutches or a cane. Because wheelchairs, walkers, crutches, and canes, especially custom appliances, are expensive and not always covered by insurance, the therapist should carefully consider the cost and benefit to the patient during the recovery process.

Although most patients with GBS are able to walk within 8 months of onset, many show a prolonged residual weakness of calf and, most commonly, anterior compartment musculature, requiring the use of an AFO. The decision whether to use a prefabricated orthosis or custom appliance is not always simple. Several temporary orthotic measures can be considered. For example, if the patient shows good gastrocnemius-soleus strength with mild weakness of the dorsiflexors, a simple elastic strap attached to the shoelaces and a calf band may be sufficient to prevent overuse of the anterior compartment muscles. An old-fashioned, relatively inexpensive spring wire brace, which can be attached to the patient's shoes to facilitate dorsiflexion, is a good choice for patients who report skin hypersensitivity when wearing a plastic orthosis.

Most therapy units today have access to varied sizes of plastic, fixed-ankle AFOs that can be used until a decision is made to have the patient fitted with custom AFOs. A system of prefabricated AFOs with adjustable ankle motion joints has been developed that allows the therapist to limit plantarflexion and dorsiflexion to the specific needs of the patient. For patients with reasonable control of plantarflexion and dorsiflexion but with lateral instability because of peroneal weakness, a simple ankle stirrup device such as the AirCast Air-Stirrup Ankle Brace (AirCast, Summit, NJ) can be used temporarily to provide lateral ankle stability. Although few patients with GBS need knee-ankle-foot orthoses (KAFOs) on a long-term basis, inexpensive air splints or adjustable long-leg metal splints to control knee position are sometimes helpful when working on weight bearing in the standing position and during initial gait training.

Psychosocial Roles and Quality of Life

Patients with GBS have a significantly reduced health-related quality of life compared with control subjects at approximately 1 year after onset, associated with decreased functional scores and changes in work status.²¹⁷ Although physical training may improve functional scores and work capabilities, Bussmann and colleagues²²⁹ found little correlation between physical fitness and actual mobility. They hypothesized that training can result in physical changes but also influence psychological components, such as positive mood and self-confidence, more closely linked to quality of life.

Psychosocial Issues

Although most patients with GBS have a good recovery over a period of 2 or more years, the acute stage of the disease can be frightening, especially to patients who progress to complete paralysis and

respiratory failure. Nancy, in Case Study 15.2, reported that she was terrified during the time she was totally paralyzed (including eyelid movement) and on a respirator. She said that nurses, doctors, and hospital staff seemed to assume she could not hear because she was unable to respond in any manner. In her words:

They acted like I was already dead, and I thought I would be from the way they were talking. The thing I hated the most was when the night nurses from the registry would come in and ask how to

make the ventilator work! I felt panicked. Can you imagine having your life depend on a machine and knowing that the person who was supposed to make it work had no idea what to do if a tube came unconnected? They were always worried about my blood pressure. Who wouldn't have high blood pressure in that situation! The thing I liked about my therapists was that they told me what they were going to do even when I couldn't respond. They didn't just start doing things or pulling on me like other people did.

CASE STUDY 15.2 NANCY

Onset, Acute Stage

Nancy, a 16-year-old girl with a history of repeated hospitalizations for asthma, was admitted to the hospital with tingling in the hands and feet and mild respiratory distress. Because staff thought her asthma attacks had a significant emotional component, her repeated complaints of paresthesias, muscle pain, and weakness were largely ignored or attributed to anxiety attacks. The day after admission, Nancy began staggering while walking and became extremely agitated and hysterical, screaming that she was dying and could not breathe. A medical assessment showed evidence of wheezing with a normal chest radiograph and decreased VC. She was uncooperative during strength testing, although strength was estimated to be within normal limits except for approximately Fair (3/5) strength of the dorsiflexors and everters and Good (4/5) strength of the plantar flexors. She became extremely upset when her feet were touched.

Because of her psychological history, she was referred for psychiatric assessment and was placed on an anxiolytic medication. Two hours later she had a full respiratory arrest and was intubated and maintained on mechanical ventilation. Over the next 3 days she developed flaccid tetraplegia, and within 5 days she had complete cranial nerve involvement. During the acute stage, she was catheterized because of urinary retention and was treated for a bowel obstruction.

Nancy's physical therapy treatment began in the ICU. Formal strength testing was inappropriate. She received passive ROM twice daily from physical therapy; passive ROM was full but felt stiff at ends of ranges in the wrist, fingers, and ankles. The goals were to assist in respiratory care, prevent joint contractures, and prevent stasis ulcers during the period of immobility. Although her postural drainage treatment was performed using respiratory therapy techniques in conjunction with aerosol medication by intermittent positive-pressure ventilation (IPPV), PTs began a course of chest stretching techniques in coordination with a fastidious ROM program performed twice a day by a therapist and on the evening and night shifts by a nurse. A pressure relief mattress was ordered for her bed. The nursing staff changed her position every 2 h despite the pressure relief mattress that altered pressure under her as she lay supine or partially turned to the left or right. To prevent contracture development, an OT fabricated bilateral wrist and finger splints; a PT molded ankle splints to maintain 90 degrees of dorsiflexion with neutral eversion-inversion. A positioning and ROM schedule in poster form with pictures of positions and ROM patterns was posted at Nancy's bedside.

Because Nancy reported severe hypersensitivity to light touch or to any passive movement of her limbs, a cradle was placed on the bed to prevent sheets from touching her and to prevent air flow changes from irritating her skin. She was fitted for above-knee light pressure stockings, which seemed to decrease her sensitivity to light touch.

Progression, Plateau, and Beginning of Recovery

Deterioration of motor ability slowed and then plateaued with full tetraplegia, dependence, and cranial nerve involvement at approximately 10 days after

onset. Within another week, Nancy started a gradual return of respiration, but weaning from the ventilator was complicated by infections. She was successfully weaned at 29 days, after several episodes of pneumonia. After extubation, she still had swallowing and speech problems.

Because weaning from the ventilator was difficult, the PT played more of a role in education and breathing instruction than was typical (the respiratory therapists collaborated so that the PT could do the instructing during twice daily ROM activities). The PT instructed Nancy, the staff, and her family in appropriate breathing exercises to be performed every 1 or 2 h. Because her parents wanted to be involved with her care, they were taught ROM techniques with special attention to correct shoulder ROM techniques. The PTs continued to follow Nancy twice a day to ensure that accessory motions were completed with physiological motions. Moist hot packs were used effectively before ROM exercises for 1 week to minimize severe muscle pain.

As part of her positioning program, Nancy was placed in a supported semi-sitting position while intubated. As muscle control returned, a muscle reeducation program was initiated that focused initially on the head and trunk and then on the upper and lower extremities. Exercise periods were limited to 15 min twice a day. She would have benefited from more frequent short sessions; however, this was not possible. Her parents were shown how to guide her active exercise program cautiously so that she was able to exercise more frequently at low repetitions. When each muscle group reached an MMT grade of Fair (3) or greater, Nancy was allowed to use the muscles in functional activities with specified limitations in activity duration. When she was able to tolerate upright sitting and had some bed mobility, Nancy was transferred to a Nelson bed in which she could begin a gradual standing weight-bearing program.

A speech therapist worked with Nancy in the ICU to help her relearn safe swallowing patterns and to reintroduce her to different-textured foods. A dietician had been working with Nancy throughout her hospitalization to ensure adequate nutrition while intubated, and she worked closely with the speech therapist to progress Nancy's diet as she became able to handle liquids and solids.

After being weaned from the ventilator and transferred to the general floor, Nancy was brought to the physical therapy department for treatment, which was frequently done in conjunction with occupational therapy. As strength increased, she began a program of resisted exercise. Trunk and upper- and lower-extremity PNF patterns were used as the primary exercise technique; however, great caution was used to avoid overworking weak muscle groups evoked during use of the PNF pattern. A full mat program with rolling and coming to sitting was also instituted. OTs focused on graduated use of Nancy's upper extremities, first using overhead slings attached to a wheelchair and later using a lap board to support her weakened shoulder musculature while practicing hand activities.

Nancy remained in inpatient rehabilitation for a further week after extubation. Upon discharge at 36 days after onset, swallowing and speech problems

Continued

CASE STUDY 15.2 NANCY—cont'd

were resolved. Sensation was normal for perception of temperature changes and deep pressure. Proprioception was diminished at the ankle, knee, and fingers. Paresthesias and hypoesthesias, aggravated by light touch, were present in a glove-like pattern in both hands and a stocking pattern in both feet, although much improved compared to the acute stage. At discharge, both the PT and OT made a home visit with the hospital social worker and parents to determine what home adaptations and support services would be necessary. Nancy was provided with an ultralight rental wheelchair through her insurance for use until a final determination was made for long-term need. Nancy was also fitted with prefabricated adjustable AFOs, which were purchased through the physical therapy department. At 3–6 months post onset, a determination would be made about expected recovery of her persistently weakened dorsiflexors. If Nancy appeared to need AFOs for a prolonged period, a set of custom molded AFOs would be ordered.

Home Work

After less than 2 months of hospitalization, Nancy was discharged home to return for daily outpatient rehabilitation.

Follow-up of Nancy's outpatient therapy showed that she continued to make gradual recovery over the next 1.5 years. She returned to school 3 months after rehabilitation discharge (about 5 months post onset) using a wheelchair. She graduated to a walker, then to forearm crutches, and finally to independent ambulation. She refused to be seen using a walker at school, so she continued to use the wheelchair at school until she was independent on crutches.

Nancy continued to wear bilateral AFOs but was weaned from full-time use approximately 14 months after discharge (16 months post onset). During the weaning process, Nancy wore her AFOs at school while walking and for any walking distance over four city blocks or if she heard her feet begin to slap from fatigued dorsiflexors. By 16 months, Nancy showed no evidence of overuse weakness after her regular activities, although she had difficulty with endurance activities in her physical education classes. When hiking, she carried her AFOs to use when she expected a long downhill trek to prevent overwork from eccentric muscle activity. By age 19 years—3 years post onset—Nancy had returned fully to her normal activity level.

Psychosocial issues, continued. Skirrow and colleagues²⁴⁵ remind clinicians that the “intensive care patient is plunged into a world of machines that flash and beep; of tubes and wires that seem to spring from almost every orifice; and of mind-numbing sedative and analgesic medications.” Evidence is increasing that patients treated in acute trauma rooms or ICUs can have posttraumatic stress disorder (PTSD). Particularly vulnerable are patients who have had previous traumatic experiences. PTSD places patients at marked risk for increased startle responses, extreme vigilance or anticipation of painful events, sleep disorders, terrifying dreams, and dissociative flashbacks after leaving the ICU; sometimes these symptoms may be left untreated for years after the experience.²⁴⁶ Patients discharged from prolonged ICU experiences, especially those who had respiratory failure, have an increased incidence of anxiety, depression, and panic disorders years after discharge.

In a nursing study of patient experiences in the ICU, researchers found that patients often felt anxious, apprehensive, and fearful. The patients expected ICU nurses to be experienced and technically adept; patients who felt most secure despite traumatic ICU experiences felt that the nurses were vigilant to their needs and offered personalized care,¹⁸⁷ a point clearly made by Nancy's comments about her perceptions while intubated. Although one might expect ICU staff to be tuned in to patient needs, the highly technical nature of modern ICUs may attract personnel less focused on individual patient care, or it may prevent caring staff from attending to the little kindnesses that are so comforting to critically ill patients. Baxter²⁴⁶ suggests that caregivers in the ICU orient patients to what is being done, to approach the patients within their field of vision, and to minimize unexpected noises and sudden touching.

Although most patients recover well from GBS, 3 to 6 years after onset of GBS 38% of patients in a Dutch study had to make a job change to accommodate their physical status, 44% had to alter their leisure activities, and nearly 50% described ongoing psychosocial changes.²⁴⁴ Similar findings were reported in a study of Japanese patients recovering from GBS.^{247,248} Regularly scheduled rehabilitation checkups and multiweek episodes of care to update the exercise program may reduce the lingering impairments, but such extensive clinical follow-up is rarely reported.

The effect of GBS on caregivers and family members is not as discussed in the literature on GBS as it is in ALS. However, sudden catastrophic illness of one member of a family inevitably affects all members.

A spouse, partner, or parent may have feelings of shock, denial, and helplessness if a patient's nadir involves dependent tetraplegia and mechanical ventilation. In Case 15.2, this manifested in the parents' desire to help with ROM activities at bedside. The financial toll can also be profound even with health insurance, with lost work or study time and the cost of nonmedical caregivers (such as babysitters for other children). For the small percentage of patients with GBS who have a fatal course or persistent severe deficits, counseling and other support may be of help to family members.

Summary of Therapeutic Management in Guillain-Barré Syndrome

In summary, the rehabilitation program for a person with GBS must be graded carefully according to the stage of illness and needs of the patient. In the acute care environment when respiratory deficits are present, the initial emphasis is directed toward support of maximal respiratory status through postural drainage, chest stretching, and breathing exercises. Because of prolonged bed rest and immobility related to weakness, passive, accessory, and physiological ROM must be maintained with around-the-clock efforts. Splinting or positioning devices are recommended to maintain functional positions during prolonged periods of immobility. A gradual program to increase upright tolerance is begun when respiratory and autonomic functions have stabilized. Therapists must keep in mind the potential to damage denervated muscles with aggressive strengthening programs when developing a rehabilitation plan and a home-based conditioning program. Perhaps as a result of cautious exercise programs, cardiovascular conditioning appears to lag significantly behind strengthening, so endurance training should specifically follow the return of strength. Adaptive equipment and orthoses should be used as needed to protect weakened muscles, facilitate normal movement, and prevent fatigue during the reinnervation process. Once MMT reaches 3 to 4/5, however, strengthening can begin to ramp up with progressive resistance. Strengthening and endurance exercise parameters do not need to remain at such a cautious level. At this point, most patients with GBS have been discharged. Although a rehabilitation program has been found to make a measurable difference in patients' recovery,¹⁹⁰ many patients do not receive follow-up care.²⁴⁹ Therefore therapists should be assertive in ensuring that their patients with GBS have ongoing contact with rehabilitation specialists who can guide the recovery process and minimize remaining impairments.

CHAPTER SUMMARY

In this chapter, discussion of two different diseases reveals the varied effects of neuromuscular pathology on a person's day-to-day function. ALS is an adult-onset degenerative disease of the UMN and LMN; GBS is an inflammatory autoimmune process affecting LMN, PNS, and ANS of children and adults. In these conditions, the therapist must design a therapy program that will provide the patient with the impetus to become or remain as active as possible without causing possible muscle damage from excessive exercise demands or overwork.

Therapists must be aware of their own feelings and reactions to patients with severe neuromuscular diseases. Working with patients with GBS is usually a positive experience because most patients attain full or nearly full recovery despite severe disability during the acute illness and a long recovery period. Working with patients with degenerative terminal diseases such as ALS, however, draws deeply on the therapist's emotional and spiritual strength. A typical response of health care professionals is to view these patients' conditions as hopeless and to assume that the patients must also perceive their existence as hopeless, depressing, and without value. Research does

suggest an increased incidence of depression and demoralization in patients with degenerative, terminal diseases compared with populations with no diagnosed diseases. Other research, however, has indicated that many patients perceive their own life satisfaction much more positively than professionals would believe. Therapists must tap into patients' positive energy to design treatment programs that respect patients' goals and life plans within the context of their environment.

Limited evidence exists to document the effectiveness of rehabilitation for patients with neuromuscular diseases. Determining the most appropriate exercise and therapeutic intervention programs therefore requires diligent examination of the dysfunctions and needs of the individual patient and assessment of the effects of interventions appropriately adapted from use in other populations. Because few medical-clinical facilities see a large enough sample of patients with these diagnoses, therapists must align with their professional organizations to institute nationwide, multisite research studies to provide clear evidence of effectiveness of therapy in these populations.

ACKNOWLEDGMENTS

The author acknowledges the contribution of Ann Hallum, PT, PhD, author of previous editions of this chapter. Thank you, also, to Andrew J. Lui, PT, DPT, who graciously reviewed and made clinical suggestions on the ALS portion of this chapter.

Abstract: In this chapter, discussion of two different diseases reveals the varied effects of neuromuscular pathology on a person's day-to-day function. Amyotrophic lateral sclerosis (ALS) is an adult-onset degenerative disease of the upper and lower motor neurons (UMN, LMN); Guillain-Barré syndrome (GBS) is an inflammatory autoimmune process affecting the LMN, peripheral nervous system, and autonomic nervous system of children and adults. In these conditions the therapist must design a therapy program that will provide the patient with the impetus to become or remain as active as possible without causing possible muscle damage from excessive exercise demands or overwork. Limited evidence exists to document the effectiveness of rehabilitation

for patients with neuromuscular diseases. Determining the most appropriate exercise and therapeutic intervention programs, therefore, requires diligent examination of the dysfunctions and needs of the individual patient and assessment of the effects of interventions appropriately adapted from use in other populations. In this chapter, the existing evidence is reviewed and applied to case studies in ALS and GBS.

Keywords: amyotrophic lateral sclerosis (ALS), disuse atrophy, dysphagia, dysarthria, Guillain-Barré syndrome (GBS), noninvasive (positive-pressure) ventilation (NIV), overwork damage, percutaneous endoscopic gastrostomy (PEG), polyradiculoneuropathy

Beyond the Central Nervous System: Neurovascular Entrapment Syndromes*

Bradley W. Stockert and William J. Garcia

OVERVIEW

The purpose of this chapter is twofold. The first purpose is to develop the concept that the entire nervous system forms a continuous tissue tract. This concept is central to the idea that movements of the trunk and/or limbs can have a profound biomechanical and physiological impact on the peripheral nervous system (PNS) and central nervous system (CNS). Mobility of the nervous system and some of the responses of the system to movement in normal and sensitized states are discussed.

The second purpose is to develop in the reader an understanding of the neurovascular entrapment syndrome. This is an underrecognized impairment present in some patients with a wide variety of diagnoses; for example, nonspecific arm pain, repetitive strain injury, carpal tunnel syndrome (CTS), and thoracic outlet syndrome (TOS). Standard medical care frequently fails with these patients. A theoretical model for the development and perpetuation of neurovascular entrapment syndrome is presented. Background information regarding the syndrome is provided, and the appropriate screening tools for assessment of the impairment are discussed. Treatment suggestions and a case study are presented at the end of the chapter.

PERIPHERAL NEUROANATOMY

The PNS is generally regarded as the portion of the nervous system that lies outside the CNS (i.e., the brain and spinal cord).^{1,2} The major components of the PNS include motor, sensory, and autonomic neurons found in spinal, peripheral, and cranial nerves. Although this partitioning is valid from an anatomical perspective, it often leads to a lack of appreciation as to the truly continuous nature and integrative function of the nervous system as a whole. The concept that the entire nervous system is a continuous tissue tract reinforces the idea that limb and trunk movements can have physiological and mechanical effects on the PNS and the CNS, which are local and global.

The nervous system is composed of two functional tissue types. One type of tissue is concerned with impulse conduction. This functional category includes nerve cells and Schwann cells. The second type provides support and protection of the conduction tissues—that is, the connective tissues.

Three levels in the organization of a peripheral nerve have been described (Fig. 16.1).^{2,3} At the innermost level the nerve fiber is the conducting component of a neuron (nerve cell). A connective tissue layer called the *endoneurium* surrounds each nerve fiber. The endoneurium surrounds the basement membrane of the neuron and plays an important role in maintaining fluid pressure within the endoneurial space. There are no lymphatic channels within the endoneurial space, and the pressure within this space increases with compression of the neuron.⁴

The second level of organization consists of a collection of many nerve fibers (a fascicle) surrounded by a layer of connective tissue called the *perineurium*.^{2,3} The perineurium acts as a selective barrier to diffusion and as such exerts significant control over the local movement of fluid and ions. This connective tissue layer acts like a pressurized container; that is, extrusion of the contents occurs if the membrane is cut. The compartment enclosed by the perineurium does not contain lymphatic channels.⁴ This may be a problem during inflammatory states when edema is present deep to the perineurium. The perineurium is the last connective tissue layer to rupture in tensile testing of peripheral nerves.⁵ The outermost connective tissue layer of a peripheral nerve is called the *epineurium*. The epineurium surrounds, protects, and enhances gliding between the fasciculi. Lymphatic channels are found within the epineurial compartment.

All three connective tissue layers are interconnected—they are not separate and distinct, but are continuous tissue layers.^{2,3} Each of the connective tissue layers contains free nerve endings from the *nervi nervorum*. As a result, all three connective tissue layers are a potential source of pain. In addition, all three layers are continuous with the homologous connective tissue layers of the CNS—that is, the *dura mater* and the *epineurium*.

The vascular supply for peripheral nerves is designed to provide uninterrupted blood flow regardless of the position of the trunk and limbs. Extrinsic vessels provide blood flow to segmental vessels that, in turn, supply an extensive intrinsic (intra-neural) vasculature within the PNS. These segmental vessels branch off of the extrinsic vessels and enter peripheral nerves in areas of low nerve mobility relative to the surrounding tissue. The intrinsic vasculature supplies all three connective tissue layers within the PNS. Arterioles and venules are found in the epineurial and perineurial spaces, but only capillaries are found in the endoneurial compartment.

Peripheral nerves are regularly subjected to compression and elongation (stretching), which have been shown to raise intra-neural pressure. Compression and elongation decrease the diameter of the intrinsic blood vessels, increase the intra-neural pressure, and result in a reduction in blood flow within the nerve. Compressive forces of 20 to 30 mm Hg have been shown to adversely affect intra-neural blood flow,⁶ while compressive forces of 50 to 70 mm Hg have been shown to result in complete arrest of blood flow,⁷ which results in damage to myelin and axons.⁶ A strain (elongation) of 6% to 8% has been shown to decrease intra-neural blood flow by 50% to 70% in the sciatic nerve of rats.^{4,8,9} A strain of 15% in the sciatic nerve of a rabbit has been shown to result in complete arrest of blood flow,⁷ and the same strain produces an 80% reduction in blood flow in the rat sciatic nerve.⁹ Strains of 11% or greater are produced by some of the positions used in neurodynamic tests of the upper limb.⁶ Significant increases in intra-neural pressure and concomitant decreases in intra-neural blood flow have been shown to adversely affect neuronal conduction.^{7,10,11}

Fig. 16.1 Three Levels of Organization of a Peripheral Nerve or Nerve Trunk. **(A)** Nerve trunk and components. **(B)** Microscopic structure of nerve fiber.

Intraneural blood flow in the median nerve at the wrist can be assessed with Doppler sonography and used in the diagnosis of CTS.¹²

The cytoplasm in cells moves and has thixotropic properties; that is, the viscosity of cytoplasm is lower when it is continuously moving.⁴ In neurons, the movement of the cytoplasm from the cell body through the axons (anterograde movement) occurs at two speeds. Fast axoplasmic flow occurs at a rate of about 100 to 400 mm/day and is used to carry ion channels and neurotransmitters (i.e., materials required for normal impulse conduction) to the nerve terminals. Slow axoplasmic flow occurs at a rate of about 6 mm/day and is used to transport cytoskeleton proteins, neurofilaments, and other materials used to maintain the physical health of the cell. A third flow occurs in the opposite direction (retrograde) at a rate of about 200 mm/day. Retrograde transport carries unused substances and exogenous materials taken up at the terminus (e.g., neurotrophic factors). The material carried back to the cell body by retrograde transport has been shown to influence activity in the cell nucleus.⁴

Compression raises intraneural pressure, which has a negative impact on the flow of cytoplasm.⁴ Anterograde and retrograde flow of axoplasm is impaired with 30 mm Hg compression on the nerve, hypoxia, or a strain of 11% or greater.^{13–15} Prolonged or intense exposure to compression can result in conduction abnormalities, endoneurial edema, fibrin deposition, demyelination, and axonal sprouting. Each of these events increases the likelihood of developing adhesions and abnormal impulse-generating sites (AIGSs).⁴ (The negative impact of AIGSs is discussed in the section on adaptive responses to pain.)

