Throughout all stages of the disease, a careful and comprehensive analysis of balance is imperative because a patient with Parkinson disease has a two to four times higher risk of hip fractures caused by falls compared to individuals without the disease.^{199,200} The Activities-Specific Balance Confidence Scale (ABC) is highly recommended owing to its excellent reliability and validity in this population.^{201,202} The ABC Scale, along with previous fall history and UPDRS motor score, were the most significant predictor of future falls.²⁰³ It has become more evident that balance impairments and increased fall risk are present even in the early stages of the disease; decreased confidence in self-perceived balance is a known contributor for future fall risk.^{204,205} Assessing challenges to balance such as tandem walking or standing on a compliant surface is important because this may be the first sign of balance impairment. Posturography is the most sensitive measure of postural instability, especially in the early stages of the disease (Hoehn and Yahr stages 1 and 2).⁶⁰ A clinically useful tool to assess dynamic balance is the functional reach test, which has been shown to be an effective, predictive tool in people with Parkinson disease as it is in the elderly, while the functional axial rotation (FAR) test has been shown to detect functional limitations in the early stages of the disease.^{206,207} Evaluation of pain in an individual with Parkinson disease is important because this can have a detrimental effect on function and quality of life, although it is frequently underrecognized and often inadequately treated. While pain may come from different origins, pain of musculoskeletal origin is the most prevalent in people with Parkinson disease.^{208,209} It is widely known that chronic pain can develop from,

and lend itself to, avoidance of activities based on the fear of pain.²¹⁰ This further exacerbates decreased participation in functional activities and, ultimately, progression of disease-related symptoms.

An assessment of chest expansion and vital capacity should also be included because of their contribution to the complication of pneumonia. For this reason, when rigidity is assessed, the muscles of respiration, extremity, and trunk movement should be included. Active and passive range of movement, general strength, chest expansion, and vital capacity should also be measured on regular intervals. Clinicians should also be aware of swallow function, sleep-disordered breathing, and cough mechanism because these can also contribute to respiratory limitations.²¹¹ Early recognition of contributors to respiratory limitations are imperative for timely interventions and, ultimately, improving quality of life and mortality. At present, a complete and easy-to-use form for evaluation does not exist for Parkinson disease.

General Prognosis, Treatment Principles, and Rationale

As with all treatment, the prognosis (functional goals, personal factors, and established time parameters) is based on the general goals related to the findings from the examination of each patient, the patient's expectations, and functional requirements. Parkinson disease must be understood as a degenerative disease when establishing the prognosis and treatment plan, initially emphasizing a recovery model of care, then evolving to a maintenance/compensatory approach. In general, goals include increasing movement and range of motion (ROM) in the entire trunk and extremities, improving endurance, chest expansion with emphasis on posture, balance reactions, and restoring or maintaining functional abilities. Increased movement may in fact modify the progression of the disease.^{212,213} Nonpharmacological and nonsurgical interventions, especially physical therapy treatment, are essential at the beginning of the disease owing to potential complications associated with chronic medication use and surgical procedures.²¹⁴ Although levodopa decreases the bradykinesia, it alone will not be effective in increasing movement or improving balance; therefore aggressive intervention in the early stages is necessary.

Overall, physical rehabilitation is effective in the treatment of people with Parkinson disease and the results are greater when treatment is started early in the disease process. Although treatment initiated while the disease is still unilateral (Hoehn and Yahr stage 1) is more advantageous, it has been shown to be effective in Hoehn and Yahr stages 1 to 3.^{215,216} The American Academy of Neurology recommends physical therapy in its practice parameters.²¹⁷ Animal studies have shown that exercise can induce neuroprotective and neurorepair changes in the brain. Neuroprotective changes can slow the disease progression by increasing DA generation and availability, while neurorepair changes slow motor deterioration and disability by improving the efficiency of available DA.^{218–220} In the later stages of the disease, adaptive and compensatory approaches are utilized with increased reliance on undamaged systems, although increased angiogenesis and decreased brain damage marker expression in the striatum occur in response to exercise in animal studies.²²¹ In the clinical setting, therapists tend to see patients after motor symptoms appear, and thus patients are already in the neurorepair or adaptation window of the disease.

Basic principles for treatment of the person with Parkinson disease will depend on the areas of impairment and functional limitations revealed in the evaluation. Certain principles, however, are true for all stages of the disease. Interventions should incorporate neuroplasticity parameters addressing intensity, repetition, specificity, difficulty, and complexity of practice. Interventions should integrate goal-based activities for skill acquisition while also requiring cognitive engagement, which is essential for learning to occur.²²² Owing to diminished automatic movements from the loss of DA in the basal nuclei, increased

cognitive control and attentional strategies are indicated. Asking the patient to generate goals and activities of their interest encourages patient investment and consistency, while a collaborative clinician-patient relationship helps improve compliance. Patients should engage in moderate to vigorous intensity-based training because higher-intensity training has been shown to induce DA D2 receptor-binding potential; this pathway has been implicated in increasing inhibitory drive, leading to motor impairments caused by decreased DA.²²³ Interventions should also address balance and an emphasis on increasing amplitude of movement because the DA-depleted state results in slower and smaller movements. Treatment should also involve strengthening, gait training, incorporating transitional movements (changes in directions and turns), and dual-tasking activities.

Variety is important to facilitate shifts in movement as well as in thought. To date, many rehabilitative techniques and exercises have demonstrated improvement in function for people with Parkinson disease, and numerous randomized clinical trials have proven the efficacy of the varied techniques. Programs that emphasize sensory-motor integration, agility, and motor learning demonstrate decreased progression of disease and improved motor function.^{224–240} Programs that involve dual motor-cognitive tasks, complex sequences of movements, and force the participant to quickly change movements dependent on environmental conditions have resulted in improved performance on the Timed Up-and-Go Test, the UPDRS, the 10 m walk test, and a variety of balance tests. The words *big*, *fun*, and *novel* are good words to remember when planning treatment.

Although a majority of evidence supports interventions in the earlier stages of the disease (Hoehn and Yahr stages 1 to 3) and there is evidence of some disease modification in the later stages, as the disease progresses, goals may shift to more task-specific activities, assessment and training for assistive devices, addressing posture and positioning for respiratory and pain management, and caregiver training. Task-specific activities often include turning in bed, getting in/out of bed, rising from a chair, dressing, grooming and hygiene activities, and being aware of posture. At the later stages of the disease, breathing exercises and positioning will need to be a more prominent aspect of treatment. Throughout the course of the disease, large amplitude movements during all activities should be emphasized. Frequent conversations with the patient and caregivers regarding expectations, concerns, and caregiver training should also be ongoing throughout the provider's care.

Therapeutic programs and approaches. As previously stated, exercise itself is important for the person with Parkinson disease. There is a relationship between longevity and physical activity, with those who exercise having lower mortality rates.²⁴¹ A link has been demonstrated between a lack of exercise and development of Parkinsonian symptoms. Some evidence also indicates that exercise may alter the magnitude of free radicals and other compounds linked to aging and Parkinsonism. Given the evidence that physical activity can induce disease-modifying changes, especially in the earlier stages of the disease, it is strongly recommended to establish a consistent exercise routine as early as possible in the disease process.^{225,242}

Individuals with Parkinson disease are strongly encouraged to achieve the World Health Organization's recommendations for physical activity. Intensity has been shown to be necessary for beneficial effects, so patients are encouraged to perform 3 days of moderate intensity activity and 2 days of vigorous intensity exercise per week, as well as at least 3 days of balance training and 2 days of muscle-strengthening exercises. For individuals who may be at a lower activity level, shorter bouts of exercise of at least 10 minutes should be encouraged to reach the recommended dosage. Clinicians are encouraged to gradually increase intensity when first introducing higher effort exercises with use of percentage of maximum heart rate and/or perceived exertion.^{234,243}

Movement throughout a full ROM is crucial, especially early in the disease process, to prevent changes in the properties of muscle itself. Rigidity of some degree is present in up to 99% of people with Parkinson disease, with the contractile elements of flexors becoming shortened and extensors becoming lengthened, enhancing the development of the flexed posture that is traditionally present.²²⁵ Rigidity can be the cause of, and further contribute to, the pain the patient may experience. For most patients, treatment proceeds better if rigidity is decreased early in the treatment session. Many relaxation techniques appear to be effective in reducing rigidity, including gentle, slow rocking, rotation of the extremities and trunk, and the use of yoga. Yoga is also beneficial to target spinal extensor strength and flexibility. Furthermore, because the proximal muscles are often more involved than the distal muscles, relaxation may be easier to achieve by following a distal-to-proximal progression. The inverted position may be used with care. Initially, this position facilitates some relaxation (increase in parasympathetic tone) and then increases trunk extension, which is important for the Parkinsonian patient. Once a decrease in rigidity has been achieved, movement must be initiated to use the newfound range in a functional way.

Implementation of aerobic exercise is essential in the management of a patient with Parkinson disease. The role of aerobic fitness itself may be a factor in reducing dysfunction, with studies showing that it may be necessary to promote neuroplasticity to help restore automatic movement.²⁴⁴ Animal studies indicate that functional exercise decreased DA loss after a variety of lesion models.^{125,215,216} As stated before, clinicians should emphasize increased intensity into their interventions to gain the aforementioned benefits. Animal research indicates that exercise and forced functional movements may protect the dopaminergic neurons, with earlier intervention having greater beneficial effects on the dopaminergic system.^{215,216} Alberts and colleagues performed a classic study investigating the use of tandem bicycling, during which a person with Parkinson disease was required to pedal at a higher rate and intensity than their preferred rate. They found this forced exercise led to increased connectivity between cortico-subcortical regions that underlie automaticity on fMRI, and the pattern of activation was similar in patients who were on medication and those following forced exercise while off medication. Furthermore, a study investigating the effects of high-intensity, moderate-intensity, and a no exercise control group demonstrated that the high-intensity exercise group had significantly lower reductions in mobility scores at 6 months follow-up compared to the control group, while the moderate group did not experience a significant change.²⁴⁵ High-intensity interval training is often utilized to help patients achieve the intensity and time necessary for neuroplastic changes to occur.

Aerobic exercise may also improve pulmonary function in patients with Parkinson disease because these functions appear to suffer from deficiencies in rapid force generation of the respiratory muscles, similar to limb musculature.²⁴⁶ If patients practice regular physical exercise in conjunction with disease-specific exercises, the ill effects of inactivity will not potentiate the effects of the disease process itself. Although most patients with Parkinson disease can achieve an adequate exercise level, many patients have low fitness levels before the medical diagnosis.¹²⁰ Exercise, even once a week, can be effective in improving gait and balance in patients with Parkinson disease when practiced over several months.^{198,220} Given these benefits, as well as known benefits of general aerobic exercise on brain and cardiopulmonary health, it is concluded that regular aerobic exercise is the single strategy with compelling evidence for slowing Parkinson disease progression.²⁴⁷ Programs emphasizing sensory awareness of the size of movement have shown improvement in both speed of limb movement and gait parameters.^{226,227,229} In Parkinson disease, for any given amplitude of movement, velocity of movement is reduced, with velocity decreasing as the amplitude of

movement gets larger. Cues for large amplitude movements result in bigger and faster movements as opposed to cues for speed.²²⁹ There are various programs that employ sensory awareness for amplitude of movement, such as PD SAFEx, LSVT BIG, and Parkinson's Wellness Recovery (PWR!). Sensory awareness programs have evolved to incorporate movements that specifically address the primary Parkinson disease movement deficits while integrating balance, coordination, and automaticity. Furthermore, patients are encouraged to perform these movements in different postures to challenge the body in functional positions. These programs have been shown to improve gait and function on the UPDRS.²²⁷ These authors concluded that programs emphasizing increased sensory feedback and awareness, with emphasis on amplitude and effort, are the best behavioral strategy to decrease hypokinesia and bradykinesia while improving the function of people with Parkinson disease.

Treadmill training has been used in Parkinson disease exercise programs, with strong recommendations of its use to improve walking speed and stride length, improve balance, reduce fear of fall, and number of falls.^{240,248,232} In addition to forward walking, multidirectional treadmill training (backward, left, and right sidestepping) at the patient's fastest tolerated speed in each direction improved spatiotemporal gait measures in all walking directions, balance performance, and gait kinematics.²⁴⁹ The use of the treadmill with body-weight support increases safety and allows the therapist to control speed of movement, introduce perturbations, and challenge multidirectional walking. Studies have shown that cued treadmill training, such as visual cues to target stride length or auditory cues for gait speed, exhibits good results and carryover to the home.^{250–251} Cognitive tasks and other dual tasks have also been added during treadmill training with good results.

Rhythmical exercise has been shown to decrease rigidity and bradykinesia and improve gait over time.^{224,243,252–271} Ballroom dancing is a form of rhythmical therapy for patients with Parkinson disease that incorporates rotation, large amplitude and multidirectional movements, weight shifting and turning, speed variation, and coordination.^{224,272} Given that dance requires high-level multitasking and progressive learning, it is both cognitively and physically challenging; the socialization aspect can help improve mood and adherence. While tango has been the mostly widely researched form of dance, other forms have also shown to have benefit. A program of tango versus waltz and foxtrot indicated that both groups improved on the UPDRS motor scale, Berg Balance Scale, 6 minute walk distance, and backward stride length, although the tango group had greater improvements.^{227,236,239} The waltz and foxtrot, which are easier dances, may be beneficial for those at more advanced stages of the disease. Latin dance and other weight-bearing exercises demonstrated similar improvements in balance and especially initiation of gait.^{224,259,271,273} Dance therapy also has beneficial effects on cognitive tasks, with improvements seen on the Brooks Spatial Test and Trail-Making Parts A and B.²⁷⁴ Similar effects were seen in tai chi as a form of rhythmical therapy, which demands attention to movement and increases challenges to balance and control of movement. Tai chi has been shown to be effective in improving gait and balance parameters, as well as nonmotor function such as mood and overall quality of life.^{233,275} There is growing evidence for the use of technologies in Parkinson disease rehabilitation. Virtual and augmented reality can be used to optimize motor learning in a safe environment, stimulating motor and cognitive processes while providing augmented feedback about performance and address repetition and task specificity. Although there is currently limited high-quality evidence, virtual reality interventions have greater effects on step and stride length compared to conventional therapy, and similar gains in balance, ADL function, Quality of Life (QOL), and cognitive function compared to conventional therapy.²⁷⁶ Mirelman

and colleagues demonstrated that an intensive treadmill program incorporating virtual reality obstacle negotiation significantly improved fall risk and fall rates 6 months after training compared to treadmill training without virtual reality.²⁷⁷ For some with Parkinson disease, even in the early stages, games are too fast or too confusing; therefore the use of disease-specific exercise programs may be superior to commercial systems and could be used and enjoyed by those with Parkinson disease.²⁷⁸ There is also growing research into biofeedback, in which a somatosensory cue is provided in real time to improve balance and weight shifting to minimize freezing of gait. Despite the limited research and evidence, technological advances and its use in rehabilitation for Parkinson disease is promising.

Physical activity and movement can increase quality of life by decreasing depression and improving mood and initiative.^{258,279} Group classes can serve as an extra support system for patients with Parkinson disease and their spouses, providing both extrinsic and intrinsic motivation. Exercise programs should be designed to meet, and progress, a patient's current functional level. A carefully structured low-impact aerobics program appears to be beneficial to patients even with long-standing disease.²⁷¹ For example, individuals in Hoehn and Yahr stage 2.5 or 3 can begin with seated activities with upper-extremity exercises (Fig. 18.8A) and combination movements (see Fig. 18.8B) then progress to standing and marching activities that incorporate coordinated

movements of arms and legs, balance, and trunk rotation (Fig. 18.9). All movements are performed to music similar to that used in aerobics classes in any gym or health club (Fig. 18.10). A cool-down period allows participants to practice fine motor coordination activities of the hands (Fig. 18.11). Many Parkinson disease associations also have audiotapes for exercises (e.g., United Parkinson Foundation).

Most studies have found that exercise under the guidance of a physical or occupational therapist or trained instructor is effective in reducing Parkinsonian symptoms.^{226,240,268,269} There is long-standing evidence of the benefits of exercise, with improvements in gross and fine motor functions, as well as of general well-being²⁷⁰; however, it is necessary for continued, consistent participation for long-term carry-over. The most successful exercise programs appear to be those that incorporate context-dependent responses and a varied environment (Box 18.1), although noncontext-dependent aerobic exercises are also effective (Box 18.2). Research has shown the importance of adjusting the response to the specific task and has also demonstrated the importance of practice for the Parkinsonian patient.^{280,281} The principles of motor learning are of paramount importance in the treatment

A

B

Fig. 18.8 Seated Aerobics or Warmup Exercises. (A) Patients are using bilateral upper-extremity patterns to facilitate trunk rotation. Instruction was to let the head follow the hands. (B) This exercise encourages trunk rotation, large movements, and coordination of the upper and lower extremities. Patients are to reach with the arms and touch the opposite foot. This coordination is difficult for those with Parkinson disease, and many patients initially could not move their arms and legs at the same time.

Fig. 18.9 Initial Warmup in Standing. Patients are to walk with their head up, with the back as straight as possible, and to take large steps. When the group began, walking was the major aerobic activity and was used to increase endurance and encourage movement. Nonambulatory patients march in place while seated.

Fig. 18.10 Walking in a "Waltz Rhythm" (Slow, Quick, Quick) Emphasizes a Big Step for the Slow Step. Note lack of automatic arm swing. Also, note flexed posture of seated patient during rest period.

Fig. 18.11 Cool-Down Period Allows Time to Work on Fine Finger Movements. Thumb abduction with rounded fingers and various rhythms are used to increase coordination. Note “masked face” appearance.

BOX 18.1 Exercises That Promote Context-Dependent Responses

The following exercises promote context-dependent responses and are recommended for people with movement disorders:

1. Walking outdoors
2. Karate and other martial arts (Tai Chi and Qi-Gong specifically)
3. Dancing (all forms), particularly to music
4. Ball sports (various types)
5. Cross-country and downhill skiing
6. Well-structured, low-impact aerobics classes
7. Treadmill training with guidance of a movement specialist

This list is a sample of activities; it should not be considered all inclusive.

Hackney ME, Lee HL, Battisto J, et al. Context-dependent neural activation: internally and externally guided rhythmic lower limb movement in individuals with and without neurodegenerative disease. *Front Neurol.* 2015;6:251.

BOX 18.2 Exercises That Promote Fitness and Increase Range of Motion But Not Context-Dependent Responses

The following exercises promote fitness and increase range of motion but not context-dependent responses and are recommended for people with movement disorders.

1. Treadmill walking without guidance or supervision
2. Stationary bicycle riding
3. Using strengthening machines and free weights (with low weights or low resistance)
4. Using step exercises and stair climbers
5. Using rowing machines
6. Swimming laps

This list is a sample of activities; it should not be considered all inclusive.

program of these patients. Random practice may enable the patient to learn the correct schema by which to regulate the extent, speed, and direction of the movement and may also be important in facilitating the ability of the patient to shift attention and to learn to access “working memory.” The Parkinsonian patient may benefit from visual instruction and mental rehearsal before performing the movement.^{135,152}

In addition, the instructions used need to be pertinent to the task at hand.

Strengthening. Strengthening exercises have been promoted for patients with Parkinson disease because disuse contributes to decreased strength. Weakness occurs with initial and prolonged contraction. Decreased leg strength is associated with increased fall risk and gait velocity, and hip strength is specifically related to sit-to-stand performance in people with Parkinson disease.²⁸² Manual muscle testing may not reveal losses in strength; however, most successful exercise programs include functional strength training as part of the program. High-resistance eccentric exercises can produce muscle hypertrophy and may affect improvements in mobility.²⁸³

Functional strength training seems to be more effective than weightlifting for the goal of ADL improvement owing to task specificity.¹⁵⁴ An important part of any strengthening program is the trunk musculature. As extensors become weaker compared to flexors, spinal and hip extensors need to be strengthened, and flexibility likewise encouraged.²⁸⁴ When implementing progressive strength training, the clinician should train effort. Large amplitude, high-velocity movements at mid-range to low resistance should be performed because bradykinesia contributes to reduced power generation at lighter loads, but not heavy loads.²⁸⁵

Use of cues for improving gait. As the disease progresses, intensive exercise programs may need to be revised or altered. By Hoehn and Yahr stage 2.5, gait disorders are the most common diagnosis for which the person with Parkinson disease will see a therapist. Owing to reduced internal control for timing and scaling of automatic and repetitive movements, external cues and attentional strategies are needed to compensate. Visual cues can be used for spatial awareness to increase amplitude of movement, while auditory or tactile cues can be utilized to improve timing and generate rhythm. As the disease progresses and attentional and executive functions become more impaired, external cues can be used to guide attention to the task.²³⁴ The problems that cause the biggest ambulation limitation are freezing and small steps. Studies have demonstrated that the use of rhythmical exercise programs, a metronome, or carefully synthesized music improved gait characteristics, such as stride length and speed, with immediate and longer-lasting improvements.^{271,286} A study by Nieuwboer and colleagues²⁵¹ used auditory, visual, or somatosensory cues during gait in the patient’s home per patient preference. The cues were provided in a variety of conditions, including dual tasking, over uneven surfaces, and multidirectional walking. Cues were effective in improving step length, gait speed, and decreasing freezing, but no carryover effects were observed at 6 weeks. The frequency of cueing is patient specific and will be activity and context specific (i.e., cueing indoors may be slower than outdoors); however, in patients who experience freezing, auditory cueing frequencies should be below the patient’s baseline frequency because higher may trigger freezing.²⁸⁷ Furthermore, cueing may be more effective for those who do not have frequent freezing episodes owing to the disordered movement rhythmicity seen in freezers.²⁸⁷

Visual stimuli has been shown to be effective in initiating movement during freezing episodes in context-specific situations. These include the use of lines on the floor and stair climbing because stairs can provide visual stimulation. Martin⁵⁷ found that parallel lines were more facilitating than other lines, with the space between lines being important. There is also increasing use of visual cues incorporated into assistive devices, such as a Laser Cane or U-Step walker;²⁸⁸ however, the use of visual stimuli has limited evidence of carryover. Morris and colleagues¹⁴⁴ have tried to increase carryover of visual stimuli by incorporating them with a visualization program. Patients practiced walking with lines until the steps were near normal in size, then progressed

to visualizing the lines on the floor as they walked; their visualization program met with initial success. Increasing the magnitude of the step, weight shifting before stepping, or the amplitude of the movement appears to be the most important component for improvement in gait and a decrease in freezing, and can be accomplished using either cueing strategies, attentional strategies, or a combination of both.¹⁴⁴

Gait rehabilitation must include walking in crowds, through doorways, and on different surfaces. Speed variations are important, as is walking with differing stride lengths, owing to varying context-dependent environmental demands. The principles of motor learning appear to be very helpful for facilitating carryover of the therapeutic effects; however, the individual with Parkinson disease can have difficulty dual tasking and may have to initially concentrate only on walking as the disease progresses to increase patient safety.^{111,124,151}

Balance. Another problem for which therapy is indicated is impaired balance, especially because drug and surgical treatments are ineffective in remediating this problem. This problem will eventually affect all persons with Parkinson disease.²⁸⁹ Fall risk earlier in the disease can be caused by proprioceptive impairments, increased trunk rigidity, and medication side effects, whereas fall risk later in the disease can be associated with increased sedentary behavior and immobility.²⁹⁰ The patient should be instructed to practice balance exercises at the early stages of the disease. Equilibrium reactions in all planes of movement and under different conditions should be addressed. Techniques to increase dynamic balance control should be included, especially turning the body and turning the head. All three balance strategies need to be addressed and then practiced in a variety of environmental conditions. Postural instability is higher in freezers than nonfreezers, with more fear-of-falling avoidance behavior; people who improved balance also improved freezing of gait most.²⁹¹ The newer computerized games that target balance have provided a fun and therapeutic method for keeping interest in balance exercises.^{124,133,134,139,140}

Dual task performance. Rarely will the patient with Parkinson disease state that he or she has difficulty performing two tasks at once; however, as dual tasking involves executive functioning, a patient with Parkinson disease will demonstrate mistakes with both mental and motor tasks when performed concurrently. This becomes quite apparent in very simple activities, such as requiring the patient to count backward and walk at the same time.^{143,292} This impaired ability to perform dual tasking is associated with increased loss of balance and freezing of gait because people with Parkinson disease tend to prioritize a cognitive task at the cost of balance and posture.²⁹³ One solution is to instruct the patient to attend to only one task at a time, while another is to have the patient practice doing two things at the same time and constantly alter activities in a random practice mode during treatment; both consecutive and integrated dual task training led to similar and sustained improvements in gait velocity without increasing fall risk.²⁹⁴

Activities of daily living. Transitional movements pose great problems for the patient, especially by Hoehn and Yahr stage 3. This is most likely because normal postural adjustments are no longer automatic and become a sequential task. Task specificity with repetition is helpful, and visualization of the task has demonstrated carryover. Some researchers report improvement in moving from a seated to a standing position after practicing techniques designed to increase forward weight shift.^{295,296} Compensatory strategies to alter the environment may become necessary if the task becomes too difficult.

Bed mobility is an important consideration for patients with Parkinson disease. Rolling in bed and rising from the supine position become difficult and should be practiced; emphasis should be placed on appropriate technique, with cues for amplitude and effort during the transitional movements. A firm bed may make getting in and out

of bed easier. Most patients report that satin sheets with silk or satin pajamas make moving in bed far easier. Adjustable beds may be helpful as the disease progresses, but while sleeping the patient should lower their head as close to horizontal as possible.

Breathing exercises are crucial for the patient with Parkinson disease. As stated previously, the most common cause of death is pneumonia. Clinicians should address both inspiratory muscle training for pulmonary function, as well as expiratory muscle function for airway clearance and protection. Chest expansion may be included during functional activities. Other interventions include LSVT LOUD and expiratory muscle strength training, which integrates the sequencing and coordination of breath support with activities such as volume production.²⁹⁷ With disease progression, specific breathing exercises may need to be incorporated, especially for patients who are no longer able to walk.

In addition to treatment in the clinical setting, patients with Parkinson disease should be given a home program that encourages moderate-to-vigorous, consistent exercise as part of the normal day. The clinician should guide and support the patient in selecting the most optimal type, intensity, and frequency of exercise to increase patient self-efficacy. This, along with periodic checks, may enhance compliance. Exercises should be graded to the individual's capability, and the therapist should keep in mind that learned skills such as various sports are sometimes less affected than automatic movements, perhaps because these skills may rely on cortical involvement.¹⁴

Fatigue is a frequent complaint of people with Parkinson disease. Although it has been correlated with disease progression, depression, and sleep disturbances, it also exists in up to 44% of those without depression or sleep difficulty.²⁹⁸ This type of fatigue is over and above what is associated with the exertion of an exercise program and may be one reason people with Parkinson disease have difficulty exercising. The patient with Parkinson disease frequently experiences post-exercise fatigue. If a person is so tired after exercise that he or she cannot perform normal ADLs, exercise will not become a part of the patient's daily routine. Post-exercise fatigue is easily alleviated by a gradual and extended cooldown period.

Patients frequently ask about the timing of medication and exercise. For any form of exercise in Parkinson disease to be effective, movement must be possible, especially movement through the full arc of the joint. Therefore exercise should be performed during the "on" period of the medication cycle given the dopaminergic effect and ability to push intensity and amplitude; however, clinicians should also assess and work with patients during their "off" period. People with Parkinson disease feel their "off" time correlates more closely with quality of life and balance confidence; therefore providing strategies for safe mobility during these periods may help improve quality of life, functional mobility, and decrease falls.²⁹⁹ "Off" times also affect non-motor symptoms and mood, and assessment during these periods may show patients that they can do more than initially believed, thereby improving confidence. Patients are encouraged to be "in tune" with his or her own response and adjust medications and exercise to a schedule accordingly.

The therapist is also involved in the prescription of assistive devices. The use of ambulatory aids for patients with Parkinson disease is an area with no clear-cut guidelines, and assessment should be specific to each individual. Because coordination of upper and lower extremities is often difficult, the ability to use a cane or walker can be limited as learning to use the device can be seen as a dual task activity. Standard walkers sometimes increase the festinating gait and are not recommended for people with freezing owing to the close extrapersonal space and management of the walker over obstacles; as such, four-wheel walkers with pushdown brakes appear to work best for

many patients.³⁰⁰ A walker that is in the brake condition at the start and requires the patient to push on handles to walk may also be safer. For patients with a tendency to fall backward, an assistive device may be positioned behind them. Walking sticks or canes can be helpful for the person who is able to walk with a heel-toe gait pattern but lacks postural stability. The height of walker or cane should be adjusted carefully to promote trunk extension, while a walking stick (or two) is less likely to promote flexion than a cane. Patients with Parkinson disease may also benefit from assistive devices for eating or writing, such as weighted utensils or devices with extra-large handles for tremor management and improved manipulation, as well as tools for fine motor tasks, such as buttoning aid hooks for dressing. A survey by Mutch and colleagues²⁵⁶ in Ireland found that nearly half of the patients responding used some type of assistive device. These devices included ones for walking, reaching, rising from bed, and performing ADLs.

As Parkinson disease progresses, the patient may experience impaired speech (hypophonia, impaired articulation, and speech rate), difficulty in chewing and swallowing, as well as decreased saliva management. Therapy for volume production and/or oral-motor control should be initiated to improve volume, respiration, intelligibility, and decrease risk of aspiration. A dietician consultation may be necessary to ensure adequate nutrition and may also be beneficial in guiding the patient's protein intake. A diet high in protein may reduce the responsiveness of the patient to DA replacement therapy, and regulating the amount and timing of protein ingestion can improve the efficacy of drug treatment in some patients.¹⁴³ The use of vitamins is a subject that appears on many websites for patients with Parkinson disease, and the patient should be reminded to consult with his or her physician when changing vitamins.

The resurgence of surgery as a treatment alternative in Parkinson disease, including stimulation of deep brain sites that may alter neuroplasticity, means that the therapist will face new and exciting challenges in treatment.³⁰¹ Intense physical therapy, especially incorporating complex motor skills, has been demonstrated to be effective in improving function after a subthalamic nucleus lesion in animal studies.³⁰² Therefore intense physical therapy after surgery should be performed to maximize benefits from all surgeries in Parkinson disease (as well as in Huntington disease and the dystonias).

Finally, therapeutic rehabilitation and exercise may modify but cannot halt or reverse the progression of this degenerative disease. The therapist should assist the patient and family in coping with the constraints of this disease, enhancing the patient's quality of life throughout its course.

Differences Between Parkinson Disease and Atypical Parkinsonisms: Theoretical and Practical Considerations

Several other neurodegenerative diseases are grouped together as "atypical Parkinsonisms" disorders. Patients with these syndromes usually have limited to no response to levodopa intervention and tend to progress more rapidly than Parkinson disease. The most common of these is progressive supranuclear palsy (PSP). Clinical features include progressive onset of symmetric symptoms, lack of tremor, bradykinesia, increased rigidity in the trunk and legs, frequent falls early in the disease, and pseudobulbar features (dysphagia, dysarthria, and emotional lability). They also present with vertical gaze palsy. These patients can be evaluated and treated in a manner similar to patients with Parkinson disease. Treatment is aimed at symptom management and relief, although within a decade the patient is typically immobile.

Multiple system atrophy (MSA) is the second most common atypical Parkinsonism that affects various areas of the CNS, with varying degrees of pyramidal, cerebellar, and autonomic dysfunction. The disease is characterized by symptoms including rigidity, bradykinesia,

postural instability, ataxia, bladder dysfunction, and orthostatic hypotension. There are two main phenotypes: MSA-P, which presents with Parkinsonism-dominant features, or MSA-C, which presents with predominantly cerebellar features. Almost all patients will develop autonomic dysfunction, while those with MSA-P are more likely to have a greater functional decline. Cognitive impairments occur in some patients, including decreased executive function, loss of verbal memory, verbal fluency, and difficulty maintaining attention.³⁰³ Assessment and treatment should be focused on addressing impairments and symptom management while maintaining/improving mobility.

The least common atypical Parkinsonism is corticobasal syndrome. As the name suggests, it involves cerebrocortical and basal nuclei dysfunction, characterized by asymmetric motor impairments, apraxia, myoclonus, postural tremor, speech and swallowing impairments, and predominantly upper limb dystonia. Cognitive deficits are not a predominant feature. In some cases, patients may experience "alien limb phenomenon." Interventions should be focused on symptom management.

Dementia with Lewy bodies is a progressive, neurodegenerative disease that shares symptoms of both Parkinson disease and Alzheimer disease caused by abnormal deposits of alpha-synuclein protein in multiple areas of the brain. One of the characteristic features is the appearance of cognitive impairments before motor symptoms. Progressive cognitive decline, confusion, changes in attention, and hallucinations or delusions are often seen. While the Parkinsonian features may be responsive to Parkinson disease medications, cognitive involvement may make rehabilitation and carryover difficulty, and treatment should be focused on symptom management.

Because these syndromes are rarer than Parkinson disease and far more variable, there are limited studies that have been undertaken regarding rehabilitation intervention efficacy. Accurate differential diagnosis is important in patient planning; thus a thorough evaluation by a neurologist is highly recommended.

Huntington Disease

Huntington disease (formerly *Huntington chorea*) is another degenerative disease of the basal nuclei resulting in hyperactivity in the basal nuclei circuitry.^{304,305} This disease gets its name from the family of physicians who described its patterns of inheritance. Huntington disease is inherited as an autosomal dominant trait and affects approximately 6.5 per 100,000 people.² The defect is on the short arm of chromosome 4, and alters DNA so that there is an increase in the cytosine-adenine-guanine (CAG) sequence; in normal individuals there are 10 to 35 CAG triple repeats, but in the individual with Huntington disease there are 36 to 125 repeats.³⁰⁵ The longer the length of the CAG triple repeats, the more likely an individual is to develop the disease. Greater than 40 CAG repeats will cause development of Huntington disease, and longer repeat lengths is correlated with earlier onset of the disease.³⁰⁶ The CAG repeat is related to glutamine. The target protein affected by the polyglutamine expansion has been named *huntingtin*. Huntingtin combines with ubiquitin and induces intranuclear inclusions and interference with mitochondrial function. The defect is characterized by severe loss of the medium spiny neurons and preservation of the ACh aspiny neurons. There are decreases in choline acetyltransferase (CAT), ACh, the number of muscarinic ACh receptors, glutamic acid decarboxylase, and substance P. There is generally no decrease in DA, norepinephrine, or serotonin (5HT), although more recent studies with single-photon emission computed tomography (SPECT) indicate that DA does diminish significantly in the later stages of the disease.³⁰⁷

Huntington disease is usually manifested between 30 and 50 years old, although childhood forms appear rarely. Those younger than

20 years with the disease account for approximately 10% of all people with Huntington disease and experience a faster rate of progression of the disease. Death from this disease occurs approximately 15 to 25 years after the onset of symptoms, although as in Parkinson disease, the earliest symptom is not known.

A marker for the Huntington gene has been detected.³⁰⁸ If the family pedigree is known and the chromosomes of the parents can be obtained, detection of which offspring have the faulty chromosome is possible pre-symptomatically. Of course, early detection of this disease involves ethical and practical issues. At present, although testing is available, it is not widely used. Furthermore, testing for Huntington disease is typically available only to those older than 18 years. Despite these problems, localization of the gene and the repeat is promising and offers hope for improved means of treatment.

Huntington disease affects neurons in the basal nuclei as well as the cerebral cortex, thalamus, and cerebellum. The movement disorders are presumed to be related to degeneration of the striatal neurons, specifically the enkephalinergic neurons, which results in excitation of the cortex via disinhibition of the thalamus, and resultant hyperkinetic, choreiform movements.¹⁴ The cognitive and emotional symptoms are associated with cortical destruction.

Symptoms

Huntington disease is characterized by a triad of signs and symptoms involving movement, cognitive, and psychiatric disorders. Some of the signs and symptoms of Huntington disease are similar to those of Parkinson disease: abnormalities in postural reactions, trunk rotation, distribution of tone, extraneous movements, as well as a decrease in associated movements (e.g., arm swing). Individuals with Huntington disease, however, are at the other end of the spectrum; rather than a paucity of movement, they exhibit too much movement, which is evident in the extremities, trunk, and face. The extraneous movements are of the choreoathetoid type—involuntary, irregular isolated movements that may be jerky and arrhythmic as in chorea, to rhythmical and worm-like as in athetosis. The gait takes on an ataxic, dancing appearance (in fact, *chorea* means to dance in Greek), and fine movements become clumsy and slowed.^{308,309} Usually, however, these movements occur in succession so that the entire picture is one of complex movement patterns. The “movement generator” aspects of the basal nuclei seem to be continuously active, as would fit the hypothesis of a disruption in the indirect pathway; however, as the disease progresses, the choreiform movements may give way to akinesia and rigidity. This is caused by the excitatory direct pathway of the basal nuclei becoming affected in the later stages of the disease, which inhibits thalamic activity and results in decreased activation of the cortex.

Disruptions in voluntary movement for the person with Huntington disease further reflect the role of the basal nuclei in movement. The person with Huntington disease, like the person with Parkinson disease, has difficulty responding to internal cues, as well as internal rhythms. Kinematic analysis of upper-extremity complex tasks demonstrates that the person with Huntington disease must rely on visual guidance in the termination of a movement. This has been interpreted to indicate impairment in the development and fine-tuning of an internal representation of the task.³¹⁰ Furthermore, these patients have increasing difficulty with more complex movements in the absence of advanced cues.^{311,312} The lack of internal cuing in the person with Huntington disease has been linked to the increased variability of response seen in these patients.³¹³

Gait patterns of the person with Huntington disease are in some ways similar to those of Parkinson disease. Gait velocity and stride length are decreased, with the decrease in velocity correlating with

disease progression. Unlike the person with Parkinson disease, however, the person with Huntington disease has a decreased cadence as well.³⁰⁹ The base of support is increased (again unlike the pattern seen in Parkinson disease). In addition, lateral sway is increased along with great variability in distal movements. Balance impairments are manifested as increased sway in static and dynamic standing, with delayed balance recovery reactions. A combination of disease severity, lower limb weakness, cognitive impairment, and executive dysfunction have been found to influence balance and mobility in people with Huntington disease.³¹⁴ The face is also affected in Huntington disease. Impaired voluntary eye movement is often the first sign of Huntington disease, with noted difficulty with initiation and control of saccadic eye movements and smooth pursuits. Speech, breathing, and swallowing lack normal control and coordination. Speech lacks rhythm, variability in volume control, and mistiming in breath control, as might be expected with decreased internal timing. Timing and coordination of the swallowing mechanism is also impaired and can lead to choking, aspiration, and weight loss. Studies suggest that a person with decreased body weight and a parental history of the disease is at greater risk of disease development and progression.^{313,315,316}

The exact mechanisms for the production of choreoathetoid movements are unknown. Because these extraneous movements are part of a person's normal repertoire of movement patterns, they may be “released” at inappropriate times and without any modulation. A post-mortem examination showed a decrease in GABA that was greater in the globus pallidus external segment than the internal segment, while the recent use of positron emission tomography (PET) scans demonstrates loss of ACh and GABA neurons.³¹⁷ A pattern may therefore be executed before it is necessary, and inappropriate portions of a movement pattern cannot be inhibited. Petajan³¹⁸ found motor unit activity indicative of bradykinesia. Recordings of single motor units in the muscles indicates that persons with Huntington disease have a loss of control evidenced by an inability to recruit single motor units.³¹⁸ As the efforts at control increased, these individuals demonstrated an overflow of motor unit activity that resulted in full choreiform movements. Those in the earlier stages of the disease demonstrated what the experimenters termed “microchorea,” or small ballistic activations of motor units.³¹⁸ As in Parkinson disease, difficulty occurs in modulating motor neuron excitability. Yanagisawa³¹⁹ used surface Electromyography (EMG) recordings to classify involuntary muscle contractions in Huntington disease patients with varying movement disorders from chorea to rigidity. He found brief, reciprocal, irregular contractions in those patients with classic chorea, and tonic nonreciprocal contractions in those patients with rigidity. Presence of athetosis or dystonia was associated with slow, reciprocal contractions. During sustained contractions, EMG activity demonstrated brief, irregular cessation of activity in the choreic patients; thus patients with Huntington disease have interruption of normal motor function at rest and during sustained activity (e.g., stabilizing contractions).

In addition to the involvement of the motor systems, the individual with Huntington disease also shows signs of cognitive and behavioral disorders that become worse as the disease progresses. Cognitive impairments include difficulties in planning, memory impairments, poor initiation, impulsivity, lack of insight, perseveration, and severe deterioration in the ability to communicate (e.g., speech and writing). Psychiatric changes include depression, hostility, irritability, paranoia, apathy, and anxiety. Ideomotor apraxia and apraxia of speech can also occur, especially as the disease progresses.³²⁰ Intellect decreases, with performance measures decreasing more rapidly than verbal levels. Neuropsychological tests are therefore part of the Unified Huntington's Disease Rating Scale (UHDRS).

	Engagement in occupation		Capacity to handle financial affairs		Capacity to manage domestic responsibility		Capacity to perform activities of daily living		Care can be provided at

Fig. 18.12 Functional Stages of Huntington Disease. (Reprinted from Shoulson I, Fahn S. Huntington's disease: clinical care and evaluation. *Neurology*. 1979;29:2.)

Stages of Huntington Disease

Huntington disease is a progressive disorder. The initial motor symptoms are most often incoordination, clumsiness, or jerkiness. A classic test for eliciting choreiform movements in this early stage is a simple grip test. People with Huntington disease displays what is descriptively called the “milkmaid’s sign”; alternating increases and decreases in the grip that are perhaps the equivalent of the electromyographic abnormalities seen during sustained contractions. Facial grimacing or the inability to perform complex facial movements also may be present very early. As mentioned, the patient with Huntington disease will initially exhibit hyperkinetic movements with deficits in gross and fine motor control, eventually progressing to a hypokinetic presentation and significant debility in the late stage.

In most cases the cognitive and psychological impairments of Huntington disease occur before the onset of the motor signs; cognitive impairments have been reported at least 15 years prior to when a motor diagnosis is given.³²¹ As the disease progresses, cognition will progress from difficulty with complex tasks to intellectual decline with impaired insight and dual tasking, ultimately progressing to global dementia in the late stages. In cases in which very subtle personality changes occur first, the diagnosis may be more difficult. Such persons may appear depressed, irritable, or forgetful, but can then develop apathy, perseveration, antisocial behavior, and experience delusions or hallucinations; the late stage is characterized by delirium. Early diagnosis may be important, and SPECT shows promise for early detection of the disease.³²²

With time, the combination of the motor, cognitive, and psychiatric problems cause the individual to lose all ability to work and perform ADLs. Eventually, this person can only be cared for in an extended care facility. By this time, the choreiform movements have given way to rigidity, and the patient is bedridden. Death is usually caused by infection, but suicide is also common. Fig. 18.12 shows the stages of Huntington disease according to Shoulson and Fahn.^{323,324}

Pharmacological Considerations and Medical Management

Advances in the pharmacological management of Parkinson disease have led to a great deal of research in an effort to find appropriate drugs for the management of Huntington disease.^{325–329} At present, however, no fully effective medication is available for this disease. Each symptom is treated with its own medication.

The symptoms of Huntington disease indicate an increase in dopaminergic effect. Owing to the decrease in GABA and ACh concentrations in the basal nuclei, drug therapy depends on drugs that are cholinergic or GABA-containing agonists and those that act as DA antagonists. To date, the DA antagonists have been more effective in ameliorating neurological symptoms and are often the first drug to be prescribed; however, these drugs have severe side effects, including depression, drowsiness, Parkinsonian symptoms, and tardive dyskinesia.³²⁴ DA antagonists for chorea management have initially shown improved gait, balance, and transfers, and further research is warranted.³³⁰

In general, pharmacological treatment is not started until the choreiform movements interfere with function, as antichoreic drugs have side effects that may be worse than the chorea.³³¹ Tetrabenazine and deutetrabenazine are the only FDA-approved drugs for management of chorea in Huntington disease and act to deplete DA in the synapse, with deutetrabenazine requiring less frequent dosing and fewer side effects;³³² however, they can exacerbate depression and suicidal actions and are not indicated in people with unmanaged mood disorders. Second-generation antipsychotics (DA antagonists), such as olanzapine, risperidone, and tiapride, are becoming more commonly prescribed owing to their effects on chorea, as well as positive effects on sleep dysfunction, mood, and weight loss prevention, and especially if psychiatric symptoms are present.³³³ Drugs such as choline, which would increase ACh concentrations, have produced only transient improvement.¹⁸⁰ Many efforts have been undertaken to find a GABA agonist that would reduce the symptoms of Huntington disease, but these have been unsuccessful so far.^{331,334} A barrier to medications that increase GABA is that such a drug may cause inhibition throughout the brain, not just in the basal nuclei; thus the individual’s level of alertness and ability to function might be reduced—something the person with Huntington disease can ill afford.³³⁴ A drug trial is currently underway and has so far delivered promising results to reduce the levels of the huntingtin protein.^{335,336} The cognitive and behavioral impairments interfere more with life tasks and quality of life than do the presence of movement disorders. Medications are usually prescribed as combinations of drugs to treat the specific emotional and psychological symptoms. Cortical degeneration is most certainly involved, but disruption of the heavy corticostriate projections may also be a factor in the progression of this disease. Although alterations in

DA have been implicated in psychiatric problems such as schizophrenia, the role of the basal nuclei in thought processes is, at best, little understood. In the words of Woody Guthrie, "There's just not no hope. Nor not no treatment known to cure me of my dizzy called Chorea."³³⁷

At present, the best hope for the person with Huntington disease lies in a better understanding of the genetic mechanisms causing destruction of the GABA-containing cells in the striatum and cortical destruction. In the meantime, correct and early diagnosis is important in providing the proper early intervention, which must include counseling.³³⁸ To facilitate research into the causes as well as the treatment of the disease, the Commission for the Control of Huntington's Disease has set up several research centers, including a brain and tissue bank. Research has also begun on the use of tissue transplantation. As with Parkinson disease, the tissue does survive, but the results are even more preliminary than for Parkinsonism.

Examination of the Patient With Huntington Disease

The standard medical evaluation is the UHDRS.³³⁹ This comprehensive evaluation examines cognitive function, motor function, behavioral, and functional ability. The physical or occupational therapy evaluation of a person with Huntington disease must be global, incorporate the different ICF domains, and include an assessment of the degree of functional ability. Initial assessment should occur as early in the disease as possible and be performed at regular intervals to optimize their progression through the disease. Patient-reported outcomes are integral to help prioritize and determine the efficacy of interventions. The SF-36 is recommended for generic assessment of health status and quality of life and is widely used in Huntington disease studies. The Huntington's Disease health-related Quality of Life questionnaire (HDQoL) is also suggested to assess disease-specific symptoms and their impact on quality of life throughout the course of the disease.³⁴⁰

The clinical exam of a patient with Huntington disease should emphasize impairments and functional abilities. Strength and ROM should be assessed, with particular attention paid to the ability to stabilize the trunk and proximal joints. Strength and ROM changes may not be evident in the early stages of the disease. As the disease progresses, the clinician should be aware that isolated strength tested may be confounded by cognitive impairments and motor impersistence; therefore functional strength assessments may be warranted. To reduce the effects of rigidity, ROM measurements become important as the disease progresses.

Assessment of chorea should include its presence in the extremities, trunk, and face. Clinicians should note how frequent the chorea occurs, its severity, and how it interferes with function; they should also make note of what may aggravate and ease the choreiform symptoms. A simple rating scale is the capacity to perform ADLs (see Fig. 18.12). A standardized ADL assessment with space to write how the patient performs these activities or why she or he cannot perform them would be helpful.

Fall risk and rate of falls is significantly higher in people with Huntington disease, warranting a thorough balance assessment, especially narrow base of support and dual tasking conditions. Patients with a falls history have higher chorea scores, increased bradykinesia, aggression, and cognitive impairments. When assessing balance, the clinician should also consider the impact of oculomotor impairments. Saccadic eye movement and smooth pursuit deficits may affect balance and walking, especially as oculomotor impairments occur early in the disease.

Gait analysis can include a timed walk test and cadence assessment; stride length can then be calculated. A subjective assessment of variability

and incoordination should also be made. In addition, posture and equilibrium reactions should be tested, with assessment of associated reactions. In assessing posture, care should be taken to observe the posture of the extremities in addition to the trunk, head, and neck. Dystonic posturing should be carefully noted, especially if the patient is taking medication. Any changes should be reported to the physician.

In the assessment of the patient with Huntington disease, the stage of psychological involvement and mental state must be reliably assessed during both evaluation and treatment. SPECT and other computer tomography scans may give some clues to the amount of cortical and basal nuclei degeneration, which can assist in determining possible cortical functioning. There does not seem to be a consensus in research or clinical practice for which measurements are most sensitive to change or best reflect function for the patient with Huntington disease.

General Treatment Goals and Rationale

As there is such wide variation of potential multisystem impairments that impact functional activity and participation within each stage of the disease, it is recommended to approach interventions with treatment-based classifications. Clinicians are encouraged to review the EHDN Physiotherapy Clinical guidelines classification and determine where the patient may fit. Using the classifications as a framework, appropriate evaluation measures and intervention strategies should be chosen. Maintenance of the optimal quality of life is the most important goal for treatment of persons with Huntington disease and their families, including maintenance of functional skills and adaptive equipment recommendations. Techniques that reduce tone may also reduce choreiform movements. Increasing stability of the core and proximal musculature helps maintain function, and respiratory function should be kept as high as possible. Examination results and patient/caregiver goals will ultimately guide treatment procedures.

Treatment Procedures

The Commission for the Control of Huntington's Disease³⁴¹ stated that these individuals are underserved by physical and occupational therapy. Peacock³⁴² surveyed physical therapists in one state. Of the 585 therapists who responded, only 15.5% had worked with at least one patient with Huntington disease, and 6.2% had worked with more than one patient; this confirmed the underutilization of physical and occupational therapy today. Hayden³³⁷ and Peacock³⁴² suggest that therapy can improve quality of life for this population. A 2008 article by Busse and colleagues³⁴³ demonstrated that there is still underutilization of therapy services. They also found that there are no routine outcome measurements for the stages of the disease, and they suggested that management of falls and decreased mobility could be a treatment goal of physical therapy interventions. Although animal models of Huntington disease exist, there have been few studies investigating possible movement interventions. In one animal study, even a little environmental enrichment improved the ability of Huntington mice on a rotarod test and slowed the progression of the disease.³⁴⁴ The mice getting even more enrichment showed improvement on more behavioral tests as well as changes in the striatum. Several articles have been published examining physical and occupational therapy treatment techniques for holistic therapy and for treating specific problems.³⁴⁵⁻³⁴⁷

A study by Zinzi and colleagues³⁴⁵ was a nonrandom pilot study that incorporated gait, balance, and transfer training. Strengthening of the extremities, trunk, and muscles of respiration as well as coordination and postural stability activities were included. The program was undertaken with occupational therapy to include cognitive, rehabilitation, and ADL training. Participants were engaged in an intensive inpatient program for 3 weeks for 8 hours per day, 5 days a week, and

three times a year. The data indicate that there was significant improvement in motor function and in ADL performance and that these subjects did not show deterioration over the 3 years of the study—a positive outcome for a degenerative disease.

Treatment of the person with Huntington disease has some parallels with the treatment of athetoid cerebral palsy; however, these techniques must be adapted to the adult. Of critical importance are the techniques for improving coactivation and trunk stability. The use of the pivot-prone and withdrawal patterns of Rood is helpful, and their benefits may be increased with the use of Thera-Band. Neck co-contraction and trunk stability may improve, or at least oral functions may be maintained. In addition, the techniques of rhythmical stabilization in all positions as well as heavy work patterns of Rood should be helpful.³⁴⁸ Movements practiced out of context may not, however, carry over into functional activities; thus practicing coactivation in functional patterns during treatment, if at all possible, is recommended. Whereas in Parkinson disease the emphasis is on large-amplitude movements, movements for the person with Huntington disease need to be of smaller amplitude and controlled.

The gait disorder of Huntington disease has been shown to respond to rhythmical auditory stimuli in one study.³⁴⁹ The ability to respond decreases in those most severely involved, indicating that treatment in the later stages of the disease may not be amenable to rhythmical stimuli. Another finding of this study was that cadence was a larger problem than stride length, especially at normal and fast speeds (compare this with the findings in Parkinson disease). Interestingly, people with Huntington disease were able to modulate gait to a metronome but had more difficulty with musical cues even when the tempos were identical. Subjects with Huntington disease demonstrated short-term carryover of metronome auditory stimuli to gait without auditory stimuli. Although the long-term carryover was not studied, using a metronome in gait training may be helpful in patients with Huntington disease. A more recent study using a metronome to cue gait during single and dual-task gait activities found that participants with Huntington disease had difficulty synchronizing steps to a metronome in all conditions.³⁴⁶

In a controlled clinical trial published by Kloos and colleagues, participation in a video dance game (Dance Dance Revolution), for 25 minutes, two times per week for 6 weeks resulted in significant reduction in double support percentage for forward and backward walking. Additionally, those with less severe motor symptoms had reductions in heel-to-heel base of support during forward walking.³⁵⁰

Relaxation aids the reduction of extraneous movements. In the early stages of the disease, methods that require active participation of the patient, such as biofeedback and traditional relaxation exercises, may be included. As dementia becomes more apparent, more passive techniques such as slow rocking and neutral warmth must be used. These techniques are also helpful in reducing the choreiform movements of the mouth and tongue, which may prove useful for the dentist and those responsible for proper nutrition of the patient. In most cases of Huntington disease, the individual is quite thin (almost emaciated) and begins to age rapidly as the disease progresses. The extraneous movements, especially as they become more severe, increase metabolic demands, and nutrition, therefore becomes increasingly important. Attention therefore must be paid to head, neck, and oral-motor control. Increased pressure on the lips may aid in lip closure and facilitate swallowing. Special straws with a mouthpiece like a pacifier may be useful. A dietician should be consulted for assistance in teaching the family how to prepare balanced and appetizing meals and snacks that are still easy to swallow.

The degree of dementia influences treatment options. Conscious efforts to control extraneous movements will be more difficult as

cognitive function decreases. New memories and new patterns of movements are more difficult to establish. The therapist must therefore use techniques that require subcortical control and must keep in mind that the patient can sometimes remember old, normal patterns of movement. An encouraging treatment method may be the use of imagery. Yáguez and colleagues³⁴⁷ found that patients with Huntington disease could use imagery to compensate for impairments in a graphomotor design task.

Peacock's study³⁴² suggests that group programs including strength, flexibility, balance, coordination, and breathing exercises may be very successful, especially in the early stages of the disease, and this was confirmed in the study by Zinzi and colleagues.³⁴⁵ No amount of physical or occupational therapy, however, can prevent neuronal cell loss. With Huntington disease being a progressive, degenerative disease, the patient's condition will get worse, although the Zinzi study suggested that the progression might be slowed with integrated therapy.³⁴⁵ Eventually, goals must be aimed at preventing total immobility and assisting caretakers in transfer techniques and advising them in the use of adaptive equipment. One aspect of treatment that cannot be measured but is important in my view is the degree of hope offered just by the fact that a health professional is providing ongoing care. This may lessen the patient's degree of despair and depression and may help maintain quality of life.

Wilson Disease

Wilson disease, or hepatolenticular degeneration, is a disease caused by faulty copper metabolism. The toxic effects of copper lead to degeneration of the liver and the basal nuclei. Wilson disease, inherited as an autosomal recessive trait, affects a very small percentage of the population. If the disease is recognized and properly treated, the patient can expect function without restriction and a normal life-span.

Wilson disease is characterized by an increase in the amount of copper absorbed from the intestinal tract, a subsequent elevation in the amount of copper in the blood serum, and an increase in the amount of copper deposited in tissue.³⁵¹ Ceruloplasmin is concomitantly reduced. The increase in tissue copper may interfere with various enzyme systems of particular cells. The connection of copper with DA metabolism may account for the basal nuclei involvement.

Neuronal degeneration is present in the globus pallidus and putamen and, to a lesser extent, in the caudate nucleus. Atrophy may be present in the gray matter of the cortex and the dentate nucleus of the cerebellum.

Symptoms

The deposition of the excess copper in the cornea results in the classic diagnostic sign of Wilson disease, the Kayser-Fleischer ring: a brownish-green or brownish-red ring found in the sclerocorneal junction.

Several forms of Wilson disease have been classified based on signs and symptoms. One type entails only liver involvement and no neurological signs. A dystonic form is most common in those with an onset of the disease after the age of 20 years. The individual shows the same abnormal positioning of the limbs and trunk that characterizes the dystonia, rigidity, and bradykinesia seen in Parkinson disease. Associated reactions and facial expressions are absent. Festinating gait and flexed posture are present. Tremor of the hand, head, and body may be present.

If the onset of the disease occurs before age 20, the appearance of choreoathetoid movements of the face and upper extremities is usually present. The gait resembles that of the individual with Huntington disease. This early-onset form is accompanied by rapid deterioration.³⁵²

Common to all forms of Wilson disease that involve brain structures are difficulty in speaking and swallowing, incoordination, and

personality changes. The personality changes are the first signs of the disease, especially emotional lability and impaired judgment. If the disease progresses, dementia and cirrhosis of the liver increase and motor function progressively decreases.

The postures and movement patterns seen in people with Wilson disease include dystonic movements involving twisting and rotation of limbs, with sustained contraction at the end of the movement.¹⁶ As Wilson disease progresses, the classic abnormal posture of increased flexion occurs, along with rigidity that can progress to the inability to move if severe enough. Dystonia, like bradykinesia and choreoathetosis, belongs on a continuum of the extraneous movements present with basal nuclei involvement. Dysfunction of the cerebellum and intralaminar nuclei of the thalamus may also contribute to these impairments of posture and movement.³⁵³ A peculiar aspect of dystonia is that it can be decreased with proprioceptive or tactile inputs.¹⁴ As with other diseases of the basal nuclei, an imbalance or abnormal response in the neurotransmitters occurs in Wilson disease; however, the precise imbalance is not yet known.

Stages of the Disease

The first symptom of Wilson disease is usually a change in the individual's personality. When this becomes severe enough or when the movement disorder appears, a diagnosis can be made by the presence of the Kayser-Fleischer ring in the eye or by an analysis of copper metabolism. Because Wilson disease is now treatable by chemical means, the full progression of this disease is usually not seen. If left untreated, the dystonia becomes worse and the person becomes more rigid. In addition, muscle weakness can occur and progress, seizures may develop, and the dementia and personality disorder become worse.

Medical Management

Wilson disease is usually one of the first diseases to be ruled out when a patient manifests movement disorders and behavioral problems, especially in the younger patient. The signs and symptoms of Wilson disease are caused by an increased absorption of copper; thus the treatment consists of drugs that will inhibit this absorption. Concomitantly, copper intake in the diet is restricted; no nuts, chocolate, liver, shellfish, dried fruit, or mushrooms. Zinc salt, which blocks the absorption of copper in the stomach and has no side effects, is now the treatment of choice. Penicillamine and trientine increase urinary excretion of copper, but there are serious side effects to these drugs. If the copper imbalance is treated, the neurological signs do not progress.

Examination and Treatment Intervention

Wilson disease is fully managed medically and can be diagnosed early; hence it may not be of concern to the therapist. If the patient is referred for therapy, treatment techniques should be wholly based on symptoms. Examination is similar to that of the person with Parkinson or Huntington disease. It consists of describing the type of extraneous movement present, when it is present, and factors that influence the degree of dystonia. Ease of movement should also be assessed and may be timed as for the patient with Parkinson disease. In addition, functional mobility (transfers, floor transfer), range of movement, and strength should be evaluated, especially if the disease is progressing.

Treatment is then designed to alleviate the problems. Extraneous movements may be reduced by any technique that will reduce tone. Positioning is important. If bradykinesia is the major sign, then treatment would be similar to that used for people with Parkinson disease; if trunk stability is poor, the therapist proceeds as in Huntington disease. The patient with Wilson disease has knowledge of what normal movement feels like and usually has good cognitive abilities at the time treatment is started. As a result of the emotional lability, which is one

of the first symptoms in this disease, the treatment session should be well planned and quite structured.

Tardive Dyskinesia

Tardive dyskinesia is usually a drug-induced disorder and thus will be used to indicate the problems that can arise from drug intoxication. This section concentrates on the problems associated with drugs that affect DA metabolism and/or reuptake, including amphetamine, methamphetamine, haloperidol, and classes of drugs used in the treatment of psychotic disorders: the phenothiazines, butyrophenones, and thioxanthenes. As the use and misuse of drugs becomes more common, these types of disorders may become more frequent.

The use of phenothiazines (one of the neuroleptics) has become a very effective and common treatment for schizophrenia. This treatment protocol has enabled many schizophrenics to leave the mental institution. These drugs are DA antagonists and thus decrease the amount of DA in the brain. The exact site of the brain involved in schizophrenia itself is not within the scope of this chapter, but the neurological signs that occur will be discussed. As might be expected, they involve structures within the basal nuclei. Tardive dyskinesia is a gradual disease that occurs after long-term drug treatment. The most typical involvement is of the mouth, tongue, and muscles of mastication; thus tardive dyskinesia may be called *orofacial* or *buccolingual-masticatory* (BLM) dyskinesia.

Symptoms

Dyskinesia is defined as an inability to perform voluntary movement.³³⁸ In practical terms, however, dyskinesia is usually a series of rhythmical extraneous movements. In tardive dyskinesia this typically begins with, or may be confined to, the region of the face. These extraneous movements may include choreoathetoid or dystonic movements. Because of abnormality in basal nuclei function, abnormalities in postural tone and postural adjustments are also present. Instead of the typical flexed posture of Parkinson disease, patients with tardive dyskinesia show extension of the trunk with increased lordosis and neck flexion.³⁵⁴ This description of the disease is rather broad, but the problems of drug-induced movement disorders are varied. They may take the form of drug-induced Parkinson disease or dystonia. In tardive dyskinesia, akinesia and rigidity like that seen in Parkinsonism may exist simultaneously with the choreoathetoid-like movements. The key factor in tardive dyskinesia is its slow onset after the ingestion of neuroleptic medications.

Etiology

Although many people take neuroleptic medication, only a small percentage acquires tardive dyskinesia. Many factors may predispose an individual to movement disorders. One of these is age.³⁵⁵ This might be expected because of the influence of aging processes on the concentration of DA. Gender may also be a factor. Women, and older women, are more at risk for tardive dyskinesia, perhaps because of decreased estrogen.³⁵⁴ The absolute amount of neuroleptic ingested may also be a factor, but to date definitive studies have not been completed. So far, the length of time the individual takes medication does not appear to be a strong predisposing factor. As the biological abnormalities of schizophrenia become better understood, further understanding of the causes of tardive dyskinesia may also be elucidated. The development of tardive dyskinesia is hypothesized to be caused by supersensitivity.^{338,356} With the use of drugs that deplete the brain of DA, the brain becomes more sensitive to it and, in fact, in humans the withdrawal of neuroleptics tends to heighten the disease; essentially, withdrawal of the DA antagonist means that far more DA is able to act on these already sensitive terminals.^{338,356,357}

As a result of the effectiveness of long-term treatment for schizophrenia provided by neuroleptics, research into the underlying cause and therefore treatment of the major side effect, the motor disorders, has greatly increased;³⁵⁸ however, as with Parkinson disease and Huntington disease, animal models are difficult to produce. Experimental evidence indicates that the basal nuclei are involved in movements about the face, especially the mouth, and buccolingual dyskinesia is the most frequently encountered symptom in tardive dyskinesia.^{359,360} The response of basal nuclei neurons to sensory input shows increasing localization of response with age; the region about the mouth becomes increasingly sensitive.³⁵⁹ Further research along these lines, both in normal animals and in those with lesions, may answer the question of what is happening at a neuronal level. This would facilitate pharmacological and therapeutic interventions.

Pharmacological and Medical Management

The most important treatment for tardive dyskinesia is prevention. Today, DA receptor agonists are prescribed only when other, newer medications are not effective. Tardive dyskinesia is often irreversible. The withdrawal of medication may, in fact, increase the movement disorders, or recovery may take even more time than that required for the onset of the disease. Strangely, sometimes the drug that caused the disease may be the drug that reduces the symptoms; that is, increasing the dose may lessen the movement disorder, and this might be expected if supersensitivity to DA is involved. Again, however, with time the increased dose will also cause a reappearance of the symptoms. The Movement Disorder Society recommends that the physician evaluate the schizophrenic patient at 3-month intervals to prevent the disease. (Refer to the list of websites at the end of this chapter.)

The use of other drugs in conjunction with the neuroleptics has been tried in various animal models of the disease. As might be expected, anticholinergic drugs (which would worsen an imbalance between DA and ACh) worsen the dyskinesia. Lithium has been successful in one animal model of dyskinesia.³³⁸ Some neuroleptic drugs seem to have less effect on movement than others; however, the side effects of one such drug, chlorpromazine, are life-threatening. Reducing the buildup of phenylalanine is also indicated as a way to decrease occurrence of tardive dyskinesia. A medical food comprising branched-chain amino acids seems to reduce concentration of phenylalanine and was effective in reducing the movement disorder in one clinical trial. More research is needed into both the mechanisms of schizophrenia and the mechanisms for the production of the abnormal movements.

Evaluation and Treatment Interventions for Dyskinesia

The effectiveness of rehabilitation therapy intervention in drug-induced dyskinesia is not yet completely known; however, because the neuroleptics do provide an effective long-term treatment of schizophrenia, and because amphetamines and methamphetamine are being abused, therapists need to become aware of the problem and offer some assistance. Early drug holidays (time without use of drugs) may be of value in treatment of tardive dyskinesia, and therefore early awareness of incipient changes in motor function may be of value. Assessment of patients receiving drug therapy could perhaps begin before treatment and then at prescribed intervals. The knowledge that postural adjustments are abnormal in most basal nuclei diseases means that analysis of posture statically and in motion might provide early clues of development of movement disorders. The same would be true for balance reactions and changes in tone with changes in position. Once movement disorders appear, an assessment of when and where the extraneous movements occur is important.

General treatment is similar to that used in Huntington disease; oral treatment corresponds to that for the athetotic child with cerebral palsy. If a hyperreactivity to sensory stimulus exists, then oral desensitization may be of value.

Ameliorating the oral grimacing, of course, would be helpful for the schizophrenic person who is trying to return to society. The effectiveness of physical and occupational therapy treatment cannot be assessed until therapists become involved with these patients and record the effectiveness of their interventions. In cases in which the Parkinsonian-like symptoms are stronger than the dyskinetic movements, treatment would follow the plan for the individual with Parkinson disease. As yet, physical therapy for drug-induced dyskinesias is not mentioned on websites to the physician or the patient.

Other Considerations

Other drugs besides neuroleptics may also produce movement disorders. Amphetamine, for example, has been shown to cause long-term changes in brain function even with very small doses.^{361–363} Adults who were hyperactive as children sometimes show a decrease in the readiness potential.³⁶⁴ Further longitudinal research and research using PET scans and fMRI are underway to determine the role that medications used in treating hyperactive children, such as methylphenidate (Ritalin), might play in changing the architecture of the basal nuclei and causing movement disorders.⁸² The problem of drug-induced movement disorders may become an ever-increasing one for the therapist.

In 1982, several young people were treated for rigidity and “catatonia” after the use of what they thought was heroin. Careful examination of these patients revealed that they had Parkinsonian-like symptoms.^{36,103} The chemical responsible for the symptomatology was MPTP, a meperidine analog that was an impurity in the designer heroin. This discovery has enabled research in animals and clinical studies in humans and may enable better understanding of the pathogenesis and, in turn, of the treatment of the disease. One hypothesized cause of Parkinson disease implicated environmental toxins (because some herbicides such as paraquat resemble the chemical structure of MPTP) and the involvement of superoxide free radicals.^{95,365,366} Epidemiological studies have shown that exposure to organophosphates is associated with an increased incidence of developing Parkinson disease.³⁶⁷

Methamphetamine use also induces movement disorders. The MRI of even infrequent users shows damage to the basal nuclei.^{368,369} A child born to a mother using methamphetamine may also have movement disorders and delayed achievement of developmental milestones. Another recreational drug, cocaine has long been known to produce Parkinsonian movement disorders.³⁷⁰

Dystonia

General Information

Dystonia is a movement disorder characterized by sustained or intermittent muscle contractions causing abnormal, often repetitive movements, postures, or both. Dystonic movements are typically patterned, twisting, and may be tremulous. Dystonia is often initiated or worsened by voluntary action and associated with overflow muscle activation.³⁷¹ In 2013 it was proposed that classification of dystonias would fall into one of five classification systems.

- **Focal.** Only one body region is affected. Typical examples of focal forms are blepharospasm, oromandibular dystonia, laryngeal dystonia, and writer’s cramp.
- **Segmental.** Two or more contiguous body regions are affected. Typical examples of segmental forms are cranial dystonia (blepharospasm with lower facial and jaw or tongue involvement) or bi-brachial dystonia.
- **Multifocal.** Two noncontiguous or more (contiguous or not) body regions are involved.
- **Generalized.** The trunk and at least two other sites are involved. Generalized forms with leg involvement are distinguished from those without leg involvement.

- Hemidystonia. More body regions restricted to one body side are involved. Typical examples of hemidystonia are caused by acquired brain lesions in the contralateral hemisphere.

In all cases of dystonia, excessive coactivation of agonists and antagonists occurs that interferes with the timing, execution, and loss of independent joint motions. Rarely are any abnormalities of muscle tone present, *per se*—that is, no increase in deep tendon reflexes or rigidity occurs. Muscle strength and ROM are usually within normal limits unless disuse leads to weakness or if Botox has been utilized as a treatment modality.

Generalized Dystonia

Symptoms. The person with generalized dystonia will begin a movement (such as walking) and will then experience a torsional contraction of the trunk; of the upper extremity, especially at the shoulder; and in the ankle, foot, and toes. These contractions may be so strong that further movement is impossible. Many patients experience pain as the muscles remain contracted for long periods of time.³⁷²

Etiology. The cause of generalized dystonia is predominantly genetic, involving the *DYT* gene.³⁷³

According to the Dystonia Medical Research Foundation, there may also be additional causes for generalized dystonia including birth injury, exposure to certain drugs, head injury, and infection.

Pharmacological and medical management. There are few treatments for generalized dystonia. DA agonists and L-dopa are sometimes effective.

Evaluation and treatment intervention. Evaluation of the person with generalized dystonia will be similar to the evaluation of the person with tardive dyskinesia or Huntington disease. Several ADLs should be examined. The way that dystonia interferes with these ADLs is of most importance for treatment. In addition to the full extent of the motoric abnormality, it is also important to test sensation, especially higher level sensory processing such as precise localization of touch, graphesthesia, and kinesthesia.

Movement therapy interventions are only now being developed for generalized dystonia. Overall, treatment similar to that in Huntington disease that emphasizes treating the symptoms may be beneficial. One successful program uses sensory integration and relearning techniques performed with attention.³⁷⁴ Practice is a crucial element of treatment, and the patient must be willing to practice the sensory tasks many, many times throughout the day for benefit.

Other considerations. As with other extraneous movements associated with basal nuclei disorders, relaxation can reduce the muscle contraction; however, I have found that the time to incorporate relaxation is before the full-blown development of the muscle contraction—a difficult task. Therefore patients should practice relaxation on a regular basis. There is frequently a psychological aspect to focal dystonias that may necessitate intervention from a psychiatrist or psychologist.

Focal Dystonias

Spasmodic torticollis is the most common focal dystonia. The person with this disorder will have involuntary contractions of neck muscles that result in head turning or tipping and head extension and flexion movements that are often sustained for long periods of time. Other common sites of focal involvement are the vocal cords; the tongue and swallowing muscles; the facial muscles, especially around the eye; the hand; and the toes. Writer's cramp is a task-specific dystonia, unlike other focal dystonias. An interesting phenomenon of dystonia is the fact that many patients will develop a sensory or motor "trick" that will decrease the severity of the muscle contraction(s) and may even stop these movements.^{372,375}

Symptoms. Symptoms of focal dystonia will depend on the site of involvement. For example, in the case of spasmodic torticollis, the

symptom is pain and an inability to control a movement of the head to the side.

The signs and symptoms of focal hand dystonia are variable. The problem may initially manifest as an abnormality in the quality of sound produced by a musical instrument (e.g., a deterioration of vibration in a violinist),³⁷⁶ increasing errors in task performance, unusual fatigue or sense of weakness, or involuntary or excessive movement of a single or multiple digits. Initially, the symptoms are subtle and virtually indistinguishable from the normal variations that may be seen in the execution experienced by all musicians studying technically demanding music or software engineers who spend excessive hours at the computer. Frequently, a person engaged in a profession with highly repetitive tasks who has minimal pain but vague motor control problems or somatosensory dysfunction is manifesting early signs of focal dystonia.³⁷⁷ Although co-contraction of flexors and extensors can be observed while an individual with hand dystonia performs the target task, while at rest and during performance of nontarget tasks the hand appears to function normally. Some patients demonstrate a variety of subtle abnormalities such as reduced arm swing; loss of smooth, controlled grasping; a physiological tremor; hypermobility of interphalangeal joints; decreased ROM in some upper limb joints (e.g., shoulder abduction, external rotation, finger abduction, and forearm pronation); neurovascular entrapment; compression neuropathy; or poor posture.^{378–383}

Etiology. The cause of focal dystonias is unknown and multifactorial. Frucht³⁷⁹ observed that task-specific hand dystonia seemed to begin after motor skills had been acquired rather than during skill acquisition; thus focal hand dystonia in a musician is probably not a disorder of motor learning but a disruption of acquired, complex, motor programs. The data also suggested that peripheral environmental influences seem to play an important role in molding the dystonic phenotype. For example, the hand performing the more complex musical tasks (e.g., right hand in pianists and guitarists, left hand in violinists) seemed to be more predisposed to the development of dystonia. In addition, the dystonia usually began in one finger and spread to adjacent fingers, rarely skipping a finger. Furthermore, the ulnar side of the hand (fingers 4 and 5) was disproportionately affected, potentially because of the challenging ergonomics and technical stresses of the musical instrument required for this part of the hand in terms of gripping and activation of individual finger movements.³⁸⁴

Pharmacological and medical management. The most common medical treatment for focal dystonias is botulinum toxin. This toxin binds with the ACh receptors on the muscle and prevents the muscle from contracting. The injections are made under electromyographic guidance so that only those motor units involved in the production of the extraneous movements are paralyzed; however, the treatment does not cause permanent change, so the patient must repeat these injections every 3 to 4 months. Some people develop antibodies to the toxin, rendering it then ineffective.^{385,386} Therefore medical management prevents the abnormal movement but is not a cure.

Evaluation and treatment. Overall, treatment of focal dystonia will depend on the joint or joints involved. The duration of the dystonia, the trigger, and the person's trick, if any, to relieve the dystonia must be noted. Tricks are sensory in nature and help relieve the pain often associated with the extreme movement. The Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS) is one evaluation of the person with spasmodic torticollis.^{387,388}

Several ADLs should be examined. For example, in hand dystonia, the person should be evaluated using the instrument producing the dystonia (i.e., the pen in writer's cramp) as well as other tools (e.g., a fork). In addition, there seems to be position dependence, so writing

while prone may not evoke the dystonia despite severe inability to hold the pen at a desk.

In addition to the full extent of the motoric abnormality, sensation, especially higher-level sensations such as precise localization of touch, graphesthesia, and kinesthesia must be assessed. Byl and colleagues found changes in the sensory cortex after development of focal hand dystonia.^{374,388–391} Recent evidence suggests that balance, particularly dynamic balance, should also be assessed in patients with torticollis.³⁹² These balance difficulties have not been relieved with botulinum toxin.

Movement therapy interventions are now being developed. One successful program uses sensory integration and relearning techniques performed with attention.³⁹³ Practice is a crucial element of treatment, and the patient must be willing to practice the sensory tasks many times throughout the day for benefit. The patient practices cognitively demanding sensory discrimination tasks throughout the day and tries to use only tension-free movements.³⁸⁸

Treatment for the person with torticollis must include a relearning of midline before the person can begin to practice normal movement away from midline. The patient may find this relearning process easier after botulinum injection.

Other considerations. As with other extraneous movements associated with basal nuclei disorders, relaxation can reduce the muscle contraction; however, the time to incorporate relaxation is before the full-blown development of the muscle contraction—a difficult task. This task requires a shift in paradigm to a health and wellness model and prevention; therefore patients should practice relaxation on a regular basis. A psychological aspect to focal dystonias frequently necessitates intervention from a psychiatrist or psychologist.

METABOLIC DISEASES AFFECTING OTHER REGIONS OF THE BRAIN

All alterations of metabolism, if allowed to continue, will affect nervous system function. This includes alterations in sodium, water, sugar, and hormonal balance. Table 18.2 lists metabolic diseases that often have neurological sequelae. Proper treatment is usually medical management of the imbalance. Physical therapeutic intervention, if necessary, should address specific neurological symptoms.

Ingestion of, or exposure to, heavy metals may also lead to CNS disease. Table 18.3 describes the sequelae of these problems.

SUMMARY

This chapter has focused on the pathophysiology, evaluation, and treatment of genetic, hereditary, and metabolic diseases affecting adults. In all of these diseases the therapist or movement specialist is an important part of the rehabilitation team. Knowledge of the possible mechanisms involved in the production of varying movement disorders may make the appropriate evaluation and subsequent treatment more meaningful. Even with degenerative, progressive disorders the therapist plays an important role in maintaining quality of life, potentially improving movement and decreasing disability, and assists the patient and family in coping with the disease. The importance of documentation and publication of cases and larger controlled studies cannot be overstressed. Both will assist in the development of improved therapeutic

techniques and may help researchers in planning and interpreting appropriate experimental studies. Establishment of efficacy is the first step toward evidence-based practice and a critical link in the evolution of professionals who have been identified as movement specialists.

With the advent of the Internet, many websites have been created to focus on diseases and conditions mentioned in this chapter. In addition, the organization Patients Like Me has a website for both patients and care providers (www.patientslikeme.com). Sites such as this answer many questions for patients and provide information on making day-to-day life easier. Local and national support groups and foundations also provide information and support for the patient and caregiver. Most also have separate sections for health care providers.

TABLE 18.2 Neurological Complications of Metabolic Disorders

Metabolic Problem	Treatment	Neurological Complication
Decreased sodium (too much water)	Restriction of water intake	Muscle twitching, seizures, and coma
Increased sodium (too little water)	Slow rehydration	Cerebral edema, muscle rigidity, and decerebrate rigidity
Decreased potassium (hypokalemia), often caused by aldosteronism	Restoration of potassium levels after assessing primary cause	Changes in resting potential of neuron; hyperpolarization; muscle weakness and fatigue with eventual total paralysis
Magnesium imbalance	Improved diet, intravenous magnesium	Mental confusion, muscle twitching, myoclonus, tachycardia, hyperreflexia, extraneous movements, and seizures
Diabetes mellitus	Proper control of diabetes	Peripheral neuropathy, pseudotabes, possible seizures, and coma
Hypoglycemia	Treatment of primary cause; diet adjustment	Anoxia of the brain, seizures, confusion
Hyperthyroidism	Thyroid-blocking agents; intravenous fluids, hydrocortisone, and propranolol if patient is in thyroid crisis	Hyperkinesia, irritability, nervousness, emotional lability, and symmetrical peripheral neuropathy
Hypothyroidism	Thyroid supplement	Sluggishness, mental and motor retardation, muscle weakness, and sometimes muscle pain
Hypercalcemia	Treatment of primary cause, which is often hyperparathyroidism, vitamin D malignancy (therefore surgical removal)	Headache, weakness, fatigue, proximal neuropathy, rigidity, tremor, and disorientation
Hypocalcemia	Intravenous administration of calcium (possible medical emergency)	Hyperexcitability of the peripheral and central nervous systems, which can lead to tetany and convulsions

TABLE 18.3 Neurological Complications of Heavy Metal Poisoning

Type of Metal	Treatment	Neurological Complication
Lead Source: lead paint, industrial (fumes of molten lead)	Elimination of source, reduction of fluids, intravenous urea or mannitol, and use of chelating agents	Interstitial edema and hemorrhage (especially in cerebellum) in acute poisoning; all levels of central nervous system affected in chronic long-term poisoning In children: seizures, mental retardation, behavior problems, and hyperactivity In adults: spasticity, rigidity, dementia, and personality changes Peripheral neuropathy may occur in adults and children
Arsenic Source: paint and insecticides	Removal of source, gastric lavage, intravenous fluids, maintenance of electrolyte balance; penicillamine used in acute poisoning	Demyelination of peripheral nerves in all extremities
Manganese Source: industrial if manganese dust is not removed; symptoms appear 2–25 years after exposure	Levodopa	Neuronal loss in basal nuclei, substantia nigra, and cerebellum Initially psychiatric disturbances, including nervousness, irritability, and a tendency toward compulsive acts Later, muscular weakness and Parkinsonian symptoms
Mercury Rare, but may affect farmers and dental office workers	Penicillamine; function returns only with physical, occupational, and speech therapy	Loss of neurons, especially in cerebellum; also in cortex near calcarine fissure Alternating periods of confusion, drowsiness, and stupor with restlessness and excitability Ataxia, dysarthria, and visual deterioration

CASE STUDY 18.1 Patient With Parkinson Disease, Hoehn and Yahr Stage 1

Ms. T. is a 55-year-old woman who was diagnosed with Parkinson disease 1 year ago. The disease began in her left arm and leg when she noticed increasing stiffness and difficulty moving. She was initially seen in physical therapy 8 months ago for potential frozen shoulder, which did respond to traditional physical therapy. She complains of some instability in walking and has recently developed a slight resting tremor in the left hand. On initial evaluation she had full active and passive ROM in all extremities, neck, and trunk. There is a mild resting tremor present in the left hand. There is mild cogwheel rigidity in the left upper and lower extremities; there is some intermittent resistance to passive movement in the right upper extremity as well. Strength is grossly within normal limits throughout. Sensation is intact throughout. Equilibrium reactions are delayed, but the patient demonstrates an ankle strategy on a flat surface and a hip strategy when standing on the balance beam; there is no mixing of the synergies, and her balance responses are appropriate to the degree of displacement.

The patient is able to stand in the sharpened Romberg position for 30 seconds with eyes open and 20 seconds with eyes closed. She can stand on the right leg for 30 seconds with eyes open and 15 seconds with eyes closed; she can stand on the left leg for 15 seconds with eyes open and 10 seconds with eyes closed. When walking, she has a heel-toe sequence, shortened stride length, and normal stride width. There is no arm swing on the left and a diminished arm swing on the right. There is no trunk rotation and very slight trunk flexion throughout the gait cycle. Speed is within normal limits for a 25-foot walk. The patient is able to turn freely to complete Timed Up and Go in less than 10 seconds and cognitive Timed Up and Go (counting backward by 3s from 50) with correct accuracy, but her speed slowed to just more than 11 seconds, and her arm swing limitations were increased bilaterally. She recently began to experience a foot dystonia, which is worse with fatigue. It has interfered with her daily walking program and her tennis, an activity she enjoys with her husband twice a week. Her only medication is deprenyl.

This patient is in Hoehn and Yahr stage 1, with some beginning of bilateral symptoms and progression to stage 2. She is young, is employed full-time, and has been involved in regular exercise for the past 10 years. Her complaints are stiffness, slowed movements, and foot dystonia. Her symptoms are mild at present, and she has good balance in standing and walking; hence this patient should be encouraged to continue exercising regularly. She should try to maintain her tennis because this requires complex, sequential, context-dependent movements. Although tennis involves motor responses to external cues, it does necessitate rapid force generation and anticipatory movements. This should encourage continued motor learning. In addition, she should be encouraged to continue walking out of doors and practice alternating speed of walking. During her walks she has been instructed to exaggerate her arm swing and keep her hands open as she works to swing them contralaterally with each leg as she steps. Use of music at a cadence of 100–120 beats per minute was encouraged to set an external rhythm. The dystonia is more difficult to resolve. It may be tied to medication, and differing medication schemes are now being tried. She is also on a program of stretching and strengthening of the ankle as well as a sensory stimulation program for the feet. Foam between the toes has helped to decrease dystonia early in the day.

Ms. T. has also been informed about the importance of maintaining chest expansion and monitoring her breathing. This will be important as the disease progresses. She attends a support group to increase her awareness of the disease, new treatments, and support. As the disease progresses, she will need a home program appropriate for her symptoms. She should start considering exercise groups because the group setting can be very valuable for a patient with Parkinson disease at any disease stage. She will be seen by her physical therapist no less than every 6 months for reassessment and progression of her home program.

CASE STUDY 18.2 Patient With a Seven-Year History of Parkinson Disease, Hoehn and Yahr Stage 3

Mr. R. is a 68-year-old man with a 7-year history of Parkinson disease. He is currently in Hoehn and Yahr stage 3 of the disease. He falls two or three times a day, has difficulty eating, and has noticed weakness in his right hand. He would like to return to full activity including golf twice a week, swimming, and skiing. On evaluation he has moderate rigidity in all extremities; the right side is worse than the left. It is most marked in the right wrist, forearm, and hand. Shoulder flexion and abduction lack 15 degrees bilaterally. He has a 15-degree knee flexion contracture on the right; all other joints in the lower extremity have range within functional limits. Strength is grossly 4 to 4+/5 on manual muscle testing throughout, including grip strength. Sensation is within normal limits throughout. Sitting balance is good during static and dynamic activities.

The patient sits with a posterior pelvic tilt, rounded shoulders, and flexed neck. On rising to a standing position, he does move forward in the chair, which positions his feet under his knees. He does not lean forward as he stands and momentarily loses his balance backward on rising from a chair. Static standing and dynamic balance is fair. When pushed on the sternum, he takes 1 or 2 steps backward, even to a gentle push. When pushed from behind he takes several steps forward. He lost his balance and required assistance when trying to catch a large ball thrown to the side. His gait pattern is typical of a patient with Parkinson disease with shortened steps and flat foot contact bilaterally. He complains of festination and freezing, but neither are observed during the evaluation. He turns “en bloc,” exhibiting no arm swing and no trunk rotation. He walks slowly

and is unable to increase his speed measurably in a 25-foot walk. He is taking carbidopa-levodopa and deprenyl. He tried taking another D2 agonist but experienced hallucinations. He was able to ski until last winter. At that time, he found that he could not stand up once he fell, and sometimes he fell without realizing that he was falling. He stated that he “did not think it was safe to ski.” He also no longer swims because he has difficulty breathing in the pool and coordinating his breathing with the strokes. He does not play golf because it takes him so long.

This patient was encouraged to continue to exercise and socialize while exercising. He was encouraged to resume golf at times when his course is less crowded. He was also encouraged to utilize a driving range so he can maintain his swing and add trunk rotation as part of his home program. In addition, he was given a home program consisting of activities to be performed in seated and standing positions that encourages trunk rotation and large movements and is coordinated with good breathing practices. He was given some balance exercises that challenge his equilibrium in a safe environment. His home program was monitored every 3 months because of the distance he must travel to come to the clinic. His wife was instructed to exercise with her husband and to exercise to music with him. He was referred to a speech pathologist for a swallowing evaluation and was given a therapeutic program for his speech and breathing. He is now able to play golf once a week; however, he is not yet ready to resume swimming or skiing. Future therapeutic interventions may include high-intensity exercise as his goals are significant for his disease level and he will need more aggressive treatment to reach these goals.

Abstract: This chapter will discuss disorders of the Basal Nuclei that are commonly encountered in physical therapy. Physical therapists must be well versed in evaluation and therapeutic interventions to address such disorders. At the completion of this chapter you will find

case studies to describe typical patient cases that a neurological physical therapist might treat.

Keywords: basal ganglia, Parkinson disease, dystonia, focal dystonia, dyskinesia

Cerebellar Dysfunction*

Susanne M. Morton, Jennifer L. Keller, and Amy J. Bastian

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Understand critical features of cerebellar anatomy and physiology and its role in motor control.
2. Describe the major movement deficits associated with damage to the human cerebellum.
3. Discuss important components of the physical therapy examination for patients with suspected cerebellar dysfunction.
4. Review the evidence for and against specific rehabilitation interventions targeting recovery of body functions, activities, and participation.
5. Discuss the factors involved in selecting recovery versus compensation approach in the physical therapy management of individuals with cerebellar dysfunctions.

KEY TERMS

ataxia
cerebellum
incoordination

motor learning
rehabilitation

OVERVIEW

The cerebellum is a highly unique brain structure, easily recognizable by its location on the dorsal surface of the brain stem and the distinct, dense folia, or foldings, of its cortex. For centuries, the cerebellum has been the object of intense investigation by scientists, in particular because of the extreme uniformity in the arrangement of neurons in the cerebellar cortex and the presence of very large Purkinje cells that have an extensive fanlike dendritic arbor. The human cerebellum contains more neurons than any other brain region, suggesting that whatever its role in behavior, it requires the integration of vast amounts of information and may perform rather complex computations. Researchers agree that the cerebellum plays a critical role in coordinating and adapting movements, although how it does so is still not fully understood. It is currently also clear that the cerebellum is connected to nonmotor regions of the brain, such as the prefrontal cortex, and therefore likely plays a role in cognitive and other nonmotor functions. Yet the most striking and debilitating effect of damage to the cerebellum is *ataxia*, which comes from the Greek and translates literally to mean “without order.” We will focus on this hallmark feature of cerebellar damage, which is incoordination of movements without overt muscle weakness. In this chapter, we will review critical features of cerebellar anatomy and physiology that help to reveal its role in motor control, and we will describe the major movement deficits associated with damage to the human cerebellum. We will highlight the most valuable and unique components of the physical therapy examination for patients with suspected cerebellar dysfunction and review the evidence for and against specific rehabilitation interventions targeting recovery of body functions,

activities, and participation. Emphasis is placed on the importance of the physical therapist’s judgment in determining whether a recovery or a compensation approach should be implemented.

Types of Cerebellar Damage

Cerebellar ataxia can result from damage to the cerebellum itself or the pathways to or from it. Damage can occur from a number of different causes, such as stroke, tumor, degenerative disease, trauma, or malformation. The etiology of cerebellar dysfunction is often an important consideration when determining a prognosis and developing a treatment plan. Other factors to consider include whether the cerebellar lesion is static or progressive, whether it involves only the cerebellum or multiple neural structures, and whether it was present at birth or acquired.

Cerebellar strokes are rarer than cerebral strokes but not entirely uncommon; they account for less than 5% of all strokes.¹ These strokes can involve any of the three arteries that supply the cerebellum: the superior cerebellar artery, anterior inferior cerebellar artery, and posterior inferior cerebellar artery. Depending on the territory supplied by the damaged vessel (Table 19.1), there are stereotyped patterns of cerebellar and extracerebellar motor dysfunction that results. However, there is certainly some variation in distributions from person to person. Stroke involving the superior cerebellar artery often leads to dysmetria of ipsilateral arm movements, unsteadiness in walking, dysarthric speech, and nystagmus.¹ Stroke involving the anterior inferior cerebellar artery often causes both cerebellar and extracerebellar signs (due to involvement of the pons) including dysmetria, vestibular signs, and facial sensory loss.¹ Finally, stroke involving the posterior inferior cerebellar artery is usually, in the long run, the most benign, although initially it often presents with vertigo, unsteadiness, walking ataxia, and nystagmus.¹ The best predictor of recovery from cerebellar stroke is

*Videos for this chapter are available at studentconsult.com.

TABLE 19.1 Territories of the Cerebellar Arteries^{1,3}

Artery	Cerebellar Territory Supplied
SCA	<ul style="list-style-type: none"> • Superior/upper approximately one-half of the dorsal and upper approximately one-third of the ventral surface of the cerebellum except for the extreme lateral wing of the hemisphere • Portions of the vermis and nodulus • Substantial upper portions of the intermediate and lateral hemispheres • Portions of the deep cerebellar nuclei • Superior cerebellar peduncle
AICA	<ul style="list-style-type: none"> • Middle approximately 10%–30% of the ventral cerebellum, sometimes wrapping laterally to encompass a small portion of the most lateral aspects of the dorsal cerebellum • Flocculus • Small portions of the lateral hemisphere • Middle and inferior cerebellar peduncles
PICA	<ul style="list-style-type: none"> • Inferior/lower approximately one-half of the dorsal cerebellum and the inferior approximately one-fourth to one-third of the ventral cerebellum • Portions of the nodulus, vermis, intermediate, and lateral hemispheres • Portions of the deep cerebellar nuclei

Note: The cerebellar arteries also supply extracerebellar regions (i.e., portions of brain stem) not listed here.

AICA, Anterior inferior cerebellar artery; PICA, posterior inferior cerebellar artery; SCA, superior cerebellar artery.

whether the deep cerebellar nuclei are involved: recovery is best when they are not damaged.²

Tumors in the posterior fossa (i.e., in or near cerebellum) do occur, although they are more common in children than adults. Depending on the type and location, tumors may be treatable with surgical resection, chemotherapy, radiation therapy, or some combination of these. Children with cerebellar tumors often have a good prognosis for recovery because many of the types of tumors most common in this population are benign and can be removed. Children also typically recover very well following cerebellar damage from tumor resection and show little signs of cerebellar ataxia. Tumors in adulthood often are due to a more aggressive form of cancer and therefore may have a poorer prognosis. Second to tumor type, damage of the deep cerebellar nuclei is an important factor that predicts recovery, even more so than age.²

Several neurodegenerative diseases can damage the cerebellum (Table 19.2). One of the more common types of degenerative diseases is a group of hereditary, autosomal dominant diseases referred to as the spinocerebellar ataxias (SCAs). Currently, there are 46 known distinct SCAs, which are named by numbers (e.g., SCA1, SCA2).⁴ Depending on the genetic abnormality, they can cause either purely cerebellar damage or combined cerebellar and extracerebellar damage.^{5,6} Most of the SCAs have onset in midlife and are slowly progressive, which means that children of an affected parent will likely not know if they are affected until adulthood. There are genetic tests for a subset of these diseases. Because onset of symptoms is delayed and there are no effective pharmacological treatments, genetic counseling is a must before families decide whether or not to have children undergo genetic testing. A related set of diseases are the hereditary episodic ataxias,⁷ which are rare autosomal dominant diseases. As the name implies, patients with episodic ataxia will have periods of ataxia, lasting minutes to hours, brought on by exercise, stress, or excitement. Some of the episodic ataxias respond well to medications.⁸

TABLE 19.2 Selected Forms of Cerebellar Damage⁵

Acquired	Degenerative Nonhereditary
1. Stroke (infarct, hemorrhage)	1. Multiple system atrophy (MSA)
2. Tumor (primary brain tumor, metastatic disease)	2. Idiopathic late-onset cerebellar ataxia (ILOCA)
3. Structural (Chiari malformation, agenesis, hypoplasia, etc.)	
4. Toxicity (alcohol, heavy metals, drugs, solvents, etc.)	Hereditary
5. Immune mediated (multiple sclerosis, gluten ataxia, etc.)	1. Autosomal dominant disorders (episodic ataxias, spinocerebellar ataxias)
6. Trauma	2. Autosomal recessive disorders (Friedreich ataxia, early onset cerebellar ataxia, etc.)
7. Infection (cerebellitis, etc.)	3. X-linked disorders (mitochondrial disease, fragile X-associated tremor, etc.)
8. Endocrine (hypothyroidism)	

Cerebellar damage can occur from other sources as well. In traumatic brain injury, damage of the cerebellum is almost always found in the presence of widespread brain damage and is seen as a predictor of poorer outcome.⁹ The cerebellum is also particularly sensitive to toxins, including certain heavy metals and alcohol. Chronic alcoholism causes cerebellar atrophy preferentially involving the anterior superior vermis.^{10,11} The inflammatory disorder multiple sclerosis also frequently produces lesions in the cerebellum. Finally, congenital brain abnormalities such as Chiari malformation damage the cerebellum by increased pressure and mechanical deformation. Recovery from cerebellar malformation is not understood; often these children have substantial damage to the brain stem or other neural structures, which may make therapy more challenging. A more comprehensive list of the variety of types of cerebellar damage is provided in Table 19.2.

Given the wide range of cerebellar disorders, it is useful for the clinician to categorize the damage as progressive or nonprogressive. Patients with progressive disorders, such as the SCAs, are likely to experience worsening ataxia and decreased mobility over time and will need periodic therapy over the life-span for optimal function. In contrast, those with nonprogressive disorders would not be expected to worsen and some may have the potential for substantial recovery. Note that when additional brain areas are involved, rehabilitation may be more challenging, theoretically because other compensatory brain mechanisms may be impaired. This type of information is vital for making an appropriate prognosis and developing a long-term plan of care for patients with cerebellar dysfunction.

CEREBELLAR ANATOMY AND PHYSIOLOGY

A brief review of specific anatomical and physiological features is critical to understanding the mechanisms by which the cerebellum helps to coordinate and adapt movement. Recall that most pathways

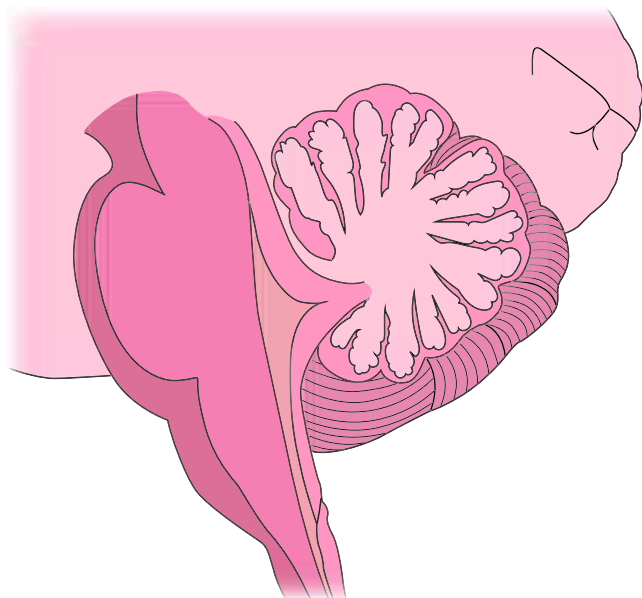

Fig. 19.1 The Cerebellum, Bisected Through the Midsagittal Plane.

between the cerebellum and spinal cord are uncrossed or double-crossed, whereas pathways between the cerebellum and cerebrum are crossed. Hence a lesion to one side of the cerebellum produces ataxia and related cerebellar deficits involving the same side of the body as the lesion. Also note that the cerebellum has relatively few direct projections to the spinal cord. Instead, it exerts a strong influence on movement through its projections to cerebral and brain stem motor structures, as described later.

Anatomical Divisions

The cerebellum is part of the hindbrain and is positioned on the dorsal surface of the brain stem at approximately the level of the pons (Fig. 19.1). It is connected to the brain stem by the superior, middle, and inferior cerebellar peduncles. The cerebellar peduncles contain all of the axons that transmit information to and from the cerebellum. The cerebellum can be anatomically divided into three lobes; the anterior, posterior, and flocculonodular lobes. The primary fissure divides the anterior and posterior lobes, and the posterolateral fissure divides the posterior and flocculonodular lobes (Fig. 19.2).

Looking at a sagittal slice through the cerebellum, distinct cellular regions can be visualized. The most superficial region is the cerebellar

cortex, which, unlike cerebral cortex, contains only three layers. The arrangement of cells within the cortex is strikingly uniform across all cerebellar lobes and plays a vital role in determining cerebellar function, which will be described later. Deep to the cerebellar cortex is the white matter layer, which contains the axons of Purkinje cells projecting out from cerebellar cortex and the axons of mossy and climbing fibers entering the cortex from other brain and spinal regions (see Fig. 19.1). The cerebellar nuclei are the output structures of the cerebellum, and they make up the deepest region. These are groups of neuronal cell bodies that receive information coming into the cerebellum from the periphery and also from the cerebellar cortex, via Purkinje cell axons. The deep nuclei are arranged in pairs, with one nucleus of each pair on each side of the cerebellum. Most medially are the fastigial nuclei, followed by the globose and emboliform nuclei and, most laterally, the broad dentate nuclei (see Fig. 19.2). The medial and lateral vestibular nuclei also receive inputs directly from the cerebellar flocculonodular lobe and are therefore sometimes considered an additional set of cerebellar output structures.

Functional Divisions and Their Afferent and Efferent Projections

Probably the most useful way of thinking about the anatomy of the cerebellum is to divide it into distinct functional longitudinal “zones.”¹² Each cerebellar zone consists of a region of cerebellar cortex and its own pair of deep cerebellar nuclei. Each zone also has projections to and from distinct areas of the brain and spinal cord. Thus despite the regular arrangement of cells over the entire cerebellum, each functional longitudinal zone is uniquely positioned to control certain types of movement but not others.^{12–14} See Table 19.3 for a summary.

The medial zone consists of the midline structure, the vermis, and the fastigial nuclei. This region of the cerebellum predominantly receives afferent information from the brain stem vestibular and reticular nuclei and the dorsal and ventral spinocerebellar pathways,^{15–20} which convey important information regarding the current sensorimotor state of the trunk and limbs.^{21–23} In turn its outputs, through the fastigial nuclei, are largely to reticular and vestibular nuclei, which will form part of the medial descending system (reticulospinal and vestibulospinal tracts), with some additional projections to the cerebral cortex via the thalamus.^{24–26} The medial cerebellar zone is involved in the control of posture and muscle tone, upright stance, locomotion, and gaze and other eye movements.

The intermediate zone is made up of the intermediate hemispheres and the globose and emboliform nuclei. This region also receives inputs from the dorsal and ventral spinocerebellar pathways and brain stem reticular nuclei, as well as some projections from cerebral cortex

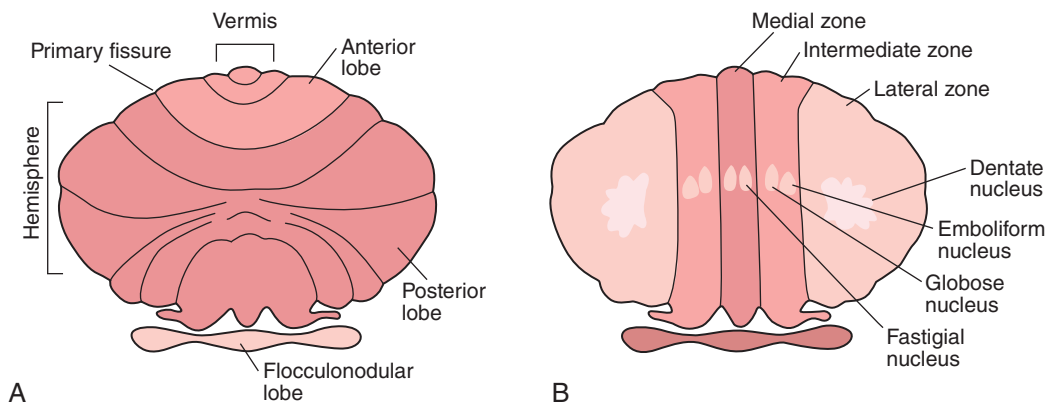

Fig. 19.2 The Cerebellum, Flattened, Showing Key Structures. **(A)** Different shading distinguishes the three lobes of the cerebellum. The cerebellar vermis and hemispheres are also shown. **(B)** Functional longitudinal cerebellar zones, distinguished by different shading, and the locations of the deep cerebellar nuclei within each zone.

that arrive via the cerebropontocerebellar pathway.^{13,15,16,27,28} Major projections from this cerebellar zone are to the cerebral cortex via the thalamus and to the red nucleus.^{25,26,29} The intermediate zone is considered to be important in controlling coordination of agonist-antagonist muscle pairs during a variety of activities including walking and voluntary limb movements. The medial and intermediate zones of the cerebellum are collectively referred to as the spinocerebellum because these are the only cerebellar regions that receive afferents from the spinal cord.

The largest region of the cerebellum is the lateral zone, which contains the two broad lateral hemispheres and their output structure, the dentate nuclei. Afferents to the lateral zone predominantly come from the cerebrum, from a wide variety of cortical areas including motor, premotor, and prefrontal cortices, parietal somatosensory and sensory association areas, and primary visual and auditory cortices.^{27,28} Outputs from the dentate travel mostly back to large areas of the cerebrum (through the thalamus), to many of the same areas from which afferents arrived in the cerebellum. Again, these include vast regions of sensorimotor cortices.^{29,30–35} Other efferent fibers project to the red nucleus in the brain stem. The lateral cerebellar zone plays a major role in control of complex, multijoint voluntary limb movements, particularly those involving visual guidance, and for the planning of complex movements and the assessment of movement errors. Because this region of the cerebellum interacts predominantly with the cerebrum, it is also commonly called the cerebrocerebellum. It is also sometimes referred to as the neocerebellum because it is considered to have arisen fairly recently in the phylogenetic tree, being much more expansive in primates than in lower animals.³⁶

The flocculonodular lobe can be considered a fourth zone of the cerebellum. It receives afferent projections directly from the vestibular primary afferents (semicircular canals and otoliths), as well as from vestibular nuclei and visual brain regions.^{13,15,16,18,20} Outputs from the flocculonodular lobe project directly to the medial and lateral vestibular nuclei of the brain stem, without a synapse in a deep cerebellar nucleus.^{14,24,37} For this reason, these vestibular nuclei are sometimes considered an additional set of deep cerebellar nuclei. This cerebellar zone helps to control eye movements and balance. The well-known vestibuloocular reflex (VOR), which provides gaze stabilization during head turning or walking, relies upon the cerebellum for proper functioning.^{38,39} Because of its critical ties to the vestibular system, the flocculonodular lobe is also known as the vestibulocerebellum (see Fig. 19.2).

Physiology of Cerebellar Neuronal Circuits

Within a longitudinal zone, thousands of microzones may exist,¹³ each consisting of a highly organized group of connected cerebellar cortical neurons. A microcomplex is the name given to a neural circuit made up of a single microzone plus the other connected neurons with which it communicates directly. The following section provides a very brief overview of the circuits important for cerebellar function and reviews the flow of neuronal signals into and out of cerebellar microzones (Fig. 19.3).

Most afferent information enters the cerebellum through one of two pathways, the mossy fiber pathway or the climbing fiber pathway. Both have important actions on cerebellar Purkinje cells. The mossy fiber pathway affects “beams” or rows of Purkinje cells oriented along the cerebellar folia. Dense mossy fiber inputs arise from a wide variety

Fig. 19.3 Schematic of the Major Cell Types and Their Connections Within the Cerebellum. Excitatory synapses are indicated with a triangle; inhibitory synapses with a bar. DCN, Deep cerebellar nucleus; IO, inferior olive. (Adapted with permission from Elsevier, Ito M. Cerebellar circuitry as a neuronal machine. *Prog Neurobiol.* 2006;78(3-5):272-303.)

of regions, including cerebral cortex, several subcortical areas, the brain stem, and spinal cord. Mossy fibers enter the cerebellar cortex and synapse onto granule cells, whose axons ascend and branch into parallel fibers. Each parallel fiber extends long distances longitudinally and synapses onto many Purkinje cells all located along the same beam.⁴⁰ Each parallel fiber has a relatively weak effect on single Purkinje cells, but the mass effect of many thousands of parallel fiber contacts with Purkinje cells drives the Purkinje cells to fire at high rates.⁴¹ In contrast, each climbing fiber arises exclusively from the inferior olive located in the brain stem and contacts only a few (approximately 1 to 10) Purkinje cells.^{14,42,43} Each Purkinje cell receives information from only one climbing fiber, yet the climbing fiber's effect on the Purkinje cell is powerful, causing large complex spikes.

The Purkinje cell provides the output for the cerebellar cortex; each Purkinje cell axon projects to one of the deep cerebellar nuclei. The mossy fiber and climbing fiber pathways affect Purkinje cells differently and are thought to transmit different types of information. Mossy fibers are active at very high rates (generating action potentials at approximately 100 Hz) and are highly modulated by various sensory stimuli and motor activity. They have been speculated to relay information related to the direction, velocity, duration, or magnitude of movements or sensory stimuli.⁴⁴⁻⁴⁷ However, climbing fibers are active at very low rates (approximately 1 to 4 Hz) and do not appear to be as strongly modulated by sensory stimuli or motor activity.^{42,48,49} There is still some disagreement regarding what sort of information is encoded in the climbing fiber signals, but the frequency of discharge appears to be too low to transmit information pertaining to specific parameters of sensory or motor events. However, the role of the climbing fiber is clearly important because its firing produces large complex spikes in the Purkinje cells and can also powerfully affect subsequent Purkinje cell firing.^{43,50} Therefore it is often considered to serve as a sort of “teaching” signal to Purkinje cells.

CEREBELLAR FUNCTION IN ADAPTING AND CONTROLLING MOVEMENT

The cytoarchitecture of the microzones is extremely stereotyped throughout the cerebellum, suggesting that it performs the same

overall function regardless of whether it is acting on circuits controlling standing balance, eye movements, or reaching and grasping, etc. So, what is the function of this cerebellar circuit? What aspect of motor control does it uniquely provide? Despite centuries of study, these questions have still not been answered completely. Although numerous theories of cerebellar function exist, here we limit the discussion to just a few that we view as particularly relevant.

Theories of Cerebellar Function

One general theory states that a primary function of the cerebellum is in coordinating multiple limb segments to generate smooth and fluid multijoint movements.⁵¹⁻⁵⁴ This “motor coordinator” theory has support from behavioral studies demonstrating that multijoint movements appear to be particularly impaired in patients with cerebellar lesions.⁵² Multijoint movements are inherently more complex than single joint movements because they require control of mechanical interaction torques, those occurring at one segment but caused by movement of other linked segments.⁵⁵ This model suggests that the cerebellum predicts the mechanical interactions between segments based on a stored internal knowledge of limb dynamics and helps to generate the correct motor commands for appropriate multijoint movements.

A second popular theory is the timer hypothesis. This idea proposes that the cerebellum is the main site for the temporal representation of movements.^{56,57} Supporters of this theory suggest that cerebellar output ultimately encodes the precise temporal sequence of muscle activation with such precision that when it is lesioned it produces obvious deficits in the spatial (e.g., movement direction and magnitude) as well as the temporal domain.⁵⁸ Other studies have shown that individuals with cerebellar damage also have impairments in perceiving time intervals, suggesting that this could be a more general cerebellar function.^{59,60}

A third idea is that the cerebellum acts as an internal model to allow predictive control of movement. Sensory feedback is inadequate for movements that need to be both fast and accurate: it is too slow, and as a result, motor corrections would be issued too late. Instead, the brain generates motor commands based on an internal prediction of how the command would move the body. This “feedforward” control requires stored knowledge of the body's dynamics, the environment, and the object to be manipulated; it is learned from previous exposure. The neural representation of this knowledge is referred to as an internal model⁶¹⁻⁶⁴ because it provides the ability to reproduce the effects of motor actions in the brain. The internal model theory for cerebellar function states that the cerebellum serves as the site of an internal model for movement. Accordingly, the incoordination of movement associated with cerebellar damage is a consequence of a disrupted internal model, which disrupts nearly all aspects of feedforward motor control.⁶⁵ This idea is appealing because it could help to explain the wide variety of motor behaviors (e.g., reaching, standing balance, eye movements) and movement parameters (e.g., force, direction) that can be impaired following cerebellar damage. Likewise, human behavioral studies have recently pointed out that cerebellar damage is frequently associated with impaired feedforward control but relatively intact feedback mechanisms.^{66,67}

A related theory originates from the seminal works of Marr,⁶⁸ Albus,⁶⁹ and Ito,⁷⁰ in which the cerebellum was theorized to be a sort of “learning machine.” This theory was based on careful examination of the anatomy and physiology within cerebellar microcircuits and continues to provide the basis for many of the current theories of cerebellar function (i.e., those described above). Central to the idea of cerebellar involvement in learning was the discovery that Purkinje cell output can be radically altered by climbing fiber induction of long-term depression (LTD) of the parallel fiber–Purkinje cell synapse.⁵⁰ Hence climbing fiber inputs onto Purkinje cells can be viewed as

providing a unique type of teaching or error signal to the cerebellum. More recently LTD, long-term potentiation (LTP), and nonsynaptic plasticity have all been shown to exist at numerous sites within the cerebellum, both in the cortex as well as the deep cerebellar nuclei.^{71–74} Thus there are multiple avenues for activity-dependent plasticity to occur within the cerebellum over relatively short time scales. It is presumed that the plastic changes in cerebellar output are responsible for changing motor behavior during the process of learning new skills.

To summarize, although the precise mechanisms are still under debate, most researchers can agree upon a few central themes of cerebellar function. First, the cerebellum is an integral structure for the coordination of movements. Second, precisely timed interactions between neurons produce activity-dependent plasticity at a number of different sites within the cerebellum. Presumably, this plasticity plays a fundamental role in motor learning. Convergence of these two themes would seem to indicate that a major cerebellar function is to maintain optimal motor control through constant adaptive learning processes, so that movements are appropriately adjusted for varying environmental demands.

CLINICAL MANIFESTATIONS OF CEREBELLAR LESIONS

Ataxia is the primary sign of damage to the cerebellum or its input structures. Ataxia refers generally to uncoordinated or disordered movement, which, although most often associated with gait (“gait ataxia”), can also be used to describe uncoordinated arm or leg movements (“limb ataxia”). Ataxia is exacerbated by moving multiple joints together and by moving quickly. Because ataxia is a nonspecific term, it is important in both clinical and research settings to use more precise terminology to describe the specific aspects of motor performance that are impaired. Around the beginning of the 20th century, Joseph Babinski and Gordon Holmes were two of the earliest investigators to describe many of these specific features we now discuss here.^{75–77}

Dysmetria

Dysmetria specifically refers to an impaired ability to properly scale movement distance. Movements are described as either hypermetric or hypometric, referring to overshooting or undershooting of targets, respectively. Many patients with cerebellar lesions will show both forms of dysmetria even during successive movements (Fig. 19.4).^{51,52} Dysmetria can be seen in both proximal and distal joints and occurs during both single-joint and multijoint movements, although multijoint movements worsen dysmetria (Fig. 19.5).^{52,78–80} Slow movements tend to produce hypometria, whereas fast movements almost always bring about hypermetria.⁵¹ For this reason, it has been speculated that hypometria represents more of a voluntary compensation for hypermetria than a primary impairment from cerebellar damage. Sometimes large end point errors can be reduced to some degree with visual feedback, but even the corrective movements themselves are still abnormal.⁸¹

One proposed mechanism for dysmetria is an impaired ability to predict and account for the dynamics of the limbs. In particular, patients with cerebellar lesions have been demonstrated to have a specific deficit in the ability to account for interaction torques,^{51,52} the rotational forces that act on a limb segment when another linked limb segment is in motion.⁵⁵ When the cerebellum is intact, the central nervous system is able to predict the effects of interaction torques and appropriately counter or exploit them so as to produce a smooth, straight, and accurate reach in a feedforward manner. When the cerebellum is damaged, an incorrect or absent accounting for interaction torques leads to an incorrect feedforward motor plan and subsequently,

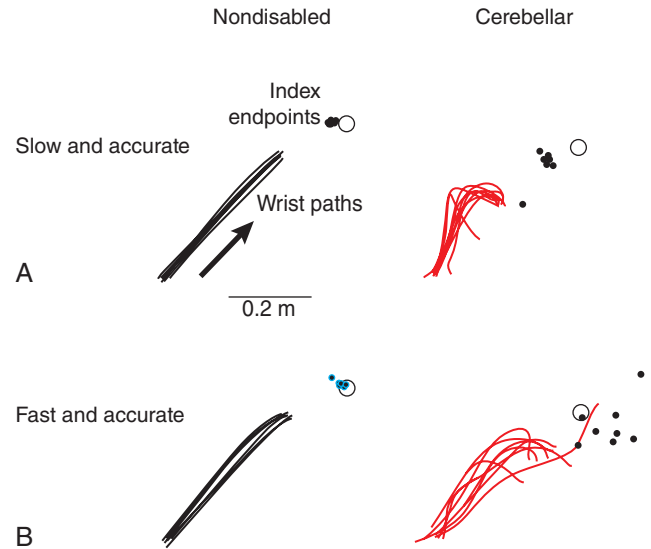

Fig. 19.4 Trajectories of the wrist (solid lines) and final end point positions of the tip of the index finger (filled circles) during (A) slow and accurate and (B) fast and accurate reaches from a typical nondisabled individual (left) and a subject with cerebellar damage (right). The subject with cerebellar damage shows dysmetria and an abnormally curved wrist path. Note also the tendency for hypometria during slow movements and hypermetria during fast movements (the same control and cerebellar subjects are shown in [A] and [B]). Several reaches are overlaid for each subject. Arrow indicates the reach direction. Large open circles indicate the target locations. (Adapted with permission from the American Physiological Society, Bastian AJ, Martin TA, Keating JG, Thach WT. Cerebellar ataxia: abnormal control of interaction torques across multiple joints. *J Neurophysiol.* 1996;76[1]:492–509.)

an uncoordinated, overly curved and hypermetric or hypometric reach that requires feedback corrections to reach the target location.

Dyssynergia

Originally, Babinski⁷⁵ coined the term “asynergia” as a deficit in the coordination of movements of one body region or in one limb segment with movements of another. Currently, dyssynergia is used to describe impairment of multijoint movements, wherein movements of specific segments are not properly sequenced or of the proper range or direction, resulting in uncoordinated multijoint movement. As indicated earlier, it is nearly universally true that patients with significant cerebellar damage show greater impairments during multijoint movements than single-joint movements. However, it is not fully understood whether the reason for that is because the deficits of single-joint movements are compounded during a multijoint movement or because the cerebellum plays a special and unique role in multijoint control. Dyssynergia appears to be related to dysmetria and therefore is probably also related to a deficit in predicting limb dynamics.⁵¹

Dysdiadochokinesia

Dysdiadochokinesia specifically refers to a deficit in the coordination between agonist-antagonist muscle pairs elicited during voluntary rapid alternating movements.⁸² It is typically tested during performance of simple, fast alternating movements such as forearm supination-pronation or hand or foot tapping. Characteristic deficits are excessive slowness along with inconsistency in the rate and range of the alternating movements, which worsen as the movement continues.⁷⁶ Dysdiadochokinesia appears to be caused by poor regulation of the timing of cessation of agonist and the initiation of antagonist muscle activity,^{83,84}

Fig. 19.5 Final end point positions of the tip of the index finger (numbers, each value corresponds to a different subject) during **(A)** single-joint (elbow only) and **(B)** multijoint (combined shoulder and elbow) reaches from nondisabled (*left*) and cerebellar (*right*) subjects. Cerebellar dysmetria (both hypometria and hypermetria) is greatly exacerbated during the multijoint reaching condition. Multiple reaches are shown for all subjects. *Arrow* indicates the reach direction. *Large open circles* indicate the target locations. (Adapted with permission from the American Physiological Society, Bastian AJ, Zackowski KM, Thach WT. Cerebellar ataxia: torque deficiency or torque mismatch between joints? *J Neurophysiol.* 2000;83[5]:3019–3030.)

which could be related to a deficit in predicting limb dynamics. Indeed, rapid reversals in movement are dynamically difficult to control.

Decomposition

Movement decomposition refers to the breaking down of a movement sequence or a multijoint movement into a series of separate movements, each simpler than the combined movement.⁷⁷ An example of this is the well-known finding that patients with cerebellar damage, when asked to reach to a target in front of and above the resting arm, will often flex the shoulder first and then, while holding the shoulder fixed, extend the elbow.⁵¹ This approach is generally slower and will produce a more curved trajectory of the finger to the target compared with nondisabled individuals who would typically perform the shoulder flexion and elbow extension at the same time to produce a nearly straight-line finger trajectory. Most likely decomposition reflects a compensatory strategy for dealing with impaired multijoint movements than it does a primary sign of cerebellar damage.^{51,85}

Lack of Check

Lack of check, sometimes also referred to as excessive “rebound,” refers to the inability to rapidly and sufficiently halt movement of a body part after a strong isometric force, previously resisting movement of the body part, is suddenly released. Individuals without cerebellar damage can very quickly halt, or “check,” this unintended movement. Individuals with cerebellar damage, on the other hand, are known to have considerable movement in the direction opposing the previous resistance, to the point that the unchecked movement risks upright

balance and/or self-injury. This phenomenon is presumed to be caused by delayed cessation of agonist and/or delayed activation of the antagonist muscles.

Cerebellar Tremor

Despite being a very common neurological sign, tremor is poorly defined and not well understood. There are several different forms of tremor, many with different etiologies, only some of which are related to cerebellar dysfunction, so it is important to distinguish among them. Tremor associated with damage to the cerebellum is typically called action tremor, reflecting the fact that it is absent at rest and elicited during muscle activation, and importantly, distinguishing it from the resting tremor associated with Parkinson disease. Action tremor can be classified as postural or kinetic tremor.⁸⁶ Postural tremor occurs in muscles maintaining a static position against gravity (e.g., holding arms out in front of the body or standing in place), whereas kinetic tremor occurs in muscles producing an active voluntary movement. Therefore the movement oscillations are most visible in the same plane as the voluntary movement. Kinetic tremor typically occurs at relatively low frequencies (~2 to 5 Hz) and can be observed during simple non-target-directed movements such as forearm pronation and supination or foot tapping, or during targeted movements such as pointing during the finger-to-nose test. Intention tremor is a specific form of kinetic tremor, which occurs during the terminal portions of visually guided movements toward a target. It may actually represent the multiple corrective movements, driven by visual feedback, to reach the target. As such, intention tremor can be tested by repeating the test movement with eyes closed: if the tremor decreases substantially or disappears, it is intention tremor.⁸¹

Classic cerebellar tremor is kinetic tremor with intention tremor at movement termination. In general, cerebellar tremor is thought to be due to an insufficient ability to anticipate the effects of movement and excessive reliance on sensory feedback loops.⁸⁷ Cerebellar tremor is highly influenced by sensory conditions and has a strong mechanical component: it is significantly reduced during isometric conditions or when vision is removed. It also can be decreased in some patients by adding an inertial load to the limb,⁸⁸ although that strategy may also act to increase dysmetria.⁸⁹ There may also be a significant central component to cerebellar tremor, possibly related to influences from the thalamus or the inferior olive.^{83,90}

Hypotonia

Hypotonia in patients with cerebellar damage was first described by Holmes.⁷⁷ It appears to arise from decreased excitatory drive to vestibulospinal and reticulospinal pathways, two major output pathways from the cerebellar vermis and flocculonodular lobe. The hypotonia usually presents as a decrease in the extensor tone necessary for holding the body upright against gravity. In cats, lesions to either the vestibular or fastigial nuclei cause this sort of postural hypotonia.^{53,91–93} More recent observations in humans indicate that hypotonia is typically most problematic in cases of severe cerebellar hypoplasias affecting the vermis, such as Joubert syndrome,⁹⁴ or in adults during the acute stage of cerebellar injury only. In cases of adult-onset acute injury, hypotonia usually resolves naturally over time and patients recover normal passive muscle tone and normal reflexes quickly. Thus hypotonia typically presents minimal to no problems for physical function.⁸³

Imbalance

Another cardinal sign of cerebellar damage is postural instability in both static and dynamic conditions. Specifically, patients with cerebellar damage usually show increased postural sway, either excessive or diminished postural responses to perturbations, poor control of equilibrium during

voluntary movements of the head, arms, or legs, and sometimes abnormal oscillations of the trunk, called titubation.

Classically, cerebellar imbalance during stance was considered to be of a similar magnitude whether or not the eyes are open (i.e., little improvement noted with visual feedback^{75,77} and a negative Romberg test). However, more recently, investigators using posturography measures have been able to distinguish several different categories of cerebellar imbalance during quiet standing, some of which do show improvement with visual stabilization.^{95,96} For instance, patients with cerebellar damage relatively isolated to the anterior lobe typically show increased postural sway that is of a high velocity and low amplitude and occurs mainly in the anterior-posterior dimension. These individuals also tend to have associated postural tremor and increased intersegmental movements of the head, trunk, and legs and tend to improve when allowed visual information. On the other hand, localized damage to the vestibulocerebellum more often leads to increased postural sway that consists of low-frequency and high-amplitude movements without a preferred direction and without increased intersegmental movements. These individuals typically show no improvement with visual information. Patients with damage limited to the lateral cerebellum tend to have only slight or even no postural instability at all.⁹⁵⁻⁹⁷

Human cerebellar damage is also associated with hypermetric postural responses to surface displacements or during step initiation (i.e., dynamic instability).^{98,99} Specifically, patients tend to produce larger than normal surface-reactive torque responses and exaggerated and prolonged muscle activity, thereby overshooting the initial posture during the return phase of the recovery from a perturbation (Fig. 19.6).

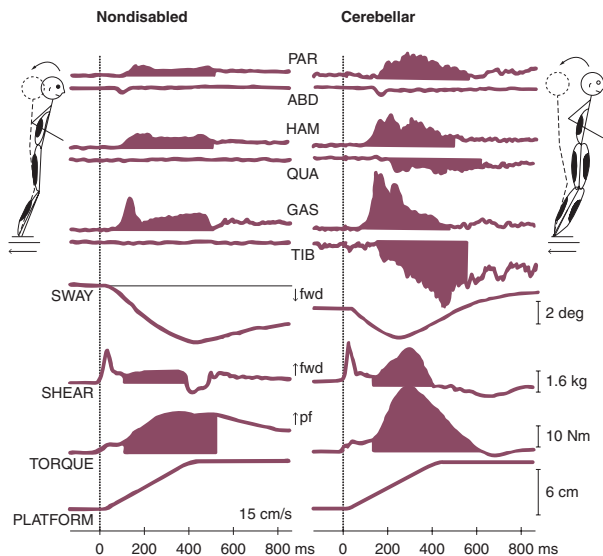

Fig. 19.6 Postural responses from nondisabled control and cerebellar groups (average of 10 trials from 10 subjects in each group) after backward platform translations of 15 cm/s for 6 cm. Traces show (top to bottom) electromyographic recordings from various postural muscle groups, postural sway, shear force, surface torque, and platform displacement. Filled areas indicate the first 400 ms of activation in the electromyographic traces and the active surface reactive forces in the shear force and torque traces. Postural responses of the cerebellar subjects are increased, with excessive and prolonged muscle activity (note especially the abnormal activation of flexor muscle groups), larger sway and greater torque production. *ABD*, Rectus abdominus; *fwd*, forward; *GAS*, gastrocnemius; *HAM*, biceps femoris; *PAR*, paraspinals; *pf*, plantarflexion; *QUA*, rectus femoris; *TIB*, tibialis anterior. (Adapted with permission from the American Physiological Society, Horak FB, Diener HC. Cerebellar control of postural scaling and central set in stance. *J Neurophysiol.* 1994;72[2]:479-493.)

Gait Ataxia

Probably the greatest complaint and the most obvious sign of cerebellar damage is gait ataxia. This abnormal pattern of walking is often described as a “drunken” gait because patients often stagger and lose balance as if intoxicated. Early work of Holmes showed that patients with cerebellar lesions have severe difficulty maintaining balance during walking, which often leads to falls, typically directed backward and toward the side of the lesion. Holmes reported specifically that walking is slowed, with steps that are short, irregular in timing, and unequal in length. The legs sometimes lift overly high during swing phase by excessive flexion at the hip and knee and then lower abruptly and with uncontrolled force. The trajectory of walking often veers erratically, and patients have difficulty with stops or turns, especially if performed quickly.⁷⁷

Those initial reports have been confirmed numerous times; patients with cerebellar damage walk without the consistency in timing, length, and direction of steps typical of healthy adults.^{79,100} In some cases, gait appears wide based. There is also increased variability in both the timing and movement excursion at the hip, knee, and ankle joints, and irregularities in the resulting path of the foot during swing. Coordination between joints of one leg and between legs (intra-limb and interlimb coordination) is also abnormal.^{79,100,101} As an example, the timing of peak flexion at one joint with respect to other joints’ positions may be altered or inconsistent. Often decomposition is also observed between hip and knee, knee and ankle, and/or hip and ankle joints.^{101,102}

A critical component of locomotor control is the requirement for stability and dynamic balance while maintaining forward propulsion. Thus imbalance, described earlier, is also a major contributor to many features of gait ataxia. In fact, it has been shown that patients with cerebellar damage and significant balance deficits also typically demonstrate nearly all the classic features of gait ataxia (i.e., reduced stride lengths, increased stride widths, reduced joint excursions, abnormal swing foot trajectories, increased variability in foot placement, and joint-joint decomposition). In contrast, patients with cerebellar damage and significant leg coordination deficits but minimal or no balance deficits typically have very few walking abnormalities (Fig. 19.7).^{103,104} Therefore during typical conditions of level walking, balance deficits contribute much more strongly to cerebellar gait ataxia than do leg coordination deficits.

Oculomotor Deficits

Eye movements are often dramatically impaired following cerebellar damage. Saccades are often slowed and dysmetric (can be hypermetric or hypometric).¹⁰⁵ Smooth pursuit may be “choppy,” referred to as saccadic pursuit, wherein the smooth tracking of a target is degraded into a series of shorter saccadic movements following behind the target.¹⁰⁶ The ability to cancel, or suppress, the VOR may be impaired or absent.¹⁰⁷ Finally, abnormal nystagmus may also be present. The nystagmus may occur during central gaze, or there may also be alternating nystagmus or rebound nystagmus. The most common form of nystagmus in cerebellar dysfunction is gaze-evoked nystagmus, indicating nystagmus elicited toward the end ranges of lateral and/or vertical gaze.^{108,109}

Patients with significant oculomotor abnormalities may be referred to vestibular specialists, but these deficits should never be ignored. Impaired eye movements may have a significant negative impact on physical function. For example, impaired saccades can prevent a patient from reading and saccadic pursuit can exacerbate already poor visually guided limb movements.¹¹⁰ Perhaps most devastating, deficits related to impaired oculomotor control and vestibular reflexes often worsen dynamic balance and walking abilities.

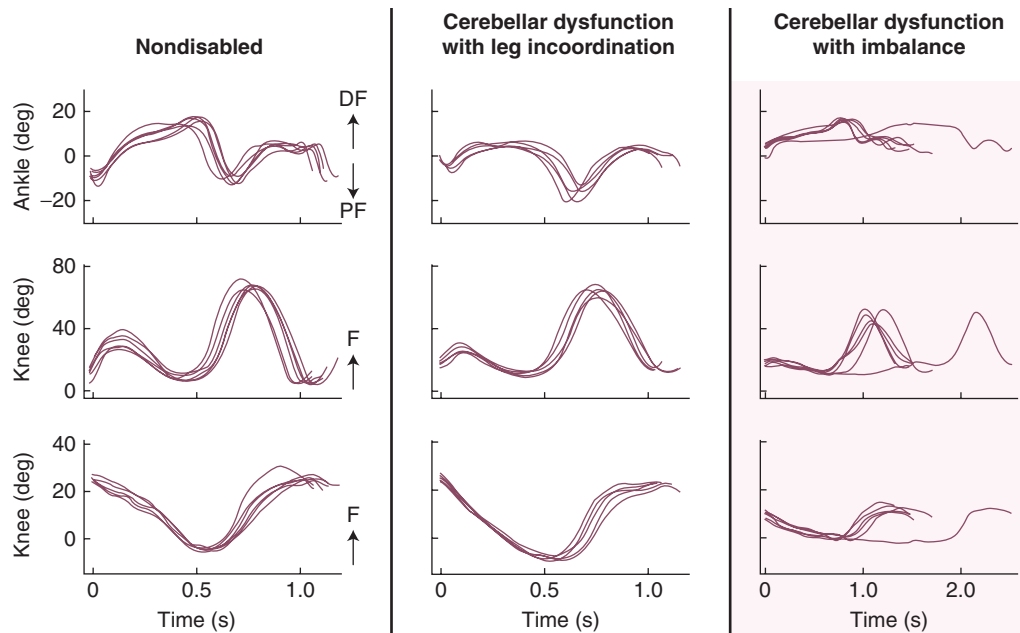

Fig. 19.7 Angular excursions at the ankle (*top row*), knee (*middle*), and hip (*bottom*) during fast walking from a typical nondisabled individual (*left column*), a subject with cerebellar dysfunction who has significant leg incoordination but minimal imbalance (*middle*), and a subject with cerebellar dysfunction who has significant imbalance but minimal leg incoordination (*right*). Several strides (from initial contact to next initial contact) are overlaid for each subject. The patient with cerebellar imbalance (*shaded*) shows significant evidence of gait ataxia, including reduced joint excursions, excessive stride-to-stride variability, and abnormal timing between joints, whereas the patient with cerebellar leg incoordination and no imbalance shows no evidence of gait ataxia. DF, Dorsiflexion; F, flexion; PF, plantarflexion. (Adapted with permission from the American Physiological Society, Morton SM, Bastian AJ. Relative contributions of balance and voluntary leg-coordination deficits to cerebellar gait ataxia. *J Neurophysiol.* 2003;89[4]:1844–1856.)

Speech Impairments

Speech production may also be impaired when the cerebellum is damaged. Classically, the speech deficit associated with cerebellar damage is referred to as “scanning speech,” although it may be more generally referred to as ataxic dysarthria. Similar to limb control deficits, the primary impairment of speech may be related to the planning and prediction of movements rather than in the execution of speech components directly.¹¹¹ Also like limb movements, most speech impairments appear to be attributable to alterations in timing and coordination.¹¹² The most consistent characteristics of ataxic dysarthria are impaired articulation (the correct pronouncement of speech sounds) and impaired prosody (the pattern of stress and intonation of certain syllables or words). Other common findings include slowed speech and either a lack of or excessive loudness variability.¹¹¹ Traditionally, speech impairments are treated primarily by speech and language pathologists.

Impaired Motor Learning

A critical problem associated with cerebellar damage is impaired motor learning. In humans, the cerebellum has been linked to learning of a wide variety of motor behaviors, including recovering balance after a perturbation,^{98,99} learning new walking patterns,^{66,102,113} adjusting voluntary limb movements,^{67,114,115} and eye movements.^{116,117} The type of learning that appears most reliant on the cerebellum is associative and procedural. Specifically, the cerebellum appears to be essential for learning to adjust a motor behavior through repeated practice of, or exposure to, the behavior and using error information from one trial to improve performance on subsequent trials. It is important to note

that cerebellum-dependent motor learning is driven by errors directly occurring during the movement, rather than other types of feedback, such as knowledge of results after the fact (e.g., hit or miss). Studies have suggested that the type of error that drives cerebellum-dependent learning is not the target error (i.e., “How far am I from the desired target?”) but instead what has been referred to as a sensory prediction error (i.e., “How far am I from where I predicted I would be?”).^{115,118}

In the laboratory setting, cerebellar learning is most easily tested via motor adaptation, a form of motor learning that requires a modification of an already well-learned motor behavior for new environmental or physical demands (in contrast to learning of a completely novel skill). Adaptation is an error-driven learning process that is acquired on a time-scale of minutes or hours, as opposed to days or weeks.^{119,120} It is an active process—movement adaptation takes trial-and-error practice of the task, where errors during one trial change movement on the subsequent trial. Storage of the adapted movement is shown by the presence of aftereffects when the new demand is removed. Specifically, aftereffects are movement errors in the opposite direction to the original errors during adaptation, and they provide strong evidence that the central nervous system adjusts the predictive control for body movements with practice.^{64,121} Thus when the new demand is removed, a process of active “unlearning” or de-adaptation must occur to return the movement to its original form. An example of a locomotor adaptation is shown in Fig. 19.8. In this case a walking adaptation is induced by having subjects walk on a splitbelt treadmill, where one belt is moving at twice the speed of the other, forcing the two legs to walk at different speeds. Nondisabled subjects are able to

rapidly restore appropriate step length symmetry after only a few minutes walking on the splitbelt treadmill. They also appear to store the newly learned set of (predictive) motor commands, demonstrated by large negative aftereffects (step length asymmetry in the reverse direction compared to early adaptation) when the treadmill belts are initially returned to a regular (nonsplit) pattern. In contrast, individuals with cerebellar damage typically show a slower rate of adaptation, a reduced magnitude of adaptation or no adaptation at all, and small or no aftereffects. See Fig. 19.8. All of these findings indicate a significant deficiency in the capability for motor adaptation in individuals with cerebellar damage. As indicated earlier, adaptation deficits have been demonstrated in this patient population with numerous behavioral tasks.^{58,66,67,98,99,113-116}

Cerebellum-dependent adaptation is not the only form of motor learning, but it is an important one for rehabilitation several reasons. First, adaptation is a highly automatic process to rapidly adjust movements for new, predictable demands (e.g., adjusting the walking pattern for snow or sand; adjusting eye movements for glasses). Individuals with impaired cerebellar adaptive learning must use other means to handle new task demands, such as conscious control strategies. This is obviously inefficient and difficult, because it means that the individuals must think much more about their movements and cannot tolerate

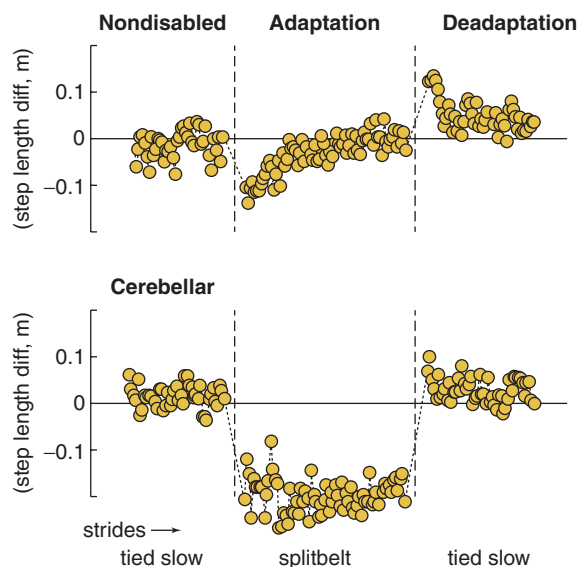

Fig. 19.8 Motor adaptation of step length symmetry during walking on a splitbelt treadmill from a nondisabled individual (*top*) and a subject with cerebellar damage (*bottom*). Each data point represents the difference in step lengths between the legs (fast minus slow) for all strides during regular walking (belts tied, speed 0.5 m/s), splitbelt adaptation walking (fast belt speed 1.0 m/s; slow belt speed 0.5 m/s), and de-adaptation walking (belts tied, speed 0.5 m/s). Perfect symmetry between legs is represented by a step length difference value of 0. Note that the splitbelt condition perturbs step length symmetry initially in both subjects. The control subject rapidly adapts the walking pattern to restore appropriate step length symmetry while walking on split belts. The cerebellar subject does not adapt. Once the belts are returned to the tied condition, the control subject shows a large negative aftereffect (i.e., perturbed step length symmetry in the reverse direction), which again is rapidly adjusted to restore near-symmetric step lengths. The cerebellar subject shows a reduced aftereffect and no de-adaptation. (Adapted with permission from the Society for Neuroscience, Morton SM, Bastian AJ. Cerebellar contributions to locomotor adaptations during splitbelt treadmill walking. *J Neurosci.* 2006;26[36]:9107–9116.)

distractions. Adaptation is also important because when it is repeated many times, it can result in more permanent storage of a movement pattern that can be called on immediately (i.e., no error-based period of adaptation required). A clear example of this is the use of new bifocal glasses. Initially, there is an adaptation process to adjust eye movements when switching between the top and bottom lenses because eye movements have to be bigger for magnified objects. Yet with repeated adaptation, the brain eventually stores two calibrations, one for viewing through the top lens and one for the bottom, that can be switched between immediately. Thus adaptation can lead to a more permanent, learned calibration that is used in specific situations. Patients with cerebellar damage will not be able to make these short-term adaptations normally, and theoretically one would expect that they will not be able to form the more permanent calibrations with repeated adaptation.

Other forms of motor learning may not depend on the cerebellum and thus may be particularly useful for rehabilitation for patients with cerebellar lesions, although this has never been formally tested. One example is use-dependent motor learning, in which a person strengthens a movement pattern with repeated practice of that same pattern.¹²² It is not clear what mechanisms subserve this form of learning, although a Hebbian-like process in the cerebral cortex seems likely (i.e., repeated use strengthens the synapses in the brain that are engaged). Another form of motor learning is reward or reinforcement learning. This may involve basal ganglia circuits to strengthen movements that are rewarded.¹²³ It has not been experimentally tested whether individuals with cerebellar damage can undergo either of these other forms of learning. Yet if they can, these learning mechanisms might provide important compensatory strategies for the loss of error-dependent adaptations.

Nonmotor Impairments

Within the past 25 years, researchers have exposed a possible role of the cerebellum in a number of nonmotor, cognitive behaviors. Much of the early evidence for cerebellar involvement in nonmotor tasks came from functional imaging studies showing increased activation within the cerebellum during performance of certain tasks with a predominant cognitive component, such as language processing.^{124,125} Speculation has since risen that the cerebellum may be involved in not only language, but also working memory,¹²⁶ learning nonmotor associations between objects,¹²⁷ and higher-order executive functions.¹²⁸ Loss of control over emotional behaviors¹²⁹ and certain neurodevelopmental and neuropsychiatric disorders have also been said to be linked to cerebellar damage.^{130,131} However, interpretation of some investigations of the relationship between the cerebellum and cognition is limited in that it is sometimes difficult to separate the cognitive and motor components of a task, particularly in imaging studies in which subjects are instructed to perform some motor task to indicate a cognitive choice.^{132,133} Nevertheless, anatomical studies have shown clearly that the cerebellum has connections to brain areas considered relatively purely cognitive in function, suggesting that a cognitive role for the cerebellum is likely.¹³⁴

Clinical Signs by Functional Division

Because of the organizational structure of the cerebellum into functional longitudinal divisions, discrete areas are associated with specific signs and symptoms. Thus depending on the location and volume of cerebellar damage, patients may have just a few or nearly all of the clinical manifestations described earlier. Patients with damage to the flocculonodular lobe or midline zone typically present with some (although usually transient) loss of postural tone, impaired upright posture and balance, gait ataxia, and oculomotor deficits.^{2,54} On the other

hand, damage to the intermediate zone often results in action tremor, dysdiadochokinesia, and dysmetria of the limbs.^{2,53} Finally, damage to the lateral zone commonly produces dyssynergia, dysmetria, and difficulty planning complex limb movements, especially those that are visually guided.^{2,53}

Often, however, multiple longitudinal zones are affected at the same time. For instance, the arteries supplying the cerebellum each span more than one longitudinal zone, such that a stroke involving a single cerebellar artery would be likely to cause signs and symptoms associated with more than one zone (see [Table 19.3](#)). Degenerative disorders affecting the cerebellum also are typically pancerebellar, affecting large regions of the cerebellum. Hence these patients will also typically present with a wide variety of signs and symptoms. A careful and thorough clinical examination is therefore a requirement before a diagnosis for physical therapy can be made in patients with cerebellar damage.

MEDICAL MANAGEMENT OF CEREBELLAR DAMAGE

The greatest limitation in caring for patients with cerebellar damage is the lack of any curative treatment for most forms of cerebellar damage. Pharmacological agents have been used but with limited success. Often, patients with ataxia and degenerative forms of cerebellar damage may be prescribed vitamin E, coenzyme Q10, and/or its synthetic analogs, but the effectiveness of these drugs in minimizing symptoms or otherwise slowing or halting the disease is largely unsubstantiated.^{135,136} Other drugs that may be used include acetazolamide, amantadine, 4-aminopyridine, and buspirone chlorhydrate,^{8,137–139} but these also have questionable effectiveness. Studies of the effectiveness of medications for cerebellar ataxia have been significantly limited by inadequate sample sizes, inappropriate outcome measures, and/or limited follow-up. Given the unsatisfactory results from pharmacological interventions thus far, most patients with cerebellar ataxias must rely primarily or solely on physical rehabilitation approaches to restore or reduce the symptoms of their disease.

PHYSICAL THERAPY MANAGEMENT OF CEREBELLAR MOVEMENT DYSFUNCTION

As is the case with all brain lesions, there is nearly always some level of natural, or spontaneous, recovery following damage to the cerebellum. The extent of recovery depends on complex interactions among numerous factors including the source of damage, the severity, location and volume of damage, the presence or absence of damage to other brain regions, the presence or absence of other coexisting medical conditions, age, and other factors. Several studies have indicated that motor recovery from a first ever ischemic cerebellar stroke is generally excellent, with minimal to no residual deficits in up to 83% of individuals.^{140–142} On the other hand, individuals with a degenerative cerebellar disorders tend to have progressively worsening clinical signs and symptoms.¹⁴³ One study has shown that people with damage to the deep nuclei do not recover as well as those with damage to only the cerebellar cortex and white matter.² Another consideration is the degree to which other brain regions are lesioned. Individuals with cerebellar stroke or tumor may also have damage of the brain stem. Patients with multiple sclerosis or head injury often also suffer from cerebral and spinal cord lesions. Moreover, the majority of the SCAs affect other neural structures well beyond the cerebellum; these are often the corticospinal tract, cerebral cortex, basal ganglia, and sometimes even the peripheral nervous system. In general, the presence of multiple lesion locations is associated with a poorer outcome, possibly because circuits that could otherwise serve in a compensatory role are also damaged.¹⁴⁴

Physical Therapy Examination

A majority of the components of the physical therapy examination for patients with cerebellar dysfunction are the same as would be performed with any patient with a health condition that is primarily neurological in origin. Therefore we will discuss only the features that are unique or of critical importance for the patient with cerebellar pathology. As follows, we highlight just a few of these specific tests. [Box 19.1](#) contains a

BOX 19.1 Typical Clinical Tests and Measures for the Physical Therapy Evaluation of Cerebellar Dysfunction

Tests of Impairments of Body Function or Structure

1. Muscle Tone

Hypotonia Particularly involving postural extensor muscle groups. Can be assessed in supine, sitting, and/or standing.

2. Voluntary Movement Coordination

*For all coordination tests, the following guidelines are recommended, when appropriate: (1) compare both sides; (2) repeat each test multiple times; (3) compare slow/preferred versus “fast as possible” speeds; (4) compare with and without vision.

Finger-to-nose test: Vary the target (fingertip) locations. Require near-full excursion at elbow and shoulder. Observe for speed, dysmetria, dyssynergia, decomposition, kinetic tremor, intention tremor.

Alternating forearm supination-pronation: Do not allow bracing of upper arm against trunk. Require elbow flexion/extension along with forearm movements. Observe for speed, dysmetria, dyssynergia, decomposition, dysdiadochokinesia, kinetic tremor.

Hand/finger tapping: Observe for speed, dysmetria, dysdiadochokinesia, kinetic tremor.

Drawing/handwriting sample: Compare with and without permitting bracing upper arm against trunk and/or forearm on writing surface. Observe for speed, dysmetria, dyssynergia, decomposition, kinetic tremor, intention tremor.

Holding static position, arms outstretched: Patient holds position for several seconds. Observe for drift, postural tremor.

Resisted movements: Compare different levels of resistance. Observe for lack of check (rebound). Note: ensure patient safety; rebound may be extreme and destabilizing and/or injurious in severe cases.

Heel-to-knee test: Patient performs in supine to test full excursion at hip and prevent bracing of thigh/hip on support surface. Patient performs (a) repeated taps on knee with heel and (b) sliding the heel up and down the lower leg. Observe for speed, dysmetria, dyssynergia, decomposition, dysdiadochokinesia, kinetic tremor, intention tremor.

Foot/toe tapping: Observe for speed, dysmetria, dysdiadochokinesia, kinetic tremor.

3. Static and Dynamic Balance

Sitting balance: Patient performs with and without upper and lower extremity support or with and without trunk support (as skill level permits), with

BOX 19.1 Typical Clinical Tests and Measures for the Physical Therapy Evaluation of Cerebellar Dysfunction—cont'd

and without vision. Test for recovery from self-imposed (upper extremity or head movements) or external (gentle pushes by examiner) perturbations. Observe resting preferred posture, tremor, sway, ability, and effort required to maintain position, recovery from perturbations or other loss of balance. Inquire about vertigo, nausea, and subjective perception of stability.

Standing balance: Patient performs with and without upper and lower extremity support, with and without vision and with feet apart and together. Test for recovery from self-imposed (upper extremity or head movements) or external (gentle pushes by examiner) perturbations. Advanced testing: assume and maintain tandem stance and single limb stance. Observe resting preferred posture, natural foot position (base of support), tremor, sway, ability, and effort required to maintain position, recovery from perturbations or other loss of balance. Inquire about vertigo, nausea, and subjective perception of stability.

4. Oculomotor Performance

Smooth pursuit: In sitting, keeping the head still, patient follows pen tip or similar small object with eyes. Test in all movement planes and directions and through full range of motion. Vary speed. Observe for saccadic (choppy) pursuit.

Saccades: In sitting, keeping the head still and when verbally prompted, patient alternately fixes gaze on one of two pen tips, or a pen tip and the examiner's nose, or other small objects. Vary the target (pen tip) locations, testing a variety of end point locations, directions of movement, and

distances traveled, including full range of motion. Observe for dysmetria, particularly on initial trials.

Gaze-evoked nystagmus: In sitting, keeping the head still, patient maintains gaze in a variety of locations, including near end-ranges of lateral gaze. Observe for nystagmus, particularly toward the direction of gaze.

Tests of Activity Limitations

1. Bed Mobility
2. Transfers
3. Gait As skill level permits, patient performs natural, narrow, and tandem gait. Compare preferred versus fastest speed and with and without vision. Test for recovery from self-imposed (upper extremity or head movements) or external (gentle pushes by examiner) perturbations. Observe on inclines and declines, uneven surfaces, negotiating introduced obstacles. Observe walking while distracted (dual-task situation) and while holding an object with the upper extremity (e.g., hold a Styrofoam cup half-filled with water). Test turns and control through narrow areas such as a doorway. Observe for speed, irregularity of step height and distance, veering walking path, losses of balance, seeking out of upper extremity support surfaces/guarding, leg dys-synergia, decomposition (e.g., stiff knees, reduced ankle motion), widened base of support, truncal sway, kinetic tremor. Note distance tolerated and need for assistive devices and/or orthotics.
4. Stair Climbing
5. Activities of Daily Living (dressing, grooming, feeding, bathing, etc.)

more complete list. One important note is that many of the tests for cerebellar movement dysfunction are sensitive but not specific to cerebellar pathologies. That is, although they often will detect abnormalities in a patient with cerebellar damage, they are frequently also observed to be abnormal in patients with other, noncerebellar disorders of a neuromuscular origin. Therefore they should not be used to rule out cerebellar pathologies.

Tests of Impairments of Body Functions or Structures

At the level of body functions or structures, physical therapists use a variety of simple tests and measures to detect the typical movement impairments associated with cerebellar dysfunction. Many of these fall into the category of limb movement coordination tests. Particularly useful in the upper extremity are the finger-to-nose test, the alternating forearm supination-pronation test, and the hand or finger tapping test. The heel-to-knee test and foot or toe tapping test provide similar information for the lower extremity. Each of these tests informs the physical therapist about the presence and severity of many components of ataxia, including dysmetria, dyssynergia, dysdiadochokinesia, decomposition, and kinetic and/or intention tremor. Some general rules should be applied when performing and interpreting the findings from these clinical tests. First, it is usually important to perform the test on and compare both sides. Each test should be repeated multiple times with the same limb, as subsequent movements may look strikingly different (e.g., hypometric on some trials, hypermetric on others). Comparing slow or preferred to “fast as possible” speeds allows the clinician to determine the severity of the ataxia (generally worst with fastest movements) and how well the patient is able to compensate when allowed full use of feedback mechanisms (the degree to which the movement is improved when performed slowly). It is also generally useful to compare the same movements with and without vision, to determine whether or not visual feedback improves movement quality.

A final caution about the tests of voluntary movement coordination is that the examiner must carefully dissociate limb incoordination from deficits of balance and/or vision. For example, if the patient has difficulty maintaining quiet unsupported sitting, he or she will most likely demonstrate several abnormal movement patterns that resemble classic limb ataxia when asked to move the limbs (e.g., dyssynergia, dysmetria) if tested in this unsupported position. In this situation the examiner cannot distinguish whether the deficits observed are caused by a true incoordination of voluntary limb movements or because of an inability to maintain the trunk in a stable and upright position that provides the limb a stable base from which to generate movement. Thus to test coordination, the examiner must give the patient the necessary head and trunk support required for the limb movement task (e.g., test sitting in a high back chair with manual support at shoulders or perform in supine) if the patient is unable to provide this support by himself or herself. Similar confusion may arise if the patient has significant visual or other oculomotor impairments such as diplopia. Here, the patient would be likely to show apparent dysmetria during visually targeted movements, but it could not be determined whether it is caused by real limb ataxia or a visual impairment preventing the patient from accurately identifying the target location in space. This is not to say that it would not be beneficial to test limb coordination in positions or situations that also challenge balance and/or vision; only that during the initial examination of the patient, one should be careful to ensure an accurate determination of the source of the movement impairment.

Another major component of almost all physical therapy examinations of patients with cerebellar dysfunction is the posture and balance examination. Posture and balance should always be observed in both static and dynamic conditions and in both sitting and standing, as the patient's capabilities allow. The examination is performed the same as for patients with other neurological disorders, so it is not described in

detail here (see [Box 19.1](#) for suggested components to emphasize with patients with cerebellar dysfunction). Important considerations specific for patients with cerebellar dysfunction include careful monitoring for symptoms of nausea or vertigo (common in acute cerebellar stroke, may resolve quickly), observation for postural tremor or titubation and observation of the recovery from perturbations, and the presence of lack of check.

As described previously, because other areas of the nervous system are also frequently damaged along with the cerebellum, it may be appropriate to test for impairments of body functions or structures associated with pathology involving extracerebellar regions of the neuromuscular system. Most commonly, this involves testing of muscle strength, somatosensation (including cutaneous sensation and proprioception), reflexes, passive muscle tone, and observation for signs of other motor abnormalities such as spasticity, dystonia, abnormal synergies, chorea, bradykinesia, or resting tremor.

It is also important to examine the patient's initial level of endurance (fatigability), both in the cardiovascular and muscular systems. For the cardiovascular system, this can be approximated by recording the response to sustained aerobic exercise on one or more measurement scales (e.g., perceived exertion, heart rate, blood pressure, respiratory rate). For the muscular system, this can be approximated by recording the maximal number of repetitions of a specific set of muscle contractions or limb movements that can be tolerated before force output or range of motion is reduced. These types of measures can provide a gross gauge of the overall level of cardiovascular and musculoskeletal fitness of the patient. Because cerebellar dysfunction often leads to movements being much more effortful and often exaggerated, it is extremely important that the patient with cerebellar dysfunction obtain adequate endurance for safe participation in daily activities.

Tests of Activity Limitations

Tests of activity limitations should typically proceed similarly to the standard neurological examination. The observation of gait should be given particular attention because gait ataxia is considered one of the most sensitive signs of cerebellar damage and the inability to walk safely is a major participation limitation for most patients with motor disorders.¹⁴⁵ [Box 19.1](#) provides suggested components of the gait analysis for patients with cerebellar dysfunction. In addition, it may be necessary to evaluate the activity limitations related to speech, visual, and/or oculomotor deficits common to cerebellar dysfunction. With careful interviewing, the patient may relay information about limitations in conversation and communication, reading, etc., that should be addressed in rehabilitation. The physical therapist may be the first health care professional to note these types of activity limitations and should refer the patient to the proper professional for additional services.

Documentation of the body function or structure impairments and activity limitations should include not only the level of assistance, if any, required to perform the skill (or for the voluntary limb coordination tests, the degree of impairment; e.g., none, mild, moderate, or severe), but also a detailed description of the deficits observed during the attempted movement (i.e., the movement quality). Specifically, the severity and frequency of the specific features of ataxia (e.g., decomposition, lack of check) should be reported when they accompany a given movement. Also useful is documentation of the time taken to perform certain tasks. For example, one might document performance of a functional reach and place task by a patient with cerebellar dysfunction in the following way: "The patient was able to perform five repetitions of a block stacking task with the right upper extremity in 9.4 seconds without significant drops or placement errors. Decomposition was observed between shoulder and elbow joints, and obvious intention

tremor was present during terminal block placement. When asked to repeat at a faster pace, the patient performed the same task in 6.0 seconds with one block dropped and two misplaced on the stack (dysmetria). Notable dyssynergia was also present."

Standardized Clinical Scales

There are two common standardized rating scales that quantify the severity of cerebellar ataxia. The more well-known is the International Cooperative Ataxia Rating Scale (ICARS).¹¹² This scale was first published in 1997 by the Ataxia Neuropharmacology Committee of the World Federation of Neurology in response to an established need for a universal scale to quantify ataxia in randomized clinical trials of pharmacological interventions for treating ataxia. The ICARS measures a patient's ability to perform 19 specific activities or movements using an ordinal scale. The activities are grouped into categories based on whether they relate to cerebellar dysfunction affecting (1) posture and gait, (2) limb movements, (3) speech, or (4) oculomotor performance. A subscore is tallied for each category, and a total score is obtained, ranging from 0 (no ataxia) to 100 (most severe ataxia). The ICARS has been found to be reliable in patients with cerebellar dysfunction and has established criterion-related and external validity.¹⁴⁶⁻¹⁴⁹ More recently, it was shown that the ICARS is sensitive to increases in ataxia severity over 1 year in persons with chronic cerebellar degeneration.¹⁴³ The Scale for the Assessment and Rating of Ataxia (SARA) is a newer tool that was devised, at least in part, out of concern over the construct validity of the ICARS subscale structure.¹⁵⁰ The SARA is similar to the ICARS, in that it quantifies performance of specific movements or activities on an ordinal scale (many of the test activities are the same or similar to those in the ICARS), but it does not categorize individual test items by body part. The SARA has fewer test items (only eight) and can therefore be administered faster in the clinical setting. The SARA has been shown to be reliable and valid for patients with SCAs.¹⁵⁰ Either the ICARS or SARA scale may be useful for longitudinal tracking of disease progression in cerebellar degeneration or for quantifying improvement of ataxia in clinical trials. The scales are detailed in [Appendices 19A and B](#).