MOBILITY OF THE PERIPHERAL NERVOUS SYSTEM

Several types of tissues (e.g., bone, fascia, and muscle) surround peripheral nerves as they “travel” to target tissues. Peripheral nerves can be thought of as passing through a series of tissue tunnels composed of various biological materials. The composition of the tissue tunnel changes with the passage of the nerve from the vertebral column (an osseous tunnel) to the target tissue (e.g., from an osseous tunnel to a soft tissue and/or fibro-osseous tunnel). A “mechanical interface” exists at the junction between the nerve and the material adjacent to the nerve that forms the tissue tunnel. Movement of the trunk and/or limbs can cause three types of movement to occur in the peripheral nerves: *unfolding*, *sliding*, and *elongation*.¹⁶

When there is little or no tension in a peripheral nerve, the axon typically contains undulations (folds). As tension is applied the axon

will *unfold* so that the undulations disappear. *Sliding* can be defined as movement between the nerve and the surrounding tissues at the mechanical interface (extraneural movement). Sliding by itself does not cause significant elongation or tension to develop within the nerve, so intraneural pressure remains relatively unchanged. Ultrasound studies have shown that the median, ulnar, sciatic, and tibial nerves undergo extraneural movement (sliding) with movement of the upper and lower limbs, respectively.^{17–20}

Elongation of the nerve occurs when tension is applied to a nerve, and there is little or no unfolding and sliding at the mechanical interface. Elongation causes movement to occur between the neural elements and connective tissue layers (intraneural movement). Elongation decreases the diameter of the nerve, resulting in an increase in the intraneural tension and pressure.¹⁶ An increase in intraneural pressure has been shown to decrease the flow of blood and axoplasm, resulting in altered neural function (see previous section). Elongation within the median and ulnar nerves has been shown to occur with movements of the upper limb.⁶

Both extraneural and intraneural movements may occur simultaneously within a nerve, but they may not be uniformly distributed. When a body moves, some parts of the PNS will undergo primarily extraneural movement (sliding) with little or no development of tension, while other areas will undergo intraneural movement (elongation), which results in an increase in intraneural tension and pressure. As a consequence, some areas within a nerve slide, developing little or no tension, whereas other areas of the same nerve elongate significantly, increasing the amount of intraneural tension.⁶ In areas repeatedly exposed to high amounts of tension (e.g., the median nerve at the wrist) the nerves are found to contain a higher-than-average amount of connective tissue.¹⁶

If one considers the entire nervous system as a continuous tissue tract, then the idea that movement and/or tension developed in one region of the nervous system can be distributed and dissipated throughout the entire nervous system becomes apparent.^{21,22} The inability of a component within the nervous system to dissipate and/or distribute movement and tension can lead to abnormal force development and lesions elsewhere in the continuous tissue tract.²³

PERIPHERAL NERVE ENTRAPMENT

Seddon’s classification of nerve injury is based upon mechanical trauma.²⁴ Schaumburg² modified this paradigm into an anatomically based scheme containing three classes of injury (Table 16.1). Injuries

TABLE 16.1 Classification of Acute Traumatic Peripheral Nerve Injury

Anatomical Classification	Class I	Class II	Class III
Previous nomenclature	Neuropraxia	Axonotmesis	Neurotmesis
Lesion	Reversible conduction block resulting from ischemia or demyelination	Axonal interruption but basal lamina remains intact	Nerve fiber and basal lamina interruption (complete nerve severance)

Modified from Schaumburg HH, Spencer PS, Thomas PK. *Disorders of Peripheral Nerves*. Philadelphia: FA Davis; 1983.

in class II and III are caused by macrotrauma, which results in some disruption to the integrity of the nerve fiber. The following discussion of entrapment is focused on microtrauma in which there is no breach in the anatomical integrity of the nerve fiber (class I). Mechanical microtrauma resulting in nerve entrapment can occur with excessive or abnormal friction, compression, and/or tension (elongation).²

Tissue tunnels, peripheral nerves, and the mechanical interfaces between them are all vulnerable to mechanical microtrauma—that is, abnormal friction, compression, and/or tension.^{2,16} Some peripheral nerves are exposed to bony hard interfaces (e.g., the lower cords of the brachial plexus at the first rib), which are potential sources of abnormal friction. Inflammation and swelling within a tissue tunnel can produce compression of a nerve, for example, the median nerve within the carpal tunnel. The point at which a nerve branches limits the amount of gliding (extraneural movement) available at that location, and increases the amount of local intraneural tension developed with movement (e.g., the tibial nerve in the popliteal fossa).^{2,16}

Microtrauma can produce an intraneural lesion that causes a decrease in intraneural flow of blood and axoplasm, demyelination, and/or conduction defects.^{2,16} If the lesion occurs in the connective tissues of the nerve, there may be pain, inflammation, proliferation of fibroblasts, and scar formation (fibrosis). Ultrasound studies have shown that the median nerve in patients with CTS is enlarged by approximately 30%.²⁵ An intraneural scar decreases the compliance of the nerve and increases the amount of intraneural pressure and tension generated with elongation.²² Intraneural lesions can impair or completely block the ability of the nerve to conduct action potentials.^{2,16,26} Partial or complete conduction blocks can result in abnormal sensation, loss of motor function, autonomic dysfunction, and atrophy of target tissue (e.g., muscle and/or skin). However, several forms of physical activity/exercise, including swimming and treadmill training, have been shown to improve recovery from peripheral nerve injury in animal models (crushed sciatic nerve) using a variety of outcome measures.^{27–31} There is no consensus about the best time to start any form of exercise following peripheral nerve injury although one study suggested earlier intervention was beneficial.²⁸

Microtrauma can produce an extraneural lesion.^{2,16,22,26} The damage in an extraneural lesion occurs in the tissue surrounding the nerve—that is, at the mechanical interface. Swelling within the tissue tunnel can produce compression of the nerve. Fibrosis can produce adhesions at the mechanical interface leading to a decrease in sliding of the nerve. A decrease in the ability of a nerve to slide within a tissue tunnel will result in an abnormal increase in intraneural tension and pressure as movement is imposed on the nerve. The increase in local intraneural tension can produce abnormal changes in the conduction of action potentials, and the tension will be distributed in an aberrant pattern throughout the continuous tract of the nervous system. The resultant abnormal distribution of tension predisposes the nervous system to the development of lesions at other sites.¹⁶

Friction, compression, and tension can produce microtrauma, which results in intraneural and extraneural pathology.^{2,16} For example, fibrosis can produce a combined pathological state that results in

a substantial reduction in the ability of a nerve to slide within the tissue tunnel and a substantial increase in intraneural tension during nerve elongation as the compliance of the nerve is decreased. Movement of the median nerve at the carpal tunnel has been shown to occur with movements of the upper limb.^{17–20} Longitudinal and transverse movements of the median nerve at the carpal tunnel have been shown to be reduced in the presence of microtrauma (i.e., CTS,^{25,32} nonspecific arm pain,^{33,34} and whiplash injury).³⁴

Intraneural and extraneural lesions result in an abnormal distribution of sliding and tension throughout the nervous system with movement of the trunk and/or limbs. The abnormal distribution of tension within a nerve increases the probability of a second lesion or abnormality developing within the nerve. This situation led Upton and McComas³⁵ in 1973 to first use the term “double crush injury.” (This term should be considered a misnomer because a “crush” does not necessarily occur.) For example, entrapment of the median nerve at the carpal tunnel can cause the development of abnormal tension in cervical spinal nerves, resulting in a lesion at that site. Upton and McComas³⁵ have shown that a lesion at the carpal tunnel increases the risk of having a second neural lesion in the cervical region.

PATHOGENESIS OF NEUROVASCULAR ENTRAPMENT

Neurovascular entrapment can occur at any point along the continuous tract of the nervous system. The carpal tunnel, a common site of entrapment, has been studied and provides a framework of information regarding the pathogenesis of neurovascular entrapments. Sunderland³⁶ has reasoned that a change in the normal pressure gradients within the carpal tunnel can lead to compression of the median nerve. In order to maintain homeostasis in the carpal tunnel and the median nerve, blood must flow into the tunnel, then into the nerve and back out of the tunnel. For blood flow to occur in the median nerve the blood pressure must be highest within the epineurial arterioles, and becomes progressively lower in the capillaries and epineurial venules and lowest within the extraneural space of the carpal tunnel. Any increase in the pressure of a single compartment has the potential to disrupt the normal pressure gradients and impair the flow of blood within the compartments of the carpal tunnel and the median nerve. Impaired intraneural blood flow can lead to localized hypoxia, edema, inflammation, and fibrosis.³⁶

An increase in pressure within the carpal tunnel can occur for a variety of reasons—for example, synovial hyperplasia, thickening of tendons, venous congestion, inflammation, and/or edema. Venous blood flow within a nerve will be impaired, and venous stasis will develop if pressure within the extraneural space of the carpal tunnel becomes greater than the pressure within the epineurial venules. Because blood pressure within venules is relatively low, partial occlusion of blood flow can begin to occur in the carpal tunnel with pressures as low as 20 to 30 mm Hg.^{16,37} Intraneural blood flow in the median nerve at the wrist can be detected with Doppler sonography.¹²

The pressure within the extraneural space of the carpal tunnel is normally about 3 mm Hg (range of 2 to 10 mm Hg) with the wrist in a neutral position.^{4,38} The pressure can rise to over 20 mm Hg with the wrist in full flexion, and pressure can rise to over 30 mm Hg when the wrist is placed in 90 degrees of extension³⁹ or with the functional task of using a computer mouse to drag or point at an object.⁴⁰ Studies have shown that the pressure within the carpal tunnel in someone with CTS can be 30 mm Hg or more with the wrist in neutral, and can increase to about 100 mm Hg when the wrist is in 90 degrees of flexion^{4,13,14} or extension.^{13,38} Compressive forces of 20 to 30 mm Hg have been shown to adversely impact intraneural blood flow,⁶ whereas compressive forces of 50 to 70 mm Hg have been shown to result in complete arrest of blood flow⁷ and cause demonstrable damage to myelin and axons.⁶ Motor and sensory abnormalities begin to manifest at about 40 mm Hg, and complete blockade of the median nerve has been shown to occur at 50 mm Hg.⁴¹ The pressure found in the carpal tunnel of people with CTS is clearly adequate to disrupt the normal flow of blood, axoplasm, and action potentials within the median nerve, causing severe impairment to normal nerve functions.

Sunderland³⁶ proposed that venous congestion or stasis within the carpal tunnel will lead to localized hypoxia, edema, and fibrosis. Hypoxia causes capillary endothelial cells to deteriorate and local C fibers to secrete substance P and calcitonin gene-related peptide,⁴ which in turn causes mast cells to release histamine and serotonin.^{42,43} Together these chemical mediators augment the inflammatory state and cause the endothelial cells of capillaries to further deteriorate by becoming flatter, larger, and leakier, enhancing exudation and edema.

Deterioration of the capillary endothelium results in exudation and the formation of a protein-rich edema in the interstitial space. Protein-rich edema stimulates proliferation of fibroblasts, resulting in fibrosis. This intensifies the abnormal pressure gradients, resulting in more tissue hypoxia; that is, a positive feedback or self-perpetuating cycle of pathology is initiated. Intraneural fibrosis decreases compliance of the nerve, and extraneural fibrosis results in the formation of adhesions at the mechanical interface between the nerve and the tissue tunnel. Fibrosis causes a nerve to become stiffer and less mobile, resulting in an abnormal increase in tension when movement is imposed on the nerve.

This set of circumstances (described above) may be referred to as a *neurovascular entrapment syndrome*, and it has the potential to cause the development of problems elsewhere in the system—that is, a double crush injury (see previous section). Upton and McComas³⁵ studied 115 subjects with CTS or ulnar impingement at the elbow. They found that 81 of the 115 subjects also had evidence of a neural lesion at the neck. Because all nerves essentially travel within tissue tunnels, the potential exists for this scenario to occur elsewhere in the continuous tissue tract of the nervous system (e.g., the thoracic outlet).^{5,16,44}

ADAPTIVE RESPONSES TO PAIN

A thorough discussion of the pain associated with neurovascular entrapment is beyond the scope and intent of this chapter. The topic of pain management is discussed in Chapter 30 of this book. However, we would like to describe the development of hyperexcitable states and AIGSs in neurons as well as their role in the development of pain associated with neurovascular entrapment.

“Normal” or physiological pain occurs when peripheral nociceptors are subjected to a stimulus that is at or above the threshold for firing. “Abnormal” or pathological pain can occur when there is a change in the sensitivity (threshold) of the somatosensory system.⁴⁵

Devor⁴⁶ wrote that “the crucial pathophysiological process triggered by nerve injury is an increase in neuronal excitability.”

Neurons that become inflamed, hypoxic, and/or demyelinated can enter a hyperexcitable state.^{2,46–54} A neuron in a hyperexcitable state can begin to discharge spontaneously and/or develop a sustained rhythmic discharge after stimulation. In addition, hyperexcitable neurons can develop mechanosensitivity,⁴⁸ chemosensitivity,⁴ and/or thermal sensitivity,⁵² all of which can result in the production of allodynia, a form of pathological pain.^{34,46,50,52,54,55} These changes in the behavior of a nerve can occur in the absence of detectable degeneration.^{47–49} The changes in impulse generation and neuronal sensitivity are characteristics of an AIGS.⁴ A hyperexcitable state and an AIGS can develop with the mechanical microtrauma and inflammation often associated with peripheral nerve pathology that result from compression, tension, and friction.^{2,46,55,56} A variety of chemical mediators have been implicated in the development of a hyperexcitable state in a neuron; for example, neurotrophins,^{57,58} histamine,⁵⁹ and other inflammatory mediators.⁶⁰ These chemical mediators are thought to act through changes in gene expression,^{52,57,58} changes in voltage-gated sodium channel expression,⁵² and a reduction in anterograde axoplasmic transport.^{51,59}

The dorsal root ganglion appears to play a significant role in the pain associated with peripheral nerve pathology.^{45,48} Mechanical microtrauma and inflammation of peripheral nerves can cause the dorsal root ganglion to become hyperexcitable (sensitized).⁴⁸ The change in sensitivity allows what were weak, subthreshold stimuli to evoke pain and suprathreshold stimuli to evoke exaggerated pain (hyperalgesia). In addition, the dorsal root ganglion can develop mechanosensitivity, chemosensitivity, and thermal sensitivity, resulting in allodynia.⁵² This change in sensitivity reflects a change in the physiology of the nerve and may be a component in the development of enhanced central sensitivity to pain and the development of a chronic pain state.⁴⁵

As noted previously, the PNS and CNS represent a continuous tissue tract. The pain and symptoms associated with musculoskeletal injury and/or peripheral nerve pathology can include changes that are the result of an alteration in the autonomic nervous system, which is considered part of the continuous tissue tract of the nervous system.^{2,61} For example, catecholamines do not normally elicit pain. However, if a nerve is injured or if there is local inflammation, the catecholamines can induce pain (chemosensitivity) and maintain or enhance pain in inflamed tissues.⁴

Some patients who are treated for musculoskeletal injuries have signs that may be related to autonomic dysreflexia.⁴⁴ Wyke⁶² demonstrated that stimulation of nociceptors in spinal joints resulted in reflex changes in the cardiovascular, respiratory, and endocrine systems. Dysregulated breathing has been documented in patients with chronic pain.⁶³ Patients with nonspecific arm pain have a reduced sympathetic vasoconstrictor response in the hand of the affected limb.⁶⁴ Thermal asymmetry has been documented in the hands of patients with neurogenic TOS.⁶⁵ Feinstein and colleagues⁶⁶ showed that injecting saline solution into the thoracic paraspinal muscles caused pallor, diaphoresis, bradycardia, and a drop in the blood pressure. These cardiovascular and respiratory changes are often associated with an alteration in the output from the autonomic nervous system.^{44,61,67}

In patients with cumulative trauma disorder (CTD), signs of abnormal autonomic nervous system output can include (1) vasomotor reflexes leading to cool, pale skin,⁶⁴ (2) changes in the pattern of sweating (hypohidrosis and/or hyperhidrosis), (3) trophic changes in the skin, (4) hyperactive flexor withdrawal reflexes, and/or (5) paradoxical breathing patterns.⁴⁴ Edgelow has described paradoxical breathing as the predominant use of the scalene muscles for ventilation during quiet breathing versus normal ventilation, which is predominantly a function of the diaphragm.⁴⁴ Edgelow found that paradoxical

breathing is present in most patients with CTD of the upper extremity.⁴⁴ A better appreciation of the contribution of the autonomic nervous system to the pathology and symptoms present in some patients with neurovascular entrapment may enhance the effectiveness of their treatment.

CLINICAL EXAMINATION AND TREATMENT OF NEUROVASCULAR ENTRAPMENT

For an effective evaluation of a patient with a neurovascular entrapment problem, the whole person must be addressed and involved in the evaluation and treatment processes. This approach requires the therapist to consider a biopsychosocial approach versus a biomedical approach. In this case, the therapist becomes the evaluator, teacher, and guide for the patient. Traditionally, a biomedical approach has been taken with disorders such as neurovascular entrapment. In a biomedical model, the patient's disability and impairments are seen as a direct correlation to the tissue pathology.⁶⁸ The biopsychosocial model addresses the whole patient and provides a means for the therapist to consider the biomedical factors (underlying tissue) and psychosocial factors influencing a patient's symptoms.⁶⁸ Utilization of this approach has become more accepted in physical therapy practice, along with the understanding that pain is often influenced by a patient's emotional well-being, thoughts about their condition, cultural beliefs, and environmental influences.⁶⁸ Given the impact that neurovascular entrapment symptoms can have on a patient, it is imperative that a clinician understand the interplay between the biomechanical impairments and any underlying psychosocial issues. Neurovascular entrapment can occur in both the upper extremity and lower extremity; however, the most common examples seen by therapists are TOS and CTS. The clinical examination discussed will highlight the specifics regarding neurovascular entrapment of the upper extremity.

Patients with neurovascular entrapment often present with severe and irritable symptoms; therefore a detailed subjective examination is necessary to understand the behavior of the symptoms and the impact the symptoms are having on the patient's life. Initial goals of the subjective exam include determining if the patient is appropriate for physical therapy, developing a hypothesis list regarding potential sources of the patient's symptoms, and determining the extent and vigor of the objective examination. The subjective exam should begin with the patient completing a detailed body chart that outlines the specific area of symptoms and the patient's description of the symptoms. A body chart provides the clinician a thorough picture of symptom location and the potential relationship between areas of symptoms. The patient's description of the symptoms may provide the clinician with potential hypotheses regarding pain mechanisms and potential neurovascular involvement. The patient with primarily *neurological symptoms* may have pain that is described as sharp or burning with numbness or paresthesia, and spasms or weakness in the extremity.^{69,70} *Vascular symptoms* may be due to either arterial or venous compression. *Arterial symptoms* may include pain in the distal portion of the extremity (vs. pain proximally at the shoulders or neck), swelling, complaints of stiffness or heaviness of the extremity, coldness of the distal extremity, pallor, and paresthesia (likely due to ischemia).⁶⁹⁻⁷¹ Symptoms that originate from venous compression are likely to be described as feelings of stiffness or heaviness of the extremity, asymmetrical extremity edema, paresthesia, and limb discomfort/pain.⁶⁹⁻⁷¹

Understanding pain mechanisms and the overlap between these mechanisms can be helpful for both the clinician and patient. It is

beyond the scope of this chapter to discuss in detail each of these mechanisms and the body of evidence supporting them. However, a brief explanation is appropriate when treating patients with painful conditions. Pain mechanisms have been classified based on the dominant neurophysiological mechanism.⁷²⁻⁷⁴ Classification of pain mechanisms is a useful way for clinicians to identify the likely neurophysiological source of symptoms. The three main pain classifications are *nociceptive*, *peripheral neuropathic*, and *central sensitization*. Smart and colleagues⁷²⁻⁷⁴ have identified common signs and symptoms to assist clinicians in classifying pain mechanisms in patients with low back pain with and without leg symptoms. *Nociceptive pain* is classified by distinct symptoms and signs: pain localized to the area of injury/dysfunction, clear and proportionate mechanical/anatomical aggravating and easing factors. Symptoms are usually intermittent with movement or mechanical provocation; no dysesthesias are present, and there is no night pain, and no description of burning or shooting symptoms. If the patient assumes antalgic postures to relieve pain, the odds of pain being nociceptive are reduced.⁷⁴ The strongest predictor of nociceptive pain is pain localized to the area of injury/dysfunction with an odds ratio (OR) of 69.⁷⁴ *Peripheral neuropathic pain* consists of three signs and symptoms: pain referred in a dermatome or cutaneous nerve distribution, a history of nerve injury (pathology or mechanical compromise), and pain or symptoms are provoked with mechanical tests such as neurodynamic testing (e.g., straight leg raise).⁷³ Symptoms that are in a dermatomal or cutaneous distribution have an OR of 24, suggesting that if symptoms are in a dermatomal or cutaneous nerve distribution the patient is 24 times more likely to have neuropathic pain.⁷³ *Central sensitization* is pain that is typically present outside of tissue pathology and is associated with an increase in sensitivity of the CNS. Four signs and symptoms have been associated with central sensitization: pain that is disproportionate and nonmechanical, and is unpredictable in terms of aggravating and easing factors; pain that is disproportionate to the extent of injury or pathology; the presence of maladaptive psychosocial factors; and diffuse nonanatomical areas of pain or tenderness to palpation.⁷² The OR for disproportionate pain with nonmechanical/unpredictable aggravating factors is 30.69. It is important for clinicians to understand that patients are likely to present with varying amounts of each of these pain mechanisms regardless of acuity of the injury. For example, a patient may present with a 2-week onset of symptoms that appears to be CTS and have symptoms that are 70% peripheral neuropathic, 20% nociceptive, and 10% central sensitization. Understanding and classifying pain allows the clinician the ability to better plan the objective examination and treatment plan. Establishing symptom behavior by obtaining aggravating and easing factors and the 24-hour behavior of the symptoms provides further insight into the patient's presentation and the clinician's potential hypotheses. A discussion of which activities, postures, and positions/movements produce the patient's symptoms—including the amount of time to onset and location/intensity of symptoms, followed by positions, movements, or activities to settle the symptoms—can aide in determining whether the neural or vascular system is a potential source of the problem and determining the level of tissue irritability. When an extended period of time is required for symptoms to ease after very little activity provokes the symptoms, then irritability may be deemed high. Motor changes of relevance to the potential problem of neurovascular entrapment include complaints of dropping things, weakness, or an inability to perform motor tasks that were done previously without difficulty. Key components that should be discussed with the patient include history of trauma, repetitive activities, sustained static or tension postures (e.g., computer keyboard work), or physical activities performed with a high level of cognitive demand, as seen in a pianist. In addition, the progression of the

symptoms or complaints should be determined. The history should include a discussion of general health and screening questions for relevant medical conditions such as asthma, diabetes, and hypothyroidism. Chapter 6 of this text provides more detail regarding medical screening and a differential diagnosis to ensure patients are appropriate for evaluation and intervention.

Health-related quality of life or patient-reported outcome measures are useful in patient management to assess multiple domains such as physical ability, psychological, emotional, and social well-being. Condition specific measures can be utilized for neurovascular entrapments, such as The Michigan Hand Outcomes Questionnaire for patients with CTS.⁷⁵ For conditions such as TOS, condition-specific measures do not currently exist; therefore clinicians may choose more generic measures such as the Neck Disability Index or the Disabilities of the Arm, Shoulder, and Hand (DASH).⁷⁶ The Fear Avoidance Beliefs Questionnaire was developed to measure fear and avoidance of activity in patients with low back pain; however, it has now gained acceptance for usage in conditions outside of low back pain, to screen for depression risk factors. The depression screening questions consist of a cluster of three questions that have established likelihood ratios (LR), +LR of 9.1 and -LR 0.05.⁷⁷ Use of these tools in daily practice provide the

clinician with a broader view of the patient's self-rated function and insight into potential psychosocial barriers to treatment. Health-related quality of life measures provide reliable, valid, and responsive tools to measure the outcome of interventions.⁷⁸

Objective Examination

The objective examination in patients with neurovascular entrapment can be complex, and the clinician needs to utilize tests and measures that help rule out potential competing diagnoses. The differential diagnosis for a suspected neurovascular entrapment of the upper extremity includes cervical spine referral/radiculopathy, brachial plexus injury, rotator cuff pathology, glenohumeral joint dysfunction, lateral epicondylalgia, medial epicondylalgia, complex regional pain syndrome (CRPS I or II), systemic disorders, and upper extremity deep vein thrombosis.⁷⁰

Given the extensive differential diagnosis list, both the subjective and objective exams will be comprehensive. The clinician must gauge the patient's level of irritability during the subjective exam to determine the vigor of the objective exam, thereby avoiding excessive or unintentional provocation of the patient's symptoms. Table 16.2 provides the suggested modifications to a standard biomechanical

examination of the upper quarter necessary to rule in/out potential neurovascular entrapment. The clinician must adjust the examination based on the patient's unique presentation and the irritability of the condition. Generally, it is recommended that the examination proceed from active movement produced by the patient to passive assessment. When possible, testing maneuvers should be performed by the patient so that he or she can learn to self-assess his or her status before and after treatment procedures. This self-assessment gives the patient control, thus decreasing the fear of movement or reinjury. The concept of the patient gaining control of the problem(s) is fundamental and must be integrated into the initial patient contact for development of an effective self-management approach. Without an effective self-management strategy, the patient is at risk for recurrent problems and the development of a chronic condition. The objective examination

scheme presented here is considering neurovascular entrapment of the upper extremity. Emphasis will be placed on CTS and TOS; however, the sequence of the examination can remain the same for the lower extremity by replacing the regions examined and the special tests utilized.

Observation is initially completed in sitting; the patient's head on neck posture should be assessed while looking for deviations of the head in the frontal and sagittal planes. The clinician should take note of rounded shoulders and an increase in thoracic kyphosis as these changes in posture may increase tension on the brachial plexus.⁶⁹ The scapular position should be assessed at rest and dynamically with active motion of the upper extremities.⁷⁰ Observation includes evaluating the integrity of the vascular system in the extremities. The hands, or feet, should be inspected for discoloration, and the skin temperature

Fig. 16.2 Diaphragmatic Breathing. As the patient inhales, the stomach should rise and the lordosis in the low back should increase. During exhalation the stomach should fall and the back should flatten against the floor.

should be determined in each of the peripheral nerve territories present in the affected limb. *Hand temperature* is assessed with an infrared hand-held thermometer. Thermal measurements are made of the second digit (innervated by the upper roots of the brachial plexus) and fifth digit (innervated by the lower roots). Temperature is assessed during rest, diaphragmatic breathing, walking on a treadmill, and repeated movements of the upper extremities. A normal response is an increase in temperature in response to these activities. A cooling response is considered abnormal. Cool, cyanotic skin can be an indication of arterial insufficiency or sympathetic dysreflexia in the area, whereas swelling can be an indication of inflammation and venous or lymphatic insufficiency. The hands should be inspected for the presence of atrophy, which can be present as a result of neurovascular entrapment. Observation of the patient's breathing pattern at rest and in the supine position should be performed.

The normal *breathing pattern* at rest is primarily diaphragmatic (Fig. 16.2). However, patients with neurovascular entrapment often demonstrate a breathing pattern at rest that relies predominantly on the scalene muscles. The scalene breathing pattern mechanically narrows the thoracic outlet area, thus potentially perpetuating a neurovascular entrapment syndrome in the area. The scalene breathing pattern may be a sign of protective posturing. The *breathing pattern* is further assessed by palpating the scalene muscles in the area between the inferior border of the sternocleidomastoid and is superior to the clavicle. This procedure is best done while the patient performs relaxed inhalation. The scalene muscles are normally quiet during relaxed inhalation. Contraction of the scalene muscles and elevation of the sternum are considered to be abnormal during quiet inhalation. Patients are instructed to breathe with the “belly” only (diaphragmatic breathing). If they are unable to do this, breathing is considered to be paradoxical.

Active/passive range of motion testing includes a screening of the upper quarter and should include the cervical spine, shoulder, elbow, wrist, and hands. The depth of assessment is based on the need to rule in or out the competing disorders. During the active and passive range of motion assessment, the examiner measures the quality and quantity of the motion as well as the joint end feel during passive motion testing. Range of motion is objectively documented using a goniometer or inclinometer at the initial assessment and is compared at follow-up

Fig. 16.3 Demonstration of clinician performing the cervical rotation and lateral flexion (CRLF) test on a patient.

visits.⁷⁰ In patients with suspected TOS, first rib mobility can be assessed via a combined movement test of cervical rotation and lateral flexion (CRLF).⁸² Fig. 16.3 demonstrates the CRLF with the patient in sitting, the uninvolved side is assessed first to establish a baseline followed by the involved side. The test is considered positive if a bony block is experienced, limiting the lateral flexion portion of the test.⁸²

Resisted testing using standard manual muscle testing procedures can be utilized to identify muscle imbalances/weakness in the shoulder, scapula, elbow, wrist, and hand.⁸³ Strength can be assessed using a 0 to 5 classification or a hand-held dynamometer. Motor function of the cervical spine, specifically the longus capitis and longus colli, is completed as described by Jull and colleagues⁸⁴ This method of assessment and treatment targets the deep neck flexor muscles and reduces recruitment of the sternocleidomastoid and scalene muscles, which can become overactive in patients with neurovascular entrapment conditions such as TOS or CTS. The reliability of hand-held dynamometer use in the upper extremity is limited with only testing of the elbow demonstrating acceptable intrarater reliability.⁸⁵

Hand strength (grip strength) assessment is done as a standard part of the objective exam for patients suspected of having neurovascular entrapment. Many patients with suspected neurovascular entrapment of the upper extremity complain of changes to grip strength, and in cases of an advanced condition demonstrate atrophy of the hand intrinsic muscles. Grip strength is commonly assessed with a grip dynamometer, and the average of three trials per hand is recorded.⁷⁶

Neurological examination is a thorough process that includes sensory testing, motor, and deep tendon reflexes (DTRs) assessment in the upper extremities. Standard assessment of sensation includes light touch and pin-prick testing. Sensation loss in conjunction with motor deficits and normal or abnormal DTRs may be indicative of neurological TOS. Sensation loss in the median nerve distribution may be indicative of CTS. Reduction of DTRs (hyporeflexia) may be due to cervical spine involvement, which suggests further examination if present. Hyperreflexia may indicate upper motor neuron involvement

and should be followed up with clinical tests such as Babinski, Clonus, and Hoffman's.

Neurodynamic testing beyond the standard neurological examination is used to assess the sensitivity of neural tissue.⁸⁶ Neurodynamics of the upper extremity are assessed with the use of upper limb neural dynamic (ULND) tests as described by Butler.⁴ Passive neck flexion is examined to assess dural sensitivity, whereas the straight leg raise test is used to assess the sensitivity of the sciatic nerve and sacral plexus. Reliability of ULND testing has been reported to be 0.54 for the median nerve, 0.44 for the radial nerve, and 0.36 for the ulnar nerve.⁸⁷ In addition to these passive neural dynamic tests performed by the examining therapist, the patient is instructed to complete the neurodynamic maneuvers actively.