Diagnosis, Prognosis, and Plan of Care

Patients with cerebellar dysfunction should be given a diagnosis for physical therapy that identifies the primary movement dysfunction and helps direct treatment interventions to return the patient to his or her desired level of activity and participation, if possible. Typically, determination of a diagnosis is based largely on both the results of the physical therapy examination and evaluation, as well as knowledge of the etiology of the disorder and the extent of the lesion. The prognosis for recovery likewise depends highly on the etiology and extent of the lesion. It is important to make a determination whether the impairments of body function or structure and activity limitations are expected to improve or expected not to improve or potentially to worsen over time (e.g., with disease progression). For impairments and activity limitations that are expected to improve, emphasis should be placed on recovery of those skills; for those expected not to improve or to worsen, emphasis should be placed on instruction and practice of compensatory strategies and general conditioning to minimize fatigue.

Physical Therapy Interventions for Patients With Cerebellar Dysfunction

The literature on the effectiveness of rehabilitation interventions for individuals with primary cerebellar damage is extremely limited: to date, there have been no randomized controlled clinical trials published, except for one small trial in patients with Friedreich ataxia.¹⁵¹ Of the few studies on the effects of rehabilitation interventions in this

patient population, all have been nonrandomized, noncontrolled small group^{35,103,152–154} or case study^{155–160} designs. The fact that there are so few studies available, each featuring different patient populations (e.g., post-stroke vs. postsurgical tumor resection vs. cerebellar degeneration) and different outcome measures, makes determining the most effective interventions difficult. Therefore we provide here a summary of the major themes that have arisen to date from these studies as well as some recent consensus reports.^{161–165}

Gait and Balance Interventions

Many of the intervention studies for cerebellar ataxia emphasize stability and balance, especially during gait.^{103,152–154,157,159} This likely is a reflection of the tight link between gait and balance¹⁰⁴ and the fact that gait ataxia is one of the most common and debilitating signs of cerebellar damage.¹⁰² Common interventions include combinations of exercises targeting gaze, static stance, dynamic stance, gait, and complex gait activities.^{103,157} Some examples of exercises in each of these categories are detailed in [Box 19.2](#). Dynamic balance activities in sitting, kneeling, and quadruped have also been advocated.¹⁰³ Other interventions specific to the patient's individual impairments of body structure

or function should be implemented as necessary (e.g., stretching of short or tight ankle plantar flexors, exercises for the VOR).^{103,157} Locomotor training over ground and on treadmills, and with and without body weight support, has also been used with some success in single case examples.^{155,166} However, it is not clear how imbalance is corrected in the body weight support environment. With all gait and balance activities, it is critical that the exercise be sufficiently and increasingly challenging, so as to facilitate plasticity in the nervous system.^{167,168} In mouse models, it has been suggested that trial-and-error practice is a requirement for regaining full motor recovery through cerebellar remyelination¹⁶⁹ and that motor training can ameliorate some symptoms of ataxia.¹⁷⁰

Aerobic Exercise and Resistance Training

Integration of aerobic exercise and resistance training into the treatment plan is recommended for a majority of patients with cerebellar dysfunction, particularly if it is expected the patient will not regain his or her premorbid status. If full recovery is not attained, nearly all types of movements will be generally more effortful, requiring increased energy expenditure and demanding greater concentration. It is well

BOX 19.2 Common Gait and Balance Interventions for Patients With Cerebellar Dysfunction^{103,157}

1. Gaze and Eye Movements
 - a. Vestibuloocular reflex (VOR): (i) visually fixate on stationary target, slow head movements; (ii) visually fixate on target moving in opposite direction, slow head movements; (iii) VOR cancellation, visually fixate on target moving in same direction, slow head movements. Progression: increase and vary speed, perform eyes closed, add complexity to background.
 - b. Saccades: active eyes alone and combined eye and head movements between two stationary targets. Progression: increase and vary speed.
2. Static Stance
 - a. Feet together, arms across chest, eyes open and closed, with and without slow head movements. Progression: increase time with eyes closed, increase and vary speed of head movements.
 - b. Stand on foam, feet apart, arms across chest, eyes closed briefly and intermittently. Progression: narrow base of support, increase time with eyes closed.
 - c. Semitandem stance, arms across chest, eyes closed briefly and intermittently. Progression: narrow base to full tandem stance, increase time with eyes closed, perform semitandem stance on foam.
 - d. Unilateral stance, arms across chest, eyes open. Progression: perform with intermittent, then longer periods with eyes closed, perform on foam.
3. Dynamic Stance
 - a. March in place, arms across chest, eyes open and closed. Progression: increase time with eyes closed, add and incrementally increase pause time in unilateral stance, add head movements.
 - b. Standing toe taps, forward/backward/side, alternating legs, arms across chest, eyes open and closed. Progression: increase step distance, increase time with eyes closed, add head movements.
 - c. March in place on foam, arms across chest, eyes closed briefly and intermittently. Progression: increase time with eyes closed, add and incrementally increase pause time in unilateral stance.
 - d. Standing 360-degree turn, rightward/leftward, arms across chest, eyes open and closed. Progression: tighten turns, increase speed.
 - e. Standing reaches, feet apart and together, eyes open and closed. Progression: increase time with eyes closed, increase reach distance, vary directions, narrow base of support to feet together position.
- f. Standing bends and squats, feet apart and together, eyes open and closed. Progression: increase time with eyes closed, narrow base of support to feet together, reach to touch the floor.
- g. Transitions: standing to supine on floor and back up. Progression: transition in and out of all possible positions, with and without upper extremity support, eyes open and closed, including kneel, half-kneel, quadruped, side sit, squat, etc.
4. Gait
 - a. Narrow base of support, arms at sides. Progression: increase gait speed.
 - b. Normal base of support, arms at sides with periodic head movements. Progression: narrow base of support, increase and vary speed and frequency of head movements.
 - c. Gait with wide turns, arms at sides. Progression: sharpen angle of the turn, increase gait speed, add head movements.
 - d. Gait with eyes closed, arms at sides. Progression: add turns, add head movements, increase gait speed.
 - e. Gait with perturbations: (i) self-imposed, e.g., large arm movements; (ii) external, e.g., pushes by therapist. Progression: increase speed and amplitude of perturbations, make external perturbations unexpected.
5. Complex Gait
 - a. Sideways and backward gait, eyes open, arms at sides. Progression: narrow base of support, add head movements, perform with eyes closed, increase gait speed.
 - b. Incline and decline gait, eyes open, arms at sides. Progression: narrow base of support, add head movements.
 - c. Gait on foam, padded or other compliant surface, eyes open, arms at sides. Progression: narrow base of support, add turns, add head movements, perform with eyes closed.
 - d. Semitandem gait, eyes open, arms at sides. Progression: narrow base to tandem gait, add head movements, perform with eyes closed.
 - e. Gait while negotiating obstacles, eyes open, arms at sides, avoid/step onto/step over. Progression: increase obstacle number and size, vary obstacle placement.
 - f. Gait while distracted, eyes open, arms at sides. Add cognitive task as a distracter; start with responding to simple yes/no questions, progress to difficult tasks (e.g., counting, performing two- or three-digit addition/subtraction).

known that repetitive fatiguing activity worsens postural control^{171,172} and therefore may contribute to trips, falls, or other injuries.¹⁷³ Because imbalance is such a common outcome for patients with cerebellar dysfunction, incorporating both aerobic exercise to improve cardiovascular endurance and submaximal resistive exercise to improve muscle fatigue-resistance appears appropriate. Aerobic exercise activities might include walking, dance, recumbent or stationary cycling, rowing, arm ergometry, swimming and aquatic exercise, and many other possibilities.

Consider More Intensive, Longer Duration Interventions

Because the cerebellum is thought to be a primary site of motor learning and individuals with cerebellar damage often have motor learning deficits, it is reasonable to consider whether these patients are capable of benefitting from any intervention that relies on trial-and-error motor practice.¹⁰³ It has been suggested that rehabilitation for patients with significant cerebellar dysfunction may take longer (more trials, more sessions) and might not ever be complete. The question remains unanswered thus far. Of course, cerebellum-dependent motor adaptation is only one of many motor learning mechanisms, so it is possible that other processes can be engaged during rehabilitation. In support of this idea, it now appears that at least partial “relearning” of more normal movement patterns is possible with selected cerebellar patient populations.^{103,174} Notably, reported gains in the literature were made under conditions of very frequent (10 hours/week) or very long (6 months) training schedules. This could be a necessity for patients with health conditions in which motor learning is impaired. Much more research is needed to determine the full range of improvements possible, the minimal dosage of intervention required, and whether the benefits can be retained over the long-term in this difficult patient population. Fig. 19.9 shows improvements in SARA scores and self-selected walking speeds in a group of individuals with significant progressive ataxia, in response to an intensive rehabilitation program targeting balance and dynamic intersegmental control.

Compensatory Strategies

Compensation is a common component of the plan of care for patients with cerebellar dysfunction. Many patients begin using compensations unconsciously, whereas others need to be taught these strategies and when to use them. If the patient is not expected to recover “normal” movement patterns, compensation can enable the individual to regain a certain prior level of activity or societal participation despite an abnormal movement pattern. Instruction in compensation can also be valuable in situations when full recovery is expected, but the patient would benefit from the use of compensatory strategies for the short term, such as for safety purposes. One compensatory strategy that works well for patients with cerebellar dysfunction is the instruction to simply slow down movements. Recall that slower movements are less dyssynergic and less hypermetric.⁵¹ Voluntarily reducing the number of segments moving at the same time (i.e., decomposition) also helps to reduce dyssynergia and dysmetria.^{51,85} In some cases, reminding patients to use visual cues can also be helpful (e.g., use vertical markings of a doorway to maintain upright stability), although for certain types of cerebellar damage this is not effective.^{95,96} For gait, deliberately widening stance can be helpful, both for maintaining balance and for preventing tripping over a foot. The use of assistive devices for gait should be considered on a case-by-case basis. For some patients, facilitating upper extremity support and increasing the base of support improves balance during gait. However, for others, the level of skill required to coordinate controlling the device with the movements of arms and legs is too difficult, and using the device actually worsens the instability. In general, patients with significant imbalance and limb ataxia but who are

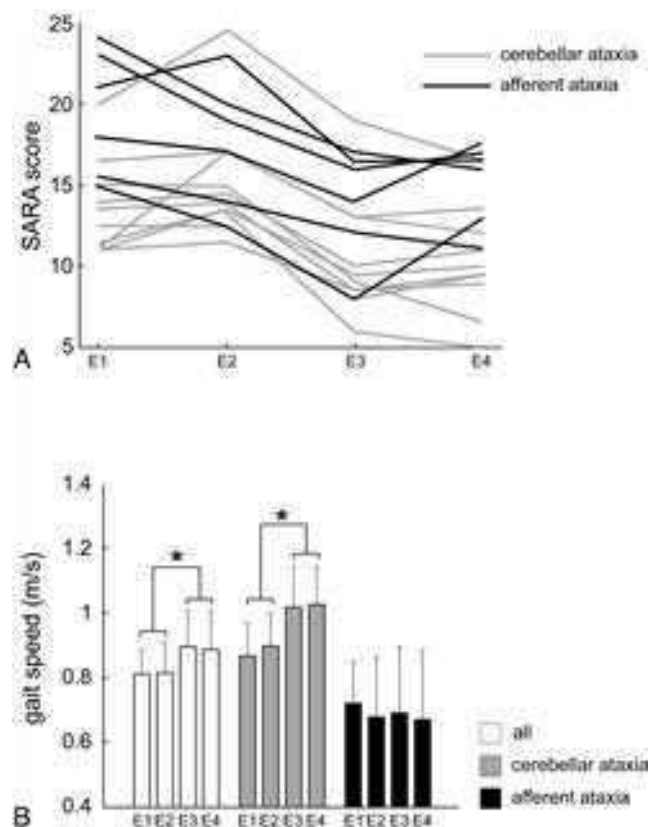

Fig. 19.9 Changes in (A) SARA score and (B) self-selected walking speed for a group of 16 individuals with progressive ataxia who completed 4 weeks of intensive (1 h/day \times 3 days/week supervised training plus 1 h/day \times 7 days/week independent home exercise) rehabilitation emphasizing balance. Measures were recorded at four time periods (E1 to E4), corresponding to 8 weeks preintervention (E1), immediately postintervention (E3), and 8 weeks postintervention (E4). Subjects were categorized as having either a predominant cerebellar ataxia (e.g., SCA 2, SCA 6, idiopathic cerebellar ataxia) or another autosomal dominant cerebellar ataxia) or a predominant afferent ataxia (e.g., Friedreich ataxia or other significant somatosensory neuropathy). The group overall showed significant improvements in both measures (reduced SARA scores and increased walking speeds) after the 4 weeks of exercise and retained these improvements over a further 8 weeks. When broken down by ataxia category, subjects with a predominant cerebellar ataxia, but not the subjects with a predominant sensory ataxia, showed a significant improvement in walking speed. SARA, Scale for the Assessment and Rating of Ataxia. (Adapted with permission from the American Academy of Neurology, Ilg W, Synofzik M, Brötz D, Burkard S, Giese MA, Schöls L. Intensive coordinative training improves motor performance in degenerative cerebellar disease. *Neurology*. 2009;73[22]:1823–1830.)

ambulatory will often not be safe with any type of cane and instead require a wheeled walker and/or the physical assistance of a caretaker to walk. A final strategy is to remove or minimize distractions during effortful activities. Distraction (e.g., dividing attention between a motor and a cognitive task) can worsen ataxia.¹⁷⁵

The Controversy of Weighting

Rehabilitation textbooks have traditionally supported the use of weights for adults and particularly children with cerebellar dysfunction and ataxia. Either the trunk may be weighted by having the patient wear a vest or pack that is weighted, increasing the load on the body axially,¹⁷⁶ or the limbs may be weighted individually^{177,178} with simple wrist or

ankle weights. Presumably this trend was based on the common finding, first noted by Holmes,⁷⁶ that patients with cerebellar dysfunction appear improved (move more smoothly and with reduced tremor) if they are asked to hold a heavy weight in the hand while moving the arm. Currently, it is known that cerebellar tremor is at least in part mechanical in nature, such that anything that adds inertia to the moving segment would reduce the amplitude of the tremor.⁸⁸ This most likely explains the improvement that has been reported. However, this apparent benefit would certainly not continue once the weight is removed, and a reduction in tremor does not indicate a normalization of any other parameters of movement. In fact, weighting of the extremities would seem a questionable choice, given the known difficulty of patients with cerebellar dysfunction to predict and account for limb dynamics or to account for interaction torques.^{51,52} Addition of weights, particularly to the distal segments, would seem to only make this task more difficult. Evidence for this has been demonstrated in a study of patients with cerebellar ataxia in which it was shown that weighting the extremities worsens the amount of hypermetria during a simple wrist movement task.⁸⁹ Furthermore, more recent work showed that weighting the extremities especially exacerbates reaching errors during multijoint movements.¹⁷⁹

One unintended consequence of weighting is that it tends to slow movements down. As described earlier, slower movements are less hypermetric and less dyssynergic than preferred-speed or fast movements. In early studies of weighting, speed was not monitored or controlled for, so a simple reduction in movement speed could account for the immediate apparent improvement described in some reports.^{177,178} Therefore weighting may indeed provide a benefit to some patients with ataxia, but it is most likely an indirect one, related more so to decreased movement speed. Accordingly, the significant potential for negative consequences of weighting (i.e., worsened hypermetria, increased interaction torques, and the annoyance and physical awkwardness of weights, etc.) makes this intervention option seem inferior when compared with the simpler strategy of instructing the patient in voluntarily moving more slowly.¹⁸⁰ It is important to note that the analysis here relates specifically to ataxia of a cerebellar origin. The topic of axial or limb weighting for people with other forms of ataxia (e.g., sensory ataxia) is beyond the scope of this chapter and should be considered to be a different approach because the mechanism of movement incoordination is entirely different.

SUMMARY

The cerebellum is highly unique, in terms of its anatomy, physiology, and the movement-related consequences individuals suffer if it becomes damaged. Ataxia, or movement incoordination, is the major sign of cerebellar damage and can affect limb movements, eye movements, speech, balancing, and walking. Depending on which cerebellar functional longitudinal zone(s) is/are lesioned, one or more of these specific categories of movements will be impaired. Although the precise mechanisms are not yet fully understood, it is widely acknowledged that the cerebellum is integral for (a) coordination of movements, particularly fast, multijoint movements and (b) adapting movements to changes in body conditions or the environment and learning new movement patterns based on trial-and-error practice

(motor learning). Unfortunately, evidence for the effectiveness of rehabilitation interventions for individuals with primary cerebellar damage is extremely limited and incomplete. One critical factor in the evaluative process is the determination whether the body function or structure impairments and activity limitations are expected to improve or expected not to improve or even worsen in the case of progressive diseases. If expected to improve, emphasis should be placed on trial-and-error practice of increasingly challenging motor activities. Balance and gait skills may be highlighted. On the other hand, if recovery is not expected, instruction and practice of compensatory strategies and general conditioning may be effective in at least partially restoring prior participation levels.

International Cooperative Ataxia Rating Scale

I. POSTURE AND GAIT DISTURBANCES

1. Walking capacities (Observe walking 10 m, near a wall, including half-turn.)

0 = Normal

1 = Almost normal naturally but unable to walk with feet in tandem position

2 = Walking without support but clearly abnormal and irregular

3 = Walking without support but with considerable staggering; difficulties in half turn

4 = Walking with autonomous support not possible; uses the episodic support of the wall

5 = Walking only possible with one stick

6 = Walking only possible with two special sticks or with a stroller

7 = Walking only with accompanying person

8 = Walking impossible, even with accompanying person (wheelchair)

Score: _____

2. Gait speed (Observe only if subject scores <4 on preceding test; otherwise automatically score this test as "4.")

0 = Normal

1 = Slightly reduced

2 = Markedly reduced

3 = Extremely slow

4 = Walking with autonomous support no longer possible

Score: _____

3. Standing capacities, eyes open (Ask subject to stand on one foot; if impossible, ask to stand with feet in tandem; if impossible, ask to stand with feet together. For the natural position, ask subject to find a comfortable standing position.)

0 = Normal; able to stand on one foot >10 s

1 = Able to stand with feet together but no longer able to stand on one foot >10 s

2 = Able to stand with feet together but no longer able to stand with feet in tandem position

3 = No longer able to stand with feet together but able to stand in natural position without support, with no or moderate sway

4 = Standing in natural position without support, with considerable sway and considerable corrections

5 = Unable to stand in natural position without strong support of one arm

6 = Unable to stand at all, even with strong support of two arms

Score: _____

4. Spread of feet in natural position without support, eyes open (Ask subject to find a comfortable position, then measure the distance between medial malleoli.)

0 = Normal (<10 cm)

1 = Slightly enlarged (>10 cm)

2 = Clearly enlarged (25–35 cm)

3 = Severely enlarged (>35 cm)

4 = Standing in natural position impossible

Score: _____

5. Body sway with feet together, eyes open

0 = Normal

1 = Slight oscillations

2 = Moderate oscillations (<10 cm at the level of head)

3 = Severe oscillations (>10 cm at the level of head), threatening the upright position

4 = Immediate falling

Score: _____

6. Body sway with feet together, eyes closed

0 = Normal

1 = Slight oscillations

2 = Moderate oscillations (<10 cm at the level of head)

3 = Severe oscillations (>10 cm at the level of head), threatening the upright position

4 = Immediate falling

Score: _____

7. Quality of sitting position (on flat, hard surface, thighs together, arms folded)

0 = Normal

1 = With slight oscillations of the trunk

2 = With moderate oscillations of the trunk and legs

3 = With severe disequilibrium

4 = Impossible

Score: _____

POSTURE AND GAIT SUBSCORE: _____ / 34

II. KINETIC FUNCTIONS

8. Knee-tibia test: decomposition of movement and intention tremor (Subject is in supine with head tilted to allow visual control. Ask subject to raise one leg in the air (to a height of ~40 cm) and place heel on opposite knee and then slide the heel down the anterior tibial surface of the resting leg toward the ankle. On reaching the ankle joint, the leg is again raised, and the action repeated. Repeat for at least three trials on each side.)

0 = Normal

1 = Heel lowering in continuous axis, but movement is decomposed in several phases (without real jerks) or abnormally slow

2 = Heel lowering jerkily in the axis

3 = Heel lowering jerkily with lateral movements

4 = Heel lowering jerkily with extremely strong lateral movements or test impossible

Score right: _____ Score left: _____

9. Action tremor in the heel-to-knee test (Same test as preceding one; visual control required. Observe action tremor of the heel when asked to hold the heel on the knee for a few seconds before sliding down the leg.)

0 = No trouble

1 = Tremor stopping immediately when the heel reaches the knee

2 = Tremor stopping in <10 s after reaching the knee

3 = Tremor continuing >10 s after reaching the knee

- 4 = Uninterrupted tremor or test impossible
Score right: _____ Score left: _____
- 10. Finger-to-nose test: decomposition and dysmetria** (Subject sitting; visual control required. Start trials with hands resting on knees. Repeat for at least three trials on each side.)
0 = No trouble
1 = Oscillating movement without decomposition of the movement
2 = Segmented movement in 2 phases and/or moderate dysmetria in reaching nose
3 = Segmented movement in >2 phases and/or considerable dysmetria in reaching nose
4 = Dysmetria preventing the patient from reaching nose
Score right: _____ Score left: _____
- 11. Finger-to-nose test: kinetic tremor of the finger** (Same test as preceding one. Observe movement tremor occurring during the ballistic phase of the movement.)
0 = No trouble
1 = Simple swerve of the movement
2 = Mild tremor, estimated amplitude <10 cm
3 = Moderate tremor, estimated amplitude 10–40 cm
4 = Severe tremor, estimated amplitude >40 cm
Score right: _____ Score left: _____
- 12. Finger-finger test: action tremor and/or instability** (Subject sitting; under visual control. Ask subject to flex and abduct shoulders and then flex elbows so as to have both index fingers pointing at each other at midline. Subject is to maintain index finger positions for ~10 s, at distance of ~1 cm apart (not touching) and hands at the level of the thorax.)
0 = Normal
1 = Mild instability
2 = Moderate oscillations of finger, estimated amplitude <10 cm
3 = Considerable oscillations of finger, estimated amplitude 10–40 cm
4 = Jerky movements, amplitude >40 cm
Score right: _____ Score left: _____
- 13. Pronation-supination alternating movements** (Subject sitting. Ask subject to raise the forearm vertically and alternate supinating and pronating the forearm on the lap, combining elbow flexion and extension with forearm supination and pronation.)
0 = Normal
1 = Slightly irregular and slowed
2 = Clearly irregular and slowed, but without sway of the elbow
3 = Extremely irregular and slowed movement, with sway of the elbow
4 = Movement completely disorganized or impossible
Score right: _____ Score left: _____
- 14. Drawing of the Archimedes' spiral on a predrawn pattern** (Subject sitting at a table with a sheet of paper fixed in place. Ask subject to trace the spiral with a pen; no timing requirements.)
0 = Normal
1 = Impairment and decomposition, the line quitting the pattern slightly but without hypermetric swerve
2 = Line completely out of the pattern with recrossings and/or hypermetric swerves
3 = Major disturbance due to hypermetria and decomposition

- 4 = Drawing completely disorganized or impossible
Score: _____
LIMB KINETICS SUBSCORE: _____ / 52

III. SPEECH DISORDERS

- 15. Dysarthria: fluency of speech** (Ask subject to repeat a standard sentence several times; e.g., "A mischievous spectacle is Czechoslovakia.")
0 = Normal
1 = Mild modification of fluency
2 = Moderate modification of fluency
3 = Considerably slow and dysarthric speech
4 = No speech
Score: _____
- 16. Dysarthria: clarity of speech**
0 = Normal
1 = Suggestion of slurring
2 = Definite slurring, most words understandable
3 = Severe slurring, speech not understandable
4 = No speech
Score: _____
DYSARTHRIA SUBSCORE: _____ /8

IV. OCULOMOTOR DISORDERS

- 17. Gaze-evoked nystagmus** (Ask subject to look laterally at examiner's finger. Observe for nystagmus, mainly horizontal, but could be oblique, rotary or vertical.)
0 = Normal
1 = Transient
2 = Persistent but moderate
3 = Persistent and severe
Score: _____
- 18. Abnormalities of ocular pursuit** (Ask subject to follow the slow lateral movement of the examiner's finger.)
0 = Normal
1 = Slightly saccadic
2 = Clearly saccadic
Score: _____
- 19. Dysmetria of the saccade** (Examiner's two fingers are placed, one in each temporal visual field of the subject whose eyes are in the primary position. Ask subject to shift eyes to look laterally at the finger, first on the right and then on the left. Average overshoot or undershoot of the two sides is then estimated.)
0 = Absent
1 = Bilateral clear overshoot or undershoot of the saccade
Score: _____
OCULOMOTOR SUBSCORE: _____ /6
TOTAL ATAXIA SCORE (sum of four subscores): _____ /100

The ataxia neuropharmacology committee of the world federation of neurology. *J Neurol Sci.* 1997;145(2):205–211.

Scale for Assessment and Rating of Ataxia

1. Gait

Subject (a) walks at a safe distance parallel to a wall including a half-turn (turn around to face the opposite direction of gait) and (b) walks in tandem (heels to toes) without support.

- 0 Normal, no difficulties in walking, turning, or walking tandem (up to one misstep allowed)
- 1 Slight difficulties but only visible when walking 10 consecutive steps in tandem
- 2 Clearly abnormal, tandem walking >10 steps not possible
- 3 Considerable staggering, difficulties in half-turn, but walks without support
- 4 Marked staggering, intermittent support of the wall required
- 5 Severe staggering, permanent support of one stick or light support by one arm required
- 6 Walking >10 m only with strong support (two special sticks or stroller or accompanying person)
- 7 Walking <10 m only with strong support (two special sticks or stroller or accompanying person)
- 8 Unable to walk, even supported

Score: _____

2. Stance

Subject stands (a) in natural position, (b) with feet together in parallel (big toes touching each other) and (c) in tandem (both feet on one line, no space between heel and toe). Subject does not wear shoes, eyes are open. For each condition, three trials are allowed. Best trial is rated.

- 0 Normal, able to stand in tandem for >10 s
- 1 Able to stand with feet together without sway, but not in tandem for >10 s
- 2 Able to stand with feet together for >10 s but only with sway
- 3 Able to stand for >10 s without support in natural position but not with feet together
- 4 Able to stand for >10 s in natural position only with intermittent support
- 5 Able to stand >10 s in natural position only with constant support of one arm
- 6 Unable to stand for >10 s even with constant support of one arm

Score: _____

3. Sitting

Subject sits on an examination bed without support of feet, eyes open and arms outstretched to the front.

- 0 Normal, no difficulties sitting >10 s
- 1 Slight difficulties, intermittent sway
- 2 Constant sway but able to sit >10 s without support
- 3 Able to sit for >10 s only with intermittent support
- 4 Unable to sit for >10 s without continuous support

Score: _____

4. Speech disturbance

Speech is assessed during normal conversation.

- 0 Normal
- 1 Suggestion of speech disturbance
- 2 Impaired speech but easy to understand
- 3 Occasional words difficult to understand
- 4 Many words difficult to understand
- 5 Only single words understandable
- 6 Speech unintelligible/anarthria

Score: _____

5. Finger chase

Subject seated comfortably, feet and trunk supported if needed. Examiner sits in front of subject and performs five consecutive sudden and fast pointing movements in unpredictable directions in a frontal plane, at approximately 50% of subject's reach distance. Movements are approximately 30 cm in distance and occur approximately 1 reach every 2 s. Ask subject to follow the movements, pointing with his index finger, as fast and precisely as possible. Average performance of last 3 movements is rated. Rate separately for each side.

- 0 No dysmetria
- 1 Dysmetria, under/overshooting target <5 cm
- 2 Dysmetria, under/overshooting target <15 cm
- 3 Dysmetria, under/overshooting target >15 cm
- 4 Unable to perform 5 pointing movements

Score right: _____ Score left: _____ Mean score (R+L/2): _____

6. Nose-finger test

Subject seated comfortably, feet and trunk supported if needed. Ask subject to point repeatedly with his index finger from his nose to examiner's finger, which is in front at approximately 90% of subject's reach distance. Movements are performed at moderate speed. Average performance of movements is rated according to the amplitude of the kinetic tremor. Rate separately for each side.

- 0 No tremor
- 1 Tremor with an amplitude <2 cm
- 2 Tremor with an amplitude <5 cm
- 3 Tremor with an amplitude >5 cm
- 4 Unable to perform 5 pointing movements

Score right: _____ Score left: _____ Mean score (R+L/2): _____

7. Fast alternating hand movements

Subject seated comfortably, feet and trunk supported if needed. Ask subject to perform 10 cycles of repetitive alternation of pronation and supination of the forearm on his thigh as fast and as precise as possible. Demonstrate the movement at a speed of approximately 10 cycles in 7 s. Record times for movement execution. Rate separately for each side.

- 0 Normal, no irregularities, performs in <10 s
- 1 Slightly irregular but performs in <10 s

- 2 Clearly irregular, single movements difficult to distinguish or relevant interruptions but performs in <10 s
- 3 Very irregular, single movements difficult to distinguish or relevant interruptions, performs in >10 s
- 4 Unable to complete 10 cycles

Score right: _____ Score left: _____ Mean score (R+L/2): _____

8. Heel-shin slide

Subject in supine on examination bed without sight of his legs. Ask subject to lift one leg, point with the heel to the opposite knee, slide down along the shin to the ankle, and lay the leg back on the examination bed. The task is performed 3 times. The slide component of the movement should be performed within 1 s. If subject

slides down without contact to shin in all three trials, rate as "4." Rate separately for each side.

- 0 Normal
- 1 Slightly abnormal, contact to shin maintained
- 2 Clearly abnormal, goes off shin ≤ 3 times during 3 cycles
- 3 Severely abnormal, goes off shin ≥ 4 times during 3 cycles
- 4 Unable to perform the task

Score right: _____ Score left: _____ Mean score (R+L/2): _____

TOTAL ATAXIA SCORE (sum of eight test scores): _____ /40

Abstract: The cerebellum is a highly unique brain structure, easily recognizable by its location on the dorsal brain stem and the distinct, dense folia, or foldings, of its cortex. For centuries, the cerebellum has been the object of intense investigation by scientists, in particular because of the extreme uniformity in the arrangement of neurons in the cerebellar cortex and the presence of very large Purkinje cells with an extensive fanlike dendritic arbor. The human cerebellum contains more neurons than any other brain region, suggesting that whatever its role in behavior, it requires the integration of vast amounts of information and may perform rather complex computations. Researchers agree that the cerebellum plays a critical role in coordinating and adapting movements, although how it does so is still not fully understood. It is currently also clear that the cerebellum is connected to nonmotor regions of the brain, such as the prefrontal cortex, and therefore likely plays a role in cognitive and other nonmotor functions. Yet the most striking and debilitating effect of damage to the cerebellum

is ataxia, which comes from the Greek and translates literally to mean “without order.” We will focus on this hallmark feature of cerebellar damage, which is incoordination of movements without overt muscle weakness. In this chapter, we will review critical features of cerebellar anatomy and physiology that help to reveal its role in motor control and we will describe the major movement deficits associated with damage to the human cerebellum. We will highlight the most valuable and unique components of the physical therapy examination for patients with suspected cerebellar dysfunction and review the evidence for and against specific rehabilitation interventions targeting recovery of body functions, activities, and participation. Emphasis is placed on the importance of the physical therapist’s judgment in determining whether a recovery or a compensation approach should be implemented.

Keywords: cerebellum, ataxia, incoordination, rehabilitation, motor learning

Balance Dysfunction*

Leslie K. Allison

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe both central and peripheral sensory and motor components of the postural control system.
2. List common postural control system impairments and sensorimotor skill deficits found in patients with neurological problems.
3. List commonly used balance tests, and distinguish which are appropriate for patients at low, moderate, and high levels of function.
4. Differentiate how test results are used to identify postural control system impairments, sensorimotor skill deficits, and activity limitations that limit participation.
5. Analyze the interaction of individual, task, and environmental factors that affect balance.
6. Describe how to plan and progress balance exercise programs to increase the use of or compensation with available sensory inputs.
7. Describe how to plan and progress balance exercise programs to facilitate anticipatory postural adjustments to prevent balance loss and provoke automatic postural responses to regain balance after unexpected disturbances.
8. Describe how to plan and progress balance exercise programs to increase the control of center of gravity in upright postures and during gait.
9. Describe how to increase the difficulty level of balance exercise programs in order to promote the automaticity of postural control during functional activities.

systems model or systems approach

volitional postural movements

No matter what the neurological diagnosis, a disease or injury that affects the nervous system is likely to compromise one or more of the postural control mechanisms. For example, patients with such diverse diagnoses as stroke, head trauma, spinal cord injury (SCI), peripheral neuropathy, multiple sclerosis (MS), Parkinson disease (PD), cerebellar dysfunction, cerebral palsy, and Guillain-Barré syndrome all experience postural control problems. One common thread among these different medical diagnoses is the presence of postural control system impairments and, consequently, sensorimotor skill deficits, including imbalance and abnormal gait. Patients with different medical diagnoses may have the same postural control system impairments, and patients with the same medical diagnosis may have different postural control system impairments, depending on which portions of the postural control system are involved.¹ To optimally understand and manage balance problems, assessment of each postural control system component and the interactive nature of the

components is important. The traditional medical “diagnostic” model does not provide this information and is not the most beneficial model for planning balance rehabilitation interventions. The medical diagnosis is relevant: knowing whether deficits are permanent or temporary, and whether recovery or progressive decline is expected is critical. This medical prognostic information will assist physical and occupational therapists in goal setting and intervention planning.

The International Classification of Functioning, Disability and Health (ICF) model described in Chapter 1 and illustrated in Fig. 20.1 describes the interactions of body function and structure problems (impairments) and activity limitations as seen in patients with neurological disease or injury, and how these functional activity limitations restrict an individual’s ability to participate in life situations, thus decreasing quality of life. As valuable and beneficial as this model has been to rehabilitation practice, researchers and clinicians alike have had difficulty reaching a consensus about whether “imbalance” should be categorized as an impairment of body structure/function, or as an activity limitation. This is perhaps because the ICF categorizes some aspects of balance as impairments of body structure/function (e.g.,

*Videos for this chapter are available at studentconsult.com.

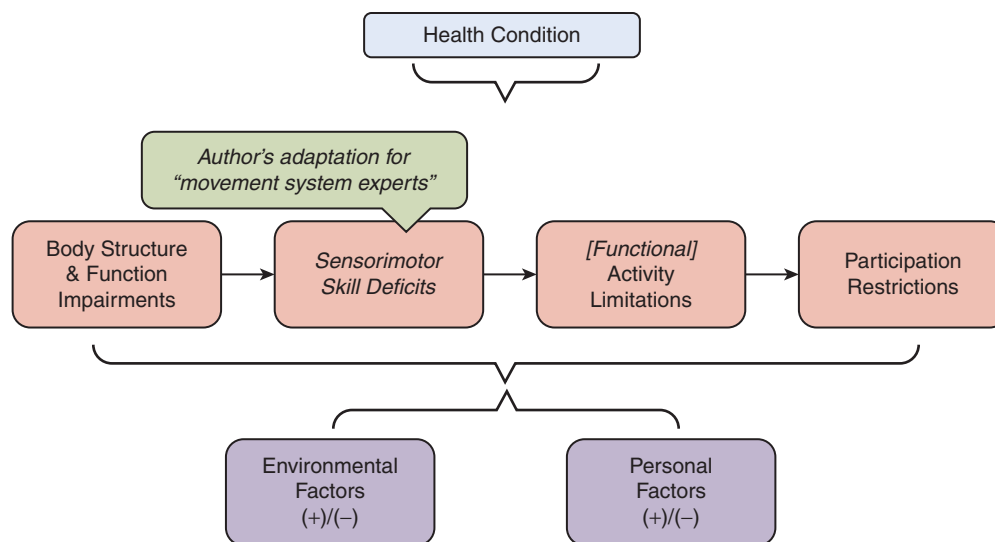

Fig. 20.1 An adapted version of the International Classification of Functioning, Disability and Health Model as conceptualized by the author. The addition of a Sensorimotor Skills category may increase the usefulness and applicability of the model for clinicians responsible for assessment and improvement of human movement.

“Involuntary movement reaction functions” including functions of postural reactions, righting reactions, body adjustment reactions, balance reactions, supporting reactions, defensive reactions) and other aspects of balance as activity limitations (e.g., “Mobility: Changing and maintaining body position,” including sitting, maintaining a sitting position, standing, maintaining a standing position, shifting the body’s center of gravity [COG]).² To align with the ICF model, in previous editions of this chapter, I have used the term “balance impairments” despite concerns that neither category offered an optimal fit. The ICF model was not developed or designed specifically for use by movement system professionals such as physical therapists (PTs), occupational therapists (OTs), or adaptive physical education teachers with expertise in normal and abnormal motor control, motor learning, and motor development. I believe it is useful to adapt the ICF model for our purposes by adding a “sensorimotor skills” category in between body “structure/function impairments” and (more functional) “activity limitations” (see Fig. 20.1). Sensorimotor skills (i.e., perceptual-motor skills) are learned, goal-directed movement abilities that require the interaction and integration of sensory inputs, perceptual processes, motor planning, and movement execution. When we consider *how* or *how well* a patient moves and are concerned with the quality of their movement or movement patterns not only their outcome, we are engaged in sensorimotor skill analysis. Balance and gait fit very well into this category.

Within this adapted ICF model, body structure/function impairments (e.g., sensory loss, leg weakness, slow reaction time) lead to sensorimotor skill deficits (e.g., imbalance, hemiplegic gait patterns, abnormal synergies in reaching), which in turn lead to real-life, functional activity limitations (e.g., requires minimum assistance for wheelchair transfers, moderate assistance for limited household ambulation with a straight cane), culminating in participation restrictions and decreased quality of life. Application of this adapted ICF model to patient-centered rehabilitation care includes the following assessment sequence: (1) identification of the patient’s participation goals, (2) hypothesis generation about and evaluation of the functional activity limitations leading to participation restriction, (3) hypothesis generation about and evaluation of the sensorimotor skills leading to functional activity limitations, and (4) hypothesis generation about and evaluation of the body structure/function impairments

leading to sensorimotor skill deficits. For example, a patient may wish to participate in a tour of historical buildings but cannot perform stair-climbing without either two handrails or assistance (activity limitation). The therapist hypothesizes that the patient’s dynamic balance is deficient and finds she cannot perform single-leg stance skills on either leg; further evaluation includes hypotheses and testing to reveal that she has weak hip extensors and abductors, and limited ankle dorsiflexion range of motion (ROM) bilaterally. Application of this adapted ICF model to the design of customized, individualized intervention programs thus requires that we **treat impairments, teach sensorimotor skills, and train functional activity abilities** if we wish to increase participation and improve quality of life. We cannot assume that doing one will automatically lead to another and should incorporate all three. For the patient described above, intervention would include treatment of impairments (e.g., closed-chain resistance exercises and ankle stretching), teaching dynamic balance skills (e.g., hands-free alternate toe touching on increasingly higher step stools, progressing to step ups/downs with dual-tasking), and training stair climbing (e.g., progressing to single or no handrail and counter-traffic).

Balance skill deficits negatively affect function, often reducing the individual’s ability to participate fully in life.³ These skill deficits often limit functional activity levels, produce abnormal compensatory motor behavior, and may require devices for support or assistance from another person. Falls can result when imbalance is severe, leading to secondary injuries. To avoid these consequences and advance the functional status of patients, therapists should understand both the demands that various environments and functional tasks place on postural control systems *and* the individual’s impairments and skill deficits that may diminish the ability of those systems to respond adequately.

BALANCE

Definitions of Balance

Balance is a complex process involving the reception and integration of sensory inputs and the planning and execution of movement to achieve a goal requiring upright posture. It is the ability to control the COG over the base of support in a given sensory environment.^{4,5} The COG is an imaginary point in space, calculated biomechanically from

measured forces and moments, where the sum total of all the forces equals zero. In a person standing quietly the COG is located just forward of the spine at approximately the S2 level. With movement of the body and its segments, the location of the COG in space constantly changes. The base of support is the body surface that experiences pressure as a result of body weight and gravity; in standing it is the feet, and in sitting it includes the thighs and buttocks. The size of the base of support will affect the difficulty level of the balancing task. A broad base of support makes the task easier; a narrow base makes it more challenging. The COG can travel farther while still remaining over the base if the base is large. The “shape” of the base of support will alter the distance that the COG can move in certain directions.

Any given base of support places a limit on the distance a body can move without either falling (as the COG exceeds the base of support) or establishing a new base of support by reaching or stepping (to relocate the base of support under the COG). This perimeter is frequently referred to as the *limit of stability* or *stability limit*.^{4,6} It is the farthest distance in any direction a person can lean (away from midline) without altering the original base of support by stepping, reaching, or falling.

Environmental Context

This biomechanical task of keeping the COG over the base of support is always accomplished within an environmental context, which is detected by the sensory systems. The sensory environment is the set of conditions that exist, or are perceived to exist, in the external world that may affect balance. Peripheral sensory receptors gather information about the environment, body position, and motion in relation to the environment, and body segment positions and motions in relation to the self. Central sensory structures process this information to perceive body orientation, position, and motion and to determine the opportunities and limitations present in the environment. This central sensory integration process also estimates where we will be in the immediate future, permitting APAs. Gravity is one environmental condition that must be dealt with to remain stable. It is a constant condition for everyone except astronauts in space. Surface and visual conditions, however, may vary significantly and may be stable or unstable. Unstable surface conditions might include the subway, a sandy beach, a gravel driveway, or an icy parking lot. Common unstable visual conditions are experienced on mass transit, in crowds, or on a boat. Rapid head movements may render even a stable visual environment unusable for postural cues, and darkness may preclude the use of vision. The more stable the environment, the lower the demand on the individual for balance control. Unstable (extrinsic) environments place greater demands on the (intrinsic) postural control systems.

Balance is also affected by an individual's intentions to achieve certain goals and the purposeful tasks that are undertaken. Volitional balance disturbances are self-initiated almost constantly, such as shifting from foot to foot, reaching for the telephone, or catching an object that is falling from a high shelf. Even reactions to involuntary balance disturbances, such as a slip or trip, are modified on the basis of the immediate task. A man carrying a bag of groceries who slips may drop the bag to reach with both hands and catch himself. If he is instead carrying his infant, he may reach with only one hand or even take the fall if by doing so he can protect the infant from harm. Often in real life we perform several tasks at once, such as carrying a laundry basket while walking or talking on a cellular phone while climbing a flight of stairs. When tasks are undertaken concurrently (dual-tasking or multi-tasking), attention must be divided between them, which may also affect balance abilities. This is especially true for individuals for whom balance skills are not automatic.

All of these variables—the location of the COG, the base of support, the limit of stability, the surface conditions, the visual environment, the intentions and task choices—are inconstant and produce changing demands on the systems that control balance. The integrity and interaction of postural control mechanisms allow a wide range of movement skills and real-life functions to be achieved without loss of balance.

HUMAN CONTROL OF BALANCE

Early studies of postural control mechanisms using selectively lesioned cats and primates focused on reflexive and reactive equilibrium responses that are relatively “hard-wired.”⁷ These valuable studies brought to light certain stereotypical motor responses to specific sensory stimuli, such as the crossed extension reflex or tonic neck reflexes. There is no doubt that these reflexive and reactive responses—for example, the vestibuloocular reflex (VOR) and protective extension reactions—are foundational to normal postural control. However, the postural control system encompasses much more than these subcortically driven components. Balance abilities are heavily influenced by higher-level neural circuitry and other systems (e.g., cognitive, musculoskeletal) as well.⁶ In addition, the nervous system is influenced by and responsive to the demands placed on it by the tasks being accomplished and the environments in which those tasks are performed.^{8–10} All of these facets are included in a systems approach to dynamic equilibrium.^{11–13} Examination and intervention methods based on this systems model have consequently evolved.^{12,14}

The Systems Approach

The systems model for dynamic equilibrium recognizes that balance is a result of interactions among the individual, the task(s) the individual is performing, and the environment in which the task(s) must be performed. These interactions are represented in Fig. 20.2. Within the individual, both sensory inputs and processing systems (left side of figure) and motor planning and execution systems (right side of figure) are critical. Both peripheral components (lower part of figure) and central components (upper part of figure) of the systems are involved in the cycle. The cycle is driven both by purposeful choices of the individual (tasks) and by demands placed on the individual by the environment. Successful function of the sensory systems allows recognition and estimation of body position and motion in relation to self and the world. The desired outcome from the motor systems is the generation of movement sufficient to maintain balance and perform the chosen, goal-directed task(s).

Peripheral Sensory Reception

The three primary peripheral sensory inputs contributing to postural control are the bilateral receptors of the somatosensory, visual, and vestibular systems.^{5,11} Somatosensory receptors located in the joints, ligaments, muscles, and skin provide information about muscle length, stretch, tension, and contraction; pain, temperature, and pressure; and joint position. The feet, ankles, knees, hips, back, neck, and eye muscles all furnish useful information for balance maintenance. Somatosensation is the dominant sense for upright postural control and is responsible for triggering automatic postural responses (APRs) in almost all cases except a primary perturbation of the head. Somatosensory loss negatively affects balance. Loss of peripheral somatosensation occurs in patients with loss or disease of or injury to the peripheral sensory receptors or afferent sensory nerves. Examples include patients with diabetic neuropathy, peripheral vascular disease, spinal cord injury, MS, or amputation.

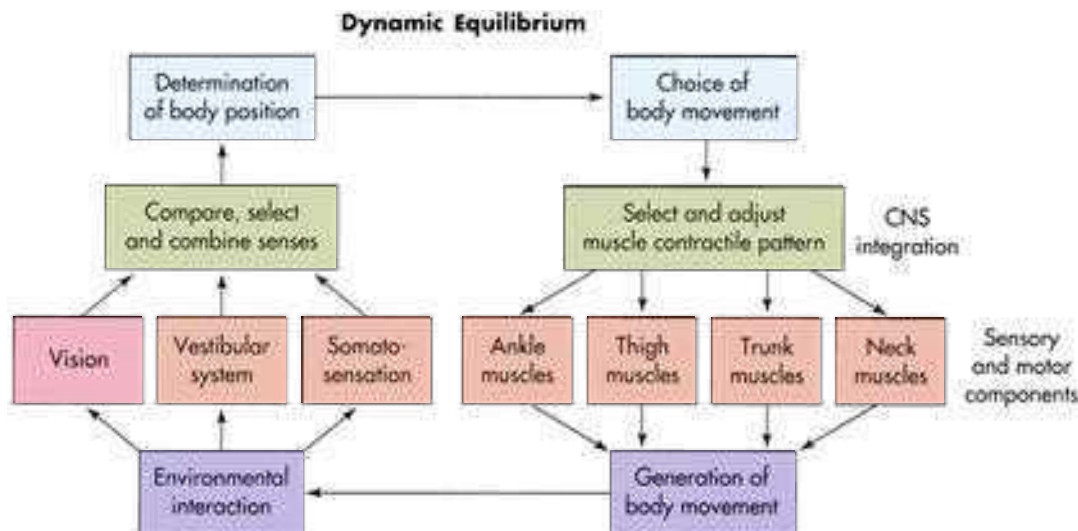

Fig. 20.2 The systems model of postural control illustrates the constant cycle that occurs simultaneously at many levels. *CNS*, Central nervous system. (Reprinted with permission from NeuroCom International, Clackamas, Ore.)

Visual receptors in the eyes support two functions. Central (foveal) vision allows environmental orientation, contributing to the perception of verticality and object motion, as well as identification of the hazards and opportunities presented by the environment.¹¹ For example, a kayaker may see rocks in a stream as a hazard to be avoided, whereas a hiker who wants to cross the stream may see the same rocks as a welcome opportunity. Peripheral (ambient) vision detects the motion of the self in relation to the environment, including head movements and postural sway. Peripheral vision is largely subconscious, whereas central visual inputs tend to receive more conscious recognition.¹¹ Both are normally used for postural control. Vision is critical for feedforward, or anticipatory, postural control in changing environments. This includes planning for functional movements such as reaching and grasping, and especially for successful navigation during gait. Vision loss also negatively affects balance. Loss of peripheral visual inputs occurs in patients with disease of or injury to the eyes or afferent cranial nerves. Examples include patients with cataracts, macular degeneration, glaucoma, or diabetic retinopathy.

The vestibular system provides the central nervous system (CNS) with information about the position and motion of the head. The position of the head in relation to gravity is detected through the otolith system. Horizontal and vertical accelerations, as in riding in a car or an elevator, are also detected by the otoliths.¹⁵ Movements of the head are detected through the semicircular canals. Head movement stimulates both sets of semicircular canals, so that the vestibular nerve on one side becomes inhibited while the other becomes excited. The vestibular system provides sensory redundancy in the information obtained from each separate vestibular apparatus. If the peripheral vestibular system is damaged on one side, the information can be captured by the intact canals on the opposite side. The vestibular system is critical for balance because it uniquely identifies self-motion as different from motion in the environment. Vestibular loss also negatively affects balance. Loss of peripheral vestibular inputs occurs in patients with disease of or injury to the peripheral sensory receptors or afferent cranial nerves. Examples include patients with head injury involving temporal bone damage, acoustic neuroma, benign positional vertigo (BPV), or Meniere disease. For a comprehensive review of the vestibular system and vestibular disorders, see Chapter 21.

Orientation to the wider environment, primarily from vision, allows feedforward, or anticipatory, postural adjustments. Prior experience and high attentional capacity improve APAs significantly. Detection of head movement by the vestibular and cervical somatosensory systems and of body sway by somatosensory and peripheral visual systems provides feedback for APRs. Note that the better anticipatory abilities become, the fewer balance errors occur. Fewer balance errors means fewer losses of balance and a reduced need to produce rapid APRs.

Disease of or damage to any of the peripheral sensory receptors or afferent pathways impairs or removes the detection capabilities of the system rendering sensory information unavailable for use in postural control. Many patients with neurological diagnoses have peripheral sensory impairments.

Central Sensory Perception

The brain processes the environmentally available sensory information gathered by the peripheral receptors in varying degrees. This processing is usually referred to as *multisensory integration* or *sensory organization*.^{5,11} Central sensory structures function first to compare available inputs between two sides and among three sensory systems. The somatosensory system alone is unable to distinguish surface tilts from body tilts. Also the visual system by itself cannot discriminate movement of the environment from movement of the body.¹⁵ The vestibular system by itself cannot tell if head movement through space is produced by neck motion or trunk and hip motion. Therefore the brain needs information from all three senses to correctly distinguish self-motion from motion in the environment.

How are sensory inputs from separate senses combined to form perceptions of position and motion? To explain this, consider the example of the movement of turning your head quickly to one side to look over your shoulder. When the head turns to one side, firing will increase in one vestibular organ and decrease proportionately in the other. This is known as *push-pull function*, and the information from each side is considered to “match” reciprocally. With the same example, if the eyes are open while the head moves, the rate of the visual flow will be equal and the direction of the visual flow will be opposite to the rate and direction of information from the vestibular inputs. The muscles on one side of the neck will shorten and on the other side will

stretch. The inputs from these three systems are congruent. If both sides and all three systems provide compatible inputs, the process of sensory organization is simplified.

When changes in the environment occur, the relative availability, accuracy, and usefulness of information from the three sensory systems may also change. Sensory organization also includes an adaptive process, called *multisensory reweighting*, that permits the CNS to prioritize the sources of sensory information when environmental conditions change.^{16,17} Available, accurate, and useful information is “upweighted,” whereas unavailable, inaccurate, or less-useful information is “downweighted.” For example, in dark environments vision would be downweighted and somatosensory and vestibular information would be upweighted. This adaptive process is imperfect, however, and balance is not as well controlled when any sense must be downweighted as it is when all three senses are available and accurate. Individuals with peripheral sensory loss or central sensory processing deficits may have difficulty reweighting quickly and fully. This impairs their ability to adapt to, and remain stable in, changing environments.¹⁸

Sensory conflict can arise when information between sides or between systems is not synchronous. Sensory organization processing then becomes more complex because the brain must then recognize any discrepancies and select the correct inputs on which to base motor responses. The vestibular system may be used as an internal reference to determine accuracy of the other two senses when they conflict. For example, a driver stopped at a red light suddenly hits the brake when an adjacent vehicle begins to roll. Movement of the other car detected by the peripheral visual system is momentarily misperceived as self-motion. In this situation, the vestibular and somatosensory systems do not detect motion, but the forward visual flow is interpreted as backward motion. Because the brain failed to suppress the (mismatched) visual inputs, the braking response was generated. Note that “perception drives action,” thus perceptual errors lead to movement errors.¹⁹

When the brain recognizes that the information coming from one sensory input is inaccurate or unavailable, as is the case when the perception of somatosensory information is diminished post-stroke, it must depend more on the remaining senses (in this case, vision and vestibular system) to determine position and motion in space. The brain then compares and uses information from senses it considers accurate for balance. An individual with the problem just described may compensate for the loss of somatosensory function by becoming visually dependent for balance during movement. If vision subsequently also becomes disrupted as this patient ages, his or her ability to orient in space will be further compromised. This will negatively affect balance and increase risk of falls.

Activities or environments that create sensory conflict or demand sensory resolution become more difficult to manage when the vestibular system is deficient or underused. These situations, such as going down stairs, riding escalators or elevators, walking on uneven ground, and making quick turns, are often avoided by patients with vestibular deficits. When sensory conflicts cannot be resolved rapidly, dizziness or motion sickness occurs.

Intrinsic central sensory processing impairments also can produce sensory conflict. An adult hemiplegic patient with pusher syndrome illustrates an inability to integrate visual, vestibular, and somatosensory inputs for midline and verticality orientation. Within a single system, discrepancies between the sides are also problematic. Unequal firing from opposite sides of the vestibular system, as in unilateral vestibular hypofunction, produces a mismatch that is subsequently interpreted as head rotation when head movement does not occur. This spinning sensation is known as *vertigo*.¹⁵ Vertigo is resolved if the

brain is able to adapt to the mismatch. For further information on vertigo, refer to Chapter 21.

Finally, the central processing mechanisms combine any available and accurate inputs to answer the questions, “What is my position and how am I moving now?” and “What will my position and motion be in the next moment?” This includes both an internal relation of the body segments to one another (e.g., head in relation to trunk, trunk in relation to feet) and an external relation of the body to the outside world (e.g., feet in relation to surface, arm in relation to handrail). CNS disease or trauma involving the parietal lobe may impair these processing mechanisms so that even available, accurate sensory inputs are not recognized or incorporated into determinations and estimations of current and future position and movement.^{20,21} Impairments of central sensory processing may occur after stroke, head trauma, tumors, or aneurysms; with disease processes such as MS and Alzheimer disease; and with aging.

Central Motor Planning and Control

Whereas sensory processing allows the interaction of the individual and the environment, motor planning underlies the interaction of the individual and the task. Aside from reflexive activity such as breathing and blinking, most motor actions are voluntary and occur because some goal is to be achieved. That is not to say that reflexes occur separately from volitional movements; for example, the VOR is active concurrently with visual tracking activity, but most actions occur because of some purposeful intent.¹⁵ These task intentions precede motor actions.^{11,22} Wrist and hand movements vary depending on what is to be grasped (a cup vs. a doorknob); foot placement and trunk position vary depending on what is to be lifted (a heavy suitcase vs. a laundry basket). The initiation of volitional motor actions depends on intention, attention, and motivation.^{11,23}

Once a task goal (Where do I want to be? What do I want to do?) has been chosen, the next step in motor planning is to determine how to best accomplish the goal given the many options that are potentially available. For example, when the task demands fine skills or accuracy, the dominant hand is preferred; when the task involves lifting a large or heavy object, both hands are preferred. In addition to which limbs, joints, and muscles will be used, motor planning also adjusts the timing, sequencing, and force modulation of muscle activity. This can be demonstrated in various reaching tasks. Reaching to remove a hot item from the oven will occur slowly, whereas reaching to put an arm through a sleeve will occur more quickly. Optimal motor plans are developed with knowledge of self (abilities and limitations), knowledge of task (characteristics of successful performance), and knowledge of the environment (risks and opportunities).²³

The motor plan is generated in the cortex and refined in the basal ganglia, which responds to goal achievement with reward signals that increase motivation and the likelihood that the correct movement will be reproduced. Next, the motor plan must be transmitted to the peripheral motor system to be enacted. A copy of the intended movement plan is sent to the cerebellum during the transmission. When the movement begins, incoming sensory inputs (feedback) about the actual movements and performance outcome are compared with the intended movements and performance outcome. Movement errors (the difference between the intended and the actual movement) and performance errors (desired goal not achieved) are detected by the cerebellum and basal ganglia and transmitted to the cortex. Corrected motor plans are then formed in the cortex and transmitted for the next attempt to achieve the goal. This process of error detection and error correction is the foundation of motor learning.

Patients with CNS disorders often have central motor planning and control system problems. After a stroke, patients may have hypertonus

and poor reciprocal inhibition; patients with head trauma may have difficulty initiating or ceasing movements; patients with PD exhibit bradykinesia; and those with cerebellar ataxia display force modulation problems.²⁴

Peripheral Motor Execution

Movement is accomplished through the bilateral joints and muscles. Normal joint ROM, muscle strength and power, and muscle endurance of the feet, ankles, knees, hips, back, neck, and eyes must be present for the execution of the full range of movements needed for normal balance skills. Decreased ankle dorsiflexion ROM, for example, restricts the forward limits of stability. Strength deficits are a primary cause of movement abnormalities in both CNS and peripheral nervous system (PNS) disorders. In addition, weakness may be the result of force modulation deficits or disuse.¹² Balance is directly negatively affected by loss of muscle strength, power, and endurance. For example, weakness of the hip extensors and abductors will impede successful use of a hip strategy for upright trunk control. Low muscle power impedes the rapid generation of sufficient force to execute a successful APR. Initially adequate toe clearance may diminish with fatigue. Many patients with neurological issues also have stiffness and contractures as a result of persistent weakness or hypertonus. Restrictions in ROM, particularly extension, also limit balance skills.

The ability to achieve static postural alignment, although necessary for normal balance, is not sufficient to allow volitional functions. Adequate strength (to control body weight and any additional loads) through normal postural sway ranges is needed to permit dynamic balance activities such as reaching, leaning, and lifting. Postural control demands are increased during gait because the forces of momentum and the interaction between recruitment, timing, and velocity also must be regulated.²⁵ Traditionally considered orthopedic problems, deficits in muscle strength and power, ROM, posture, and endurance have a negative impact on balance skills. Attention must be given to these musculoskeletal system problems in examination of and intervention for patients with neurological diagnoses.

Influence of Other Systems

Balance skills are also influenced by other systems. Attention, cognition and judgment, and memory are critical for optimal balance skills and are often impaired in hemiplegic and head-injured patients, as well as those who have progressive neurological disorders such as MS and Alzheimer disease. Attentional deficits reduce awareness of environmental hazards and opportunities, interfering with anticipatory postural control.¹³ When balance is threatened, an inability to allocate attention to the necessary task of balance versus a secondary, less necessary task increases the risk of falls. Cognitive problems such as distractibility, poor judgment, and slowed processing also increase the risk of falls. Memory loss may preclude recall of safety measures. Depression, emotional lability, agitation, or denial of impairments also can increase the risks for loss of balance. Fear of falling may lead to self-imposed participation restrictions that precipitate a downward spiral of more sedentary behaviors (leading to increased stiffness and weakness) and social isolation (leading to depression); all of these negatively affect balance and raise the risk of falls. In addition to having a direct impact on balance skills themselves, these cognitive and behavioral problems impede motor learning processes, which are crucial for the relearning of balance skills.

Constant Cyclic Nature

The systems model of postural control previously presented illustrates the constant cycle that simultaneously occurs at many levels. Attention and intention allow feedforward processing for active sensory search of

the environment and motor planning, both of which are needed for anticipatory postural control. Movements are initiated and executed with resultant sensory experiences and error detection, or feedback. Successful movements are repeated and refined; unsuccessful ones are modified. The nature of this cycle presents the clinician with opportunities for intervention after the appropriate examination of sensory, motor, and cognitive functions. Through feedback and practice, balance skills can improve.²⁶

Motor Components of Balance

Reflexes

Many levels of neuromuscular control must be functioning to produce normal postural movements. At the most basic level, reflexes and righting reactions support postural orientation. The VOR and the vestibulospinal reflex (VSR) contribute to orientation of the eyes, head, and body to self and environment.¹¹

When motion of the head is identified by the semicircular canals, it triggers a response within the oculomotor system called the *vestibulo-ocular reflex (VOR)*. This causes the eyes to move in the opposite direction of the head but at the same speed. Stimulation of the otoliths drives the eyes to respond to linear head movement. Quick movements of the head will trigger the VOR.²⁷

The VOR allows the coordination of eye and head movements. When the eyes are fixed on an object while the head is moving, the VOR supports gaze stabilization. Visuo-ocular responses often work concurrently with the VOR. They permit “smooth pursuit” when the head is fixed while the eyes move and visual tracking when both the eyes and the head move simultaneously.¹¹

The VSR helps control movement and stabilize the body. Both the semicircular canals and the otoliths activate and modulate muscles of the neck, trunk, and extremities after head movement to maintain balance. The VSR permits stability of the body when the head moves and is important for the coordination of the trunk over the extremities in upright postures. Righting reactions support the orientation of the head in relation to the trunk and the head position relative to gravity and include labyrinthine head righting, optical head righting, and body-on-head righting.¹¹

Automatic Postural Responses

At the next level, APRs operate to keep the COG over the base of support. They are a set of functionally organized, long-loop responses that act to keep the body in a state of equilibrium.^{4,5} *Functionally organized* means that the responses, although stereotypical, are matched to the perturbing stimulus in direction and amplitude. If the stimulus is a push to the right, the response is a shift to the left, toward midline. The larger the stimulus, the greater the response. APRs always occur in response to an unexpected stimulus and are typically triggered by somatosensory inputs. Because they occur rapidly, in less than 250 ms, they are not under immediate volitional control.

Four stereotypical APRs have been described. Ankle strategy describes postural sway control from the ankles and feet. The head and hips travel in the same direction at the same time (“in-phase”), with the body moving as a unit over the feet (Fig. 20.3A). Muscle contractile patterns are from distal to proximal (i.e., gastrocnemius, hamstrings, paraspinals). This strategy is used when sway is small, slow, and near midline. It occurs when the surface is broad and stable enough to allow pressure against it to produce forces that can counteract sway to stabilize the body. Ankle strategy is typically used to control anterior-posterior sway, because most of the degrees of freedom at the ankle are in this direction.

Hip strategy involves postural sway control from the pelvis and trunk. The head and hips travel in opposite directions (“out-of-phase”),

Fig. 20.3 Automatic Postural Responses. (A) Ankle strategy. (B) Hip strategy. (C) Suspensory strategy. (D) Stepping strategy. (From Hasson S. *Clinical Exercise Physiology*. St Louis: Mosby; 1994.)

with body segment movements counteracting one another (see Fig. 20.3B). Muscle contractile patterns are from proximal to distal (i.e., abdominals, quadriceps, tibialis anterior). This strategy is observed when sway is large, fast, and nearing the limit of stability or if the surface is too narrow or unstable to permit effective counterpressure of the feet against the surface. Hip strategy is used to control both anterior-posterior and medial-lateral sway. Hip strategy in the medial-lateral direction involves weight shifts from foot to foot; any patient with difficulty weight-shifting quickly and accurately will have difficulty with medial-lateral hip strategy.

Suspensory strategy involves a lowering of the COG toward the base of support by bilateral lower-extremity flexion, or a slight squatting motion (see Fig. 20.3C). By shortening the distance between the COG and the base of support, the task of controlling the COG is made easier. This strategy is often used when a combination of stability and mobility is required, as in windsurfing.

Stepping and reaching strategies involve steps with the feet or reaches with the arms in an attempt to reestablish a new base of support with the active limb(s) when the COG has exceeded the original base of support (see Fig. 20.3D). A successful stepping strategy (sufficiently large and fast) is the best way to avoid a fall after a slip or trip.

Misconceptions about these APR strategies are common. First, these strategies do not function in daily life as separately as they are described in the early research literature. In quiet standing, for example, frequency analysis of unperturbed postural sway in healthy adults reveals that both ankle and hip strategies occur in combination, simultaneously.²⁸ In perturbation studies, mixed use of strategies is often seen unless the perturbation is clearly below or above certain-sized thresholds. Second, these strategies occur in response to disturbances from all directions, not just in pure anterior-posterior or medial-lateral directions.²⁹ Third, although these strategies are stereotypical in humans, great individual variation in strategy selection and performance comes from other influential factors. For example, many people use stepping strategy for most perturbations unless specifically instructed not to step or unless the conditions do not permit a step. An anxious person may reach or step much sooner than a relaxed person with similar physical deficits. Last, all these strategies do *not* occur in sequence with every balance disturbance.^{30,31} In other words, individuals normally do not try ankle strategy and wait until it fails before trying hip strategy, then wait until it fails before trying stepping strategy (although early learning in children may involve such exploration). Because these responses must occur extremely rapidly to prevent balance loss, such a sequential approach would be inefficient and ineffective. Instead, the normal adult response is the near-immediate emergence of the single strategy best suited to the particular perturbation, the limitations of the individual, and the conditions in the environment.

Abnormal use of APRs is often observed in individuals with neurological disorders. Patients with vestibular deficits typically rely on ankle strategy, which permits the head to remain aligned with the body and sustains congruence between vestibular and somatosensory inputs. Use of hip strategy may be modified or limited because when the head is moving in the opposite direction as the COG, vestibular and somatosensory inputs are not congruent. Activities that require use of hip strategy, such as standing in tandem or on one leg, can be a problem for patients with bilateral vestibular loss or an uncompensated vestibular lesion. However, some cases involve excessive use of hip strategy on a level surface (when an ankle strategy would suffice).³² This may reflect abnormal integration of the somatosensory and vestibular information. If peripheral somatosensation is impaired, as in diabetic neuropathy, or central sensory weighting of somatosensory inputs is inadequate, hip strategy may dominate.

Patients with somatosensory loss, distal lower extremity weakness or hypertonus, restricted ankle ROM, and/or reduced limits of stability typically rely on hip strategy. This occurs because the patient cannot feel the surface or the feet well enough to modulate foot pressure against the surface, because the person cannot rapidly generate sufficient force against the surface with the ankle muscles, or because restricted ankle ROM prevents COG sway. The use of hip strategy is normal when the COG is at or near the limits of stability and a step is either not possible or not desired.

When the brain perceives that hip or ankle strategy will not be efficient enough to control the movement of the center of pressure, or if conditions and instructions permit a stepping response, stepping strategy may be preferred. Individuals who are fearful of falling often perceive even slight body sway as threatening instability. They may use stepping and reaching strategies exclusively whether or not these “rescue” strategies are actually necessary.

Anticipatory Postural Adjustments

APAs activate muscles in a manner similar to APRs, but they occur before the actual disturbance.²² If a balance disturbance is predicted, the body will respond in advance by developing a “postural set” to counteract the coming forces. For example, if an individual lifts an empty suitcase thinking it is full and heavy, the anticipatory forces generated before the lift (to counter the anticipated weight) will cause excessive movement and brief instability. Failure to produce properly calibrated anticipatory adjustments increases the risk of sudden balance loss, creating the need to use rapid, reactive APRs to prevent a fall. For patients with deficits in reaction time or APRs, superior use of anticipatory postural control can help the patient avoid the unexpected perturbations that make APRs necessary.

In balance laboratories, APAs are studied using electromyography so that muscle activity before observable movement can be measured. In the clinic, problems with anticipatory adjustments may be observed when the patient fails to counteract a predicted disturbance, such as “don’t let me push you backward,” or fails to integrate postural control tasks during other activities; this can include the inability to step smoothly over an anticipated obstacle during gait or inability to maintain sitting balance when both arms are intentionally lifted overhead.

Patients with neurological disease or injury involving the cortex may have difficulty recognizing the need for and/or producing APAs. For example, individuals post-stroke or post-traumatic brain injury (TBI), or with MS, PD, or Alzheimer disease. Age-related white-matter changes in fall-prone older adults may also contribute to deficient APAs. Note that the motor learning needed to know when to generate and how to calibrate APAs requires practice and experience. Patients who are learning a novel task like a wheelchair “wheelie”—even patients

without cortical involvement (e.g., individuals with SCI or Guillain-Barre)—need extensive repetition to be able to develop successful APAs for that task.

Volitional Postural Movements

Volitional postural movements are under conscious control. Weight shifts to allow an individual to reach the telephone or put the dishes in the dishwasher, for example, are self-initiated disturbances of the COG to accomplish a goal. Volitional postural movements can range from simple weight shifts to complex balance skills of skaters and gymnasts. They can occur after an external stimulus or be self-initiated. Volitional postural movements can occur quickly or slowly, depending on the goal at hand. The more complex or unfamiliar the task, the slower the response time. Use of a variety of movements that might successfully achieve a goal is possible. Volitional postural movements are strongly modified by prior experience and instruction. Automatic and anticipatory postural responses allow the continuous unconscious control of balance, whereas volitional postural movements permit conscious activity. This level of postural motor control is the most frequently tested and treated in clinical practice, but it is by no means sufficient by itself to produce normal balance.

CLINICAL ASSESSMENT OF BALANCE

Objectives of Testing

The patient interview should include determination of participation restrictions and the patient's goals. Then, when present, activity limitations need to be identified and measured. Functional scales (e.g., Functional Independence Measure) are typically used to determine the presence and severity of these limitations, not necessarily why those limitations exist. From these functional tests, decisions can be made about whether intervention is required and, if so, what tasks need to be practiced. If intervention is indicated, clinicians must make

judgments about what should be included in the intervention plan. Further testing to identify and measure sensorimotor skills deficits and body structure/function impairments is then necessary to know what systems are involved. A comprehensive evaluation of balance includes functional activity abilities/limitations, sensorimotor skills, and postural control system impairment tests.¹³

No single quick-and-easy test of balance can adequately cover the many multidimensional aspects of balance, although many such tests have great value as screening tools. However, a comprehensive test battery, called the Balance Evaluation Systems Test (BESTest), based on the systems model has been developed that provides clinicians with a thorough examination covering the six major components of the postural control system (Fig. 20.4).³³ The BESTest takes more time to administer than, for example, a single-leg stance test, but results from the BESTest give the clinician a far more complete and accurate picture of the patient's balance deficits than any single-item test or screening test can. Armed with these results, the clinician can develop interventions specifically targeted to the deficient systems. For patients whose primary problems include imbalance, the clinician's investment of time to perform this comprehensive test battery yields a valuable outcome. Shorter versions of this test, the Mini-BESTest and the Brief-BESTest, have subsequently been published.^{34,35} They take less time to administer but likewise provide a less complete picture of the patient's balance systems. Specifically, they do not include any items from the biomechanical constraints or stability limits categories. Even so, they are superior to single-item tests or screening tests that are not based on the systems model and do not identify balance system deficits that should be addressed in the intervention plan.

For some patients at lower functional levels, the BESTest may be too difficult. If this is the case, the Berg Balance Scale (BBS) is also an excellent test battery. Though not specifically designed to align with the systems model of dynamic equilibrium, the BBS contains 14 items

I. Biomechanical Constraints	1. Base of support	2. CoM alignment	3. Ankle strength and ROM	4. Hip/trunk lateral strength	5. Sit on floor and stand up		
II. Stability Limits/Verticality	6. Sitting verticality (left and right) and lateral lean (left and right)	7. Functional reach forward	8. Functional reach lateral (left and right)				
III. Anticipatory Postural Adjustments	9. Sit-to-stand	10. Rise to toes	11. Stand on one leg (left and right)	12. Alternate stair touching	13. Standing arm raise		
IV. Postural Responses	14. In-place response, forward	15. In-place response, backward	16. Compensatory stepping correction, forward	17. Compensatory stepping correction, backward	18. Compensatory stepping correction, lateral (left and right)		
V. Sensory Orientation	19. Sensory integration on balance (modified CTSIB). A: Stance on firm surface EO; B: stance on firm surface EC; C: stance on foam EO; D: stance on foam EC			20. Incline, EC			
VI. Stability in Gait	21. Gait, level surface	22. Change in gait speed	23. Walk with head turns, horizontal	24. Walk with pivot turns	25. Step over obstacles	26. Timed "Get up & Go" Test	27. Timed "Get up & Go" Test with dual task

that do challenge several different components of postural control. Selection of one of these two test batteries (based on patient ability level) to initiate a comprehensive balance evaluation is a valuable approach because results from these tests permit extensive hypothesis generation about what balance skills may be deficient and what postural control system impairments may be present.

No single, simple test for balance is possible because balance is such a complex sensorimotor process.³⁶ Many relatively simple balance tests exist, but not all tests are appropriate for all patients. Different tests may be needed to answer specific questions. For example, several good tests have been developed to determine the risk of falls in elderly people. These would be insufficient to discern whether an injured dancer can resume practice, or an injured roofer is ready to return to work. Clinicians should understand the advantages and limitations of different balance tests in order to be able to select appropriate evaluative tools.

In general, a balance test will not be useful unless it sufficiently challenges the postural control system being tested. Tests for stability (“static balance”) are appropriate for patients who are having difficulty simply finding midline or holding still in sitting or standing. They are of much less value for patients with higher-level abilities. Conversely, single-leg stance tests or sensory tests with a foam surface may be far too difficult to perform for patients with lower-level abilities. Certain tests permit the use of arms and/or assistive devices, while others do not; clearly test choices are then limited for patients dependent on the use of upper extremities for balance.

A word of caution about interpreting test results is indicated. Most clinical tests rely on observations of motor behavior to arrive at some conclusion about what systems have problems and how they affect movement. Abnormal motor behavior has many causes, and clinicians should be careful before concluding that an observed behavior is caused by problems in a certain system. For example, the Romberg test is commonly assumed to test the use of vestibular inputs. Yet during the test, both somatosensory and vestibular inputs are (normally) used for balance control. If balance control is deficient, is the vestibular system necessarily the culprit? Could somatosensory system deficits also result in a poor test result? Or, alternatively, because the Romberg test is performed with feet together, what effect would hip weakness have on the ability to stand with a narrowed base of support? When using a test whose results may be altered by problems in more than one system, any relevant system should be evaluated. If multiple system deficits exist, and they often do in patients with neurological conditions, then use caution in making “commonly assumed” conclusions on the basis of clinical test results.

Because so many balance tests are available, several questions must be asked to determine whether a test is appropriate for use.³⁶ For what purpose and population was the test designed? Can that test be used legitimately for a different purpose or with a different population? Is it valid? Is it reliable, that is, repeatable by different examiners or by the same examiner multiple times? In what populations is it valid and reliable? What is the threshold (minimal detectable change [MDC]) for this test—that is, how large must true performance changes be before this test can detect them? Are normative data available for comparison? These questions are being investigated but have not yet been answered for many of the clinical balance tests commonly used by therapists with the many different neurological populations they treat. Some of the evidence already reported may be frustrating to clinicians. For example, the Timed Up-and-Go test (TUG) predicts falls in community-dwelling older adults but not in acute-care hospital populations.^{37,38} For several balance tests such as the TUG, the BBS, and others, the cutoff scores used for accurate prediction of falls in patients with Parkinson disease are different from the cutoff scores used in older adults without Parkinson disease.³⁹ These examples make

it clear that clinicians must understand their patients and the characteristics of the various balance tests in order to select the most appropriate tests and interpret test results for each patient.

Types of Balance Tests

Balance tests can be grouped or classified by type. Different types of tests measure different facets of postural control (Table 20.1). Quiet standing (static) refers to tests in which the patient is standing and the movement goal is to hold still. Disturbances to balance, called *perturbations*, may or may not be applied. Active standing (dynamic) tests also position the patient standing, but the movement goal involves voluntary weight shifting. Transition tests require that the patient

TABLE 20.1 Types of Balance Tests

Type	Tests
Quiet standing (with or without perturbation)	Romberg Sharpened Romberg or tandem Romberg One-legged stance test (OLST) Timed stance battery Balance Error Scoring System (BESS) Postural sway via forceplate, accelerometry Nudge or push Push and Release Test Motor Control Test (MCT)
Active standing	Functional Reach Test (FRT) Multi-Directional Reach Test (MDFR) Limits of Stability (LOS) Star Excursion Balance Test (SEBT) and Y Balance Test
Sensory manipulation	Sensory Organization Test (SOT) Clinical Test of Sensory Interaction on Balance (CTSIB)
Active transitions and stepping	5-Times Sit-to-Stand Test (5XSTS) 30-s Chair Stand Test (CST) 4-Square Step Test (4SST)
Functional scales	Berg Balance Scale (BBS) Timed Up-and-Go Test (TUG) Tinetti Performance Oriented Mobility Assessment (POMA) (Balance subscale) Tinetti Performance Oriented Mobility Assessment (POMA) (Gait subscale) Gait Abnormality Rating Scale (GARS) Modified Dynamic Gait Index (mDGI) Functional Gait Assessment (FGA) Environmental Analysis of Mobility Questionnaire (EAMQ)
Combination test batteries	Balance Evaluation Systems Test (BESTest) Fregly-Graybiel Ataxia Test Battery High-level Mobility Assessment Test (HiMAT) Community Balance and Mobility Scale (CBM) Fugl-Meyer Sensorimotor Assessment of Balance Performance
Dual-task	Stops walking when talking (SWWT) Dual-Task TUG, Manual and Cognitive Multiple Tasks Test (MTT) Walking and Remembering Test (WART)
Balance confidence	Activities-Specific Balance Confidence Scale (ABC) Falls Efficacy Scale—International (FES-I) Survey of Activity and Fear of Falling in the Elderly (SAFFE) Fear of Falling Avoidance Behavior Questionnaire (FFABQ)

move from one point to another, but do not require walking; examples include items #1 Sit-to-Stand, and #4 Transfer in the BBS, and the 4-Square Step Test (4SST).⁴⁰ Sensory manipulation tests use altered surface and visual conditions to determine how well the CNS is using and reweighting sensory inputs for postural control. Functional balance, mobility, and gait scales involve the performance of whole-body movement tasks, such as Item #9 “Pick up object from floor” in the BBS, walking, and stepping over objects. A few test batteries offer a combination of the preceding tests. The BESTest is the most comprehensive test battery to date. Dual-task tests have been developed to examine the effect of concurrent activities and divided attention on balance and mobility performance. Tests of sitting balance in adults are being developed because patients with neurological problems often need sitting balance retraining in early stages of recovery. Examples include the Seated Functional Reach Test⁴¹ (used to measure excursion in seated individuals with spinal cord injuries), Postural Assessment Scale for Stroke Patients⁴² (PASS), Trunk Impairment Scale,⁴³ Kansas University Sitting Balance Scale,⁴⁴ Sitting Balance Assessment Tool⁴⁵ (SitBAT), Function in Sitting Test,⁴⁶ and Ottawa Sitting Scale.⁴⁷

Quiet Standing

The classic Romberg test was originally developed to “examine the effect of posterior column disease upon upright stance.”⁴⁸ The patient stands with feet parallel and together and then closes the eyes for 20 to 30 seconds. The examiner subjectively judges the amount of sway. Quantification of sway can be accomplished with a videotape, forceplate, or, more recently, accelerometer.^{49,50} Excessive sway, loss of balance, or stepping during this test is abnormal. The sharpened Romberg,⁴⁸ also known as the *tandem Romberg*, requires the patient to stand with feet in a heel-to-toe position and arms folded across the chest, eyes closed for 60 seconds. Often four trials of this test are timed with a stopwatch, for a maximum score of 240 seconds.

One-legged stance tests (OLSTs) are commonly used.^{48,51} Both legs must be alternately tested, and differences between sides are noted. The patient stands on both feet and places hands on the hips or crosses the arms over the chest, then picks up one leg and holds it with the hip in neutral and the knee flexed to 90 degrees. The lifted leg may *not* be pressed into the stance leg. This test is scored with a stopwatch. Five 30-second trials are performed for each leg (alternating legs), with a maximum possible score of 150 seconds per leg. Normal young subjects are able to stand for 30 seconds, but this may not be a reasonable expectation for frail older patients.⁴⁸

In both the Romberg test and the OLST, problems in sensory organization processes can be observed. To determine how much of the stability is achieved through visual stabilization, each test can be repeated with eyes closed. The patient with visual dependency for balance will often have an immediate loss of balance when the eyes are closed. (Remember, visual dependency may be a sign of somatosensory or vestibular loss, or both.) As noted earlier, the patient with somatosensory or vestibular loss may have difficulty producing the hip strategy necessary to perform these tasks.

A battery of timed stance tests has been developed by Bohannon and Leary⁵²; designed for acute care bedside use, it can be used in other settings as well. This set of tests varies the foot position (apart, together, tandem, and single leg) and the availability of visual information (eyes opened and closed) to produce eight different combinations. Maintenance of balance in each condition is timed for a maximum of 30 seconds; the assigned score is the total number of seconds that balance could be maintained. The best possible score on this test is 240 seconds. This test is reliable, valid, and sensitive to change over time.⁵²

A related test is the Balance Error Scoring System, or BESS test, which was developed for use with athletes to screen for concussion

effects.^{53,54} The original BESS test involved three stance positions (double-leg stance with feet together, single-leg stance, tandem stance) on two surfaces (firm and foam), thus providing six conditions. The eyes are closed in all conditions. Each trial is 20 seconds in duration. The examiner observes and counts the number of balance errors that are made in each condition. The six observed errors include hands lifted off waist; opening eyes; step, stumble, or balance loss; moving a hip past 30 degrees of abduction; lifting the forefoot or heel; and remaining out of the test position for more than 5 seconds. If more than one error occurs at the same time, for example, opening eyes and hands off waist, only one error is counted. When measured in high-level young adults, the reliability of this test improved with the removal of the double-leg stance condition, which produced few to no errors in this high-functioning population, and the addition of three trials in each of the remaining four conditions. The modified BESS test thus includes only four conditions.⁵⁵ This test has not been investigated for use in traditional neurological rehabilitation populations but may be a valuable alternative for high-functioning young patients post-concussion or mild TBI.

Objective postural sway measures can be obtained by computerized force plates (Fig. 20.5) or wearable accelerometers (Fig. 20.6).^{50,56–58} The patient is asked to adopt a standardized foot placement, if possible (this varies by manufacturer), and to stand quietly with arms at the sides or hands on the hips for 20 or 30 seconds. Sway with both eyes open and eyes closed is commonly measured. Graphic and numerical quantification is provided. Normative data may be provided. These more technical measures are able to detect more subtle problems and are more sensitive to change in performance after treatment than are rating scales or timed measures.

APRs are assessed by the patient’s response to perturbations. It is imperative that clinicians include APR testing in their balance

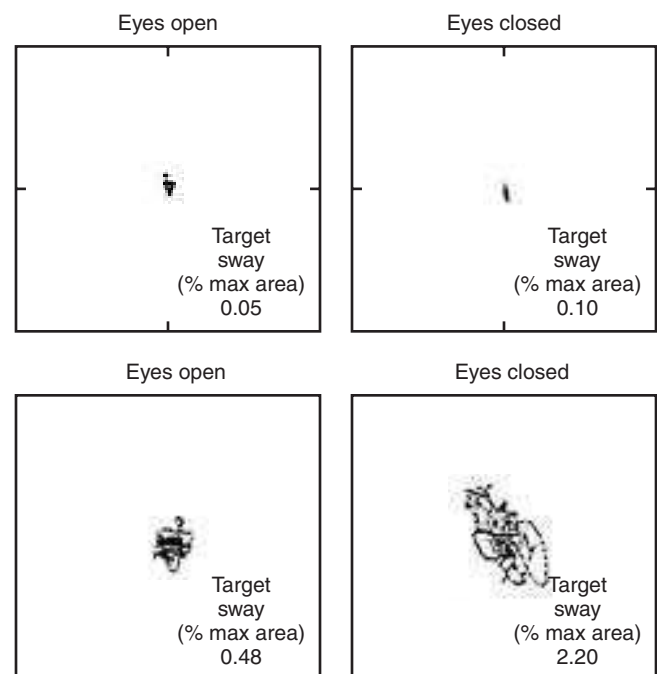

Fig. 20.5 Graphic and Numerical Postural Sway Measures Using a Computerized Force Plate System. *Top left*, Normal subject, eyes open. *Top right*, Healthy subject, eyes closed. *Bottom left*, Patient with Parkinson disease, eyes open. *Bottom right*, Patient with Parkinson disease, eyes closed. (C) Postural sway data recorded by the accelerometer. (Photographs courtesy McRoberts B, The Hague, The Netherlands.)

assessment because APRs are the motor responses necessary to prevent loss of balance and falls. The push-and-release test is a clinically useful method with a five-point ordinal rating scale.^{33,59,60} Testing for ankle and hip strategies (“in-place” strategies) requires that the clinician (1) place his or her hands on the front or back of the patient’s shoulders, (2) ask the patient to remain still and centered by resisting the pressure applied by the hands (producing isometric muscle activity), (3) watch for the toes or heels to begin to raise slightly (the clinician increases pressure until this occurs), then (4) suddenly release the push. Both forward and backward directions are tested. For safety, the clinician always stands where he or she can support the patient in case of balance loss. Testing for stepping strategy follows the same concept but is performed differently. Instead of keeping the patient’s COG at midline, the patient leans his or her weight into the clinician’s hands, shifting the COG away from midline toward the outer limit of stability before the release. The correct patient response is to step to reestablish a new base of support underneath the new position of the COG. Forward, backward, and both lateral directions are tested. When nudge or push tests are performed predictably (i.e., “Don’t let me push you backward.”), this is assessment of anticipatory postural control. When the release happens unpredictably (no cues, unpredictable timing), APRs can be assessed. Perturbations of different strengths from multiple directions should be given.

The Motor Control Test (MCT) is a computerized test of APRs that perturbs the patient through surface displacement (Fig. 20.7B).⁴ The patient stands on a dynamic (movable) forceplate with feet parallel and arms at sides. The support surface rapidly translates (slides) forward or backward. This surface displacement results in a rapid shift in the relation between the COG and the base of support. The expected responses are directionally specific (to the direction of the stimulus) forces generated against the surface to bring the COG back to the center. Response latencies, strength, and symmetry are measured. Normative data are available. This test can be used to look for abnormal stepping strategies when failure to select hip strategy occurs. The MCT is the most standardized and reliable test of APRs but is less widely used because it requires computerized equipment.

Active Standing

Volitional control of the COG is evaluated by asking the patient to make voluntary movements that require weight shifting. The Functional Reach Test (FRT) was developed for home health use with older adults to determine risk of falls.⁶¹ The patient stands near a wall with feet parallel. Attached to the wall at shoulder height is a yardstick. The patient is asked to make a fist and raise the arm nearest the wall to 90 degrees of shoulder flexion. The examiner notes the position of the fist on the yardstick. The patient is then asked to lean forward as far as

Fig. 20.7 Surface perturbations during **(A)** the adaptation test and **(B)** the motor control test using computerized dynamic posturography. Forceplate measures include latency and amount of response and adaptation of the response to repeated perturbations. (From Hasson S. *Clinical Exercise Physiology*. St Louis: Mosby; 1994.)

possible, and the examiner notes the end position of the fist on the yardstick (Fig. 20.8). Beginning position is subtracted from end position to obtain a change unit in inches. Three trials are performed. Normative data are available, and the test is reliable. However, the standard error of measurement for this test may be as high as 2 inches, meaning that a change in score of less than 2 inches cannot be attributed to clinical improvement because it may reflect only measurement error. Subsequent studies have not shown that this test is useful for fall prediction.^{62–64} For these reasons the FRT is not recommended as a stand-alone test, rather it should be used in conjunction with other tests. Both the BBS and the BESTest include the FRT.

One serious limitation of the FRT is that it measures sway in only one direction (forward). An expansion of this test has been devised to measure sway in four directions.⁶⁵ The multidirectional functional reach test (MDFR) is conceptually equivalent but measures sway anteriorly, posteriorly, and laterally to both sides. This test should provide a more comprehensive picture of volitional COG control limitations. Validity and mean values have been established for community-dwelling older adults.⁶⁶ The BESTest includes the forward and lateral directions from the MDFR test.

The Limits of Stability test (LOS) uses a computerized forceplate to measure postural sway away from midline in eight directions.^{56,67} Patients assume a standardized foot position and control a cursor on the computer monitor by shifting their weight. They are asked to move the cursor from midline to eight targets on the screen (Fig. 20.9). Measures include movement velocity, directional control (path sway), measures of excursion (length of the trajectory of the COG), and reaction time. This test should be performed once for familiarization, then a second time for scoring purposes. Second and subsequent tests are reliable and normative data are available.

A very challenging test used primarily in athletic populations is the Star Excursion Balance Test (SEBT) (Fig. 20.10).^{68,69} The SEBT could be used, for example, in high-level TBI patients who require more demanding test conditions. However, although there is evidence for the validity and reliability of this test in orthopedic populations, as yet this test has not been investigated for use in neurological populations. The SEBT is in concept a lower-extremity functional reach test, requiring single-leg stance on one leg and a reach with the other leg. The original SEBT included eight directions; currently the SEBT is

Fig. 20.8 During the Functional Reach Test, the patient is asked to reach forward as far as possible from a comfortable standing posture. The excursion of the arm from start to finish is measured by a yardstick affixed to the wall at shoulder height. **(A)** Functional reach, starting position. **(B)** Functional reach, ending position.

typically performed in three directions: center-forward, right-rear, and left-rear.⁷⁰ Three tape measures are taped to the floor, radiating out from the same center point. The two rear tape measures are at a 45-degree angle from the center line. The patient stands on one foot with the great toe on the center point, then reaches the maximum distance away from the center with the lifted foot. The distance is recorded by the examiner. This is done in all three directions, with the lifted leg having to cross behind the stance leg to reach to the opposite-side rear tape. Six practice trials in each direction are given before recording scores to eliminate a learning effect, although recent evidence suggests four practice trials may be sufficient.⁷¹ Three scored trials in each direction are performed; both legs are tested.⁷² A commercial version of this test, the Y Balance Test, is available and has the advantage of being portable.

Sensory Manipulation

Sensory inputs play a critical role in postural control, but few tests to measure their use to produce a balance performance outcome have

Fig. 20.9 Graphic postural sway measures from the limits of stability test using a computerized forceplate system (numerical measures not shown). Patients are asked to move away from and return to midline. **(A)** Subject with normal postural sway. **(B)** Hemiplegic patient on initial evaluation. **(C)** Hemiplegic patient on discharge evaluation. Fig. 20.10 The floor grid layout for the original Star Excursion Balance Test (SEBT) with eight directions. Bolded arrows in the anterior, posteromedial, and posterolateral directions indicate the three directions used in the modified SEBT. (From Brumitt J. Assessing athletic balance with the Star Excursion Balance Test. *NSCA Perform Train J.* 2008;7:6.)

been developed. The Sensory Organization Test (SOT) uses a computerized, movable forceplate and movable visual surround to alter the surface and visual environments systematically.^{4,5} The patient stands on the forceplate with feet parallel and arms at the sides and is asked to stand quietly. Three 20-second trials under each of six sensory conditions are performed (Fig. 20.11). In conditions one, two, and three the support surface (forceplate) is fixed. During conditions four, five, and six the support surface is sway referenced to the sway of the patient. In other words, the movement of the surface is matched to the movement of the patient in a 1:1 ratio. This responsive surface movement maintains a near-constant ankle joint angle despite body sway, rendering the somatosensory information from the feet and ankles inaccurate for use in balance maintenance. Visual inputs are undisturbed in conditions one and four. Vision is absent (eyes are closed) in conditions two and five. The movable visual surround is sway referenced in

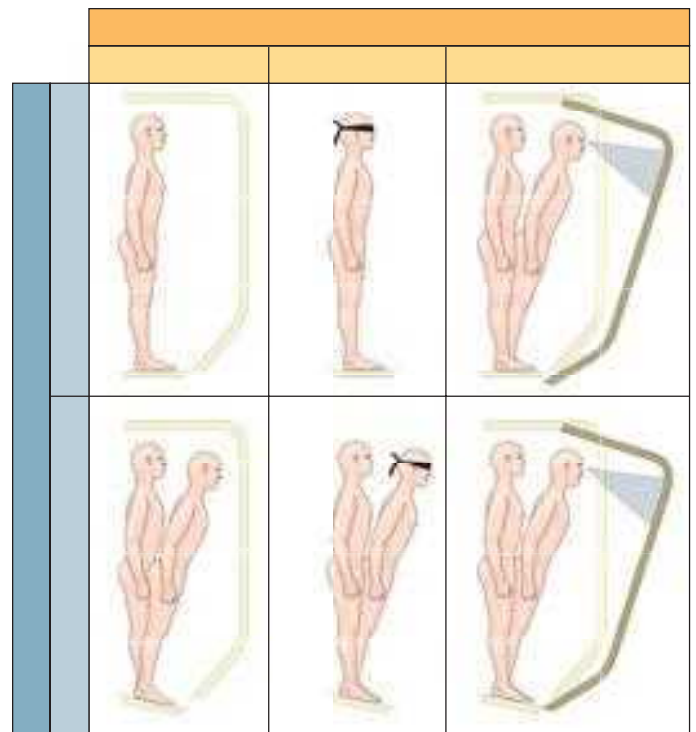

Fig. 20.11 The Six Sensory Organization Test (SOT) Conditions. The SOT determines the relative reliance on visual, vestibular, and somatosensory inputs for postural control using computerized dynamic posturography. (From Hasson S. *Clinical Exercise Physiology.* St Louis: Mosby; 1994.)

conditions three and six. This responsive visual surround movement maintains a near-constant distance between the eyes and the visual environment despite body sway, rendering visual inputs from the eyes inaccurate for balance maintenance in those two conditions.

Under condition one, all three senses (vision, vestibular sense, and somatosensory sense) are available and accurate. Body sway is measured by the forceplate; this initial measurement forms the baseline against which subsequent measures are compared (Fig. 20.12).

SENSORY ANALYSIS			
Ratio Name	Test Conditions	Ratio Pair	Significance
SOM Somatosensory	 	Condition 1 Condition 2	Question: Does sway increase when visual cues are removed? Low scores: Patient makes poor use of somatosensory references.
VIS Visual	 	Condition 4 Condition 1	Question: Does sway increase when somatosensory cues are inaccurate? Low scores: Patient makes poor use of visual references.
VEST Vestibular	 	Condition 5 Condition 1	Question: Does sway increase when visual cues are removed and somatosensory cues are inaccurate? Low scores: Patient makes poor use of vestibular cues, or vestibular cues unavailable.
PREF Visual Preference	 	Condition 3 + 6 Condition 2 + 5	Question: Do inaccurate visual cues result in increased sway compared to no-visual cues? Low scores: Patient relies on visual cues even when they are inaccurate.

Fig. 20.12 Postural sway measures from each of the six sensory organization test conditions are compared, and the ratios are used to identify impairments in the use of sensory inputs for postural control. (From Jacobson GP, Newman CW, Kartush JM. *Handbook of Balance Function Testing*. St Louis: Mosby; 1993.)

Under condition two the eyes are closed, so only somatosensory and vestibular cues remain. In an individual with normal movement function, the somatosensory inputs will dominate in this condition. By comparing sway during condition two with sway during condition one, detection of how well the patient is using somatosensory inputs for balance control is possible. Patients with somatosensory loss from incomplete SCI, diabetes, or amputation have difficulty in condition two. Functional situations with inadequate lighting or unusable visual cues (e.g., busy carpeting) are similar to condition two.

Under condition four, the support surface is sway referenced (somatosensory cues are available but are inaccurate), so only visual and vestibular cues remain useful. In a normal patient the visual inputs will dominate in this condition. Comparing sway during condition four with sway during condition one indicates how well the patient is using visual inputs for balance control. Patients with visual loss caused by diabetes, cataracts, or field loss have difficulty in condition four. Functional situations that correlate with condition four include compliant surfaces (beach, soft ground, gravel driveway) and unstable surfaces (boat deck, slipping throw rug).

Under condition five, the eyes are closed (visual cues are absent) and the support surface is sway referenced (somatosensory cues are inaccurate), leaving the vestibular inputs as the only remaining sensory inputs that are both available and accurate. Comparison of sway during condition five with sway during condition one indicates how well the patient is using vestibular inputs for balance control. Patients with vestibular loss caused by head injury, MS, or acoustic

neuroma may have difficulty with condition five. Many older patients with age-related vestibular loss also may be unstable in this condition. Functional situations in which these patients may be at risk for falls would have both inadequate lighting and compliant or unsteady surfaces (e.g., walking on a gravel driveway or thick carpet in the dark).

Under both conditions three and six, the visual surround is sway referenced (visual cues are available but inaccurate). By comparing sway during these two conditions with sway in the absence of vision (conditions two and five, with eyes closed), determining how well the patient can recognize and subsequently suppress inaccurate visual inputs when they conflict with somatosensory and vestibular cues is possible. Some patients with CNS lesions (e.g., head injury, stroke, tumor) may have difficulty with this condition. Patients who cannot recognize or ignore inaccurate visual cues cannot distinguish whether they are moving, or the environment is moving. If they perceive that they are moving (away from midline) when they are not, they may often actively generate postural responses to "right" themselves. These responses, invoked to bring the COG to midline, then result in movement away from the midline. The inaccurate perception leads to a self-initiated loss of balance. Functional situations that correlate with this test condition include public transportation, grocery and library aisles, and moving walkways.

The SOT is valid and reliable in the absence of motoric problems, which increase sway for reasons unrelated to sensory reception and perception. Normative data are available.

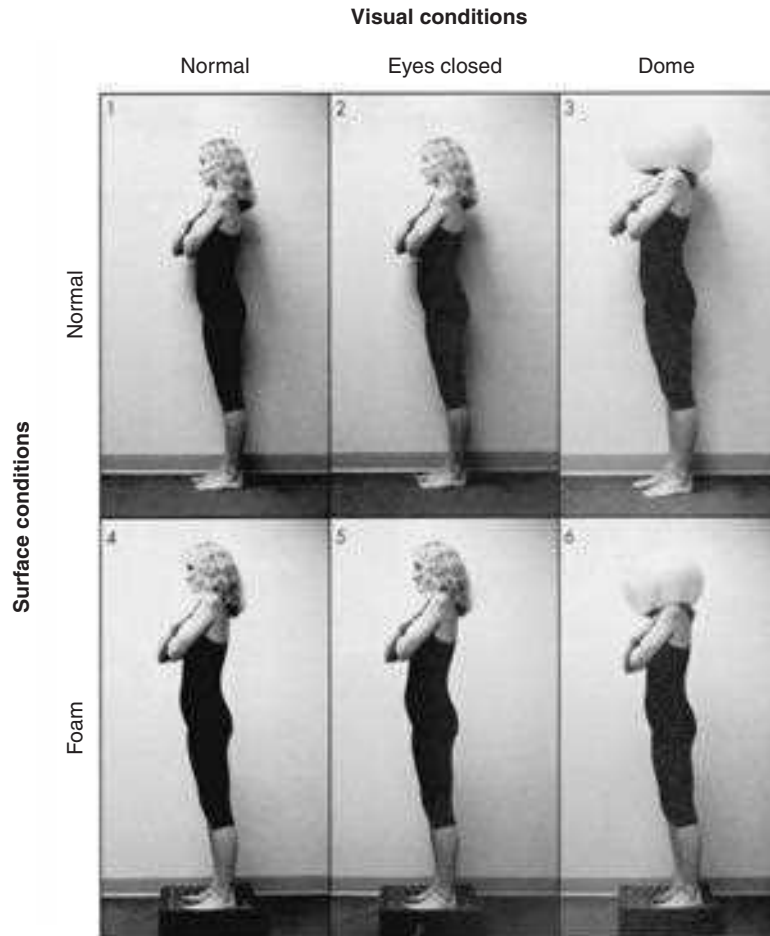

Fig. 20.13 The clinical test of sensory interactions on balance uses foam and a Japanese lantern to replicate the six sensory conditions. A stopwatch is used to time trials.

The Clinical Test of Sensory Interaction on Balance (CTSIB) is a clinical version of the SOT that does not use computerized force-plate technology.⁷³ The concept of the six conditions remains intact (Fig. 20.13). Instead of sway measures, the examiner uses a stopwatch and visual observation. A thick foam pad substitutes for the moving forceplate during conditions four, five, and six. In normal individuals and patients with peripheral vestibular lesions, measures with foam correlate to moving forceplate measures.⁷⁴ Originally, a modified Japanese lantern substituted for the moving visual surround in conditions three and six. Studies have not shown that measures using the Japanese lantern correlate with the moving visual surround measures. Most clinicians now perform the modified CTSIB with just four conditions, eyes open and closed on a firm surface and eyes open and closed on the foam surface. The patient is asked to stand with feet parallel and arms at the sides or hands on the hips. At least three and up to five 30-second trials of each condition are performed.²⁰ The watch is stopped if the patient steps, reaches, or falls during the 30 seconds. If the patient is very steady for 30 seconds on the first trial of a condition, some clinicians choose not to test the remaining trials in that condition and will give the patient a full score for that condition. A maximum score for five trials of each condition is 150 seconds. Individuals with normal movement abilities are able to stand without stepping, reaching, or exhibiting loss of balance for 30 seconds per trial per condition. It is normal for sway to increase slightly as the conditions increase

in difficulty. The CTSIB may not be a reliable measure in patients with hemiplegia or other conditions that involve motor deficits in, or abnormal response time through, the lower extremities and trunk.⁷⁵ The clinician can use the information regarding patient response in a variety of environmental conditions to determine intervention management strategies.⁷⁶

Vestibular System Tests

Please refer to Chapter 21 for a thorough presentation of vestibular disorders and their management.

Active Transitions and Stepping

The ability to change the base of support without balance loss and then to reestablish COG stability over the new base of support is a balance-dependent skill critical for functional activities. The 5-Times Sit-to-Stand Test (5XSTS) and the 30-second Chair Stand Test (CST) are both quantifiable measures of the sit-to-stand skill often used to screen for leg weakness.^{77,78} For both tests, the patient sits with arms crossed over chest in a stabilized standard height chair without arms. The starting position is seated slightly forward so that the patient is not resting against the back of the chair, with the feet underneath and slightly behind the knees. In the 5XSTS the patient is asked to stand up (all the way up to an erect stance) and sit all the way back down (weight transferred from feet to buttocks) 5 times; the clinician uses a

Fig. 20.14 The Floor Grid for the Timed 4-Square Step Test. Arrows indicate the direction of the steps. (From Dite W, Temple VA. A clinical test of stepping and change of direction to identify multiple falling older adults. *Arch Phys Med Rehabil.* 2002;83:1568.)

stopwatch to time the performance beginning when the clinician says “Go” and ending when the patient is fully seated the fifth time. In the CST the instructions to the patient and their performance of full sit-to-stand motions are the same, but the clinician counts the number of times the patient can perform the motion in a 30-second timeframe. Rests are permitted but the timer continues to run, so rests should only be taken if needed. The longer duration of this test requires muscle endurance in addition to strength. Normative data and cutoff points for fall risk screening are available for both tests.

The 4-Square Step Test is a timed stepping test in a standardized, structured format in forward, backward, and lateral directions (Fig. 20.14).⁴⁰ A simple plus sign-shaped grid is laid out on the floor using four straight canes, dowel rods, or lengths of plastic piping. This creates four quadrants. The patient begins standing in the rear-left quadrant, steps forward over the first bar to stand with both feet in the front-left quadrant, steps rightward over the second bar to stand with both feet in the right-front quadrant, steps backward over the third bar to stand with both feet in the right-rear quadrant, steps leftward over the fourth bar to stand with both feet in the left-rear quadrant (starting location). The patient then reverses direction, going back through each quadrant in the same way until standing again with both feet in the rear-left quadrant. The outcome measure is the time it takes the patient to perform this task correctly, clearing each bar completely with each foot. This test has been used with older adults, individuals with vestibular disorders, and with patients post-stroke.^{79,80}

Functional Scales

A comprehensive balance evaluation must include impairment-based tests of body systems, tests of balance skills, and activity-based functional measures. Functional scales help identify the activity limitations. By asking the patient to perform functional tasks that demand balance skills, the clinician can determine the presence of activity limitations that will affect the individual’s ability to participate in life and identify

the tasks that the patient needs to practice. Three mobility scales and three gait scales focus on postural control; five of these were developed for the elderly population to determine risk of falls. Many clinicians are also using them to assess patients with neurological conditions, although their usefulness with neurological populations is less well-documented. Far fewer standardized tests for high-level balance skills have been developed; some clinicians adapt tests used by athletes, but these are often too difficult for many neurologically involved patients.

The BBS consists of 14 tasks that the patient is asked to perform.⁸¹ The examiner rates the patient on each task by using an ordinal rating scale of 0 to 4, in which 0 is unable to perform and 4 is able to perform without difficulty. This test is highly reliable. It was originally designed for assessing risk of falls in older adults, and cutoff scores for fall risk vary depending on which of several studies is consulted.^{82,83} Use of higher cutoff scores may erroneously identify nonfallers as fallers; use of lower cutoff scores may erroneously identify fallers as nonfallers. The BBS has also been used with patients after stroke.^{84–87}

The original Get-Up-and-Go Test is made up of seven items and subjectively scored on an ordinal rating scale of 1 to 5, in which 1 is normal and 5 is severely abnormal.⁸⁸ This test has been modified by making it a timed measure to increase its objectivity and reliability, which is now high. The TUG test eliminates the “standing steady” segment and uses a stopwatch to time the performance.⁸⁹ Patients are asked to rise from a chair with arms, walk 3 meters as fast as they safely can, turn, walk back to the chair, and sit down. This test may be performed with an assistive device; however, the use of a device will alter the speed at which the task can be accomplished, and any retesting must be done with the same device to produce comparable results. Originally designed to assess frailty in older adults, the test is now more commonly used to assess fall risk in this population. Young adults typically perform this task in 5 to 7 seconds, healthy older adults in 7 to 9 seconds (low-risk), moderate-risk older adults in 10 to 12 seconds, and high-risk older adults in 13 seconds or more.^{90,91} These cutoff scores are for older adults walking without assistive devices. Improvements in test performance that are not captured by the time score alone should also be documented; for example, if the patient can now perform the test without the use of chair arms to stand up, or without an assistive device.

The Tinetti Performance-Oriented Mobility Assessment—Balance subscale (POMA-Balance) is a list of nine items scored on scales of either 0 to 1 or 0 to 2, with the higher numbers reflecting better (more normal) performance.⁹² The score value is specific to the item. The best possible score is 16, with a score of 10 or lower indicating a high risk of falls.⁹³ This test is appropriate for onetime use, for example at a health fair, but is not ideal for documenting progress over time due to the limited scoring range.

Most balance and mobility scales have been developed to assess risk of falls in older adults. Many share similar items. See Table 20.2 for a summary of scale items.

The Tinetti Performance-Oriented Mobility Assessment—Gait subscale (POMA-Gait) is a list of seven normal aspects of gait that are observed by the examiner as the patient walks at a self-selected pace and then at a rapid but safe pace.⁹² Scoring scales are again either 0 to 1 or 0 to 2, and higher numbers indicate better performance. Score values are specific to the item being observed (Table 20.3). The best possible score is a 12; scores of 8 or below indicate a high risk of falls. When combined, the Tinetti POMA balance and gait scales offer a best possible score of 28, with scores of 19 or less indicating a high fall risk. Again, if the clinician will need to document change over time, the scoring range of this test renders it less able to detect that change.

^aDuring gait.

^bItems that were retained for the Modified GARS. ROM, Range of motion.

The original Gait Abnormality Rating Scale (GARS) is a list of 16 abnormal aspects of gait observed by the examiner as the patient walks at a self-selected pace (see Table 20.3).⁹⁴ These abnormalities are commonly seen in older adults who fall, who are fearful of falling, or both. The items are scored on a scale of 0 to 3, with lower numbers reflecting better (less abnormal) performance. The best possible score is 0. This gait scale provides some relative numerical indication of the quality of gait. A shorter, modified version of this test, the Modified GARS (GARS-M), has been developed. The GARS-M includes nine of the original items plus a gait velocity measure. It provides equivalent sensitivity and takes less time to perform.⁹⁵ These two gait scales were developed to assess risk of falls in older adults.

The Dynamic Gait Index (DGI) is a gait test specifically designed to look at postural control during gait.¹³ It includes eight items requiring changes in gait speed, walking with horizontal and vertical head turning, whole-body turns during gait, stepping over and around obstacles, and stair ascent and descent. The presence of head motion and whole-body turns in this test may help identify patients with potential vestibular dysfunction.

Items on this test were originally scored with a focus on the gait pattern using a 4-point ordinal scale of 0 to 3, with 3 being normal performance and 0 indicating severe impairment. The best possible score on the original test is a 24, and scores of less than 19 points were associated with impairment of gait and fall risk. The reliability of this test is high.^{83,96,97} The Modified DGI (mDGI) includes the same eight test items, but the scoring system has been changed by the original test developers to better capture multiple aspects of gait performance.⁹⁸

Each item is now scored using a combination of gait pattern, time to complete the task, and level of assistance needed, on the same scale of 0 to 3. The maximum possible score for this test is also 24. The mDGI is a valid, reliable measure in persons with stroke, TBI, vestibular dysfunction, and gait abnormalities.⁹⁹

A modified and slightly more difficult version of this test, the Functional Gait Assessment (FGA), has been developed specifically for use with patients with vestibular disorders.¹⁰⁰ The FGA has 10 items, seven of which are identical to the DGI. The FGA eliminates the “step around obstacles” item and adds three new items, gait with narrow base of support, gait with eyes closed, and backwards walking. The best possible score on the FGA is 30 points, and a score of 22 points or below can be used to classify fall risk and predict unexplained falls in community-dwelling older adults.¹⁰¹ Normative data for community-dwelling older adults is available.¹⁰²

The three gait tests listed previously are distinct from traditional gait tests because they focus on elements of postural control during gait. Two very important traditional gait measures that should be included in the assessment of balance and gait in older adults and patients with neurological disorders are gait speed and distance/endurance. Gait speed has been termed “the sixth vital sign” for older adults because of its strong association with level of dependence in activities of daily living (ADLs) and instrumental ADLs (IADLs), probability of hospitalization, risk of falls, eventual discharge location, and ambulation category.¹⁰³ Reliable and valid measures of gait speed and distance include the Six-meter and Ten-meter Walk tests for speed, and the Two-minute and Six-minute Walk tests for distance and endurance^{104–107}

Patients whose balance and gait deficits negatively affect their ability to manage environmental demands on mobility are considered to have “mobility disability” and are likely to have limited community participation.^{108,109} Eight environmental dimensions that together describe the demands placed on an individual for community mobility include distance, time/speed, ambient conditions (lighting, weather, etc.), physical load (carrying), terrain, attentional demands, postural transitions, and traffic level (density and need to accommodate others). To minimize mobility disability and maximize community participation, clinicians need to assess their patients’ abilities in all of these eight dimensions (and where deficient, intervene to improve patient capacity in those dimensions). Most clinical measures of gait do not capture the level of complexity and challenge found in community mobility activities.¹¹⁰ As yet, no standardized performance measure of these dimensions of community mobility has been developed, however, a self-report measure based on these eight dimensions is available and does correlate with directly observed performance. The Environmental Analysis of Mobility Questionnaire (EAMQ) has 41 questions about “trips away from home” that address how frequently the patient encounters various environmental demands, and how often the patient intentionally avoids those encounters.¹¹¹ Improved scores on the EAMQ may demonstrate increased capacity for community-level participation.

Combination Test Batteries

Because no single test can give a complete picture of a patient’s balance abilities, individual test items are often combined to form a test battery. Several of the tests described earlier, such as the BBS and the Tinetti POMA, include a combination of multiple items and could be categorized as combination test batteries. Different items on a test may challenge different components of the postural control system to permit a more complete assessment of the patient’s balance abilities.

The BESTest is an excellent comprehensive test battery based on the systems model of postural control (see Fig. 20.4).³³ It includes 36 items

grouped into six categories of balance “sub-systems” representing components of postural control: biomechanical constraints; stability limits/verticality; APAs; APRs; sensory orientation; and stability during gait. Within each category are individual test items and, in some cases, existing tests. For example, the sensory orientation category contains the individual item “Stand on incline with eyes closed” and the four-condition CTSIB discussed earlier. Each item is scored on a 0 to 3 scale, with a maximum score of 108. Although the BESTest takes approximately 30 minutes to administer, the information acquired helps to identify which underlying components of the postural control system are causing the observed balance problems. Armed with this critical information, the clinician can design a customized, individualized intervention program that targets the sources of imbalance in each patient.

Two shorter versions of this test have been developed. The Mini-BESTest (see Fig. 20.4)³⁴ includes 14 of the original 36 items in four of the original six categories. It has a compressed rating scale (0 to 2), a maximum score of 28, and takes approximately 15 minutes to administer. It does not include any items from the biomechanical constraints category or the stability limits/verticality category. This does not mean that these components need not be measured, however. Biomechanical constraints such as hip and ankle weakness, and constricted limits of stability, seriously negatively affect balance and should be tested in addition to administration of the Mini-BESTest. The compressed rating scale may reduce the ability of this test to reflect a patient’s progress over time. The Brief-BESTest (see Fig. 20.4)³⁵ includes 6 of the original 36 items, one in each of the original 6 categories. Two of the 6 items are tested bilaterally, for a total of 8 scored items using a 0 to 3 scale, and a maximum score of 24. The Brief-BESTest takes the least time to administer and provides the highest sensitivity for discriminating fallers from nonfallers. Normative data for older adults is available for all three versions of the BESTest.¹¹²

For patients with higher-level balance skills, more challenging test batteries are needed. The Fregly-Graybiel Ataxia Test Battery includes eight test items that the patient must perform (Fig. 20.15).⁴⁸ Standing trials in tandem stance both off and on a rail with eyes open and closed are timed. Timed single-leg stance trials also are performed for each leg. Walking 10 steps with eyes closed is included. Five trials of each task are given. Trials are stopped if the patient uncrosses the arms, opens the eyes (during eyes-closed trials), steps (during standing trials), or falls. Trials are judged on a pass-fail basis. This test battery is valid for use with patients who have peripheral vestibular dysfunction. Normative data are available from a normative database composed primarily of findings in young men. As noted earlier, patients must be at a high level motorically to perform these tasks. This test is a good choice for patients with higher-level abilities because it does provide more demanding balance tasks. Interpretations regarding a patient’s use of sensory inputs when motor involvement is also present cannot be made with certainty.

The High-Level Mobility Assessment Tool¹¹³ (Hi-MAT) is a balance-challenging mobility measure that was designed to quantify mobility outcomes after TBI. It includes a total of 11 items, 9 are timed (walk, walk backwards, walk on toes, walk over obstacle, run, skip, hop on affected leg, ascend/descend stairs), and 2 are distance measures (bound on affected leg/unaffected leg). Each of these interval measures is converted to an ordinal scale score (0 to 4 or 1 to 5 depending on item), and these are added together to obtain a total score. The maximum possible score is 54. For many young patients, tests designed for older adults are much too easy; this test was designed for young adults and is challenging.

The Community Balance and Mobility Scale¹¹⁴ is likewise a balance-challenging mobility scale designed for young adults post-TBI. Despite the title, the test is performed in a clinical setting. It contains 13 items,

FREGLY TEST

Condition	Trials				
	1	2	3	4	5
1. Sharpened Romberg, EC (60 s; feet in tandem)					
2. Walk on Rail, EO (5 steps; best 3/5 trials)					
3. Stand on Rail, EO (3 trials; 60 s/trial)					
4. Stand on Rail, EC (3 trials; 60 s/trial)				x	x
5. Stand on Right Leg, on Floor, EC (5 trials; 30 s/trial)				x	x
6. Stand on Left Leg, on Floor, EC (5 trials; 30 s/trial)					
7. Walk on Floor, EC (3 trials; 10 steps each)				x	x
8. Stand sideways on rail (characterize sway) ⁹					

⁹Added by the author to observe the movement strategy used by the individual.
EO, eyes open; EC, eyes closed.

Fig. 20.15 A combination of tasks (Romberg test, one-legged stance test, walking) and environments (eyes open, eyes closed, rail) are included in the Fregly-Graybiel Ataxia Test Battery. (From Newton R. Review of tests of standing balance abilities. *Brain Inj.* 1989;3:335.)

6 of which are assessed on or to both right and left sides. These items are unilateral stance, tandem stance, tandem pivot, lateral foot scooting, hopping, crouch walking, lateral dodging, waking and looking, walk-look-and-carry, run with controlled stop, forward-to-backward walking, descend stairs, and step-ups. A majority of items are graded using both movement performance quality combined with either time, distance, or quantity. Each item is scored on an ordinal scale of 0 to 5, and the maximum score is 96.

The Fugl-Meyer Sensorimotor Assessment of Balance Performance is a subset of the Fugl-Meyer Physical Performance Battery, which was designed for use with hemiplegic patients (Fig. 22.16).²⁰ Three sitting and four standing balance activities are listed. The items are scored on a 0 to 2 scale, with score values specific to each item. Higher scores indicate better performance; the maximum (best) score is 14. However, a patient could achieve this score of 14 and still not have normal balance.

Dual-Task Tests

In everyday life tasks, normal balance is largely unconscious and does not compete for attentional resources. In patients with balance disorders, however, the challenge of maintaining postural control during upright activities and gait is often sufficient to demand the use of attentional resources. The interaction of cognitive demands and postural control demands is examined in dual-task tests that add concurrent cognitive and motor tasks to gait tasks. At the simplest level are the walking while talking (WWT) and stops walking when talking (SWWT) tests.^{115–118} In these tests the patient is asked to walk and while the patient is walking, the clinician asks the patient one or more questions and observes if the patient must stop walking to answer the question(s). If so, the test result is positive—that is, the patient must stop attending to the postural control demands of walking to reallocate attention to the cognitive task. These are gross measures, apt to identify only those with more severe attentional balance problems or to misidentify patients who prefer to chat and rest rather than keep walking. A more formalized dual-task test is the Multiple Tasks Test (MTT), which includes eight items involving gait plus other verbal cognitive and motor tasks such as carrying a tray and avoiding obstacles.^{119,120} Two dual-task versions of the TUG have been developed. The TUG-Manual involves performing the TUG while carrying a cup nearly full of water. The TUG-Cognitive involves performing the TUG while subtracting backward from a randomly selected number or spelling words backward.¹²¹ The Walking and Remembering Test (WART)

requires the patient to remember a set of numbers or grocery list items that the tester speaks aloud while the patient walks as quickly as possible while trying not to step off of a narrow path.¹²² Once the walk is completed, the patient must repeat the numbers/items in sequence. For all dual-task tests, performance of each single task is measured separately first. Then the dual-task performance is recorded. The difference for each of the two scores (physical and cognitive performance) between undivided attention and divided attention conditions is calculated. This is calculated as (dual-task score minus single-task score) divided by the single task score, then multiplied by 100 to provide a percentage score termed the “dual-task cost” or “dual-task effect.” This calculation can be done once using the physical single- and dual-task scores (e.g., time in seconds for the TUG), and again using the cognitive single- and dual-task scores (e.g., number of shopping list items recalled for the WART).

Balance Confidence Tests

Reduced participation in functional activities may occur not only because balance impairments impede participation, but also when patients are anxious about falling. Fear of falling may lead individuals to avoid activities that they remain quite capable of doing.¹²³ In turn, prolonged self-restriction of activity leads to the many negative consequences of being sedentary—decreased ROM, weakness, low endurance, and so on—and thus ironically further impairs balance and increases fall risk.^{124,125} As this worsening balance and increased risk is perceived by the patient, further activity restriction occurs, creating a self-perpetuating downward spiral leading to social isolation, anxiety, and depression.^{126,127} It is just as important to address poor balance confidence as it is to address poor balance, for without sufficient balance confidence a patient will not participate in activities even if balance abilities permit him or her to do so. The patient will lose all the gains made in therapy if he or she does not remain active, and he or she will not be active if fearful of falling. Evidence-based group programs like “Stepping On” and “A Matter of Balance” are designed to educate and empower older adults^{128,129}; participation in these programs decreases the fear of falling and increases willingness to engage in balance-challenging exercise programs like “Otago,” “Tai Chi Moving for Better Balance,” or “FallProof.”^{130–132}

The two most commonly used measures of balance confidence are the Activities-specific Balance Confidence Scale (ABC Scale) and the Falls Efficacy Scale (FES) or Falls Efficacy Scale—International (FES-I).^{133,134,135} Both are questionnaires that are easy to administer.

FUGL-MEYER

Test	Scoring	Maximum Possible Score	Attained Score
1. Sit without support _____	0—Cannot maintain sitting without support 1—Can sit unsupported less than 5 min 2—Can sit longer than 5 min		
2. Parachute reaction, non-affected side _____	0—Does not abduct shoulder or extend elbow 1—Impaired reaction 2—Normal reaction		
3. Parachute reaction, affected side _____	Scoring is the same as for test 2.		
4. Stand with support _____	0—Cannot stand 1—Stands with maximum support 2—Stands with minimum support for 1 min		
5. Stand without support _____	0—Cannot stand without support 1—Stands less than 1 min or sways 2—Stands with good balance more than 1 min		
6. Stand on unaffected side _____	0—Cannot be maintained longer than 1–2 s 1—Stands balanced 4–9 s 2—Stands balanced more than 10 s		
7. Stand on affected side _____	Scoring is the same as for test 6.		
		Maximum Balance Score	/14

Fig. 20.16 The Fugl-Meyer sensorimotor assessment of balance performance includes both low-level and high-level tasks. (From DiFabio RP, Badke MB. Relationship of sensory organization to balance function in patients with hemiplegia. *Phys Ther.* 1990;70:20.)

The ABC Scale consists of 16 items that range in difficulty from “walk around the house” to “walk outside on icy sidewalks.” Several of the items inquire about activities in public places, for example, parking lots and escalators. Patients are asked how confident they are that they could do each of the activities without losing their balance or becoming unsteady. Responses are given on a scale from 0 to 100 in increments of 10, with higher numbers indicating higher confidence. More recently a short version, the ABC-6, has been developed. It has 6 of the original 16 items and takes less time to administer yet retains good reliability and correlation with balance and fall risk measures.¹³⁶ The FES consists of 10 activity items that are less difficult than the items on the ABC Scale. Items on the FES include getting in and out of a chair and answering the door or a phone. All of the items refer to activities done in the home. Patients are asked how confident they are that they could do each of the activities without falling. Responses are given on a scale from 1 to 10, with lower numbers indicating higher confidence. The Modified FES (MFES) has 14 activity items and includes 2 activities done outside the home and 3 activities done in public spaces. It also takes into account whether or not an assistive device is used.¹³⁷ Scoring is identical to that of the original FES. The FES-I is a 16 activity-item questionnaire that includes 7 of the original 10 items from the FES and adds 9 more difficult items, 2 household and 7 community-based. Responses are given on a scale from 1 to 4, with lower numbers indicating higher confidence. There is also a Short FES-I with 7 items using the identical scoring system.¹³⁸

A third measure of fear of falling is the Survey of Activities and Fear of Falling in the Elderly (SAFFE).¹³⁹ This measurement instrument is more involved than the ABC Scale or FES-I; however, it provides additional information specific to activity restriction that is valuable to the clinician. The SAFFE has 11 activity items that are similar in nature to the items on the other 2 scales, including community activities. This questionnaire asks if the patient actually does the

activity or not. If he or she does the activity, the questionnaire asks how worried the patient is that he or she might fall during the activity, on a scale from 1 to 4. Lower numbers indicate increased worry. If the patient does not do the activity, the patient is asked whether the reason he or she does not do the activity is fear of falling, with degree of fear scored on the scale from 1 to 4, or whether the patient does not do the activity for reasons other than fear, and what those other reasons are. For each item, patients also indicate whether the frequency of doing the activity has increased, decreased, or remained the same. The SAFFE takes longer to administer than the ABC Scale or FES/MFES/FES-I/S-FES-I but provides explicit results about activity restriction not obtained from the other two scales. Improvement on this measure captures both reduction in fear and increase in participation.

The Fear of Falling Avoidance Behavior Questionnaire (FFABQ) is a recently developed instrument with a focus on activity avoidance versus fear.¹⁴⁰ It lists 14 different activities, ranging in difficulty from walking and preparing meals to going up and down stairs to engaging in recreational activities such as sports or traveling. Patients rate whether or not they agree with a statement that they avoid a specified activity on a 5-point scale from 0 (completely disagree) to 4 (completely agree). This questionnaire is reliable with scores that discriminate between previous fallers and nonfallers, and more versus less active individuals. The shift from an emphasis on fear or confidence as in the ABC and FES, to activity avoidance as in the SAFFE and FFABQ is an important and positive one for PTs and OTs. As the ICF health and disablement model describes, the goals are to increase activity and participation to achieve an improved quality of life for patients.

Tests Recommended by Expert Consensus or Systematic Review for Specific Populations

The sheer number of available balance tests has on one hand made it much easier for clinicians to use standardized measures with good

to excellent psychometric properties, while on the other hand has resulted in a lack of standardization between clinical institutions and research sites. Consequently, though individual patient documentation may have improved, the ability to compare clinical outcomes and research findings has become more complicated. In response the American Physical Therapy Association Section on Research formed the Evaluation Database to Guide Effectiveness (EDGE) Task Force to produce recommended outcome measures including but not limited to balance. Subsequently the Academies of Neurologic Physical Therapy and Geriatric Physical Therapy (ANPT and AGPT, respectively) have convened clinician groups with shared expertise in various patient populations to produce recommendations about which outcome measures are best and ought to be used most consistently. See [Table 20.4](#) to locate recommended balance tests for

neurological patients with stroke, PD, TBI, MS, and community-dwelling older adults undergoing fall-risk screening.

Considerations in the Selection of Balance Tests

To determine the type and level of challenge of the tests to be used during the examination, a thorough subjective history is critical. In describing the symptoms and the situations that cause imbalance or falls, the patient offers clues to possible deficits and thereby the measures that will help identify them.

Many of the functional balance scales previously reviewed were designed to determine whether balance is abnormal in elderly patients who have no medical diagnosis (i.e., as screening tools). Clinicians working with clearly diagnosed patients with neurological conditions often do not need such tools to establish that balance skills are

abnormal because the deficits are patently obvious. These screening tools can be useful, however, to identify disabilities, establish a baseline, monitor progress, and document outcomes.

Many clinical facilities have their own therapy evaluation forms that include a section on balance. Items and scoring are usually defined by the facility. They are not standardized across sites, as are published scales, and are rarely tested for measurement qualities such as validity and reliability. As rehabilitation professions evolve toward evidence-based practice, nonstandardized tests with unknown measurement quality are no longer acceptable. Clinicians should use standardized, objective, quantifiable, valid tests with high reliability, sensitivity, and specificity whenever possible. If a test will be used to document progress following intervention, it also needs to be responsive to change over time. A functional balance rating scale is important in the evaluation of patients with neurological impairment. To be responsive enough to measure changes in patients who clearly are not (and may never be) clinically normal, ordinal scales should have at least five, and perhaps seven, possible relative scores.

Following functional balance testing, additional impairment tests are necessary to assess the systems that may affect postural control to help identify and measure impairments (e.g., ROM, strength, sensation and sensory organization, motor planning and control). These types of measures should be sensitive, objective, and quantifiable. Unfortunately, some body system components do not have objective, quantifiable clinical measures (e.g., motor planning, coordination). In these cases, clinicians must continue to use subjective rating scales.

Other factors to include when deciding what tests to use are the time required to perform the test, the number of staff members who must be present, and the space and equipment needed. Clinicians must weigh the potential benefits of technological tools (e.g., computerized forceplates, accelerometers, isokinetics, motion analysis, electromyography) against their cost and practicality (i.e., their cost-effectiveness). The test must be suitable for the patient's level of functioning (physical

and cognitive). Many head-injured patients, for example, cannot initially participate in traditional forms of testing because of cognitive limitations.

PROBLEM IDENTIFICATION, GOAL SETTING, AND TREATMENT PLANNING

Clinical Decision Making

Treatment of patients with neurological diagnoses is based on the particular set of impairments, skill deficits, and activity limitations possessed by each individual. Remediation of balance skill deficits similarly must be specific to the involved body systems and functional activity losses in each patient. Clinicians should generate an overall problem list for each patient; if imbalance is a listed problem, then a sublist of balance problems also can be developed (Fig. 20.17).

To direct and establish priorities for treatment, clinicians must review the problem list and ask themselves the following questions (Fig. 20.18): Which impairments are temporary and can be remediated? How much improvement can be expected? How soon will it occur? Which impairments are permanent or progressive and must be compensated for? What other body systems can be counted on to substitute? What external compensations may be needed?

For some patients with neurological impairments, knowing whether a problem is permanent or temporary is not possible, as in recovery from a stroke or head injury. In others with progressive diseases such as Parkinson disease or MS, the rate of decline is unknown and abilities may fluctuate. In these cases the clinician should consider the following issues: Would a consultation provide the required information? If so, referral is appropriate. Do any contraindications to treatment exist? What are the risks and benefits of providing versus withholding treatment? Is some amount of functional improvement possible? If no contraindications are present, the benefits outweigh the risks, and

EXAMPLE OF BALANCE PROBLEM LIST

General Problem List	Balance Problem List
1. Decreased strength (L) side	
2. Decreased ROM (L) shoulder	
3. Decreased endurance	
4. Impaired sensation (L) side	
5. Decreased balance:	<ul style="list-style-type: none"> a. Decreased weight bearing on left (L) LE b. Unable to maintain midline orientation c. Extraneous sway with eyes closed d. Unable to stand on (L) LE e. Decreased limits of stability to 40/100% f. Unable to shift to (L) side g. Unable to establish stable base of support h. Unable to stand on unstable surface i. Unable to perform hip strategy
6. Increased tone (L) side	
7. Synergistic movement (L) side	
8. Min. assist transfers	
9. Mod. assist ambulation	

Fig. 20.17 An example of a balance-specific problem list (as a subset of a general problem list), which should be developed to guide balance rehabilitation treatments.

functional improvement is expected, then a trial of treatment may be given, even if knowing for certain whether the problem(s) will respond to the treatment is not possible. In these cases especially, a baseline must be established against which to measure any change. Change for the worse or no change after a reasonable trial period indicates that treatment should be altered or discontinued.

Using the Systems Model to Identify Postural Control Impairments

The systems approach is useful to develop a balance problem list because it can be applied to different diagnoses equally well and allows deficits in multiple systems to be recognized. Table 20.5 illustrates several examples of ways this framework is used to identify balance deficits in patients with different neurological diagnoses.

For each patient, problems affecting postural control should be described in objective, measurable terms whenever possible. For example, the term “impaired vision” is too vague; “four-line drop on eye chart” is more specific. “Poor use of visual inputs for balance control” is an interpretation; the objective result could be stated “Loss of balance after less than 15 seconds on 5/5 trials of standing on foam, eyes open.” Documenting problems in this manner makes goal writing (and subsequent treatment planning) much easier.

Writing Goals on the Basis of Body Structure and Function Impairments, Balance Skill Deficits, and Activity Limitations

Goals also should be stated in objective and measurable terms so that their achievement can be judged. “Improved balance” is open to any interpretation, whereas “able to stand on right leg for 30 seconds on 3/3 trials” and “walks tandem entire length of balance beam without misstep 7/10 times” are measurable goals. These types of goals may be helpful to the clinician who understands the link between

TABLE 20.5 Examples of Medical Diagnoses and Related Impairments Affecting Balance

Impairments From Systems Model	Diabetic Patient With Stroke	Older Patient With Parkinson Disease	Patient With Incomplete Paraplegia
Peripheral Sensory			
Vision	Retinopathy	Cataracts	
Vestibular		Hair cell loss	
Somatosensory	Peripheral neuropathy	Slowed transmission time	Complete loss below level of lesion
Central Sensory			
Vision	Hemianopia	Vision dominant	Needs superior use to compensate
Vestibular	Failure to use inputs		Needs superior use to compensate
Somatosensory	Failure to use inputs	Failure to use inputs; unaware of posture and small movements	
Strategy selection	Step dominant	Ankle dominant	Hip dominant
Perception of position in space	Midline shift with left neglect	Flexed posture; restricted limits of stability	Cannot detect relationship of body to feet/surface
Central Motor			
Timing	Increased reaction time	Bradykinesia	
Sequencing	Disordered	Co-contraction	
Force modulation	Spasticity, hypertonus, weakness	Hypokinesia, rigidity	Flaccid paralysis below level of lesion
Error correction	Use right side only	Loss of automaticity; must use intentional cortical attention	Relearning abilities and limitations of “new” body
Peripheral Motor			
Range of motion	Knee hyperextension	Bilateral ankle plantar flexor contractures	Hip flexion contractures
Strength	Decreased left side	Decreased bilateral extremities and trunk	Paralysis bilateral lower extremities and trunk
Endurance	Severely impaired	Moderately impaired	Mildly impaired

impairments, skill deficits, and functional activity limitations, but they may seem nonfunctional (and therefore unnecessary) to others who read them (e.g., case managers, third-party payers). From their standpoint, incorporating the functional task that will be positively affected by its achievement into the impairment goal is beneficial; for example, “able to stand on right leg for 10 seconds at a time so that stairs can be ascended and descended step-over-step without railing,” or “walks tandem on balance beam to demonstrate ability to avoid falls using hip strategy.” By describing the specific system problem (e.g., muscle power, joint range) or skill deficit (e.g., “unable to stand in on one leg”) as it relates to function in the treatment objectives, clinicians force themselves to focus on functional outcomes and illustrate for others reading the documentation why these goals are meaningful. The need for and validity of the intervention are then more likely to be clearly perceived. At times, goal documentation requirements may specify that the goals be purely functional in nature. Writing goals without impairment components may meet the needs of the reviewer, but they will not help to direct clinical interventions to the specific components that need to be addressed in each individual patient. Documentation must meet reviewer requirements, but for one’s own benefit, writing a separate set of goals with the dual impairment-function or skill deficit-function components will assist the clinician with planning and prioritizing treatment.

If a problem cannot be alleviated and requires compensation, the goal(s) should reflect this as well. For example, a patient with diabetes has progressive peripheral neuropathy with somatosensory loss and ineffective ankle strategy. If the patient’s visual and vestibular sensory systems and proximal strength are relatively intact, however, then the goals might mention improved use of visual cues and successful substitution of hip and stepping strategies. Educational and environmental modification goals for safety also are appropriate in these situations.

Developing an Intervention Plan

Once the goals have been listed and priorities established, the intervention plan is developed. The most effective and efficient treatments focus first on those problems with the greatest impact on function and address more than one problem at a time. Teaching balance skills on an unstable surface contributes to the use of visual and vestibular inputs as well as to the use of hip strategy, increased lower-extremity

strength, and increased motor control (skill) on that type of surface. Gait training on an inclined treadmill with eyes closed or head movement increases the use of somatosensory and vestibular inputs, endurance, postural control, ROM, and lower-extremity strength. Creative clinicians develop comprehensive intervention plans with this type of multiple-problem approach to maximize the time available with patients.

The clinician must thoughtfully choose environments and tasks that together stimulate and challenge the appropriate postural control systems. To stimulate one sensory system, the other systems must be placed at a disadvantage to force reliance on the targeted system. The environment is then structured to put the other systems at a disadvantage (e.g., training with eyes closed or in the dark puts vision at a disadvantage and forces the use of somatosensory and vestibular inputs). If one side or limb is significantly more affected, such as in hemiplegia, then the other side must be disadvantaged to force reliance on the targeted side. Tasks are then selected to disadvantage the less affected side. For example, placing the less affected leg on a step or small ball makes it more difficult to use for balance and forces the transference of weight to the more affected leg. To achieve optimal function, however, all systems and all sides must be capable of working together, so *treatment* to improve postural control system impairments and *teaching* to improve balance skill deficits must be incorporated and interspersed with *training* functional tasks. For effective teaching of balance skills that results in carryover of improvements into real-life situations, training tasks should be varied enough to promote motor problem solving on the part of the patient.¹⁴¹ For example, sitting balance and transfers should be taught using stable and unstable surfaces, with different heights and levels of firmness, with and without armrests and back supports, and using both right and left sides. This technique may improve the patient’s abilities to perform safe sitting and transfers in new situations not previously practiced in therapy.²⁶

Tables 20.6 and 20.7 illustrate the process of test choice, problem identification based on test results, goal setting based on impairments and disabilities, and treatment planning based on goals in three different types of patients. Note that only selected tests were performed for each patient. Goals were directly related to the problems that were identified by the tests, and treatment plans followed directly from the goals.

TABLE 20.6 Example of How Treatment Planning Flows From Test Results in an Older Adult Patient With Frequent Falls

<i>Patient profile:</i> 72-year-old woman <i>Diagnosis:</i> Disequilibrium of aging, frequent falls <i>Course of examination and treatment:</i> Cardiologist → neurologist → outpatient physical therapy			
Test	Problems Identified	Goals Set	Treatment Plan
Peripheral sensory	Mildly decreased vibration sense bilateral lower extremity	Compensate for permanent sensory loss	Educate about safe surfaces and lighting
Somatosensory			Home safety evaluation
Vision	Acuity, cataracts Depth perception		
SOT	Absent use of vestibular inputs 0/Decreased use of somatosensory inputs 60/Dependent on vision	Increase use of vestibular inputs to 30/increase use of somatosensory inputs to 75/100	Somatosensory and vestibular stimulation ^a
Static postural sway	Excessive sway—2 standard deviations outside normal range for age	Standing sway within normal limits for age	COG control training
Nudge or push test	No use of ankle or hip strategy Steps immediately	Survives 5/10 pushes with hip strategy	Hip strategy exercises ^a

BALANCE RETRAINING TECHNIQUES

Motor Learning Concepts

Although covering the principles of motor learning is not within the scope of this chapter, the discussion of balance retraining methods is not possible without some consideration of several motor learning concepts that must be incorporated into treatment. The clinician must remember that successful treatments address the interaction of the individual, the task, and the environment (Fig. 20.19).^{13,26}

Individual

Therapists should know their patients' impairments: sensory and motor, peripheral, and central. Whenever possible, therapists should know which impairments can be rehabilitated and which require compensation or substitution. Because of the nature of neurological insult, this includes an awareness of cognitive and perceptual impairments that may affect the ability to relearn old skills or develop new ones.

Fig. 20.19 Interactions of the individual, the environment, and the task are critical to postural control skills. Although they may be isolated in the mind of the clinician for assessment purposes, they are never isolated in the function of the patient.

Optimal learning of skilled movement requires that the patient have (1) knowledge of self (abilities and limitations), (2) knowledge of the environment (opportunities and risks), (3) knowledge of the task (critical components), (4) the ability to use those knowledge sets to solve motor problems, and (5) the ability to modify and adapt movements as the task and environment change. To the extent that a patient is missing these characteristics, the clinician should attempt to support his or her development or even supply them until they are present. Different types of patients vary with regard to which characteristics are likely to be missing. For example, a cognitively impaired, head-injured patient may lack awareness of self and environment, even though his or her physical abilities make modifying and adapting movements possible. Conversely, a quadriplegic patient may be aware of his or her limitations, the environment, and the task demands but may initially have limited experience to know how to solve a motor problem and limited physical ability to modify movements.

The clinician must also ask what motor learning stage the patient is in for different skills needed to successfully perform tasks. Skill acquisition is the first stage. The objective is for the patient to “get the idea of the movement” to begin to acquire the skill.¹⁴² In this stage, errors are frequent and performance is inefficient and inconsistent. Within the nervous system only temporary changes are occurring. Skill refinement is the second stage. The goal is for the patient to improve the performance, reduce the number and size of the errors, and increase the consistency and efficiency of the movements. Skill retention is the final stage. The ability to perform the movements and achieve the functional goal has been accomplished, and the new objective is to retain the skill over time and transfer the skill to different settings. Retention and transfer are the hallmarks of true learning, in which some relatively permanent changes have occurred within the nervous system. A patient may have attained the skill retention phase for sitting balance tasks, be in the skill refinement stage for standing balance tasks, and be in the skill acquisition stage for locomotor balance tasks.

Therapists use practice and feedback to teach motor skills. Repetition is necessary to develop skill; feedback is necessary to detect and correct errors. During skill acquisition, frequent repetition of a movement or task and frequent feedback are beneficial to help the patient begin to be able to perform the desired movements and tasks. As soon as the patient progresses to the skill refinement stage (the clinician observes reduced errors and less variable performance), however, then practice should be varied and feedback briefly delayed. For example, the task of standing and reaching to one side to take an object from the therapist might initially be repeated to the same side and at the same height several times. Then the therapist should begin to vary the task demands gradually: reach farther or faster; take different objects of various weights, shapes, and sizes; and take the object from higher and lower heights and alternately reach to right and left sides. This variation introduces a problem-solving demand for the patient: modifications in timing, force, and sequencing are now necessary.

Feedback, which is especially helpful for those with sensory reception or perception problems, initially may contain information to assist the patient in detecting errors about the goal achievement (knowledge of results, such as “you stood up five times without using your hands”) or about a movement error (knowledge of performance, “you did not straighten your knee enough last time”).¹⁴³ Early feedback also may contain cues about what to do better next time, such as “straighten your knee before you shift weight onto that leg.” If feedback is always provided by an external source, such as the therapist, a mirror, or a computer monitor, then the patient is not given the opportunity to develop internal error detection and error correction mechanisms and will not be as likely to retain or transfer the skill. By delaying the feedback and asking the patient to estimate or describe her or his own errors, and afterward providing the feedback, the therapist allows the patient to compare her or his own developing internal frame of reference with the correct external frame of reference. By asking patients to suggest what might be done to correct the errors, the therapist shifts the error correction process from the external source to the patients, supporting motor problem-solving processes. As patients progress to the skill retention level, variations should increase (including task and environmental demands) and feedback delays should be longer. The clinician must develop a sense of how to use practice variation and feedback delay therapeutically to progress patients through the stages of motor learning. Too much variation and too little feedback early on impede skill acquisition; insufficient variation and excessive feedback later on hamper skill retention and transfer.

Task

Functional rating scales performed as a part of the evaluation yield information about what tasks, or functional activities, are limited by the postural control system impairments and balance skill deficits. Bed mobility, sitting, sitting to standing, transfers, standing, walking, working, and sports participation may be affected. Repeating the problematic tasks over and over is one approach; however, analyzing the problematic tasks to determine what postural control demands are placed on the patient when undertaking those tasks is far more productive for the clinician. Does a task demand predominantly stability? Mobility? Both? For example, standing to take a photograph demands the ability to hold still; standing to move laundry from the washer to the dryer requires weight shifting; and standing to don a pair of pantyhose calls for both steadiness and movement. All three are standing dual-tasks, but each places different postural control demands on the patient. By using task analysis, the therapist may consciously select or design tasks to place specific demands on the patient such that the postural control systems that need improvement will be challenged to respond, and skills that need to improve will be practiced extensively.

Analysis of mobility tasks includes attention to timing, force, and duration of movements. Consider the different timing demands for weight shifting and reaching to catch an item falling from a shelf, take a hot casserole out of the oven, or open a door. Compare the different amounts of force necessary to pick up a heavy suitcase, pick up a baby from a crib, or replace a ceiling light bulb. The duration of a balance demand may be brief, as in recovering from a trip, or extended, as in walking across an icy parking lot. Clinicians should choose tasks that vary these parameters to prepare patients for activities with various mobility demands. Activities that incorporate changing head positions will further challenge the individual with vestibular insufficiency.

Therapists also need to consider whether the elements of the task are predictable or unpredictable. In other words, will the postural control demand be a voluntary movement (e.g., sweeping the porch), an APR (e.g., missing the last step on a flight of stairs), or an APA (e.g., preceding a lift)? Patients need to learn to respond in all three conditions, which are often combined. For instance, lifting is a voluntary movement. Predicting the load to be lifted leads to anticipatory postural preparation. Counteracting the destabilizing force of a greater-than-predicted load requires an APR. If during therapy the clinician says “don’t let me push you” before nudging the patient, the demand is for APA. If the disturbance is provided without warning, the demand calls for APRs. If the clinician requests a lean to the right, that is a voluntary postural adjustment. Activities that demand all three types of balance control, either one at a time or in combination, should be included in balance retraining programs.

Environment

Just as tasks can be purposefully selected to promote improved postural control, environmental conditions also must be included in the design of the therapy plan to stimulate the necessary systems and challenge the deficient skills. Gravity cannot be manipulated by the clinician, but the patient needs to learn to counteract it at different speeds and from different positions, among other things. Familiarity with how gravity can aid movement, as in walking, is also important. The therapist can vary the surface conditions. They may be stable, even, and predictable (hospital hallway, sidewalk), unstable (boat, subway, gravel driveway), uneven (grass, curbs, stairs), or compliant (beach, padded carpeting). Visual conditions also may be manipulated. Visual cues may be available and accurate (daylight, fluorescent lighting), unavailable (darkness or poor lighting, or lack of environmental cues such as a busy carpet pattern on a stairway), unstable (moving crowd, public transportation), used for purposes other than balance (fixation on a ball in tennis), or dependent on head movements. Clinicians should help prepare their patients to function in the real world by training them to maintain balance under different combinations of surface and visual conditions. This includes situations in which cues from the environment agree—that is, visual, somatosensory, and vestibular inputs are all sending the same message, so to speak—as well as in sensory conflict environments where cues from one system may disagree with cues from the other sensory systems. Functional situations in which sensory conflicts may exist include elevators, escalators, people movers, airplanes, and subways. An emphasis on being able to adapt to changes in environmental conditions rapidly and effectively is important.

Intervention

Successful intervention for the individual with a balance disorder depends on the ability of the *clinician* to identify the components of the problem. The therapist must create a program that addresses several components at a time, not just for efficiency, but because these systems should be able to function together, and multiple skills must

be simultaneously coordinated to perform functional activities in real-world environments. *Treatment* is oriented toward multiple impairments, with tasks and environments selected to best correct involved or facilitate compensatory systems. *Teaching* is focused on critical balance skills, with tasks and environments chosen to develop adaptive sensorimotor problem-solving abilities. *Training* is targeted to the patient's real-life functional activity limitations, with tasks and environments designed to replicate real-life situations as closely as possible.

The intervention must be matched to the level and combination of body system impairments and the degree of skill deficits. For example, tasks related to the different functions of the sensory systems should be identified and not treated as a single body system problem. The clinician should have a good idea of the level of stimulus during each exercise program so that the facilitation is as accurate as possible. Progression of the program follows the changes seen from one session to the next to promote carryover and retention of learning. The exercise progression integrates activities that reflect those changes. This usually involves more complex movement skills and more demanding tasks in a greater range of gradually more challenging environments.

Sensory Systems

In general, the less sensory information available, the more difficult the task of balancing. An intervention progression might therefore start with full sensory inputs (vision, somatosensory, and vestibular: 3/3) available in the environment and perhaps augmented feedback if intrinsic sensory channels are deficient, as with somatosensory loss or a vestibular disorder. Challenge is added by manipulating either visual or somatosensory inputs so that equilibrium must be maintained by using only two of three senses (vision and vestibular or somatosensory and vestibular). If both vision and somatosensory inputs are manipulated, then only the vestibular inputs are a reliable source of sensory information and balance is accomplished with only one of three senses.

Most patients with permanent or progressive vestibular or somatosensory losses naturally compensate and become visually dependent. In cases in which improving the use of somatosensory or vestibular inputs is necessary, the training of vision for stability can be counterproductive, teaching compensation versus improvement of normal function. On the other hand, visual retraining is entirely appropriate for the patient with severely compromised somatosensation that cannot be changed, as is common in persons with diabetes.

To stimulate the use of visual inputs, environments are designed to disadvantage somatosensation while providing reliable visual cues (stable visual field with landmarks). Somatosensation cannot be removed as can vision, but it can be destabilized by having the patient sit or stand on unstable surfaces (rocker board, biomechanical ankle platform system [BAPS] board, randomly moving platforms) or confused by having the patient sit or stand on compliant surfaces that give way to pressure, such as foam, "space boots," or responsively moving platforms.

To stimulate the use of somatosensory inputs, environments are designed to disadvantage vision while providing reliable somatosensory inputs (stable surfaces, level or inclined). Having the patient close the eyes or practice in low lighting or darkness removes or decreases visual inputs. For patients with an overreliance on visual input for balance, the somatosensory system needs to be facilitated while the visual system is disrupted. This can be accomplished by having the patient sit or stand on a stable surface while performing quick head turns. For the patient with self-limited head movement, the intervention may begin with head movement during quiet standing and progress to head movements during weight shifts and then walking. Eyes-closed standing and weight shifting also increase the use of somatosensation for balance. Optokinetic stimuli in the visual surround also stimulate use of somatosensory inputs.

To stimulate the use of vestibular inputs for adaptation of the CNS, environments are designed to disadvantage both vision and somatosensation while providing reliable vestibular cues (detectable head position). Practicing on unstable or compliant surfaces, with vision either absent (eyes closed), destabilized (eye movements or head movements), or confused (e.g., optokinetic stimulation) provides challenging combinations. Adding neck extension and rotation to place the vestibular organs at a disadvantaged angle can increase difficulty. Gaze stabilization with head turns while standing on an uneven surface or while walking creates a higher-level challenge. Quick movements of the head, head tilts, or forward bending trigger vestibular signals to add input to the system. Combining these types of activities can create progressively more complex challenges. Standing or weight shifting on foam with eyes closed, and head and eye movement while walking all require vestibular input for successful performance.

Additional vestibular challenge can be added by including activities that require quick changes of position in a superior or inferior direction, such as a lunge or going up and down stairs. Other exercises involving up-and-down body movements, such as sitting to standing, seated bouncing on a Swiss ball, and standing bouncing on a mini-trampoline, all with eyes closed to eliminate use of vision for stability, increase the demand on the vestibular system. To train the patient who is overreliant on vision to improve the use of vestibular inputs versus vision, activities such as watching a ball being tossed from hand to hand while walking, walking backward, or walking with eye movements can be used. Reading while walking requires the use of vision for reading so that it cannot be used for postural orientation, forcing the other sensory sources to be used for orientation.

Multisensory and Motor Control Dysfunction

Older patients often have dysfunction in all three sensory systems—that is, a multisensory balance disorder. Disease-related disruptions of the somatosensory or visual system (e.g., a peripheral neuropathy or cataracts) are combined with age-related declines in the vestibular system. In some cases therapy aimed at increasing vestibular function can have a significant impact on postural stability. If sensory loss is permanent or progressive, safe function may require the use of an assistive device.¹⁴⁴ Choosing an assistive device for these patients can be a challenge. An individual with cerebellar or visual-perceptual problems may have more difficulty using an assistive device, and thus it may be contraindicated. For these patients, careful assessment of safety and gait both with and without the device is demanded. A single cane often does not allow for compensation for changes in direction of an impending fall, and a standard aluminum walker does not provide support when changing directions because it must be lifted. The ideal walker has four rotating wheels and thus the ability to change direction without being lifted. This device greatly increases stability, and the patient usually describes a significant increase in confidence. Of course, the use of a walker also limits normal use of the upper extremities and trunk during gait and restricts the types of environments that can be negotiated. Making sure the patient stands erect in walking versus leaning forward into a permanent flexed position is important in order to retain and/or improve existing postural function.

Many patients with neurological conditions have temporary difficulty with head control early in their recovery, and others have chronic head control problems. Their ability to orient the vestibular organs, eyes, and neck proprioceptors properly is impaired, which negatively affects the ability to perceive internal and environmental cues that could assist in balance maintenance. Thus developing head control is very important. Patients with spasticity or contractures of the ankles and feet who cannot place their feet in full contact with the floor are at a biomechanical disadvantage and also have difficulty

receiving somatosensory inputs that could support postural control processes. The more accurate and reliable sensory information there is available, the greater the chances that the sensoriperceptual processes that contribute to balance can fulfill their role. Intervention progressions should include attention to increasing the patient's ability to receive and process sensory information pertinent to balance control through oculomotor, head, and peripheral limb positioning and movement.

Control of the Center of Gravity

Effective control of the COG depends on accurate awareness of body position and motion in space and the relation between body parts (perception), as well as biomechanical and musculoskeletal systems (execution). Trunk and head control abilities are primary. For patients with paralysis or degenerative disease that limits the ability of arms and legs to assist with postural stability, head and trunk control may be the dominant means of balance. Both the head and neck and the trunk need to be able to achieve and hold a midline position, rotate around this midline axis, and move away from and return to the midline without loss of balance. The term *midline* here refers not to a line between right and left sides, but to a point at which the right and left and forward and backward components are centered in all planes—medial-lateral, anterior-posterior, rotary, and side bending (shortening and elongation on either side). Midline problems can certainly be caused by body system problems such as weakness, pain, or sensory deficits but can also be caused by perceptual problems (e.g., patients with “pusher syndrome” following stroke).

Sitting balance. In sitting, the pelvis and posterior thighs form the primary base of support, with additional stability provided by the feet in contact with the floor. The axis of anteroposterior movement rotates around the greater trochanter, and forward and backward leans are achieved through pelvic and trunk movement. Anterior pelvic tilt with upper trunk extension allows forward reaching and begins the sitting-to-standing transition. Lateral weight shifts with trunk elongation precede right and left reaching and scooting. Lateral weight shifts with trunk rotation permit cross-midline reaching and begin the sitting-to-supine progression. The use of arms to prop in sitting is an extension of the base of support.

Standing balance. In standing, the feet form the base of support. The axis of anteroposterior movement rotates around the medial malleolus. Mediolateral movement occurs with weight shifts from foot to foot. Weight shifts move the COG through space for reaching and lifting tasks as well as in preparation for stepping. Ankle strategy is most effective for forward and backward movement of the COG through the central range of the limits of stability on a stable surface. As the COG nears the sway boundary, hip strategy works to restrict its travel. If this fails, stepping or reaching strategies are used to reestablish a new base of support.

Balance during gait. During gait, the COG follows a sinusoidal path as forward progression of the body mass combines with alternating lateral weight shifts to the stance foot (Fig. 20.20).²⁵ Each step creates a new base of support. Assistive devices such as canes, walkers, and crutches extend the base of support and thus reduce the demands on the intrinsic balance control system. In sitting, standing, and walking, control of the COG involves the ability to establish a stable base of support and transfer weight over it. Treatment progressions for COG control then involve training to establish, maintain, and reduce the base of support and to produce automatic, anticipatory, and voluntary postural responses to restrict or produce weight shifts.

Early treatment progression for COG control may include “neurodevelopmental sequence activities” (e.g., prone on elbows, all fours, kneeling, right or left side sitting, half-kneeling), not for the purpose of “reflex

Fig. 20.20 The Trajectory of the Center of Gravity (*C of G*) and the Center of Pressure (*C of P*) During a Gait Cycle. *LHC*, Left heel contact; *LTO*, left toe-off; *RHC*, right heel contact; *RTO*, right toe-off. (From Palia AE, Winter DA, Frank JS, et al. Identification of age-related changes in the balance control system. In Duncan P, ed. *Balance: Proceedings of the APTA Forum*. Alexandria, VA: American Physical Therapy Association; 1990.)

development” in the traditional sense but because the task demands are to balance with progressively less surface contact (i.e., shrinking the base of support). Additional benefits include greater control, coordination, and generation of power of the neck, trunk, and axial muscles. It also is useful for simultaneously addressing impairments such as lower extremity extensor tone, trunk weakness and asymmetries, and head and neck extensor weakness. Note, however, that for adults these activities should be considered exercises to remediate impairments and improve skills, not as directly transferable to many adult functional tasks. Functionally, bed mobility and floor-to-stand transfers are related to these progressive position exercises and should be practiced concurrently in low- and high-level patients, respectively.

Sitting balance can be progressed by (1) removing upper-extremity support (hands on firm surface to movable surface [e.g., ball, bolster, rolling stool], one hand free and both hands free); (2) making the seating surface less stable (mat to bed to rocker board to Swiss ball); and (3) removing the use of one foot by crossing the leg, or of both feet by raising the height of the seat so the feet do not touch the floor. Tasks might include multidirectional weight shifts with the hands in contact with a bolster or ball that is pushed or pulled to and fro, reaching or passing objects, performing upper body tasks (grooming, dressing), managing socks and shoes, wheelchair armrests and footrests, and so forth.