Self-neurodynamic tests are encouraged prior to the passive techniques in all patients; however, it is highly encouraged in patients who have high severity. Care must be taken to educate the patient to stop at the first sensation of tension and not to linger with the arm in any self-test position that provokes symptoms. The self-neurodynamic tests are performed by guiding the patient through a series of positions using the upper extremity (Fig. 16.4). This is an active test that the patient, the medical provider, and the physical therapist can use as an indicator of upper quarter neural sensitivity. The test provides immediate feedback regarding the patient's response to an exercise or other form of intervention. The test results can be used as an indicator of a change in patient status. The test is an important tool that helps the patient recognize and manage symptom flares. The self-neurodynamic test is one of the self-assessment tools that encourage the patient to take control of his or her treatment. The provided example (see Fig. 16.4) demonstrates a self-neurodynamic test of the median nerve. A modification to this test in an irritable patient can include instructing the patient to turn his or her head to the involved side and/or having the patient look at the palm of the hand prior to initiating the test. Once the upper extremity is in the tension position, the patient is instructed to look straight ahead, adding additional tension to the test maneuver. Testing of the radial and ulnar nerves can be carried out in a similar fashion with the components of the active test mimicking the standard passive test. (Please refer to the references at the end of this chapter for more information on neural dynamic tests.)

Palpation is used to determine whether tenderness or tightness is present in the soft tissues. Palpation of the subclavius, pectoralis minor, and scalene muscles is significant because of the relationship these muscles have with the subclavian vein, brachial plexus

Fig. 16.4 Demonstration of Arm Self-Neurodynamic Test Positions. The arm self-neurodynamic test is an active upper extremity neural dynamic test.

components, and subclavian artery, respectively. The results of palpation should be correlated to the neurological and vascular changes found elsewhere in the extremity. Nerve palpation is a means to examine mechanosensitivity of the nerve in addition to ULND testing.⁴ The reliability of nerve palpation ranges from moderate to substantial, 0.59 (0.46, 0.72).⁸⁷ Palpation of the nerve and the self-neurodynamic are often the preferred methods of examination of mechanosensitivity in the irritable patient.

Accessory mobility testing of the cervical and thoracic spine is commonly necessary for patients with TOS and/or CTS. Impairments identified in corresponding levels to the upper extremity (C5 to C7) may have an impact on neurovascular disorders when taking a “double crush” syndrome into consideration. The joints of the shoulder, elbow, wrist/hand are assessed passively for accessory mobility as indicated.⁷⁶ For further information regarding accessory mobility testing of the cervical and thoracic spine, refer to Magee.^{16,76}

Special tests in the upper extremity can be utilized to contribute to the process of ruling in/out neurovascular entrapments. The number of special tests available for CTS and TOS are extensive with varying diagnostic utility given the range in sensitivity (Sn), specificity (Sp), and LRs. It is beyond the scope of this chapter to discuss all the tests available; however, the tests with the best diagnostic utility will be discussed. Given the potential confusion between a diagnosis of CTS and TOS, tests that differentiate between the two conditions are recommended.⁷⁰ Typically, tests for TOS assess a change in or the obliteration of the pulse. The reliability of a change in pulse is poor; therefore it is recommended that symptom provocation be assessed as well as a change in the patient's pulse. There are several clinical tests for TOS; however, Gillard and colleagues identified a cluster of tests that can be used to rule in/out TOS. Adson maneuver, Wright's, ROOS, hyperabduction test, and Tinels are the five clinical tests that make up the cluster identified by Gillard. Tinels is conducted at the supra and infraclavicular region with symptom provocation assessed. During Wright test and the hyperabduction test, it is recommended that the clinician monitor both the pulse and symptoms. Five positive tests yield a +LR of 5.3 while five negative tests yield a -LR of 0.19.⁷⁹ A combination of clinical tests for TOS is valuable for ruling in/out the condition.

Clinical tests for CTS are primarily provocative tests directed at the carpal tunnel. Phalen test is the most widely accepted test used in the clinic. The patient sustains a position of wrist flexion while holding both forearms vertical for 60 seconds. Phalen's has a reported Sn of 0.59 to 0.64 and Sp of 0.75 to 0.93.^{80,81} The negative predictive value (NPV) for Phalen's is 0.65, and the positive predictive value (PPV) is 0.91.⁸⁰ Tinels is utilized on the median nerve as it enters the carpal tunnel. Tinels has a reported Sn of 0.41, Sp of 0.90, an NPV of 0.56, and a PPV of 0.83.⁸⁰ The compression test or pressure pain provocation test is performed using sustained pressure at the carpal tunnel \times 1 minute. The test has an Sn range of 0.14 to 0.42 and an Sp range of 0.96 to 0.99.^{80,81} The NPV for the pressure provocation test is 0.58 and PPV is 0.97.⁸⁰ Given the current range in the diagnostic tests for TOS and CTS, it is important that the clinician consider all exam findings from the subjective and objective exam along with the results of the special tests when attempting to rule in/out a neurovascular disorder.

Symptom Patterns Characteristic of Neurovascular Entrapment

1. Symptoms often present as severe and irritable with a combination of pain mechanisms including nociceptive, peripheral neuropathic, and central sensitization.
2. Function is markedly reduced in the target task (injury-producing activity) and activities of daily living.

3. The patient reports feeling that his or her emotions are in a state of “being out of control.”

The examination scheme is designed to evaluate for the presence of a neurovascular entrapment syndrome; however, the examination should be planned out to match the patient’s current presentation and tissue irritability. The common signs in addition to the more traditional musculoskeletal signs are reassessed after intervention and serve as guides in determining the effectiveness of treatment.

Common Signs of Neurovascular Entrapment

1. Abnormal hand temperature within the following parameters:
 - a. Cold hands defined as in the 70°F range at rest and during activity at the target task
 - b. Asymmetry between the temperatures of the second digit and the fifth digit, with the fifth digit being colder⁸⁸
2. Abnormal breathing pattern: accessory, chest, or paradoxical rather than diaphragmatic.
3. Abnormal mobility and sensitivity of the nervous system: specifically, the dura, the brachial plexus, the sciatic nerve, or sacral plexus.
4. Sensory dysfunction of the involved hand.
5. A combination of positive diagnostic tests to help rule in the condition.

This combination of symptoms and signs can identify a neurovascular component of the patient presentation. Improvements in these signs and symptoms serve as markers that identify treatment effectiveness—namely, a decrease in pain, an improvement in function, and a feeling of being more in control.

Neurovascular Entrapment Interventions

Treatment must follow the same principles that guide the examination; that is, the patient is taught self-assessment techniques and strategies to encourage active self-control of their treatment and activities of daily living. The patient may use any of the following self-assessment techniques, as appropriate, to guide the course of treatment: pain scale, hand temperature, active neurodynamic test, or grip strength test. Any treatment or activity that increases symptoms, and any protective posturing or tension is modified or discontinued.

Maximizing a positive treatment response requires a unique partnership between the physical therapist and the patient that facilitates a therapeutic alliance and the patient’s feeling of being in control. The feeling of being in control is thought to have a positive impact on the response to treatment. The patient–therapist relationship is enhanced by providing simple, clear explanations of the condition.⁸⁹ Treatment should reflect the individual needs of the patient and their preferences.⁸⁹ By doing this, the therapist is likely to improve the patient’s compliance with their program and active participation in the rehabilitation process. The patients are provided with self-assessment tools and treatment options. They are taught methods for self-assessment of the immediate impact of each intervention. They are taught to assess their responses to the core program on the basis of signs and symptoms as indicated above (pain scale, hand temperature, active neurodynamic test, or grip strength test).

Our intention is not to present every component of a total treatment program, but rather to highlight those core components that address common impairments identified in patients with neurovascular disorders. Treatment is initiated by addressing breathing patterns if an abnormal breathing pattern is observed, such as a scalene breathing pattern. The patient is guided through a series of breathing exercises designed to improve the circulation to the extremities, calm the nervous system, and retrain the diaphragm and scalene muscles, if appropriate. The breathing exercises are progressed through the use of foam rollers (Fig. 16.5), which are used to increase the mobility of the spine

Fig. 16.5 Foam Roller Exercise for Mobilization of the Spine. The roller is placed underneath the spine with the patient in the supine position. The patient gently rolls from side to side to increase mobility of the spine.

Fig. 16.6 Patient in a Quadrupedal Position on a Therapy Ball With the Chin Tucked and the Neck Straight. The patient can lift an upper or lower extremity to provide a challenge to the muscles that stabilize the spine.

and rib cage. The breathing exercises are combined with functional movements of the trunk and extremities in a manner that mobilizes the nervous system. In Fig. 16.5, a strap was utilized to support the involved extremity. Once the patient is able to manage the symptoms, their treatment can progress to stabilization exercises with a gym ball (Fig. 16.6).

Core Components of Treatment

Intervention is prioritized based on the patient’s tissue irritability. Beyond addressing abnormal breathing patterning, it is recommended to initiate treatment at the most proximal impairments. Specific muscle reeducation for the longus capitis and longus colli of the cervical spine is accomplished utilizing Jull’s protocol.⁸⁴ The patient is taught to minimize mechanical stress to the cervical and thoracic spine through instruction in body mechanics. Manual therapy techniques to address impairments at the cervical and thoracic spine are also utilized, and the patient is taught self-mobilization techniques, as appropriate, for use at home. Manual therapy interventions and patient generated exercises commonly target the first rib and scalene musculature as these structures can impact neurovascular tissue in patients

with TOS and even CTS. If scapula dyskinesis is identified during the active motion portion of the examination and use of correction techniques alter the patient's symptoms, then scapula position is addressed in the rehabilitation process.⁹⁰ Scapula control is progressed from basic setting exercises for the patient to obtain the optimal position followed by progression to control of the scapula with humeral active motion.⁹⁰

Hand temperature, neurodynamic impairments, and breathing dysfunctions are addressed by training the patient to perform relaxed diaphragmatic breathing with spinal motion (see Fig. 16.2). The expected outcomes are to normalize hand temperature and to increase range of motion of the involved extremity while decreasing sensitivity of the nervous system. Adverse neurodynamics are also addressed by treating soft tissue impairments identified along the course of the nerve with utilization of slider techniques. Slider techniques produce

the largest amount of nerve excursion with minimal strain compared to tensioner techniques.⁹¹ Coppiters and Alshami,⁹² in a cadaver study of nerve gliding, noted increased strain on the median nerve in positions of wrist extension combined with elbow extension. Addressing the interfacing soft tissue along with slider techniques can contribute to a reduction in neuromechanosensitivity of the involved extremity. Low cardiovascular endurance is addressed by having the patient begin a progressive aerobic conditioning program of walking. The goal of treatment should not only focus on improving the clinical signs and symptoms found on examination, but also the patient's overall functional status. Continual reassessment of key clinical indicators throughout treatment, and reassessment of the patient-reported outcome measures, inform the patient and clinician how to progress each element of the entire rehabilitation program.

CASE STUDY

The following case example describes brief components of this patient's initial physical therapy examination and treatment. This presentation is not meant to describe a complete case but rather to illuminate key concepts in the clinical reasoning behind the physical therapy examination, the assessment, and the plan of care in a patient with signs and symptoms of neurovascular entrapment.

Patient Description

The patient was a 50-year-old male who was left-hand dominant. He presented with a 12-week history of tingling and pain in his left hand. The symptoms were located in the palmar aspect of the hand and included the thumb, index, and long fingers. The body chart demonstrates the location and description of the patient's symptoms (Fig. 16.7). He denied any specific injury to the left hand and stated the symptoms had progressed over the past 12 weeks. The symptoms were described as constant and variable and were worse at night. The patient was unable to work as a carpenter and martial arts instructor due to these left-hand symptoms.

The patient reported the following *aggravating factors*: (1) Playing drums would increase left-hand symptoms within 5 minutes. (2) Unable to play the guitar due to left-hand symptoms within 2 to 3 minutes. (3) Diminished left-hand coordination/dexterity. The patient noted consistently dropping items from his left hand. *Easing factors* for the patient's symptoms included shaking his left hand or avoiding the use of the left hand. *24-hour behavior*: Sleep was interrupted due to left-hand tingling. The patient indicated that left-hand symptoms were more intense at night and required frequent position changes. He reported waking every 2 hours and his ability to return to sleep varied. He complained of feeling fatigued due to lack of regular sleep. Symptoms in the morning and during the day were largely dependent on the use of his left hand.

Past history included neck pain that was diagnosed as a C6 disc herniation 12 years ago. He indicated multiple upper extremity injuries from martial arts training and three bicycle accidents. The current symptoms in his left hand had not been experienced in the past.

Clinical Reasoning

Diagnostic hypothesis is based on the subjective examination findings:

1. Potential C6/7 referral due to past history of neck pain and location of symptoms
2. Potential carpal tunnel syndrome (CTS) due to location and description of symptoms
3. Potential median nerve entrapment proximally with altered neural dynamics
4. Nonmusculoskeletal condition:
 - a. Night symptoms require further screening

Physical Examination

In sitting, the patient demonstrated an increase in thoracic kyphosis without evidence of head on neck deviations. The patient's breathing pattern appeared

normal at rest while sitting. Based on the patient's body chart and symptom description, the nervous system was considered a potential source of symptoms. (See Table 16.2 for suggested modifications to a biomechanically based musculoskeletal examination to use when the nervous system is considered a significant source of dysfunction.)

The patient was instructed to complete active motions to the limit of his range and indicate the onset of symptoms during movement testing. The physical examination was planned to help rule in/out competing hypotheses such as the cervical spine and CTS. The general health screen and basic vital sign assessment assisted in reducing the suspicion of a nonmusculoskeletal source of symptoms. The patient was asked to complete a functional test mimicking guitar playing. Modification of cervical position did not produce symptoms; however, manual cervical traction provided relief of the patient's left-hand symptoms.

Active cervical range of motion revealed motion loss with left rotation and lateral flexion with a firm end feel compared to right rotation and lateral flexion. Limitations in left rotation and lateral flexion produced local neck pain; however, these movements did not aggravate his left-hand symptoms. Grip strength was tested using a grip dynamometer and revealed a significant side-to-side difference, with the right at 105 pounds and the left at 75 pounds.

Neurovascular examination revealed reproduction of the patient's left-hand symptoms with direct palpation of the median nerve proximally at the humerus. Neurodynamic testing emphasizing the median nerve, both active and passive, reproduced the patient's left-hand symptoms. Special tests utilized to rule in/out CTS, including Phalen, Tinel, and the compression test at the carpal tunnel, all reproduced the patient's symptoms.

Based on the patient's past history, cervical motion loss with left rotation and lateral flexion, and relief of symptoms with manual traction, an accessory mobility test of the cervical spine was conducted. This test revealed hypomobility of the C6 and C7 motion segments as well as T1 to T3 motion segments. The left-hand symptoms were not reproduced during accessory mobility testing.

Clinical Reasoning

Diagnostic hypothesis is based on physical examination findings:

1. Carpal tunnel syndrome
2. Double crush syndrome
3. Altered neural dynamics based on the presence of:
 - a. Provocation of distal symptoms with direct palpation of the median nerve
 - b. Active and passive neurodynamic test of the median nerve produces left hand symptoms

Intervention

The patient was taught a neural dynamic self-assessment technique that primarily sensitized the median nerve. He was instructed to use this test to evaluate his response to activity. If he had a negative response to an exercise or activities

CASE STUDY—cont'd

of daily living—as evidenced by an increase in symptoms or a decrease in the range of his arm self-test—he was instructed to modify or discontinue the activity and perform a self-treatment that restored his tension-free range.

Given the physical examination findings and hypothesis regarding a double crush pathology, manual therapy was deemed appropriate. The patient was treated with left downglide mobilizations into tissue/joint resistance directed at C6 and C7, followed by manual cervical traction. Immediate reassessment of median nerve palpation and upper limb neurodynamic testing revealed reduction in symptoms and improvement in mobility. Active cervical left rotation was unchanged. Instruction in self-traction with a towel was provided as part of his home exercise program, including instruction to use his self-test before and after traction (Fig. 16.8).

A slider exercise was implemented and directed primarily at the median nerve. An active slider exercise was chosen for excursion of the median nerve with minimal tensile stress. The slider exercise was followed by instruction in exercise on the foam roller. The intention of the foam roller exercise was to help mobilize his thoracic spine to improve his cervical posture on his own. After the slider and foam roller exercise, he maintained improvement in the tension-free range of his left arm self-test. The patient was instructed to complete these exercises 3 to 4 times per day and consistently monitor for changes in his signs and symptoms. Education included positioning for sleep at night, the use of a towel roll to support the cervical spine, and the use of a body pillow for arm support. Given the relief experienced with traction, the patient was encouraged to utilize towel traction prior to bed in an attempt to reduce symptoms and to improve sleep.

The plan for future visits should include continued use of manual therapy intervention targeting hypomobility of the cervical and upper thoracic spine as needed. Exercise progression should be based on the patient's symptoms and neural irritability. Progression of his exercise program should include scapula stabilization prone on a therapy ball (see Fig. 16.6), postural strengthening, and functional grip. Simulated work tasks, ergonomic improvements, and progression to recreational activities should be addressed, including emphasis on continued self-assessment of the response of the nervous system to the progression of activity.

Discussion

This case illustrates the importance of evaluating the role of the nervous system in patients with signs and symptoms associated with repetitive use of the upper extremity. In this case example the patient's problem was chronic without a specific injury. On further investigation he reported cervical symptoms in the past that needed to be explored given the potential relationship to his current complaint. The cervical symptoms could have delayed his recovery if not appropriately assessed on initial examination. As discussed earlier in this chapter, Upton and McComas³⁵ first reported the double crush phenomenon, and this case demonstrates the relationship between lesions at the carpal tunnel and the cervical spine. It is likely that the patient's past cervical involvement at the C6 level contributed to the restricted neural mobility along the median nerve; however, one is only able to theorize about the order of these lesions. Pain mechanisms for this patient were classified as primarily peripheral neuropathic with a nociceptive component. There was no evidence of central sensitivity based on the signs and symptoms presented by Smart and colleagues.⁷² The most significant finding is that treatment directed at the cervical spine impacted the distal symptoms and reduced the neural sensitivity. There can be a wide spectrum of presentations of neurovascular entrapments ranging from subtle signs and symptoms of nervous system involvement to dramatic, life-altering, complex problems in patients who have undergone multiple medical and surgical interventions without obtaining symptom relief. The key to success in treating patients with neurovascular entrapments is recognizing the signs and symptoms of subtle nervous system involvement early. Neural sensitization⁴ and possible processing changes in the central nervous system^{72,73} necessitate evaluation of the nervous system as a potential source of symptoms in patients with symptoms

of repetitive use. If the issues of nervous system irritability and sensitization are not addressed during evaluation and throughout treatment, then the risk for increasing the patient's symptoms and continuing the cycle of nervous system hypersensitivity is high.

The indicators that this patient may have had a nervous system dysfunction were his description of symptoms, aggravating factors that included repetitive use, and the pattern of his symptoms. The indicators of nervous system dysfunction on physical examination were the restricted upper limb neural dynamic test (active and passive) and symptomatic response to palpation of the median nerve. Another objective indicator not assessed initially that may have further guided the treatment could have been measuring the temperature of the patient's hands.⁸⁸

A key concept to keep in mind is the role of education in treating patients with a problem such as neurovascular entrapment. Patient–clinician communication is extremely important when dealing with all patients, but the clinician's communication skills are especially challenged when dealing with a patient who has a neurovascular entrapment. Describing the dysfunction of a neurovascular entrapment to the patient in succinct, nonmedical terminology can be quite difficult, but it is a critical step in the patient encounter to help him or her develop an understanding of what is wrong so he or she can engage in self-treatment. Teaching patients self-assessment tools restores their control, allowing them to guide their own treatment and to be more responsible for their own well-being.

Questions

1. How vigorous should the objective exam be in a patient with suspected neurovascular entrapment?

Answer: The objective or physical exam vigor is based on the patient's tissue irritability. This is established during the subjective exam and is monitored over the course of the physical exam. In this patient case, the patient's symptoms were worse at night and resulted in the patient waking every 2 h. This piece of information alone could lead the clinician to suspect a higher level of irritability; however, when one considers that during the day the patient is able to complete functional tasks without significant worsening in the intensity of his symptoms, then irritability is considered low. Classifying the patient's irritability as minimal allowed the examination to proceed with active and passive movements to the limits of available motion while monitoring symptom onset/response. If the patient had presented with irritability that was classified as moderate to high, then the examination would have been altered, instructing the patient to move just to the onset of symptoms. The number of examination items was not limited in this patient case given the low irritability and the desire to rule in/out CTS. If the irritability was classified as moderate to high, then the number of examination items would have been reduced with emphasis placed instead on symptom control.

2. How would you instruct a patient to do an active self-test of the arm?

Answer: I say to the patient "I am going to ask you to place your arm in a sequence of positions. I want you to stop when you feel tightness anywhere in your arm or if you feel an increase or change in your symptoms. We will redo the self-test after we have done some exercises. That way you can decide which exercise helps you the most." After the patient has completed one form of treatment followed by a reassessment self-test, then I help the patient interpret the symptom response. "If your self-test result was worse (less arm range or increased pain), it means that your nervous system was moved too far and is more sensitive. This means that the exercise we tried is too vigorous for you at this time. If your self-test result was better (greater range, less pain), then this exercise was helpful and was calming to your nervous system. The self-test is something you can always use to help you evaluate whether an exercise or activity is going to be appropriate or too vigorous for your arms."

Fig. 16.7 Body Chart With Symptomatic Areas Marked by the Patient in the Case Study.

Abstract: The purpose of this chapter is twofold. The first purpose is to develop the concept that the entire nervous system forms a continuous tissue tract. This concept is central to the idea that movements of the trunk and/or limbs can have a profound biomechanical and physiological impact on the peripheral nervous system (PNS) and central nervous system (CNS). The second purpose of this chapter is to develop in the reader an understanding of neurovascular entrapment syndrome. This is an underrecognized impairment present in some patients with a wide variety of diagnoses—for example, nonspecific arm pain, repetitive strain

injury, carpal tunnel syndrome, and thoracic outlet syndrome. Standard medical care frequently fails with these patients. A theoretical model for the development and perpetuation of neurovascular entrapment syndrome is presented. Background information regarding the syndrome is provided, and the appropriate screening tools for assessment of the impairment are discussed. Treatment suggestions and a case study are presented at the end of the chapter.

Keywords: neurovascular entrapment, peripheral nerve entrapment, peripheral nervous system mobility, adverse neurodynamics, neurological tension tests, neurodynamic testing

Multiple Sclerosis

Gail L. Widener and Kristin Horn

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the pathological processes, prevalence, and clinical presentation of people with multiple sclerosis.
2. Compare and contrast the subtypes of multiple sclerosis and the common disease progression in each.
3. Discuss the medical management of the disease and the disease symptoms, including diagnosis and treatment.
4. Describe the concept of variability and how it applies to people with multiple sclerosis, pathology, medical management, and rehabilitation.
5. Describe how the International Classification of Functioning, Disability and Health provides a common language for describing the impact of disease on people with multiple sclerosis and how it provides a framework for rehabilitation management.
6. Describe the outcome measures that can be used to examine people with multiple sclerosis that cover body system problems (impairments), functional skill and activity limitations, participation restrictions, and quality of life.
7. Develop a rehabilitation plan of care using evidence-based interventions to maximize patient function and quality of life.

remission
secondary progressive

OVERVIEW OF MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a progressive disease of the central nervous system that can impact the brain, spinal cord, and optic nerve. Because there is no known cure for the disease, rehabilitation is fundamental to management of the various symptoms and dysfunctions that occur. One key aspect of this disease for rehabilitation clinicians to understand is variability. This applies to how the disease initially manifests, how it progresses, and the medical and rehabilitation interventions used to slow disease progression and enhance function. The clinical presentation and disease progression of each person with MS will be unique. This requires clinicians to assess each patient/client individually and collaborate with them to determine the optimal plan of care.

Incidence and Prevalence

MS is one of the most common causes of nontraumatic disability in young people and adults¹ and is the most common inflammatory condition of the central nervous system (CNS). It is reported that approximately 400,000 people in the United States and over 2.5 million people worldwide have the disease.² People are most commonly diagnosed between 20 to 50 years of age, with the average age around 31.¹

However, MS can be diagnosed in people of almost any age. Approximately 3% to 5% of all people with MS are diagnosed before their 18th birthday, with an estimated 10,000 children and adolescents with MS in the United States.³⁻⁵ Another 15,000 people aged 18 years or less have symptoms consistent with MS.²

MS is found in people who reside above the northern or below the southern latitude of 40 degrees with greater frequency than in those who live closer to the equator (Fig. 17.1). Given the increased sun exposure of people living closer to the equator, lack of vitamin D is being investigated as a potential factor contributing to disease development⁶; there is a reduced relapse rate noted with higher blood levels.⁷ Other environmental risk factors include smoking, obesity,⁸ and exposure to infectious agents: Epstein-Barr virus and infectious mononucleosis are currently considered the most likely candidates.^{9,10} Additionally, genetics may play a role in the development of MS. An identical twin with MS means that the other twin will have a 25% chance of diagnosis, suggesting something beyond genetics. Having a first-degree relative with MS will increase the risk of disease from 1 in 750 to 1 in 40.² Currently, the most likely genetic factor linked to MS is a form of the HLA-DRB1 gene.¹¹

Women are affected 1.5 to 2.5 times more frequently than men.¹² Men are, however, more likely to have a more aggressive disease progression and a worse prognosis.^{13,14} It has been generally accepted that

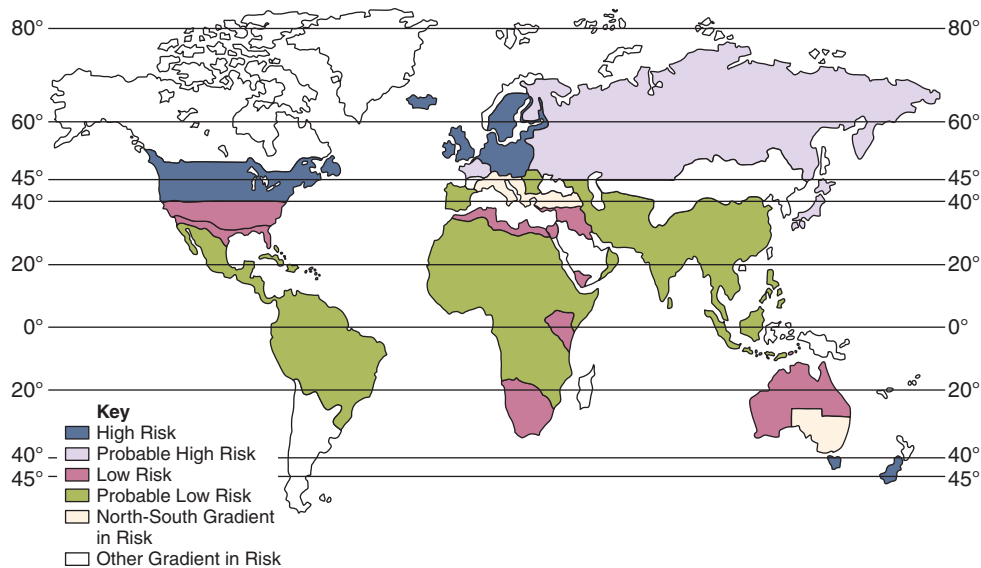

Fig. 17.1 World Distribution of Multiple Sclerosis. (From Multiple Sclerosis Resource Center, www.mscc.co.uk.)