Sitting to standing and transfer balance. Transitional movements such as sitting to standing and transfers involve large COG excursions over a stable base of support. For sitting to standing, the base of support must change from the seat to the feet. The feet begin to accept the weight first by downward pressure through the heels as the pelvis rolls anteriorly. The weight moves to the front of the feet as the trunk comes forward and the pelvis lifts from the surface, then backward toward midline as the trunk extends into standing. The COG stays near midline if both legs are participating equally, but it will often deviate to a preferred side during the transition in patients with hemiplegia. Training should include disadvantaging the preferred leg (perhaps by moving it a bit forward) to allow the more affected leg and foot to experience the weight transference. During transfers, a lateral weight shift is required in addition to the partial stand. The COG does not remain near midline; it instead moves forward to load the feet and then laterally toward the side of the transfer. Progression of balance skills in sitting to standing and transfer tasks may involve gradually lowering the height of the surface, removing armrests to preclude upper-extremity assistance, and transferring to surfaces of different heights and levels of firmness. Remember that velocity is a normal part of sitting-to-standing movements because the momentum is used to assist the weight transfer from seat to feet, so the clinician must allow some speed during this task. If the patient is unsteady on arising (cannot dampen or slow the speed in a controlled manner), working gradually from standing to sitting initially may be beneficial before progression to sitting to standing. Practice of sitting to standing with the eyes closed can be an effective way to train patients who are over-dependent on vision for balance. Without the use of vision for stability, integration of vestibular and somatosensory systems can be facilitated.

Standing balance. Standing balance tasks also can begin with finding midline and becoming stable there. Controlled mobility (volitional) should be encouraged as soon as possible, first on a stable surface with slow, small weight shifts. Challenge is added by increasing the distance traveled away from midline, moving toward restricted regions of the limits of stability, altering speed of sway, adding combined upper-extremity activities (e.g., dribbling a basketball, reaching), or adding resistance (manual, flexible bands). Narrowing the base of support (Romberg, tandem, single leg) makes control of the COG more demanding. Placing the feet in a diagonal stride position is more desirable for pre-gait weight shifting than is symmetrical double stance. Attention should be given to the stance (loading) leg with regard to pelvic protraction, hip and knee extension, and ankle dorsiflexion, with the tibia traveling forward over the foot. Focus on the swing (unloading) leg should include pelvic drop with knee flexion as the heel comes up and pressure through the ball of the foot and toes to load the opposite leg maximally. Standing balance exercises can be made more difficult by training on a less stable surface (carpet, foam, rocker board, BAPS board) and by adding combined head and eye movements or closing the eyes. The goals for dynamic sitting and standing balance exercises are to increase the size and symmetry of the limits of stability and improve the ability to transfer weight to different body segments

with control at different speeds and with varied amounts of force. To facilitate somatosensory and vestibular integration, these activities can be performed with decreased or distorted visual cues. Closing the eyes, turning the head quickly, turning the lights down low, or wearing sunglasses may decrease the use of vision for stabilization.

Strategy training. Training ankle, hip, and stepping strategies may begin in a voluntary manner but must progress to an automatic level of use to develop more normal balance and for real-life prevention of balance loss. Before strategy training, the clinician should be sure that the patient has the ability to develop the desired strategies. The observed dominance of other strategies is appropriately compensatory, not dysfunctional, if a missing strategy cannot be effectively executed. Patients use these strategies to prevent loss of balance, so the clinician must take care not to reduce reliance on an effective strategy but to add additional strategies to the repertoire.

Ankle strategy should be practiced on a firm, broad surface. Patients can be asked to sway slowly in anterior-posterior, right-left, and diagonal directions, first to and from midline, progressing to passing midline, and finally progressing to sway toward the periphery without return to midline. Head and pelvis should be traveling in the same direction at the same time. Patients can practice standing near a wall with a table in front of them, swaying forward to touch the table with the stomach (leading with the pelvis) and backward to touch the wall with the back of the head. Cues are given not to “bow” to the table and not to touch the wall with the buttocks. As soon as the patient is able to perform this protocol, functional meaning should be added with maneuvers such as forward or lateral reaching tasks, hands over head to take things off shelves, and leaning backward to rinse hair in the shower. To improve anticipatory and automatic ankle strategy use, add slight perturbations to the body or the surface when midline, progress to gentle perturbation when away from midline, and finally progress from predictable to unpredictable perturbations.

Hip strategy is practiced on either a narrow or an unstable surface, such as standing sideways on a balance beam, a two-by-four, a half-slice foam roller, foam, or a rocker board. The head and pelvis travel in opposite directions to counterbalance each other in a forward-backward bending motion for anterior-posterior sway. Rapid sway is requested in forward-backward, right-left, and diagonal directions. By using the wall and table setting previously mentioned, patients can be cued to how to touch the nose toward the table while simultaneously touching the wall with the buttocks. Lateral hip strategy can be trained similarly, with the patient standing sideways to the wall, touching the table with one hip and the wall with the opposite shoulder. Sway close to the edge of the patient’s limit of stability should produce a shift from ankle to hip strategy, so to enhance the use of hip strategy the patient should practice sway control as far away from midline as possible without stepping. As soon as the patient demonstrates the ability to perform this strategy, it should be incorporated into functional tasks such as low reaching (e.g., trunk of car, laundry dryer). To promote anticipatory and automatic use of hip strategy, the patient is in midline and given moderate, rapid perturbations to the body or the surface such that ankle strategy will be insufficient to counteract the force. Then the size of the disturbance is increased, and the patient is positioned away from midline when the perturbation is given so that righting to midline is appropriate. The shift should be made from predictable (“don’t let me make you step or fall”) to unpredictable perturbations.

Stepping strategy can be practiced first from atop a step, curb, or balance beam. Both legs should be included in training because real-life situations such as a slip or trip often preclude the use of one limb and demand the use of the other. It may be necessary to fix one foot in position to prevent stepping by the less affected leg in order to allow a stepping response on the more affected leg to emerge

(a forced-use paradigm). Progress is made by stepping on a level surface and then to stepping up onto a step or curb or over progressively larger obstacles (appliance cord, shoe, phone book). All directions should be practiced, including lateral and diagonal perturbations, if safe recovery from real-life unexpected balance losses is to be learned. Large, rapid perturbations are given such that ankle and hip strategies will be inadequate and stepping or reaching is demanded. Again, progress should be made from predictable to unpredictable disturbances. For any APR—ankle, hip, stepping, protective reaching—to be effective in real life, successful demonstration of the response to *unexpected* perturbations is imperative.

Many patients, especially those who are fearful of falling, are dependent on the use of hands for stability. Therapeutic balance retraining activities should provide the maximal level of challenge that can be managed without the need for upper-extremity support. If the patient physically needs to hold on, then the activity is at too high a level and should be modified. Otherwise, what is being taught is a “hand strategy” that will not be useful if the patient experiences loss of balance when nothing firmly fixed is available to grasp for stability. Extremely anxious patients may initially benefit from training with an overhead harness system that will permit hands-free motion but provide tangible reassurance that a fall will be prevented if balance loss occurs. In this case, treatment progression would include weaning the patient off the use of the harness. If the only harness available is on a body-weight support treadmill or gait system, move the balance retraining to that harness. The treadmill does not need to be moving.

Gait training. The initial focus for controlling the COG during gait is a stable base of support that can be continually reestablished quickly and reliably through stepping. Unlike standing balance in which the base is stable and the COG moves over it, during locomotion the base is moving and the COG moves to stay over the base. Achieving a symmetrical, smoothly oscillating COG movement is the objective, with the forces of gravity and momentum being exploited.

The training is begun first in the forward direction but also includes backward and sideways directions (sidestepping, braiding, or carioca) to increase postural control demands. Challenge can be added by narrowing the base of support (tandem) or reducing the foot-surface contact (walk on toes or heels). Training to integrate postural control with locomotor skills is best accomplished not through continuous, steady-pace walking, but by starting, stopping, turning, bending, varying the speed, and avoiding or stepping over obstacles. Difficulty is added by increasing the abruptness, frequency, and unpredictability of these types of tasks and by adding tasks such as carrying or reading while walking. Altered surface conditions (carpets, ramps, curbs, stairs, grass, gravel) or reduced lighting conditions also heighten the challenge. Head and eye movements while walking should be

added as the patient improves. Walking quickly while reading signs on the wall or room numbers, for example, or looking toward and away from the therapist while walking makes vision more difficult to use for stability. Walking in crowds or in busy, cluttered environments is also challenging. Locomotion training on the treadmill reduces some abnormal asymmetries and increases control of gait with increased extension of the trailing limb.¹⁴⁵ Again, gait training specifically for balance enhancement should occur without holding onto fixed surfaces with the hands, for example, parallel bars or the side rails of the treadmill. This is because the nervous system needs to learn to solve the balance problem using the legs and trunk, not the hands.

Patients with somatosensory loss in the feet should use a cane or walker. They may not need the device for biomechanical support, but they do need to obtain as much information about the surface as possible. Through use of a cane or walker, preserved somatosensation in the hands can detect surface information that is important for balance control, and biomechanical support is available if needed in case of balance loss.

Other Considerations

Treatment Tools

Therapists use both high-technological and low-technological equipment in the remediation of balance deficits; each has advantages and disadvantages. High-technological options include accelerometers with motion biofeedback, forceplate systems with postural sway biofeedback, electromyographic biofeedback, optokinetic visual stimulation (from visual surround or moving lights), videotaping, and treadmills with biofeedback. Options for the evaluation and treatment of balance and gait deficits are expanded with the addition of advanced technology such as forceplate measures of postural sway and pressure mat measures of gait, giving the therapist a more quantitative and sensitive measurement than visual observation or timed measures. Most high-technological systems provide computer-generated reports with charts and graphs quickly. For training, overhead harness systems allow safe, hands-free practice, and computerized sway feedback supports motor learning (Figs. 20.21–20.24). Computerized systems allow advanced monitoring of progress and biofeedback, which supports motor learning. Fig. 20.21 is an example of technology in which force plates measure pressure-generated signals (center of force [COF]). The systems shown use height and COF data to calculate the COG, which is used to measure postural sway. The COG icon may be displayed on the monitor screen for feedback to the individual if desired. Fig. 20.22 is an example of how surface motion provides both biomechanical and somatosensory challenges. Balance measurement characteristics vary; some systems measure the motion of the

Fig. 20.21 Advanced Technology to Support Balance and Gait Retraining. The forceplates shown here are static, or fixed when in use. They are portable. The patient using these systems may be given static balance exercises (“Hold still”), or dynamic balance exercises (“Move with control”). These systems provide visual feedback options, which may be given during or after the balance exercise task, or not at all. **(A)** Bertec Portable Essential. **(B)** Bertec Portable Functional. (Courtesy Bertec, Inc.)

Fig. 20.22 Advanced Technology to Support Balance and Gait Retraining. Other systems provide surfaces that can be made unstable (**A**) or made to move (**B**). The surface motion provides both biomechanical and somatosensory challenges. Amplitude and velocity capacity also vary from system to system. Both systems shown here provide omnidirectional motion. (**A**) Biodex Balance System SD measures the motion of the surface, (**B**) Proprio Reactive Balance System uses motion sensors on the body placed at the level of the center of gravity. (**A**, Photo courtesy of Biodex Medical Systems, Inc. **B**, Courtesy Perry Dynamics, Decatur, IL.)

surface (see Fig. 20.22A), whereas others use motion sensors on the body placed at the level of the COG (see Fig. 20.22B). Other systems provide the ability to generate visual motion. Fig. 20.23A shows a system with a three-sided booth with unidirectional motion combined with a movable forceplate with unidirectional motion. Both visual and somatosensory inputs can be manipulated for testing (e.g., SOT) and training. Omnidirectional visual motion (see Fig. 20.23B) can be produced by rotating display systems that are used in a dark room.

The ability to challenge balance during gait training is improved if the patient is secure in an overhead harness system as seen in Fig. 20.24A and C. These systems allow hands-free training as soon as possible to increase reliance on the lower extremity and trunk reactions critical for balance recovery strategies. Rapid and recordable measurement of gait characteristics (e.g., velocity, step length, step width) is possible with instrumented systems. Some systems are made for overground walking (see Fig. 20.24B) and are portable. Other systems are incorporated into treadmills and provide feedback during gait training. All motorized systems provide the ability to manipulate the environment easily and efficiently and to graduate tasks and environmental challenges safely. Drawbacks to high-technological equipment include cost, space requirements, and operator training requirements.

Low-technological options include mirrors, soft foam pads, hard foam rollers, rocker boards, BAPS boards, tilt boards, Swiss balls, mini-trampolines, balance beams, and wedges or incline boards. All these items are accessible (low cost, easy to obtain), portable, and easy to use.

The main drawbacks for low technological equipment are that it does not provide novel feedback, objective scoring, or graphic recording, and clinicians must be skilled and creative in the use of such equipment in order to provide appropriate gradation of task difficulty and environmental conditions.

Safety Education and Environmental Modifications

Remediation of balance deficits is not always possible, but the clinician is always responsible for ensuring the safety of each patient. When permanent deficits exist, the patient and the family should be taught in what environments the patient is at risk (e.g., a patient with vestibular loss on a gravel driveway at night), what tasks are unsafe (e.g., ladder climbing, changing ceiling light bulbs), how the patient can compensate (e.g., use a cane at night or in crowds), and what changes in the home or workplace are needed (e.g., night lights, stair stripes, raised toilet seats). Clinicians can ask the patient (or family) to problem solve risky situations: “What would the patient do?” Home evaluations should be followed by a list of recommended safety modifications. Falls are frightening and dangerous, so clinicians should do their utmost to prevent them. If falls are likely, patients and families should be taught what to do if a fall occurs and, once the patient is on the floor, how to perform floor-to-standing or floor-to-furniture transfers. Home monitoring services such as Lifeline may be indicated if the patient lives alone and is prone to falling. Hip protectors will not prevent falls but do significantly reduce the risk of hip fracture.

Fig. 20.23 Advanced Technology to Support Balance and Gait. **(A)** The Bertec Computerized Dynamic Posturography system allows the manipulation of somatosensory and visual inputs via surface motion (unidirectional anterior/posterior) and visual screen motion (omnidirectional or optokinetic), respectively. Evaluation components include the Sensory Organization Test, Motor Control Test and Adaptation Test; intervention components include progressive multisensory integration training. **(B)** The Bertec Vision Trainer system, used in conjunction with a static forceplate, offers dual task/concurrent task balance training exercises incorporating visual, cognitive, and upper extremity motion task demands. Home Programs

Strengthening, stretching, posture, and endurance exercises can all be performed safely at home so that time in the clinic can be spent on balance-challenge exercises requiring supervision. Improvements in strength, ROM, posture, and endurance support improvements in balance. Many balance exercises can and should be performed at home if safety and adherence can be ensured; however, *unstable patients should always be supervised*. Standing balance tasks can be completed in a corner or near a countertop so that in case of balance loss the patient can use the hands (reaching strategy) to prevent a fall if other APR strategies are inadequate. However, balance exercises should not be routinely done while holding onto countertops, furniture, or other surfaces. If the patient needs to use her or his hands to perform the balance task, the task is too difficult and should be modified so that it can be safely performed without needing to hang on to a stable object. The community setting is ideal for postural control gait training. Grocery or library aisles, public transportation, elevators, escalators, grass, sandboxes or beaches, ramps, trails, hills, and varied environmental conditions in general provide both challenge and functional relevance.

Concurrent Tasks

Normal balance is largely subconscious. One objective in balance retraining is to force the nervous system to solve postural control problems at the automatic, subconscious level. A great deal of practice and dual-task training are necessary to accomplish this; the conscious brain is focused on accomplishing some other goal(s) and thus balance control must be achieved at a less conscious level. Alternative tasks can be physical in nature, such as carrying a tray or dribbling a basketball, or cognitive, such as conversing or solving verbal or math problems, or a combination of physical and cognitive demands.

This objective is not universal. Patients with permanent or progressive deficits in automatic motor processing, particularly those with advanced Parkinson disease, lose automaticity. They must learn to produce motor actions volitionally, with attention and intention, unless there are external sensory cues to drive the motor system.

Fall Prevention

Patient safety is always paramount; for any patient with balance deficits the risk of falls is increased and must be addressed in every clinical management program. In older adults, even those without documented neurological conditions, falls are prevalent and may lead to severe injury (including head trauma) and death. Fall risk is even greater and is especially high in persons with stroke and Parkinson disease. Fall prevention is a critical primary objective for clinicians serving patients with neurological conditions who have impaired balance and gait.

Fall risk factors are categorized as intrinsic, relating to the individual, and extrinsic, relating to the environment. Intrinsic risk factors include but are not limited to medical conditions (e.g., stroke, Parkinson disease); medications; impaired balance and gait; somatosensory, visual, or vestibular sensory loss; central processing problems; slow reaction time and other central motor deficits; lower-extremity weakness and decreased ROM; cognitive deficits; depression; urinary urgency or incontinence; and footwear. Extrinsic risk factors are hazards in the environment, such as inadequate lighting or excessive glare; slippery or cluttered surfaces; lack of handrails or grab bars; attention distracters; and timing demands (e.g., hurrying to answer the phone). The more risk factors present, the greater the likelihood of falls. Most falls in community-dwelling older adults are trips and slips and occur because of a combination of intrinsic and extrinsic risk factors. For example, a patient with hemiplegia

who has limited ability to rapidly and maximally dorsiflex the ankle who encounters a trip hazard such as a rumpled doormat may not be able to clear the obstacle by lifting the hemiplegic leg and foot quickly. If the number and/or severity of intrinsic risk factors is great, falls may occur without any provoking extrinsic hazard.

Additional factors influence fall risk levels. The location of the patient may have an effect on fall risk. While in an institutional setting, the physical environment may be safer and the level of supervision and assistance higher, thus lowering risk. Yet if the surroundings are unfamiliar or confusing to the patient, the patient does not remember to call for assistance before getting up, or the environment holds barriers such as bedrails, wheelchair footrests, and so on that must be dealt with when hurrying to the bathroom, then an institutional setting may pose increased risk. The amount of supervision or assistance the patient receives may alter risk level. Confused or forgetful patients in facilities with high staff-to-patient ratios or who have family or caregiver supervision most of the time will have lower risk than those in facilities or homes where supervision and assistance are sparse. Lastly, the relative dependence-independence level of the patient, both physical and cognitive, affects risk level. Very dependent patients who cannot get up by themselves, and very independent patients with high-level balance and gait skills, are both at lower risk than patients in the middle of that spectrum. Patients who have sufficient ability to get up out of the bed or chair, and perhaps to walk, but who have impaired balance and gait skills and poor judgment or memory are at a much higher risk level.

A separate but equally important risk to consider is the risk of injury from a fall. Injury risk also depends on both intrinsic and extrinsic factors. Patients with low bone mineral density (BMD), low body mass, and impaired protective responses (APRs, especially reaching or protective extension) are more likely to be injured. Falls that occur from a greater height onto a harder surface are more apt to result in injury. An overweight patient with adequate BMD who, while in her yard gardening, stumbles and falls to the grassy ground from standing height with both arms out to break her fall would have a lower risk of injury. A thin patient with osteoporosis who, while at the store shopping, stumbles off a curb and falls to the concrete parking lot without getting her arms out in time to protect her would have a higher risk of injury.

Clinicians should consider fall risk and injury risk factors as they carry out their assessments and evaluation. This would begin with the chart review or history taking; as problems are noted, the clinician should be “red-flagging” those that are risk factors for falls. For example, you might note that the patient is on more than six prescription medications; polypharmacy is a risk factor for falls. You also note that one of the medications is a drug to remediate bone loss, and further inquiry reveals that the patient does have a diagnosis of osteoporosis, a risk factor for injury. During your own therapy assessment, you find substantial lower-extremity weakness, balance impairments, and gait limitations requiring the use of an assistive device, all major risk factors for falls. One of the identified balance impairments includes deficient APRs, a risk factor for injury. Later, during a team meeting to discuss the new patient, you learn from the OT that the home safety survey completed by the patient’s spouse indicates numerous safety hazards, extrinsic risk factors for falls and perhaps injury. For fall prevention and injury prevention purposes, a list of all fall and injury risk factors pertaining to that patient should be generated for use in intervention planning.

The aim of intervention for fall prevention is to eliminate or minimize risk factors, with emphasis on four risk factors that appear to be more influential than others (in community-dwelling older adults). These four interventions are exercise, medication management, home safety modification, and vision management. The

single best intervention for fall prevention is exercise—specifically, individualized exercises that target balance, gait with balance challenges, and leg strength. The challenge level of the balance and gait exercises should be high in relation to the patient's abilities. The balance and gait training program must be of high intensity and frequency and of long duration. For a reduction in fall rates in community-dwelling older adults, a minimum of 50 hours of exercise delivered over at least 2 months but not more than 6 months, is required.¹⁴⁶ For more neurologically involved patients, the overall amount of practice would likely need to be greater. Gains that are made during therapy will not be maintained unless exercise or physical activity that includes balance challenge is continued after therapy. Patients should be intentionally transitioned from therapy to a community-based balance exercise or physical activity program as an integral part of their discharge plan. Clinicians may consider doing their last therapy session or two at the community-based program to support the patient through the transition and increase the probability of follow-through. It is critical for patients to persist with physical activity to maintain or even further lower their fall risk level.

The second area of intervention is medication management. This requires a team approach and tactful, professional communication with the patient's physician(s). The goal is to have the patient take as few medications as possible, in the smallest doses possible, and to eliminate or when necessary replace certain drugs that are known to raise the risk of falls substantially (e.g., benzodiazepines). (Refer to Chapter 36 for a discussion of the impact of drug therapy on patients undergoing neurological rehabilitation.) Clinicians must understand that medication management for fall prevention is a difficult balancing act for the physician. For example, antidepressants and sleeping pills raise the risk of falls. Yet depression and sleep disorders are serious conditions with many negative effects, and depression, inattention, and fatigue are all risk factors for falls. Both the condition and its treatment increase risk! Patients on blood-thinning medication who are at risk for falls are also at risk for serious bleeding problems should a fall occur; the physician, patient, and family or caregiver should all be alerted to this risk. Medication management guidance for fall prevention directed to physicians is available from the American Geriatrics Society.

Home safety modification is an effective intervention for those who are already at high risk for falls. Ideally an in-person home safety evaluation is performed by a trained professional, usually a physical or occupational therapist. If this is not possible, a home safety survey may be completed by a reliable source (patient, family member, or caregiver). The clinician and patient or their responsible decision makers should then have a frank discussion about recommended home safety modifications. The clinician should convey what is recommended and why, highlighting the benefits. However, factors such as time, expense, and personal preference also influence patient and family decisions. Identification of barriers to safety modification implementation is helpful and may lead to solutions that permit initial resistance to be overcome.

Vision management is critical for any patient with visual deficits. (Refer to Chapter 28 for a discussion of disorders of vision and visual-perceptual dysfunction.) These visual impairments might be at the peripheral level, such as macular degeneration, or the central level, such as homonymous hemianopsia. Occupational therapy is recommended for a visual-perceptual evaluation and potentially for low-vision rehabilitation, if needed. Vision professionals (ophthalmologists, developmental optometrists), preferably those with specialization in neurological populations if indicated (e.g., TBI, cerebrovascular accident [CVA], MS), should also be involved. Objectives include

maximizing vision for the patient and including visual support within the home safety modification plan, if needed.

Footwear assessment is important. Walking indoors barefoot or in socks is associated with increased fall risk. The footwear most highly associated with hip fractures is slippers. Shoes and slippers that do not provide adequate foot support, or that have slick soles, are unsafe and not recommended. Footwear lacking a secure back (flip-flops, mules, or sling-backs), high-heeled shoes, and platforms are poor choices for patients at risk for falls. Running shoes with very thick, cushioned soles and a heavy tread are also not ideal. The optimal shoes for fall risk reduction are well fitted with thin, hard soles. Shoes with a tread sole and a tread beveled heel are more stable on wet or slippery surfaces.¹⁴⁷ Just as with home safety modifications, factors such as expense, habit, and personal preference may create obstacles to patient adoption of suggested footwear changes. These obstacles should be recognized, respected, and addressed directly with professional communication strategies designed to facilitate positive behavior change.

Clinicians should assume that patients at risk for falls will fall when they are discharged home. Though clinicians work to ensure this will not happen, they also prepare for the possibility that it will. Patients who are able must be taught how to get up from the floor independently, with and without furniture if the latter is possible. If patients cannot get up from the floor by themselves, then family members or caregivers should be taught how to assist patients to get up from the floor. This may be as simple an act as bringing a chair close to the patient so the patient can use the chair to get up independently. Patients at risk for falls who will be home alone for extended periods of time would benefit from a wearable home alerting system. If such a system is cost-prohibitive, the patient should develop the habit of carrying a cell phone at all times. For patients without cell phones, a landline phone should be left on the floor or a chair seat so that it is within reach from the floor should a fall occur. Older patients with osteoporosis should consider wearing hip protectors. Hip protectors do not reduce the risk of falls but when properly fitted and worn may reduce the risk of hip fracture. Adoption of and adherence to wearing hip protector apparel is typically low and requires commitment and effort.

The combined aim of balance retraining and fall prevention is to assist the patient to become as active as is safely possible. With improved balance and gait skills, the patient achieves higher levels of function and physical activity. With attention to and emphasis on fall prevention, safety is maintained, injury is prevented, and the opportunity for improved quality of life is preserved.

CONCLUSION

Many patients who once thought their quality of life was permanently diminished and their ability to participate in meaningful activities had been taken away now show tremendous improvement in postural control system components, balance and gait skills, and functional abilities. The effectiveness of therapists working with these patients depends on their understanding the breadth and depth of the clinical problems, the use of standardized outcome tests that show measurable change, and the design and implementation of interventions that treat impairments, teach balance skills, and train functional activities. The importance of active patient participation cannot be overemphasized when discussing motor control and motor learning principles needed to optimize positive changes in balance disorders. Balance problems dramatically affect an individual's function, participation, and quality of life, and the role occupational and physical therapists play in providing appropriate interventions has established efficacy in practice.

CASE STUDY 22.1 Andy

Andy is a 27-year-old man who sustained a severe closed-head injury in a skiing accident. He was hospitalized for 2 months and resided at a long-term care facility for 6 months before cranial surgery for removal of bilateral subdural hygromas and revision of a ventriculoperitoneal shunt. After surgery he demonstrated marked improvement and was transferred to a rehabilitation unit. His initial physical therapy assessment revealed the following impairments, which had a negative effect on postural control:

1. Oculomotor deficits (difficulty tracking to the right and upward)
2. Disorientation
3. Delayed and slow motor responses
4. Bilateral ankle plantarflexion contractures (1–10 degrees left, 1–15 degrees right); limited right shoulder flexion (0–100 degrees) and external rotation (0–20 degrees)
5. Hypotonic trunk (right, moderate; left, mild), hypertonic (extensor) lower extremities (right, moderate; left, mild), hypertonic right upper extremity (mild)
6. Fair head control
7. Poor trunk control with right scapular atrophy, shortened right side, strength 3–/5
8. Left upper and lower extremity movement isolated and coordinated but slow, strength 4/5 at shoulder, 4+ /5 elbow, wrist, hand, 4/5 hip and knee, 3+ /5 ankle, able to place and hold for weight bearing
9. Right upper extremity rests and moves in synergistic pattern but can move out of synergy with request or demonstration; strength 3–/5 at shoulder and 4–/5 distally; coordination is poor; can place and hold for weight bearing if cued but not spontaneously
10. Right lower extremity moves in flexor-extensor pattern, grossly 3+ /5 in hip and knee flexion, 20° hip extension, 3+ /5 knee extension, no isolated ankle movement, cannot place or hold for weight bearing

Functional activity and balance skill tests found the following activity limitations:

1. Minimum assist supine-to-sit
2. Sitting balance, poor
3. Moderate assist sit-to-stand
4. Standing balance, unable
5. Moderate assist transfers
6. Nonambulatory

Body system impairment goals were the following:

1. Increase ROM to within normal limits throughout
2. Increase trunk tone to normal and strength to 4+ /5
3. Decrease right-sided tone to normal
4. Increase spontaneous use, isolated movement, and strength (4+ /5) in right extremities
5. Able to place and bear weight on right lower extremity

Short-term functional and skill goals were the following:

1. Independent in all bed mobility
2. Independent in wheelchair transfers
3. Good static and fair dynamic sitting balance
4. Contact guard sit-to-stand
5. Minimal assist static standing balance

Note: Ambulation goals were temporarily deferred because of the ankle contractures and balance deficits.

Early treatments included the following:

1. Standing frame activities for head control, visual tracking, trunk control, reduced lower-extremity extensor tone, and heel cord stretching with ultrasound
2. Neurodevelopmental sequence activities for head and trunk control; trunk strengthening; decreased lower-extremity extensor tone; balance on all fours, heel-sitting, kneeling
3. Supine to and from sitting, especially over the right arm
4. Sitting balance with upper-extremity functional tasks (e.g., putting glasses on and taking them off, taking shirt off and putting it on, wiping nose with tissue), with focus on right visual tracking, right trunk elongation, and incorporation of right lower-extremity ground pressure for stability
5. Transfer training with incorporation of right upper extremity to push up, reach and grasp, and right lower-extremity placing and weight bearing

As soon as Andy's ankle dorsiflexion ROM was near neutral on the right (was then 0 to 5 degrees on the left), neurodevelopmental activities were phased out and standing balance and pre-gait activities in the parallel bars were initiated with moderate assistance. He rapidly progressed to minimal-assistance gait in the parallel bars but with significant scissoring of the lower extremities. Gait outside the bars was begun with a quad cane on the left, but Andy was not able to organize the sequence for cane use and did not use the cane when loss of balance occurred, so use of the cane was discontinued. Gait without an assistive device required moderate assistance from the therapist for balance. A line drawn on the floor provided a visual cue to remind him to keep his feet apart; when walking without this cue, approximately 25% of his steps were close or crossed.

At discharge 2 months after admission, Andy had good visual tracking; normal ROM with the exception of right lower-extremity dorsiflexion, which was limited to 0 to 5 degrees; normal tone in the left extremities; mildly increased tone in the right extremities with slight extensor patterning in the leg; good head and trunk control; and strength grossly 4+ /5 throughout. Functionally, he was independent in bed mobility, wheelchair mobility, and activities requiring sitting balance such as grooming and dressing. He required supervision for safety in transfers and standing activities and minimal to moderate assistance for indoor ambulation without an assistive device depending on his fatigue level.

CASE STUDY 22.2 Doris

Doris is a 73-year-old woman with a long history of Parkinson disease who had fallen 4 times within the 6 months before referral to physical therapy. As a result of her most recent fall during which she hit her head, Doris had ear pounding, lightheadedness, and headaches. After referral to an otolaryngologist, she was diagnosed with unspecified peripheral vestibular dysfunction and referred to outpatient therapy. Her therapist found that Doris reported increased lightheadedness and dizziness with anterior-posterior head movements, rolling in bed, sit-to-stand, and the Hallpike-Dix maneuver (worse to the right). Multiple impairments that could be contributing to her instability and falls, as well as symptoms related to the vestibular disorder, were also noted. Doris had mildly decreased

ROM in her left ankle, shoulders, and neck; mild left-sided weakness and lack of coordination; marked bilateral upper-extremity tremor; and moderately forward-flexed posture.

She could not perform an ankle strategy at all and continually used hip strategy; she also used stepping strategy frequently with the least shift or sway. Static postural sway tests indicated that Doris had excessive sway when attempting to stand still and that she kept her COG slightly posterior and to the right of midline. Sway increased tenfold with eyes closed, indicating poor use of somatosensory inputs for postural control. Doris could not perform repeated weight shifts in either anterior-posterior or medial-lateral directions. Her limits

Continued

CASE STUDY 22.2 Doris—cont'd

of stability were severely restricted to less than half of normal sway range anteriorly, and her movement time was slow.

Functional testing revealed that Doris had several disabilities. She had to use a walker or have manual assistance to ambulate and could negotiate level surfaces only. Without her walker or handhold assistance, Doris could stand for less than 30 seconds and take a maximum of 10 steps. For community ambulation, Doris needed minimum assistance with her walker and could go only short distances. She also required minimum assistance with bathing and household tasks.

Doris participated in therapy twice a week for 6 weeks and also performed a home exercise program daily. Her treatment plan included vestibular exercises for the dizziness and balance retraining exercises for instability and falls. The vestibular exercises she was given were designed to provoke her symptoms repeatedly and included head turning in supine and sitting (progressed to standing), rolling in bed, rocking in a rocking chair, and sit-to-stand practice. As her dizziness subsided, her home program was modified to increase the number and rate of head movements. To improve her use of somatosensory and vestibular inputs, Doris also practiced standing on a firm surface with eyes closed (with family supervision). In the clinic, Doris did stretching, strengthening, and postural extension exercises to address her musculoskeletal limitations. For

increased use of somatosensory and vestibular inputs, she practiced standing and weight shifts with optokinetic stimulation. By using postural sway biofeedback, she practiced achieving the midline position, controlled anterior and left-sided weight shifts at progressively faster speeds, and ankle strategy. Gait training included starts, stops, turns, and obstacle avoidance and progressed to community ambulation tasks such as curbs and ramps. As her endurance improved, she also did gait training on the treadmill to increase the gait speed, stride length, hip strength, and use of vestibular inputs.

Despite her multiple problems, Doris was able to reduce the severity of her impairments and consequently improve her functional level. Her dizziness resolved completely. Although she still had excess sway during static standing, she was able to achieve and hold a midline position, and her sway with eyes closed reduced by more than half. Doris could shift her weight in both anterior-posterior and medial-lateral directions at moderate speeds by using ankle strategy without stepping. Her limits of stability were expanded from 35% to 80% of normal, and she was able to shift her weight much more quickly. Functionally, she could stand without the walker for 8 minutes and walk independently indoors on level surfaces without the walker for short distances. She was independent in community ambulation with the walker. At a 3-month follow-up visit, Doris reported that she had experienced no more falls.

ACKNOWLEDGMENT

I wish to extend my gratitude to Darcy Umphred, PT, PhD, FAPTA, and Rolando Lazaro, PT, PhD, DPT, for the opportunity to share my passion for balance rehabilitation through this chapter. I thank Kenda Fuller, PT, NCS, for her insightful contributions to this chapter revision.

Abstract: This chapter presents a systems model of the postural control system and explains how to use the model as a framework to understand postural control system impairments and their consequences. These negative effects include deficient sensorimotor balance skills, which in turn lead to functional activity limitations and participation restriction. An extensive set of objective balance measures is described with guidance for appropriate test selection and interpretation. Using a task-oriented approach to intervention, this chapter explains how to plan and progress balance exercise programs that target sensory inputs and organization, automatic postural responses (APRs) and anticipatory postural adjustments (APAs), and voluntary balance control

within salient, real-life functional tasks. The clinician is provided with a comprehensive and flexible view of intervention emphasizing the need to treat impairments, teach sensorimotor balance skills, and train functional abilities.

Keywords: activity limitation, anticipatory postural adjustments, automatic postural responses, balance, base of support, body structure and function impairments, center of gravity, impairment, limit of stability, motor learning stages, participation restriction, sensorimotor skills, sensory conflict, sensory environment, strategies, systems model or systems approach, volitional postural movements

Vestibular Dysfunction*

Kenda Fuller

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify and analyze the function of the vestibular system.
2. Describe how to facilitate adaptation and central nervous system reorganization to regain control of balance and eliminate dizziness.
3. Identify patterns of recovery that influence choices of intervention.
4. Recognize intervention strategies related to common functional patterns.
5. Identify common disorders that affect vestibular system function.

KEY TERMS

balance
dizziness
gait

vertigo
vestibular

OVERVIEW: THE ROLE OF THE VESTIBULAR SYSTEM

The vestibular system is critical for postural control because it uniquely identifies self-motion of the head as different from motion in the environment. The vestibular system is a mechanical system that creates neural output to create this sense. Fig. 21.1 shows the components of the vestibular mechanism as it sits with the cochlea, the organ of hearing. The vestibular system detects the direct pull of gravity to identify head position during balance activities and maintains vertical alignment of the eyes. This contributes to the head righting or labyrinthine response and activates the ocular tilt triggered by lateral head bend as seen in Fig. 21.2. Horizontal and vertical accelerations, such as riding in a car or an elevator, are detected by the vestibular otolith mechanism depicted in Fig. 21.3. The otolith structures provide this input during head movement by identifying the degree and direction of deflection of the hair cells projecting into the macula of the saccule in the vertical plane and macula of the utricle in the horizontal plane. It is the mass of the otoconia that sits on top of the macula and creates the mechanical pull on the hair cells when the head accelerates or tilts. The vestibular system calibrates the speed of head movement or degree of tilt in relation to the input from the nerve cells that project from the otoliths.

The vestibular spinal reflex (VSR) creates the response from the otolith structures of the vestibular mechanism to the muscles to provide postural control through the activation of the vestibulospinal tracts. The medial vestibulospinal tract (MVST) descends only to the axial cervical musculature. The coordination of head movements and the integration of head and eye movements are activated through the

medical tracts. The lateral vestibulospinal tract (LVST) descends to the muscles of the trunk, providing orientation for body position in space to support upright balance activities and gait. Together these tracts provide efficient head righting. Activation will cause ipsilateral increased tone in extensors with reciprocal inhibition of reciprocal inhibition of flexors. Someone with an acute vestibular disorder that affects the VSR will often increase weight shift to the side of the lesion. It is important to remember that vestibular nuclei are connected to other sensory and motor systems involved with balance. The connection to the cerebral cortex is associated with spatial orientation. Both top down and bottom up referencing (see later) are used to create the necessary integration for balance. The inferior vestibular nuclei connect to the reticular activating system, which is the cause for the nausea and anxiety often associated with disruption within the vestibular system.

Angular and linear acceleration of the head are detected through the semicircular canals that are part of the labyrinth on each side. When the head moves or changes position, there is movement of endolymph fluid within the canal that moves in the opposite direction of the head movement. The ampulla, which appears as a bump in the canal, houses the cupula containing a group of hair cells; the kinocilia are the longer hair cells, and the stereocilia are shorter hair cells. The hair cells are deflected as the endolymph pressure increases or decreases, reflecting the speed and direction of the head motion. When the stereocilia move toward the kinocilium, the canal is excited, and when the pressure moves the kinocilium toward the stereocilia, the canal is inhibited. In the posterior canal and anterior canal the stereocilia are closest to the otolith, whereas in the horizontal canal the kinocilium is closest to the otolith. This relationship will determine the how the nervous system will react to changes in head position and rotation of the canal. The canals are aligned to provide information about head position and angular acceleration in all planes of movement. For example, the posterior canal

on one side is in relative alignment with the anterior canal on the opposite side. This allows for redundant information to be provided by the canals through a push-pull relationship.

To maintain a stable gaze during head movement, the eyes respond through the vestibulo-ocular reflex (VOR). This is achieved as the excitation signal is activated as described previously in the direction of head turn. For example, in a right head turn, the movement of the fluid in the semicircular canal is in the opposite direction, or toward the left. The endolymph presses the kinocilium of the right horizontal canal toward the otolith (excitation), and the endolymph in the left horizontal canal pulls the kinocilium away from the otolith (inhibition). The excitation moves through the vestibular nerve to the level of the oculomotor nuclei activating the medial rectus muscle of the ipsilateral eye and the lateral rectus of the contralateral eye. This pulls the eye in the opposite direction as the head turn. At the same time, the medial rectus of the contralateral eye is inhibited

along with the lateral rectus of the ipsilateral eye, which allows the eyes to move without resistance. In a properly functioning system, the eyes move at the same time and at a speed exactly opposite the head, providing a gain of 1:1 (eye movement speed reflects head movement speed). The relationship between eye movement and head movement can be seen in Fig. 21.4.

When the signals from the labyrinth mechanisms are not equal and opposite, usually when there is damage to one side anywhere along the pathway, nystagmus results. Nystagmus is nonvoluntary, rhythmic oscillation of the eyes, with movement in one direction clearly faster than movement in the other direction. Nystagmus reflects the abnormal VOR response when the system is not calibrated. The eye movements represent the slow drift of the eye with a fast catch up saccade returning the eye to the original position. This is due to the unopposed neural activity in the intact vestibular pathways. The slow phase represents the vestibular insult, and the fast phase is the central reset.

Fig. 21.2 Patterns of excitation and inhibition for the left utricle and saccule when the head is upright (A), tilted with the left ear 30 degrees down (B), and tilted with the right ear 30 degrees down (C). The utricle is seen from above and the saccule from the left side. (From Haines DE. *Fundamental Neuroscience for Basic and Clinical Applications*. 3rd ed. Philadelphia: Churchill Livingstone; 2006.)

Nystagmus is labeled by the fast phase. In a patient with a peripheral vestibular disorder, horizontal nystagmus will intensify with the gaze toward the fast phase; this is known as Alexander's Law. Disruption of the vestibular system resulting in nystagmus causes an immediate sensation of blurriness of vision or the sense the room is moving, known as vertigo. Vertigo is a specific type of dizziness that reflects the vestibular system involvement. Vertigo can cause imbalance as it disrupts the visual reference for head position.

Abnormal eye movements can also reflect the vestibular system function as it passes through the cerebellum, where the Purkinje cells provide inhibitory control of the vestibular nuclei. The flocculonodular lobe and medial zone of the cerebellum will affect postural control

and eye movements. For example, dysfunction in the flocculus will cause abnormal smooth pursuits, abnormal VOR suppression, and nystagmus patterns, which include downbeat, gaze-evoked, and rebound. Central positioning and periodic alternating nystagmus (PAN) patterns are seen in nodulus lesions. Saccadic movement, or the ability to move the eyes quickly between targets, is controlled in the vermis so a lesion can cause hypometric eye movements. Disruption of function in the fastigial nucleus can cause hypermetric eye motion. The cerebellum also has a role in motor skill adaptation and error correction. Disease processes, such as multiple sclerosis, which can progress to disruption of cerebellar pathways, can cause nystagmus and loss of postural control. Strokes that affect the cerebellum can cause

Fig. 21.3 The Otoliths Register Linear Acceleration and Static Tilt of the Head. (From Hain TC, Ramaswamy TS, Hillman MA. *Anatomy and physiology of the normal vestibular system*. In: Herdman SJ, editor. *Vestibular Rehabilitation*. 3rd ed. Philadelphia: FA Davis; 2007.)

persistent dizziness as well as imbalance, even when the vestibular testing is normal and there is no concomitant hemiplegia.

The hippocampus is linked to the functionality of the vestibular system and contains “place cells” that create an inner map of our environment. These cells work together with connections in the entorhinal and thalamic areas to assist us in way finding, or spatial orientation. These cells become dysfunctional with peripheral vestibular lesions. The evolutionary gravity sensing function of the otoliths may be connected to both spatial and cognitive functions. There is a further connection to the striatal component of the basal ganglia, which has an additional impact on both spatial orientation and cognition.¹ This may be the reason that diseases affecting the basal ganglia, such as Parkinson disease, have components that may overlap. There appears to be a connection to vestibular dysfunction related to atrophy of the hippocampus and changes in the posterior parietal–temporal, medial temporal, and cingulate regions seen in people with Alzheimer disease, mostly in the subset known to have spatial disorders that lead to wandering.²

The vestibular projections to the cortex pass through other parts of the brain. The thalamus works as part of the sensory relay system. It has a connection with the vestibular cortex and the reticular formation, so it affects arousal and conscious awareness of the body to provide the determination of self-movement compared to environmental movement as described in the opening paragraph. Vestibular connections to the cortex provide spatial orientation and perceived

vertical. The roles of the vestibular cortical areas, such as the parieto-insular vestibular cortex, are the focus of research directed toward changing firing patterns in the brain to address concerns as mal de débarquement noted later in this chapter. The connections to the autonomic nervous system, such as the locus coeruleus, amygdala, and parabrachial nucleus, provide the link to symptoms of stress and panic, activation of the fight or flight response, emotional memories, and the malaise that includes nausea. This is another area of active research (see Fig. 21.5).³

It is very important to remember that the vestibular system never works in complete isolation; it is always integrated with the somatosensory system or the visual system. Vestibular rehabilitation as an intervention is always dependent on sensory integration. The vestibular and somatosensory systems preferentially operate at different velocities of postural sway because of differences in sensory thresholds and sensitivities. It is believed that misinterpretation of multisensory inputs during postural sway may underlie the imbalance associated with either vestibular or somatosensory impairments. The term “sensory reweighting switch” describes the unconscious shift from a surface reference using somatosensory input to a gravitational reference that relies on the vestibular system information. This can be described as a switch from a “body on support” to a “body in space” orientation.

Top Down Postural Control

Vestibular inputs are critical to determine whether the body is moving on a fixed surface or if the surface is moving.⁴ The perception of verticality used to orient to gravity, when the support surface is perceived to be unstable, is provided by the vestibular system. Vestibular inputs are used to recognize the changes in angle of the support surface.^{5,6} The vestibular system provides a top-down reference for the head and trunk stability in line with gravity, while the leg segment is coordinated to maintain surface reference. It is important to remember that at the same time the vestibular system is activated in this moving surface condition, the somatosensory system is still providing feedback about the relationship to the surface.⁷ Resulting patterns of muscle activation reflect vestibular and somatosensory integration to maintain continuous upright postural control.

Studies performed on rotating surfaces demonstrate how the use of vestibular, visual, and somatosensory reference differs under conditions that mimic environmental situations. At very slow speeds, somatosensory reference is the primary reference used. As a surface rotates greater than 6 degrees of tilt and increases velocity (range of 2 to 8 degrees per second) there is more focus of the sensory systems away from the somatosensory reference toward the vestibular and visual references. Correct visual information can compensate for loss of vestibular information. However, when the eyes are closed, individuals with vestibular deficits will typically lose balance as the surface tilts at 4 degrees per second. Patients with missing or maladapted vestibular function lack the awareness of angle changes and demonstrate abnormal firing patterns in the muscles of the lower leg, aligning their bodies with respect to the surface instead of gravity, which is described as active postural destabilization. Instead of changing the ankle angle to adjust to the tilt, the torque around the ankle remains locked with excessive reference to the surface. The head and trunk follow the direction of the surface tilt.⁸ This concept can be seen in Fig. 21.6. As the surface tilt angle exceeds 8 degrees, the individual who cannot activate gravitational reference or adjust the ankle angle will be unable to maintain balance without visual input.^{4,9} When the surface is uneven, compliant, or narrow, the vestibular system will provide adequate information on head position, even if vision is occluded.

Fig. 21.4 Vestibuloocular Reflex. When the head is turned to the right, inertia causes the fluid in the horizontal semicircular canals to lag behind the head movement. This bends the cupula in the right semicircular canal in a direction that increases firing in the right vestibular nerve. The cupula in the left semicircular canal bends in a direction that decreases the tonic activity in the left vestibular nerve. Neurons whose activity level increases with this movement are indicated in solid lines. Neurons whose activity level decreases are indicated in dotted lines. For simplicity, the connections of the left vestibular nuclei are not shown. Via connections between the vestibular nuclei and the nuclei of cranial nerves III and VI, both eyes move in the direction opposite to the head turn. (From Felten DL, O'Banion K, Maida M. Sensory Systems. In: *Netter's Atlas of Neuroscience*; 3rd ed. Elsevier; 2016.)

Bottom Up Reference for Postural Control

As stated previously, the somatosensory system can determine the orientation of the head compared to the surface tilt through cutaneous, proprioceptive, pressure, and stretch receptors of the muscles and joints, primarily related to pressure through the balls of the feet.

The somatosensory system is necessary to interpret vestibular information.⁷ It contributes significantly to balance when the surface is stable or moving slowly (at less than 4 degrees per second). At the other end of the spectrum, in very fast oscillations, the muscle spindles provide stabilizing information that can contribute to head and trunk stability. Patients with vestibular deficits typically rely primarily on their ankle strategy during typical activities by keeping the head aligned with the body. This can be seen in a patient who demonstrates rotation "en bloc"; the head will stay aligned with the body while turning. This can be seen in Fig. 21.7 during a lateral tilt where the trunk will follow the direction of the platform.

The vestibulospinal system also activates the neck muscles in response to head motion. When the vestibular system function is missing or inaccurate, there is abnormal muscle activation in the muscles of the neck.⁷ This is usually seen as excessive co-contraction of both flexors and extensors. Abnormal firing of the sternocleidomastoid (SCM) with restriction of rotation of the head is often seen in both acute and chronic settings. The suboccipital muscles can develop a pattern of overuse that can contribute to headache. See cervical spine function and dysfunction in concussion in Chapter 23.

Having even the slightest touch reference, so that the somatosensory system can orient the trunk through upper extremity joint position sense, is another way to substitute somatosensation for vestibular reference.¹⁰ The position of the head and trunk can be determined by this touch even when the vestibular system function lacks normal function and the eyes are closed. Because the arm stabilizes the trunk more than the legs do, reaching for a stable surface is a common way

Fig. 21.5 Potential Location of Lesions That May Affect the Vestibular System. (From Felten DL, O'Banion K, Maida M. Sensory Systems. In: *Netter's Atlas of Neuroscience*; 3rd ed. Elsevier; 2016.)

to maintain balance when challenged. The therapist must recognize when the patient is using this touch reference to substitute for gravity orientation.

When the brain is not able to use somatosensation to identify the relationship between appropriate body segments and the surface, the patient often will report feeling lightheaded or has the sense of floating. When somatosensory inputs from the neck are reduced, absent, or distorted, it affects the stability and mobility of the individual spinal segments. Co-contraction of the SCM, levator scapulae, upper trapezius, and superficial neck extensors may indicate abnormal sensory feedback, altered afferents, and recruitment patterns, which are ineffective. Nociception from cervical segments can create “noise” in the postural control system contributing to dysmetric postural responses and nausea. Impaired cervical afferents will cause changes in cadence and length of stride when neck motion is

introduced to gait. This should be considered in planning interventions for patients who are sent for vestibular rehabilitation.^{11,12}

Visual Reference for Postural Control

Orientation of the head in space is possible through predictive control of vision. A stable environment provides visual vertical and horizontal references for balance. Recognizing self-movement as it relates to visual movement can be disrupted momentarily in a normal individual experiencing unexpected movement in the peripheral visual environment. This is a common sensation noticed when the car next to you rolls backward, and you press the brake, thinking that you are rolling forward. Vestibular system function is necessary for a comparison of self-motion to motion in the environment. For example, when you are walking and someone is walking toward you, your visual system will detect that the person is getting closer; however, you cannot determine

Fig. 21.6 In anterior tilt of the platform, the head and trunk follow the reference of the platform rather than maintaining a gravity-neutral position. This is reported as surface reference. (Courtesy Perry Dynamics, Decatur, IL.)

Fig. 21.7 (A) The patient references her trunk to the platform, shifting weight downhill to the downhill leg. **(B)** The patient has referenced her trunk and head to gravity, resulting in improved postural control. (Courtesy Perry Dynamics, Decatur, IL.)

how fast the other person is moving unless your vestibular system is able to independently recognize your own speed to calibrate the relative movement in the visual field. This is why driving can be challenging; it is hard to determine the distances and speeds of other cars when the vestibular system is not providing accurate information about self-movement.

Visual disorders can independently disrupt balance, cause the sensation of dizziness, and limit the function. Information from both smooth pursuits and saccades are integrated with the vestibular system information to help interpret the relationship of the body to the environment. Accurate evaluation of the visual system is critical in differential diagnosis. A clue that the visual system is causing dizziness can be discovered when the patient reports less dizziness with eyes closed than when the eyes are open. Disorders of convergence are common in the vestibular-deficient patient and can cause delay in the process of adaptation.

If there is a visual–vestibular mismatch, the patient will complain of motion sickness or visual motion sensitivity. These individuals will have dizziness when there is movement in the visual environment, especially if there is a pattern to it, as when driving on a wooded mountain highway or in the presence of optokinetic stimulation. The brain is unable to use the visual reference to determine body motion, speed, or upright position. In this visual environment, it is the vestibular system that provides the correct reference. If the visual–vestibular integration is faulty in these circumstances, the result is dizziness often with nausea. The oscillopsia associated with acute VOR disruption or with bilateral loss gives the patient a sensation that the room is moving around them, or bouncing as they walk. Oscillopsia as a result of visual system disorders is less common and is usually evaluated and treated by a specialist in vision.

A normal visual response called physiological diplopia (double vision) can contribute to visual discomfort in patients with vestibular dysfunction. See [Box 21.1](#). When a person looks at an object close to them (within 6 to 12 inches), there is an apparent doubling of the objects in the peripheral field of view. Because this is normal, the awareness of the double vision is typically extinguished and not perceived. Patients with uncompensated vestibular systems, who rely excessively on visual reference, can become sensitive to this physiological diplopia as it destabilizes the visual field. This can cause a sense of visual motion hypersensitivity during daily activity as they attempt to look at near objects. When there is sensitivity to this apparent movement, it is difficult for the patient to distinguish this when there is movement in the visual field. Optokinetic stimulus, or movement in the visual field, especially if it is in a pattern, will cause dizziness and loss of balance. Visual motion sensitivity can be measured and tracked via the Visual Vertigo Analogue Scale or the Pediatric Visually Induced Dizziness Questionnaire.¹³

Abnormal responses in neck muscle activity associated with eye motion have implications for control of posture and movement. The smooth pursuit neck torsion test (SPNT) is used to delineate abnormal cervical afferent influences on oculomotor function from vestibular influences. There is considerable evidence to support the importance of cervical afferent dysfunction in the development of dizziness especially with visual disturbances during head movement following neck trauma, especially in those with persistent pain. This should become an essential part of the routine assessment and management of those with traumatic neck pain, including those with concomitant injuries

BOX 21.1 Physiological Double Vision

- Everything in front of and behind the central focal point is perceived as double
- The closer the focal point, the more distance appears to be between the *perceived* double images
- As the central focal point moves in space, the background image appears to move

BOX 21.2 Smooth Pursuit Neck Torsion Test

Test: Smooth pursuits tested in the head-neutral position, and then compared with the head rotated right and left

Findings: Compare gain in three head positions

Considerations: Shows relationship to cervical pain, proprioception, and oculomotor control

such as concussion, vestibular system damage, and visual pathology or deficits.¹⁴ Testing of SPNT is described in [Box 21.2](#).

GAIT DYSFUNCTION

Chapter 20 on Balance describes automatic postural responses and describes balance testing in detail. It is important to understand the role of the vestibular system in movement disorders related to balance. These consequences can have an impact on the gait patterns related to vestibular dysfunction.

Vestibular system losses can result in motor responses that are larger than necessary for the task, which can predispose a patient to falling. This can be seen in the gait cycle when the body center of mass moves faster and farther than the individual can control. This movement appears similar to that of the patient with cerebellar dysfunction, and indeed may represent the loss of vestibular input to the Purkinje cells in the cerebellum that would normally modulate vestibular pathways.^{7,15} The gait pattern reflected by vestibular dysfunction, or lack of integration, often involves flat-foot gait with minimal heel strike and abnormal foot placement requiring larger than normal trunk adjustment. To control the position of the trunk, the base of support is widened. Speed of gait is another indication of vestibular function from the perspective that patients with bilateral loss or uncompensated vestibular loss demonstrate a slower self-selected speed. Typically, there is increased double limb stance time and decreased stability at heel strike.¹⁶ Vestibular control of position for the upper body and head appears to be separated from the lower body in gait in a similar pattern as noted during perturbed stance. Head and trunk stability normally remain constant throughout the phases of gait, and vestibular inputs appear to be most critical during initiation of gait, toe off, and heel strike. Vestibular information contributes to the planned foot trajectory and placement of the foot to prevent disequilibrium. It is interesting to note that during steady state gait—and even more so with running—vestibular contribution appears to diminish in importance. This may be because movement in running is highly automatic and the trajectory remains steady.¹⁷

When the vestibular system does not accurately inform the patient about the speed and direction of head movement, visual cues are used to determine movement speed and direction of gait in relation to non-moving objects. However, in environments with a lot of motion, or when someone approaches in the opposite direction, determining speed and direction of self-movement becomes more difficult. Patients often report dizziness and imbalance in a crowd. Walking with head turns becomes even more challenging as the vestibular system is activated and the somatosensory and visual systems are disadvantaged. Head turns included in the Functional Gait Assessment provide a way to identify this impairment. Because head movement can cause visual disturbances and dizziness, the patient with a vestibular disorder will significantly limit head movement while walking. When visual cues are used predominantly for balance, the patient will try to keep the body in line with vertical and horizontal visual targets. This will decrease the

small, natural movements typically made during the gait cycle. A change in visual environments can trigger imbalance in the patient with visual dependency. Walking into a darkened room, especially if the surface is uneven (e.g., in a theater where the surface is sloping), can often trigger a fall or stumble. Patients with permanent vestibular loss should be educated about these potentially high-risk environments and taught compensatory strategies to ensure safe mobility. Patients with potentially recoverable vestibular function should be trained to walk with eye and head movements, trunk rotation, and arm swing.

Vestibular contributions to stability during transitions from sit-to-stand, initiation of gait, and abnormal foot placement can be identified during standard tests such as the Timed Up and Go, the Tinetti, and Dynamic Gait Index. Scores are adversely affected when vestibular system functions are diminished. The Functional Gait Assessment has been developed specifically for use in patients with vestibular disorders (see [Table 20.1](#) in Balance chapter).¹⁸

RECOVERY OF FUNCTION: ADAPTATION VERSUS SUBSTITUTION

During most daily functions, the vestibular system creates little awareness or sensation that it has been activated. When it is stimulated beyond the typical level (e.g., during a fast spin or when a roller coaster suddenly drops), it creates a strong sensation of uneasiness or dizziness. This is often accompanied by nausea, sweating, and feeling out of control. Often the balance system is also affected for a short time, causing an unsteady gait. The dizziness that occurs in the normal individual when the vestibular system is overstimulated can mimic the feeling of dizziness that occurs when the brain encounters sudden changes or losses of input from the vestibular system.

Acute disorders of the vestibular system can cause devastating lack of visual stability, loss of balance, and inaccurate sense of movement. As stated previously, there is an initial loss of trunk and gaze stability with vestibular dysfunction. Central nervous system (CNS) adaptation is critical to recovery of function.¹⁹ During recovery, the visual or somatosensory systems may be used excessively to counteract the loss of information from the vestibular system.

In the patient with an acute unilateral vestibular disorder, the brain identifies this abnormal state, recognizing that the perceived motion from the visual system is not congruent with the feedback provided by the somatosensory system. If there is stable visual input available, the brain will begin to use the stable visual input to assist the CNS recalibration. There is usually adequate central adaptation to stop the spontaneous nystagmus in a lighted environment within 3 days.²⁰ The spontaneous nystagmus may continue to be active in a dark room, and even for weeks after the insult there may still be a sensation that the head is rotating when the eyes are closed.

CNS adaptation represents the highest level of recovery in the patient with a vestibular dysfunction, and therefore as much adaptation as possible should be facilitated to improve functional outcomes.^{21,22} Although some patients with vestibular lesions appear to be well-compensated, they often require increased attention to perform daily activities. This increased demand for attention appears to extend beyond postural control and may be associated with sensory integration resolving multiple sensory signals for spatial orientation.²³ Vestibular adaptation programs should challenge the patient at the limit of his or her ability. Patients often choose to do the easiest exercise and avoid the more difficult exercises if they are not educated about the need to trigger the symptoms. Conversely, if the challenge is too far above the ability of the patient, the CNS will fail to adapt. Comorbid dysfunction can also affect functional recovery, especially if it affects the visual or

somatosensory inputs. Disorders that effect the autonomic nervous system can significantly impede recovery. Trauma, either physical or psychological, can cause maladaptive responses that are inconsistent with typical recovery. Conditions such as concussion and persistent postural-perception dizziness (PPPD) are prime examples of this concept and are discussed later in the chapter.²⁴

Clinicians are exposed to patients at many different levels of adaptation in clinical settings. It is critical to understand the level of adaptation and potential for recovery for each patient. For example, tests such as video nystagmography (VNG) will identify an existing impairment; the level of physiological adaptation is identified by nystagmus in room light or tests such as the head impulse test. Functional adaptation is determined through activities such as dynamic visual acuity (DVA), loss of balance during gait with head turns, tandem gait, and walk with sudden stops. Dependency patterns are identified by observing the change in status when vision or somatosensation is removed, for example, by using the sensory organization test, namely Clinical Test of Sensory Organization and Balance, or moving platforms. Functional scales (e.g., the Functional Gait Index) can help the knowledgeable clinician identify which impairments may be having the greatest impact on the activity limitation of the patient. Successful intervention is achieved by accurate analysis of both the missing and available components of the system—facilitating adaptation, avoiding excessive sensory substitution, and determining appropriate compensatory strategies when necessary. Home exercise programs must be created to optimize the recovery process while keeping the patient safe. The patient should clearly understand the purpose for each exercise and the progression to higher-level activities. Guided home-based vestibular rehabilitation programs will likely become more widely used with enhanced education and increased adherence.²⁵

IMPORTANCE OF TAKING THE HISTORY

The term “dizziness or dysequilibrium” can mean something different to each person who describes the experience. For the therapist, this description is the first opportunity to begin the differential diagnosis to determine the appropriate impairments to focus on during the evaluation process. The onset or circumstance that created the dizziness can give a clue to the cause. In patients with long-term dizziness, it is important to determine the most recent concern, or the reason that brought the patient in for this evaluation. The intensity of symptoms and what makes them better or worse can guide both the evaluation and intervention. A true spin, or vertigo, indicates an asymmetry of neural activity from the vestibular system that occurred rapidly. This most often represents a lesion below the pons or cerebellum, such as vestibular neuritis, or a disruption of blood flow in the basilar or vertebral artery. Lightheadedness can indicate problems with maintaining postural tension of blood pressure, lesions deeper into the CNS that likely involve somatosensation, peripheral somatosensory loss such as diabetic neuropathy, or the inaccurate somatosensory input after whiplash or concussion. When dizziness is accompanied by dysphagia, dysarthria, diplopia, and dysmetria, this can be a red flag for brain stem lesions or those that may involve the cerebellar or cerebral cortex.

Dizziness can be reported as panic, heart palpitations, tingling in the face or hands, or feeling out of touch with the environment. This may be associated with PPPD or may be the phenomenon of posttraumatic stress. Autonomic nervous system dysregulation can cause dizziness that can be orthostasis, exercise induced, and related to other factors such as headache and gastrointestinal symptoms. In these cases, the underlying disorder needs to be diagnosed and managed properly as noted later in the chapter.

The temporal course of the symptoms can assist diagnosis. Slow onset of dizziness especially with progressive imbalance can indicate a mass effect, perhaps an acoustic schwannoma or infratentorial meningioma. Determining the timing of the symptoms when there is a sudden onset can determine the cause. When it is described in seconds, one might think first of benign paroxysmal positional vertigo (BPPV), but when it is hours or days, a migraine or Meniere disease is suspected. A report of continuous dizziness with exacerbations will lead toward a diagnosis of possible fistula, perhaps superior canal dehiscence, mal de débarquement, or other causes of inhibited adaptation. Provocation with head motion gives additional clues to the diagnosis. Motion-provoked symptoms may indicate inadequate adaptation. Head position dizziness can be related to BPPV if symptoms are brief, or central dysfunction if symptoms persist. Maladapted patients can describe constant and vague symptoms. Comorbid complaints of hearing loss, tinnitus, and fullness in the ear are indications of conditions that involve the cochlea. These conditions will be described in detail at the end of this chapter.

DETERMINING THE ADAPTATION STATUS THROUGH EXAMINATION THAT GUIDES INTERVENTION

There are many known ways to identify acute vestibular lesions. To determine the level of adaptation using visual cues, look for nystagmus in room light with the patient looking at a stable object. Nystagmus from peripheral vestibular lesions is easily inhibited with visual fixation. Nystagmus caused by central lesions of the brain stem or cerebellum is not inhibited with visual fixation. Blocking visual fixation to look for spontaneous nystagmus is achieved with the use of infrared goggles or Frenzel lenses.

Videonystagmography (VNG) captures eye movements related to vestibular dysfunction using video goggles or electrodes surrounding the orbit (electronystagmography). Oculomotor testing is included in this test to determine the status of saccades and smooth pursuits as well as eye speed and optokinetic response. It is critical to determine the baseline oculomotor functions because, as noted previously, this can be an independent cause of dizziness. Nystagmus patterns are determined to be spontaneous, positional, with head motion, or during the Dix Hallpike positioning. The vestibular component of the VNG is the caloric test, the use of warm and cold air to manipulate the fluid in the horizontal canal to isolate the ear and indicate the relative function on one side compared to the other. Central disorders will produce nystagmus patterns that are different than those related to a peripheral lesion. The caloric portion of this test is reported as a relative percentage of reduced vestibular response in the affected ear.

Vestibular-evoked myogenic potentials (VEMP) is based on the principle that the saccule of the otolith is sensitive to sound and responds in a similar fashion to clicking sounds as it does to tilt. A click produced in the ear stimulates the saccule that in turn inhibits the synchronous discharges of muscles in the SCM on the same side. It is thought that this reflex allowed the head to turn toward the sound of a predator. Abnormal hearing can interfere with the ability to perform the test as will dysfunction in the SCM muscle.

The rate of firing or tone of the SCM is inhibited during the recorded sounds, and this change is captured using surface electromyography (SEMG). Surface electromyography the response in one ear can be compared to the response on the other side in the same person. VEMPs are abnormal when they are very asymmetrical such that one side is more than two times as large as the other, low in amplitude, or absent. An

abnormal VEMP can represent an ipsilateral lesion in the saccule, the inferior vestibular nerve, the lateral vestibular nucleus, or the MVST. The inferior component of the vestibular nerve can be preserved in a neuritis, and the VEMP can be normal even with loss of superior innervation of the horizontal canal. Intervention in this case would be determined with enhanced use of head righting and the adaptation of VOR.

Subjective visual vertical (SVV) is used to test the degree of ocular torsion present in unilateral lesions. The SVV is tested in absolute darkness or an environment that prevents visual reference to the vertical. The patient is asked to orient a rod to gravity, and the degree of off-axis tilt represents the torsion of the eye, or skew deviation, which is common in acute unilateral lesions.²⁶ When looking at skew it is important to realize that the vestibular system skew is a nonparalytic ocular misalignment due to utricle-ocular motor pathway asymmetry. This should not be confused with a paralytic skew that represents a nerve palsy or intranuclear ophthalmoplegia (INO). This can be tested with a Maddox rod, or the Cover-Uncover and Alternate Cover tests can help determine a con-concomitant or nonconcomitant dysfunction. Medullary and medial longitudinal fasciculus lesions need to be ruled out as well when a skew is identified.

Sensation of Motion at Rest

The tonic firing of the vestibular system, when the head is in a neutral nonmoving state, is symmetrical, at approximately 90 spikes per second recorded in the canal and otolithic systems. When there is disruption of signal from only one side of the vestibular pathway, it will change the relative input into the CNS resulting in a perception of the head rotating even if the head is not actually moving.

To determine the degree to which the patient has adapted using somatosensory cues, ask them to sit still on a stable surface with eyes closed. If there is a sensation of motion, the somatosensory system and vestibular system are still out of synch. If the sensation is that of rotation, it is likely that the CNS has not adapted to the unequal signals caused by vestibular system lesion.

Enhanced input through stable joint surfaces can facilitate the CNS recalibration early in the adaptation process. This appears to be most effective through mechanical pressure through the top of the head or as shown in Fig. 21.8 with the use of weights on the shoulders to increase the vertical reference of the spine in a neutral position with vision occluded. In the very acute patient, this may need to be started in the supine position. This allows the vestibular system to calibrate using somatosensory input as a reference. This activity, known as settling, is a good way to allow the patient to manage symptoms when they have been exacerbated by activity. Using the weight or pressure for several minutes at a time can control symptoms. The use of settling is reduced as the system adapts during movement—the final goal of the intervention. If the use of weights increases the sensation of movement with a report of being lightheaded, the clinician should suspect abnormal central sensory weighting of somatosensory inputs. Slow progressive introduction of weights may be necessary to achieve decreased sensation of movement. Closer examination of the musculoskeletal system may be necessary. Joint position sense and neck torsion smooth pursuits should be examined and treated as well. It is a critical first step in the rehabilitation process to achieve accurate CNS recalibration with the head at rest before initiating intervention that requires movement of the head.

Gaze Stability

The ability to hold the eyes fixed on a target while the head is moving is known as gaze stabilization and is a manifestation of the VOR. The gain of an intact VOR is should be equal to one (1:1) as stated previously, which means movement of the eyes is equal to the movement of

Fig. 21.8 The use of 5-pound weights on each shoulder to increase the somatosensory reference allows the vestibular system to recalibrate to the body reference. Eyes are closed so that the head position is not referenced by vision.

the head.²⁷ To test the accuracy of the vestibular system gain, the head is rotated and/or moved up and down at a rate of 2 Hz to 4 Hz. This is the rate the head moves during typical daily tasks increasing with sports activity. When an individual is unable to achieve similar clarity of vision at rest and at 2 Hz, you would expect that the VOR is not sufficiently calibrated.²⁸

Head Impulse Testing Paradigm

In the presence of vestibular system dysfunction, when the head is passively rotated or tilted while a patient is looking at a fixed target, there are saccadic eye movements required to move the eye back to the target, as the gain falls below the 1:1 ratio. The eye moves in the same direction as the head; hence, a saccade is required to move the eye back in the opposite direction where the target remains. This can be tested manually as the clinician asks the patient to fixate on a target and then grasps the patient's head performing a fast passive horizontal or vertical head thrust, observing the eyes during the thrusts. A normal VOR will allow the patient to maintain the eyes on the target. If there is a refixation saccade, it indicates abnormal gain of the VOR. This refixation saccade can be recorded electronically with a video head impulse test using the head impulse testing paradigm (HIMP) protocol, so that catch-up saccades can be identified and measured. This is an indicator of vestibular loss.

Suppression Head Impulse Testing Paradigm

The suppression of the VOR is a way to identify the remaining function in an individual with partial loss of vestibular function. It is a way to determine the level of adaptation using a quick head turn as

indicated in the HIMP, but the target moves with the head so that the VOR must be suppressed. There is a reversal of saccades in this test, with smaller and later saccades in the same direction as the head movement. The parameters for the suppression head impulse testing paradigm (SHIMP) testing can be integrated into video head impulse testing and may be more useful for the therapist to have an idea of the level of function that remains in the vestibular system.²⁹ This can be especially useful in conditions that cause bilateral vestibular loss but may have sparing of anterior canal function such as ototoxicity and progressive Meniere disease.

Rotary Chair Testing

In this test the patient is rotated in a sitting position while eye movements are measured. It is used to confirm the degree of bilateral loss and determine whether there is adaptation after a unilateral lesion by testing the gain of the system during these full body rotations. Lesions of the central VOR patterns can lead to changes in the gain of rotation-induced nystagmus. Cerebellar dysfunction will result in abnormal amplitudes.

Dynamic Visual Acuity

DVA can be tested with manual head turns using a Snellen chart, with the patient reading the smallest line that is possible when the head is still, then the therapist passively rotates the head at 2 Hz and the patient attempts to read the same line.³⁰ When acuity drops more than three lines, the patient will be unable to maintain visual acuity during typical daily activity. Quantified DVA can be recorded as the logarithm of minimal angle of resolution (LogMAR). As seen in Fig. 21.9 this can be tested and quantified by use of equipment such as inVision (NeuroCom Int.). Gaze stability also can be quantified using the same equipment, but the measure is one of function, reporting the head speed that can be obtained while maintaining gaze stability. This is a good way to clarify the amount of deceleration that is necessary for the patient to maintain proper vision.

In the clinical examination, the VOR is reported as abnormal only if there is loss of gaze stability that leads to blurring of target object with head movement at 2 Hz to 3 Hz.

If the vestibular ocular reflex is not functioning efficiently and it does not drive the eyes to the correct position for a stable gaze, the result is known as vestibular driven oscillopsia, causing visual targets to appear to move as the head moves. This disorder has significant

Fig. 21.9 Quantified Dynamic Visual Acuity Is Possible With Systems Such as in Vision. (Courtesy NeuroCom International, Clackamas, OR.)

functional implications: the individual will try to limit the head motions that cause gaze instability, walk with increased base of support to enhance somatosensation, and increase the use of hand holds or use wall walking (touching the wall to stay upright while walking). Gait speeds slow while trunk and head remain locked in relation to each other during turns. This can often be observed during the initial evaluation.

VOR adaptation requires movement of images on the retina, or retinal slip. Therefore intervention begins with head movement at the speed that allows stable vision.^{27,31} Adaptation of the VOR is accomplished by having the patient move the head while trying to maintain gaze stabilization, keeping a stationary object in clear focus.³² As the system adapts, the speed of head movement increases, with the goal of achieving head movement at 2 Hz without the object blurring. Initially, the patient can focus on the thumb or a business card held at arm's length. The activity is progressed to a higher level of difficulty by adding background visual stimulus such as a television set or a visually complex environment. Gaze stabilization with head turns while standing on an uneven surface or while walking creates a higher-level challenge. Many patients have avoided head movement, so simply turning the head may initially trigger dizziness. As stated previously, dizziness with head motion should not be confused with abnormal VOR; in VOR dysfunction, the visual image blurs as the head moves.²⁸

Vestibulo-Ocular Reflex Cancellation (VOR Cancel)

VOR cancel reflects the ability to synchronize simultaneous eye and head movements in the same direction; it is associated with the ability of the brain to suppress the VOR. This function allows an individual to track an object while moving the head at the same speed. Testing is reported as normal if the eye can remain in the center of the orbit as the head and eyes track an object as it moves across the visual field. If the central integration capabilities are abnormal, the patient will not be able to override the reflex activity and cannot keep the eye and head moving at the same rate in the same direction. The clinician must also be aware that the peripheral visual field will appear to move in the opposite direction to the head movement during these testing procedures. This normal visual phenomenon can cause dizziness in the patient with visual dependence or visual motion sensitivity.

Head Motion Dizziness

The quality of somatosensation in the spine and muscles of the upper body can contribute to dizziness with head motion. The vestibular nuclei have the job of integrating somatosensory information on its way to the cortex. There must be adequate input from both the somatosensory and vestibular systems to distinguish between head on body or body on head movement. Impaired somatosensation, pain, and guarding of movement will disrupt the accuracy of calibration related to head movement. The patient who has an abnormal VOR will be constantly decelerating his head movement to less than 2 Hz to try to prevent blurred vision. That unconscious deceleration by the muscles in the neck can cause stiffness and decrease the sensitivity of the somatosensory mechanisms in the neck and shoulders. Dizziness with head movement can persist even after the VOR has recalibrated if the somatosensory system continues to send abnormal signals from the muscles of the neck. Most often this is described as a lightheaded sensation rather than the spinning sensation that is associated with vestibular dysfunction.

Abnormalities of head motion related to the quality of somatosensation known as head motion–provoked dizziness can be tested by holding the head upright and still, in gravity-neutral position while the patient rotates back and forth in a chair, known as body rotation under a stable head (BRUSH). This should be done with the eyes closed to

eliminate the use of visual cues. The movement may illicit dizziness if the somatosensory system is impaired. If the patient has been relying on somatosensation as a primary reference for head position, there may be co-contraction of the cervical muscles to keep the head aligned to the trunk to provide head position reference. This will feel like resistance to the motion, often reported as neck stiffness. To eliminate the co-contracted pattern this movement should be initiated by teaching a family member to gently hold the head in place while the patient rotates the chair side to side. Using a mirror for feedback about head position while rotating the body in a chair also can be effective but relies on visual cues.

Rotation of 360 degrees in a chair at 1 Hz to 3 Hz allows the head to move at the same speed as the body and isolate the vestibular system response to rotation of the head. This should be done with the eyes closed to eliminate visual feedback. Movement at this speed will cause an increase in dizziness even in a normal system, reflecting the velocity storage mechanism of the vestibular system. In an intact vestibular system, dizziness should resolve in less than 10 seconds once the rotation has stopped. If the dizziness persists for greater than 15 seconds, it represents abnormal vestibular calibration. This can be used as a home exercise to enhance recalibration. The patient sits in a swivel chair, rotating around three times at a speed that is tolerable but increases vertigo, then stops moving, keeping his and her eyes closed, and counts to see how long it takes for the dizziness to stop. Calibration is achieved when the dizziness lasts less than 10 seconds. This can increase normal head motion without dizziness during typical activities and can reduce the fear of increasing symptoms.

Sensory Substitution for Postural Control

When, as noted several times previously, critical information from one system is absent or inaccurate, the CNS will begin to rely more heavily on the other systems for necessary reference. While this is used initially to provide stability during the recalibration process, it can limit adaptation over the course of recovery. Visual or somatosensory dependency patterns develop when the patient persistently makes use of either or both of those systems in preference to vestibular references when the most efficient reference for the environmental condition would be the vestibular system. This can persist as evidence that an individual has not achieved complete adaptation of vestibular function. On testing there was an average of only 50% use of vestibular system weighting (trunk in gravity neutral) resulting in trunk sway in reference to the surface tilt, when tested on a rotating (tilting) surface. Individuals with normal functioning systems showed 100% reliance on gravity by the time the surface made the 6-degree rotation and the individuals showed minimal head and trunk sway following the surface tilt.⁷

Dependency patterns are typically observed in an individual who does not recover satisfactory adaptation and integration of the sensory systems required for normal balance responses in a variety of environmental conditions. Clinically, these substitution patterns often present as hyperreliance on vision or somatosensory cues even when the vestibular system may have adequate potential for recovery.^{33,34} When given standard vestibular rehabilitation, these patients often do not recover a full return to activity and are left with activity and participation limitations, or complain of symptoms that have a negative impact on their lives.

Visual Dependency

Patients may experience discomfort when their eyes are closed or may find it impossible to walk down an incline in a visually challenging environment without the need to hold on to a railing. Patients with visual dependency often report excessive fatigue after activity because

of the strain of using vision for postural stability. When these patients are in situations with excessive visual stimulation, reports of dizziness increase. The subtle eye movements associated with viewing a computer monitor cause more fatigue for the individual with vestibular disorder when they display visual dependency. These individuals also often avoid crowds as in a mall, grocery store, or airport. Attending religious services, which are often characterized by low lighting, visual stimulation, and the need to stand with eyes closed or read a hymnal while singing, can create challenges to the vestibular system and can reduce an individual's participation.

Destabilization can occur when the peripheral visual references appear to move as a component of physiological diplopia. When the eyes are tracking something moving in the central gaze field, the background or peripheral visual field will appear to move in the opposite direction. During diagonal smooth pursuit tracking, for example, the patient with visual dependence will orient the head and trunk to the perceived movement in the room creating postural adjustment patterns as if the room is tilting. The patient is pulled off balance when they align themselves with the apparent visual motion. This can also be tested when a patient is standing on a compliant surface or on a single leg, tracking a target moving in a figure of eight. Head and trunk sway match the apparent visual field movement instead of actual gravity vertical in the patient who is visually dependent. This test can be used in a clinical battery to determine degree of visual dependence to compensate for missing the gravity reference. Patients can be taught to perform this and other activities at home to increase the use of the vestibular system function as seen in Fig. 21.10. Tossing a ball in the air and following it with the eyes while standing on a compliant surface, or while walking, will allow for balance without visual fixation as seen in Fig. 21.11.

Walking backwards while tossing the ball increases the challenge. Increased efficiency of vestibular weighting can improve the ability to accomplish activities of daily living and improve balance confidence.³⁵

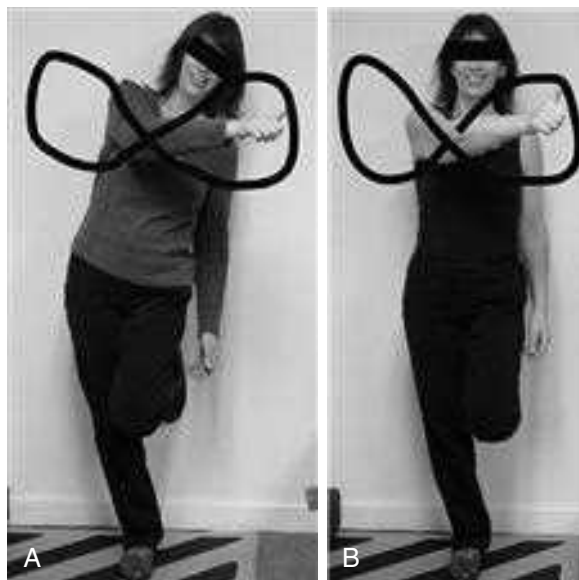

Fig. 21.10 When the visual reference is dominant for the head position, the position of the head changes to match the tilted peripheral visual reference that results from the eye following the thumb in a figure-of-eight. **(A)** The head tilts off-center as the perception of the visual field tilts. **(B)** If the vestibular system is dominant, suppression of the apparent shift in the visual field allows the head to stay in alignment over the base of support. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, CO.)

Fig. 21.11 Keeping the gaze directed at the moving ball while standing on a compliant surface eliminates the primary use of visual targets to stabilize the head and is an effective way to shift reference from visual to vestibular. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, CO.)

Fig. 21.12 Projecting Peripheral Movement Activates the Optokinetic Response. Individuals with visual dependence for balance, or visual motion hypersensitivity, are not able to adequately achieve gaze stability of the central object or will lose balance as they match head position to the peripheral reference. In the patient with maladapted responses, this stimulus can cause significant nausea and other abnormal autonomic nervous system responses.

Elimination of visual dependence is a therapeutic goal with these patients. The optokinetic stimulus, which provides full field stimulus in a clinical setting as seen in Fig. 21.12, can be used to stimulate the use of vestibular references and decrease the visual dependence that leads to visual hypersensitivities. For the visually sensitive, this can start with the patient sitting and progress to standing on a compliant surface, or walking.

Fig. 21.13 The “Spot Turn” for the Patient With Bilateral Vestibular Loss. (A) When the patient is ready to turn, the front foot is planted to provide somatosensory reference. (B) Once the foot is planted, the head is turned. (C) Visual reference on a nonmoving target is maintained while the body turns under a stable head. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, CO.)

Somatosensory Dependency

To increase somatosensory input, patients with a vestibular disorder often put the whole foot down at once to get better input on the position of the body relative to the ground. The normal heel-toe weight progression over the ball of the foot is diminished. The use of touch through the upper extremities increases, especially during turning or reaching. Allowing a patient to touch a stable surface during balance training should be quickly eliminated from intervention to avoid dependence on surface reference when attempting to activate the vestibular system. Walking on uneven surfaces can be a challenge if the patient is primarily reliant on somatosensory input. Balance training on compliant foam, unsteady or perturbed surfaces, with eyes closed will facilitate use of vestibular input. Adding optokinetic stimulus, head turns, and other visual challenges will further facilitate adaptation. Gait training on progressively less-stable surfaces is appropriate for patients who need to reduce dependence on somatosensory cues and improve visual-vestibular interaction. Walking backwards on a treadmill with the trunk gently supported can be a good task to improve balance in gait. Patients often have difficulty reaching the foot backwards as they have become dependent on the foot forward to determine head position. Standing with a ball supported against a corner and reaching one foot backward at a time is a way to work on trunk control for balance.

Permanent bilateral vestibular loss requires the substitution of somatosensation and vision to orient to the environment. A cane or walking stick can increase the use of somatosensation and allow more time to prepare for the next step, thereby increasing confidence in gait. Control of turns can be achieved by the use of double limb support while the head is turning, performing a rapid saccade to find a stable visual target, and then completion of the turn with a fixed gaze on the target as the body turns as shown in Fig. 21.13. This process can become second nature and be performed on a regular basis to increase stability during daily tasks.³⁶ Driving can be trained in a safe manner by controlling head turns and visual references.³⁷

Head-Righting Responses

The otolithic labyrinthine reflex, commonly reported as head righting, is developed early in life. As stated earlier, it provides input to maintain eyes in horizontal and nose vertical by identification of the pull of

gravity by the vestibular system. Ocular skew and abnormal subjective visual vertical testing reflect this dysfunction. Another way this phenomenon can be tested is by observing the head-righting response while a patient has his or her vision blocked while sitting on a tilt board. The tilt starts at the pelvis; this should trigger the head-righting response to keep the head in the gravity neutral upright position. In the patient with vestibular dysfunction causing abnormal gravity reference, co-contraction of the neck muscles occurs to lock the head into position with the trunk. The head stays in alignment to the trunk and orients to the surface tilt, which causes imbalance. Because the lateral head-righting response is absent, the patient will often institute a parachute reaction with the arms out to the side to support the trunk. In addition, you will also see an attempt to increase the base of support through the legs and feet. Often there is a startle response activated, which is further evidence of somatosensory responses. This is evidenced in higher-level activities that require gravity reference, such as a tandem walk in visually stimulating environments or with vision occluded. The narrow stance of tandem will limit the contribution of surface reference in the lateral plane, and the patient must take a step out to control the excessive lateral tilt of the trunk and head. Normal and abnormal responses are seen in Fig. 21.14. It is the vestibular inputs that should drive the appropriate lateral head righting and resulting postural strategies that are required in these conditions. Observation of the alignment of the head during a tandem walk or single leg stance is critical in patients with vestibular deficits. Training should always include feedback on head position.

Head turns during balance tasks will decrease the ability to substitute somatosensory input. Activities that require quick changes of position in a superior or inferior direction, such as a lunge or going up and down stairs, can be difficult when the otoliths are damaged. Good program components for otolith stimulation are activities involving up-and-down body movements. Examples include sit-to-stand and seated bouncing on a Swiss ball—with eyes closed to eliminate the use of vision for stability. The use of the hip strategy may be modified or limited in the vestibular-deficient patient because when the head is moving in the opposite direction as the center of gravity (COG), vestibular and somatosensory inputs are not congruent.³⁸ Standing on a narrow surface such as a 2×4 piece of wood should activate a hip strategy. The clinician can identify functional deficits as the patient locks the ankles at 90 degrees and the entire body tilts forward or backward causing the 2×4 to tilt. Often the patient will avoid using an appropriate stepping strategy as well and falls without recovery. As an exercise this is performed in the corner so that the walls will catch the patient and the patient has room to perform a backward step. In this exercise, a stepping strategy is preferable to reaching out to the wall.

As stated previously, the vestibular system provides a top-down point of reference that the somatosensory system uses to prevent the head and trunk from aligning with surface changes. Perturbations in the form of oscillating surfaces provide a mechanism to activate the gravity receptors, and feedback about the alignment of the trunk to gravity neutral can help to discourage surface dependence when it should not be the dominant reference.³⁹ Certain positions or movements of the head during upright activities can affect balance even if just one part of the vestibular system has abnormal function. If the otoliths are damaged or hypersensitive, a voluntary lateral tilt of the head when standing with the eyes closed can cause destabilization. Training strategies with head tilts will improve stability.

Central Maladaptation

There can be many conditions that create inadequate sensory reference for the adaptation process to occur. The problem may be that the competent information from the periphery is not processed correctly at the

Fig. 21.14 (A) When a surface reference is used in preference to a vestibular cue, the head remains in alignment with the surface. (B) As the patient is able to regain vestibular function and gravity reference, the head remains in alignment with gravity, as a head-righting response. (C) Lack of head-righting responses can cause excessive use of upper-extremity activity to try to reference to the surface, with bottom-up firing patterns; hip strategy is activated but inefficient. Abnormal reference patterns result in loss of balance in a tandem stance with eyes closed. (D) When the vestibular reference is restored, the head remains over the feet, so balance is restored. This is why it is important to observe the angle of the head during examination of a tandem stance or gait. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, CO.)

CNS level. The vestibular, visual, and somatosensory systems may test normal, but the individual is not able to use them adequately for functional activity. The peripheral information also can be so disrupted that the CNS is not able to adapt; this can be the case in concussion wherein the visual, somatosensory, and vestibular systems may all be damaged to some degree. When the vestibular information fluctuates, as in the case of Meniere disease, migraine dehiscence, or fistula, the adaptation process cannot stay effective over time. Autonomic nervous system disorders are common contributors to maladaptation. Postural orthostatic tachycardia syndrome (POTS), dysautonomia, and autoimmune ear disease fall into this category and will be discussed later. The mechanisms that underlie chronic pain in terms of sensitization of either the peripheral nervous system or CNS may have a parallel construct to chronic dizziness. This concept is under investigation and may help identify the hypersensitivity to stimulus that is often a part of this disorder.^{40,41}

Hypersensitivity patterns can create intolerance of typical environmental conditions that include apparent visual motion, ground vibrations, or conflict between sensory references. As described previously in visual sensitivity, many patients will avoid provoking environments, such as airports or malls, often wear dark glasses when inside, and self-limit their driving. **Box 21.3** presents environmental conditions that may drive hypersensitivities.

These patients often report abnormal sensations with the head at rest with eyes closed, such as “flickers, explosions, or racing,” which do not reflect vestibular or somatosensory deficits. They will often demonstrate fear or avoidance behaviors during the testing process. Often they will perform better on the tests of balance that are harder to perform, such as eyes closed on foam, especially when distracted by a concurrent mental task. This can be misinterpreted as malingering. Visual motion hypersensitivity during oculomotor testing is common, and excessive startle is often seen during tests of head righting as noted previously.⁴²

Visual motion hypersensitivity is a hallmark of PPPD (see later) and other disorders that affect the autonomic nervous system. These patients typically have not been able to return to previous function despite time and therapies, and generally under-perform in life roles. Routine vestibular rehabilitation is usually not successful unless sensitivities are identified early in the intervention process so that the correct referrals can be made.⁴³ A patient in this category may become identified only when several other treatment regimens fail. Based on the status of normal vestibular testing the patient has often been told that there is nothing wrong and thus the problem is in their heads. Indeed, this category of patient often has an overlapping psychological disorder that should be treated concomitantly.

BOX 21.3 Environmental Conditions That May Cause Visual Motion Hypersensitivities

Grocery stores—cans and boxes appear to be moving backward when one walks down an aisle
 Airports with moving sidewalks
 Malls with open walkways and glass elevators
 Disco lights
 Escalators, if the “down” and “up” escalators are side by side
 Department stores, especially during holidays or when displays are moving
 Large “box” stores where the ceiling is unusually high
 Large-format TV and movies, especially IMAX or 3D
 Walking outside when the wind blows the tree limbs
 Driving in rain or snow with windshield wipers active

Anxiety, depression, posttraumatic stress, and a history of physical or verbal abuse are common comorbidities that will affect intervention and outcome. Management of these patients should include focus on self-regulation, which can include referral to someone to assist with the identification and treatment of psychological or psychiatric components. Successful outcomes with interventions are possible; however, the process may take longer because the central modulation of sensory input is compromised, and therefore adaptation will occur in smaller increments.⁴⁴ Most types of central dysfunction will negatively affect the recovery rate. Patients with persistent dizziness had significantly more anxiety and depression, which correlated with a higher emotional subscale of the Dizziness Handicap Inventory.⁴⁵ The patient with maladaptation will often have more difficulty with relationships and may create more demands on the health care system, families, or caregivers. Activities such as scheduling appointments, attendance for sessions, and compliance with home programs are often compromised and can cause frustration for the clinician. It is critical for the clinician to have a proper understanding of the behavioral aspect of intervention to avoid burnout with these patients. Mindfulness training for both the clinician and the patient can have a positive impact on interventions and follow through.

Head Position Dizziness

Sometimes just changing the position of the head, such as when bending forward or looking up, can cause dizziness. BPPV is the most common form of head position dizziness in adults. The onset is sudden and often severe.

In this condition, otoconia from the utricle floats into the semi-circular canal. The canals are designed to respond to fluid movement that accompanies head motion as described previously. Think of the otoconia in the endolymph as steel balls in corn syrup. The otoconia drifts through the fluid in the canal as the head moves into a gravity-dependent position. This causes a drag on the endolymph, which pulls on the cupula, causing excessive deflection of the hair cells. The increased firing of the hair cells creates a sensation of rotation of the head. **Fig. 21.14** shows how the falling otoconia activates the cupula. The VOR is stimulated in response to the abnormal message that the head is rotating quickly. The eyes are activated to respond to the perceived movement, and as the VOR is attempting to establish the appropriate gain of the system, there is nystagmus. As soon as the head stops moving, otoconia come to rest at the lowest point in the canal, the pressure on the hair cell is relieved, and the nystagmus subsides. This takes about 20 to 60 seconds. There is no nystagmus until the head is moved into another gravity-dependent position causing the otoconia to roll once again through the canal.⁴⁶

By looking at experimentally induced canalithiasis using the principles of mechanics of the falling otoconia the clinician can identify the nature of the nystagmus, and this can help determine the likely cause. The otoconia will typically fall to the lowest portion of the canal in relationship to the head position. Depending on the exact head position, the otoconia will fall through the center of the canal, creating a strong nystagmus, or it may roll along the wall of the canal, moving slower and causing less drag on the cupula, thereby resulting in a smaller amplitude nystagmus. The timing of the fall, or sedimentation, is dependent on how many of the otoconia have stuck together, which determines the canalith size. A single large canalith will fall faster and create more drag than several smaller canaliths falling at the same time in the canal.⁴⁷ Due to the architecture of the canals in relation to the otoliths, the otoconia can appear on either side of the cupula appearing in the short arm or the long arm of the canal. The otoconia will either push or pull the hair cells depending on the head position, and this will determine the nystagmus pattern. Identification of the

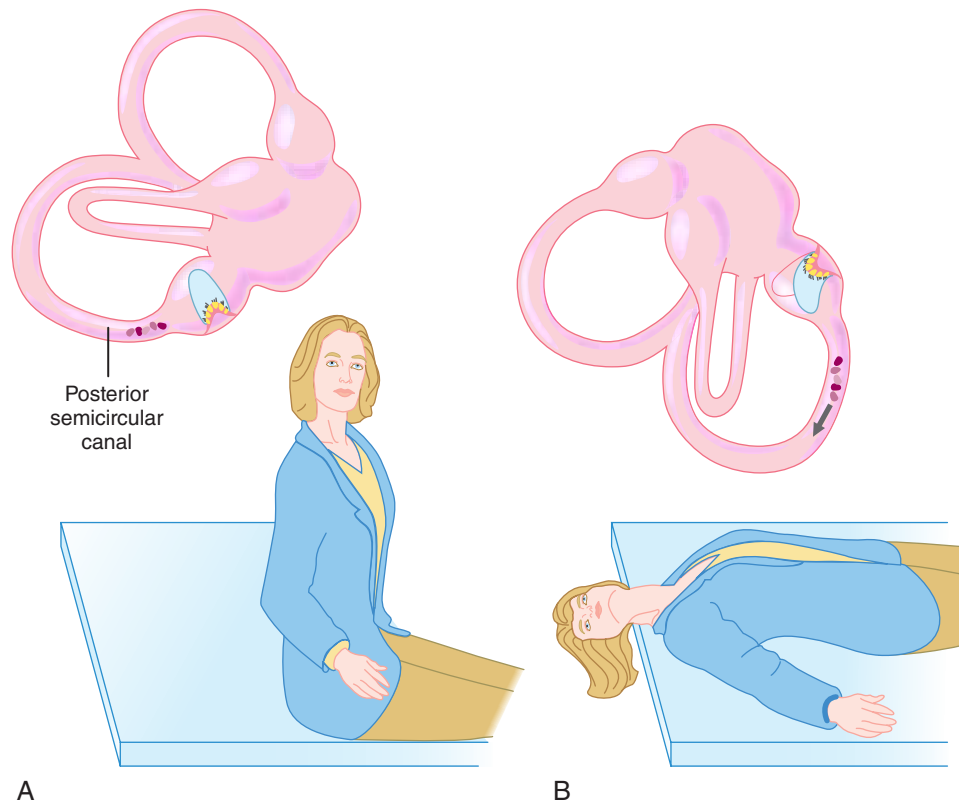

Fig. 21.15 The Hallpike-Dix Maneuver. **(A)** Starting position with head rotated toward the side to be tested. **(B)** Lowering the patient's head backward and to the side allows debris in the posterior canal to fall to its lowest position, activating the canal and causing eye movements and vertigo. (From Lundy-Ekman L. *Neuroscience: Fundamentals for Rehabilitation*. 3rd ed. Philadelphia: Saunders; 2007.)

nystagmus pattern with respect to the involved canal is key to determining the appropriate intervention as each canal will create its unique nystagmus pattern.

Cupulolithiasis occurs when the otoconia is adhered to the cupula, which causes a direct pull on the hair cells and is not dependent on the drag of the endolymph. This changes the nature of the nystagmus pattern, with immediate onset and longer duration before there is accommodation to the stimulus. The otoconia can adhere to either side of the cupula, depending on which part of the canal it entered. The nystagmus pattern will reflect the direction of pressure on the cupula and the resulting bend of the kinocilium.

Positional testing is indicated when a patient describes episodic vertigo or other symptoms such as dizziness, nausea, or imbalance.⁴⁸

Vertical Canals

The Dix-Hallpike maneuver is the gold standard test to establish the diagnosis of posterior and anterior BPPV.⁴⁹ With posterior or anterior canal BPPV, the patient typically experiences symptoms with bending forward, looking up, and rolling in bed. These movements place the vertical canals in the plane of gravity, causing loose debris (otoconia) to shift and stimulate the cupula.⁵⁰

To perform the Dix Hallpike test, the patient is brought from long sitting to supine position with the head turned 45 degrees to one side and the neck extended 20 degrees. The examiner holds the head in this position for 20 to 30 seconds while monitoring for symptoms of vertigo and observing the eyes for nystagmus.³⁸ A positive response for posterior canal BPPV is torsional upbeat nystagmus with a latency of 3 to 15 seconds. The intensity of the nystagmus increases

before decreasing until it completely resolves, typically fatiguing in less than 60 seconds.⁵¹

When the Dix-Hallpike test indicates BPPV, specific and highly effective procedures can be performed in the clinical setting to remediate the disorder.⁵² Canalith repositioning is a series of passive movements designed to move the otoconia through the canal and back into the otolith. During the Epley maneuver for posterior or anterior canal BPPV, the patient is first brought down into the extended and rotated position that causes the nystagmus and vertigo (the positive Hallpike-Dix position). The head is held in that position until the symptoms fade completely or for 60 to 90 seconds. The head is maintained in extension and then slowly rotated toward the unaffected side and kept in that position for an additional 1 to 2 minutes to allow movement of the otoconia through the canal. The patient then rolls to side-lying position with the head turned to a 45-degree position relative to the ground and is kept in the position for another 1 to 2 minutes. This position often produces more vertigo and nystagmus as the otoconia continue to move through the canal. The head is then tipped toward the chest, and the patient is assisted into the sitting position. The stages of the Epley maneuver are shown in Fig. 21.16.

An alternate maneuver for posterior canal BPPV is the Semont liberatory maneuver. The patient quickly moves from sitting on the edge of a table to lying on the affected side with the head turned up. This position is held for at least 20 seconds after nystagmus has resolved. The patient then moves quickly through the sitting position to lying on the unaffected side with the head facing up. This nose down position is held for 60 seconds or longer. The patient then moves back

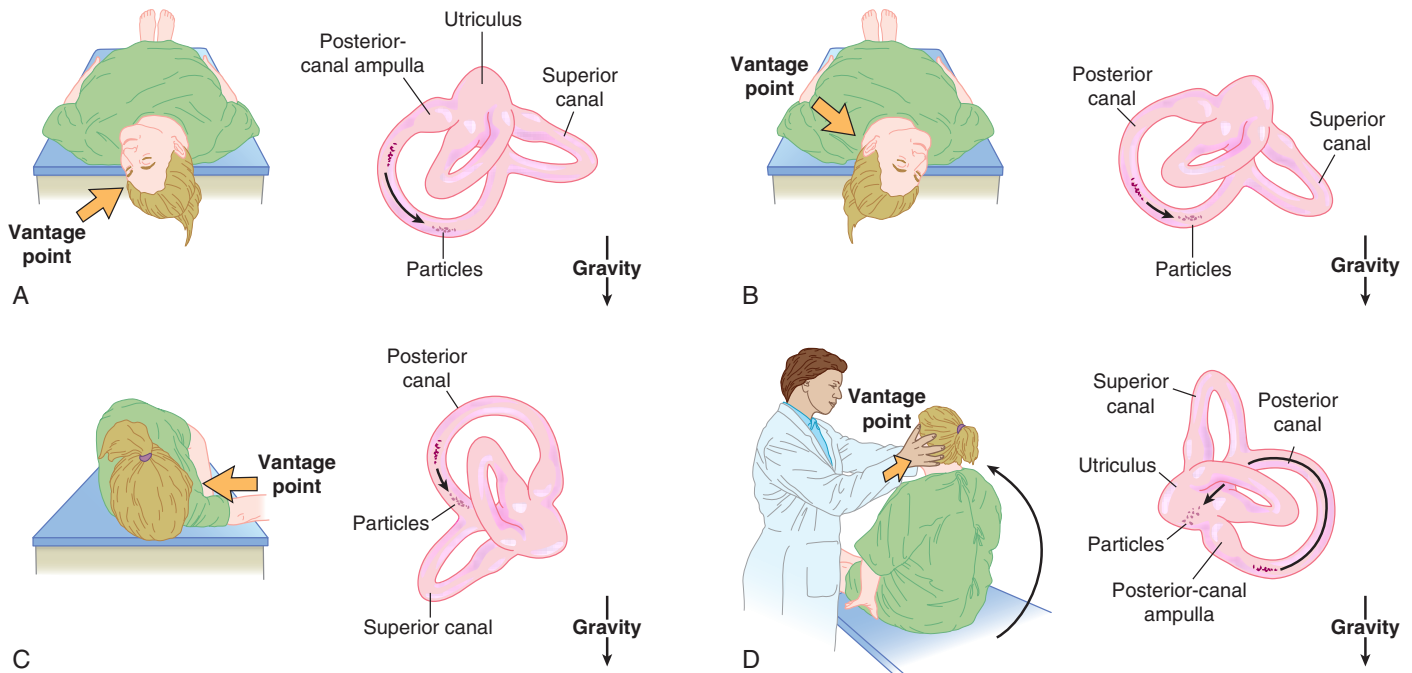

Fig. 21.16 Epley maneuver: Canalith repositioning maneuver for the patient with posterior canal benign positional vertigo (BPPV). The figure represents the procedure for right-side BPPV. The movement of particles through the canal is shown in each position.

to sitting.⁵³ Some recent clinical recommendations for the Semont maneuver are to maintain an extension angle of head and neck at 110 degrees in the nose up position and 220 degrees in the nose down position. A velocity of 135 degrees per second, which should take 0.66 seconds for the nose up, and 1.33 seconds to move to the nose down position should be achieved during the movement. It is recommended that resting time between movements should be at least 45 seconds. If the patient requires slower movement, there should be more resting time between movements (up to 60 seconds).^{54,55}

Horizontal Canals

When otoconia are present within the horizontal canal, the patient will experience vertigo with rolling in either direction, especially when the head is elevated on a pillow, and may have vertigo with bending forward. Horizontal canal BPPV is usually associated with autonomic symptoms such as lightheadedness, nausea, and vomiting. The supine horizontal roll test⁵¹ is the most commonly used test to determine the presence of horizontal canal BPPV. During the roll test, the patient lies in supine with the head held in 30 degrees flexion to keep the horizontal canal perpendicular to the ground. The head is then turned 90 degrees to one side while the eyes are observed for nystagmus. The head is returned to neutral and then rotated 90 degrees to the other side. A positive response is horizontal nystagmus that changes direction when head position is changed (e.g., right beating with the head turned right and left beating with the head turned left) and is stronger on one side than the other. The nystagmus can be either geotropic or apogeotropic. In geotropic horizontal canal BPPV, the more intense nystagmus beats toward the affected ear (toward the ground) when the patient is lying on the affected side. This suggests the otoconia are located in the long or posterior arm of the horizontal canal. In the apogeotropic type, the more intense nystagmus beats away from the affected ear (away from the ground) when the patient is lying on the affected side.

Apogeotropic nystagmus indicates the otoconia is adhered to the ampulla on either the utricular or canal side (cupulolithiasis) or is located in the short arm or in the anterior portion of the long arm of the horizontal canal (canalithiasis).

The posterior arm of the canal opens to the otolith, which allows the otoconia to be moved back into place. It is the goal of repositioning maneuvers to shift the otoconia toward the otolith. When the otoconia is in the anterior portion of the horizontal canal, it must be moved into the posterior portion of the canal to be removed from the canal.

Identification of the involved side is critical to treating horizontal canal BPPV. The bow and lean tests can be performed in addition to the horizontal roll test to provide increased certainty about the side of involvement. The bow test is performed by having the patient bend the head forward by 90 to 120 degrees in sitting position, while the lean test is performed by having the patient lean the head backward by 45 to 60 degrees or by having the patient lie supine with the head supported on a pillow.⁵⁴ The direction of nystagmus is noted.⁵⁶ In geotropic BPPV, nystagmus will beat toward the affected ear in the bow test and away from the affected ear in the lean test. In apogeotropic BPPV, the reverse is true with nystagmus beating away from the affected ear in the bow test and toward the affected ear in the lean test.

For horizontal canal BPPV, several canalith repositioning maneuvers are effective. During the barbecue roll, the patient lies in supine, and the head or full body is turned toward the affected ear. The head is then turned away from the affected ear before turning the head down toward the ground. Traditionally, the maneuver was performed by turning the patient a full 360 degrees before returning to sitting with the head tucked. However, some recommend finishing the roll by having the patient sit up from the nose down position. Each position is held for 15 to 30 seconds.⁵⁷

An alternate maneuver for horizontal canal repositioning is the Gufoni maneuver, during which the patient moves from sitting to lying on the unaffected side for 30 seconds. The head is then rotated quickly down 45 to 60 degrees and is held for 1 to 2 minutes. The patient then sits up with the head rotated toward the unaffected side. This moves the otoconia, which is in the posterior portion of the canal, toward the otolith.⁵⁸ The Gufoni maneuver is modified for apogeotropic BPPV to have the patient lying on the affected side. This moves the otoconia from the anterior toward the posterior portion of the canal to gain access to the otolith.⁵⁹ A final treatment that can be used in conjunction with the barbecue roll or the Gufoni maneuver is forced prolonged positioning during which the patient lies on the unaffected side (for geotropic BPPV) or the affected side (for apogeotropic BPPV) for the entire night. Again, the goal is to move the otoconia to and through the posterior portion of the canal to the otolith.⁵⁷

Traditionally, the patient was instructed to follow specific instructions for 24 hours following canalith repositioning to prevent displacement of the otoconia back into the treated canal.⁶⁰ These instructions included sleeping with the head elevated to at least 30 degrees and avoiding head movement.⁶¹ More recent studies suggest there is insufficient evidence to support the recommendation of these restrictions following canalith repositioning for posterior canal BPPV.⁶² However, some patients, such as those with frequent recurrence of BPPV, may still benefit from these restrictions.

Because BPPV is the most common cause of dizziness and should not require a hospital stay, emergency room personnel are being trained to identify, rule out other causes, and provide the appropriate repositioning procedures.⁶³

When BPPV is not found to be the cause, position-provoked dizziness may alternatively be related to canal sensitivity, a light or heavy cupula (see later), or abnormal firing through the brain stem or cerebellum as described previously. In this case, exercises may be done to increase the patient's tolerance to the provocation. For example, rolling on a bed or spinning in a chair can help the adaptation process when it involves the horizontal canal. In cases of maladaptation creating sensitivity of head position, moving gradually into the position of discomfort while minimizing input from the other sensory systems can be successful. In addition to exercise sessions, incorporating the provoking positions into daily activities is important.

FEEDBACK

Biofeedback is used to improve adaptation to vestibular disorders. Feedback regarding the correct postural responses remains the task of the therapist in the training paradigm. Visual feedback about the head and trunk movement versus total movement on a perturbed surface can provide the patient with knowledge of the abnormal pattern and

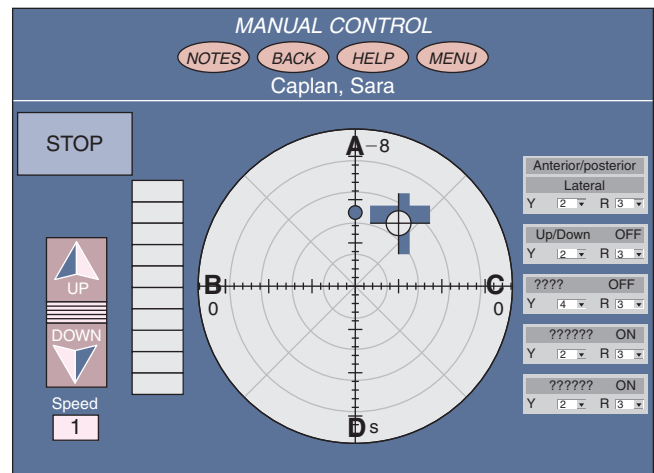

Fig. 21.17 Feedback regarding the position of the trunk in relation to the center of the platform, as well as feedback regarding the amount of trunk flexion, extension, and rotation, can be provided to the patient during the perturbations. The patient can also receive summary feedback after sessions performed with the eyes closed. (Proprio 5000, Perry Dynamics, Decatur, IL.)

give clues of correct postural responses as seen in Fig. 21.17. Feedback has been used to supplement the center of pressure reference for the control of weight shifting using vision to supplement vestibular integration to somatosensory inputs. When visual feedback is provided, it is important to consider the patient's level of visual sensitivity and recognize the need for modified feedback. Audio feedback has been used in the patient with vestibular system loss to provide information about sway when surface and visual reference is lacking. Vibrotactile feedback using accelerometer or gyroscopic information can assist the alignment of body position and movement. This has been successful on many levels, and the modes of input are becoming less intrusive to those who wear them.

ACKNOWLEDGMENT

Chelsea Van Zytveld assisted in this chapter with a focus on head position dizziness. Thanks to Leslie Allison for years of working on the integration of the vestibular system into the larger concepts of balance and function. It has been wonderful to work with Rolando Lazaro who is bringing forward the wisdom and wonder that Darcy Umphred shared with all of us over the years. Thanks to my many patients who have taught me the importance of knowing how to help.

CASE STUDY 21.1 Mr. Hu

At the initial visit, Mr. Hu reported dizziness that started approximately 12 years ago with vertigo that woke him up in the night. He was unable to get out of bed for 2 days following that episode. He reported that this has happened about four times in the past 10 years, with the most recent episode about 5 years ago. He reported that his balance has not felt normal for years. His vestibular testing (VNG) showed a 48% reduced vestibular response on his right side with a suspected viral etiology. He scored 50/100 on the Dizziness Handicap Inventory (moderate impairment). He had difficulty at work at the botanical gardens with both visual discomfort and pain when lifting. He had difficulty when he had to walk across the gardens.

He reported a comorbidity of neck pain with radiation to the hand, which has been progressive. His orthopedic surgeon has recommended surgery.

Patient's reported problem list:

1. Head motion provoked dizziness primarily with horizontal head turns and when looking up.
2. Visual motion hypersensitivity creating dizziness and discomfort with computers, fluorescent lights, loud and crowded restaurants, and similar environments.
3. Increased anxiety.
4. Hyperventilation with exertion.

CASE STUDY 21.1 Mr. Hu—cont'd

Examination Highlights

- Sensation of motion at rest with eyes closed reported as a tilting sensation. Increased sense of being lightheaded with 5-pound weights on shoulders.
- Normal oculomotor exam. Visual motion hypersensitivity with oculomotor testing.
- Vestibulo-ocular reflex testing normal with one line drop on dynamic visual acuity. Dizziness reported during testing.
- Increased dizziness with body rotation under stable head. Excessive stiffness and guarding of his cervical paraspinals.
- Head on body orientation during sitting side tilts, inefficient head righting, strong startle and parachute responses.
- Positive smooth pursuit neck torsion test on right.
- Increased sway during standing with eyes closed on firm surface. Increased sway but no loss of balance on foam. Loss of balance on foam with eyes closed head turns.
- Excessive sway with evidence of strong visual dependence and surface reference during standing perturbations.
- Positive Dix Hallpike test with torsional up-beating nystagmus about 20 seconds duration, indicating probable right posterior canal BPPV.

Progression of Intervention in First Month

The Epley maneuver was performed 2× with the resolution of nystagmus. This remained resolved in subsequent visits, so a balance program was initiated. This started with work to integrate the somatosensory system and vestibular with eyes closed. He was given 2-pound weights to put on his shoulders when sitting with his eyes closed. He was given sequential numbering activities to perform during sitting with weights, which was progressed to 5 pounds. Standing activities began with weights on shoulders, eyes closed. Small fast perturbations were initiated with eyes closed to facilitate the use of somatosensation for balance. Slower deeper tilts were used with eyes closed to facilitate vestibular response. Feedback was provided to maintain the trunk in a gravity neutral position. The cervical spine was addressed with soft tissue work to decrease stiffness along with the use of laser light and targets to improve the efficiency of kinesthesia in the neck. Sitting tilts were performed to activate normal head righting starting with manual feedback for the gravity neutral head position.

Progression of Intervention

In the following months, Mr. Hu was able report no sensation of tilt with eyes closed with 5-pound weights on each shoulder; however, he had increased anxiety when his eyes were closed. He showed improved head righting and could stand on perturbed surfaces during both fast and slow speed, but again had increased guard when his eyes were closed. His exercises were progressed to stand on a single leg with eyes closed and with visual pursuits. He stood on foam tracking a ball toss and would do this while walking as well. He worked to activate hip and stepping strategies while standing on a 2×4. His balance was improved in testing. Functional gait assessment improved from 20/30 to 28/30. Improvements were seen in walking with head turn and tilt, tandem gait, backward walking, step over obstacle, and stair climbing. He was given optokinetic stimulus in the clinic while standing on both a firm surface and on foam with follow-up computerized optokinetic flow exercises performed at home, which he had downloaded from various internet sites.

His kinesthesia continued to be abnormal, and it was felt that this was associated with the extensive pain and movement disorder related to his cervical spine.

Of concern, he continued to complain of the same vague dizziness that had plagued him for years, and with further questioning, he reported that this would fluctuate daily and persisted despite his improved balance. He continued to experience hyperventilation with exertion. His neck surgery was approaching, and he was reporting increasing anxiety and dizziness. During the session that was designed to begin to work on self-regulation through modulation of the autonomic nervous system, he became extremely fearful and agitated when asked to lie quietly in a dark room and begin controlled breathing. During this session, he reported that his father, who was in his home country, has Alzheimer disease and was doing poorly. His father had also had episodes of dizziness during his lifetime, and the patient had connected his own experience of dizziness to the probable onset of Alzheimer disease. This was likely related to his high levels of anxiety surrounding the dizziness. His orthopedic surgeon told him that his dizziness might be worse during recovery, so Mr. Hu wanted to postpone the surgery.

The patient was educated to gain the understanding that his father may have also been having bouts of BPPV or other vestibular events in his life, but this was not the direct cause of his Alzheimer disease. Imbalance is a part of Alzheimer disease, but it is not the primary precursor. As the patient began to understand this his agitation decreased.

In the weeks before surgery, his sessions were devoted to continued work on self-regulation and control of his ANS response. He was able to participate in the sessions without fear and was referred to a physical therapist dual trained as a psychotherapist as well, who specializes in trauma work.

His cervical spine surgery was performed as scheduled. The rehabilitation for that surgery was incorporated into continued work with kinesthesia, progressing to performing during both sitting and standing perturbations. As his cervical kinesthesia improved, he was able to tolerate increasing optokinetic challenges. With significantly increased tolerance to required activities, he was able to return to work and the.

It has been 3 years since this patient's initial visit. He has had occasional return of BPPV and will have increased dizziness when he is over stressed. He continues to work on improvement of cervical function with integration of balance tasks. He benefits from clinical intervention when he has episodes of head position dizziness. His anxiety will increase when he is dizzy but is not disabling as it had been in the past. He reports that he will be forever grateful for the understanding of his problem within this context and feels like he "got his life back."

Summary

This case highlights the need to understand how a vestibular event can trigger PPPD and the need for comprehensive history taking. Although the BPPV brought him into therapy at this time, the reduced vestibular response was likely related to the report of dizziness that occurred 12 years ago. He did not have full adaptation without therapy at that time, which led to anxiety and persistent symptoms. Intervention targeted to the ANS can have a positive impact. In the patient with maladapted sensory system integration, the visual, somatosensory, and vestibular systems should be modulated throughout the program. Improvement in one area often leads to increased capacity for other sensory systems to integrate. Research may someday uncover a link to the vestibular system and dementia, as noted earlier in this text. At the same time, there may be more options for intervention and prevention.

Common Vestibular Disorders

BENIGN PAROXYSMAL POSITIONAL VERTIGO

This is the most common cause for head position dizziness with vertigo as its primary symptom. It is a common sequela of concussion, viral labyrinthitis, hydrops, and vascular occlusion in the distribution that feeds the inner ear. The mechanism and intervention of benign paroxysmal positional vertigo (BPPV) are described in the *Head Position Dizziness* section. Any of the six semicircular canals can collect the loose otoconia. The posterior canal is most common because of its relationship to the otoliths when the person is in the recumbent position. The horizontal canal, while less common, can have more intense symptoms. This dizziness seems more persistent and more easily triggered with the typical head movements of daily life.

Despite the use of the term *benign*, the symptoms related to positional vertigo are intense and can cause significant disability. There is often a strong sense of falling or spinning out of control, even when the individual is lying on a bed. Before the individual is aware of the mechanism, the symptoms seem uncontrollable and the person will avoid head movement. Spontaneous remissions are common, and many current patients will describe an earlier episode that resolved without intervention. Recurrent episodes may reflect an underlying disorder such as hydrops or migraine-induced ischemia. Infections or inflammations may occur months or years before the onset; it is believed that the otoconia may loosen as the nerve degenerates. Adverse life events are reported to trigger an episode, especially in those individuals with an underlying disorder.⁶¹ It is critical to rule out other conditions that can cause head position dizziness. (Common causes are described in [Box 21.4](#).)

BOX 21.4 Alternative Causes of Head Position Dizziness and Nature of Dizziness

Unilateral vestibular dysfunction: Dizziness when changing head position while supine

Vestibular migraine: Episodic dizziness that can usually be related to specific triggers

Cerebellar nodulus: Nystagmus is downbeat without torsion, fatigue, or habituation

Vertebral artery compression: Nystagmus with extreme rotation or extension of neck

Central vestibular pathways: Nystagmus without dizziness, usually unidirectional

Geriatric supine nystagmus: Vertical nystagmus when supine

Perilymph fistula: Episodic dizziness after trauma increases with Valsalva or head hanging

Superior canal dehiscence: Dizziness with loud noises or change of head position

Hypermobile stapes: Unstable at oval window; allows fluid pressure changes that cause dizziness with head positions

Head extension: Otoliths outside of functional range, causing dizziness

Orthostatic intolerance: Dizziness when bending or quickly standing from sitting; never when lying

There is often some imbalance reported that may take some time to improve after the dizziness has resolved. Evaluation of underlying vestibular function and sensory integration should be done for patients with BPPV.

INFECTION

Acute unilateral vestibulopathy affects the vestibular nerve directly or associated with the labyrinths. Most often the infection is viral in nature and is known as neuronitis or neuritis. It can also be due to bacterial infection from a variety of causes, either as a primary infection or secondary to bacterial meningitis or encephalitis. Vestibular neuritis can be partial, affecting the superior afferents from the horizontal and anterior semicircular canals primarily along with the utricle. This can leave the saccule function intact so that the head motion concerns are greater than the imbalance.

The infection often is preceded by a systemic illness or an upper respiratory tract infection, but it can be an isolated infection affecting the nerve or labyrinths. Initial impairment may include ocular tilt, skew deviation, or lateropulsion as described previously. Recovery reflects central adaptation to loss of input on one side of the vestibular system. Herpes virus infection can result in a condition known as Ramsay Hunt syndrome. It is often seen along with unilateral facial weakness as the facial nerve is also affected by the infection. The patient is usually treated with antiviral medications. In Ramsay Hunt syndrome, the symptoms follow the typical pattern of acute vestibular and hearing loss, but these are not as profound as the facial weakness.

The adaptation mechanisms described previously are typically successful. In patients with less than a 40% loss, adaptation is achieved with typical vestibular rehabilitation strategies to facilitate adaptation. When there is 40% to 70% unilateral loss, the adaptation will take longer, and it is more likely that dependency patterns will develop, so the clinician should look for these patterns and isolate challenges to the vestibular system to avoid dependency. When the loss is greater than 70% and the nerve does not heal, the patient may have a much harder time with the adaptation process and may need to be trained on substitution strategies. Even a moderate vestibular loss can trigger symptoms of hypersensitivity when the adaptation process is prolonged or incomplete.

ENDOLYMPHATIC HYDROPS

Increased fluid pressure within the labyrinth, known broadly as hydrops, will cause vertigo. The increased size of the endolymphatic cavity can be imaged with magnetic resonance imaging (MRI).⁶⁴ The pressure may increase within the canal because the fluid cannot move out of the system through the endolymphatic sac, which normally provides drainage of excess fluid. This is usually a unilateral problem. As the fluid pressure increases on the cupula, the hair cells are activated as if there was quick head movement and results in the sensation of spinning with the vestibulo-ocular reflex activated.

Ménière disease is a type of hydrops that occurs intermittently with spontaneous vertigo. There is often concurrent low-frequency loss of hearing related to the fluid pressure in the cochlea. The episode can last from just a few minutes to a day but is usually between 2 and 4 hours in duration. A low-salt diet is usually the first line of defense. The use of diuretics can control the fluid changes and decrease the number and intensity of symptoms. In some cases, steroid injections are administered.

In the early course the person has normal balance and hearing when not in an episode. However, there appears to be a gradual degradation of the vestibular system over time, resulting in symptoms associated with chronic unilateral vestibular loss associated with progressive hearing loss. These patients often have a diffuse dizziness and complain of imbalance between episodes. Intervention is targeted at the adaptation of the abnormal vestibular responses, and this can improve symptoms, although it cannot remedy the disease itself. Tinnitus⁶⁵ may persist beyond hearing loss, and often this is one of the biggest complaints. If episodes persist, a Minette device can be helpful, or the ear function can be ablated via gentamicin injections or shunt surgeries.⁶⁶ **Box 21.5** gives the criteria for the diagnosis of Ménière disease.

Traumatic hydrops can be the result of a blow to the head during a fall or a whiplash injury. The mechanism is not fully understood, but it may be related to damage of the endolymphatic sac during the trauma, resulting in inflammation or scarring that limits the regulation of fluid in the sac. Patients often appear drunk during an episode; therefore they may limit social interactions or driving for fear of an attack. Drop attacks can develop over time, and in some individuals an attack can include the “crisis of Tumarkin,” resulting in feeling as if they are thrown to the ground without a sensation of dizziness. Intratympanic gentamicin can be used to manage the drop attacks.⁶⁷ However, there is a sudden unilateral vestibular loss associated with gentamicin. Progressive introduction of gentamicin can be considered along with prehab for those who are appropriate for the procedure but do not want to experience the severe symptoms of sudden loss of function.⁶⁸

PERILYMPH FISTULA

Fistula, or an abnormal communication of the inner and middle ear, can occur at the round or oval windows. This may be related to congenital temporal bone deformity or trauma through the middle ear by surgery, blasts, head injury, or even sneezing. The Valsalva maneuver or tragal pressure can trigger an intense sensation of dizziness and cause abnormal lateral weight shift because of the increased pressure in the system. Loud sounds can trigger the same responses and is described as the Tulio phenomenon. Daily activity can produce an almost persistent sense of dizziness that is relieved by recumbent positions with minimal head movement. Typical vestibular testing is nondiagnostic,

BOX 21.5 Definite Ménière Disease

- A. Two or more spontaneous episodes of vertigo, each lasting 20 min to 12 h
- B. Audiometrically documented low to medium frequency hearing loss in the affected ear on at least one occasion before, during, or after one of the episodes of vertigo
- C. Fluctuating aural symptoms (hearing, tinnitus, or fullness) in the affected ear
- D. Not better accounted for by another vestibular diagnosis

Diagnosis criteria from the International Classification of Vestibular Disorders

but the use of pressure in the ear may assist this diagnosis. Vestibular rehabilitation for adaptation fails because the system has a persistent fluctuating nature. Successful surgical repair of the fistula produces the stability needed to resume rehabilitation efforts.

SUPERIOR SEMICIRCULAR CANAL DEHISCENCE SYNDROME

Dehiscence or thinning of the bone overlying the superior (anterior) semicircular canal creates a “third mobile window,” and the effect of change in pressure of the canals appears to mimic the fistula. Loud noise or pressure can cause disequilibrium, vertigo, and oscillopsia. Surgical repair usually produces good results.

VESTIBULAR MIGRAINE

The aura or even the primary symptom of migraine may be dizziness. Diagnosis of vestibular variant of migraine is based on the episodic nature with the specific reports of one or more of the following: spontaneous vertigo, visual motion hypersensitivity, sensation of disrupted spatial orientation, head motion dizziness often with nausea, and occasional head position dizziness without evidence of BPPV. Recognition of triggers, history of migraine, and combination of dizziness with the other typical prodromes of migraine, including photophobia, nausea, and vestibulo-cochlear symptoms of tinnitus as well as sensitivity to sound can help identify migraine.⁶⁸ Symptoms are moderate or severe intensity. Duration of acute episodes is limited to a window of between 5 minutes and 72 hours.⁶⁹ Younger to middle-aged females are affected the most, often with a history of motion sickness or a family history of migraine.^{70–72} **Box 21.6** describes the criteria to determine vestibular migraine.

BOX 21.6 Vestibular Symptoms Associated With Vestibular Migraine as Defined by the Barany Society’s Classification

- A. At least five episodes with vestibular symptoms of moderate or severe intensity lasting 5 min to 72 h
- B. Current or previous history of migraine with or without aura according to the International Classification of Headache Disorders (ICHD)
- C. One or more migraine features with at least 50% of the vestibular episodes
 - headache with at least two of the following characteristics: one sided location, pulsating quality, moderate or severe pain intensity, aggravation by routine physical activity
 - visual aura
 - photophobia (visually induced vertigo, triggered by a complex or large moving visual stimulus)
 - phonophobia
 - spontaneous vertigo including:
 - internal vertigo or a false sensation of self movement
 - external vertigo, a false sensation that the visual surround is spinning or flowing
 - positional vertigo, occurring after a change of head position
 - head motion induced vertigo, occurring during head motion (can be accompanied by nausea)
- D. Not better accounted for by another vestibular or ICHD diagnosis

Modified from Lempert T, Olesen J, Furman J, et al. Vestibular migraine: diagnostic criteria consensus document of the Barany society and the International Headache Society. *J Vestib Res.* 2012;22:167–172.

BOX 21.7 Factors to Consider for Return to Play and Learn, Which May Represent Vestibular Involvement

1. Report of sensation of motion at rest with vision occluded
2. Abnormal oculomotor findings
3. Visual dependence or visual motion hypersensitivity
4. Somatosensory dependence or hypersensitivity
5. Head-motion-provoked dizziness
6. Loss of gaze stability with head motion
7. Abnormal smooth pursuit neck torsion test
8. Headache and/or neck pain
9. Abnormal head-righting response
10. Abnormal exertion test and excessive fatigue

The pathophysiology follows that of migraine headache in which there are multiple levels of dysfunction from gene defects that drive familial autosomal disorders and an inherited migraine threshold, brain stem activity that can trigger vascular responses of dilation or restriction, serotonin platelet activity, and spreading neuronal depression. Afferent vestibular and pain information in pre-parabrachial and pre-thalamic pathways have consequences on cortical mechanisms influencing perception, interoception, and affect. There are remarkable parallel neurochemical phenotypes for the inner ear and trigeminal ganglion cells, and these afferent channels appear to converge in shared central pathways for vestibular and nociceptive information processing. These pathways share the expression of receptors targeted by anti-migraine drugs.⁷³ It can be difficult to distinguish vestibular migraine (VM) from Ménière disease in its early stages. VEMPs may provide a way to help discriminate between these two vestibular disorders.^{74,75} The criteria to determine VM is described in [Box 21.7](#).

Patients with vestibular migraines have increased anxiety compared to migraines without vertigo.^{76,77} The autonomic nervous system plays a major role in all migraines and can be related to dysregulation in the activity of the parasympathetic–sympathetic branches. Interventions targeting control of the autonomic nervous system (ANS) through mindfulness meditation can help normalize related phenomenon such as heart rate variability.⁷⁸

Rehabilitation is indicated when avoidance of activity has changed the sensory integration, or when multiple episodes have influenced the system toward dependency or hypersensitivity patterns.⁷⁹ Visual sensitivity can be addressed in the patient with vestibular migraine, but the exposure must be introduced slowly and for brief episodes.

VASCULAR DISORDERS

Ischemia or bleeds in the areas of the vestibular system (brain stem, cerebellum, parietal-insular cortex) can cause dizziness and imbalance. The anterior inferior cerebellar artery feeds the peripheral vestibular system and the lower two-thirds of the pons and the ventrolateral cerebellum. The posterior inferior cerebellar artery feeds the dorsolateral medulla and posterior inferior cerebellum. Vertebral basilar artery insufficiency syndrome and lateral medullary syndrome (Wallenberg syndrome) present with dizziness and nystagmus, but will have associated brain stem findings. Ischemia is usually seen in individuals older than 50 years, but it can also be associated with bleeding disorders such as leukemia. Bleeds near the brain stem can be seen in younger individuals associated with recreational drug use. Migraine headache can cause intermittent dizziness from the compromise of blood flow in the

areas of the vestibular system. See chapters on cerebellar disorders and hemiplegia. Identification of direction changing gaze evoked nystagmus and presence of skew deviation can be used to assist early diagnosis of stroke. Oculomotor findings are used to assist in diagnosis.⁸⁰

NEOPLASIA

This can compromise vestibular function when it occurs near any part of the vestibular system. Vestibular schwannoma (commonly, but mistakenly, known as acoustic neuroma) can cause damage as it slowly grows on the sheath of the vestibular nerve. Because the tumor grows slowly, the system may have adapted to the gradual compression of the nerve so dizziness is not the primary complaint. Hearing loss is the most typical phenomenon, and sometimes when it is excised, the patient will develop dizziness and imbalance due to acute swelling around the tumor, or damage inflicted by surgical techniques. The schwannoma can grow into the pontocerebellar angle and cause symptoms typically associated with cerebellar lesions. Meningiomas (encapsulated tumors found most often deep in the brain) growing near the temporal lobe can cause pressure on the vestibular mechanism.

OTOTOXICITY

Aminoglycosides and antibiotics used in cases of massive or systemic infection can be ototoxic (causing damage to the vestibular hair cells). Although a small percentage of users experience this adverse effect, it can affect both sides of the bilateral vestibular apparatus and cause significant disability. Often the patient does not begin to experience the symptoms until the medication has been used for more than a week.

TRAUMATIC BRAIN INJURY AND CONCUSSION

A brain injury, either considered moderate/severe or mild (concussion), can affect the vestibular system in several ways. It can cause direct damage to the vestibular end organ (in the temporal bone), cause BPPV, and, in many cases, disruption of the integration of the vestibular nuclei (in the brain stem) and cerebellum. Comorbid visual dysfunction often results from damage to brain stem areas such as the pontine gaze centers or central damage in the medial longitudinal fasciculus, or from direct damage to the third, fourth, or sixth cranial nerves. The oculomotor system should be carefully examined for efficiency of saccades, pursuits, and convergence. Initial training of oculomotor function should start with minimal background visual stimulus. If the oculomotor system is functioning normally, but the testing makes the patient dizzy, interventions to reduce visual sensitivity should be initiated.⁸¹

Recognition of the connections between the cervical spine and eye movement is also critical in the early stages of recovery. Excessive co-contraction in the neck and upper back may represent disrupted signals between the eye muscles and the cervical musculature. Neck torsion smooth pursuits should be tested when there is dizziness and neck pain. If the VSR is not providing appropriate signals to the cervical musculature, the small intrinsic cervical muscles that fire in response may be overpowered by the extrinsic stabilizers of the neck and shoulders. Often overactivity is noted in the sternocleidomastoid, levator scapulae, and upper trapezius. This will affect the ability to perform head-righting tasks and can lead to tension-type headaches. This is further explained in the Cervical Spine Function and Dysfunction in Chapter 23. Excessive surface reference during balance and gait can lead to lack of confidence in mobility and increase energy costs.⁸²

The autonomic nervous system function is negatively affected post brain injury and may represent the prolonged recovery and symptoms that interfere with daily tasks. Conditions related to ANS dysfunction are prevalent post traumatic brain injury (TBI; see below in Autonomic Nervous System Dysregulation) and may lead to postconcussive symptoms of anxiety and depression. Preexisting issues may be exacerbated after TBI and should be evaluated and addressed concurrently by a professional who is familiar with brain injury.⁸³

These multiple impairments are responsible for the central maladaptation pattern seen in brain injury that leads to hypersensitivities and avoidance of environmental stimulus. Intervention should be directed toward physiological function and symptom control. Increased recovery times may be related to the lack of precision in the examination and poor choice of interventions. Traditional vestibular rehabilitation that depends on intact visual and somatosensory integration for adaptation has limited success for the individual with brain injury. As new understanding of the factors related to maladaptation arise, there will likely be a way to achieve better outcomes in rehabilitation.^{84,85}

Box 21.7 describes the basic criteria to consider during return to play decisions. (See Chapter 23 for more information on the vestibular system testing and vestibular rehabilitation for the concussed individual.)⁸⁶

METABOLIC DISORDERS

Vertigo and dizziness are often reported with metabolic disorders such as diabetes. Autoimmune diseases such as rheumatoid arthritis, lupus, and human immunodeficiency syndrome infection can also cause symptoms when the disease process damages components of the vestibular system. Management of the underlying disorder is essential to create as much stability in the system as possible for adaptation to occur.

AUTOIMMUNE EAR DISEASE

Autoimmune ear disease (AIED) appears most commonly in females between 20 and 50 years of age. A rapidly progressive, often fluctuating, bilateral sensorineural hearing loss (SNHL) occurs over a period of weeks to months. The progression of hearing loss is often too rapid to be diagnosed as presbycusis and too slow to conclude a diagnosis of sudden SNHL and is likely to be bilateral. Imbalance, ataxia, motion intolerance, and episodic vertigo are often present. Systemic autoimmune diseases coexist in about one-third of patients such as systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, myasthenia gravis, Hashimoto disease, Cogan syndrome, sarcoidosis, colitis, and polychondritis. There is strong evidence that immune mechanisms are involved in the pathogenesis of inner ear damage, together with viral infection, trauma, vascular damage, and genetic factors. Steroid responsiveness is high, and with prompt treatment hearing loss may be reversible.⁸⁷

AUTONOMIC NERVOUS SYSTEM DYSREGULATION

Dizziness, vertigo, nausea, and instability can be attributed to dysautonomia. A larger constellation of symptoms is often present, and symptoms are typically elicited in orthostatic postures, during exertion or postprandial. Additional signs of dysautonomia may be orthostatic intolerance, POTS, presyncope or syncope, headaches, fatigue, lightheadedness, tremulousness, blurry vision, reduced mental clarity, changes in bowel and bladder function, gastrointestinal motility issues, altered sleep, and body temperature dysregulation. Diagnostic testing

for assessment of the ANS function includes multiple studies as there are many subtypes of dysautonomia that fall along a spectrum of severity, some of which involve hereditary disorders, autoimmune diseases, and metabolic disorders.⁸⁸ Adrenergic function is examined through heart rate and blood pressure responses during passive head-up tilt table testing (TTT) and Valsalva maneuver studies as well as variation in plasma norepinephrine measures in supine and standing positions. Sudomotor function testing involves a combined quantitative sudomotor axon reflex test (QSART) and thermoregulatory sweat test (TST), and cardiovagal response is evaluated by heart rate variability (HRV) during deep breathing and Valsalva maneuver studies.

Increased evidence has steadily emerged regarding the involvement of peripheral and central vestibular pathways in ANS regulation⁸⁹ when hemostasis is disrupted by viral, infectious, allergic and immunological, or traumatic stressors. Vestibular contributions exist throughout the afferent and efferent pathways from the brain stem to the thalamus and include neurotransmitters and antibody receptors that influence orthostatic tolerance and blood pressure modulation.⁹⁰ Improved functional mapping of the central vestibular system and specific vestibular and ANS testing promote obtaining a differential diagnosis for what historically involved complex management of a very broad and evasive symptoms of dizziness.⁹¹ For example, in a prospective study of patients with chronic dizziness lasting longer than 6 months, a significant number of participants who tested positively for the presence of dysautonomia also demonstrated alterations in smooth pursuits and otolithic function testing.⁹² Additionally, a lesser portion of subjects classified as having vestibular migraine, psychogenic dizziness, or unspecified chronic dizziness had abnormal findings on sympathetic and cardiovagal autonomic function testing. Larger volumes of research have been conducted following traumatic brain injury and concussion to describe a transient dysautonomia, which often coexists with vestibular and oculomotor dysfunction as well as migraine patterns, as discussed in the (Chapter 23). Proper diagnosis of the etiology of symptoms related to dizziness is imperative as medical management for regulation of autonomic dysfunction, such as plasma volume expansion, may contrast from specific vestibular syndromes that indicate the use of diuretic therapy, such as Ménière disease.

MAL DE DEBARQUEMENT (DISEMBARKMENT SYNDROME)

This is a phenomenon described as “sickness of landing.” The symptom of continued rocking, or the sensation that one has just gotten off a boat, is the hallmark of this phenomenon. It usually occurs after a long boat ride or airplane ride, often when there is turbulence. The vestibular system seems to be activated to a high degree, then is unable to calibrate back to normal in reference to the somatosensory input available.⁹³ In addition to the oscillating sensation there are complaints of fatigue, mental clouding, visual motion intolerance, anxiety, tinnitus, and headaches. The sensation is greater when the patient is at rest, and movement is actually preferable to standing or sitting. The sensation nulls or is reduced when reexposed to passive motion. Many patients describe relief of symptoms when they are riding in a car. The system typically remains maladapted, and the condition can persist over months and years, causing significant disability and frustration. Rehabilitation is directed toward recalibration of the somatosensory and vestibular systems with a focus on the somatosensory input activities. Traditional vestibular rehabilitation is not helpful with this population. The use of transcranial stimulation may give some

insight into the condition as well as some potential intervention. The assumption that the brain is made up of oscillators and Mal de Debarquement occurs after exposure to oscillation (passive movement of the boat) is the basis of this approach.⁹⁴ It appears that the neural activity in the brain in the individuals who develop Mal de Debarquement is different than the control population in studies performed. The hypothesis of introducing oscillation through TMS may be able to uncouple the abnormal functional connectivity associated with Mal de Debarquement. Ongoing research is targeted toward the most appropriate area of the brain to stimulate.⁹⁵

PERSISTENT POSTURAL-PERCEPTUAL DIZZINESS

Persistent postural-perceptual dizziness (PPPD or 3PD) is a syndrome that unifies key features of what was known as chronic subjective dizziness, phobic postural vertigo, and related disorders. It describes a common chronic dysfunction of the vestibular system and brain that produces persistent dizziness, nonspinning vertigo, and/or unsteadiness. The disorder constitutes a long-term maladaptation to a neuro-otological, medical, or psychological event that triggered vestibular symptoms, such as vestibular neuritis or BPPV, and is believed to be a specific complication to healing following an inner ear crisis. The phenomenon appears to negatively affect normal adaptation and therefore creates a more conscious effort into maintaining control of posture.

The increased burden of abnormal self-monitoring results in the common occurrence of dissociation and fatigue resulting from mental overload. The cycle of fear and avoidance can give rise to secondary phobic disorders such as agoraphobia.

Symptoms of PPPD include hypersensitivity to visual motion environment with an intolerance of apparent visual motion in the environment. Strong visual patterns can trigger symptoms, and there can be discomfort in moving surrounds such as crowds, grocery stores, airports, and theaters. Misleading vertical reference cues can cause both dizziness and imbalance. Tasks that require specific eye/hand coordination can become difficult. There can be intolerance to head and body movement often associated with changes of visual focus, such as moving from a text book to a projected screen, which is typical of current classroom activity. These patients will also avoid anything that would normally trigger dizziness, which usually involves head turns or quick movements. This can cause neck stiffness as they avoid movement. Patients often develop secondary functional gait disorder, anxiety, avoidance behavior, and severe disability.

There is interest in the possibility of inherited vulnerabilities in sensory processing that may underlie the processing disorder. Brain imaging shows some distinct areas of decreased functional connectivity during functional MRI.⁹⁶ Early neuroimaging studies suggest that there may be an additional pathophysiological mechanism underlying PPPD, perhaps a deficiency in cortical processes that supports locomotion and spatial orientation. Activity and connectivity appear to be greater in visual versus vestibular regions of the cortex, in keeping with physiological data on visual dependence. Activity and connectivity between key cortical regions that process space/motion

BOX 21.8 Cardinal Symptoms of Persistent Postural Perception Dizziness

1. Symptoms present for 3 months or more
2. Symptom must be present for prolonged periods on most days but will wax and wane in intensity
3. Dizziness triggered by visual motion or visually complex environments
4. Hypersensitivity to any passive motion
5. Generalized head motion dizziness that is not reported as vertigo
6. Symptoms cause significant distress or functional impairment
7. Symptoms are not better attributed to another disease or disorder
8. Persistent postural perception dizziness may coexist with other diseases or disorders. Evidence of another active illness does not necessarily exclude this diagnosis but may indicate the presence of a comorbid condition

Symptoms according to AA51.53 Persistent Postural-Perceptual Dizziness

information, such as the posterior insula and hippocampus, are decreased. Threat responses modulated in the anterior cingulate cortex are reduced. The abnormal functionality in the cortical networks may fail to suppress the bottom-up influences of instinctive threat on postural control and spatial orientation, leading to the sustained use of high guard balance strategies. This understanding may lead to new intervention strategies.⁹⁷

PPPD has also been documented in association with migraine, concussion, primary anxiety, panic attacks, dysautonomia, or an acute medical crisis that disturbs postural stability orthostasis or syncope. (See section on autonomic nervous system disorders.) Increased levels of distress measured using the Hospital Anxiety and Depression Scale or the Generalized Anxiety Disorders Scale in patients with chronic symptoms suggest that the emotional status of the patients may contribute to prolongation of dizziness symptoms from the acute phase. Medical management⁴⁵ includes the use of low-dose selective serotonin reuptake inhibitor/serotonin norepinephrine reuptake inhibitor medications.⁹⁸ Therapy should include visual/optokinetic, motion desensitization, and recalibration of the somatosensory reference. Management of the autonomic phenomenon through interventions that decrease the fight or flight response can increase tolerance to the adaptation process and can be critical as noted previously. While diagnostic tests and conventional imaging usually remain negative, patients with PPPD present in a characteristic way that fits with positive diagnostic criteria.⁹⁹ Box 21.8 describes the characteristics associated with the diagnosis of PPPD.

Abstract: This chapter reviews the critical components of evaluation, examination, and intervention based on the physiology of the vestibular system and the connection to the peripheral and central nervous system. The effect of pathological processes is outlined within the text.

Keywords: vestibular, dizziness, vertigo, balance, gait

Traumatic Brain Injury*

Doris Chong and Sheri Miami

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the epidemiology, pathophysiology, and mechanisms of injury of moderate to severe traumatic brain injury.
2. Describe common clinical changes after traumatic brain injury.
3. Describe common medical interventions for traumatic brain injury.
4. Plan and select appropriate physical therapy examination techniques and tests and measures for people with traumatic brain injury using the Hypothesis-Oriented Algorithm for Clinicians (HOAC) II and International Classification of Functioning, Disability and Health (ICF) framework.
5. Develop a comprehensive plan of care with appropriate physical therapy interventions for people with moderate to severe traumatic brain injury using the ICF framework.
6. Describe prognosis and outcomes for people with moderate to severe traumatic brain injury using evidence-based prognostic indicators.

KEY TERMS

axonal injury
brain injury
contusions

hematomas
hemorrhages
ischemia

SECTION I—OVERVIEW OF TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) is defined as a blow or jolt to the head or a penetrating head injury that disrupts the function of the brain. Not all blows or jolts to the head result in a TBI. The severity of such an injury may range from mild—a brief change in mental status or consciousness—to severe—an extended period of unconsciousness or amnesia after the injury. www.cdc.gov/traumaticbraininjury/get_the_facts.html. A TBI can result in short- or long-term problems with independent function.¹

Epidemiology of Traumatic Brain Injury

TBI is a global health issue and is affecting around 10 million people in the world each year.² The Centers for Disease Control and Prevention (CDC) estimated in 2010 (www.braintrauma.org/faq) that approximately 1.7 million Americans sustain a TBI every year.³ More than 2.5 million emergency department (ED) visits in the United States are related to TBI.⁴ Of these, falls constituted the most frequent visits (45%), followed by motor vehicle accidents (43%), and violence (6%).⁵ The admission diagnoses include concussion, skull fracture, cerebral laceration and contusions, and different types of hematoma/hemorrhages. The most prevalent age groups include 0 to 4 years old,

15 to 19 years old, and those who are older than 75 years of age.¹ Males (around 64%) are more likely to sustain a TBI than females.⁵ The TBI-related hospital admission costs in 2010 were \$21.4 billion.⁴

The incidence of TBI is 506.4 per 100,000 population, with around 43% of those hospitalized experiencing long-term activity limitation.⁶ It is estimated that 3.2 million to 5.3 million people are living with TBI-related disabilities.⁷ The estimated lifetime cost for each individual with severe brain injury exceeds \$4 million. Annual costs for all TBIs in the United States exceed \$60 billion. It is thought that the incidence and costs related to TBI have been underestimated due to gaps in capturing data in certain populations, for example sports-related injuries, or for those who do not seek medical advice after an injury. The actual burden of care is estimated to be much higher than the reported data and figures.

Mechanisms of Injury

There are four main types of injury, as follows:

1. Those from external forces hitting the head or the head hitting hard enough to cause brain movement. Injuries include those with skull fracture and those without skull fracture (closed head injuries). Direct blows to the head can cause coup injuries (at the site of impact) and contrecoup injuries (distant from the site of impact).
2. Severe acceleration and deceleration of the head, which can cause TBI without the head hitting an object. An example is shaken baby syndrome.
3. Blast injuries mainly affecting military personnel.

*Videos for this chapter are available at studentconsult.com.

4. Penetrating objects causing direct cellular and vascular damage. Injuries to the face and neck can cause brain injury by disrupting the blood supply to the brain.⁸

Pathophysiology of Injury

Acceleration, deceleration, rotational forces, and penetrating objects cause tissue laceration, compression, tension, shearing, or a combination, resulting in primary injury.

Primary Damage

- **Contusions.** A bruise or bleeding on the brain and lacerations can occur with or without skull fractures. Either an object hits the head, neck, or face, or the head hits an object. Damage can be to any area of the brain. Occipital blows are more likely to produce contusions than are frontal or lateral blows. Areas in which the cranial vault is irregular, such as on the anterior poles, undersurface of the temporal lobes, and undersurface of the frontal lobes, are commonly injured. Lacerations of blood vessels within the brain itself or of blood vessels that feed the brain from the neck or face reduce the flow of blood carrying oxygen to the brain. Contusions and lacerations can also injure the cranial nerves. The most commonly injured are the optic, vestibulocochlear, oculomotor, abducens, and facial nerves. Lacerations of the dura or in the arachnoid space may cause cerebrospinal fluid to discharge from the nose (cerebrospinal fluid rhinorrhea discharge increases with neck flexion, coughing, or straining).⁹
- **Epidural hematomas or hemorrhages.** These occur mostly in adults when tearing of meningeal vessels results in blood collecting between the skull and dura. Skull fracture is present in the majority of cases. This is accompanied by intervals of lucidness and can result in death unless treated early.
- **Subdural hematomas.** These occur with acceleration-deceleration injuries when bridging veins to the superior sagittal sinus are torn. Blood accumulates in the subdural space. Symptoms include weakness and lethargy. Symptoms such as weakness and lethargy that come on acutely are life-threatening. Symptoms caused by slow bleeding may not be present for several weeks.
- **Diffuse axonal injuries.** Also known as diffuse injuries, these are among the most common types of primary lesions in persons with brain trauma.^{10,11} Brain tissues that differ in structure or weight experience unequal acceleration, deceleration, or rotation of tissues during rapid head movement or during impact, causing diffuse axonal injury and changes in chemical processing. Severing of the axons may be severe enough to result in coma. In milder forms, more spotty lesions are seen, including deficits such as memory loss, concentration difficulties, decreased attention span, headaches, sleep disturbances, and seizures. Damage often involves the corpus callosum, basal ganglia, brain stem, and cerebellum.^{10,11}
- **Penetrating injuries.** These usually happen with objects with high velocities, such as bullets or shrapnel from explosives, and can cause additional damage remote from the areas of impact as a result of shock waves. Foreign objects such as sticks and sharp toys cause low-velocity injuries, directly damaging the tissues they contact.
- **Blast injuries.** These occur when a solid or liquid material explodes, turning into a gas. The expanding gases form a high-pressure wave, called an overpressure wave, that travels at supersonic speed. Pressure then drops, creating a relative vacuum or a blast underpressure wave that results in a reversal of air flow. This

is then followed by a second overpressure wave. Blast-related injury can occur through several mechanisms. The primary blast wave generates extreme pressure changes that can cause stress and shear injuries. For example, rupture of the tympanic membranes is very common after blast injury, and lung and gastrointestinal injuries also occur. The exact mechanism of injury to the brain is unknown, with speculation about both axonal shearing and shearing of vasculature.^{12,13}

Secondary Damage or Insult

Secondary injuries are mainly caused by a lack of oxygen in the highly oxygen-demanding and dependent brain. Secondary problems may result from the following:

- **Increased intracranial pressure (ICP)** resulting from swelling or intracranial hematoma. Swelling of the brain causes distortion because the brain is held in the skull, a rigid, unyielding structure. The resultant increased ICP can lead to herniation of parts of the brain. The most often seen herniations include cingulate herniation under the falx cerebri, uncus herniation, central (or transtentorial) herniation, and herniation of the brain stem through the foramen magnum.¹⁴ Acute hydrocephalus occurs when blood accumulates in the ventricular system, expanding the size of the ventricles and causing increased pressure on brain tissue being compressed between the skull and the fluid-filled ventricles. The increased pressure can then result in changes in P_{CO_2} , which is harmful to nervous tissue. Increased ICP has been correlated with poorer outcomes and higher mortality rates.¹⁵
- **Cerebral hypoxia or ischemia** occurs when blood vessels are ruptured or compressed. Hypoxia can occur from a lack of blood to the brain or from lack of oxygen in the blood as a result of airway obstruction or chest injuries.
- **Intracranial hemorrhage** causes hypoxia to tissues fed by the hemorrhaging blood vessels and adds pressure and distortion to brain tissue. Metabolic products from damaged cells and blood bathe the brain. Cell death occurs within minutes after injury from ischemia, edema, necrosis, and the toxic effects of blood on neural tissues.
- **Electrolyte and acid-base imbalance.** Secondary cell death occurs either by swelling and then bursting of the cellular membrane (necrosis), or by destruction from within the cell through changes in the deoxyribonucleic acid (DNA)—apoptosis. Cell death can occur days, weeks, or months after injury.¹⁶
- **Infections.** Infections may arise from open wounds (e.g., penetrating injuries) or from prolonged invasive monitoring (e.g., ICP monitoring). If infection is present in brain tissue, it may cause swelling and cell death.
- **Seizures from pressure or scarring.** Seizures are most common immediately after injury, and 6 months to 2 years after injury. Seizure activity can cause additional brain damage owing to high oxygen and glucose requirements.

Clinical Features of Traumatic Brain Injury

Disorders of Consciousness

Disorders of consciousness (DOCs) is a collective term describing conditions where consciousness or arousal have been affected by brain damage. The damage can be of direct insult to structures and systems regulating arousal and awareness, or of indirect damage to systematic neural connections of the brain.¹⁷ The main DOCs are coma, vegetative state (VS), and minimally conscious state (MCS). Some clinicians and scientists include locked-in syndrome as a DOC, while some perceive it as a differential diagnosis. A brief

description of the various disorders under this broad spectrum is provided below.

- **Coma.** *Coma* is defined as a complete paralysis of cerebral function or a state of unresponsiveness. The eyes are closed and there is no response to painful stimuli. There are no obvious sleep-wake cycles.¹⁷ Oculomotor and pupillary signs are valuable in assisting with the diagnosis, localizing brain stem damage, and determining the depth of coma.¹⁸ In coma, brain stem responses may include grimacing to pain, which is frequently associated with a flexor or localizing motor response, loss of hearing or balance, abnormal palate and tongue movements, loss of language, and loss or distortion of taste.
- **Vegetative State.** This state is characterized by a wakeful, reduced responsiveness with no evident cerebral cortical function. The difference between coma and VS is that there are intermittent periods of wakefulness in VS.¹⁷ VS can result from diffuse cerebral hypoxia or from severe, diffuse white matter impact damage. The brain stem is usually relatively intact. Patients may track with their eyes and show minimal spontaneous yet involuntary motor activities, but they do not speak, nor do they respond to verbal stimulation.¹⁹ When VS lasts for over 1 month after TBI, the term persistent vegetative state (PVS) may be applied, though some now advocate for the term chronic VS due to the fact that brain injury is a dynamic rather than static process. Functional magnetic resonance imaging (fMRI) was recently used to test patients who were diagnosed with PVS. Five of 54 patients diagnosed with PVS demonstrated “willful, neuroanatomically specific blood-oxygenated–level–dependent responses when told to visualize one of two tasks.”²⁰ The diagnosis of PVS indicates lack of cortical function, and fMRI may be useful in this diagnosis in the future. Recovery of consciousness, if it occurs, includes a gradual return of orientation and recent memory.¹⁸ The duration of each of these stages is variable and can be prolonged. Improvement can stop at any point.
- **Minimally Conscious State.** In MCS, consciousness is severely altered but there are signs demonstrating self or environmental awareness.¹⁷ Patients will have to be able to demonstrate motor response in a reproducible manner. That is, for a diagnosis of MCS a person must be able to follow simple one-step commands inconsistently and may even demonstrate some verbal responses to stimuli. Smooth pursuit may be present. MCS is often viewed as a transitional state signifying improvement of consciousness. The previous terminology for this state includes obtundity. It describes the condition of a person who sleeps a great deal and who, when aroused, exhibits reduced alertness, disinterest in the environment, and slow responses to stimulation.
- **Posttraumatic Confusion or Clouding of Consciousness.** In this state the person is awake most of the time, but is confused, easily distractible, with faulty memory, and with slowed but consistent responses to stimuli. Functional communication emerges in this state and is a clinical sign of improvement.

Autonomic Nervous System Changes

Changes in the autonomic nervous system (ANS) after TBI are not uncommon. Hilz and colleagues²¹ found that in persons with mild TBI, cardiovascular regulation shifts from parasympathetic activities to sympathetic activities at rest and there is a decrease in orthostatic responses. The dysfunctions are thought to be due to the close connections between the frontal cortex and various ANS functions.²² Because the ANS is a system that functions without voluntary control and it regulates multiple systems in the body, autonomic dysfunctions can

BOX 22.1 Possible Autonomic Nervous System Symptoms Resulting From Brain Injury

- Variabilities in heart rate (e.g., tachycardia) and respiratory rates
- Irritable bowel syndrome
- Temperature elevations
- Blood pressure changes
- Excessive sweating, salivation, tearing, and sebum secretion
- Dilated pupils
- Vomiting
- Anxiety, panic disorder, and posttraumatic stress disorder

cause system-wide abnormalities and increase mortality.²² It is recently reported that autonomic dysfunction at rest and in standing are more prominent in persons with moderate to severe TBI and dysfunctions can be prolonged after TBI.²¹ Box 22.1 lists possible ANS symptoms resulting from brain injury.

Motor, Sensory, Perceptual, and Functional Changes

Motor impairments are common after TBI yet understudied in humans due to the overwhelming focus on consciousness and cognitive changes. A cohort study showed that during the inpatient rehabilitation phase, 20% or more of patients had paresis in upper extremity (UE) and/or lower extremity (LE), 30% or more had incoordination, and between 13% and 27% had gait and balance problems.²³ Dizziness and disequilibrium were reported in 30% to 65% of people with TBI.²⁴ Although dystonia appears not to be a significant issue in people post-TBI,²³ spasticity could develop as soon as one week after the injury.²⁵ It is still not well understood why these changes occur, but animal studies point towards imbalance between excitation and inhibition neuronal signals after brain injury. In particular, the imbalance favors excitation causing sensory deficits, which in turn causes cognitive and motor deficits in TBI.²⁶ Box 22.2 lists common motor changes and provides symptoms of sensory and perceptual involvement.

Cognitive, Personality, and Behavioral Changes

Cognitive and behavioral sequelae can result from generalized or focal brain injuries. For example, emotional changes may be seen with lesions in the orbitofrontal areas. Septal area lesions result in rage and overall irritability. Pseudobulbar injuries can result in emotional lability of involuntary laughing or crying not associated with feelings of emotions. Memory impairment, a very common finding after TBI, is an aftermath of generalized lesions.

Amnesia is a term that describes memory impairment. Posttraumatic amnesia (PTA) is defined as “the time lapse between the accident and the point at which the functions concerned with memory are judged to have been restored.”²⁷ Two types of PTA are frequently associated with brain injury: retrograde and anterograde. Retrograde amnesia is a deficit in memory retrieval with inability to recall events that occurred prior to the injury.²⁸ Anterograde amnesia refers to the inability to form new memories after the injury, and it is often more impaired in declarative tasks as compared to procedural.²⁸ The duration of PTA is considered a clinical indicator of the severity of the injury; it may guide clinical management decisions, and it is also one of the prognostic indicators in TBI.^{27,28}

The patient’s inability to develop new memories can be quite challenging for the rehabilitation team and for the patient because memory is an important component of learning.²⁹ There are two types of memory: declarative and procedural. Memory in which the patient

BOX 22.2 Motor, Sensory, Perceptual, and Functional Changes Resulting From Brain Injury

Motor changes may include any or all of the following:

- Paralysis or paresis such as monoplegia or hemiplegia
- Cranial nerve injury resulting in paralysis of eye muscles, facial paralysis, vestibular and vestibuloocular reflex abnormalities, slurred speech (dysarthria), swallowing abnormalities (dysphagia), and paralysis of the tongue muscles
- Poor coordination of movement
- Abnormal reflexes
- Abnormal muscle tone: flaccidity, spasticity, or rigidity. (The terms *decorticate rigidity* and *decerebrate rigidity* are often used to denote abnormal posturing. *Decerebrate rigidity* denotes extension in all four limbs. *Decorticate posturing* includes flexion of the upper extremities and extension of the legs.)
- Combinations of asymmetrical cerebellar and pyramidal signs and of bilateral pyramidal and extrapyramidal signs have all been reported¹⁵
- Loss of selective motor control
- Poor balance
- Loss of bowel or bladder control

Sensory and perceptual may include any or all of the following:

- Hypersensitivity to light or noise
- Loss of hearing or sight
- Visual field changes
- Numbness and tingling (peripheral nerves are often injured)
- Loss of somatosensory functions
- Dizziness or vertigo
- Visuospatial abnormalities
- Agnosia
- Apraxia

BOX 22.3 Cognitive, Personality, and Behavioral Changes Resulting From Brain Injury

Cognitive changes might include any or all of the following:

- Temporary or permanent disorders of intellectual function
- Memory loss
- Shortened attention span
- Concentration problems
- Confusion
- Changes in motivation
- Difficulty sustaining attention
- Executive function loss
- Reduced problem-solving skills
- Lack of initiative
- Loss of reasoning
- Poor abstract thinking
- Shortened attention span

Behavioral changes could include the following³¹:

- Agitation
- Aggression
- Irritability
- Substance abuse
- Behavior with legal consequences
- Apathy
- Depression
- Anxiety
- Posttraumatic stress disorder
- Obsessive-compulsive disorder
- Psychosis
- Suicidal ideation and attempts
- Suicide

can recall facts and events of a previous experience is declarative memory. Explicit learning, a conscious verbal learning, is based on declarative memory. However, many patients who cannot reproduce memories through conscious recollection do have the ability to learn new motor skills. Implicit learning, a noncognitive type of learning in which patients can show changes in performance after prior experience, is based on procedural memory. Patients can show the ability to change motor, perceptual, or cognitive behaviors with practice or training but may lack declarative memory. Another type of short-term memory that is often compromised after TBI is working memory, which is crucial for processing everyday life information. An example of working memory is the ability to remember the steps of a recipe during cooking. Quality of life is thought to be affected when working memory is impaired.³⁰

Behavioral changes can be present even without cognitive and physical deficits. A recent systematic review³¹ grouped behavioral changes after TBI into four categories: (1) Disruptive behaviors by excess, for example agitation, aggression, irritability, drug addiction, and behaviors with legal consequences; (2) disruptive behaviors by default, such as apathy and decreased goal-oriented behaviors; (3) affect disorders, including depression, anxiety, and post-traumatic stress disorder (PTSD); and (4) suicidal attempts and suicide. Even though the extent and types of behavioral changes depend upon the severity of injury, all of these behaviors (except for substance abuse) have higher prevalence rates among persons who have sustained a TBI than the general

population. The social consequences of inappropriate behavior can be disastrous and interfere with achieving therapy goals.

Box 22.3 lists common cognitive and behavioral changes resulting from brain injury.

Other Complications

A list of the complications that may accompany brain injury would be limitless. In addition to any concomitant injuries, some of the diagnostic, monitoring, and therapeutic procedures themselves carry hazards as does prolonged bed rest. Catheters, nasogastric tubes, and tracheotomies can cause iatrogenic injuries. Infections, contractures, skin breakdown, thrombophlebitis, pulmonary problems, heterotopic ossification (HO), and surgical complications are but a few of the risks. Posttraumatic epilepsy is also a possible sequela. Depression occurs frequently after brain injury and appears to be the most prevalent mental disorder post-TBI.³² It appears that a combination of neuroanatomical, neurochemical, and psychosocial factors is responsible for the onset and maintenance of the depression.³² Depression post-TBI often negatively impacts outcomes related to productivity and quality of life.

Locked-in syndrome may be grouped differently from DOCs. In this syndrome the patient cannot move any part of the body except the eyes but cognition remains intact and the person is conscious.³³ Communication disorders are also common complications after TBI and may include expressive and receptive aphasia, dysarthria, loss in reading comprehension and social communication, and many others.

Types and Classifications of Traumatic Brain Injury

Severity of TBI is categorized as mild, moderate, or severe based on specific measurements on scales such as the Glasgow Coma Scale (GCS) (Box 22.4), duration of loss of consciousness, and duration of PTA. See Table 22.1 for details. In addition, the Brain Injury Association of America³⁴ provides qualitative descriptions according to the severity of injury. For mild TBI, there is usually a brief to no loss of consciousness and there may be vomiting, dizziness, lethargy, and memory loss. For moderate TBI, unconsciousness can last up to 24 hours. There are signs of trauma, contusions, and/or bleeding on neuroimaging. For people with severe TBI, coma persists for more than 24 hours, there are no obvious sleep/wake cycles, and there are signs of trauma on neuroimaging.

Another scale that is commonly used to classify levels of TBI is the Rancho Los Amigos Levels of Cognitive Functioning Scale (LOCF).³⁵ The scale measure levels of consciousness, cognition, and behavior post-TBI and is often used as an outcome measure for these impairments as patients progress through various stages of TBI. Briefly, there are eight levels describing persons' responses and behaviors, namely no response (LOCF I), generalized response (LOCF II), localized response (LOCF III), confused-agitated (LOCF IV), confused-inappropriate (LOCF V), confused-appropriate (LOCF VI), automatic-appropriate (LOCF VII), and purposeful-appropriate (LOCF VIII). See Appendix 22.A for detailed descriptions of typical behaviors observed in each level.

TABLE 22.1 Severity of Traumatic Brain Injury

Measurement	Mild	Moderate	Severe
Glasgow Coma Scale	13–15	9–12	3–8
Loss of consciousness	<30 min	30 min–24 h	>24 h
Posttraumatic amnesia	0–1 day	>1 to ≤7 days	>7 days

SECTION II—MEDICAL MANAGEMENT OF TRAUMATIC BRAIN INJURY**Initial Care and Acute Management**

For persons with severe TBI, medical management begins at the pre-hospital phase where the person is monitored for oxygenation, blood pressure, cognitive function (using the GCS), pupillary function, and signs of brain stem herniation. Transport to a trauma center with CT scanning, neurosurgical evaluation, and ICP monitoring is the goal to monitor and minimize secondary injuries.³ A determination of GCS score is performed either at the prehospital stage or in the ED to test the function of the brain stem and the cerebrum through eye, motor, and verbal responses.³⁶ It provides a measure of the level of consciousness and an idea of injury severity. Scores range from 3 to 15, with lower scores associated with lower levels of function. Scores from 13 to 15 indicate a mild brain injury, 9 to 12 a moderate brain injury, and 8 or less a severe injury.

On admission to the ED, a neurosurgeon usually assumes initial and primary responsibility for the person. The first priority in acute care is resuscitation and prevention of secondary insult. The Brain Trauma Foundation³⁴ recommends the following guidelines for severe TBI management in the acute phase: airway control and ventilation to optimize oxygenation, monitoring and maintenance of cerebral perfusion pressure (CPP) and blood pressure, monitoring and management of ICP, fluid management, hyperosmolar therapy, sedation, and prophylaxis of infections, deep vein thrombosis (DVT), seizures, and hypothermia.^{3,9,27,37} The details of the guidelines can be found at www.braintrauma.org.

In addition to the traditional neuroimaging such as CT, magnetic resonance imaging (MRI), and positron emission technology (PET) scan for monitoring of neurological functions, advanced multimodal neuromonitoring is recommended to improve outcomes of TBI. These include jugular venous oxygen saturation (SjvO₂), focal brain tissue oxygen tension (PbrO₂), cerebral microdialysis, and continuous electroencephalography (EEG). For patients who are candidates for decompressive craniectomy due to elevated ICP, a large frontotemporo-parietal approach is recommended versus a small one as it has been found to have better neurological outcomes.³⁷

Common Neurosurgical Interventions

Decompressive craniectomy, as mentioned above, is a procedure where a large portion of the skull is removed to allow the brain to swell. This procedure is used when ICP is elevated over 25 mm Hg for 1 to 12 hours despite other medical interventions.³ The goal is to prevent brain stem herniation and maintain CPP for brain tissue viability.

External ventricular drain (EVD) is another frequently used neurosurgical procedure to control elevated ICP. Usually a catheter is inserted through the skull into the anterior horn of one of the lateral ventricles to drain cerebrospinal fluid. The catheter is also connected to an external transducer for constant ICP monitoring. The amount of fluid drained from the ventricle needs to be precise and, oftentimes, a few milliliters of drained fluid results in a decrease in ICP. Although EVD may increase the risk of infection, there is strong evidence proving its effectiveness in immediate reduction of ICP.³⁸

Persons with epidural hematomas often undergo craniotomies with blood evacuation to relieve pressure within the cranium. Subdural injuries are frequently treated by removing the blood through bur holes.

Common Pharmacological Interventions

Medications are chosen according to symptoms to be treated.

Medications That Decrease Intracranial Pressure

Osmotic agents such as mannitol are used to pull fluid from brain tissue back into the blood system, thus lowering ICP. Use of mannitol is recommended for patients who have perfusion problems,³⁵ and the evidence is strong for the effectiveness of mannitol to reduce ICP.³⁸ Propofol, a barbiturate (sedative), may reduce the need for ICP treatment. Sedative treatment may be reduced as well if it is used together with morphine.³⁸ Propofol is recommended only if ICP cannot be controlled by other means because it may potentially reduce CPP.^{39,40} Hypertonic saline is another osmotherapy to control ICP, although the best solution and administration has yet to be determined. The Brain Trauma Foundation in 2016 recommended a stepladder approach using mannitol or hypertonic saline, together with other procedures for best control of elevated ICP.³⁷ Corticosteroids are commonly used in the acute phase to stabilize brain injury; however, it has been shown that mortality may be increased by methylprednisone, and it should be avoided.³⁸ See Chapter 36 for additional information.

Medications That Control Blood Pressure and Cerebral Perfusion Pressure

Blood pressure control is important in patients with brain injury. CPP⁴¹ or adequate blood pressure to maintain cerebral blood flow against increased ICP is calculated by subtracting the ICP from the mean arterial pressure. If fluid management cannot maintain adequate blood pressure, then vasopressor medications such as phenylephrine (Neo-Synephrine) are used to constrict peripheral vessels but not the vessels of the brain. Norepinephrine is also shown to support CPP in a consistent and predictive manner.³⁷ The Brain Trauma Foundation recommended to maintain the systolic blood pressure at ≥ 100 mm Hg for persons aged between 50 and 69 and ≥ 110 mm Hg for persons aged between 15 and 49 or those over the age of 70.⁴² In general, CPP should be maintained between 60 and 70 mm Hg for positive outcomes.

Medications That Decrease Intracranial Bleeding

Intracranial bleeding is common after TBI, and it can cause permanent disability and even death. Therefore controlling intracranial bleeding is usually a goal in the acute management of TBI. Hemostatic drugs work by increasing coagulation. Antifibrinolytic medications, including lysin analogues and plasmin inhibitors, work by reducing fibrinolysis and increasing clot stability.⁴⁰ Although some studies have shown effectiveness, systematic reviews fail to show reliable evidence on their effects for reducing mortality and morbidity.⁴⁰

Medications to Control Seizure

Seizure is a common complication after TBI, and its presence may have an adverse effect on ICP; therefore anticonvulsants are routinely used in acute TBI as a preventative measure. Examples of anticonvulsants include phenytoin, sodium valproate, levetiracetam, and carbamazepine. Recent systematic review and the Brain Trauma Foundation guidelines recommended that an anticonvulsant should be routinely administered within the first week of acute TBI.^{40,42} The effectiveness for late seizure prevention remains inconclusive.

Medications for Prevention of Brain Cell Death

Hypothermia is frequently used in acute severe TBI because of its possible neuroprotective effect. Although it does not appear to change the mortality rate, it is associated with improved functional outcome on the Glasgow Outcome Scale (GOS) (Box 22.5).⁴³ Progesterone is a hormone that has been shown to reduce cerebral edema and neuronal loss in acute TBI; however, further research is still needed to support its use in medical management of TBI.⁴⁰

BOX 22.5 Functional Outcomes on Glasgow Outcome Scale

Vegetative State

A persistent state characterized by reduced responsiveness associated with wakefulness. The patient may exhibit eye opening, sucking, yawning, and localized motor responses.

Severe Disability

An outcome characterized by consciousness, but the patient has 24-h dependence because of cognitive, behavioral, or physical disabilities, including dysarthria and dysphasia.

Moderate Disability

An outcome characterized by independence in activities of daily living and in home and community activities but with disability. Patients in this category may have memory or personality changes, hemiparesis, dysphagia, ataxia, acquired epilepsy, or major cranial nerve deficits.

Good Recovery

Patient able to reintegrate into normal social life and able to return to work. There may be mild persisting sequelae.

Modified from Jennett B, Bond M. Assessment of outcome after severe brain damage: a practical scale. *Lancet*. 1975;1:480.

Medications for Prevention of Infections

Antibiotics may be used after TBI due to risk of infection from injuries, wounds, or invasive monitoring. It is recommended that antibiotics be delivered for 1 to 2 weeks for persons sustaining penetrating injuries.³⁷ However, the evidence on the use of antibiotics in other forms of TBI is unclear and may even lead to an increased rate of infection.

Medications That Affect Behavioral and Cognitive Functions (also see Chapter 36)

Medications to treat behavioral or cognitive dysfunction are difficult to standardize. A recent systematic review suggested the following medications for various behavioral dysfunctions after TBI.⁴⁴ There is some evidence to use carbamazepine (Tegretol) and valproate as a first line treatment for agitation and aggression. Propranolol (Inderal) can also help to improve aggression. For persons with depressive symptoms, selective serotonin reuptake inhibitors (SSRIs) are recommended. Confusion and other neuropsychotic symptoms have been treated using neuroleptic medications; however, there is no evidence of their efficacy.

For patients with attention deficits, monoaminergic agonists such as amantadine or methylphenidate may increase information processing, aid functional recovery, and prevent permanent functional loss in some patients, but the evidence remains inconclusive.^{40,45} In a recent systematic review, amantadine is recommended for people with DOC to improve arousal.⁴⁶

Medications That Affect Motor Functions (see Chapter 36)

Medications also may be prescribed for motor abnormalities involving increases in tone. Oral medications for treating spasticity include baclofen, diazepam, dantrolene sodium, and tizanidine.²⁵ They can be used alone or in combination depending on the severity of spasticity. Baclofen works at the CNS level and may cause drowsiness. Baclofen can also be delivered intrathecally where the side effect is less. Dantrolene sodium works directly at the muscle level and therefore is

less likely to cause cognitive disturbances but more likely to cause generalized weakness.⁴⁷ Botulinum toxin type A (Botox) is commonly used to treat focal muscle hypertonicity, such as the finger flexors, biceps, or gastrocnemius. Diazepam (Valium) initially was the drug most commonly administered for spasticity or high tone. However, diazepam also promotes drowsiness and decreased responsiveness and can increase muscle weakness and ataxia.⁴⁸ Regardless of the medication used, it is recommended that medications be combined with complementary therapies, such as transcranial magnetic stimulation (TMS) and therapeutic exercise, in order to achieve greater benefits of tone reduction medications and improve functional outcomes.²⁵

Regenerative Medicine and Management of Traumatic Brain Injury

Regenerative medicine is an interprofessional field of research and clinical practice for the repair, replacement, or regeneration of cells, tissues, and/or organs in order to restore function lost due to disease or damage.⁴⁹ Recent advances in stem cell and tissue engineering technology have led to a rapid proliferation of research, though limitations exist, including the survival and appropriate differentiation of implanted cells. Studies on the combined effects of regenerative approaches and physical rehabilitation following stroke and TBI, referred to as regenerative rehabilitation, are very promising and show greater recovery than either approach used in isolation in animal model studies.^{50–53} Several clinical trials are underway to explore the impact of regenerative rehabilitation in stroke and TBI, as well as muscular conditions such as muscular dystrophy.⁴⁹ Scientists in this field are encouraged by positive results to date, and predict that with further advances in the stem cell and tissue technologies and rigorous interprofessional research, regenerative medicine has the potential to become the standard of care in the treatment of many neuromuscular and other health conditions.⁴⁹

SECTION III—REHABILITATION MANAGEMENT OF TRAUMATIC BRAIN INJURY

Terminology and Structure for Patient Management

The World Health Organization (WHO), in the International Classification of Functioning, Disability and Health (ICF),⁵⁴ has developed a common terminology that is used in this chapter. Definitions are as follows (see also Chapter 1):

- *Body functions* are physiological functions of body systems (including psychological functions).
- *Body structures* are anatomical parts of the body such as organs, limbs, and their components.
- *Impairments* are problems in body function or structure such as a significant deviation or loss.
- *Activity* is the execution of a task or action by an individual.
- *Participation* is involvement in a life situation.
- *Activity limitations* are difficulties an individual may have in executing activities.
- *Participation restrictions* are problems an individual may experience in involvement in life situations.
- *Environmental factors* make up the physical, social, and attitudinal environment in which people live and conduct their lives.

The American Physical Therapy Association (APTA) has published levels of patient management leading to optimal outcomes.⁵⁵ The Association's Guide to Physical Therapist Practice, which uses examination, evaluation, diagnosis, prognosis, intervention, and outcomes as its basis, will be followed in this chapter. Although this is the terminology used by physical therapists, its application and integration into the

BOX 22.6 Development of Intervention Approaches Based on HOAC II Model

1. Collect initial data.
2. Have patient and family identify patient problems with activity and participation limitations.
3. Develop an initial set of hypotheses based on a task analysis of identified activity limitations; choose and apply examinations to test those hypotheses.
4. Reassess hypotheses in light of examination findings and confirm or deny. Repeat first three steps if denied.
5. Develop list of non-patient-identified problems, including anticipated problems (such as skin breakdown when sensation is impaired).
6. Choose and apply appropriate outcome measures to monitor progress that address the impairments or activity limitations.
7. Develop an evaluation and diagnosis identifying why the problems exist or are likely to occur in the future.
8. Establish a prognosis and set goals with time frames for achievement.
9. Develop interventions that most effectively ameliorate the problems based on current literature or best practice.
10. Reexamine using outcome measures to determine progress.

HOAC, Hypothesis-Oriented Algorithm for Clinicians.

From Rothstein JM, Echternach JL, Riddle DL. The hypothesis-oriented algorithm for clinicians II (HOAC II): a guide for patient management. *Phys Ther*. 2003;83:455–470.

profession of occupational therapy should be simultaneously acknowledged. The method used in this chapter for gathering the guide information is based on the Hypothesis-Oriented Algorithm for Clinicians (HOAC) II model.⁵⁶ See Box 22.6 for an overview of this method, and see the text that follows for details of how to perform these procedures.

Examination

Data are collected from referral information, from the medical record, via observation, and from the patient or family interview. A history is taken and should include information regarding the mechanism of injury, initial GCS score, extent and time since onset of injury, patient's age, and duration of PTA. This information will be used to help establish a prognosis. Other information about education, family support, and living circumstances will also help with the prognosis and discharge planning. Complications, as well as coexisting diseases, are reviewed with the patient in order to discuss a thorough plan of care and determine appropriate referrals. Included under examination are systems review and tests and measures. Systems review is considered a screening of major systems that helps therapists to identify areas of focus during selective tests and measures. Therapists use information collected in examination to identify service needs.

Examination should lead to an understanding of the underlying causes of the activity limitations and participation restrictions and should be the basis of the intervention program. Patients usually present their chief complaints as activity limitations, for example, "I can no longer walk very far." Once activity limitations have been determined, a task analysis can be completed by having the patient demonstrate the problem—in this case, walking. The therapist will develop a hypothesis as to why the observed deviation from typical performance is present. Tests and measures and standardized outcome measures will be chosen on the basis of the therapist's knowledge of their importance in the task being performed and recommendations from peer-reviewed resources, such as the Academy of Neurologic Physical Therapy,⁵⁷ to confirm the hypothesis and to establish baseline measurements. For example, in a patient who drags the foot

in initial swing, the patient might lack 45 degrees of full passive knee flexion, but this is not critical in the task of walking. However, being able to dorsiflex the foot at initial swing is important. Therefore testing of both the ability to dorsiflex with the leg in the extended position and the speed at which the patient can perform this task would be appropriate. The tests and measures should be chosen on the basis of the hypothesis that the therapist generates from the task analysis. Details of task analysis and examinations of impairments, activity limitations, and participation restrictions will be provided in later sections of this chapter.

The Academy of Neurologic Physical Therapy Outcome measures recommendations, and Evidence Database to Guide Effectiveness (EDGE) Task Force developed recommendations for outcome measures for selected clinical conditions (e.g., stroke, TBI) based on vigorous evaluations of available measures.⁵⁸ The recommendations of outcome measures are classified according to settings and practices. Physical therapists should choose outcome measures from the recommendations for TBI when possible.⁵⁷ For example, gait outcome can be measured using the 6 minute walk test or 10 m walk test in the inpatient or outpatient setting, or the High-Level Mobility Assessment Tool (HiMAT) if the patient is high-functioning and seen in an outpatient setting. Recommended outcome measures by settings/practices are presented in Tables 22.2 to 22.4. For various components of examination, see Box 22.7.

Evaluation

Evaluation identifies the needs that can be managed by the therapist; serves to delineate those factors that influence or restrict the choice of therapeutic approaches; and states which components are most critical for the identified activity limitations. Evaluation provides a qualitative means of determining why a need is present. It includes considerations of subjective findings, objective findings, and environmental/contextual and personal factors (as illustrated in the ICF model). Thus the evaluation determines goals and intervention. The purpose of the evaluation is to

determine what prevents the patient from performing in a functional, acceptable manner as identified by the patient, the therapist, and society.

Diagnosis

Diagnosis takes into consideration the integrated evaluation findings and classifies the problems into diagnostic categories. These diagnostic categories define the primary dysfunctions of an individual and in turn enable the therapist to formulate appropriate intervention. The diagnostic process involves discernment of what the individual desires to achieve and the capacity of the individual at the moment. Additional information from other healthcare professionals may need to be sought during the diagnostic process. Likewise, the therapist may need to share information with other healthcare professionals if the diagnostic process reveals problems outside of the therapist's scope of practice. The ultimate goal of diagnosis for the therapist is to verify the needs of the individual and act accordingly.

Prognosis and Outcomes

Prognosis is the determination of the optimal level of functional improvement and the time required to reach that optimal level. In addition to the highest functional level the individual is capable to obtain, the therapist needs to consider the individual's habitual level of function in order to identify a realistic and reasonable prognosis. This is important to manage expectations of the individual and the therapist and is crucial to motivate the individual during intervention. Prognosis often includes short- and long-term goals that are specific to improve functions along with duration and frequency of intervention to achieve those goals.

On the other hand, outcomes are the actual results of intervention and are chosen to measure all levels of dysfunction from impairment through participation limitation to determine effectiveness of the intervention strategies and whether or not the patient has met rehabilitation goals. Again, outcomes should ideally follow the recommendations listed above by TBI EDGE Taskforce.⁵⁷ An example of the process is presented in Box 22.8.

TBI, Traumatic brain injury.

BOX 22.7 Examination Framework SPECIFIC for TBI

- I. History: injury, age, PTA, GCS score, job, home environment, educational level, previous injuries, etc.
- II. Patient and family data: patient and family perception of the limitations, goals, personal factors, socioeconomic factors relating to participation limitations
- III. Other health care team member evaluations
- IV. Screens
 - A. Systems review to emphasize precautions during intervention and to identify any “red flags” that will require referrals.
 1. Circulatory and respiratory
 2. Integumentary
 3. Musculoskeletal
 4. Autonomic nervous system—bowel, bladder
 5. Cognitive
 6. Language
 7. Emotional
 - V. Assess activity limitations (perform task analyses) of patient-identified problems
 - VI. Formation of underlying impairments (hypotheses) from the task analyses
 - VII. Choose specific tests and measures and recommended outcome measures to test underlying impairments or confirm the hypotheses; these might include:
 - A. Sensory
 1. Somatosensory
 2. Vestibular
 3. Visual
 4. Hearing
 - B. Integrated, perceptual
 - C. Motor
 1. Muscle strength
 2. Muscle flexibility
 3. Response speed
 4. Tone
 5. Movement speed
 6. Endurance and fatigue
 7. Complex impairments
 - Basic motor patterns available
 - Modification of motor patterns possible
 - Anticipatory and adaptive responses
 - Variability of performance
 - D. Autonomic nervous system
 - E. Cognitive
 - F. Language
 - G. Emotional

GCS, Glasgow Coma Scale; PTA, posttraumatic amnesia.

Examination for People With Traumatic Brain Injury

Task Analysis of Activity Limitations

Often the physical therapist begins the examination at the activity limitation level. This involves observing those functions that the patient or family identifies as problematic. Activity limitations in patients with

TBI may include loss of mobility in bed, coming to sit, sitting to standing; impaired static and dynamic balance; loss of household and community ambulation and stair negotiation; loss of running, jumping, and kicking skills; poor reach and grasp; loss of activities of daily living (ADLs) such as dressing, toileting, and feeding; and loss of instrumental ADLs such as shopping and driving. The physical or occupational

BOX 22.8 Case Example of Examination, Evaluation, and Prognosis for a Patient With Traumatic Brain Injury

Examination

A patient comes to your clinic reporting that he falls several times a week during walking and would like to improve his balance. He is 21 years old and suffered a moderate traumatic brain injury (TBI) 6 weeks ago. He had a Glasgow Coma Scale (GCS) score of 11 initially and 1.5 days of posttraumatic amnesia (PTA). He was at ABC Rehabilitation Center for 5 weeks and was discharged home last week. He lives with his parents in a single-story house. He is in his third year of college studying geology. His systems review demonstrates slight decreased vital capacity of 3.8 L (4.6 L would be normal), but no abnormalities in the musculoskeletal systems or integumentary system. His cognitive functions are within normal limits according to neuropsychological testing, except for memory deficits.

Task Analysis

You observe this patient during walking and note that he has decreased knee flexion in preswing and decreased dorsiflexion throughout swing phase, with the toe intermittently catching on the carpet when you have him speed up his walking. He also has decreased dorsiflexion at initial contact and in terminal stance.

Testing of Impairments

Because of the decreased dorsiflexion in terminal stance (which is passive), you hypothesize that the decreased dorsiflexion is secondary to gastrocnemius-soleus muscle tightness rather than anterior tibialis weakness. You test the range of motion (ROM) at the ankle, and it is within functional limits. You now develop a second hypothesis that there is increased tone in the gastrocnemius-soleus. On an Ashworth test, the patient scores a level 3 for the gastrocnemius-soleus. Because the patient does not get adequate plantarflexion at preswing (neutral vs. 15 degrees for typical adults), you also hypothesize that the patient is unable to generate plantarflexion fast enough in preswing to achieve the normal 15 degrees of plantarflexion. Testing by having the patient plantar flex rapidly in standing shows that it takes a full 3 seconds (s) to achieve 15 degrees of plantarflexion—much too long to be used in walking.

Outcome Measures for Activity Limitations

The patient is in an outpatient setting and appears to be high functioning. The high-level mobility assessment tool (HiMAT), 6 min walk test, 10 m walk test for gait speed, and various balance scales appear to be appropriate.

Evaluation

The patient is experiencing multiple weekly falls secondary to toe drag at initial swing when walking at speeds over 1.17 m/s. The toe drag comes from decreased dorsiflexion and decreased knee flexion at initial swing because of inadequate plantarflexion. Testing demonstrated both increased gastrocnemius-soleus tone (Ashworth level 3) and decreased ability to generate adequate plantarflexion to achieve the normal 40 degrees of knee flexion during preswing.

Prognosis and Outcomes

The patient has a good prognosis. He is early postinjury, is young, and has good family support and a high education level. There is no history of previous TBI. The patient started rehabilitation immediately and in a center specialized for people with TBI. His PTA was short.

therapist performs a task analysis of the impaired function by comparing the patient's performance of the task with typical task performance. For example, the therapist would observe the patient performing the sitting-to-standing activity, observing that there is inadequate forward trunk momentum in the preextension phase.⁵⁹ A reasonable hypothesis may be that the patient is fearful of falling forward. If the problem is

loss of balance in the extension phase, a hypothesis may be poor timing of the gastrocnemius firing. Both of these hypotheses are based on the task analysis but also on the literature, which defines the importance of trunk momentum to initiate seat-off and timing of gastrocnemius firing during the end of the sitting-to-standing activity to maintain balance.

Examining activity limitations requires knowledge of typical movement patterns and task performance among persons without neuromuscular disorders of about the same age as the patient. Tasks that are described in the literature for typical performance include rolling, rolling to sit, sitting, sitting to standing, standing to sitting, standing balance, walking, hopping, jumping, kicking, running, reaching and grasping, throwing, batting, and golfing. The form is a bit messy and we have decided to remove it from the chapter.

Assessing Underlying Impairments

Once the task has been analyzed, the impairments leading to poor performance of the task are identified. Breaking motion down to its most basic components may be helpful, but two caveats are necessary. First, improvement in abnormal components may not lead to improvement in activity limitations. Some critical impairments will have more influences on an activity than will others. For example, Perry and colleagues⁶⁰ showed that for normal walking velocity to be attained, although cadence and stride length are important, a strength level of 3+/5 is a critical component in the ankle muscles. Deficiencies of timing, strength, or sequencing can contribute to poor hand function, but sensory deficits at the hand level may be the critical impairment related to poor manipulation skills. In addition, impairments in the circulatory, respiratory, integumentary, and musculoskeletal systems can account for activity limitation in the patient with TBI (Fig. 22.1). Relative contributions of the impairments to the activity limitation or participation limitation are addressed by the therapist's task analyses, hypothesis, subsequent evaluation, and diagnosis,⁶¹ which will determine the focus of the intervention program.

The second caveat is treating the individual impairments will not necessarily result in the patient learning a skill. Skills result from an organization of many motor functions together and require whole task practice. Conversely, not having a critical component, such as arm strength, may be the one factor preventing a person from learning to perform a skill (e.g., enough force cannot be generated to throw a ball 5 feet in the air to hit a basket). Commonly seen impairments after TBI are reviewed below along with recommended measures.

Impaired consciousness and cognition. As previously mentioned, changes in consciousness are common in the acute phase of TBI. The duration of this change varies depending on the extent of the injury and recovery. Physical therapists often include measures of consciousness to capture changes in this impairment, as consciousness commonly depicts different stages of interventions. Recommended outcome measures for consciousness include Coma Recovery Scale-Revised, LOCF, and GCS.⁵⁷

Cognitive impairments are also common after TBI and may affect overall disability more significantly than physical impairments.⁶² It was reported that cognitive impairment was the primary contributor to activity limitation in most patients with TBI who scored at moderate to severe levels on the GOS.⁶³ The spectrum of cognitive dysfunctions include, but are not limited to, impaired attention, frustration, lack of spontaneity, easily distractible, impaired executive functions, inappropriate affects, altered memory, slowed information processing, and impaired judgment. Traditionally, neuropsychologists, speech pathologists, and occupational therapists all perform testing of cognitive function. Depending on the profession and types of cognitive impairment,

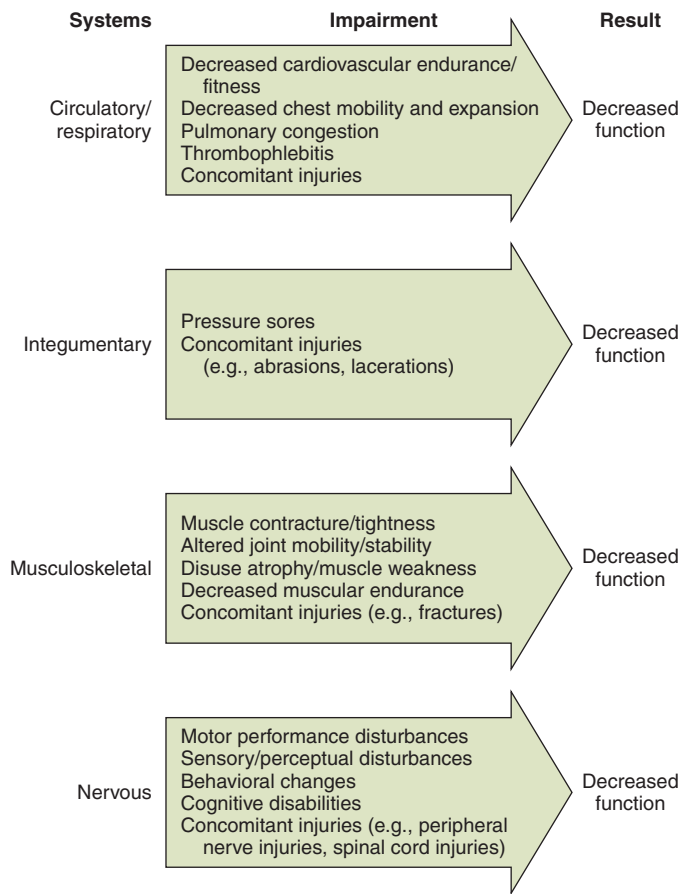

Fig. 22.1 Therapists develop intervention strategies to deal with functional deficits that may result from a variety of problems occurring primarily in one or more of the body systems depicted.

various cognitive tests are employed, and it is beyond the scope of this chapter to introduce all of these cognitive tests and batteries. For physical therapists, the TBI EDGE Task Force highly recommended a physical therapy examination to include the Coma Recovery Scale-Revised or Moss Attention Rating Scale in inpatient settings for moderate to severe TBI.⁵⁷ The LOCF (see Appendix 22.A) is also a commonly used measure by physical therapists to record changes of cognitive functions as the patient progresses through various stages of consciousness. The Montreal Cognitive Assessment (MoCA) is a recommended test that has memory testing embedded within it. Refer to Box 22.2 to 22.4 for the full recommendation list by setting and practice.

Autonomic dysfunctions. As mentioned earlier, changes in the ANS after TBI may cause system-wide issues due to the broad spectrum of body functions regulated by the ANS. These functions can directly or indirectly affect the rehabilitation process, and therefore it is important for therapists to measure these functions from time to time. These measures surround vital sign measurements, for example heart rate, respiratory rate, blood pressure, etc. Since orthostatic challenge is reported,²¹ therapists should monitor appropriate vital signs in various patient positions, especially when persons are symptomatic. Sophisticated measurements of ANS functions are usually performed by physicians, for example, using electrocardiographic marker to track sympathetic and parasympathetic activities, measuring pupillary light reflex, measuring arterial pulse wave, and measuring eyeball pressure.²²

Impaired strength or force production. Evidence consistently shows that strength and force production are common impairments in both the UEs and LEs after TBI. When strength control or force gradations are significantly impaired at initial admission (about 25% of patients), research has shown improvements with near to full resolution at a 2-year follow-up, with only 12% impairment remaining in the UEs and 7% in the LEs.²³ Low power production is also thought to be the major contributor to impaired mobility.⁶⁴

In the case of upper motor neuron lesions, weakness can be a major problem. The number of motor neurons activated, and the type of motor neurons and muscle fibers recruited, affect force. Motor neurons in the motor cortex can be deficient, leading to disordered and reduced recruitment. Individuals with brain damage show early atrophy and loss of motor units, as well as motor units that fatigue easily.^{65,66} Disuse, cast immobilization, joint dysfunction, improper nutrition, medications, and aging can cause differential weakness with altered morphological, biochemical, and physiological characteristics within the muscle.⁶⁷ Electromyography (EMG) studies by numerous investigators^{68,69} suggest that reduced activity alters motor unit properties, discharge frequency, and recruitment patterns. Performance problems are reflected in the inability to generate force in different directions and against different loads, as well as in problems sustaining force output.¹⁴

Changes in muscle length affect strength. In patients who have had a cerebrovascular accident (CVA), shortened muscles tend to be strong in short ranges and lengthened muscles are strongest in lengthened ranges but weak in shorter positions compared with the strength-length curves of normal muscles.⁷⁰

Strength may be examined functionally—for example, by seeing if the patient has enough strength to lift the arm overhead, out to the side, and up to the mouth, or is able to go from sitting to standing. In some cases, such as those in which the patient is unable to perform balance reactions or has been on extended bed rest, testing individual muscles may be important. Traditional manual muscle testing (MMT) with force transducers or strength testing with isokinetic testing⁷¹ throughout the range provides good strength information. The level of testing chosen should be consistent with the deficit and the therapist's knowledge of its importance in contributing to the activity limitation.

Muscle endurance refers to the ability of a muscle to produce the same level of contraction over time. The subjective feeling of effort and weakness after fatiguing exercise may be related to the need to recruit more motor units and to increase the mean firing frequency of the motor units to maintain constant force output.⁷² EMG with medium-frequency analysis can test this type of fatigue. Fatigue can also be assessed by measurement of maximal voluntary force, maximal voluntary shortening velocity, or power.⁷² Decreased force production, prolonged time to relaxation of muscle fibers, and recruitment of additional muscles during an activity are characteristic of fatigue.⁷³ Although repeated muscle testing can pick up decreased strength in specific muscles, in most instances overwork fatigue is first noted by an altered pattern of movement of body segments during activity.

Impaired muscle length and joint range of motion. Flexibility at the muscle and joint level is critical for normal posture and movement. Muscle atrophy occurs rapidly,⁶⁵ and changes in muscle fiber type and function can be seen as early as 3 days. Viscoelastic properties change with paralysis so that the muscle feels stiffer.^{74,75}

The examination should determine the contribution of muscle tone, joint structure, and tissue factors in limiting flexibility. Active and passive motion should be compared because stiffness (not contraction) often prevents normal function. For example, active dorsiflexion is often limited in patients who have full passive ankle range of motion (ROM) because stiffness begins at neutral. The functional result is foot drop or toe catch in the early part of the swing phase of gait because

the anterior tibialis muscle cannot generate adequate force production to overcome the stiffness in the gastrocnemius and soleus. This restriction also may limit forward movement of the tibia over the foot during the stance phase of gait, resulting in hip retraction or an apparent balance loss. Knee hyperextension also can result from lack of forward motion of the tibia. Flexibility measurements are done with goniometers, motion analysis systems, tape measures, inclinometers, photographs, or electronic devices. Taking both passive and active measurements is critical in identifying intervention approaches.

Abnormal muscle tone and reflexes. In the motor learning theories of today, many of the behaviors and resulting motor patterns after brain injury are seen as attempts by the CNS to compensate for loss. For example, spasticity may be the result of an attempt to compensate for the patient's inability to increase force. When the amplitude of a contraction cannot be increased because of the injury, the CNS may increase the length of time the muscle fires or may recruit muscles not normally used in a particular pattern of movement; both are characteristics seen in spasticity.

Whatever the cause of increased tone, the therapist can evaluate tone at two levels: is it interfering with function, and, if so, can it be changed? Spasticity is not a single problem.^{66-69,74,76-80} Spasticity can have any or all of the following characteristics:

- Changes in response to stretch
- Decreased ability to produce appropriate force for a specific task
- Increased latency of activation
- Inability to rapidly turn off muscles
- Loss of reciprocal inhibition between spastic muscles and their antagonists
- Changes in the intrinsic properties of the muscle fibers
- Inability to generate enough antagonist power to overcome spastic muscles

Examination begins with identifying whether there is increased or decreased muscle tension at rest. If it is increased, is the tension at the muscle level (stiffness or sarcomere involvement) or the neurological level? Muscle stiffness resulting from tissue changes is common in the patient with brain injury. If there is increased tone during movement, EMG may be beneficial to determine the nature of the tone. Is it a problem of co-contraction of agonist and antagonist at a joint? Is it a problem of prolonged contraction? Or is it poor sequencing, either temporally or spatially, of other muscles involved in the movement?

Spatial sequencing of movement involves the contraction of a preset group of muscles. Temporal sequencing involves the contraction of muscles in a fixed sequence. EMG and video analysis provide additional depth of information regarding the sequence and timing of movement patterns. For example, is the normal temporal sequencing in the distal-to-proximal manner present in the UE during a reaching task? In a balance reaction, are the ankle, hip, and back extensors (spatial sequencing) all contracting in response to a forward perturbation?

The most commonly used tool in examination of tone is the Ashworth Scale or Modified Ashworth Scale (MAS) (Box 22.9).⁸¹ The Tardieu Scale⁸² is similar, but testing is done at three different velocities and may provide a clearer picture of what is caused by tone versus muscle shortening. Testing of deep tendon reflexes identifies problems with stretch reflexes, and surface EMG (sEMG) can determine the presence of co-contraction, prolonged contraction, sequence and timing problems, and increased latencies.

Impaired coordination. Ataxia was one of the most common findings among military personnel who had sustained TBI,²³ with 32% of patients showing ataxia initially and 14% at the 2-year follow-up. There are many subcategories of ataxia, including dysmetria, dysynergia, rebound phenomenon, dysdiadochokinesia, and intention tremor.

BOX 22.9 Modified Ashworth Scale

Grade	Description
0+	No increase in muscle tone
1+	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion (ROM) when the affected part(s) is moved in flexion or extension
1+	Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM
2	More marked increase in muscle tone through most of the ROM, but affected part(s) easily moved
3	Considerable increase in muscle tone, passive movement difficult
4	Affected part(s) rigid in flexion or extension

Reprinted from Bohannon R, Smith M. Interrater reliability of a Modified Ashworth Scale of muscle spasticity. *Phys Ther.* 1987;67:207, with permission of the American Physical Therapy Association.

Many clinical tests to assess coordination impairments are available. Common tests include finger-nose-finger test for UE coordination, and heel to shin/heel slides for the LEs.

Impaired sensory function. Sensory functions are often impaired after a moderate to severe TBI. Problems in the sensory system are often reflected in the motor system, creating distorted movement through faulty information in the feedforward or feedback processes.

Two broad categories of sensations can be defined on the basis of the type of information: primary sensation and cortical, or integrative, sensation. This arbitrary division is useful functionally, but it is not anatomically based. Primary sensation includes exteroception and proprioception. The exteroceptors of smell, sight, and hearing are sometimes referred to as teloreceptors. Vision, hearing, olfaction, gustation, pain, touch, temperature, proprioception, and kinesthesia are commonly affected primary sensations. Sensation cannot be clinically tested without patient participation.

- **Proprioception.** Deficits associated with poor balance included a high number of subjects with discriminative touch deficits in one study,⁸³ an impairment related to poor UE function. Traditional examinations of proprioception include the ability to distinguish motion and motion direction at each joint. Some patients who cannot distinguish direction or movement still function well. They may have proprioceptive function at the unconscious level (e.g., cerebellar) while not perceiving the input at the parietal level (conscious level).

Testing is performed by having the patient close his or her eyes; then the therapist places a joint in a specific position (e.g., flexed, extended) and asks the patient to name/identify the position either verbally or with the uninvolved limb. Asking the patient to close the eyes and identify when the therapist passively moves a joint while the patient indicates specific direction of movement can test joint movement sense, or kinesthesia, especially for those with multilimb involvement. Very small joint movements of about 1 degree are within the discrimination level of typical individuals.

- **Light touch.** Light touch is tested with a brush for localization and quality of sensation. For more definitive light-touch discrimination, especially on the hands and feet to determine peripheral neuropathies, a monofilament test⁸⁴ can be used.

- **Two-point discrimination.** Two-point discrimination can be tested with instruments specifically designed to measure how far apart two separate spots of contact need to be to identify them as distinct. For patients who are thought to be ignoring stimuli on one side, testing at the same time bilaterally is first performed, and then each limb is retested separately. Patients who extinguish stimuli will respond that they feel only one stimulus when both limbs are tested simultaneously but will perceive the stimulus just fine when each limb is tested separately. This is called the bilateral extinction test.
- **Stereognosis.** Stereognosis, the ability to identify objects placed in the hand without visual assistance, may be critical to normal hand use. The therapist places multiple common and culturally appropriate objects, such as pens, coins, and safety pins, in the hand and asks the patient to identify the objects while the eyes are closed.

Impaired vision and visual perception. Vision is critical in recovery of many motor functions because it is responsible for much of the feedforward, or anticipatory, control of movement and the initial development of a movement pattern. For example, balance can be maintained through the visual system by modifying synergies before surface change occurs. Feedback through the peripheral field via the movement of the visual array on the retina can also trigger balance responses. Campbell⁸³ found problems with visual functions in most patients with mild to moderate TBI; these problems involved poor visual acuity (48%) and problems with vergence (85%), which can cause blurring and doubling of vision, and smooth pursuit (63%), which can cause a “jumping” of the visual image.

Some patients are able to use their hands for grasp and release, in spite of severe somatosensory deficits, when they are able to use vision to guide the motion. Many of the standard movement tests should be performed with and without vision.

General visual functions can be screened by the physical or occupational therapist as follows:

1. Tracking is assessed by use of an H pattern of movement of the object being tracked with the eyes and not with head movement. The examiner observes any nystagmus or refixation saccades. Eye muscle paralysis can be observed during tracking if the patient cannot move the eye(s) laterally, up, down, or medially.
2. Focus, or accommodation, can be checked by observing constriction and dilation of the pupil. Constriction occurs as an object is moved toward the nose, and dilation as the object is moved away from the nose.
3. Binocular vision is controlled through feedback from blurred or doubled vision. This reflex signals whether the eyes and fovea are focused on a single point or target, as the images in both eyes fall on the same retinal points. A “cover test” can screen for binocular vision. The patient stares at an object at about 18 inches from the nose. The therapist covers one eye. If there is movement to adjust the remaining uncovered eye back to the object, both retinas may not be focusing on the same point. Observing whether light reflections fall on exactly the same place on both pupils is useful in evaluating binocular eye focus. Vergence testing can also be an indicator of binocular visual functions.
4. Visual fields can be grossly tested by having the patient look forward at a point (observer sits in front of the patient to be sure the patient remains focused straight ahead). The patient indicates when he or she first sees an object coming into the peripheral field from behind, or the “spotter” notes when the patient looks toward the object.
5. Vergence is tested by having the patient observe an object or pen tip as it is brought from about 20 inches away. The patient is told to follow the object with his or her eyes. The object is moved at a moderate speed toward the bridge of the nose, and the patient

reports when the object becomes blurred or doubles. When typical convergence is present, there will be no blurring or doubling until the object is 2 inches away or closer, and when the object is moved back out, the patient will report the object as single within 4 inches.

6. Visual interactions with the vestibular system are assessed through the vestibuloocular reflex (VOR). This reflex allows people to maintain a fixed gaze on a target as the head moves. The object should not appear to blur, move, or double during head motion at various speeds.
7. Perceptual tests that evaluate how visual information is used include visual memory tests, cancellation tests, and figure-ground tests.
8. Visual acuity is tested using a Snellen eye chart. Poor acuity can affect balance responses. Neuro-optometrists and neuro-ophthalmologists are appropriate referrals for patients needing in-depth visual workups, especially when visual perception is involved. See Chapter 28 for additional information on vision and visual testing.

Deficits in the vestibular system. The vestibular system monitors the position of the head in space and helps distinguish if the body or the visual surrounding is moving. It also provides a vertical reference to gravity to maintain the head upright. Vertigo, dizziness, eye-head incoordination, and postural and balance complications occur as a result of problems in the vestibular-cerebellar systems. Details of vestibular rehabilitation are described further, and readers are encouraged to see Chapter 21 for more information.

Vestibular deficits are common after TBI with an estimated 30% to 65% of people affected.⁸⁵ Patients with mild or moderate TBI have a high rate (23.8% to 81%) of complaints of dizziness.^{86,87} In many cases dizziness is a sign of vestibular dysfunction and may prolong recovery from TBI.^{23,87} TBI-related vestibular disorders can be central or peripheral, for example benign paroxysmal positional vertigo (BPPV), central vertigo, or perilymphatic fistula. Testing of the vestibular system should be conducted according to the patient’s complaints of symptoms. A comprehensive history and vestibular examination are instrumental for accurate diagnosis, targeted interventions, and promoting recovery.

In general, a vestibular system examination should include assessment of the oculomotor system (e.g., smooth pursuit, saccades, vergence), assessment of VOR function (e.g., head thrust test), and position test (e.g., Dix-Hallpike) according to the patient’s complaints.⁸⁷ For example, symptoms occurring only with specific head movements can be an indicator of problems in the semicircular canals, which points toward the diagnosis of BPPV. Dizziness with head tilts might indicate problems in the otolithic system and VOR tests should be conducted. Other advanced evaluation tools, such as electronystagmography, may be used when symptoms and complaints are more complex. Since postural instability is also a common manifestation in patients with vestibular disorders, outcome measures on balance and/or sensory organization are common tests to be included, which will be discussed in the following section on Assessing Activity Limitations. See Chapter 20 and 21 for additional information on balance and vestibular testing.

Impaired cardiovascular endurance (deconditioning).

For persons after TBI, peaked aerobic capacity is found to be lowered by 25% to 35% compare to matched sedentary group.⁸⁸ In addition, the ventilatory anaerobic threshold (submaximal exercise response correlated with cardiovascular fitness) after TBI is also found to be below the demand of many everyday activities.⁸⁹ It is therefore imperative to investigate cardiovascular endurance in people with TBI. Mossberg and colleagues⁹⁰ in their review paper stated that maximal

graded exercise tests using leg cycle ergometry and treadmill are both reliable for persons after TBI, though treadmill is preferred over cycle ergometry due to its functional nature. Submaximal tests are good alternatives when equipment and time are concerns. The 6 minute walk test is a recommended choice by both Mossberg and colleagues⁹¹ and the TBI EDGE Task Force.⁵⁷

Fatigue, which is separate from impaired endurance, may result from increased energy requirements resulting from less efficient motor patterns or from more CNS activity. Fatigue is a common complaint after TBI⁹² and is associated with insomnia.⁹³ Testing for fatigue is challenging because it is multifactorial. The Global Fatigue Index is recommended for physical therapists to assess fatigue in outpatient settings.⁵⁷

Impaired communication. Primary damage to the language and communication centers in the brain sustained during the accident or injury, alone or in combination with cognitive, motor and sensory impairments, often result in impaired communication following a TBI. Various communication disorders after TBI are reported in the literature (e.g., aphasia, dysarthria, social communication,⁹⁴ reading comprehension⁹⁵). Although it is not within the scope of practice for physical therapists to formally assess and treat communication disorders, it is a domain included in many commonly used measures by physical therapists, for example the MoCA. Physical therapists need to be aware of the deficits and modify communication strategies during rehabilitation intervention. The speech and language therapist typically assesses and treats communication disorders, and makes recommendations for interprofessional team members regarding augmented or alternative communication strategies.

Emotional and behavioral problems. Examining behavioral changes after TBI is important because they are major sequelae of the injury. These changes include impulsiveness, disinhibition, anger, lack of initiative, and apathy, among others. Because the effect of behavioral changes is multidimensional, it is thought that all health care professionals play a role in evaluating behavioral issues in persons post-TBI.⁹⁶ It is, however, still best for neuropsychologists or neuropsychiatrists to administer neurobehavioral tests as special training is required.⁹⁶ Some measures are appropriate for physical therapists to administer, namely the Agitated Behavior Scale, Apathy Evaluation Scale, and LOCF.⁵⁷

Assessing Activity Limitations

Activity in the ICF model is defined as the execution of tasks or an action with a functional purpose. Examples of activities include bed mobility (e.g., rolling), transfer, balance, ambulation, wheelchair mobility, running, bathing, grooming, toileting, and dressing. When assessing these activities, it is important to evaluate both the quality of movements, as well as the quantitative components (e.g., speed of movement, distance). Physical therapists should pay attention to the following quality of movements when assessing a task:

- Is the patient able to use the basic motor patterns for the task in a functional manner?
- Is the patient able to modify and then accomplish the task?
- Is there good interlimb coordination as demonstrated by coordinated two-handed activities, good timing between limbs in walking, and jumping?
- Does the patient appear to have the ability to coordinate motions (decrease the degrees of freedom), or are they limited by too few degrees of freedom?
- Does the patient respond correctly to environmental changes or stimuli such as stepping over or around objects or being able to walk on different terrain?

- When motor patterns are used, are they appropriate for the stimulus? For example, is the ankle strategy used for standing on a firm surface and when stopping walking?
- Are automatic movement patterns present (e.g., balance synergies, walking, and running)? Are volitional or voluntary movements present?
- Can the patient accomplish the same task in several ways? Can the patient adapt to different task demands?

The following subsections reviewed the commonly seen activity limitations after TBI and recommended outcome measures in this ICF domain.

Basic functional mobility. Functional mobility usually includes bed mobility, transfer (sit to/from stand and transfer to/from different surfaces), basic locomotion, and basic ADLs. After a TBI, approximately 40% of patients experience limited functional mobility⁹⁷ due to physical and cognitive impairments, resulting in need for personal assistance.⁹⁸ Assessing functional mobility is therefore imperative, especially during the early phase of rehabilitation. Recommended outcome measures for assessing basic functional mobility include Functional Independence Measure (FIM), Functional Assessment Measure (FAM), and Barthel Index.⁵⁷ More than one functional mobility type is usually included in the measure to capture a comprehensive picture of the person's mobility and functional level. These measures are often administered in acute or inpatient rehabilitation settings when patients require more assistance in mobility and improvement in this area is more substantial.

Sitting balance. Brown and colleagues⁹⁹ found sitting balance to be impaired in 52% of the patients with TBI at initial examination in their review. Testing usually includes static sitting without arm support and dynamic sitting with the patient reaching in multiple directions or ability to resist perturbations. These are not standardized tests but are commonly used clinical tests to assess sitting balance.

Standing balance. Standing balance after TBI is usually affected in mild, moderate, and severe injuries, with 82% of patients exhibiting standing balance deficits. Deficits include both motor strategy problems and appropriate use and integration of somatosensory, visual, and vestibular information. Newton¹⁰⁰ reported that patients with moderate and severe TBI showed significantly impaired reaction times to perturbation in standing. Although they could grade their responses to the perturbations appropriately, the responses were often asymmetrical.

The TBI EDGE Task Force recommended various outcome measures for assessing standing balance in patients with TBI.⁵⁷ Depending on the patient's functional level and settings where therapy occurs, different measures should be selected. For example, the Berg Balance Scale and Community Balance and Mobility Scale are recommended for both inpatient and outpatient rehabilitation settings. The Balance Error Scoring System is recommended for outpatient rehabilitation settings where the patient is tested on the types of standing balance error in double leg stance, single leg stance, and tandem stance on firm and foam surfaces. Sensory Organization Test is also a recommended test and is an appropriate choice for the patient with vestibular symptoms.⁸⁷

Gait and dual-task gait ability. The motor impairments of TBI often result in spatiotemporal gait deficits, including a decrease in velocity, asymmetry of step lengths, increased double limb support time, reduced step length, and increased mediolateral sway.^{101,102} Tandem gait (ataxia) is also prominent post-TBI and can remain at 2-year follow-up.²³ For individuals with ataxia after TBI, it was found that they have reduced interjoint coordination during gait, and this coordination further deteriorated during more complex walking situations such as narrow base of support or when carrying an object.¹⁰³

Impaired gait mobility is also perceived as a contributor to falls in post-TBI.¹⁰⁴ It is obvious that gait abnormalities after TBI can pose a significant limitation in everyday activity and warrant detailed measurement.

There is a wide range of gait outcome measures. Similar to other impairments and activity limitations, selection of appropriate gait outcome measures is based upon patients' functional level and settings where therapy takes place. For acute care and inpatient rehabilitation settings, gait assessment is oftentimes included in generic functional mobility measures such as FIM and FAM.⁵⁷ Together with these outcome measures, a qualitative gait description through task analysis should be done in order to identify underlying impairments.

For individuals with basic ambulatory function, more robust gait outcome measures are recommended and include the 6 minute walk test, 10 m walk test, HiMAT, and Functional Gait Assessment.⁵⁷

Another type of gait outcome measure that should be included for high-functioning patients with TBI is gait ability during dual-task situations. Dual tasking is a common daily function (e.g., walking while attending to a conversation) and entails performing one cognitive and one motor task at the same time. Since motor and cognitive impairments are major sequelae of TBI, it is expected that dual-task abilities are even more compromised. In fact for persons post-TBI, despite well recovery of motor gait ability, reaction time during dual-task gait activity is significantly longer compared to age-matched group.¹⁰⁵ The TBI EDGE Task Force recommended the Walking and Remembering Test to assess dual-task gait ability in persons post-TBI.⁵⁷ In addition, the modified Walking and Remembering Test and Timed Up and Go-Cognitive together with the Walking and Remembering Test have been shown to be reliable and feasible for persons in inpatient rehabilitation settings.¹⁰⁶ Physical therapists are encouraged to include dual-task measures when appropriate because they may be more indicative of functional outcomes.

Upper extremity function. UE function includes tasks that require reaching, grasping, pinching, etc. and can be affected after TBI. Clinical presentations for upper limb dysfunction after TBI may be similar to those with hemiplegia or hemiparesis—for example, impaired timing and reduced accuracy of reaching and grasping.¹⁰⁷ The Action Research Arm Test and Wolf Motor Function Test are recommended outcome measures specifically for assessment of upper limb function.⁵⁷ There are also generic outcome measures that assess activities requiring upper limb functions. An example being FIM where grooming is included as a test item and is a task where upper limb function is highly indicative.

Assessing Participation Restrictions

Participation restrictions refer to limitations an individual experiences in his or her life roles. As such, each individual's participation restrictions after TBI can be very different and limitless. Examples include inability to drive, restriction in work duties, inability to participate in school activities, or restriction in carrying out the role as a parent. While the focus of rehabilitation programs for TBI is on improving motor and cognitive outcomes at the impairment and activity limitation levels, measuring participation is equally important as it affects the patient's quality of life after an injury. The ultimate goal for rehabilitation is for patients to resume participations at preinjury level, such as returning to work or school.¹⁰⁸ A recent Cochrane review¹⁰⁹ included several indicators as primary and secondary outcomes when investigating effectiveness of cognitive rehabilitation programs. These outcome indicators include return to work, independence in ADL, community integration, and quality of life. Most of these outcomes are in the participation category of the ICF model, implying the ultimate long-term goal of effective rehabilitation is to improve patients' functioning in society, and hence assessment in this area should be included.

Some common participation measures are introduced for inclusion in the examination process. The ultimate choice depends upon the patient's role and meaningful function in the society in which they live. From the physical therapy perspective, the TBI EDGE Task Force recommends to include outcome measures on community integration and quality of life in outpatient settings.⁵⁷ These measures include Disability Rating Scale, Quality of Life after Brain Injury, Community Integration Questionnaire, and Sydney Psychosocial Reintegration Scale. Usually, participation restriction measures are administered in outpatient or community clinical settings because this is the time when patients and family/caregivers focus on long-term life plans. Specific participation measures associated with certain impairments can also be included. For example, if balance and falling is an issue after TBI, therapists could include the Activity-specific Balance Confidence Scale to assess the impact of balance on daily life.

Interventions for People With Traumatic Brain Injury

Roles and Responsibilities of the Interprofessional Rehabilitation Team

TBI results in a myriad of physical, psychological, behavioral, and cognitive impairments. Comprehensive rehabilitation requires an interprofessional team approach due to the complex clinical presentation following a moderate to severe TBI. Research has shown that medical management, in addition to early onset and continuous rehabilitation, is most effective when delivered in a specialized neurotrauma/brain injury unit by an interdisciplinary health care team.^{110,111}

As most people who have experienced a moderate to severe TBI have cognitive impairments and reduced ability to learn, consistency and repetition of management strategies is required to optimize effectiveness. This requires regular, ongoing communication among interprofessional team members, including the patient, family, and friends involved in their care. Each member of the interprofessional team will focus their plan of care on interventions within their primary scope of practice. However, all providers will need to carefully consider other aspects of the injury and incorporate recommendations for managing impairments outside their scope of practice into their plan of care to optimize patient outcomes. For example, PT's should incorporate strategies for managing communication impairments, memory loss, reduced orientation, as well as behavior modification, into their interventions in order to be effective. See [Table 22.5](#) for a list of interprofessional health care team members and their primary role in caring for people with TBI.

Physical Therapy Interventions Through the Care Continuum

The continuum of care and common practice settings for persons with moderate to severe TBI are presented in [Fig. 22.2](#). As each person and brain injury is unique, the settings required for optimal care, and length of time spent in each, will differ. The focus of rehabilitation will vary depending upon the practice setting, severity of the brain injury, the person's level of consciousness, physical functioning, and personal goals. However, there are general physical therapy management goals that are prioritized among the settings. Regardless of practice setting or patient acuity, physical therapists should work with the interprofessional team to prevent secondary complications, including pneumonia, pressure sores, adaptive shortening of soft tissue, disuse atrophy, heterotopic ossification (HO), joint contractures, and deep vein thrombosis (DVT) through aggressive bronchopulmonary hygiene, positioning schedules, tone management techniques, pressure relieving mattresses, cushions and splints, and daily ROM and stretching programs. Physical therapists working with individuals with head injury should also receive competency training on the medical monitoring and treatment devices commonly used in the neurological intensive

TABLE 22.5 Interprofessional Team and Roles/Responsibilities in Care of Persons With Traumatic Brain Injury

Discipline	Roles and Responsibilities
Social Worker/Case Manager	Coordination of care and discharge planning with team, family, and insurance company
Neuropsychologist/Neuropsychiatrist	Evaluate and treat cognitive, emotional, and behavioral issues due to CNS disorders
Neuro-optometrist/Ophthalmologist	Diagnose and treat visual disorders due to CNS injury
Neurologist/Neurosurgeon	Physicians specializing in diagnosis and treatment of nervous system disorders
Physiatrist	Physicians specializing in physical medicine and rehabilitation; often coordinates care during the rehabilitation process
Pharmacist	Experts in medications and drug interactions; prepare medication as ordered by prescribers
Nurse	Maintain and/or restore health of all body systems; administer medications ordered by prescribers
Occupational Therapist	Focus on improving activities of daily living such as feeding, bathing, grooming, driving, etc.; address cognitive, visual, and social skill impairments
Physical Therapist	Movement specialists; focus on improving functional mobility by addressing the movement system and movement dysfunction
Speech and Language Pathologist	Focus on improving ability to speak, swallow, and communicate orally, through writing or augmented communication devices
Recreational Therapist	Focus on improving self-esteem, social skills, motor skills, coordination, endurance, cognitive skills, and leisure skills

Brain Injury Association of America. CNS, Central nervous system.

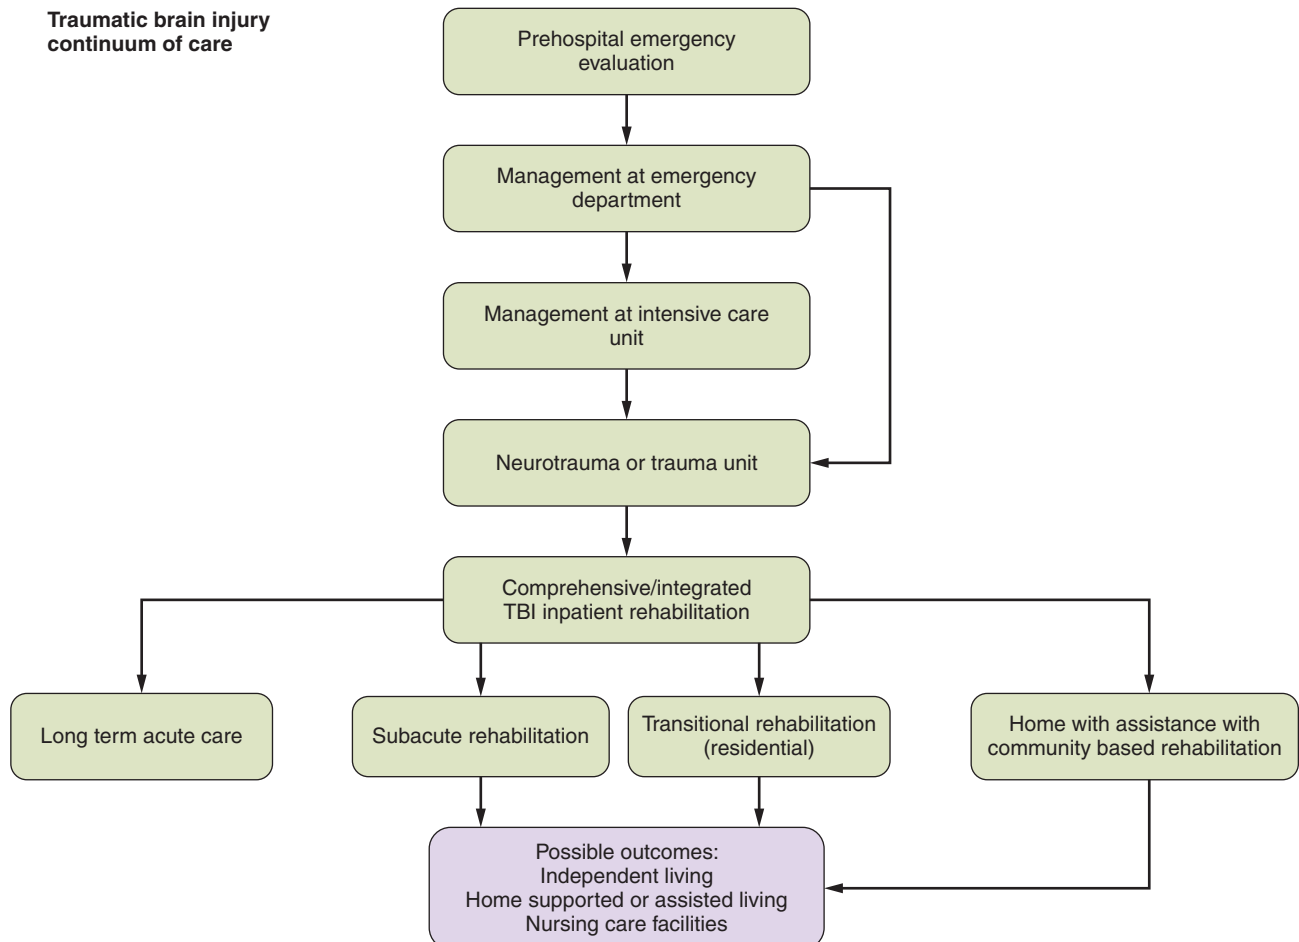

Fig. 22.2 Continuum of care following moderate to severe brain injury. *TBI*, Traumatic brain injury.

care unit (ICU) and acute care settings. Precautions for all of the devices must be observed, and therapists should closely monitor all lab values and vital signs throughout physical therapy sessions to maintain patient safety and prevent complications.

Within the ED, neurological ICU, and/or trauma center, the primary focus of all care is on preservation of life and neural tissue, and prevention of secondary complications. In these acute stages of a moderate to severe TBI while the person is in the ICU or trauma center, physical therapy interventions that should be prioritized are early mobility, and improving level of arousal and awareness for people with DOC. Early mobilization is well supported in the literature to improve long-term outcomes and reduce costs of care and has been shown to be safe for people in the neurological ICU.¹¹²⁻¹¹⁴

Once the person is transferred to a step-down unit or is in a neurological acute care unit and level of arousal is improved, the priorities shift towards increasing mobility and improving meaningful interactions with the environment. In acute or subacute rehabilitation, priorities are on maximizing safety and independence with functional mobility, performance of ADLs, and appropriate interactions with others and the environment. For persons who remain in a lower level of consciousness such as coma or VS, discharge is often to a long-term care facility due to payor issues and eligibility requirements for rehabilitation facilities. Unfortunately, signs of emerging from VS and progressing to MCS and beyond are often missed in this setting, and people do not receive regular or intensive physical therapy as they are not capable of making consistent progress early in recovery. Further, the time it takes for physical recovery from DOC is often much longer than the short length of stay, which is predetermined by insurance companies in the United States, currently.¹⁷ It has been demonstrated that a specialized early treatment program for people with DOC can lead to over half of participants' progress to a level of consciousness that makes them eligible for admission to a mainstream inpatient rehabilitation facility.¹¹⁵ Therefore a paradigm shift is needed in the clinical management for persons with trauma-related DOC.

The post-rehab goals for a person with moderate to severe TBI will depend on residual deficits and level of function; however, the focus is typically on participation in society and community reintegration, including return to school/work/family responsibilities and independent function. Despite advances in medical care and rehabilitation interventions, most people experience chronic effects of brain injury, including residual functional deficits, emotional problems, and cognitive impairments. Evidence now suggests that TBI may also lead to chronic brain injury (CBI), a degenerative process that can progress over a person's life-span and result in Alzheimer disease, as well as progressive motor deficits.^{116,117} Thus long-term, individualized care plans with lifelong supports are needed to manage chronic effects of brain injury whether they are static or progressive.¹¹⁸ Many clinicians now advocate for periodic therapy, sometimes referred to as a "dental model of care," for persons with CBI and other neuromuscular conditions such as Parkinson disease, multiple sclerosis, cerebral palsy, and others. The goal of periodic therapy is to improve overall health, physical function, and participation in life roles through self-management with an emphasis on healthy behaviors, including exercise, proper nutrition, and avoidance of substances like nicotine and alcohol.¹¹⁹

Interventions for Disorders of Consciousness (Levels of Cognitive Functioning I-III)

Consciousness comprises the domains of arousal, or level of alertness, and awareness to both self and environmental factors. As stated in the clinical features section of this chapter, DOCs are common after a TBI and may also be experienced by persons diagnosed with a stroke, brain

tumor, infectious process, alcohol overdose, or poisoning.¹¹⁹ The primary focus of management for people with DOC is on prevention of secondary complications and restoration of cognitive-behavioral functions.¹⁷ The DOC state corresponds to LOCF I-III.

Standards of care for clinical management for DOC are lacking, and there is a dearth of evidence-based interventions shown to improve outcomes for this population despite many recent advances in understanding the neuropathophysiology, standardization of terminology, and improving accuracy of diagnosis.¹²⁰ The logistical and ethical issues related to placebo-controlled studies constrain this type of research.¹²¹ However, clinicians are reminded that a tenant of evidence-based medicine is the integration of clinical expertise with best available external evidence, thus past clinical experience should be utilized in decision making for the management of persons with DOC.¹²² Further, clinicians are obligated to provide reasonable treatments within their scope of care regardless of the state of the published literature.¹²⁰ Lastly, the considerable data on long-term outcomes (which will be discussed at the end of this chapter) shows that the majority of people emerge from DOC following head trauma, providing justification for physical therapy interventions and other rehabilitation measures.

The physical therapy plan of care for people with DOC should include interventions previously mentioned for limiting common secondary complications, including contractures, thrombo-embolic disease, HO, pulmonary infections, and pressure sores. Additionally, diligent management of spasticity is recommended to prevent contractures, limit need for costly tendon release surgeries, improve positioning and comfort, and promote readiness for active therapy such as transfers and standing balance, which would be precluded if there were plantarflexion contractures. Effectively managed hypertonia can also decrease the effort and time required to provide all other routine care and possibly reduce caregiver burnout.^{115,123} It has been demonstrated that frequency of physical therapy influences spasticity in a positive manner, and that persons with DOC who receive four sessions of therapy per week have less spasticity and fewer contractures than persons who receive less therapy.¹²³ Interventions, including prolonged stretch, prolonged positioning with splints and/or serial casts, modalities such as heat and cold, and weight bearing have all been shown to reduce spasticity. If conservative measures fail to address the hypertonicity, communication with team members, including the neurologists and physiatrist, are indicated for further medical management, which may include phenol or Botox injections, oral medications, or intrathecal pump delivery of Baclofen.

Restorative treatments within a physical therapist's scope of practice include increasing level of arousal to promote normal sleep-wake cycles.¹²⁰ There are two primary types of interventions used in neuro-rehabilitation to increase arousal level: upright positioning and sensory stimulation. Placing a person with head injury in an upright position has been shown to increase responsiveness and behaviors.¹²⁴ People post brain injury who are diagnosed with VS or MCS are most responsive in standing, but also more responsive sitting in a wheelchair compared to lying supine.¹²⁵ This is widely believed to be due to increased activation of the reticular formation, the central core of nuclei that run through the brain stem and are responsible for maintaining consciousness.¹²⁶ Sound clinical reasoning with careful consideration of factors such as medical stability and comorbidities, level of consciousness, activity orders, precautions (spine, weight bearing, craniectomy, aspiration, behavior, seizure, etc.), and availability of equipment and personnel should be used to determine the safest method of mobilizing a person and achieving upright positioning. For persons who are in a coma and/or medically unstable, a hospital bed that moves into a reverse Trendelenburg position or converts to a chair may

Fig. 22.3 Hospital bed converts to chair for upright positioning to improve level of arousal.

Fig. 22.4 Use of tilt table to promote arousal, increase weight bearing through lower extremities, and improve cardiovascular tolerance to position changes.

be most appropriate to initiate upright positioning if available (Fig. 22.3).

Use of a tilt table (Fig. 22.4) to gradually increase upright posture and position is also used for this patient population due to the fact that safety can be maintained even when the patient is unable to follow commands or actively participate in the treatment. The person can be transferred via a slide board or with bed sheets from hospital bed to the tilt table, then safely strapped to the table with harnesses and belts before moving the person to an upright position, which limits risk of a fall. Additional benefits of using a tilt table include early weight-bearing to promote circulation and prevent DVT, redistribution of pressure points on skin, improve renal function, improve ankle ROM, decrease spasticity in the LE, improve respiration, preserve bone density, reduce orthostasis, and improve cardiovascular response to

position changes after prolonged bedrest.¹²⁷ Rolling and transferring the person to sitting position on the edge of the bed is another option; however, this method requires participation of several clinicians to prevent a fall for a person with DOC as total assist will be required for maintaining sitting balance. Transfer of a person from bed to a recliner or wheelchair via active, dependent transfers or using a mechanical lift are also indicated. Activity orders should be specified in the medical record prior to mobilizing the person, and ranges of acceptable vital signs, including ICP for mobility, should be checked as well. Abdominal binders and compression stockings may be beneficial for improving venous return, limiting orthostasis, and improving tolerance to upright position during early mobilization procedures.

Many people with TBI have concomitant internal injuries, orthopedic injuries, including fractures and subluxations, as well as soft tissue damage such as skin tears, lacerations, and muscle contusions. Therefore with mobilization and other interventions, therapists should observe persons for signs and symptoms of pain such as grimacing, agitation, withdrawal responses, and/or increased heart rate, blood pressure, and ICP. If any of these symptoms are noted during physical therapy, the therapist should discontinue the treatment and try to return the person to a comfortable state. The findings should be documented and reported to the interprofessional team, and a plan of care should be implemented to premedicate the person before treatment for comfort and safety. For people in MCS, aggressive pain management protocols are encouraged because subjective awareness of pain is intact but ability to communicate is often limited.^{128–130} Additionally, therapists must carefully observe patients for sign and symptoms of seizure activity at all times as this is a common complication following TBI. Most people will be prescribed antiseizure medications prophylactically; however, seizures may still occur, and therapists must respond in an appropriate manner to maintain patient safety. Medical personnel and nursing should be alerted immediately, sharp objects should be removed from the immediate area, and the person's head should be supported with a pillow.

Sensorimotor stimulation has historically been the primary non-pharmacological treatment intervention used for rehabilitation of persons with DOC.¹²⁰ A study published in 1990 by Mitchell and colleagues found that a rigorous program of olfactory, visual, tactile, auditory, and gustatory stimuli provided by trained family members for 1 to 2 hours per day for 7 to 12 days shortened the time it took to follow commands and execute purposeful movements among people with severe TBI.¹³¹ A Cochrane review published in 2002 did not find any evidence to support multisensory interventions; however, this was due to poor study quality, variable study designs, and lack of consistent outcome measures used in the reviewed articles.¹³² More recently, an early interprofessional rehabilitation program for people with DOC consisting of a minimum of 90 minutes of therapy per day, mean length of stay 39.1 days and standard deviation of 29.4 days, resulted in improved levels of consciousness for most participants and only a 13% discharge rate to long-term care facilities.¹¹⁵ Despite the lack of rigorous research studies to support the practice, sensory stimulation is routinely used in the treatment of persons with DOC with the purpose of increasing the level of arousal.

Examples of commonly used sensory stimuli are listed in Table 22.6. Noxious stimuli, including deep pressure or pin prick to the nail beds or palmar surfaces of the hands and feet, as well as sternal rub, may be used initially for nonresponsive people with DOC. Loud, brisk auditory stimulation introduced via dropping a book on the floor, clapping, or banging on an object may also be used in an attempt to induce an alerting, startle response. Education that includes thorough explanations of physiological rationales and potential benefits of these interventions should be provided as family members

TABLE 22.6 Types of Sensory Stimuli to Increase Awareness and Arousal Levels

Mode	Examples
Auditory	<ul style="list-style-type: none"> • Conversation, voice of family members • Reading books, magazines • Sounds, e.g., ringing bell, hand clapping • Play music
Tactile	<ul style="list-style-type: none"> • Light touch, massage • Temperature (hot/cold) • Brushing or stroking • Pressure, e.g., inflate a sphygmomanometer cuff or air sleeve • Noxious: sternal rub, deep nail bed pressure, pin prick
Visual	<ul style="list-style-type: none"> • Colored papers • Pen light, room lights • Daylight • Faces of the patient's family, friends, pet, etc. • Pictures of the patient's family, friends, pet, etc.
Olfactory	<ul style="list-style-type: none"> • Perfume • Vinegar • Orange • Lemon • Coffee
Gustatory	<ul style="list-style-type: none"> • Oral swabs • Lollipop • Popsicle • Providing oral hygiene care
Kinesthetic	<ul style="list-style-type: none"> • Any change of position, e.g., rolling, supine to sit • Vestibular, head turns if not contraindicated, rolling • Passive range of motion

present may perceive them as torturous or distressing if not well understood, and especially if the family believes there is little potential for meaningful recovery.¹³³

Many other types of sensory stimulation, including visual, vestibular, kinesthetic, sensory, and gustatory, may be introduced to increase levels of arousal (see Table 22.6). Whenever the therapist is using sensory stimuli to promote arousal, it is recommended that the stimuli be presented in a graded manner to achieve an optimal level of arousal while maintaining sensory integration. If too many are introduced, or they are too intense, the person may become overloaded and overwhelmed. They may become agitated or shut down and not respond to any further stimulation. Thus it is best to start with one type of stimulation at a time, then gradually add additional forms, and/or increase the intensity of the stimuli, until arousal is achieved. People in lower levels of consciousness may need repeated presentation of stimuli to maintain a state of wakefulness, but often only remain awake for short periods of time and need frequent periods of rest. Therapists should document patient response to types and intensity of stimuli and avoid forms and intensities that agitate the person, as well as communicate these findings to interprofessional team members for consistency and efficiency. As people emerge and move to higher levels of consciousness, they may respond differently to stimuli, and any changes in response should also be documented and communicated with team members.

For persons in and emerging from MCS, physical therapy goals should focus on increasing the level of awareness of self and the environment. Persons in this stage of recovery may respond to stimuli and

demonstrate purposeful behaviors, albeit inconsistently. Nonetheless, therapists should encourage purposeful responses, eye and/or head tracking of familiar visual and auditory stimuli, and activities such as reaching, grasping, and placing objects. As learning will be compromised due to the brain damage and anterograde amnesia, activities should be familiar to increase the automaticity and motivation to participate. Sessions should be stimulating but not overstimulating. Delayed processing is also present, so allow adequate time for the person to respond to cues before attempting another trial or repeating cues. Therapists should carefully consider environmental factors such as temperature, lighting, and ambient noise and attempt to control these factors to keep the person as alert as possible for as long as possible but without overstimulating them. Treatment may need to be performed in a closed environment free of external distractions to promote participation.

Physical Therapy Considerations for Persons With Levels of Cognitive Functioning IV-VI

For persons emerging from DOC, or those who present in LOCF IV-VI immediately following their injury, the focus of rehabilitation is on motor recovery, and improving safety and independence with functional mobility. Motor learning principles, as well as the neurophysiological principle of neuroplasticity, should be applied throughout interventions for persons recovering from a TBI. Refer to Chapter 3 for more information on this topic.

Motor learning strategies specific to the TBI population and those with impaired awareness include use of implicit memory tasks in therapy. Several studies have demonstrated impairments in explicit memory tasks with preservation of implicit tasks, including priming and procedural learning following TBI.^{134,135} Thus it is recommended that rehabilitation professionals utilize implicit-memory tasks, including priming and procedural learning, for interventions as this type of learning does not rely upon conscious awareness. Persons in LOCF IV through VI often benefit from use of priming, or fostering learning through prior exposure to the stimuli, and procedural tasks, such as riding a bike. These tasks are more automatic, and automaticity may be augmented by use of familiar and desirable items and objects. For example, a therapist may hand a basketball to a person who played on their high school team before the injury, then place a hoop in front of them to encourage them to place or throw the ball. This seemingly simple task provides an internal perturbation for sitting or standing balance, promotes trunk stabilization and motor coordination, is a functional strengthening task for the UEs, and may even improve activity tolerance if repeated multiple times. Therefore the therapist can simultaneously address several impairments of body structure and function commonly present in persons with TBI through this procedural task.

Therapists are encouraged to consider environmental factors and ensure context specificity whenever possible. If the person in the above example is not responding in the desired manner when in their hospital room, a more appropriate motor response of throwing the basketball may be elicited if taken to a gym or basketball court. Similarly, if the goal of the therapy session is to improve performance of an ADL such as brushing one's teeth, the individual should be brought to the bathroom, placed in front of the sink and mirror, then handed a toothbrush and tube of toothpaste. Therapists need to carefully consider the individual's premorbid preferred activities and hobbies, life roles, and impairments to develop and structure individualized physical therapy interventions that promote implicit learning.

An additional consideration for persons in LOCF IV-VI is the need for behavior modification strategies to be utilized during therapy sessions. Some examples of behaviors commonly observed for person

recovering from a head injury, and examples of management strategies, are listed in Table 22.7. This list is not exhaustive, and therapists are highly encouraged to work with interprofessional team members to develop strategies that are then used consistently by all team members, visiting family members, and friends. Consistency is critical for success due to impaired learning and cognition. Simple cues and

strategies often work best. For example, a simple verbal response such as “that is inappropriate,” or “that is not safe,” will be most helpful to extinguish unwanted behaviors such as swearing, hitting, or inappropriate sexual touching. Positive reinforcement plans are also encouraged. One example of this may be if the person does not exhibit an unwanted behavior throughout the entire therapy session, they

TABLE 22.7 Sample Behaviors and Suggested Interventions

Behaviors	Interventions
<p>Agitation</p> <ul style="list-style-type: none"> • Removing restraints/tubes • Crawling/getting out of bed • Mood swings • Screaming, crying, restlessness • Pacing, wandering 	<ul style="list-style-type: none"> • One-to-one supervision • Remove restraints if order in place to do so • Redirection to tasks • Reduce stimulation (turn off TV, dim lights, check needs for bathroom or pain, limit visitors, keep door closed, etc.) • Education on importance of tubes, IVs, lines, etc. • Do not argue or yell, and stay calm • Consistent response by all team members to undesired behaviors
<p>Aggression</p> <ul style="list-style-type: none"> • Verbal (increase in voice volume and tone, swearing, name calling) • Physical (hitting, kicking, biting, choking, hair pulling, object throwing, etc.) • Demanding unreasonable requests (e.g., demanding to leave or go home) 	<ul style="list-style-type: none"> • Remove breakable or sharp objects from reach • Keep safe distance from patient • Do not respond with physical force or restrain person unless for their safety • Reduce stimulation (turn off TV, dim lights, check needs for bathroom or pain, limit visitors, keep door closed, etc.) • Minimize safety risks: lower bed, lock brakes • Do not argue or yell, stay calm • Give patient breaks from activity/stimulation
<p>Noncompliance</p> <ul style="list-style-type: none"> • Refuse to take meds • Refuse to participate in therapy 	<ul style="list-style-type: none"> • Identify motivators and use positive reinforcement • Education regarding purpose of interventions • Give patient some control and/or choices • Involve family who induce cooperation • Set goals with person • Behavioral contract-avoid punitive measures
<p>Impulsivity</p> <ul style="list-style-type: none"> • Quick verbal response without awareness of consequences • Quick physical action without safety awareness 	<ul style="list-style-type: none"> • Verbalize or rehearse steps prior to starting a task or activity • Provide verbal cues for safety throughout task performance • Safe environment (use of assistive device, grab-bars, handrails, etc.) • Review consequences of unsafe movements or behaviors • Utilize bed alarm or door alarm if ordered • Restraints if ordered and all other interventions have failed
<p>Confusion/Disorientation</p> <ul style="list-style-type: none"> • Where am I? • What time is it? • Not recognizing staff members • Hallucinations or delusions 	<ul style="list-style-type: none"> • Provide frequent orientation • Utilize same staff members (nurses and therapists) • Utilize consistent therapy schedule • Use bed alarm or door alarm if ordered • Give simple explanations prior to activity • Limit change and be consistent
<p>Inappropriate Sexual Behavior</p> <ul style="list-style-type: none"> • Inappropriate comments • Masturbation • Grabbing or groping staff 	<ul style="list-style-type: none"> • Provide education that inappropriate sexual behavior is not allowed • Keep distance from patient • Utilize same sex staff if effective and able to do so • Involve family members to minimize inappropriate behavior if effective • Consistent verbal cues among the interprofessional team, e.g., “that is not appropriate”
<p>Fatigue</p> <ul style="list-style-type: none"> • Poor endurance or tolerance for therapy/activity • Frequent rests or desires to go back to bed • Always sleeping or requesting to skip treatment 	<ul style="list-style-type: none"> • Identify cause of fatigue if possible (medication, depression, poor sleep/wake cycle, restlessness at night, etc.) • Use frequent rest breaks during and between therapy sessions • Minimize time in bed during the day to promote sleep at night • Education regarding need for breaks and cause of fatigue
<p>Denial</p> <ul style="list-style-type: none"> • Low insight into deficits • Unrealistic about abilities and outcomes 	<ul style="list-style-type: none"> • Set up experiences with patient that bring out the deficit for patient’s own observation (within safe limits) • Review deficit areas/outcomes with patient • Gradually prepare patient for outcomes and highlight progress • Provide support for acceptance of deficits/outcomes, social worker involvement

receive a reward such as watching a TV show, playing a game, going outside to the garden, etc. When possible, the reward should be predetermined and chosen by the patient, and delivered as soon as the goal is achieved, to increase motivation. Allowing personal choices in types or sequencing of activities may also be helpful with improving motivation to participate and limit unwanted behaviors. If you have to address a therapy goal that is less desirable to the patient, you could tell them that it is critical to do those interventions and provide a rationale but let them choose a desired activity to do next. Punitive measures such as isolating the person, not allowing them to eat dessert, etc. should not be used for behavior modification as these may be considered neglectful or abusive and are often less effective.

Communication and processing issues common after TBI may also impact the provision of therapy. Therapists working with persons in LOCF IV-VI may need to allow increased time for processing commands and use multimodal cues, including visual, verbal, and/or tactile, depending upon which systems are intact. Augmented communication devices may be beneficial, and the physical therapist should work closely with the speech and language pathologist to determine which systems are most effective.

Dosing factors, including timing and intensity of therapy, are also important factors to consider. Several published studies on timing and intensity of therapy for people with moderate to severe head injury report better outcomes, including less time to achieve independence with functional tasks, shorter hospital stays, and faster improvement in level of consciousness, with early and more intense therapy.^{115,135-137} A recently published meta-analysis concluded that early provision of rehabilitation in the trauma center and more intense therapy in rehabilitation facilities promote improved functional recovery among people with moderate to severe TBI.¹³⁸ Unfortunately, many people with TBI do not engage in the number of repetitions of activities required for neuroplastic changes during therapy sessions.¹³⁹ This may be due to service delivery models that limit number of hours in therapy per day and require provision of therapy in a one-to-one manner. Further, persons with TBI are often limited in their attention span and activity tolerance, which may prevent active participation in highly intense therapy sessions. To address this problem and increase number of repetitions, alternative service delivery models such as group sessions and robotic assisted therapy have been suggested. Kimberley and colleagues¹³⁹ frequent, short duration rest breaks or split sessions, such as 30 minutes in the morning and 30 minutes in the afternoon rather than 60 consecutive minutes, may also allow more repetitions needed for improved recovery following TBI.

Interventions to Improve Motor Performance and Physical Function After Traumatic Brain Injury

Motor deficits commonly seen after a TBI include loss of selective or isolated control, weakness, impaired force production, altered tone, poor timing and sequencing, and loss of coordination. Physical therapy approaches to improving motor performance and improving function are similar to those used for persons with other neurological insults such as stroke, cerebellar lesions, and brain tumor, while incorporating the above considerations for changes in mood, cognition, personality, communication, and others. Refer to Chapter 24 for specific interventions aimed at improving motor function for hemiplegia, as these are currently the same as those recommended for persons with TBI.

Traditional approaches such as Bobath, neurodevelopmental treatment (NDT), and proprioceptive neuromuscular facilitation (PNF) are often blended by contemporary therapists into general neuromuscular reeducation and functional task-oriented retraining approaches. Constraint-induced movement therapy (CIMT) is also commonly

used to improve UE function and ADL performance for people post-TBI even though the research on this intervention has primarily used subjects who are post-stroke. Compared to stroke, there is limited research on outcomes for specific types of rehabilitation interventions for people post-TBI. Many published studies include subjects with hemiplegia due to both stroke and TBI; however, they are not a homogenous group, as people post-TBI often have extrapyramidal disorders from more extensive CNS damage. As a result, rehabilitation practices for persons with TBI are highly variable.¹⁴⁰

Regardless of the limitations in research and variable nature of interventions, considerable evidence exists that supports the fact that persons with TBI make functional gains in rehabilitation.^{141,142} Therapists should therefore engage persons post-TBI in intense, repetitive, task-oriented training to promote recovery of function and optimal motor performance with all functional mobility tasks, including rolling, transferring supine to/from sitting, sit to/from stand, bed to/from wheelchair, wheelchair mobility, ambulation, and stair mobility. Additional contemporary neurorehabilitation approaches for persons with TBI, areas of physical rehabilitation that are critical to address for this population, as well as emerging treatment interventions for TBI will be discussed in more detail below.

Treadmill training. Improvement of walking ability is often a priority for people who have had a TBI, and repetitive, intensive, task-oriented practice is required for recovery. The use of treadmill training, with or without body-weight support and robotic assist, has become common practice in rehabilitation of gait. The use of body weight supported treadmill training (BWSTT) has several potential benefits, including that it may allow a greater number of steps per therapy session than overground walking, and therapists have hands free to facilitate appropriate motor patterns (Fig. 22.5). However, it may require multiple staff members to facilitate the trunk and each limb. It may also allow earlier gait training and weight bearing for persons who have not recovered sufficient postural control to commence overground training safely. However, treadmill training as a gait intervention post-TBI has been shown to be no better than overground training.¹⁴³ Moreover, there is a lack of high-quality studies to support any gait interventions for people with TBI and higher-quality studies with standardized treatment approaches are needed in this area.

Robotic-assisted treadmill training (RATT) has grown in popularity recently as it can decrease the physical burden of gait training on the therapists and allow persons to take more steps per day than overground training, but the systems are quite expensive and not widely available in rehabilitation facilities. Studies on the use of RATT are also limited. Recent studies with small sample sizes found that people with chronic TBI benefit equally from RATT and manually assisted treadmill training to increase gait velocity, endurance, and mobility domain Stroke Impact Scale scores, but the RATT group showed greater improvements in symmetry of step length.^{101,144}

Some participants reported skin irritation from the robotic assist. More high-quality research is needed to guide physical therapist practice in gait training for people with TBI. Factors that need to be considered in clinical decision making on use of these devices at this time, in addition to patient safety, which is always paramount, are availability and cost of equipment, as well as staff availability and training.

Virtual reality. Virtual reality (VR) involves the use of a 3-dimensional, computer-generated environment in which a person is immersed and is able to interact with or manipulate the objects in the virtual setting, thereby creating a safe and controlled milieu for therapy sessions (Fig. 22.6).¹⁴⁵ VR has been reported to increase motivation and compliance, especially among pediatric populations, which promotes

Fig. 22.5 Body Weight Support Treadmill Training. (A) Front view. (B) Back view.

Fig. 22.6 Virtual Reality.

neuroplasticity and recovery through increased repetitions of activities. The recent decrease in cost for systems, as well as the emergence of commercially available serious games that create interactive, virtual environments, has resulted in an increased use of this technology in neurorehabilitation and for home-based programs. Research on VR in stroke rehabilitation is more robust than for TBI, and clinical practice guidelines now include using VR to address spatial, visual, verbal, mobility, and upper limb impairments post-stroke.¹⁴⁶ Recently published literature reviews agree that there is emerging evidence to support VR in rehabilitation for people post-TBI; however, the strength of existing evidence is limited by research design and methodology as most studies are case studies or noncontrolled trials with low numbers of participants.^{145,147,148} There is a need for large, randomized controlled studies to demonstrate cost-effectiveness and efficacy.

Reported benefits of VR for adults and children post-TBI in studies included in these reviews include improved gait kinematics, motor coordination, cognition, memory, attention, balance, dual-task function, and

visual vertigo symptoms.^{145,147,148} Further, it has been shown that VR can be an effective pain distractor and have an analgesic effect for persons during physical therapy sessions in inpatient treatment centers.¹⁴⁸ In available studies that include control groups, it is important to note that VR and conventional therapy groups typically have similar outcomes indicating that while VR may be more enjoyable and increase compliance for some persons, similar results may be achieved with traditional therapies.^{145,147,149}

Interventions to improve vestibular function. Dizziness and balance issues can be a source of long-term disability following a head injury, and presence of dizziness after TBI is a risk factor for a longer recovery.^{85,87} Unfortunately, these symptoms are often overlooked and undertreated in rehabilitation. Brain injuries have potential to damage all of the structures involved in visual-vestibular function, thus it is possible to have peripheral, central, or mixed vestibular pathology following a head injury.^{85,150} Damage to the inner ear from the force of impact or blast may rupture the bony or membranous labyrinth or produce a hemorrhage that can result in BPPV, traumatic hydrops, or perilymphatic fistula. Contusions, hemorrhage, and axonal damage, involving the vestibulocochlear nerve, brain stem, cerebellum, or cerebral hemispheres, may produce central vestibular pathology. These may be compounded by the frequent presence of neck injuries and cervicogenic dizziness, as well as high rates of psychiatric conditions after TBI, including anxiety, which is also associated with dizziness.^{85,150} While there is limited research on this issue and nearly all published literature to date focuses on persons who have sustained mild TBI or concussion, the VOR may be impaired in brain injuries of any severity, yet VOR testing is not routinely performed during assessments.⁸⁷ Thus visual-vestibular examination should be included in the physical therapy evaluation of all persons post-TBI, as stated in the Examination section earlier in the chapter. This will allow for an accurate differential diagnosis that can guide appropriate clinical management. Readers can refer to the chapter on Vestibular Disorders for details of examination and treatment procedures.

An interprofessional approach to management of vestibular symptoms, and balance and dizziness problems, is required for people

post-TBI due to the complex nature of the clinical presentation, multitude of systems commonly involved, and the wide-ranging effects of most moderate to severe brain injuries. A neuro-ophthalmologist can assist in diagnosing a nervous system pathology that affects vision and eye movement. Occupational therapists are specially trained to treat visual and perceptual deficits, as well as improve function. Neuropsychologists and psychiatrists are experts in diagnosing and treating the psychological disorders common after TBI, which may exacerbate visual-vestibular dysfunction and dizziness.

Interventions to improve endurance and benefits of aerobic exercise. The physical, cognitive, and psychological sequelae of TBI often lead to reduced physical activity and a sedentary lifestyle, which results in reduced cardiorespiratory fitness and endurance. It also increases risk of developing secondary health conditions, including hypertension, coronary artery disease, osteoporosis, type II diabetes, and obesity.^{90,151} Physical activity following TBI has been shown to improve neuroplasticity and promote recovery, as well as lower risk of secondary health complications associated with inactivity. Furthermore, it has been shown to have a positive impact on sleep, mood, and cognition, which are also frequently impaired after TBI.^{90,152–155}

The physiological mechanisms related to brain injury, exercise, and recovery have been well documented in animal model studies, and more recently in research involving human subjects and advanced neuroimaging modalities and lab tests.¹⁵¹ In brain injured animals and humans, activity-based rehabilitation induces neurogenesis and angiogenesis. Exercise also increases the production of molecules such as brain-derived neurotrophic factor (BDNF), a protein vital to neuroplasticity and essential to cognition, as well as insulin-like growth factor-1 (IGF-1), a growth factor that mediates exercise-induced neurogenesis and angiogenesis and upregulates BDNF during exercise.^{156,157} Studies have also shown that regular exercise and activity increases levels of these molecules in healthy older adults who were previously sedentary, and that neuroplastic changes also occurred in subjects in the parahippocampal region and medial temporal gyrus, which are areas of the brain involved in learning and memory.¹⁵⁸ These effects have not been demonstrated yet in people who are recovering from a head injury; however, the neuroprotective effects of regular exercise prior to TBI have been and will be discussed further in the prognosis and outcomes section of this chapter.^{159,160}

Experimental data supports the use of aerobic exercise in the clinical management of people who have sustained a head injury as it has been shown to promote neuroplasticity, speed recovery of physical functioning, and improve cognition, mood, and sleep. Dosing factors and timing must be carefully considered. Exercise that is introduced in acute stages, when there is inflammation, excess glutamate, and glucose metabolic depression in the brain, has been associated with decreased performance on learning tasks and cognition, and does not lead to an increase in BDNF levels in animal model studies.¹⁵² As metabolic depression may last anywhere from days to weeks, therapists are cautioned to avoid implementing aerobic training when brain tissue is metabolically compromised, in order to prevent further loss of function and reduced neuroplastic potential.^{152,161} Studies regarding the intensity of exercise required for optimizing recovery after TBI are lacking in the literature. Thus further research is required in human subjects to determine optimal time for commencing exercise programs, as well as appropriate intensity of exercise, post-TBI.

Modes of exercise should be chosen based on the patient's personal preferences and safety considerations. If the activity is safe and enjoyable, the person is more likely to engage in it on a regular, long-term basis. Typical activities for aerobic conditioning such as stationary bicycle, recumbent bicycle, walking on a treadmill or overground at a faster speed, jogging, upper body ergometry, and swimming may be

appropriate, and other interventions such as VR and serious games can also be used if parameters are intense and the person participates for longer periods of time. Therapists working with people in chronic stages of TBI across practice settings are encouraged to educate patients on the multiple health benefits of aerobic exercise programs and encourage regular participation in exercise for optimal health status.

Interventions to improve dual-task performance. As mentioned earlier in the chapter, impairments in attention, executive function, and working memory are common following TBI and contribute to reduced ability to engage in tasks regarding divided attention, or the ability to complete two tasks simultaneously.^{106,162} Deficits in dual task, such as reduced gait speed and postural stability, have been correlated with restricted participation in life roles such as school and work, and affect social interactions.^{105,163–165} Attentional deficits are one of the most commonly reported problems following moderate to severe TBI. Assessing and treating single-task gait will not necessarily translate into real-world environments requiring divided attention such as walking down busy city streets and safely navigating crosswalks, or remembering items to purchase while shopping in busy grocery stores.¹⁶⁶ Further, it has been shown that people who have had a TBI exhibit difficulty with dual task while walking even if they have normal gait speed.^{105,165} Therefore it is essential to assess and treat dual-task performance for persons with TBI to promote participation in life roles and social functioning.

An international team of clinicians and researchers with expertise in TBI and cognition, known as INCOG (International Cognitive working group), recently published their recommendations for rehabilitation of attention.¹⁶⁷ They reported a lack of research in the area of interventions aimed at improving attention following TBI, yet concluded that there is moderate support for including dual-task training in rehabilitation when each task is trained singly then simultaneously, and that gains should only be expected on the specific tasks trained or very similar ones. Specificity of training principles need to be applied to dual-task interventions, and one cannot assume that skills will be generalized to environments or types of dual tasks that are not included in interventions. Therapists should therefore determine which dual-task skills are required of the individual patient based on their life roles and environmental conditions, and train them in these specific domains for optimal outcomes.

Emerging technology for the rehabilitation of moderate to severe traumatic brain injury. There are many emerging technologies currently being used and further investigated for neurorehabilitation, including robotics, VR, and noninvasive brain stimulation (NBS) techniques, including transcranial direct current stimulation (tDCS) and TMS (Fig. 22.7). Within this chapter, recent findings on NBS for persons with TBI will be explored.

Studies involving NBS for persons with a history of TBI are limited, yet promising. There is a strong theoretical basis for their use following TBI to modulate cortical activity and limit inflammation in acute stages, then enhance reorganization of neural networks for recovery.¹⁶⁸ Animal model studies have demonstrated that TMS is capable of reducing secondary damage in TBI by modulating glutamatergic and GABAergic processes, and reversing biomarkers associated with oxidative stress and apoptosis.^{168,169} Additionally, tDCS and TMS have been shown to promote neuroplasticity and improve motor function in people with chronic stroke.^{170–174} When combined with physical therapy interventions to promote motor relearning, effects of NBS could be further enhanced. Indeed, studies on the combined effects of NBS for priming and/or consolidating are yielding positive results.^{175,176} While further studies with people post-TBI need to be conducted, the positive effects on motor recovery in those with brain injury from stroke are overwhelmingly favorable. One factor that may limit utility in people post-TBI compared to those post-stroke is the higher

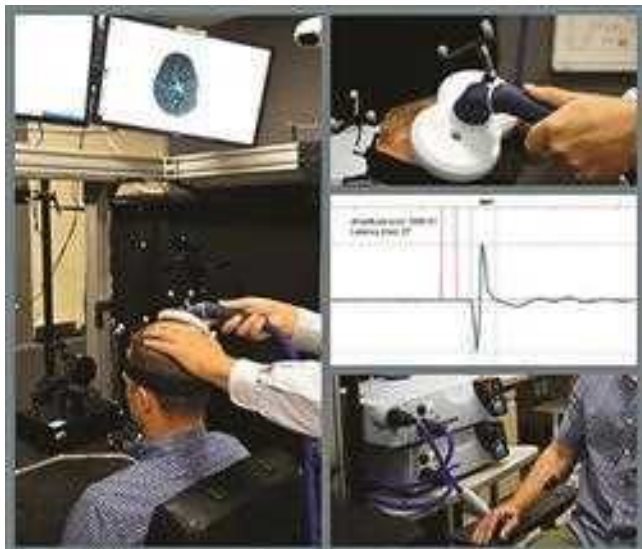

Fig. 22.7 Transcranial Magnetic Stimulation.

risk of seizure with brain stimulation after TBI; however, protocols and parameters that could make it safer to use in this population are being investigated.¹⁷⁷ Several low-level studies also support the use of NBS to improve cognition, attention, and depression following TBI.^{178,179} Lastly, there is also low-level evidence to support use of NBS to increase the level of arousal among some people with DOC, especially those in MCS.^{180,181}

SECTION IV—PROGNOSIS AND OUTCOMES AFTER TRAUMATIC BRAIN INJURY

Prognostic Models and Indicators

Predicting outcomes of TBI is challenging due to the complex clinical features of the condition. TBI is a heterogeneous condition, and each individual's presentation and clinical course is different.¹⁸² Other confounding factors include the number of variables that are included in the prediction as it varies according to the model used, the possible effects of intervention strategies and bias in treatment on the basis of predictions, validity of prediction models (which include the percentage of error in prediction and generalizability), and the definition of positive outcomes. Understanding these problems is imperative because the therapist can provide persuasive suggestions regarding the type and intensity of rehabilitative care after injury.

Two models for predicting outcomes of TBI have been developed based on the largest population data, and they have been widely used in recent decades—the Corticosteroid Randomization After Significant Head Injury (CRASH)¹⁸³ and the International Mission for Prognosis and Analysis of Clinical Trials (IMPACT) in TBI.¹⁸⁴ The CRASH trial was based on 10,008 persons with TBI and was validated externally on 8509 persons. Two models were developed from the CRASH trial, where the basic model included demographic and clinical variables only, while the CT model included CT results in addition to the basic model. The predictors are age, GCS, pupil reactivity, and the presence of extracranial injury. CT scan predictors include obliteration of the third ventricle or basal cisterns, midline shift, nonevacuated hematoma, petechial hemorrhages, and subarachnoid bleeding. The models predict death at 14 days, and death and disability at 6 months after the injury. Overall, the models possess excellent discrimination

and are simple enough to be used in different geographical regions for outcome predictions.

The IMPACT trial¹⁸⁴ is similar to the CRASH trial in that it uses admission variables to predict outcomes at 6 months after injury. The strongest predictors that this model identified are age, motor score, pupillary reactivity, and CT scan results. Again, the model discriminates persons with good and poor outcomes especially when CT scan results are included. Although both models are widely used and are relatively simple to administer, criticisms on these models include lack of consideration of secondary insults and persons' responses to treatment.¹⁸⁵

In fact, there are more predictor models than the above two mentioned. Lingsma and colleagues¹⁸⁶ did an extensive review and identified 27 prognostic models for TBI in the literature. After reviewing the models, they listed several factors that are strong prognostic predictors for TBI. These factors include age, clinical severity, secondary insults, abnormalities on CT scan, and laboratory variables. The factors will be briefly described below with other evidence.

Age

Among all patient characteristics such as genotype, demographic factors, socioeconomic status, and education and medical history, age is a strong predictor of outcomes for TBI, with older age associated with poorer outcomes.^{183–187} It was also found that increasing age is correlated with increased mortality.¹⁸⁵ The threshold depends on the individual studied population and may vary between 30 and 60 years of age.

Clinical Severity

It is well known that lower GCS, which indicates more severe injury, is associated with poorer outcomes.^{183–187} In addition, clinical severity of TBI may need to be evaluated together with injury types. It was found that if TBI is milder, the coexistence of an extracranial injury may lead to higher morbidity and early mortality. Lingsma and colleagues¹⁸⁶ suggested that for persons with less severe injuries, health care professionals should pay more attention to the eye and verbal components of GCS as they may provide more relevant information than the motor component. Whereas for persons with more severe TBI, the motor component may be more indicative. Nonetheless, GCS should be conducted at regular intervals for better prediction of outcomes. It was found that a 1-point drop in GCS led to an increase of mortality rate by 19%.¹⁸⁵

For persons under sedation or who are paralyzed, using pupillary reflex should be a better prognostic indicator compared to GCS.^{183,184,186} Junior and colleagues¹⁸⁵ found that anisocoria (asymmetrical pupils) is associated with 38% of mortality in their studied population. Therapists should pay attention to this point as a number of persons in the acute phase are under these conditions.

Abnormalities on Computed Tomography Scan

For characteristics on CT scan, the strongest predictors of poor outcomes are the presence of subarachnoid hemorrhage and the obliteration of the basal cisterns.^{183,184} Lingsma and colleagues¹⁸⁶ added that consideration of location of subarachnoid hemorrhage is also an important factor and should be included in any prediction model. Lesions in the brain stem do appear to cause poorer outcomes on the GOS than other lesions.¹⁸⁸ Junior and colleagues¹⁸⁵ reported similar findings that any category of Marshall classification of head injury based on CT scan, except for level I (no visible pathology), is associated with increased mortality rate.

Secondary Insults

Secondary insults such as hypoxia or hypotension (e.g., below 90 mm Hg) after TBI are shown to have adverse effects on clinical

outcomes.^{186,189} Literature in this area is sparse compared to other predictors and warrant more research.

Biomarkers

In the past few decades as more people survive moderate to severe TBI, a plethora of research has focused on biomarkers and genetic variations that may influence recovery.^{190–193} There is a great deal of variability in the rate and extent of recovery, even among survivors of the same age who have experienced similar injury types and severity. A better understanding of the influence that biomarkers and genetic variation have on recovery has the potential to foster development of novel, targeted interventions for TBI. The research to date, however, has not been conclusive, and several limitations exist, including the complex pathophysiology of TBI and focus on a single marker of cell damage or gene that fails to account for the interrelationship of many factors in the nervous system.¹⁹⁴ Nonetheless, it is apparent that biochemical markers of brain damage and genetic factors influence neuroplasticity and outcomes after TBI. Some of the most frequently studied factors will be discussed further here.

Several different biomarkers have been studied in relation to TBI pathology and recovery, as well as in many other neurological conditions, including stroke, Alzheimer disease, and Parkinson disease. BDNF is one of the most commonly studied biomarkers. BDNF is widely distributed throughout the brain and is vital to the growth and differentiation of neurons, maintaining neuronal health, activity-dependent neuroplasticity, and memory formation.^{190,195,196} Following brain injury, BDNF is believed to have a role in reducing secondary cellular damage through its neuroprotective effects and aid in the process of recovery through structural neuroplastic changes.^{160,197} Animal and human studies have demonstrated changes in BDNF levels and gene expression in the acute phase of TBI, and the changes may be proportional to the severity of injury.^{190,193} The serum BDNF levels measured on day of injury have also been shown to have predictive value for severity of injury and 6-month outcomes, as well as mortality when examined along with age.^{193,198} Further, serum BDNF levels measured on the day of injury have been able to accurately discriminate TBI from nontrauma controls even in the absence of findings on CT scan, making it a good prospect for diagnosing mild TBI and guiding appropriate clinical management for concussion.¹⁹³ Future research on biomarkers will likely contribute to the knowledge of the highly complex pathophysiology of TBI and improve ability to accurately diagnose and treat TBI.

Genetic Factors

Similarly, the study of genetic polymorphisms and gene expression hold promise for improving treatment and promoting recovery after brain injury. While research to date is inconclusive, it is widely accepted that polymorphisms lead to variability in outcomes among TBI survivors.¹⁹⁴ That is, genetic factors influence the brain's susceptibility to injury and influence repair and regeneration.¹⁹⁹ There are many inconsistencies in research findings on this topic however, as gene expression is incredibly complex and interdependent on a confluence of personal, demographic, and environmental factors.¹⁹¹ Much of the research on genetic polymorphisms have focused on BDNF and apolipoprotein E (APOE). Many studies have shown that the Val66Met polymorphism of BDNF and APOE-4 allele are associated with poorer outcomes following TBI and stroke.^{200–203} However, a recent systematic review found incongruous results about the influence of APOE-4 allele on recovery after TBI, with stronger evidence of its negative consequence on recovery among people with severe TBI compared to moderate and mild brain injuries.¹⁹² Large scale, multicenter genomic studies are currently being conducted and will hopefully shed more

light on this promising new approach to TBI management and allow for better functional, psychological, social, and cognitive outcomes following TBI.

Laboratory Values

For laboratory values, in general, high glucose concentration indicates poorer prognosis, but this laboratory value needs to be considered with other predictors. Subsequent persistent high glucose concentration and coagulopathy may cause poorer outcomes and higher mortality.¹⁸⁶

Duration of Coma and Posttraumatic Amnesia

Duration of coma and PTA are well-known factors predicting outcomes after TBI. Shorter duration of coma¹⁸⁹ and PTA are strong predictors of better outcomes as measured by FIM^{182,204}; and when PTA is combined with age, sitting balance, and limb strength at admission, prediction of outcome is high.²⁰⁵ When comparing individual factors (e.g., age, employment status) and injury-related factors (e.g., duration of coma), PTA is the only injury-related factor that is equally predictive as individual factors.²⁰⁶ It was found that when PTA lasted less than 4 weeks, a severe activity limitation was unlikely; however, if longer than 8 weeks, a good recovery was unlikely when measured by GOS.²⁰⁷ As such, duration of PTA can be used as a functional prognostic indicator for therapists when setting goals and intervention strategies in rehabilitation.

Outcomes After Traumatic Brain Injury

Long-term impairments, activity limitations, and participation restrictions after TBI commonly exist due to the wide array of health issues this condition brings, be it physical or cognitive-behavioral. According to the Traumatic Brain Injury Model Systems National Data and Statistical Center, around 30% of persons with moderate to severe TBI worsen in their conditions within 5 years post-injury, around 26% of them stayed home, and around 22% of them died.²⁰⁸ These persons are likely to die from seizures, accidental drug poisoning, infections, and pneumonia.²⁰⁸ Overall, around 57% of persons who are still living have moderate to severe disability.

From an impairment level, emotional and cognitive impairments, for example memory problems, attention deficits, irritability, slowness, anxiety, and depression, were most common in people with severe TBI.¹⁸² Depending on the cohort study, these emotional and cognitive problems may present in around 30% to 90% of persons with severe TBI even after 3 to 4 years of injury.^{209,210} Motor impairment is less commonly reported but may be present in around 25% of persons.²¹⁰ Other somatic complaints were also reported, such as fatigue, headaches, and pain.²¹⁰ Communication and language impairments exist in around 15% to 25% of persons with mild to moderate TBI, and these impairments were found to correlate with quality of life and participation in work and leisure activities.²¹¹

With regards to activity limitations, balance, locomotion, and ADL limitations were reported in the literature. Balance complaints were reported in over 40% of persons with severe TBI 4 years post.²¹⁰ About 70% of persons with severe TBI still needed walking aids after a mean of 8 months of rehabilitation.²¹² About 33% of persons needed help for daily activities²⁰⁸ and 40% needed help for mobility-related ADLs.²¹⁰

Most studies on long-term outcomes in TBI investigated areas in the participation level, such as quality of life, return to work, and/or community integration. Despite persistent cognitive and motor impairments post-TBI, persons were able to show improvements in time productivity and community integration with standard TBI programs or cognitive rehabilitation programs.¹⁰⁸ Return to work has been shown in around 20% to 36% of persons with TBI.^{210,213,214} National Data and Statistical Center Traumatic Brain Injury Model Systems

reported that 55% of persons are unemployed at 5 years post-injury.²⁰⁸ Factors related to unemployment included low initial GCS score, low GOS score at discharge, low GOS-extended score at 1 year, long length of stay in ICU, longer time for following instructions, low Dysexecutive Questionnaire Revised score, transportation issues, residual cognitive impairments, and depression.^{213,214}

Quality of life in all domains (social, physical, and emotional) post-TBI has been shown to be affected despite the severity of conditions, though persons with severe TBI improved the least, especially in mental

health aspect.²¹⁵ The predictors for lower quality of life after TBI included being female, older age, having comorbidities, and a more severe injury.²¹⁵ National Data and Statistical Center Traumatic Brain Injury Model Systems reported that 29% of persons are unsatisfied with life at 5 years post-injury.²⁰⁸ With greater understanding of optimal medical management, effects of various rehabilitation protocols, and the long-term consequences of TBI, it is likely that medical guidelines, policies, and innovative rehabilitation programs will be developed that improve outcomes and meet the needs of this population.

CASE STUDY 22.1 Mrs. E.K.

Examination

History

Mrs. E.K. is a 60-year-old woman who sustained a brain injury in a fall 1 year ago. Injury was to the cerebellum and brain stem, resulting in left-sided involvement and incoordination. Currently she reports falling approximately two times per month. She complains of feeling tired constantly and not having enough energy to even accomplish her housework. She lives with her husband and 29-year-old son in a two-story house 1.5 h from a large western city. Her son is an alcoholic and is unemployed. Patient OR Mrs. EK's goals include being able to sew again and to return to square dance at her club.

Task Analysis of Activity Limitations

Gait (With Use of the Observation Gait Analysis Based on the Rancho System)

Mrs. E.K. has significantly decreased trunk rotation during right leg swing and a right pelvic drop in left leg stance. Left hip flexion during swing phase is reduced, and the leg circumducts. The left knee has limited flexion, and the foot has excessive plantarflexion. In stance phase on the left, she lacks hip extension during midstance and late stance, and initial contact is made with the foot flat. The left arm is held tightly against her chest with the elbow in flexion and the forearm in full supination. When she is asked to put her left arm to her side during ambulation, the arm swings uncontrolled in large arcs, actually hitting her in the chest. Gait speed is 0.8 m/s as measured by the 10 m walk test. Cadence is 73 steps per minute with a 0.8-m stride length.

Testing of Underlying Impairments for Gait Limitation

- Strength (manual muscle testing): 2+/5 left hip flexor and ankle dorsiflexors.
- Range of motion testing: Left rectus femoris reduced length with 100 degrees knee flexion test in prone. The gastrocnemius-soleus is shortened permitting dorsiflexion to neutral only.
- Tone: Modified Ashworth Scale (MAS) of 3 for left quadriceps and gastrocnemius-soleus.
- Balance testing: no ankle strategy on left, only combined hip-ankle strategy to all perturbations. There is a proximal-to-distal balance response during small perturbations.
- Proprioception is impaired when Mrs. E.K. is asked to note small changes in flexion and extension of the great toe and ankle; within normal limits for knee and hip.
- Motor patterns are poor in trunk. There is no trunk rotation during walking, and anticipatory responses are poor as measured by rapid forward reaching resulting in forward balance loss in standing.
- Vestibular function: underuse of vestibular system during sensory integration of balance as tested by the Clinical Test of Sensory Interaction on Balance (CTSIB). She also has a positive Head Thrust test indicating impaired vestibuloocular reflex (VOR) function, and a positive VOR cancellation test and positive convergence, indicative of a central vestibular disorder.

Outcome Measures for Activity Limitations (Gait, Balance and Upper Extremity Function)

- For measuring gait speed, the 10 m walk test was chosen, and it was 0.8 m/s on evaluation. Because Mrs. E.K. has two falls per month and her traumatic brain injury involved the cerebellum, it is imperative to test her balance stressing the vestibulocerebellar system and when out in the community. The Community Balance and Mobility Scale appears to be appropriate for her level as she is ambulatory and living in the community. She scored 45 out of 96 on the scale, indicating she may be at risk for community integration.
- For her upper extremity (UE) function, the Action Research Arm Test was chosen as it includes fine hand motor tasks mimicking sewing. She scored 43 out of 57.
- Since Mrs. E.K. also reports a lack of energy, the Global Fatigue Index and 6-min walk test could be included.

Upper Extremity Activity Limitation

Sewing (Large 4-Inch Needle With Yarn Through 1-Inch Square Holes in Plastic Grid)

Mrs. E.K. hits the hole with the needle in one of three attempts. The left hand does not work in a distal-to-proximal manner. The scapula and shoulder initiate the reach rather than the hand, and moderate dysmetria is present, resulting in overshooting or undershooting of the target. The hand remains excessively supinated throughout the task. Fine motion of the fingers is within normal limits.

Hypothesis of Underlying Impairment for Sewing Limitation

Unable to perform sewing task because of poor timing and coordination of the scapula and shoulder muscles producing a sequentially uncoordinated movement pattern.

Testing of Underlying Impairments for Sewing Limitation

- Timing of movements: surface EMG—Poor sequencing and timing of movement of the scapular muscles with hand and wrist motion. Tremor of high frequency in the scapular stabilizers, especially in the external rotators at rest and with movement. There are lower-frequency tremors of larger amplitude in the wrist flexors and extensors during voluntary motion. Co-contraction of the biceps occurs with all shoulder and hand motions.
- Coordination: Finger-nose-finger test takes 10 s for 10 repetitions for right upper extremity, 20 s for left upper extremity. Amplitudes of movement are far too large for tasks but are repeated with each trial without modification.

Hypothesized Underlying Impairment for Gait Limitation

Gait is impaired in kinematics and speed as a result of poor force production in the left hip flexor and ankle dorsiflexors complicated by quadriceps and gastrocnemius spasticity. Slowed gait is also present because of poor trunk rotation during arm-fixed gait and instability when the arm is not fixed to her chest. Reduced muscle length of quadriceps and gastrocnemius-soleus may also contribute to the poor

CASE STUDY 22.1 Mrs. E.K.—cont'd

movement patterns, and there may be a disruption of the normal temporal sequencing of muscle firing in stance on the left. Ataxic gait qualities such as variable left foot placement are consistent with damage to the cerebellum and may be exacerbated by proprioceptive impairments. Mrs. E.K. may have anticipatory postural adjustment issues because gait is not compensated during the arm movements.

Outcome Measures for Participation Restriction

- In terms of participation restriction, Mrs. E.K.'s goals were to resume her social events (sewing and dance club). The Community Integration Questionnaire was administered, and she scored 20 out of 29.
- Quality of Life after Brain Injury could be added as a supplementary measure.

Evaluation and Diagnosis

UE is not being used functionally secondary to impaired coordination with poor sequencing and timing of muscle firing. Mrs. E.K. also exhibits impaired motor control of the left UE. The arm is held in co-contraction during walking and other activities to decrease the instability in balance caused by large movements of the entire arm. Impaired gait, slow gait velocity, and reduced balance are the result of impaired proprioception L foot and ankle, decreased strength in left hip flexors and ankle dorsiflexors, spasticity, and reduced muscle length of left quadriceps and gastrocnemius. Underuse of the vestibular system also contributed to poor balance during community mobility. Due to the above impairments and activity limitations, participation in community events is limited, and quality of life is reduced.

Interventions

Mrs. E.K. was referred to a psychologist, as it was suspected that fatigue was related to depression and she had a flat affect. She was diagnosed with depression. Mrs. E.K.'s physician then prescribed an antidepressant medication, which was not highly effective. She was later referred for repetitive transcranial magnetic stimulation (TMS) treatment sessions over several weeks, which improved her subjective complaints of fatigue and depression. Aerobic exercise was prescribed to improve endurance as well as symptoms of depression and fatigue.

Because Mrs. E.K. lived 70 miles from the treatment clinic, much of her treatment consisted of a home program. She was seen in the clinic once every 3 weeks, for 3 months, and then once a month for a year.

The initial home program focused on the basic impairments of improving quadriceps and gastrocnemius-soleus muscle length and reducing spasticity with a regular stretching program for these muscle groups. Strengthening exercises for her hip flexors and ankle dorsiflexors were prescribed and progressed accordingly. Exercises included sitting arm hip flexion and ankle dorsiflexion, standing marching, side stepping and walking on her heels while holding kitchen counter for support, sitting-to-standing repetitions with the knees bent past 100 degrees, keeping the heels on the floor.

Mrs. E.K. walked on a treadmill starting at 1.8 miles/h for 20 min, 3 days/week. Over a few months' time, she progressed to a walking speed of 3.2 miles/h for 30 min, 4–5 days/week, and she was starting to take walks with her husband outdoors. Lower-extremity (LE) interventions included improving coordination, balance, and vestibular function. Standing exercises with dim lights progressed to eyes closed while on variable surfaces such as a mat then foam were conducted in the clinic. Part-task activities for gait, including swing of left LE to target encouraging heel strike, were progressed to whole task walking over solid ground with occasional verbal cues for heel strike on the left side. Ankle strategies were promoted through rapid walking while the patient's husband told her to stop abruptly and the patient tried not to take a step after being

told to stop. She also stood 6 inches from the wall and kept the upper body rigid while she swayed back and forth around the ankle joints. This was progressed to doing the same activity with eyes closed. External perturbations were also applied by the therapist to her lower then upper trunk with increasing amplitudes to tolerance in the anterior-posterior directions to promote ankle strategies.

sEMG was used in standing to increase the force of contraction of the anterior tibialis. As the amplitude of arm motion decreased with use, Mrs. E.K. was able to walk with her hands clasped behind her back and worked on trunk rotation coordinated with gait. When this was accomplished, she was able to allow her arm to hang freely at her side and had improved natural trunk rotation in gait. Mrs. E.K. practiced line dancing with her husband, using an introduction videotape on line dancing. This activity provided higher-level balance challenges and provided enjoyment.

Virtual reality was used in the outpatient sessions to improve UE use for functional activities such as drinking from a cup, accurately placing kitchen items in drawers and on shelves. Biofeedback was also used to decrease the co-contraction of the biceps during functional activities of the arm. Blocked then eventually random practice of UE activities was utilized. To reestablish some control of amplitude of movement in the left arm, gross motor activities of the hand were done with the elbow stabilized on the support surface and a wrist splint to limit the degrees of freedom; for example, drawing large circles with a pen and pulling long pieces of yarn through some large holes. She also used her left forearm to stabilize paper while writing, finally progressing to using the hand only for stabilization. Fine motor tasks of the hand were also performed, including sewing with yarn on a mat with large, 1-inch squares, molding clay, and playing the organ. These activities were first performed with the elbow stabilized and a wrist splint, then with the elbow not stabilized, and finally without the wrist splint.

Vestibular rehabilitation exercises were used in the clinic, instruction provided for home exercise program (HEP), and were progressed accordingly on subsequent visits. These included VOR \times 1 in sitting at slow speeds, for 1 min periods and plain background. VOR \times 1 exercises were progressed to standing, faster speeds for up to 3 min and full (checkerboard) background for the visual target over a 2-month period. She was encouraged to repeat these exercises 3 times a day and reported compliance. She was also prescribed vergence exercises, or "pencil push-ups," and gaze substitution exercises, which were added to her HEP after 1 month. In the clinic she was challenged with higher level activities to improve vestibular function with dynamic activities. She participated in obstacle courses requiring walking on variable surfaces, direction changes, head turns to targets, and eventually dual task of counting forward and backward by 3's while in the obstacle course.

Outcomes

At discharge, Mrs. E.K. had improved patterns of motion in the left LE. An articulated ankle-foot orthosis was used for long walks or when she was fatigued. She walked with 90 steps per minute with a 1.2-m stride length. Spasticity of her gastrocnemius was 2 on the MAS. Hip flexion improved to 20 degrees in midswing, but dorsiflexion was still limited to 5 degrees. She performed within normal limits on the CTSIB. Her gait speed had improved to 1.1m/s, and her Community Balance and Mobility score improved by 20%.

UE testing showed 100% accuracy in putting the needle through the 1-inch squares. She was able to sew and use the left arm for most activities, although a mild intention tremor persisted. She scored close to normal in the Action Research Arm Test. She reported attending the square dance once every 3 months. Medication, aerobic exercise, and TMS treatment had controlled her depression, and her fatigue was resolved.

Continued

CASE STUDY 22.2 C.H.

Examination**History**

C.H., a 21-year-old woman, was in an automobile accident and sustained a severe brain injury and fractures of the left scapula, left radius, right ankle (fused), and jaw. She developed heterotopic ossification (HO) in the right elbow. C.H. was in a coma and vegetative state for 1 month and minimally conscious state for another 2 months. Her Glasgow Coma Scale score was 8 at 2 h after the accident. She had 8 days of posttraumatic amnesia. Her Rancho Los Amigos Level of Cognitive Function (LOCF) score was a V (confused, inappropriate) at 2.5 months. She is now at 5 months postinjury, and her LOCF is a VII (automatic, appropriate).

Expressive language is minimal with severe expressive aphasia and dysarthria. C.H. is able to follow two-step commands consistently and is able to nod her head “yes” or “no” appropriately. Her behavior is impaired, and she continuously tries to hug and kiss her boyfriend when he is present. She is easily frustrated by challenging tasks, and becomes extremely agitated and self-injurious, scratching herself to the point of bleeding.

Her memory and overall cognition are impaired, as noted by her score of 19/30 on the Montreal Cognitive Assessment (MoCA).

Mobility is by manual wheelchair. C.H. is independent in transfers. She can roll and come to sitting independently, but she needs moderate assistance to come to standing, minimal assistance for standing with feet shoulder width apart, and maximal assistance to ambulate. She is unable to perform self-care such as personal grooming, hygiene, and dressing or to do household chores. She has impaired posture with severe forward flexed head; however, she is able to extend her neck when asked to do so.

C.H. is a junior in college majoring in elementary school teaching. She worked part time in a clothing store prior to the accident, where she had to wait on customers, put out stock, and ring up purchases. She lives at home with her mother in a single-story house. Dancing and cooking were her hobbies.

C.H.’s goals include use of the left arm to put on makeup and dance with her boyfriend. Her mother, who is a psychologist, would like her daughter to hold her head upright, be able to walk again, and have better balance.

Review of Systems

- **Musculoskeletal system:** C.H. had HO in the right elbow; it was surgically removed 1 month ago with range of motion (ROM) 25–110 degrees. Scapular and clavicle fractures are healed. Left gastrocnemius is shortened, and she is only able to reach neutral dorsiflexion. Left shoulder has active flexion to 20 degrees but can hold at 90 degrees. Left elbow ROM is 20–135 degrees. Strength testing shows weakness in the left shoulder rotator cuff, lower trapezius, and deltoid with rapid fatigue by third repetition of movements.
- **Cardiopulmonary system:** She demonstrated poor endurance. Resting heart rate was 85 beats per minute (bpm) and 130 bpm after 5 min of standing balance and UE exercise. There was a 10-mm Hg increase in blood pressure of 115/65 to 125/72 after 5 min of examination. Vital capacity is documented as low normal (3 L).
- **Integumentary system:** Unremarkable. No pressure sores since her injury. Incision healed over right elbow.
- **Cognitive and behavioral system:** C.H. became easily frustrated, and on each occasion she scratched her left forearm with her right hand for approximately 30 s. C.H. was referred to a neuropsychologist for assistance with reducing frustration and self-injurious behaviors.

Task Analysis of Activity Limitations**Limited Reach and Grasp with Left Hand**

C.H. is right handed. As her goal was to be able to put on her own makeup again, performance of this task was analyzed on evaluation. C.H. was asked to pick up an eyeliner pencil, switch it to her right hand, and apply the eyeliner to her

eyelids. Her neck was flexed with her chin resting on her chest. There was no anticipatory hand shaping before initiating the reach on the left. Reach component was with forward trunk lean, 20 degrees of left shoulder flexion, and elbow remaining at 90 degrees. She picked up the pencil with inferior lateral pinch and excessive grip force. She was able to switch the pencil to the right hand but had difficulty applying it to her eyelids.

Motor patterns appeared intact except in the cervical area, where her head was not held upright to maintain level eyes, and the left arm, in which there was a proximal-to-distal pattern of movement. C. H. was unable to modify the motor patterns in the left elbow, and intralimb joint coordination was poor.

Anticipatory responses were absent in reach and grasp; there was no hand shaping before the reach was initiated, and fingers were held wide open even as she approached the pencil. C.H. was able to reach and grasp and bend in many different ways with the right arm and was limited only by elbow ROM. The left arm was maintained in an adducted, internal rotation pattern with the elbow flexed at 90 degrees on the left. She also appeared limited in the degrees of freedom available at the forearm and hand.

Hypothesized Underlying Impairments for Upper Extremity Dysfunction

Disuse weakness and limited ROM in the left deltoid and rotator cuff group was present, likely due to immobilization after scapular fracture and prolonged bed rest. There was increased tone at the elbow and wrist on the left, likely to be contributing to impaired reaching. Problems with force production and gradation of force were the result of poor somatosensory function in the left hand. Loss of ROM in the right elbow from postoperative swelling after HO removal restricted movements of this limb. C.H. was unable to maintain her head in upright likely due to visual and proprioceptive deficits, and possibly altered perception of verticality. She may have had lack of head-righting reflexes, and overstretch weakness of the neck extensor muscles as well.

Impaired Standing Balance

C.H. stood in static standing, feet shoulder width apart with contact guard assist (CTG). There was hip flexion of 20 degrees with forward trunk lean, and she had asymmetrical weight bearing with greater weight on R LE. Upper trunk was rotated 20 degrees to the left, and she had a 15-degree upper-trunk left lean. Her chin was resting on her chest. She exhibited anterior-posterior sway in standing with no loss of balance after 30 s; sway increased moderately with eyes closed. Feet-together stance caused loss of balance in 15 s and in 10 s with eyes closed. When asked to reach rapidly forward, she fell forward and needed maximal assistance to recover her balance. She demonstrated a hip strategy with small perturbations to the trunk, and she continued to flex at the hips and knees with larger perturbations, again requiring assistance to recover her balance. When asked to take a step with the right foot in response to a perturbation, C.H. did not shift the weight to the left and required maximum assistance for balance recovery.

Hypothesized Underlying Impairment for Impaired Standing Balance

Forward lean may be caused by impaired vertical perception (seen with lack of head righting with and without vision) from visual, proprioceptive, and possibly vestibular dysfunction. There is overuse fatigue of hip extensors for maintaining continuous contraction whenever C.H. is upright. Trunk rotation may be secondary to increased tone in trunk, UE (scapular retraction), and LE. Balance losses were secondary to lack of anticipatory responses when reaching forward and for weight shift before right-foot stepping. The losses of balance with perturbation were secondary to a lack of stepping strategy and use of a mixed strategy for all standing conditions. Weakness of the gastrocnemius resulted in the premature use of the hip strategy.

CASE STUDY 22.2 C.H.—cont'd

Testing of Impairments of Body Structure and Function for Upper Extremity Dysfunction

- Strength: Manual muscle testing (MMT)—neck extensors: 3–/5. Left arm—not able to actively abduct shoulder but able to actively hold if placed at 90 degrees. Shoulder flexion and external rotation, elbow flexion and extension—3/5 (but range was limited). Wrist extension—2+/5 (half range) and flexion 3+/5.
- Grip strength: Poor on use of a dynamometer. C.H. could not regulate her force output; she either gripped with full grip or used minimal force when asked to change her grip from minimal, 1 pound per square inch (psi) to 5 psi to 8 psi to 12 psi.
- Passive ROM—Left shoulder limited to 100 degrees of flexion and abduction, 45 degrees of external rotation. Right elbow ROM—20–90 degrees in flexion and extension and 10 degrees in supination.
- Tone: Modified Ashworth Scale (MAS)—Left arm, 3 in biceps, triceps, and wrist flexors, 2 in the finger flexors, otherwise 0 or 1 throughout.
- Sensation: Proprioception and kinesthesia were impaired for left UE and hand. Stereognosis—identified 4 of 10 objects placed in the left hand.
- Visual-perceptual: C.H. complained of diplopia and identified a pen as vertical when in a left 10-degree tilt.

Testing of Underlying Impairments of Body Structure and Function for Limited Standing Balance

- Strength: MMT: 3/5 strength in left leg except 2+/5 in the left hip extensor and gastrocnemius.
- Tone: MAS 3 in the left quadriceps and gastrocnemius. The left lumbar extensors exhibited hypertonicity and forward bending elicited an extensor spasm.
- Muscle endurance: Poor in trunk and LE muscles; there was a reduction in amount of resistance tolerated after approximately five repetitions with isolated muscle testing of the quadriceps, hip extensors, back extensors, and cervical extensor muscles.
- Sensation: Proprioception was decreased (needs larger movement for accuracy) in the left ankle, knee, and hip.
- Visual testing: C.H. had a left hemianopsia. No nystagmus was present. (Vision and vestibular systems are also addressed under the activity limitation.) Left tilt off vertical 15 degrees in standing with eyes open and with eyes closed.
- Vestibular testing: C.H. complained of double vision and objects “jumping” with moderate and fast head motion with trying to maintain eye fixation on a pen tip. C. H. had increased sway during this test (in sitting). Unable to maintain balance for CTSIB testing.
- Verticality: Unable to hold head up consistently; no head righting reflexes to tilts. Did not right lower body to floor in standing. No change with eyes closed.
- Balance synergies to large and small perturbations: sEMG—appeared intact, in the right LE, but ankle strategy is absent in the left. Small perturbations to upper trunk are responded to with synergies showing a proximal-to-distal firing beginning in the trunk flexors and extensors. Amplitude of muscle contraction at the gastrocnemius was small even for large perturbations, less than 25% of her maximal contraction. Gastrocnemius reaction times were 400 ms to perturbation on sEMG.
- Anticipatory responses were generally absent in the left LE and trunk during stepping. C.H. fell to the right each time she tried to raise her right leg. There was no anticipatory shift of weight to the left. sEMG showed no left gastrocnemius firing before rapid forward reaching.
- Cognitive deficits: Attention span was about 2 min during therapy. Moss Attention Rating Scale score was 65/100, and she scored 19/30 on the MoCA.

Outcome Measures for Activity Limitations

- C.H. was in an inpatient rehabilitation setting, and she required assistance for her general mobility and activities of daily living (ADLs), thus the Functional Independence Measure is an appropriate outcome measure to use. Her score was 79/126 on admission.

- Since she requires maximum assistance with ambulation, it is not appropriate to include a gait outcome measure. Instead, the Berg Balance Scale is appropriate for her level, and it is also a recommended outcome measure for traumatic brain injury (TBI). She scored 25 out of 56, indicating high fall risk.
- For UE function, the Nine-Hole Peg Test was done, and she scored 1 min. She scored 1/5 in the Frenchay Arm Test.

Outcome Measures for Participation Restriction

The Quality of Life after Brain Injury is a recommended measure for persons post-TBI in the inpatient rehabilitation setting. However, since C.H. still exhibited abnormal behaviors such as anger, frustration, and self-destructive responses, it was not appropriate to conduct the test. As a result of her behaviors, she is restricted with participating in social activities with friends. Her impaired balance, as well as reach and grasp with the left hand, restricts her from performing her job in a clothing store. Cognitive impairments limit her ability to return to college at this time.

Evaluation and Diagnosis and Prognosis

Poor force control, timing and sequencing, lack of wrist and finger proprioception, co-contraction of the biceps and triceps, and poor anticipatory hand shaping during reach and grasp resulted in nonuse of the left UE. Contributing to the lack of use of the hand was poor strength in the scapular stabilizers due to a scapular fracture that was immobilized and prolonged bed rest from disorders of consciousness (DOC) for 3 months. Lack of adequate elbow ROM from HO and postoperative swelling in the right elbow prevented independent grooming, personal hygiene such as teeth brushing, and applying makeup when combined with deficits in the left hand.

C.H. was unable to stand or walk without moderate to maximum assistance because of a lack of appropriate balance responses to perturbations, lack of anticipatory responses to movements of her center of gravity, and impaired vertical orientation. Poor left gastrocnemius strength contributed to lack of an ankle strategy. Standing posture is with a forward lean owing to poor perception of vertical. The forward lean overstretched the back and hip extensors, and perhaps the gastrocnemius, which were weak from prolonged bed rest during the time when C.H. was in DOC.

C.H. has problems perceiving the vertical position in sitting and standing because of visual, vestibular, and proprioceptive impairments. Head righting is absent owing to loss of visual and proprioceptive head righting, as well as overstretch weakness of the cervical extensors. She has poor muscular endurance from prolonged bed rest. Her poor attention span and cognitive status likely contributed to all her activity limitations.

Prognosis

- *Long-term goals:* In 4 months C.H. will be independent in all self-care activities and ADLs using the left hand as an assist. C.H. will be able to participate in activities without exhibiting self-injurious behaviors 100% of the time. She will be able to stand with UE support with MI. C.H. will have fair + standing static and dynamic balance.
- *Short-term goals:* Improved force production and timing of left gastrocnemius using functional electrical stimulation (FES) daily for 15 min on a home exercise program and electromyography (EMG) biofeedback 3 × weekly for 2 weeks in rehab. Improved force gradation for grasp so C.H. can grasp and release a paper cup filled with water and not deform the cup or spill the water in 2 weeks.

The prognosis for meeting the above goals is good because C.H. is young, has a supportive family (sister and mother), and showed focal lesions on brain magnetic resonance imaging rather than diffuse injury. Return to college and work will be dependent upon cognitive recovery and progress with occupational therapy (OT), speech and language pathologist (SLP), and psychologists. Team will work with neuropsychologist to develop and implement a behavioral modification plan to improve emotional responses and limit self-injurious behaviors.

Interventions

Initial goals included addressing impairments that did not allow higher levels of functioning. These were improvements in neck and hip strength, gastrocnemius

CASE STUDY 22.2 C.H.—cont'd

strength and length, visual skills, particularly in tracking of objects into the left visual field, and perception of verticality.

Development of proper head control was a priority. FES was applied to the posterior cervical muscles (5:1 duty cycle and frequency at 35 pulses per second [pps]) for strengthening and upright head position. A sterno-occipital-mandibular immobilization support was worn intermittently to prevent further stretch weakness, then was weaned to a Philadelphia collar. Visual focus on a doorframe was used to encourage visual control of head and body position for improved alignment. Complex neck activities to encourage basic synergy use and modification included seated activities in which C.H. wore a “hat” with a flat top from which she tried to prevent an object from falling off (first flat stable objects and later more rounded objects). This exercise was performed first on a firm, flat surface and progressed to sitting on an exercise ball. The ball promoted automatic neck muscle motor patterns in which the body moves and the head is kept upright and still. To make the activity at the automatic level, C.H. did side-to-side leans while sitting on the ball, looking in a mirror to monitor head verticality, and then doing the activity without visual proprioception.

Upper extremities: Traditional basic left UE strengthening exercises included the use of Thera-Band. Functional activities that required scapular use such as emptying the dishwasher with the left hand were assigned homework. Bilateral hand use was encouraged early on. After C.H. could accomplish this, then only left-hand use was allowed; a 1-lb wrist weight was added, which was gradually increased to 3 lb.

PROM program for UE was implemented with nursing, family, OT, and PT daily, and she made slow gains with bilateral UE ROM. C.H. worked on picking up and manipulating objects of different sizes and shapes, throwing balls at targets, and doing two-handed carrying with a laundry basket, and quick release of the basket. She sorted different-sized objects by retrieving them from a bucket that also contained marble-sized balls with her vision occluded to force the development of stereognosis.

C.H. enjoyed cooking, so tasks were used in therapy that involved elbow extension, such as rolling out cookie dough. Exercises such as washing the dishes with hands in soapy water for proprioceptive feedback and practice of slip grip for enhancement of feedback through the fingertips were used. Setting the table with plastic dishes using the left hand helped improve functional use of the UE.

Bimanual UE tasks were added to her treatment plan. C.H. hooked a small rug. When able, she began two-handed typing. Two of her most motivating activities were applying makeup and inserting contact lenses.

Visual treatment used exercises that required visual fixation at different points in space and at different distances using letters and objects, while moving the head left and right with the goal of seeing only one image. These exercises advanced to include moving objects and head moving with a fixed object and progressed to both the object and head moving while a single image was maintained. Finally, full body movement with eyes fixed on a moving object was accomplished. Vergence exercises were worked on, first using a ball with an “X” marked on it on a string, swinging the ball toward and away from her. She did five swings at a time and wrote down how many times the X stayed single. The ball was swung side to side, and C.H. had to point at it with her finger for left visual field loss.

Standing balance exercises focused on developing anticipatory responses via throwing a gym ball and reaching activities. She also worked on kicking a ball to a goal with the right foot. Exercises to promote ankle strategy included gentle “tug-of-war” with a dowel, and Wii balance board games to improve gastrocnemius firing and timing.

After C.H. was able to stand and weight shift without support, small-angle, slow random tilts on a tilt board were used to promote both vertical upright and

vestibular responses for balance. To promote vertical trunk control and anticipatory responses, C.H. practiced taking a full step forward with each foot. C.H. had a penlight attached by velcro to a belt she wore on her waist. The goal was to keep the light, aimed at a wall target in front of her, from moving more than 2 inches side to side. This was also facilitated by moving the parallel bars extremely close together (about 1 inch from each hip) and asking C.H. not to touch the bars with either hip as she practiced stepping.

Tone was modified with rhythmic rotation and aggressive passive range of motion (prom) with prolonged stretch, as well as deep pressure on tendons of spastic muscles. Biofeedback to teach decreased co-contraction during activities such as reaching and lifting improve motor performance of her UE.

C.H. used a Nustep bike and upper body ergometer to improve cardiovascular fitness and activity tolerance. The goal C.H. had when first starting therapy was “to dance with my boyfriend.” To encourage functional use of postural and balance motor patterns, dancing was used. She started first with slow dancing with her boyfriend. Gradually she was able to dance to faster music without being held, by using trunk and arm motion and a sidestepping motion. Finally, forward-backward movements and turning and bending were added. In addition, C.H. agreed to model in the Brain Injury Association fashion show that was scheduled for 6 months later, which provided motivation to walk independently.

C.H. did not adhere to Home Exercise Program (HEP) despite maximal encouragement, reward programs, and education regarding benefits. A behavioral modification program was established so that she was given control to stop activities that were too stressful for her. She participated in a volunteer program with farm animals two or three times a week on a fixed schedule to establish personal responsibility and provide a positive learning environment. A program of rewards and withholding of rewards was established to extinguish self-destructive behavior. Verbal feedback was provided when immature behavior was exhibited. C.H. kept a diary of duties and accomplishments to help with memory and reinforce successes.

Motor learning was enhanced by using a program of blocked feedback to start, with only three trials before feedback was given. The number of trials increased to about 10, and then she progressed to random feedback, as C.H. was able to tolerate higher frustration levels. She began doing her own self-assessment of her performance after about 2 months of therapy for each of her activities.

Outcomes

C.H. reached the goals of independent standing static and dynamic balance in 6 weeks. She had vertical upright trunk and head posture but still needed the collar support intermittently for her neck. The left arm had good assistive and gross independent use. Tone in the left arm and left quadriceps was at a level 2 MAS at 6 weeks; however, the trunk tone was still interfering with standing posture and left side rotation remained, although at only about 50% of the initial rotation. Her attention had improved and scored 77/100 on Moss Attention Rating Scale. C.H. was independent in all grooming and with most other ADLs, except showering. The Functional Independence Measure score was 110/126, 10 m walk test revealed a gait speed of 1.2 m/s, Frenchay Arm Test scored 5/5, and Nine-Hole Peg Test 18 s. C.H. had no episodes of scratching herself and much higher tolerance for more difficult tasks. She continued to have some atypical behaviors, but the work at the farm helped her to assess her own deficits better. She made new friends, participated in social activities, and walked in the fashion show fundraiser for the Brain Injury Association after discharge.

reader to a Medline abstract for the article cited. There are 215 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Family Guide to the Rancho Los Amigos Levels of Cognitive Functioning

Cognition refers to a person's thinking and memory skills. Cognitive skills include paying attention, being aware of one's surroundings, organizing, planning, following through on decisions, solving problems, using judgment, reasoning, and being aware of problems. Memory skills include the ability to remember things before and after the brain injury. Because of the damage caused by a brain injury, some or all of these skills will be changed.

The Rancho Los Amigos Levels of Cognitive Functioning is an evaluation tool used by the rehabilitation team. The eight levels describe the patterns or stages of recovery typically seen after a brain injury. This helps the team understand and focus on the person's abilities and design an appropriate treatment program. Each person will progress at his or her own rate, depending on the severity of the brain damage, the location of the injury in the brain, and the length of time since the brain injury. Some individuals will pass through each of the eight levels, whereas others may progress to a certain level and fail to change to the next higher level. It is important to remember that each person is an individual and there are many factors that need to be considered when assigning a level of cognition. There are a range of abilities within each of the levels, and your family member may exhibit some or all of the behaviors listed below.

COGNITIVE LEVEL I

No Response

A person at this level will:

- Does not respond to sounds, sights, touch, or movement.

COGNITIVE LEVEL II

Generalized Response

A person at this level will:

- Begin to respond to sounds, sights, touch, or movement.
- Respond slowly, inconsistently, or after a delay.
- Respond in the same way to what he hears, sees, or feels. Responses may include chewing, sweating, breathing faster, moaning, moving, and/or developing increased blood pressure.

COGNITIVE LEVEL III

Localized Response

A person at this level will:

- Be awake on and off during the day.
- Make more movements than before.
- React more specifically to what he or she sees, hears, or feels. For example, he or she may turn toward a sound, withdraw from pain, and attempt to watch a person move around the room.
- React slowly and inconsistently.
- Begin to recognize family and friends.

- Follow some simple directions such as "Look at me" or "Squeeze my hand."
- Begin to respond inconsistently to simple questions with "yes" and "no" head nods or shakes.

What family and friends can do at Cognitive Levels I, II, and III:

- Explain to the individual what you are about to do. For example, "I'm going to move your leg."
- Talk in a normal tone of voice.
- Keep comments and questions short and simple. For example, instead of "Can you turn your head toward me?" say, "Look at me."
- Tell the person who you are, where he or she is, why he or she is in the hospital, and what day it is.
- Limit the number of visitors to two or three people at a time.
- Keep the room calm and quiet.
- Bring in favorite belongings and pictures of family members and close friends.
- Allow the person extra time to respond, but don't expect responses to be correct. Sometimes the person may not respond at all.
- Give the person rest periods. He or she will tire easily.
- Engage the person in familiar activities, such as listening to favorite music, talking about the family and friends, reading out loud to the individual, watching TV, combing his or her hair, putting on lotion.
- The person may understand parts of what you are saying. Therefore be careful what you say in front of the individual.

COGNITIVE LEVEL IV

Confused and Agitated

A person at this level may:

- Be very confused and frightened.
- Not understand what he or she feels or what is happening around him or her.
- Overreact to what is seen, heard, or felt by hitting, screaming, using abusive language, or thrashing about. This is because of the confusion.
- Be restrained to prevent injury.
- Be highly focused on basic needs—that is, eating, relieving pain, going back to bed, going to the bathroom, or going home.
- May not understand that people are trying to help.
- Not pay attention or be able to concentrate for a few seconds.
- Have difficulty following directions.
- Recognize family and friends some of the time.
- With help, be able to do simple routine activities such as feeding himself or herself, dressing, or talking.

What family and friends can do at Cognitive Level IV:

- Tell the person where he or she is and reassure the person that he or she is safe.
- Bring in family pictures and personal items from home to make the individual feel more comfortable.
- Allow the person as much movement as is safe.

- Take the person for rides in the wheelchair, with permission from nursing.
- Experiment to find familiar activities that are calming to him or her, such as listening to music or eating.
- Do not force the person to do things. Instead, listen to what he or she wants to do and follow this lead, within safety limits.
- You may need to give breaks and change activities frequently because the person often becomes distracted, restless, or agitated.
- Keep the room quiet and calm. For example, turn off the TV and radio, don't talk too much, and use a calm voice.
- Limit the number of visitors to two or three people at a time.

COGNITIVE LEVEL V

Confused and Inappropriate

A person at this level may:

- Be able to pay attention for only a few minutes.
- Be confused and have difficulty making sense of things outside himself or herself.
- Not know the date, where he or she is, or why he or she is in the hospital.
- Not be able to start or complete everyday activities, such as brushing the teeth, even when physically able. Step-by-step instructions may be needed.
- Become overloaded and restless when tired or when there are too many people around.
- Have a very poor memory (the person will remember past events from before the accident better than the daily routine or information the individual has been told since the injury).
- Try to fill in gaps in memory by making things up (confabulation).
- Get stuck on an idea or activity (perseveration) and need help switching to the next part of the activity.
- Focus on basic needs such as eating, relieving pain, going back to bed, going to the bathroom, or going home.

What family and friends can do at Cognitive Level V:

- Repeat things as needed. Don't assume that the person will remember what you say.
- Tell the individual the day, date, name and location of the hospital, and why he or she is in the hospital when you first arrive and before you leave.
- Keep comments and questions short and simple.
- Help the person organize and get started on an activity.
- Bring in family pictures and personal items from home.
- Limit the number of visitors to two or three at a time.
- Give frequent rest periods when he or she has problems paying attention.

COGNITIVE LEVEL VI

Confused and Appropriate

A person at this level may:

- Be somewhat confused because of memory and thinking problems; he or she will remember the main points from a conversation but forget and confuse the details. For example, the person may remember having had visitors in the morning but forget what they talked about.
- Follow a schedule with some assistance but become confused by changes in the routine.
- Know the month and year, unless there is a severe memory problem.
- Pay attention for about 30 min but have trouble concentrating when it is noisy or when the activity involves many steps. For example, at an intersection, the person may be unable to step off the

curb, watch for cars, watch the traffic light, walk, and talk at the same time.

- Brush teeth, get dressed, feed himself or herself, and so on, with help.
 - Know when he or she needs to use the bathroom.
 - Do or say things too fast, without thinking first.
 - Know that he or she is hospitalized because of an injury but will not understand all of the problems he or she is having.
 - Be more aware of physical problems than thinking problems.
 - Associate his or her problems with being in the hospital and think that he or she will be fine once at home.
- What family and friends can do at Cognitive Level VI:*
- Repeat things as needed. Discuss things that have happened during the day to help the individual improve his or her memory.
 - If needed, help the person with starting and continuing activities.
 - Encourage the individual to participate in all therapies. He or she will not fully understand the extent of the problems and the benefits of therapy.

COGNITIVE LEVEL VII

Automatic and Appropriate

A person at this level may:

- Follow a set schedule.
- Be able to do routine self-care without help, if physically able. For example, he or she can dress or feed himself independently.
- Have problems in new situations and may become frustrated or act without thinking first.
- Have problems planning, starting, and following through with activities.
- Have trouble paying attention in distracting or stressful situations—for example, family gatherings, work, school, church, or sports events.
- Not realize how the thinking and memory problems may affect future plans and goals; therefore the person may expect to return to previous lifestyle or work.
- Continue to need supervision because of decreased safety awareness and judgment. He or she still does not fully understand the impact of the physical or thinking problems.
- Think more slowly in stressful situations.
- Be inflexible or rigid and may seem stubborn. However, these behaviors are related to the brain injury.
- Be able to talk about doing something but will have problems actually doing it.

COGNITIVE LEVEL VIII

Purposeful and Appropriate

A person at this level may:

- Realize that he or she has a problem in thinking and memory.
- Begin to compensate for the problems.
- Be more flexible and less rigid in thinking—for example, the person may be able to come up with several solutions to a problem.
- Be ready for driving or job training evaluation.
- Be able to learn new things at a slower rate.
- Still become overloaded with difficult, stressful, or emergency situations.
- Show poor judgment in new situations and may require assistance.
- Need some guidance to make decisions.
- Have thinking problems that may not be noticeable to people who did not know the person before the injury.

What family and friends can do at Cognitive Levels VII and VIII:

- Treat the person as an adult by providing guidance and assistance in decision making. His or her opinions should be respected.
- Talk with the individual as an adult. There is no need to try to use simple words or sentences.
- Be careful when joking or using slang, because the individual may misunderstand the meaning. Also, be careful about teasing.
- Help the individual in familiar activities so he or she can see some of the problems in thinking, problem solving, and memory. Talk to the person about these problems without criticizing. Reassure him or her that the problems are because of the brain injury.
- Strongly encourage the individual to continue with therapy to increase thinking, memory, and physical abilities. He or she may feel completely normal. However, he or she is still making progress and may possibly benefit from continued treatment.
- Be sure to check with the physician on the individual's restrictions concerning driving, working, and other activities. Do not just rely on the individual for information, because he or she may feel ready to go back to the previous lifestyle.
- Discourage the individual from drinking or using drugs, because of medical complications.
- Encourage the individual to use note-taking as a way to help with the remaining memory problems.
- Encourage the person to carry out self-care as independently as possible.
- Discuss what kinds of situations make the person angry and what he or she can do in these situations.
- Talk with the person about his or her feelings.
- Learning to live with a brain injury can be difficult, and it may take a long time for the individual and family to adjust. The social worker and/or psychologist will provide the family and friends with information regarding counseling, resources, and/or support organizations.

LEVEL IX—PURPOSEFUL, APPROPRIATE: STAND-BY ASSISTANCE ON REQUEST

- Independently shifts back and forth between tasks and completes them accurately for at least 2 consecutive hours.
- Uses assistive memory devices to recall daily schedule, make “to do” lists, and record critical information for later use with assistance when requested.
- Initiates and carries out steps to complete familiar personal, household, work, and leisure tasks independently and unfamiliar

personal, household, work, and leisure tasks with assistance when requested.

- Is aware of and acknowledges impairments and disabilities when they interfere with task completion and takes appropriate corrective action but requires standby assistance to anticipate a problem before it occurs and take action to avoid it.
- Is able to think about consequences of decisions or actions with assistance when requested.
- Accurately estimates abilities but requires standby assistance to adjust to task demands.
- Acknowledges others' needs and feelings and responds appropriately with standby assistance.
- Depression may continue.
- May be easily irritable.
- May have low frustration tolerance.
- Able to self-monitor appropriateness of social interaction with standby assistance.

LEVEL X—PURPOSEFUL, APPROPRIATE: MODIFIED INDEPENDENT

- Able to handle multiple tasks simultaneously in all environments but may require periodic breaks.
- Able to independently procure, create, and maintain own assistive memory devices.
- Independently initiates and carries out steps to complete familiar and unfamiliar personal, household, community, work, and leisure tasks but may require more than usual amount of time and/or compensatory strategies to complete them.
- Anticipates impact of impairments and disabilities on ability to complete daily living tasks and takes action to avoid problems before they occur but may require more than usual amount of time and/or compensatory strategies.
- Able to independently think about consequences of decisions or actions but may require more than usual amount of time and/or compensatory strategies to select the appropriate decision or action.
- Accurately estimates abilities and independently adjusts to task demands.
- Able to recognize the needs and feelings of others and automatically respond in appropriate manner.
- Periodic episodes of depression may occur.
- Irritability and low frustration tolerance when sick, fatigued, and/or under emotional stress. Social interaction behavior is consistently appropriate.