Caucasians with Northern European ancestry have the greatest incidence of MS, whereas people of Asian, African, or Hispanic ethnicity are at lower risk. However, these findings may represent a significant bias as few studies have looked at the incidence and prevalence of MS in many parts of the world, including Africa, Asia, and the Middle East,¹⁵ which may put the longitudinal hypothesis into question. A recent investigation in the US found that African Americans have a greater incidence than whites, with black females having the highest incidence.¹⁶ African Americans develop MS at an earlier age,¹⁷ have more frequent relapses and become disabled earlier than Caucasians,¹⁸ and have a greater risk of developing progressive disease.¹⁹ These factors suggest that tissue destruction occurs earlier and progresses more rapidly in this population.¹⁸ Additionally, African Americans with MS have poorer responses to disease modifying medications.²⁰ In contrast,

Inuits, Yakutes, Hutterites, Hungarian Romani, Norwegian Lapps, Australian Aborigines, and New Zealand Maoris do not appear to develop MS.²¹ Overall, being diagnosed with MS may be related to age, sex, genetics, geography, or ethnic background.

Subtypes of Multiple Sclerosis

Several MS disease phenotypes or subtypes have been identified (Fig. 17.2). Importantly, the course of the disease is highly variable regardless of the subtype of MS.

The initial neurological episode or attack is typically identified as the *clinically isolated syndrome* (CIS). Symptoms must last for at least 24 hours and can be monofocal or multifocal. If lesions are present on magnetic resonance imaging (MRI), there is a high risk of developing MS. In one group of people with CIS followed for 20 years, 63% were

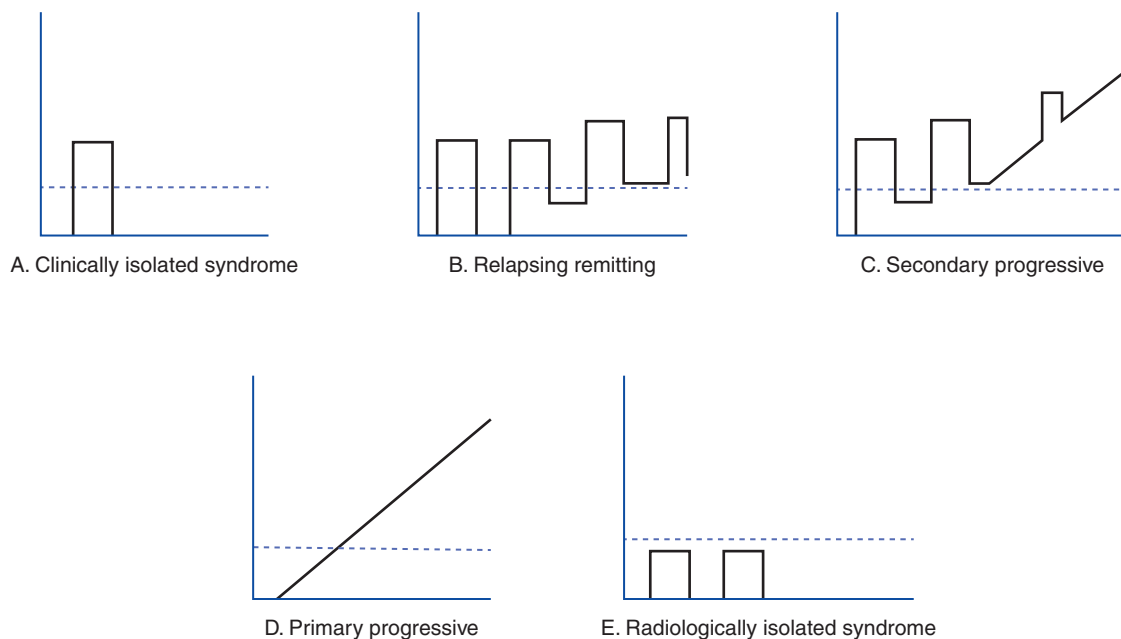

Fig. 17.2 Types of Multiple Sclerosis.

eventually diagnosed with definite MS.¹⁰ The newly revised McDonald criteria for diagnosing MS²² encourages the identification of lesions on MRI that indicate prior disease activity, thus allowing earlier diagnosis (see Fig. 17.2A).

Relapsing remitting MS (RRMS) (see Fig. 17.2B) represents about 85% of people with MS, characterized by exacerbations (attacks, relapses) that can last days to months and are typically followed by periods of less active disease or remissions. During remissions, function can return to prerelapse levels, but most frequently recovery is not complete. Attacks normally occur with a frequency of one or two per year. Approximately 90% of people with RRMS transition to *secondary progressive MS (SPMS)* 10 to 15 years after diagnosis (Fig. 17.2C).^{11,23}

With SPMS, relapses may occur early but gradually lessen over time and convert to a steady progression of increasing disability and disease severity. It is thought that the clinical disability associated with SPMS results from the neurodegeneration that occurs as a result of tissue injury that accumulates from early in the disease process. In addition to less inflammation, there is a greater amount of brain atrophy in people with SPMS compared with RRMS. Fig. 17.3 shows the natural history of RMS and SPMS, comparing the change in brain volume with increasing clinical disability and disease burden.²⁴

Primary progressive MS (PPMS) is less common, affecting only 10% to 15% of people with MS. From disease onset, progression results in a gradual worsening of symptoms without relapses. People tend to be older when diagnosed (late 30s or early 40s), have fewer abnormalities on brain MRI, and respond less favorably to standard MS drug therapies. Progressive myelopathy is commonly associated with PPMS (see Fig. 17.2D).

The term *radiologically isolated syndrome (RIS)* is used to describe a group of individuals whose imaging studies (MRI) strongly suggest the presence of MS; however, they have no clinical manifestations of the disease (see Fig. 17.2E). These individuals are typically identified after MRI has been prescribed for an unrelated concern, such as headaches. Small studies indicate that about a third of these people develop MS within 5 years; there is an increased risk of developing MS in individuals with asymptomatic lesions in the spinal cord.²⁵

Fig. 17.3 Natural history of relapsing remitting multiple sclerosis (RRMS)—conversion to secondary progressive multiple sclerosis (SPMS). Figure shows the typical clinical course of RRMS with conversion to SPMS. Magnetic resonance imaging (MRI) activity (gray line and boxes) indicates the inflammatory lesions; they occur more frequently early in the disease and occur with greater frequency than in clinical disability (solid black line). Brain volume indicated by the stippled line shows brain atrophy increasing as the inflammatory component of the disease slows and is replaced by neurodegeneration.

There is a push to categorize people with MS as either relapsing (RMS) or progressive (PMS), with primary or secondary as two types of progressive disease.²³

Pathology

Multiple sclerosis is an incurable autoimmune disease resulting from dysregulation of the immune system, both T-cells and B-cells. Initiation of immune system dysregulation may occur in response to genetic and environmental factors discussed above.⁸ The disease is characterized by inflammation, demyelination, axonal injury, and death that are present in lesions throughout the CNS.^{15,26} Initially, MS was thought to be a disease of the white matter (WM) or myelinated parts of the neurons; however, the gray matter (GM), primarily neuron cell bodies, is significantly involved from early in the disease. Areas of demyelination and axonal damage interfere with normal conduction of neural signals, leading to a disruption of function.

Early in the course of the disease, lesions are composed of proinflammatory immune system components that produce demyelination, axonal injury, and loss of oligodendrocytes, referred to as *active disease*. Astrogliosis activated by the damaged neurons produces gliotic scarring called *plaques*. Plaques are visualized as sclerosis in postmortem brain tissue, hence the name multiple sclerosis. Active disease is followed by periods of remission in which acute inflammation is reduced (*inactive disease*). Axonal remyelination occurs but is highly variable and in RMS is related to recovery of function during periods of remission. Treatment in the initial stages of the RMS disease is aimed at reducing inflammation and immune system dysfunction with disease-modifying therapies (DMTs).

Later in the course of the disease inflammation becomes more diffuse while demyelination and axonal loss continue, suggesting a greater neurodegenerative process.²⁷ In most individuals, disease progression becomes more constant with a lack of exacerbation. Owing to the lack of inflammation, DMTs are less effective in progressive forms of the disease.

Brief Description of the Common Clinical Manifestations

MS can affect the optic nerve and any tissue within the brain or spinal cord, so almost any neurological symptom can result. Individual assessments are required to identify the problems present. The following list, however, constitutes the most common problems encountered by people with MS.

Due to the heterogeneous nature of the disease, symptoms are widespread according to the part or parts of the CNS that are affected. Common symptoms include fatigue, weakness, spasticity, sensory impairments (vision, somatosensation, vestibular, and hearing), pain, bladder or bowel dysfunction, tremor, incoordination or ataxia, sexual dysfunction, disorders of emotion, dysarthria, and dysphagia. Dysfunctions related to the disease include mobility and balance impairments and cognitive deficits. The most commonly reported problems in RMS are paresthesia, fatigue, and weakness, while PMS includes balance dysfunction and fatigue.²⁸ The symptoms most related to a reduced health-related quality of life for people with relapsing disease are balance dysfunction, spasticity, and depression while spasticity, paralysis, weakness, and pain have the greatest impacts in PMS.²⁸

MEDICAL MANAGEMENT

Diagnosis

Historically, people with MS would wait for a diagnosis for a year or more—sometimes even longer. Although there are no definitive tests that diagnose MS, the addition of MRI has accelerated diagnosis. In 2001 the International Panel on the Diagnosis of Multiple Sclerosis

updated criteria to include MRI, visual evoked potentials, and cerebrospinal fluid (CSF) analysis published as the McDonald criteria.²² Revisions to these criteria occurred in 2005 and 2010, with the latest iteration in 2017.

Key requirements for MS diagnosis in the 2017 McDonald criteria include dissemination of lesions in the CNS in space and time. Demonstration of dissemination in space on clinical exam or MRI plus the presence of oligoclonal bands found in CSF enable the diagnosis of MS. Additionally, lesions on MRI with clinical sequelae can be used to demonstrate the presence of disease in space or time in patients with supratentorial, infratentorial, or spinal cord lesions. Cortical lesions can be used to indicate dissemination in space.

Due, in part, to the increased use of paraclinical assessments (MRI, CSF, and evoked potentials) the diagnosis of MS is occurring earlier, and treatment is begun more quickly with the hope that this will result in a slower accumulation of clinical disability or even reduction in the total disability experienced by individuals with MS. Even with the improved technological measures used to facilitate diagnosis, an accurate clinical history is critical. Historically, diagnosis of MS often required many years with the onset of more than one clinical episode of MS. Often patients recall episodes of transient symptoms that did not last long enough to require attention by a primary care provider.

MRI studies have shortened the time taken to diagnose MS. Although T2-weighted MRI images show MS lesions as hyperintense and identify new or active inflammatory lesions, MRI has been shown (Fig. 17.4) to overestimate clinical relapses. Conventional MRI with T1 weighting identifies older lesions (with less inflammation) as hypointense (black holes) and can identify brain atrophy. T1 imaging demonstrates a stronger correlation with clinical status and disease severity than the lesion load found with T2 weighting. Gadolinium-enhanced T1-weighted MRI images also show active inflammatory MS lesions as hyperintense (white). Lesions identified on MRI that are characteristic

Fig. 17.4 T2-weighted magnetic resonance imaging scan of plaques associated with multiple sclerosis. Plaques are indicated by arrows. (From Frey H, Lahtinen A, Heinonen T, et al. Clinical application of MRI image processing in neurology. *Int J Bioelectromagnet.* 1999;1[1].)

of MS include periventricular, cortical or juxtacortical, and infratentorial lesions, as well as lesions that span 1 to 2 segments in the spinal cord.²² Therefore the presence of both old and new lesions on MRI fulfills the criterion of dissemination in time.

Two additional paraclinical tests can be used to aid in the diagnosis of MS and differentiate it from other diseases and conditions. The first is analysis of CSF. This requires a lumbar puncture in which CSF is gathered and analyzed to identify *oligoclonal bands* indicating the presence of immune system proteins (immunoglobulins) or active inflammation. The majority of people with MS have oligoclonal bands; however, because people with other diseases or conditions also have oligoclonal bands, the test is not specific for MS. The lack of oligoclonal bands at diagnosis has been related to a slower progression of the disease and increased time to reach markers of disability such as walking with an assistive device.

Evoked potentials record the nervous system's response to stimulation of a specific sensory pathway (visual, auditory, vestibular, or general somatosensory). Evoked potentials use an externally evoked sensory stimulus to activate the specific sensory system while the timing of the response to the stimulus is monitored. Demyelination and axonal degeneration cause a slowing of signal transmission along stimulated neurons and therefore will increase the time it takes to respond to the presented stimulus. Damage to the optic system is a common first symptom in MS, and therefore visual evoked potentials are often helpful in diagnosis.

Quantifying Disease Severity

Evidence supporting many interventions for individuals with MS has been researched according to how severely an individual is impacted by the disease. Severity of disease and progression can be monitored by ongoing clinical assessments, MRI imaging, and the use of several outcome measures. The Kurtzke Disease Severity Scale,²⁹ an outcome measure, was initially developed to allow primary care providers a way to measure clinical disability and monitor disease progression. It has been replaced by the Expanded Disability Status Scale³⁰ (EDSS) (Table 17.1). The EDSS is a 11-point ordinal scale completed by a physician or physician extender, with 0 indicating no disability and 10 indicating death caused by MS. The scale addresses 8 functional systems (pyramidal, cerebellar, brain stem, sensory, bladder/bowel, visual, cerebral [mental], and ambulatory status).³¹ Mild disease severity is related to EDSS scores of 0 to 3, moderate disease 4 to 6.5, and severe disease indicated by scores greater than 6.5. Scores greater than 4 are primarily determined by ambulatory status. Using a unilateral assistive device such as a cane or crutch equals an EDSS score of 6.0, while a 6.5 indicates the need for bilateral assistance. Levels beyond 6.5 indicate a progressive non-ambulatory status. The National MS Society (NMSS) Task Force on Clinical Outcomes Assessment also recommends the Multiple Sclerosis Functional Composite (MSFC)³² as a measure of disease severity and progression. This set of outcome measures is used to chart change in physical and cognitive function. It includes three tests that measure upper-extremity function (Nine-Hole Peg Test [NHPT]), lower-extremity function and mobility (25-Foot Timed Walk [25FTW]), and cognitive function (Paced Auditory Serial Addition Test [PASAT]). In the past, the EDSS and MSFC outcome measures have been used extensively in research evaluating the impact of various pharmaceuticals or rehabilitation interventions on people with MS. Disease severity can also be measured by therapist observation of ambulation (Disease Steps)³³ or via patient self-report (Patient Determined Disease Steps)³⁴ with both of these measures having high correlations with the EDSS.

TABLE 17.1 Expanded Disability Status Scale

Score	Description
0	Neurologically normal
1.0	No disability, minimal signs in one FS
1.5	No disability, minimal signs in more than one FS
2.0	Minimal disability in one FS
2.5	Mild disability in one FS or minimal disability in two FS
3.0	Moderate disability in one FS, or mild disability in 3 or 4 FS. No walking impairments
3.5	Moderate disability in one FS and more than minimal disability in several others. No walking impairment
4.0	Significant disability and self-sufficient and able to be up and about 12 h a day. Able to walk without aid or rest 500 m
4.5	Significant disability and up and around much of the day, able to work a full day, may have some limitation of full activity or require minimal assistance. Able to walk without aid or rest 300 m
5.0	Disability severe enough to limit full day activity and ability to work a full day without special requirements. Able to walk without aid or rest 200 m
5.5	Disability severe enough to limit full day activity. Able to walk without aid or rest 100 m
6.0	Requires assistance to walk—one cane or crutch, etc. Able to walk 100 m with or without rest
6.5	Requires two walking aids—canes, crutches, walker, etc. Able to walk about 20 m without rest
7.0	Unable to walk more than 5 m with or without aid. Essentially restricted to wheelchair (WC) for mobility. Can independently propel self in WC, perform transfers. Able to be up and about for about 12 h a day
7.5	Unable to take more than a few steps. Restricted to WC and may need aid in transferring. Can wheel self and cannot carry on in a standard WC for a full day, may require a motorized WC
8.0	Essentially restricted to bed, chair, or dependent in WC. May be out of bed for much of the day. Retains many self-care abilities. Generally, has effective use of arms
8.5	Essentially restricted to bed much of the day. Has some arm function and retains some self-care abilities
9.0	Confined to bed. Can still communicate and eat
9.5	Confined to bed and totally dependent. Unable to communicate effectively or eat/swallow
10.0	Death due to MS

FS, Functional systems (FS include pyramidal, cerebellar, brain stem, sensory, bladder/bowel, visual, cerebral, and ambulatory status); MS, multiple sclerosis; WC, wheelchair.

Medical Management of Disease

Disease-Modifying Therapeutics

Disease-modifying therapeutics (DMTs) are aimed at reducing immune system dysfunction, thereby reducing damage to neural tissue and long-term disability for people with RMS. There are several different medications that act on various components of the immune system with the intention of modifying the course of the disease (Table 17.2). These drugs can be injected, taken orally, or infused. In general, most of the drugs are approved for use with RMS and have been shown to reduce the number of attacks experienced. These drugs are often used off-label for other forms of MS. Measurement of therapeutic effectiveness includes relapse rate, progression of disability (EDSS), and quantitative evidence of lesions on MRI. All DMTs have side effects (see Table 17.2), and some of them are very serious. Medications with more serious side effects are generally used if drugs with fewer side effects have failed or produced breakthrough relapses. It is common that people will try several DMTs before finding the one they best tolerate.

Ocrelizumab is a new drug that targets B-cells and is the first to be approved by the FDA for use with PMS. Several of the DMTs are typically used with RMS and PMS when there is evidence of inflammation in the form of relapses or active disease on MRI, but they appear to be less effective if inflammation is no longer present.

Management of Acute Relapses (Antiinflammatory Medications)

High-dose corticosteroids (such as prednisone or methylprednisolone) are used to reduce the inflammatory response during exacerbations for people with RMS. These drugs are generally given over 3 to 5 days via IV (Solu-Medrol) or orally (Deltasone). An additional medication is injection of HP Acthar Gel, a purified form of adrenocorticotrophic hormone. Lastly, plasmapheresis can be used for severe relapses that do not respond to the other forms of treatment. Although no medications have demonstrated effectiveness in people with PMS, anecdotal evidence suggests that intermittent pulses of intravenous methylprednisolone can help slow progression of clinical disability in some patients.²⁴

TABLE 17.2 Disease Modifying Therapeutics for Multiple Sclerosis

Disease Modifying Agent	Indication	Common Side Effects	Disease Modifying Agent	Indication	Common Side Effects
Injectable Medications (All Can Have Infusion Site Reactions)			Infused Medications (All Can Result in Infusion Reactions)		
IFN β -1a (Avonex, Rebif)	RMS	Flulike symptoms Injection-site reactions	Alemtuzumab (Lemtrada)	RMS	Infections (urinary, respiratory, viral, and fungal) Itching Pain and paresthesia
IFN β -1b (Betaseron, Extavia)		Depression Elevated liver enzymes			Dizziness Diarrhea Vomiting
Glatiramer acetate (Copaxone, Glatopa)	RMS	Systemic reactions/immediate postinjection Elevated liver enzymes	Mitoxantrone (Novantrone)	RMS SPMS	Cardiotoxicity Treatment related leukemia Infections Alopecia Amenorrhea Nausea
Peginterferon β -1a (Plegridy)	RMS	Hepatotoxicity Depression or suicidal thoughts			
Daclizumab (Zinbryta)	RMS	Withdrawn from worldwide market 2018	Natalizumab (Tysabri)	RMS	Hepatotoxicity Muscle weakness Headache Fatigue Pain Infections Depression
Oral Medications					
Dimethyl fumarate (Tecfidera)	RMS	Flushing Diarrhea Nausea Pain Elevated liver enzymes	Ocrelizumab (Ocrevus)	RMS PMS	Itching and hives Rash Fatigue Dizziness Shortness of breath and coughing Tachycardia Headache Pain
Fingolimod (Gilenya)	RMS	Flulike symptoms Increased liver enzymes Headache Diarrhea Pain Cough			
Teriflunomide (Aubagio)	RMS	Liver damage Diarrhea Nausea Influenza Alopecia Peripheral neuropathy			

PMS, Progressive multiple sclerosis; RMS, remitting multiple sclerosis; SPMS, secondary progressive multiple sclerosis.

Prognosis

More aggressive forms of MS are related to greater number of relapses in the first 2 years postdiagnosis, short intervals between first and second relapses, incomplete recovery from first attack and poor recovery from relapses, male sex, African American descent, older age at disease onset, initial symptoms involving the cerebellum or motor systems, or multifocal involvement at onset.^{35,36} Paraclinical factors related to more destructive disease include greater disease burden on MRI, evidence of brain atrophy, and low serum levels of vitamin D.²⁵ Previous research had reported that people with MS have a suicide rate that is twice that of the general population, with recently diagnosed younger males at greatest risk (Feinstein 2017).^{36a} A systematic review³⁷ found that suicide in MS was only slightly higher than an age-matched cohort. In general, people with MS live about 6 to 7 years less than healthy cohorts.^{38,39}

MULTIDISCIPLINARY MANAGEMENT OF CLINICAL MANIFESTATIONS

Overview

Physical rehabilitation has changed over the past 20 years for people with MS. Increasing evidence^{40–42} indicates that patients respond well

to exercise that was previously thought to be too fatiguing or led to increased relapses in this population. Such evidence provides guidance for those who can apply exercise appropriately. Appropriate application, however, varies from patient to patient. The myriad locations and combinations of CNS lesions in MS, along with the differences in individual lifestyles and genetic makeup, result in variable clinical presentations. No one approach represents the gold standard for rehabilitation management. Thus clinicians must assess the preferences and needs of each individual before negotiating with the patient/client the best interventions to prescribe.

Rehabilitation for people with MS occurs in every setting: inpatient hospital, outpatient clinics, skilled nursing facilities, home care, and community-based support or exercise groups. With the current health care climate of decreasing access to and reducing coverage for rehabilitation, therapists and the interprofessional team must be able to make evidence-based decisions for intervention effectiveness to insurers as well as patients. Effective interventions across settings and disciplines achieve the goals of optimal physical and cognitive functioning, safety, and quality of life for the individual with MS.

Throughout the episode of care, the patient/client's preferences and goals should guide rehabilitation—from assessment through intervention. An important framework for patient/client assessment is the

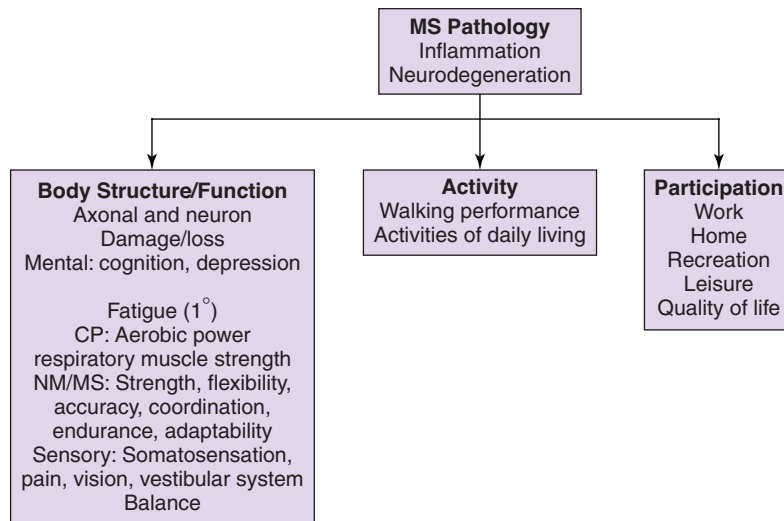

Fig. 17.5 Common Problems That Occur in People With Multiple Sclerosis. *CP*, Cardiopulmonary; *MS*, musculoskeletal; *NM*, neuromuscular.

Now		Would Like
6	My range of motion is like that of a star athlete or great performer.	6
5	My range of motion lets me move easily through both usual and nonroutine activities.	5
4	I have enough range of motion for all my daily activities.	4
3	My range of motion is limited at times, but I can usually do what I need to.	3
2	My lack of range of motion limits me so that I need help with some usual daily activities.	2
1	My range of motion is so poor that helpers have to do most of my daily activities for me.	1

Fig. 17.6 Sample Questions From the Movement Ability Measure.

International Classification of Functioning and Health: ICFH model (2001). See Chapter 1 for a complete description of this model. Fig. 17.5 describes the common problems that occur in people with MS.

Understanding the patient or patient's perspective is critical to achieving best results from rehabilitation. Several tools exist for documenting patients' preferences and have been used with MS; the Goal Attainment Scale (GAS),⁴³ the Canadian Occupation Performance Measure (COPM),⁴⁴ and the Patient-Specific Functional Scale (PSFS).⁴⁵ A more broad-based assessment of movement ability is the Movement Ability Measure (MAM) developed and validated by Allen (2007a and 2007b).^{45a,45b} This measure includes the six dimensions of movement—flexibility, strength, endurance, speed, accuracy, and adaptability—based on the Movement Continuum theory.⁴⁶ This self-report instrument records a patient's current and preferred movement ability in the performance of daily activities during home, work, and leisure. See Fig. 17.6 for a sample of the questions for flexibility. Examining patient-identified gaps between current and preferred abilities should guide therapists' assessment and interventions. In people with MS, these gaps correlate strongly with measures of physical performance, with the dimension of speed showing the greatest overall gap.⁴⁷ Fig. 17.7 illustrates the Movement Ability levels and gaps from an individual with MS.

To be most effective, rehabilitation must *challenge* each individual with sufficient *intensity* and *repetition*, be *specific* to the goals of the patient/therapist, and be *salient* to the patient. Application of these five concepts are critical to produce a relatively permanent change in the

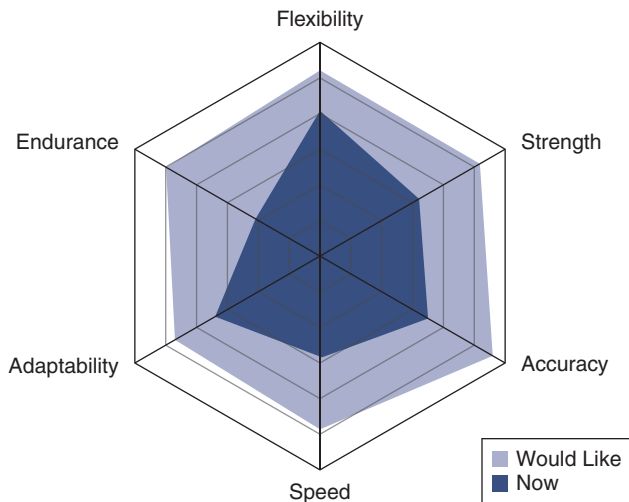

capacity to perform physical activities and skilled movement via physiological adaptation. To determine the correct dosage of intervention, assessment must be finely tuned to the individual's abilities and needs. Whenever possible, the goal should include restoration of impaired function rather than simply compensation for lost abilities as was common in the past. This section reviews and describes a multidisciplinary approach to addressing the common dysfunctions that occur with MS. It includes assessment tools for examining the patient's and patient's status, frameworks for applying rehabilitative techniques and interventions, and special considerations for rehabilitation in this population.

Assessment

The initial interview should include a quick screen or questioning about the body systems and areas that are commonly impaired in people with MS and the problems commonly encountered: motor strength, coordination, spasticity, sensory disruption (vestibular, visual, and somatosensory), bladder control, depression, and cognition. If impairments are present, there is a strong likelihood of negative impact on the patient's ability to perform activities of daily living (ADLs) or participate in meaningful life roles related to work, home, and leisure.