Concussion*

Brian M. Moore

Nicole Miranda (*Tests and Measures in Acute Concussion, Headaches, and Management of Cervical Spine Dysfunction*), Heather Campbell (*Management of Cervical Spine Dysfunction*), and Lisa D'Angelo (*Cognitive/Neuropsychological Dysfunction, Cognitive Assessment, and Rehabilitation*)

OBJECTIVES

After reading this chapter the reader will be able to:

1. Define concussion/mild traumatic brain injury (mTBI), sports-related concussion (SRC), postconcussive syndrome (PCS), and persistent postconcussion symptoms (PPCS).
2. Describe the epidemiology, pathophysiology, and the economic/personal costs associated with concussion.
3. Describe screening tools and medical tests used to diagnose the acute concussion and the medical management for individuals following a concussion.
4. Discuss considerations for cognitive and physical rest and recommendations for return to play (RTP) and return to school/learn for student-athletes following an SRC.
5. Describe the prognosis and outcomes for patients with persistent symptoms following an SRC considering pediatric/youth, adolescent, and adult athletes.
6. Describe the epidemiology, prognosis, and return to meaningful activities (e.g., work) for individuals following concussion including young adults, older adults, and military personnel.
7. Describe the clinical examination and evaluation for a rehabilitation specialist for individuals with PPCS and describe interventions for individuals with a slow recovery using a targeted approach to match intervention to a specific clinical profile.

KEY TERMS

cognitive rehabilitation
mild traumatic brain injury (mTBI)

return to learn/play
sports-related concussion (SRC)

INTRODUCTION

Concussion is one of the most common neurological conditions in the world, with at least 3 million cases each year in the United States alone.^{1,2} Concussion may cause a variety of impairments that can impact an individual's ability to return to meaningful activities such as an athlete returning to sport, a student returning to school, a civilian returning to work, or a service member returning to duty. Due to the frequency of concussions, which some reports estimate to occur every 7 seconds in the United States, and the detrimental effect concussion can have on function, the Centers for Disease Control and Prevention (CDC) has labeled concussion a major public health issue³ that is accompanied by considerable personal and social economic costs. The annual economic burden associated with concussion has been estimated to be \$16.7 billion USD, with an estimated direct cost of \$35,000 to \$45,000 USD per patient.^{4,5}

Concussion, also referred to as mild traumatic brain injury (mTBI), has been defined by the International Consensus Conference

of the Concussion in Sport Group (CISG) as a complex pathophysiological process affecting the brain, induced by biomechanical forces⁶ that can cause sudden deceleration and rotation forces to the brain.⁷ It is unclear and debatable whether concussion results in structural damage (e.g., microvascular hemorrhage) or functional injury characterized by transient metabolic damage.⁸ What is clear is that concussion may cause a variety of short-lived neurological signs and symptoms that, in most cases, resolve spontaneously.⁶ However, in a minority of concussive events, symptoms will evolve and persist over a number of days or weeks leading to a slow, prolonged recovery.^{3,6,9}

Once termed the "silent epidemic,"¹⁰ concussion has moved to the forefront of the public's consciousness in recent years. Perhaps the catalyst to the public's interest in the United States were reports that developed surrounding the potential long-term consequences of concussion in professional American football players. Since that time, several educational initiatives¹¹ have been developed to increase the public's awareness of the critical nature of concussion, how to recognize a concussion, and what action to take if a concussion is identified. By January 2014, laws had been established in all 50 states mandating

*Videos for this chapter are available at studentconsult.com.

school districts to develop information and policies related to concussion in children and adolescents. And if Twitter can be used as a measurement tool to gauge change in public awareness, the number of tweets related to traumatic brain injury increased twofold over a 6-year period, from 2010 to 2016.^{12,13} These examples may point to increased public awareness of concussion; yet, unfortunately, there continues to be disheartening evidence, both empirical and anecdotal, which suggests continued mismanagement in the care of patients who sustain a concussion.

Although concussion research has increased in the last 25 years, in rehabilitation, there is still much that is not well understood.^{3,14} Because of the challenges that exist in returning individuals to their life activities, it is imperative that medical professionals and rehabilitation specialists understand the risks, functional and medical consequences, level of evidence, current recommendations for management, and effective preventions programs to inform local, state, and federal policies.

This chapter was developed to review all stages of care following a concussion with an emphasis on topics for the rehabilitation specialist providing services to children, young adults, and older adults. The chapter was developed with an emphasis on sports-related concussion (SRC) as this is the well-developed area of research related to concussion. One substantial contribution to the literature comes from the CISG, which has provided recommendations from a formal

consensus process in 2001 (Vienna), 2004 (Prague), 2008 (Zurich), 2012 (Zurich), and 2016, its last updated consensus statement in Berlin. For the most recent consensus statement,⁶ specific clinical questions related to management of SRC were developed and a formal systematic review was completed by committee members and authors of the CISG to answer each of these clinical questions. The reports from the systematic reviews provided the basis for the updated recommendations. Throughout the chapter, the CISG will be used interchangeably with “international consensus.” While the bulk of published evidence is found in the SRC and service member populations, the recommendations for evaluation and management of concussion injuries may be applied to individuals of all ages who sustain a concussion following falls, violence/abuse, motor vehicle collisions, and recreational or work-related trauma.

An important point of clarification for the reader regarding terms used in this chapter: although there are some texts that use the terms concussion and mTBI to refer to the same condition and others that use the terms to refer to different injuries,⁶ the terms concussion and mTBI will be used interchangeably in this chapter to refer to the same health condition. [Table 23.1](#) provides definitions of common terms used in concussion literature. The reader may find it useful to become familiar with the terms and consider how the definitions differ, depending on the organization or consensus body providing the definition.

TABLE 23.1 Definitions of Common Terms Used in Concussion-Related Literature and Care

Concussion

International Consensus: A complex pathophysiological process affecting the brain, induced by biomechanical forces⁶

American Academy of Neurology: A clinical syndrome of biomechanically induced alteration of brain function, typically affecting memory and orientation, which may involve loss of consciousness¹⁵

Cantu Grading Scale¹⁶:

Grade 1: posttraumatic amnesia <30 min and no loss of consciousness

Grade 2: loss of consciousness <5 min or amnesia 30 min to 24 h

Grade 3: loss of consciousness >5 min or amnesia >24 h

Mild Traumatic Brain Injury (mTBI)

International Consensus: Physiological disruption of brain function resulting from traumatic force transmitted to the head¹⁷

WHO-ICD-10: Head injury resulting in a score of 13–15 on the Glasgow Coma Scale, without other factors such as acute substance abuse, other focal or systemic injuries, coexisting medical conditions, or penetrating craniocerebral injury. The patient must endorse one of the following: confusion or disorientation, loss of consciousness of <30 min, posttraumatic amnesia of <24 h, or transient neurological abnormalities.¹⁸

Term used to categorize the severity of a traumatic brain injury (mild, moderate, and severe) based on the Glasgow Coma Scale score of 13–15 and limited post-traumatic amnesia. The term may include concussion, but may also include small intracranial hematomas or skull fractures.^{5,19}

American Congress of Rehabilitation Medicine: A traumatically induced physiological disruption of brain function including (1) any period of loss of consciousness; (2) any loss of memory for events immediately before or after the accident; (3) any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused); and (4) focal neurological deficits that may or may not be transient but where the severity of the injury does not exceed the following: loss of consciousness of 30 min, Glasgow Coma Scale of 13–15, and posttraumatic amnesia of 24 h.

Postconcussive Syndrome

WHO-ICD-10: A head injury usually sufficient to result in loss of consciousness after which at least 3 of 8 common symptoms arise within 4 weeks. The symptoms include headache, dizziness, fatigue, irritability, sleep problems, concentration problems, memory problems, and/or problems tolerating stress/emotionality/alcohol.^{21,22}

American Psychiatric Association (DSM-IV): Diagnosis provided if the following criteria are met: (1) A history of head trauma that has caused significant cerebral concussion, the manifestation of which includes loss of consciousness, posttraumatic amnesia, and less commonly, posttraumatic onset of seizures; (2) evidence from neuropsychological testing or quantified cognitive assessment of difficulty in attention or memory; (3) three (or more) of the following occur shortly after the trauma and last at least 3 months: fatigue, sleep disturbance, headache, vertigo or dizziness, irritability or aggression on little or no provocation, anxiety or depression, changes in personality. Note: Diagnosis supported when symptoms in criteria (2) or (3) have onset following head trauma or worsening of preexisting symptoms, which causes significant impairment in social or occupational functioning or decline from previous level of functioning.^{21,23}

Continued

TABLE 23.1 Definitions of Common Terms Used in Concussion-Related Literature and Care—cont'd**Persistent Postconcussion Symptoms (PPCS)**

International Consensus: A constellation of nonspecific posttraumatic symptoms that may be linked to coexisting and/or confounding factors that reflects failure of normal clinical recovery where symptoms persist beyond expected time frames of more than 10–14 days in adults and >4 weeks in children. Persistent symptoms do not reflect a single pathophysiological entity and do not necessarily reflect ongoing physiological injury to the brain.⁶

Sports-Related Concussion (SRC)

International Consensus: A traumatic brain injury induced by biomechanical forces. Several common features that may be utilized in clinically defining the nature of a concussive head injury include⁶:

A direct blow to the head, face, neck, or elsewhere on the body with an impulsive force transmitted to the head

A rapid onset of short-lived impairment of neurological function that resolves spontaneously. However, in some cases, signs and symptoms evolve over a number of minutes to hours

Neuropathological changes, but the acute clinical signs and symptoms largely reflect a functional disturbance rather than a structural injury and, as such, no abnormality is seen on standard structural neuroimaging studies

A range of clinical signs and symptoms that may or may not involve loss of consciousness.

Clinical Recovery

International Consensus: A resolution of postconcussion-related symptoms and a return to clinically normal balance and cognitive functioning that leads to a return to normal activities, including school, work, and sport, after injury⁶

Physiological Recovery

International Consensus: Time of recovery that may outlast the time for clinical recovery for which there is no modality (e.g., neuroimaging, biomarkers) that can define a single 'physiological time window' for recovery following a concussion⁶

Second Impact Syndrome

A rare, often critical condition that arises when an individual, typically an athlete, sustains a second head injury before symptoms associated with an initial head injury have fully cleared. The second injury, it is believed, results in catastrophic brain swelling and can lead to death.^{24,25,26}

Complicated mTBI

Mild traumatic brain injury that results in a visible trauma-related intracranial abnormality on structural neuroimaging (e.g., hemorrhage, contusion, or edema) such as a CT scan or MRI.²⁷

International consensus: consensus statements, definitions, and recommendations provided by the 2017 Concussion in Sport Group international conference held in Berlin; *WHO-ICD-10, World Health Organization International Classification of Diseases*, 10th edition; *DSM-IV, Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. (Note: the definitions provided for the WHO-ICD-10 and DSM-IV are abbreviated definitions. Complete definitions can be found on the respective websites for the World Health Organization and American Psychiatric Association. *CT*, Computed tomography scan; *MRI*, magnetic resonance imaging; *mTBI*, mild traumatic brain injury.

Epidemiology

The most recent population data estimates 2.5 million traumatic brain injury–related emergency department (ED) visits, hospitalizations, and deaths each year in the United States.²⁸ According to the Nationwide ED Sample, the rate of mTBI in ED visits was 807 per 100,000 visits in 2012,²⁸ with the highest rates of mTBI requiring medical attention occurring in 0- to 4-year-olds, followed by male 15- to 24-year-olds, and females 65 years and older. The lowest rates were found for 45- to 64-year-olds.²⁸ Across all age groups, males were found to have a higher rate of mTBI ED visits compared with females, except among those patients aged 65 years and older.²⁸ Among all patients diagnosed with mTBI, falls were found to be the most common external cause of injury.²⁸

In the United States, estimates of 1.6 to 3.8 million athletes sustain an SRC each year, a statistic that includes those for which no medical attention is sought.³¹ With nearly 8 million participants annually, high school athletes make up the single largest athletic cohort in the country who may be susceptible to head injuries.³² The National High School Sports-Related Injury Surveillance Study³³ showed that concussion moved from the fourth most

commonly reported category of injury in 2005–06 (9% of all sports-related injuries) to the most commonly reported injury category in 2016–17, accounting for 24.8% of all sports-related injuries.³³ The National Athletic Treatment, Injury and Outcomes Network (NATION) study that used a convenience sample of 147 high schools drawn from 26 states to compile data on 31 sports³⁴ found a total of 2004 SRCs across 3 academic years (2011–2014), leading to an overall SRC rate of 3.89 per 10,000 athletic exposures (defined as one student participating in one athletic practice or competition). High school football had the highest overall SRC rate, followed by boys' lacrosse and girls' soccer (Table 23.2). For all sports, the rate of SRC was higher during competition compared with practice.³⁴ Nearly 3% of all SRCs were reported to be recurrent concussions³⁴; however, recurrent concussions, specifically in the high school athlete population, have been reported to account for 11% of all SRCs.³⁵

During the 2009–10 to 2013–14 academic years, it was estimated that SRCs constituted 6.2% of all injuries that occurred during participation in collegiate athletics.³⁷ Wasserman and colleagues reported a total of 1670 SRCs in schools participating in the National Collegiate

TABLE 23.2 Concussion Counts and Rates Among Collegiate and High School Athletes

Sport	NUMBER OF CONCUSSIONS		CONCUSSION RATE/10,000 ATHLETIC EXPOSURES ^c (95% CONFIDENCE INTERVAL)		
	Competitions	Practices	Competitions	Practices	Overall
High School Athletes^a					
Boys' football	409	611	19.87 (17.95, 21.80)	6.78 (6.24, 7.31)	9.21 (8.64, 9.78)
Boys' lacrosse	74	37	17.51 (13.52, 21.49)	2.97 (2.01, 3.93)	6.65 (5.41, 7.89)
Boys' soccer	60	23	11.33 (8.46, 14.20)	1.48 (0.87, 2.08)	3.98 (3.12, 4.83)
Boys' wrestling	45	92	10.21 (7.23, 13.20)	4.75 (3.78, 5.72)	5.76 (4.80, 6.73)
Boys' basketball	45	47	4.93 (3.49, 6.36)	1.72 (1.23, 2.21)	2.52 (2.01, 3.04)
Girls' soccer	66	40	17.16 (13.02, 21.30)	2.96 (2.04, 3.88)	6.11 (4.94, 7.27)
Girls' lacrosse	30	26	11.75 (7.55, 15.95)	3.44 (2.12, 4.76)	5.54 (4.09, 6.99)
Girls' basketball	81	47	10.52 (8.23, 12.82)	2.22 (1.59, 2.86)	4.44 (3.67, 5.20)
Girls' field hockey	39	27	9.83 (6.74, 12.91)	2.47 (1.54, 3.40)	4.42 (3.36, 5.49)
Girls' softball	24	26	6.33 (3.80, 8.86)	2.54 (1.57, 3.52)	3.57 (2.58, 4.56)
Girls' gymnastics	2	6	5.27 (0.00, 12.58)	2.28 (0.45, 4.10)	2.65 (0.81, 4.49)
Girls' volleyball	28	46	3.67 (2.31, 5.03)	2.09 (1.49, 2.69)	2.50 (1.93, 3.06)
Collegiate Athletes^b					
Men's wrestling	46	40	55.46 (39.43, 71.48)	5.68 (3.92, 7.44)	10.92 (8.62, 13.23)
Men's football	262	341	30.07 (26.43, 33.71)	4.20 (3.75, 4.64)	6.71 (6.17, 7.24)
Men's ice hockey	170	54	24.89 (21.14, 28.63)	2.51 (1.84, 3.18)	7.91 (6.87, 8.95)
Men's soccer	33	22	9.69 (6.39, 13.00)	1.75 (1.02, 2.48)	3.44 (2.53, 4.35)
Men's lacrosse	25	26	9.31 (5.66, 12.96)	1.95 (1.20, 2.69)	3.18 (2.31, 4.05)
Men's basketball	26	58	5.60 (3.45, 7.75)	3.42 (2.54, 4.31)	3.89 (3.06, 4.72)
Women's ice hockey	60	25	20.10 (15.01, 25.18)	3.00 (1.82, 4.17)	7.50 (5.91, 9.10)
Women's soccer	101	35	19.38 (15.60, 23.16)	2.14 (1.43, 2.85)	6.31 (5.25, 7.37)
Women's lacrosse	27	28	13.08 (8.15, 18.02)	3.30 (2.08, 4.52)	5.21 (3.84, 6.59)
Women's field hockey	10	5	11.10 (4.22, 17.99)	1.77 (0.22, 3.32)	4.02 (1.99, 6.06)
Women's basketball	50	66	10.92 (7.89, 13.95)	4.43 (3.36, 5.50)	5.95 (4.87, 7.04)
Women's volleyball	26	30	5.75 (3.54, 7.96)	2.69 (1.73, 3.69)	3.57 (2.64, 4.51)
Women's softball	36	17	5.61 (3.77, 7.44)	1.75 (0.92, 2.58)	3.28 (2.40, 4.17)
Women's gymnastics	2	10	4.83 (0.00, 11.52)	2.43 (0.92, 3.93)	2.65 (1.15, 4.14)

^aStatistics from the National Athletic Treatment, Injury and Outcomes Network (NATION), 2011–12 through 2013–14 academic years.³⁴

^bStatistics from the National Collegiate Athletic Association (NCAA) Injury Surveillance Program (ISP) in collegiate athletes from 2009–2010 through 2013–2014 academic years.³⁶

^cAthletic Exposures = One athlete participating in one sanctioned practice or competition.

Note: Table comprises the sports with the *highest rate of concussion during competitions*. The table does not report all sports included in the NATION³⁴ or NCAA ISP³⁶ studies.

Adapted from O'Connor KL, Baker MM, Dalton SL, Dompier TP, Broglio SP, Kerr ZY. Epidemiology of sport-related concussions in high school athletes: National Athletic Treatment, Injury and Outcomes Network (NATION), 2011–2012 through 2013–2014. *J Athl Train.* 2017;52(3):175–185 and Wasserman EB, Kerr ZY, Zuckerman SL, Covassin T. Epidemiology of sports-related concussions in National Collegiate Athletic Association athletes from 2009–2010 to 2013–2014: symptom prevalence, symptom resolution time, and return-to-play time. *Am J Sports Med.* 2016;44(1):226–233.

Athletic Association (NCAA) Injury Surveillance Program (ISP), leading to a yearly national estimate of 10,560 SRCs in collegiate sports.³⁶ Although football contributed the greatest number of SRCs (36.1%), followed by men's ice hockey (13.4%) and women's soccer (8.1%), of the 25 collegiate sports investigated in the NCAA ISP, men's wrestling and men's and women's ice hockey were found to have the highest

overall concussion rates (see Table 23.2).^{36,37} Similar to high school athletes, a higher rate of concussions occurred during competition compared with practice, with an injury rate of 14.59 and 2.57 per 10,000 athletic exposures, respectively.³⁶ Nearly 1 in every 11 SRCs that occurred were reported to be recurrent concussions.³⁶ Overall, most concussions were related to player contact; however, other mechanisms, such as contact

with the playing surface and equipment such as sticks and balls, have been described.³⁷

It is well documented that females are at greater risk of experiencing an SRC compared with males participating in high school and collegiate sports.^{34,37–39} In high school athletics, the rate of SRCs has been found to be 56% higher in girls than in boys,³⁴ and the disparity in SRC incidence between girls and boys has been reported to be twice as high when considering contact sports alone.³⁵ Some researchers have suggested that structural and physiological differences in cervical spine morphology, strength, and dynamic stability^{37,40,41} account for sex differences in the incidence of SRCs; however, given the evidence that female athletes are more likely than male athletes to report a concussion,^{42,43} it is unlikely that potential structural and physiological differences solely explain the biological sex gap in SRC incidence.

Pathophysiology

The basic neurobiology of concussion has been described as a neuro-metabolic cascade of events that does not always result in cell death, but will lead to a functional injury where cells undergo a significant energy crisis. This process, referred to as the *bioenergetic crisis*, is characterized by a mismatch between energy supply and demand.⁴⁴

Neurons have a relatively high consumption of oxygen and depend almost exclusively on oxidative phosphorylation for energy production. Mechanical deformation of neurons, termed *mechanoporation*, caused by an acceleration/deceleration force quickly leads to two mechanisms of dysfunction: failure of energy-dependent ion transport pumps and release of large quantities of glutamate. Failure of the energy-dependent ion pumps allows charged ions to move across their electrical and concentration gradients, leading to an efflux of potassium and an influx of calcium and sodium. Excessive concentrations of calcium and sodium within the cell causes degradation of cytoskeletal proteins and cytotoxic edema as water follows positively charged ions into the cell. The ionic flux leads to an energy crisis as a considerable amount of the cell's energy reserve is spent attempting to restore ionic homeostasis by pumping calcium and water out of the cell. A direct consequence of the excessive calcium influx is release of excessive glutamate, a potent excitatory molecule, into the extracellular space. Glutamate then binds to *N*-methyl-D-aspartate (NMDA) receptors on neighboring neurons leading to calcium influx and release of more glutamate into the extracellular space. This process, referred to as *excitotoxicity*, leads to a self-perpetuating, deleterious cycle of hyperexcitability and cellular instability.

Another contribution to the energy crisis is an initial decrease in cerebral blood flow, which creates a mismatch between energy supply and demand (increased glucose metabolism to support increased neural activity) in the initial stages of concussion.⁴⁴ Functionally, the cell is then vulnerable to subsequent injury,⁴⁴ meaning the cell has less energy reserve or resources to address a subsequent stress, be it a second biomechanical stress (e.g., second impact syndrome) or a functional stress such as an increased cognitive or physical load. This point is important for medical professionals who consider return to play protocols in acute concussion as the impaired metabolic state can extend for weeks to months.^{44–46}

Cytoskeletal and axonal alteration due to axonal stretch can interfere with axonal transport, leading to impaired synaptic transmission and in severe cases result in retraction and degeneration of the synapse.⁴⁴ This process, referred to as *axonal disconnection*, can be a transient event and in some cases may recover, but due to the poor regenerative capacity of the central nervous system, such stretching may lead to permanent axonal damage.^{47,48}

Recent studies suggest that inflammatory changes are also triggered by mTBI⁴⁴ and cause functional disruption of neural activity.

Cytokines, cytokines, and immune-mediated responses may play an important role in neuroinflammation after injury.⁴⁹ Immunoassay of plasma cytokines, chemokines, epinephrine, and norepinephrine in individuals following brain trauma has revealed a relationship between systemic inflammation and autonomic nervous system dysregulation with an acute hyperadrenergic state.⁵⁰ A preliminary study of rugby players who have sustained concussion injuries indicates that genetic influences may trigger a postinflammatory brain syndrome (PIBS) that is congruent with prolonged symptoms after injury.⁵¹

It appears there is little to no cell death associated with mTBI; however, the impact of subsequent head injury or potential detrimental structural and physiological degeneration that occurs over time is unclear. In longitudinal studies of mTBI using rodent models, there is evidence of cortical and subcortical atrophy and depletion of dopaminergic neurons in subcortical nuclei⁴⁴; however, the degree to which the changes occur in humans or how they relate to impaired cognitive, physical, and emotional function following a concussion in humans has not been determined at this time.

Persistent Symptoms/Prolonged Recovery

Injuries that seem mild initially can occasionally cause a constellation of somatic, cognitive, emotional, and behavioral symptoms.⁵² In most cases, the majority of individuals will have a complete functional recovery and return to their life activities without the burden of these sequelae.^{6,53} But a “miserable minority,”⁵⁴ approximately 10% to 33% of patients, will experience an incomplete recovery, and their symptoms often persist for months or even years after the initial injury.^{52,55–58} Using these numbers, an estimated 200,000 to 600,000 individuals every year in the United States are likely to experience persistent symptoms after a head injury. With few longitudinal studies, there is limited information related to time periods that persistent symptoms may last; however, for concussions in general, the prevalence of persistent symptoms at 1 year following the injury is estimated to be 5%.⁵⁹

As one may expect, differences have been found across age groups for patients who continue to endorse persistent symptoms following a concussion. For SRCs, higher rates of persistent symptoms have been reported following concussion in cohorts of high school athletes compared with collegiate and professional athletes. Using American football as an example, 17% to 30% of high school athletes have persistent symptoms greater than 21 days following injury,^{60,61} and 10% to 15% of collegiate athletes have symptoms beyond 10 days,⁶² while it is uncommon for professional athletes to experience persistent symptoms beyond 7 days.⁶³

Although a small number of patients may have symptoms that persist for 1 year, several reports from specialty concussion clinics in rehabilitation have described children and adults who present for treatment with continued symptoms that have persisted for 2 to 5 years following injury,^{64–66} which may represent up to 20% of the patients with mTBI who are referred for care in these specialty clinics.⁶⁴

Several terms have been used to characterize symptoms following a concussion, such as postconcussion syndrome (PCS), persistent postconcussion syndrome,⁵⁹ persistent postconcussion symptoms (PPCS), prolonged recovery,⁶⁷ protracted recovery,^{68,69} or slow-to-recover (see Table 23.1).⁷⁰ Importantly, there is continued controversy related to the time period used to classify individuals into one of these categories and what the underlying cause of the continued symptom complaint may be. Barlow and colleagues and Yeates and colleagues showed individuals who endorse somatic, cognitive, emotional, and/or behavioral symptoms following a biomechanical force to the head recover differently than those who endorse similar symptoms following an injury to the body without sustaining a hit to the head.^{21,71} Barlow and colleagues conducted one of

the largest prospective, population-based studies comparing symptom complaints of children (aged 0 to 18 years) after mTBI (as defined by the American Congress of Rehabilitation Medicine) to children who presented to the ED with an extracranial injury (ECI). Three months after injury, 11% of children were symptomatic in the mTBI group compared with 0.5% in the ECI group. Between group differences were even larger when considering children and adolescents between the ages of 6 and 18, where 13.7% of the mTBI group were symptomatic 3 months following the injury compared with only 1% of the ECI group.²¹

For simplicity, but not to suggest consensus in the literature related to proper classification of such individuals, we will use the term PPCS to refer to adults who continue to be symptomatic 10 to 14 days following injury and children (aged 0 to 18 years) who continue to be symptomatic 28 to 30 days following injury.⁶ Risk factors and outcomes associated with PPCS and treatment options for different clinical profiles will be reviewed in later sections.

EXAMINATION OF THE ACUTE CONCUSSION

Given that a concussion is broadly defined as a complex pathophysiological process affecting the brain, induced by biomechanical forces, there are challenges for physicians to diagnose a concussion. The primary challenge is the absence of a valid and reliable diagnostic test or battery of diagnostic tests that can be used to diagnose concussion. In addition, signs and symptoms of concussion can mimic other health conditions, and the evolving nature of the clinical presentation can present a challenge to medical professionals as signs and symptoms, such as headache or change in mental status that may not appear immediately or may emerge minutes to hours later either when an individual is at rest or undergoes cognitive or physical exertion.⁷² In relation to SRC, time constraints or pressures from coaches and parents can also pose challenges to diagnose the acute concussion.

For these reasons, during sporting events, it is recommended that licensed medical personnel, which may include a sideline physician and at least one athletic trainer, should use the Recognize, Remove, and Evaluate (Reevaluate) framework in the medical management of the acute concussion.^{6,9,72} In short, where concussion is suspected (Recognize), the athlete must be removed (Remove) from participation in the sport to undergo an assessment (Evaluate) by a physician or other licensed medical professional. The sideline evaluation should be composed of multimodal testing that includes, at least, an evaluation of symptom complaint, mental status, cognitive performance, and motor control (Table 23.3).^{6,72} It is important to note that standard orientation questions (e.g., time, place, person, and situation) are unreliable in sport situations; therefore more comprehensive mental status and cognitive testing is recommended.⁶

Recognize

Parents, coaches, spectators, and most importantly licensed medical professionals must understand that the brain can undergo a neurometabolic crisis without the head coming in contact with an object or the brain coming in contact with the inside of the skull.^{6,9,72} The only requirement for a concussive event is the presence of a large enough acceleration/deceleration force, which can result from a direct blow to the head, or a blow to the body, that subsequently causes a whiplash movement of the head and neck.⁷² Importantly, the injury does not require loss of consciousness, loss of memory, or the presence of apparent neurological decline.^{6,72} Suspected diagnosis of SRC can include one or more of the following clinical domains⁶:

- Symptoms: somatic (e.g., headache), cognitive (e.g., feeling like in a fog), and/or emotional symptoms (e.g., lability)

TABLE 23.3 Tests and Measures Used for Preinjury Baseline Assessment and Sideline Examination for Acute Concussion

Preinjury/Preparticipation Baseline Evaluation

Full Neurological Examination

Clinical History

Past Medical History: previous number of concussions, recovery from previous concussions, prior history of migraine headaches, prior history of mental health problems/mood disorders, attention and learning disorders, sleep disorders and/or disorders
Family History: mood disorders, learning disability, ADHD, migraine headaches

Tests and Measures

Mental status, cranial nerves, reflexes, sensorimotor systems, gait, balance and coordination assessment

Cognitive Tests

Standardized Assessment of Concussion (SAC)^{73,74}
Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT)⁷⁵
Axon Sports Computerized Cognitive Assessment Tool (CCAT)⁷⁶

Physical Tests

Reaction time test: "Stick drop" test⁷⁷
Oculomotor assessment: King-Devick test for visual tracking⁷⁸
Balance assessment: Balance Error Scoring System^{79,80}
Cervical Spine Joint Position Sense Error⁸¹

Sideline Examination

Cognitive Tests

SCAT5 or Child SCAT5⁶
Standardized Assessment of Concussion (SAC)^{73,74}
Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT)⁷⁵
Axon Sports Computerized Cognitive Assessment Tool (CCAT)⁷⁶

Physical Tests

Reaction time test: "Stick drop" test⁷⁷
Oculomotor assessment: King-Devick test for visual tracking⁷⁸ or Vestibular/Ocular Motor Screening⁸²
Balance assessment: Balance Error Scoring System^{79,80}

Symptom Assessment

Postconcussion Symptom Inventory (PCS)⁸³
Post Concussion Symptom Scale⁸⁴ (PCSS)
Rivermead Postconcussive Symptom Questionnaire (RPSQ)⁸⁵
Health and Behavior Inventory⁸⁶
Graded Symptom Checklist⁸⁷

Mood/Anxiety Assessment

Center for Epidemiologic Studies Depression Scale (CES-D)⁸⁸

ADHD, Attention-deficit hyperactivity disorder.

- Physical signs (e.g., loss of consciousness, amnesia, neurological deficit)
 - Balance impairment (e.g., gait unsteadiness)
 - Behavioral changes (e.g., irritability)
 - Cognitive impairment (e.g., slowed attention speed)
- Given the circumstances that may provide sufficient force to cause a functional injury, combined with the fact that such

signs and symptoms can be observed or reported following physical exertion in a nonconcussed athlete,^{58,89,90} it can be difficult for the medical professional to make the correct choice to Recognize and Remove in every case. It is therefore strongly recommended that the medical professional always error on the side of caution.^{6,9} Once a concussion is suspected, the athlete should be removed from participation in the sport, and the athlete will not return to participation: (1) within the same day, and (2) until an evaluation by a licensed medical professional (Evaluate) has been completed.

Remove

There is overwhelming agreement across position statements and consensus reports that an athlete who is suspected of sustaining a concussion should not return to participation within the same day.^{6,72,15} In fact, this recommendation is mandated by law in all 50 states in the United States with regard to children and adolescent concussions.⁷² Athletes are removed from participation in sports, especially contact sports, to remove the risk of impact during a time when the brain is vulnerable to damage from an initial injury. The time period of this vulnerable state is unclear, as it has been shown to last up to 5 days in rodent models,⁹¹ but it is not known how this time frame translates to human populations. Therefore it is important to note, the medical professional is not withdrawing the athlete from physical activity in general, although there is evidence that vigorous exercise during this vulnerable period of brain recovery can lead to delayed recovery in rodent models of mTBI⁹²; instead, the athlete is removed from participation at the time of suspected concussion to reduce the risk of another mechanical force occurring on an already injured brain during the acute neurometabolic crisis, an event known as the rare but potentially dangerous second impact syndrome.^{24,25}

If a concussion is suspected, medical personnel must address first aid issues including an assessment of the “ABCs” (airway, breathing, circulation). If any of these are compromised, or if there is prolonged loss of consciousness, seizure, suspicion, or evidence of cervical spine instability or a rapidly deteriorating level of consciousness, emergency medical services should be activated immediately.^{6,72}

Evaluate

In the majority of cases the athlete is able to leave the playing area independently or with assistance from medical personnel and should be escorted to a safe, isolated environment⁷² for a sideline evaluation. The objective of the sideline evaluation is to provide a rapid screening for a suspected SRC that may rule out the need for urgent referral to emergency services to address critical medical conditions (e.g., hemorrhage, elevated intracranial pressure, cervical spine instability).

The sideline evaluation should be composed of tests and measures that assess the functional system domains known to be affected by concussion, and at a minimum should include a neurocognitive, motor control, and symptom complaint assessment,^{6,9,15} which could be accomplished by using the Sport Concussion Assessment Tool 5 (SCAT5) or Standardized Assessment of Concussion (SAC), combined with a physical test and a self-report checklist for symptom complaints (see Table 23.3). The following section describes the tests and measures that should be used in the sideline evaluation. The National Institute of Neurological Disorders and Stroke (NINDS) has supported the collaboration of basic science researchers, clinician-researchers, and clinicians to develop a recommendation for Common Data Elements (CDE) to be used in the assessment of individuals following SRC during the acute (less than 3 days), subacute (3 days to 3 months), and chronic (greater than or equal to 3 months) phases of recovery following

concussion.⁹³ Recommendations from the NINDS CDE can be obtained at https://www.commondataelements.ninds.nih.gov/SRC.aspx#tab=Data_Standards.

Neurocognitive Assessment

The SCAT5 was designed to provide an organized framework for performing a neurological sports concussion assessment^{72,94} and currently represents the most well-established and rigorously developed instrument available for sideline assessment.⁶ The SCAT5 is the most recent version of a comprehensive concussion assessment agreed upon by international consensus.⁶ There is a brief version created for a sideline assessment, which takes 15 to 20 minutes to complete, and a more complete “off-field” evaluation designed to be completed in the clinic as a follow-up (Reevaluate) after the time of injury. The SCAT5 is most useful in differentiating concussed from nonconcussed athletes immediately after injury, as its utility appears to decrease significantly 3 to 5 days after injury.⁶ The SCAT5 is designed for athletes 13 years and older, and the Child SCAT5 should be used for children 12 years and younger. Each test may be freely copied and distributed to individuals, teams, groups, and organizations to use; however, it is important to emphasize that the tools should be used and results should be interpreted by licensed medical professionals. Each tool can be found at the British Journal of Sports Medicine website: SCAT5: <http://dx.doi.org/10.1136/bjsports-2017-097506SCAT5>, Child SCAT5: <http://dx.doi.org/10.1136/bjsports-2017-097492childscat5>.

The Standardized Assessment of Concussion (SAC) is an instrument designed for rapid assessment (5 minutes) immediately following a suspected concussion consisting of four neurocognitive domains: orientation, immediate memory, concentration, and delayed recall.⁷² The total score ranges from 0 to 30, with lower scores indicating more severe cognitive impairment. The assessment has poor test-retest reliability with an intraclass correlation coefficient (ICC) value of 0.39 with 95% confidence intervals of 0.36 to 0.42.⁹⁵ Similar to the SCAT5, the diagnostic utility of the SAC diminishes over time, as the ability to distinguish concussed from nonconcussed athletes decreases after 2 days.⁸⁹

The Immediate Post-Concussion Assessment Tool (ImPACT) is a 25-minute test that assesses different neurocognitive domains such as attention span, working memory, sustained and selective attention time, visual processing speed, nonverbal problem solving, and reaction time.^{95,84} The components of the ImPACT have fair-to-good test-retest reliability, ranging from ICC values of 0.47 for ImPACT reaction time to 0.72 for ImPACT visual motor speed.⁹⁵ The sensitivity (Sn) of the ImPACT has been found to be 81.9% and the specificity (Sp) to be 89.4% to rule in or rule out a concussion, respectively.⁹⁶ This product must be purchased, and the cost differs depending on the organization purchasing the rights to perform the test.

Oculomotor Assessment

The King-Devick concussion screening test. The King-Devick test requires patients to rapidly read single-digit numbers from a series of three cards, with cards uniquely arranged and spaced for progressively more challenging reading tasks with each successive card. Patients can be asked to read each card in right-left or up-down direction as fast as possible without making an error, as a means to evaluate saccadic eye movements. The time to complete each card is measured and the number of errors are calculated. The best time (fastest) of two trials without errors is used as the timed value for the test.⁹⁷ Worsening of time and/or errors identified during testing have been associated with concussive injury.^{78,98,99} The King-Devick test has been found to have excellent test-retest reliability with ICC values of 0.96⁹⁸ and 0.97.⁹⁷ The King-Devick test can be administered in less than 2 minutes.

TABLE 23.4 Tool Used to Monitor Symptom Complaint During the Vestibular/Ocular Motor Screening Assessment

Vestibular/Ocular Motor Screening

The vestibular/ocular motor screening (VOMS) assessment was created in part due to the absence of a brief, comprehensive clinical bedside assessment that could be used to evaluate vestibulo-ocular and ocular motor eye movements, as common tests completed at the time of injury such as the King-Devick, SCAT5, or Balance Error Scoring System (BESS) do not include comprehensive assessments of the vestibulo-ocular and ocular motor systems.⁸² The VOMS tool measures symptom provocation after each assessment of smooth pursuit, horizontal and vertical saccades, near point convergence (NPC), horizontal and vertical vestibulo-ocular reflex (VOR), and visual motion sensitivity. Near point of convergence (NPC) testing is assessed based on the average measurement of three trials of NPC distance. Before the assessment, patients are instructed to rate symptoms of headache, dizziness, nausea, and fogginess on a scale ranging from 0, meaning *no symptoms at present*, to 10, meaning *severe symptoms at present*.¹⁰⁰ After each assessment, patients are asked to reevaluate their symptoms, paying specific attention to how their symptoms may have changed (Table 23.4).⁸² The VOMS tool has demonstrated strong internal consistency and significant correlation with the Post Concussion Symptom Scale (PCSS). The VOMS can potentially differentiate children who sustain an SRC within 14 days as they were found to score significantly higher on all VOMS items, compared with healthy controls.^{82,100} Specifically, an NPC distance of greater than or equal to 5 cm increases the probability of a concussion by at least 34% (positive likelihood ratio [LR+] = 5.8).

Elbin and colleagues¹⁰¹ evaluated prospective changes in the VOMS at three time points (baseline, 1 to 7 days, and 8 to 14 days following SRC) in 83 high school athletes aged 14 to 18 years and found the total and change from baseline scores revealed significant impairment at 1 to 7 days with return to baseline levels by 8 to 14 days. The authors concluded that the interpretation of the VOMS cutoff values should be compared with baseline values (e.g., preparticipation scores), as there is a higher probability of a false-positive if the total score is assessed in isolation. In fact, up to 35% of high school athletes¹⁰¹ and 11% of collegiate athletes¹⁰² report total symptom scores above the clinical cutoffs on the VOMS at preparticipation assessments.

Balance Assessment

Balance error scoring system. The Balance Error Scoring System (BESS) is a clinical balance assessment of postural stability, which is a component of the SCAT5 and can be completed within 5 minutes.^{79,103,104} The BESS was designed to evaluate steady-state balance for clinicians without instrumented laboratory equipment. The BESS has been validated in children, adolescents, and adults with concussion, and has compared favorably to laboratory-based posturography tools such as the sensory organization test (SOT).¹⁰⁴ The BESS consists of three stances: double-leg stance (hands on hips and feet together), single-leg stance (standing on the nondominant leg with hands on hips), and a tandem stance (nondominant foot behind the dominant foot) in a heel-to-toe fashion.⁷⁹ The six testing conditions are shown in Fig. 23.1. The stances are performed on a firm surface and on a foam surface with the eyes closed, with errors counted during each 20-second trial. An error is defined as any one of the following: opening eyes, lifting hands off hips, stepping, stumbling or falling out of position, lifting forefoot or heel, abducting the hip by more than 30 degrees, or failing to return to the test position in more than 5 seconds.⁷⁹ Multiple errors that are committed simultaneously are counted as a single error. The maximum number of errors in each trial is 10, and the maximum number of errors in total is 60.¹⁰³

The BESS has high sensitivity (94%), when combined with a brief neurocognitive examination and symptom report, to detect individuals with concussion.¹⁰⁵ However, the sensitivity of the BESS declines rapidly in the days postinjury.^{89,105} Test-retest reliability has been found to be moderate in children aged 9 to 18 years and young adults,⁷⁹ with large ranges of intrarater (ICC values of 0.60 to 0.92) and interrater (ICC values of 0.57 to 0.85) reliability depending on the age and mechanism of injury.⁷⁹ Scores can be compared with normative data for community-dwelling adults,¹⁰⁶ which may not be appropriate for comparison of performance in the child and adolescent populations. For this reason, Alsalaheen and colleagues¹⁰⁷ described percentile scores for the 6 testing conditions of the BESS in 91 high school students (mean age 15.6 years), which can be used to gauge age-normed performance on each of the conditions for the test. Findings from Alsalaheen and colleagues were consistent with previous studies showing the average number of errors accumulated in high school and

Fig. 23.1 Six Conditions of the Balance Error Scoring System to Assess Balance Performance in Acute Concussion. Stances used in Balance Error Scoring System: **(A)** double-leg stance; **(B)** single-leg stance (standing on the nondominant limb); **(C)** tandem stance; **(D)** double-leg stance with foam; **(E)** single leg on foam; and **(F)** tandem stance on foam. (Adapted from Bell, 2011.⁷⁹)

collegiate athletes without history of concussion ranges from 12 to 13 errors.¹⁰⁷ Therefore there is evidence to support the use of the BESS test, in combination with cognitive and symptom scales, as a diagnostic measure early following concussion or as a screening tool to compare a patient's performance to age-match norms for adolescents and adults. However, psychometric properties of the test do not support its use as an outcome measure, as it is not responsive to change in performance over time, nor has it been validated for use in the subacute and chronic stages of recovery following concussion.

Symptom Complaint

Postconcussion symptom inventory. The Postconcussion Symptom Inventory (PCSI) is a standardized self-report questionnaire that allows an individual to provide an overall rating of symptoms following concussion.⁹³ The scale covers six domains: affective, amnesia, cognitive, fatigue, physical, and sleep. The PCSI was modified from the original Postconcussion Scale¹⁰⁸ for appropriate use in children. The PCSI has three forms for children of different ages; the PCSI-SR5 (<https://www.commondataelements.ninds.nih.gov/ReportViewer.aspx?/nindscdereports/rptNOC&rs:Command=Render&rc:Parameters=false&crfID=F2351>) for ages 5 to 7 years; the PCSI-SR8 (<https://www.commondataelements.ninds.nih.gov/ReportViewer.aspx?/nindscdereports/rptNOC&rs:Command=Render&rc:Parameters=false&crfID=F2355>) for ages 8 to 12 years; and the PCSI-SR13 (<https://www.commondataelements.ninds.nih.gov/>

[ReportViewer.aspx?/nindscdereports/rptNOC&rs:Command=Render&rc:Parameters=false&crfID=F2354](https://www.commondataelements.ninds.nih.gov/ReportViewer.aspx?/nindscdereports/rptNOC&rs:Command=Render&rc:Parameters=false&crfID=F2354)) for children aged 13 to 18 years.⁸³ The tool has been found to have fair-to-good to excellent reliability with ICC values of 0.65 to 0.89 over a 2-week testing period for the four patient-centered questionnaires.⁸³ A questionnaire has also been developed for parents to report observations of symptom complaints in their children aged 5 to 18 years (PCSI-P; <https://www.commondataelements.ninds.nih.gov/ReportViewer.aspx?/nindscdereports/rptNOC&rs:Command=Render&rc:Parameters=false&crfID=F1978>). Interestingly, for individuals following concussion, parent-child concordance was low to moderate for individual symptom but moderate to strong for the subscales and the total score of the PCSI.⁸³ Test-retest reliability of the parent administered test has not been reported, and no information related to the responsiveness to change in the measure has been established.

Post concussion symptom scale. The PCSS is a portion of the SCAT5 that allows the patient to identify symptoms they are experiencing and attempts to quantify the severity of each symptom (Fig. 23.2).⁶ The PCSS requires the patient to rate the severity of 22 different symptoms of concussion on a 0 to 6 scale, with higher scores indicating greater severity of symptoms. Patients can be assigned a symptom severity score from 0 to 132.

In the subacute and chronic stages of recovery, the scale has been validated for individuals with PPCS, though there are no cutoff values reported to rule in/out the condition. Instead, there are established norms for males and females, which the rehabilitation specialist could use to quantify symptom severity.⁸⁴ The scale can also be used as an outcome measure to monitor within subject changes in the number and intensity of symptom complaints over time. The PCSS was found to have a standard error of measurement (SEM) value of 5.3 points for high school and collegiate males and females who have sustained a concussion.⁸⁴

Rivermead post-concussion symptoms questionnaire. The Rivermead Post-Concussion Symptoms Questionnaire (RPQ) is a 16-item self-report questionnaire in which patients rate the severity of cognitive, emotional, and physical symptoms in comparison with how the patient perceived they were functioning prior to their injury.⁸⁵ Items in the RPQ can be divided into two subcategories: the RPQ-3 and the RPQ-13. The RPQ-3 is associated with common sequelae of postconcussive symptoms (e.g., headaches, dizziness, nausea and/or vomiting) that often occur early following the injury (score range 0 to 12). The RPQ-13 is associated with having a greater impact on individuals' participation, psychosocial functioning, and lifestyle (score range 0 to 52).¹⁰⁹ For both subcategories, a higher score indicates a more impaired condition. The RPQ has been shown to be a valid measure of outcome, particularly after a mild to moderate head injury.¹¹⁰

Health and behavior inventory. The Health and Behavior Inventory (HBI) is a 50-item self-report questionnaire, which requires parents and children to rate the frequency of somatic, cognitive, emotional, and behavioral symptoms over the past week on a four-point scale, ranging from "never" to "often."¹¹¹ Significant parent-child agreement at the item level and on composite symptom dimensions have been reported,¹¹² revealing two underlying dimensions of the HBI—cognitive and somatic symptoms.^{111,113}

Graded symptom checklist. The Graded Symptom Checklist (GSC) is a 17-item self-rated survey of postconcussive symptoms, where patients score each item on a Likert scale of 0, indicating no symptoms to 6 indicating severe symptoms.⁹⁰ The total score ranges from 0 to 102, with lower scores reflecting a lower symptom burden. The tool is estimated to take 2 to 3 minutes to complete.

How do you feel?

“You should score yourself on the following symptoms, based on how you feel now.”

	None	Mild	Moderate	Severe
Headache	0	1	2	3
“Pressure in head”	0	1	2	3
Neck Pain	0	1	2	3
Nausea or vomiting	0	1	2	3
Dizziness	0	1	2	3
Blurred vision	0	1	2	3
Balance problems	0	1	2	3
Sensitivity to light	0	1	2	3
Sensitivity to noise	0	1	2	3
Feeling slowed down	0	1	2	3
Feeling like “in a fog”	0	1	2	3
“Don’t feel right”	0	1	2	3
Difficulty concentrating	0	1	2	3
Difficulty remembering	0	1	2	3
Fatigue or low energy	0	1	2	3
Confusion	0	1	2	3
Drowsiness	0	1	2	3
Trouble falling asleep	0	1	2	3
More emotional	0	1	2	3
Irritability	0	1	2	3
Sadness	0	1	2	3
Nervous or anxious	0	1	2	3

Total number of symptoms (maximum possible 22)

Symptom severity score (maximum possible 132)

A

Circle one for each listed	None	Rarely	Sometimes	Often
I have trouble paying attention	0	1	2	3
I get distracted easily	0	1	2	3
I have a hard time concentrating	0	1	2	3
I have problems remembering what people tell me	0	1	2	3
I have problems following directions	0	1	2	3
I daydream too much	0	1	2	3
I get confused	0	1	2	3
I forget things	0	1	2	3
I have problems finishing things	0	1	2	3
I have trouble figuring things out	0	1	2	3
It’s hard for me to learn new things	0	1	2	3
I have headaches	0	1	2	3
I feel dizzy	0	1	2	3
I feel like the room is spinning	0	1	2	3
I feel like I’m going to faint	0	1	2	3
Things are blurry when I look at them	0	1	2	3
I see double/two of things	0	1	2	3
I feel sick to my stomach	0	1	2	3
I get tired a lot	0	1	2	3
I get tired easily	0	1	2	3

B

Fig. 23.2 (A) Postconcussion symptom scale within SCAT5. **(B)** Postconcussion symptom score checklist recommended for children, kindergarten to sixth grade. (A, Modified from McCrory P, Meeuwisse WH, Aubry M, et al. B, Modified from McCrory P, Meeuwisse WH, Aubry M, et al. Consensus statement on concussion in sport: the 4th International Conference on Concussion in Sport held in Zurich, November 2012. *Br J Sports Med.* 2013;47[5]:250–258.)

The sideline evaluation does not need to resemble the full, comprehensive neurological evaluation performed in the clinic by a physician with experience in the examination of individuals with brain injury (Reevaluate) or the complete evaluation used as the preparticipation baseline assessment (both of which may use neuropsychological testing). Although there is debate for the need of the preparticipation assessment across all youth, high school, and collegiate sports, it is recommended that all athletes participating in contact or collision sports undergo a baseline assessment.^{9,15,72} It is true that the degree of cognitive, physical, emotional, and/or behavioral change that may occur in the athlete following a concussion can be assessed more accurately when compared with information obtained from a preparticipation assessment, the results of the sideline assessment can be interpreted without a preinjury baseline assessment.⁶ Further consideration should be taken when comparing postinjury findings to preinjury baseline assessments as a recent analysis of the test-retest reliability for

many tests and measures used in the baseline assessment have poor to fair test-retest reliability with a 1- and 2-year test interval.⁹⁵

Reevaluate

It is beyond the scope of this chapter to describe the clinical interview and physical examination performed by a physician for a patient presenting with symptoms following a concussion. For a full discussion, the reader is directed to the following reviews: Matuszak and colleagues¹¹⁴; Ellis and colleagues¹¹⁵; McKeag and colleagues¹¹⁶; Kutcher and Giza.⁷²

There is a strong recommendation that the reevaluation include neuropsychological testing (pencil and paper or computerized), which may be administered without a licensed Neuropsychologist or Speech-Language Pathologist (SLP), but requires the knowledge base and skill set of a Neuropsychologist or SLP to interpret the results of the neuropsychological tests.⁷² For the majority of patients, a neurological screening examination will reveal no abnormalities^{17,115}; however, any

focal neurological deficits or severe neck pain presenting with malalignment or radicular symptoms should indicate imaging of the appropriate body area.^{114,115} The objective of the follow-up clinical evaluation, performed by a neurologist or sports medicine physician who is experienced in the examination and treatment of athletes following a concussion, is to determine the diagnosis of concussion, inform medical management, and to determine recommendations for return to play/sport and return to school/learn.

Determination of Diagnosis of Concussion

As mentioned previously, no single test or battery of tests has the absolute sensitivity and specificity to diagnose a concussion; therefore concussion is a clinical diagnosis and requires the judgment of a physician. For this reason, a classification system has been proposed, which is based on the level of certainty for diagnosis of concussion being possible, probable, or definite.⁷² The physician should consider if the mechanism of injury and the signs and symptoms follow a reasonable pattern and time course of concussion. The natural course of concussion being early symptom provocation within the first 1 to 2 days of injury improves gradually over time, given that no introduction to exacerbating activities occurs in that time.^{17,72} Therefore an athlete who was unresponsive for ten seconds following a head-to-head collision in a soccer match who presents 36 hours later with headache, dizziness, and difficulty concentrating while reading would have a reasonable mechanism of injury (witnessed head-to-head collision) combined with a decline in mental status (loss of consciousness) to meet the criteria for a diagnosis of definite concussion. However, in the case of the athlete with a prior medical history of migraine who presents to the physician with complaints of headache, dizziness, and nausea exacerbated by physical exertion, which began 2 weeks

following a cross-country event where the athlete states she “may have hit her head,” concussion is not the most likely cause of the clinical presentation given the absence of a reasonable mechanism of injury, the extensive delay in symptom provocation, and the symptoms that mimic a known comorbidity of migraine. The female cross-country athlete would likely be diagnosed with possible concussion, and the medical management of whether to treat as though this female athlete has a concussion would be the physician’s discretion.

Medical Management

Some postconcussion injury symptoms may be addressed in the early stages with pharmacological therapies. Following concussion, pharmacological agents can be prescribed to treat headache, sleep disturbances, nausea, mood disorders, and cognitive deficits (e.g., attentional deficits), as they are indicated for nonconcussed patients.⁷² Table 23.5 provides examples of commonly prescribed medications and side effects to manage postconcussion symptoms. It is important to note there is limited evidence demonstrating efficacy of such medications to address symptoms following concussion, and to date, there is still no FDA-approved pharmacological treatment for SRC.^{3,14} Expert opinion suggests that medications should be tapered and then limited 2 to 10 days following the concussion, and then stopped by 2 weeks postinjury.⁷² In the case of PPCS, pharmacological interventions should be combined with active rehabilitation programs and lifestyle management for optimal treatment.³

The final outcome of the reevaluation by a physician is to determine return to play/sport and return to school/learn recommendations. Given the absence of a direct method for measuring the pathophysiology of the injury to determine when the neurometabolic cascade has recovered (i.e., physiological recovery), once the patient is asymptomatic, he/she

TABLE 23.5 Commonly Prescribed Medications for Postconcussion Symptoms

Medication	Classification	Side Effects
Migraine Headache		
Aspirin	NSAID	Gastritis, gastrointestinal bleeding, peptic ulcer disease, rebound headache
Acetaminophen	Analgesic	Gastritis, gastrointestinal bleeding, peptic ulcer disease, rebound headache
Triptans	Serotonin 1B/1D-receptor agonists	Dizziness, fatigue, headache, numbness or tingling
Sleep Disturbances		
Trazodone	SSRI	Headache, nausea, vomiting, diarrhea, constipation
Melatonin	Hormone	Drowsiness, headache, nausea, depression
Amitriptyline	TCAs	Nausea, vomiting, drowsiness, weakness, headache
Mood Disorders (Depression)		
Sertraline (Zoloft)	SSRI	Nausea, diarrhea, constipation, vomiting, sleep disturbances, dizziness, fatigue, headache
Citalopram (Celexa)	SSRI	Nausea, diarrhea, constipation, vomiting, stomach pain, heartburn, decreased appetite, weight loss
Escitalopram (Lexapro)	SSRI	Nausea, diarrhea, constipation, change in sex drive, drowsiness, increased sweating, dizziness
Fluoxetine (Prozac)	SSRI	Nervousness, anxiety, sleep disturbances, nausea, diarrhea, weakness, loss of appetite, weight loss
Cognitive Deficits		
Amantadine	Neurostimulant	Diarrhea, constipation, nausea, orthostatic hypotension, increased irritability
Methylphenidate (Ritalin)	Neurostimulant	Elevated heart rate and blood pressure
Donepezil	Acetylcholinesterase inhibitor	Nausea, vomiting, diarrhea, loss of appetite, weight loss, urinary issues

NSAID, Nonsteroidal antiinflammatory drug; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

should engage in routine activity and begin the process of graduated exertion.⁶ For information related to rest and activity guidelines following concussion, see “Recommendations for Return to Play and Return to School/Learn.” A critical point related to return to play that licensed medical providers must consider is that student-athletes must be asymptomatic prior to beginning a graduated return to activity, and should not be taking any pharmacological agents that may mask or modify symptom provocation when the decision to return to full participation is determined.⁶

Risk Reduction/Prevention of Sports-Related Concussion

Perhaps no other topic related to concussion has engrossed the general public more than how to reduce the risk for SRC, especially in children. Many organizations have disseminated information to school personnel, parents, coaches, athletes, and clinicians related to prevention of SRC. The most well-known program is the CDC’s “Head Up to Schools: Know Your Concussion ABC’s.” As a result of the high incidence of concussion and the limited knowledge of the long-term consequences associated with concussion (e.g., chronic traumatic encephalopathy [CTE], dementia, mental health disorders), there has been misinformation related to what types of actions and/or policies are effective in reducing the risk of concussion. Table 23.6 provides a list of factors and characteristics associated with concussion risk.

It is well documented that a history of prior concussions is a strong risk factor for subsequent concussion.⁶ Guskiewicz and colleagues found a dose-response relationship between the number of prior concussions and the likelihood of sustaining a future concussion, where collegiate football players with a history of three or more previous concussions were three times more likely to sustain a concussive injury than those without a history of concussion.¹²⁰ It is difficult to determine if these individuals have a decreased threshold/increased vulnerability due to never achieving a full physiological recovery, or if the phenomenon could be explained by “history repeating itself,” as these

individuals continue to put themselves in high-risk situations that increase the likelihood of sustaining a sufficient blow to the body/head. Still, this explains the importance of obtaining information related to the number of previous concussions in a medical evaluation (preparticipation baseline assessment or reevaluation), as the athlete can be identified as high-risk for concussion, which should impact future decisions made by the medical team. Identification of high-risk athletes can also be an opportunity for education to the athlete related to SRC prevention. The strongest and most consistent evidence leading to decreased incidence of SRC has been the adoption of policy to eliminate body checking in ice hockey for youth under the age of 13.⁶ Other strategies used with the objective to reduce risk for SRC, such as helmets in American football and soccer or use of mouthguards, have not provided clear results in decreasing the risk for SRC.⁶ Perhaps most surprising is the evidence that policy changes for fair play rules in youth ice hockey, tackle training without helmets and shoulder pads in youth American football, and tackle technique training in professional rugby do not lead to a reduction in SRC risk.⁶ There is also insufficient evidence to determine whether age or level of competition (e.g., youth, collegiate, amateur, professional) increases the risk of SRC¹⁵; however, the argument could be made for continued attention toward reducing risk of SRC in children due to the potential added vulnerability of the developing brain at this age.

Potential Long-Term Effects Associated With Sports-Related Concussion

There is evidence that some former athletes in contact and collision sports experience depression and cognitive deficits later in life.¹²¹ In addition to impaired clinical findings, there is evidence from advanced neuroimaging and electrophysiological studies of changes in brain function, activation patterns, and white matter fiber tracts in athletes with PPCS months and years following injury.⁵⁸ Perhaps more concerning, such structural and physiological changes have been identified even when the athlete has achieved clinical recovery (e.g.,

Prior history of multiple concussions⁶

^aIndicates independent significant association with poor outcome, slow recovery, and/or persistent postconcussion symptoms.

asymptomatic at rest and with cognitive and physical exertion) and returned to play.⁵⁸ For example, Gosselin and colleagues¹²² found a reduction in amplitude and increased latency in auditory evoked potentials in 20 symptomatic and asymptomatic athletes compared with 10 control athletes. Interestingly, the asymptomatic athletes had a similar electrophysiological profile to that of the symptomatic athletes, suggesting continued physiological impairment in athletes who were determined to be clinically recovered. At this time, it is unclear how to interpret these findings as abnormal brain activation patterns and white matter tract findings are not specific to concussion injury, and, due to a lack of methodologically sound, longitudinal investigations, the impact of structural and functional changes in neuroimaging studies on an individual's function across his or her life-span is unknown.

Due to the current level of discourse related to the association between neurodegenerative disease (e.g., Alzheimer disease and CTE) and concussion, it is worth discussing the state of evidence for the causal relationship between these two conditions. The most extensive review related to long-term effects of SRC was completed by Manley and colleagues,¹²¹ who reviewed 47 studies that investigated neuroimaging, clinical, and neuropathology outcomes in athletes who sustained a concussion. The authors concluded there is emerging evidence that some retired athletes have mild cognitive impairment, neuroimaging abnormalities, and differences in brain metabolism disproportionate to their age, and there is an association between cognitive and psychological deficits and a history of multiple concussions in former athletes. However, the authors emphasize that *the majority* of former athletes report functioning at a similar level to the general public and are not at increased risk for death by suicide. Further, former high school American football players do not appear to be at increased risk for neurodegenerative diseases later in life. Finally, in terms of the link between CTE and repeated neurotrauma, there is consensus that a cause-and-effect relationship has not been established between neurodegenerative disorders and SRCs or exposure to contact sports; thus the implication that repeated concussion causes CTE remains undetermined.^{6,121}

Retirement From Sports

For a select number of athletes, it may be important for medical professionals to discuss retirement from continued participation in sports-related activities, especially those with increased risk of concussion in contact or collision sports. At the foundation of this decision is consideration of the potential risks of prolonged or permanent neurological effects weighed against the positive aspects of continued participation in the sport, which may include the athlete's personal athletic goals (e.g., future aspirations of participation at a professional level), financial incentives (e.g., scholarship or athletics as a career), and/or the individual's identity as an athlete.¹²³ Unfortunately, the decision for retirement depends on many factors, for which there is limited supportive evidence to be used for guidance as there is uncertainty related to the long-term effects of repeated concussion.¹²¹

Kutcher and Giza⁷² provide three scenarios that medical professionals should consider in the decision to recommend retirement from contact sports: (1) evidence of a clear lowering of a threshold for injury, meaning that over time, less force is required for an athlete to acquire postconcussion symptoms; (2) cases where the clinical syndrome is more severe than the average presentation and may last for several weeks, which outweighs the benefits of playing the sport; and (3) cases where an athlete demonstrates objective signs of declining or persistently impaired brain function (e.g., neuropsychological testing and/or diminished academic/work performance) without a plausible explanation other than exposure to impact forces (e.g., depression,

migraine headache). In addition to the considerations provided by Kutcher and Giza, medical professionals may use the Columbia SRC Retirement Algorithm proposed by Davis-Hayes and colleagues¹²³ to determine when a *discussion* related to retirement from sport may be indicated versus circumstances where a *recommendation* for retirement from sport should be provided to an athlete. For example, medical professionals should provide a recommendation for retirement where there is evidence of structural abnormality on routine neuroimaging (e.g., frontotemporal contusions or gliosis). Conversely, in cases where the cumulative effects of repeated concussions lead to relative contraindications for continued exposure, retirement from sports or recommendations for a replacement activity with reduced risk for contact or collisions¹²³ may be warranted. Symptoms or neurological signs persisting greater than 3 months, persistent cognitive impairment, diminished academic performance or social engagement, and evidence of a decreased threshold to trigger postconcussion symptoms may be useful criteria to suggest altered activities to prevent further injury.

CONSIDERATIONS FOR REST AND RETURN TO PLAY/LEARN FOLLOWING SRC

The rationale for rest draws from findings that functional injury and physiological dysfunction due to a neurometabolic crisis⁴⁴ may worsen in the presence of increased physical¹²⁴ and cognitive¹²⁵ load, suggesting the existence of a vulnerable period where the brain may be susceptible to further dysfunction or injury.^{44,126,127} This has been shown in mice that exhibited impaired cognitive function when subjected to a second concussive brain injury within 3 or 5 days of the initial injury, but those subjected to a second injury at a later time (day 7 postinjury) showed normal cognitive function.⁹¹ Similarly, Griesbach and colleagues found rats with an mTBI exposed to exercise within the first week of injury had impaired cognitive performance (learning acquisition and memory) compared with rats with delayed exposure to exercise 14 to 20 days after injury.⁹² Likewise in humans, Majerske and colleagues reported that strenuous physical and cognitive exertion in acute concussion leads to poorer neurocognitive outcomes in adolescent athletes following an SRC.¹²⁸ Such findings suggest that rest following concussion may be necessary to (1) reduce the potential for a repeat concussion (e.g., second impact syndrome) while the brain may still be vulnerable from the initial concussion^{44,120} and (2) facilitate recovery by preventing excessive physiological demands (e.g., physical exertion) that may hinder restoration of normal neurotransmission and neurometabolic function.^{129,130}

Although rest has been considered a cornerstone of best practice^{5,6,129,131–133} and is widely prescribed in the care of individuals who have sustained a concussion,¹³⁰ it has not been well defined. The term “rest” is quite broad when one considers the range of tasks children and adults engage in during daily activities. When a physician or medical professional provides instructions for rest, does she mean complete withdrawal from all recreational, social, academic, and work-related activities? Only some of those activities? Or is it the intensity of the activities that matters most? Perhaps not surprisingly, there are variations in what might qualify as rest. Thomas and colleagues¹³¹ recommended 5 days of what the authors defined as “strict rest,” which consisted of rest at home (specifically, no school, work, or physical activity) for which participants were provided excuses for missed days of school and work. Buckley and colleagues¹³⁴ provided a more detailed list of what constituted physical and cognitive rest. For 40 consecutive hours, student-athletes were instructed not to attend any classes, team meetings, or study hall, and not to perform any

academic work. Participants were provided medical documentation for class absence, and coaches were informed of the restrictions for team activities. Further, to decrease cognitive load, participants were to refrain from excessive television, computer, or other electronics usage, and to limit text messaging, although no operational definitions of what constituted excessive or how much time to limit activities were provided. Finally, to encourage physical rest, student-athletes were withheld from all athletic activities, personal exercise, and instructed to rest in a quiet environment throughout the day.¹³⁴ Moser and colleagues¹³⁵ provided parents and adolescent athletes with a more exhaustive list of cognitive and physical activities to avoid, which included attending school, taking tests or notes, doing homework, performing general household chores, driving, taking trips outside of the home, visually watching TV, playing video games, using a computer or phone, reading, playing a musical instrument, engaging in aerobic exercise, or lifting weights. Participants were advised to avoid activities that might produce a sweat or exacerbate symptoms but were encouraged to engage in light exertion activities such as listening to an audiobook, relaxing music, or low-volume TV, folding laundry, setting the table, taking a slow walk outside, sleeping, and visiting with family members in the home. The examples of these three studies^{131,134,135} show the variability in protocols for rest. Perhaps not surprisingly, there were mixed results in terms of persistent burden of symptoms, return to play/school, and performance on standardized physical and cognitive tests found across these three studies. Moser and colleagues¹³⁵ reported benefits following 1 week of restricted activity, whereas Thomas and colleagues and Buckley and colleagues found worse outcomes associated with rest.^{131,134}

There is also variation related to the optimal amount of time an individual should rest following a concussion. There is agreement across international consensus, practice guidelines, and position statements^{6,9,136,137} that an athlete should rest until asymptomatic. Using this recommendation, some medical professionals instruct athletes to spend several days in a darkened room (a type of rest referred to as “cocoon therapy”)¹³⁸ or recommend prolonged rest where physical and cognitive activities are discouraged for weeks, months, or even longer, especially in children.¹³⁰ Although it may be advantageous in a minority of cases to recommend an extended period of rest in children,^{6,132} there is convincing evidence emerging in the literature that shows rest, especially strict rest (e.g., withdrawal from all activities), and prolonged withdrawal from physical and cognitive activity during recovery of the acute concussion are associated with increased symptom burden^{131,134} and delayed recovery.^{128,131} The detrimental effects of prolonged rest and activity withdrawal are thought to occur, in part, because of anxiety formed by a patient’s expectations of a lengthy recovery, physical deconditioning that can mimic postconcussive symptoms such as sleep disturbances and fatigue, and psychological complications arising from an inability to cope with reduced participation in life activities.^{129,130} To this last point, one must consider the importance of self-identity, autonomy, and social engagement through recreational, sport, school, and work-related activities in adolescents. Current concussion management involves withdrawal from these activities, and an unintended consequence may be that missing social interactions and falling behind academically may contribute to an exacerbation of physical and emotional symptoms in some individuals.^{130,131} This may help explain why it seems that adolescents are at greatest risk for experiencing PPCS, leading to a protracted recovery. Therefore medical professionals must be observant of this phenomenon for all individuals, but especially for adolescents, who may require additional encouragement of the likely positive outcome following concussion and potentially a referral for psychological or counselling services.

What Is the Evidence for Physical and Cognitive Activity in Acute Concussion?

Conversely, there is evidence that rather than strict rest, engaging in moderate levels of physical and cognitive activity can be beneficial for decreasing the burden of postconcussion symptoms,¹³⁹ promoting earlier return to baseline performance on standardized neuropsychological and physical assessments,¹²⁸ earlier return to play/sport,¹⁴⁰ and earlier return to school/work.¹⁴⁰ Majerske and colleagues¹²⁸ performed a retrospective chart review and found that individuals who engaged in moderate levels of exertion (slow jogging and sports practice) demonstrated better outcomes on neuropsychological testing compared with individuals with the least (no school or exercise) or greatest (full school and competition participation) level of activity. Lawrence and colleagues¹⁴⁰ reviewed charts of adolescents (aged 15 to 20 years) who engaged in either self-initiated or physician-prescribed physical activity within 14 days of an SRC. Although each athlete was symptomatic at the time of initiating aerobic exercise, the authors reported a shorter time to initiation of aerobic exercise (e.g., earlier physical activity) was associated with faster full return to sport and school/work-related activities.¹⁴⁰ Grool and colleagues¹³⁹ conducted a large prospective study investigating the association between participation in physical activity within 7 days and PPCS in children aged 5 to 18 years. Participants who met the criteria for concussion as defined by the CISG¹⁷ completed surveys (via internet or phone) related to current level of physical activity and symptom complaint (using the PCSI). Among 2413 participants, 69.5% participated in some form of physical activity within 7 days following concussion, primarily with light aerobic exercise, which was associated with lower risk of symptom complaint at 28 days compared with no physical activity. The proportion of participants with PPCS at 28 days was 28.7% compared with 40.1% for those engaging in early physical activity versus no activity, respectively.¹³⁹ Therefore it appears that moderate physical and mental activity during the acute phase of recovery may be beneficial.

What Criteria Should Be Used to Determine Recovery?

Similar to diagnostic testing, at this time there is no single test or biomarker that can be used to determine prognosis for recovery following concussion.^{5,44} Here, it is important to distinguish two types of recovery: clinical recovery and physiological recovery. Clinical recovery is the proxy that medical professionals (typically a neurologist, sports medicine physician, or rehabilitation medicine physician) use to determine an individual is able to perform all previous life activities without presence or exacerbation of baseline symptoms. The operational definition of clinical recovery provided by the CISG⁶ encompasses a *resolution* of postconcussion-related symptoms and a *return to clinically normal* balance and cognitive functioning, which results in a return to normal activities, including school, work, and sport. However, using clinical recovery as the benchmark for return to activities, it is unclear to what extent there is continued physiological dysfunction (e.g., impaired metabolic activity, abnormal synaptic and neurotransmission, impaired cerebral blood flow, inflammation), as neurobiological recovery might extend beyond clinical recovery in some individuals. Results from neuroimaging studies^{44,141–144} suggest that physiological recovery time may outlast the time to clinical recovery.⁶ However, many of the neuroimaging techniques used to identify such dysfunction are not available in most medical clinics and are not used as a standard of care for individuals following concussion. Further, abnormalities found on neuroimaging studies are not specific to injury following concussion. Still, advanced neuroimaging and fluid biomarkers continue to be investigated for use in identifying physiological recovery.

At this time, fluid biomarkers to identify concussion injury are in development and are critical to the ability to diagnose and determine prognosis for recovery. On February 14, 2018, the FDA released approval for TBI Endpoints Development (TED) and TRACK TBI to study ubiquitin carboxyl-terminal hydrolase L1 (UCH-L1) and glial fibrillary acidic protein (GFAP), which are proteins released from the brain into the blood after brain injury.¹⁴⁵ A multicenter prospective study of 1947 adult blood samples showed that the Banyan Brain Trauma Indicator, a blood test that measures the presence of UCH-L1 and GFAP, was able to predict intracranial lesions that would not appear on standard imaging (e.g., computed tomography).¹⁴⁷ Many other neuroimaging techniques and biomarkers for impaired neuroplasticity, inflammatory processes, and autoimmune antibodies are being investigated to better understand factors associated with comorbidities and prolonged recovery. For a discussion on neuroimaging and fluid biomarker research in concussion, the reader is referred to the following reviews: Makkissi and colleagues,⁵⁸ Kevin and colleagues,¹⁴⁸ Dambinova and colleagues,¹⁴⁹ and Schmidt and colleagues.⁴⁶

The physician must rely on behavioral measures as a proxy for recovery; therefore at this time, recovery is synonymous with clinical recovery because the full physiological recovery process remains unclear. For this reason, clinical recovery constitutes waiting until the patient is asymptomatic and has returned to baseline on cognitive and physically based performance measures,^{6,9,150} before initiating a graduated return-to-play (RTP) strategy.⁵

Recommendations for Return to Play and Return to School/Learn

Statements generated from international consensus, position statements, practice guidelines, and reviews related to RTP (also referred to as return to sport⁶ and return to activity) can be found in [Box 23.1](#).

Recommendations for Return to Play

International consensus makes the following recommendations for RTP progression⁶:

1. An athlete diagnosed with a concussion should not be allowed to return to practice/competition the same day.⁶ This recommendation is made to reduce the potential for a repeat concussion and decrease the risk for the rare but dangerous second impact syndrome.^{24,44,120}
2. After a brief period of initial rest (24 to 48 hours), symptom-limited activity can begin while staying below a cognitive and physical exacerbation threshold⁶ (see stage 1 in [Table 23.7](#)). As there is no single test (or combination of tests) that can be used to determine physiological recovery, the clinician must use clinical recovery (ability to perform activity without symptom exacerbation) as a guide. Therefore the patient should be encouraged to engage in light-to-moderate-intensity, symptom-limiting physical and mental activities in order to avoid the detrimental effects of full withdrawal from activity^{129,131,134} that may delay recovery^{128,131} and potentially facilitate recovery.^{128,139}

BOX 23.1 Recommendations From International Consensus, Position Statements, and Practice Guideline for Return to Play and Return to School/Learn

Considerations for Return to Play and Return to School/Learn

Return to Play

- Management of concussions include no same-day RTP^a and prescribed physical and cognitive rest until asymptomatic.^{3,5,6,9,137}
- Although most individuals follow a rapid course of recovery over several days to week following injury, concussions may involve varying lengths of recovery.^{3,5,6,9}
- In the presence of continued symptom complaint following concussion, verbal or written education should be provided for reassurance that a good recovery is expected.^{9,130}
- There is limited empirical evidence for the effectiveness of prescribed physical and cognitive rest.^{3,6}
- Prescribed physical and cognitive rest may not be an effective strategy for all patients following concussion.³
- Strict brain rest (e.g., stimulus deprivation, “cocoon” therapy) is not indicated and may have detrimental effects on patients following concussion.^{3,5,130,151}
- There is limited empirical evidence that physical and mental activity may be beneficial in acute concussion.³
- Return to school protocol should be prioritized over a return to sport strategy, so that the student-athlete should return to school with academic accommodations (if necessary) prior to advancing with return to sport progression.⁶
- Graduated activity strategy/progression should be used to guide a clinician’s decision making for RTP.^b
- Existing RTP progressions require validation as this approach has not been substantiated with prospective, randomized controlled comparative-effectiveness trials.¹³³

Return to School/Learn

- When initiating return to cognitive (school-related) activities, there is a strong recommendation for academic accommodations,^{3,5,6,152} which may include the following areas: attendance,¹⁵¹ curriculum,^{137,150,151,153} environmental modifications,^{151,153} and activity modifications.^{137,150,151,153}
- Concussions may involve varying lengths of recovery, with adolescents at greatest risk for protracted recovery. It may therefore be advantageous, in a minority of cases, to recommend an extended period of rest in children.^{6,151}
- If symptomatic within first 72 h, the student should refrain from attending school and participation in all academic activities, to support cognitive rest and facilitate recovery.⁵ A more conservative approach that children, symptomatic or asymptomatic, should stay away from school for 1 week has been recommended.¹⁵¹
- If symptomatic after 72 h postinjury, the student should refrain from attending academic activities for 1 full week.⁵
- After 2 weeks postinjury, the student should start attending school (non-physical activities) with accommodations, even if he/she is still experiencing symptoms, to prevent psychological complications.^{5,151}
- If reintegration into school is ineffective or unproductive at 4 weeks (symptoms persist or worsen), consider (1) greater academic accommodations, (2) move student’s courses to audit status, or (3) consider whether student should continue in program for that term/semester.⁵

RTP, Return to play.

TABLE 23.7 International Consensus for Graduated Return to Sport Strategy and Return to Participation Protocol

Stage of Rehabilitation	Functional Exercise	Objective of Each Stage
No activity	Complete physical rest	Recovery
Light cardiovascular activity	Stationary bike, walking, swimming, light skating	Increased HR and CBF
Sport-specific activity	Interval training, conditioning drills, running or skating drills, ball work sprints, etc.	Fluctuation in HR adding cognitive function to activity, adding movement
Noncontact practice	Complex training drills, noncontact team practices	Increased cognitive load, assess coordination and processing speed
Full-contact practice	Participation in normal training activities—only with medical clearance	Assess functional skills, assess for recurrence of symptoms by applying smaller magnitude of forces, ensuring self-confidence, and readiness to play
RTP	Full participation in game play	

CBF, Cerebral blood flow; HR, heart rate; RTP, return to play.

Adapted from McCrory P, Meeuwisse W, Johnston K, et al. consensus statement on concussion in sports, 3rd International Conference on Concussion in Sport held in Zurich, November 2008. *Clin J Sport Med.* 2009;19(3):185–200.

- Once concussion-related symptoms have resolved, the athlete should continue to proceed to the next level (see stage 2, Table 23.7) if he/she meets all the criteria (e.g., activity, heart rate, duration of exercise) without a recurrence of concussion-related symptoms.⁶ At this stage, the medical professional, including the rehabilitation specialist, may use a subsymptom exercise tolerance test¹⁵⁴ (Fig. 23.3) to guide exercise recommendations.
- In general, each step should take 24 hours, so that athletes would take a minimum of 1 week to proceed through the full rehabilitation protocol once they are asymptomatic at rest.⁶ If any concussion-related symptoms occur during the stepwise approach, the athlete should drop back to the previous asymptomatic level and attempt to progress again after being free of concussion-related symptoms for a further 24-hour period at the lower level.⁶
- The time frame for RTP may vary with player age, history, and level of sport; therefore management must be individualized.⁶
- For RTS, athletes should be symptom free, but also should not be taking any pharmacological agents that may mask or modify the symptoms of concussion at the time of returning the athlete to full participation in sport.^{5,6}

Recommendations for Return to School/Learn

Statements generated from international consensus, position statements, practice guidelines, and reviews related to return to school/learn can be found in Box 23.1. Similar to RTP, providing cognitive rest

and academic accommodations are two foundational components of return to school/learn protocols.^{5,6,151} Removal from school-related activities until students are asymptomatic, followed by a graduated return to school-related activities (e.g., reading/writing, studying, homework), as the student can complete the tasks at a tolerable level has been recommended.^{5,6} When returning to school-related activities, it has been reported that as many as 73% of students have academic difficulty,¹⁵⁵ which may substantiate the recommendation for instituting academic accommodations that may include the following: extension of assignment deadlines, rest periods during the school day, postponement or staggering of tests, reduced workload, and/or accommodation for light or noise sensitivity.¹⁵³ Such findings likely explain reports that student-athletes who sustain a concussion receive more academic accommodations and take longer to return to school compared with their student-athlete counterparts who sustain musculoskeletal injuries to other body parts.¹⁵⁶

Although consensus and position statements recommend immediate withdrawal from school-related activities for 48 hours,⁶ 72 hours,⁵ and up to 2 weeks^{5,151} following injury, the level of evidence supporting such recommendations is limited^{128,157} (primarily based on prospective observational or retrospective reviews), as to date there are no multicenter randomized controlled trials (RCTs) validating the recommendations. In fact, there is evidence from a randomized control trial in children aged 11 to 22 years, which showed withdrawal from mental activity in acute concussion led to poorer outcome.¹³¹ Thomas and colleagues¹³¹

Fig. 23.3 Exercise Prescription Guided by Results of a Subsymptom Exercise Tolerance Test. Use of a subsymptom exercise tolerance test, Buffalo Concussion Treadmill Test (BCTT), and exercise prescription for return to activity for individuals with exercise intolerance following concussion, as described in Leddy and Willer.¹⁵⁴ APMHR, Age-predicted maximum heart rate; bpm, beats per minute; CISG, concussion in Sport Group; HR, heart rate; HRT, heart rate achieved at symptom-exacerbation determined by stopping criteria.
^aAfter 3 weeks of persistent symptoms; ^b5 bpm for nonathletes, 10 bpm for athletes.

found a longer time to symptom resolution for students instructed to rest at home (e.g., no school-related work or physical activity) for 5 days compared with students who were provided instructions to rest for 24 to 48 hours prior to engaging in mental and physical activities below an exacerbation threshold. Evaluation of patient adherence in this study showed the physician's instructions did not significantly alter the amount of physical activity between groups, but did lead to a decreased amount of time spent performing mental activities in the strict rest group, which, in practice, suggests a detrimental effect on burden of symptoms due to withdrawal from cognitive activities alone (as physical activity levels were similar between groups). Again, withdrawal from social engagement with school-related activities and falling behind academically may contribute to an exacerbation of symptoms in some children.^{130,131} In summary, similar to guidelines for RTP, return to school/learn recommendations lack strong evidence to support statements (see [Box 23.1](#)). This should emphasize the importance of a balanced approach between cognitive and physical rest with activity that should be modified to account for the age, severity of initial symptom complaints, and premorbid health conditions that may impact length of recovery.

PROGNOSIS AND OUTCOMES FOLLOWING CONCUSSION

Prognosis and Outcomes Following Sports-Related Concussion

There is a critical need to determine demographic characteristics and clinically relevant factors that are associated with clinical recovery prior to injury, at the time of injury, and postinjury. Such information would be useful for decision making for medical and rehabilitation approaches. For example, demographic and preinjury characteristics could be used by medical professionals to identify athletes who are at high risk for developing PPCS during preparticipation screenings and ensure careful monitoring and appropriately timed referrals for pharmacological and/or rehabilitation therapies in the event of a concussion. In addition, knowledge of variables at the time of injury and following the injury that contribute to a protracted recovery could impact clinical decision making for medical professionals on the field and in the clinic to better utilize resources for those at highest risk for protracted recovery, to promote successful and timely return to play and return to learn strategies.

The Predicting and Preventing Postconcussive Problems in Pediatrics (5Ps) study¹¹⁹ was designed to develop and validate a clinical risk score in order to stratify PPCS risk after acute concussion in children and youth. Zemek and colleagues¹¹⁹ completed a multicenter cohort study from 9 pediatric EDs within the Pediatric Emergency Research Canada network, where children aged 5 to 18 years underwent a comprehensive evaluation in the ED and completed electronic surveys at 7, 14, and 28 days following a diagnosis of concussion.¹⁷ Out of 47 risk factors associated with PPCS (defined as 3 or more new or worsening symptoms as measured by the PCSI at 28 days compared with prior injury state), Zemek and colleagues¹¹⁹ found 9 factors that independently predicted PPCS at 28 days, including age, sex, prior concussion and symptom duration, physician-diagnosed migraine history, answering questions slowly, number of errors for BESS tandem stance position, headache, sensitivity to noise, and fatigue. Depending on the PPCS risk score, the group was able to establish a probability of developing PPCS at 28 days. Although the clinical utility of the PPCS risk score needs to be established, the use of such a stratification system has the potential to individualize concussion care and lead to the identification

of children who are at risk for developing PPCS during the acute stage of recovery following a concussion.

A systematic review completed as a part of the CISG conference⁶ synthesized the evidence regarding predictors of clinical recovery following concussion.¹¹⁷ In general, Iverson and colleagues reported that the literature is mixed with positive and negative findings related to predictive factors of clinical recovery, because many of the included studies were found to use different criteria to establish clinical recovery, which made it difficult to provide definitive conclusions.¹¹⁷ Still, Iverson and colleagues¹¹⁷ reported that preinjury mental health problems (prior personal or family psychological history), especially depression, and prior concussions appear to be risk factors for PPCS. Importantly, adolescent years might be a particularly vulnerable time for experiencing persistent symptoms, with greater risk for girls than boys.^{6,15,115,117}

It is also worth noting the variables that were not found to be associated with increased risk for protracted recovery or the development of PPCS, such as complaint of dizziness, initial severity of cognitive deficits, or development of oculomotor dysfunction, and individuals with prior cognitive and learning disabilities, and individuals with prior cognitive and learning disabilities (e.g., attention deficit hyperactivity disorder). There were also inconsistent findings related to "Red Flags" and memory assessment (e.g., loss of consciousness and posttraumatic amnesia) at the time of injury leading to PPCS.

A list of factors associated with increased risk for PPCS (continued symptoms beyond 14 days in adults and 28 days in children) is provided in [Table 23.6](#).

Prognosis and Outcome Following Non-Sports-Related Concussion in Adults

To date, most studies evaluating outcomes for individuals following concussion have been directed almost exclusively toward clinical recovery after SRC. However, young and older adults sustain mTBI due to falls, motor vehicle accidents, physical assault, and participation in recreational activities. Similar to student-athletes, the majority of adults who sustain a concussion will resume normal activities within 10 to 14 days; however, a minority of these individuals will endorse PPCS and experience a slow return to participation in meaningful activities,⁵⁵ perhaps the most important of which is return to work (RTW).

Following concussion, perhaps due to instructions provided by a physician, but more than likely due to postconcussion symptoms, many patients will miss work for a period of time. Absence from work can lead to lost or reduced income, psychological stress due to pressures placed on family relationships, and secondary physical and mental health conditions due to prolonged withdrawal from typical activities (e.g., deconditioning and psychological distress). All of these factors can add to normal work-related, household, and financial stressors already present in most adult's lives.¹⁵⁸

Because of various external or internal pressures, some adults will RTW while still symptomatic,¹⁵⁹ which can lead to an unsuccessful return and more time away from productive work, resulting in profound negative financial and emotional consequences.¹⁶⁰ Even for those whom are asymptomatic, it is possible that the increased physical or cognitive load may cause somatic, cognitive, emotional, and/or behavioral impairments. Despite these well-known complications that can create barriers for successful RTW, there is a paucity of literature related to RTW following mTBI.

The International Collaboration on mTBI Prognosis group completed a systematic review of the literature from 2001 to 2012 to update

the previous World Health Organization Collaborating Centre Task Force on mTBI findings on RTW in 2004.¹⁶¹ The group reported most workers returned to work within 3 to 6 months¹⁶²; however, RTW rates varied widely based on the time from injury and the geographic area of the investigation. For example, as many as 84%¹⁶³ and as little as 41%¹⁶⁴ of individuals were found to RTW 1 week following mTBI, while other investigations reported a range of 25% to 100% of individuals returning to work 1 month postinjury.¹⁶⁰ Wäljas and colleagues¹⁶⁰ followed a group of 109 patients with an average age of 37.4 years, 76% of whom were working full time, 5.6% working part time, with the remaining patients being students, who were diagnosed with an mTBI at a University Hospital ED in Finland, and found the vast majority of the group (91.7%) returned to work within 2 months. Due to the repeated measure design of the study, the following RTW rates were reported; 46.8% RTW at 1 week, 59.6% RTW at 2 weeks, 70.6% RTW at 1 month, 91.7% RTW at 2 months, and 97.2% RTW at 1 year following mTBI.¹⁶⁰

One major limitation of studies investigating RTW following mTBI is considering whether the patient achieves a full return to preinjury work-related activities. Two studies have somewhat disparate findings for full RTW rates at 6 months following injury, where 41.7% of individuals presenting to an outpatient concussion clinic¹⁶⁵ and 76% of individuals presenting to an ED¹⁶⁶ were reported to have a full RTW 6 months postinjury.

Perhaps it is obvious that work disability includes time off from work and sick leave, but it also incorporates reduced productivity or working with functional limitations.^{162,167} However, few studies have evaluated RTW as a continuum based on a RTW hierarchy considering reduced workload, a change in roles/responsibilities, or lower productivity due to functional impairments such as cognitive deficits or symptom provocation.^{66,159,165,168} Evaluating RTW as a dichotomy (employed vs. unemployed) rather than a hierarchy can lead to a drastic underestimation of disability an individual may experience when attempting to fully return to preinjury work. In 79 patients recruited from concussion specialty clinics in Vancouver, Canada, Silverberg and colleagues¹⁶⁵ reported that although 58.2% (46) of patients returned to any level of work, only 41.7% of patients fully returned to their preinjury work responsibilities at 6 months following injury. Importantly, at 6 months, 1 in 4 patients who had returned to work were still on modified duties, working reduced hours, or receiving accommodations, or took a different, less demanding job. Further, nearly 50% of patients who fully returned to work continued to report multiple somatic, cognitive, and emotional symptoms.¹⁶⁵

A secondary objective of the study by Wäljas and colleagues¹⁶⁰ was to examine factors that influence RTW status in individuals who are slow to recover following mTBI. Wäljas and colleagues¹⁶⁰ concluded appearance of the following combination of factors within the first 4 weeks following mTBI strongly predicted RTW status: age, multiple bodily injuries, intracranial abnormalities on CT scan the day of injury, and fatigue ratings. Consistent with other studies, the authors reported that injury severity variables (e.g., duration of unconsciousness, Glasgow Coma Scale score, and duration of posttraumatic amnesia) were not associated with length of time to RTW.^{160,169}

Based primarily on the Veteran's Affairs/Department of Defense (VA/DoD) Clinical Practice Guideline for Management of Concussion/mTBI, Marshall and colleagues provided the following recommendations for RTW following a concussion⁵:

- In some cases, vocational modifications are required and may include:
 - Modification of the length of the workday
 - Gradual work reentry (e.g., starting at 2 days/week and expanding to 3 days/week)
 - Additional time for task completion

- Change of job
- Environment modifications (e.g., quieter work environment)
- Individuals who continue to experience persistent impairments following mTBI or those who have not successfully resumed preinjury work duties following injury should be referred for an in-depth vocational evaluation by clinical specialists and teams (e.g., occupational therapist, vocational rehabilitation counsellor, occupational medicine physician, neuropsychologist, SLP) with expertise in assessing and treating mTBI.
- A referral to a structured program that promotes community integration (e.g., volunteer work) may also be considered for individuals with PPCS that impede return to preinjury participation in a customary role.

Prognosis and Outcomes Following Mild Traumatic Brain Injury in Military Personnel

Advances in the types of weapons used in warfare over the last 25 years have led to changes in the types of injuries inflicted on military personnel in combat. As a result, mTBI has been referred to as the “signature” injury of the two most recent US military operations in Afghanistan and Iraq,^{170–172} where 15% to 22% of deployed US military service members sustained an mTBI.^{172,173} Although service members may sustain an mTBI from falls, motor vehicle accidents, blunt head trauma, or recreational activities, blast-induced mTBI are the most concerning, not only because of the high frequency at which they occur (accounting for 78% to 80% of all injuries sustained in combat),¹⁷⁴ but also the limited understanding of how blast-induced mTBI differentially impacts outcome in service members.

Similar to SRC and non-SRC in the civilian population, blast-induced mTBI can lead to somatic, cognitive, behavioral, and emotional symptoms. One key difference is the increased risk for severe psychological effects that impact recovery from mTBI in military personnel.^{175,176} It has been estimated that as many as 44% of deployed US military return from combat with posttraumatic stress, depression, and/or anxiety.¹⁷⁷ This is problematic, as it is clear from the literature in mTBI that psychological problems negatively impact recovery and may lead to slow recovery in service members, resulting in delayed return to duty (RTD) following injury. Although many reports have concluded most service members with combat related mTBI recover within 7 days, Kennedy and colleagues¹⁷⁶ evaluated rates of RTD in 377 US service members who sustained a concussion (52% with a loss of consciousness) while serving in Afghanistan and found 51.1% experienced an average RTD 7.6 days (range 0 to 13 days) following injury, whereas 48.9% experienced a delayed average RTD 24.4 days (range 14 to 51 days) following mTBI. The findings showed that in comparison to the recovery times for SRC, recovery time appears to be far greater in blast-induced mTBI.¹⁷⁶

Just as it is important to ensure that athletes are asymptomatic with physical and mental exertion prior to RTP in order to decrease the risk of secondary injury (musculoskeletal injuries^{178,179} as well as second impact syndrome), it is important that service members be able to perform a combat role effectively before RTD. Perhaps, because of the serious nature of responsibilities, full recovery is even more important for service members because RTD too soon has the potential to lead to catastrophic consequences.¹⁷⁶ The VA/DoD clinical practice guideline¹⁸⁰ for RTD recommends that all service members exposed to a potentially concussive event should be screened using the Military Acute Concussion Evaluation (MACE), a clinical assessment tool that was developed to assess the subjective symptom report, cognitive performance, and the neurological status (via a gross neurological screen) at the point of injury by a field medical provider. The cognitive

performance section is based on the SAC,⁷³ and the neurological screen involves an assessment of visual, speech, and motor capacity. Regardless of the results, service members are required to rest for at least 24 hours¹⁸⁰; however, beyond the initial rest period, there seems to be discrepancies in RTD strategy, as some studies require full symptom resolution at rest and during an aerobic exertional test, as well as neuropsychological testing (Automated Neuropsychological Assessment Metric [ANAM] results that are consistent with predeployment testing¹⁷⁶). Conversely, the VA/DoD clinical practice guideline provides a strong recommendation not to use neuropsychological tests such as the ANAM or the ImpACT within the first 30 days of concussion to guide decision making.¹⁸⁰

Mac Donald and colleagues¹⁷⁵ compared outcomes from 50 active-duty US military who sustained a blast-induced concussion to 44 combat-deployed control service members at 1 year and 5 years to investigate the long-term consequences of blast-induced mTBI. At 5 years postinjury, service members who sustained a blast-induced mTBI fared worse than their nonconcussed counterparts on global outcome measures (Glasgow Outcome Scale and Quality of Life After Brain Injury), reported greater headache impairment, and had significantly more mental health issues, including posttraumatic stress, depression, anxiety, and disrupted sleep. Further, Mac Donald and colleagues¹⁷⁵ reported that a number of service members with blast-induced mTBI continued to experience a worsening of symptom severity from 1-year to 5-year follow-up, which points to the need for effective treatments in this group of individuals. At this time, the VA/DoD clinical practice guideline¹⁸⁰ emphasizes that active and pharmacological therapy protocols should use a targeted approach to address delayed recovery and PPCS after blast-induced mTBI that matches the therapy to the clinical presentation and symptom complaint rather than the mechanism of injury. For information related to active therapy for service members with slow recovery following blast-induced concussion, the reader is directed to Morris & Gottshall.²³

CLINICAL EXAMINATION FOR PERSISTENT POSTCONCUSSION SYMPTOMS

Concussion can produce a constellation of signs and symptoms that evolve over time, which reflect physical, cognitive, and emotional dysfunction.^{5,23,154,181} Therefore the examination used by the rehabilitation specialist for the individual with PPCS should be comprehensive so as to consider all potential motor, sensory, cognitive, and psychological systems that may contribute to a patient's symptoms and functional limitations. Ideally, the examination should lead the therapist to identify the underlying impairments of functional systems that contribute to a patient's activity and participation restrictions, movement dysfunction, and/or symptom provocation.

Several frameworks have been proposed for the examination of the individual with PPCS.^{68,70,115,182} Although some authors have proposed minor variations, most approaches are composed of similar components, which include:

- Description and documentation of baseline symptom complaint(s)
- Assessment of cognitive dysfunction
- Assessment of orthostatic tolerance and dysautonomia
- Assessment of exercise tolerance via a subsymptom exercise tolerance test
- Examination of the vestibular and oculomotor systems
- Assessment of the musculoskeletal and sensorimotor components of the cervical spine
- Appropriate screening and identification of comorbid conditions such as headaches, affective disorders, and sleep disturbance

A template describing the components of a comprehensive examination that may be performed by a rehabilitation specialist is provided in Table 23.8.

Symptom Complaint

A high prevalence of complaints of headache (83%), dizziness (65%), and confusion (57%) is reported by athletes following SRC.¹⁴ Other common symptoms endorsed by patients who have sustained a concussion include nausea, intermittent vomiting, disturbances of balance or gait, tinnitus, photophobia, phonophobia, difficulty focusing, slowed speech, lightheadedness or foggy, extreme fatigue, and other impairments in cognitive processing and memory.^{44,115,186,187} Following concussion, 10% to 33% of patients will continue to endorse symptoms, which may persist for months or even years.^{52,55–58} Although the time course of recovery that characterizes PPCS continues to be debated and has changed over time,^{5,17,188,189} PPCS should be considered if symptoms continue for longer than 10 to 14 days for adults and more than 28 days for children.⁶

Special consideration should be taken for clinicians providing care to children and adolescents with persistent symptoms following concussion. Often children and adolescents do not have the insight or vocabulary to identify or articulate the symptoms they are experiencing.¹¹⁵ It is recommended that clinicians working with this population, especially children, phrase interview questions in contexts that are appropriate to the child's life, such as inquiring about the child's experience for specific activities such as going to the grocery store, walking up the stairs, playing video games, and riding in the car, and will often illicit confirmatory evidence that those activities make the child feel anxious, foggy, or "not right."¹¹⁵ Also, it is important to consider the method of obtaining symptom complaints can influence the number and severity of the symptoms reported,^{190,191} and on average, even healthy children and young adults will endorse concussion symptoms listed on common symptom complaint assessments.¹⁹² The Pediatric Visually Induced Dizziness (PVID) Questionnaire is an example of a

IV. Examination
A. Self-Report Measures
Symptom Complaint Scales (PCSI, PCSS, RPQ)
Health and Behavior Inventory (HBI)
Pain Rating Scale (visual analogue scale, McGill Pain Questionnaire)
B. Subsymptom Exercise Tolerance Test
Treadmill (BCTT) or cycle ergometer exercise test
C. Vestibular System Assessment
i. Self-report tests/measures
Dizziness Handicap Inventory (DHI)
Activities-specific Balance Confidence scale (ABC)
ii. Performance/clinical measures
Sensation of motion at rest
Positional testing (Dix-Hallpike, side-lying test, supine roll test)
VOR assessment (head thrust test, cDVA/GST)
Head tilt for otolithic assessment
Self-Motion Sensitivity (Motion Sensitivity Quotient) ¹⁸³
Visual Motion Sensitivity (Pediatric Visually Induced Dizziness Questionnaire) ¹⁸⁴
Gait and Balance assessment (FGA, DGI, SOT, mCTSIB, Push-and-Release test)
D. Oculomotor System Assessment
Visual fixation
Ocular motility—H-test
Smooth pursuit and saccades
Vergence
E. Cervical Spine Assessment (musculoskeletal and sensorimotor components)
i. Self-report tests/measures (Neck Disability Index)
ii. Safety tests
a. Ligament integrity test
b. Vertebral basilar artery insufficiency test
iii. Performance/Clinical measures
a. Musculoskeletal evaluation (AROM, flexibility, PAVIM, strength, endurance)
b. Special tests (Spurling's, CFRT, Head lift, CCFT, neurodynamics)
c. Cervical proprioception (Joint Position Error test) ¹⁸⁵
e. Cervical influence on oculomotor control (SPNT)
f. Craniovertebral muscle recruitment with eye motion
g. Head righting response
h. Cervicothoracic extension (motion, motor control, strength, endurance)
i. Shoulder girdle screening
j. Respiratory pattern and thoracic cage motion

AROM, Active range of motion; BCTT, Buffalo Concussion Treadmill Test; CCFT, Craniocervical flexion test; cDVA, computerized dynamic visual acuity; CFRT, cervical flexion rotation test; DGI, Dynamic Gait Index; FGA, Functional Gait Assessment; GST, gaze stabilization test; mCTSIB, modified clinical test for sensory integration in balance; PAVIM, passive accessory intervertebral motion (PROM); PCSI, Postconcussion Symptom Inventory; PCSS, Post Concussion Symptom Scale; POTS, postural orthostatic tachycardia syndrome; RPQ, Rivermead Post-Concussion Questionnaire; SOT, sensory organization test; SPNT, smooth pursuit neck torsion test; VAS, visual analog scale; VOR, vestibulo-ocular reflex.

tool that has been developed and validated alongside the Pediatric Vestibular Symptom Questionnaire (PVSQ) to assess visually induced dizziness (ViD) in children aged 6 to 17 years.¹⁸⁴ The PVID shows utility in identifying and quantifying symptoms of ViD related to concussion, migraine, and other vestibular conditions—an important consideration in the assessment of children and adolescents, as they have been found to rely on the visual system as the predominant system for balance and to resolve sensory conflict until multisensory processing reaches maturation, even in the absence of injury.¹⁹³

Tests and Measures to Evaluate Persistent Postconcussion Symptom Complaint

The NINDS CDE⁹³ recommends that symptom complaints of patients with PPCS be monitored using the PCSI, PCSS, RPQ, and the HBI. Information related to these self-reported symptom complaint questionnaires has been provided earlier in the chapter. A review of the decision making process of the rehabilitation specialist as it relates to symptom complaint is discussed here.

Clinicians are advised not to use the results from either the PCSI, PCSS, RPQ, or the HBI alone to direct their care. Symptoms can be nonspecific and can mimic symptoms associated with chronic pain, depression, and anxiety disorders⁵; therefore symptom complaints alone cannot be used to identify underlying impairments of functional systems that may cause common symptom complaints following concussion.^{58,90,194} For example, a symptom complaint of a headache could be due to visual problems or cervical spine dysfunction, or could be related to prior history of migraines. Similarly, a symptom complaint of dizziness could be caused by orthostatic hypotension, vestibulo-ocular problems, or anxiety associated with the inability to return to sports, school, or social activities. Further, symptom complaints endorsed by individuals following a concussion are commonly reported among nonconcussed individuals.^{58,89,90} For athletes specifically, the accuracy of symptom report from adolescents recovering from SRC has been questioned, as athletes may not disclose concussive signs and symptoms as they may intentionally withhold reporting them or, conversely, they may be motivated to inflate or continue reporting symptoms despite injury resolution as a means to leave a sport.^{89,195,196} Therefore symptom complaints alone are not sensitive to either diagnose concussion or to identify underlying causes of dysfunction.

For this reason, the clinical examination should be made up of tests and measures that can provide the clinician with objective data about potential impairments of physical or psychological systems, or personal circumstances that may contribute to the reported symptoms. This point cannot be emphasized enough: the rehabilitation specialist should structure the examination to identify underlying impairments in functional systems and activity limitations so that interventions can be matched to the findings of the physical examination. In our experience, clinicians who rely on symptom complaint to guide decision making do not have successful outcomes in the management of concussion-related functional deficits.

Cognitive/Neuropsychological Dysfunction

As discussed previously, there is evidence that concussion may lead to neurocognitive dysfunction secondary to axonal shearing, secondary neuronal death, altered cerebral blood flow, and dysregulated biochemical function.^{44,197} In most clinical cases, there are no obvious initial neuroimaging results that identify this damage or dysfunction.¹⁹⁸ However, the pattern of neurocognitive deficits is relatively consistent when evaluated clinically and behaviorally. Although the research debate continues on the existence of a constellation of

neurocognitive deficits, the primary deficits reported by researchers, patients, and clinicians include attention, memory, executive functions, word retrieval, and social skills/pragmatics.^{199–201}

Attention. Attention skills are critical for all cognitive function.^{202–204} Attention domains have been identified and described in a variety of ways and with various names, but generally relate to sustaining attention, selective attention, alternating attention, and divided attention.²⁰⁵ Sustained attention is the ability to maintain focus on a task, or for a period of time (i.e., completing a written task or listening to a phone conversation). Selective attention is the ability to attend to a task with distractions such as auditory, tactile, or visual stimuli (i.e., holding a conversation in a busy environment). Alternating attention is the ability to switch focus from one task to the next and back again (i.e., driving a car and watching the traffic in front, behind, while managing the controls). Divided attention is the ability to do one or more tasks at the same time (i.e., taking notes in class and scrolling through social media).²⁰⁶

Those with PPCS generally report these areas as the most frustrating deficits. The complaints typically focus on noise and feeling overstimulated while attempting to complete daily tasks.²⁰⁷ Most individuals with PPCS report that they are able to generally sustain attention, but not for the length of time as they were able to pre-morbidly. In addition, any tasks that require alternating and divided attention result in significant fatigue, frustration, and sometimes lability. Frequently, the reduced abilities in sustained, selective, alternating, and divided attention are not evident to the person with PPCS until they return to their work or school responsibilities. Patients will sometimes attempt to ameliorate these deficits with sunglasses, noise-cancelling headphones, dimming lights, and reducing/controlling the amount of tasks.²⁰⁸

Memory. Memory is a broad category of cognition that is integral to daily and independent function, and learning throughout the lifespan. Memory domains include immediate memory, working memory, delayed memory, episodic memory (daily recall of a person's experience), prospective memory, semantic memory (i.e., vocabulary, general knowledge), procedural (i.e., recall of an overlearned motor task such as brushing teeth, riding a bike), and long-term/personal memory.²⁰⁹ Memory abilities are closely aligned with attention domains: if a patient is unable to attend to information, it will be difficult to store and recall the information.²¹⁰ Processes involved in memory include attention, encoding (preparing information to store), storage, and recall. In general, the longer the information is stored and retrieved, the more stable in memory storage (i.e., name, address, family members are units of information that are easily recalled and automatic).²¹¹ Memory can be visual, auditory, olfactory, and tactile. Memory systems are closely connected with attention and emotional areas of the brain.²¹²

Memory is also one of the most common cognitive deficits reported by those with PPCS. Procedural, long-term, and personal memory units are not typically reported areas of concern. Semantic memory will be discussed further in relation to word retrieval. More recent memory that has not had extensive retrieval and recall over time are the areas those with PPCS identify as deficit areas: immediate, delayed, episodic,²¹³ working,²¹⁴ and prospective memory.²¹⁵ Common complaints include being unable to recall conversations, planned events, information just read, when or if medication was taken, and other daily interactions and new information. Most with PPCS indicate that when visual or auditory distractions are present, recall of new information is further impaired.

Executive functions. Executive functions are cognitive abilities that support personality, attention, flexibility, problem solving,

reasoning, awareness, and social skills/pragmatics.²¹⁶ These abilities are frequently impacted in those with PPCS.²¹⁷ These areas are also critical in daily human interaction, and may be conscious or subconsciously managed. For the most part, these abilities are not taught, but are learned through experience or subconsciously.²¹⁸ For example, awareness of self allows a person to interpret another person's reaction and change their own behavior in response. Flexibility supports a person's ability to make a choice, realize that it was not an appropriate choice, and change the plan or choice.

Executive function complaints with PPCS may not be as obvious to the patient. However, they may be identified by the family and significant others. Changes in mood and emotional control are reported: lability with anger, sadness, and laughter at inappropriate times or not consistent with premorbid status.²¹⁹ Inability to manage schedules, make adjustments with change, identify alternate solutions, and predict outcomes are demonstrated. Social skills/pragmatics differences are also experienced: inappropriate comments, difficulty with humor and sarcasm, and "personality changes" (i.e., those around the patient report that they are changed in some way). These deficits are further impaired by the lack of awareness and social repair abilities.

Word retrieval. Word retrieval refers to the ability of generating and producing the desired word. This ability is related to overall vocabulary level, speed of processing, and the expressive language system. Aphasia is the inability to express or comprehend language, typically after a cerebrovascular accident (CVA), TBI, or other neurological injury. Those with TBI sometimes present with various levels of aphasia, although their semantic memory system appears to be relatively preserved.²²⁰ In PPCS, patients experience and report inconsistent difficulty in word retrieval that is significantly increased from premorbid levels. Speed of word retrieval is also significantly reduced from premorbid function.²⁰⁰ This impairment can dramatically impact daily life.

Social language/pragmatic skills. Social language (i.e., pragmatic skills) are the skills used throughout interactions in daily life. They are skills that are generally not taught, but rather learned through experience or subconsciously.²²¹ Pragmatic skills include, but are not limited to, eye gaze, voice modulation, body language, topic maintenance, turn taking, appropriate behavior related to setting, emotional control, and overall Theory of Mind behaviors and abilities (i.e., consciously or subconsciously thinking about what others are thinking and adjusting behavior related to that perception).²²² Pragmatic skills significantly impact human communication. Notably, when they are appropriate, these skills go relatively unnoticed. When they are impaired, or deviant in some way, they are perceived and responded to sometimes in ways that are not overt and may be subconscious at some level (i.e., when a person is too close physically for the situation at hand, the other person will respond physically by moving away; when a person does something unexpected in a situation, the others in the interaction will make a judgment, consciously or subconsciously, and indicate their disapproval in a subtle or not subtle way).

Those with PPCS may experience subtle changes in their social language/pragmatic skills (SLPS).²²³ As stated previously, due to the impaired executive function system, the patient may not be aware of these differences, although family and friends may notice. The frequent comment from family members usually is that the patient is "changed" or "different." Impairments frequently include difficulty with topic maintenance, inappropriate behavior for the setting, inability to use or understand humor or sarcasm, difficulty with social repair skills, perseveration on topics, and emotional control.²²⁴ SLPS are

sometimes confounded with personality. With typical lack of obvious physical impairment or injury, an added caveat is that those who do not know the patient may respond to impaired SLPS in a way that may socially isolate the patient, in that they assume the impaired behavior is by choice.

Cognitive/Neuropsychological Assessment

Two disciplines take the lead in cognitive/neuropsychological assessment. In some settings, specifically sports rehabilitation and/or concussion clinics, the two disciplines work together in the assessment process. Typically, however, neuropsychologists focus solely on assessment and counseling/support for the trauma and adjustment. In general, neuropsychological evaluations involve in-depth testing on all cognitive-communication domains, as well as intelligence testing, emotional adjustment, and visual-motor skills. This testing is usually completed many months or even years after the injury, and is typically part of vocational assessment, legal cases relating to the injury, and RTW and school. Notably, there is not always a neuropsychologist in every clinic or therapy setting, and their services may be cost-prohibitive.²²⁵ Furthermore, as their focus is on assessment and support, neuropsychologists rarely provide direct cognitive-communication rehabilitation.

SLPs play a pivotal role in concussion management because of their expertise in the assessment, diagnosis, and treatment of persons with cognitive-linguistic disorders associated with traumatic brain injury.²²⁶ SLPs are typically part of the clinical rehabilitation environments. The Scope of Practice for SLPs includes assessment and treatment for all areas of communication and cognition.²²⁷ SLPs who work in medical and outpatient clinic settings specialize in the neurological population.

Cognitive-communication assessment should always be dynamic in nature and should be as functionally valid as possible. Artificial clinical environments with unfamiliar clinicians may not be as functional or ecological as real-life experiences. Therefore interviews with the patient and family and observations may also provide meaningful information. Several concussion symptom scales include parent or family ratings as well.¹¹²

Many tests are able to target cognitive-communication deficits in PPCS, and a partial list for all age ranges follows (Table 23.9). Some tests have specific subtests that target areas most critical in PPCS evaluation, and those are noted. In addition, intake interview questions are part of the interpretation of testing results. Prior level of function (PLF), including level of education, work experience, learning history including strengths and weaknesses, social history and

TABLE 23.9 Tests for Assessment of Persistent Postconcussion Symptoms Cognitive-Communication Function

Test	Standardization Age Range	Measures
California Verbal Learning Test—Children's Version California Verbal Learning Test (CVLT-2)	5–16:11 16–89	Memory for list learning, new information with repetition and semantic association, verbal learning and memory (differentiates encoding and retrieval) from retrieval skills
Comprehensive Assessment of Spoken Language–2 (CASL-2)	3–21:11	Supralinguistic skills: use of language in which meaning not directly available from the surface lexical and syntactic, pragmatics, and abstract language Pragmatic language: knowledge of language that is appropriate across different situational contexts and ability to modify language according to the social situation
Controlled Oral Word Association Test (COWA)	16–70	Semantic and phonetic verbal fluency
Clinical Evaluation of Language Fundamentals–5 (CELF-5)	5–21	Language memory for sentences and paragraph details/inferences, pragmatics checklist/profile Metalinguistics test for higher level language
Behavior Rating Inventory of Executive Function (BRIEF)—SR Behavior Rating Inventory of Executive Function (BRIEF)—A	11–18 18–90	Rating scales with indexes for behavior regulation, emotion regulation, and cognitive regulation
Developmental Neuropsychological Assessment, 2nd Edition (NEPSY-II)	3–16	Attention, memory, new learning, theory of mind
Rey Auditory Verbal Learning Test (RAVLT)	5–18	Immediate recall of words presented auditorily
Wisconsin Card Sorting Test (WCST)	7–89	Executive functions, mental flexibility
Test of Everyday Attention for Children (TEA-C) Test of Everyday Attention (TEA)	5–15 18–80	Attention: sustained, selective, alternating, divided
Elementary Test of Problem Solving—Elementary 3 (TOPS-E3) Adolescent Test of Problem Solving (TOPS-2 A)	6–15:11	Problem solving, perseveration, and abstract thinking: critical thinking based on students' language strategies, logic, and experiences, making inferences, determining solutions, interpreting perspectives, insights
Student Functional Assessment of Verbal Reasoning Executive Strategies (S-FAVRES)	12–19	Evaluates aspects of complex comprehension (sarcasm, humor, intent, gist or central theme) discourse, social communication, verbal reasoning, problem solving, meta-cognition, executive functions
Functional Assessment of Verbal Reasoning Executive Strategies (FAVRES)	17–89	Evaluates aspects of complex comprehension (sarcasm, humor, intent, gist or central theme) discourse, social communication, verbal reasoning, problem solving, meta-cognition, executive functions

TABLE 23.9 Tests for Assessment of Persistent Postconcussion Symptoms Cognitive-Communication Function—cont'd

Test	Standardization Age Range	Measures
Repeatable Battery for Neuropsychological Assessment	12–89:11	Immediate memory, language, attention, visuospatial memory, and constructional abilities
The Word Test–3 Elementary	6–11:11	Word retrieval/expressive vocabulary (associations, synonyms, semantic absurdities, antonyms, definitions, and flexible word use)
The Word Test–2 Adolescent	12–17	
Pediatric Test of Brain Injury (PTBI)	6–16	Story recall, naming, immediate and delayed memory, verbal fluency, complex language comprehension, semantic associations
Boston Naming Test–2	18–79	Word retrieval/naming
Wide Range Assessment of Memory and Learning (WRAML-2)	5–90	Multiple tests for verbal and visual memory, immediate and delayed
Rivermead Behavioral Memory Test–Child (RBMT-C)	5–11:11	Verbal, visual memory immediate and delayed
Rivermead Behavioral Memory Test–3	16–96	
Test of Adolescent/Adult Word Finding (TAWF)	12–80	Word finding for nouns and verbs, sentence completion, description naming, and category naming
Test of Auditory Processing–4 (TAPS-4)	5–21	Four subtests for auditory memory, and three for auditory comprehension, inferences
Woodcock-Johnson Psychoeducational Battery: Tests of Cognitive Ability–3	2–90+	General intellectual ability and specific cognitive abilities: working memory, processing speed, cognitive efficiency
Ross Information Processing Assessment–P (RIPAP)	5–12	Immediate memory, recent memory
RIPA–2 (RIPA-2)	15–90	
Expressive Vocabulary Test–2	2–90	Expressive vocabulary and word retrieval
Cognitive-Linguistic Quick Test-Plus (CLQT+)	18–89:11	Attention, memory, executive function, visuospatial skills, language ^{228–258}

support, as well as prior injuries, are important clinical evidence to use in when interpreting assessment results. The medical history of the injury and any prior therapy and testing should also be shared.

Standardized testing is critical in the assessment of PPCS. A study out of the military identified several tests in a battery that were comprehensive in evaluating the specific target areas in mild TBI(mTBI). Parrish and colleagues at the Naval Medical Center in San Diego²⁵⁹ developed a standardized battery, including the Woodcock-Johnson III Tests of Cognitive Abilities (WJ-III),²⁶⁰ the Attention Process Training Test (APT),²⁶¹ and the Functional Assessment of Verbal Reasoning and Executive Strategies (FAVRES; MacDonald, 2005).²⁶² In addition, for informal assessment, they developed a questionnaire about symptoms/concerns and observed SLPS in conversations with familiar and unfamiliar partners. Results of their evaluation of their assessment battery indicated that it was sensitive to the concerns and symptoms of their mTBI population. The Miami University Concussion Management Program utilized several different tests with the same goals in mind: Hopkins Verbal Learning Test,²⁶³ Trail Making Tests A and B,²⁶⁴ Controlled Oral Word Association Test,²²⁸ Digit Span from the Wechsler Memory Scale (WMS), Grooved²⁶⁵ Pegboard Test (GPT²⁶⁶), and the Post-Concussion Symptom Scale (PCSS⁸⁴). In addition, they include the ImPACT computerized test, since they include that as baseline testing for all athletes at their university.

For TBI assessment, many studies recommend a combination of standardized and nonstandardized assessments to assess functional abilities.^{268,269} An important aspect is the inclusion of nonstandardized and “informal” assessments, as the testing conditions themselves may

scaffold cognitive-communication skills that TBI patients have in the real world.²⁷⁰ According to Coelho and colleagues,²⁷¹ the use of language within social contexts, communication competence, is best evaluated outside of the clinical setting in conversation, rather than in structured interviews in the clinic setting. Overall, cognitive-communication/neuropsychological assessment should provide the patient and the clinician with a clear picture of deficit areas, strengths, and the understanding of how these areas relate to the patient’s life and goals.

Exercise Intolerance

Concussion can lead to physiological dysfunction, including neuro-metabolic challenges, altered cerebral blood flow, and/or autonomic dysfunction.^{127,154,272} Patients with concussion have been found to have higher resting heart rates,²⁷³ and there is evidence from imaging studies of abnormal cerebral blood flow volume and distribution in humans both acutely after concussion²⁷⁴ and in those with PPCS.²⁷⁵ Such cellular and physiological alterations lead to a mismatch between energy supply and demand that is thought to be a major contributing factor to exercise intolerance and prolonged recovery following concussion.

As mentioned previously, international consensus guidelines provide a strong recommendation for a period of rest (1 to 2 days), followed by a graduated return to activity (see Table 23.7). However, the clinician and patient with PPCS are often stuck in a gray area, questioning: What is the optimal amount of rest? When should exercise begin? And how can the exercise progress safely? For this reason, John Leddy’s group at SUNY Buffalo developed a subsymptom exercise tolerance test, the Buffalo Concussion Treadmill Test (BCTT), to

identify individuals with exercise intolerance following a concussion and provide clinicians with a tool for guidance in exercise prescription related to return to activity.

Assessment of Exercise Intolerance: Subsymptom Exercise Tolerance Test

The BCTT¹⁵⁴ has been shown to be a safe^{276,277} and reliable²⁷⁸ measure, which can be useful for identifying levels of exercise tolerance in patients following SRC, quantifying the clinical severity of the concussion, and developing exercise prescription for patients with PPCS.^{115,154} Using a standardized Balke protocol, patients perform an incremental treadmill exercise test (Fig. 23.4) that is terminated upon provocation of new symptoms, elevation of symptoms beyond established criteria, or maximum exertion is achieved. The starting speed is set to 3.2 to 3.6 mph. During the first minute, the treadmill is set at a 0% incline. After 1 minute, the incline is increased by 1% grade and then by 1% grade each minute thereafter while maintaining the same speed until the patient can no longer continue, whether because of symptom exacerbation or fatigue. Rating of perceived exertion (RPE, using the Borg Rating scale) and symptoms, using a 1- to 10-point visual analog scale (VAS), are assessed every minute. Blood pressure (with an automated or manual cuff) and heart rate (HR) are measured every 2 minutes. For the most accurate information, it has been recommended that a heart rate monitor be worn across the chest during the test²⁷⁷ (HR, by Polar HR monitor, Model #FIT N2965; Kempele, Finland).

The predetermined stopping criteria consists of either exacerbation of symptoms, or voluntary exhaustion (RPE of 18 to 20). Symptom exacerbation is defined as a greater than or equal to 3 point change from that day's overall pretreadmill resting symptom score on the VAS,

where a point is given for each increase in a symptom (e.g., headache) or the appearance of a new symptom (e.g., dizziness).¹⁵⁴ The heart rate at which this event occurs is referred to as the threshold heart rate (HRT) and should be documented, as this threshold will be used as a reference for exercise prescription.²⁷⁷

The test should be deferred for individuals with significant pretest resting symptoms of greater than or equal to seven on the VAS or those with a history indicating increased risk for cardiopulmonary disease as defined by the American College of Sports Medicine.¹⁵⁴ A complete list of absolute and relative contraindications for exercise testing can be reviewed in Leddy and colleagues.¹⁵⁴ Special considerations should be established for transient dysautonomia, which has been identified in some cases of concussion, and has been described as the prolonged physiological response in individuals with exercise and activity intolerance.^{279–281} There is a lack of consensus among medical professionals on the routine assessment of dysautonomia following mTBI in the acute phase postinjury. Evidence regarding heart rate variability testing is conflicting, and data is limited to within 2 weeks postinjury.²⁸² Autonomic function testing is not readily available, though the passive tilt table test is recommended for the diagnosis of postural orthostatic tachycardia syndrome (POTS) with well-established heart rate criteria in the presence of orthostatic symptoms.^{283,284} In the absence of access to autonomic function testing or as a screening tool, an active standing test can be performed to compare the supine resting heart rate (obtained after 10 minutes of quiet rest) to the heart rate after 10 minutes of quiet standing. Sustained tachycardia may be an indication of dysautonomia as cerebral hypoperfusion may cause lightheadedness, blurry vision, or cognitive dysfunction brought on in upright postures or during exertion. Identification of signs consistent with dysautonomia or

Fig. 23.4 (A) Subsymptom exercise tolerance test (Buffalo Concussion Treadmill Test) using a treadmill and (B) subsymptom exercise tolerance test using a bicycle, while medical professional monitors heart rate, blood pressure, rate of perceived exertion (Borg exertion scale), and a visual analog scale for symptom provocation

POTS requires consultation for medical management to improve response to vestibular neurorehabilitation. For those individuals with apparent dysautonomia or who meet diagnostic criteria for POTS, medical management and recumbent exercise may need to precede upright exertion testing.^{285,286}

The safety of the test has been established for adult and adolescent patients aged 15 to 53 years with persistent symptoms at 3 weeks or more postinjury who attended a sports medicine clinic.^{115,276} Because of a lack of evidence indicating the BCTT was safe to conduct during the acute phase of concussion recovery, Leddy and colleagues assessed the safety and potential predictive value of the BCTT in adolescents performed within 1 to 9 days following concussion.²⁷⁷ Assessment of exercise tolerance using the BCTT a median of 4 days after injury did not significantly affect symptom reporting in the short-term (within 24 hours), did not delay recovery, nor did it increase symptoms in the long term (14 days postinjury). In addition, Leddy and colleagues²⁷⁷ found exercise intolerance within the first week after concussion (as indicated by the HRt) strongly predicted recovery after concussion injury. Adolescents with a HRt below 135 bpm were approximately 45 times more likely to have a prolonged recovery (odds ratio = 44.75) than adolescents with a HRt above or equal to 135 bpm. The authors suggested academic and athletic teams use this cutoff with caution, as the study was not powered to determine sensitivity, specificity, or the positive predictive value associated with this cutoff. Still, the findings make a significant contribution to the utility of the BCTT, which has already been established as a useful guide for exercise prescription and return to play decision making.^{17,154,188} Although it appears additional studies to establish the optimal modes and protocols for various populations are required to validate the BCTT as a diagnostic and prognostic biomarker,²⁸⁷ the test's clinical utility and ability to predict prolonged recovery is promising.

Due to the common symptom complaint of dizziness, a stationary bicycle (see Fig. 23.4) can be used in place of a treadmill in order to reduce the magnitude of head excursion while walking or running on a treadmill²⁸⁸ and to minimize conflicting sensory stimulation.²⁸⁹ *Supplementary videos are available to provide examples of subsymptom exacerbation exercise tests using a treadmill and stationary bicycle. These videos can be found in the online resources for this text.*

A comprehensive examination of impairments that contribute to exacerbation of symptoms and decrease of function should be completed before the exertional assessment is started. When the examination identifies that there is a sensation of motion at rest, for example, that sensation will cause a decrease in the tolerance level when head motion is increased, as when walking on the treadmill. As intervention targeting sensation of motion at rest decreases this phenomenon, there will be more tolerance to most activity. This is further incorporated into activities that demand head turning, such as when turning the head to interact with the tester. If the somatosensory system is providing abnormal reference through the spine and weight-bearing joints, this can impact the sensation of stability when walking on a moving surface. Modifications and intervention for the visual system should be addressed as soon as possible so that the dizziness triggered by visual or visual/vestibular dysfunction can be reduced prior to testing. Other sensorimotor system changes, described as follows, will create exercise intolerance and should be addressed in an intervention regime prior to exertion.

Vestibular System Impairment

Function of the vestibular system relies on accurate information from the peripheral vestibular apparatus (sensory receptors and afferent pathways) and integration of the information by subcortical nuclei for appropriate motor output through the vestibulo-ocular and

vestibulo-spinal reflexes, in order to provide gaze stability and postural control, respectively. Therefore damage to the peripheral or central vestibular structures can result in a cluster of signs, such as impaired gaze stability, gait, and balance, and symptoms including vertigo, dizziness, motion sensitivity, and/or imbalance.^{115,187,290} Recent studies mapping the vestibular system through diffusion tensor imaging (DTI) and functional magnetic resonance imaging (fMRI) demonstrate the extensive network of interhemispheric and decussating relays between the vestibular nuclei and the parieto-insular vestibular cortex that could be affected by prolonged neurometabolic changes that may impact the integrity of vestibular reflexes and compensatory strategies.²⁹¹

To perform efficiently the vestibular system information must be compared with the information provided by the visual and somatosensory systems to create the appropriate motor response. Central adaptation for vestibular dysfunction depends on intact references from these systems, or sensory integration. Concussion, in which dysfunction appears in more than one of the sensory systems, significantly challenges the adaptation process and leads to persistence of symptoms when compared with a person with primarily vestibular deficits. This is why an endorsement of dizziness during acute concussion has been shown to be a marker of poorer prognosis for athletes following an SRC.⁶¹ Dizziness after concussion may be attributable to a variety of conditions. This point is critical, as “dizziness” is a nonspecific term that includes diffuse symptoms of disorientation and lightheadedness that may represent the somatosensory dysfunction. Early symptoms of vertigo (spinning) reflect unequal signals through the vestibular structures that can also affect balance problems²⁹² due to dysfunction of any combination of the peripheral vestibular system, central vestibular pathways, or comorbid conditions, including labyrinthopathy, vestibular migraine, autonomic nervous system dysfunction, or anxiety. Also, symptoms consistent with persistent postural-perceptual dizziness (PPPD) are common after concussion. For this reason, a comprehensive and thoughtful clinical interview, examination, and evaluation should be completed to identify the source of the symptom complaint,¹⁸¹ and modifications of traditional vestibular rehabilitation strategies are often required to accommodate the visual and somatosensory deficits.

Common impairments and examination procedures observed in this patient population as they relate to the vestibular system are discussed in this section, which include positional vertigo, impaired dynamic gaze stabilization, ocular motor deficits, motion sensitivity, and balance and gait impairment.

Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) following traumatic brain injury accounts for 8.5% to 20% of all cases of BPPV.²⁹³ Therefore it is important that patients with symptoms of BPPV be screened with the Dix-Hallpike and side-lying tests to evaluate for potential BPPV of semicircular canals.^{5,115,294-296} Treatment of BPPV for individuals with PPCS should follow the same clinical reasoning as non-concussed patients who present with signs and symptoms suggestive of BPPV. Ahn and colleagues²⁹³ reviewed medical records of 192 consecutive patients with positional vertigo to determine if there were clinical differences between BPPV after TBI and idiopathic BPPV. Of the 32 patients with BPPV following TBI, the majority (75%) had posterior semicircular canal BPPV, while the remaining patients had BPPV of the horizontal semicircular canal, which is consistent with prevalence of canalith involvement in idiopathic BPPV. Although recurrence rates were similar between the two groups, patients with BPPV following TBI required more treatment sessions than individuals with idiopathic

BPPV to lead to full resolution.²⁹³ Posttraumatic hydrops may account for the need for increased intervention and may need to be addressed with use of diuretic in combination with the repositioning. Procedures for canalith repositioning maneuvers have been described in sufficient detail previously. Damage in the central structures can cause head position dizziness. When there is purely vertical nystagmus noted in supine head hanging that does not fatigue within 1 minute, it likely is of a central nature. For a review of this content, the reader is referred to Chapters 20 and 21.

Impaired Dynamic Gaze Stabilization

The VOR produces eye movements equal and opposite to head movements for the purpose of visual stability when the head is in motion. Proper function of the VOR requires intact peripheral and central vestibular pathways, which consist of the vestibular nuclei, cerebellum, thalamus, cerebral cortex, and the projections that connect subcortical and cortical areas to the ocular motor system to provide dynamic gaze stability. The forces that cause a concussion can disrupt the neurons that control the VOR,^{187,297,298} causing blurred or unstable vision, difficulty focusing during head motion. This may lead to complaints of vertigo, nausea, and fogginess, or discomfort in busy environments (e.g., visual motion sensitivity).^{100,115} There is evidence that symptom complaints suggestive of pathology to the vestibular system are associated with prolonged recovery¹⁰⁰; it is therefore important that the rehabilitation specialist select reliable and valid measures that provide objective information related to the degree of involvement of the vestibulo-ocular system for patients following a concussion.

Dynamic gaze stabilization assessment. As measures used to evaluate the vestibulo-ocular system have been described previously in Chapters 20 and 21, special considerations of tests and measures (including their relevance as assessment tools and outcome measures for individuals with impaired dynamic gaze stabilization following a concussion) are discussed here.

The dynamic visual acuity (DVA) test and the gaze stabilization test (GST) are two functional measurements used for assessment of the VOR in individuals with vestibular disorders. The DVA can be assessed using a manual bedside test or a computerized version; however, reliability and validity studies support the use of the computerized DVA (cDVA) test^{299–301} when available. Reliability and responsiveness of the cDVA and GST have been established for individuals with vestibular dysfunction. Due to the incidence of concussion in high school and collegiate sports, Kaufman and colleagues³⁰² investigated the psychometrics associated with the cDVA for high school and collegiate athletes as the required head speeds for athletic performance must be greater than the demands of regular daily activities. Test-retest reliability for the cDVA was found to be good in the yaw plane and fair-to-good in the pitch plane, with ICC values of 0.77 and 0.72, respectively. The minimal detectable change was found to be 0.16 logMAR and 0.21 logMAR in the yaw and pitch plane motions, respectively.³⁰² Findings show that even at high head speeds of 150 to 200 degrees per second (deg/s), which is considerably faster than the head velocity used for individuals with vestibular dysfunction (80 to 120 deg/s), the cDVA may be reliably used as an outcome measure to show change over time.

It is important to note that clinical examination tests used to assess the vestibular system may lead to general symptom provocation, which may not be sensitive to a specific vestibular impairment.¹⁸¹ For example, symptom provocation during the VOR test as performed in the VOMS test is not equivalent to reduced VOR gain. Reduction of VOR gain can be detected using a head thrust test or with use of a functional assessment of the VOR, such as the cDVAT or GST. The symptom

provocation alone during one of these tests does not equate to dysfunction of the VOR. In this way, negative findings on tests used to evaluate the function of the VOR (head thrust test, cDVAT, GST), but with symptom provocation while performing head motion with visual fixation, should be recorded as such and addressed with interventions addressing *head motion provoked dizziness*, which may be related to vestibular-somatosensory maladaptation (see section on cervical spine) and does not necessitate the strict prescription of VOR exercises for patients with peripheral vestibular hypofunction, as described in Chapters 20 and 21. VOR retraining can increase symptoms in the presence of visual sensitivity, somatosensory impairments in the cervical spine, or stiffness caused by attempting to decelerate the head to avoid dizziness. These impairments should be addressed in the intervention before initiating dynamic gaze stability exercises.

Murray and colleagues³⁰³ performed a systematic review of the literature to determine if specific outcome measures could be identified within vestibular rehabilitation treatment paradigms. Ten articles met the study inclusion criteria, including two RCT, two prospective cohort studies, one retrospective study, and five case studies. Three of the ten studies included children and/or adolescents; the remaining seven studies included young/older adults or military personnel. Interestingly, although 9 of the 10 included studies reported the incorporation of gaze stabilization or adaptation exercises, only two studies measured gaze stabilization using the DVA test. Schneider and colleagues³⁰⁴ used the bedside DVA test, while Gottshall and colleagues³⁰⁵ used the cDVA and GST. Although the symptom complaint of dizziness is not specific to impaired dynamic gaze stabilization, it is important to mention that self-report measures such as the Dizziness Handicap Inventory (DHI), the Vertigo Symptom Scale, and the dizziness analogue scale have been used in studies providing vestibular rehabilitation to patients with PPCS.³⁰³

Ocular Motor Impairment

The objective of the visual motor system, or the ocular motor system, is to direct the gaze to visual targets so that light waves land centrally over the fovea of the retina for best visual acuity. Eye movements can be driven voluntarily by motor control centers at the level of the cerebral cortex (frontal, occipital, and temporal eye fields) or reflexively by centers located in the brain stem (midbrain and paramedian pontine reticular formation, and vestibulocerebellum). The ocular motor system uses four primary eye movements to achieve its goals: saccades, smooth pursuit, vergence, and the VOR. This section reviews saccades, smooth pursuit, and vergence eye movements.

Saccades are rapid movements of the eyes that are used during voluntary searching movements from one target to another. Smooth pursuit eye movements are used to track moving objects or maintain the gaze on a moving target. Although the origin of voluntary movements for saccades and smooth pursuit eye movements originate in different areas of the cerebral cortex, the frontal eye fields or temporal eye fields, respectively, each system shares a final common pathway of cranial nerve nuclei to cause contraction of the extraocular muscles for horizontal (originating from paramedian pontine reticular formation) and vertical (originating from midbrain reticular formation) movements of the eyes.

Vergence eye movements require that the eyes move toward the midline (convergence) or away from the midline (divergence) of the visual field. Therefore vergence is used while maintaining fixation on a visual target as it moves from the far visual field to the near visual field or vice versa. Such eye movements are controlled reflexively by control centers at the level of the brain stem and cerebellum.

Ocular motor impairments are common after concussions, as oculomotor control can be compromised through axonal injury or blunt trauma to the ocular motor systems. Injury to the cerebral cortex can directly impact volitional saccades and smooth pursuit movements

and damage to subcortical nuclei, and white matter structures may disrupt reflexive vergence eye movements resulting in convergence or divergence insufficiency. However, damage to the ocular motor system following concussion may not be isolated to central nervous system structures, as damage to cranial nerves (specifically oculomotor, trochlear, and abducens nerves) may occur following concussion leading to selective impairment to the extraocular muscles. Such injuries have the potential to cause indirect and direct limitations in daily functioning, including symptom provocation, cognitive deficits, impaired reading, and poor academic performance.

Similar to dysfunction of other functional systems, the symptoms associated with impairment to the ocular motor system are varied, nondescript, and are not sensitive to diagnose concussion. Symptoms may include blurred vision, diplopia, eye strain, difficulty in reading, dizziness, headaches, ocular pain, and poor concentration. In children and adolescents, guided questions may be necessary to obtain information related to ocular motor deficits, such as difficulty losing their spot or skipping words when reading, difficulty copying notes off the board at school, or feeling “outside of” or “one step behind” themselves.^{100,115} In addition, children may endorse feelings of intense anxiety or overwhelming nausea when working on a computer for long periods or when inside a grocery store.

Ocular Motor Assessment

It is important to consider that examination tests used to detect the presence of BPPV, motion sensitivity, and vestibulo-ocular deficits can be some of the more provocative tests used in the evaluation of the patient following a concussion. Therefore tests used to assess the ocular motor system should be performed prior to the examination of positional vertigo, motion sensitivity, or the vestibulo-ocular system. In this way, the performance by the patient for the visual examination may not be influenced by the presence (or increased presence) of symptoms, such as dizziness and headache. This gives the clinician the opportunity to identify the degree of impairment to the static ocular motor system, prior to evaluating the more demanding task of gaze stability during head movement.

The rehabilitation specialist should begin with observation for ocular malalignment using the cover-uncover test that can help reveal esophorias and exophorias and an evaluation of the cardinal plane movements for ocular motility using the H-test, which should be completed under monocular and binocular conditions. A comprehensive oculomotor examination includes tests of fixation, saccadic, smooth pursuit, and NPC eye movements. Further, testing for fixation, saccadic, and smooth pursuit eye movements should be performed under monocular and binocular viewing conditions.

For visual fixation, the patient is instructed to look at a target (blunt end of a pen or pencil) at a 40 cm viewing distance. The clinician should evaluate the ability of the patient to maintain a steady fixation on the target for 10 seconds. An abnormal result would include ocular drift or gaze instability.

Saccadic eye movements are tested by asking the patient to look back and forth between two horizontal or two vertical targets separated by 20 cm at a 40 cm viewing distance. Eye movements should be evaluated in the horizontal, vertical, and oblique planes for accuracy, speed, and response to stimulus for no more than five repetitions in each direction. In healthy individuals, the target can be reached with a single eye movement or with one small corrective saccade. It is important to have discrete targets to observe so that the clinician can definitively determine if the patient consistently overshoots or undershoots the target position.

Smooth pursuit is tested by asking the patient to track, with the eyes, an object moving in the central 20 degrees of the visual field at a

40 cm viewing distance while the head is stationary. Smooth pursuit is abnormal if, during tracking, the eye movements are disrupted or interrupted by saccades. It is important to note that use of the VOMS in the acute screening of concussion involves testing smooth pursuits by tracking an object moving in the horizontal and vertical directions for two repetitions each. In the evaluation of PPCS, reduced ability to perform smooth pursuits, as evidenced by catch-up saccadic movements, may be detected with fatigue by increasing the number of repetitions or by tracking a more complex motion such as an H or figure-eight pattern.

NPC measures the ability to view a near target without diplopia and is tested under binocular conditions with the patient wearing appropriate lenses necessary for near vision. The patient is asked to track a pen that is held in the vertical position at the midline of the visual field, as it is moved toward the nose from a 60 cm viewing distance to the point at which the object blurs or becomes double (NPC). From that position, the pen is moved back toward the 60 cm viewing distance and the patient is then asked to report when the object becomes a single, fused target again (divergence). The clinician should document the distance at which the patient is no longer able to maintain a single, clear perception of the target during the test for convergence and the distance at which the patient regains the perception of a single target for the test of divergence. Normal NPC values are within 5 cm. If there is visual dependence or visual motion sensitivity, performing convergence testing may trigger dizziness as the images in the peripheral visual field appear to move as the target moves closer. It is important to make sure that the normal physiological diplopia associated with this testing is not interpreted by the patient as double vision.

Motion Sensitivity

The topics of visual (e.g., environment) and self-motion sensitivity have been discussed in Chapters 20 and 21, as it relates to patients with vestibular dysfunction. Sensitivity to visual and self-motion are thought to be caused by impairment of primary sensory systems or the integration of sensory information by multisensory processing in the higher order cortical areas of the occipitoparietal and occipitoparietal-temporal areas.^{184,291,306} The global neurometabolic and neural transmission injury caused by concussion can lead to dysfunction throughout cortical and subcortical areas that process information related to orientation to the environment and perception of self-motion.

Following concussion, children and adults have shown impaired postural responses and have reported exacerbation of concussion-related symptoms when exposed to visual motion^{82,289,307} that can persist for months following injury.^{184,307,308} Special consideration should be taken for adolescents, and adults with preexisting history of motion sensitivity may exhibit more prolonged vestibular dysfunction,³⁰⁷ have a greater likelihood of experiencing posttraumatic migraine (PTM),¹⁵⁸ and, perhaps of more concern, may experience more symptoms of anxiety or mood disorders early in recovery.³⁰⁷

Brosseau-Lachaine and colleagues³⁰⁷ found that objective perceptual impairment to simple and complex visual stimuli is present up to 3 months following injury in children and, interestingly, do not correlate with symptom complaints of dizziness and visual motion sensitivity endorsed by children on self-reported symptom complaint questionnaires. This points to the need for the rehabilitation specialist to use self-report measures as a supplement to objective measures of motion sensitivity in order to optimally target treatment to impaired functional systems. In addition to the assessment for visual and self-motion sensitivity already discussed for patients with vestibular dysfunction, Pavlou and colleagues¹⁸⁴ described the pediatric visually induced dizziness questionnaire (ViD), which has been shown to be a reliable and valid measure to assess for visual motion sensitivity specifically for children.

Sensation of motion at rest. As noted previously, when the sensory systems are not calibrated sufficiently, the brain is challenged to determine movement versus stability. If the vestibular system is the origin of the offset, there is a sensation of spinning. The CNS uses the visual system and somatosensory systems to assist in comparing movement to nonmovement. A persistent sense of spinning when the eyes are closed reveals poor adaptation through the vestibulospinal system. If the somatosensory system is off set, it limits the recalibration process, and a sense of being lightheaded may be prominent. (See section on cervical spine.) This can have significant functional implications and contribute to sense of disorientation. It is critical to determine stability in the perception of head motion during steady-state tasks before moving toward movement exercises. Interventions are included in Chapters 20 and 21 (*sensation of motion at rest*) and include settling, which is effective in controlling symptoms when they have been exacerbated.

Balance and Gait Impairment

Impaired postural control is also commonly reported following concussion.^{14,65,290} This can be an issue especially for youth and adolescents with SRC, as returning to play with balance and gait impairments may lead to musculoskeletal injury.^{178,179} While the mechanisms are not fully understood, it is reasonable to suspect forces that result in a concussion can disrupt the function of the vestibular system, especially with respect to integration of balance information between the vestibular nuclei, cerebellum, and the descending vestibulospinal tracts.^{69,158,291} Such changes could result in impairment in the components of the balance system that the nervous system uses to maintain postural orientation and equilibrium^{309,310} including, but not limited to, the inability to properly weight the three sensory systems (somatosensory, vestibular, and visual sensory systems), control graded and timed anticipatory postural adjustments, and provide adequate reactive postural responses. It is well documented that concussion can cause impairments under steady-state balance conditions, as well as during activities that require an individual to achieve or regain equilibrium under more dynamic conditions.^{289,311,312} Following concussion, patients typically will use inappropriate righting reactions and have increased use of stepping and hip strategies for even the smallest losses of balance. This may be the result of dependency patterns (described later), which can extinguish the normal use of the *head righting reflex*. Testing of head righting is described in Chapters 2, 20 and 21. The contribution to abnormal head righting related to cervical spine dysfunction is described in the section on cervical spine.

It is the function of the vestibular system to maintain the trunk in a vertical position for balance on tilted or uneven surfaces when the visual system is not available. The somatosensory system can substitute at both slow and fast speeds, but there is a range in which the vestibular system must provide upright control. Horak and colleagues³¹³ determined that individuals with vestibular deficiency lost their balance in more than 90% of trials during the 4 deg/s tilt condition, but never fell during slower tilts (0.25 to 1 deg/s) and fell only very rarely during faster tilts (16 to 32 deg/s). If the somatosensory system is dominant, there is a loss of balance at the midrange speeds. The trunk and head follow the direction of the tilt beyond the point, at which the somatosensory system can provide adequate reference to remain upright. See Chapters 20 and 21 for further information on methods to isolate the vestibular system in this context.

Balance and Gait Assessment

Many of the same self-report measures, such as the Activities-specific Balance Confidence (ABC) scale and performance-based outcome measures such as the Modified Clinical Test for Sensory Integration in

Balance (mCTSIB), SOT, BESS test, Timed Up and Go (TUG), Five Times Sit to Stand (FTSTS), Dynamic Gait Index (DGI), and Functional Gait Assessment (FGA), which have been described previously in Chapter 22, are useful for evaluation of balance impairment following a concussion. Body-worn sensors have also been shown to have clinical utility to monitor center-of-mass displacement in the assessment of balance impairment and function following concussion.^{314,315}

It is important to consider that many of the performance-based balance assessments (mCTSIB, SOT, and BESS) primarily evaluate the contribution of the sensory systems (visual, vestibular, and somatosensory) to postural control. The nervous system uses many different components of the balance system to maintain, achieve, and recover postural orientation and equilibrium during daily activities^{309,310}; therefore the rehabilitation specialist should select a battery of performance measures that evaluate all components of the balance system,^{310,316} rather than restricting the assessment to the sensory systems. For this reason, the importance of a thorough examination cannot be overlooked as impairments in strength, flexibility, range of motion (ROM), coordination, muscle tone, and cognition can also impair postural stability.

Murray and colleagues³⁰³ performed a systematic review of the literature to determine if specific outcome measures could be identified within vestibular rehabilitation treatment paradigms. The authors concluded that standardization and consensus on outcome measure usage is required for future studies to allow for comparisons across studies to perform meta-analyses. In terms of balance assessments, it was interesting that only four of the 10 studies included in the review used self-report balance measures, while 8 of the 10 studies used performance-based balance and gait measures, including DGI, FTSTS, SOT, BESS, FGA, TUG, High-Level Mobility Assessment Tool (HiMAT), and an instrumented mat for spatial-temporal variables of gait. As these measures have been described previously in Chapter 22, special considerations of the FGA have been highlighted here to report the appropriate use of each test for patients, with imbalance following a concussion. Importantly, recommendations from the NINDS CDE⁹³ suggest the BESS test should be used in acute concussion. Consistent with this recommendation, the test has not been validated for use in the subacute or chronic stages of recovery following concussion, and the psychometrics of the test do not support its use as an outcome measure, as it is not responsive to change in performance over time. Therefore the recommendation for motor control assessment from the NINDS CDE for individuals with PPCS includes the DGI and FGA.

Functional gait assessment. The FGA assesses postural stability during various walking tasks. It is a 10-item test that is scored on a 4-level ordinal scale (0 to 3). Aggregate scores range from 0 to 30, with lower scores indicating greater impairment. The FGA has demonstrated concurrent validity with other commonly used balance measures³¹⁷ and excellent intra- and interrater reliability. An important point to consider for the use of the FGA for individuals with concussion is a ceiling effect, which has been reported in a study of 180 adolescents, where 25% of participants reached the maximum score of 30 points.¹⁰⁷ In addition, there is limited evidence that a ceiling effect may also be a concern for the FGA when used with young and older adults with PPCS.⁶⁶ However, the components in the FGA such as head turns, quick stops, tandem, and backward gait can help identify impairments for those individuals in which vestibular deficits limit function.

Dependency Patterns

Central nervous system adaptation for vestibular disorders requires the use of vision and somatosensory references to recover function. As

the vestibular system becomes more efficient, the need for substitution of the other systems should decrease. However, in the compromised CNS, this return to normal reliance on the vestibular system can be limited. Persistent overdependence on vision or somatosensory information can create inefficient strategies. The patient with visual dependence will rely on vision and will have abnormal increases in sway or instability when the eyes are closed. Instability can result in the presence of visual stimulation during pursuits and optokinetic stimulation. There is often a complaint of dizziness when the eyes are closed or when walking in the dark. Avoidance of activity where there is excessive visual stimulation is common. Somatosensory dependence is often seen as an overdependence on an ankle strategy for balance, even when a hip strategy would be more appropriate. This can be seen by examination using a compliant or narrow surface, or when tested on a tilting surface. Increased dependence on somatosensory input for postural stability can also be observed in attempts to reduce head motion by clenching to load the temporomandibular joint, extended neck posture to increase facet joint loading, or cocontraction of neck musculature. This concept is further defined in Chapters 20 and 21.

Cervical Spine Function and Dysfunction

The cervical spine has a unique role in supporting and orienting the head in space and to the trunk (or trunk to the head) to serve the sensory systems. Concussion is frequently, if not always, accompanied by cervical spine stress due to direct biomechanical attachment of the head and neck, and contributes to sensorimotor impairment. Symptoms of traumatic cervical injury, particularly whiplash-associated disorders (WADs), overlap with many of those associated with the clinical threshold for concussion. Overlapping symptoms from the SCAT and the Quebec Task Force (QTF) on Whiplash Associated Disorders³¹⁸ include headache, dizziness/unsteadiness, nausea/vomiting, ringing in the ears, memory problems, problems concentrating, and vision problems.³¹⁹ Cervical spine assessment is recommended as standard practice in the detailed clinical examination for concussed patients to aid in differential diagnosis and targeted management planning.^{14,114,115,182} Surprisingly, Feddermann-Demont and colleagues³²⁰ reviewed 46 prospective studies covering 3284 athletes and found no studies meeting their review criteria that reported on neck pain, despite being a frequent concomitant injury after a head trauma, contrary to current recommendations and research. Primary domains were neurocognitive testing, balance, and symptom complaint. Interestingly, the studies focused on the total number rather than type of symptoms, an unexpected emphasis since symptoms typically guide the diagnostic decision and therapeutic management. Finally, studies related to the non-SRC population were not examined or evaluated

for inclusion. The authors' recommendation for future research focus was to explore the less-studied domains of vestibular, ocular motor, visual, psychological, and cervical symptoms, including baseline test results.

Due to the number of sensory and motor pathways of the cervical spine that may be damaged following a concussion, it is critical that the physical therapist carefully identifies specific impairments in the context of any functional disruption. An impairment directed approach may lead to more efficient and effective management and intervention strategies with positive outcomes.

Movement, stability, and somatosensory components of the cervical spine. The neck is the most mobile portion of the human spine, houses all neural traffic between the body and brain, and encases 100% of the brain's life support. The articulations from the cranium to C2 (also referred to as upper cervical spine, subcranial spine, or craniovertebral region) provide one-third of the sagittal plane motion and nearly half the rotational (transverse plane) motion of the neck. Ligaments supply structural stability while joint morphology permits great motion, as seen in [Table 23.10](#).

All ligaments, but particularly the facet capsules, are vascularized and innervated with nociceptors and mechanoreceptors. As in all synovial joints, facet mechanoreceptors respond to loading and tensile forces throughout their full ROM and stimulate firing from muscle spindles. Thus they are vital for stability³²¹ and motor control. Facet afferents have cell bodies in the Dorsal Root Ganglia (DRG), projecting to the deep laminae of the dorsal horn. Afferents from C2 and C3 DRG may converge upon other nociceptive afferents arising from the subnucleus caudalis of the trigeminal nerve, which extends into the spinal cord at least to the level of C3, creating the neural mechanism for pain referral from upper cervical structures to the face and cranium.^{319,322}

Neck musculature can be classified in three groups: craniocervical, typical cervical (within the neck), and those that span both regions. The trapezius and levator scapulae attach the head to the shoulder girdle and thorax. Cervical musculature is arranged in two "sleeves": the deep intrinsic sleeve provides tonic activity, intersegmental stability, guidance, and coordination, which includes the subcranial group, multifidus, longus colli. Greater torque production for head-on-body motion is produced by the phasic functioning of the superficial extrinsic sleeve,³²³ which includes the splenius capitis and cervicis, scalene group, infra hyoid groups, and platysma. The sternocleidomastoid is a prime mover of the head on the body, with great leverage and no attachments in the cervical spine.

The intrinsic group of subcranial muscles are nearly a 60/40% mix of type I postural slow fatiguing and type II fast twitch (phasic)

TABLE 23.10 Cervical Spine Ligaments

Region	Ligament	Function
Intrinsic craniovertebral	Tectorial membrane	Prevents distraction of cranium from spine
	Alar-Odontoid (paired)	Limits side bending of cranium on C2
	Transverse ligament of the atlas	Limits forward nod of C1 on C2 and preserves the A-P dimension of spinal canal under foramen magnum
C2–S1 anterior and posterior vertebral bodies	Anterior and posterior longitudinal ligaments	Limit extension and flexion, respectively, invest in the outer layers of intervertebral discs from C2–C3 through L5–S1
C2–S1, lamina to lamina posterior border of the spinal canal	Ligamentum flavum (paired)	Elastic ligament forms anterior aspect of all facet capsules, limits excessive spine flexion, may assist in return from flexion
Cranium to cervicothoracic junction	Ligamentum nuchae	Limits excessive neck flexion, most superficial, thick, ropelike

fibers.³²⁴ Thus the intrinsic group has both postural support and primary segmental movement roles. The subcranial musculature has an exceptionally rich density of muscle spindles with up to 240 spindles (γ) per gram of wet muscle weight, which is required for exquisite fine motor control. Such spindle densities are consistent with their important role in head/neck and eye coordination and segmental stability.³²⁵ Twelve intrinsic subcranial muscles create a 360 degrees “rotator cuff” for the cranium on the neck, with direct neural connections to the cerebellum, vestibular nuclei, and oculomotor nuclei via the superior colliculus. In healthy subjects, deep cervical musculature may be facilitated with gaze direction but functions independently of neck rotation direction.³²⁶

Muscle spindles are important organs of proprioception, which can be considered the most important somatosensory component needed to integrate information from the visual and vestibular systems for normal movement and postural control.^{327–329} As a group, mechanoreceptors in the neck help the nervous system distinguish between head motion accompanied by body center of mass, and head on body movements not accompanied by motion of the body center of mass.³³⁰ Their disruption leads to sensorimotor changes with adverse effects on the feedback and feedforward mechanisms of motor control, as well as regulation of muscle stiffness needed for stability. **Box 23.2** summarizes conditions that disturb muscle spindle function. Locally these conditions interfere with smooth and appropriately timed motor responses. Centrally, inaccurate afferents disturb sensory integration. The importance of anatomical structures in the cervical spine responsible for position sense cannot be overstated, as their integration within the CNS affects our ability to plan and execute effective purposeful movements.³²¹

For a review of somatosensory neuroanatomy and function, the reader is directed to <https://clinicalgate.com/the-somatosensory-system-i-tactile-discrimination-and-position-sense>.

Through cerebellar, brain stem, midbrain, and cortical projections, neck afferents contribute to the integration and coordination of a trio of reflex pathways that help recruit deep neck muscles for stability during head and body movements. The tonic neck reflex (TNR) promotes extensor recruitment to stabilize the neck for head motion in response to gravity, the cervicocollic reflex (CCR) is activated by the body moving under the head, and the vestibulocollic reflex (VCR) helps stabilize during rapid head motions. The cervico-ocular reflex (COR) complements the VOR by contributing to gaze stabilization during object tracking at slow head speeds and when the body is moving under the head. An important distinction to consider is the COR and VOR are usually inversely active.

BOX 23.2 Conditions That Disturb Muscle Spindle Function

- **Pain** can alter reflex activity and the sensitivity of the gamma muscle spindle through chemosensitive type III and IV nociceptors, and centrally by somatosensory cortex reorganization.
- **Joint effusion** impairs proprioception by inhibiting skeletal muscle, even in the absence of pain.
- **Direct trauma** may result in loss of muscle tissue and mechanoreceptors.
- **Fatigue** alters the metabolic state, changes motor activation patterns and muscle spindle discharge, increases a sense of effort, and results in clumsiness and decreased fine motor control.
- **Ligamentous hypermobility and joint instability** evoke inconsistent and late mechanoreceptor firing, affecting the useful timing, tuning, and intensity of muscle spindle activation.
- **Psychological distress and anxiety** can upregulate sympathetic tone, increasing tonic firing.

Mechanisms of cervical injury in concussion events. Neck trauma includes whiplash, defined by the QTF as an acceleration-deceleration mechanism of energy transfer to the neck and head from indirect neck trauma, beyond the tissue’s ability to dissipate.³¹⁸ Indirect transfer of rotational forces to the cranium may result in concussion injury during a whiplash effect. Cervical spine soft tissues are disrupted at much lower impact forces than those measured in typical football concussions.³³¹ Direct head impact is likely to create compression or tension forces within the cervical spine. Although any combination of forces can lead to injury, common examples include impact to the mid- or lower face, causing upper cervical extension/compression, lateral impact creating sudden side bending and rotation, posterior impact causing forced flexion, and vertex or crown impact creating compression. Indirect compression forces can be transferred to the cranium and upper cervical spine from a fall on the pelvis (e.g., falling off of a horse) or unexpectedly stepping into a hole with an extended leg. In blast-induced injuries, there is frequently a trauma component from being thrown into structures or the ground, or being struck by flying objects. Understanding the mechanism of injury may assist in directing assessments and interventions, although mechanism of injury is not a strong factor in prognosis of recovery.³³²

Morphological and functional changes in cervical spine structures have been identified after neck trauma injuries and in response to pain whether from trauma or nontraumatic etiology. These include transition of fiber types from slow fatiguing oxidative type I into fast fatiguing glycolytic type IIB fibers,³³³ atrophy and fibrofatty infiltrate into both superficial and deep cervical musculature,³³⁴ and mitochondrial changes. Endurance, strength, and power are adversely affected by any or all of those changes. Loss of muscle spindle density and quality impairs afferent quality and ultimately sensorimotor function. Cortical reorganization of motor strategies to avoid pain, and loss of endurance at low contractile loads is detrimental to cervical stability during prolonged static tasks such as desk work.^{323,335} Damage to ligamentous and joint structures potentially causes pain, but also leads to impaired mechanics and deleterious tissue changes over time that compromise structural stability. The faster the intended movement task or pattern, the greater the impact of biomechanical constraints, with a more evident disruption of smooth motor control. **Fig. 23.5** shows the interactions between peripheral and central cervical spine motor control.

Cervical Spine Assessment

As part of an overall assessment of the somatosensory system after concussion, the region of the cervical spine should also include temporomandibular, thoracic cage, and shoulder girdle function. Findings upon screening will direct a more detailed assessment. As noted in previous sections, contribution of any individual musculoskeletal finding needs to be considered in the global context of sensory integration and motor control. For the purpose of this chapter, the focus is cervical spine function. A hypothesis-driven approach will help prioritize assessment tool choices and lead to appropriate tailored interventions. Categories of cervical spine assessment are included in **Box 23.4**.

The interview with the patient should tease out red flag issues (**Box 23.3**), establish the time from injury, mechanism(s) of injury, nature and behavior of symptoms, status of irritability, and patient report on functional limitations and goals for recovery. The clinical interview is also an important screening tool for comorbid or contributing factors, and an opportunity to obtain information related to prior concussion history and recovery. Psychosocial contributions are particularly important in stratifying risk for chronicity in individuals with concussion and neck pain, particularly WAD.^{336,337} Chronic conditions will be characterized by many adaptive—or maladaptive—changes in

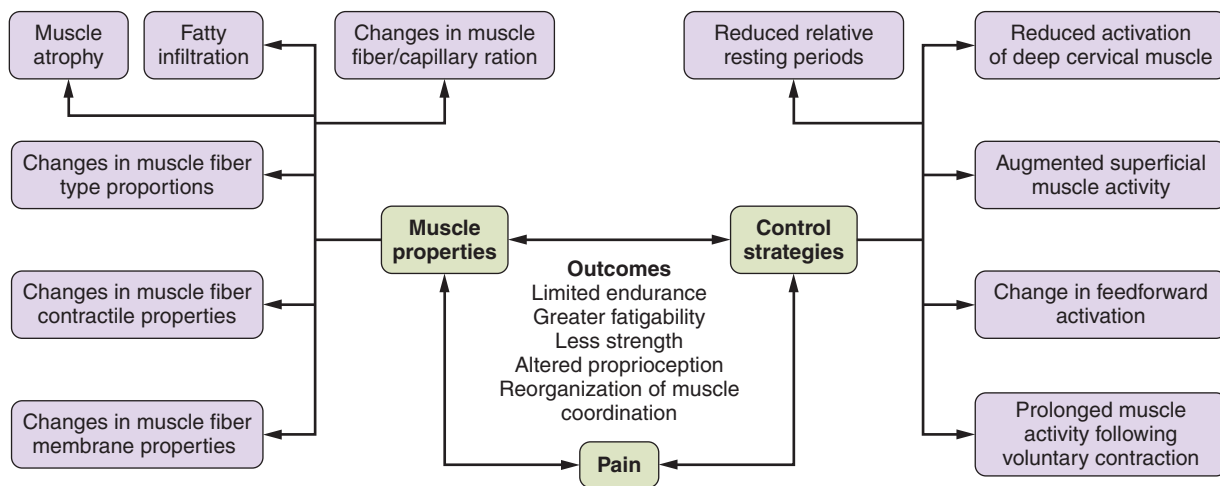

Fig. 23.5 Interrelationships between pain, altered control strategies, and peripheral changes of the cervical muscles. (Reproduced from Jull G, Sterling M, Falla D. *Whiplash, Headache, and Neck Pain*. St Louis: Churchill Livingstone; 2008:51, fig. 4.6.)

BOX 23.3 Red Flags for the Cervical Spine After Acute Concussion and Trauma

- Emergent referral: Risk and symptoms of myocardial infarction (risk factors, chest pain, nonmechanical arm pain, pallor, sweating, dyspnea, nausea, palpitations)
- Emergent referral: signs/symptoms of cervical artery dissection (see below)
- Neurological cord signs or cerebellar signs
- Rheumatoid conditions, heritable disorders of connective tissue (Ehlers-Danlos, Marfan), genetic conditions such as Down syndrome, oral contraceptive use, and pregnancy all are risks for hypermobility and craniocervical ligament injury.
- Congenital anomalies (canal stenosis, Klippel-Feil syndrome, os odontoideum)
- Diabetes mellitus II is a risk factor for delayed healing and excessive stiffness.
- Upper extremity motor or sensory loss (radiculopathy from spine segment disruption)
- Spinal accessory nerve (direct trauma, overstretch, asymmetry of the neckline, inability to shrug shoulders)
- Axillary nerve (>40 years. with shoulder dislocation, traction injury, shoulder abduction and flexion weakness, lack of sensation lateral aspect of upper arm)
- Long thoracic nerve (serratus anterior weakness with scapular winging)
- Endocrine changes—the thyroid may be injured in neck hyperextension.
- Vagus nerve dysfunction—cranial nerve X follows under the sternocleidomastoid muscle and can be overstretched during hyperextension with rotation.

response to the initial injury, healing response, resilience, and contextual factors.³³⁶

Craniocervical ligament tests. Craniocervical ligament tests for signs of instability have moderate correlation to imaging findings and are more sensitive to degree of motion than imaging. Unfortunately, reliability and validity studies are scarce, and results are variable^{338,339}; however, such tests are still recommended to identify patients who are not candidates for end-range subcranial treatments. Craniocervical

BOX 23.4 Components of a Typical Cervical Spine Assessment

Components of a Typical Cervical Spine Assessment

- Interview: history of presenting complaint/medical history/nature and behavior of pain/pain and disability inventories/systems review/differential diagnosis begins
 - Posture
 - Active ROM
 - Palpation
 - Safety tests (ligaments, vertebral artery dependence)
 - Spurling compression to rule out radiculopathy
 - If radiculopathy is suspected, neurological examination of the limb including sensation, vibration, reflexes, and strength.
 - If canal stenosis is known or suspected, neurological assessment of lower limbs, including cord signs.
 - Passive accessory intervertebral joint motion
 - Strength and endurance of neck and shoulder girdle musculature
 - Shoulder girdle and thoracic spine screen
 - Neural dynamic testing
 - Functional assessment of movements or activities of concern to the patient
 - Diagnosis, prognosis, plan, education

ligament tests include the Sharp-Purser test for transverse ligament integrity, the alar-odontoid integrity test, and the tectorial membrane distraction test. [Table 23.10](#) provides a summary of cervical spine ligaments and function. For details of strain tests for each ligament, the reader is directed to [Aspinall](#).³⁴⁰

Vertebral artery dissection and vertebral basilar insufficiency.

Craniocervical ROM is an important factor in treatment of cervicogenic headache (CGH), cervicogenic dizziness (CGD), and head righting responses (HRRs) after concussion. It is imperative that clinicians screen carefully for evidence of compromised vertebral basilar circulation, including history, risk, and symptoms suggesting potential artery dissection ([Box 23.5](#)).

The population occurrence of cervical artery dissection is 2.5 per 100,000 for internal carotid dissection, and 1 to 1.5 per 100,000 for vertebral artery dissection (VAD).³⁴¹ Cervical artery dissection is a

BOX 23.5 Signs and Symptoms of Vertebral Artery Dissection and Vertebral Basilar Insufficiency

The 5 Ds: dizziness, diplopia, dysarthria, dysphagia, drop attacks
 Distress—feeling of impending doom
 Nausea/vomiting
 Presyncope/lightheadedness
 Disorientation or anxiety
 Tinnitus
 Pallor, tremors, diaphoresis
 Unexplained cranial nerve disturbances (facial paresthesia/anesthesia)
 New headache and neck pain, unlike any other, moderate to severe
 Cerebellar signs (finger to nose incoordination, limb or gait ataxia)
 Unilateral limb weakness
 Nasal speech pattern
 Hiccups

significant cause of stroke in young people (<55 years), representing 20% of strokes affecting young people and 2.5% incidence of all strokes.³⁴² Traumatic dissection (TD) can be precipitated by head-neck motion, manipulation, violent coughing or sneezing, sudden deceleration, nonpenetrating head-neck injury, or direct arterial injury. Spontaneous dissection (SD) is associated with hereditary disorders of connective tissue (HDCT), such as Ehlers-Danlos or Marfan syndromes, cystic medial necrosis, polycystic kidney disease, osteogenesis imperfecta, and fibromuscular dysplasia.³⁴² Further risk factors include recent or current bacterial or viral infections, history of another arterial dissection (aortic, renal), or pregnancy.³⁴³ Healthy arteries are not easily disrupted, suggesting that cases of dissection following minor trauma may carry some predisposition to arterial wall weakness. Kumar and colleagues³⁴⁴ described a 16-year-old male wrestler who was injured in a forced “face plant” during a match. He was confused, slow to rise, and experienced nausea and vomiting in transport to hospital. His Glasgow Coma Scale score was 15 and initial CT scan was negative. He was diagnosed with a concussion but continued to develop neurological signs and experienced seizures. His presentation was misinterpreted, and he was not given anticoagulant therapy before developing a significant cerebellar infarct. The authors recommended that VAD should be suspected in any adolescent with advancing neurological signs, and that the threshold for ordering CTA or MRA should be lowered for males. For a comprehensive review of pathoanatomy, etiology, and current research, the reader is directed to Thomas.³⁴¹

Clinical testing for vertebral basilar insufficiency (VBI) is intended to determine the safety of asking a patient to assume craniovertebral extension or rotation without signs of posterior ischemia. The test is for perfusion adequacy and not intended as a diagnostic test. Although possible, there is insufficient evidence to indicate that posterior circulation will be compromised in these positions; therefore a positive test (symptoms) is sensitive to ischemia, but a negative test does not rule out compromised posterior circulation.³⁴⁵

Somatosensory testing. For the assessments of individuals following concussion and neck trauma, the literature recommends several specific additions due to a preponderance of findings in the sensorimotor realm. The recommended order of screening and testing reflects a clearing of one component on to the next, a

reasonable order of physical movement, and an effort to minimize symptom aggravation.

Posture. Observe sitting and standing for comfort, symmetry, unusual alignment (e.g., subluxation of C1 to C2), head position relative to thoracic cage (forward head posture, FHP), and active support verses end-range support (resting in cervical extension to support the head).

Sensation of motion at rest (seated without support, eyes closed). This test assesses whether somatosensory references to stationary firm support surfaces are calibrated to vestibular references without visual inputs. Patients report feeling still or not. Recall that a hallmark of concussion is a global decrement in sensory integration. Observe for sway. CGD symptoms may include lightheadedness, imbalance, vertigo, or the sensation of floating. For a more detailed description, the reader is directed to Chapters 20 and 21.

Active range of motion (standing or seated, caution if patient complains of dizziness). Flexion, extension, side bending, and rotation are assessed overall and can be measured with a Cervical ROM device or inclinometers and compass. Gross restrictions or splinting (e.g., co-contraction that prevents motion) are signs for concern and may precipitate imaging. Note motions that reproduce symptoms—particularly headache or dizziness. Observe for symmetry and smooth execution. Observe for cervical movement progressing into the thoracic cage and screen shoulder girdle motion. Subcranial motion is observed separately, by asking the patient to nod “yes,” nod “up,” turn “no,” and tilt “maybe” with just the face. Individuals with poor motor control, guarding, or restriction will have difficulty with such small localized motions.

Palpation (seated or supine). Examine for tone, guarding, muscle stiffness, edema, effusion of facets or sternoclavicular joints, myofascial trigger points. Palpate for tenderness or reactivity over the greater occipital nerve (GON), lesser occipital nerve (LON), and third occipital nerve (TON), which are also often reactive in CGH. A normal scalp is mobile and nontender, but after impact, or in cases of chronic headache, the scalp may be rigid due to stiffness in the occipitofrontalis or temporalis muscles. Subcranial stiffness and tenderness are common in CGH.

Passive accessory intervertebral motion (seated or supine). Each facet can be tested according to its biomechanical orientation. Normal synovial articulations have passive “give” or accessory motion due to capsular stretching. Range, discomfort, quality, effusion, or any other symptom provocation is recorded.

Of particular interest in patients following concussion are the atlanto-occipital joints (C1 to C2), where 40 to 45 degrees rotation from midline is normal and the concentration of mechanoreceptors is richest.

The cervical flexion rotation test (in supine). The cervical flexion rotation test (CFRT) is a validated method for measuring C1 to C2 rotation.³⁴⁶ In supine, the head and neck are flexed toward the trunk to stabilize the midcervical joints and the head is rotated on the central axis right and left to end range, if tolerated. Capsular end range in the C1 to C2 articulation is soft and elastic, as the capsule permits so much motion. Less than 30 degrees is considered restricted. The test is not as useful in generally hypermobile people, those with a very thick chest, or when neck extensors are too stiff or painful to achieve sufficient flexion. An alternative is to cup the laminae and spinous process of C2 (using the thumb, webspace, and second and third fingers) to block motion below C1 to C2 and passively rotate the head (C1 turns with the cranium).

Joint position error test (seated, 90 cm from a wall). The joint position sense error test^{347,348} (JPE or JPET) assesses the ability to relocate the head to a neutral position with vision occluded, or to relocate the trunk under a stable head to a neutral position.¹⁸⁵ Reacquiring a prescribed position can also be tested. A systematic review by de Vries and colleagues³⁴⁹ looked at trials using JPE, and considered the possibility of vestibular effect. However, results were no different in patients with vestibular loss, indicating an increased weight on cervical proprioception for head repositioning. Deficits were consistently greater and of significance in subjects with neck pain compared with asymptomatic controls. Instrumented versions of testing are available. In the clinic, a small laser attached to a headband or hat brim suffices for an accurate depiction of head position. An error of 4.5 degrees (7 cm linear measurement) or greater is associated with poor proprioception and occurs more frequently in persons with neck pain of any etiology than in healthy asymptomatic individuals. A convenient calibrated color target is available for clinicians: <http://www.skillworks.biz/Resources/Documents/JPE%20Target%20and%20Instructions.pdf>. Due to printer differences in sizing, it is not suitable for research.

Hides and colleagues⁸¹ included JPE testing in a preseason screening battery for 190 rugby football athletes to determine risk factors for head or neck injuries during the playing season. Previous SRC, a known risk factor for new concussion, was related to impaired or asymmetrical trunk muscle function and size, but not to vestibular, oculomotor, or cervical proprioceptive measures. Preseason cervical proprioception deficit was an independent risk factor with high specificity and sensitivity. Players who demonstrated 3 or more of 5 identified risk factors, including JPE, were 14 times more likely to have a head/neck injury than players with 2 or less risk factors. The study results were a strong endorsement for including JPE in preseason screening for contact sport athletes.

Kinesthetic sense. The assessment of kinesthetic sense is a variation on the JPE test, with an evaluation of coordination, motion accuracy, and time. The patient is asked to trace a figure or maze on the wall, where accuracy requires the patient to keep a head-mounted laser within 1 cm of the center line. The task can be timed and compared with the patient's future performance. Kristjansson and colleagues³⁵⁰ demonstrated less accuracy in tracing computer-generated cursor patterns with the head in those with whiplash injuries and nontraumatic neck pain compared with healthy controls, with greater errors recorded in those who also complained of dizziness.

Smooth pursuit neck torsion test (performed seated or standing). The smooth pursuit neck torsion test (SPNT) assesses smooth pursuits while the body is maintained at 45-degree rotation under a stable head to each side compared with performance in a neutral position.³⁵¹ Disturbances in oculomotor control during this test, seen as jerky pursuits or saccadic intrusions, are only seen in patients with complaints of neck pain, not in individuals with general CNS dysfunction or vestibular dysfunction. Therefore a positive test would suggest sensory impairment of afferent input from the cervical spine impacting the motor output of the COR.^{352,353} In patients with whiplash injuries, the COR is augmented without the VOR being diminished, which may contribute to the sensory conflict reported as symptoms of dizziness and visual disturbances.^{354,355} SPNT has been validated with electrooculography as a clinical method to detect oculomotor dysfunction induced by afferent inputs from rotation in the neck.³⁵⁶

Eye-head coordination, changes in neck recruitment and gaze in whiplash-associated disorder. Eye-head control is a complicated interaction among the cervically generated reflexes (CCR, COR), the

VOR, optokinetic reflex, cortically generated saccades and pursuits, and cerebellar influences. Gaze stability during head/neck motion is impaired in persons with whiplash injuries, as are sequential coordinated movements of eyes and head, or head and eyes.³⁵⁷ Patients report dizziness, unsteadiness, trouble reading and driving, with measured loss of visual field, blurry vision, photophobia, and disordered fusion. Treleaven and colleagues measured reduced ROM when turning the head during stable gaze. They also recorded reduced angular velocity of the head when gaze was offset 30 degrees then followed by head position, and subsequently reversed. Without electronic laboratory equipment, the rehabilitation professional can post targets for the patient to acquire visually, and with head position change. A head-mounted laser brings more precision to the task.

As a follow-up to their study of head/neck and eye motion in healthy subjects,³²⁶ Bexander and Hodges recorded significant disruptions in the intricate coordination required for normal eye/head/neck control in subjects with chronic whiplash associated disorders.³⁵⁸ By tracking muscular activity, eye motion, and slow head movement combinations, they discovered that superficial neck muscles (sternocleidomastoid) co-contract in both rotation directions in pain subjects; deep neck muscles showed a loss of independence from neck movement direction, reducing their fine motor control of segmental movement; and eye motions facilitated neck muscle responses far more than in asymptomatic controls activity. Their findings have implications for neck fatigue, chronic pain, and impaired eye-head/neck coordination. Muscle recruitment with eye motion can be palpated clinically and detected with surface EMG. Abnormal patterns may cause symptoms during rapid eye/head movement tests such as VOR and dynamic gaze stability, and should be screened for in advance.

Head righting response (seated). HHR develops in infancy and is driven by otolith inputs and the tonic labyrinthine reflex, which allows orientation of the head upright relative to gravitational force. The reader is directed to Chapters 2, 20, and 21 for more in-depth information. Although typically measured using the Functional Reach Test, it is the ability to maintain or recover an upright head position during eccentric trunk postures that is of interest. Instrumented measures using motion capture, such as with the PROPRIO Reactive Balance Systems (<https://www.perrydynamics.com>) can measure, record, and give the clinician visual feedback as to the patient's performance. A qualitative method of assessing HRR using observation is to perturb the seated patient at the shoulders, eyes closed. More challenging is to seat the patient on an unstable surface such as a tilt board or gym ball and observe the ability to maintain an upright head posture when perturbed. The HRR is also tested by observation in narrow based stance, single leg stance, or during gait. Following concussion, individuals have demonstrated increased medial-lateral displacement,^{359,360} which may be a manifestation of impaired HRR. Biomechanical constraints in the cervical spine (restrictions, weakness, delayed speed of response, impaired proprioception) may disrupt a normal HRR despite an intact vestibular system. As concussion may cause global sensory system deficits, tests specific to the cervical spine may help elucidate its contributions to impaired head righting. Conversely, vestibular impairment of HRR may increase demand on neck function throughout the day and exacerbate symptoms.

Body rotation under a stable head. Walking and running require tolerance of rhythmic repeated trunk rotation under a head facing forward, as well as small amounts of subcranial side bending and sagittal plane motion described under HRR. When a patient is

asked to swivel the body under a stable head, either seated or standing, the vestibular and auditory inputs are challenged to maintain dead-heading (straight on) by rotational torque in the neck. Individuals with increased dependence on neck somatosensation, poor proprioception, abnormal VCR or CCR, or musculoskeletal stiffness will have difficulty, particularly without visual input. The motion may also elicit complaints of dizziness. Although as yet this has not been published as a formal test, visual observation is sufficient to identify a deficit. Using a head-mounted laser aimed at a measured target during repeated body turns provides quantitative measures.

Strength and endurance tests. Strength and endurance at various percentages of maximum voluntary contraction (MVC) have been measured in healthy control and patients with neck pain. Deficits of endurance in the deep cervical flexors have been recorded across the spectrum of MVC in patients with neck pain and dysfunction, of both traumatic and nontraumatic origin.³⁵⁵ Manual muscle testing can be performed at any level in the cervical spine, for gross or segmental control functions. The craniocervical flexion test (CCFT) captures the neuromotor control strategy of deep cervical flexors to sustain a prescribed level of contraction by flattening the cervical lordosis, measured using an air bladder device.³⁶¹ The cervical flexor endurance test (CFET), also referred to as the Head Lift Test, measures the time a subject can support the head in neck flexion one inch from the surface in a supine position.³⁶² The test ends when the subject is observed to lose chin tuck position and recruits more superficial flexors. Normal mean hold times are 39 seconds for males and 29 seconds for females. Neck extensor endurance is also reduced in adults and adolescents with neck pain of a variety of etiologies.³⁶³ Tested in prone, a strap is used to stabilize the thoracic spine at T6. The head is supported off the table surface in a neutral position of the subcranial region and cervicothoracic junction. Unsupported hold is timed until the posture changes notably or the head drops more than 5 degrees. Adding a 2 kg weight suspended from the head by a wide strap reduces the hold time and is equally valid.³⁶⁴

Balance and gait. Tests of balance and gait represent multisensory system integration. Recommended assessments are described elsewhere in this chapter. It is important to observe all performance tests for neck guarding, changes in head-neck posture, and increased headache symptoms. Numerous authors have established gait parameter deficits in neck pain patients. Uthairkhum and colleagues demonstrated that patients with chronic neck pain produced shorter step lengths, slower gait speed with head pitches and turns, and slower “fast walk,” which correlated to higher pain and perceived disability scores. In a cohort of older adults, after considering visual, vestibular, activity, lower extremity function, and health influences, Quek and colleagues ruled out all but neck pain and its detrimental influences on proprioception for gait disturbances and a twofold increased fall risk.³⁶⁵

By using pupillometry, Kahya and colleagues³⁶⁶ demonstrated greater cognitive load during vision-occluded postural stability tests in normal healthy young adults. Although not yet tested in injured persons, the increased cognitive demand should be considered when testing acutely concussed individuals, as cerebral blood flow is reduced for 7 to 10 days.

Cervicogenic Dizziness

As a clinical diagnosis of exclusion, there is no single clinical test that identifies a patient's complaints of dizziness as generating from cervical structures. However, the collection of tests provided can implicate cervical contributions. A hypothesis-driven impairment-directed approach will lead the clinician to plan and prioritize

patient education and intervention. As discussed earlier, concussion injuries implicate global sensory system integration deficits, making specific identification much more difficult. A sensation of spinning in the head suggests a high cervical spine dysfunction. Dizziness or disequilibrium with trunk movements under a stable head, and oculomotor disturbances with neck torsion (SPNT), strongly suggest disturbed cervical afferents. Proprioceptive impairment (JPE) is consistently worse in neck-injury patients who complain of dizziness. Postural instability and gait disturbances may involve all subsystems, but specific testing may elucidate a particular contributor while ruling out others.

Cervicogenic Headache

The possible neural mechanisms for head pain that is generated by cervical structures are discussed above. It is important to differentiate cervical involvement, as CGH responds well to physical therapy intervention and contributes to multiple maladapted pain and motor behaviors when unresolved. Typical findings that alert the rehabilitation professional to primary cervical causes of head pain include unilateral pain, often episodic, worse with fatigue, which may be aggravated by neck motion; tender and tight suboccipital myofascial; trigger points referring to the head or face; restricted C1 to C2 rotation; sensitivity or tenderness over the GON, TON, or LON; JPE of 4.5 degrees or greater; strength and endurance deficits in deep cervical musculature; guarded neck behavior during activities that require head righting or rapid repeated motion; and reduced neck rotation range when stable gaze is required.³⁶⁷

Prognosis in Cervical Spine Dysfunction following Concussion

Stratifying persons by risk factors for protracted recovery can help identify those who may need more focused early intervention, as well as those who clearly will need multidisciplinary care. The statistics for chronic pain and disability in the WAD population have remained at 50% for the past 30 years of data collection, and the risk of PPCS has also been stable at up to 20%. This occurs despite research that recommends successful interventions. The heterogeneity of concussion and neck trauma injuries has not traditionally been captured, particularly in systematic reviews. The most frequently used outcome measures are pain and self-perceived disability, which may not represent meaningful participation in life. Newer studies featuring tailored interventions to identified problems, particularly considering sensorimotor function and sensory integration, demonstrate positive changes.

Risk factors associated with delayed recovery following WAD are described in Table 23.11.³³⁷ Characteristics reported not to be useful for establishing prognosis include angular deformity of the neck (flattened lordosis or scoliosis), impact direction, seating position in the vehicle, awareness of impending collision, presence of a headrest, stationary or moving when hit, and older age.³⁶⁸

Not factored into the prognosis analyses, but potentially impactful, are conditions such as rheumatoid conditions (RA, ankylosing spondylitis, psoriatic arthritis), other autoimmune disorders, fibromyalgia, chronic fatigue syndrome, endocrine disorders, or autonomic dysfunctions, including POTS. Inflammatory markers are only recently being explored in concussion and are potentially significant for neck trauma injuries as well.

Mood and Psychological Disorders

A small but important proportion of patients present with mood or psychological disorders including anxiety, depression, and posttraumatic stress following a concussion. Importantly, a premorbid mood disorder diagnosis or the development of a mood disorder, such as

TABLE 23.11 Risk Factors Associated With Delayed Recovery Following Whiplash Injury

Construct	Recommended Tool	Useful Cut Score for Prognosis
High pain intensity	Numeric rating scale (0–10)	6 or greater
High self-reported disability	Neck Disability Index, original or shorter adaptations	>30%
High pain catastrophizing	Pain Catastrophizing Scale	20 or greater
High acute posttraumatic stress	Impact of Events Scale-Revised; here this scale is used to predict symptom chronicity, not to assess for posttraumatic stress disorder.	33 or greater
Cold hyperalgesia	Gold standard is the TSA-II NeuroSensory Analyzer (Medoc Ltd., Ramat Yishai, Israel), though cost may render it impractical for clinicians. Alternatives include the cold pressor task as a test of cold endurance (similar but not identical to cold pain threshold), use of an ice cube, or use of cold metal bars.	

Adapted from Table 6, Neck Pain Guidelines, Revised 2017.³³⁷

depression, following a concussion is a strong predictor of PPCS.^{3,6,130,369,370} Considering long-term consequences of psychological disorders, specifically for athletes experiencing an SRC, a strong association has been reported between individuals with multiple concussions and affective disorders, particularly the development of depression.¹²¹ Sandel and colleagues have described a pattern of symptoms and deficits that develop in some athletes, who may be classified by an anxiety and mood clinical profile where mental health or emotional disturbances become the primary concern for medical and rehabilitative management following concussion.³⁷⁰ Sandel and colleagues³⁷⁰ suggested that the anxiety and mood clinical profile is characterized by emotional disturbance such as experiencing anxiety, feelings of depression, apathy, hypervigilance of somatic complaints, panic, and/or sleep disturbances.

It is likely that a combination of physiological, psychosocial, and cultural factors may underlie the development of mood disorders following concussion. Preinjury risk factors such as personal or familial mental health history, female sex, and neurophysiological alterations, specifically in the emotional centers of the brain, may lead to changes in emotional responses of patients following concussion.³⁷⁰ As mentioned earlier in the chapter, prior history of emotional instability,³⁷⁰ a poor coping approach to lifestyle changes following injury,^{129,130,370} and/or misguided clinical management such as prescribing unnecessarily long withdrawal from activities (physical, school-, or work-related) may exacerbate postconcussion symptoms, particularly anxiety or depression, and lead to prolonged recovery.^{67,129,130} It is important to emphasize this latter point for adolescents following SRC as student-athletes who are removed from social, educational, and sporting activities for prolonged periods of time might develop, or cause an exacerbation of previous psychological problems, which can in turn disrupt social, recreational, and academic functioning, generating a vicious cycle leading to social and functional impairments.^{67,130} It is well documented that diagnosed psychological distress or depressive disorders can impact cognitive function, even in patients who merely endorse symptoms of depression.³⁶⁹

For the assessment of mood and psychological disorders, a detailed history of previous psychological disorders, history of prior concussion(s), and response/recovery from previous concussion(s) are important to obtain, as each has been shown to increase the risk for development of emotional disturbance following concussion and contribute to prolonged recovery.⁶⁷ Medical professionals should document family history of mental health disorders (e.g., anxiety, major depressive disorder, posttraumatic stress, psychiatric disorders) and monitor current symptoms of emotional disturbance using general questions such as “Do your thoughts race when trying to sleep?”³⁷⁰ or “Are headaches brought on by stress?”³⁷⁰ or validated self-report

questionnaires, such as the Beck Depression Inventory II³⁷¹ or Beck Anxiety Inventory.³⁷² Medical professionals must acknowledge that elevated values on self-report questionnaires alone are not sufficient to diagnose patients with mood or psychological disorders. Symptoms caused by impairment of other functional symptoms may mimic or overlap with symptoms suggestive of emotional disturbances following concussion.^{67,130,370} For example, sadness, excessive sleep, and fatigue may be clinical manifestations of chronic pain or injury to the cervical spine rather than symptoms of depression, just as endorsement of irritability, nervousness, and being more emotion may be related to impairment of the vestibular system rather than anxiety. Thus a detailed interview by a neuropsychologist or clinical psychologist with experience managing patients with brain injury may be required.

For the treatment of mood and psychological disorders following concussion, behavioral therapies, such as cognitive behavioral therapy, are recommended as an overall first-line treatment for anxiety and depression.^{67,373} If emotional disturbances persist under conservative treatment, pharmacological therapies in conjunction with behavioral therapies are recommended.^{67,370} Table 23.5 describes commonly prescribed pharmacological agents used to address mood and psychological disorders following concussion.

Headaches

Posttraumatic Headache

As previously mentioned, headache is the most common symptom reported after concussion injury and is referred to as posttraumatic headache (PTH) when there is a known traumatic event. The 3rd edition of the International Classification of Headache Disorders (ICHD-3) contains updated diagnostic criteria for primary and secondary headaches, as well as cranial neuralgias, facial pain, and other headaches.³⁷⁴ PTH following mTBI is classified as a secondary headache attributed to trauma or injury to the head and/or neck,³⁷⁴ as shown in Fig. 23.6. The diagnostic criteria require a 7-day temporal relationship between the date of injury and onset of headache symptoms. Secondary headaches attributed to trauma or injury to the head and neck are further differentiated into acute headaches lasting less than 3 months or persistent headaches lasting for more than 3 months from the date of onset of either a concussion or whiplash related injury. In some cases, where there is no known date of a traumatic event, but rather a potential for repeated minor events, the diagnosis is less precise. However, the diagnostic criteria for PTH is the same for children and adults.

The incidence of headache following head and neck injury has been reported in a variety of populations, typically investigated quarterly through the first year from the date of injury. In a retrospective study

5. Headache attributed to trauma or injury to the head and/or neck

- 5.1 Acute headache attributed to traumatic injury to the head
 - 5.1.1 Acute headache attributed to moderate or severe traumatic injury to the head
 - 5.1.2 Acute headache attributed to mild traumatic injury to the head
- 5.2 Persistent headache attributed to traumatic injury to the head
 - 5.2.1 Persistent headache attributed to moderate or severe traumatic injury to the head
 - 5.2.2 Persistent headache attributed to mild traumatic injury to the head
- 5.3 Acute headache attributed to whiplash
- 5.4 Persistent headache attributed to whiplash
- 5.5 Acute headache attributed to craniotomy
- 5.6 Persistent headache attributed to craniotomy

General comment

Primary or secondary headache or both? The general rules for attribution to another disorder apply to 5. *Headache attributed to trauma or injury to the head and/or neck.*

1. When a *new headache* occurs for the first time in close temporal relation to trauma or injury to the head and/or neck, it is coded as a secondary headache attributed to the trauma or injury. This remains true when the new headache has the characteristics of any of the primary headache disorders classified in Part One of ICHD-3.
2. When a *preexisting headache* with the characteristics of a primary headache disorder becomes *chronic* or is made *significantly worse* (usually meaning a two-fold or greater increase in frequency and/or severity) in close temporal relation to such trauma or injury, both the initial headache diagnosis and a diagnosis of 5. *Headache attributed to trauma or injury to the head and/or neck* (or one of its types or subtypes) should be given, provided that there is good evidence that the disorder can cause headache.

Fig. 23.6 Diagnostic Criteria for Posttraumatic Headache. From Headache Classification Committee of the International Headache Society (IHS) The International Classification of Headache Disorders, 3rd edition Cephalalgia 2018, Vol. 38(1) 1–211. DOI: 10.1177/0333102417738202

of 1953 pediatric patients aged 10 to 19 years who attended a hospital-based sports medicine clinic, headache was the most frequently identified symptom in 69.4% of participants following concussion.³⁷⁵ At a medical university-based concussion clinic, 72% of 254 patients who were seen for concussion had PTH that was significantly related to symptoms severity scoring, which was reported using the SCAT3 even in those with non-SRC injuries.³⁷⁶ In a population of active duty service members with PTH, who were evaluated retrospectively by a headache specialist postconcussion, more than 50% described more than one headache variant. Seventy-four percent of service members reported a continuous headache, which increased the odds of a medical discharge/retirement by 3.98 (95% Wald confidence interval 1.05 to 15.07).³⁷⁷ There is some evidence that genetic predisposition may play a role in PTH, as athletes who carry the apolipoprotein (APOE) e4 allele are more likely to report headaches and have headaches of increased severity compared with those who do not carry the allele.³⁷⁸

The clinical manifestation of secondary headaches in PTH is most consistent with the presentation of primary headaches in the following frequency of occurrence: migraine, probable migraine, tension-type (TTH), and CGH. A prospective study of 212 adults in a level 1 trauma center following mTBI were evaluated for headache without inclusion of ICHD-3 classification available at the time, but instead assessed

headaches as primary migraine, TTH, cervicogenic, or another headache type.³⁷⁹ Through the full year postinjury, 54% of subjects were found have new or worsened preinjury headache. For those who had headaches throughout the year, 49% were consistent with migraine or probable migraine, while 40% of people with headaches at 6 months presented with TTH profiles. In the case of head and neck trauma, the migraine and TTH are not considered primary because they are precipitated by a traumatic event within a 7-day window, but the clinical presentation and management is similar to that of primary headache and the classification criteria can be utilized to assess the headache behavior. Extensive details regarding headache pathology and implications for physical therapy can be found in Goodman and Fuller; the following sections provide an overview of headache topics specific to and commonly encountered during concussion recovery.³⁸⁰

Posttraumatic Migraine

PTM is a common headache type observed after concussion as reported in youth sports and recreation, high school, collegiate, and professional sports, and service member populations.^{375,381,382} A familial history of migraine in a first degree relative has been found to increase the likelihood of having PTM in the first 2 weeks postconcussion by 2.6 times compared with those without a family history of migraine.³⁸³ The presence of PTM is recognized as a poor prognostic factor in concussion recovery, as those with PTM have been shown to be seven times more likely to have prolonged recovery.³⁸⁴ A preliminary study used brain network activation (BNA) to record electroencephalography (EEG) activity, which is known to detect the neuro-metabolic cascade of events that results in ionic changes following concussion, and evoked response potentials (ERP) during neurocognitive tasks in individuals postconcussion with and without PTM versus noninjured controls.³⁸⁵ The results of this SRC study indicate there may be a future role for BNA analysis to investigate neurocognitive, vestibular, and oculomotor pathway involvement with PTM, and potentially to compare data pre- and postinjury in athletes.

Migraine headaches can occur with or without aura, and especially in children, migraine aura can occur without headache. The diagnostic criteria for different patterns of migraine headache are described in detail in the ICHD-3.³⁷⁴ There are some important pediatric diagnoses to recognize as potential migraine precursors or variants, especially related to vestibular migraine (VM). Benign paroxysmal vertigo of childhood (BPVC) presents as spontaneous episodic vertigo or imbalance lasting seconds to minutes.³⁸⁶ Children as young as 3 years of age diagnosed with BPVC were followed over a 15-year span into adulthood; 33% of those with BPVC developed migraine in young adulthood, which is nearly double the prevalence in the general population.³⁸⁷ Benign paroxysmal torticollis of infancy (BPTI) is another vestibular disorder that can result in sudden onset head tilting, ataxia, dizziness, and signs of autonomic dysregulation.³⁸⁸ BPTI has been associated with acquisition of BPVC in some children, and both disorders show an increased risk of developing VM through adolescence. Finally, abdominal migraine presents as recurrent periumbilical pain and discomfort, often in the absence of headache that lasts hours to days and significantly restricts participation in daily activities with overlay of dysautonomia symptoms such as nausea and pallor. Onset of abdominal migraine typically occurs between 3 and 10 years of age and is a poor prognostic indicator for the development of migraines later in life.^{389,390}

Family history and developmental history are thus an important aspect of the patient interview after head and neck injuries that result in headache and dizziness. The use of a migraine diary or facilitated interview, as found in digital applications such as My Migraine Triggers, can be useful tools to track details of events and associated symptoms. Educating individuals to collect and present subjective and

objective event data to medical providers can facilitate diagnosis of migraine headache, particularly when symptoms of dizziness, vertigo, and instability do not match other vestibular disorders and there is a known risk of head or neck injury. Common reported triggers for migraine headache may include stress, altered sleep, food exposures, dehydration, weather changes, hormone cycles, light, smoke or scented products/perfumes, exercise/exertion, or sexual activity.³⁹¹ Preexisting migraine history should be differentiated from altered migraine patterns that may occur following a novel injury.

Physical therapy following concussion involves complex sensory-motor processing of vestibular, oculomotor, cervical, and somatosensory neural pathways. Challenging any of these systems during an active migrainous event is counterproductive to therapeutic interventions aimed at neuroplasticity, habituation, and adaptation for recovery. The role of physical therapy in PTM involves recognition of migraine activity, referral for medical consultation if not already in place, and patient education to reduce any ongoing stimulating triggers that promote hyperexcitability and symptom burden. Efficacy of physical therapy assessment management of headache, dizziness, pain, and other symptoms between migraines is an area of ongoing investigation.³⁹²

Recognition of VM is of particular importance, due to the high incidence of both headache and dizziness following concussion.¹⁵⁸ Diagnostic criteria for VM has been developed from original studies that have resulted in a consensus between the International Headache Society and the International Bárány Society for Neurootology for the ICHD-3.^{374,393–395} A person must have five episodes of vestibular symptoms lasting 5 to 72 hours with at least one of the following: headache (two of the four criteria: unilateral, pulsing, moderate to severe, aggravated by physical activity), photo and phonophobia, or visual aura. Much effort has been focused on use of imaging techniques to study the cortical and subcortical vestibular pathway activation during vestibular stimulation and as a diagnostic tool for vestibular dysfunction.^{291,392,396} One particular study of individuals with VM found alterations in mediadorsal thalamic activation, correlated with the frequency of VM, compared with those with migraine without aura or healthy controls.³⁹⁷ Future studies in advanced neuroimaging may help explain the role of vestibular and thalamic activation in the perception of pain and hypersensitivity patterns, such as motion perception, photophobia, and phonophobia. Successful medical management of VM requires proper recognition of symptoms to support effective use of prophylactic and/or abortive agents in both pediatric and adult populations.^{398,399}

Tension-Type Headache

Tension-type headache (TTH) is another presentation of PTH found to occur after concussion and whiplash-associated disorders. According to the ICHD-3 diagnostic criteria, TTH can be differentiated into infrequent episodic, frequent episodic, or chronic based on the frequency of occurrence and duration of the headaches. All forms of TTH may or may not be associated with pericranial tenderness.³⁷⁴ Primary TTH is described as bilateral pain and discomfort with a pressing or tightening sensation that is not exacerbated by physical activity or exertion, and most often does not include phonophobia or photophobia, nausea, or vomiting. While there is no current diagnostic test to differentially diagnose migraine and TTH, some imaging techniques show promising developments. An MRI and voxel-based morphometry (VBM) study of individuals diagnosed with episodic or chronic migraine or TTH were compared with health controls.⁴⁰⁰ Reduction in gray matter volume found in the superior frontal gyrus and cerebellar regions appeared consistent with reduction in cognitive processing and in heightened pain due to reduced cerebellar inhibition of the trigeminal neuron activation in migraine compared with

TTH.⁴⁰⁰ Further, changes in gray matter volume were found to have potential utility differentiating between headache types in veterans.⁴⁰⁰

A palpation examination and referred pain patterns may be hallmark clinical signs differentiating TTH from migraine activity, and headache diaries can be extremely helpful in deciphering symptom patterns. Patient questionnaires such as the Headache Disability Index (HDI), Headache Impact Test (HIT-6), and the Migraine Disability Index Assessment (MIDAS) are highly recommended to measure headache severity and to monitor change over time. The beginnings of a clinical prediction rule have been presented to differentiate between frequent episodic and chronic TTH through a correlation between pressure pain threshold testing and four strict criteria related to frequency and duration of headache, and bodily pain and vitality scores on the SF-36.⁴⁰¹ Subjects with less frequent and lower intensity headaches who met the prediction rule classification demonstrated generalized hyperalgesia and central sensitization with higher impact on quality of life, which may become a risk factor for development of chronic TTH and perhaps other generalized pain syndromes such as fibromyalgia.

Headache Attributed to Whiplash

Headache attributed to whiplash injury is classified as acute until persistence beyond 3 months from the date of injury, at which time it is deemed chronic.³⁷⁴ This form of PTH is associated with a known whiplash associated injury that could include a concussive event. Whiplash injury is described as an unexpected acceleration/deceleration force of the head causing rapid flexion/extension of the neck at high or low speed. Keep in mind that few injuries occur in a pure head-on or rear-end fashion, in which case some rotational forces are present, causing diffuse axonal and diffuse vascular injuries to the brain and brain stem. Similar to other forms of PTH, the headache onset following whiplash injury must occur within 7 days of injury, and management follows that of other PTH headaches that mimic migraine, TTHs, or CGH if there has been injury to the cervical spine or soft tissues.

Cervicogenic Headache

By definition, a diagnosis of CGH can only be made if clinical or imaging evidence exists of a disorder or lesion related to the cervical spine or soft tissues that is known to cause headache.³⁷⁴ Further diagnostic criteria from the ICHD-3 include all of the following: a temporal relationship between the cervical spine dysfunction and onset of headache pain, reduction of the headache in response to improvement in the cervical spine pathology, cervical ROM reduction causing headache exacerbation when provoked, and full resolution of headache with diagnostic blockage or a cervical structure or its nerve supply. See previous sections for a more detailed discussion of the diagnosis and management of cervical spine pathology.

Headache, Intracranial Hypotension, and Cerebral Spinal Fluid Leaks

There is an increasing awareness of headache associated with changes in cerebrospinal fluid (CSF) pressure after traumatic injury to the head and neck. However, the evidence for clear diagnostic workup of CSF leakage is limited in the published literature, and the diagnostic classification is restricted to headache related to low CSF pressure due to CSF fistula or spontaneous intracranial hypotension.³⁷⁴ In individuals recovering from concussion and whiplash injuries, there is evidence that hereditary connective tissue disorders are a risk factor for CSF leak in the presence or absence of headache. Patients should therefore be screened for signs of hypermobility spectrum disorders, including Marfan's syndrome and Ehlers-Danlos syndrome.⁴⁰² The presence of

headache or neurological symptoms, particularly with orthostatic positional changes, should be cause for referral for potential neuroimaging,⁴⁰³ as altered CSF volume can occur in both the brain and spinal cord as a result of CSF leakage.⁴⁰⁴

Sleep Disturbances

Sleep is a critical function of human behavior; recent evidence support that sleep contributes to restoration of mental functions,⁴⁰⁵ including learning and memory consolidation. Perhaps most importantly for rehabilitation following brain injury, sleep quantity and quality has been shown to be important for neural growth and plasticity,⁴⁰⁶ and recent animal studies suggest sleep may even provide a neuroprotective role⁴⁰⁷ in the presence of disease and injury to the nervous system.

Disrupted sleep is one of the most common complaints of patients who have experienced an mTBI. Interestingly, studies indicate greater subjective complaints and objective impairment in sleep experienced by patients with mTBI, compared with those with moderate and severe brain injury.^{405,408,409} Following mTBI, sleep disturbances can persist for months following injury and may be the cause of, or lead to an exacerbation of, common postconcussion symptoms such as anxiety, headaches, fatigue, and irritability.^{67,405,410} Further, sleep disturbances can cause impairments in cognitive function and physical performance, lead to diminished health-related quality of life, and are predictive of a prolonged recovery.^{405,410,411} For these reasons, sleep disturbances should be an important consideration in the management of patients following mTBI.

The most common sleep disturbances that occur following mTBI include insomnia (difficulty falling asleep or staying asleep), hypersomnolence (daytime sleepiness), and circadian rhythm disorders (abnormalities of the timing of sleep).^{67,405} Conservative management begins with emphasis on sleep hygiene, including regular bedtime and wake time, avoiding stimulants (e.g., caffeine) and heavy exercise late in the day, limiting technology use before bed, and avoiding spending time in bed awake.⁴¹² However, in most cases, education for sleep hygiene will be insufficient, and a combination of rehabilitative strategies such as cognitive behavioral therapy and pharmacological agents are required for successful management of disrupted sleep in individuals following mTBI.⁶⁷ Table 23.5 describes commonly prescribed pharmacological agents used to address sleep disturbances. In general, there is limited evidence regarding medications to address sleep disorders in mTBI,⁶⁷ and the use of medications (over-the-counter and prescription) follow similar indications for patients with sleep disorders without brain injury, which include selective serotonin reuptake inhibitors (SSRIs), melatonin, and tricyclic antidepressants (TCAs) for insomnia, nonbenzodiazepine hypnotics or other neurostimulants to address hypersomnolence, and melatonin or regulated exposure to daylight/night (e.g., phototherapy) can be used in cases of circadian rhythm dysfunction.^{67,405}

A critical component of the assessment related to a patient who endorses sleep disturbances following mTBI is consideration of other comorbid factors such as pain, psychiatric disorders (e.g., anxiety and depression), history of headaches, or fatigue. As mentioned previously, each of these disorders can be the cause of, or can be exacerbated in the presence of, sleep disturbance⁴⁰⁵ and must be identified as a possible confounding factor leading to disrupted sleep. In addition, medical professionals should obtain information related to sleep history and current sleep patterns using self-report questionnaires that have been validated to assess sleep in patients with TBI, such as the Pittsburgh Sleep Quality Index⁴¹³ or the Epworth Sleepiness Scale.⁴¹⁴ The Pittsburgh Sleep Quality Index is composed of nine questions related to quality and patterns of sleep during the previous month. A cutoff score

of 8 has been established to identify patients with clinically significant insomnia following mTBI.⁴¹⁵ It is important that medical professionals consider that, similar to self-report measures of postconcussion symptoms, symptom complaint does not correspond well with objective sleep impairment. Several reports suggest an overestimation of sleep disruption on self-report measures of disrupted sleep in patients following mTBI.⁴¹⁶ Therefore in the presence of continued sleep disturbances, it is important that medical professionals consider referral to sleep specialists who have access to advanced clinical equipment to measure sleep, such as actigraphy and/or polysomnography, to better guide treatment approaches to address the underlying factors.

INTERVENTION

Education

The importance of education in providing care to individuals following a concussion cannot be emphasized enough. Education related to the patient's *current condition*, as well as discussing *expectations* about the patient's potential course of recovery, should not be overlooked by medical professionals, including the rehabilitation specialist. This aspect of care is critical for the individual at the time of injury, the patient who is in the acute stages of recovery following a concussion, and the patient who presents to the clinic with PPCS. Marshall and colleagues⁵ published an updated clinical practice guideline in 2015 for concussion and persistent symptoms following concussion, as a synthesis of existing guidelines. The following recommendations related to education are supported by evidence of at least one randomized controlled trial, meta-analysis, or systematic review:

- Patients should be advised that they are likely to experience one or more symptoms as a consequence of the concussion/mTBI that may persist for a short period of time and that this is usually expected (normal course).⁴¹⁷
- The patient should be advised that a full recovery of symptoms is seen in the majority of cases.⁴¹⁷
- Education should be provided in printed material and combined with verbal review and consists of:
 - Symptoms and expected outcomes
 - Normalizing symptoms (education that current symptoms are expected and common after injury event)
 - Reassurance about expected positive recovery
 - Gradual return to activities and life roles
 - Techniques to manage stress

Active Training Intervention

Taken together, the findings from recent research indicate that active rehabilitation programs should be considered for management of individuals with concussion and PPCS. Across patient populations, the introduction of activity after concussion is potentially beneficial.^{128,131,304,418}

A variety of treatment approaches have been described to assist the rehabilitation specialist in decision making to develop a training program, which includes models that use a classification system that match patients to a specific clinical profile,^{115,381} an approach based on stage of recovery with a variation on international consensus for return to activity,^{17,69} and a cognitive-behavioral approach with emphasis on self-efficacy and self-management in combination with active rehabilitation training designed for children and adolescents with PPCS.⁷⁰

Given the subjective nature of a concussion diagnosis and the range of clinical signs and symptoms that can result after a concussion, there is consensus that rehabilitation strategies should be based on a targeted

approach that matches interventions to a specific clinical profile.^{14,115,419} Further, international consensus guidelines advocate for a multifaceted clinical approach for the assessment and treatment of concussion, which may include training of the cardiopulmonary and cardiovascular system, the vestibular and oculomotor system, and the musculoskeletal and sensorimotor systems of the cervical spine.^{6,58,115,181,189,304} An example of such an approach has been proposed by Ellis and colleagues,¹¹⁵ where results of an examination can lead the rehabilitation specialist to categorize a patient's presenting signs and symptoms into three clinical syndromes, defined as postconcussion disorders (PCD)—physiological PCD, vestibulo-ocular PCD, or cervicogenic PCD—which in turn provides targeted options for intervention.

It is important to consider that the current consensus of using a multifaceted approach has not yet been validated. Therefore despite these published models, there is little information to help guide clinicians on how to optimally match patients to specific interventions or in what order to address impairments, should the patient present with multiple needs.¹⁸¹ Future research is needed to evaluate the efficacy and effectiveness of single as well as multidimensional active training programs, including cognitive/cognitive-behavioral, aerobic, cervical, vestibulo-ocular, vision, and postural control interventions for individuals following concussion.^{181,420} Ultimately, a greater understanding of the optimal treatments, with consideration for the timing, dosage, and effects of multiple treatments, will inform best practice and potentially minimize health-related disability following concussion.^{5,181}

The pharmacological therapies available for patients following concussion have already been discussed earlier in this chapter. For this reason, the reader is presented with evidence supporting the use of active rehabilitation strategies for individuals with slow recovery or PPCS following injury, which include cognitive rehabilitation, aerobic exercise, vestibular rehabilitation, vision therapy, management of cervical spine dysfunction, and multidisciplinary care.

Cognitive Rehabilitation

Cognitive rehabilitation is evidenced-based practice for the treatment of multiple neurological disorders, including TBI, right hemisphere CVA, neoplasms, and Parkinson disease.⁴²¹ Due to the heterogenic nature of TBI injuries, it is often difficult to initially assign a descriptor such as *mild* or *severe*: some of the most devastating injuries can present with mild deficits, while some of the most mildly appearing injuries can result in severe deficits). This is due to the fact that there are multiple variables affecting the injury: speed of impact, type of impact, premorbid functional levels, age, gender, drug or alcohol history, and prior injuries. Therefore though a person can be diagnosed with a concussion or a complex mild TBI versus a TBI, it is really a continuum, due to this injury heterogeneity. For the SLP, PPCS is not a different category of deficits, but rather on one side of the continuum of TBI, and as such, the treatment naturally connects to the evidence-based practice used in TBI cognitive rehabilitation. Notably, though there has been a paucity of research in PPCS cognitive rehabilitation, recent research has been robust in evaluating the outcome of cognitive rehabilitation for PPCS.⁴²²

The constellation of the cognitive-communication deficits reported by those with PPCS are similar to those with more severe injuries, although typically the PPCS patient is higher functioning and able to maintain independence (but may need support in some areas). As stated earlier, some tests or batteries may not identify the specific higher level cognitive-communication deficits.²⁵⁹ This is consistent with rehabilitation efforts in this area, as well. Furthermore, as with assessment, rehabilitation therapy must be functional and ecologically valid for the PPCS patient's life and goals.

Results from assessment directly relate to development of therapy goals in all rehabilitation therapies. All cognitive-communication

intervention/therapy is completed in a hierarchical approach, with cueing as needed, and with gradual fading or removal of cues.⁴²³ Furthermore, in order to maximize outcomes, evidence-based practice recommendations include not only restorative practice (i.e., cognitive stimulation, practice in isolation), but also training on compensatory strategies, and practice in context or real-world situations.⁴²⁴ A more recent approach in this area is the addition of Goal-Attainment Scaling (GAS).⁴²⁵ This involves the patient and the therapist developing goals that relate specifically to the patient's life. A rating scale defines each level, with the patient describing and naming each level of the scale, and then as they move through therapy, the patient identifies where they are on the scale. This can be a very powerful tool, and a functional real-life connection of cognitive-communication skills and how we use them in life.

Cognitive-communication rehabilitation for PPCS generally addresses attention, memory, executive functions, social language/pragmatics, and word retrieval. Due to the heterogeneity of this population overall, it is possible that other specific deficits will be identified in assessment such as stuttering/dysfluency or writing; however, these are the primary areas that will be addressed in this chapter in relation to intervention.

Attention Training

Attention training can be completed for all domains of attention. Several programs have been developed to address sustained, selective, alternating, and divided attention, with one specifically for the mild TBI/concussion patient.⁴²⁶ The starting point is identified through assessment results. Therapy usually involves starting where the patient is able to participate, and then gradually increasing in complexity, speed, and distractions. One example for divided attention from the APT program involves listening for two numbers presented slowly in an auditory list, while also crossing out numbers on a visual task.⁴²⁷ Should the patient be able to complete at an 80% to 90% accuracy level, the next step will potentially be a list read more quickly, or more auditory or visual targets. An example of a selective attention task, without using a prepackaged therapy program, would be having the patient complete a checkbook balancing worksheet while an environmental noise tape or a TV program is on. Compensatory strategies may be identified, trained, practiced, and utilized, and ultimately gradually removed or diminished in usage (i.e., noise-cancelling headphones to complete sustained attention tasks, taking breaks frequently during tasks, working on one task at a time). The final goal for this therapy would be the patient being able to attend to tasks in their daily life with noise and distractions, as they were able to premorbidly.

Memory

Memory therapy for immediate, delayed, working memory similarly is based on the same hierarchical and cueing principles. Restorative practice and stimulation is also primary, as well as training on compensatory strategies, practicing use, and gradually incorporating them into real-life tasks.⁴²⁸ Internal compensatory strategies may include visualization, repeating or reauditorization, association, mnemonics, and note-taking.⁴²⁹ External strategies or aids may include smartphones, timers, visual schedules, dayplanners, and keeping items in the same location.⁴³⁰ An example of a therapy activity for immediate memory could be listening to a factual paragraph, and the patient using strategies such as visualization, reauditorization, and association, then repeating or summarizing main points. The same task could be part of a delayed memory task with a timer set for a 20-minute delay, where the patient recalls the details or is asked detail questions. Cueing to support can also be involved. Prospective memory tasks can include scheduling tasks in the future, using compensatory strategies. This

could start at minimal amounts of time up to future appointments, days and weeks ahead. Sohlberg and colleagues developed and evaluated the Prospective Memory Screening and Prospective Memory Training program, and this is one example of a program available in a hierarchical approach.⁴³¹

Executive Functions

The ability to plan, organize, solve problems, be flexible in thought and generate multiple solutions, and reason through possible solutions are all used in daily life.⁴³² The best example in real life is creating and planning out chores with multiple units of information. (For example, say you need to go to the bank to get rolls of change for laundry, but they are only open until 4:00, and you do not get out of class until 4:30. And you need to get your laundry done by tonight since you need to have that shirt ready for your presentation in class in the morning. How are you going to get this done?) Executive functions also involve awareness of self, adjusting our behaviors to settings, and being able to see others' perspectives. Therapy for these behaviors and abilities can be more concrete for things like problem solving, or more abstract, as with role playing for awareness and perspective practice.⁴³³ Compensatory strategy training can also be part of this hierarchy: taking notes, extra time, and breaking tasks down are just a few examples. Feedback from the therapist is also a powerful tool. An example of problem-solving/reasoning/planning could be the patient given and using a map, determining a route based on a few targeted stops. The next step in the hierarchy could be having the patient identify their daily chores from their life or home, and planning out the schedule and the tasks in the most appropriate order. Examples of perspective taking and awareness therapy activities could include role-playing, with videotaping of facial expressions, body language, and interactions, followed by guided review and feedback. A next step in this hierarchy could be a structured interaction with a planned script with another individual or the therapist, with videotaping and guided review and feedback. Much of this therapy is guided by identified deficits from assessment, as well as input from the family about premorbid executive function abilities, in addition to knowledge about cultural and personal strengths and weaknesses before the injury.

Word Retrieval

Word retrieval intervention involves stimulating the ability to generate specific words and training in the use of compensatory strategies. The inconsistency of word retrieval issues is very frustrating for the patient. Therapy can involve the production of specific words for description or in response to a question. This can be simple to complex in nature, and therapy is also hierarchical. For the PPCS patient, therapy usually focuses on this therapy process with the compensatory strategy training at the same time.⁴³⁴ Strategies can include describing the word or concept (e.g., target word is *roller coaster*, and the patient describes a fast ride at an amusement park), gestures, and using semantically related words (e.g., "It's like a train").⁴³⁵ These are the strategies that most people use in daily normal word retrieval issues. The PPCS patient may have to use these more consistently and automatically, and training in this will make it more automatic and reduce frustration. As reaction time or speed of processing is a related issue with word retrieval,⁴³⁶ this extra time for processing used in compensatory strategy use can sometimes allow for the target word to be accessed.

Social Language/Pragmatic Skills

As stated previously, SLPS are highly correlated with executive functions and attention. They are also very abstract and sometimes subconscious in expression and perception. Therapy is driven by the weaknesses or deficits identified in observations, interviews, and rating

scales by patient and family. Typically with the PPCS patient, the deficits are more subtle, and many in their inner circle may not even provide feedback to the patient since they feel as if they are being "rude" themselves by pointing it out. Therapy then involves identifying the issues, having the patient be able to identify (i.e., discriminate appropriate versus inappropriate behavior), providing specific training on target behaviors, and then practicing in structured situations through real-life scenarios.⁴³⁴ An example would be perseverance on a topic and not recalling that the patient had shared that information multiple times prior. This could be identified via videotape review; the behavior could be negatively practiced (i.e., the patient can do it voluntarily), and then practiced using appropriate compensatory strategies or soliciting feedback (i.e., "Have I told you about my accident?"), and from there, the patient could practice being able to avoid the topic or getting back on the interaction topic. This would involve videotaping, practice, and role-playing, with eventual practice with structured and then unstructured real-life interactions. Cueing is a critical feature in SLPS therapy: the therapist must act as the frontal lobe external aid, and this cueing will eventually be faded.

Aerobic Exercise Training

It has been suggested that PPCS and exercise intolerance, which may be caused by persistent alterations in cerebral cellular metabolism, can be managed successfully with graduated, individualized aerobic exercise programs.^{115,154,188} The use of subsymptom exacerbation exercise testing to assess for exercise intolerance of individuals following concussion has been discussed previously. Here the reader is presented with the prescription and progression of aerobic training and the evidence to support the use of graduated exercise training programs for the athlete and nonathlete of various age groups.

Schneider et al. completed a rigorous systematic review related to aerobic training for exercise tolerance as part of the CSG.⁶ Authors concluded that closely monitored active rehabilitation programs involving controlled submaximal, subsymptom threshold exercise may be of benefit for adults and adolescents with PPCS.¹⁸⁹ Individuals with persistent symptoms at rest who experience an exacerbation of symptoms during the BCTT, or an equivalent subsymptom exacerbation exercise test, are considered to have exercise intolerance and should be prescribed aerobic conditioning at 60% to 80% of HRT obtained on the exercise test.^{115,188,276,437} There is evidence showing superior outcomes in exercise tolerance and symptom complaints for individuals performing exercises at 60% to 80% HRT compared with those performing active training at 40% to 60% HRT achieved on a subsymptom exacerbation exercise test.⁴³⁷

Although the subsymptom exercise test has been deemed safe to perform acutely (3 to 7 days postinjury) and at 3 weeks postinjury for adolescents and young adults,²⁷⁷ the exercise test and graduated exercise program has not been performed with children 10 years and younger; therefore clinicians should be cautious in the initiation of and prescription of graded exercise in children. As mentioned in [Box 23.1](#), in the presence of persistent symptoms at rest and with cognitive load in children, it is important to establish academic accommodations and begin a structured return-to-learn program prior to return to activity, which can be safely initiated 4 weeks postinjury.⁷⁰

Baker and colleagues¹⁸⁸ performed a study using a case series of 91 patients referred to a university clinic for treatment of persistent symptoms (individuals with more than 3 persistent symptoms at rest for a period of more than 3 weeks). Following a subsymptom exercise assessment (BCTT), 65 patients (71%) were found to have exercise intolerance, who were classified with physiological-postconcussive disorder (P-PCS). All patients were offered a graded exercise program; however, some declined to participate. More than two-thirds of the

patients who completed the graded exercise program, whether or not the exercise prescription matched the patient clinical profile, returned to full function, on average 2 years following injury, while only 1 in 6 (16%) of the patients who declined to participate in the graded exercise reported return to full functioning. These findings show a potential benefit of graded aerobic training; however, the results should be interpreted cautiously, as there were differences between the two groups. The groups were not of equal size (65 patients were found to be classified as P-PCS compared with 26 patients without exercise intolerance), and follow-up for outcomes of return to function was completed by telephone, where 62% of the P-PCS group compared with 88% of patients without exercise intolerance were available for reporting their functional level.

Leddy and colleagues²⁷⁶ performed a prospective cohort study with 12 participants (6 athletes and 6 nonathletes) with persistent postconcussive syndrome (diagnosis using WHO ICD-10 definition) and symptom exacerbation during the BCTT to show that controlled exercise is safe for individuals with PCS to perform and that graded exercise can improve PCS symptoms when compared with an individual's no-treatment baseline. After testing, athletes and nonathletes performed aerobic exercise for the same duration that they had achieved during the prior treadmill test, but at an intensity of 60% to 80% HRT once per day for 5 to 6 days per week. All of the participants reached age-predicted HR_{max} without symptom exacerbation within a range of 11 to 112 days. Although there was no difference in the amount of improvement between the two groups, athletes achieved maximum aerobic exertion (18 to 20 RPE) without symptom exacerbation in a shorter duration than nonathletes.

Leddy and colleagues⁴³⁷ performed a quasi-experimental study to compare exercise capacity, symptoms, and fMRI activation patterns during a cognitive task in 10 athletes and nonathletes with PCS (using WHO ICD-10 definition). Ten athletes were assigned to an exercise treatment group ($n = 5$) or a placebo stretching group ($n = 5$), and were compared with a healthy control group ($n = 5$). Participants in the aerobic exercise group were instructed to perform a controlled, progressive aerobic exercise program at 60% to 80% HRT, attained on the BCTT for 20 minutes a day with a heart rate monitor for 6 days per week. All participants had an fMRI examination at baseline and again after approximately 12 weeks (range, 33 to 270 days). No adverse events were reported. A statistically significant increase in exercise heart rate was reported for the exercise group, while there was no significant change in exercise heart rate for the stretching group. The exercise group also experienced a statistically significant decrease in number of symptoms (measured by PCSS), whereas no change was observed in the stretching group. The fMRI results indicated that participants in the exercise group showed activation patterns that resembled those of healthy controls during the cognitive task, whereas the activation patterns for the stretching group continued to show impaired function.

Gagnon and colleagues⁷⁰ completed a case series of 16 children and adolescents (aged 10 to 17 years), which showed involvement in a controlled and closely monitored rehabilitation program initiated after 4 weeks of injury may be beneficial to children who are slow to recover following concussion. All participants showed improvements in aerobic activity duration tolerance and in symptoms, with a mean duration of 4.4 weeks in the program. In addition, Gagnon and colleagues⁴³⁸ investigated outcomes in 10 adolescent athletes, between 14 and 18 years of age, who were referred consecutively to an aerobic and general coordination exercise program lasting a mean of 6.8 weeks (range, 3.6 to 26.2 weeks). Overall, a clinically meaningful decrease in postconcussion symptoms was found from initial assessment to the second assessment (Cohen's $d = 1.83$). In addition, moderate to large

effect sizes were found for fatigue levels, depression scores, and performance on cognitive processing (Cohen's d ranging from 0.48 to 2.44).

In a randomized pilot study, Maerlender and colleagues⁴³⁹ enrolled 33 college athletes who were removed from play due to concussion immediately into an exertion group (performed aerobic exercise on stationary bike for 20 minutes daily at a "mild to moderate level" measured by a 0 to 6 on RPE scale) or standard care group who were asked to engage in no systematic exertion other than normal activities for school. Median number of days to clinical recovery (measured by test scores on ImPACT and poststride symptom complaint following bicycle exercise test) and number of athletes with prolonged recovery were no different between the two groups. The study findings provide emerging evidence that moderate physical activity may have a positive effect on time to recovery; however, the preliminary results should be interpreted with caution, because as a pilot study, it was not adequately powered to show between-group differences and the subsymptom exercise test protocol, nor if the RTP program was consistent with recommendations from international consensus guidelines.^{17,154}

Chan and colleagues⁴⁴⁰ randomized 19 adolescents aged 12 to 18 years with PPCS following an SRC into a treatment as a usual group (symptom management and RTP advice, return-to-school facilitation, and physiatrist consultation) and a treatment as a usual group plus an active rehabilitation program with subsymptom aerobic training, coordination exercises, visualization and imagery techniques, and a home exercise program for 6 weeks (mean, 3.4 sessions). The study corroborated with findings from previous studies^{70,441} that an active rehabilitation program is safe to perform with adolescents with PPCS. In addition, a statistically significant treatment effect in symptom complaint as measured by the PCSS (Cohen's $d = .55$) was found for adolescents completing the treatment as usual plus active rehabilitation program.

Kurowski and colleagues⁴²⁰ demonstrated the benefits of subsymptom exacerbation aerobic training in adolescents (mean age 15 years, range 14 to 17 years) with an average of approximately 2 months of persistent symptoms after concussion compared with adolescents randomized to a full-body stretching program. Medium to large effect sizes (Cohen's $d = 0.5$ – 0.8) were found between groups for the Postconcussion Symptom Inventory (PCSI) ratings of the parent/guardian and concussed adolescents, with a trend of greatest improvement found at 5 weeks of the 6-week-long aerobic training program. Interestingly, the study found a similar magnitude of effect size to that found in Chan and colleagues for aerobic exercise in adolescents.⁴⁴⁰

It is important to note, as mentioned previously, that a small population of individuals will experience prolonged signs of autonomic dysregulation and may have sustained exercise intolerance with poor ability to engage in aerobic exercise.²⁸⁰ Symptoms of dizziness, particularly described as lightheadedness, nausea, heaviness of the extremities, tremulousness, reduced mental clarity, and generalized fatigue, can be signs of POTS, which is another syndrome whose clinical presentation mimics many symptoms of PPCS.^{442,443} For those who have PPCS, it is suggested a monthly reassessment of orthostatic intolerance is prudent to rule out the development of POTS. Recumbent exercise training may be required as a mechanism to gradually build tolerance for upright aerobic training, and other comorbidities may further restrict participation in successful exercise training.²⁸⁶ See Table 23.12 for levels of evidence to support the use of monitored, graduated aerobic exercise following concussion.

Vestibular Rehabilitation

Vestibular rehabilitation involves the use of a problem-oriented approach in which impairments are clearly identified in the examination to determine impact on activity limitations. Specific, targeted

TABLE 23.12 Levels of Evidence, as Described by the Center for Evidence Based Medicine,⁴⁴⁴ to Support the Use of Monitored, Graduated Aerobic Exercise Training Following Concussion

	Acute Stage of Recovery (Training Initiated Within 14 Days Postinjury)	Persistent Postconcussion Symptoms (Training Initiated \geq 3 Weeks Postinjury)

Older adults	NA/unknown	NA/unknown
Military personnel	NA/unknown	NA/unknown

interventions to decrease vertigo, lightheadedness, and disorientation should be introduced at the appropriate level. Balance exercises should be established focused on the impairment that is most likely to improve with the goal of avoiding the development of dependency patterns. The cervical spine should be examined to determine the contribution to both dizziness and pain. Posttraumatic headache is a common comorbidity and should be addressed early in the intervention. The concussed patient will likely have maladaptation issues, as there is potential damage to all three of the sensory systems involved, and there may be abnormal motor programs initiated that need to be corrected. The rehabilitation specialist should consider the following general guidelines related to vestibular rehabilitation in concussion:

- Determine the appropriate activity levels to avoid needless exacerbation of symptoms. Exercises that are likely to exacerbate symptoms should be saved for the end of a treatment session or home exercise program, and these should be carefully monitored for progression. The patient should be informed about which exercises are designed to decrease symptoms, and the ones that require the activation of vertigo for the recalibration process. Settling exercises should be provided to the patient to increase the ability to manage symptoms.
- When increasing one activity, reduce or keep other activities at the same level.
- Exercises should be introduced slowly to give the patient and therapist a chance to monitor responses. Remember that exercise for acute vestibular deficits are based on an intact visual and somatosensory system response, so they may be too aggressive for the concussed patient.
- Encourage rest that includes settling between activities (use the visual hygiene instructions provided later on in this chapter) and provide breaks during exercises to improve adherence and limit exacerbation of symptoms. For this reason, treatment sessions may be lengthened to allow sufficient time for active treatments to

promote recovery and decrease potential of worsening symptom provocation.

- Discuss medical management and refer when appropriate for control/resolution of headaches early in rehabilitation to increase exercise and activity tolerance.²⁹⁰
- Gradually include exercises with visual flow and complex visual stimuli.
 - Avoid complex environments initially (e.g., shopping malls, heavy traffic), followed by gradual exposure based on symptoms and tolerance.
 - Encourage the use of indoor and outdoor settings that patients typically encounter to promote reintegration into daily activities.

The trigger of symptoms can be aspects of the vestibular rehabilitation program as exercises are used to drive a change in the output of the vestibular system (VOR and VSR), which is in the business of providing stability in gaze and stability of the postural control system during daily activities, especially with head motion. However, specific considerations should be made for the concussed individuals compared with the patient who has intact vision and somatosensation available for the adaptation process.

Eye-Head Coordination Exercises

Impairments in eye-head coordination have been reported after brain injury⁴⁴⁵ and may result from disruption in the VOR⁴⁴⁶ or reflect increased symptoms with head and eye movement⁴⁴⁷ (e.g., self-motion sensitivity). Eye-head coordination exercises involve movement of the head and/or eyes designed to enhance VOR adaptation. Oculomotor reeducation, if needed, should precede work on VOR and dynamic gaze stabilization exercises, which include eyes-open head movement.⁴⁴⁵ The patient must be able to determine when the head is not moving when the eyes are closed. This can be achieved with settling exercises if necessary. It may also be appropriate to start performing eyes-closed head turns prior to starting eye-head coordination exercises to calibrate the somatosensory and vestibular systems if head motion is determined to contribute to symptoms. Body rotation under a stable head (BRUSH) can be performed in the clinic, as well as by caregivers, to decrease the stiffness in the cervical spine often associated with the habit of self-deceleration of head motion. This can be critical to allow normal speeds for VOR training.

Eye-head coordination exercises while standing, walking, and changing direction can be prescribed as an adjunct to adaptation exercises (e.g., VORx1) to incorporate the change in VOR gain into a functional activity. The direction of the head turn (yaw, pitch, roll plane motion), as well as the magnitude of the head turn, can be modified (head center to head right, head center to head left, head center head up, etc.), according to the determination of somatosensory sensitivity in the cervical spine. To active normal VOR, the head should be moved without stopping in the center. In all head turning activity, it is important that the patient does not stop at the end ROM to abnormally access somatosensory input. This should also be integrated into the frequency of the head motion, which can be modified by timing the head turns to the patient's steps as the patient walks. For instance, a clinician may ask a patient to turn their head to the left for three steps, then right for three steps, then back to the left for three steps, repeating this motion as they walk down a quiet, dimly lit corridor. As the patient progresses, the frequency of the head turns may be increased as the patient is asked to turn their head to the left for two steps, then right two steps, left two steps, and so on as they walk forward. In the advanced stage, head turns of 150 to 160 degrees can be made in the yaw or pitch plane every step as the patient walks forward. An important consideration is that rather than the clinician audibly instructing the patient when to turn the head, the patient can be

encouraged to turn the head while counting the steps so that the movements can be anticipated and planned rather than unpredictable, as both types of perturbations are experienced during typical daily activities. In this way, the task could be considered in the divided attention paradigm.

Visual motion sensitivity can impact the performance of the eye-head coordination exercises and should be addressed concurrently. Use of activities that allow the patient to normalize responses to visual flow can be initiated early in the program. Visual pursuits, saccadic training, vergence, and VOR cancellation exercises are some examples. This can be started in supine or sitting, and progressed to standing on firm and compliant surfaces. Tossing a ball from hand to hand while tracking it can promote decrease in visual motion sensitivity and can be progressed through changes of surface and walking. Use of optokinetic stimulation can be integrated into the program.

Due to the limited guidance provided for vestibular rehabilitation exercise prescription and progression following concussion,

Alsalaheen and colleagues⁴⁴⁵ reviewed home exercise programs designed by 8 physical therapists for 104 patients with persistent symptoms following a concussion that were referred to a tertiary clinic a mean of 58 days from injury. Exercises were categorized as eye-head coordination, sitting balance, standing static balance, standing dynamic balance, or ambulation exercises. Eye-head coordination exercises were the most commonly prescribed category, where 95% of patients received VORx1 viewing (88%) and VOR cancellation (64%) with common modifications to posture and the size of the base of support. Standing static balance exercises were prescribed in 88% of patients with common modifications of changing the surface, size of the base of support, direction of head movement, and visual input. Ambulation exercises were prescribed in 76% of patients with modifications to the size of the base of support and direction of head movement. Examples of prescription and progression of vestibular rehabilitation for individuals with PPCS are described in Table 23.13.

TABLE 23.13 Exercise Prescription and Progressions for Vestibular Rehabilitation Programs Published for Young Adults With Non-Sports-Related Concussion⁴⁴³ and Children and Adults With Sports-Related Concussion and Non-Sports-Related Concussion⁴⁴⁵

Exercises	Kleffelgaard et al. ⁴⁴³	Alsalaheen et al. ⁴⁴⁵
Patient population/modality	Young adults, Non-SRC/Group-based VR program	Children and adults, SRC and Non-SRC
Adaptation/Gaze stability and eye-head coordination	VORx1: working most on far targets (2–3 m away) VORx2: target held in hand	Movement of head and/or eyes for the purpose of VOR gain adaptation, symptom habituation, or oculomotor re-education: VORx1, VOR cancellation, convergence VORx2
Habituation	Brandt-Daroff exercises, sitting or standing exercises with head tipped to knee, head turns, head pitches, standing whole-body turns, walking with head and body turns	Movement of head and/or eyes for VOR symptom habituation: VORx1, VOR cancellation, convergence VORx2
Oculomotor training	Substitution exercises for static gaze stability: active eye-then-head movement between 2 targets, remembered target	Convergence eye movement training
Balance	Circle training with different balance tasks: sitting on big ball/Airex mat, weight shifting, bouncing, turning head, standing on rocker boards, dual tasks	Seated, standing steady-state, standing dynamic balance exercises
Gait	Walking with head and body turns, start and stops, picking up objects from floor, catching/throwing beanbags, figure eight	Patient walks forward, backward, on stairs, with turns, skipping, jogging, and running
HEP	2–5 exercises, as appropriate + aerobic exercise program: 15–20 min of nonspecific activity (not guided by graded exercise test)	Participants were provided a HEP; however, no frequency or duration provided
Posture	Posture: sitting, standing, walking, jumping, running	Posture: sitting, standing, walking
Surface	Surface: level, mats, foam, Bosu balls, trampolines, wedges, wobble boards, obstacles, stairs	Surface: level, foam, uneven, obstacle, stairs, ramps
Base of support	Base of support: feet apart, feet together, semitandem, tandem, one foot	Base of support: feet-apart, feet-together, semi-tandem, tandem
Arm position	Arm position: away from body, close to body, crossed over chest, hands on hips, reaching, juggling	Arm position: close to body, away from body, reaching, carrying, juggling
Head movement	Head movement: still, nodding, rotating	Head movement direction: still, yaw, pitch, roll
Visual input	Visual input: eyes closed, eyes open, complex patterns, visually quiet environment, visually busy environment	Visual input: eyes closed, eyes open, complex visual patterns
Cognitive task	Cognitive task: secondary motor and cognitive tasks	Cognitive dual task: no examples provided
		Trunk position: upright, leaning, rotated
	Twice per week for 8 weeks (16 sessions)	Median 4 visits (range, 2–13)

HEP, Home exercise program; SRC, sports-related concussion; VOR, vestibulo-ocular reflex; VORx1, adaptation training strategy where the eyes match speed and distance of target (gain = 1); VORx2, adaptation training strategy for the VOR, gain = 2; VR, vestibular rehabilitation.

When considering the progression of exercises described by Alsalaheen and colleagues,⁴⁴⁵ it is difficult to provide a clear recommendation due to the significant variability in the number of visits patients completed (7 to 181 days); however, it is worth noting that at initial evaluation the majority of patients were prescribed the VORx1 viewing exercise while standing with feet apart (43%), followed by standing with feet together (31%), and sitting (23%), demonstrating the modifications necessary to minimize potential symptom provocation. One interesting finding was that the VORx2 viewing exercise was prescribed less frequently (9%) than is typically prescribed for patients with unilateral vestibular hypofunction.⁴⁴⁵ It is difficult to provide a definitive reason for the discrepancy in exercise prescription between the two groups. It may be due to the increased visual flow created by moving the head and the target in opposite directions. It may also suggest that patients become symptomatic with advanced adaptation exercises, and therefore the VORx2 viewing exercise should be reserved for the very late stages of return to play and after successful intervention for visual sensitivity when individuals are returning to intensive sport-specific activities that require precision of the VOR (e.g., dancing, skating, basketball) during repetitive, high velocity head turns. See Chapters 20 and 21 for more comprehensive information on the appropriate progression of intervention and exercise for sensory integration during eye-head movement exercises.

Balance Exercises

Prescription of balance exercises should follow the same guidelines related to sensory integration as eye-head coordination. They should be both specific to the impairments determined during examination and comprehensive enough to address all components of the balance system. In addition, modifications to steady state and dynamic balance exercises may need to be performed in a progression from seated to standing, then walking, changing direction, jogging, running, and athletic-specific movements if required for the patient's recreational/sports-related activities.

Effective use of hip strategy in both the anterior-posterior and lateral directions should be encouraged as soon as possible. Head-righting exercises and work on tilt surfaces are critical to avoid development of dependence pattern through the somatosensory system. Head righting can be initiated in sitting and progressed to tandem gait. These activities should be progressed to performance with eyes closed to avoid visual dependence. See Chapters 20 and 21 for a more complete description of the appropriate progression of exercise to facilitate normalization of balance.

Examples of balance prescription and progressions described in the literature are presented in [Table 23.13](#).

Alsalaheen and colleagues⁶⁵ used a case series of 114 consecutive patients (67 children, 47 adults) to show that patients referred for vestibular rehabilitation after a concussion (median of 96 days postinjury; range 8–2566 days) may benefit from therapeutic interventions. Alsalaheen and colleagues⁶⁵ reported a significant treatment effect for self-report and performance-based measures for balance and gait impairment, including DGI, FGA, gait speed, and FTSTS. In addition, a significant interaction between treatment and age was found with children experiencing greater improvements in dizziness severity reports and balance performance.

The authors reported the group-based program, modified from a program developed at Oslo and Akershus University College for patients with chronic dizziness, is safe, feasible, and may be beneficial for individuals with targeted problems of dizziness and balance following concussion. Interestingly, one benefited from a prolonged vestibular rehabilitation period and might have continued to improve if provided an additional 4 to 8 weeks.⁴⁴⁹ However, findings from Adams and colleagues⁴⁵⁰ suggest that even long rehabilitation programs (up to

24 weeks) will not always lead to improved outcomes in this patient population. Evidence of potential “responders” and “non-responders” to physical rehabilitation programs point to the need for more sensitive biomarkers to determine who and when individuals are likely to benefit from active rehabilitation strategies, if those individuals can be identified clinicians could potentially match patients to an effective treatment regimen at the ideal time for an optimal outcome. Future studies are needed to address these important questions in rehabilitation.

The highest quality of evidence to provide support for the use of vestibular rehabilitation has been reported by Schneider and colleagues³⁰⁴ who performed an RCT comparing return to sport for 31 adolescents and young adults (mean age, 15; range, 12–30) receiving a combination of aerobic training, vestibular rehabilitation, and cervical spine physical therapy to a control group receiving aerobic training alone, one time a week for 8 weeks. At 8 weeks, a significantly higher proportion of patients who were treated with vestibular rehabilitation and cervical spine physical therapy (73% of the intervention group) were medically cleared to return to sport compared with just 7% of the control group. Although all individuals who were medically cleared reported feeling 100% and reported zero symptoms of headache and dizziness, it is unclear if this was at rest or if it was following the return to sport guidelines described by international consensus guidelines.¹⁷ Another important limitation was the range of days from injury in the intervention group were within 30 days of injury while the control group was not—8 to 276 days compared with 31 to 142 days, respectively. Thus spontaneous recovery may have favored the vestibular rehabilitation and cervical spine physical therapy group.

Details related to the exercise prescription and progressions of the vestibular rehabilitation programs used in these studies^{304,305,445,448} are provided in [Table 23.13](#).

Reviews on vestibular rehabilitation following concussion have shown a paucity of strong evidence in support of vestibular rehabilitation for patients following concussion.^{303,451} Evidence surrounding interventions to address vestibular impairment following concussion suggests that the potential benefits do outweigh the potential risks and vestibular rehabilitation may be most beneficial for a specific subset of patients with persistent symptoms following a concussion.⁴⁵¹ There is now a clear requirement for more high-quality RCTs for vestibular rehabilitation programs used to address vestibular impairment of patients following a concussion to determine the effectiveness of the treatment approach ([Table 23.14](#)).³⁰³

Vision Therapy

The most common oculomotor deficits that have been shown to be amenable to vision therapy include ocular misalignment, impaired visual fixation, versional dysfunction (saccadic and pursuit eye movements), and vergence ocular motility deficits.^{100,453}

In the presence of visual fixation deficits, common treatment approaches are composed of rapidly changing focus on command and sustaining visual focus on targets for extended periods of time using attentional grids and near-far-vision focal shifting.¹⁰⁰ Basic scanning and searching exercises can be used in the presence of saccadic and smooth pursuit deficits, where the focus of the exercises should be on accuracy first and then building up to rapid saccadic eye movements or tracking tasks. For vergence ocular motility deficits, prisms may be used to accommodate motility deficits or to be used as a training tool, and far and near viewing (e.g., Brock string) can be performed as a restorative treatment option as well. Often these tasks involve the use of equipment that is only available through licensed optometrists and ophthalmologists, and there is evidence that the care of individuals with functional vision changes should be directed by qualified specialists

TABLE 23.14 Levels of Evidence, as Described by the Center for Evidence Based Medicine,⁴⁴⁴ to Support the Use of Vestibular Rehabilitation Following Concussion

^aImprovements in symptom complaint of dizziness.

^bImprovements addressing dynamic gaze stabilization.

^cImprovements addressing self-report and/or performance related to balance and gait impairments.

such as a neuro-optometrist or ophthalmologist.^{5,454} For this reason, underlying visual dysfunction should be given consideration for referral to specialists such as optometrists, ophthalmologist, neuro-optometrists, or occupational therapists, who specialize in vision therapy for individuals with brain injury.^{100,290}

Special considerations should be incorporated for vision therapy in regards to patients with signs and symptoms consistent with impairment to the ocular motor system and visual perception following concussion. The rehabilitation specialist should provide:

- Instructions to the patient to “rest” eyes by looking at targets at a distance or by cupping hands around eyes to limit visual input
- Advice on the use of filter screens and glasses or printing on colored paper for visual comfort while reading
- Education to avoid/decrease exposure to light by dimming lights, using curtains, wearing sunglasses/filtered lenses, or wearing caps to shade the sun or indoor lighting

Overall, empirical evidence is limited for the effectiveness of vision therapy to address symptoms and functional deficits following concussion.¹⁰⁰ Preliminary evidence suggests that combined oculomotor therapies that target multiple impairments, including convergence and

accommodative insufficiency and versional problems, may be effective in reducing symptoms and improving reading.^{454,455}

Thiagarajan and colleagues⁴⁵⁵ found oculomotor rehabilitation composed of versional (fixation, saccades, and smooth pursuit), vergence, and accommodation training two sessions per week for 6 weeks led to significant improvements in reading rate and was associated with improved subjectively based visual comfort and visual attention during reading in young adults (age range, 23 to 33 years) who were 1 year postinjury. Further, when oculomotor training was performed in conjunction with multiple therapies (vestibular, cognitive-behavioral therapy, speech therapy, and/or psychotherapy), Ciuffreda and colleagues⁴⁵⁶ reported marked improvement in individuals’ attentional state while reading under simple and complex environmental conditions for those with mTBI. However, given the small sample sizes, nonrandom group assignments, and inclusion of individuals with acquired and traumatic brain injury, findings from Thiagarajan and colleagues⁴⁵⁵ and Ciuffreda and colleagues⁴⁵⁶ need to be interpreted cautiously (Table 23.15).¹⁰⁰

Management of Cervical Spine Dysfunction

Because of the heterogeneity of findings in people with neck dysfunction after concussion and whiplash injury, multimodal interventions based on identified impairments represent the most successful outcomes. Unfortunately, large-scale systematic reviews and meta-analyses present such inconsistent findings that it is difficult for clinicians to meaningfully synthesis research findings and draw informed conclusions.⁴⁵⁷ The challenge remains to “provide the right intervention for the right person at the right time,”⁴⁵⁷ which is a difficult approach to measure with conventional research methods.

Malmström and colleagues⁴⁵⁸ used a clinical reasoning approach to assess and treat 22 patients with comorbid neck pain and dizziness, in whom vestibular dysfunction and trauma were ruled out. All improved whether acute or delayed care was rendered. Positive effects persisted at 6 and 24 months after treatment in 76% of subjects, suggesting that some may have required more specific maintenance strategies. As discussed in other sections, Schneider and colleagues³⁰⁴ employed a multimodal treatment regimen addressing both vestibular and cervical findings. Cervical spine interventions included nonprovocative ROM exercises, stretching, postural education, manual therapy of cervical and thoracic spine regions, neuromotor retraining, and sensorimotor retraining. In order to control headache symptoms, cervical spine treatments preceded vestibular interventions. All participants in both the treatment and control groups had clinical findings suggesting cervical involvement, and 80% to 90% had clinical signs of vestibular dysfunction. The integrated approach resulted in student-athletes returning to play sooner than those not treated. Likewise, a case series of six pediatric athletes with PCS where multimodal assessments and care included cervical, aerobic activity, oculomotor, and postural control demonstrated successful return to activity.⁶⁸

^aImprovements in symptom complaint.

^bImprovements in functional activities related to static gaze (i.e., reading, computer work).

Studies on the effects of neck treatment in the acute stage after concussion are few. Schneider and colleagues⁴⁵⁹ identified a constellation of cervical impairments within 4 days of concussion in a cohort of elite youth ice hockey athletes that pointed toward appropriate treatment choices. A psychometrically sound battery of tests was used to explore cervical spine function, vestibulo-ocular function, dynamic balance, and divided attention tasks. Although individuals with persistent postconcussion often report issues in all categories, cervical spine dysfunction was most significant for this acute group. Impaired sensory integration was evident. Cervical tests included the CFET, cranial flexion rotation test, anterolateral neck strength, and joint position error.

Investigations of specific treatment approaches for individuals with traumatic neck injuries of greater than 3 months' duration have focused on proprioceptive retraining,⁴⁶⁰ deep cervical muscle strength and endurance,^{461,462} neuromotor retraining,^{321,463} and manual therapy^{464,465} interventions, including active mobilizations called sustained natural apophyseal glides (SNAGs). Shoulder girdle control also contributes to CGH treatment.⁴⁶⁶ The methods of the recommended assessments outlined previously can not only identify impairments but be transitioned into interventions. Important principles to keep in mind for treating the cervical spine after concussion are:

1. Identify and prioritize impairments, and understand the known or theoretical mechanisms.
2. Group impairments into functional classifications, if possible, to maximize intervention effect.
3. Consider cognitive demands of multisensory processing after concussion.
4. Understand prognostic risk factors for chronicity, including psychosocial and contextual factors.
5. Invest the patient in the plan, provide appropriate images, and minimize written directions, as individuals with concussions may have difficulty following or remembering directions. Photos or videos captured on the patient's phone are very helpful.
6. Address basic impairments before advancing to complex activities.
7. Employ sound motor learning concepts to engender the most robust and lasting changes. In particular, consider appropriate feedback (both internal and external), high repetitions, attention, and salience to the patient.
8. Progress patients through sensory reweighting demands for enduring sensorimotor improvements. This also helps avoid developing excessive dependence on one sensory system.

The Neck Pain Clinical Practice Guidelines Revision 2017³³⁷ promote four classifications of patients with neck pain: neck pain with mobility deficits, neck pain with movement coordination impairments, neck pain with headaches of cervical origin, and neck pain with radicular pain. Interventions with stringent levels of evidence are assigned by category with recommendations divided into acute, subacute, and chronic stages. The reader can appreciate that each of those categories can apply to concussed individuals with neck pain.

A selection of example interventions based on evaluative findings and test protocols follows:

- Repetitive nonaggravating small nods will encourage synovial joint healing and promote normal joint mechanoreception and motor recruitment in the highly problematic craniocervical region. Sucking the body of the tongue to the back of the hard palette encourages localized subcranial motion and reduces temporomandibular compression. Midcervical and cervico-thoracic movements may be localized by placing a hand, rolled towel, belt, or strap across the lower half of the target motion segment. Self-assisted localized facet and soft tissue mobility can be augmented with carefully placed belts or straps. Stretching exercises must not create excessive leverage across impaired articulations.
- Joint mobilization and manipulation in the cervical and upper thoracic regions where restrictions are identified are helpful in pain

reduction during the acute phase, but less so in the subacute and chronic phases. When supported by specific exercises for motion control, mobilization/manipulation can improve ROM.

- Cervical proprioception can be improved with progressive activities using the head-mounted laser, for head and trunk relocation activities as well as kinesthetic control such as tracing figures or mazes. More complex activities, including static and dynamic balance and gait, can incorporate proprioceptive tasks.
- Proprioception is also improved through strength and endurance training of deep cervical musculature. Beginning in the vertical position, the weight of the head may be increased as the trunk approaches horizontal. Limits must be set to ensure perfect form and control, just as in any skill development. Difficulty may increase through load, speed, and duration. For example, deep subcranial extensors may be challenged to meet their dual performance tasks of support and coordination in a four point kneel, head, and neck held in neutral, with nodding and turning added. The activity limit is reached when the two functions cannot both continue accurately.
- Eye-head coordination is described in detail in the vestibular intervention section. Serial eye-head motions should also be included, where gaze changes first, followed by head motion match, or gaze remains stable while head position changes with eyes following afterward. Slower speeds may help reset the COR. Additional tasks can be layered on, such as isometric head support in prone, four point kneel, side lying, or partial supine to challenge deep cervical musculature. "Foveal Glasses"⁴⁶⁷ (only the pupil of each eye is exposed, with the remaining lens area taped over) are used to prevent eye drift during neck motion activities intended to strengthen the VOR cancellation, strengthen gaze stability, and improve cervical-visual coordination. Their effects are theoretical and untested. The clinician must decide if vision is the correct and desired feedback for the intended purpose.
- BRUSH movements may help normalize the CCR (eyes closed) and COR (eyes opened), reduce neck muscle guarding, and improve perception of head position relative to neck and body activity. Feedback may be visual, including use of a head-mounted laser for accuracy, somatosensory (rotating with a firm prop behind the head against a door frame), or auditory (ticking clock set straight ahead). Speed, repetitions, and duration constitute the dose, as well as choice of surface and body position.
- Head righting progression might include sitting or bouncing on an exercise ball, swinging hips and trunk from side to side under a stable head, or reaching into eccentric positions while maintaining a vertical head. On a firm seat, if ROM permits, the patient can tilt sideways until the elbow touches the sitting surface, alternating sides and maintaining a vertical head. This has the dual benefit of exercising the trunk. In standing, simple trunk side bending by sliding a hand down the leg can progress into more challenging stance positions and surfaces. Many yoga asanas are ideal for the challenge.
- Cervico-thoracic posture and mobility, respiratory patterns, and scapular carriage and control contribute to pain management and more efficient function (Table 23.16).

Multidisciplinary Care

Following concussion patients may experience symptoms and functional limitations caused by impairments of multiple systems, which can be best managed by practitioners across disciplines. For this reason, there is substantial, mostly anecdotal, support for multidisciplinary care for patients following a concussion.^{58,118,181,303} Despite the number of reports advocating for the use of multidisciplinary care for the management of functional limitations following concussion, the recommendation is largely consensus based, as there is limited empirical evidence to demonstrate its superiority to isolated pharmacological or nonpharmacological (e.g., education, active intervention) treatments.

TABLE 23.16 Levels of Evidence, as Described by the Center for Evidence-Based Medicine,^{4,44} to Support the Use of Management of the Musculoskeletal and Sensorimotor Deficits of the Cervical Spine Using Active Training Following Concussion

	Acute Stage of Recovery (Training Initiated Within 14 Days Postinjury)	Persistent Postconcussion Symptoms (Training Initiated ≥ 3 Weeks Postinjury)
Children (<10 years)	NA/unknown	NA/unknown
Adolescents (10–18 years)	NA/unknown	Level 2: Schneider et al. ³⁰⁴ Level 4: Hugentobler et al. ⁶⁸
Young adults (18–55 years)	NA/unknown	Level 2: Schneider et al. ³⁰⁴
Older adults	NA/unknown	NA/unknown
Military personnel	NA/unknown	NA/unknown

Several large medical centers across the United States, Canada, and the United Kingdom have developed multidisciplinary Concussion Centers that incorporate teams dedicated to patient care and research from the acute stages through full recovery. For a detailed discussion related to the variety of disciplines that may be included in a comprehensive concussion center team and the roles of each team member, the reader is directed to the following reviews: Makkissi and colleagues,⁵⁸ Reynolds and colleagues,¹⁸² and Ahmed and colleagues.⁴⁶⁸

Effective multidisciplinary care begins with a thorough assessment, which should start with a complete neurological examination ideally performed by an experienced sports medicine physician, neurologist, or neurosurgeon.¹¹⁸ Results of a thorough examination by a medical physician specializing in brain injury can lead to referrals to different health care providers for specialized assessment and management of functional limitations that are within the rehabilitation specialist's scope of practice (see Ellis and colleagues¹¹⁸ for review). This may include referral to a(n)

- or exercise physiologist physical therapist for a subsymptom exercise tolerance test and graduated aerobic exercise prescription;
- physical therapist for assessment and management of potential vestibular and cervical spine impairments;
- occupational therapist, optometrist, and/or ophthalmologist for visual deficits;
- psychiatrist or neuropsychologist to manage mood and psychological dysfunction;
- SLP or neuropsychologist for assessment and management of cognitive deficits;
- neurologist specializing in the management of headaches for migraine or migraine-like clinical presentation.

Schneider and colleagues³⁰⁴ showed adolescents and young adults with PPCS, following an SRC who received a multimodal intervention of vestibular rehabilitation and management of cervical spine impairment performed by a physical therapist, were 3.91 (with 95% confidence interval of 1.34 to 11.34) times more likely to be medically cleared by 8 weeks, compared with a control group. The multimodal approach was completed by one physical therapist with 13 years of clinical experience and expertise in the area of vestibular rehabilitation and musculoskeletal physical therapy with treatments once per week that consisted of neuromotor retraining, manual therapy, and sensorimotor retraining exercises prior to initiating vestibular rehabilitative exercises.

Hugentobler and colleagues⁶⁸ carried out a case series including six adolescent athletes (age range 15 to 19 years) with postconcussion symptoms for a median of 80 days (range, 19 to 192 days) following injury. Although the study describes a problem-based assessment and treatment (similar to that described by Ellis and colleagues¹¹⁵) for physical therapists, including aerobic training, vestibular rehabilitation,

and management of the cervical spine, each patient received multidisciplinary care from rehabilitation specialists, including sports medicine, neuropsychology, psychiatry, physical therapy (vestibular rehabilitation and/or musculoskeletal physical therapy of the cervical spine), and headache specialist care, on average for 6.8 session over an average of 8.9 weeks. Outcomes suggest that a physical therapy program incorporating a multidisciplinary approach may help facilitate symptom reduction, improve self-management abilities, and safely enhance function in adolescents. In spite of improvements, only one of the six patients had returned to full preinjury activity levels at the time of their final physical therapy assessment; however, the majority (4/6) returned to preinjury levels and types of activity within 3 to 6 months. Similar findings for return to activity and RTW were reported by Moore and colleagues⁶⁶ in 14 young and older adults (median age = 43 years, range 18 to 72) with PPCS for a median of 107 days (range 14 to 992), who received multidisciplinary care, on average, for 19 sessions (range 12 to 27) over 24 weeks of treatment. The majority of patients did not return to preinjury work or physical activities until the 6-month assessment (86% and 57%, respectively) compared with the number of patients who returned to preinjury work and physical activities at the 3-month assessment (36% and 21%, respectively). In addition to aerobic exercise training, vestibular rehabilitation, and musculoskeletal cervical spine physical therapy, patients received vision therapy provided by an occupational therapist, cognitive therapy provided by a neuropsychologist, and psychology and vocational counseling, if appropriate.

Vikane and colleagues⁴⁶⁹ randomized 150 participants with PPCS 2 months after an mTBI into an intervention group who received a multidisciplinary outpatient treatment program consisting of a specialist in rehabilitation medicine, a neuropsychologist, occupational therapist, social worker, and a nurse compared with a comparison group who received follow-up by a general practitioner. Intervention was performed once per week for 4 weeks, with a median of two sessions completed. The occupational therapist helped the patients with memory aids and structuring the day. Psychological distress or cognitive difficulties were followed-up by a neuropsychologist, who used cognitive behavioral treatment when appropriate. There was no difference on the primary outcome of *return to work* (defined as 5 consecutive weeks without absence), and there was no statistically significant difference in number of symptoms endorsed or severity of symptoms reported on the RPQ. Limitations of the study include potential differences in the type of nonpharmacological intervention provided, differences in scope of practice for rehabilitation services (study was completed in Norway), and most importantly, the severity of injuries in this sample population as 25% of the sample received a Glasgow Coma Scale score of 13 to 14 (75% were assigned a 15) and were hospitalized following injury. See Table 23.17 for a summary of levels of evidence to support multidisciplinary or multimodal care.

TABLE 23.17 Levels of Evidence, as Described by the Center for Evidence-Based Medicine,⁴⁴⁴ to Support the Use of Multidisciplinary or Multimodal Care Following Concussion

	Acute Stage of Recovery (Training Initiated Within 14 Days Postinjury)	Persistent Postconcussion Symptoms (Training Initiated \geq 3 Weeks Postinjury)
Children (<10 years)	NA/unknown	NA/unknown
Adolescents (10–18 years)	NA/unknown	Level 2: Schneider et al. ³⁰⁴ Vikane et al. ⁴⁶⁹ Level 4: Hogentobler et al. ⁶⁸ Cordingley et al. ⁴⁷⁰ Grabowski et al. ⁴⁷¹

Older adults	NA/unknown	Level 2: Vikane et al. ⁴⁶⁹ Level 4: Moore et al. ⁶⁶
Military personnel	NA/unknown	Level 4: Janak et al. ⁴⁷²

CASE STUDY 23.1

Ciara, a 17-year-old female, was a healthy adolescent, with no history of previously documented concussions or psychological disorders, sustained a high velocity direct ball-to-head contact injury during a soccer match. She was observed by coaching and athletic training staff to stagger and seemed disoriented as she ran the opposite direction of play once she arose from a downed position for 10 s following the hit. Due to the strong suspicion of a concussion because of her behavior following the injury, Ciara was pulled from the match and, as per mandated state laws to prevent a potentially life-threatening second impact syndrome, Ciara did not return to play.

During the on-the-field assessment using the Sport Concussion Assessment Tool 5 (SCAT5) testing, performed by the athletic trainer, Ciara endorsed headache, dizziness, and noise sensitivity with no evidence of impaired cognitive function. Results of the SCAT5 did not indicate the need for emergent care. The athletic trainer provided the recommendation for Ciara to not return to any sport or school-related activities until a full evaluation was completed by a Sports Medicine Physician. Her symptoms continued for the rest of the day and evening.

Acute Concussion

Follow-up examination by a Sports Medicine Physician 2 days following injury resulted in the following problem list:

- Posttraumatic headache described as dull, constant, and occipital in location, with some component of upper cervical discomfort
- Sleep disturbance of hypersomnolence (daytime sleepiness)
- Impaired cognitive function—specifically attention and memory
- Exercise intolerance as symptom exacerbation and abnormal heart rate response recorded during 4th minute of the subsymptom exercise tolerance test
- Endorsement of dizziness when rising from laying down or seated position
- Impaired balance as measured by the Balance Error Scoring System
- Slowed scanning right-to-left with multiple errors on King Devick test
 - eliminate

Education and Recommendations From Sports Medicine Physician

The nursing staff at the Concussion Center provided education to Ciara, through verbal report and physical pamphlets, indicating that it is common to experience a myriad of symptoms following a hit to the head, but in the majority of cases patients will return to prior functional activities without symptom provocation. Ciara was also

provided education for sleep hygiene with a discussion on regular bedtime and limiting technology use before bed. (Note: although not yet validated, the results of this examination indicate a score of 10 points on the PPCS risk categories reported by Zemek and colleagues,¹¹⁹ with a 69% probability of developing PPCS.)

Recommendation for Return to Learn

As Ciara had already been kept from engaging in school for 2 days, the physician recommended partial return to school with accommodations. Communication with school counsellor and school nurse determined the following classroom accommodations:

- ½ day school for 2 weeks, but increase to full day of school if able
- Double time for homework and tests
- *Recommendation for return to play:*
- No engagement in vigorous physical due to failed subsymptom exercise tolerance test. Ciara was permitted to perform light activities such as daily chores, walking, and social activities.

Intervention (medical management): prescribed acetaminophen to manage continued headaches.

Reevaluation at 14 Days Following Injury

At 14 days following injury Ciara continued to be limited to ½ day of school, which resulted in an exacerbation of headaches, dizziness, and the development of new symptoms, including fatigue, “feeling like in a fog,” and eye strain. She refrained from physical activity as instructed. Ciara was found to have exercise intolerance, as she had symptom exacerbation at 40% age-related heart rate maximum during the subsymptom exercise tolerance test. Ciara continued to be engaged in social activities, although she stated that this also caused an exacerbation of the previously listed symptoms. Further, Ciara was found to have continued sleep disturbances, cognitive dysfunction, and balance impairment.

Education and Recommendations From Sports Medicine Physician

Education was provided indicating that the majority of children and adolescents return to unrestricted school and sport-related activities within 28 days. Therefore Ciara was expected to continue to improve over time and, as able, she should increase the amount of time engaged in school-related activities.

Continued

CASE STUDY 23.1—cont'd

Recommendation for Return to Learn

No changes to the above listed recommendations for ½ day school and double time for homework and tests

Recommendation for Return to Play

Begin engaging in light jogging activities and individual soccer drills of low-to-moderate physical exertion below a symptom exacerbation level.

Reevaluation at 30 Days

At 30 days following injury, Ciara had returned to full days at school; however, she continued to report an exacerbation of nondebilitating headaches, dizziness, fatigue, and eye strain most days of the week. These symptoms were exacerbated during social engagement as well. She was able to engage in light aerobic exercise, but when she attempted to perform more intense soccer drills, she reported headaches and dizziness. Ciara was found to have exercise intolerance as she had symptom exacerbation at 80% age-related heart rate maximum during the subsymptom exercise tolerance test. Further, Ciara was found to have continued sleep disturbances, cognitive dysfunction, and balance impairment. In addition, screening for affective disorders indicated the presence of an anxiety disorder, potentially caused by her protracted recovery and inability to engage in school, social, and sport-related activities without an exacerbation of symptoms and unknown cause of the symptoms.

Patient met the classification for persistent postconcussion symptoms and was referred to the following health care providers (examination findings and interventions from a multidisciplinary team are provided):

- Referred to neurologist: headache management.
- Referral to sleep specialist for continued sleep disturbances
- Referral to psychologist for development of anxiety

- Referred to speech-language pathologist
 - Assessment findings
 - Impaired selective attention, alternating and divided attention per Test of Everyday Attention (TEA)
 - Impaired immediate memory, delayed memory on the Repeatable Battery for the Assessment of Neuropsychological Status (R-BANS) and the California Verbal Learning Test (CVLT-2)
 - Impaired executive functions per Functional Assessment of Verbal Reasoning and Executive Strategies
- Referred to Physical Therapist
 - Assessment findings
 - Oculomotor system
 - convergence insufficiency and slowed saccades
 - Vestibular system
 - Dynamic gaze stabilization
 - Impaired dynamic visual acuity testing
 - Motion sensitivity
 - Dizziness exacerbated by head turns in seated, standing, and walking activities
 - Balance assessment
 - Impaired vestibular functional test on sensory organization test
 - Unable to complete tandem walking with dual task
 - Cervical spine function
 - Musculoskeletal system
 - Reproduction of headaches with palpation of sub occipital musculature
 - Impaired active range of motion and passive accessory intervertebral motion for right rotation and extension in the mid to lower cervical spine
 - Sensorimotor system
 - Impaired cervical proprioception and head righting response

Examination and Intervention for Multidisciplinary Care Approach

Personnel	Examination Findings	Initial Intervention Provided
Neurologist	Posttraumatic headaches	Unclear whether posttraumatic headaches are posttraumatic migraine versus tension type headache. Conservative management through physical therapy as first-line management of headaches
Athletic trainer	Exercise intolerance on subsymptom exercise tolerance test: symptom exacerbation at 80% age-related heart rate maximum	Aerobic exercise at 70% heart rate maximum for 2 weeks prior to increasing to 80% heart rate maximum
Psychologist	Found to have posttraumatic anxiety and disrupted sleep	Cognitive behavioral therapy to begin addressing posttraumatic anxiety and sleep disturbances
Speech language pathologist	Impaired selective, alternating, divided attention. Impaired immediate memory, delayed memory. Impaired executive functions for identifying alternate solutions to problem, planning for task.	Cognitive-linguistic rehabilitation, with hierarchical approach and cueing, goal attainment scaling with patient goals for school
Physical therapist	Impaired dynamic visual acuity testing, motion sensitivity to self-motion, and dizziness exacerbated by head turns with seated, standing, and walking activities. Impaired vestibular contribution on sensory organization test and unable to complete tandem walking with dual task. Reproduction of headaches with palpation of suboccipital musculature. Impaired active range of motion and passive accessory intervertebral motion for right rotation and extension in the mid to lower cervical spine. Impaired cervical proprioception and head righting response.	Dynamic gaze stabilization: VORx1 at a distance, seated Standing and walking with head turns Balance: tandem walking with EO/EC and with head turns Nonprovocative range-of-motion exercises, stretching and manual therapy for range of motion deficits. Sensory reweighting exercises for sensorimotor impairment.
Occupational therapist	Convergence insufficiency and slowed saccades	Convergence eye movement training (e.g., Brock string exercises). Basic scanning and searching exercises. Education on visual hygiene.

reader to a Medline abstract for the article cited. There are 472 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: Concussion is one of the most common neurological conditions in the world. Due to the frequency at which individuals sustain concussions and the detrimental effect concussion can have on function, the Centers for Disease Control and Prevention (CDC) has labeled concussion a major public health issue. Concussion, also referred to as mild traumatic brain injury (mTBI), has been defined by the International Consensus Conference of the Concussion in Sport Group (CISG) as a complex pathophysiological process affecting the brain, induced by biomechanical forces. Whether concussion results in structural damage or a functional injury is unclear and has been debated over centuries. What is clear is that concussion may cause a variety of short-lived neurological signs and symptoms that, in most cases, resolve spontaneously. However, in a minority of concussive events, symptoms will evolve and persist over a number of days or weeks leading to a slow, prolonged recovery, which can impact an individual's

ability to return to meaningful activities. Unfortunately, despite the recent boom in research in the last 25 years related to concussion, there continues to be disheartening evidence, both empirical and anecdotal, which suggests continued mismanagement in the care of patients who sustain a concussion. This chapter was developed to provide a review of the information at all stages of care following a concussion with an emphasis on topics for the rehabilitation specialist who provides services to children, young adults, and older adults. In this way, the rehabilitation specialist is provided information to better understand who is affected, who is at increased risk, in what ways individuals may be impacted, the level of evidence and current recommendations for management of concussion, and effective prevention programs to inform local, state, and federal policies to address this critical topic.

Keywords: sports-related concussion, mild traumatic brain injury (mTBI), cognitive rehabilitation, return to learn/play

Movement Dysfunction Associated With Hemiplegia*

Susan D. Ryerson and Lauren F. Hurt

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the various types of neurovascular disease.
2. Identify the atypical patterns of movement in patients with residual hemiplegia.
3. Identify significant primary and secondary body system (impairments) that interfere with functional movement patterns and limit ability to perform activities and participate in life.
4. Describe reeducation intervention strategies for improving functional activities in patients with hemiplegia.

KEY TERMS

aberrant movements
atypical movements
composite impairments
edema
evaluation of movement control
goal setting
hemiplegia

movement deficits
muscle activation deficits
orthoses
postural control
predictors of recovery
primary impairments
secondary impairments

shoulder pain
shoulder subluxation
standardized evaluations of function
trunk and arm linked movements
trunk and leg linked movements
trunk control
undesirable compensations

OVERVIEW

In this chapter, pathological conditions, body system problems (impairment), activity limitations, and intervention strategies for individuals with hemiplegia from stroke are reviewed. Although hemiplegia from neurovascular pathological conditions is the focus of the chapter, therapists can use this information and apply it to adults with hemiplegia caused by other central nervous system (CNS) pathological conditions, such as tumor, trauma, multiple sclerosis, and demyelinating diseases. Movement components and their relationship to functional performance are used as a basis for selection of therapy interventions.

Definition

Hemiplegia, a paralysis of one side of the body, is the classic sign of neurovascular disease of the brain. It is one of many manifestations of neurovascular disease, and it occurs with strokes involving the cerebral hemisphere or brain stem. A stroke, or cerebrovascular accident (CVA), results in a sudden, specific neurological deficit and occurs when a brain blood vessel is either occluded by a clot or bursts. It is the suddenness of this neurological deficit—occurring over seconds, minutes, hours, or a few days—that characterizes the disorder as vascular. Although the motor deficits of hemiplegia may be the most obvious sign of a CVA and a major concern of therapists, other symptoms are equally disabling, including sensory dysfunction, aphasia or dysarthria, and cognitive and

behavioral impairments. CVAs can be classified according to location, size of lesion, pathological type—thrombosis, embolism, or hemorrhage—or according to temporal factors, such as completed stroke, stroke-in-evolution, or transient ischemic attacks (TIAs).

GENERAL MEDICAL ASSESSMENT

Epidemiology

In the United States, stroke is the fifth-ranking cause of death—nearly 133,000 people die each year—and is a leading cause of serious long-term disability.¹ The National Stroke Association estimates that 795,000 new or recurrent strokes occur each year: 610,000 are first attacks and 185,000 are recurrent attacks. The incidence of stroke rises rapidly with increasing age: two-thirds of all strokes occur in people older than the age of 65 years; and after the age of 55 years, the risk of stroke doubles every 10 years. With¹ the over-50-years age group growing rapidly, more people than ever are at risk. In the United States, the incidence of stroke is slightly greater in women than men. Stroke symptoms are more likely in blacks than whites, in those with lower income and educational status, and among people with fair to poor perceived health status. American Heart Association (AHA) projections demonstrate that from 2012 to 2030 there will be a 20.5% increase in stroke prevalence with the highest increase being in white Hispanic males.¹

Cerebral infarction (thrombosis or embolism) is the most common form of stroke, accounting for 70% of all strokes. Hemorrhages account for another 20%, and 10% remain unspecified. Stroke is the largest single cause of neurological disability. Approximately 7.2 million

*Videos for this chapter are available at studentconsult.com.

Americans have self-reported having a stroke and are dealing with impairments and disabilities from a stroke. Of these, 31% require assistance, 20% need help walking, 16% are in long-term care facilities, and 71% are vocationally impaired after 7 years. One study reported that 12% of subjects have complete functional arm recovery and 38% have some dexterity 6 months after stroke. In addition, loss of leg movement in the first week after stroke and no arm movement at 4 weeks are associated with poor outcomes at 6 months.²

The three most commonly recognized risk factors for cerebrovascular disease are hypertension, diabetes mellitus, and heart disease. Since the most important of these factors is hypertension, intensive blood pressure lowering is a critical factor in reducing stroke risk.³ Because high blood pressure is the greatest risk factor for stroke, human characteristics and behaviors that increase blood pressure, including increased high serum cholesterol levels, obesity, diabetes mellitus, heavy alcohol consumption, cocaine use, and cigarette smoking, increase the risk of stroke. In addition, atrial fibrillation, an independent risk factor, increases the risk of stroke by 5 times.⁴

Ostfeld⁵ noted that mortality rates for stroke declined, slowly at first (from 1900 to 1950) and then more quickly (from 1950 to 1970), with a sharp drop noted around 1974. From 1995 to 2005 the stroke death rate decreased by 30%. Experts have speculated that the greater use of hypertensive drugs in the 1960s and 1970s started this decline, and the creation of screening and treatment referral centers for high blood pressure may account for the continued marked decline.⁴

Outcome

The long-term follow-up on the Framingham Heart Study revealed that long-term stroke survivors, especially those with only one episode, have a good chance for full functional recovery.⁶ For people left with severe neurological and functional deficits, studies have demonstrated that rehabilitation is effective and that it can improve functional ability.^{7,8} It has been demonstrated that age is not a factor in determining the outcome of the rehabilitation process.⁹ Currently it is thought that patients should be given an opportunity to participate in the rehabilitation process, regardless of age, unless it is medically contraindicated.

The prediction of ultimate functional outcome has been hampered by the heterogeneity of common stroke impairments and the diversity of commonly used predictors (medical items, income level, intelligence, functional level). Computed tomography (CT), magnetic resonance imaging, and regional cerebral blood flow studies are used to determine location and amount of insult for diagnosis, as predictors of functional recovery, and for research inclusion criteria.^{2,10}

Pathoneurological and Pathophysiological Aspects Classification

The pathological processes that result from a CVA can be divided into three groups—thrombotic changes, embolic changes, and hemorrhagic changes.

Thrombotic infarction. Atherosclerotic plaques and hypertension interact to produce cerebrovascular infarcts. These plaques form at branchings and curves of the arteries. Plaques usually form in front of the first major branching of the cerebral arteries. These lesions can be present for 30 years or more and may never become symptomatic. Intermittent blockage may proceed to permanent damage. The process by which a thrombus occludes an artery requires several hours and explains the division between stroke-in-evolution and completed stroke.¹¹

TIAs are an indication of the presence of thrombotic disease and are the result of transient ischemia. Although the cause of TIAs has not been definitively established, cerebral vasospasm and transient systemic arterial hypotension are thought to be responsible factors.

Embolic infarction. The embolus that causes the stroke may come from the heart, from an internal carotid artery thrombosis, or from an

atheromatous plaque of the carotid sinus. It is usually a sign of cardiac disease. The branches of the middle cerebral artery are infarcted most commonly as a result of its direct continuation from the internal carotid artery. Collateral blood supply is not established with embolic infarctions because of the speed of obstruction formation, so there is less survival of tissue distal to the area of embolic infarct than with thrombotic infarct.²

Hemorrhage. The most common intracranial hemorrhages causing stroke are those resulting from hypertension, ruptured saccular aneurysm, and arteriovenous (AV) malformation. Massive hemorrhage frequently results from hypertensive cardiac-renal disease; bleeding into the brain tissue produces an oval or round mass that displaces midline structures. The exact mechanism of hemorrhage is not known. This mass of extravasated blood decreases in size over 6 to 8 months.

Saccular, or berry, aneurysms are thought to be the result of defects in the media and elastica that develop over years. This muscular defect plus overstretching of the internal elastic membrane from blood pressure causes the aneurysm to develop. Saccular aneurysms are found at branchings of major cerebral arteries, especially the anterior portion of the circle of Willis. Averaging 8 to 10 mm in diameter and variable in form, these aneurysms rupture at their dome. Saccular aneurysms are rare in childhood.

AV malformations are developmental abnormalities that result in a spaghetti-like mass of dilated AV fistulas varying in size from a few millimeters in diameter to huge masses located within the brain tissue. Some of these blood vessels have extremely thin, abnormally structured walls. Although the abnormality is present from birth, symptoms usually develop at ages 10 to 35 years. The hemorrhage of an AV malformation presents a pathological picture similar to that for the saccular aneurysm. The larger AV malformations frequently occur in the posterior half of the cerebral hemisphere.¹²

Clinical Findings

The focal neurological deficit resulting from a stroke, whether embolic, thrombotic, or hemorrhagic, is a reflection of the size and location of the lesion and the amount of collateral blood flow. Unilateral neurological deficits result from interruption of the carotid vascular system, and bilateral neurological deficits result from interruption of the vascular supply to the basilar system. Clinical syndromes resulting from occlusion or hemorrhage in the cerebral circulation vary from partial to complete. Signs of hemorrhage may be more variable as a result of the effect of extension to surrounding brain tissue and the possible rise in intracranial pressure (ICP). Table 24.1 summarizes the clinical symptoms and the anatomical structures involved according to specific arterial involvement.

The frequencies of the three types of cerebrovascular disease—thrombosis, embolism, and hemorrhage—vary according to whether they were taken from a clinical study or from an autopsy study, but they rank in the order presented in this section. The clinical symptoms and laboratory findings for each type are condensed in Table 24.2.

Medical Management and Pharmacological Considerations

Acute Medical Care

Evaluation. Assessment for severity of symptoms, time of onset, and differentiation of type of stroke as ischemic or hemorrhagic is critical in medical decision making. Speech difficulty and hemiparesis are the most common symptoms of an ischemic stroke. Facial weakness, arm or leg numbness, confusion, headache, and nonorthostatic dizziness may also occur. Severe and sudden headache is the

TABLE 24.1 Clinical Symptoms of Vascular Lesions

Affected Vessel	Clinical Symptoms	Structures Involved
Middle cerebral artery	Contralateral paralysis and sensory deficit	Somatic motor area
	Motor speech impairment	Broca area (dominant hemisphere)
	“Central” aphasia, anomia, jargon speech	Parieto-occipital cortex (dominant hemisphere)
	Unilateral neglect, apraxia, impaired ability to judge distance	Parietal lobe (nondominant hemisphere)
	Homonymous hemianopia	
	Loss of conjugate gaze to opposite side	Optic radiation deep to second temporal convolution
	Avoidance reaction of opposite limbs	Frontal controversial field
	Pure motor hemiplegia	Parietal lobe
	Limb—kinetic apraxia	Upper portion of posterior limb of internal capsule Premotor or parietal cortex
Anterior cerebral artery	Paralysis—lower extremity	Motor area-leg
	Paresis in opposite arm	Arm area of cortex
	Cortical sensory loss	Post central gyrus
	Urinary incontinence	Posteromedial aspect of superior frontal gyrus Medial surface of posterior frontal lobe
	Contralateral grasp reflex, sucking reflex	Uncertain
	Lack of spontaneity, motor inaction, echolalia	Uncertain
	Perseveration and amnesia	Supplemental motor area
Posterior cerebral artery		
Peripheral area	Homonymous hemianopia	Calcarine cortex or optic radiation
	Bilateral homonymous hemianopia, cortical blindness, inability to perceive objects not centrally located, ocular apraxia	Bilateral occipital lobe
	Memory defect	Inferomedial portions of temporal lobe
	Topographical disorientation	Nondominant calcarine and lingual gyri
Central area	Thalamic syndrome	Posteroventral nucleus of thalamus
	Weber syndrome	Cranial nerve III and cerebral peduncle
	Contralateral hemiplegia	Cerebral peduncle
	Paresis of vertical eye movements, sluggish pupillary response to light	Supranuclear fibers to cranial nerve III
	Contralateral ataxia or postural tremor	
Internal carotid artery	Variable signs according to degree and site of occlusion—middle cerebral, anterior cerebral, posterior cerebral territory	Uncertain
Basilar artery	Ataxia	Middle and superior cerebellar peduncle
Superior cerebellar artery	Dizziness, nausea, vomiting, horizontal nystagmus	Vestibular nucleus
	Horner syndrome on opposite side, decreased pain and thermal sensation	Descending sympathetic fibers Spinal thalamic tract
	Decreased touch, vibration, position sense of lower extremity greater than that of upper extremity	Medial lemniscus
	Nystagmus, vertigo, nausea, vomiting	Vestibular nerve
Anterior inferior cerebellar artery	Facial paralysis on same side	Cranial nerve VII
	Tinnitus	Auditory nerve, lower cochlear nucleus
	Ataxia	Middle cerebral peduncle
	Impaired facial sensation on same side	Fifth cranial nerve nucleus
	Decreased pain and thermal sensation on opposite side	Spinal thalamic tract

Continued

TABLE 24.1 Clinical Symptoms of Vascular Lesions—cont'd

Affected Vessel	Clinical Symptoms	Structures Involved
Complete basilar syndrome	Bilateral long tract signs with cerebellar and cranial nerve abnormalities	
	Coma	
	Quadriplegia	
	Pseudobulbar palsy	
	Cranial nerve abnormalities	
Vertebral artery	Decreased pain and temperature on opposite side	Spinal thalamic tract
	Sensory loss from a tactile and proprioceptive	Medial lemniscus
	Hemiparesis of arm and leg	Pyramidal tract
	Facial pain and numbness on same side	Descending tract and fifth cranial nucleus
	Horner syndrome, ptosis, decreased sweating	Descending sympathetic tract
	Ataxia	Spinal cerebellar tract
	Paralysis of tongue	Cranial nerve XII
	Weakness of vocal cord, decreased gag	Cranial nerves IX and X
	Hiccups	Uncertain

TABLE 24.2 Clinical Symptoms and Laboratory Findings for Neurovascular Disease

Disease Type	Clinical Picture	Laboratory Findings
THROMBOSIS	<p><i>Extremely variable</i></p> <p>Preceded by a prodromal episode</p> <p>Uneven progression</p> <p>Onset develops within minutes or hours or over days (“thrombus in evolution”)</p> <p>60% occur during sleep—patient awakens unaware of problem, rises, and falls to floor</p> <p>Usually no headache, but may occur in mild form</p> <p>Hypertension, diabetes, or vascular disease elsewhere in body</p>	<p>Cerebrospinal fluid pressure is normal</p> <p>Cerebrospinal fluid is clear</p> <p>Electroencephalogram: limited differential diagnostic value</p> <p>Skull radiographs not helpful</p> <p>Arteriography is definitive procedure; demonstrates site of collateral flow</p> <p>CT scan helpful in chronic state when cavitation has occurred</p>
Transient ischemic attack (TIA)	<p>Linked to atherosclerotic thrombosis</p> <p>Preceded or accompanied by stroke</p> <p>Occur by themselves</p> <p>Last 2–30 min</p> <p>A few attacks or hundreds are experienced</p> <p>Normal neurological examination findings between attacks</p> <p>If transient symptoms are present on awakening, may indicate future stroke</p>	Usually none
EMBOLISM	<i>Extremely variable</i>	
Cardiac	Occurs extremely rapidly—seconds or minutes	Generally same as for thrombosis except for the following:
Noncardiac	There are no warnings	If embolism causes a large hemorrhagic infarct, cerebrospinal fluid will be bloody
Atherosclerosis	Branches of middle cerebral artery are involved most frequently; large embolus will block internal carotid artery or stem of middle cerebral artery	30% of embolic strokes produce small hemorrhagic infarct without bloody cerebrospinal fluid
Pulmonary thrombosis		
Fat, tumor, air	<p>If embolus is in basilar system, deep coma and total paralysis may result</p> <p>Often a manifestation of heart disease, including atrial fibrillation and myocardial infarction</p> <p>Headache</p> <p>As embolus passes through artery, patient may have neurological deficits that resolve as embolus breaks and passes into small artery supplying small or silent brain area</p>	

TABLE 24.2 Clinical Symptoms and Laboratory Findings for Neurovascular Disease—cont'd

Disease Type	Clinical Picture	Laboratory Findings
HEMORRHAGE		
Hypertensive hemorrhage	<p>Severe headache</p> <p>Vomiting at onset</p> <p>Blood pressure >170/90; usually from “essential” hypertension but can be from other types</p> <p>Abrupt onset, usually during day, not in sleep</p> <p>Gradually evolves over hours or days according to speed of bleeding</p> <p>No recurrence of bleeding</p> <p>Frequency in blacks with hypertensive hemorrhage is greater than frequency in whites</p> <p>Hemorrhaged blood absorbs slowly—rapid improvement of symptoms is not usual</p> <p>If massive hemorrhage occurs, the individual may survive a few hours or days as a result of brain stem compression</p>	<p>CT scan can detect hemorrhages larger than 1.5 cm in cerebral and cerebellar hemispheres; it is diagnostically superior to arteriography; it is especially helpful in diagnosing small hemorrhages that do not spill blood into cerebrospinal fluid; with massive hemorrhage and increased pressure, cerebrospinal fluid is grossly bloody; lumbar puncture is necessary when CT scan is not available</p> <p>Radiographs occasionally show midline shift (this is not true with infarction)</p> <p>Electroencephalogram shows no typical pattern, but high voltage and slow waves are most common with hemorrhage</p> <p>Urinary changes may reflect renal disease</p>
Ruptured saccular aneurysm	<p>Asymptomatic before rupture</p> <p>With rupture, blood spills under high pressure into subarachnoid space</p> <p>Excruciating headache with loss of consciousness</p> <p>Headache without loss of consciousness</p> <p>Sudden loss of consciousness</p> <p>Decerebrate rigidity with coma</p> <p>If severe—persistent deep coma with respiratory arrest, circulatory collapse leading to death; death can occur within 5 min</p> <p>If mild—consciousness regained within hours then confusion, amnesia, headache, stiff neck, drowsiness</p> <p>Hemiplegia, paresis, homonymous hemianopia, or aphasia usually absent</p>	<p>CT scan detects localized blood in hydrocephalus if present</p> <p>Cerebrospinal fluid is extremely bloody</p> <p>Radiographs are usually negative</p> <p>Carotid and vertebral arteriography is performed only when diagnosis is certain</p>

CT, Computed tomography; TIA, transient ischemic attack.

Modified from Adams RD, Victor M. *Principles of Neurology*. New York: McGraw-Hill; 1981.

most common symptom of a hemorrhagic stroke. Hemorrhagic strokes may also present with gradual development of reduced consciousness, vomiting, and hemiparesis. A neurological exam will help quantify the severity of symptoms by assessing mental status, focal weakness of the arm, leg and/or face, speech impairments, gait impairments, impaired eye movements, and visuospatial perceptual impairments. The National Institutes of Health Stroke Scale (NIHSS) is highly recommended due to its diagnostic and prognostic power of stroke severity. Additionally, imaging should be performed for differential diagnosis of other conditions as well as to differentiate the type of stroke as ischemic or hemorrhagic. Noncontrast head CT will help rule out hemorrhagic origin while an MRI is more sensitive for identifying ischemic stroke.¹³ Other tests that may be performed include blood glucose, renal function, electrocardiogram (ECG), complete blood count, oxygen saturation, toxicology screen, blood alcohol level, and electroencephalography (EEG). Additionally, continuous cardiac monitoring is strongly recommended for a minimum of 24 hours.¹³

Ischemic stroke. Although infarcted tissue cannot at present be restored, medical management of the acute stroke from thrombosis or TIA is geared toward improving the cerebral circulation as quickly as possible to prevent ischemic tissue from becoming infarcted tissue. Cells that have 80% to 100% ischemia will die in a few minutes because they cannot produce energy, specifically adenosine triphosphate. This energy failure results in an activation of calcium, which

causes a chain reaction resulting in cell death. Around this area of infarction is a transitional area, the penumbra, where the blood flow is decreased 50% to 80%. Cells in the transitional area are not irreversibly damaged.^{14,15}

An established pharmaceutical approach to acute ischemic stroke management is tissue plasminogen activator (t-PA) (see Chapter 36). t-PA must be given within 3 hours of symptom onset but is most effective if used within the first 90 to 180 minutes. It is absolutely contraindicated for hemorrhagic stroke. Permissive hypertension is often prescribed to assist with improving perfusion beyond the clot to limit the area of penumbra. Cerebral edema, if present, is managed pharmacologically during the first few days. Antiplatelet drugs such as aspirin are used to prevent clotting by decreasing platelet “stickiness” following TIA and/or within 24 to 48 hours following ischemic stroke.¹³

Endovascular surgical intervention may be indicated for ischemic stroke to remove/reduce the blood clot. Areas accessible to and suitable for surgery include the carotid sinus and the common carotid, innominate, and subclavian arteries. Although both surgery and anticoagulant therapy are used for TIAs, recently Ropper extensively reviewed the wide divergence of opinions.¹²

For individuals who have had a stroke yet recovered quickly and well, medical care focuses on prevention of recurrent stroke. Prevention usually includes maintaining blood pressure and blood flow, monitoring hypotensive agents (if given), and avoiding oversedation,

especially for sleep, to prevent cerebral ischemia. Long-term anticoagulant therapy is effective in preventing embolic infarction in persons with cardiac problems such as atrial fibrillation, myocardial infarction, and valve prostheses.

Hemorrhagic stroke. Medical management to reduce ICP includes sedation, hyperosmolar agents, and hyperventilation. Surgical interventions including decompressive craniotomy and craniectomy are recommended only under extreme circumstances of rapid deterioration or if the ICP is not responding to other efforts. Following surgical intervention, medical management consists of lowering arterial blood pressures. Pharmaceutical management of hypertension for hemorrhagic stroke differs from that of ischemic stroke with an emphasis on reducing blood pressure as quickly as possible to reduce bleeding. Antiseizure medication may be used. Often a systemic anti-fibrinolytic is given to impede lysis of the clot at the site of rupture. Vasospasms are a common secondary condition following subarachnoid hemorrhage (SAH). Vasospasms result in secondary cerebral ischemia following the initial hemorrhage and result in increased morbidity and mortality. Nimodipine is considered a first-line drug to reduce the risk of vasospasm.¹⁶

Regardless of the type of the stroke, individuals who are comatose are managed by (1) treatment of shock; (2) maintenance of clear airway and oxygen flow; (3) measurement of arterial blood gases, blood analysis, CT, and spinal tap; and (4) control of seizures. Hypertensive hemorrhage is one of the most common vascular causes of coma.¹⁷

Recent studies indicate that 42% of patients who have sustained a stroke wait 24 hours before getting care, with the average being 13 hours.¹⁵ The importance of community-wide programs to increase awareness of symptoms and effectiveness of emergency medical responses is immense in order to administer t-PA for best possible outcomes. The American Heart Association and the National Stroke Association are creating community campaigns to increase awareness of the medical emergency nature of stroke symptoms. These campaigns encourage people to call 911 immediately when any of the following warning signs, entitled BEFAST, occur:

- Balance – trouble walking, dizziness, loss of balance or coordination
- Eyes – trouble seeing with one or both eyes
- Face – numbness or weakness of the face
- Arm – numbness or weakness of the arm (or leg) especially on one side of the body.
- Speech – confusion or trouble speaking and/or understanding
- Time – call 911 immediately

Medical Management of Associated Problems

Spasticity. Research findings have refuted the earlier belief that spasticity is the cause of the atypical movement patterns in people with CNS dysfunction.^{18,19} Spasticity, a reflex measured by velocity dependent stretch in the passive state, is an indication of damage to the CNS. The term “spasticity” is often used synonymously with hypertonicity, a resistance to passive stretch that is not velocity-dependent. Its treatment constitutes a major medical problem after stroke because patients complain about it and physicians continue to treat it aggressively. The pharmacological and surgical means are examined here, and therapy management is discussed later.

Two types of drugs are used to counter the effects of spasticity: centrally acting and peripherally acting agents. Centrally acting drugs, such as diazepam, have been used to depress the lateral reticular formation and thus its facilitatory action on the gamma motor neurons. This form of drug is used widely to treat spasticity, although the greatest disadvantage of centrally acting drugs is that they depress the entire CNS. Drowsiness and anxiety are common side effects.

Peripherally acting drugs are used to block a specific link in the gamma group. Procaine blocks selectively inhibit the small gamma motor fibers, resulting in a relaxation of intrafusal fibers. The effect of procaine blocks is transient. Intramuscular neurolysis with the

injection of 5% to 7% phenol has been used to destroy the small intramuscular mixed nerve branches.²⁰ Phenol blocks relieve hypertonicity and improve function, especially when followed by an intensive course of therapy.²¹ It can provide relief for 2 to 12 months, and the effects have been documented to last as long as 3 years.^{20,21} Disadvantages of phenol use include its toxicity to tissue and the complications of pain that occasionally result.²²

Botulinum toxin type A (Botox) is also used to decrease the effects of spasticity on functional movement in hemiplegia.^{23–25} Local²⁶ injection of the toxin into spastic muscles produces selective weakness by interfering with the uptake of acetylcholine by the motor end plate. The effect of the toxin is temporary, depends on the amount injected, and is associated with minimal side effects. Repeat injections are recommended no sooner than 12 to 14 weeks to avoid antibody formation to the toxin. Researchers report positive functional results when botulinum toxin A injections are followed by intensive muscle reeducation and appropriate splinting.²⁶

Dantrolene sodium is used to interrupt the excitation-contraction mechanism of skeletal muscles. Trials have shown that it has reduced spasticity in 60% to 80% of individuals while improving function in 40% of these patients. The side effects—drowsiness, weakness, and fatigue—can be decreased through titration of dosage. Serious side effects, including hepatotoxicity, precipitation of seizures, and lymphocytic lymphoma, have been reported when the drug has been used in high doses over a long time.²⁷

Baclofen, in pill form, is used as a skeletal muscle relaxant to decrease spasticity. It can now be delivered intrathecally into the spinal cord with a pump that is surgically inserted into the body. It relieves spasticity with a small amount of medication (10 mg/20 mL, 10 mg/5 mL). Intrathecal baclofen has had dramatic results in cases of severe spasticity because it acts directly on the affected muscles instead of circulating in the blood. It is used for extremity spasticity that interferes with the ability to assume functional positions in patients with severe stroke, multiple sclerosis, head injury, and cerebral palsy.²⁸

The surgical treatment of spasticity through tenotomy or neurectomy is considered when all other treatments fail, and it is used to correct deformity, especially of a hand or foot. A peripheral nerve block is often used as a diagnostic tool to evaluate the effect of surgical treatment. If anatomical or functional gains are made through a temporary nerve block, consideration is given to surgical release. The surgical treatment of spasticity does not necessarily result in increased movement control and, with the increased understanding of the causes of spasticity, does not seem appropriate in stroke.

Seizures. The highest risk for seizure after a stroke is immediately after the event; 57% of seizures occur in the first week and 88% occur within the first year.²⁹ Seizures after thrombotic and embolic stroke are usually of early onset, whereas seizures after hemorrhagic stroke are of late onset.³⁰ The management of seizures after stroke is usually with antiseizure medication. Commonly used drugs include phenytoin (Dilantin), carbamazepine (Tegretol), gabapentin (Neurontin), and divalproex (Depakote).³¹ Side effects that interfere with movement therapy include drowsiness, ataxia, distractibility, and poor memory.

Respiratory involvement. Fatigue is a major problem for the person with hemiplegia. This fatigability, which interferes with everyday life processes and active rehabilitation, is attributed to respiratory insufficiency resulting from paralysis of one side of the thorax. Haas and colleagues³² studied respiratory function in hemiplegia and found decreased lung volume and mechanical performance of the thorax to be significant factors, in addition to abnormal pulmonary diffusing capacity. Individuals with hemiplegia consume 50% more oxygen while walking slowly (regardless of the presence or absence of orthotic devices) than subjects without hemiplegia.³² The decreased respiratory output and the increased oxygen demand that result from

atypical movement patterns are responsible for early fatigue in persons with hemiplegia. Treatment objectives and techniques must reflect the understanding of this respiratory problem. For patients who walk at velocities greater than 0.48 m/s, a gain in walking capacity is associated with an increased peak VO_2 . Research exploring the role of exercise after stroke indicate that gains in respiratory fitness were associated with increased walking capacity. In clinical practice, therapists should remember to include standard respiratory measures and functions to evaluate the efficacy of treatment techniques.³³

Stroke fatigue syndrome. Another potential cause of fatigue following stroke is Stroke Fatigue Syndrome or post-stroke fatigue. Although its etiology is not well understood, post-stroke fatigue is reported in 23% to 75% of individuals following a stroke. It is known to reduce the quality of life and increase the risk of death in those who experience it. Research related to etiology and intervention for prevention and treatment is relatively new. Suspected mechanisms under current research include biological, psychosocial, and behavioral causes. Suggested interventions under recent and current investigation include pharmacological agents such as antidepressants and stimulants; psychological approaches including cognitive behavioral therapy and educational programming; and physical training including graded aerobic training. A recent systematic review indicated continued, high-quality research is needed to identify the most effective treatment intervention strategy.³⁴

Cardiovascular health. In the chronic stage of recovery, patients may have significant cardiovascular deconditioning with half the fitness levels of age-matched controls. This decrease in fitness affects the performance of daily activities and adds to these patients' morbidity and mortality risk. This decreased fitness results in part from decreased mobility of the leg, muscular atrophy, altered muscle physiology, increased muscular fat, and altered peripheral blood flow.^{35,36}

Fractures. If the patient with hemiplegia has severe extremity or trunk weakness and relies heavily on the nonparetic extremities for function, poor balance and falls are possible. After a stroke the risk of hip fracture is greatest in the first year of recovery. Eighty percent of hip fractures occur on the paretic side and are the result of bone loss or falls.³⁷ In addition, other common fracture sites are the humerus and wrist.

Therapy intervention for a hip fracture with a hemiplegia is complicated by increased difficulty sustaining a symmetrical trunk posture over the fractured hip, decreased strength in the leg, pain, and spasticity. In addition to the loss of balance and protective mechanisms, the development of osteoporosis from disuse is a limiting factor for functional recovery after a fracture.³⁸

Thrombophlebitis. Thrombophlebitis may occur in the acute and subacute stages of recovery and rehabilitation. Deep vein thrombosis is caused by altered blood flow, damage to the vessel wall, and changes in blood coagulation times. The vascular changes are aggravated by the inactivity and dependent postures of the weak extremities. Deep vein thrombosis is many times more common in the weaker leg.³⁹

Complex regional pain syndrome. Formerly known as reflex sympathetic dystrophy, *complex regional pain syndrome* is a chronic pain condition affecting the paretic arm or leg. The extremity pain is reported as intense and burning and may be accompanied by swelling and redness. It leads to changes in bone and skin and, if left untreated, becomes debilitating. Medical treatment includes the use of chemical sympathetic blocks and oral or intramuscular corticosteroids. The use of blocks and corticosteroids often stops the burning pain. The length of time of the relief varies from patient to patient. Adverse reactions from blocks and corticosteroids occur about 20% of the time.^{40,41}

Pain. The pharmacological management of joint pain after stroke (usually shoulder pain) includes the local injection of corticosteroids.

Sequential Stages of Recovery From Acute to Adaptive Phase

Evolution of Recovery Process

The evolution of the recovery process from onset to the return to community life can be divided into three stages—acute, active (rehabilitation), and adaptation to personal environment. The acute state involves the stroke-in-evolution, the completed stroke, or the TIA and the decision whether to hospitalize.

The stroke-in-evolution develops gradually with distinct demarcation of the damaged area over 6 to 24 hours. Thrombosis, the most common cause of stroke, results first in ischemia and finally in infarction. If ischemic tissue can be treated and saved before infarction occurs, the neurological damage may be reversible. Small hemorrhages also may become a stroke-in-evolution by effusing blood along nerve pathways and by attracting fluid.^{42,43} A completed stroke has a sudden onset and produces distinct, nonprogressive symptoms and damage within minutes or hours. In contrast, the TIA has a brief duration of neurological deficit and spontaneous resolution with no residual signs. TIAs vary in number and duration.

The physician decides the extent of hospitalization. The trend to hospitalize is more common today than years ago.⁴⁴ However,⁴³ a mild stroke or TIA may produce minimal physical and mental symptoms, and the person may not even seek medical help. Cost-containment measures in hospitals and managed care have led to decreased lengths of stay and the development of critical pathway plans to deliver services more efficiently. The inpatient length of stay for acute stroke is currently around 5 days. After the inpatient stay, the patient follows one of four typical pathways: a return home with or without home care services, a rehabilitation hospital stroke unit stay, a subacute facility stay until able to tolerate a rehabilitation regimen, or to a long-term care facility for rehabilitation or maintenance care.

Once the stroke is completed, the clinical symptoms begin to decrease in severity. A person with a stroke caused by an embolic episode may have symptoms that reverse completely in a few days; more frequently, however, improvement occurs noticeably at first and then more slowly with varying degrees of functional recovery. The fatality rate is high within the first day but decreases substantially in the following months of recovery.⁴³ Evidence from efficacy studies of rehabilitation programs that aim at improving functional performance is limited. Studies by Bamford and colleagues indicate that early rehabilitation intervention reduces disability and improves compensatory strategies.⁴⁵

The Framingham Heart Study has revealed that long-term stroke survivors have a good chance of returning to independent living. The greatest deficit in persons with hemiplegia who have recovered basic motor skills and who have returned home is in the psychosocial and environmental areas.⁶

Recovery of Motor Function

Recovery of motor function after a stroke was thought historically to be complete 3 to 6 months after onset. More recent research has shown that functional recovery from a stroke can continue for months or years.^{46,47} Measuring recovery is difficult because the definition of "successful" or "complete" recovery varies greatly. Duncan reports that if recovery is defined at the disability level (Barthel score >90), 57% of stroke survivors have a complete recovery. However, if impairments are measured, less than 37% recover fully. If recovery is related to prior physical functioning, less than 25% are considered completely recovered.⁴⁸

The initial functional gains after the stroke are attributed to reduction of cerebral edema, absorption of damaged tissue, and improved

local vascular flow. However, these factors do not play a role in long-term functional recovery. The brain damage that results from a stroke is thought to be circumvented rather than “repaired” during the process of functional recovery. The CNS reacts to injury with a variety of potentially reparative morphological processes. Two mechanisms underlying functional recovery after stroke are collateral sprouting and the unmasking of neuropathways: regeneration and reorganization.⁴⁶ Research continues to provide important insights into the fundamental capabilities of the brain to respond to damage. Methods of intervention that use the environment and help the patient learn lead to long-term improved recovery.

The CNS has some predictable traits in response to injury. Twitchell, in his classic study, first documented the initial loss of voluntary function.⁴⁹ Although paralysis with flaccidity initially exists, there is seldom, if ever, total paralysis. He reported both an increase in deep tendon reflexes after 48 hours and the emergence of synergistic patterns of movement.⁵⁰ The synergistic movement patterns of the upper extremity and lower extremity have been described in detail by many.^{51–53} Verbal description of a visual phenomenon often leads to differences in written and spoken communication, yet the visual array or behavioral patterns may be exactly the same.⁵⁴ Although it is stated that the leg recovers more quickly or better than the arm, a leg that is bound by an extensor synergy and that is as “rigid as a pillar” during gait has not recovered more quickly and has no better function than an arm that is flexed and held across the chest and that can only grasp in a gross pattern with no ability to manipulate or release.

Although studies continue to investigate the exact nature of the relationship between voluntary movement and spasticity, clinical evidence demonstrates that as voluntary function increases, the dependence on synergistic movement decreases.¹⁹ With the knowledge that the CNS is capable of reacting to injury with a variety of morphological processes, we should no longer view the effect of a stroke as a fixed event. Because the brain immediately institutes neuromechanisms that reconstitute typical functions, therapy interventions should emphasize use of movement patterns on the affected side to maximize return and to help the patient achieve the highest level of function.

Predictors of Recovery

Research in motor recovery shows that although motor recovery may continue after 6 months, the functional status usually remains constant, and that 86% of the variance in 6-month recovery is predictable at 1 month.⁵⁵

It would be useful to be able to predict recovery of functional activities both for intervention planning and to allow efficient utilization of post-stroke care. However, there are few multivariate models that take into account the various data points that must be taken into account: clinical, neurophysiological, and neuroimaging.^{56,57}

Existing predictive studies that use clinical measures give us a general idea. In one study, although 58% of the patients regained independence in ADLs and 82% learned to walk, 30% to 60% of patients had no arm function.⁵⁸ Initial return of movement in the first 2 weeks is one indicator of the possibility of full arm recovery. However, failure to recover grip strength before 24 days was correlated with no recovery of arm function at 3 months.^{57,58} In another study that used the modified Rankin scale as the outcome measure, half of the patients recovered within 18 months with the greatest amount of recovery present at the 6-month mark. Predictors of recovery in this group included stroke severity, no previous ischemic stroke, peripheral artery disease, or diabetes.⁵⁹

As clinicians we can help minimize the problems in research methods by precisely formulating functional goals, stating movement components and significant impairments that interfere with functional

performance, and following a model when making clinical decisions to postulate cause and effect during intervention.⁶⁰

Classification of Atypical Movement Patterns

Although the *Guide to Physical Therapist Practice* groups patients with neurological dysfunction according to pathological condition, therapy intervention rarely is directed by the diagnosis of stroke and resultant hemiplegia.⁶⁰ The WHO classification system, the International Classification of Function (ICF-2), provides a model that allows us to consider multiple factors that impact our interventions: body function/structure, activity, and participation limitations as well as personal and environmental factors.^{61,62}

Although the main focus of this chapter is the evaluation and treatment of activity limitations and impairments resulting from a loss of movement control, a stroke may result in damage to other systems that affect the patient’s ability to perform functional skills. There may be deficiencies in sensory processing (vision, somesthetic sensation, and vestibular systems) and disorders of cognitive integration (arousal and attention, awareness of disability, memory, problem solving, and learning), which all have a large impact on functional retraining. Depression and, most important, problems of language and communication also affect the patient’s ability to participate in a therapy program.

Impairments Contributing to Activity and Participation Limitations

Individuals with hemiplegia from stroke have movement problems—impairments—that lead to activity and participation limitations. These movement problems manifest themselves as loss of movement in the trunk and extremities, atypical patterns of movement, and involuntary nonpurposeful movements of the affected side that lead to compensatory functional strategies. These impairments interfere with normal functional movements and may lead to loss of independence in daily life.

Impairments are the signs, symptoms, and physical findings that relate to a specific disease pathology. Schenkman and Butler were among the first to apply a model of impairments to neurological physical therapy practice. Ryerson and Levit, using a similar format, specifically defined the impairment categories as primary, secondary, and composite (Box 24.1).^{63,64}

Primary and secondary impairments. Primary impairments are a direct result of the brain damage and are present immediately. Secondary impairments develop over time and in body systems not originally affected by the brain lesion.

Composite impairments. Composite impairments are the combined effects of the primary and secondary impairments, stage of motor recovery, previous treatment, and behavioral factors.

The composite impairment category used in this chapter has three generalized movement patterns that create one model of classification: (1) movement deficits, (2) atypical movements, and (3) undesirable compensatory patterns.⁶³

Movement deficits result from severe neurological weakness with either gradual, balanced return or no significant return. Functional movement patterns and levels of independence are based on the distribution and amount of return: trunk control greater than extremity control, extremity control greater than trunk control, distal extremity return greater than proximal extremity return or vice versa, and arm control greater than leg control or vice versa. These individuals do not have problems with hypertonicity but, when neurological weakness is severe, have long-term problems with the secondary impairments of muscle shortening and loss of joint range.

In the acute stage, the arm hangs by the side, the humerus is internally rotated, the elbow is extended, and the forearm is pronated. Inferior shoulder subluxation is common. The trunk is weak, the ribs flare, and spinal alignment is impaired: a convex lateral curve is seen

BOX 24.1 Impairments That Interfere With Functional Movement

Primary Impairments

Neurological weakness

Changes in muscle activation

- Initiation/cessation
- Difficulty sequencing patterns of muscle activity within an extremity
- Inappropriate timing of muscle activation
- Altered force production

Changes in sensation

- Touch
- Proprioception

Changes in muscle tone

- Hypotonicity
- Hypertonicity

Secondary Impairments

Changes in alignment and mobility

Changes in muscle and soft tissue length

Pain

Edema

Composite Impairments

Movement deficits

Atypical movements

Undesirable compensations

Modified from Ryerson S, Levit K. *Functional Movement Reeducation: A Contemporary Model for Stroke Rehabilitation*. New York: Churchill Livingstone; 1997.

on the affected side. In standing, the patient has problems recruiting sufficient force production in the affected leg to counteract the downward pull of gravity. The pelvis lists downward, the hip and knee flex, and the ankle moves into plantarflexion. As the patient relearns to walk, the hip and knee may remain in flexion from weakness or the patient may compensate and push/lock the knee into extension.

A reliance on a cane for balance and the accompanying compensatory weight shift of the upper body onto a cane results in the use of pelvic elevation for swing initiation (Figs. 24.1 and 24.2).

Atypical movement patterns are found in patients with unbalanced muscle return and deficits of muscle activation not only in initiation/cessation, but also sequencing and timing. Atypical movements are movements that deviate from normal patterns of muscle coordination. They use patterns of muscle activation and sequences of joint movement that deviate from normal muscle synergies or biomechanical rules. Atypical movement patterns develop as a consequence of primary and secondary impairments. When motor recovery is incomplete, patients use the muscles that are available to produce movement. During attempts at functional activities, patients' movement patterns may occur with excessive effort and cocontraction (Fig. 24.3).

Undesirable compensatory patterns are patterns of function that may arise from either of the two previously described movement categories. Compensations are alternative movements or movement substitutions used to circumvent the challenge to the impaired side during daily activities. Although compensatory movements may be necessary and desirable to achieve the highest level of activity performance when there is no ability for recovery to occur, some may be more desirable than others. Undesirable compensatory patterns are noticeably one-sided; they rely on movements of the uninvolved arm and leg and are accompanied by asymmetrical postural trunk movements. They lead to unsafe patterns, or to secondary impairments, or

Fig. 24.1 (A) Patient with right hemiplegia. Movement deficit: neurological weakness (lack of initiation); patient was unable to move arm or leg in standing or sitting. (B) Patient uses cane and tries to shift to the right as he gets ready to step forward with the left leg. Note how the heavy weight of the right arm pulls the upper body into forward flexion and rotation left. (C) Patient prepares to step forward with the right leg. Note that his attendant has corrected his upper-body position. (D) Patient leans heavily onto cane (his upper body translates laterally to the left) to lessen weight on the right leg. He will accomplish the “step” by rotating his upper body to the left, a compensation for the loss of leg control in standing.

contribute to strategies that may have the potential to block or hinder future motor recovery. These undesirable compensatory patterns create “learned nonuse” of the affected arm and leg and foster asymmetrical postural patterns. Recent research findings indicate that limiting compensatory trunk movements may actually increase the performance of arm-reaching activities.⁶⁵

Patients in the subacute to chronic phase of recovery who come into therapy with strongly established undesirable compensatory patterns do not respond quickly to any type of intervention. Although therapists may be tempted to train a one-sided pattern in early rehabilitation to quickly meet a stated goal, the long-term effects of learned nonuse of one side of the body include increased severity of secondary impairments and poor balance with an increased chance of falls (Fig. 24.4).

PHYSICAL THERAPY EVALUATION OF GENERAL NEUROLOGICAL FUNCTION

Evaluation is a process of collecting information to establish a baseline level of performance to plan interventions and to document progress. This section reviews mental status evaluation, communication, perception, cranial nerves, reflexes, and sensation.

Fig. 24.2 (A) Individual with right hemiplegia. Movement deficit: Difficulty sequencing; patient is able to walk with a brace and does not need a cane. (B) During stance, his upper body moves laterally to the right and his right femur internally rotates as his knee hyperextends. (C) He has enough trunk control to stand and balance and sufficient leg control to lift the leg with knee flexion.

Fig. 24.3 (A) Individual with right hemiplegia. Movement deficit: atypical movement patterns—loss of initiation/cessation, timing, and sequencing. (B and C) Patient walking.

Mental Status Evaluation

The mental status evaluation requires arousal and alertness as prerequisites. If this is missing, the evaluation begins with an assessment of level of consciousness and then, when appropriate, considers the mental, affective, and emotional states.⁶⁶

Levels of Consciousness

Consciousness consists of wakefulness and awareness. Wakefulness is identified by observing physical or electrophysiological evidence of

arousal. Awareness requires reproducible and meaningful response to stimulus and/or evidence of comprehension of language. From these two components of consciousness, three levels of disordered consciousness have been defined, including coma, unresponsive wakefulness syndrome (UWS)—also known as vegetative state—and minimally conscious. When in a coma, a patient has no sleep-wake cycle and no response to stimulus. In UWS, a patient will have spontaneous eye opening, semiregular sleep-wake cycles, but no meaningful or reproducible response to stimulus. The patient has established wakefulness

Fig. 24.4 Patient With Right Hemiplegia. Severe compensatory patterns. She walks with a quad cane and standby assistance. Pelvis rotates to the right, upper body rotates to the left, hip flexes, and knee hyperextends. There is strong lateral translation of upper body to the left (to the stable cane).

without awareness. In the minimally conscious state, a patient has established regular sleep-wake cycles and awareness as demonstrated by meaningful responses to visual, auditory, tactile, and/or noxious stimuli; however, the responses may be delayed and/or inconsistent. Further categorization of the minimally conscious state has been introduced based on higher versus lower levels of behavior response.⁶⁷

Scales of varying types are used to measure the patient's level of consciousness, to assess the initial severity of brain damage, and to prognosticate recovery curves. The Glasgow Coma Scale, devised by Teasdale and Jennett in collaboration with Plum,⁶⁸ has been used for nontraumatic comas caused by stroke, head injury, and cardiac disease. This scale records motor responses to pain, verbal responses to auditory and visual clues, and eye opening. It assigns numerical values according to graded scales. Plum and Caronna⁶⁹ and Levy and colleagues⁷⁰ have also established criteria for correlating clinical signs of coma with prognosis.

The Coma Recovery Scale-Revised (CRS-R) is also a highly recommended, standardized clinical assessment of disordered consciousness. It consists of 23 hierarchically arranged categories with six subscales that evaluate level of arousal, auditory and language comprehension, expression, visuoperceptual ability, motor function, and communication. The lowest score on all subscales is 0 while the maximum score ranges from 2 to 6 depending on the subscale. Higher scores indicate higher levels of function.⁷¹

These descriptions of coma and related states are correlated with areas of suspected CNS damage but often leave a gap in the understanding of how the patient functions in life.⁶⁸ This gap was narrowed by the creation of a behavioral rating scale: The Levels of Cognitive Functioning Scale, developed at Rancho Los Amigos Hospital. This

behavioral rating scale is not a test of cognitive ability but is an observational rating of the patient's ability to process and respond to information.⁷²

Mental, Emotional, and Affective States

The history portion of the neurological evaluation leads to an assessment of the mental, emotional, and affective states. The patient's ability to describe the illness gives information on memory, orientation to time and place, the ability to express ideas, and judgment. If the examiner suspects a particular problem, a more thorough review is undertaken of the higher cortical function: serial subtraction, repetition of digits, and recall of objects or names. Patients with right hemiplegia may be cautious and disorganized in solving a given task, and patients with left hemiplegia tend to be fast and impulsive and seemingly unaware of the deficits present. These different response patterns stem from hemispheric involvement and prior hemispheric specialization.

Communication

A general evaluation of communication disorders is noted while taking the history. Cerebral disorder resulting from infarct or hemorrhage may produce aphasia—loss of production or comprehension of the spoken word, the written word, or both. Therapists should be familiar with expressive, receptive, and global aphasia and be prepared to modify their mode of communication to establish a good patient relationship.

Perception

Perceptual deficits in patients with hemiplegia are complex and intimately linked to the sensorimotor deficit. Sensory integration theory has begun to establish normative values and objective data for testing and documenting perceptual deficits in children. Currently, norms and testing procedures for adults have not been standardized, but perceptual deficits have been identified in patients with hemiplegia. Common perceptual deficits found in left and right brain damage are listed in [Box 24.2](#).

Cranial Nerves

Thorough cranial nerve evaluation is necessary in hemiplegia because a deficit of a particular cranial nerve helps determine the exact size and location of the infarct or hemorrhage. In hemiplegia, it is imperative to check for visual field deficits, pupil signs, ocular movements, facial sensation and weakness, labyrinthine and auditory function, and laryngeal and pharyngeal function.

Tone

Tone, the resistance of muscles to passive movement, exists on a continuum from hypotonicity through normal to hypertonicity and finally, rigidity. Patients in the acute phase of hemiplegia exhibit, for varying periods of time, a lower-than-normal tonal state. The extremities feel like “dead weight” as the therapist moves them. As neuromuscular return slowly begins, the extremities may feel heavy, but some “following” of passive movement patterns is detected. At the further end, hypertonicity is defined as abnormal increase in resistance to passive movement and may be an indication of muscle shortening or the beginnings of joint contracture. Hypertonicity may be present without spasticity and vice versa ([Box 24.3](#)).