Special Dysfunctions Associated With Multiple Sclerosis

All patients with MS must be asked if they have fallen in the last 6 months because of the high fall rate in this population.^{48–50} Results

Dimension	Now	Would Like	Gap
Flexibility	4.1	5.2	-1.1
Strength	3.2	5.2	-2
Accuracy	3.5	5.6	-2.1
Speed	2.8	4.8	-2
Adaptability	3.4	4.7	-1.3
Endurance	2.1	5	-2.9
Total	19.1	30.5	-11.4

Fig. 17.7 Example of Patient Determined Gaps on the Movement Ability Measure.

of the patient/client interview and chart review will help develop hypotheses about which potential impairments might be contributing to the patient’s or patient’s presentation and difficulty participating in meaningful life roles. These hypotheses can help guide the therapist’s examination plan. The examination needs to be designed to observe the problematic tasks identified by the individual and test the therapist’s hypotheses about the causes of these activity limitations or participation restrictions.

During the assessment, examiners must determine if the problems identified by the patient (or those found by the assessor) fit within their scope of practice or whether the patient requires a referral to an appropriate health care professional. The Patient Health Questionnaire-2⁵¹ is a two-question depression screening tool found accurate for adolescents, adults, and older adults in the general population.⁵² See Fig. 17.8. A score of 3/6 indicates that major depression is likely, particularly in groups at higher risk for depression (such as people with MS), and

should trigger a referral to the patient’s primary care provider for follow-up. See Table 17.3 for signs and symptoms that may indicate a referral to another health care professional.

The physical examination should start with testing the patient’s ability to perform functional activities that the patient or his or her caregivers have identified as problematic. Activities may include performance of transfers, gait, ADLs, or cognitive tasks as well as the specific activities that the person states are impaired in his or her work, home, and recreational life. Examining the movement analysis of patient-identified key functional tasks will likely give the therapist insights into which body, structure, and function impairments are influencing the patient’s ability to complete the task in an optimal manner.

To gain a greater understanding of a patient’s prognosis and current presentation and track changes throughout the rehabilitation program, therapists may consider choosing a couple of outcome measures. Outcome measure selection is unique for each individual and should be dependent on the patient’s chief complaints and therapist-identified problematic areas. It is recommended that both subjective and objective outcome measures are included to gain a greater understanding of patient perspective and presentation. Comprehensive lists of standardized tests and measures for impairment, activity limitations, and participation restrictions and QOL are provided in Chapter 7. The next section of this chapter will focus on the tests and outcome measures found to be valid and reliable in the examination of individuals with MS. In 2011, the Academy of Neurologic Physical Therapy, a component of the American Physical Therapy Association, charged a group of experts in MS to recommend outcome measures for use in clinical practice, education, and research. The recommendations

TABLE 17.3 Common Referrals for People With Multiple Sclerosis

Signs/Symptoms	Appropriate Health Professional Referral
Changes in vision	Neuroophthalmologist/optometrist
Bladder dysfunction (nocturia, urgency, frequency, retention)	Neurologist, urologist, neurourologist, and pelvic physical therapist
Increase/change in spasticity/muscle tone	Neurologist
New onset of potential exacerbation	Neurologist
Depression/anxiety/other mental health manifestations	Psychologist
Balance deficits, falls, weakness	Physical therapist

Patient Health Questionnaire-2: Screening Instrument for Depression

Over the past two weeks, how often have you been bothered by any of the following problems?	Not at all	Several days	More than one-half the days	Nearly every day
Little interest or pleasure in doing things	0	1	2	3
Feeling down, depressed, or hopeless	0	1	2	3

Fig. 17.9. APTA MSEDGE Recommended Outcome Measures.

of this group were published in 2014 and are included in Fig. 17.9.⁵³ Through a modified Delphi process, this group chose outcome measures based on an extensive review of the literature concerning psychometric properties and clinical utility of outcome measures in people with MS. The critical review and recommendations for each outcome measure were entered into the Evaluation Database to Guide Effectiveness (EDGE) form and are available at: <https://www.google.com/search?q=APTA+MS+EDGE&ie=utf-8&oe=utf-8&patient=firefox-b-1>. Measures were chosen for use in people across the span of EDSS levels; across the ICF constructs of (1) body structure and function, (2) activity, and (3) participation; in settings in which patients with MS are managed—inpatient, outpatient, and at home; and use of the outcome measures in clinical practice, education, and research. Ratings of the outcome measures ranged from 1 to 4 with 4 representing the highest recommendation and 1 indicating not recommended due to low clinical utility, poor psychometric properties, and or the measure was not tested in MS.

Assessing Impairments and Activity

In general, standardized methods of examining muscle strength and endurance, somatosensation, vision, coordination, cardiovascular status and endurance, posture, muscle tone, reflexes, fatigue pain, and cognition are useful in examining individuals with MS. As with many neurological conditions, abnormal posturing or pain may necessitate using nonstandardized test positions or methods that must be noted in the patient documentation. If a patient is unable to attain the normal test position while performing a muscle strength test, the assessed strength is documented along with the position in which the muscle or muscle group was tested. Functional movement analysis is used to assess patients' and patient's ability, strategies, and the quality of movements used to perform ADLs such as transfers, bed mobility, and gait. Outcome measures standardize the assessment of activity or task performance and are an excellent way to document change in ability over time.

Spasticity. Therapists can use several tools to assess spasticity in people with MS. Clinicians typically measure spasticity using the

Modified Ashworth Scale.⁵⁴ The numerical rating scale (NRS)—spasticity⁵⁵ is good scale for assessing change over a single session or intervention. These two scales have been shown to have a moderate correlation in people with MS (Anwar, 2009).⁵⁵ Clinicians should be aware that because spasticity is typically measured while the patient is at rest in the MAS protocol, the scores may not reflect the degree to which spasticity may be interfering with movement. Careful observation of the patient's movements may also inform the clinician about how spasticity is affecting the patient's physical function. Several spasticity self-report measures are recommended by the MS EDGE Taskforce and might be more valuable to assess change in the perception of the impact of spasticity on function over time, such as across an episode of care (see Fig. 17.9).

Ataxia and incoordination. Few standardized tests have been developed to specifically measure ataxia. The Scale for the Assessment and Rating of Ataxia (SARA)^{56,57} and the International Cooperative Ataxia Rating Scale (ICARS)⁵⁸ are examples of standardized tests that clinicians may use to assess an individual's ataxia. Both the SARA and ICARS have good psychometric properties and have been tested in people with MS.⁵⁹ The ICARS includes four subsection assessments of posture and gait, limb ataxia, dysarthria, and the oculomotor system. The maximum score is 100 with higher scores indicating greater disability. While the ICARS has shown high correlation with EDSS, the clinical utility of the SARA may be greater due to its brevity.⁵⁹ The SARA does not include an ocular motor examination; therefore clinicians should be sure to include these tests in other portions of their evaluation. Due to cerebellar damage or loss of somatosensation and proprioception, people with MS can also experience uncoordinated movement.

Tests of nonequilibrium coordination are designed to measure the presence of dysmetria or dysidiadochokinesia, both of which occur in patients with MS. However, these tests (including finger to nose and heel to shin) are somewhat subjective and are therefore difficult to use to demonstrate improvement pre- and post-intervention. However, using a stopwatch during these tests can increase the objectivity of the measurements. Counting the number of repetitions of a given activity

performed in a set amount of time (e.g., how many alternating forearm supinations and pronations can be performed in 30 seconds), or recording the time it takes to complete a set number of repetitions of a given activity (e.g., how long it takes to complete five alternating supination-pronation movements), can quantify otherwise subjective impressions. Refer to Chapter 7 for additional assessment tools.

Vestibular dysfunction. The vestibular system can be affected by MS both centrally (lesions in the vestibular nucleus, cerebellum, or sensory pathways)⁶⁰ or peripherally with conditions such as benign paroxysmal positional vertigo.⁶¹ The techniques used to assess vestibular disorders are similar to those discussed in Chapter 21. Computerized platform posturography (CPP) assessment is reliable and valid for people with MS and can identify vestibular dysfunction.⁶² It is important to keep in mind that people with MS will often have additional problems that might require modification of the vestibular intervention—for example, heat intolerance, additional visual or somatosensory deficits, spasticity, and motor weakness.

Fatigue. Identifying if and when fatigue occurs in individuals with MS is important to assessment and the structuring of intervention. Questions should address the type of fatigue, whether mental or physical; when during the day it occurs; whether it is related to physical or mental exertion; and what the person with MS does, if anything, to relieve it. In addition, fatigue-related self-report scales can help the rehabilitation professional gain an understanding of the perceived impact that fatigue may be having on a patient with MS. Two of the commonly used self-report scales recommended by the MS EDGE Taskforce are the Modified Fatigue Impact Scale (Fisk 1994)⁶³ and the Fatigue Scale for Motor and Cognitive Function.⁶⁴ These measures may also aid the therapist in determining if the intervention had any impact on the patient's perceived level of fatigue.

Cognition. Cognitive deficits common to people with MS include deficits in learning and memory, information processing speed, and executive functions such as planning, organization, and initiation.⁶⁵ In MS, delays in processing speed are connected to learning impairments.⁶⁶ The Paced Auditory Serial Addition Test (PASAT)⁶⁷ is recommended by an expert panel of the National MS Society as a test for disease-related cognitive impairments in people with MS. Components of the PASAT specifically assess working memory and processing speed.

Balance. Balance is foundational to upright movement and is produced by a complex interaction among sensory inputs, central processing, and motor responses. It can be discussed under both body structure and function or activity. In either case balance dysfunction has been identified in people with MS with minimal as well as more advanced disability.^{68,69} Cameron and Lord⁷⁰ report the three most common problems with balance to be delayed response to postural perturbations, increased body sway while standing quietly, and an inability to move outside the base of support.

Some balance tests focus on stationary or static tasks that allow observation of body sway in standing, including single-leg stance test, Romberg test with eyes open or eyes closed, tandem stance, and CPP; others add movement and challenge dynamic balance. Other tests challenge anticipatory balance (reactions to perturbations related to self-generated movement) or reactive balance. The MS EDGE Taskforce recommends Berg Balance Scale and Functional Reach Test to assess balance. See Fig. 17.9. Frzovic and co-workers⁷¹ found that single-leg stance, tandem stance, response to external perturbations, and the Functional Reach Test were able to distinguish people with MS from healthy controls.

Developed by Horak and colleagues,⁷² the Balance Evaluation Systems Test (BESTest) is an instrument examining complex balance disorders that includes the six domains that underlie orientation and postural stability: biomechanical constraints, stability limits and

verticality, transitions and anticipatory postural reactions, reactive postural responses, sensory orientation, and stability in gait. The BESTest has been shown valid and reliable for people with MS.⁷³ The authors suggest that total test scores should be used because several of the subsections of the test showed ceiling effects. There is an abbreviated version of the BESTest, the mini-BESTest,⁷⁴ that covers four of the six systems, focusing on dynamic balance. These promising tests may offer the clinician a better way of identifying which components of orientation and postural control are dysfunctional and which may allow more targeted interventions. A systematic review of the use of the miniBESTest demonstrated it to be reliable, valid, and responsive in community-dwelling elders, people with Parkinson disease, and people post-stroke.⁷⁵

CPP provides an objective assessment of sensory contributions to balance dysfunction in people with MS,⁷⁶ which is reliable in people with MS.^{77,78} The Sensory Organization Test (SOT) is useful in identifying the relative sensory contributions (visual, vestibular, and proprioceptive) to stationary balance and response to perturbation. Understanding the sensory conditions under which the patient loses balance and falls assists the therapist in providing exercises that will challenge those conditions in a safe and controlled manner. For example, the patient who relies heavily on visual input to maintain balance (conditions with eyes closed in the SOT) would be prescribed exercises and activities that challenge the vestibular and proprioceptive systems, such as standing on foam while the eyes are closed. An additional measure that may be more assessable for clinical use is the Nintendo Wii Balance Board (WBB).⁷⁹ Keune and co-workers found excellent internal consistency and reliability when testing individuals with MS for 4 minutes on the WBB, 4 months apart. They found that WBB had consistent results with both the Timed Up and Go test and the Berg Balance Scale (BBS) and showed increased body sway in people with EDSS scores greater than 3.

Two self-report measures of balance ability and confidence are Activity-specific Balance Confidence scale (ABC) and the Dizziness Handicap Inventory (DHI). Both have been used extensively in MS. Cattaneo and colleagues⁸⁰ found that both the ABC and DHI tools discriminated between fallers and nonfallers and were therefore good predictors of fall status in people with MS. Refer to Chapter 20 for additional information on balance.

Gait. Gait can be measured in myriad ways depending on the goal of the assessment. Speed, distance, and quality may all be important to the patient and therapist. Observational gait analysis is the gold standard for clinical measurement of gait quality. Although motion-analysis laboratories are able to provide detailed kinetic and kinematic assessment of joint angles and gait cycle, it is costly and typically not available in most clinical settings. Instrumented mats can provide clinicians with temporal and spatial gait parameters such as step length, step width, cadence, and single-leg support and double-leg support times. Although this is less costly than motion analysis, it may still be out of reach for many clinics. Gait speed and velocity can also be measured by having the patient walk a given distance while being timed. These walks can occur at a self-selected pace or as fast as the person can walk safely. See Fig. 17.9 for recommended gait assessment measures. Gijbels and co-workers⁸¹ report that the 6-Minute Walk Test (6MWT) was better at predicting habitual walking in people with mild to moderate MS than the 25-Foot Timed Walk (25FTW). However, the 25FTW may be more sensitive to change when compared with the EDSS.⁸² The 6MWT distance was reduced in people with MS compared with healthy controls and was inversely related to disability.⁸³

The Multiple Sclerosis Walking Scale-12 (MSWS-12)^{84,85} is a 12-item patient-rated questionnaire that measures the perception of

the impact of MS on walking ability and is recommended by the MS EDGE Taskforce.

Upper-extremity tests of function. Movement impairments of the upper extremities can result in decreased ability to perform ADLs and other functional activities. Standardized tests such as the Box and Block Test (BBT)⁸⁶ or the Nine-Hole Peg Test (NHPT)⁸⁷ provide objective data about unilateral manual dexterity or the ability to manipulate objects. Both tests are inexpensive but do require some equipment and a stopwatch. The NHPT is part of the MSFC and therefore has been used extensively in evaluating people with MS.

Assessing Quality of Life and Participation.

For people with MS, participation restrictions are associated most strongly with cognitive deficits and to a lesser amount with walking, balance, and upper extremity dysfunctions.⁸⁸ The following are participation and quality of life (QOL) measures commonly used in people with MS. See Fig. 17.9 for a list of the measures recommended by the MS EDGE Taskforce. An individual's perceived ability to participate may also be included in some QOL outcome measures that are included in the following sections.

QOL measures are patient-report tools that evaluate the value a person places on his or her abilities and limitations and how these affect the individual's social, emotional, and physical well-being. Many of these tools include questions that address an individual's perception of how well he or she is able to fulfill life roles and how the disease affects this participation. In a meta-analysis of exercise training on QOL in people with MS, Motl and Gosney⁸⁹ found that disease-specific measures of QOL detected larger changes than generic QOL measures. The two highly recommended outcome measures are the Multiple Sclerosis Quality of Life–54 (MSQOL-54)⁹⁰ and the MS Impact Scale–29. While both have strong psychometrics, the MS Impact Scale is easier to score and is a shorter questionnaire for patients/clients to take.

The MSQI was developed by the Consortium of Multiple Sclerosis Centers Health Research Subcommittee in 1997. It is composed of 10 components covering issues important in MS. It includes the Health Status Questionnaire, Modified Fatigue Impact Scale, MOS Pain Effects Scale, Sexual Satisfaction Survey, Bladder Control Scale, Bowel Control Scale, Impact of Visual Impairment Scale, Perceived Deficits Questionnaire, Mental Health Inventory, and MOS Modified Social Support Survey. It takes about 45 minutes to administer the complete set of questionnaires and does not provide a sum score for all tests.

There is good test-retest reliability for the MSQI even in people with MS and cognitive dysfunction.⁹¹ A shortened version of the tool exists, but the psychometric properties have not been thoroughly tested. The MS EDGE task force document recommends that the MSQI be used only in the outpatient MS population.

Interventions

Benefits of Exercise in Multiple Sclerosis

Exercise is an important intervention given that people with MS are less physically active than their healthy peers.⁹² Exercise is one of the interventions that have shown consistent benefits for people with MS, similar to healthy adults and people with other neurological dysfunctions. The literature examining the impact of exercise on impairments, activity, and participation/quality of life for people with MS has exploded in the past 10 years. A recent review reiterated that exercise is safe and well tolerated in this population.⁹³

The benefits of exercise have been determined by both systematic review and meta-analysis. Meta-analysis has confirmed the benefits of exercise on the impairments of aerobic capacity,⁹⁴ lower extremity muscle strength,⁹⁵ fatigue,⁹⁶ and depression⁹⁷; reduced activity limitations such as walking performance⁹⁸ and balance⁹⁹; and confirms that it positively impacts quality of life.^{100,101} Systematic reviews have also revealed that exercise reduced fatigue,¹⁰² improved cognition,¹⁰³ and improved health-related quality of life.⁹⁵

In addition to the benefits outlined above, Motl and Pilutti¹⁰⁴ reviewed the growing evidence that exercise may play an additional role as a disease-modifying treatment. They reported that potential slowing of disease progression and reducing relapse rate,^{105,106} a reduced progression of walking disability,^{107,108} and decreased lesion volume on MRI.^{98,109–111} However, according to a recent systematic review, the impact of aerobic or resistance training on markers of inflammation have shown equivocal results.¹¹² The authors hypothesize that the reason for a lack of results may be due to two main factors: the low level of fitness in people with MS compared with a healthy cohort and training periods of less than 8 weeks duration in most of the studies.

While evidence supporting the benefits of increased physical activity and exercise is clear, in order for people with MS to achieve the best result, exercise prescription must be tailored to the individual's needs. Appropriate assessments must be completed to link deficits in underlying capacity and movement with the necessary exercise intervention. Table 17.4 presents a summary of the exercise guidelines for aerobic, resistance, and flexibility training for people with MS based on

TABLE 17.4 Aerobic, Resistance, and Flexibility Training Guidelines for People With Multiple Sclerosis

	Aerobic	Resistance	Flexibility
Mode	Cycling, walking, swimming, elliptical, etc.	Free weights, weight machines, body weight, resistance bands, and pulleys	Static stretching
Intensity	Moderate intensity 64%–75% HR_{max} (12–15/20 RPE) Start lower if sedentary	60%–80% 1 RM (use ≥ 3 RM to estimate 1 RM) Start lower if sedentary or older	Static stretch to point of mild discomfort or tightness Do not cause pain
Duration	10–60 min of accumulated moderate activity Use interval or intermittent training for people with heat sensitivity	10–15 repetitions/set 1–2 sets per session At least 2–5 min rest between sets	30–60 s stretches 2–4 repetitions
Frequency	2–5 times/week	2–3 times/week	5–7 times/week 1–2 times/day

HR_{max} , Heart rate maximum; RM , repetition maximum; RPE , rate of perceived exertion.

Recommendations based on White 2004, Dalgas 2012, Latimer-Cheung 2013, and ACSM's Guidelines for Exercise Testing and Prescription 2018.

guidelines from White and Dressendorfer,¹¹³ Dalgas and colleagues¹⁰⁵ Latimer-Cheung and colleagues⁹⁵ and the American College of Sports Medicine.¹¹⁴ When beginning an exercise program, the initial prescription should be based on the goals of the individual, the initial level of fitness, familiarity with the type of exercise, and the individual's preferences for type of exercise. As with every exercise intervention, the intensity, duration, and frequency should be gradually increased with the individual's tolerance. For people with MS that have heat intolerance, intermittent exercise and shorter exercise bouts, interspersed with periods of rest that allow heat to dissipate, will allow a greater volume of exercise to be performed.^{115,116} Cooling before exercise has improved physical performance in people with MS.¹¹⁷

To make physiological or neuroplastic changes, exercise interventions need to be tailored to individuals with MS. This means that the exercise program needs to be meaningful to the individual, practiced at a high intensity with sufficient repetition, as challenging or difficult as the individual can tolerate, and specific to the changes that need to be made for the person to achieve his or her goals.

Multidisciplinary Management of Multiple Sclerosis Symptoms

Fatigue. Fatigue is one of the most frequent and disabling symptoms associated with MS and is best managed with a multidisciplinary team composed of physicians, physical therapists, occupational therapists, and nurses. As described earlier, the causes of fatigue can be divided into two basic categories: primary and secondary. Primary fatigue related to demyelination and neurodegeneration may have fewer options for treatment. Secondary fatigue caused by deconditioning, comorbidities such as thyroid disease, depression, poor nutrition, heat intolerance, sleep disturbance, and medications may be more easily managed.

Pharmaceutical combined with rehabilitation interventions have been recommended for management of fatigue.^{118,119} While amantadine (Symmetrel) and modafinil (Provigil) have been frequently prescribed to help manage fatigue, newer research has cast doubt on the effectiveness of modafinil. A meta-analysis comparing the effects of amantadine, modafinil, and rehabilitation interventions found that rehabilitation produced stronger, longer-lasting reduction in patient-reported fatigue and fatigue severity than pharmacological agents.¹²⁰

Several rehabilitation strategies for fatigue management have been reported and show promise¹¹⁸; however, few research studies have demonstrated effectiveness in randomized controlled trials or in comparisons among approaches. Interventions for fatigue management include cooling devices and garments, energy conservation education training, exercise, and a multifaceted class aimed at teaching people with MS how to manage their fatigue. One study found that the cooling suits used in the home improved fatigue and participant's independence in ADLs.¹²¹ Another study found that 60 minutes of neck or head cooling resulted in improved 6MWT times.¹²² The use of cooling is recommended in the Multiple Sclerosis Council's Clinical Practice Guidelines on fatigue (MSC Clinical Practice Guidelines) and by expert opinion.

People with both RMS and PMS of mild to moderate disability can benefit from exercise to reduce self-reported fatigue. Exercise shows promise as an intervention that can improve fatigue for people with MS, but to date, no one type of exercise—resistance, aerobic, mixed, or other (e.g., yoga or balance training)—has been proven most effective.^{95,96,102} Most reviewed studies have a small number of participants, do not pre-define people with fatigue, and generally only include people with mild to moderate levels of disability and frequently no control or comparison groups. Specific guidelines about the correct dosage of exercise needed to reduce fatigue are still lacking.¹²³

Energy conservation is defined by the fatigue and MS guidelines of the Multiple Sclerosis Council for Clinical Practice Guidelines¹²⁴ as energy effectiveness, and includes an analysis of individuals' home, work, and leisure activities and the environments in which they occur to develop activity modifications designed to reduce fatigue. This can include a variety of strategies such as reducing energy expenditure through activity and modification, workspace organization, and improving efficiency of movements; balancing work and rest periods; delegating tasks; evaluating standards and prioritizing activities; and using assistive technologies that conserve energy usage.¹²⁵ In a systematic review, energy conservation was effective at making immediate improvements in the physical, social function, and mental health subscales of the Fatigue Impact Scale.¹²⁶

Assistive devices may reduce energy expenditure while performing ADLs. Using wheeled mobility (such as wheelchairs or scooters) for longer-distance outings (to the shopping mall, an extended event, on vacation) can conserve energy and extend the time a person can participate in activities of importance to him or her. However, therapists should be aware that using assistive devices such as walkers or crutches actually increases energy expenditure for elderly people,¹²⁷ and therefore the need for improved support must be balanced with the increased energy demands that an assistive device might add.

Spasticity. Spasticity, present in up to 80% of people with MS, is more common in the lower extremities. It commonly impacts walking, stair climbing, sexual activity, and sleep.¹²⁸ While often interfering with physical function, spasticity can also add support to weakened limbs, allowing more effective mobility. Therefore spasticity management must include a thorough assessment of the impact of the spasticity on an individual's function. The goal of medical management of spasticity is to maintain full range of motion (ROM) of muscle and soft tissue structures to allow maximal physical function and proper hygiene. Haselkorn and colleagues¹²⁹ developed the clinical practice guidelines for managing spasticity in people with MS for the Multiple Sclerosis Council. To date, this is the most comprehensive set of guidelines developed. They indicate that successful management includes both pharmaceuticals and rehabilitation strategies.

Medical management of spasticity includes the use of first-line oral pharmacotherapy agents including baclofen (Lioresal), tizanidine (Zanaflex), or gabapentin (Neurontin).¹³⁰ Adjuvant therapies are recommended if the previous drugs are unsuccessful and include diazepam (Valium) or dantrolene (Dantrium).¹³⁰ Nabiximols or cannabis extracts (such as Sativex) can be used in addition to the drugs previously mentioned.¹³⁰ Many of these drugs, since they are given as oral agents, can have negative side effects that interfere with movement and increase fatigue, both of which can impact daily life and rehabilitation.

Management of focal or more severe spasticity may include local anesthetics such as lidocaine, bupivacaine, etidocaine, all of which are short-acting with side effects of CNS and cardiovascular toxicity and hypersensitivity. Neurolysis treatment with phenol or alcohol is longer acting; however, these agents can have the side effects of pain, swelling, fibrosis, and dysesthesias. Focal spasticity affecting functional muscle groups can also be effectively treated with neuromuscular blocking agents, including alcohol, phenol, or botulinum toxin. Blocks last 1 to 3 months with relatively few side effects.¹³¹ Clinical practice guidelines¹²⁹ recommend that neuromuscular blocks be performed by appropriate specialists in conjunction with a rehabilitation program.

Refractory spasticity is defined as unsuccessful treatment with oral medications and/or rehabilitation. In this situation two other options exist: surgery or placement of an intrathecal baclofen pump (ITB).¹³⁰ Intrathecal pumps, inserted into the spinal cord, allow adjustable drug delivery. Baclofen, the drug of choice for the intrathecal pump, can be

given in higher doses; use of the pump avoids the side effects often encountered when the drug is taken orally. Other surgical procedures include tendon lengthening or tendon transfer and are performed to maintain adequate hygiene or prevent or correct contractures and therefore preserve function.

Several rehabilitation strategies to manage spasticity are available, including ROM, stretching tight or spastic muscles, strengthening opposing muscles, electrical stimulation, and education. Although none of these interventions is supported by strong research evidence, many are used routinely in clinical practice. Other approaches (cold therapy, light pressure, or stroking) are recommended for use in conjunction with stretching or ROM programs. Regardless of the technique employed, educating individuals and caregivers about the importance of adhering to a spasticity management program is essential. The Multiple Sclerosis Council for Clinical Practice Guidelines¹²⁹ recommends, based on expert opinion, stretching a muscle with spasticity for at least 60 seconds or using braces or splints to provide a prolonged stretch. A group-delivered self-management program based on the MSC guidelines found that people with MS who completed the *Spasticity: Take Control* program compared to a usual care group had significant improvements in the self-reported impact of spasticity, even though scores on the MAS remained unchanged.¹³²

Nilsagård and co-workers¹³³ found subjective reports of improved spasticity after a single session of cooling, although no statistically significant differences in spasticity measures were found. Stationary bicycling may improve blood flow to lower extremity spastic muscles by increasing alternate contraction and relaxation of muscles, which may increase the delivery of oxygen and removal of lactate from continuously contracting muscles and reduce pain. However, while a 4-week unloaded cycling program reduced the impact of spasticity on participants self-reported function, physiological measurement of spasticity did not change.¹³⁴

Pain. The occurrence of pain in people with MS is often underestimated. Pain can be acute, as in optic neuritis, trigeminal neuralgia, or Lhermitte syndrome, or chronic, as in dysesthesias in the limbs or joints or mechanical pain related to abnormal positions or repeated movements that cause abnormal wear and tear on the musculoskeletal system. Therefore both nociceptive and neuropathic pain can be present. It is important to discern the type of pain in order for the most appropriate treatment to be rendered. The classes of drugs used to treat pain are anticonvulsants, antidepressants, cannabinoids, dextromethorphan/quinidine, and opioids/opioid antagonists.¹³⁵

Nociceptive pain can often be treated with analgesics (acetaminophen, nonsteroidal antiinflammatory drugs [NSAIDs], or opioids) and is generally more amenable to physical therapy. Neuropathic pain generally requires pharmacological intervention, although an interdisciplinary team approach may be valuable. First-line medications for neuropathic pain that occurs in the spinal cord are calcium channel blockers (gabapentinoids) or *N*-methyl-D-aspartate (NMDA) antagonists (ketamine). Treatment of trigeminal neuralgia is opioid drugs such as antidepressants (nortriptyline, duloxetine) or anticonvulsants (gabapentin, pregabalin).¹³⁵ Refer to Chapter 30 on pain management for additional information.