Postural tone refers to the overall state of tension in the body musculature. During the beginning of the 20th century, tone was thought of as postural reflexes. In the 1950s, the concept of tone was thought of as a state of light excitation or a state of preparedness.⁷³ Granit⁷⁴ later encouraged us to think of the relatedness of both these views. He believed that the same spinal organization is mobilized by the basal

BOX 24.2 Perceptual Deficits in Central Nervous System Dysfunction

Left Hemiparesis: Right Hemisphere—General Spatial-Global Deficits

Visual-perceptual deficits

- Hand-eye coordination
- Figure-ground discrimination
- Spatial relationships
- Position in space
- Form constancy

Behavioral and intellectual deficits

- Poor judgment, unrealistic behavior
- Denial of disability
- Inability to abstract
- Rigidity of thought
- Disturbances in body image and body scheme
- Impairment of ability to self-correct
- Difficulty retaining information
- Distortion of time concepts
- Tendency to see the whole and not individual steps
- Affect lability
- Feelings of persecution
- Irritability, confusion
- Distraction by verbalization
- Short attention span
- Appearance of lethargy
- Fluctuation in performance
- Disturbances in relative size and distance of objects

Right Hemiparesis: Left Hemisphere—General Language and Temporal Ordering Deficits

Apraxia

- Motor
- Ideational

Behavioral and intellectual deficits

- Difficulty initiating tasks
- Sequencing deficits
- Processing delays
- Directionality deficits
- Low frustration levels
- Verbal and manual perseveration
- Rapid performance of movement or activity
- Compulsive behavior
- Extreme distractibility

BOX 24.3 Continuum of Tone

ganglia to produce both manifestations of tone: a state of preparedness and the postural reflexes.⁷⁴ Postural tone is tone that is “high” enough to keep the body from collapsing into gravity but “low” enough to allow the body to move against gravity. It is influenced by the input from the corticospinal tracts, the vestibular system, the α and γ systems, and peripheral-tactile and proprioceptive receptors.⁷⁵

Reflexes and Spasticity

Standard areas of reflex testing include the triceps, biceps, quadriceps, and gastrocnemius muscles. According to Adams,¹¹ there are four plantar reflex responses: (1) avoidance–quick, (2) spinal flexion–slow, (3) Babinski–toe grasp, and (4) positive support.

Spasticity. Let’s separate the definitions of spasticity and tone. Spasticity is a velocity-dependent reflex measured in the passive condition and is a sign of CNS injury. Spasticity, most likely, is the result of hyperexcitability of the medial rubrospinal tract.⁷⁶ Clinical characteristics of a muscle with spasticity include this increased velocity-dependent resistance to stretch, a clasp-knife phenomenon, and hyperactive tendon responses.

Spasticity versus hypertonicity. The terms hypertonicity and spasticity are often used interchangeably. This is incorrect. They are not the same construct. Spasticity is velocity-dependent, and hypertonicity is a resistance to passive stretch in a relaxed state and is NOT velocity-dependent (see Underlying Causes of Aberrant Movement).

Sensation

Traditional sensory testing is used to assess sensory deficits in the adult with hemiplegia: light touch, deep pressure, kinesthesia, proprioception, pain, temperature, graphesthesia, two-point discrimination, appreciation of texture and size, and vibration. A comparison of the differences in the two sides of the body and qualitative and quantitative measurements are important features of sensory testing. Sensory testing is difficult because it relies on the person’s interpretation of the sensation, the patient’s general awareness and suggestibility, and the person’s ability to communicate a response to each test item.

The presence and quality of sensory loss must be considered during the process of reeducating motor control. Although Sherrington established the principle of interdependence of sensation and movement, current researchers have refined the concept and hypothesize that sensation modifies continuing movement by providing feed-forward information, feedback, and corollary discharge. They have provided evidence that sensation is not an absolute prerequisite for isolated movement⁷⁷; however, impaired proprioception is a poor prognostic factor in recovery of functional movement.⁷⁸

EVALUATION OF FUNCTIONAL MOVEMENT

Functional activities rely on the foundation of postural control and skilled extremity movement. These two elements are affected by primary impairments in the motor and sensory systems and secondary impairments in muscle and soft tissue that occur following a stroke. This section reviews normal components of postural control and skilled extremity movement and describes how the common primary and secondary impairments influence the performance of functional activities.

When evaluating functional activities, the therapist follows a pathway that includes the following: observation of the functional task, comparing what you observe with what you expect, generating hypotheses as to why differences are present, and finally assessing these hypotheses with assisted movement or objective tests and measures (see Objective Outcome Measures).

We assess the three phases of the movement pattern: *initiation*, which includes the body segment initiating the movement, the direction of movement, and the establishment of antigravity control; *transition or execution*, representing the point in the functional activity at which there is a switch in the muscle groups that provide antigravity control; and *completion/termination* of the activity, involving a final weight shift and the ability to maintain a steady state.⁶³ Assessing the

TABLE 24.3 Upper-Body Initiated Weight Shift Pattern: Sitting

Direction of Movement	Spinal Pattern	Muscle Activity
Anterior movement—reach down to floor	Flexes	Eccentric extensor activity
Posterior—to sit back up	Extends	Concentric extensor activity
Lateral—reach sideways and down to right	Laterally flexes with concavity on right	Eccentric lateral activity on left
Lateral—comes back up to middle	Spine moves back to neutral	Concentric lateral activity on left

three phases of movement is performed with the concepts of both postural control and skilled extremity movement in mind.

Postural Control

Postural control allows the body to remain upright, to adjust to extremity movements, and to change and control body position for balance and function.^{94–100} The postural control system has two major components: anticipatory and compensatory postural adjustments.^{100–103}

Anticipatory Postural Adjustments

Anticipatory adjustments allow the coordinated linkage of trunk and extremity patterns before the activation of extremity movements: anticipatory postural adjustments (APAs) allow us to maintain our upright posture and balance in anticipation of a perturbation from an extremity or from the environment. Their presence minimizes changes in body alignment by correcting the effect of inertial forces on body segments. Clinically, we might say they link the trunk with the extremities. Researchers have identified altered anticipatory postural responses in people after stroke in both sitting and standing positions. The pattern or sequence of anticipatory responses post-stroke appears to be preserved, but the timing of the response is impaired; it may occur after a focal movement.¹⁰⁴

Compensatory Postural Adjustments

Compensatory postural adjustments (CPAs) occur during activity when postural control is insufficient for the task. They occur after an unpredictable perturbation and serve to reorganize posture and regain balance.

Trunk Control

In a movement component model of postural control, trunk control forms the building blocks for anticipatory and compensatory adjustments.¹⁰⁵ Research in the field of postural control shows that the level of trunk control correlates with sitting balance and that extremity function correlates with trunk control.^{106–108}

Levels of trunk control. Trunk control can be divided into levels of increasing complexity. The first level of trunk control is the ability to perform the basic movement components. Trunk control at this level provides a base that allows extremity movement to be combined and used for function. Retraining control of basic trunk movements in the three cardinal planes is a prerequisite for the coordination of trunk and extremity patterns for functional tasks.

Trunk movements in sitting are initiated from the upper trunk (head, C1 to T10) or the lower trunk (T11–pelvis) according to the demands of the task. In standing, functional trunk movements are initiated from the upper body (if the head or arm is initiating a task) or the lower body (if the leg is initiating a task). The two initiation patterns result in different spinal patterns, different types of muscular activity, and changes in the distribution of weight (Tables 24.3 and 24.4).⁶³

The second level of trunk control allows the trunk to remain stable yet adapt to movement of the arms and legs.^{104,109} There are three ways

this happens: the trunk remains stable during extremity movement around midline, during movements within extremity length, or during movements that extend the reach of the extremities. These coordinated movements can occur in supine, sitting, or standing positions as demonstrated in the following three examples.

1. Around midline: in sitting, the patient lifts up a leg to tie a shoe; the lower body initiates a posterior weight shift as the patient moves the lower extremity around midline.
2. Within arm's length: in sitting, the patient reaches a hand onto the edge of a table for support while the trunk remains active, yet stable.
3. Beyond arm's length: in sitting, the patient reaches down or sideways to the floor to pick up a shoe or cane. As the arm reaches down, the upper trunk initiates the anterior weight shift to extend the reach of the arm while the lower trunk provides stability and adjusts.
4. Beyond leg's length: in standing, the patient initiates a forward step with the right leg while the trunk and left leg follow the forward movement to extend the reach of the right leg to allow the foot to strike the ground.

The third level of trunk control allows stability and adaptability when the extremity receives or delivers impetus, for example, to push or pull an object. This highest level of trunk control allows for propulsive activities such as stair climbing, jumping, running, throwing, hitting, and rowing.

The model is summarized in Box 24.4.

Extremity Control

We use our extremities to perform a wide variety of tasks and functional movements. These functional movements of the extremities can be divided into two categories; movements in space and weight-bearing movements. Functional performance in the arm is more closely associated with the ability to move in space while functional performance in the leg occurs more evenly divided between movements in space and in weight bearing. Skilled extremity movements in space rely on well-timed and sequenced movements of proximal, mid, and distal joints to position the limb for function. Extremity movements in weight bearing are used to support body weight, to lift or move the body during transitional movements, and to stabilize objects for function. These weight-bearing patterns allow active, dynamic

TABLE 24.4 Lower-Body Initiated Weight Shift Pattern: Sitting

Direction of Movement	Spinal Pattern	Muscle Activity
Posterior weight shift	Flexes	Concentric flexor activity
Anterior weight shift	Extends	Concentric extension activity
Lateral weight shift to right	Laterally flexes with concavity on right	Eccentric lateral activity on right Concentric lateral activity on left

BOX 24.4 Movement Component Control Model of Postural Control

Postural control

- Anticipatory postural adjustments
- Compensatory postural adjustments

Trunk control

Level I: Basic movement components

- Upper-body and lower-body initiated movement
- Anterior/posterior; lateral; rotational

Level II: Coordinated trunk and extremity patterns

- Trunk stabile in quiet sitting/standing
- Trunk stabile and adjusts to extremity movements
 - *around midline
 - *within extremity length
 - *beyond extremity length

Level III: Power production

- Trunk stabile and adjusts when extremity delivers/receives impetus

functional movement. Control of these skilled extremity movement patterns is altered post-stroke by both primary and secondary impairments. Patients who have had a severe stroke may have no visible movement in the extremities; the extremities display no resistance to passive movement and feel heavy. As strength and control in the muscles of the trunk and extremities increase, this hypotonicity lessens. If muscle activation deficits persist, the secondary impairments of poor joint alignment, muscle and soft tissue tightness, and eventually joint deformity or contracture will become predominant.

Objective Outcome Measures

During the initial interview the therapist and the patient together form a list of strengths and limitations and relate them to the patient's activity goals and personal and environmental needs. Objective baseline measurement is needed to follow recovery patterns and to document changes following rehabilitation interventions.

Objective Measures of Participation, Activity, Motor Function, Balance, Quality of Life

In 2018, the American Physical Therapy Association Stroke special interest group published outcome measure recommendations. The recommendations, known as StrokEDGE II, include outcome measures that are "highly recommended" as well as "recommended" based on their validity and reliability. They are divided into three groups: (1) core measures for all neurological disorders (6-minute Walk test, 10-Meter Walk test, Berg Balance Scale, Functional Gait Assessment, Activities-Specific Balance Confidence Scale, and 5 Times Sit-to-Stand), (2) post-stroke acute care (Orpington Prognostic Scale, Postural Assessment Scale for Stroke [PASS], and Stroke Rehabilitation Assessment of Movement [STREAM]) and, (3) post-stroke in/out patient rehabilitation (Fugl-Meyer Assessment, Functional Independence Measure, PASS, STREAM, and Stroke Impact Scale⁷⁹). A Clinical Practice Guideline Task Force for stroke rehabilitation has additionally reviewed balance and gait measures and recommend the Functional Reach Test and the Timed-Up-and-Go (TUG).⁸⁰

Descriptors of Gait Patterns

The evaluation of gait patterns includes the assessment of gait speed mentioned previously, including kinetic and kinematic descriptions of gait patterns to identify improvement in walking ability.^{81,82} Gait speed assists with discharge planning in the acute and subacute phases of rehabilitation and is correlated with future health care utilization and functional decline.

Historically, gait deviations in persons with hemiplegia have been described according to their spatiotemporal and kinematic abnormalities and in terms of the loss of centrally programmed motor control mechanisms.^{83,84} For example, Perry⁸⁴ described common problems of the hemiplegic person's gait in three phases: (1) loss of controlled movement into plantarflexion at heel strike, (2) loss of ankle movement from heel strike to midstance (resulting in loss of trunk balance and forward momentum for push-off), and (3) loss of the normal combination of movement patterns at the end of stance (hip extension, knee flexion, and ankle extension) and at the end of swing (hip flexion with knee extension and ankle flexion).

Knutsson and Richards⁸³ classified the motor control problems of the hemiplegic gait into three descriptive types. Type I is characterized by inappropriate activation of the calf muscles early in the gait cycle with corresponding low muscular activity in anterior compartment muscles. In the type I activation pattern, the calf musculature is activated before the center of gravity passes over the base of support. This thrusts the tibia backward instead of propelling the body forward in a push-off as normally occurs. The patient with hemiplegia compensates for the backward thrust of the tibia by anteriorly tilting the pelvis or flexing forward at the hip. Type II consists of an absence of or severe decrease in electromyographic activity in two or more muscle groups of the involved lower extremity. This pattern of markedly decreased muscular activity results in the adoption of compensatory mechanisms to gain stability. Type III activation patterns consist of abnormal coactivation of several limb muscles with normal or increased muscular activity levels in the muscle groups of the involved side. This type of pattern results in a disruption of the sequential flow of motor activity.

Mulroy classified post-stroke gait abnormalities of speed and weakness into four groups: fast walkers (44% of normal speed) with weakness in stance propulsion, moderate walkers (21% of normal speed) with greater weakness especially in hip and knee extensors leading to terminal stance abnormalities, and slow-flexed or slow-extended walkers (10% to 11% normal speed). Slow-flexed walkers have excessive hip and knee flexion in midstance while slow-extended walkers learn to use knee hyperextension to support body weight.⁸⁵

A shift in conversation regarding hemiparetic gait pattern is occurring in the literature. To address the relationship between neural control, biomechanical constraints, and the variability of environmental constraints, Ivanenko described a module-based framework for human gait.⁸⁶ The modules describe the timing and activation profiles of groups of muscles during the phases of the gait cycle. Following stroke, as a result of damage to the cortex and the descending pathways, fewer modules are used.⁸⁷ Clark and colleagues identified four altered combinations of modular categories in the stroke population. They found people post-stroke merged these categories as the CNS's way of simplifying the task of walking: the altered ability to differentially activate muscle modules due to impaired motor initiation, cessation, and timing resulted in the "merging of module activation timing."⁸⁸

They described the use of two modules as a low-complexity gait pattern, the use of three modules as a moderate-complexity gait pattern, and the use of four modules as a high-complexity gait pattern. These levels of complexity were correlated with functional mobility through measures of self-selected gait speed, fast gait speed, and step length asymmetry. A review of this modular-based framework was recently published.⁸⁹

Evaluation of Movement Control

After the standardized testing has been performed, the therapist continues to a subjective evaluation of movement components to gather information to answer the question of "why" it is difficult for the patient to perform specific movements or tasks.

Patients who have sustained a stroke have difficulty moving the trunk and the arm and leg on the affected side because of the presence of primary motor impairments and secondary impairments.

In years past, weakness and paralysis after stroke were largely ignored because of a lingering focus on spasticity. Recent studies have shown that the inability of the muscle to produce force is, in fact, present and interferes with the ability to achieve functional performance.^{90–92} Insufficient force production is present in 75% to 80% of patients after a stroke. There appears to be no difference in patients with left- or right-sided hemiplegia in terms of frequency or severity.⁹³

When clinically assessing control of active movement patterns, the therapist observes, analyzes, and identifies the patient's functional patterns of posture and movement in the trunk and extremities and compares them to what is expected. Verbal directions or demonstrations may be necessary to help the patient understand what is desired. In this phase of the evaluation, the therapist should not physically assist the patient's movement but should be prepared to prevent loss of balance.

Assisted Movement

After the evaluation of movement during activity, therapists may use their hands while reevaluating the movements to gain additional information about the relationships between impairments. Whereas the use of handling must be judicious, handling is used during an assessment for the following purposes:

1. To correct alignment to gather additional information about strength, control, and orthopedic impairments (Fig. 24.5)
2. To limit degrees of freedom of one of the joints to assess relationships between intralimb segments
3. To assist the movement of a weak muscle
4. To block or stabilize a joint to assess the performance of a weaker muscle group or to limit the degrees of freedom of an intralimb segment (Fig. 24.6).⁶³

Example.

Step 1. *Assessment of forward reach in sitting by patient with left hemiplegia.* Active movement patterns on left: patient initiates movement

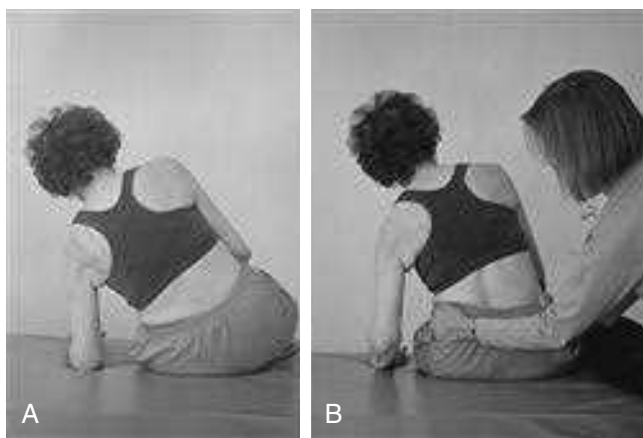

Fig. 24.5 (A) Patient with right hemiplegia trying to perform an upper-body-initiated lateral weight shift to the left. Note that the spine is straight and the right hip is off the surface. **(B)** Therapist uses her hands to correct and stabilize the lower trunk as the patient initiates the upper-body lateral movement to the left. The therapist gains information about trunk and hip control and secondary impairments of trunk muscle tightness. Note that the spine is beginning to curve as the patient uses eccentric activity of the right lateral musculature to control the movement. Active stretching of the right quadratus lumborum and latissimus occurs if tight muscles are present.

Fig. 24.6 (A) Patient with right hemiplegia moving from sitting to standing. Note the tendency to use the left leg more than the right, the left rotation of the upper body, and the position of the right arm. **(B)** Therapist uses her hands to stabilize the lower leg and to assist lower-leg movements as the patient initiates sit-to-stand. Note the change in upper-body position and the decrease in arm posturing.

proximally; shoulder flexes to 60 degrees, with internal humeral rotation; abducted, downwardly rotated scapula elevates during the movement; elbow flexes, forearm supinates to 10 degrees; wrist remains in flexion and radial deviation. Patient leans trunk forward to assist with task but cannot reach arm forward to place it on table.

Step 2. *Clinical judgment or hypothesis 1:* Weakness of scapula and humeral external rotators prevents antigravity use of elbow extensors during forward reach. Supination of forearm comes from strong proximal initiation and use of elbow flexors to lift arm. *Clinical judgment or hypothesis 2:* Forearm, wrist, and hand position prevent distal initiation and biases shoulder in internal rotation, thus blocking use of elbow extensors.

Step 3. *Test hypothesis 1:* Therapist uses her or his hands to externally rotate the humerus to neutral and asks patient to reach again. *Result:* Patient activates elbow extension halfway through range with shoulder forward flexion and places wrist and hand on table. *Clinical intervention implication:* Increased control of humeral external rotation and increased control of accompanying scapular pattern are important intervention goals to regain forward reach of arm. Retrain trunk, scapular, and humeral movement patterns, with emphasis on shoulder external rotation and scapular upward rotation. Assess secondary impairments of pectoral and rotator cuff tightness (rotator cuff is shortened if scapula is in an abducted position). *If result is unchanged, test hypothesis 2:* Therapist supports wrist and hand with wrist splint or with his or her hand and asks patient to reach again. *Result:* Patient activates elbow extension and places the wrist and hand on the table. *Clinical intervention implication:* Prevention or blocking of wrist flexion limits the degrees of freedom, changes the internal rotation moment on the distal portion of the lever arm, and allows use of existing elbow extensors. Use small wrist splint during independent practice or use object to assist or preset distal segment during practice.

DEVELOPING A PHYSICAL THERAPY ASSESSMENT

Following an evaluation of movement dysfunction, the physical therapist identifies the primary influencing factors to develop an effective

treatment plan. The physical therapist considers the contributions of primary and secondary impairments.

Primary Impairments

Primary impairments are physical findings that are associated with a specific brain lesion. The primary impairments of stroke that relate to functional recovery of movement include neurological weakness, changes in muscle activation patterns, and changes in sensation.

Neurological Weakness

Weakness from stroke differs from generalized weakness and orthopedic weakness: it involves one entire side of the body and includes the trunk and extremities. After a stroke, the trunk, perhaps because of its bilateral cortical innervation, does not display the degree of weakness found in the extremities. As a result of differences in testing methods, position, and design, there is no consensus on the degree of trunk muscle weakness after a stroke: some research findings indicate a loss of lateral paretic-side trunk strength,^{110,111} others report no significant difference in lateral trunk strength,^{112,113} and others find slight weakness in the trunk extensors.^{114,115} However, it is clear that weakness in the extremities interferes with functional use in either weight bearing or movement in space.^{63,116}

Muscle Activation Deficits

Common muscle activation deficits include impaired initiation and cessation of the muscle, the inability to sequence muscles for selective extremity movement, and the inability to grade timing and force production.

Impaired initiation/cessation. Impaired initiation or cessation of muscle activity can take either of two forms: (1) an inability to turn a muscle on or off, or (2) improper initiation such as initiating a forward reach movement proximally instead of distally. The inability to turn a muscle on may be a result of the CNS damage or neurological weakness combined with altered alignment. The inability to turn a muscle off results in muscle overactivity and if combined with activity from neighboring muscles may result in cocontraction. Common examples of improper initiation are described below.

Example 1. The patient reaches forward to grasp an object and initiates the movement proximally with shoulder elevation (using the stronger proximal shoulder muscles) instead of initiating distally from the hand and forearm (due to weaker distal muscles).

Example 2. The patient initiates the swing phase of gait proximally (using stronger pelvic and hip muscles) instead of initiating distally from the ankle and foot.

Impaired sequencing. Impaired sequencing is inappropriate muscle selection or fixed patterns of muscle activity that do have a functional purpose. After a stroke, muscle sequencing patterns are related to the extent and area of insult. Abnormal sequences emerge as mass flexion or extension in the extremities. As the brain recovers, sequences become more complex and include the ability to combine patterns of flexion and extension. The level of ability to generate these sequences is assessed with the Fugl Meyer Assessment Scale.¹¹⁷

Inappropriate timing. During functional movements, muscles are activated in a particular sequence at a particular time to achieve a desired goal. Timing patterns that are too early, too late, or disorganized each contribute to loss of functional abilities.

Altered force production. Force production is the ability to move the body's mass. Altered force production, including difficulty producing sufficient force, or difficulty grading force, requires the therapist to consider a variety of possible contributing factors. These factors include the inability to turn a muscle on or off, inappropriate timing of muscle activation, neurological weakness, impaired trunk-limb coordination (the inability to keep the upper trunk aligned over the lower

trunk), abnormal sequencing of lower extremity flexors and extensors (the inability to combine flexor and extensor patterns), and/or incorrect joint alignment. Consider the task of sit-to-stand: a patient may have difficulty transitioning from a sitting to a standing position. A clinician must use observational skills to hypothesize which factor(s) are contributing to the difficulty of the task. If all factors have been addressed and the patient continues to have difficulty, the clinician may need to modify the environmental demands of the task to allow the patient to work within their force production ability.

Equilibrium and Protective Reactions

Equilibrium reactions help us to maintain or regain balance by keeping the center of gravity within the base of support. Equilibrium reactions are often referred to as the body's "first line of defense" against falling. They occur when the body has a chance of winning the battle against gravity. If equilibrium reactions cannot preserve balance, the second line of defense emerges: protective reactions. One of the best-known protective responses in the arm is the "parachute reaction." Protective responses in the leg in standing positions include hopping and stepping.

Equilibrium reactions are assessed while slowly moving either the limb or trunk away from the base of support. The amount of control in the trunk and supporting limb, the size of the base of support, and the available range of motion, as well as the evaluator's handling skills, affect the response (see Chapter 20). As the body moves outside the base of support, the extremities are recruited to help the postural system retain the body's balance. Once the control of the body is no longer sufficient to maintain balance, the extremities will respond in a protective fashion to prevent a fall.

Evaluation of Secondary Impairments

Secondary impairments occur as a consequence of the stroke or because of other medical and environmental influences, such as inactivity, falls, pneumonia, or phlebitis. As they develop, they influence one another and the primary impairments. Secondary impairments influence the patient's level of disability by contributing additional physical problems. There are four major categories of secondary impairments: changes in joint alignment and mobility, changes in muscle and soft tissue length, pain, and edema. During the chronic stage of rehabilitation, therapeutic interventions often focus on reducing secondary impairments to improve compensatory patterns of function, since the possibility of neurological recovery is lessened.

Changes in Joint Alignment

Weakness and activation deficits are the underlying causes of altered joint alignment in the acute recovery phase post-stroke. Included in this category are alterations in the normal resting alignment of bones (changes in spinal alignment) and changes in the normal mechanical relationships of joints (changes in glenohumeral alignment). Changes in resting posture arising from shortened muscles place the articular surface of joints in atypical positions, leading to changes in joint mechanics. In the foot, a shortened gastrocnemius muscle leads to a superior glide of the calcaneus and an equinovarus position. When the foot is placed into weight-bearing mode, the heel is not in contact with the ground and body weight is shifted to the mid or forefoot. This shift may result in additional changes of joint alignment in the foot. Changes continue in the subacute and chronic phase of recovery, especially with incomplete recovery of motor function.

Alignment changes develop quickly in the acute recovery phase, as in shoulder subluxation, when the pull of gravity and the weight of the paretic extremity exert traction on joints.

Shoulder subluxation. Shoulder subluxation occurs when any of the muscular and biomechanical factors contributing to glenohumeral

joint stability are interrupted. In persons with hemiplegia, subluxation is related to a change in the angle of the glenoid fossa occurring because of muscle weakness. In the frontal plane the scapula is normally held at an angle of 40 degrees. When the slope of the glenoid fossa becomes less oblique (and more vertical), the humerus will “slide” down and out of the fossa.¹¹⁸ Ryerson and Levit¹¹⁹ first described three types of subluxation in patients with hemiplegia: inferior, anterior, and superior.

Inferior subluxation. The most common type of subluxation is an inferior subluxation. It occurs in patients with severe weakness and is present in the acute recovery stage. Weakness and the weight of a heavy arm result in downward rotation of the scapula. Downward rotation orients the glenoid fossa vertically, the unlocking mechanism of the capsule is lost, and the humerus subluxates inferiorly with internal rotation. With an inferior subluxation, the capsule is taut superiorly and vulnerable to stretch. Any downward distraction of the humerus will place an immediate stretch on the upper part of the capsule and the coracohumeral ligament, another superior structure. The rupture of this ligament is thought to be a contributor to shoulder pain.¹²⁰

Anterior subluxation. Anterior subluxation occurs when the humeral head separates anteriorly from the glenoid fossa. Anterior subluxation occurs when the downwardly rotated scapula elevates, tilts forward on the rib cage, and the humerus hyperextends. An anterior subluxation places increased pressure on the proximal biceps tendon. This pressure on the tendon may lead to elbow flexion and forearm supination (actions of the biceps muscle). This subluxation is often found in patients with atypical patterns of return and trunk rotational asymmetries.⁶³

Superior subluxation. A superior subluxation occurs when the humeral head lodges under the coracoid process in a position of internal rotation and slight abduction. The humeral head is “locked” in this position so that every movement of the humerus is accompanied by scapular movement. The scapular position in this subluxation is one of abduction, elevation, and neutral rotation. With a superior subluxation, the humerus abducts with elbow flexion. A superior subluxation occurs in patients with neurological weakness, unbalanced return, and cocontraction.

Subluxation itself is not painful but results in changes in muscle length–tension relationships, muscle shortening, and permanent stretch of the joint capsule. To correct a subluxation, the therapist corrects trunk, scapula, and humeral alignment before reeducating functional arm movement patterns.

Prevention of subluxation requires (1) proper assessment of secondary alignment problems (rib cage, scapular, humeral position), (2) early reeducation of trunk and arm linked patterns in sitting and standing, and (3) prevention of shoulder capsule stretch, including support and positioning as the patient sits, stands, and practices walking.

Changes in Muscle and Tissue Length

In the subacute or chronic recovery phase, continued loss of alignment leads to muscle shortening. Remember, this is a circular event: neurological weakness and/or muscle activation problems leads to altered joint alignment that leads to muscle and tissue shortening. Loss of alignment occurs early in recovery, whereas muscle and tissue shortening continue to occur over time. This muscle shortening (hypertonicity) is preventable through interventions that maintain range in key joints until motor control and activity levels increase. When evaluating muscle shortening, the therapist pays close attention to the functional consequences of two-joint muscle tightness.

Example. In sitting (hip and knee flexed), the patient may have ankle joint dorsiflexion range from 0 to 10 degrees; but in standing

(hip and knee extended), ankle joint dorsiflexion range may be significantly greater, for example, –20 degrees. This functional loss of ankle range due to two-joint muscle shortening causes significant problems for standing and walking. Loss of ankle joint range in standing may be the result of gastrocnemius and soleus shortening or two-joint muscles that influence the knee, such as tensor fasciae latae, or hamstring muscles. (Fig. 24.7).

Extremity muscles that cross multiple joints are the most common groups to shorten and limit joint range in hemiplegia. With prolonged changes in alignment and joint range, some two-joint muscle tendons may slip or shift.

Example. Long-standing wrist flexion may cause the ulnar wrist extensor to slip volarly and function as a wrist flexor. Similarly, a prolonged position of rearfoot equinovarus may lead to shifting of the anterior tibial muscle belly. As the muscle shifts, tension on the muscle belly results in increased foot supination.

Pain

In the patient with hemiplegia, arm pain can be caused by an imbalance of muscle activity, altered joint alignment, improper weight-bearing patterns, and muscle shortening; or it may be related to diminished or altered sensation. Although evidence-based approaches should be used to manage shoulder pain after stroke, systematic reviews show that there are few rigorous studies that can be used to guide treatment.¹²¹

The presence of pain in hemiplegia is devastating for the patient and makes movement reeducation difficult. Shoulder pain is the most frequent pain complaint after stroke.^{122,123} Pain must be evaluated specifically and should not be allowed to occur during intervention; the “no pain, no gain” message that is sometimes used in orthopedic interventions should not be used in neurorehabilitation. Pain is an indicator that joint alignment or movements are incorrect. See Box 24.5 for questions helpful when identifying the cause and location of pain.

Joint pain. Joint pain is caused by poor shoulder joint mechanics during movement. Two common alignment problems are loss of scapular and humeral rhythm and insufficient humeral external rotation.^{122,124,125} With a shoulder subluxation, the humeral head is not correctly seated in the glenoid fossa. At 60 to 90 degrees of forward flexion, impingement of the capsule may occur and the patient will report sharp pain on the superior aspect of the shoulder joint. The pain ceases when the arm is lowered. The subluxation and loss of scapulohumeral rhythm result from loss of trunk and arm movements or muscle tightness from either persistent arm posturing or weakness.

If the patient reports joint pain, the therapist should lower the humerus immediately, reestablish the mobility of the scapula, reseat the humerus if necessary, and maintain appropriate humeral rotation while moving the arm up again. Trunk movements in forearm weight bearing are used to teach a self-ranging practice routine that ensures scapulohumeral rhythm.

Muscle and tendon pain. When a shortened or posturing muscle is stretched too quickly or beyond available length, a strong “pulling” type of pain is often reported in the region of the muscle belly being stretched. If the amount of stretch is decreased a few degrees, the reported pain subsides.

If the inappropriate stretching is not stopped, muscle pain progresses to tendon pain. Proximal biceps tendonitis, distal biceps tendonitis radiating into the forearm, and wrist flexor tendonitis are most common. The usual cause of tendonitis is improper weight bearing, with an inactive trunk and “hanging” of the arm. The treatment of tendonitis is rest and modalities (i.e., heat, ultrasound, or electrical stimulation) or injection of corticosteroids. When movement

Fig. 24.7 (A) Patient with right hemiplegia with limited range in hamstring, tensor fasciae latae, and gastrocnemius and soleus muscles. (B) Patient has sufficient range at ankle to keep foot on the floor in sitting and as she initiates the rise to standing. (C) As she stands and reaches the limit of range of these two muscle groups, her body compensates. The pelvis rotates right, and the tight medial hamstring adducts and internally rotates the femur and pulls the knee into extension as its medial insertion becomes more anterior to the joint. (D) As the knee extends more, the calcaneus moves into equinus and varus. The foot supinates as a result of calcaneal varus and external tibial rotation from the tight tensor fasciae latae.

BOX 24.5 Questions for Subjective Evaluation of Pain

Location: Where is the pain? Pinpoint the location.

Type: What does it feel like?

- Sharp and stabbing
- Aching
- Dull
- Pulling
- Pins and needles

Occurrence: When does the pain occur?

- At rest
- During movement
 - Range-of-motion exercises
 - Weight-bearing exercises
 - A specific part of the movement

reeducation is restarted, it is important to avoid the “exercise” that caused the pain and to create a new intervention plan.

Complex regional pain syndrome: Shoulder-hand syndrome.

One type of complex regional pain occurs in the shoulder and hand. It begins with tenderness and swelling of the hand and diffuse aching pain from altered sensitivity in the shoulder and entire arm.¹²⁵ This pain interferes with the reeducation of movement patterns and causes a general desire on the part of the patient to “protect” the arm by not moving it. Edema and limited shoulder, wrist, and finger range of motion soon occurs.

The second stage includes further loss of shoulder and hand range of motion, severe edema, and loss of skin elasticity. This is followed by the third stage, which includes demineralization of bone, severe soft tissue deformity, and joint contracture.^{125,126}

Not every edematous hemiplegic hand leads to shoulder-hand complex regional pain syndrome. Hand edema results from an upper extremity that remains dependent and that does not move for long

periods of time. It is essential to teach the person with hemiplegia how to properly care for the hand and to give the responsibility for the care of the hand and arm to the patient.

Ryerson and Levit⁶³ propose five intervention steps for severe or chronic shoulder pain: (1) eliminate pain from intervention or the home program, (2) desensitize the arm and hand to touch, (3) eliminate hand edema, (4) introduce pain-free arm movements by reestablishing scapular mobility, and (5) beginning with guided arm movements below 60 degrees, gradually increase the variety and complexity of arm movements.

Objective measures of pain. Two commonly used objective pain measurement scales are the Visual Analog Scale and the McGill Pain Questionnaire.^{127,128} These scales focus on the intensity of pain and provide an objective measure of intervention effectiveness. For an in-depth discussion of the topic of pain management (see Chapter 30).

Edema

Edema in the hand and foot is another common secondary impairment that develops as a consequence of loss of movement control and hospitalization factors such as intravenous infiltrates and dependent limb positioning. Edema limits joint range and tissue mobility. The edematous fluid places the skin on stretch and acts as an interstitial “glue” that bonds the skin, fascial tissue, muscle tissue, and tendons. Hand edema is associated with the development of shoulder-hand syndrome. Foot edema is as common as hand edema, limits ankle joint dorsiflexion range, and is often ignored during intervention programs. Edema begins on the volar surface of the hand and foot, progresses dorsally, and then moves proximally across the wrist or ankle.

Edema interferes with the retraining of functional movement patterns by preventing the smooth glide of tissues. It must be eliminated before active reeducation begins. Edema has defined stages. When the involved tissue feels soft and fluid, the condition responds to retrograde massage and elevation. When the tissue is gelatinous and pitting, the edematous fluid cannot be physically expressed. At this stage, it begins to adhere to underlying tissues. The edema must be softened and liquefied through transtissue massage. The last stage of edema is characterized by hard, lumpy tissue that does not “pit” in response to manual pressure. This stage of edema requires gentle bilateral compression to break up the hard, solid areas into regions of softness. The soft regions then act as open spaces into which fluid released by massage of hard tissue is directed. The goal is to reverse the process of hardening—from hard, to pitting, to soft and fluid. In the pitting and hard stages, when the edematous tissue is not fluid, elevation, elastic gloves, bandaging, and retrograde massage are not effective. When edematous tissue is soft and fluid, active and active assistive extremity movement patterns produce muscular contractions that assist venous and lymphatic return of the fluid.⁶³

Aberrant Extremity Movement

There is considerable debate in the academic and clinical therapy community over the clinical relevance of spasticity and the need to address it in treatment.^{90,129} For years, spasticity, a velocity-dependent reflex measured in the passive condition and a sign of CNS injury, was thought to be a direct cause of atypical voluntary movement post-stroke. In the 1980s, scientists challenged this concept, and a new construct emerged that acknowledged the contribution of both neural and non-neural elements to the phenomenon of these atypical movement patterns. This newer concept helps explain why the stretch reflex or tendon tap response is an “epiphenomenon” and is not the cause of the “spastic movement problem.”^{18,130} Dietz¹³¹ recommended that we assign different names to these two different phenomena of increased

tone: he suggested we reserve the term “spasticity” for the reflex and create a new term, “spastic movement disorder,” to describe the extremity posturing that occurs during active movement. We suggest renaming Dietz’s second category of spastic movement disorder *aberrant movements*. A knowledge of the underlying causes of aberrant movement is important for intervention planning. If we label aberrant extremity movement “spasticity,” we may plan a treatment intervention that focuses on the aberrant movement itself instead of the underlying causes. For interventions to be successful, it is important to understand the situations in which this aberrant/atypical movement occurs.

Underlying Causes of Aberrant Movement

Ryerson and Levit along with Fisher have proposed several contributing factors. At least three different situations come to mind: (1) the patient’s postural control ability is insufficient for the task, (2) altered biomechanical alignment results in increased tension on extremity muscles, and (3) voluntary activation of existing muscle sequences.^{63,132} These situations are divided into three groups for ease of description, but, in reality, overlap may occur between groups.

Insufficient postural stability and trunk control. If postural control is insufficient for the functional task, extremity patterns of arm flexion or leg extension occur as a balance strategy; the body is recruiting activity in the limbs to help remain stable.

Example. If a patient has sufficient trunk control in sitting, the arm and leg display normal resting positions. However, during the rise to stand, the arm postures in flexion. The arm postures most obviously during the transition phase of the stand when the hips are off the surface and the center of gravity of the body is behind the feet, the new base of support.

Treatment of the increased tone, in this case, would not be directed at the arm. Rather, intervention would focus on increasing postural stability of the body, especially during the execution phase of the movement when the center of mass is behind the base of support. During this phase, trunk-limb coordination, lower-extremity sequencing, and sufficient force production are needed. As the trunk and leg gain more control, the arm posturing decreases (see Fig. 24.6).

Altered biomechanical alignment. A second cause of aberrant extremity movement, altered biomechanical alignment, may result in increasing tension and unwanted activity, especially in two-joint muscles.

Example 2A: Lower extremity. In sitting, tightness in the gastrocnemius muscle across the knee may not affect the ability to keep the heel on the floor. However, as the patient rising to stand and extends the knee, the limit of tightness in the gastrocnemius is reached, the distal end of the tendon shortens and the ankle plantar flexes. Gastrocnemius tightness pulls the calcaneus into equinovarus, resulting in foot supination (see Fig. 24.7).

However, after lengthening of the gastrocnemius across the ankle and knee in standing and correction of the calcaneal position, the patient can stand and keep the foot on the floor. Now, movement re-education begins to restore the muscle activation control and strength needed to prevent this shortening from reoccurring.

Example 2B: Upper extremity. In anterior shoulder subluxation, the anterior movement of the humeral head increases tension on the biceps tendon proximally, resulting in increased elbow flexion. As the tension increases, the forearm may begin to supinate. With the knowledge that this altered alignment may be the underlying cause of the atypical movement, the therapist repositions the humeral head and scapula, the tension on the biceps is diminished, and the forearm slowly pronates and then the elbow extends.

For the atypical posturing to permanently stop, therapy interventions must help increase strength and muscle activation components to maintain active typical alignment.

Inappropriate voluntary muscle activation. This third underlying cause of aberrant movement occurs when the patient is actively using available patterns of return when trying to use the arm or leg. The patient uses the muscles in the only way he or she knows: patterns in synergy or combining synergies or with prolonged contraction. Historically, these patterns were labeled “spastic patterns.” If we now think of these patterns as inappropriately initiated, sequenced, or timed, therapy intervention is directed at these underlying causes rather than at the symptoms (the aberrant movements). The aberrant movement of the extremity will change when the patient learns new activation patterns. Often, these are “learned” patterns and are difficult to change. Early reeducation should include training in these skills of more complicated sequencing, intensity, and duration of firing.

Conclusions

Hypertonicity is the increased resistance that you feel when you move a joint/muscle through its range during a state of relaxation. It may lead to contracture, but neither contracture nor hypertonicity are the cause of aberrant movement in patients post-stroke.

Using this new construct, inhibition techniques are inappropriate because they focus on the symptom, not on the underlying cause. Intervention techniques that focus on inhibition of extremity tone—maximal elongation, vibration, biofeedback, cold, or relaxation or static weight bearing—rarely result in a permanent change in the tone. The temporary decrease of clinical hypertonicity that occurs with any of these methods does not by itself directly lead to an increase in function.^{133,134}

Motor Evaluation Forms

The foregoing information, once gathered, can be placed on an evaluation form in many ways. Every medical institution seems to have its own evaluation form and its own system of recording data. Active movement at the shoulder joint may be described in one institution in terms of percentages of synergistic stages, at another institution by a narrative of degrees and planes of movement, and at still another by functional outcomes of shoulder movement. At one hospital the documentation of pain may be descriptive, and at another it may be numerical. It is important to keep in mind the substance of the evaluative material, not the form in which it is described. A detailed motor evaluation form is necessary for the establishment of realistic goals and for subsequent treatment planning, but the specific form depends both on the needs of the specific clinical setting and on the clinician's choice.

Recognizing Needs

The information obtained from the total evaluation provides the basis for answers to the following questions:

- What activities are possible?
- What activities are not possible?
- How do the movement impairments and secondary impairments relate to activity performance?
- How do the environmental and personal considerations impact the ability to perform the activity?

By understanding the impairments and their relationship to activity limitations, the therapist can answer the following question: What significant movement components are missing? The answer to this question becomes a hypothesis for intervention planning. How the possible is accomplished and why the impossible exists provide logical suggestions for selection of intervention techniques.

If assistive devices are used, the following questions should be asked: Is the device always used? If not, when is it used? How is the device used? Could the device be used another way that would foster trunk symmetry and allow activity of the affected extremities?

Therapy intervention occurs at either the level of activity limitation or the level of movement-related primary and secondary impairments. The process of establishing goals and selecting activities for intervention begins with clinical decision making or problem solving.

CLINICAL DECISION MAKING AND PROBLEM SOLVING

Problem solving is a process of gathering and analyzing evaluation information from movement analysis, organizing and reflecting on this information to develop hypotheses for causal relationships between activity limitations and significant impairments, and establishing and prioritizing goals for therapeutic intervention. The problem-solving process is also used to hypothesize how the movement problems of the trunk, arm, and leg are interrelated and how these problems relate to the ability to perform tasks. Movement control deficits, secondary impairments, and compensatory movement patterns should be identified in relation to each significant activity limitation.

Analyzing Evaluation Material

The relationship between activity performance and primary and secondary impairments in people post-stroke, the basis for therapy intervention, is derived from clinical experience and judgment. Clinical reflection guides the evaluation process—what should be evaluated and how. As a result of the evaluation, the therapist has a list of functional skills that are difficult or impossible for the patient to perform and a list of primary and secondary impairments that relate to the attempted performance of that task. The therapist analyzes this information with the goal of identifying common impairments in categories of tasks: Which primary impairments are major impediments in each task analyzed? Are there secondary impairments that interfere with the patient's ability to perform specific critical movement components? What is the level of trunk-extremity control during task performance in each functional position evaluated? While analyzing the evaluation material, the therapist pays attention to all significant factors that limit performance of tasks, including environmental, cognitive, perceptual, and emotional barriers.

Common Combinations of Primary and Secondary Impairments

Therapists evaluating and planning interventions for people post-stroke need to identify both primary impairments of the motor and sensory systems along with the resulting secondary impairments of altered alignment and muscle length. Below are a few examples of common combinations of these impairment categories.

Acute Recovery

A patient after an acute stroke with left hemiplegia cannot perform morning daily care activities at the sink while sitting in a wheelchair, cannot transfer from bed to chair, and cannot rise to stand. Common primary impairments may include (1) neurological weakness of the left arm and leg, (2) inability to sequence forward arm movements, (3) an inability to coordinate trunk and lower-body movements to allow forward weight shifts in sitting and/or to perform transfers from bed to chair, and (4) impaired extremity sensation. Secondary impairments that begin to appear by the end of the acute recovery phase might include trunk asymmetries (lateral trunk flexion with a left

spinal convexity, inferior shoulder subluxation, loss of extremity muscle length in the pectorals and gastrocnemius, and/or edema in the hand and foot).

During the acute recovery stage, weakness of the trunk on one side results in a flaring of the rib cage and lateral flexion of the spine with the *convexity on the affected side*. The appearance of a low shoulder contour on the affected side often is associated with trunk shortening (lateral flexion with the concavity). The heavy weight of the weak, hypotonic arm pulls the upper quadrant into *excessive forward flexion*. In this position, the scapula elevates and tips forward on a flexed, rotated thoracic spine (Fig. 24.8).

Inpatient/Subacute Recovery

In the inpatient rehabilitation phase of care, these primary impairments begin to improve. However, as the patient performs tasks that

Fig. 24.8 (A) Patient with right hemiplegia. Contour of right shoulder appears lower and longer than on the left. Pelvis lists downward on the right. (B) Therapist lifts the patient's upper body up out of forward flexion and corrects the position of the glenohumeral joint. Note that the contour of the right shoulder is now higher and shorter than the left shoulder contour. The trunk is laterally flexed with the convexity on the right. These movement components, convexity of a lateral curve, high shoulder, and low pelvis, are compatible. (C) Patient's arms are supported symmetrically by a table. Note the convexity of the curve on the right and the low pelvis on the right. (D) Same patient moving forward and down with an upper-body anterior weight shift. This position allows the therapist to evaluate the position of the trunk. Note the tendency to avoid weight on the right hip. The trunk is laterally flexed with the convexity on the right, and the right shoulder is higher than the left shoulder.

exceed their level of postural control, aberrant movement in the arm or leg may increase as a strategy for maintaining balance. Secondary impairments of shoulder pain may increase, along with increasing instances and degrees of muscle tightness and altered alignment. These altered alignment patterns in the spine and girdles, as a result of muscle activation deficits and loss of trunk control, create an atypical starting position for functional movement.

If the patient relies heavily on the use of one-sided compensatory strategies (reliance on the nonaffected side with relative nonuse of the affected extremities) during sit-to-stand and walking, *lateral translation of the thoracic spine* may occur. This altered spinal alignment pattern also occurs when the patient relies heavily on a quad cane or hemiwalker. As the patient uses their arm to lean on and push down into this stable external assistive device (a "third leg"), the trunk translates laterally (from the hypermobile point of T10). This pattern creates a lower shoulder contour that may be mistaken for shortening of the affected side (see Fig. 24.4).

In standing, because the need for leg stability and movement control is much greater than in sitting, the trunk compensates to accommodate the demands of the leg. Often the upper body and lower body patterns are opposite one another (i.e., counterrotational). This counterrotational pattern is accompanied by a noticeable skin fold. However, the spinal asymmetry is rotational, not lateral (see Fig. 24.4).

Chronic Recovery

Another compensatory pattern, excessive spinal flexion throughout the spine, occurs in the chronic recovery stage especially with severe injury to the CNS. As patients with this asymmetry shift weight onto the stronger side, *spinal rotation toward the affected side occurs*. This pattern of spinal flexion and rotation to the affected side develops over time in patients who sit more than they stand or walk.

Distal and Proximal Relationships

Alignment problems in the distal extremity segments are related to loss of movement control and proximal alignment changes. Patterns in the distal arm and distal leg are strikingly similar. When the midjoint (elbow or knee) is extended, the proximal rotational alignment asymmetry translates down into the distal segment: into the hand or foot. Shoulder internal rotation translates across an extended elbow, resulting in forearm pronation (Fig. 24.9A). Similarly, when the knee is extended, hip internal rotation asymmetries translate across the knee and occur with tibial internal rotation and midfoot pronation. However, if the mid-joint is flexed, the proximal pattern no longer dictates distal asymmetries.

Example

A patient has an inferior shoulder subluxation resulting in humeral internal rotation. This tendency for internal rotation places tension on the biceps tendon, resulting in beginning elbow flexion and forearm supination. With unbalanced return and weakness of arm muscles, the emerging biceps activity predominates and reinforces a posturing pattern of shoulder internal rotation, elbow flexion with forearm supination (see Fig. 24.9B).

The weakness pattern of ankle plantarflexion and calcaneal equinovarus biases return in the anterior and posterior tibialis. During movements of the leg in space with hip and knee flexion, this distal supination pattern pulls the tibia into external rotation. To place the supinated foot on the ground, the patient compensates proximally by rotating the pelvis and femur, as a unit, toward the unaffected side. This incompatible tibial external rotation and femoral internal rotation may result in knee hyperextension.

Fig. 24.9 (A) Patient with left hemiplegia and severe weakness. The left arm and hand are in shoulder internal rotation, elbow extension, and forearm pronation. The left wrist flexes, and the hand pronates and radially deviates on the wrist. **(B)** Patient with left hemiplegia with atypical movements. The left arm is positioned in shoulder internal rotation and elbow flexion. As the elbow flexes, the forearm begins to supinate on the internally rotated humerus. The wrist flexes and radially deviates with finger flexion.

Developing Hypotheses for Significant Impairments

The process of motor performance evaluation results in a list of activities and related impairments. However, not all these impairments directly relate to each activity limitation of the patient. The therapist, using clinical judgment, hypothesizes a causal relationship between frequently occurring impairments and activity limitation. These impairments, called *significant impairments*, are the ones that must be changed for measurable changes in movement and function to occur.⁶³ The other impairments are not forgotten but are reevaluated later as improvement begins and new activity goals are chosen. The significant impairments are often used as the focus of short- and long-term goals because they are the underlying building blocks of the selected activity goal. Because functional movement depends on the linkage of trunk and extremity movements, the therapist develops hypotheses between impairments in the extremities and specific levels of trunk control to set goals that result in improved activity performance. (See Chapters 3 and 7.)

Goal Setting

Once the therapist reviews the desired functional goal and identifies the underlying significant impairments, the intervention plan is created and discussed with the patient.

Functional Goals

Functional goals are based on the environment and personal needs of the patient and on the functional impairments that were identified by the therapist during the initial assessment. Functional goals should

represent a significant change in the patient's level of independence, be practical, and reflect improvement in a specific activity limitation. They state the desired function and the expected level of performance.⁶³

Example. Patient will stand independently and safely while performing self-care activities at the bathroom sink.

Long-Term Goals

A long-term goal should reflect a major improvement in a primary or secondary impairment or an increase in level of performance of an existing skill. The time it takes to accomplish a long-term goal varies tremendously depending on the frequency of treatment and the length of time after stroke. Long-term goals may be stated in functional terms, but they usually reflect a change in a primary impairment: an increase in strength, movement control, or balance. The therapist may set many short-term goals to achieve one long-term goal.⁶³

Examples.

Functional goal. Patient will be able to perform meal preparation activities in the kitchen safely (while standing).

Long-term goals.

1. Patient will independently perform upper-body initiated movement (lateral and rotational) while standing, supporting hips against a kitchen counter.
2. Patient will safely stand near the kitchen counter and maintain balance during reach movements within and beyond arm's length.

Short-Term Goals

A realistic short-term goal should be achievable quickly and should be based on the result of the patient's response to handling during the evaluation of movement. Short-term goals should directly relate to the accomplishment of the long-term goal. Short-term goals are compiled from the list of relevant primary and secondary impairments. These goals are measurable but do not in and of themselves result in a functional change.⁶³

When stated in terms of movement control rather than functional performance, these goals include the reestablishment of generalized movement patterns that link movement patterns of the trunk and extremities (Box 24.6).

Choosing Intervention Techniques

Once the problem-solving process of goal setting is finished, therapists can select specific intervention techniques and activities. Therapists have many techniques to choose from to meet their goals.

Controversy exists as to the means of increasing functional mobility and performance in patients who have had a stroke. One school of thought teaches compensatory patterns or hopes for some use of the affected side through task-specific practice without direct intervention for the neurological impairments. The other prevalent practice pattern is to increase functional movement patterns on the affected side to help achieve an activity goal by increasing control and strength of movement sequences of the trunk and limb through specific levels of reeducation.^{63,135–137}

BOX 24.6 Component Goals in Functional Training

Component goal (power): Restore strength in trunk and extremity patterns (individual muscles, components, sequences)

Component goal (structure): Minimize or eliminate secondary impairments

Component goal (control): Reeducate patterns of control (sequencing and timing)

BOX 24.7 Reeducation Strategy for Intervention

Reeducating basic trunk movement components

Linking coordinated trunk and extremity patterns

- Weight bearing
- Movements in space

Preventing, minimizing, eliminating secondary impairments

Teaching appropriate compensations

Teaching independent practice routines

A combination of these two practices may be useful: impairment-based intervention strategies to reeducate movement, and task training strategies to foster desirable compensations—a functional reeducation strategy. This type of intervention includes activating trunk- and extremity-linked patterns of movement, minimizing or eliminating secondary impairments that interfere with regaining control, teaching appropriate compensations, and training the patient to practice functional movement patterns in the context of daily tasks (Box 24.7).^{63,138} Research findings support a link between the trunk and upper extremity and the trunk and lower extremity during reaching activities.^{139,140} One result of this research has been to design treatment interventions that restrain trunk movements during forward reach retraining to increase control of elbow extension movement in the paretic arm.^{141,142}

For reeducation to be effective, therapists must allow the patient to initiate the active trunk and extremity pattern, must move from assisted practice to independent practice with the assistance of appropriately selected objects or verbal cues, and must teach the patient appropriately staged practice patterns. Studies based on the “learned nonuse” phenomenon demonstrate that when patients are encouraged to use the affected arm, movement and functional use, even if limited, are possible.^{143,144}

Regardless of intervention type used, task-performance practice, or a reeducation strategy, there comes a time in the recovery process when therapists help the patient select practical compensatory strategies. Compensatory strategies are taught when the patient needs to function independently and cannot yet use the affected extremity because of insufficient recovery or the severity of damage. To be appropriate, the strategy should incorporate the use of the involved extremities and use appropriate trunk movement patterns to maximize future return of movement. Undesirable compensations are patterns that are so asymmetrical that they fail to incorporate available movements of the affected trunk and extremities (Fig. 24.10). Although there is a trend to stress task-based techniques, therapists in clinical settings use hands-on approaches to increase muscle strength and control and to decrease impairments that block the emergence of new functional patterns.⁶³ As research in movement science and recovery of movement increases, therapists must critically analyze research findings and judiciously integrate them with their clinical experience and judgment.

Fig. 24.10 (A) Patient with left hemiplegia using his right side to move to sitting and not incorporating movement of the left side—an undesirable compensation. (B–D) Patient moving to sitting while using as much control as possible on the left side to assist the movement to sitting.

INTERVENTION STRATEGIES FOR FUNCTIONAL RECOVERY

Functional mobility movement analysis, intervention techniques, and suggestions for task practice are documented in therapy literature.^{145–147} In this section, representative mobility skills are selected in three functional positions: supine, sitting, and standing. For each task selected, the focus is on the basic trunk and extremity control patterns used, significant impairments in addition to weakness that make it difficult for the patient to perform the task, and observations from the clinic that relate to intervention and practice.

General Considerations

Weakness and loss of muscle activation control in the trunk and extremities results in ineffective and inefficient functional patterns in daily life. Interventions for extremity deficits include reeducation of movements in space, reeducation of weight-bearing movements, retraining appropriate initiation/cessation, sequencing of movement, and specific task practice. Most patient with hemiplegia regain enough control in the leg to stand and walk, but those same patients may not be able to use the arm for any purpose. Today the concept of “learned nonuse” may help therapists understand why this discrepancy between arm and leg recovery exists.

Distal reeducation is an important component of early reeducation that has been neglected by therapists because of a previous belief that proximal return comes before distal that has now been questioned.¹⁴⁸ Distal reeducation trains the patient to be able to initiate movements from the hand (foot), instead of the common proximal initiation patterns seen during attempted reach (stepping) (Fig. 24.11). Weight bearing on either the forearm or extended arm is used as a postural assist, may be used to reestablish scapulohumeral rhythm, to maintain range of motion in the arm, or to strengthen movement sequences in the arm (Fig. 24.12). The muscles of the arm are linked with trunk weight shifts during active weight bearing.⁶³ Table 24.5 presents the linked trunk and arm muscle activity during active weight bearing for one functional task.

The ability to support body weight on both legs for stability and movement control is similarly important. Movements of the trunk in sitting and standing occur with constant changes of muscle activity in the legs as part of the base of support, to adjust to demands of weight shifts, and to increase activity levels of leg muscles to initiate standing weight shifts. Loss of control of weight bearing on both legs or on one leg has an immediate effect on balance. Problems of weight-bearing control of the leg may exist as a result of insufficient force production, sequencing difficulty, or muscle shortening. When the leg cannot actively support body weight, undesirable asymmetrical compensations may result. A significant and often overlooked prerequisite for active

Fig. 24.11 (A–C) Patient with left hemiplegia. Therapist assists movements of forearm, wrist, and hand as patient practices increasing distal arm control. (D–F) Therapist introduces object and assists patient as he learns to control the object and the movement. (G) Independent practice. (H) Patient uses same movements with a similar object.

Fig. 24.12 Patient performs lower-body-initiated posterior movement during forearm weight bearing at a table. The therapist uses her hands to stabilize the humerus, and as the patient moves back, the therapist's left hand slowly stretches or releases tight tissue in the rotator cuff.

Fig. 24.13 (A) Patient with right hemiplegia practicing home program. During standing forearm weight bearing (providing upper-body stability), she initiates a lower-extremity forward-backward movement. As she moves her hips and lower leg forward, she thinks of keeping her knee straight and stretching her calf. (B) As she moves her hips backward, she may feel a stretch in the back of her thigh, on the lateral aspect of her trunk, or under her axilla.

initiation. These patterns link the trunk with either the arm or leg during the roll.

Trunk and extremity linked patterns. The *upper-trunk flexion rotation initiation pattern* links upper-trunk flexion rotation with arm reach across the body. Active assistive patterns, with the patient holding both hands together for a bilateral arm reach, are encouraged when strength is insufficient to lift the arm against gravity or, through therapist handling, when arm muscle weakness results in such a heavy feeling that the patient cannot control the extremity with the unaffected hand. If the therapist assists the arm, the goal of practice is for the patient to initiate the active antigravity trunk pattern.

A *lower-trunk extension rotation initiation pattern* is coordinated with either a leg-reach pattern or a flexed-leg “push” pattern. Active assistive patterns can be implemented through therapist handling to help train the sequencing or to grade the firing patterns of the leg when it is pushing into the bed. As the lower body moves from supine toward side lying, the upper body and arm follow the movement. The patient is encouraged to practice independently with a focus on the sequence. During independent practice, the therapist may provide verbal cues to help the patient with timing the movement of the upper body.

The *symmetrical lateral flexion initiation pattern* is known as “log rolling”: in this pattern, the trunk does not rotate but is active in a coordinated fashion with the arm and leg on the same side; the arm and leg “reach or push” on the leading side. In rolling from supine to side lying, the trunk flexors initiate the antigravity movement, and when rolling from side lying to supine, the trunk flexors act as the antigravity movement control.

Impairments that interfere. Shoulder joint pain may occur when the patient rolls onto the affected side. Pain occurs if the shoulder is trapped under the trunk as the patient moves to side lying or when the humeral-scapular alignment causes the shoulder capsule to be impinged. If pain occurs during the roll, the therapist should teach the patient to stop, roll back a few degrees, adjust the position of the arm away from the trunk, and then continue the roll. Therapists should teach their patients how to avoid shoulder pain during all activities, especially during rolling or when lying on the more affected side.

In rehabilitative or outpatient care, muscle tightness in the latissimus, quadratus lumborum, biceps, or tensor fasciae latae may limit trunk rotation or trunk and extremity linked movements.

TABLE 24.5 Trunk and Arm Coordinated Movements in Forearm Weight Bearing

Functional Task

Sit at a table with both forearms supported on the table. Keeping both arms on the table, move lower body back rounding spine, stop, then move body forward straightening spine.

	Anterior Weight Shift Lower Trunk Moves Forward	Posterior Weight Shift Lower Trunk Moves Back
Spine	Extends	Flexes
Scapula	Adducts and depresses	Abducts and elevates
Glenohumeral joint	Less flexion	More flexion
Elbow	Flexes	Extends

control of the lower body/leg in standing is a stable, aligned upper body. The use of forearm or extended-arm weight bearing in standing may provide external stability to the upper body while allowing the therapist to reeducate control lower extremity movements and provide environmental support when practicing at home (Fig. 24.13).

Supine Rolling

Basic trunk movement patterns for rolling include (1) upper-trunk flexion and rotation initiation, (2) lower-trunk extension and rotation initiation, and (3) symmetrical (log-rolling) lateral flexion

Clinical observations. Weakness in the extremities is a significant factor during rolling because the arm and the leg assist the trunk initiation patterns. Rotational patterns are difficult in the acute stage because they require an integration and sequencing of flexor and extensor muscle patterns. Symmetrical rolling may be the easiest independent pattern to train. Therapists should incorporate active assistive strategies and extremity strengthening in the early recovery period. Patients have an easier time rolling to the affected side because they use the strength of the unaffected side to initiate the roll. But they may not want to stay on that side because of shoulder pain, instability of the hip, or decreased sensation and the accompanying fear. The patient may prefer rolling to the unaffected side because it is easier to rest on, but initiating the movement is difficult because of loss of control on the affected, leading side.

The family is educated to understand the nature of the loss of movement and sensation and the effects of these losses on body awareness and early bed mobility. Family members are encouraged to sit with, visit, talk to, feed, and touch the person from the patient's affected side. They are instructed in simple movements such as rolling to promote symmetry, midline control, and activation of trunk and extremity muscles.

Feeding and Swallowing

Although detailed facilitation and inhibition of oral and neck muscle movement for feeding and articulated language are a specialty of speech pathologists, the movement therapist activates upper-body control to prepare for more automatic chew and swallow.

Basic trunk patterns to be reeducated include (1) lower-body anterior and posterior movement control to move toward a table and back into a chair and (2) upper-body anterior and posterior and lateral movement control to provide control for head and arm movements.

Impairments That Interfere

Oral problems include the following:

- Forward head, poor lip closure, loss of saliva and food
- Facial asymmetry during function greater than at rest
- Inability to swallow
- Inability to chew
- Inability to lateralize foods
- Inability to take liquids from cup or spoon
- Muscle weakness

Central problems are as follows:

- Poor postural control
- Inability to feed self

Compensations include the following:

- Use of gravity—head and neck extension
- Chewing on one side only
- Using the hand to place food in the mouth
- Using the hand to pull food from the cheek
- Using thicker food than liquids

Clinical Observations

Excessive drooling occurs with loss of head control and a decreased ability to automatically close the mouth and swallow if excessive extension is present. If the patient tries to extend the head from a flexed cervical spine position, the head may jut forward into a position of axial extension. As a result of the biomechanics of the forward head position, the jaw opens, automatic swallowing becomes difficult, and saliva runs out of the open mouth.

Drooling from one side of the mouth is annoying and embarrassing. The patient may not be able to maintain lip closure and, in addition, may not feel the saliva running out or may not identify a need to swallow.

In the majority of cases, swallowing problems are transient in persons with hemiplegia. After the initial insult, many patients exhibit a decreased gag reflex. In acute care settings, where liquid diets are often routinely given to persons with hemiplegia, education of hospital staff regarding the merits of using thicker foods should be considered. Thicker, chopped food is easier to swallow than soft food. Soft food is easier to swallow than liquids. Liquids with distinct taste or texture are easier to swallow than water.

Sitting

Function in sitting is based on the ability to maintain the trunk in an upright position, to automatically adjust the trunk when the arms or one leg moves around midline, and to follow movements of the arm and leg as they extend their reach. Control in sitting is also used to help change position, such as moving from sitting to standing, or lying down. The reestablishment of control in sitting for function is an important early goal in rehabilitation care.

Basic trunk movement patterns include the following:

1. Anterior, posterior, and lateral upper-trunk initiated movements. Upper-trunk movements are easier to retrain than lower-trunk movements because during upper-trunk movements the base of support (the lower trunk and thighs) remains on the surface.
2. Anterior and posterior lower-trunk initiated movements. With lower-trunk initiated movement, the upper trunk needs to be controlled and stable, yet adjust to and follow the movement of the lower trunk.
3. Lateral lower-trunk initiated movements. These movements are more difficult to reeducate than upper-trunk movements because as the movement begins, the base of support narrows.
4. Rotational movements. In sitting, upper-body rotational movements are easier to perform than lower-body rotational patterns for the reason noted previously.

Trunk and Arm Linked Patterns (Representative Examples)

Postural adjustments to arm movements around midline require the trunk to be upright, to be active, and to perform small adjustments. When the hand functions in front of the body, the trunk adjusts with small posterior weight shifts, whereas as the hand(s) move to function behind the body, the trunk adjusts with a small anterior weight shift.

The trunk moves with an arm to extend reach. If the reach is forward and down to the floor, as if to reach a shoe, the upper body initiates an anterior weight shift and the spine moves into flexion with control from eccentric contraction of the spinal extensors. If the reach is forward as if to grab an object on the front side of a table, the lower body initiates an anterior weight shift as the upper body remains stable and adjusts to the demands of the arm movement.

Trunk and Leg Linked Patterns (Representative Examples)

Small trunk adjustments occur with leg movements around midline. If the feet move back under the hips, the trunk adjusts with a small amount of anterior weight shift. When one foot is lifted up to slide into a slipper, the lower body adjusts with a small lateral weight shift. Upper-trunk stability allows lower-trunk initiated patterns when rising to stand. As the legs extend and the buttocks lift off the chair, trunk adjustments accompany the changing leg pattern to control trunk position over the legs.

Impairments That Interfere

Changes in alignment of the arm resulting from weakness and muscle shortening affect the position of the thoracic spine and rib cage. The weight of an extremely weak arm pulls the upper trunk into forward flexion.

Shoulder subluxation results in muscle shortening (biceps, pectorals, latissimus, subscapularis), alters the line of muscle pull, and interferes with scapulohumeral rhythm. Muscle shortening contributes to loss of upper-body alignment and interferes with reestablishing arm and trunk control.

Loss of trunk alignment as a result of extremity weakness and loss of trunk control creates an atypical starting position for movement and can become an undesirable compensation.

Clinical Observations

Alignment changes in the arm influence strength and control of the upper body. Therefore intervention techniques to restore alignment and control of the arm in relation to the upper trunk must be included in the list of short-term goals to achieve the functional goal of safe, independent task performance in sitting.

Active control of the pelvis in a neutral position is necessary for the reeducation of lower-body lateral and rotational weight shifts. Pelvic position influences leg position. If the pelvis is held in a posterior tilt, the leg initially tends to abduct; and if it is held in an anterior tilt, the leg initially adducts.

Patients with poor hip control do not regain functional trunk patterns while sitting until they can activate and strengthen hip muscles for stability during weight shifts. Loss of control in the hip results in a need to shift weight to the stronger side, thus creating pelvic and/or spinal asymmetry.

Lower-body-initiated lateral weight shift patterns are difficult to train because they require a narrowing of the base of support. Forearm weight-bearing movement patterns are used to increase the base of support to allow practice of these patterns that are needed for functional activities such as scooting, toileting, and lifting one leg off the surface.

Transfers

Transfers in the half-stand, pivot pattern require upper-body control over the lower body and combined trunk and leg control patterns. The squat, pivot position is trained when leg strength and control are weak and the goal is to train the patient to use the affected leg. Transfers are interim patterns that are trained before safe standing and stepping is possible.

The patient practices transfers to different objects (chair, bed, toilet) to either side. This promotes symmetry, encourages the use of the affected leg, and allows practice with varying environmental constraints. Transfers to the unaffected side have the advantage of being familiar to hospital staff because they are the “traditional” textbook way of transferring the person with hemiplegia. Nevertheless, transfers to the affected side need to be trained by therapists to allow function in either direction.

Sitting to Standing

Moving from sitting to standing is an important skill to retrain early after a stroke because it is used many times a day during functional activities. In a study investigating the relationship between sitting to standing and walking, Chou and colleagues¹⁴⁹ found that a critical component of sitting to standing was between leg vertical force displacement, the amount of weight transferred down into the floor. Those who had a maximal between-leg vertical force difference of less than 30% body weight between both legs displayed faster walking speeds and more typical gait parameters.

Two initiation patterns are commonly used, with or without the use of momentum, to train sitting-to-standing. A *lower-body initiated* anterior weight transfer occurs with a neutral spine as the shoulders move forward. Therapists should emphasize the forward weight shift

component of this pattern and hip flexion; the requirement of sitting to standing is a forward shift of the upper body and shoulders. Although individuals with a tendency for lumbar extension may have an anterior pelvic tilt as they shift forward, the anterior pelvic tilt is not as important a component as is a forward weight shift.

An *upper-body initiated* anterior weight transfer during sitting to standing requires control in spinal flexion. This pattern keeps body weight over the feet, the new base of support, but does not link the extension of the legs with the lower trunk. The demand on the trunk from liftoff to standing is greater than in the previous pattern because of the need to move the spine from flexion to upright neutral. In the previous pattern, the spine starts and remains in a neutral position through to standing. The upper-body initiated pattern is used in rehabilitation and extended care centers because it allows caregivers to keep weight firmly over the feet, thus allowing a safe, maximal-assistance transfer.

During transfer and sitting-to-standing training, techniques of directing manual pressure from the top of the knee through the tibia into the foot help the patient remember to keep weight on both feet and increase the dorsiflexion movement at the ankle. Full standing should not be attempted if loss of control in the leg results in nonuse. If the patient cannot activate leg muscles in a weight-bearing position in attempts to stand, the standing position will be precarious with undesirable trunk compensatory patterns.

Standing

Standing Control

Control in standing is a difficult early goal to achieve because not only is there a need for trunk and leg coordinated movements, but there is also a prerequisite need for upper-body (trunk and arm) control over the lower body. Control of basic movement patterns in standing is divided into upper-body-initiated control patterns and lower-extremity-initiated control patterns.¹⁵⁰

Upper-body control in standing includes the ability to move the trunk and arm in all planes with appropriate lower-extremity responses, the ability to respond and adjust to weight transfer to each leg, and to provide postural stability for movements of each leg in space. As a prerequisite for reeducation of these movements, the upper body must have enough strength and control to provide stability and postural adjustments for movements of the lower extremity.

Basic trunk movements to be reeducated include the following:

1. Upper-body initiated anterior, posterior, lateral, and rotational patterns with critical corresponding adjustments in the leg (either hip, knee, or ankle strategies).
2. Control of the upper body over the lower trunk during lower-extremity-initiated weight-bearing movements.
3. Linked trunk and leg patterns during movements of the leg in space. These are easiest when the leg moves around midline and increase in difficulty as the leg moves within and beyond limb length and when movement in space increases in amplitude or speed.
4. Increased upper-body control to support power production for pushing, pulling, or lifting objects and increased upper- and lower-body control to support power production of the legs for activities such as stair climbing, hopping, jumping, and running.

Trunk and Arm Linked Patterns

Trunk and arm linked patterns include the following:

1. Upper-body initiated flexion movements that occur with forward and downward arm reach patterns
2. Upper-body initiated extension that occurs when the arm reaches up or up and back

3. Upper-body initiated lateral flexion when the arm reaches down and to one side
4. Upper-body flexion and rotation when the arm reaches down and to one side.
5. Upper-body extension and rotation when the arm reaches up and back to one side

Trunk and Leg Linked Patterns in Weight Bearing

Control of the upper and lower trunk during unilateral stance on either leg is one of the most difficult patterns to retrain. Control of the trunk in unilateral stance is linked with the need for abduction control on the stance leg. In patients with hemiplegia, the complicated control demands for leg and trunk control in standing combined with the presence of weakness and control problems result in loss of alignment in multiple joints and undesirable compensatory patterns.

Trunk and Leg Linked Patterns as the Leg Moves in Space

When the leg moves in space in small ranges, the adjusting movements of the upper body are small and occur as postural adjustments. The movement pattern of the femur and pelvis has a linked rhythm similar to that of scapulohumeral rhythm: the first 30 to 45 degrees of hip flexion occurs with no pelvic movements; from 45 to 90 degrees the pelvis flexes (posteriorly tilts) with the flexing hip; with continued hip flexion the upper trunk flexes. This pelvic-hip relationship occurs in the other planes of movement as well and is seen during the following functional movements:

1. Pelvic and lower trunk flexion occurs when the leg reaches forward and up; stepping up.
2. Pelvic and trunk extension occurs when the leg reaches back.
3. Pelvic elevation or depression with trunk lateral flexion occurs when the leg moves laterally.

Impairments That Interfere

In standing, loss of alignment in the upper body on the hemiplegic side may result in undesirable compensatory patterns that interfere with functional standing movements and balance. These patterns include (1) forward flexion of the upper trunk, (2) upper-body rotation toward the affected side, and (3) upper-body rotation away from the affected side.

Ankle range may decrease within a few days after stroke and needs to be minimized to allow early standing functions. Loss of ankle joint dorsiflexion range interferes with the ability of the body to recruit ankle strategies, and limited ankle joint dorsiflexion range often accompanies knee hyperextension in standing.

Loss of knee control during standing may result from loss of sufficient lower-extremity force production or low-level limb sequencing. Loss of knee control is also influenced by the position and movement control of the hip and ankle joints. Initially the knee flexes as more weight is shifted to the unaffected side, and the pelvis lists downward. If the pelvic position is not corrected (leveled) and the patient actively straightens the knee, a compensatory pelvic rotation (toward the affected side) may occur. Because of the instability of a weak, flexing leg, the patient may learn to “lock” the knee in hyperextension as a means of gaining stability (Fig. 24.14).

Clinical Observations

In the acute phase, therapists can help the patient practice standing with the hips and shoulders back against a wall to provide support for the trunk and pelvis while creating a safe situation for practicing active self-initiated leg weight-bearing movements. The patient can slide down the wall, activating eccentric control in the legs, and then slide back up, activating concentric control. By using the wall to assist the

Fig. 24.14 (A) Patient with left hemiplegia with knee hyperextension wearing a lightweight prefabricated posterior leaf-spring brace that does not control his knee hyperextension. (B) A solid ankle brace with foot control that decreases knee hyperextension by providing distal stability.

stand, the therapist frees his or her hands to help correct leg alignment problems and lets the patient practice the initiation of movement early, independently, and safely.

The patient can practice controlled lateral weight transfer with appropriate trunk activity in this position. Whereas one study concluded that there is no relationship between lateral weight shift and walking, therapists should not conclude that unilateral weight acceptance is inappropriate functional training.¹⁵¹ What may be more relevant than lateral weight transfer over the leg is learning to depress the foot into the floor, the vertical force, as it equalizes weight between the two legs.¹⁵²

Upper-extremity forearm or extended-arm weight bearing provides upper-trunk stability for lower-extremity initiated practice. This practice pattern also allows a means of self-ranging for the ankle, knee, hip, and pelvis. This position is used not to inhibit tone in the extremities but to activate and strengthen the trunk and legs in linked patterns.

Walking

Independent, functional, and safe walking is difficult to retrain in the early phases of intervention because it requires control of the second level of the trunk: a stable yet adaptable trunk during extremity movement beyond limb length. Sufficient force production and appropriate timing in the leg is also needed to support body weight, to sequence complex patterns, and to control momentum and balance. Walking patterns in individuals who have experienced stroke are characterized by slow speed, uneven step and stride lengths, impaired balance with aberrant movement patterns in the arm and leg, and reliance on adaptive equipment.

In the current healthcare environment with the emphasis on limited therapy visits, therapists are confronted with major intervention dilemmas: Should they encourage the individual to walk without minimal prerequisites? Should they allow undesirable compensations although they predict future secondary problems? Should they use the benefits of the large health care systems to divide responsibility for continued gait training among therapy divisions (inpatient, rehabilitation, home care, outpatient)?

Prerequisites for functional, safe walking include the following:

- Upper-body control to support leg movements in unilateral stance and during swing
- Lower-trunk control to prevent atypical pelvic patterns
- Strength and control of the leg to initiate weight shifts
- Strength and control of the leg to move in space

Because gait is the most extensively studied, analyzed, and discussed in terms of intervention, this section describes the prerequisites for walking training and common impairments that interfere with walking.^{153–155} Common impairments that interfere with walking are separated into three divisions of the walking cycle: (1) forward progression, (2) single- and double-limb support, and (3) swing.^{156,157}

Impairments that interfere with functional walking are summarized in **Box 24.8**.

Research on and equipment for partial-body-weight supported treadmill walking training with or without robotic assistance have been ongoing.^{158–162} In a 2004 review of randomized controlled studies, there was strong evidence for post-stroke treadmill training with or without body-weight support (**Fig. 24.15**).¹⁶³ Task specificity, speed, intensity, and symmetry of practice in this type of equipment were thought to contribute to improved overground walking performance.¹⁵⁸ However, a Cochrane review reported no statistically significant effect of treadmill training with or without body-weight support.¹⁶⁴ A 2011 randomized

Fig. 24.15 (A and B) Patient with right hemiplegia walking on a treadmill with partial body-weight support.

BOX 24.8 Summary of Significant Functional Impairments

Forward Progression—Heel Strike to Midstance

Impaired trunk control

- Altered alignment and control upper trunk over lower trunk
- Insufficient upper trunk control as leg initiates forward weight shift

Lack of proper initiation pattern

- Excessive forward trunk flexion
- Excessive lateral weight shift

Insufficient ankle joint dorsiflexion

- Muscle tightness
- Impaired muscle activation
- Edema

Inappropriate foot contact

- Weakness and altered muscle activation in foot and ankle muscles
- Muscle tightness

Single and Double Limb Support

Insufficient trunk control to maintain alignment over one leg

- Asymmetries during unilateral stance
- Loss of control of upper trunk over lower trunk

Altered lower-extremity control

- Hip instability
- Loss of knee control in unilateral stance
- Altered sequencing and timing of lower leg musculature

Loss of ability to transfer weight through foot

- Inability to maintain leg on floor behind body
- Loss of muscle length
- Weakness and inappropriate activation of leg muscles

Swing—Early and Late

Atypical leg muscle firing patterns

- Lack of distal initiation
- Inability to control trunk and lower-extremity sequencing patterns

Inability of the body to continue to move forward as leg swings

Aberrant foot movement

controlled trial comparing body-weight-supported locomotor training with a therapist-supervised home progressive exercise and balance program reports improvements with both training methods.¹⁶⁵ Hershberg has extended that trial by developing an algorithm for clinical decision making in progressing either protocol based on patient presentation.¹⁶⁶ In the 2016 Clinical Practice Guideline, the authors point toward the potential impact body-weight support and robotic technologies may have; however, they state further clinical trials are needed to establish recommendations and protocols.⁸⁰

Clinical Observations

If impaired sequencing in the lower extremity results in difficulty clearing the foot during stepping, compensatory strategies of hip hiking, circumduction, or posterior pelvic tilting arise. If allowed to persist, these atypical initiation strategies become difficult to retrain. Consider the post-stroke modular framework from Clark's study: intervention strategies should aim to improve muscle sequencing and timing to improve normal hip, knee, and ankle movements during swing phase.⁸⁸ Ferrante and Routson were able to demonstrate improved modular complexity and/or timing with the use of functional electrical stimulation and body-weight support treadmill training respectively.^{167,168}

Additionally, consider minimal ankle and foot support during early walking as a means of preventing distal compensatory strategies and promoting distal initiation (**Fig. 24.16**). (See Chapter 32 for additional suggestions.)

Cardiovascular Health

A comprehensive physical therapy plan of care should include reducing the risk of recurrent stroke by addressing a patient's cardiovascular health through the prescription of physical activity and exercise. Physical activity and exercises have been shown to improve multiple aspects of stroke recovery including physical and psychosocial components; however, current research demonstrates underutilization and underprescription of cardiovascular rehabilitation programs.¹⁶⁹

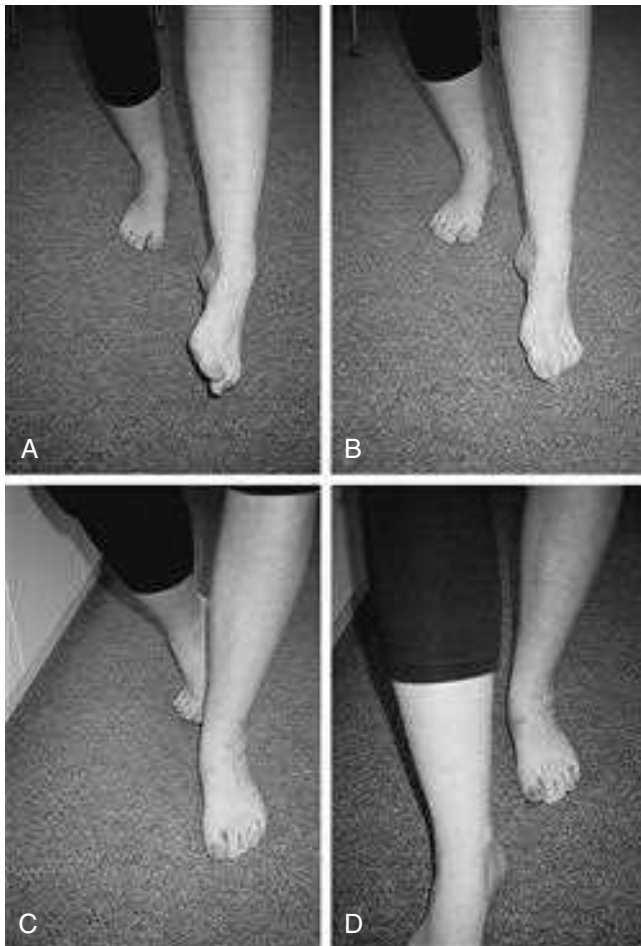

Fig. 24.16 (A and B) Patient with left hemiplegia. Supination of the foot during swing and during foot contact with ankle joint plantarflexion and calcaneal varus. (C and D) Compensatory pronation of the midfoot to allow the foot to contact the ground during stance.

Exercise counseling should aim to overcome identified barriers to participation in physical activity, including understanding of the benefits and feasibility of participation, access to resources, and limited knowledge on appropriate activities and intensity of activity.

Clinical Considerations

In the acute phase, early mobilization is recommended to abate orthostatic intolerance, limit edema, maintain joint mobility, and prevent deep vein thrombosis. Prior to initiating an exercise regimen in the outpatient setting, patients should undergo graded exercise testing. It is highly recommended initial graded testing be performed with ECG monitoring; however, if this is not feasible, an individualized training program should still be initiated. The current available data indicate a low risk of severe cardiovascular complications during submaximal graded exercise testing in stroke survivors when performed under appropriate guidelines including monitoring of heart rate, blood pressure response, O₂ saturation, subjective reporting of cardiac symptoms, and ratings of perceived exertion. The Bruce protocol and the modified Bruce protocol are appropriate graded tests for patients who are able to perform an ambulatory treadmill test. Other protocols are available for upright and recumbent cycle ergometers and upper extremity ergometers. It is recommended to discontinue a graded test when the patient has reached 70% age-predicted maximum heart rate

or greater than 250 mm Hg systolic or 115 mm Hg diastolic blood pressure to reduce the risk of adverse events.

Prescription of physical activity should be individualized to the patient based on their tolerance to activity, stage of stroke recovery, available social and environmental resources, activity preferences, and their unique impairments and limitations. Billinger and colleagues recommend exercise frequency to be three or more days per week for 20 to 60 minutes. They also support an interval training model including multiple sets of exercises (3 to 4× per day) for 10 to 15 minutes depending on the patient's capacity and exercise tolerance. Strength training is also recommended with higher repetitions (10 to 15 repetitions) and reduced loads performed 2 to 3 days per week. Exercises should focus on the torso and the major muscle groups of the upper and lower extremities.¹⁷⁰

EQUIPMENT

Equipment for persons with CNS dysfunction can be thought of as supports or extra assists to allow better alignment, stabilization, or balance so that the patient can move and function more independently. Too much support or equipment may hinder the development of new movement control. Equipment should never be a substitute for treatment and should not be given without practice during treatment. One-handed equipment that is used as a compensation for trunk control is less successful than equipment that is used to compensate for loss of extremity function. Therapists should perform continuing assessments of the appropriateness of the equipment in relation to gains made in therapy.

Example

A “reacher” compensates for loss of trunk and limb linked control (reach beyond arm's length), but use of a reacher may prevent the development of this control, whereas an electric can opener designed for one-handed use substitutes for the ability to use the affected hand (when recovery is not possible).

Bedside Equipment

In acute and rehabilitation settings, pillows, blankets, or towels are used to position the patient in bed. With the patient in the supine position, the head pillow can be angled so that it slips under the shoulder and scapula to prevent loss of alignment: to prevent humeral hyperextension and internal rotation. A soft towel roll or pillow under the leg—greater trochanter or knee—maintains alignment of the leg in the first few days after a stroke. Once the patient begins to move to both sides in bed, the use of pillows for support is not necessary.

Wheelchairs

Wheelchairs must have a solid surface and, when possible, a supportive backrest. The soft leather seats and backs of transport chairs act as slings and allow the pelvis to posteriorly tilt and the spine to flex. Solid seats and backs allow the pelvis, trunk, and extremities to be more normally aligned. Wheelchairs specifically for patients with hemiplegia who are not expected to become household ambulators have lower seat heights and one-armed drive (two hand rims on one wheel). These adaptations make it easier for patients to propel the chair with the unaffected hand and foot.

Support for the hemiplegic arm when the patient is sitting in a wheelchair reduces the effect of the downward pull of gravity on the weak or paralyzed arm. Lapboards support both arms and provide symmetry for the upper body. However, in some health care settings, they are considered a form of restraint and cannot be used. The use of a pillow in the lap is another option for bilateral support of the arms.

Half-lapboards or arm troughs are used to support the arm. If an arm support is used, the patient should be taught how to protect the arm and hand while on the support.

Slings

Slings are used to support the glenohumeral joint to prevent capsular stretch, to temporarily maintain alignment that is gained in treatment, and to take some of the weight of the paralyzed arm off the upper trunk as the patient begins to learn to stand and walk. Capsular stretch accompanies shoulder subluxation, and it is difficult to reverse an existing subluxation once the capsule is stretched. Because subluxation is not inherently painful, a sling is not used to prevent pain. However, use of a sling can take the heavy weight of a weak arm off the trunk and may help break the cycle of shoulder pain.

Various reviews and comparisons of slings are available.^{171–173} Shoulder subluxation is the result of loss of strength and control in the shoulder girdle and trunk, especially scapular upward rotation. There is no sling available that corrects a subluxation because no existing sling provides scapular upward rotation control. Slings act as an assist to “hold” a scapulohumeral position that has been restored in treatment.

The ideal shoulder sling helps maintain the normal angular alignment of the glenoid fossa, decreases the tendency of the humerus to internally rotate, takes some of the weight of the arm off the upper trunk, and allows the upper extremity freedom of movement. Therapists should not prescribe slings that cradle the arm in front of the body, prevent any movement, and in effect teach learned nonuse. The orthopedic-type *envelope arm sling* was used in the 1950s and 1960s is of this type. In the 1970s, influenced by Bobath,¹⁰¹ sling use was thought to be undesirable. As more information about tone and movement became available, new slings were designed to allow the arm to be supported while movement was reeducated. Slings have different suspensions, provide different means of control for the arm, give differing “messages” to the arm and trunk, and have individual uses. Table 24.6, adapted from the work of Levit,¹⁷⁴ lists available slings and their characteristics.

Patients who come into therapy with a sling but who do not require one are weaned from a supportive sling into a less controlling one. Patients state that the *clavicle support* provides support during household tasks that require upper-body flexion, such as bed making or

vacuuming. Patients who complain of “aching” in the arm at the end of the day may relieve this ache by using a support for a few hours around midday.

If the arm dangles or bangs against the body during active periods, the *shoulder saddle sling* can be adjusted to protect the arm from bruising. This sling is also helpful to patients with severe shoulder-hand pain because it allows full support of the arm and can be adjusted by the patient to allow the elbow to extend as the pain subsides. The *GivMohr sling* combines a humeral cuff with a hand support. *Humeral cuff slings* are the most practical from a functional standpoint because they do not restrict scapula, arm, or trunk position.

Canes

Canes are given to patients with hemiplegia to provide extra balance, not as a means to support body weight. Canes should be used after upper-body and lower-extremity initiated movements have been practiced.

If quad canes or hemiwalkers are used before trunk and leg activity is minimally established, they encourage lateral translation of the spine or counter rotation of the upper spine and pelvis. When patients shift off the weak leg onto the stable cane, the cane acts functionally as a third leg. This one-sided compensation encourages learned nonuse of the affected leg.

Single canes provide a balance assist. Often patients use the cane while walking outdoors or in crowded situations but not inside their homes. Reliance on a cane for walking eliminates the possibility of carrying objects and makes it difficult to perform one-handed tasks such as opening a door. Wrist loops allow the patient to use the unaffected hand without having to put the cane aside. Weighted cane tips, such as the AbleTripod¹⁷⁵ rubber cane tip, or the HurryCane¹⁷⁶ provide a bridge between quad canes and straight canes and allow a standard cane to remain upright.

Orthotics

Ankle-foot orthoses (AFOs) are used to allow foot clearance during walking, to ensure heel strike, to provide distal stability for early standing and walking in patients with severe weakness, to provide lateral lower-leg stability in patients who need an assist because of lateral hip weakness, and to control knee hyperextension caused by loss of ankle dorsiflexion control. Different design types provide different functions. Solid ankle bracing with plastic beyond the malleoli limits distal

TABLE 24.6 Examples of Slings and Their Characteristics

Basic Type	Supplier	Suspension	Message	Common Use
Clavicle support	DePuy (clavicle fracture sling with 1-inch soft foam axilla pad)	Figure-of-8 between scapulae Support under axilla	“Spine extend, scapula adduct”	Acute care Minimal support To wean out of other supports
Humeral cuff	Rolyan Hemi Arm Sling	Figure-of-8 between scapulae Velcro cuff support to humeral shaft	“Arm up”	Rehabilitative care
Unilateral shoulder orthosis	Bauerfeind Rolyan	Across body Elastic or spandex cuff support to humeral shaft	“Lift humerus up”	Rehabilitative care
Shoulder-saddle sling	Sammons	Saddle sits on top of shoulder Strap across body Forearm cuff—adjustable straps allow changes in elbow position	Maximal support of arm	To prevent “banging” of flaccid arm in active patients or during sports activities To provide support for painful arm
GivMohr sling	GivMohr	Figure-of-8 between scapulae Plastic cone in palm of hand	“Arm up”	To relieve weight of “heavy” flaccid arm

freedom but allows patients with severe weakness to practice gaining control of trunk and hip movements.

Polypropylene Orthotics

The use of polypropylene bracing to control foot posturing in adults began in the 1970s with information from pediatrics and podiatry. Foot control in a brace stops supination of the foot in swing and compensatory pronation of the foot in stance. This control is achieved through neutral rear foot positioning and long medial and lateral foot counters. Custom-made AFOs provide the best fit and control, but excellent prefabricated polypropylene braces are available through companies such as Orthomerica, or Wheaton Brace. These orthoses have long medial and lateral foot edges for control of foot posturing, come in multiple models and sizes, and can be ordered with regular or long foot plates or as blanks that can be self-trimmed (see Chapter 32).

Carbon Fiber Orthoses

Newer, lighter braces constructed from carbon fiber allow greater propulsive forces during late stance. The Phat brace, a custom fabricated energy-storing carbon fiber brace, allows exacting control of foot supination and pronation and with varying resistance strengths to replicate

the forces needed during walking (www.phatbraces.com). Techniques of Aquaplast fabrication have also created new possibilities for inexpensive, immediate, remoldable bracing for the foot and ankle.^{177,178}

Wireless FES systems

Wireless Functional Electrical Stimulation (FES) foot-drop systems, the Bioness L300 and the WalkAide, are available for clinical use. These systems use low-level electrical activity to stimulate the nerves that lift the foot and are timed with walking stance and swing patterns.

Patients should be encouraged to spend time standing or walking short distances without the brace so that dependence is not established. Patients like to be able to walk to the bathroom at night without a brace. Orthopedic ankle and foot supports provide alternatives to plastic bracing. The MalleoLoc ankle support controls rear foot equinus and varus while allowing ankle and forefoot movement (Bauerfeind USA/Alimed). Patients with moderate supination posturing report a reassuring feeling of security with this support while walking short distances and during sports participation. This support, a substitute for the Aircast and Ace support, is a good choice for sports activities such as golfing, bicycling, jumping, and running.

Functions and limitations of commonly used braces are found in Table 24.7 and orthotic manufacturers in Appendix 24.A.

TABLE 24.7 Ankle-Foot Orthoses Used in Patients With Hemiplegia From Stroke

Orthotic Design	Function	Limitations	Patient Types (Categories)
Solid ankle with foot control	Heel strike Distal stability Lateral hip stability Assists forward progression Assists knee control Stops foot posturing	No ankle mobility No toe break	Severe weakness in trunk and leg Need for distal stability
Modified solid ankle with foot control	Heel strike More distal mobility, less ankle control Stops foot posturing	Less knee control Reduced message of forward progression No control of knee	Increasing leg strength Increasing trunk and leg control
Posterior leaf spring	Toe clearance	No control of foot posturing	Good return of control in trunk and leg Need for minimal dorsiflexion assistance
Articulated ankle	Free dorsiflexion Heel strike if plantar stop used	Limited control of foot posturing Bulky at ankle	Normal ankle range—if range is limited, the movement of brace is translated into foot Functional needs; climb hills, stairs, move to and from ground
Supramalleolar foot orthoses in Aquaplast	Foot control Assist heel strike Used for weaning from AFOs Sports	No knee control Short shelf life of material	Increasing leg control Desire to begin increasing activity level
Foot orthoses	Balance small asymmetries of foot	No control of foot posturing No ankle or knee control	Persistent but minimal rear foot–forefoot asymmetries
Klenzak metal, double upright	Toe clearance Reminder of forward progression	No foot control Control of ankle and foot through shoe	Used before creation of polypropylene to provide heel strike and stop foot supination
Alternative Functional Electrical Stimulation Foot Drop Devices			
Bioness L300	Foot control Knee control assist Operates via heel pressure switch	Expensive Requires cognitive ability to don and adjust settings	
WalkAide	Foot control Operates via tibial tilt	Requires cognitive ability to don and adjust settings	

See Chapter 34 for additional suggestions.
AFOs, Ankle-foot orthoses.

Toe Curling/Clawing Aids

There are two patterns of toe posturing: toe clawing and toe curling. Toe clawing, metatarsal hyperextension with phalangeal flexion, is a result of altered alignment of the metatarsals and tarsals; and toe curling, metatarsal and phalangeal flexion, is a response to insufficient postural stability for the task: standing or walking.⁶³

Toe curling and toe clawing interfere with comfort and may become painful. Problems of blistering on pads of the toes and on the top of the proximal interphalangeal joint are common in the later stages of recovery. Relief from pressure and pain on the toe pads (tips) comes with use of commercially available “hammertoe crest pads” or a “toe crutch” available from distributors¹⁷⁹ or from medical pharmacies.

Movable Surfaces

Movable surfaces such as gymnastic balls of varying sizes, large rolls, and adjustable stools with casters are used as environmental support for the trunk or extremities. Gymnastic balls provide symmetrical support to the rib cage when used in the hands-and-knees position and may be used to maintain spinal alignment or girdle muscle length. When spasticity was considered the major impairment in hemiplegia, therapists often placed patients prone over balls to “inhibit” tone. This is an inappropriate technique, considering advances in understanding of movement control and recovery.

Hand Splints

The practice of splinting the hemiplegic hand is controversial. Historically, the hand in patients with hemiplegia was splinted in a “resting” position of 15 degrees wrist flexion and a finger extension platform. After the introduction of neurophysiological approaches, splinting became “inhibitory” in design.^{180–182} Now, with the understanding that spasticity is not the major problem, splinting the wrist and hand has undergone another change. A splint designed by Levit¹⁸³ as a neutral functional splint promotes functional retraining and hand use while minimizing secondary impairments. This splint, designed to hold the wrist and hand in a position of orthopedic neutral, helps maintain muscle length across the wrist and decreases aberrant movement that occurs with poor alignment or unbalanced muscle return. The splint promotes support of the wrist and hand to avoid the secondary impairments of muscle tightness, muscle shifting, and overstretching of weak wrist and finger muscles. This type of splinting has been reported to decrease hand edema and pain.¹⁸⁴

Therapists custom-make the splints with the goals of supporting the wrist in neutral, preventing radial or ulnar deviation with long, high sides, and maintaining the palmar arches. The fingers are not incorporated into the splint but are left free to allow movement reeducation and practice. This functional splint is worn mainly during the day when aberrant arm movement may be greater and when support of critical joints decreases the degrees of freedom, thus allowing the emergence of active functional hand use.

Design Considerations

If joint range is limited, the therapist makes the splint to support available range. The splint can be revised as range increases. Alignment is corrected in three steps: (1) keeping the wrist in flexion, the lateral deviation is corrected by aligning the third metacarpal with the middle of the radius; (2) the carpal position is corrected (usually by gently lifting up from a low position under the radius); and (3) the hand is moved to wrist neutral (see *Functional Movement Reeducation*⁶³ for a step-by-step analysis). The warmed, soft splinting plastic captures this corrected position as it cools. The length of palmar support is decided by the therapist after assessment of degree and distribution of muscle return and muscle tightness patterns. The thumb is supported at its base in a neutral position, not one of abduction. As beginning grip returns, the thumb hole is widened to allow function.

A variety of neutral functional splints have been designed. The neutral wrist and thumb hole splinting design makes the splint hard to keep on the hand of patients with severe weakness. They sometimes find ulnar or radial trough splints or wide opponens splints easier to keep on.

As wrist extension control against gravity emerges, the therapist can fabricate a wide opponens splint to maintain the palmar arches as the patient begins practicing finger movements. The wide opponens splint supports the base of the hand and assists in maintaining carpal alignment. Patients can switch between the two splints as needed.

Patients with severe hand pain prefer a neutral wrist splint with a resting area for the thumb. This splint is fabricated with little or no correction initially but with gentle support for the wrist and palmar arches. As the pain decreases, this splint is modified to become the original neutral functional splint.

Although the move away from “inhibitory” splints and from night splinting to daytime functional splinting breaks many of the “rules” from the past, it is more compatible with concepts from research and clinical experts.

Recommended resources for practical solutions to one-handed functioning and devices that assist in independence are listed in [Appendix 24.B](#) at the end of this chapter.

PSYCHOSOCIAL ASPECTS AND ADJUSTMENTS

The suddenness of a stroke and the dramatic change in motor, sensory, visual, and perceptual performance and feedback may leave the person with hemiplegia confused, disoriented, angry, stressed, frustrated, and fearful.

Psychosocial issues may be more detrimental than any functional disability to long-term stroke survivors.¹⁸⁵ Decreased interest in social activity inside and outside the home and decreased interest in hobbies as a result of psychosocial disability hamper the hemiplegic individual’s return to a normal social life.¹⁸⁶ Feelings of rejection and embarrassment may interfere with the hemiplegic person’s interaction with people outside the home environment. Individuals with long-standing hemiplegia often become clinically depressed, with symptoms of loss of sleep and appetite, self-blame, and a hopeless outlook. The usual psychosocial adjustments to disability are compounded in persons with hemiplegia resulting from stroke by the issues associated with aging.

Family members and spouses may have difficulty assessing the capabilities of the hemiplegic person and may be overprotective. Overprotection among spouses may be a sign of affection and support or a sign of guilt.¹⁸⁷ Long-standing marriages do not tend to dissolve when one member has a stroke. However, previous marriage problems and personality traits may become exaggerated as a result of the presence of increased and changing demands and stresses that occur when the person returns home.

A comparison of occupational status of long-term stroke survivors in the United States and in Sweden reveals that 40% of the Swedes returned to a form of employment (including part-time work) but none of the US group returned to work.¹⁸⁸ The scarcity of part-time work and a shorter treatment period dictated by third-party payers in the United States may account for this discrepancy.

Age is a general predictor for return to employment, and younger people are more attractive to employers. Barriers to return to work for the person with hemiplegia include speech, perceptual, and cognitive deficits along with a need for psychosocial support. Architectural barriers also can create severe problems for hemiplegic patients with regard to both work and recreational activities. Stroke clubs, usually organized through hospitals, the National Stroke Association, or the American Heart Association, provide educational, social, and recreational support for the hemiplegic person and her or his spouse.

The impact of psychosocial disability and the need for its long-term treatment is great. Programs need to be established and continued for years to allow patients and their families to deal with the many problems that result from the stroke. Refer to [Appendix 24.C](#) for resources.

Sexuality

Most persons with hemiplegia experience a decline in sexuality through a decrease in frequency of sexual intercourse without a change in the level of pre-stroke sexual desire.¹⁸⁹ On return home, the person with hemiplegia faces uncertainty about sexual skills and the risk of failure. Sexual dysfunction that results from a stroke depends on the

amount of cerebral damage and includes a decreased ability to achieve erection and ejaculation in men and decreased lubrication in women.^{190,191} The sensory, motor, visual, and emotional disturbances of hemiplegia may cause awkwardness, but these disturbances can be overcome through the education of the spouse in alternate positioning and ways to provide appropriate sensory experiences. The normal factors of aging also interfere with the sexual performance of persons with hemiplegia. A person's pre-stroke sexual activity is a good indicator of post-stroke sexual activity. The closeness between partners achieved through a satisfactory sexual relationship can add to the quality of life after stroke (see Chapter 5).

SUMMARY

This chapter reviews the neuropathology of stroke, the evaluation of impairments that interfere with functional movement patterns, and intervention planning. Both evaluation of outcomes and evaluation of movement components are described. The chapter highlights significant impairments and provides clinical observations on critical areas of intervention. A detailed process of clinical problem solving helps the

therapist organize and prioritize impairments to plan intervention programs that retrain movement components and train desirable compensatory patterns to help the patient gain the highest level of functional performance and independence in daily life. An example of the synthesis of this chapter's concepts and ideas can be found in [Case Study 24.1](#).

CASE STUDY 24.1 History of Present Illness

Patient is a 61-year-old female who presents to outpatient physical therapy with right hemiparesis following hemorrhagic left anterior cerebral artery cerebrovascular accident. She began noticing right leg weakness resulting in a fall. Patient was admitted to inpatient rehab and participated in intensive therapy for 3 weeks. She currently reports difficulty with bed mobility, transfers, and ambulation. She arrives to therapy with a single-point cane and a Giv-Mohr sling provided by her inpatient therapy team.

Past Medical History: Hypertension

Medications: Lisinopril, Acetaminophen

Social History/Prior Level of Function: Patient is a retired FBI agent and now works in the executive offices of a department store. She also owns her own part-time baking business. She is currently not working due to medical status. She normally lives alone; however, she has been living with her brother to have assistance with activities of daily living (ADL) and independent ADLs. Patient's home is a multilevel home with two stairs with no rail to enter and bilateral rails for flight of stairs to second level.

Personal Goals: Patient wants to be more confident in walking, she is fearful of falling. Activities-Specific Balance Confidence Scale: 53%

Review of Systems

Integumentary: 3-mm wound on right lateral malleolus, no obvious signs of infection, normal granulation tissue.

Cardiopulmonary: At rest in supported sitting: blood pressure 140/80; heart rate: 70.

Mental Status/Communication/Preferred Learning Style: No cognitive or speech impairments. Patient demonstrates appropriate insight into deficits.

Objective Findings

Hypotonic Hemiparesis: Right-side affected.

Dominant Extremity: Right

Pain: No complaints of pain at this time.

Posture

Unsupported sitting: asymmetrical weight bearing with reduced weight bearing on right pelvis, mild concavity to right, wearing Givmohr Sling. Right hip externally rotated with knee extended and foot contact to floor at lateral heel. Left lower extremity appropriately aligned for sitting posture with knee flexed approximately 90 degrees with complete foot contact to floor.

Unsupported standing: weight bearing primarily through left lower extremity, mild left hip Trendelenburg.

Tone: Normal tone left hemi-body; Hypotonic right hemi-body

Sensation: Right side; light touch sensation impaired, proprioception severely impaired—tested at ankle and knee

Strength:

Motion	Left	Right
Hip flexion	5/5	3+/5
Knee extension	5/5	3+/5
Knee flexion	5/5	3+/5
Ankle DF	5/5	2+/5
Ankle PF	5/5	2/5

Objective Outcome Measures

Upright Motor Control Test:

Hip Extension: 1
 Knee Extension: 1
 Ankle Extension: 1
 Hip flexion: 3
 Knee Flexion: 3
 Ankle Flexion: 1
 Score: 10/18

Trunk Impairment Scale:

Static: 6/7
 Dynamic: 5/10
 Coordination: 2/6
 Score: 13/23

Balance: not formally tested; however, demonstrates balance impairments related to deficits in:

Sensation/Sensory orientation
 Biomechanical constraints including impaired base of support, neuromuscular weakness
 Impaired trunk control as observed with Trunk Impairment Scale

CASE STUDY 24.1 History of Present Illness—cont'd

Impaired anticipatory postural control related to impaired motor control of trunk and right hemi-body

Functional mobility: Patient is modified independent during sit-to-stand, from supine to and from long sitting requiring increased time to perform; modified independent with sit-to-stand with limited weight bearing on right LE, R knee extended with poor foot contact with ground, left lateral trunk lean and significant use of left UE to assist the stand.

Gait: With rigid Ankle-foot orthose and Givmohr sling: Patient ambulates with single point cane in L upper extremity with good coordination of cane use, step-to with intermittent step-through 3-point gait pattern.

Right Lower Extremity:

Initial Contact: forefoot/foot flat

Loading Response: limited knee flexion, increased ankle plantarflexion

Midstance: knee extension thrust, pelvis rotated right, left pelvis depressed, with insufficient anterior translation of the tibia

Terminal Stance: limited heel off, reduced knee flexion

Pre-Swing: reduced hip and knee flexion

Mid-Swing: mild circumduction with contralateral vaulting

Left Lower Extremity:

Initial contact: heel

Mid stance: vaulting to assist right foot clearance

Stride length: shortened length and duration (response to limited R stance time)

Assessment

Current impairments: Right hemiparesis: upper extremity > lower extremity, impaired trunk stability and motor control and impaired sensation resulting in limited functional strength and mobility. She will benefit from skilled care to improve functional strength and increase safety with transfers and ambulation to achieve modified independence with ADLs and IADLs. Patient's prognosis is limited by impaired sensation and limited activity tolerance. However, patient is relatively young and highly motivated with excellent social and family support. Her movement disorder is classified in the composite movement category with severe movement deficits.

Functional Limitation 1: Patient Is Unable to Perform Morning Self-Care at Bedside or Sitting in Wheelchair in Front of a Sink

Why?

Patient cannot perform anterior and posterior or lateral trunk movements in sitting without loss of balance and falling to left. Patient cannot feel right arm, and it hangs by side.

Evaluation

Primary Impairments

Neurological weakness in right arm and leg

Inability to initiate movements

Loss of postural control

Inability to coordinate trunk–limb movements

Decreased sense of touch in right arm, trunk, and right leg

Secondary Impairments

Loss of trunk alignment in sitting

Right shoulder subluxation

Muscle tightness—pectorals, latissimus, wrist flexors, ankle dorsiflexors

Loss of alignment of lower trunk and pelvis in sitting—spine laterally flexed, convexity on left, left pelvis lists downward

Loss of 10 degrees of right ankle joint dorsiflexion range

Functional Limitation 2: Patient Is Unable to Transfer From Bed to Chair Independently

Why?

Patient cannot control upper body while trying to activate bilateral leg activity when initiating transfers to either side. Right arm hangs by side with an inferior shoulder subluxation. Cannot lift right leg against gravity in sitting. Cannot depress left leg into surface. Tends to use left side exclusively during transfer with loss of balance. Patient uses left arm to support self at edge of bed.

Evaluation

Primary Impairments

Neurological weakness in upper trunk and right leg

Inability to coordinate trunk–leg patterns in weight bearing

Inability to sequence movement patterns in right in weight bearing

Secondary Impairments

Loss of upper-body alignment

Loss of right ankle joint dorsiflexion range

Functional Limitation 3: Patient Is Unable to Stand up From Chair Independently

Why?

Patient is unable to control upper body over lower trunk during lower-body–initiated transfers and sit-to-stand. Patient is unable to use right leg for support and movement during the transition of sit-to-stand. Patient is unable to keep weight (depress leg into floor) on right foot in standing.

Evaluation

Primary Impairments

Inability to control upper body over lower body, resulting in an inability to initiate lower trunk and leg movements

Inability to coordinate trunk–leg patterns in weight bearing

Impaired force production in right leg

Secondary Impairments

Loss of right ankle joint dorsiflexion range

Tightness in right gastrocnemius

Significant Impairments for Functions Evaluated

1. Loss of upper-body control during lower-body initiated movements, especially anterior-posterior plane
2. Shoulder subluxation contributes to loss of upper-body control
3. Loss of muscle activation control and neurological weakness of right arm and leg
4. Loss of ankle joint dorsiflexion range

Treatment Goals

Functional Goals

- A. Perform morning self-care activities in wheelchair in bathroom independently
- B. Transfer from chair to bed and back with contact guarding
- C. Rise to standing with assistance of one person

Long-Term Movement Goals

- A. Sit safely while performing tasks with right arm and leg around midline; that is, perform upper-body– and lower-body–initiated trunk movements in sitting independently
- B. Increase upper-body control to prepare for independent, safe, lower-body–initiated movement patterns (extended-arm reach, sitting to standing, and standing balance)

Continued

CASE STUDY 24.1 History of Present Illness—cont'd

- C. Increase leg strength and establish trunk and leg coordinated patterns in weight bearing (to allow transfers, rising to stand, and standing with minimal assistance to the upper body)
- D. Establish a home or bedside program that the patient can perform independently

Long-Term Functional Goals (in 24 visits)

1. Patient will ambulate at self-selected gait speed >1.0 m/s with assistive device to achieve gait speed required for safe community ambulation
2. Pt will demonstrate improved R Lower Extremity single limb stance time and stability for overall improved efficiency of gait.
3. Pt will report performing light home care activities including light cooking, light cleaning, and laundry with moderate assist to progress toward independent living
4. Pt will score greater than 85% on Activities Based Confidence Scale to demonstrate reduced fall risk and progress toward patient's goal.

Short-Term Movement Goals

- A. Perform basic trunk movement patterns in sitting with contact guarding
- B. Increase muscle activation control in upper body and shoulder girdle to decrease shoulder subluxation

- C. Protect shoulder joint from excessive capsular stretch
- D. Increase sequencing and force production in left arm: be able to lift arm up onto sink with unaffected arm, maintain sitting balance during morning ADL activities
- E. Increase ankle joint dorsiflexion range in standing
- F. Increase sequencing and force production in left leg and during trunk and leg linked patterns during lower-bodyinitiated transfers, during sit-to-stand, and in supported standing to allow lower-extremity assisted practice

Short-Term Functional Goals (in 10 visits)

1. Pt will demonstrate improved R Lower Extremity functional strength with increase in Upright Motor Control Test Score from 10/18 to 14/18 to improve R Lower Extremity stability in gait.
2. Pt will improve trunk impairment scale score from 13/23 to 20/23 to improve gait and functional mobility.
3. Pt will list at least three techniques to care for skin integrity.
4. Pt will perform sit-to-stand with bilateral upper extremity support, appropriate alignment and foot contact of R lower extremity to promote recovery of symmetrical use of lower limbs.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the

reader to a Medline abstract for the article cited. There are 191 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: In this chapter, pathological conditions, body system problems (impairment), activity limitations, and intervention strategies for patients with hemiplegia from stroke are reviewed. Although hemiplegia from neurovascular pathological conditions is the focus of the chapter, therapists can use this information and apply it to adults with hemiplegia caused by other central nervous system (CNS) pathological conditions, such as tumor, trauma, multiple sclerosis, and demyelinating diseases. Movement components and their relationship to functional performance are used as a basis for selection of therapy interventions.

Keywords: aberrant movements, atypical movements, composite impairments, edema, evaluation of movement control, goal setting, hemiplegia, movement deficits, muscle activation deficits, orthoses, postural control, predictors of recovery, primary impairments, secondary impairments, shoulder pain, shoulder subluxation, standardized evaluations of function, trunk and arm linked movements, trunk control, trunk and leg linked movements, undesirable compensations

Brain Tumors*

Corrie J. Stayner, Rachel M. Lopez, and Karla M. Tuzzolino

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the categories of primary brain tumors.
2. Recognize and interpret signs and symptoms of primary brain tumors specific to tumor location.
3. Recognize current diagnostic tests used to detect brain tumors.
4. Identify the types of medical and surgical management for brain tumors and how that management will affect functional movement.
5. Describe the side effects associated with the treatment of brain tumors and recognize their impact on therapeutic intervention.
6. Discuss the multiple considerations necessary to plan and execute an intervention program for the patient with a brain tumor.
7. Recognize the emotional and psychosocial impact of the disease process on the patient, the patient's support system, and the interdisciplinary team.

AN OVERVIEW OF BRAIN TUMORS

The rehabilitation clinician serves many different populations, including patients with brain tumors. Despite the prognosis for limited survival associated with primary brain tumors, these individuals have shown progress in the rehabilitation setting similar to that noted in patients with diagnoses of stroke or traumatic brain injury.¹ Advances in medical and surgical treatment for patients with cancer have resulted in improved survival rates and longer life expectancy, yet only incremental improvements for patients with brain tumors.² Progressive impairments, physical or cognitive or both, result from the disease process and require an interdisciplinary team approach to best facilitate the individual's participation in a meaningful lifestyle. In addition, clinicians must recognize the psychological and emotional needs of the individual given this diagnosis, and be sensitive and flexible in accommodating the patient's feelings. Improved quality of life, especially the opportunity to return home, remains the ultimate goal of the rehabilitation process.

The clinical presentation of patients with brain tumors mimics that of persons with other central nervous system (CNS) conditions. The location of the tumor or vascular accident determines the impairments the patient will exhibit. However, in the brain tumor patient, the burdensome effects of standard medical intervention and the aggressive nature of the disease course itself provide obstacles to therapeutic intervention. The patient's increased probability of eventual physical and functional deterioration provides a challenge to the clinician

attempting to formulate realistic goals and plan for future needs. Therefore a thorough knowledge of the tumor's natural history, the complications and side effects of treatment, and the neurological impairment the patient exhibits will assist the clinician in best developing a comprehensive, individualized plan of care.

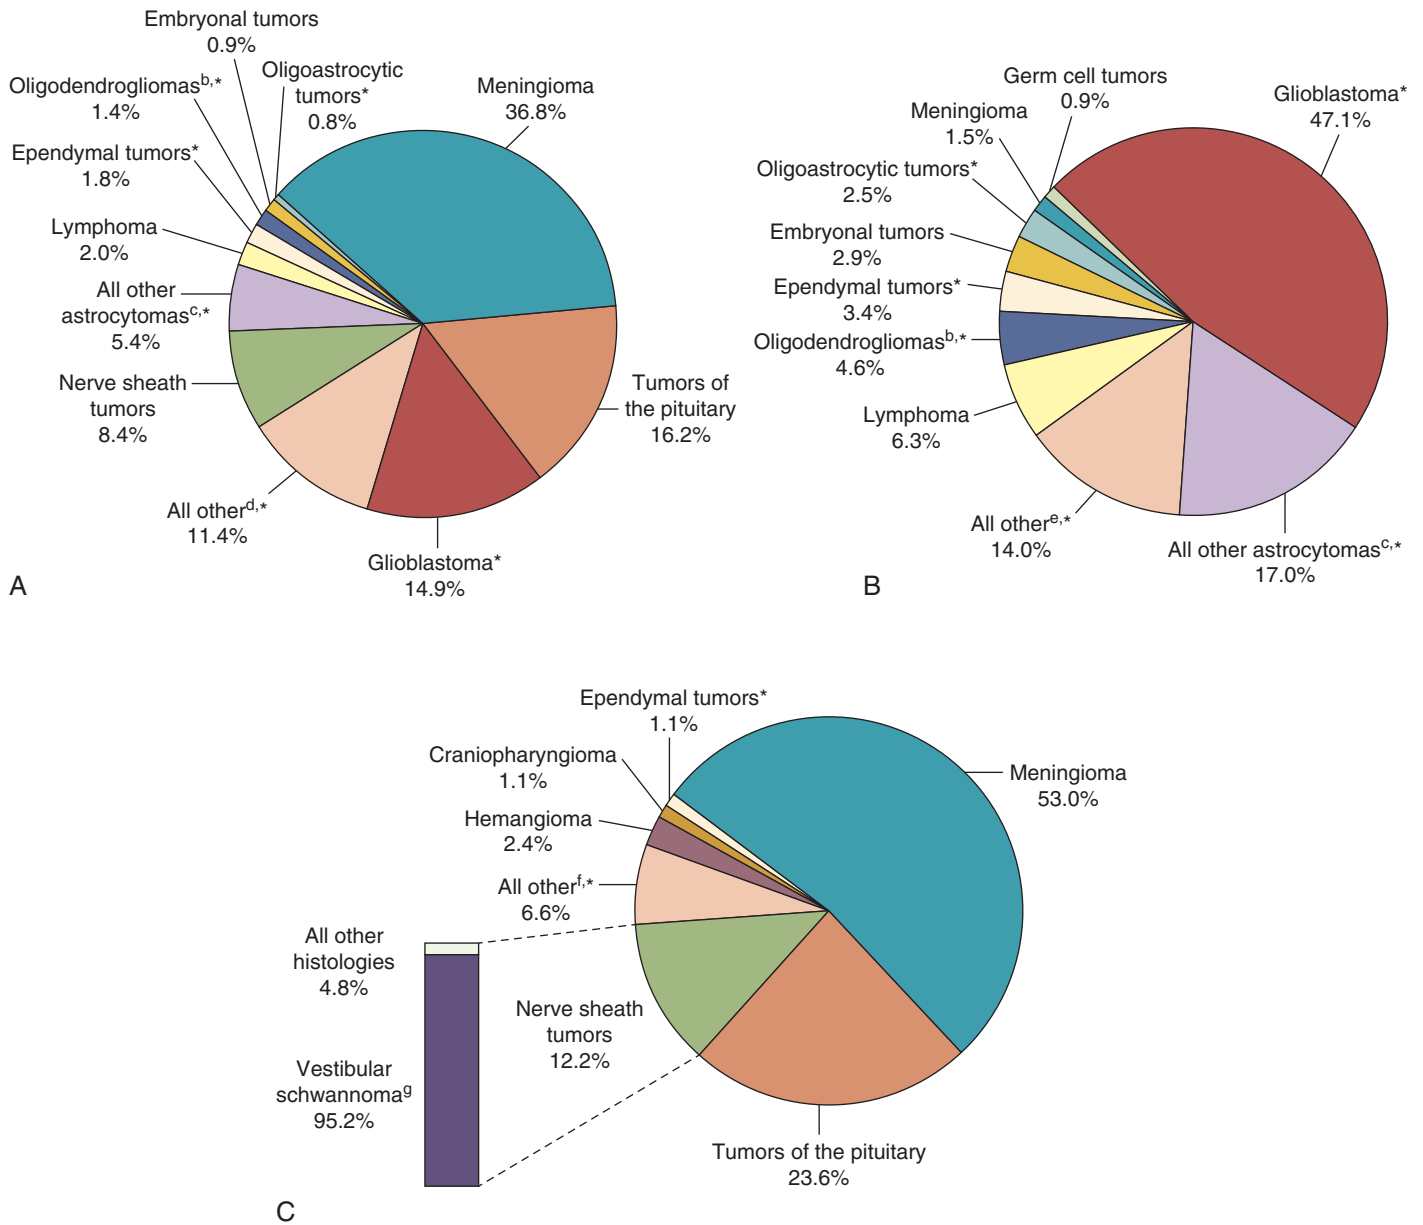

Incidence and Etiology

The incidence of adult brain tumors is on the rise in the United States and has been for the past 3 decades,³ with an estimated 86,970 new cases of primary benign or malignant brain and other CNS tumors anticipated for 2019.⁴ It is estimated that 26,170 will be malignant and 60,800 will be nonmalignant.² For children aged 0–14, 3720 new cases of childhood primary and nonmalignant brain and other CNS tumors are expected in 2019.⁴

In the United States, brain tumors typically occur in two distinct categories of patients: (1) children aged 0 to 15 years and (2) adults in the fifth to seventh decades of life. In adults, white Americans have a higher incidence than black Americans, and in both pediatric and adult populations males are more frequently affected than females. A primary brain tumor is now the most common cause of cancer death in children and adolescents aged 0 to 19, and brain and other CNS tumors are the most common cancer site in children aged 0 to 14, with an annual average of 5.54 per 100,000.²

The frequently occurring meningioma, typically benign, accounts for 36.8% of all primary brain tumors. Glioblastoma, a malignant tumor, accounts for 14.9% of adult primary tumors and 47.1% of malignant primary brain tumors (Fig. 25.1).² The largest percentage

of childhood tumors, age 0 to 14 years (15.4%), are located in the frontal, temporal, parietal, and occipital lobes of the brain, 15.2% in the cerebellum, and 13.4% in the brain stem.²

The etiology of brain tumors remains unclear, and many environmental and behavioral risk factors have and are being investigated. The influence of cellular phones and occupational/industrial hazards has been researched; however, the results have been inconclusive.⁵ Several hereditary CNS syndromes may be associated with increased risk of brain tumor; however, 95% of brain tumors are nonhereditary in nature.⁶ Exposure to moderate to high doses of ionizing radiation (radiation generated by atomic bombs, computed tomography [CT] scans, x-rays, and therapeutic radiation) has shown an increased risk factor for primary brain and other CNS tumors.^{3,7} Ionizing radiation, used therapeutically in high doses to treat tumors, has been found to have a causal relationship as well to the development of a second brain tumor.³ A decreased risk for brain and other CNS tumors, specifically gliomas, has been linked to a history of allergy or other atopic disease, including eczema, psoriasis, and asthma.^{3,8} Continued investigation into possible causal relationships is still ongoing and is essential if the incidence and mortality rates associated with brain tumors are to decrease.

Classification of Tumors

The World Health Organization (WHO) first published a universal classification system for CNS tumors in 1979, with its fourth edition published in 2007 and an update to the fourth edition in 2016.⁹ This system grades tumors (grades I to IV) according to their microscopic (histologic) characteristics and has been accepted as the universal method for the classification of brain tumors. In the 2016 update, tumors are now classified by genetic molecular characteristics, in addition to the specific histology.⁹ The hope is that by more specifically classifying tumors, treatment efficacy will improve.

Primary Brain Tumors

Primary tumors originate in the CNS, whereas metastatic or secondary tumors spread to the CNS from systemic cancer sites outside the brain.

Characteristics of the most common brain tumors are discussed in the following paragraphs, with information provided regarding age at onset, location, medical treatment, and prognosis.

Gliomas are primary tumors that arise from supportive tissues of the brain and are frequently located in the cerebral hemispheres. These tumors may also occur in the brain stem, optic nerve, and spinal cord. In children, the cerebellum is a primary location for gliomas.¹⁰ Gliomas have four primary categories and are classified by their predominant cellular components: astrocytomas and oligodendrogliomas originate from glial cells, ependymomas from ependymal cells, and medulloblastomas from primitive cells.¹¹

Astrocytomas are derived from astrocytes, which are star-shaped glial cells, and are the most common glial tumor in adults and children.² Astrocytomas vary in morphology and biological behavior, from those that are diffuse and infiltrate surrounding brain structures, to those that are circumscribed with a decreased likelihood of progression. In adults, the typical age of onset is after age 45, with the tumor frequently found in the frontal lobe. Most childhood astrocytomas occur in the cerebellum.^{10,12}

Astrocytomas are further classified into four grades: pilocytic astrocytoma (grade I), which are well-differentiated, relatively benign low-grade tumors most common in children and young adults; diffuse astrocytoma (grade II), which are well-differentiated, low-grade tumors that grow slowly; anaplastic astrocytoma (grade III), which are high-grade tumors that typically have tentacle-like projections growing into the surrounding brain tissue and grow more rapidly; and glioblastoma (grade IV), which is the most aggressive of the astrocytoma tumors. The glioblastoma can be primary or evolve from a lower grade astrocytoma (secondary). The higher the grade, the worse the prognosis.^{10,11}

Astrocytomas are typically treated with surgery, radiation therapy, and chemotherapy, depending on the grade, location of the tumor, age of the patient, and Karnofsky performance scale score (Table 25.1).^{10,11,13} Typically, lower grade tumors are treated with surgery followed by radiation if necessary. Grade III tumors are treated with surgery, followed by radiation and possibly chemotherapy when needed. The

TABLE 25.1 Karnofsky Performance Status Scale

Condition	Performance Status (%)	Comments
A. Able to carry on normal activity and to work; no special care is needed	100	Normal; no complaints; no evidence of disease
	90	Able to carry on normal activity; minor signs or symptoms of disease
	80	Normal activity with effort; some signs or symptoms of disease
B. Unable to work; able to live at home, care for most personal needs; a varying degree of assistance is needed	70	Care of self; unable to carry on normal activity or to do active work
	60	Requires occasional assistance but is able to care for most of personal needs
	50	Requires considerable assistance and frequent medical care
C. Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly	40	Disabled; requires special care and assistance
	30	Severely disabled; hospitalization is indicated, although death not imminent
	20	Very sick; hospitalization necessary; active supportive treatment necessary
	10	Moribund; fatal processes progressing rapidly
	0	Dead

Adapted from Karnofsky DA, Burchenal JH. The clinical evaluation of chemotherapeutic agents in cancer. In Macleod C, eds. *Evaluation of Chemotherapeutic Agents*. New York: Columbia University Press; 1949.

lower grade tumors, pilocytic astrocytomas, carry a 5-year survival rate of 94%; however, patients with grade III astrocytomas have a 5-year survival rate of only 29.8%.²

Glioblastoma is the distinct name given to the highly malignant grade IV astrocytoma. These tumors grow rapidly, invade nearby tissue, and contain highly malignant cells. Glioblastomas are predominantly located in the deep white matter of the cerebral hemispheres, but may be found in the brain stem, cerebellum, or spinal cord. Fifty percent of these tumors are bilateral or occupy more than one lobe of a hemisphere.¹¹ Glioblastomas account for 14.9% of all primary brain tumors and 47.1% of all primary malignant brain tumors (see Fig. 25.1).² They are most common in older adults, with males having a 1.6:1 incidence rate over females. In children and adolescents (aged 0 to 19 years), only 3% of brain and other CNS tumors are glioblastomas.² The medical prognosis is poor for patients with glioblastoma: less than 40% survive more than 1 year and less than 5.5% survive 5 years.² Researchers have recently discovered that glioblastomas have four distinct genetic subtypes that respond differently to aggressive therapies, making treatment difficult and challenging.⁹ These tumors are treated by surgical resection (only part of the tumor is typically resected), radiation therapy, stereotactic radiosurgery, and chemotherapy.^{10,11}

Oligodendrogliomas are slow-growing but progressive tumors that typically develop over a period of several years. These tumors are most commonly located in the frontal and temporal lobes; however, they can be found anywhere in the cerebral hemisphere.¹¹ Seizures, headaches, and personality changes are the primary clinical manifestations of the tumor.¹⁰ Oligodendrogliomas typically appear in the fourth to sixth decades of life, and the ratio of affected males to females is 2:1.¹¹ These patients have a 5-year survival rate of 81% and 10-year survival rate of 65%.² The 5-year survival rate decreases to 56% with anaplastic oligodendroglioma.² Treatment is dependent on symptoms and ranges from observation and seizure control with anticonvulsant drugs to surgical resection, radiation, and chemotherapy.^{10,11}

Ependymomas are tumors arising from ependymal cells—cells that line the ventricles of the brain and central canal of the spinal cord.¹⁰ These cells have glial and epithelial characteristics. Ependymomas grow into the ventricle or adjacent brain tissue. The most common site is the fourth ventricle (70% originate here), and they occur less frequently in the lateral and third ventricles.¹¹ Ependymomas are primarily treated with surgical resection followed by radiation therapy; however, chemotherapy is also used to treat tumor recurrence or when trying to delay radiation in young children.^{10,11} Because of increased intracranial pressure (ICP), a shunt is commonly placed to improve survival. These tumors frequently recur, and prognosis is dependent on the success of resection, with a 5-year survival rate approaching 84%.²

Medulloblastomas are malignant embryonal tumors thought to arise from primitive neuroectodermal cells—specifically pluripotential stem cells that have been prevented from maturing to their normal growth-arrested state.¹¹ These tumors are typically located in the cerebellum.¹⁰ Medulloblastomas typically grow into the fourth ventricle, blocking cerebrospinal fluid (CSF) flow, and cause hydrocephalus and ICP.¹¹ These tumors primarily occur in children or adults under the age of 45, accounting for 8% of childhood (0 to 14 years) brain tumors. The most common age of onset is 7 years old, with a prevalence in males over females.^{2,11} An overall 5-year survival rate of 73% has been noted among adults and children, and the most common treatment is surgery followed by radiation and chemotherapy.^{2,10,11}

Meningiomas are slow-growing tumors that primarily originate from cells located in the dura mater or arachnoid membrane, and account for 36.8% of reported brain tumors.^{2,11} The incidence increases

with age, with a more dramatic increase over age 65, and in females at a 2:1 ratio over males.^{2,10,11} Often clinical symptoms are not manifested until the growing tumor compresses adjacent structures. Headache and weakness are the most common symptoms, followed by seizures, personality changes, and visual deficits.^{10,11} If possible, tumors are treated with surgical resection. Recurring tumors are treated with surgery, radiation therapy, or stereotactic radiosurgery. Tumors in highly eloquent areas of the brain, however, may best be treated with serial scans to monitor for growth and compression of neural structures.^{10,11} Patients with nonmalignant meningiomas (most meningiomas are not malignant) have a 10-year survival rate of 81.4% versus a 10-year survival rate of 57.4% with malignant meningiomas.²

Pituitary adenomas are benign epithelial tumors originating from the adenohypophysis of the pituitary gland and frequently encroach on the optic chiasm.¹¹ These tumors are characterized by hypersecretion or hyposecretion of hormones.¹¹ Age at onset spans all ages, but pituitary adenomas are rare before puberty, more common in older people, and more common in females than males, especially during child bearing years. These tumors are primarily treated by surgical resection, drug therapy, and radiation.^{10,11} Prognosis is dependent on tumor size and cell type, with a 5-year survival rate of 96%.²

Schwannomas are encapsulated tumors composed of neoplastic Schwann cells that can arise on any cranial or spinal nerve.¹¹ A schwannoma on the eighth cranial nerve is called an *acoustic neuroma*. The tumors' location on the nerve produces otological, focal, or generalized neurological impairments. These tumors are often located in the internal auditory canal but may extend into the cerebellopontine angle.^{11,12} Treatment typically involves surgical resection; however, stereotactic radiosurgery is increasing in popularity as an alternative method of treatment when the tumor is near vital nerves or blood vessels.¹¹ The prognosis for patients with these tumors is good, yet complications can result from treatment, including facial paralysis, deafness, and equilibrium impairments.¹¹ Deficits after surgery vary depending on the size and location of the tumor. A 10-year follow-up study looking at low dose linear accelerator stereotactic radiosurgery confirmed excellent tumor control and acceptable cranial neuropathy rates but a continual decrease in hearing preservation.¹⁴

Primary CNS lymphomas are rare tumors arising from cells in the lymphatic system, representing only 2% of primary brain tumors.² These lymphomas have a slightly higher incidence in men and peak in the sixth through eighth decades of life.² The tumor cells are similar in histology to systemic non-Hodgkin lymphoma cells, but it is uncertain how this tumor arises, as the CNS lacks lymphatic tissue.^{11,15} The tumor may be solitary or multifocal, forming a poorly defined mass that may be difficult to distinguish from an astrocytoma.¹¹ Primary brain lymphomas appear primarily in the cerebral hemispheres, and the most common symptoms are behavioral and personality changes, confusion, dizziness, and focal cerebral signs, rather than headache and other signs of increased ICP.^{10,11} Surgical resection is typically ineffective because of the deep location of these tumors. Radiation, chemotherapy, and steroids are the most common forms of treatment; however, the tumor recurs in 90% of individuals.¹¹ CNS lymphoma carries a poor prognosis, with only 33% of patients surviving longer than 5 years.²

Secondary Brain Tumors: Metastatic Brain Tumors

Metastatic brain tumors originate from malignancies outside of the CNS and spread to the brain, typically through the arterial circulation.¹¹ Approximately 25% of individuals with systemic cancer develop brain metastases, with approximately 80% of tumors in cerebral hemispheres and 20% in the posterior fossa.^{11,15} One-third of brain metastases originate in the lung, followed by the breast, skin, gastrointestinal

tract, and kidneys in order of frequency. Common clinical manifestations of metastatic brain tumors are similar to those of gliomas, including seizures, headache, focal weakness, mental and behavioral changes, ataxia, aphasia, and signs of increased ICP.¹¹

Treatment for these tumors is tailored to the individual and dependent on the management of the systemic disease, the accessibility of the lesion, and the number of lesions.¹¹ Current treatment regimens include surgery and radiosurgery if the lesions are limited in number and accessible. Chemotherapy and whole brain radiation therapy (WBRT) may also be used. The average survival with treatment is approximately 6 months but varies widely and is affected by the extent of other systemic metastases. With some radiosensitive tumors, survival increases to 15% to 30% for 1 year and 5% to 10% for 2 years.¹¹

Signs and Symptoms

The clinical manifestations of a brain tumor are dependent on the type and site of the tumor and rate of growth. These manifestations range from decreased speed in comprehension or minor personality changes to progressive hemiparesis or seizure.¹⁶ Patients with brain tumors typically have headaches, seizures, nonspecific cognitive or personality changes, or focal neurological signs.^{10,11} The presenting signs may be general, specific neurological symptoms, or a combination of both.

General Signs and Symptoms

General signs and symptoms of the presence of a brain tumor include headache, seizures, altered mental status, and papilledema. *Headache* is the presenting symptom in 50% of brain tumor cases; however, it is rarely the sole complaint or symptom in these patients.^{10,16} It is important to identify the specific nature of the headaches, as certain features often indicate the presence of a brain tumor. These features include the following:

1. The headache interrupts sleep or is worse on waking and improves throughout the day.
2. The headache is elicited by postural changes, coughing, or exercise.
3. The headache of recent onset is more severe or a different type than usual.
4. The new onset of headache occurs in an older person.
5. The headache is associated with nausea and vomiting, papilledema, or focal neurological signs.^{10,11,16}

Headaches can be caused by local tissue edema, distortion of blood vessels in the dura overlying the tumor, and increased ICP. The location of the headache is typically determined by the tumor's location. Tumors above the tentorium cause headaches on the same side as the tumor and the immediate surrounding area. Posterior fossa tumors cause headaches in the occipital lobe and ipsilateral retroauricular area. Increased ICP causes bi-frontal or bi-occipital headaches regardless of the tumor location.^{10,11}

Seizures are a frequent symptom in patients with a brain tumor, and a first seizure during adulthood is suggestive of a brain tumor.^{11,16} Seizure incidence and management is dependent on the tumor type, location, and at what point in the disease course the seizure presents.¹⁶ Seizures may be solitary or occur frequently, preceding or following other symptoms.¹¹ More than 50% of patients with gliomas experience recurrent seizures, while only 11% of patients with brain metastases experience recurrent seizures.¹⁶ Tumors can cause epilepsy, and the prognosis for complete seizure control in patients with tumor related epilepsy is poor.¹⁶

Altered mental status including cognitive and mental deficits are frequently seen in patients with brain tumors.¹⁶ Cognitive changes range from decrease in concentration, memory, affect, personality, initiative, and abstract reasoning to severe cognitive deficits and confusion.¹⁶ Subtle changes may be incorrectly attributed to worry, anxiety,

or depression.¹¹ Changes in mentation are common with frontal lobe tumors and in the presence of elevated ICP. Increased ICP causes drowsiness and decreased level of consciousness, which can progress to stupor or coma if edema is not immediately reduced.¹¹

The incidence of *papilledema*, swelling of the optic nerve, is less frequent today because brain tumors are being diagnosed earlier with the use of sensitive imaging techniques. Papilledema is associated with symptoms of transient visual loss, especially with positional changes, and reflects evidence of ICP transmitted through the optic nerve sheath. Papilledema is more common in children than adults.¹⁶

Vomiting and dizziness are other less common symptoms associated with brain tumors located in the posterior fossa.^{11,16} Vomiting can indicate a generally elevated ICP but can also occur due to pressure on the vomiting center (posterior fossa) with brain stem tumors. Projectile vomiting is usually seen in posterior fossa tumors in children but not adults.¹⁶ Dizziness and/or positional vertigo can be a symptom of a tumor in the posterior fossa but also has other more common benign causes.¹¹

Specific Signs and Symptoms

Certain clinical features are related to functional areas of the brain and thus have a specific localizing value in medically diagnosing a brain tumor. Therefore it is essential that clinicians be familiar with the lobes of the brain and their distinct functions to effectively manage the impairments resulting from the tumor (Fig. 25.2). These symptoms may vary among individuals and result in physical and cognitive deficits that range from mild to severe.

The *frontal lobe* is responsible for motor functioning, initiation of movement, and interpretation of emotion, including motor speech, motor praxis, attention, cognition, emotion, intelligence, judgment, motivation, and memory. Therefore frontal lobe tumors may result in movement disorders such as hemiparesis, seizures, aphasia, and gait difficulties, and cognitive impairments including personality changes such as disinhibition, irritability, impaired judgment, and lack of initiation. Initially, the tumor may be clinically silent; however, as the tumor grows, progressive symptoms develop based on the tumor's location in the frontal lobe.¹⁶

The *parietal lobe* processes complex sensory and perceptual information related to somesthetic sensation, spatial relations, body schema, and praxis. General symptoms of a parietal lobe tumor include contralateral sensory loss and hemiparesis, homonymous visual deficits or neglect, agnosias, apraxias, and visual-spatial disorders. If the dominant parietal lobe is involved, agraphesthesia, left-right confusion, and finger agnosia are typically present. With nondominant parietal lobe involvement, contralateral neglect and limited awareness of impairments is commonly found. Seizures with focal onset are often associated with tumors in the parietal lobe—particularly those in the region of the motor cortex.¹⁶

The *occipital lobe* is the primary processing area of visual information. Therefore lesions of the occipital lobe often result in dysfunction of eye movement and homonymous hemianopsia. If the parieto-occipital junction is involved, visual agnosia and agraphia are often present. Seizures are not common with occipital lobe tumors.¹⁶

The *temporal lobe* is responsible for auditory and limbic processing. If the lateral hemispheres are involved, auditory and perceptual changes may occur. When the medial aspects are affected, changes in cognitive integration, long-term memory, learning, and emotions may be seen. Anomia, agraphia, acalculia, and Wernicke aphasia (fluent, nonsensical speech) are specific to left temporal lobe lesions. Similar to the parietal lobe, seizures are common with temporal lobe tumors.¹⁶

The *cerebellum* is responsible for coordination and equilibrium. Midline cerebellar lesions can compromise CSF flow and produce

Fig. 25.2 Correlation between clinical symptoms and anatomical location of the tumor. (Used with permission from Barrow Neurological Institute.)

hydrocephalus, resulting in truncal ataxia. Lateral tumors are typically larger and are associated with limb ataxia (upper greater than lower extremity) and impaired coordination and nystagmus. Tumors invading the cerebellar pontine angle present with hearing loss, headache, ataxia, dizziness, and tinnitus. Facial palsy may occur due to cranial nerve compression, especially in the facial and acoustic nerves. If the cerebellar tumor infiltrates the meninges at the foramen magnum causing cerebellar tonsil herniation, sudden death may occur due to fourth ventricle obstruction and compression of the medulla.¹⁶

The *brain stem*, which communicates information to and from the cerebral cortex via fiber tracts, controls vital life functions. Even small tumors invading or compressing the brain stem can lead to death or devastating signs and symptoms. Within the brain stem, the reticular formation of the pons and medulla controls consciousness, sleep, and attention. If the reticular system is involved, symptoms of apnea, hypoventilation or hyperventilation, orthostatic hypotension, or syncope may occur. Symptoms of a brain stem tumor have an insidious onset and may include gait disturbances, diplopia, focal weakness, headache, vomiting, facial numbness and weakness, and personality changes. If the dorsal midbrain is involved, Parinaud syndrome, characterized by loss of upward gaze, pupillary areflexia to light, and loss of convergence, may be seen.^{12,16}

The *pituitary gland* is an endocrine gland that secretes the hormones necessary to regulate the functions of the other endocrine glands in the body. The symptoms of pituitary tumors are caused by either a hypersecretion of hormones or the tumor compressing the gland itself, resulting in hormone hyposecretion (pituitary hypofunction). The symptoms that present are based on the specific hormone

excess or deficiency, which can include headache, depression, vision loss, nausea and/or vomiting, behavior and cognitive changes, abnormal weight gain, abnormal growth in hands and feet, hair growth in women, amenorrhea, and impotence in men.^{10,11}

Medical Diagnosis of Disease or Pathology

A clinical diagnosis is determined from the information that the physician gathers during a comprehensive evaluation. Information obtained while discussing the patient's medical history and the specific nature of the signs and symptoms is critical at the initial stages of the diagnostic process. Signs of an intracranial hemorrhage or infarction typically have an abrupt onset, whereas brain tumors usually have a more gradual onset and progressive symptoms.¹⁷ The neurological examination may identify visual, cognitive, sensory, or motor impairments that may help identify the affected areas. However, sometimes symptoms may be subtle, depending on the tumor's location or if the brain has adapted to a low-grade glioma. In these cases, the patient may have a normal neurological exam in the presence of an underlying glioma.¹⁸ After a thorough history and physical is performed, if the presence of a brain tumor is suspected, the next diagnostic step, tumor imaging, is warranted.¹¹

In addition to imaging, specialized tests may be used to confirm the diagnosis and assess the structure and pathology of the brain tumor.^{15,17} Advances in research and imaging techniques allow for earlier detection of brain tumors and more specialized treatment options. Conventional and advanced imaging in combination with biopsy and molecular diagnostics have revolutionized the diagnosis and management of brain tumors.¹⁹

Conventional Imaging

CT and magnetic resonance imaging (MRI) are the most common imaging modalities used to assess neurological deficits. Acutely, CT is a cost-effective method to quickly detect a hemorrhage; however, MRI is the modality of choice to evaluate a brain tumor. Conventional MRI provides exquisite anatomical details about tumor size and location, as well as surrounding intracranial structures. With MRI, different signal intensities differentiate normal brain from tumor and contrast enhancement sharpens the definition of a lesion. MRI enhanced with gadolinium can distinguish between tumor and edema.¹¹ Conventional MRI sequences with T1W, T2W, and fluid attenuated inversion recovery (FLAIR) are commonly used with cerebral malignancy.^{20,21} Although conventional MRI can evaluate edema, hydrocephalus, and hemorrhage, it cannot reliably predict subtype or grade of glioma, and advanced imaging may be indicated to identify the pathophysiological characteristics of the tumor.²⁰

Advanced Imaging

After the diagnosis has been confirmed, advanced imaging techniques are utilized to evaluate the cellular, hemodynamic, metabolic, and functional properties of the tumor have been shown to improve diagnostic, intraoperative, and postoperative management. Understanding pathophysiological properties such as microscopic tumor infiltration, microvascular characteristics, and early response changes is critical to the ongoing management of brain tumors. Advanced imaging improves the delineation of tumor margins and evaluates the extent of tumor invasion, including its relationship to eloquent cortical areas and major white-matter tracts. This advanced knowledge of the tumor has allowed for improvements in identifying optimal biopsy sites and making critical preoperative decisions, resulting in more effective treatment interventions.^{17,20}

Diffusion-Weighted Imaging

Diffusion-weighted imaging (DWI) is a quantitative technique routinely used in research and clinical settings.²² DWI utilizes MR to analyze the diffusion of water molecules in the extravascular extracellular space and determines an apparent diffusion calculation (ADC).²¹ ADC can measure cellularity, cell density, and properties of the extracellular matrix. Restricted diffusion favors increased cellularity and therefore is a sign of tumor progression.²⁰ DWI has the capability of detecting tumor progression before it can be seen with contrast enhancement.²¹

Functional Magnetic Resonance Imaging

Functional MRI (fMRI) has become an important clinical tool in surgical planning by identifying eloquent areas of the cortex and their relationship to the tumor. When patients perform different tasks, fMRI can identify the different areas of the brain activated during the task. Research has shown that fMRI can be used for accurate mapping of motor, sensory, and language areas.^{17,20} Identifying these critical areas preoperatively can ultimately improve a patient's quality of life by preserving these critical areas during surgery.¹⁷

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) is used in conjunction with other imaging techniques to assess the molecular content of brain tumors by using an imaging voxel.¹⁷ Placement of the voxel in the center of the tumor ensures the sample contains only tumor cells. MRS has been shown to discriminate tumor recurrence from radiation necrosis.²³ Studies have identified Cho, a marker that identifies membrane turnover, which can identify the progression of low to high-grade malignant tumors.²⁴

Perfusion Weighted Imaging

Perfusion weighted imaging (PWI) evaluates microvasculature and can indirectly measure the metabolic activity of a tumor. Tumors can initiate angiogenesis, developing blood vessels that are histologically disorganized, tortuous, and more permeable than normal. These pathological vessels lead to hemodynamic changes that can be identified with perfusion imaging. Newer methods of MR perfusion with arterial spin labeling are completely noninvasive and do not require contrast media.²¹

Molecular Imaging

Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are molecular imaging techniques that utilize radioactive compounds to study the metabolism and physiology of the brain tumor and the surrounding tissue. PET scans using radioactive markers to measure glucose metabolism can be useful in determining the grade of primary brain tumors and in differentiating tumor regrowth from radiation necrosis. PET with carbon 11 methionine tracer can differentiate between high- and low-grade tumors.¹⁷ PET, along with MRS and magnetic resonance perfusion, are being explored as possible methods to distinguish tumor progression from treatment-related pseudoprogression.¹⁸ SPECT evolved from PET and uses isotopes to assess cerebral blood flow and determine tumor location.¹² SPECT with Thallium-201 chloride can be used to stage gliomas and assess the tumor postoperatively; however, its anatomical resolution is limited.^{11,25} PET and SPECT are not commonly used clinically due to high expense and limited availability, especially if other more cost-effective imaging modalities yield the same reliable diagnosis.²⁵

Biopsy

Surgical biopsy is performed to obtain tumor tissue as part of tumor resection or as a separate diagnostic procedure.¹⁰ Stereotactic biopsy is a computer-directed needle biopsy. When guided by advanced imaging tools, stereotactic biopsy yields the lowest surgical morbidity and highest degree of diagnostic information. This technique is frequently used with deep-seated tumors in functionally important or inaccessible areas of the brain in order to preserve function.

In the past, the biopsy site of a deep inoperable lesion was selected based on areas of solid enhancement on T1-weighted gadolinium-enhanced MRI or contrast-enhanced CT. However, sometimes a higher grade glioma would be misdiagnosed as a lower grade if necrotic tissue was centrally located and contained in the biopsy.¹⁷ Newer modalities, MRS and PET imaging, highlight those areas of greatest metabolic activity, thereby improving diagnostic yield and minimizing sampling error.¹⁷ PET with carbon 11 tracer can detect the most malignant areas of the tumor improving the accuracy of diagnosis.²⁵ Recently, a procedure in which a neuroendoscope simultaneously treats hydrocephalus while obtaining the biopsy (endoscopic tumor biopsy) has been successful with midline paraventricular gliomas.²⁶

Molecular Diagnosis

As discussed earlier in the chapter, molecular and genetic characteristics of glial tumors are now being incorporated into tumor classification. Studies of the molecular pathology of gliomas have led to the discovery of molecular biomarkers that can be used to improve diagnosis, estimate prognosis, and determine treatment efficacy.¹⁸ Researchers have discovered specific tumor mutations can be used as prognostic indicators and imaging can play a vital role in identifying these characteristics. Conventional MRI can identify enhancement, necrosis, and edema, which are associated with poor outcomes. Mutations specific to oligodendrogliomas and glioblastomas are also visible

on MRI.²⁰ MR imaging with 5-ALA increases the concentration of intracellular iron by synthesizing heme in glioblastoma.²⁵

Medical and Surgical Management

After diagnosis of a brain tumor has been confirmed, specific treatment must be selected. The ultimate goals of tumor management are to improve quality of life and extend survival, by preserving or improving body function and structures.²⁷ Treatment techniques are determined by histological type, location, grade, and size of tumor; age at onset; and medical history of the patient.^{12,27} Four types of treatment are discussed: (1) traditional surgery, (2) chemotherapy, (3) radiation therapy, and (4) stereotactic radiosurgery.

Traditional Surgery

The primary goal of traditional surgery is maximal tumor resection with the least amount of damage to neural or supporting structures. Gross total resection is associated with longer survival rates and decreased neurological impairment.²⁸ Benign tumors, if accessible, are resected completely, whereas malignant tumors are typically partially resected secondary to location or size of the tumor.²⁷ The *purposes* of surgery in the management of brain tumors include the following:

1. Biopsy to establish a diagnosis
2. Partial resection to decrease the tumor mass to be treated by other methods
3. Complete resection of the tumor²⁹

Biopsies are performed through open, needle, and stereotactic needle techniques. Open biopsies involve exposure of the tumor followed by removal of a sample through surgical excision. Needle biopsies involve insertion of a needle into the tumor through a hole in the skull and the excision of the tissue sample drawn through the needle. Stereotactic needle biopsies use computers and MRI or CT scanning equipment to assist in directing the needle into the tumor. This type of biopsy is useful for deep-seated or multiple brain lesions.²⁷

Partial and complete resections are accomplished through craniotomy. Craniotomy involves removal of a portion of the skull and separation of the dura mater to expose the tumor. Stereotactic craniotomy uses technology to create computed three-dimensional pictures of the brain to guide the neurosurgeon during the procedure. CT scanning and MRI scanners are used to provide an evaluation of the tumor resection during the procedure.²⁹ Awake craniotomy allows for intraoperative brain mapping that helps identify and protect functional cortex, and in recent years has been used more frequently for most supratentorial tumors.³⁰

Preoperative management. Before surgery, patients are evaluated for general surgical risks and the possibility of tumors in additional locations. Unless medically contraindicated, steroids are administered before surgery if brain edema is present or if extensive manipulation is anticipated during surgery. Anticonvulsant medications are also administered preoperatively to prevent seizures during or after surgery.²⁷

Intraoperative management. During surgery, precautions are taken to prevent an increase in edema or ICP. Mannitol, a vasodilator to decrease ICP, is used to shrink the surrounding brain tissue, thus providing easier access to the tumor. Steroid use is continued and antibiotics are administered to prevent infection. Hyperventilation, with a carbon dioxide (CO₂) level of 25 mEq/L, is also used to reduce ICP.²⁷

Postoperative management. Patients are observed in an intensive care unit for at least 24 hours for possible intracranial bleeding or seizures. Blood pressure is monitored continuously. After surgery, patients are at risk for developing deep vein thrombosis or pulmonary embolism, secondary to decreased muscle activity. Anticoagulants cannot be given, because these patients are at risk for intracranial bleeding. Therefore mechanical prophylaxis is used in an attempt to

prevent deep vein thrombosis. Steroids are tapered after surgery over 5 to 10 days. Antiepileptic medications are continued after surgery, with the length of time dependent on the presence of seizure activity before and after surgery.²⁷ The primary limitations of traditional surgery include the following:

1. Medical complications such as hematoma, hydrocephalus, infection, and infarction from the surgical procedure
2. Complications resulting from general anesthesia
3. Increased cost of the hospital stay and surgical procedure²⁷

Chemotherapy

Chemotherapy is another treatment frequently used to manage brain tumors. It can be used independently or as an adjuvant to surgery or radiation. Chemotherapeutic drugs are not effective on all types of tumors. Some tumors are known to be resistant to certain drugs, and other treatment options must be pursued. Drugs can be given in combination to target all cell types present within the tumor. Because different drugs have different modes of action and side effects, combined drug therapy often proves to be one of the most effective treatments.³¹ Chemotherapy can be administered in a number of different ways. Most agents are delivered intravenously through a peripheral intravenous line or through a catheter such as a peripherally inserted central catheter (PICC) or tunneled access central catheter (TACC). Other drugs are placed directly into the tumor bed or are given intramuscularly, orally, or by means of an implanted device.

Chemotherapy drugs impede cellular replication of the tumor cells, interfering with their ability to copy deoxyribonucleic acid (DNA) and reproduce. Once the replicating capability of the tumor cell has been disrupted, the cell dies. In this way, the tumor is prevented from growing and is destroyed at the cellular level.

Methotrexate is a highly toxic drug and is usually paired with an antidote drug, leucovorin, to reverse the side effects on normal cells.³¹ Typically methotrexate is used to treat cancer outside of the CNS; however, it is the major chemotherapy drug used to treat CNS lymphoma.¹¹ The introduction of methotrexate has been found to increase the median survival for patients with primary CNS lymphoma, even those older than 60 years of age.³²

Neurotoxic to surrounding tissue, methotrexate and cytarabine are drugs able to be introduced directly into the CSF through an intraventricular Ommaya reservoir.³³ The reservoir, implanted under the scalp, is filled by use of a syringe, and the medication is then circulated through the ventricles to the brain.³¹ The drugs are routinely given in a clinic setting by a registered nurse certified in chemotherapy administration. A patient's chemotherapy schedule varies depending on the drug given. An on-off cycle is used to allow the patient time to recover from the drugs' harmful side effects.

One of the challenges in delivering cytotoxic drugs to the brain is the blood-brain barrier (BBB). The BBB is the brain's natural protective barrier against transmission of foreign substances from the blood into the brain.³¹ One class of drugs that does penetrate the BBB is the *nitrosoureas*. These include BCNU (carmustine) and CCNU (lomustine), which are lipid soluble and cell cycle specific. These drugs are given in high doses and typically used to treat glioblastoma multiforme and anaplastic astrocytoma; however, often these high-grade tumors invade and destroy the BBB.

BCNU can also be administered in the form of wafers placed by the neurosurgeon directly into the brain tumor. An initial study for recurrent malignant gliomas found that patients' tumors responded to the treatment. This report was followed by an upfront study for glioblastoma.³⁴ The US Food and Drug Administration (FDA) granted approval for these wafers (Gliadel) for newly diagnosed high-grade glioma in 2002.³⁴

Temozolomide is an orally available chemotherapeutic agent introduced in the 1990s for the treatment of malignant gliomas.³⁴ Initial results in treating recurrent anaplastic astrocytoma and glioblastoma were so successful that the drug was approved for the treatment of recurrent brain tumors by the FDA.³⁵ For recurrent tumors the drug is administered orally 5 days per month. Temozolomide was then tested for the upfront treatment of glioblastoma. This occurred in a multicenter study in which the drug was given daily as part of the initial treatment with radiation therapy, followed by five doses per month for maintenance treatment.³⁵ Survival increased substantially with this regimen, and as a result the FDA approved the use of temozolomide as part of first-line treatment of newly diagnosed high-grade glioma in 2005. The CATNON trial, just completed in 2017, demonstrated temozolomide chemotherapy was associated with significant survival benefits in patients with newly diagnosed anaplastic glioma.³⁶

Another major breakthrough in chemotherapy for brain tumors was the finding that the antiangiogenesis monoclonal antibody Avastin (Bevacizumab) improved the progression-free survival and tumor images on MRIs of patients with glioblastoma.³⁷ The drug targets vascular endothelial growth factor (VEGF) and is administered intravenously. In 2017, the FDA granted full approval for the use of Avastin in the treatment of adults with recurrent glioblastoma. It is usually administered in combination with another chemotherapy agent such as irinotecan.³⁷

Radiation Therapy

Radiation therapy can be used alone or in conjunction with surgery or chemotherapy to treat malignant brain tumors. It is typically chosen as a treatment option for tumors that are too large or inaccessible for surgical resection and to eradicate residual neoplastic cells after a surgical debulking. Radiotherapy consists of the delivery of high-powered photons, with energies in a much greater range than that of standard x-rays, as an external beam focused directly at the tumor site. The external beam is transmitted to the tumor through a linear accelerator or a cobalt machine that uses cobalt isotopes as the radiation source. External beam radiation is the most widely used form of radiation treatment.³⁸

Conventional radiation therapy, as described previously, is fractionated into small doses delivered over a period of weeks. Often, if a large fraction is to be delivered, the dose is divided and given in multiple small doses; this is called *hyperfractionation*. The aim is to decrease the damage done to healthy surrounding tissue. Studies are investigating the use of a few high ablative doses of radiation known as hypofractionation radiotherapy. Preliminary findings suggest hypofractionation improves tumor growth control and may offer an increase in antitumor immune response as compared with hyperfractionation radiotherapy.^{39,40}

Conformal radiation is the use of high-dose external beam radiation, produced by a linear accelerator, to precisely match or “conform” to the tumor shape. This method attempts to deliver a uniform amount of radiation to the tumor and minimize irradiation of healthy brain tissue.⁴¹

Radiosurgery involves relatively high-dose hypofractionated radiation beams directed at small tumor areas through the use of computer imaging.⁴¹ This type of treatment includes the Gamma Knife, linear accelerators, and the Cyberknife, which are discussed later.