Occupational and physical therapists can address poor body mechanics and weakness and poor movement patterns with retraining, and soft collars may help reduce Lhermitte syndrome. However, little evidence supports these interventions.¹³⁶ In a systematic review of non-pharmacological management of pain in people with MS, Jawahar¹³⁷ found that low frequency (4 Hz) transcutaneous electrical nerve stimulation was found to be most beneficial for reducing neuropathic pain. Other interventions included in the review were education, yoga and exercise, and robotic assisted gait training. While the evidence was

lacking in most cases, the educational interventions of cognitive restructuring and self-hypnosis showed the greatest reduction in pain scores.¹³⁷

Cognitive-behavioral therapy has been successful in managing chronic pain in many populations using both in-person and online delivery systems¹³⁸; however, little evidence exists for using it in people with MS. A recent pilot study suggests that a self-management program of telephone-supported home-based cognitive behavioral therapy (CBT) may be effective for people with MS.¹³⁹

Balance and postural control. Balance is foundational to the ability to stay upright and perform dynamic movements. Balance dysfunction is a frequent problem in people with MS and results in a person limiting his or her participation in home, work, and leisure activities—even for people using wheelchairs or scooters. Poor balance along with cane use and poor performance on tests of balance and ambulation are associated with an increased risk of falls.^{140–142} Other fall risk factors that have been identified include fear of falling, male sex, poor concentration or forgetfulness, and urinary incontinence.^{140,143} Rehabilitation is the primary intervention used to improve balance in people with MS. However, factors contributing to falls such as urinary urgency/incontinence can also be addressed through specific pelvic floor rehabilitation and pharmacological interventions and will be discussed later in this section.

Rehabilitation programs must be based on a thorough understanding of the impairments and personal and environmental factors that may be contributing to the balance dysfunction. In a recent systematic review Gunn and colleagues found that exercise interventions produced changes in balance ability with moderate effect sizes, but did not change falls outcomes.⁴⁸ Several exercise strategies were used to improve balance including specific balance and gait training, aerobic and resistance exercise, and combined programs.^{48,144}

An additional technique that shows promise for improving balance and reducing falls in people with MS uses small amounts of weight applied strategically at the torso in response to identified balance loss. In torso weighting using the balance-based torso-weighting method (BBTW), a trained clinician assesses the directional loss of balance and asymmetry when the standing patient is perturbed with nudges and maximal rotational force at the shoulders and pelvis. Small amounts of weight (generally less than 1% to 1.5% of body weight) are then placed on a vestlike garment to counter the balance loss. The lightly weighted vest can then be worn during the performance of activities in therapy or daily for home, work, or leisure activities.¹⁴⁵ While wearing the orthotic, people with MS showed improved body sway compared to a no-orthotic condition and compared with healthy age-matched controls.¹⁴⁶ Another study showed that the weighted condition produced fewer falls and improved balance during the Sensory Organization test, a type of computerized dynamic platform posturography.¹⁴⁷

Although no systematic reviews have been performed, results from recent randomized controlled trials suggest that customized vestibular rehabilitation programs, such as the Balance and Eye-Movement Exercises in Persons with Multiple Sclerosis (BEEMS),¹⁴⁸ result in improvements in balance, fatigue, and quality of life.^{148,149} These programs incorporate comprehensive approaches to ensure that balance and eye movements are continually challenged by systematically narrowing the base of support, moving from static to more dynamic movements, and integrating eye movement challenges.

Regardless of the type of exercise, the critical component of successful programs is maintaining a high level of challenge to the individual, thereby forcing physiological adaptations.

Mobility. People with MS rate gait as one of the most important bodily functions.¹⁵⁰ Gait is often adversely affected in people with MS.

Approximately 40% to 75% of people with MS report gait difficulties, with many claiming it is the most challenging aspect of the disease.^{151,152} Gait disturbances have been reported in people with MS even before mild disability occurs and deficits that increase with faster walking speeds.¹⁵³ Lesions in the brain and spinal cord produce a wide variety of potential impairments that can adversely affect gait.⁹² Physical rehabilitation is the primary intervention used to manage mobility dysfunctions. However, one medication is FDA-approved for use to improve walking ability in people with MS: dalfampridine (Ampyra). In clinical studies dalfampridine demonstrated the ability to improve walking speed in people with MS.¹⁵⁴ However, changes in the quality of gait or movement were not measured. A recent study showed that after 2 years of using dalfampridine, participants have improvements in the 25TWT, 6MWT, and the MSWS-12, indicating that this drug could be an effective option to improve walking ability in MS.¹⁵⁵

A review article by Kelleher and colleagues¹⁵⁶ revealed that imbalance, fatigue, spasticity, incoordination, muscle weakness, and sensory system impairments were all reported to negatively affect ambulation ability. Therefore addressing each of these impairments has the potential to improve gait. A variety of rehabilitative methods can improve ambulation. Snook and Motl¹⁰⁷ performed a meta-analysis of exercise studies aimed at improving walking mobility in people with MS and found that larger effects were associated with supervised exercise training, programs of less than 3 months duration, and mixed samples of people with RRMS and progressive MS. A meta-analysis of the impact of aerobic and resistance exercise training on walking ability found that exercise made significant improvements to walking speed and endurance, but had little impact on Timed Up and Go (TUG) scores.⁹⁸

Several systematic reviews have shown an association with improved aerobic capacity and muscle strength while reporting a smaller yet meaningful impact on mobility.^{40,95} Guidelines for exercise in people with MS have been developed (see Table 17.4). Based on these studies, exercise should be an important component of interventions designed to promote improved mobility in people with MS. Additionally, high-intensity resistance training programs are being explored in people with MS, and while there are some mixed results, high-intensity training shows promise in improving walking as well as other aspects of individual's function.^{157,158}

Task-specific gait training has been evaluated in people with MS. Treadmill training has been investigated in several small, pilot, or case studies with promising results of improved QOL, energy expenditure, and gait parameters.^{159,160} A systematic review found little evidence to support either treadmill training or robot-assisted training due to the small, heterogenous samples.¹⁶¹ A more recent analysis of robot-assisted gait training shows some promise in people with MS, with a modest impact on walking endurance compared to conventional walking training.¹⁶²

Torso weighting, using the BBTW method, has also shown improvements in walking ability in people with MS. In a randomized controlled trial in people with MS who reported gait abnormalities, wearing the weighted orthotic increased their gait speed compared with no weight controls and improved TUG scores compared with a standard weighted control.¹⁶³ In a separate study, researchers found that the gait parameters of velocity, cadence, time in single limb support improved in people with MS when wearing the BBTW orthotic compared to the no-weight condition, and became closer to values found in age-matched healthy controls.¹⁶⁴

When people with MS do not respond to therapeutic interventions to restore function, mobility assistive devices such as canes, crutches, walkers, wheelchairs, and scooters are used to enhance mobility through compensation. Mobility-assisted technology (MAT) can improve function in people with moderate to severe impairments of

ambulation and may reduce activity limitations and participation restrictions by reducing fatigue and enhancing energy conservation to allow greater involvement in work, family, social, vocational, and leisure activities. Other MAT technologies include functional electrical stimulation (FES), neuroprostheses, and orthotics. FES is applied to specific muscles or muscle groups to activate weak muscles. Some of these stimulators can be built into a neuroprosthesis that can be set up for use during exercising or walking.¹⁶⁵ In a single group, pre-post study, increased gait velocity and improvement on the MSWS-12 and the MSIS-29 were reported after wearing a neuroprosthesis for two weeks that facilitated dorsiflexion during the swing phase of gait.¹⁶⁶

Orthotics such as the ankle-foot orthosis (AFO) or hip flexion assist orthosis (HFAO)¹⁶⁷ can compensate for muscle weakness in the lower extremity, improve foot and knee positioning, and reduce energy expenditure. Therapists often work cooperatively with orthotists to ensure proper fit. Use of wheeled mobility devices such as a manual wheelchair, power wheelchair, or scooter requires a formal evaluation by an occupational or physical therapist with justification that it is required for mobility at home at least on a part-time basis. Therapists must take a long-term view of the projected needs of the patient when prescribing wheeled mobility, as most insurance companies will replace this equipment only every 5 years.

Tremor. Tremor in MS has been self-reported in 25% to 58% of patients.¹⁶⁸ People with tremor reported as mild or greater were more likely to retire early, be unemployed, and have higher levels of disability compared with MS patients without tremor. Pharmacological management was common in over 50% of individuals with mild to severe tremor. Individuals with more severe tremor are more likely to report benefits from using pharmacological interventions. The most commonly used drugs for symptomatic management of tremor are benzodiazepines and anticonvulsants.¹⁶⁸ Cannabinoids, B-blockers, antispasmodics, mood stabilizers, ethanol, and Alzheimer's dementia treatment have also been reported.¹⁶⁸ Please refer to Table 17.2. GABA agonists were reported as the most successful in reducing tremor. Surgical interventions, including stereotaxic thalamotomy and deep brain stimulation, have been studied, but the evidence to support the effects on functional status and disability is lacking. The effectiveness of other options including physical therapy, tremor-reducing orthoses, and extremity cooling have yet to be proven beneficial in clinical trials.¹⁶⁹

Bowel and bladder management. Urinary incontinence and retention are common and often embarrassing problems for people with MS. A systematic review of interventions for the treatment of lower urinary tract symptoms in patient with MS notes that 80% to 100% of people will have symptoms at some time, and 70% categorize the impact of bladder or urinary problems on their lives as "high" or "moderate."¹⁷⁰ Physical therapy can help decrease incontinence leakage episodes and improve quality of life through pelvic floor muscle training and biofeedback by physical therapists with specialized training in pelvic floor rehabilitation.^{171,172} Patients may also be advised to avoid bladder irritants including caffeine and alcohol, and to maintain proper hydration. Persistent problems may require pharmacological intervention or catheterization, although unwanted side effects and increased risk of infection make these choices less desirable for many. A few medications have been shown to be helpful: anticholinergic agents are used to manage detrusor overactivity or dyssynergia, and underactivity is treated with cholinomimetic agents.¹⁷³

Bowel dysfunction has been estimated to occur in 39% to 73% of people with MS, with constipation and fecal incontinence as the primary dysfunctions.¹⁷⁴ Assessment of bowel dysfunction using the Wexner Constipation and Incontinence scale¹⁷⁵ and using a 2-week bowel diary will facilitate an understanding of the problem and its significance to the individual.¹⁷⁶ People with constipation are encouraged

to combine adequate fluid intake with dietary fiber or to take medications that increase bulk formation, soften stool, or stimulate stool expulsion; prucalopride is also prescribed.¹⁷⁶ When bowel problems persist, people are encouraged to follow a regular bowel management program that entails establishing routines for mealtimes, fluid intake, and uninterrupted periods after meals for bowel elimination.^{173,176,177} Additional interventions can include biofeedback, transanal irrigation, sacral neuromodulation, and surgery (colostomy or ileostomy).¹⁷⁶

Cognitive impairments. Strategies for managing cognitive impairments include compensation techniques such as memory notebooks, diaries, calendars, and computer-assisted programs for memory, attention, or other executive functions. Neuropsychologists, speech-language pathologists, and occupational therapists can all direct cognitive rehabilitation programs. Strategies for coping with cognitive impairments are often shared with the other members of the health care team for reinforcement with patients. A recent cross-sectional investigation found a weak correlation in people with MS with poorer cognition and a lower aerobic capacity.¹⁷⁸

Direct interventions addressing specific cognitive tasks have been reported, but the results are mixed, with the best support for verbal learning and memory.^{179,180} Cognitive behavioral therapy, exercise, and education programs are promising psychosocial interventions to improve coping and lessen cognitive symptoms.¹⁸¹ The evidence is promising with small effects of fitness, physical activity, or exercise on cognition.¹⁰³ In a systematic review Maitra¹⁸² found that cognitive behavioral therapy programs performed by occupational therapists were positively correlated with improvement in Functional Independence Measure (FIM) scores.

Depression is very common in people with MS, yet it is infrequently identified or treated.¹⁸³ Therapy can include supportive psychotherapy and medication given individually or in combination. To date two pharmacological therapies have shown the most promise in reducing cognitive deficits (L-amphetamine sulfate and donepezil), and neither has serious adverse effects.¹⁸⁴ There is growing evidence to support psychological interventions for people with mild to severe MS-related cognitive deficits, aimed at alleviating depressive symptoms and helping people cope with and adjust to their impairments.^{179,180,185} Refer to Chapter 27 for additional information regarding interventions with individuals with cognitive impairments.

Dysarthria and dysphagia. Dysarthria is reported in up to 40% of people with MS. It is the disruption of muscular control in the central and peripheral speech mechanisms, which leads to abnormalities of speed, range, timing, strength, sound, and accuracy of speech movements.¹⁸⁶ Speech language pathologists (SLPs) address dysarthria by determining interventions that take into consideration the stage of the disease and speech quality. Typical programs may include exaggerating articulation, increasing voice volume, and increasing strength of oral musculature. The SLP will collaborate with other therapists to encourage follow-through with these programs to improve verbal communication during therapy sessions. Exercise programs designed to increase expiratory muscle strength have not been successful in improving voice quality or production but have shown increased respiratory muscle strength.¹⁸⁷

Dysphagia or difficulty with chewing and swallowing is noted in 15% to 20% of people with MS¹⁸⁸ and becomes more prevalent in people with MS as the disease progresses.¹⁸⁹ SLP and occupational therapists facilitate proper swallowing with exercises that will improve posture to prevent aspiration and strengthen muscles of mastication. Other interventions may include diet modifications and education for the patient and his or her family or caregivers. Dieticians may be consulted to facilitate proper food choices.

Special considerations. Several special considerations for this population have been incorporated into the sections above, including

patient preference, fall risk, fatigue, spasticity, and heat intolerance. Consideration of these factors must be incorporated into planning interventions and during the execution of a therapy session. Patient/client preferences must be integrated into the plan of care. For example, if a patient prefers fishing to soccer, for example, therapy might target overhead casting for an upper extremity limitation rather than throwing a soccer ball, and maintaining balance on an unstable surface (in a rocking boat) rather than while kicking a ball. Adapting exercises and physical activities to the patient's or patient's identified values and limitations should increase motivation to incorporate activities into an ongoing lifestyle. If a patient has a high fall risk, close guarding, a harness system, or partial body-weight supported activities overground or on a treadmill should help mitigate the risk while still practicing responses to increasing balance challenges. Pre-activity cooling might help reduce spasticity or heat intolerance, along with prolonged stretch for muscles with spasticity. If the patient/client is easily fatigued, the clinician might incorporate intermittent exercise/activity, introducing brief mandatory rests as soon as the first degradation of movement quality is noted.

Each of these special considerations along with other patient/client characteristics can affect response to treatment. Effectiveness of rehabilitation has been mixed for many types of interventions, frequently because the sample of people with MS is heterogeneous.¹⁵⁷ Average response to an intervention will seem nil or small if one group responds with an increase on an outcome and another group cancels out that effect because it responds not at all or with a decrease. The objective of comparing characteristics of different groups is to determine which characteristics are associated with positive response to that intervention.

One important consideration for therapists is movement variability. Traditionally, skilled movement is less variable than unskilled movements. However, *optimal movement variability*¹⁹⁰ theoretical perspective suggests that both too little variability and too much variability can indicate potential problems. Therefore successful interventions require therapists to facilitate the development of an optimal movement variability, somewhere between too much and too little. Using nonlinear tools to describe the structure of variability over time during a quiet standing task in people with MS, Hunt and colleagues¹⁹¹ noted a strong, significant correlation between the direction of change with an intervention and the baseline level of movement variability. For participants at the higher end, with more random patterns of center-of-pressure movement, their nonlinear values decreased with intervention. For participants at the lower end, with more repetitive center-of-pressure patterns of movement, their nonlinear values increased with intervention. If the optimal movement variability was somewhere in the middle, then both groups converged on the more optimal value with intervention.¹⁹¹

When attempting to achieve optimal movement variability, therapists must consider the patient's abilities and the types of activities that are likely to challenge them to increase or reduce movement. If patients are constraining movement so tightly that they cannot respond to environmental changes or challenges, the objective is to increase variability in their movements. Intervention for people in this group might include unpredictable environmental challenges that will encourage error detection and self-correction of their movements.¹⁹⁰ If patients' movements are random such that they have difficulty accomplishing target tasks consistently, the objective is more regularity in their movement patterns. Interventions for this group might include facilitating co-contraction proximally for enhanced stability, extrinsic feedback about performance, repetition of tasks within the constraints of environmental factors (such as the use of a walker or other device), substituting different sensory modalities (vision) for an individual that has deficits (somatosensation), and reducing task complexity by limiting the number of joints moving simultaneously.¹⁹²

SUMMARY

This chapter has focused on the pathology, clinical presentation, multidisciplinary management, and rehabilitation of people with MS. Understanding the type of MS, clinical disability, and severity of the disease will help therapists determine the best assessment and intervention strategies to manage the rehabilitation program. Using the ICF framework will facilitate the assessment of the impairments, activity limitations, and participation restrictions affecting each patient or client. In addition, assessing the environmental and personal factors present will help tailor the program to the patient's needs. Using outcome

measures that are valid and reliable for people with MS will assist the therapist's understanding of the entire range of impairments, activity limitations, participation restrictions, and QOL issues patients are facing in their everyday life. Therapists need to link the findings from examination and collaborate with the patient to set appropriate goals for therapy. Lastly, to achieve the best outcomes therapists should design interventions that are salient to the patient, have sufficient repetition and intensity, be specific to the goals, and be challenging enough to focus the individual's attention.

CASE STUDY 17.1 Initial Interview

Mrs. P. is a 54-year-old woman with a 28-year history of MS. She was first diagnosed with relapsing disease after her first daughter was born and remembers having a lot of trouble walking. Mrs. P. is concerned about her trunk weakness, back pain, and difficulty with walking; she often stumbles. She reports having fallen twice in the past year when she lost her balance and was unable to catch herself. One fall was at home, and one in the backyard. Therefore she has been using a single-point cane, especially on days when she feels off balance. Mrs. P. is limited to 10 minutes of walking and standing secondary to fatigue and difficulty balancing. She is overweight (BMI 29) and reports some bladder incontinence and heat sensitivity. Mrs. P. is a homemaker with 4 children; the youngest is 6. Leisure activities include playing the piano, singing, doing the Wii balance exercise for 10 min several times a week, and walking 10 min on a treadmill at 2.5 mph after using a cooling vest twice a week. After her treadmill walking, she feels fatigue for 3 to 4 h. Recently she has noted having more difficulty with singing and at times feels out of breath. Mrs. P.'s goals are improved posture, better breath control, no back pain, the ability to walk without stumbling or using a cane, and the ability to keep up with her children and her busy life.

Assessment

Mrs. P.'s Disease Steps classification is 3 (she uses a cane intermittently and is able to walk for 100 feet without it), and her EDSS score is 6.0. Vital signs are within normal limits (WNL) at rest and for exercise. This patient is cognitively intact and reliable in her response to questions. Her active and passive ROM is WNL throughout her extremities, trunk, and neck. She has selective motor control with normal tone. Manual muscle tests of bilateral upper extremity (UE) were normal, with the lower extremity (LE) 4/5 except for right hip flexion 3+/5, hip extension-abduction and plantarflexion 3/5. Abdominals 2/5, back extensors 3/5 (able to lift trunk against gravity through full range with difficulty and unable to take resistance). Sensation to light touch (LT), pain, and proprioception are intact throughout except for bilateral (B) feet, noted to have diminished sensation to LT. In sitting her posture is extremely slumped (from 30 to 45 degrees when fatigued) with notable thoracic kyphosis. She requires standby assist from supine to prone secondary to trunk weakness and instability. She requires use of B UEs in weight bearing to move from sitting to standing. During observational gait analysis, she demonstrates an asymmetrical step length with the left longer than the right and a right heel strike that is notably loud or audible. Her TUG score is 8 s using B UEs to stand up. The 25FTW is 5.6 s. The 6MWT was 324 m with one short rest. BBS was 45/56, putting her at risk of falls. Standing perturbation tests reveal loss of stability with an anterior nudge (posterior loss of balance [LOB]), posterior nudge (anterior LOB), and lateral and upper and lower trunk (LOB to opposite side). Rotational resistance tests to the right upper and lower trunk result in a stepping response, and the patient is unable to maintain stability, resulting in a stepping response. Results of rotational resistance tests to left upper and lower trunk are normal. The ABC scale score was 60% and the MSWS-12 score was 38/60 (63%).

Plan of Care and Goals

Mrs. P. had weakness in B LEs, balance problems, and an unsteady gait with at least two falls in the past 6 months. The ABC and MSWS-12 score were also low.

All of these results indicate that her gait and balance dysfunctions were interfering with her functional mobility and QOL. The physical therapy plan of care included balance and gait training, improved posture and time standing, and increased muscle strength, endurance, and cardiovascular fitness. Goals included a decreased fall risk with an improved BBS score of 54/56, increased MSWS-12 of 85%, and improved B LE and trunk strength (4/5 in all muscle groups), improved endurance to walk 450–500 m in 6 min without rest, decreased back pain to 0 to 1/10 on most days in 12 to 24 weeks. Additionally, the patient was referred to a PT with a specialty in women's health to manage her urinary incontinence.

Intervention

BalanceWear orthotic applied with placement of 1.5 pounds of weight to the torso to address the perturbation and rotational asymmetries (posterior right upper and lower trunk and anterior near navel) improved her reactive balance control. After applying the BW orthotic with the rigid component back pain resolved immediately; she felt better breath control and trunk support. The BBS score increased to 51/56, a significant improvement. TUG score remained the same, but she no longer needed her UE to stand up. Her posture also improved to 50% less kyphosis. During gait while weighted, a softer (inaudible) right heel strike was noted, and her step length was even and her 25FTW decreased to 4.8 s. Mrs. P. expressed that she felt much steadier and more balanced with the BalanceWear orthotic and was thrilled to have no back pain.

Mrs. P. was seen in a managed care setting and was able to make significant progress with her physical therapy program. She was seen in physical therapy (1×/week × 1 month, 2×/week × 2 months, 1×/month × 3 months) to improve her posture, strength, balance, and fitness. Breath-control exercises using her diaphragm were implemented to improve singing, monitoring progress with an inspiratory spirometer. Because this patient understood the principles of exercise, she was advised to perform the specific exercise until she experienced a decrease in the quality of movement or the muscles fatigued. A general stretching program was initiated, including specific stretches to improve her posture in sitting and standing. For strengthening exercise she started with one set of 8 to 15 reps; resistance was increased by 2% to 5% when 15 reps were efficient for major muscle groups including hip flexion-extension-abduction, heel raises for plantarflexion, rowing (shoulder retraction) with yellow Thera-Band in standing, curl-ups in hook-lying, and quadruped weight shifts, which were performed 2× to 3×/week. To address her deconditioning, an interval treadmill-training program was implemented on alternating days. Recommendation was to maintain the intensity of 2.5 mph at 64% to 75% of HRmax and do intervals of four blocks of 3 minutes with 1- to 2-min rest breaks in between and to continue to use the cooling vest before exercise. She was instructed to increase the blocks she was performing up to 7 as she tolerates. She continued with the Wii balance program, increasing to 30 min on the days she was not doing the treadmill. On those days she also performed specific balance exercises in the corner, beginning with her eyes open (single-leg stance; tandem stance). Mrs. P. was advised to use the BalanceWear orthotic for 2 h during functional activities and walking and to perform her exercises with it every other day. If she became less steady, she was advised to wear the orthotic an additional 1–2 h per day.

RESOURCES

Many websites are available to assist therapists and their patients with MS to understand the disease and find resources to help them manage the disease.

Abstract: This chapter describes the rehabilitation management of people with multiple sclerosis (MS). The chapter reviews the incidence, prevalence, pathology, prognosis, and medical management of the disease. The chapter then focuses on the multidisciplinary management of disease sequelae resulting in impairments that limit the ability to perform activities and participate fully in life.

Keywords: Multiple sclerosis, rehabilitation, multidisciplinary management, assessment, intervention, impairments, activities, participation, quality of life

Disorders of the Basal Nuclei

Erin Vestal, Angela Rusher, Kristin Ikeda, and Marsha Melnick

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the circuitry of the basal nuclei.
2. Relate the anatomy and physiology of the basal nuclei to its roles in sensorimotor and cognitive processes.
3. Use the information on anatomy, physiology, and pharmacology to explain the signs and symptoms seen in classic disease states—for example, Parkinson disease, Huntington disease, and dystonia.
4. Develop an evaluation plan for patients with diseases of the basal nuclei.
5. Develop an intervention plan for patients, with the rationale for treatment methods.
6. Determine treatment effectiveness, especially in the case of degenerative disease.

KEY TERMS

basal nuclei
dystonia

Huntington disease
Parkinson disease

This chapter considers the degenerative, metabolic, hereditary, and genetic disorders that typically have their onset in adulthood, including Parkinson disease, Parkinsonian syndromes, Huntington chorea, Wilson disease, dystonias, heavy metal poisoning, and drug intoxication. Owing to the wide variety of diseases with their wide variety of causes, the concentration is on understanding the clinical problems and commonalities that exist within this grouping. The predominant area of the brain affected by these disorders is the basal nuclei: this group of central nervous system (CNS) structures is therefore discussed in some detail.

THE BASAL NUCLEI

The most commonly seen disorders affecting the basal nuclei include Parkinson disease, Huntington chorea, and dystonias, including drug-induced dyskinesias. All of these medical diagnoses involve impairments in muscle tone, movement coordination and motor control, and postural stability and the presence of extraneous movement. Taken together, these disorders now affect approximately 1 million people in the United States and more than 10 million people worldwide.¹⁻³

To understand how this area of the brain can account for such a wide variety of symptoms, the anatomy, physiology, and neurochemistry of the basal nuclei structures must be considered.

Anatomy

The dorsal or sensorimotor basal nuclei are composed of three nuclei located at the base of the cerebral cortex—hence their name. These nuclei are the caudate nucleus, the putamen, and the globus pallidus. Two brain stem nuclei, the substantia nigra and the subthalamic nucleus, are included as part of the basal nuclei because they have a close

functional relation to the forebrain nuclei. In addition, connections between the basal nuclei and the pedunclopontine nucleus (PPN) are important in regulating underlying tone. Other parts of the basal nuclei, the ventral basal nuclei, are intimately related to the limbic system. The anatomical location of the various parts of the basal nuclei is shown in Fig. 18.1.

The caudate nucleus and the putamen are similar structures embryologically, anatomically, and functionally and, together, are often referred to as the neostriatum—a term derived from the word *striate*—and used to denote pathways from and to the caudate and putamen. An older term, *corpus striatum*, refers to the caudate, putamen, and globus pallidus. The various connections and interconnections of this system are discussed on the basis of these definitions.

Afferent Pathways

Functionally, the basal nuclei can be divided into an afferent portion and an efferent portion (Fig. 18.2). The afferent structures are the caudate and putamen. They receive input from the entire cerebral cortex, the intralaminar thalamic nuclei, and the centromedian-parafascicular complex of the thalamus as well as from the substantia nigra and the dorsal raphe nucleus, both located within the brain stem. The projections from the cortex are systematically arranged so that the frontal cortex projects to the head of the caudate and putamen and the visual cortex projects to the tail. In addition, the prefrontal cortex projects mainly to the caudate, whereas the sensorimotor cortex projects mainly to the putamen.⁴⁻⁷ Projections from the cortical regions that represent the proximal musculature, and those from the premotor regions, may be bilateral.^{5,6,8-11} These close and profuse connections between the cortex and the basal nuclei suggest a close interfunctional relationship. The projections from the thalamus to the caudate-putamen are also somatotopically arranged. The heaviest projections

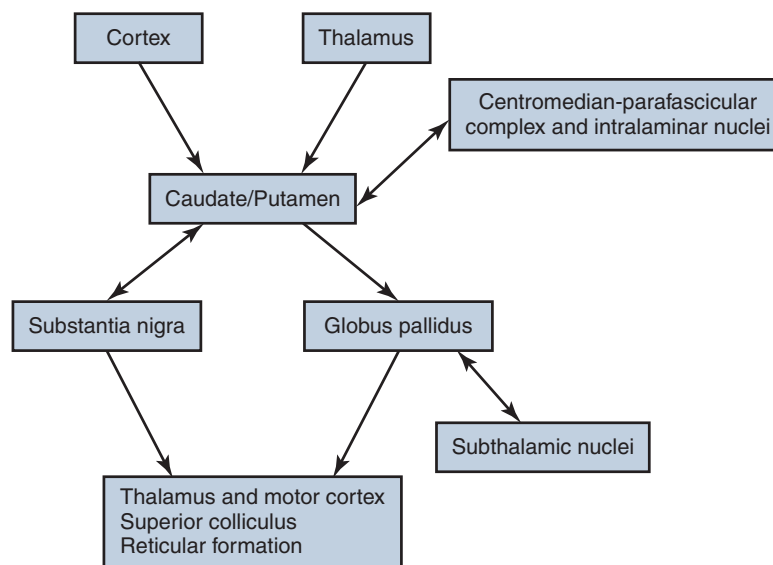

Fig. 18.2 Afferent and efferent portions of the basal nuclei.

are from the centromedian nucleus, and these nuclei also receive massive input from the motor cortex.^{6,7-11}

The somatotopic arrangement of the cortico-striatal-thalamic-cortical pathways is maintained throughout the loop. This finding has led to an important functional hypothesis that the basal nuclei form parallel pathways subserving specific sensorimotor and associative functions.⁴ The putamen is linked to the sensorimotor functions and the caudate to the associative, including cognitive functions.^{8,11}

As knowledge of the circuitry of the basal nuclei has advanced, so has the knowledge regarding the microscopic structure. The caudate-putamen looks somewhat homogeneous because of the

predominance of one cell type. Careful analysis using precise staining methods has demonstrated the appearance of patches within these nuclei. It is hypothesized that this organization is important for the ability of the basal nuclei to modulate ongoing sensory input and choose the appropriate motor response.¹¹ The intrinsic structure of the caudate-putamen also suggests that at least nigral input occurs in a way that could immediately modulate the input coming from the cortex.^{12,13}

Efferent Pathways

The input that has been processed in the caudate-putamen is sent to the globus pallidus (pallidum) and substantia nigra (nigra), which

constitute the efferent portion of the basal nuclei. The globus pallidus and substantia nigra are each divided into two regions. The globus pallidus has an external and an internal region; the substantia nigra consists of the dorsal pars compacta and the ventral pars reticulata. Embryologically and microscopically, the internal segment of the globus pallidus and the pars reticulata of the substantia nigra are similar. These two regions are the primary efferent structures for the basal nuclei. The projections from the caudate and putamen to the pallidum and nigra maintain a somatotopic arrangement.^{9,14,15} From these structures the information is transmitted to the thalamus and then to the cortex, still maintaining somatotopy. The superior colliculus, the PPN, and other, less-defined brain stem structures (perhaps the reticular formation) also receive pallidal and nigral output. All output of the basal nuclei has then been processed through the globus pallidus and/or the substantia nigra before proceeding to other areas of the brain (see Fig. 18.2).

Pathways to the Motor System

Information processed in the basal nuclei can influence the motor system in several ways, but no direct pathway to the alpha or gamma motor neurons of the spinal cord exists. The first route is the projection to the ventroanterior and ventrolateral nuclei of the thalamus, which then project predominantly to the premotor cortex. Another pathway is through the superior colliculus and then to the tectospinal tract. Pathways exist from the globus pallidus and substantia nigra that terminate in areas of the reticular formation (e.g., the PPN) and therefore may influence the motor system through the reticulospinal pathways. Research also supports the connection of the basal nuclei and the cerebellum and thus these two regions of the brain have the opportunity to further integrate movement responses.¹⁶ This includes support for the cerebellar-basal nuclei connection contributing to the Parkinsonian tremor and dystonia.^{17–19}

The basic circuitry of the basal nuclei comprises two loops.⁶ The loops for the sensorimotor system are shown in Fig. 18.3. The direct loop is the loop that begins in the motor regions of the cortex and projects to the putamen and then directly to the globus pallidus, the internal segment, and on to the thalamus. The indirect pathway adds the subthalamic nucleus between the globus pallidus, external segment, and internal segment before sending the signal on to the thalamus. The subthalamic nucleus also receives direct input from the premotor and motor cortex as well as from the pallidum.^{20,21} The darkened neurons represent inhibitory connections, and the open neurons represent excitatory connections. In general, the direct pathway, by disinhibition, activates the thalamocortical pathway; the indirect pathway inhibits the thalamocortical system. The role of these loops in normal and diseased states is clarified in the discussion of the physiology and pharmacology of the basal nuclei.

In summary, input from the motor cortex, all other areas of the cortex, parts of the thalamus, and the substantia nigra enter the basal nuclei through the caudate and putamen. Here they are processed and sent on to the globus pallidus and substantia nigra. The appropriate “gain” of the system is adjusted, for example, how large a movement is necessary or how much postural stability is needed. The information is sent to the muscles by way of the thalamus and motor cortex, the superior colliculus, and/or the reticular formation.

Physiology

The caudate and putamen are composed of neurons that fire slowly; the globus pallidus neurons fire tonically at high rates. The

low firing rates of the caudate-putamen are partially a result of the nature of thalamic inputs. Input from the cortex seems to have priority over input from the thalamus and substantia nigra. These data indicate that the cortex is instrumental in regulating the responsiveness of caudate and putamen neurons.²² In turn, basal nuclei stimulation may prepare the cortex for subsequent inputs; this might be especially important when a response must be withheld until an appropriate stimulus occurs, such as keeping the foot on the brake until the light turns green.^{22,23–25} Mink hypothesized that basal nuclei inputs to the cortex activate only the most necessary pathways and inhibit all unnecessary pathways (Fig. 18.4).²⁶

The pattern of neuronal firing in the direct and indirect pathways also suggests that the basal nuclei modify input to the cortex. The neurons of the efferent portion of the basal nuclei respond with either phasic increases or phasic decreases in activity, which, in turn, will affect the activity in the thalamus and hence the cortex. A decrease in

Fig. 18.4 The net effect of basal nuclei circuitry to produce an area of excitation (the desired program) surrounded by an area of inhibition (all other unnecessary programs). *GPi*, Globus pallidus internal segment; *STN*, subthalamic nucleus; *VLo/VA*, ventral lateral nucleus/ventral anterior. (Adapted from Mink JW. The basal nuclei: focused selection and inhibition of competing motor programs. *Prog Neurobiol.* 1996;50:381–425.)

activity of the internal segment of the globus pallidus removes inhibition to the thalamus and thus enables cortical activation. Whether the two pathways are activated concurrently or whether different activities activate the two pathways separately is not yet known; either way, the basal nuclei would have a role in cortical activation and modulation. One of the current views in relationship to disease processes is that an underactive direct pathway and/or an overactive indirect pathway would lead to decreased activation of the cortex and hence bradykinesia and akinesia, whereas an overactive direct pathway and/or underactive indirect pathway would lead to the presence of extraneous movements (see Fig. 18.3).^{5,27}

How do these pathways relate to everyday function? Rigidity could be explained by too much muscle activity (through the pathways from the basal nuclei to the PPN and on to the spinal cord). Akinesia and bradykinesia typical of individuals with Parkinson disease are caused by insufficient excitation or too many conflicting patterns of movement. Increased extraneous movements are characteristic of basal nuclei diseases and can be attributed to the dysfunctions within these pathways. If the amount of muscle activity and the sequence and timing of activation are inappropriate, the individual will have difficulty in selecting the environmentally appropriate behavior.^{26–29} Aldridge and colleagues found that the basal nuclei were modulated dependent on the purpose of the impending movement.²⁸

Relationship of the Basal Nuclei to Movement and Posture

Lesion experiments; single and multiple unit recordings in awake, behaving animals; careful observations of the sequelae of human

disease processes; and the results of functional magnetic stimulation studies in humans have provided some answers regarding the precise role of the basal nuclei in movement and posture.

Automatic Movement

The earliest view of the basal nuclei came from Willis in 1664. He hypothesized that the corpus striatum received “the notion of spontaneous localized movements in ascending tracts ... Conversely, from here tendencies are dispatched to enact notions without reflection [automatic movements] over descending pathways.”³⁰ Willis possessed great insights in the discussion of the signs and symptoms of basal nuclei disease. Magendie in 1841 demonstrated that removal of the striatum bilaterally produced compulsive movements, whereas removal of only one striatum produced no visible effect.³¹ Studies by Nothnagel³² demonstrated that lesions of the nigra tended to produce immobility. With the advent of the use of electrical stimulation in the late-19th century, further information on the function of the basal nuclei was gathered. Stimulation of the caudate nucleus did not (and does not) produce movement of muscles or limbs, as occurs with stimulation of the motor cortex; however, at higher levels of current, total-body patterns and postures were usually evoked. The earliest stimulation of the caudate nucleus produced an increase of flexion of the head, trunk, and limbs and tonic contraction of the facial muscles.²⁸ These early studies are mentioned because of the insights they provide for the symptoms of the disorders of today.

Motor Problems in Animals

Contemporary experiments using lesion paradigms show a wide variety of motor problems in a variety of animals. Hypokinesia, a decrease or poverty of movements, a decreased amount of exploration of novel environments, and a tendency to assume a fixed posture are the most common problems after a lesion in the basal nuclei. These motoric dysfunctions are seen regardless of the method by which the lesion is made: pharmacological, surgical, or by stimulation. In essence, movements are altered in scale (related to the gain), take longer for completion, and take place under altered conditions of antagonistic muscle interactions (e.g., contraction).^{33–41}

Movement Initiation and Preparation

The hypothesis that the basal nuclei are involved in movement initiation and preparation has been an area of some research disagreement. A “readiness potential,” recorded from the scalp of human beings before movement and thought to reflect basal nuclei activity, is more apparent in complex than in simple movements, for example, before dorsiflexion with gait but not before dorsiflexion when sitting.^{42–45}

Neuronal recordings from awake, behaving animals found that units in the basal nuclei alter their activity before changes in the electromyographic activity of the prime movers of the task.^{46–52} Studies recorded from multiple units in animals moving freely in their home environment suggest that neurons in the caudate-putamen and in the substantia nigra are activated in sequential, purposeful movements.²⁸ More recent functional magnetic resonance imaging (fMRI) studies emphasize the role of the mesial premotor cortex and its role as part of the cortico-basal nuclei-thalamo-cortical network for motor planning and movement initiation. This includes the role of the substantia nigra during motor planning caused by the dopaminergic gating of motor sequences.⁵³

Postural Adjustments

The basal nuclei have been implicated in the process of posture and postural adjustments. People with diseases of the basal nuclei assume

flexed or other fixed postures as the disease progresses (Fig. 18.5). In addition, these individuals have decreased postural stability and are therefore at risk for falls. Animal experiments indicate that a deficit exists in determining response based on one's own body position, or "egocentric localization."^{54–56} This deficit decreases the ability of a person with basal nuclei disease to modify a postural response to the precise environmental demands.

Martin,⁵⁷ in his extensive studies of individuals with Parkinson disease, was the first to describe severe disturbances in posture, especially when vision was occluded. Melnick and colleagues⁵⁸ showed that a decrease in static postural adjustments in persons with Parkinson disease could be seen early in the disease process.⁵⁹ Bloem and colleagues^{60–62} and Visser and colleagues⁶³ meticulously studied the reflexes involved in postural adjustments and described deficits in the longer loop reflexes but not in the short latency reflex associated with the stretch reflex.

Others have investigated the interactions of the sensory systems involved in balance in those with Parkinson disease.^{63–67} Bloem and colleagues⁶¹ and Visser and colleagues⁶³ concluded that postural instability was caused by a decrease in proprioception. In a recent review of proprioception and postural stability and motor control,

Nicola and colleagues also describe the kinesthetic and proprioceptive deficits in people with Parkinson disease. Nicola and colleagues concluded that there was a "failure" in the body map similar to the failure in egocentric localization described previously.^{55,59} A decrease in the ability to use proprioceptive and kinesthetic information to properly scale the input and response also contributes to a loss of balance reactions.

Perceptual and Cognitive Functions

The basal nuclei are not solely motor systems. The previous paragraphs demonstrate the role of the basal nuclei in sensory integration, but they are also involved in cognitive functions and responses associated with reward.^{37,38,48,50,68} Researchers have found that learned movements are more affected by basal nuclei lesions than reflexes, neurons in the basal nuclei are responsive to some sensory input, especially proprioceptive input, and neurons in other parts of the basal nuclei are responsive to reward and anticipation of the reward.^{29,69,70} Klockgether and Dichgans,⁷¹ as well as Jobst and colleagues,⁷² found that patients with Parkinson disease likewise had impairments in kinesthesia and that as a person moved a limb further from the body's center, kinesthetic sense decreased. Schneider and colleagues⁷³ found that animals that developed parkinsonian symptoms from a neurotoxin had deficits in operantly conditioned behavior. They suggested that the decrease in performance resulted from a "defect in the linkage" between a stimulus and the motor output centers. These sensory difficulties may be important factors in evaluation and treatment of basal nuclei diseases, especially those associated with dystonia.

The basal nuclei appear to be involved in the process of withholding a response until it is appropriate.⁷⁴ A deficit in alternation of response may be the result of a tendency toward perseveration of a previously reinforced cue.⁷⁵ Additional deficits exist in remembering or relearning tasks requiring a temporal sequence.⁷⁶ Graybiel²⁹ integrated the behavioral findings with information from her anatomical and chemical studies to suggest that the basal nuclei are important in providing behavioral flexibility. She hypothesizes that the basal nuclei are involved in procedural learning that leads to the development of habits. These habits become routine and are easily performed without conscious effort; we are free to react to new events in our environment and to think. Graybiel and colleagues have performed electrophysiological experiments that explain this learning process, and these studies demonstrate great plasticity in basal nuclei networks.^{77,78} This enables the individual to select the proper movements in the proper environmental context. These cognitive dimensions are important to remember when developing a plan of care for a patient with basal nuclei dysfunction.

The ability to perform cognitive activities involves integrating sensory information and, on the basis of this information, making an appropriate response. Humans with basal nuclei disease may show problems in perceptual abilities, including deficits in tasks that involve perception of interpersonal and intrapersonal space.⁷⁹ The basal nuclei seem to have a sensory integrative function as evidenced by experiments that show a multisensory and heterotopic convergence of somatic, visual, auditory, and vestibular stimuli.^{29,69} Segundo and Machne,^{70,80} as well as Nicola and colleagues,⁵⁵ hypothesized that the function of the basal nuclei was not subjective recognition of the stimuli but rather in the regulation of posture and movements of the body in space and in the production of complex motor acts.

For movements to be properly controlled and properly sequenced, the two sides of the body need to be well integrated. There is

Fig. 18.5 Typical posture of a patient with Parkinson disease from the front (A) and from the side (B). Note the flexed spine, mild flexion at the hips and knees, and excessive dorsiflexion with weight predominantly on the heels. Patient was at Hoehn and Yahr stage 2.5.

anatomical evidence that suggests some means of bilateral control for the basal nuclei. A lesion of one caudate nucleus or nigrostriatal pathway produces a change in the unit activity of the remaining caudate.^{76,81} Studies of the dopaminergic pathway also indicate interactions between the two sides of the body.⁸¹ For this reason one may find deficits in function even on the “uninvolved” side of an individual with disease or lesion of the basal nuclei. It is also possible that diseases of the basal nuclei may go unnoticed until damage is found bilaterally.

This summary of experimental results on the function of the basal nuclei illustrates several points. At least in some general way the basal nuclei are involved in the processes of movement related to preparing the organism for future motion and future reward. This may include preparing the cortex for approximate time activation, setting the postural reflexes or the gamma motor neuron system, organizing sensory input to produce a motor response in an appropriate environmental context, and inhibiting all unnecessary motor activity. Owing to the multilevel involvement of the basal nuclei in movement, it is crucial that clinicians carefully observe all aspects of movement (simple and complex) with and without interference of sensory cues or

performance of dual tasks as well as postural tone during examination, treatment, and the responses to treatment.

Neurotransmitters

Before a detailed analysis of the diseases of the basal nuclei can be considered, a brief description of the neurotransmitters of this region is necessary. The most prevalent diseases discussed in this chapter indicate a deficit in specific neurotransmitters. The pharmacological treatment of Parkinson disease and, in the future, perhaps other “Parkinson’s plus” or “basal nuclei plus” diseases, is based on these neurochemical deficits. The basal nuclei possess high concentrations of many of the suspected neurotransmitters: dopamine (DA), acetylcholine (ACh), γ -aminobutyric acid (GABA), substance P, and the enkephalins and endorphins. This discussion, however, includes only the first three neurotransmitters. A diagram of the basal nuclei pathways, which includes the neurotransmitters, is shown in Fig. 18.6.

DA is the major neurotransmitter of the nigrostriatal pathway and is produced in the pars compacta of the substantia nigra. The axon terminals of these dopaminergic neurons are located in the caudate

(Reprinted from Alexander GE, Crutcher MD. Functional architecture of basal nuclei circuits: neural substrates of parallel processing. *Trends Neurosci.* 1990;13:266–271.)

nucleus and putamen. DA appears to be excitatory to the neurons in the direct pathway (GABA and substance P neurons) and inhibitory to the neurons in the indirect pathway (GABA and enkephalin neurons).¹ This dual effect means that a loss of DA will lead to a loss of excitation in the direct pathway and an excess of excitation of the indirect pathway, leading to a powerful decrease in activation of the thalamocortical pathway.

Several DA receptors exist; however, their chemical interactions permit the continued use of D1 and D2 receptor classes.⁶ The role of DA may modulate the effects of other neurotransmitters such as glutamate. Many new drugs (called the *dopamine agonists*) influence only one of these receptors. Recent experiments have been trying to determine which behaviors are mediated by which DA receptor in the hope that this research may lead to more effective drug treatment with fewer side effects.

Because various drugs and chemicals can act as agonists (similar to) and antagonists (blocking the action of) of DA, they are used in treating disease involving the basal nuclei. Agonists include amantadine, apomorphine, and a class of drugs called the *ergot alkaloids* (e.g., bromocriptine). Amphetamine, which prevents the reuptake of DA, can enhance the effect of any DA present in the system. Antagonists include haloperidol, clozapine, and antipsychotic drugs of the phenothiazine class. With time these drugs may deplete the basal nuclei of DA and therefore cause Parkinson disease or tardive dyskinesia. Similar effects on the DA system are observed in a single dose of methamphetamine.⁸²

ACh is believed to be the neurotransmitter of the small interneurons of the caudate and putamen. It is presumed to inhibit the action of DA in this region and classically must be “in balance” with DA (and GABA). Dopaminergic axon terminals are found on cholinergic neurons. Substances that increase dopaminergic activity decrease release of ACh and vice versa.⁸³ The antagonists of ACh, such as belladonna alkaloids and atropine-like drugs, were one of the first class of drugs used in the treatment of Parkinson disease. ACh antagonists are still used as adjuncts to treatment for patients with Parkinson disease. As some of the drugs to treat dementia are ACh agonists, care must be used when these are prescribed for the person with basal nuclei dysfunction, especially Parkinson disease.

GABA is an inhibitory neurotransmitter that is found throughout the brain. In the basal nuclei, it is synthesized in the caudate nucleus and putamen and transmitted to the globus pallidus and substantia nigra.⁸⁴ GABA in the basal nuclei may permit movement to occur by allowing a distribution of neuronal firing. It may also provide a means of feedback inhibition in the efferent parts of the basal nuclei so that the program of activity is not repeated unless needed.⁸⁴ Individuals with Huntington disease have a deficiency of this chemical. Although agonists of GABA exist (e.g., muscimol and imidazole acetic acid), a successful drug for the treatment of Huntington disease has not yet been found. This may be a result of either the ubiquitous nature of GABA or the very complex circuitry and interrelationships that exist among GABA, ACh, and DA.

In addition to the transmitters discussed, co-transmitters may be found in the basal nuclei. Two such co-transmitters are cholecystokinin and neurotensin. The interactions of these co-transmitters may alter the sensitivity of DA receptors. Fuxe⁸⁵ suggests that the interactions of co-transmitters may alter the “set point” of transmission in synapses. They may therefore be important in supersensitivity, which is one of the side effects of DA therapy.

Lastly, the neurotransmitter from the cortex to the caudate nucleus and putamen is glutamate. Studies are ongoing to investigate glutamate antagonists as a treatment for Parkinson disease. Glutamate

receptors use calcium, and in the future, drugs affecting calcium channels may also have a therapeutic effect.

SPECIFIC CLINICAL PROBLEMS ARISING FROM BASAL NUCLEI DYSFUNCTION

Parkinson Disease

Parkinson disease is a diverse disorder with a long list of motor and nonmotor symptoms. It is a slowly progressing degenerative disease defined by a decrease in the DA stores of the substantia nigra and associated with striatal Lewy bodies (intracellular inclusions) and α -synuclein deposition. It is DA that gives the substantia nigra its coloration (and hence its name); therefore the lighter the nigra, the greater the DA loss. The term Parkinsonism is often used and is an umbrella term that refers to a group of disorders that produce abnormalities of the basal nuclei. Primary Parkinsonism is known as idiopathic Parkinsonism and what people are referring to when using the term Parkinson's. Secondary Parkinsonism has a determined etiology including tumors, viruses, and drugs. While no two people will experience the exact combination of symptoms, there are some commonalities. It was first described by Parkinson in 1807 as a disease characterized by rigidity, bradykinesia (slow movement), micrographia, masked face, postural abnormalities, and a resting tremor.

Parkinson disease is among the most prevalent of all CNS degenerative diseases. Presently, there are an estimated 1 million people in the United States with this disease, with approximately 60,000 new cases each year; the incidence is 4.5 to 20.5, and the prevalence is 31 to 347 per 100,000 (refer to the list of websites at the end of this chapter). Incidence increases with advancing age, and it is estimated that one in three adults over the age of 85 will have this disease.¹ Four percent are diagnosed before the age of 50 years. The personal and societal burden of Parkinson disease is estimated at 25 billion a year in the United States alone and includes the cost of treatment, the burden of caregiving, and the cost of lost earnings in patients below the age of 65 years.⁸⁶

The cause of Parkinson disease remains unknown, and the consensus is that it is multifactorial.^{87,88} Some evidence indicates involvement of environmental factors and that interaction of environment and aging lead to a critical decrease in DA. Several investigators have found a link between growing up in a rural area and Parkinson disease, with connections to pesticide and insecticide exposure, as well as elements in well water.⁸⁹⁻⁹⁵ Accumulation of free radicals, cell death to excitatory neurons from toxins, and dysfunction of nigral mitochondria have all been implicated in the pathological process. The genetics of Parkinson disease was in debate for many years, but it is now known that at least 10% to 15% percent of all cases of Parkinson disease are familial. Recent studies have discovered the presence of altered autosomal dominant (α -synuclein, LRRK2), autosomal recessive (PARK7, PINK1, PRKN), and altered risk factor modifier genes that may put you at risk of developing the disease. Research is still underway regarding genetic links, but it is believed that a complex interaction between genetic and nongenetic-factors is the cause of PD; thus a family history may be an important risk factor.^{94,96-100} Beyond genetics, there is new research investigating the link between early symptoms of Parkinson disease and the nerve cells lining the digestive tract. Large toxic amounts of the alpha-synuclein protein—hallmark of Parkinson disease—have been found in the gut of people who developed Parkinson disease. There is also evidence that people who have a vagotomy (one or more branches of the vagus nerve are cut) have a lower risk of developing PD, supporting the brain-gut connection.¹⁰¹ So the debate continues, with most neurologists agreeing that the multifactorial approach will yield the best opportunity to develop a cure.

Symptoms

Bradykinesia, akinesia, and complex motor planning. Bradykinesia (a decrease in motion) and akinesia (a lack of motion) are characterized by an inability to initiate and perform purposeful movements. They are also associated with a tendency to assume and maintain fixed postures. All aspects of movement are affected, including initiation, alteration in direction, and the ability to stop a movement once it has begun. Spontaneous or associated movements, such as swinging of the arms in gait or smiling at a funny story, are also affected. Bradykinesia is hypothesized to be the result of a decrease in activation of the supplementary motor cortex, premotor cortex, and motor cortex.¹⁰² The resting level of activity in these areas of the cortex may be decreased so that a greater amount of excitatory input from other areas of the brain would be necessary before movement patterns could be activated. In the individual with Parkinson disease, an increase in cortically initiated movement even for such “subcortical” activities, such as walking, supports this hypothesis. Automatic activities are cortically controlled, and each individual aspect seems to be separately programmed. Associated movements in the trunk and other extremities are not automatic, which means that great energy must be expended whenever movement is begun.¹⁰³

Bradykinesia and akinesia affect performance of all types of movements; however, complex movements are more involved than simple movements, such as dorsiflexing the foot at toe-off in walking as opposed to dorsiflexing the foot in a seated position.^{70,104–107} In addition, patients with parkinsonism have increased difficulty performing simultaneous or sequential tasks, over and above that seen with simple tasks. Parkinsonian patients must complete one movement before they can begin to perform the next, whereas control subjects are able to integrate two movements more smoothly in sequence. This deficit has been shown in a variety of tasks, from performing an elbow movement and grip to tracing a moving line on a video screen. The patient with Parkinson disease behaves as if one motor program must be completely played out before the next one begins, and there is no advance planning for the next movement while the current movement is in progress.^{105–109} Morris and colleagues demonstrated a similar phenomenon in walking. Patients with parkinsonism were unable to perform walking while carrying a tray with a glass of water and had even more difficulty when walking and reciting a numerical sequence.^{110,111}

Sequential movements become more impaired as more movements are strung together; for example, a square is disproportionately slower to draw than a triangle and a pentagon more difficult than a square.^{4,107} These results indicate that patients with Parkinson disease have difficulty with transitions between movements. Transitional difficulties are more impaired in tasks requiring a series of different movements than tasks requiring a series of repetitive movements. For example, an individual will have less difficulty continually riding a stationary bike than movement requiring transitions such as coming from a chair to standing, walking, and turning a corner. Therefore treatment must include complex movements with directional changes to ensure that the patient is safe outside the treatment setting.

Bradykinesia is not caused by rigidity or an inability to relax. This was demonstrated in an electromyographic analysis of voluntary movements of persons with Parkinson disease.¹¹² Although the pattern of electromyographic agonist-antagonists burst is correct, these bursts are not large enough, resulting in the inability to generate muscle force rapidly enough. Even in slow, smooth movements, these individuals demonstrated alternating bursts in the flexor and extensor muscle groups. This type of pattern, expected in rapid movements that require the immediate activation of the antagonist to halt the motion, interferes with slow, smooth, continuous motion. Other researchers have

found an alteration in the recruitment order of single motor units.^{113,114} These alterations included a delay in recruitment, pauses in the motor unit once it was recruited, and an inability to increase firing rates. These people would therefore have a delay in activation of muscles, an inability to properly sustain muscle contraction for movement, and a decreased ability to dissipate force rapidly.^{26,113,115} Such changes may account for perceived decreases in strength that are seen in persons with Parkinson disease. They are also important to remember in both treatment planning and the efficacy of treatment efficiency.

Rigidity. The rigidity (increased resistance to passive movement) of Parkinson disease may be characterized as either “lead pipe” or “cogwheel.” The cogwheel type of rigidity is a combination of lead-pipe rigidity with tremor. In rigidity, there is an increased resistance to movement throughout the entire range in both directions without the classic clasp-knife reflex so characteristic of spasticity. Procaine injections can decrease the rigidity without affecting the decrease of spontaneous movements, confirming that rigidity is not the same phenomenon as bradykinesia.^{116,117}

Rigidity is not caused by an increase in gamma motor neuron activity, a decrease in recurrent inhibition, or a generalized excitability in the motor system.¹¹⁸ Long- and middle-latency reflexes are enhanced in Parkinsonism, and the increase in long-latency reflexes approximates the observable increase in muscle tone. Short-latency reflexes (i.e., deep tendon reflexes), on the other hand, may be normal in persons with Parkinson disease.

Tatton and others¹¹⁹ found differences in certain cortical long-loop reflexes in normal and drug-induced Parkinsonian monkeys, which led them to speculate that the “reflex gain” of the CNS may lose its ability to adjust to changing environmental situations. For example, in normal people, the background level of motor neuron excitability is different for the task of writing from the task of lifting a heavy object; in individuals with Parkinson disease, motor neuron excitability would be set at the same level. Similarly, in the normal individual, there would be a difference in excitability if the environmental demands were for excitation or inhibition of a muscle; for the individual with Parkinson disease, there would be similar motor neuron excitability regardless of task demands. Furthermore, this lack of modulation may mean that the person with Parkinsonism perceives himself or herself to be moving farther than he or she is actually moving. It is also consistent with a decrease in system flexibility and an inability to adjust to equilibrium perturbations.^{60,62,65}

An important aspect of rigidity is that it might increase energy expenditure.¹²⁰ This would increase the patient’s perception of effort on movement and may be related to feelings of fatigue, especially postexercise fatigue.¹²¹

Tremor. In those diagnosed with Parkinson disease, about 70% will experience a tremor at some point in the disease. The tremor observed in Parkinson disease is present at rest, usually disappears or decreases with movement, and has a regular rhythm of about 4 to 7 beats per second; however, it may worsen with intense emotions, fatigue, or anxiety. Tremor often occurs unilaterally and then progresses bilaterally in the hands, described as “pill rolling,” but can also appear as a postural tremor, or in other parts of the body including the lower lip, jaw, or leg. The electromyographic tracing of a person with such a tremor shows rhythmical, alternating bursting of antagonistic muscles. Tremor can be produced as an isolated finding in experimental animals that have been treated with drugs, especially DA antagonists. DA depletion, however, is not the sole cause of tremor. It appears that efferent pathways, especially from the basal nuclei to the thalamus, must be intact because lesions of these fibers decrease or abolish the tremor.¹²² Tremors can be severely disabling, affecting all aspects of activities of daily living (ADLs) requiring fine motor control such as

eating, drinking, dressing, shaving, and writing. Upper extremity tremors are what lead many people to seek initial treatment and diagnosis.

Postural Instability. Postural instability is a serious problem in Parkinsonism that leads to increased episodes of falling, with the sequelae of falls contributing to morbidity. More than two-thirds of all patients with Parkinsonism fall, and more than 10% fall more than once a week.¹²³ People with Parkinson disease have a ninefold risk of recurrent falls compared with age-matched control subjects.^{61,124–128} Patients have an increased likelihood of falling as the duration of the disease increases. Drug treatment is not usually effective in reducing the incidence of falls. Deep brain stimulation (DBS) and exercise, on the other hand, have been shown to be effective in increasing functional skills and/or motor performance that, in turn, may decrease the number of falls.^{129–132} Large randomized clinical trials have been performed to determine the efficacy of exercise and will be discussed later in the chapter.¹³³

Although the pathology of postural instability is unknown, several hypotheses exist. One explanation for postural instability is ineffective sensory processing. Several investigators have found deficits in proprioceptive and kinesthetic processing.^{57,72,115,134} For example, Martin⁵⁷ found that labyrinthine equilibrium reactions were delayed in patients with Parkinson disease. Studies of the vestibular system itself, however, have shown that this system functions normally. Pastor and colleagues¹³⁵ studied central vestibular processing in patients with Parkinson disease and found that the vestibular system responds normally and that patients can integrate vestibular input with the input from other sensory systems. This group hypothesized that the parkinsonian patients had an inability to adequately compensate for baseline instability. This theory is in partial agreement with studies by Beckley, Boehm, and others^{60,62,65} demonstrating that patients with Parkinson disease were unable to adjust the size of long- and middle-latency reflex responses to the degree of perturbation. These patients are therefore unable to activate muscle force proportional to displacement. Melnick and colleagues⁵⁸ found that subjects with Parkinson disease were unable to maintain balance on a sway-referenced force plate. Glatt¹³⁶ found that patients with Parkinson disease did not demonstrate anticipatory postural reactions and, in fact, behaved exactly as a rigid body with joints. In a variety of studies, Horak and colleagues^{137,138} reported similar findings and found defects in strategy selection as well; patients with Parkinson disease chose neither a pure hip strategy nor a pure ankle strategy but mixed the two in an inappropriate and maladaptive response. Investigators have found that antiparkinsonian medications could improve background postural tone but did not improve automatic postural responses to external displacements.^{60,62,65,137} Other studies have demonstrated deficits in proprioceptive perception—what has been termed an “impaired proprioceptive body map.” Patients with Parkinson disease did not alter anticipatory postural adjustments in response to step width changes, unlike control subjects.¹³⁹ Increased step width requires increased lateral reactive forces to unload the stance leg. The lack of ability to prepare for these extra forces may indicate that narrow stance width, start hesitation, and freezing of gait are compensatory mechanisms to proprioceptive loss.¹³⁴ Likewise, when patients could not see their limbs, they had difficulty moving the foot to a predetermined location in response to perturbation. Control subjects had no difficulty.^{140,141} Taken together, it appears that postural instability results from inflexibility in response repertoire; an inability to inhibit unwanted programs; the interaction of akinesia, bradykinesia, and rigidity; and some disturbance in central sensory processing.

Gait. The typical Parkinsonian gait is characterized by decreased velocity and stride length.^{142–143} As a consequence, foot clearance is decreased, which places the individual at a greater fall risk.¹⁴⁴ In many

patients, especially as the disease progresses, speed and shortening of stride progressively worsen as if the individual is trying to catch up with his or her center of gravity; this is termed *festination*. Forward festination is called *propulsion*; backward festination is known as *retropulsion*. One hypothesis is that festinating gait is caused by the decreased equilibrium responses. If walking is a series of controlled falls and if normal responses to falling are delayed or not strong enough, then the individual will either fall completely or continue to take short, running-like steps. The abnormal motor unit firing seen with bradykinesia may also be the cause of ever-shortening steps. If the motor unit cannot build up a high enough frequency or if it pauses in the middle of the movement, then the full range of the movement would decrease; in walking this would lead to shorter steps. Festination may also be the result of other changes in the kinematics of gait.

The changes in gait kinematics include changes in excursion of the hip and ankle joints (Fig. 18.7). Instead of a heel-toe, the patient may have a flat-footed or, with disease progression, a toe-heel sequence. The flat-footed gait with poor weight shifting decreases the ability to step over obstacles or to walk on carpeted surfaces. The use of three-dimensional gait analysis has shown that there is a decrease in plantarflexion at terminal stance. Changes are also seen in hip flexion, which may alter ankle excursion; however, qualitative aspects of the timing of joint excursion appear intact. Fig. 18.7 illustrates the joint angles in a 55-year-old patient with Parkinson disease compared with adults without basal nuclei dysfunction.¹⁴⁵

Impaired gait and postural instability are the two impairments that contribute to the greatest activity limitations to persons with Parkinsonism. The inability to ambulate safely and the high fall risk of these patients are the major elements contributing to mortality and preventing independence in home and work as the disease progresses.

Perception, attention, and cognitive deficits. Especially in recent years, researchers have tried to address the cognitive and perceptual impairments of people with Parkinson disease.^{134,146–149} The learning and perceptual deficits are hypothesized to be caused by a decrease in cortical excitation from the caudate nucleus,¹⁰⁸ whereas the movement deficits are hypothesized to be caused by a decrease in putaminal excitation of the cortex. Cognitive involvement can also include memory loss, confused thinking, and dementia. Parkinson disease medications may worsen these cognitive impairments.

The deficits are of frontal lobe function and include an inability to shift attention, an inability to quickly access “working memory,” and difficulty with visuospatial perception and discrimination. Research attention has focused on the specific deficits of parkinsonian patients compared with patients with Alzheimer’s disease, patients with frontal lobe damage, and those with temporal lobe damage.^{146,149,150} The perceptual deficits of all groups appear to increase with progression of the disease process. In general, patients have difficulty in shifting attention to a previously irrelevant stimulus, learning under conditions requiring selective attention, or selecting the correct motor response on the basis of sensory stimuli.^{151–153} There is also evidence that DA is involved in selection of responses that will be rewarding.⁵⁵ These impairments will affect treatment strategies.

Learning deficits also have been found in patients with Parkinsonism; procedural learning has been particularly implicated, as would be indicated based on the physiology of the system. Procedural learning is learning that occurs with practice or, as defined by Saint-Cyr and colleagues,¹⁵⁴ “the ability gradually to acquire a motor skill or even a cognitive routine through repeated exposure to a specific activity constrained by invariant rules.” In their tests, patients with Parkinson disease did very poorly on those related to procedural learning, but their declarative learning was within normal limits. Pascual-Leone and colleagues¹⁰⁸ studied procedural learning in more detail. They found

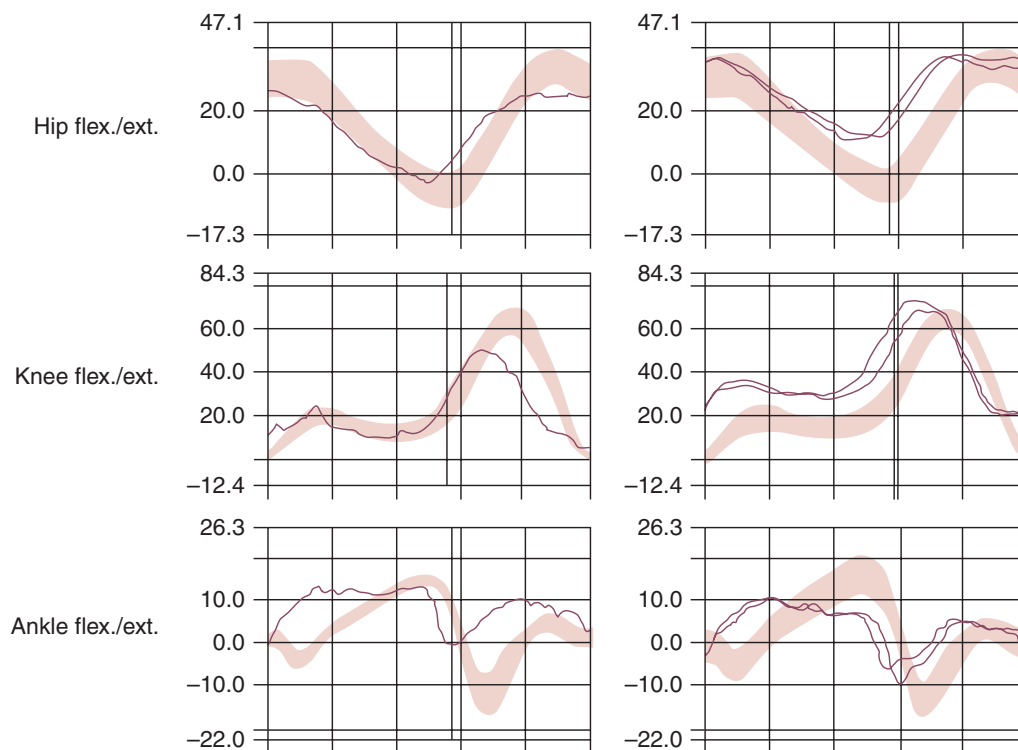

Fig. 18.7 Angles of Excursion During Gait in a Patient With Parkinson Disease. *Shaded areas* are mean \pm standard deviations for adults *without* Parkinson disease; *black lines* represent a patient *with* Parkinson disease. Movement shown for right- and left-lower extremities. Note decreases, especially in left lower extremity for extension and bilateral decreased plantarflexion.

that patients with Parkinson disease could acquire procedural learning but needed more practice than control subjects did. They also found that the ability to translate procedural knowledge to declarative knowledge was more efficient if it occurred with visual input alone rather than the combination of visual input with motor task. This may be a rationale for more therapy, not less.

Nonmotor symptoms. Nonmotor symptoms are consistently seen in patients with Parkinson disease and may be attributable to dopaminergic pathways outside the basal nuclei. Braak and colleagues^{155,156} hypothesized that Parkinson disease actually begins with DA deterioration in the medulla and progresses rostrally. Often, the first signs are loss of sense of smell, constipation, vivid dreams (rapid-eye movement [REM] behavior disorder), and orthostatic hypotension.¹⁵⁷ Orthostatic hypotension may cause some dizziness and requires coordination of medications for other medical problems. L-Dopa and DA agonists may lower blood pressure. These symptoms alone do not indicate Parkinson disease, but combined they may indicate risk. Physical therapy may be most effective when started early, so researchers are trying to learn more about these early symptoms.

Other nonmotor symptoms that decrease quality of life include incontinence in men and women, sexual dysfunction, excess saliva, weight changes, and skin problems. Urinary incontinence may increase the risk of hospitalization and mortality.¹⁵⁸ Nonmotor symptoms that can interfere with and complicate physical and occupational treatment include fatigue, fear, apathy, anxiety, and depression. Referrals to medical professionals for these symptoms are imperative.

Sleep disorders are widespread in Parkinson disease and include more than just REM sleep disorder.¹⁵⁶ The patient may experience daytime drowsiness and decreased sleep at night, as well as the presence of restless leg syndrome.¹⁵⁹ Daytime drowsiness may be a side

effect of medication; however, it can also be exacerbated after therapeutic exercise, so a cool-down period is necessary before the patient sits down and relaxes.

Another side effect of medication is the presence of hallucinations. Many patients report seeing very ugly creatures or monsters, and when such hallucinations occur in the therapeutic session, they can be most uncomfortable for the therapist and the patient. These hallucinations also make it difficult for the patient to use adjunct treatments such as computer games and virtual reality activities. These and other nonmotor symptoms often predominate as the disease progresses,¹⁵⁶ contributing to severe disability, impaired quality of life, and shortened life expectancy.

Stages of Parkinson Disease

Staging of Parkinson disease uses the Hoehn and Yahr scale (Table 18.1).¹⁶⁰ Originally developed as a 5-point scale, in recent years 0, 1.5, and 2.5 measurements have been added. The 1.5 and 2.5 ratings have not been validated, but because their use is so common, the latest recommendation is to continue using them while the validity is studied.¹⁶¹

In stage 1 of the disease, initial motor symptoms, often a resting tremor or unilateral micrographia (bradykinesia of the upper extremity), is present. Stage 2 progresses with rigidity and bradykinesia bilaterally, and postural alterations and axial symptoms begin to occur. This commonly starts with an increase in neck, trunk, and hip flexion that, accompanied by a decrease in righting and balance responses, leads to a decreased ability to maintain the center of gravity over the base of support.

While these postural changes are occurring moving into stage 3, so does an increase in rigidity, which is most apparent in the trunk and

TABLE 18.1 Hoehn and Yahr Staging Scale for Parkinson Disease

Stage	Progression of Symptoms
0	No signs of disease.
1	Unilateral symptoms only.
1.5	Unilateral and axial involvement.
2	Bilateral symptoms. No impairment of balance.
2.5	Mild bilateral disease with recovery on pull test.
3	Balance impairment. Mild to moderate disease. Physically independent.
4	Severe disability, but still able to walk or stand unassisted.
5	Needing a wheelchair or bedridden unless assisted.

The Hoehn and Yahr scale is commonly used to describe how the symptoms of Parkinson disease progress. The original scale included stages 1 through 5.¹⁶² Stage 0 has since been added, and stages 1.5 and 2.5 have been proposed to best indicate the relative level of disability in this population.¹⁶³

proximal and axial musculature. Trunk rotation becomes severely decreased; there is no arm swing during gait and no spontaneous facial expression; and movement becomes more and more difficult to initiate. Movement is usually produced with great concentration and is perhaps cortically generated, thereby bypassing the damaged basal nuclei pathways. This great concentration then makes movement tiring, which heightens the debilitating effects of the disease, requiring assistive devices to ambulate in stage 4.

Eventually the individual becomes wheelchair bound and dependent. In the late and severe stages of the disease, especially without therapeutic attention for movement dysfunctions, the patient may become bedridden and may demonstrate a fixed trunk-flexion contracture regardless of the position in which the person is placed. This posture has been called the “phantom pillow” syndrome because, even when lying supine, the person’s head is flexed as if on a pillow.

Throughout this progressive deterioration of movement, there is also a decrease in higher-level sensory processing. In addition, the patient can perform only one task at a time. Reports of dementia range from 30% to 93% in patients with Parkinson disease.¹⁶⁴ The presence of dementia in this population may indicate involvement of the ACh or noradrenergic mesolimbic system. In this case, treatment with anticholinergic drugs may increase a tendency toward dementia, especially in older patients. Sometimes, cognitive deficits are inferred because of slowed responses, spatial problems, sensory processing problems, and a masked face.

The most serious complication of Parkinson disease is bronchopneumonia. Decreased activity in general and decreased chest expansion may be contributing factors. Aspiration pneumonia can also contribute to mortality because patients may experience dysphagia and dysarthria. The mortality rate is greater than in the general population, and death is usually from pneumonia.

Pharmacological Considerations and Medical Management

The knowledge that the symptoms of Parkinson disease are caused by a decrease in DA led to the pharmacological management of this disease. Because DA itself does not cross the blood-brain barrier, levodihydroxyphenylalanine (L-dopa), a precursor of DA that does, has been used to treat Parkinson disease since the late 1960s.^{162,165–166} An inhibitor of aromatic amino acid decarboxylation (carbidopa) is usually

given with L-dopa to prevent the conversion to DA before entering the brain. The decarboxylase inhibitor allows a reduction in dosage of L-dopa itself, which helps decrease the cardiac and gastrointestinal side effects of DA.

Amantadine is another drug that has been effective in the treatment of patients with Parkinson disease. Although the mechanism of action of this antiviral medication is unknown, it is thought to include a facilitation of release of catecholamines (of which DA is one) from stores in the neuron that are readily releasable. It is often administered in combination with L-dopa.

Treatment of Parkinson disease with L-dopa in these various combinations is extremely helpful in reducing bradykinesia and rigidity. It is less effective in reducing tremor and the postural instability. Because Parkinson disease involves the nigral neurons, the receptors and the neurons in the striatum (which are postsynaptic to dopaminergic neurons) remain intact and, initially, are somewhat responsive to DA.^{163,167} With time, however, the receptors appear to lose their sensitivity, and the prolonged effectiveness (10 years or more) of L-dopa therapy is questionable.^{168–170} A further complication of L-dopa therapy is the development of involuntary movements (dyskinesias) and the “on-off” phenomenon—a short-duration response resulting in sudden improvement of symptoms followed by a rapid decline in symptomatic relief and perhaps the appearance of dyskinesias and/or dystonias.^{171,172} With time the “on” effect becomes of shorter and shorter duration.^{168,171,173,174} Controlled-release or slow-release L-dopa may decrease these side effects. The effectiveness of L-dopa does not appear to be closely correlated with the stage of the disease.

The use of L-dopa alone or in combination with carbidopa has not provided a cure or even prevented the degeneration of Parkinson disease.^{173,174} As more has become known about the DA receptor, specific agonists have been developed. Ropinirole, pramipexole, pergolide, and bromocriptine are examples of DA receptor D2 agonists that are used alone or with L-dopa. The agonists are thought to decrease the wearing-off effects as well as decrease the dyskinesias that occur with long-term L-dopa use, but L-dopa remains the most effective medication. It is quite likely that newer D2 and/or D2-D1 (DA receptor D1) agonists will be developed. Pharmacological interventions also include drugs that prevent the breakdown of DA (e.g., catechol-O-methyltransferase [COMT] inhibitors) and/or its reuptake. Entacapone is an example of a COMT inhibitor.¹⁷⁵

Another approach to pharmacological treatment of individuals with Parkinson disease was developed from research on a designer drug that contained the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). It was found that the conversion of MPTP to the active neurotoxin MPP⁺ could be prevented by monoamine oxidase inhibitors such as deprenyl and pargyline.^{71,173} Deprenyl, rasagiline, and selegiline are now used before the initiation of, or in conjunction with, L-dopa and carbidopa.

Another treatment alternative is surgery performed in precise areas of the basal nuclei, known as *stereotaxic surgery*. Stereotaxic surgery is an old technique that has made a comeback based on the new knowledge of basal nuclei connectivity and improvements in the procedural instrumentation. Initially, one of the structures of the basal nuclei was lesioned with freezing or high-frequency stimulation. Today, the globus pallidus internal segment or the subthalamic nucleus is stimulated with implanted electrodes. This technique is known as *DBS*. DBS has now been approved by the US Food and Drug Administration (FDA). An advantage of DBS over permanent lesions is that DBS is reversible and is safer for bilateral surgeries. Stimulation of the globus pallidus internal segment or subthalamic nucleus has been shown to decrease all symptoms; subthalamic nucleus stimulation is also effective in reducing dyskinesias and may lessen the amount of medication

taken.^{176–178} Effects of stimulation are greater for symptoms manifested in the “off” state. DBS has been demonstrated to improve rigidity, bradykinesia, and akinesia, as well as gait^{59,178–182} and balance.^{58,183} It has also been demonstrated to improve movement velocity and speed of muscle recruitment for activity.^{181,183} The proposed mechanism of action is interference with the abnormal neuronal firing.^{184,185} In a randomized, controlled clinical trial, DBS was more effective in reducing symptoms and increasing quality of life than medication.^{186,187} This group also found that although some side effects were worse (e.g., brain hemorrhage), the total number of adverse reactions was greater in the medication group. Whether stimulation of the subthalamic nucleus is neuroprotective, that is, prevents further degeneration, is presently under investigation. Thalamic stimulation is used for decreasing tremor. Therapists may find that intense treatment immediately after these surgeries may be able to take advantage of neural plasticity.

Fetal transplantation of the substantia nigra to the caudate nucleus remains under investigation. A double-blind, placebo-controlled trial was completed with mixed results.^{184,188–190} Studies continue, including those of dose, cell type, and placement of cells. Recently, however, there was a report of Lewy-body inclusions in grafted cells 14 years after the transplant.¹⁹¹ The authors concluded that Parkinson disease was an ongoing process and that what caused the disease initially also affected the grafted cells.

Examination of the Patient With Parkinson Disease

Examination of an individual with Parkinson disease should assess impairments and functional activities and draw correlations of impact on participation in the individual's life. Additionally, information regarding quality of life and the patient's perception of their function and disease is extremely valuable. The use of objective outcome measures for the different International Classification of Functioning Disability and Health (ICF) domains is strongly recommended, with population specific cut-offs that correlate with function and predictors of future events (i.e., falls). It is essential to perform outcome measure testing at initial exam, with re-assessment at regular intervals to assess changes, modify interventions as appropriate, and allow for open, updated communication with patients, family, and physicians.

When assessing the overall clinical presentation of a person with Parkinson disease, the Hoehn and Yahr scale (see [Table 18.1](#)) is the most commonly and widely used to describe the severity of the disease. It is based on clinical features and functional disability, assigning a numerical value of dysfunction as it relates to unilateral or bilateral involvement, and whether postural stability is compromised.^{160,161} Progression through the Hoehn and Yahr scale has prognostic implications—stage 3 has been correlated with increasing physical and cognitive impairment scores despite medication adjustments and therefore a marked deterioration in quality of life;¹⁶¹ however, it should be understood that this tool is not linear and does not include non-motor functions. Because the scale provides an overall assessment of impairment and disability combined, clinicians should use it to create a general clinical picture of their patient and, as such, help guide their interventions and decision making.

The Movement Disorder Society Sponsored-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) is the most widely used clinical rating scale for Parkinson disease. The scale assesses both nonmotor and motor symptoms associated with the disease, including nonmotor experiences, motor experiences of daily living, motor examination, and motor complications.^{188,189,191,192} The tool gathers information from the clinician's exam, as well as from patient/caregiver response. It is sensitive in terms of detecting change in function and disability as the disease progresses (especially in the earlier stages of the disease), while having a high correlative value with the Hoehn and Yahr scale.^{161,193} Another clinical scale is the Core Assessment Program for

Surgical Interventional Therapies in Parkinson's Disease (CAPSIT-PD), which includes timed tests for motor evaluation and neuropsychological testing.^{194–196} This scale was designed to provide minimal requirements and standardize assessments for those undergoing surgical intervention, and is used during the evaluation and consideration of a patient being considered for DBS surgery. Knowledge of these scales will help the therapist communicate with other health care professionals.

When completing an examination of a patient with Parkinson disease, subjective and quality of life questionnaires, in combination with functional activities assessment, will provide the most valuable information to guide treatment planning and goal setting. The Parkinson's Disease Questionnaire (PDQ)-39 is a self-reported questionnaire that assesses how the disease impacts function and well-being. It is the most frequently used measure to assess health status in people with Parkinson disease and is recommended for all stages of the disease.¹⁹⁷ The abbreviated PDQ-8 takes one item from each of the eight dimensions of the PDQ-39. Both the PDQ-39 and PDQ-8 are valid and reliable instruments to assess disease and health-related changes.¹⁹⁷ Construct-specific subjective measures are also strongly recommended, including the Freezing of Gait questionnaire and Parkinson's Fatigue Scale.

Five core areas should be assessed: physical capacity, transfers, manual activities, balance, and gait. In addition, a clinician should also assess respiratory function and pain.¹⁹⁸ In the clinical setting, the exam should focus on impairments and functional activities. Highly recommended measures in the Body Structure and Function domain include MDS-UPDRS part 1 and the Montreal Cognitive Assessment (MOCA), while those in the Activity Limitation domain include 6-minute Walk Test, 10 m walk, mini-BESTest, Functional Gait Assessment (FGA), MDS-UPDRS part 2, five times sit-to-stand, and 9 Hole Peg Test. An integral component of the exam is a complete and thorough movement analysis during the tasks to generate links between impairments and activity limitation. Additionally, the time it takes to complete an activity must be measured. It is also valuable to address the effects of adding interfering stimuli (motor and cognitive) and complexity to a task to determine at which point a patient may begin having difficulties.^{142,143}