The radiation oncologist determines the dosage, frequency, and method of radiation delivery, depending on tumor type, location, growth rate, and other medical issues for each patient. A typical course of radiation therapy will last 6 weeks. Patients are irradiated for just 1 to 5 minutes, 5 days a week. The radiation is intended to destroy the malignant cells and preserve healthy ones; however, some rapidly

growing cells, such as skin tissue and mucosa, are killed, also producing the common side effects known to radiation.³⁸

Radiation therapy has considerable limitations and disadvantages. There is an accepted maximum lifetime dosage of radiation that the brain and body can tolerate. As doses come close to this limit, the risk of radiation necrosis increases. Because the brains of young children are particularly vulnerable to radiation, other therapies, such as chemotherapy, are used until the developing brain is more tolerant of radiation. Metastatic lesions have invaded multiple organs or body systems; therefore a more systemic treatment such as chemotherapy is most effective for this type of brain cancer.⁴¹

Stereotactic Radiosurgery

Stereotactic radiosurgery is defined as delivery of a high dose of ionizing radiation, in a single fraction, to a small, precisely defined volume of tissue.^{42,43} The high-energy accelerators involved improve the physical effect of radiation by allowing energy to travel more precisely in a straight line and penetrate deeper before dissipating. The goal is to arrest tumor growth by disrupting the tumor’s DNA. This technique has been shown to be most beneficial for treating centrally located lesions less than 3 cm in size and for patients with increased surgical risk factors.³⁸ Advantages of stereotactic radiosurgery are as follows:

1. It is a noninvasive procedure using local anesthesia and sedation to place the stereotactic frame.
2. It avoids risks of general anesthesia and immediate postoperative risks such as bleeding, CSF leak, and infection.
3. It lowers treatment cost and shortens hospital stays.⁴²

Stereotactic radiosurgery is used to treat benign, malignant, and metastatic tumors; vascular malformations; and functional disorders.⁴³ The primary modes of administration for stereotactic radiosurgery include the Gamma Knife, linear accelerators, and the Cyberknife.⁴² The radiosurgery team consists of a neurosurgeon, radiation oncologist, medical physicist, oncology nurse, dosimetrist, and radiation therapist.

The Gamma Knife was first introduced in Sweden in 1968 and is now used worldwide at more than 300 sites (Fig. 25.3). The Gamma Knife uses 201 discrete sources of cobalt 60, which are focused precisely to one point in three-dimensional space within the cranium. The Gamma Knife is typically used for deeply embedded small tumors, often metastatic, that require precise delivery of radiation.^{44,45}

MRI, CT scanning, or angiography is used to identify the exact location of the lesion to be treated after the stereotactic frame is placed on the patient’s head. The stereotactic frame is then fixed to the machine and attached to a collimator helmet containing 201 holes

Fig. 25.3 The Leksell Gamma Knife.

for the radiation to pass through. The patient is then locked into position. The prescribed dose is given over 20 minutes to 2 hours. After treatment the frame is removed, the patient is observed and is frequently discharged after 24 hours. Return to previous activity typically occurs within a few days.^{44,46}

With the Gamma Knife, the full dose of radiation is received only at the point where the 201 beams intersect, thereby giving only a minimal dose to uninvolved tissue when targeted accurately. Side effects are rare, but headache and nausea may occur. The primary limitations of the Gamma Knife are the limited brain volume that can be treated with one dose and the cost of the Gamma Knife machine.^{27,44}

Linear accelerators used for conventional radiation can be modified for stereotactic radiosurgery. The brain lesion to be targeted is stereotactically placed in the center of the arc of rotation of the machine. A single, highly focused beam of radiation is delivered over multiple sweeps around the lesion. Linear accelerators can be used to treat larger tumors with precise shape while maintaining uniform dose. Because linear accelerators are used for conventional radiation, a quality check for beam accuracy is imperative before the machine is used for stereotactic radiosurgery.^{12,27}

The *Cyberknife* uses a compact linear accelerator mounted on a robotic arm, with the robotic arm moving around the linear accelerator to multiple precalculated positions (Fig. 25.4). At each position, the accelerator fires a beam of radiation at the tumor or lesion. A high cumulative dose of radiation is achieved at the tumor or lesion at the convergence of the beams. This dose is typically strong enough to destroy the abnormal cells while minimizing the damaging effects of radiation to healthy surrounding tissue. The Cyberknife differs from other stereotactic radiosurgery because a linear accelerator is combined with an image guidance system. The robotic arm allows the Cyberknife to target difficult-to-reach areas of the body, as well as adjust quickly for changes in target location during treatment.^{47,48}

These stereotactic radiosurgery techniques are widely used, due to the ability to precisely and accurately deliver a high dose of radiation to a target while sparing surrounding healthy tissue and minimizing the overall dose needed to ablate the tumor.⁴⁹ In recent years, studies have proven Gamma Knife to be a safe treatment modality for brain stem metastases.⁵⁰ A 2016 study looked at the use of stereotactic radiosurgery to the postoperative tumor bed after surgical resection.

Fig. 25.4 The Cyberknife.

Results for local control and overall survival rate were comparable to WBRT.⁵¹ Historically, microsurgical resection and radiosurgery have been utilized to treat acoustic neuromas, depending on the size and presence of brain stem compression. In these cases, stereotactic radiosurgery avoids the risk of an open procedure, has minimal side effects, and due to the overall decreased amount of radiation the cochlea receives, hearing is often preserved.⁵²

Research suggests recurrent high-grade gliomas treated with stereotactic radiosurgery have median progression free survival and median overall survival estimates of 5.42 and 20.19 months, respectively. The combined rate of radiation necrosis was 5.9%.⁵³ The addition of radiosurgery at the time of recurrence after surgery and radiation has been found to aide in an increase in overall survival of patients with glioblastoma.⁵⁴

The preferred treatment for *meningiomas* is surgical resection, if complete resection is possible. However, for meningiomas situated in the skull base, stereotactic radiosurgery is a good option, allowing for tumor control and preserved neurological function.⁵⁵ Cerebellopontine angle meningioma patients demonstrated a 98% progression free survival at 3 years and a low rate of adverse radiation effects.⁵⁶

Research Trends

The standard of treatment for primary brain tumors has not changed much in the last two decades; most are still treated with surgical resection followed by chemotherapy and radiation. However, there are some promising new discoveries in the research and possible new treatment options and techniques on the horizon.

One such area of promise centers on inhibiting proteins responsible for the growth and division of glioblastomas by targeting glioma stem cells and glioblastoma stem cells (tumor precursor cells). Scientists from Massachusetts Institute of Technology (MIT) have identified the mechanism by which a specific protein, called PRMT5, drives glioblastoma tumor growth. By using PRMT5 inhibiting drugs to block this mechanism, glioblastoma growth was halted in mice. The finding indicates PRMT5 could be involved in a form of “gene splicing” that causes the tumor to grow out of control.⁵⁷ Another protein, oligodendrocyte transcription factor (OLIG 2), has been found to be a requirement for the proliferation of glioma stemlike cells. OLIG 2 is expressed in the CNS only; therefore it is a good target for highly targeted drug therapy. Ongoing research is being conducted to inhibit proliferation by targeting OLIG 2.⁵⁸

The challenge of highly targeted drug therapy is getting through the BBB. Researchers are developing scaffolds for growing cell cultures, using polymers as carriers to transport drugs into the brain, and even using viruses. Preliminary studies have shown the Zika virus, devastating to the neural precursor cells in the developing fetus, seeks out and kills glioblastoma stem cells relative to normal neuronal cells.⁵⁹ Natural bioactive compounds, including retinoids and cannabis, have been shown to inhibit cell proliferation and migration in cultures of human glioblastoma.^{60,61}

The FDA has begun Phase 0 advanced clinical trials, allowing new drugs to be entered into clinical trials with a smaller number of subjects much sooner. One such drug, AZD1775, was given to a recurrent glioblastoma patient prior to craniotomy resection to assess whether the drug had reached the tumor bed and was modulating as intended, thereby directing the course of further treatment.⁶²

Tumor treating fields (TTF) is an FDA-approved antimitotic treatment modality that interferes with glioblastoma cell division and cellular assembly by delivering low-intensity, alternating electric fields to the tumor through transducer arrays applied on the shaved

Fig. 25.5 Tumor Treating Fields (TTF) Device. Courtesy of Novocure.

scalp, connected to a portable device (Fig. 25.5). Studies completed using TTF and Temozolomide have resulted in both longer progression-free survival and median overall survival than with chemotherapy alone.⁶³

REHABILITATION

Overview

Rehabilitation is a key component in the management of the patient with a brain tumor. With advances in technology and treatment intervention, survival rates of cancer patients with CNS involvement have improved over recent decades. Consequently, people are living longer with physical impairments resulting from the disease or its treatment, necessitating skilled therapeutic intervention.⁶⁴ The medical and psychological issues typically associated with cancer diagnosis are further complicated by loss of function and cognition specific to brain cancer. By preventing complications, maximizing function, and providing support, rehabilitation specialists ultimately improve the patient's quality of life.¹³ Research has shown that the functional outcomes and discharge to home for individuals with brain tumors are comparable to those of individuals with stroke or traumatic brain injury.⁶⁵ The most effective rehabilitation plan is flexible, to allow for increasing impairment, and sensitive, to accommodate the highly emotional impact that accompanies the diagnosis of a primary brain tumor. The tumor's invasion is marked by complaints of pain and growing activity limitations. These functional consequences of the disease process are the target of the rehabilitation team. In addition to the side effects of therapeutic intervention, functional progress may be affected by cerebral edema, hydrocephalus, tumor regrowth, infection, and radiation necrosis. Compared with patients with other diagnoses, patients with brain tumors have a higher rate of unplanned transfers back to acute care, primarily due to infection.⁶⁶

The management of a patient with a brain tumor is different from that of other CNS disorders, despite a similar clinical presentation. To establish an appropriate plan of care, the clinician must understand the nature of the specific tumor, consider the patient's fluctuating neurological status, and prepare for the likelihood of progressive decline. The preferred approach is holistic, addressing quality-of-life issues such as physical, psychosocial, and emotional needs,

incorporated into the systems model of motor control. Factors defining quality of life are unique to each individual, and therefore clinicians should identify and use these factors to construct a meaningful treatment program.⁶⁵ Individuals with advanced cancer who participated in exercise therapy have reported increased physical functioning, improved quality of life, and decreased fatigue.⁶⁷

Evaluation, clinical analysis, intervention, discharge planning, and psychosocial issues specific to the management of the patient with a brain tumor are discussed in the following sections.

Evaluation

The evaluation process must include a comprehensive examination and assessment of all systems in order to establish an appropriate impairment diagnosis, problem list, prognosis, and plan of care. Before a neurological assessment is performed, a thorough review of the patient's medical history and an understanding of the medical diagnosis are necessary. The patient's occupation, support system, personal goals, and role in the family are important psychosocial factors that should be identified in the evaluation. These factors, along with a thorough functional and neurological examination, assist the clinician through the diagnostic process. This process includes identification of clinical problems, establishment of realistic and appropriate goals, selection of the most effective intervention, and discharge planning.

Although the neurological examination yields important information regarding strength, reflexes, sensation, vision, and cognition, it is important not to rely solely on its findings to determine an appropriate intervention. Because multiple systems interact to produce normal movement, it is difficult to examine isolated systems and apply the findings accurately to movement patterns. Therefore clinicians are encouraged to examine all systems through functional tasks to understand how the impaired neurological, musculoskeletal, and cognitive systems are affecting the patient's movement. During the evaluation process, the clinician notes systems that are functioning normally, identifies abnormal components of movement, and determines appropriate interventions to optimize motor recovery.⁶⁷ The progressive nature of the disease necessitates ongoing assessment followed by accommodating treatment intervention.

Goal Setting

The functional impairments and objective neurological findings provide the clinician with valuable information to establish goals and determine a treatment plan based on the patient's anticipated functional level. Despite the progressive nature of the disease, treatment goals should maximize the potential for function, introduce effective, task-oriented movement strategies, and offer multiple movement options.⁶⁴

To set realistic and patient-oriented goals, it is important for the clinician to envision where the patient will be at discharge based on present level of function, prognosis, and disease course, while considering patient and caregiver personal goals. Appropriate goals range from comprehensive caregiver training to independent mobility with transition back to a work environment. Goals need to challenge the patient to attain an optimal level of function while also allowing for modifications due to disease progression. Patients who have the potential to return to work may require additional intervention from neuropsychology, vocational rehabilitation, or a multidisciplinary day program, depending on the nature of the job and the patient's specific deficits.

Because the rehabilitation potential for patients with brain tumors varies greatly, it is imperative that the patient, family members,

rehabilitation team, and third-party payers understand and agree with the purpose of the patient's rehabilitation program. If a patient has a poor prognosis, the rehabilitation team can successfully train family members and order equipment within 1 week if the family understands the goals and the need to be present during treatment sessions. The patient's prognosis should be considered to make an ethical decision that ensures that time in rehabilitation does not compromise valuable time at home with family.⁶⁴

Functional Assessment

Historically persons with primary malignant brain tumors have not been considered rehabilitation candidates because of the progressive nature of their disease. Physicians, health care providers, and third-party payers have questioned the efficacy of rehabilitation in this population because of poor prognoses and limited survival rates. However, advances in medical diagnosis and intervention are resulting in longer survival of people with multiple limitations that require rehabilitation. Functional assessment scales provide objective evidence that rehabilitation is effective and worthwhile for these patients.⁶⁴

The functional assessment is a critical component in the development of the treatment intervention. It provides a method of analyzing deficits, compiling a problem list, developing a treatment plan, and measuring functional outcomes. The Functional Independence Measure (FIM) is a functional assessment tool used to measure degree of disability, regardless of underlying pathology, and burden of care to demonstrate functional outcomes of rehabilitation and assist clinicians with discharge planning.⁶⁷

Functional outcome scales such as the FIM provide a means of documenting the patient's response to therapy intervention for clinicians, physicians, and third-party payers in the rehabilitation setting. Research using FIM data demonstrates efficacy for inpatient rehabilitation of brain tumor patients similar to that noted in those with traumatic brain injury or stroke when matched by age, sex, and functional status on admission.^{64,68} In 2016, the Center for Medicare and Medicaid implemented a new functional outcome measure; however, these studies have not yet been published.⁶⁹

Physicians use specific functional evaluation scales to measure the success of treatment. The Karnofsky performance scale, which rates patients' functional performance, is the tool most widely used in clinical research and treatment decisions (see [Table 25.1](#)). The patient receives a score from 0 to 100 based on independence or level of assistance required for normal activity. The scale is used in research to evaluate an individual's physical response to treatment.¹³

Side Effects and Considerations

Through advances in chemotherapy and radiation therapy, the ability to reduce tumor mass has greatly improved. Unfortunately, despite the often favorable long-term results of these treatments, the immediate effects create physical and psychological challenges for the patient and clinician. Patients who are receiving aggressive tumor treatment during the rehabilitation phase will probably experience a decline in neurological or hematological status. These declines often limit the individual's tolerance for treatment intervention and increase patient and caregiver feelings of depression and hopelessness. Clinicians have the opportunity to provide more than physical restorative services and should offer psychosocial support when possible to enhance successful rehabilitation.⁶⁷

The side effects and special considerations that arise with this population range from physical to cognitive to psychosocial and emotional. The following paragraphs relate the spectrum of complications

and side effects the patient may experience when undergoing medical treatment, and the impact these may have on therapeutic intervention.

Not everyone undergoing chemotherapy or radiation treatment will experience physical side effects; however, the possibilities include hair loss, fatigue, nausea, skin burns or irritation, difficulty eating or digesting food, anorexia, and dry, sore mouth.^{67,70} The side effects are caused by the toxic effects the drugs have on healthy, rapidly dividing cells, including bone marrow cells, cells lining the mucosa, and hair cells.⁷⁰

The toxic effect chemotherapy has on bone marrow impairs the patient's ability to produce red and white blood cells and platelets.² The patient may develop anemia, infection, or hemorrhage as a result of depressed hematological values.

The lining of the mouth, esophagus, and intestines may become inflamed and irritated and interfere with the ability to eat or digest food. The patient may experience nausea, vomiting, diarrhea, or constipation, any of which will impair mobility and energy for daily activities.⁶⁷

Hair loss is a common side effect of brain radiation and chemotherapy. This requires an especially difficult adjustment for most people, because it causes a drastic change in appearance.⁴¹

Clinicians involved in the management of patients who are currently receiving radiation therapy or chemotherapy need to be mindful of these side effects when developing a plan of intervention. Fatigue, low blood count, and gastrointestinal complaints may limit a patient's ability to fully participate in the planned therapy session or may call for a modification in activity or environment.⁷¹ Moreover, the clinician must use these factors to determine if the patient's health or safety would be jeopardized by therapeutic intervention at any particular time. In addition, the clinician must be flexible to determine the optimal time when intervention is most effective and does not interfere with medications or meals.

Together with the physical side effects mentioned previously, many patients with brain tumors have changes in cognition or personality as a result of the tumor's location. A patient with a frontal lobe tumor who was previously quiet and withdrawn may, over time, become loud and disinhibited as a result of tumor growth. Tumors that invade the speech-language area cause communication and comprehension difficulties that create challenges for the patient and clinician. The patient who has a left parietal tumor may be aphasic and not respond to verbal commands. In this case, the clinician must engage in alternate means of communication or provide therapeutic facilitation with tactile cues. An observant, critical analysis of the patient's physical deficits and impaired communication, comprehension, and feedback mechanisms is essential to select an effective, patient-specific intervention plan.

Because of the emotionally charged nature of the disease process, psychosocial and emotional issues frequently arise. Clinicians should be sensitive to fluctuations in temperament and mood that the diagnosis itself and subsequent treatment strategies create. Clinicians can offer psychosocial support and direct the patient and family to resources that may give direction and guidance during difficult transitions.

Intervention

The ultimate goal of rehabilitation is to achieve maximum restoration of function, within the limits imposed by the disease, in the patient's preferred environment. The clinician must recognize that the physical, cognitive, and emotional status of these individuals is inconsistent and changing as a result of the disease process or medical intervention. Treatment plans must be flexible to effectively manage fluctuations in the patient's presentation. A comprehensive rehabilitation plan is

individualized to accommodate progressive changes in functional mobility and provides problem-solving experiences to prepare the patient and caregiver for these situations. The rehabilitation process typically begins in the intensive care unit and continues in the inpatient, outpatient, and home health settings.

In the intensive care unit, communication with nursing staff regarding the patient's present medical status and an understanding of ICP, hemodynamic values, and monitoring devices are crucial to determining tolerance for therapy intervention (Fig. 25.6). Mobilizing a patient with a ventriculostomy (a catheter placed in the third ventricle to drain CSF and to monitor ICP) is possible; however, nursing staff must close the drain before any positional change and should inform the clinician of appropriate treatment parameters. A patient's dependence on these monitoring devices does not prevent therapeutic intervention, but the critical status of these individuals must be considered. The monitoring equipment provides constant feedback that assists the clinician in assessing the patient's tolerance to activity and his or her ability to proceed with treatment.

As the patient becomes more medically stable, the clinician progresses mobility and prepares the patient for the next stage of rehabilitation. Despite the patient's upgraded medical status allowing for transfer to the rehabilitation setting, clinicians must continue to reassess functional and neurological status and alert physicians to any changes. Clinicians spend many hours with patients, and these daily interactions give them the opportunity to connect on a personal level and observe the patient in different settings. Intuitive therapists are often the first to notice physical, cognitive, and emotional changes. Communication to the physician of significant changes is imperative for appropriate follow-up procedures and referrals to provide optimal care.

In the inpatient rehabilitation setting, treatment focuses on optimizing functional capabilities to prepare the patient and family for discharge. Integrating the patient's personal goals and interests into therapeutic intervention invests the patient and family in the rehabilitation process. The incorporation of these quality-of-life issues encourages the pursuit of a meaningful lifestyle at discharge. If clinicians believe the patient's goals are unrealistic, gentle redirection is helpful to channel energy toward achievable goals. Goals for inpatient rehabilitation range from returning the patient to an independent lifestyle to training family members to be caregivers in the home environment.

The restoration of previous functional movement patterns is desired. The literature reports increasing evidence that the CNS has dynamic properties, including neural regeneration and collateral

sprouting, which supports the concept of plasticity. Plasticity allows intact neural centers to recognize and assume functions of areas of the brain impaired or destroyed by the lesion or its medical management. The treatment focus may need to turn to compensatory strategies if the potential for motor recovery and learning is lacking. Once compensatory patterns are established, it is not clearly known whether recovery of normal movement will be achieved.^{72,73} Compensatory techniques may be beneficial in increasing safety and efficiency with mobility and activities of daily living (ADLs), or in providing more independence for the patient. Increasing independence can assist in improving quality of life for the patient and may permit return to work or participation in previous recreational activity. For example, an avid golfer with right-sided hemiparesis and impaired standing balance can modify his clubs and return to the game at the wheelchair level.

The rehabilitation program should prepare the patient and caregivers for an efficient transition from the structured care setting to the home. Using motor learning principles (refer to Chapter 3) to teach functional mobility will best produce transfer of learning from a constant environment to an unpredictable home environment. Repetitious practice of specific parts of a skill in fixed surroundings, with physical and verbal guidance throughout the movement and frequent feedback during and after completion of the task, are beneficial in teaching acquisition of a specific movement or activity.^{74,75} Recently, clinicians have incorporated more technology into treatments, including robotics to allow patients to perform high repetitions of movements with feedback mechanisms to promote motor learning. Studies have shown more accurate movement and positive affective responses of patients after ambulating with robotic-assisted gait training. Although research with robotics has focused on patients with spinal cord injury and stroke, the same principles can be applied to patients with brain tumors.⁷⁶⁻⁷⁸

Practicing the whole activity in a variable context, with irregular feedback and decreased physical and verbal guidance, expedites learning.⁷⁴ Learning results in the ability to execute a task in any setting. Community outings and home passes naturally provide an environment that facilitates learning. The clinician can measure retention and transfer of learning by the patient's performance in the community or at home. This information should be used to adjust the treatment plan and make recommendations for environmental modifications that minimize physical and cognitive demands on the patient. A patient whose individual treatment focus is transfers gains confidence when able to transfer from a wheelchair to a table chair in a crowded restaurant.

Fig. 25.6 A Patient After a Partial Tumor Resection. Labels indicate the equipment commonly seen in the neurological intensive care unit.

An interdisciplinary team approach is used for community reentry to provide a meaningful experience for the patient. Recreational therapists play an integral part in identifying the individual's interests, reintegrating the patient into the community, and modifying leisure activities to meet physical abilities. Activities addressed in daily therapy sessions are practiced in the community, and feedback is provided to the appropriate clinician as well as the patient. Initial reentry into the community can be intimidating to the patient and may cause changes in the patient's behavior that will affect mobility performance. Therefore it is necessary for the clinician to be sensitive and recognize the issues the patient may be experiencing.

For caregiver training and education to be successful, a good rapport must be established among clinician, patient, and the family members or caregivers. Caregiver training includes mobility training and education regarding the effect the tumor may have on the patient's present and future mobility. Instruction should be given based on present level of function, but the probability of progressive decline should not be overlooked. An intuitive clinician should offer effective techniques and problem-solving to address potential obstacles created by the disease process. For example, when performing transfer training, the clinician may demonstrate a stand-pivot transfer but may also suggest a squat-pivot transfer if physical or cognitive changes mandate increased assistance by the caregiver.

Discharge Planning

Discharge planning is initiated early, continues throughout the rehabilitation process, and must allow for changes in the patient's functional status. On discharge from the rehabilitation setting, the patient will make the transition to one of the following settings: home, skilled nursing facility, or hospice. The transition to home is typically preferred by the patient, caregiver, and interdisciplinary rehabilitation team. If the patient cannot be physically or medically managed at home, then placement in a skilled nursing facility may be necessary. The patient may choose hospice care when medical treatment is no longer providing control of the tumor and the physical demands of the patient are not manageable by the caregivers. The case manager contacts insurance providers to determine coverage and, after conferring with the interdisciplinary team, gives the patient and family information regarding discharge options.

Patient and caregiver training and education constitute an integral part of discharge planning. Before discharge, the patient and caregiver should be instructed in functional mobility and ADLs, informed of equipment needs and vendor resources, and provided with community resources for support and education. During individual training, the clinician is able to provide feedback to the caregiver and patient to facilitate an easier transition to home. Documentation of caregiver education and training should be included in the progress and discharge notes.

Equipment necessary to assist the patient and family with mobility and ADLs is recommended by the appropriate clinician. When equipment is ordered, fluctuations in the patient's present status, as well as the probable progressive decline in function, are considered. If the patient is functioning without equipment at discharge, it is helpful to include resources of local charitable organizations and vendors for future equipment needs.

Prior to discharge, local and national resources specific to brain tumors should also be provided. These resources can be found on the internet or through communication with previous patients or health care professionals. Support groups provide the caregiver and the patient with an opportunity to share experiences and information, prevent isolation, foster hope, allow the patient and caregiver to discover coping skills, and offer emotional support.^{79,80} National

organizations can provide educational information and support to patients (Box 25.1). These organizations can help the patient find local resources unfamiliar to the clinician.

PALLIATIVE CARE AND HOSPICE

As the disease process progresses, the patient and family often are faced with difficult decisions. When the prevalence of symptoms increase, and antitumor treatment is no longer effective, the end-of-life (EOL) phase has begun. During this phase, care is focused on reducing symptom burden while preserving quality of life, without inappropriate prolongation of life.⁸¹ Both palliative care and hospice are resources that can provide support to patients and their families.

Palliative care provides for patients and families who are facing a life-threatening illness. The American Board of Medical Subspecialties has recognized palliative care since 2006. Palliative care is multidisciplinary care addressing the complex medical decisions necessary to identify patient and caregiver wishes regarding the prevention of suffering and EOL. The physical therapist focus is on mobility, caregiver training, and positioning to alleviate pain and promote comfort. Palliative care should be introduced early, soon after diagnosis, especially with a high-grade glioma. Due to the high likelihood of cognitive decline, possible seizures, and decreased consciousness as the disease progresses, sensitive EOL preferences and decisions need to be discussed early to ensure caregivers, if necessary, are aware and able to fulfill the patient's wishes.⁸¹ Palliative care services may continue for a prolonged period of time until the illness is no longer deemed life threatening or the patient and family have decided to no longer seek curative treatment, choosing hospice.

Hospice always provides palliative care; however, patients choose hospice when they are no longer seeking curative therapy. Hospice refers to a type of care, not a place. Hospice care can be provided in the patient's home, in the hospital setting, in long-term care or nursing homes, or in freestanding hospice facilities. The hospice philosophy centers around the belief that we all have the right to die without pain and with dignity, and our loved ones are provided with the support they need to allow us to do so.⁸² The dying patient experiences physical, psychological, social, and spiritual aspects of suffering. The hospice team is fully equipped and trained to support the primary caregiver (usually a family member) with a variety of services.

PSYCHOSOCIAL CARE

For many patients living extended lives with brain tumors, it is important to measure the efficacy of treatment not only in terms of functional outcome, but in terms of its effect on quality of life. *Health-related quality of life* (HRQOL) is a multidimensional concept

that refers to an individual's functioning and well-being as measured by a personal perception of overall quality of life, including physical, emotional, spiritual, and intellectual functioning.⁸³ Despite advances, malignant brain tumors and metastases remain incurable. The treatment goal is to extend a patient's survival. Therefore in addition to overall survival, progression-free survival, and radiological response to treatment, HRQOL has become an important outcome measure. Recently, several self-reporting instruments to measure HRQOL specific for individuals with brain tumors have been developed.⁸⁴

A strong supportive relationship with the patient and caregiver(s) is key to successful rehabilitation. This process begins with respecting the patient's unique experience and requires continual assessment of changing psychosocial needs. Many individuals with brain tumors experience higher levels of anxiety and depression, as well as feelings of loss, specifically loss of independence, loss of self, and loss of relationships.⁸⁵ Most people have a family, community, or belief system they identify with, and the acknowledgement and involvement of that bond should be part of their treatment.⁸⁶ The burden and strain on direct caregivers and family members can be devastating. The clinician must feel invested, demonstrate good communication skills, and exhibit self-confidence in the ability to discuss sensitive issues with the patient and family in order to develop a caring relationship. By active listening, the clinician can identify the patient's true concerns and feelings and assist the patient and family in coping with the cancer diagnosis. The clinician's consistent interaction with the patient can foster a supportive and safe environment in which the patient or caregiver feels comfortable sharing emotional and spiritual feelings. Once a trusting relationship has been established,

the clinician's empathy can help decrease common feelings of isolation and helplessness and support the patient through the different stages of the disease.⁸⁶

Hope is a key psychosocial need of the individual with cancer. It is an important coping strategy that can help patients with brain tumors face an uncertain and often fearful future. Clinicians working with brain tumor patients should see the preservation of hope as a therapeutic goal. A high level of hope for both the patient and family corresponds positively to a sense of well-being and good quality of life.⁸⁷ The clinician needs to maintain some degree of hope while remaining as realistic and honest as possible, focusing on short-term goals and functional improvements that are both achievable and meaningful to the patient.⁸⁷

Psychological and social problems are not identified in 80% of physically ill persons, possibly owing to clinicians' personal behaviors or beliefs. Clinicians may find it easier to focus on the physical aspect of care to avoid becoming emotional or experiencing the patient's distress. Persons with cancer often experience feelings of powerlessness and isolation, which may be increased by distancing behaviors demonstrated by clinicians. Before offering support to patients, clinicians need to examine their own thoughts, feelings, and past experiences with death and dying. This awareness may prevent the clinician from internalizing the patient's grief, from protecting the patient and family members from the pain of grieving, and from allowing personal values to adversely influence their psychosocial support.⁸⁶ By recognizing that psychosocial care involves holistic healing, clinicians will be able to develop the best environment for interventions to improve multiple aspects of the patient's quality of life.⁸⁶

SUMMARY

It is important for the clinician involved in the treatment of a patient with a brain tumor to anticipate the physical and cognitive deficits and the subsequent activity limitations that will develop as the patient deteriorates from the tumor progression or medical treatment. These limitations provide the foundation for treatment planning and goal setting. Improved quality of life is the goal of the rehabilitation process. This means restoring the patient to maximal functional capacity

with the least amount of assistance from others. Regardless of the patient's life expectancy, the rehabilitation process should enable the patient to pursue a productive and meaningful life. Case Study 25.1 is an example of the complexity of the problems faced by an individual with a CNS tumor. These problems include both the medical condition and the functional activity limitations caused by the tumor and/or the medical management.

CASE STUDY 25.1 Medical Diagnosis: Metastatic Brain Tumor

Mr. S is a 66-year-old man diagnosed 13 years ago with melanoma, without lymph node involvement. He lived in Austria for 25 years, working in finance for the United Nations. Last July, he began to experience dizziness, mild weakness, and unsteadiness. He was diagnosed with a right frontal brain tumor and underwent a surgical resection (craniotomy) followed by WBRT in Austria. After surgery, he required a quad cane for ambulation; however, he was able to return to most activities of daily living (ADLs) except driving, due to his history of seizures. Prior to his initial diagnosis and surgery, he enjoyed playing squash, hiking, and "doing taxes."

Mr. S retired and returned to the United States in October to seek further cancer treatment and began taking Keytruda (pembrolizumab). In February, after progressive left hemiparesis, twitching, and numbness, diagnostic imaging revealed a large recurrent metastatic tumor in his right frontal lobe, causing cerebral edema and brain compression. He underwent a second craniotomy to resect this large tumor, situated directly adjacent to his primary motor strip. Postoperatively, he underwent CyberKnife radiosurgery to target five new areas of metastases. The following week, he was admitted to the neurorehabilitation

unit to address his functional deficits due to impaired strength, coordination, balance, and motor planning.

Initially, he presented with impaired balance and motor planning impacting all ADLs and mobility. He required moderate assistance for bed mobility, maximal assistance for stand pivot transfers with a front-wheeled walker (FWW), and could ambulate only 5 feet with a FWW and maximal assistance, demonstrating shortened, inconsistent step length and left knee hyperextension during stance phase. After only a short week, his activity tolerance, high-level balance, and coordination significantly improved. He reached a functional level of modified independence for ADLs and ambulation on indoor, even surfaces using a four-wheeled walker. He required supervision in busy environments and on uneven surfaces due to impaired attention/concentration and intermittent decreased left-foot clearance with fatigue. At this point, Mr. S was discharged home with his brother and sister-in-law, after his family demonstrated safe proficiency, assisting him with all mobility tasks including ambulation, stair/curb negotiation, and car transfers. He continued to make slow but steady gains with physical and occupational therapy twice a week in the outpatient setting.

CASE STUDY 25.1 Medical Diagnosis: Metastatic Brain Tumor—cont'd

Mr. S returned to visit friends in Austria in June; however, he was forced to return home when his hemiparesis worsened. He had Gamma Knife Radiosurgery without significant improvement. Imaging revealed additional metastases and an increase in cerebral edema near the right frontal metastasis. This July he underwent his third craniotomy (this time a bifrontal craniotomy) to resect a right paramedian metastatic tumor. A few days after surgery, once again he returned to the neurorehabilitation unit.

It was a smooth transition back to rehab, as he was familiar with the process, the facility, and the staff; however, Mr. S's neurological deficits were significantly worse than at his previous admission. He required maximal assistance for bed mobility, maximal assistance of two for transfers, and moderate to maximal assistance for ADLs. He returned to rehab with a positive attitude, motivated to do his best despite the progression of his metastatic disease and his poor functional mobility. The therapists quickly positioned Mr. S. in a wheelchair and

instructed him in wheelchair propulsion to provide him with some degree of independence; however, this task proved challenging due to his poor motor planning. The rehab team incorporated traditional treatment interventions with newer technology to allow him to perform movements that otherwise he was dependent or required maximal assistance to complete. For example, the occupational therapist utilized the Diego to perform active assisted arm exercises with a feedback monitor. With the assistance of the EKSO, the physical therapist was able to work with him on standing balance, weight shifting, and gait training. Assisted walking in the EKSO provided him with a sense of pride and accomplishment, as well as motivation to continue. As the weeks passed and Mr. S continued to need maximal assistance for mobility, it became clear that to maximize his independence and safety, he would need to discharge home at the wheelchair level. After many sessions of family training, ordering of adaptive equipment, and a wheelchair, he was discharged home with his family.

Abstract: The rehabilitation clinician serves many different populations, including patients with brain tumors. Despite the prognosis for limited survival associated with primary brain tumors, these individuals have shown progress in the rehabilitation setting similar to that noted in patients with diagnoses of stroke or traumatic brain injury.¹ Advances in medical and surgical treatment for patients with cancer have resulted in improved survival rates and longer life expectancy, yet only incremental improvements for patients with brain tumors.² Progressive impairments, physical or cognitive or both, result from the disease process and require an interdisciplinary team approach to

best facilitate the individual's participation in a meaningful lifestyle. In addition, clinicians must recognize the psychological and emotional needs of the individual given this diagnosis, and be sensitive and flexible in accommodating the patient's feelings. Improved quality of life, especially the opportunity to return home, remains the ultimate goal of the rehabilitation process.

Inflammatory and Infectious Disorders of the Brain

Judith A. Dewane

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify and comprehend the terminology for classifying different types of inflammatory and infectious disorders within the brain.
2. Discuss the range of neurological sequelae that occur.
3. Discuss the components of the comprehensive evaluation process and their interrelationships.
4. Structure the examination process to gather the information required to generate an appropriate plan of care.
5. Discuss the general goals of the intervention process.
6. Plan the interventions to meet the needs of the patient.

KEY TERMS

brain abscess
encephalitis
functional activities

hypertonicity
hypotonicity
intervention goals

meningitis
postural control

The diversity of neurological sequelae that may occur after an inflammatory disorder in the brain (brain abscess, encephalitis, or meningitis) provides a range of challenges to the rehabilitation team. The therapist must identify the problems underlying the individual's movement dysfunctions without the template of the cluster of "typical" problems available with some other neurological diagnoses. Each patient presents a combination of problems unique to that patient that requires the creative design of an intervention program. The following discussion of the therapeutic management of individuals recovering from an inflammatory disorder in the brain focuses on the process of designing an intervention plan to address the specific dysfunctions of the individual patient. Because the management of the clinical problems is built on an understanding of the underlying pathological condition and because therapists may not be as familiar with these disease processes, an overview of the inflammatory disorders of the brain is presented.

OVERVIEW OF INFLAMMATORY DISORDERS IN THE BRAIN

Categorization of Inflammatory Disorders

Inflammatory disorders of the brain can be categorized based on the anatomical location of the inflammatory process and the cause of the infection, which are as follows:

- A. Brain abscess
- B. Meningitis (leptomeningitis)
 1. Bacterial meningitis
 2. Aseptic meningitis (viral)
- C. Encephalitis
 1. Acute viral
 2. Parainfectious encephalomyelitis

3. Acute toxic encephalopathy
4. Progressive viral encephalitis
5. "Slow virus" encephalitis

In most individuals, the defense mechanisms of the central nervous system (CNS) provide protection from infecting organisms. Compromises of the protective barriers can result in CNS infections as complications of common infections. The response of the CNS to the infection depends on several factors, including the type of organism, its route of entry, the CNS location of the infection, and the immunological competence of the individual. CNS infections occur with greater frequency and severity in individuals who are very young or elderly, immunodeficient, or antibody deficient.

The inflammatory process may be a localized, circumscribed collection of pus; may involve primarily the leptomeninges; may involve the brain substance; or may involve both the meninges and the brain substance. The infecting agents may be bacteria, viruses, prions, fungi, protozoa, or parasites. The most common agents producing meningitis are bacterial; the most common agents producing encephalitis are viral. However, bacterial encephalitis and viral meningitis also are disease entities. The following overview of the inflammatory processes within the brain is organized based on the anatomical location of the infection. More comprehensive discussions based on specific infecting organisms can be found in the references at the end of the chapter.¹ The site of the infection will determine the signs and symptoms of the CNS infections, whereas the infecting organism determines the prognosis, including the time course and severity of the problems.²

Brain Abscess

Brain abscesses occur when microorganisms reach brain tissue from a penetrating wound to the brain, by extension of local infection such as sinusitis or otitis, or by hematogenous spread from a distant site of

infection. The route of infection influences the CNS region involved. The extension of a local infection tends to produce a solitary brain abscess in an adjacent lobe. Multiple abscesses may originate from the spread of microorganisms through the blood. The introduction of microorganisms by a penetrating trauma may result in an abscess soon after the trauma or several years later. As with the disorders presented in the subsequent discussions, circumstances that result in a compromised immune system (chronic corticosteroid or other immunosuppressive drug administration, administration of cytotoxic chemotherapeutic agents, or human immunodeficiency virus [HIV] infection) may predispose the individual to develop opportunistic infections.

The site and size of the abscess influence the initial symptoms. Evidence of increased intracranial pressure, a focal neurological deficit, and fever are described as the classic presenting triad.³ However, the classic triad occurs in less than 50% of patients.⁴ Most individuals experience an alteration of consciousness. In 47% of the cases, the frontal, parietal, or temporal lobe is involved.^{4,5} Medical management of the abscess typically consists of antibiotic therapy (depending on the infecting agent and size and site of the abscess) and, often, surgical aspiration or excision. Bharucha and colleagues³ describe neurological sequelae in 25% to 50% of the survivors, with 30% to 50% having persistent seizures, 15% to 30% having hemiparesis, and 10% to 20% having disorders of speech or language.

Meningitis

Meningitis (synonymous with leptomeningitis) denotes an infection spread through the cerebrospinal fluid (CSF) with the inflammatory process involving the pia and arachnoid maters, the subarachnoid space, and the adjacent superficial tissues of the brain and spinal cord. Pachymeningitis denotes an inflammatory process involving the dura mater. Meningitis can be caused by a wide variety of organisms, some of which cross the blood-brain barrier and the blood-CSF barrier. The CSF also can become contaminated by a wound that penetrates the meninges as a result of trauma or a medical procedure, such as implantation of a ventriculoperitoneal (VP) shunt. Once the organism compromises the blood-brain and blood-CSF barriers, the CSF provides an ideal medium for growth. All the body's typical major defense systems are essentially absent in the normal CSF. The blood-brain barrier may

impede the clearance of infecting organisms by leukocytes and interfere with the entry of pharmacological agents from the blood. The infecting organism is disseminated throughout the subarachnoid space as the contaminated CSF bathes the brain. Entry into the ventricles occurs either from the choroid plexuses or by reflux through the exit foramen of the fourth ventricle. The spread of the organism through the CSF circulation accounts for the differences in the variety and extent of the neurological sequelae that can result from meningitis.

Bacterial meningitis.

Clinical problems. The diagnostic categorization of meningitis depends on the infecting agent (e.g., *Haemophilus influenzae* meningitis, *Streptococcus pneumoniae* meningitis, and viral meningitis) and on the acute or chronic nature of the meningitis (acute, subacute, or chronic meningitis). The term *acute bacterial meningitis* denotes infections caused by aerobic bacteria (both gram-positive and gram-negative).^{5,6} The most common infecting organism producing acute bacterial meningitis varies according to the age of the population. During the neonatal period and in the older adult, infections by gram-negative enterobacilli, especially *Escherichia coli*, and group B streptococci occur most frequently. Typical causative agents in children include *H. influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*.⁷ *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* are the most common causes of community-acquired meningitis.^{5,7,8} Individuals with a condition such as sickle cell anemia, alcoholism, or diabetes mellitus and individuals who are immunosuppressed are at increased risk.^{1,9} Meningococci have been implicated in meningitis that strikes young children most often but can also infect adolescents and young adults. Freshman who live in dormitories are almost four times more likely to get meningitis when compared with other college students.

An example of an organism that uses a typical systemic route of bacterial infection is the *H. influenzae* organism—a member of the normal flora of the nose and throat. During an upper respiratory tract infection, the organism may gain entry to the blood. The route of transmission of the organism from the blood to the CSF is not well established.

The circulation of CSF spreads the infecting organism through the ventricular system and the subarachnoid spaces (Fig. 26.1). The pia and arachnoid maters become acutely inflamed, and as part of the

Fig. 26.1 The meninges, showing the layers of the dura, arachnoid, and pia mater and their relationship to the subarachnoid space and brain tissue. CNS, Central nervous system.

inflammatory response, a purulent exudate forms in the subarachnoid space. The exudate may undergo organization, resulting in an obstruction of the foramen of Monro, the aqueduct of Sylvius, or the exit foramen of the fourth ventricle. The supracortical subarachnoid spaces proximal to the arachnoid villi may be obliterated, resulting in a noncommunicating or obstructive hydrocephalus caused by the accumulation of CSF. As the CSF accumulates, the intracranial pressure rises. The increased intracranial pressure produces venous obstruction, precipitating a further increase in the intracranial pressure. The rise in the CSF pressure compromises the cerebral blood flow, which activates reflex mechanisms to counteract the decreased cerebral blood flow by raising the systemic blood pressure. An increased systemic blood pressure accompanies increased CSF pressure.

The mechanism producing the headaches that accompany increased intracranial pressure may be the stretching of the meninges and pain fibers associated with blood vessels. Vomiting may occur as a result of stimulation of the medullary emetic centers. Papilledema may occur as intracranial pressure increases.

Other routes of bacterial infection may involve a local spread as the result of an infection of the middle ear or mastoid air cells. Meningitis may occur as a complication of a skull fracture, which exposes CNS tissue to the external environment or to the nasal cavity. Fractures of the cribriform plate of the ethmoid bone producing CSF rhinorrhea provide another route for infection. Meningitis may be a further complication to the clinical problems of a traumatic head injury.

Clinical features of acute bacterial meningitis include fever, severe headache, altered consciousness, convulsions (particularly in children), and nuchal rigidity. Nuchal rigidity is indicative of an irritative lesion of the subarachnoid space. Signs of meningeal irritation are painful cervical flexion, the Kernig sign, the Brudzinski sign, and the jolt sign.¹⁰ Cervical flexion is painful because it stretches the inflamed meninges, nerve roots, and spinal cord. The pain triggers a reflex spasm of the neck extensors to splint the area against further cervical flexion; however, cervical rotation and extension movements remain relatively free.

The *Kernig sign* refers to a test performed with the patient supine in which the thigh is flexed on the abdomen and the knee extended (Fig. 26.2A). Complaints of lumbar or posterior thigh pain indicate a positive test result.¹⁰ This movement pulls on the sciatic nerve, which pulls on the covering of the spinal cord, causing pain in the presence of meningeal irritation. The same results are achieved with passive hip flexion with the knee remaining in extension. This is the same procedure described by Hoppenfeld¹¹ as the straight leg raising test for determining pathology of the sciatic nerve or tightness of the hamstrings. Passive hip flexion with knee extension can be painful because of meningeal irritation, spinal root impingement, sciatic nerve irritation, or hamstring tightness. The *Brudzinski sign* refers to the flexion of the hips and knees elicited when cervical flexion is performed (see Fig. 26.2B).¹⁰ These signs will not be present in the deeply comatose patient who has decreased muscle tone and absence of muscle reflexes. The signs may also be absent in the infant or elderly patient. Finally, the jolt test, which has the patient turn his or her head from side to side quickly (two to three rotations per second), has a positive result if the maneuver worsens the patient's headache.¹⁰

The diagnosis of bacterial meningitis can be established based on blood cultures and a sample of CSF obtained by a lumbar puncture. CSF pressure is consistently elevated. The CSF sample in bacterial meningitis typically reveals an increased protein count and a decreased glucose level.

The type and severity of the sequelae of acute bacterial meningitis relate directly to the area affected, the extent of CNS infection, the age and general health of the individual, the level of consciousness at the

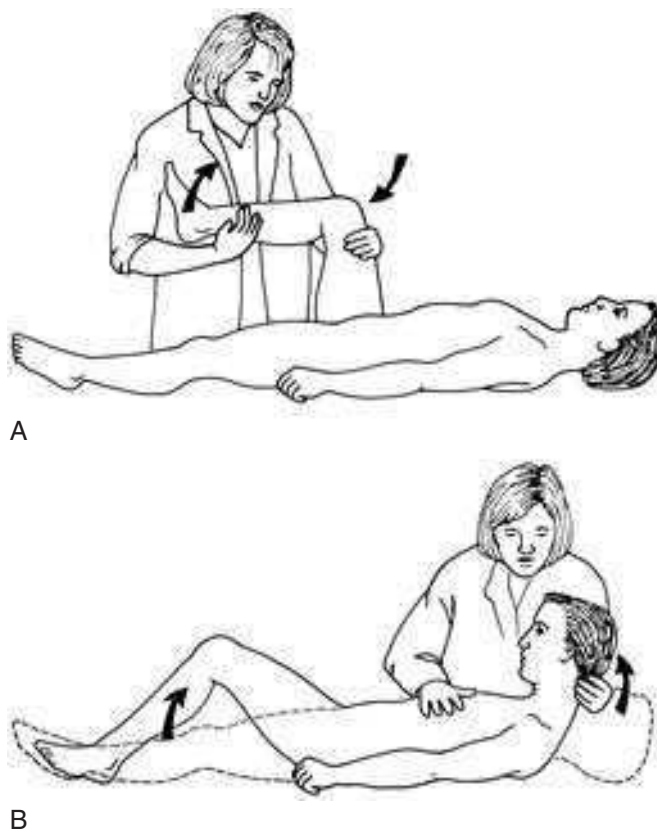

Fig. 26.2 (A) Kernig sign. (B) Brudzinski sign.

initiation of pharmacological therapy, and the pathological agent involved. Some of the common CNS complications include subdural effusions, altered levels of consciousness, seizures, involvement of the cranial nerves, and increased intracranial pressure.

Medical management. Medical management of bacterial meningitis consists of the initiation of the antimicrobial regimen appropriate to the infecting organism and procedures to manage the signs and symptoms of meningitis that have been described in the preceding paragraphs. Medical intervention strategies in both these areas change with the development of new pharmacological agents. Thus medical management can change within short periods. The reader is encouraged to always review recent literature for additional information on current aspects of the medical management of the patient with meningitis.

Prevention. Vaccination has significantly decreased the incidence of meningitis from *H. influenzae* type B in young children and infants. College freshmen who live in dormitories are four times more likely than other college students to develop meningococcus meningitis, and there is now a vaccine that has shown promise in reducing the outbreak rate.

Potential neurological sequelae. Even with optimal antimicrobial therapy, bacterial meningitis continues to have a finite mortality rate, which varies with the infecting organism, age of the individual, and time lapse to initiation of treatment, and has the potential for marked neurological morbidity. Neurological sequelae occur in 20% to 50% of the cases.^{1,9} Bacterial meningitis is considered a medical emergency; delays in initiation of antibacterial therapy increase the risk of complications and permanent neurological dysfunction.^{1,9}

Reports of the long-term outcome of individuals with bacterial meningitis indicate that up to 20% have long-term neurological

sequelae.^{1,5} The sequelae may be the result of the acute infectious pathological condition or subacute or chronic pathological changes. The acute infectious pathological condition could result in sequelae such as inflammatory or vascular involvement of the cranial nerves or thrombosis of the meningeal veins. Cranial nerve palsies, especially sensorineural hearing loss, are common complications. The risk of an acute ischemic stroke is greatest during the first 5 days.⁹ Weeks to months after treatment, subacute or chronic pathological changes may develop, such as communicating hydrocephalus, which manifests as difficulties with gait, mental status changes, and incontinence.^{10,12} Approximately 5% of the survivors will have weakness and spasticity.⁶ Focal cerebral signs that may occur either early or late in the course of bacterial meningitis include hemiparesis, ataxia, seizures, cranial nerve palsies, and gaze preference.^{1,13} Cognitive slowness has been found in 27% of patients after pneumococcal meningitis, even with good recovery as documented by a Glasgow Outcome Scale score of 5.¹⁴

Damage to the cerebral cortex can result in numerous expressions of dysfunction. Motor system dysfunction may be the observable expression of the damage within the CNS, but the location of the damage may include sensory and processing areas, as well as those areas typically categorized as belonging to the motor system. Perceptual deficits or regression in cognitive skills may present residual problems. Cranial nerve involvement is most frequently expressed as dysfunction of the eighth cranial nerve complex and produces auditory and vestibular deficits.

Aseptic meningitis. Aseptic meningitis refers to a nonpurulent inflammatory process confined to the meninges and choroid plexus, usually caused by contamination of the CSF with a viral agent, although other agents can trigger the reactions. The symptoms are similar to those of acute bacterial meningitis but typically are less severe. The individual may be irritable and lethargic and complain of a headache, but cerebral function remains normal unless unusual complications occur.^{5,15} Aseptic meningitis of a viral origin usually causes a benign and relatively short course of illness.^{16,17}

A variety of neurotropic viruses can produce aseptic (viral) meningitis. The enteroviruses (echoviruses and the Coxsackie viruses), herpesviruses, and HIV are the most common causes.^{5,7,18} The primary nonviral causes of aseptic meningitis are Lyme *Borrelia* and *Leptospira*.¹⁹ The diagnosis of this type of aseptic meningitis may be established by isolation of the infecting agent within the CSF or by other techniques. The glucose level of the CSF in bacterial meningitis is usually depressed; however, the glucose level in viral meningitis is normal.²

Treatment of aseptic meningitis consists of management of symptoms. The condition does not typically produce residual neurological sequelae, and full recovery is anticipated within a few days to a few weeks.

Encephalitis

Clinical problems. *Encephalitis* refers to a group of diseases characterized by inflammation of the parenchyma of the brain and its surrounding meninges. Although a variety of agents can produce encephalitis, the term usually denotes a viral invasion of the cells of the brain and spinal cord.

Different cell populations within the CNS vary in their susceptibility to infection by a specific virus. (For example, the viruses responsible for poliomyelitis have a selective affinity for the motor neurons of the brain stem and spinal cord. Viruses such as Coxsackie viruses and echoviruses typically infect meningeal cells to cause the benign viral meningitis discussed in the previous section.) In acute encephalitis, neurons that are vulnerable to the specific virus are invaded and undergo lysis. Viral encephalitis causes a syndrome of elevated temperature, headache, nuchal rigidity, vomiting, and general malaise (symptoms of aseptic or viral

meningitis), with the addition of evidence of more extensive cerebral damage such as coma, cranial nerve palsy, hemiplegia, involuntary movements, or ataxia. The difficulty in differentiating between acute viral meningitis and acute viral encephalitis is reflected in the use of the term *meningoencephalitis* in some cases.

The pathological condition includes destruction or damage to neurons and glial cells resulting from invasion of the cells by the virus, the presence of intranuclear inclusion bodies, edema, and inflammation of the brain and spinal cord. Perivascular cuffing by polymorphonuclear leukocytes and lymphocytes may occur, as well as angiitis of small blood vessels. Widespread destruction of the white matter by the inflammatory process and by thrombosis of the perforating vessels can occur. Increased intracranial pressure, which can result from the cerebral edema and vascular damage, presents the potential for a transtentorial herniation. The likelihood of residual impairment of neurological functions depends on the infecting viral agent. Patients with mumps meningoencephalitis have an excellent prognosis, whereas 20% to 60% of the individuals with herpes simplex encephalitis treated with acyclovir have some neurological sequelae.²⁰ Because of the slow recovery of injured brain tissue, even in patients who recover completely, return to normal function may take months.²¹

Plum and Posner²² discuss viral encephalitis in terms of five pathological syndromes. Acute viral encephalitis is a primary or exclusively CNS infection. An example would be herpes simplex encephalitis, in which the virus shows a partiality for the gray matter of the temporal lobe, insula, cingulate gyrus, and inferior frontal lobe. Other examples are the mosquito-borne viruses, such as St. Louis encephalitis, California virus encephalitis, and most recently West Nile virus (WNV). While from 1999 to 2005 in the United States, the incidence of infection from the WNV increased from 62 cases to 3000 cases, the incidence has decreased in recent years to 2097 cases in 2017.²³ Currently all states have some level of WNV activity, and only two states are without human cases (Fig. 26.3). The majority (80%) of people infected by the WNV will be asymptomatic; of the remaining people infected, less than 1% will develop severe illness.²³ Risk of neuroinvasive disease from WNV is 40%; neuroinvasive disease involves meningitis, encephalitis, or poliomyelitis, with wide variety in clinical presentation (Fig. 26.4).²⁴ Parainfectious encephalomyelitis is associated with viral infections such as measles, mumps, or varicella. Acute toxic encephalopathy denotes encephalitis that occurs during the course of a systemic infection with a common virus. The clinical symptoms are produced by the cerebral edema in acute toxic encephalopathy, which results in increased intracranial pressure and the risk of transtentorial herniation. Reye syndrome is an example. Global neurological signs, such as hemiplegia and aphasia, are usually present, rather than focal signs. The clinical symptoms of the previous three syndromes may be similar. Specific diagnosis may be established only by biopsy or autopsy.

Progressive viral infections occur from common viruses invading susceptible individuals, such as those who are immunosuppressed or during the perinatal to early childhood period. Slow, progressive destruction of the CNS occurs, as in subacute sclerosing panencephalitis. The final category of encephalitis syndromes consists of “slow virus” infections by unconventional agents (the prion diseases) that produce progressive dementing diseases such as Creutzfeldt-Jakob disease and kuru.²⁵

Medical management. The medical management of virally induced encephalitis has been, and with many infecting agents remains, primarily symptomatic. In some cases, intensive, aggressive care is necessary to sustain life. Pharmacological interventions are available to treat some viral infections, such as herpes encephalitis. The probability of neurological sequelae differs according to the infecting agent. Aggressive management of increased intracranial pressure is required

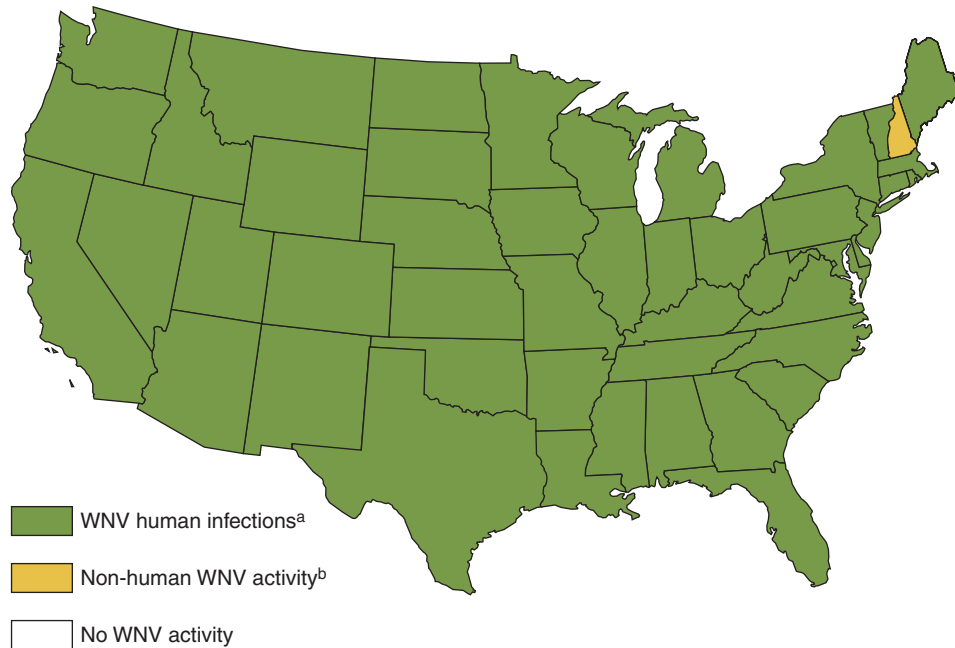

Fig. 26.3 West Nile virus (WNV) activity in the United States 2018. (From <https://www.cdc.gov/westnile/statsmaps/preliminarymapsdata2018/activitybystate2018.html>.)

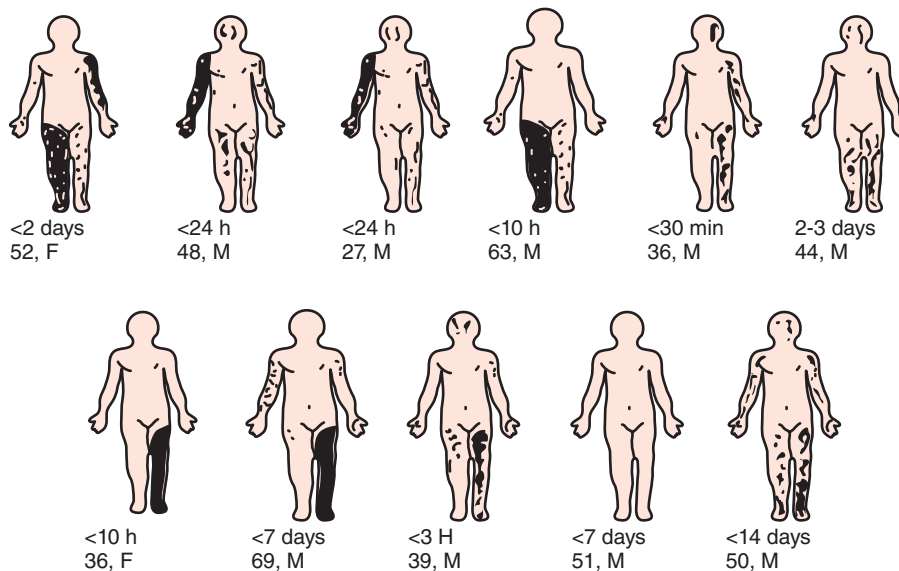

Fig. 26.4 Clinical Presentation of West Nile Virus. Weak limbs at the peak of paralysis are darkened. Degree of darkness corresponds to the severity of weakness. Duration of weakness and characteristics (age [years] and sex [F, female; M, male]) are listed below each patient. (From Cao NJ, Ranganathan C, Kupsky WJ, Li J. Recovery and prognosticators of paralysis in West Nile virus infection. *J Neurol Sci.* 2005;236:73–80.)

because persistently elevated intracranial pressure is associated with poor outcome.^{1,26} Further information concerning the clinical features, medical management, and potential for neurological sequelae of a specific type of encephalitis should be sought in the literature based on the infecting agent.

Clinical Picture of the Individual With Inflammatory Disorders of the Brain

An individual within the acute phase of meningitis or encephalitis or with residual neurological dysfunction from these disorders may demonstrate signs and symptoms similar to those of generalized brain

trauma, tumor disorder, or other identified abnormal neurological state. The variability in the clinical picture is reflected in the inclusion of the category “infectious diseases that affect the central nervous system” in the *Guide to Physical Therapist Practice*.²⁷ It is therefore important for return to optimal function and return to quality life that the therapist understands the impairments of body functions and structures, the patient’s activity limitations and participation restrictions, given the unique personal and environmental factors.

These concepts and selection of evaluation and intervention procedures are just as applicable for occupational therapists and other individuals working on movement dysfunction. In the acute phase the

inflammatory process may result in impairments in arousal and attention that range from nonresponsiveness to agitation. The degree of agitation may range from mild to severe, depending on both the patient's unique CNS characteristics and the degree of inflammation. The agitated state may be the result of alterations in the processing of sensory input, with the consequence of inappropriate or augmented responses to sensory input. The patient may respond to a normal level of sound as though it were an unbearably loud noise. Low levels of artificial light may be perceived as extremely bright.

Perceptual and cognitive impairments may be present, resulting in a variety of functional limitations and disabilities. Patients may have distortions in their perception of events as well as memory problems. As their memory returns, accuracy of time and events may be distorted, leading to frustration and anxiety for both the patient and those family members and friends who are interacting within the environment.

In addition to alterations in mentation, the individual may demonstrate impaired affect, such as a hypersensitivity or exaggerated emotional response to seemingly normal interactions. For example, when upset about dropping a spoon on the floor, a patient may throw the tray across the table. When another individual was told his girlfriend would be a little late for her afternoon visit, the patient became extremely upset and stated his intent to kill himself because his girlfriend did not love him anymore.

Because of the variety of pathological problems after acute inflammation, the patient may have residual problems manifested as generalized or focal brain damage. The specifics of these impairments cannot be described as a typical clinical picture because they are extremely dependent on the individual patient. These variations require the therapist to conduct a thorough examination and evaluation process to develop an appropriate individualized intervention program. Although content from the *Guide to Physical Therapist Practice* has been incorporated into the discussion of the examination, evaluation, and intervention processes, the model presented provides a structure that can accommodate the specific disciplinary expertise of both occupational and physical therapists.

EXAMINATION AND EVALUATION PROCESS

Just as the medical intervention with patients who have an inflammatory disorder of the CNS is, to a large extent, symptomatic, so is the intervention by therapists. Designing an individualized intervention program based on the patient's problems requires a comprehensive initial and ongoing evaluation to define the impairments, functional limitations, and disabilities and to note changes in them. Although the discussion of examination procedures is separated from the discussion of intervention strategies, it must be recognized that the separation is artificial and does not reflect the image of practice. The evaluation process should be considered in relationship to both the long-term assessment of the individual's changes and the short-term within-session and between-session variations. For example, documentation of the level of consciousness of a patient on day one of intervention will provide a starting point for calculation of the distance spanned at the time of discharge. Perhaps more critical to the final outcome is determination of the level of consciousness before, during, and after a particular intervention technique to determine its impact on the individual's level of arousal and ability to interact with the environment. The evaluation process is a constant activity intertwined with intervention. The observations and data from the process are periodically recorded to establish the course of the disease process and the success of the therapeutic management of the patient.

Observation of Current Functional Status

The examination process should be conceptualized as a decision making tree that requires the therapist to determine actively which components are to be included in a detailed examination and which can be eliminated or deferred. The first step in this process is the observation of the patient's current functional status. If the patient is comatose and nonmobile, the focus of the initial session might be an assessment of the stability of physiological functions, level of consciousness, responses to sensory input, and joint mobility. If the patient is an outpatient with motor control deficits, the initial session might focus on defining motor abilities and components contributing to movement dysfunctions with a more superficial assessment of physiological functions and level of consciousness. The therapist must be alert to indications of the need for a more detailed evaluation of perceptual and cognitive function (e.g., the patient cannot follow two-step commands, indicating the need to assess cognitive skills).

Some of the components discussed in this process may be examination skills that are more typically possessed by other professions (e.g., assessment of emotional or psychological status). The inclusion of these items is not meant to suggest that the therapist must complete the formal testing. The items are included to indicate factors that will affect goal setting for the patient and that will have an impact on the intervention strategy. Although the therapist may not be the health care team member who has primary responsibility for evaluation of these areas, he or she should recognize these areas as potential contributors to movement dysfunctions.

Observation of the current functional status of the patient provides the therapist with an initial overview of his assets and deficits. This provides the framework into which the pieces of information from the evaluation of specific aspects of function can be fitted. The therapist must not allow assumptions made during the initial observation to bias later observations. The therapist might note that the patient is able to roll from the supine to the side-lying position to interact with visitors in the room. When the same activity is not repeated on the mat table in the treatment area, the therapist, knowing the patient has the motor skill to roll, might conclude that he is uncooperative or apraxic or has perceptual deficits. The therapist may have failed to consider that the difference between the two situations is the type of support surface or the presence or absence of side rails, which may have enabled the patient to roll in bed by pulling over to the side-lying position. It is characteristic of human observation skills that we tend to "see" what we expect to see. The therapist must attempt to observe behaviors and note potential explanations for deviations from normal without biasing the results of the subsequent observations.

The following discussion of the specific considerations within the examination process does not necessarily represent the temporal sequence to be used during the data collection process. As different items are discussed, suggestions for potential combinations of items will be made. The sequence of the process is best determined by the interaction of therapist and patient. [Fig. 26.5](#) outlines the components that should be considered during the evaluation process and provides a synopsis of the following discussion.

The general philosophy in the evaluation of the patient with neurological deficits as a result of brain inflammation is a whole-part-whole approach. General observations of the patient's performance provide an overall description of the patient's abilities while indicating deficits in his or her performance. The cause(s) of the deficits (impairments) are explored to provide the pieces of data defining her or his performance. These pieces of data then are arranged within the framework provided by the general observation to define the whole of the

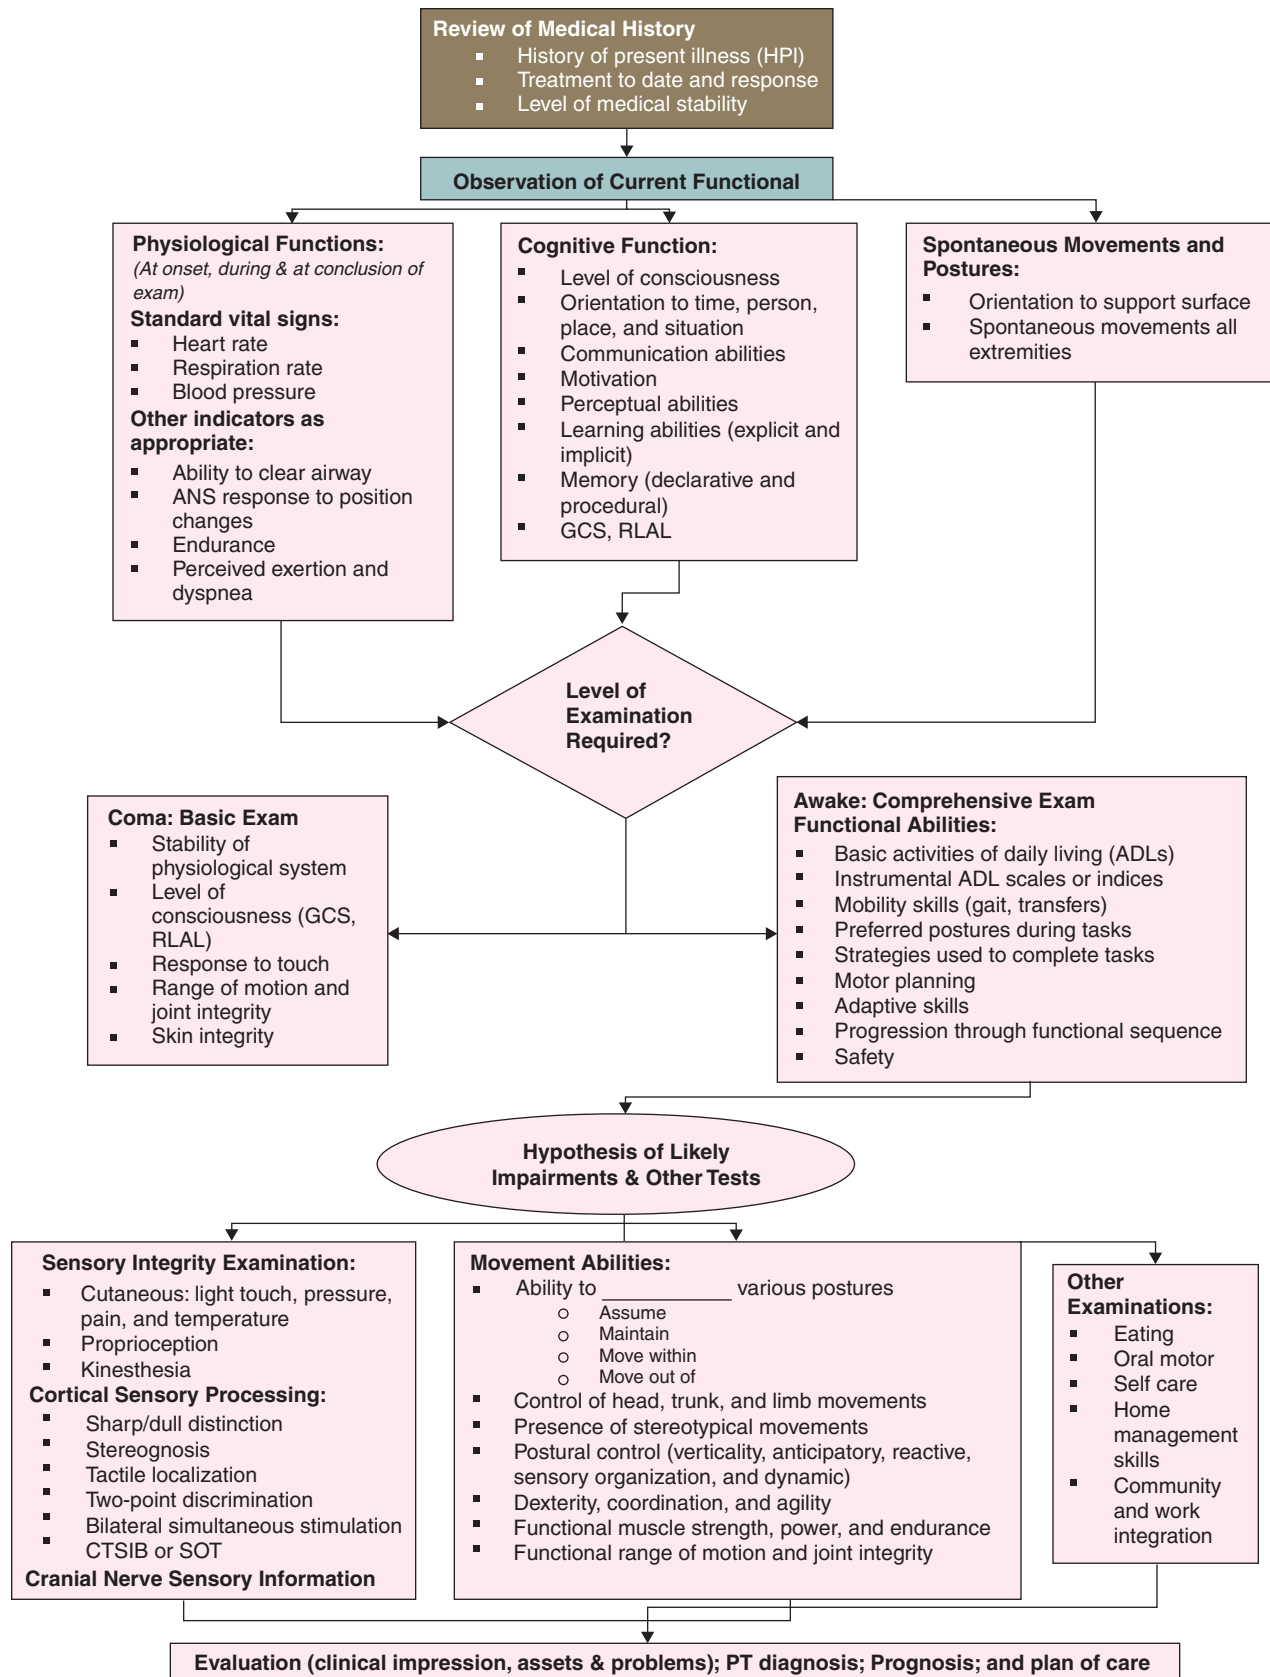

Fig. 26.5 Flow Chart of the Evaluation Process. ANS, Autonomic nervous system; GCS, Glasgow Coma Scale; RLAL, Rancho Los Amigos Level; PT, physical therapy.

patient's assets and deficits. As the whole picture is established (with the realization that it will be constantly adjusted), the process of goal-setting is initiated. These goals need to consider the patient's and family's desires. The process presented for refining evaluation data into an intervention plan is applicable whether the patient's neurological dysfunction is the result of a bacterial or viral infection, cerebrovascular accident, trauma, or other factors.

Evaluation of Physiological Responses to Therapeutic Activities

It is assumed that the therapist enters the initial interaction with a patient after reviewing the available background information. This may provide the therapist with information on the baseline status of the patient's vital physiological functions. Any control problems in these areas should be particularly noted. Until the therapist determines that the vital functions, such as rate of respiration, heart rate, and blood pressure, vary appropriately with the demands of the intervention process, these factors should be monitored. The monitoring process should include consideration of the baseline rate, rate during exercise, and time to return to baseline. The pattern of respiration and changes in that pattern also should be noted.

Other tests and measures of the status of ventilation, respiration, and circulation may be indicated in specific individuals. Individuals with limited mobility or motor control of the trunk or those with cranial nerve dysfunctions may demonstrate difficulty with functions such as moving secretions out of the airways. Inactivity during a prolonged recovery period may result in cardiovascular adaptations that compromise endurance and contribute to increases in the perceived exertion during activities.

Autonomic nervous system dysfunctions may be expressed as inappropriate accommodations to positional changes, such as orthostatic hypotension. Patients with depressed levels of consciousness may display temperature regulation dysfunctions. One mechanism for assessing the patient's ability to maintain a homeostatic temperature is to review the nursing notes. The events surrounding any periods of diaphoresis should be examined. If no causative factors have been identified, then interventions that involve thermal agents as discussed elsewhere in this text should be used judiciously.

Evaluation of Cognitive Status

Because the evaluation process encompasses the stages of recovery from the critical acute phase through discharge from therapy, a range of aspects are included under the evaluation of cognitive status. As indicated previously, the observation of current functional status will direct the therapist toward the appropriate component tests and measures.

Acute bacterial meningitis and various forms of viral encephalitis may result in changes in the patient's level of consciousness. *Consciousness* is a state of awareness of one's self and one's environment.²¹ *Coma* can be defined as a state in which one does not open the eyes, obey commands, or utter recognizable words.²⁸ The individual does not respond to external stimuli or to internal needs. The term *vegetative state* is sometimes used to indicate the status of individuals who open their eyes and display a sleep-wake cycle but who do not obey commands or utter recognizable words. DeMeyer²⁹ presents a succinct description of the neuroanatomy of consciousness and the neurological examination of the unconscious patient. Plum and Posner²² also provide extensive information in this area.

Several scales have been developed to provide objective guidelines to assess alterations in the state of consciousness. The Glasgow Coma Scale²⁸ assesses three independent items: eye opening, motor performance, and verbal performance. The scale yields a figure from 3

(lowest) to 15 (highest) that can be used to indicate changes in the individual's state of consciousness. The Rancho Los Amigos scale assesses level of consciousness and behavior.²⁸ The therapist can use assessment tools such as the Glasgow Coma Scale and the companion Glasgow Outcome Scale to determine if the intervention program has resulted in any recordable changes in the patient's level of consciousness. Ideally, the patient with decreased levels of consciousness will be monitored at consistent intervals to determine changes in status. Any carryover or delayed effects of the intervention could then be noted. The record of the patient's level of consciousness might also display a pattern of peak awareness at a particular point in the day. Scheduling an intervention session during the patient's peak awareness time may maximize the benefit of the therapy.

Performed in conjunction with the assessment of the patient's state of consciousness is the determination of the individual's orientation to person, time, place, and situation. Because the individual's level of orientation (documented as oriented times 4) is frequently recorded by multiple members of the rehabilitation team, the information in the medical chart may provide insights into fluctuations over the course of a day or a week.

Gross assessment of the individual's ability to communicate, both the expressive and receptive aspects of the process, is an important component of the examination. If a dysfunction is present in the patient's ability to communicate, the patient should be evaluated by an individual with expertise in this area so that strategies for dealing with the communication deficit can be developed. Evaluation of the movement abilities of the patient with communication deficits requires creative planning on the part of the therapist but usually can be accomplished if generalized movement tasks are used. With the patient who cannot comprehend a verbal command to roll, the therapist should use an alternate form of communication, such as manual cueing or guidance. The therapist could structure the situation to elicit the desired behavior by activities such as placing the patient in an uncomfortable position or positioning a desired object so that it can be reached only by rolling.

As the therapist progresses through the examination and intervention process, ongoing data collection should be occurring on factors that influence the motivation of the individual. Individuals with damage to certain areas within the frontal lobe will have difficulty with committing to long-term projects and may not be motivated to work during a therapy session by an explanation detailing the relationship of the current activity to the larger goal of returning home. In these situations, the therapist must create appropriate immediate rewards, such as a 2-minute rest break after completion of a specific movement task.

Deficits in cognition may be evident as problems in the area of explicit (declarative) or implicit (procedural) learning. Explicit learning is used in the acquisition of knowledge that is consciously recalled. This is information that can be verbalized in declarative sentences, such as the sequential listing of the steps in a movement sequence. Implicit or procedural learning is used in the process of acquiring movement sequences that are performed automatically without conscious attention to the performance. Procedural learning occurs through repetitions of the movement task (refer to Chapter 3). Because explicit and implicit learning use different neuroanatomical circuits, implicit learning can occur in individuals with deficits in the components underlying explicit learning (awareness, attention, higher-order cognitive processes) (refer to Chapter 3 for additional information regarding implicit and explicit learning).

The emotional and psychological aspects of the patient and the higher-order cognitive and retention skills of the patient should be evaluated informally by the therapist, with referral to appropriate

professionals if dysfunction in these areas is suspected. A coordinated team approach is necessary for patients with emotional and psychological, cognitive, perceptual, or communication problems or a combination of these problems. A consistent strategy used by all team members eliminates the necessity on the part of the patient of trying to cope with different approaches by different people in an area in which she or he already has a deficit. The impact of cognitive deficits on the process of learning motor skills is further discussed in the next section on movement assessment. The assessment of the impact of perceptual dysfunctions is incorporated within the evaluation of sensory channels.

Examination of Functional Abilities

As indicated in the introduction to the evaluation of patients with inflammatory and infectious disorders of the brain, the examination process is not compartmentalized. As the therapist is examining the movement abilities of the individual through the format described in the previous section, he or she is also collecting information on the functional abilities of the individual. The components underlying the movement abilities of the patient can be examined within the framework of the basic or instrumental activities of daily living (ADLs), depending on the functional level of the person. The treatment setting and documentation requirements within that setting will determine whether the data on basic ADL and instrumental ADL skills are recorded with use of a formal scale or index or are gathered through an individualized process.

The introduction of specific tasks provides the therapist with the opportunity to observe the preferred posture used to accomplish the different tasks. The therapist should construct situations that require the individual to respond to unexpected occurrences to provide some insight into the person's ability to adapt to the unexpected. Throughout the process of examining a patient's movement abilities and functional abilities, the therapist is assessing the individual's awareness of safety considerations and judgment in attempting tasks.

The presence of motor planning dysfunctions can be noted as the patient attempts a movement sequence or a functional task. The therapist may have to cue the patient physically to initiate the sequence, which then flows smoothly. The therapist may observe that the patient has the correct components to a movement sequence, but that the sequence of the components is incorrect. Or the patient may demonstrate the ability to produce a movement sequence under one set of conditions but not another. Indications of these types of motor planning problems can be observed during the initial interactions with the patient. Similarly, the therapist also should be aware of indications of problems with dexterity, coordination, and agility, as well as with signs of cerebellar dysfunctions.

Another aspect of the evaluation process that can be integrated in the observations of movement abilities is identification of perceptual deficits. Aspects of the patient's motor performance can provide indications for detailed perceptual testing to classify the deficits. This testing should be conducted by the health care team member qualified in the area of perceptual testing. During the general evaluation procedures, the therapist can screen the patient for signs of perceptual deficits. Patients' abilities to cross their midlines with their upper extremities can be demonstrated in movement sequences, such as moving from the supine to the side-sitting to the sitting position (Fig. 26.6). The quality of the integration of information from the two sides of the body can be indicated by the symmetry or asymmetry of posture in positions that should be symmetrical. The therapist may suspect that the patient has a deficit in body awareness or body image by the poor quality of movement patterns that are within the motor capability of the individual. Spontaneous comments by the patient as to how he or she feels when moving ("my leg feels so heavy") also add to the thera-

apist's assessment of the patient's body image. Problems with verticality can be seen with the patient who lists to one side when in an upright posture. When the therapist corrects the list to a vertical posture, patients may express that they now feel that they are leaning to one side. Individuals who cannot appropriately relate their positions to the position of objects in their environments may have a figure-ground deficit or a problem with the concept of their position in space. When approaching stairs, these patients may fail to step up or may attempt to step up too soon. These examples should provide an indication of the observations that can indicate the need for detailed perceptual testing.

The preceding aspects of evaluation of movement abilities focused on facets of motor performance. Within this process the therapist should intertwine an appraisal of the individual's ability to learn motor tasks (or elements of the task). The therapist attempts to determine whether the patient can maintain a change in the ability to perform a movement throughout a therapy session and into the next session. The patient's ability to capture and integrate changes into the movement repertoire is fundamental to the success of the intervention program. The program can focus on the learning of movement sequences and the generalization of these sequences to movements within other contexts. Individuals with lowered levels of consciousness (typically Rancho Los Amigos Levels I to III) will be unable to learn or have difficulty learning and generalizing new motor skills. Therapy sessions may be more successful if the focus remains on the performance of motor tasks that were previously "overlearned" and automatic. Although the therapist may be able to manually guide the individual in coming to sit on the edge of the bed, until the individual demonstrates a higher level of processing, it may be unrealistic to expect that he or she will consistently reposition the legs without cueing before attempting the movement sequence. From looking at the "whole" of function, the therapist needs to determine the impairments that require further examination.

Evaluation of Sensory Channel Integrity and Processing

The examination process must include an assessment of the channels for sensory input. Knowledge gained in the assessment of the sensory systems will be used in the program-planning process to select the intervention strategies that have the highest probability of success. Although movements can be performed (and in some cases even learned) in the absence of typical sensory feedback, the presence of altered sensory function creates more challenges for both the patient/learner and the therapist/teacher. The therapist assesses both the patient's ability to perceive the sensory stimulus and the appropriateness of the response to the stimulus. Therefore it is important to determine if the sensory modality is intact, impaired, or absent, and if it is impaired, whether it hyperresponsive, hyporesponsive, or inconsistent. In addition, variations in the interpretation of sensory input may occur in some patients. Gentle tactile contact may be perceived by the person as a noxious input. Some individuals will have difficulty processing and discriminating information with high levels of one type of sensory input (e.g., the noisy clinic area) or with multiple simultaneous inputs (e.g., talking to the therapist while walking down a hallway with people moving toward the individual).

The therapist should develop a systematic approach to the initial cursory screen of the sensory systems. Deficits identified in the initial examination will provide structure for scheduling more comprehensive evaluation of deficits in specific systems. The therapist must also monitor changes in the status of physiological vital functions during sensory input, especially if the patient has a history of instability of heart rate, blood pressure, or rate of respiration.

Based on the information from the screen, the therapist will organize the components of the more detailed examination. Components to be considered include the integrity of the peripheral sensory

Fig. 26.6 Movement sequence from the supine to side-sitting to sitting positions. **(A)** Supine position. **(B)** Handling to side lying. **(C)** Handling toward side sitting; arm positions are important. **(D)** Side sitting; note propping patterns with arms. **(E)** Handling to symmetrical sitting.

circuits, the cortical level processing of the sensory information, the integrity of the cranial nerve sensory circuits, and the processing of multichannel input.

Cutaneous input has several aspects that must be assessed. Some of the inflammatory diseases of the brain may result in cutaneous distributions in which sensation is absent or diminished. These areas should be routinely evaluated for changes in distribution of level of sensation. Tests of light touch, pressure, and pain can be used if the patient can communicate reliably. In most cases, inclusion of assessment of differentiation of hot and cold will not add appreciably to the information needed for treatment planning unless thermal modalities are a consideration.

A gross assessment of the intactness of the touch system can be made in the noncommunicative patient by introducing a mildly aversive (not painful) stimulus, such as a light scratch, while monitoring the patient for changes in facial expression, posture, or tonus. The possibility of a spinal-level reflex response should be kept in mind when interpreting the results of such a gross assessment.

Assessment of the patient's response to proprioceptive input is incorporated within the assessment of the patient's movement abilities and is intertwined with the intervention process because a variety of intervention techniques are based on proprioceptive input. Evaluation of the proprioceptive channels can be conducted through assessment of the patient's static position sense and dynamic kinesthesia. These

tests allow the therapist to make inferences concerning the patient's cognitive abilities to interpret proprioceptive information. Inherent in the successful completion of these tests is the necessity for the patient to be able to understand directions and to be able to communicate data to the therapist. Because information input, processing, and output are involved in these tests, failure to comply with the test instructions cannot be definitively attributed to dysfunction of the proprioceptive system. The therapist also should consider information obtained from watching the patient move before drawing a conclusion concerning the intactness of the proprioceptive channels. Some of the factors to consider include disregard of an extremity and variations in quality of performance between visually directed and nonvisually directed movements. Although tests of position sense and kinesthetics provide one aspect of the evaluation of the proprioceptive system, the therapist also must be involved constantly in assessing the patient's response to the intervention techniques that are part of the treatment plan. This again illustrates the intermingling of assessment and intervention. Intervention places a demand for movement on the patient. As the movement occurs, the therapist assesses the quality of the movement. If the quality is not appropriate, the therapist initiates intervention to improve the quality. If the technique does not produce the desired result, a second technique can be tried and the cyclical process continues.

In addition to determining the integrity of the peripheral sensory pathways and recognition of the input, it is important to assess the individual's ability to process more complex presentations of cutaneous input. Difficulties in the cortical-level processing of cutaneous stimuli are identified through tests of sharp and dull discrimination, stereognosis, tactile localization, texture recognition, two-point discrimination, and bilateral simultaneous stimulation.

Central processing and integration of sensory information as it affects postural control can be examined using the Clinical Test of Sensory Integration and Balance (CTSIB)³⁰ or with computerized dynamic posturography using the Sensory Organization Test (SOT). With both tests, the effectiveness of using vision or somatosensory or vestibular sensation at the appropriate time (sensory weighting) and changing from one sensory system to the other is examined.

Assessment of the integrity of the cranial nerve sensory channels is typically incorporated within the standard cranial nerve examination. Review of the physician's notes may provide sufficient information; however, the therapist may need to complete more specific tests before considering certain intervention techniques. Of specific note are vision and vestibular screening, both of which are discussed in detail elsewhere in this text. Simple visual system tests, such as identification of field deficits, assessment of tracking abilities, and a gross evaluation of visual acuity, can be performed quickly.

The complex functions of the vestibular system can be assessed through a variety of avenues such as the Ayres Post-Rotatory Nystagmus Test,^{31,32} the SOT, and tests of the vestibular ocular reflex (head-thrust test, head-shaking test, and test of dynamic visual acuity [DVA]), and are discussed in detail elsewhere in this text. It is important to examine the vestibular influence in both postural control and gaze stability. The integrity of the connections underlying a vestibular-induced nystagmus response is assessed by physicians through the caloric test (warm and cold water or air introduced into the ear channel to induce nystagmus). The effect of rapid linear accelerations and decelerations can be evaluated as potential activating mechanisms increasing the level of consciousness or level of muscle activity. An example is the Dynamic Gait Index, a functional test that incorporates changes in speed and head movements during walking.³³ Slow, rhythmical reversals of linear movements may have a calming effect on the patient's behavior or level of muscle activation. Linear movements in all planes and diagonals should be explored.

During the evaluation of the patient as well as during intervention with the patient, the therapist must be aware of the potential to bombard him or her with sensory input and overload his or her ability to respond discriminatively to it. If the therapist detects that the patient has difficulty in responding appropriately to sensory input, as with a patient in a lowered state of consciousness or an agitated state, or demonstrating tactile defensiveness, sensory input should be used selectively during the initial examination or intervention sessions. If multiple sensory inputs are used, the positive or negative effects cannot be attributed to a specific input or necessarily to the series of inputs. Evaluation as well as intervention with sensory inputs should proceed in a controlled fashion. Inclusion of additional sensory modalities in the intervention plan should occur systematically.

The individual's response to multichannel sensory conflict input is typically assessed as a component of higher-level balance assessment and locomotor abilities. A more thorough discussion of sensory assessment is discussed elsewhere in the text. The therapist should apply these concepts during the evaluation of all motor tasks. Consider the following example: a patient who relies on visual input to supplement vestibular and somatosensory information is performing the task of sitting on the edge of the mat table. She remains relatively steady until someone walks directly toward her from across the clinic. This change in the environmental context of the performance requires her to assess whether she is moving toward the individual or the individual is moving toward her. Without reliable vestibular and somatosensory check points, the patient may activate a postural response to the incorrect assessment. As this example demonstrates, the evaluation of the sensory channels is intertwined with the evaluation of the person's movement abilities.

Examination of Movement Abilities

The initial assessment of the individual's movement abilities is conducted by observing as she or he moves through a sequence of functional postures. The therapist determines the functional postures to be examined for a specific patient, ranging from bed mobility activities (assessment of movement in prone and supine positions) through upright ambulation. The medical status of the individual, the extent of involvement, the intervention setting, and the age of the individual are considerations in determining the appropriate functional postures to be examined. The therapist gathers information on the movement abilities of the patient as he or she moves into, within, and out of the position.

The assessment focuses on both the quantity and quality of motor performance. The quantitative aspect of the movement assessment involves the number of different functional postures the individual can use. The quality of the movement abilities is assessed within the posture as well as in the process of moving between postures. For example, the therapist should assess the quality of the head, trunk, and extremity control demonstrated throughout the movement sequences. The use of stereotypical movement patterns should be noted because their presence may limit the adaptability of movements required to accomplish functional tasks. Other items relating to the patient's movement abilities are assessed during this process.

Indications of abnormal ranges of movement of all joints can be obtained. The range may show a limitation of movement or an indication of joint instability. Once the gross deviations are identified, these joints can be examined to determine the source of the problem: joint capsular, ligamentous, bony, skin, or muscular and fascial dysfunction. Conducting the gross assessment of range while the patient is moving eliminates the time spent in performing a joint-by-joint goniometric evaluation of articulations with normal excursions.

As the individual is moving (either independently or with the therapist assisting), an assessment of the distribution and fluctuations

in muscle activity can be made and will provide information on functional muscle strength, power, and endurance. The timing, accuracy, and sequencing of muscle activation within the movement should be noted. The therapist can identify the postures that will be the most conducive to optimal motor performances and those that should be avoided. As the patient is moving through various postures, the function of specific musculature can be examined. Muscle groups should be examined with regard to their ability to function in both stability (distal segment fixed) and mobility (distal segment free) situations. Because numerous demands are being placed on each muscle group, therapists can assess the ability to perform isometric and isotonic (concentric and eccentric) contractions. Each different posture introduces a new set of variables; therefore the performance of a muscle group must be reexamined as each new movement pattern is performed.

The therapist can identify postural control in a variety of functional positions. Within each posture, the therapist must examine the control the patient displays over the posture. Because the assessment takes place as part of a dynamic sequence, the therapist can assess the patient's ability to assume the posture. If the posture cannot be achieved independently, the therapist assesses the factors interfering with achieving the position, the type of assistance necessary to facilitate assumption of the posture, and the effect of the various intervention techniques used to assist the patient in achieving the position. Once the patient is in the posture, her or his ability to maintain the posture is examined. Factors that interfere with the performance are noted. The patient's ability to move within the posture is identified. Movement demands placed on the patient should include aspects of both static and dynamic equilibrium. Static balance in the sitting position (such as on the side of the bed) could be demonstrated by the individual matching the strength of a force attempting to displace him backward and maintaining the position when the force is suddenly released.

The presence of dynamic balance of the upper torso in the sitting position could be demonstrated by the individual reacting to a quick sideways displacement force administered to the shoulder by activating the trunk lateral flexors to compensate for the displacement. Equally important is the individual's ability to demonstrate appropriate equilibrium responses to self-imposed perturbations. The absence of anticipatory control in standing could be demonstrated by having the patient do the rapid arm raise test with a 5-lb weight and noticing reactive stepping instead of doing a posterior weight shift in anticipation of the destabilizing force.

The final stage in examining the individual's movement abilities explores the individual's ability to move out of the posture. The patient should have the ability to move out of the posture to a lower-level posture and to a higher-level posture before mastery of the posture is considered to have been achieved.

Many aspects of the patient's performance are analyzed simultaneously. When the therapist assists the patient in moving to a new posture, an analysis of the influence of facilitation and inhibition techniques is being conducted. The individual's response to these handling techniques cues the therapist in projecting the patient's response to an intervention program. The therapist is constantly monitoring the patient for changes in physiological functions or changes in the level of consciousness. Anything that results in expressions of pain by the patient should be noted. Intervention programs should be a learning experience for patients. If they are attending to pain, they cannot attend to learning. The factor(s) producing the pain should be identified and measures instituted to eliminate the factor(s). If the factors producing the pain cannot be resolved, the intervention program should be designed to avoid triggering the pain.

In addition to looking at postural control in a variety of postures, it is also important to determine the type of postural control dysfunction, such as vertical orientation to the surface or to gravity as the situation dictates, anticipatory postural control, reactive postural control, sensory organization for postural control, and dynamic balance for gait.

DIAGNOSIS, PROGNOSIS, AND GOAL SETTING

Having collected data from the examination process, the first steps are to interpret the findings and integrate those findings with other information collected during the history to determine a diagnosis amenable to physical therapy management. Physical therapists identify the *impact of a condition on function at the level of the system (especially the movement system) and at the level of the whole person.*²⁷ This includes integrating specific problems (body functions [impairments], activity and participation limitations) and to interpret within the context of the individual and the environment. The individual factors will include her or his assets. Formulating an asset list focuses on the positive data elicited from the evaluation process and is critical for prognosing outcomes. Items on the asset list could be observations, such as the patient being able to assume the position of sitting on the side of the bed with setup assistance only, improved head control in this posture being facilitated by approximation, and controlled weight shifting being elicited by alternated tapping. The asset list provides a reference defining the postures and intervention techniques that are effective. This reference is used to develop the intervention goals and plan. Formulating and recording a problem list and an asset list can be completed relatively quickly as one gains familiarity with the process. Whereas novice therapists will benefit from generating a written asset list, experienced clinicians may formulate a mental asset list while completing the written evaluation format required by the facility. Just as the evaluation process is ongoing, so are the steps involved in goal setting. The asset and problem lists are redefined as the patient's status changes.

After assets and problems have been identified, the next step is to establish the expected outcomes from this episode of care. This is considered the prognosis. Ideally, the process of establishing the prognosis and setting the goals for a patient is a coordinated effort that involves all members of the health care team, including the patient (if feasible) and family. If the therapist is not functioning in a setting where involvement of many disciplines is viable, the therapist can progress through the goal-setting process in the context of his or her role in the patient's care.

These outcome statements represent the general objectives toward which the intervention process is oriented. They identify the end point of the intervention process and are the exit criteria for terminating the episode of care.

The *Guide to Physical Therapist Practice* views outcomes in relationship to "minimization of functional limitations, optimization of health status, prevention of disability, and optimization of patient/client satisfaction," whereas goals "relate to the remediation (to the extent possible) of impairments."²⁷ The breadth of acceptance of these definitions with the neurorehabilitation professions remains to be determined. These definitions at least give professionals a place to start communicating with consistency. The International Classification of Functioning, Disability and Health (ICF) model of the World Health Organization provides similar definitions, with the focus being patient centered.

Measurable, interim objectives should be established in relation to the outcome statements. To determine if the objective has been achieved, the objective should be measurable—either in terms of producing a numerical indicator of performance, such as time span,

number of repetitions, distance covered, or accuracy of performance, or in terms of a precise description of the target motor behavior. The appropriate objective indicator must be carefully selected. Performing a movement more quickly may indicate that the individual is performing it with more normal control and therefore greater ease of movement, or it may indicate that the individual has become more skilled in using an abnormal pattern based on inappropriate muscle activation. If it is not appropriate to formulate the objective in terms of a numerical indicator, the objective can be formulated in terms of an observable behavior. The therapist can precisely describe body segment movements based on the component method of movement analysis presented by VanSant.^{34,35} For example, the task of coming to standing from supine can be described in terms of the upper-extremity component, axial component, and lower-extremity component.³⁶ Formulation of an appropriate short-term objective could specify use of the upper extremities in a push-and-reach pattern during the task of coming to standing from supine. The interim objectives should be constructed so that observing the patient's behavior will allow the therapist to state whether the criteria of the short-term objective were achieved. Table 26.1 gives an example of some components of short-term objectives leading to mastery of functional activities in sitting.

The outcome statements define the patient's destination. The interim objectives define the mileposts. The therapist then uses the asset list to design the intervention program, which is the vehicle to get the patient to his or her destination. From the asset list, the therapist knows the intervention techniques that have the highest probability of success. Adopting this process simplifies the task of outlining the strategy for intervention.

As the therapist considers the appropriate outcomes and goals for the patient, a decision must be made as to whether the format of the intervention will focus on a "training" approach or a "motor learning" approach. During the assessment process, if the therapist concludes that the individual's level of cognitive function precludes the development of insight into movement errors (both the detection and correction of an incorrect performance) or the ability to retain the insight over time, then the therapist should delineate the outcomes and intervention plan to accommodate this limitation. The "training" approach requires more structure and repetition of activities within that structure. If it is more appropriate to design the intervention plan according to motor learning considerations, the therapist must consider the appropriate schedule and environmental context for the practice, the type and schedule for the feedback provided, and techniques to promote the generalization of the learning beyond the specific practice session.

General Goals for the Intervention Process

Whereas the goal-setting process described earlier results in specification of the outcomes, goals, and objectives for a specific patient, the general goals for the intervention process can be delineated to guide the process. As described in the overview of inflammatory disorders at the beginning of this chapter, the extent of the neurological sequelae may range from a single discrete problem to a devastating clinical picture composed of compromised functions in multiple areas. The goals for the intervention process address the problem areas that (1) jeopardize the efficiency and effectiveness of functional activities and (2) are the primary or secondary results of compromised neurological function. The listing of goals does not directly include consideration of secondary problems (such as decreases in joint range of motion [ROM], cardiovascular fitness, and endurance). The therapist should integrate these considerations in the overall assessment of the components of the movement problems.

The following goals are written as outcomes of the intervention process and not as goals for a specific patient. Because of the broad nature of the goals, other professions also will contribute to the attainment of the goals. The goals of the therapeutic intervention program for patients with inflammatory CNS disorders are as follows:

- Goal 1: Postural control is optimized as demonstrated by the ability to maintain a position against gravity and the ability to automatically adjust before and continuously during movement.
- Goal 2: Selective, voluntary movement patterns within functional activities are optimized.
- Goal 3: Performance of functional activities is enhanced.
- Goal 4: Integration of sensory information is fostered.
- Goal 5: Cognitive status and psychosocial responses are optimized.

Each of these goals is discussed in conjunction with the general therapeutic intervention procedures that can be used to achieve the goal.

GENERAL THERAPEUTIC INTERVENTION PROCEDURES IN RELATION TO INTERVENTION GOALS

- *Postural control is optimized as demonstrated by the ability to maintain a position against gravity and the ability to adjust automatically before and continuously during movement.*

Because it is assumed that functional abilities are built on the base of the ability to control postures, the intervention goal of promoting optimal postural control underlies the ability to make selective, voluntary movement patterns (goal 2) and the performance of functional

TABLE 26.1 Examples of Short-Term Objectives Relating to Mastery of Functional Activities in Sitting

	Condition Variables ^a	Activity	Criteria
1. When sitting on a mat	a. Using the upper extremities for support	The patient will maintain the posture	For _____ seconds
2. When sitting on the edge of a mat table	b. Using one upper extremity for support c. Without using the upper extremities for support		
3. When sitting in a chair	d. With the therapist displacing the position of the: pelvis shoulders head lower extremities e. Leaning forward and returning to erect sitting	The patient will make postural adjustments of the head and trunk The patient will bring the right foot to the left knee (as if to put on a shoe)	Appropriate to the degree of displacement

^aTherapist needs to consider all aspects of each variable (i.e., 1—a, b, c, d, e; 2—a, b, c, d, e; 3—a, b, c, d, e).

Outcome: The patient will master functional activities in sitting. Short-term objective: Select one phrase from each column.

activities (goal 3). Optimization of a postural set includes the concepts of decreasing muscle activity that is too high to allow performance of movement sequences, augmenting activation that is too low to support the accomplishment of a movement sequence, and fostering proper timing of the postural responses. Intervention techniques to achieve this goal demand that the therapist constantly monitor the patient's performance so that appropriate interventions are added when needed and continued only as long as they are needed.

Optimal postural control is defined by two elements. The patient should have the ability to maintain a vertical orientation with regard

to gravity and should be able to maintain balance in the presence of both internal and external perturbations. Automatic adjustments in the postural set should occur in anticipation of and continuously during movements (internal perturbations). Both elements should be performed with minimal physical or cognitive effort on the part of the patient. Horak describes five components of normal postural control, including vertical orientation; anticipatory, reactive, sensory organization; and dynamic postural control for gait.³⁶ By looking at the subsets of postural control, interventions can be designed to specifically match the impairment (Table 26.2).

TABLE 26.2 Interventions for Postural Control Problems

Postural Control Problem	Possible Interventions
Malalignment and verticality problems	Augment sensory feedback: <ul style="list-style-type: none"> • Mirror • Static force plate • Flashlight on target • Videotape • Align without vision and check (knowledge of results) • Stepping with eyes closed
Limits of stability perception problems	Computerized feedback of actual versus possible Weight shifting exercise with feedback and targets (somatosensory, visual, both) Surface orientation exercises (static, ankle sway, hip strategies)
Anticipatory control problems	Hold on and slow down (lessen the need for anticipatory control—substitution) Mental rehearsal (weight shift, then move) Practice limb movements where balance must be controlled (start slow and get faster) <ul style="list-style-type: none"> • Interactions with the environment with a static base of support, such as reaching up in a cupboard, opening a door, opening a drawer, lifting a suitcase, lifting a bag of groceries, wearing a backpack • Interactions with the environment with a dynamic base of support (stepping up a step, kicking a ball, stepping over an object, stepping around an object, changing the pitch of the surface—inclines) Practice rapid limb movements where balance must be controlled (opening a door, opening a drawer, lifting a briefcase, lifting a bag of groceries, lifting a suitcase, wearing a backpack). Practice order: <ul style="list-style-type: none"> • Practice the anticipatory postural adjustment • Practice the focal action while supported • Combine the anticipatory postural adjustment with the focal action unsupported (slow to fast) • Practice varying similar tasks (predictable to unpredictable) Example: After the patient is doing better on a lifting task involving one object, he or she can work to be successful with several objects of different weights; first cognitively solve what must change for achievement of success in lifting one object versus another; then much repetition of alternating one object versus another; and eventually, work with a variety of objects in a varied pattern
Reactive postural control problems	Work to regain balance strategies (ankle, hip, and stepping) Remediate any biomechanical issues that affect use of balance strategies Begin with self-perturbation and progress to reacting to external perturbations Need to learn to match the magnitude and direction of perturbation Physioballs, T-stools, tilt boards, reaching, weight shifting
Sensory integration problems	If patient is overreliant on vision, be sure to help patient with another strategy before you take vision away Surface orientation exercises (tuning into somatosensory feedback) <ul style="list-style-type: none"> • Textured surface • Textured surface + visual tracking • Textured surface with vision occluded Enhancing use of vestibular system: <ul style="list-style-type: none"> • Compliant surface with stationary visual target • Compliant surface + visual tracking • Compliant surface with moving visual background • Changing surface + head turns • Changing surface + head turns + moving visual background • Obstacle course with varying sensory demands

Continued

TABLE 26.2 Interventions for Postural Control Problems—cont'd

Postural Control Problem	Possible Interventions
Dynamic balance problems in gait	Alter the sensory contexts (e.g., resisted walking) Walking and reading signs right and left Carrying objects and looking at items carried Walking with quick stops (predictable distances and reactive) Practice falling without injury and getting up; practice slips and trips Walking and negotiating obstacles (around and over) <ul style="list-style-type: none"> • Practice both around and over obstacles • Larger steps, standing on one foot, changing directions • Practice stopping quickly with feet in target • Practice shorter steps, on a slippery surface; braiding Gesturing while walking

Verticality, or maintaining an upright posture, first requires the patient to recognize the desired alignment. Augmenting internal feedback mechanisms with the use of mirrors, force plates, or scales or even using a flashlight attached to the patient that shines on a target when he or she is vertical can be effective. Manual skills such as positioning the patient and using approximation to reinforce the position can be added to the treatment. Progression of intervention strategies can be done by having the patient maintain the posture and then begin to manipulate objects with the extremities. Research suggests that the CNS is organized around tasks and not movement patterns. Therefore as the patient learns to maintain a vertical orientation and moves in and out of the position, designing a task will likely give a better outcome. For example, Paul developed encephalitis, which left him with residual deficits in verticality. The simple task of keeping a book balanced on his head while sitting or walking gave him the type of feedback he needed without constant cues to “stand up straight” being the focus. Further progression involves teaching the patient to move to his limits of stability and find vertical again.

Anticipatory postural control involves the postural preset, which positions the trunk to allow skilled use of the extremities without loss of balance. It requires the patient to recognize the situation and the likely destabilizing force that will result, and posturally preset so destabilizing will not occur. The process requires memory and the ability to recognize the critical environmental and task cues. Interventions focus on practicing both the postural adjustment and the focal action before the two components are combined. Table 26.2 also has suggested interventions for reactive, sensory integrative, and dynamic balance in gait problems. Postural control is affected as well by biomechanical constraints, such as tonal abnormalities.

The patient's ability to demonstrate optimal postural control may be restricted by the presence of hypertonicity or hypotonicity in various muscle groups. These states may be relatively static or may fluctuate with the demands of a particular situation. Inappropriately high levels of muscle activity may be present in a stereotypical muscle distribution in the extremities, whereas the activity of the trunk musculature may be too low to support an antigravity posture. The therapist must design the interventions creatively to meet the shifting responses of the demands of a particular activity.

Being cognizant that spasticity is a reaction to initial peripheral instability, the therapist must select treatment that deals with the fact that as spasticity is modified, weakness or hypotonicity may be present. Inappropriately high levels of activity in a muscle group or groups may limit the patient's ability to demonstrate optimal postural control (and optimal selective movements as addressed in the second goal). The therapist can select intervention techniques that are mediated through

any of the sensory channels functional for that patient. The choice of which channel or combination of channels to use for the input is based on the therapist's initial and continuing evaluation of the patient's response to specific types of sensory input.

The therapist must address the hypertonicity influencing postural control as a generalized problem before demanding selective voluntary activation of specific muscle groups. Vestibular input that is slow and rhythmical may promote a generalized relaxation of skeletal muscle activity. In some patients, the trunk remains “stiff” in movement sequences in which a segmental response between the upper and lower trunk should occur. Repetitions of rhythmical movements in side-lying in which the therapist gently and progressively stretches the patient's pelvis in one direction around the body axis while moving the shoulder girdle in the opposite direction and then reverses the movement may effectively alter the biomechanical and neurological contributions to the stiffness (Fig. 26.7).

For some patients, changing the dynamics of a spastic extremity may permit the emergence of more optimal levels of postural control. The appropriately designed ankle-foot orthosis (AFO) may alter the individual's need to rigidly control the position of the pelvis to remain upright. Use of a soft webbing thumb loop to alter the resting position of the first metacarpal may change the overactivity of musculature throughout the upper extremity and allow appropriate adjustment of the shoulder girdle as part of postural responses.

If the patient is sufficiently alert that attending to and understanding directions is a possibility, the therapist should direct the person to focus on the effects of the movement responses rather than focusing attention on the movement of the body.³⁷ As the person begins to appreciate the consequences of what is transpiring, he or she should be

Fig. 26.7 Counterrotation of shoulder girdle backward (retraction) and the pelvis forward. Hand placement of therapist is important so that shoulder and hip movements can occur freely.

asked to assist in maintaining the changes that promote the more skillful movement response. Unless otherwise indicated by the patient's status, interventions must actively involve the individual in the process of planning, initiating, completing, and evaluating the movement. Although the therapist may manipulate the environment (internal and external) in which the response is made, the patient must be an active participant for learning to occur.

Although some patients will demonstrate a pattern of generalized overactivity of the postural muscles of the trunk, many will have difficulty generating sufficient activity in the appropriate groups to sustain a posture or to permit movement in the posture. With generalized hypotonia, temporary improvement in postural responses may occur by providing vestibular input that is characterized by rapid and irregular changes. The labyrinths should be stimulated by quick stops and starts with changes in direction. The program should include the introduction of movements in all planes. Approximation can be effective in developing appropriate postural activity from a state of either hypertonicity or hypotonicity. Empirically, it seems that more force is applied to increase than to decrease the postural response. Approximation appears to elicit a response in all the muscles surrounding a joint in preparation for responding to the demands on the erect posture or the demands of weight bearing. Approximation lends itself to combination with other proprioceptive techniques, such as quick stretch or tapping. Although the changes evoked by these techniques may be of short duration, the alterations can evoke movement components that would not otherwise occur and thereby provide the opportunity for the individual to learn from the movement. As the therapist applies various techniques in an attempt to elicit a specific response, the therapist must evaluate the desired response in relationship to the environmental context. If the patient is sitting on the edge of a mat table, the activity of the trunk musculature will vary depending on whether the feet are flat on the floor, the patient is engaged in an activity, the patient is leaning on one arm for support, or the patient is resting between activities. The patient who slouches in sitting when fatigued, bored, or overwhelmed by the sensory input may present a different clinical picture when the appropriate factors are altered.

- *Selective, voluntary movement patterns within functional activities are optimized.*

The concept of the influence of the environment on the quality of a movement response, discussed in relation to the first goal of the intervention process, is also incorporated in the second goal. High-quality, selective, voluntary movement patterns are sought within the framework of functional activities, rather than as isolated and abstract movements. Optimization of the selective movement patterns may require a decrease in the stereotypical linkages of certain muscle groups, an increase in the ability to selectively activate certain muscle groups, the development of the ability to execute the movement in different postures, or a number of other variations.

Performance of functional activities requires that the individual be capable of performing both mobility and stability patterns with the extremities. Mobility patterns are open kinetic chain movements in which the distal segment is free. These patterns are necessary for placing the extremities (e.g., swing phase of gait or reaching for a doorknob).

Patients who exhibit stereotypical posturing of the upper extremity with a restricted repertoire of available movement patterns require intervention to change the initial position of the extremity before movements are attempted. The influence of the spasticity that interferes with the repositioning of the extremity can be reduced by applying approximation through the long axis of the extremity. Preferably, the therapist's manual contacts for the application of the approximation force are on the weight-bearing surfaces of the hand. If

the flexed position of the wrist prohibits application of the force to the heel of the palm, the approximation can be applied gradually through the fist. As the resistance to passive movement diminishes, the wrist can be moved toward the neutral position so that the therapist can apply the approximation through the heel of the palm (Fig. 26.8). The therapist is moving the extremity toward an alternative resting position so that a new movement sequence can be attempted. It is important to use an intervention technique, such as approximation, to reduce the level of spasticity before passive movement is attempted, so that a more appropriate position can be assumed without inappropriately stretching the spastic muscles.

The patient is asked to assist the therapist with the movement, with the person being cued to do so with a minimum of effort. Too often, patients attempt to make a selective movement through a massive effort and overactivation of the muscle groups, which compounds the underlying spasticity. Patients should be encouraged to make easy, effortless movements—those they are instructed to perform with reduced effort so that they can relearn selective activation of motor units rather than mass firing patterns. Working “harder” often creates additional impairments versus increasing normal functional movement responses. It is critical that the movements requested relate to a functional activity or skill. Research suggests that skilled movements require attention and therefore motivation. Shaping the activity to both interest the patient and afford some level of success is important.³³

Electrical stimulation can be used as an adjunct to facilitate performance of a particular component of a mobility pattern. The wrist extension component of the proprioceptive neuromuscular facilitation (PNF) pattern of flexion, abduction, and external rotation can be reinforced by using a portable electrical stimulation unit with adjustable surge duration. The electrical stimulation elicits the correct movement so that the patient can learn from the feel of the correct pattern. Adjusting the practice schedule so that the pattern is performed with and without the electrical stimulation support of the movement avoids the potential problem of reliance on the device to produce the movement. Electromyographic biofeedback can be a useful adjunct to achieve activation of specific muscle groups or to guide the patient's attempts to reduce the level of activity of a muscle group.

Mobility patterns in the upper extremity have as their foundation the freedom of the scapula to adjust appropriately to the position of the humerus. The mobility of the scapula can be addressed through techniques that result in a general decrease in muscle activity and diagonal movement patterns of the scapula. The scapular stabilizers, such as the rhomboids, trapezius, and serratus anterior, must be capable of allowing appropriate adjustment of the scapula, as well as providing the fixation base on which humeral elevation can occur.

In stability patterns, the distal segment of the extremity is fixed (closed kinetic chain). These patterns are used in the weight-bearing components of the functional activities, such as the stance phase of gait or creeping. The components of the stability patterns are enhanced by proprioceptive input, such as approximation. During the performance of both stability and mobility patterns, the therapist should control the situation so that the patient learns the appropriate movement patterns and not those imposed on top of inappropriate muscle activation.

Performance of movement patterns should progress toward an ability to easily reverse the direction of the movement. This can be promoted by incorporating rhythmical movements within a posture or between postures as early as possible in the intervention sequence. The end point at which the reversal is required should vary. In preparation for mastering the movements required to move from supine to sitting on the edge of the mat table, the patient might be

Fig. 26.8 Facilitating Opening of the Hand. **(A)** Fisted hand; stretch to the extensors and approximation through hand, wrist, and elbow is applied. **(B)** Approximation is continued; some resistance to the extensors may be applied. **(C)** Approximation is applied to thenar eminence to further facilitate extensor tone. **(D)** Full extension is achieved; approximation is maintained.

asked to move from the supine position to side sitting and back to supine; then the patient could move from the supine position to side-lying propped on one elbow (the halfway point in the overall movement), then reverse to supine. Incorporating reversal of movement patterns within the intervention program prepares the patient to deal with situations that mandate unexpected adjustments in the movement sequence.

Patients who demonstrate problems with the sequencing of movements, such as those with motor dyspraxia, frequently perform better if the movement is performed at a speed that is close to normal. Patients who had normal movement sequences before the brain infection seem to be able to trigger better movement responses at normal speeds than at slower speeds. The slower movement speeds appear to disrupt the typical flow of the movement. In working with patients with sequencing problems, all team members should provide the same, consistent sensory cues to elicit a movement pattern. For example, the therapist may establish a coupling of the verbal cue “roll” with a quick stretch to the ankle dorsiflexors to elicit a rolling pattern. These same cues can be used by other team members to assist the patient in changing positions in bed or in performing dressing activities. The consistency of cues may elicit a consistent response from the patient. Once the pattern is well established, the intervention program can be designed to reduce the cues progressing toward the ability of the patient to perform the activity in response to the demands of the situation rather than to externally imposed cues.

The flow of a movement pattern may be disrupted by problems categorized as incoordination. The origin of the coordination problems could be dysfunction of the visual-perceptual system (see Chapter 28) or vestibular system (see Chapter 21), dyspraxia (see Chapter 12), or dysfunction caused by cerebellar damage (see Chapter 19). If possible, the factors involved in producing a lack of coordination should be identified.

- *Performance of functional activities is enhanced.*

As the patient develops more appropriate postural control and the ability to perform selective movement patterns within functional activities, she or he is developing the basis to perform increasingly challenging functional activities. The movement patterns (and the postural control that underlies them) provide the building blocks for mastering an expanding variety of activities.

As the therapist designs the expansion of activities within the intervention program, the demands of each new functional activity and posture must be scrutinized. The patient’s ability to meet these demands was examined in the evaluation process. The intervention strategy must focus on the quality of the patient’s ability to assume a posture, maintain the posture, move within the posture (static and dynamic equilibrium responses to both self-generated and external perturbations), and move out of the posture. The therapist will change the sequence of this progression of activities to meet the needs of the patient. The patient may achieve independence in maintaining a posture while still requiring assistance in assuming the posture.

This progression should be grounded within the context of functionally relevant activities. Unless the individual has difficulty tolerating change, activities should be practiced within different environments to enhance generalization of learning. The creative therapist can design a variety of functionally relevant activities that require similar movement components.

With infants, the therapist may choose to use the developmental sequence as a general model for the functional activities progression. Progression through the developmental sequence should be viewed as a dynamic process so that the intervention incorporates movement both within and between postures. For individuals through the remainder of the life-span, the focus should be on the age-appropriate functional activities essential to the individual's daily life, such as bed mobility, sitting to standing, standing to sitting, ambulation, reaching, and manipulation.

Examples of handling techniques that can be adapted to enhance the individual's progression through the sequence of functional activities can be found in the works of Bobath,³⁸ Carr and Shepherd,^{39,40} Duncan and Badke,⁴¹ Levitt,⁴² Ryerson and Levit,⁴³ Sullivan and Markos,⁴⁴ and Voss and colleagues,⁴⁵ as well as throughout this book. These authors can provide the therapist with ideas for ways to enhance the patient's performance within a specific activity.

- *Integration of sensory information is fostered.*

At the same time that the therapist addresses the previous intervention goals, the goal of fostering integration of sensory input must be considered. Unless the therapist has advanced knowledge of sensory integration theories, this goal may be secondary rather than primary; nevertheless, it cannot be ignored.

The potential for an exaggerated and inappropriate response to sensory input was discussed as part of the clinical picture. Before the therapist expects the patient to exhibit adaptive behavior to the potential bombardment of input from combinations of cutaneous, proprioceptive, auditory, and visual input, the therapist must assess the patient's ability to respond to multisensory inputs. The ability to respond adaptively progresses from a response to a single sensory system input, to a response to the input in the presence of multiple-system input, and then to an adaptive response based on inputs from two or more sources. The therapist must be sure that adding more sensory inputs augments an adaptive response rather than detracting from it. The patient may respond to handling techniques that provide proprioceptive and cutaneous cues but may demonstrate a deterioration of performance when auditory input is added. When verbal cues are added, the therapist should follow the philosophy that verbal commands should be concise, sparse, and appropriately timed.⁴⁶

All sensory inputs should evoke the correct response on the part of the patient, rather than cause her or him to sift through the jumble of inputs to recognize the appropriate inputs to which a response should be made. At the highest level the patient will demonstrate cross-modal learning in which input from one sensory system will evoke a response based on input previously obtained through a different system. Recognition of a comb by touch is based on the precept of "combness," usually obtained initially by visual input. If the therapist recognizes the hierarchy in the process of integrating sensory input, intervention situations that require too high a level of performance from the patient can be avoided. The patient who can respond adaptively to input from only one source would not be expected to perform in a crowded treatment area that presents extraneous visual and auditory input. The therapist will also recognize the need to include in the intervention plan situations that involve the controlled introduction of sensory inputs so that the patient progresses toward the ability to deal with multiple inputs. Carr and Shepherd⁴⁰ discuss some general principles that can be used during

the training of motor tasks in the presence of somatosensory and perceptual-cognitive impairments.

Dysfunctions in perceptual integration are addressed as the patient moves through functional sequence activities. Although these movement activities would not provide the total program for an individual with a specific perceptual integration dysfunction, goals in this area can be addressed if the therapist is aware of indications of dysfunctions. The therapist must critically observe the performance of a movement sequence to identify substitute actions to compensate for problems such as inability to cross the midline. The therapist must then attempt to redesign the demands of the situation to elicit the desired behavior. The patient who moves from the supine to the side sitting to the long sitting positions without the upper extremities crossing the midline could be required to side sit to the left and transfer objects with the right hand from the left side of the body to the right side (Fig. 26.9). The therapist must determine whether the patient is truly crossing the midline or rotating the midline of the body to continue to avoid crossing it.

Therapists may be most aware of disturbances in the patient's ability to integrate sensory information into an appropriate response when this dysfunction disrupts balance. The ability to maintain and move in upright postures requires successful processing of information from the sensory triad of postural control: the visual, vestibular, and somatosensory systems. When one component is missing, unreliable, or discrepant with the other two, the person is at risk for loss of balance. During the ongoing evaluation process, the therapist gathers

Fig. 26.9 Child crossing midline of body when transferring objects from left to right. **(A)** Beginning act on contralateral side. **(B)** Ending sequence by crossing midline and placing objects on ipsilateral side.

information on the integrity of each system and any evidence of central processing difficulties. Incorporated within the practice of activities to develop postural control, to promote selective movements with functional activities, and to develop mastery of increasingly difficult functional activities is the simultaneous practice of integrating sensory information so that a successful response can be generated.

Patients who are performing at higher levels can be challenged to maintain balance when one element of the sensory triad is missing (e.g., vision occluded) or altered (e.g., sitting, standing, or walking on a soft, compliant surface). Successful maintenance of balance outside the protective environment of the therapy clinic requires the ability to switch the primary information source to any one of the three systems. Walking in the dark requires the person to rely on vestibular and somatosensory input. Standing on a moving bus looking out a window requires resolution of the conflict between visual input (the external world is moving), vestibular input (you are moving), and somatosensory input (you are stationary). Movement experiences within the therapy program should foster practice of this sensory integration process (see Table 26.2).

- *Cognitive status and psychosocial responses are optimized.*

In addition to attending to the factors directly related to motor performance, the therapist also must attend to the patient's psychosocial and cognitive responses. Although the therapist does not have primary responsibility in this area, a goal of the intervention process should be to enhance the individual's psychosocial and cognitive responses.

Particularly in the agitated state that may be a component of the response to the inflammatory process, the patient may demonstrate exaggerated and inappropriate emotional responses to events. Dealing with these emotional fluctuations can become a major determinant in goal attainment in the other areas. Maintaining a positive, nonthreatening interaction allows the patient to use the therapist as a reference for judging the appropriateness of emotional responses.

If the patient's state of agitation is interfering with the intervention program, the therapist may alter the program to include techniques that have a calming effect. For example, the individual can be wrapped in a cotton sheet blanket and rocked in a slow, rhythmical, repetitive manner to decrease agitation. Auditory and visual input should be controlled to avoid overloading sensory processing mechanisms.

Earlier in this text, the psychosocial adjustment that occurs in the process of recovering from a neurological disability was discussed. The therapist must be aware of how the patient's regression in affective and cognitive domains affects the intervention process. The therapist should seek assistance from the health care team members responsible for intervention in these areas to deal with the patient constructively. The therapist must remember that both the family members and the

patient are in the process of adjusting to the patient's changed and, it is hoped, changing status. Family members may be an asset or a liability to the patient's recovery process. During the therapist's interactions with the family members in activities such as instructions in the patient's home program, the therapist should be prepared to deal with expressions of the individual's difficulty in adjusting to the situation. The therapist also should be prepared to assist family members in identifying appropriate sources to help them deal with their problems.

Changes in mentation, perception of events, and memory losses present challenges to both the patient and the therapist. Repetition in the recounting of past events may help reorder past knowledge. Use of brief verbal or visual cues may assist the patient in recalling safety instructions or the components of the exercise program. The therapist should try to generate a nonstressful environment when working on these deficits so that attention and recall are not overshadowed by emotional pressure. As the therapist works with the patient on an intervention program, situations arise that require problem solving to determine a way to accomplish a task. If the task is to accomplish an independent transfer from a wheelchair into a bathtub, decisions must be made concerning the sequence of movements. Therapists can approach this situation in two ways. They can instruct patients step-by-step in what to do, or they can involve patients to the extent possible in the process of deciding what to do. If the therapist instructs the patient step-by-step, the patient may master the task but may not be able to perform it under different conditions. If the therapist involves the patient in the decision making process, the patient may be learning not only how to accomplish the specific task, but also how to accomplish the task under varied conditions. The intervention process should lead to the ability to respond to the demands of a situation, and involvement of patients in the problem-solving process helps prepare them for independence. The therapist must structure the patient's role in decision making to the level of the patient's ability to participate so that the experience is not frustrating. Although the patient's participation may initially increase the time required to complete a task, it promotes skills that may lead more quickly to independence of function.

INTERACTION WITH OTHER PROFESSIONALS

The therapist needs to design an intervention program that is articulated with that of other members of the health care team. The recovery process of the patient should be facilitated by a care plan in which each team member reinforces the goals of the other team members. The care of the person must be a collaborative effort. Each patient deserves an intervention process that considers him or her as a whole person, not as a set of fragmented problems.

SUMMARY

This chapter has presented a brief discussion of the pathology and medical management of various inflammatory processes that affect the brain. The process of assessment, the role of assessment in designing an intervention program, the goals of the intervention process, and the means to meet those goals were presented to assist the reader in more effective management of patients with these diagnoses.

Although the problem-solving process presented in this chapter for assessment, prognosis, goal identification, and treatment planning is not limited to patients with inflammatory supraspinal disorders, its application in the presence of typical neurological sequelae has been described. When dealing with inflammatory disorders of the brain, the variability of neurological sequelae is examined based on the

anatomical location of the inflammatory process and the cause of the infection.

Although the neurological disorders discussed in this chapter are life threatening, many patients recover and return to their previous lifestyles. Patients will vary within the spectrum of minimal to severe involvement and from specific to generalized CNS dysfunction and will demonstrate a range of recovery after the acute distress, from little recovery to full recovery. Prognosis for recovery depends on the type of infecting organism and the extent of involvement. The therapist must remain flexible and willing to adjust every aspect of therapeutic intervention to meet the specific needs of each patient. Yet the therapist must also remember that learning requires active participation on the part of the patient.

CASE STUDY 26.1

A 74-year-old patient with cryptococcal (*Cryptococcus gattii*) meningitis was seen in the outpatient setting 1½ years after onset with residual complaints of constant dizziness, imbalance, and need for assistance with mobility tasks.

History of Present Illness

Patient manifested dementia and overt meningitis 1½ years prior. He was treated with liposomal amphotericin B + 5FC for 3 weeks and then put on fluconazole. He was transferred to a skilled nursing facility with dementia and need for significant assistance for all ADLs. His cognition and functional status continued to diminish over the next 3 months, when it was determined he had hydrocephalus, and a VP shunt was placed. This resulted in significant improvement in mentation and function, and he was discharged home with home care 3 months later.

Past Medical History

The past medical history included profound bilateral sensorineural hearing loss postmeningitis, chronic obstructive pulmonary disease (COPD), and possible Parkinson-like symptoms.

Summary of Key Findings

The patient was alert and oriented to person, place, time, and reason for referral. He had some short-term memory loss. He lived with his wife in a single-story home. He was walking with a two-wheeled walker with standby assistance as his primary mode of mobility. He had difficulty with steadiness during transfers and when turning. He complained of constant dizziness, which he described as a sense of movement and at times spins. All movements worsened the symptoms, and being still decreased the symptoms.

Vision screen was normal, but he complained of increased dizziness with eye movement. Vestibular ocular testing findings were abnormal; patient had a positive head-thrust test result bilaterally, and abnormal DVA with head movements at 2 Hz. Light touch and proprioception were intact for both legs. The accompanying table presents a summary of objective findings.

	FTSST	Strength	Berg	SOT	Ambulation	DVA (2 Hz)
Initial	18.73 s	LE 5/5, except hip extensor 4/5, and PF 2/5 bilaterally	38/56	28% (fell 9/18 trials—all sway referenced support)	Two-wheeled walker with SBA	20/200
1 month	15.12 s	Not tested	55/56	Not tested	Two-wheeled walker independent	20/125
2 months	Not tested	LE 5/5 except PF 4/5	Not tested	39% (fell 6/18 trials—conditions 5 and 6) Use of vision significantly improved from 0% to 55%	Single-point cane	20/80 horz
3 months	15 s	Not tested	55/56	Not tested	Single-point cane	20/63–2 ^a at 2 Hz (horz); 20/80 (vert)
4 months	12.1	LE 5/5 with PF 4/5	Not tested	56% (fell 4/18 trials—first 2 attempts conditions 5 and 6)	No device on level surfaces, cane on uneven surfaces	20/50
5 months	51 s	Hip abductor 4/5 and ankle PF 2+/5	34/56	Fell conditions 3 and 4 of M-CTSIB in <5 s	Two-wheeled walker	20/100
10 months	16.9 s	LE 5/5 except PF only 2+/5	52/56	Only falls condition 4 of M-CTSIB	Single-point cane all surfaces	20/125

^aThe patient read the line with two errors.

DVA, Dynamic visual acuity test; FTSST, five-times-sit-to-stand test; horz, horizontal; LE, lower extremity; M-CTSIB, Modified Clinical Test of Sensory Interaction and Balance; PF, plantar flexors; SBA, standby assist; SOT, Sensory Organization Test; vert, vertical.

Physical Therapy Movement Diagnosis

The patient had an increased risk of falls, with significant balance impairment and gaze instability consistent with mixed peripheral (bilateral hypofunction) and central vestibular dysfunction postmeningitis (Physical Therapy Practice Patterns 5D and 5A). He also had lower-extremity weakness and reduced vertical orientation. His strengths included supportive family and excellent motivation.

Goals

1. Patient will be able to ambulate independently in his home without assistive device (4 months).
2. Patient will improve gaze stability to 20/80 with head movements at 2 Hz in either direction (4 months).

3. Patient will be independent and safe to negotiate a flight of stairs with rail (2 months).

4. Patient will be able to maintain standing with eyes open on foam surface >30 s (2 months).

Interventions

The patient lived 2 h from the clinic, so many of the interventions were through progressive home exercises. Patient was seen one or two times each month, and the program consisted of balance retraining, gaze stability exercises (vestibulo-ocular reflex [VOR] retraining beginning in sitting, plain background), lower-extremity strengthening, endurance activities, and gait training. Given the patient's hearing loss and memory deficits, teaching included demonstration, written instructions, and instruction of the patient's wife. The patient

Continued

CASE STUDY 26.1—cont'd

progressed steadily the first 4 months, then he began not feeling well. He complained of increased nausea and trouble eating and had a slow decline in mentation. At the 5-month visit, the patient's condition had declined significantly, and after discussion with the patient's physician, he underwent a series of tests that concluded the patient was having intermittent shunt malfunction. After the shunt revision, the patient did improve as noted at the 10-month follow-up visit.

Key Take Home Points

1. It is not unusual to have both cranial nerve and CNS involvement with meningitis.
2. Remember to monitor for signs of shunt malfunction, and the importance of educating the patient and family members concerning this.
3. Use standardized objective measures in case management.

ACKNOWLEDGMENT

I would like to thank Dr. Rebecca Porter, PhD, PT, for her contributions to the first four editions of this book. She not only has made a significant contribution through her publications and this chapter in the book but also is an inspiration to many of us within the profession of Physical Therapy.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 46 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: The diversity of neurological sequelae that may occur after an inflammatory disorder in the brain (brain abscess, encephalitis, or meningitis) provides a range of challenges to the rehabilitation team. The therapist must identify the problems underlying the individual's movement dysfunctions without the template of the cluster of "typical" problems available with some other neurological diagnoses. Each patient presents a combination of problems, which is unique to that patient and which requires the creative design of an intervention program. The following discussion of the therapeutic management of

individuals recovering from an inflammatory disorder in the brain focuses on the process of designing an intervention plan to address the specific dysfunctions of the individual patient. Because the management of the clinical problems is built on an understanding of the underlying pathological condition and because therapists may not be as familiar with these disease processes, an overview of the inflammatory disorders of the brain is presented.

Keywords: brain abscess, encephalitis, functional activities, hypertonicity, hypotonicity, intervention goals, meningitis postural control

Aging, Dementia, and Disorders of Cognition

Mark David Basco, Edward James Gorgon, Ronald Barredo, Osa Jackson Schulte, James Stephens, and Joyce Ann

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Define the basic terminology and discuss the prevalence of cognitive disturbances seen in older persons.
2. Describe normative changes in brain function with normal aging and their relevance to the diagnoses of delirium and dementias.
3. Discuss how symptoms are altered with normal aging (specifically related to the Arndt-Schulz principle, law of initial values, and habitual biorhythms) for an individual.
4. Describe normal sensory changes with aging and how they alter a person's overall ability to adapt to stress.
5. Describe how (and for what type of patient) to use the Mini-Mental State Examination as a part of the physical or occupational therapy examination.
6. Describe common sensory changes with dementia and implications for adapting physical or occupational therapy evaluation and intervention.
7. Discuss common changes in learning styles with aging and implications for adapting physical or occupational therapy intervention to enhance patients' ability to perform at their highest functional level.
8. Describe how environmental design and ergonomics can enhance patient performance in activities of daily living and instrumental activities of daily living.
9. Describe a strategy to evaluate a patient's emotional capacity to participate in a learning task and its clinical relevance to both occupational and physical therapy outcomes.
10. Describe criteria for delirium and reversible dementia and sample strategies for modifying evaluation and treatment procedures.
11. Discuss symptoms and disease progression in irreversible dementia.
12. Discuss the therapist's role on the treatment team in educating key caregivers and support personnel and sample training strategies.
13. Discuss treatment skills that are helpful in working with persons who have irreversible dementia.
14. Describe research activities and new findings that affect physical evaluation and treatment of the patient with dementia or delirium.

caregiver training and support
dementia and delirium
function

physical and occupational therapy examination and intervention
problem solving
risk reduction and rehabilitation
therapeutic environment

THE STARTING POINT WITH OLDER PERSONS IN PHYSICAL OR OCCUPATIONAL THERAPY

Older persons can adapt to new physical problems. It is critical to use the processes of habilitation and rehabilitation to train caregivers (family, friends, or staff) to bring out the best functional performance in the older person. The health care staff, caregivers, family, and friends relating to the older person in a time of crisis need to prioritize creating a sense of safety, acceptance, and support based on the patient's preferences and habits. The specific actions in this process include the following:

1. Evaluate, document, and make available to the hands-on caregivers what the patient "likes"—his or her preferences and habits for all

activities of daily living (ADLs) and instrumental activities of daily living (IADLs).

2. Train caregivers to create a care plan for daily living and nursing that builds in the patient's preferences to support his or her personal identity and self-image.
3. Create specific physical therapy or occupational therapy functional goals that build on and reinforce patient preferences with regard to mobility, eating, bathing, grooming, dressing, socialization, and so on. (Note: If caregivers change, training needs to be added and new goals may need to be developed because not all caregivers have the same capacity to relate to the patient.)
4. Train caregivers with the older person to use specific strategies to (a) enhance breathing, (b) increase bed mobility, (c) improve

balance in sitting and standing, (d) perform active range of motion (AROM) and active assisted range of motion (AAROM) for ADLs and IADLs, (e) achieve skeletal weight shift for ADLs and IADLs, (f) encourage head, neck, and spine to upright postural response during ADLs and IADLs, and (g) encourage walking and stair climbing safely and as able.

5. Screen for signs of reversible cognitive losses.
6. Provide adaptations and training for performance of ADLs when chronic cognitive problems exist.
7. Train caregivers and the older person in ways to adapt the ADLs and IADLs to maximize ability.

PARADIGM FOR AGING, THE BRAIN, AND LEARNING

Aging is a process that requires ongoing adaptation to and compensation for the losses that are imposed on human beings from the *outside* world and the internal physiological changes that occur with the passage of time, physical activities, emotional state, fatigue, digestive and elimination processes, and habitual rest-activity cycle. If a person's health is altered by illness or trauma, then he or she goes through an adaptive process. If too many changes happen too quickly, the brain is unable to create a functional adaptive response, and the individual must alter or simplify her or his life processes or face negative mental or physiological reactions. As human beings explore coping with unfamiliar experiences, they require more nurturing, rest, and physical contact that are perceived as empowering.

Human beings progress to adulthood through the millions of perceptions and choices that are recorded and responded to throughout the developmental years. With advancing age, there is a gradual decrease in the acuity of the kinesthetic and sensory information received. These changes can affect interactive learning for the older adult.¹⁻³ Active participation has a positive impact on recall and learning,⁴ predictable events support recall,⁵ and ordered events are easier to recall. Differentiations in the nervous system for human beings do not happen uniformly.^{6,7} As a person grows, the result of this lack of uniformity is that some adults prefer to relate to the world visually, others aurally, and still others by touch or kinesthetically. Therefore people specialize with their sensory processing and, at the same time, become more vulnerable to issues of sensory adaptation and selection.⁸

The adult phase of central nervous system development will, for most people, involve a gradual narrowing of the focus in the development of new skills as well as increased repetition of certain activities. The tendency is to narrow down one's activities more and more to those in which a person excels or feels comfortable. Intuitive or practical people continue to pursue self-knowledge and explore ways to maximize their talents. By accident or through mentoring, these people discover that lifelong learning is the gift of life itself. Ongoing and ever-increasing self-awareness allows for enhanced adaptability at any age.

Indeed, the human brain has been found to be malleable and adaptable in old age, and even in the presence of various neurological insults. Neural growth has been observed in mature neurons,⁹ hippocampal volume increases with physical activity, and myokines derived from muscle contraction have been found to modulate brain function.¹⁰⁻¹⁵ Thus the presence or absence of physical experiences (e.g., human movement) and an enriching environment¹⁶ provide powerful stimuli for brain activity.¹⁷⁻¹⁹ The challenge for the rehabilitation professional is how to harness such potential and structure the therapeutic environment to attain an optimal outcome for the patient/client.

In this chapter, the paradigm for aging and lifelong learning presumes the following:

1. The central nervous system is viewed as the master system and the controller of other human systems (e.g., digestive, cardiovascular, muscular, and endocrine).
2. Capacity exists for ongoing learning (self-awareness), self-regulation, and adaptability throughout the life-span.
3. The whole (human being) is greater than the sum of its parts.
4. Language shapes reality and the experience and perceptions of life.
5. Enjoying a comfortable and easy pace for new learning is beneficial. Being able to learn new skills is important for adaptability and lifelong well-being.
6. The mind and body are not separate. Multiple chronic medical conditions, smoking, lack of physical mobility, and loss of muscle strength (among others) impact the mind, while a physically active lifestyle, healthy dietary intake, and lack of cardiovascular diseases mitigate the risks associated with an aging mind and body.²⁰⁻²³
7. Optimal aging begins in early adulthood. It is rooted in advocating for a healthy lifestyle, which reduces one's risk of acquiring debilitating mental and physical illness in later life.^{24,25}
8. Personal variations in learning style and preferences for relating can be used to maximize adaptation in the presence of physical and cognitive decline.
9. The activation of the limbic system for "fight or flight" is normal, and the ability to release the limbic activation and return to a resting state once a crisis (real or imagined) is over becomes a critical skill for adapting as people grow older.²⁶
10. The creation of environments that encourage safe exploration of new ideas and ways of self-expression can generate lifelong human growth and development.

FRAMEWORK FOR CLINICAL PROBLEM SOLVING

Therapists working with patients with cognitive impairments need to have received adequate advanced training in the assessment of communication skills and neurological functioning as well as gerontology so they can work with maximal efficacy and enjoy the clinical interactions with each patient. In the United States, there is a lack of adequately trained professionals to address the many health issues that accompany the rising number of older adults in the general population.²⁷ In 37 BC, the Roman poet Virgil wrote, "Age carries all things, even the mind, away."²⁸ Nearly 400 years ago, Shakespeare described the last stage of human life as "second childishness and mere oblivion, sans teeth, sans eyes, sans taste, sans everything."²⁹ This pessimistic view of the fate of older adults persists among health care workers today despite the fact that significant cognitive deficits affect only 9%³⁰ of older adults (people older than age 65 years) in the United States.^{31,32} Clinicians therefore should not assume that older individuals have impaired cognitive functioning.³³

Perhaps the most crucial concept for clinical problem solving is that the clinician must not assume that the current abilities reflect the true capacity of the person. When a patient is observed to have altered brain function, description of the extent and type of the distortion of intellectual capacity and determination of the time of onset (sudden or gradual) are necessary to enable a diagnosis and the provision of appropriate and effective treatment and care. The capacity to learn is a possibility, although the process of learning may be altered or different from that of unaffected older adults.³⁴⁻³⁷ When age, illness, or medications create a temporary or permanent change in cognitive abilities, all functional training requires alteration to meet the unique cognitive abilities of the patient at the moment. For example, the son of a patient who needed physical and occupational therapy showed staff how to communicate with his mother so that she would not get scared. The

therapist walked slowly into the room and greeted the patient by touching her softly on the cheek with the back of her hand. The patient looked up and smiled. The therapist smiled back and stroked the patient softly on the top of her head. The patient smiled again. The therapist knelt down so that she was eye-to-eye with the patient sitting in the wheelchair. She took the patient's hand in her own hand and with her other hand slowly stroked the back of the patient's hand. The patient smiled again. The therapy session had begun. For this patient, words were actually confusing, so they were avoided.³⁸ The need for tactile nurturing input persists as people age.³⁹ Nurturing tactile input done at a pace that is pleasant for the patient can actually support a positive clinical outcome.⁴⁰

Definition of Terms

Neurocognitive disorders, including dementia, arise from acquired changes in the brain, which lead to declines in the cognitive function of an individual.^{41,42} They differ from mental retardation (developmental disability) in which changes arise early in life and baseline cognitive function do not necessarily decline. Though commonly associated with older adults, neurocognitive disorders in the younger population do occur, especially among individuals with human immunodeficiency virus (HIV) infection and traumatic brain injury.^{41,42} In 2013, the American Psychiatric Association published the 5th edition of its Diagnostic and Statistical Manual (DSM-5) and incorporated concepts such as “dementia” and “mild cognitive impairment” into its revised classification system. Major neurocognitive disorder corresponds with dementia, while minor neurocognitive disorder is similar to mild cognitive impairment (Table 27.1).

Major neurocognitive disorders are differentiated from minor neurocognitive disorders in the (a) severity of cognitive decline from a previous level of performance and (b) interference with independence in everyday activities. Cognitive decline in one or more domains could be expressed by the patient or a reliable informant, and/or observed by a clinician. The severity of decline could then be classified as modest or substantial using standardized testing procedures or similar objective clinical evaluation tools.

- Modest cognitive decline: Test score between 1 and 2 standard deviations below the appropriate norm, or between 3rd and 16th percentile rank.
- Substantial cognitive decline: Test score below 2 standard deviations of the appropriate norm, or below 3rd percentile rank.

Cognitive decline in both Major and Minor Neurocognitive disorders could manifest in one or more of these domains: complex attention, executive function, learning and memory, language, perceptual-motor-visual perception praxis, and social cognition. Recognizing early signs of decline (red flags) in any of these domains is paramount in establishing a diagnosis and formulating a timely management plan.

Delirium differs from major and minor neurocognitive disorders in its *sudden and rapid onset*.^{41,43} A person with delirium shows an acute disturbance in attention, environmental awareness, and cognition from baseline; changes in sleep-wake cycle and emotional states; and worsening of behavioral problems.^{41,44–46} The patient is often less alert than normal and may be sleepy or obtunded; however, many are hypervigilant and may be extremely agitated and suspicious. Early identification of the symptoms as well as formal medical assessment and treatment are critical to ensure the return of a normal level of

TABLE 27.1 DSM-V Diagnostic Criteria for Major and Minor Neurocognitive Disorders

Diagnostic Criteria	Major Neurocognitive Disorder (Dementia)	Minor Neurocognitive Disorder (Mild Cognitive Impairment)
A	<p><i>Significant cognitive decline</i> in one or more cognitive domains, based on:</p> <ol style="list-style-type: none"> 1. Concern about significant decline, expressed by individual or reliable informant, or observed by clinician 2. Substantial impairment, documented by objective cognitive assessment 	<p><i>Modest cognitive decline</i> in one or more cognitive domains, based on:</p> <ol style="list-style-type: none"> 1. Concern about mild decline, expressed by individual or reliable informant, or observed by clinician 2. Modest impairment, documented by objective cognitive assessment
B	Interference with independence in everyday activities	No interference with independence in everyday activities, although these activities may require more time and effort, accommodation, or compensatory strategies
C	Not exclusively during delirium	
D	Not better explained by another mental disorder, e.g., major depressive disorder, schizophrenia	
E	<p>Specify one or more etiological subtypes, “due to”</p> <ul style="list-style-type: none"> • Alzheimer’s disease • Cerebrovascular disease (Vascular neurocognitive disorder) • Frontotemporal lobar degeneration (Frontotemporal neurocognitive disorder) • Dementia with Lewy bodies (Neurocognitive disorder with Lewy bodies) • Parkinson disease • Huntington disease • Traumatic brain injury • HIV Infection • Prion Disease • Another medical condition • Multiple etiologies

TABLE 27.2 Key Characteristics in Depression, Delirium, and Dementia

	Delirium	Depression	Dementia
Onset	Acute (hours to days)	Acute or insidious	Insidious (months to years)
Course	Fluctuates hourly, lucid periods in a day, confusion usually worsens at night Commonly results from acute illness, medical emergency	Episodic; may be self-limiting, recurrent, or chronic	Chronic, slow progression Starts in mid-life, may take 20 years from onset of mild cognitive impairment to severe dementia
Duration	Days to months Usually reversible	Variable	Months to years Irreversible
Consciousness	Reduced, fluctuates	Clear	Clear in the early stages, progressively gets worse in the later stages
Hallucinations	Frequent, usually visual and/or auditory in nature	Variable, predominantly auditory	Often absent in early stages; may have visual hallucinations in the later stages
Delusions	Fleeting, poorly systematized	May have sustained, systematized delusions	Often absent
Poor attention	Variable	Variable	Present, progressive
Disorientation	Present	Variable	Progressively gets worse in the mid-late stages
Memory	Immediate and short-term memory impaired	Variable, may be minimally or selectively impaired	Gradually worsens with disease progression
Psychomotor	Variable, may be increased or reduced	Variable, may range from hypoactivity to hyperactivity in the case of agitation	Often normal
Speech	Often incoherent Slow or rapid	Normal	Initially coherent; speech impairment worsens in later stages
Thinking	Disorganized	Impoverished	Limited, executive functions deteriorate with disease progression
Affect	Variable	Depressed, presents with apathy and anhedonia	Variable, may present also present with anhedonia and apathy in later stages
Sleep/wake cycle	Disturbed; changes every hour	Disturbed; hypersomnia may be present during the day	Disturbed; day/night reversal

WRHA Occupational Therapy Cognition Toolkit FAQs, Winnipeg Regional Health Authority, Feb. 2013. Available at: www.wrha.mb.ca/professionals/cognition/files/Survey-07.pdf. Accessed December 24, 2018. Updated data from Downing LJ, Caprio TV, Lyness JM. Geriatric psychiatry review: differential diagnosis and treatment of the 3 D's—delirium, dementia, and depression. *Curr Psychiatry Rep.* 2013;15(6): 365. doi:10.1007/s11920-013-0365-4 and Reisberg, Barry, et al. "Staging Dementia." *Principles and Practice of Geriatric Psychiatry*, 3rd ed. Hoboken, NJ: John Wiley & Sons; 2011:162–166.

alertness and intellectual function and to prevent the development of secondary functional impairments.^{43,47,48}

Psychiatric problems may be present before old age or may develop as a result of dementia and need to be assessed and treated along with the dementia. Depression, for example, can mimic dementia and may be hard to recognize given its atypical and subtle nature among older adults. Pain, weakness, headaches, agitation, fatigue, unexpected change in weight/appetite, chronic constipation, insomnia, hypersomnia, and irritability may be observed. Table 27.2 outlines the key characteristics of delirium, depression, and dementia.^{49,50}

Epidemiology

Currently, 50 million people worldwide have dementia, with nearly 10 million new cases every year.^{33,51} In the United States, 5.7 million Americans and one in ten people over the age of 65 years are estimated to have Alzheimer's disease (AD),⁵² the most common cause of dementia.^{33,51,52} By 2050, the number of people with AD is estimated to increase to 13.8 million in the United States and 132 million globally, if current trends continue and no cures or effective preventive

measures are found.⁵² The percentage of adults aged 85 years and older with AD will increase from 2.1 million in 2018 (37% of all older adults) to 7 million (51% of all older adults) in 2050.⁵² The prevalence of dementia rises from approximately 3% at ages 65 to 74 years to 17% at ages 75 to 84 years, and to 32% at age 85 years^{52,53} or higher (Fig. 27.1). The increasing number of people older than the age of 85 will be paralleled by an increase in the incidence of dementia. Disorders causing cognitive deficits are expected to continue to be a growing public health problem for at least the next 50 years.

More than 70 conditions are known to cause dementia.⁵⁴ Secondary behavioral problems in the patient with dementia can be interpreted as a response to somatic, psychological, or existential stress. Because memory impairments, impairments of abstract thinking or judgment, or global cognitive impairments in an older adult may be symptoms of acute physical illness, the patient's physical, emotional, social, and cognitive status and physical, social, and caregiver environment need to be systematically evaluated.⁵⁴

Gradual or sudden changes in intellectual capacity or memory function are not a normal part of the aging process. Any change,

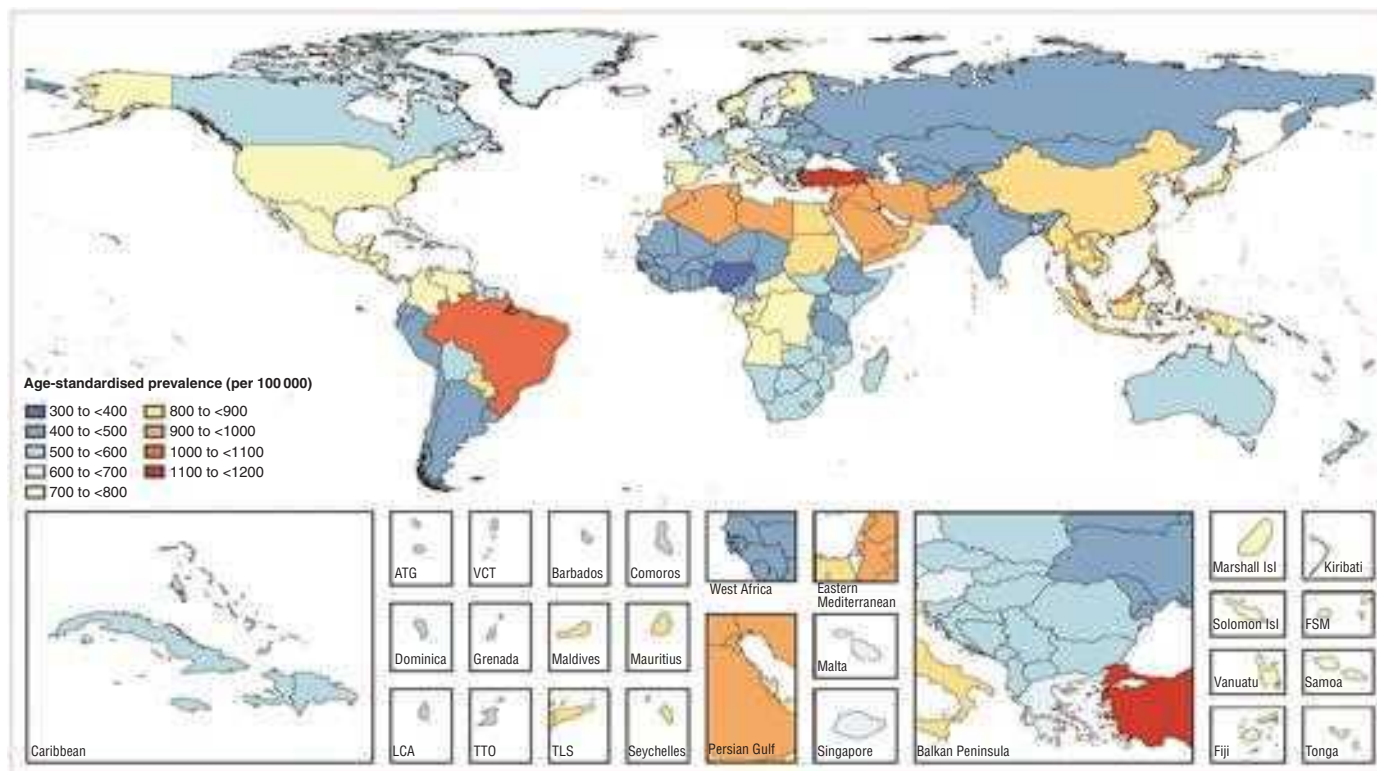

Fig. 27.1 Global age-standardized prevalence of Alzheimer's disease and other dementias by sex, 2016. (From GBD 2016 Dementia Collaborators. "Global, Regional, and National Burden of Alzheimer's Disease and Other Dementias, 1990–2016: a Systematic Analysis for the Global Burden of Disease Study 2016." *The Lancet Neurology*, vol. 18, no. 1, 26 Nov. 2018, pp. 88–106.)

whether it develops slowly over time or happens suddenly, should be diagnosed, and when possible, the underlying cause(s) of the delirium or dementia should be treated. Even if the cause of the dementia is untreatable, teaching the patient and significant others strategies to make the patient's ADLs and IADLs easier to manage is always possible.

Physical and occupational therapists are an important part of the comprehensive evaluation, treatment, and caregiver training for patients with delirium or dementia.^{55–59} All treatment planning should occur as a part of a team effort in which the patient, the family or significant others, physician, nurses, social worker, physical therapist, and occupational therapist collaborate so that a consistent treatment plan and orientation are followed. Inclusion of the day-to-day caregivers is crucial for all training because they—more than anyone—need to know and use the adaptations for the patient's personal style of communication and how to facilitate functional movement for ADLs and IADLs.

PHYSIOLOGY OF AGING: RELEVANCE FOR SYMPTOMATOLOGY AND DIAGNOSIS OF DELIRIUM AND DEMENTIAS

The Normal Brain

The brain of a normal person at age 80 years shows several significant anatomical, physiological, and neurochemical changes when compared with the brain of a younger person. Brain weight decreases with advancing age.⁶⁰ Neuropathological changes, such as the deposition of senile plaques and neurofibrillary tangles, and multiple-domain cognitive decline do occur. However, such changes are not associated with

significant functional limitations in healthy older people. In contrast, older people with neurodegenerative conditions demonstrate tremendous neuronal loss and substantial declines in cognitive function.^{61–63} Normal age-related changes vary from person to person in degree and severity and can include the following:

- Disturbance in the ability to register, retain, and recall certain recent experiences^{33,64}
- Slowed rate of learning new material³⁶
- Slowed motor performance on tasks that require speed^{36,65}
- Difficulties with fine motor coordination and balance^{66–72}

A motivated, upbeat older adult who is not undergoing emotional stress will show few negative changes in intellectual capacity and may actually demonstrate an increase in intellectual functioning over time.^{29,73–75} Neuroplastic changes continue through old age and research has shown that specific parts of the brain can increase in volume, functional connectivity in the brain can improve, and cognitive performance can be enhanced if older persons are immersed in optimal experiences and exposed to enriched environments.^{12,76–81}

Because many of the variables that need to be considered as part of the clinical evaluation of the rehabilitation potential of the person with dementia are affected by both aging and disease, therapists working with the older adult should be aware of these variables. The therapist explores ways to compensate for these changes; as a result, the patient will have a greater possibility of achieving her or his potential for self-care and contentment.

A slowing of the natural pace of movement is commonly noted in older adults. This slowdown is manifested in the brain as a slowing of resting electroencephalogram (EEG) rhythms (e.g., the mean frequency of the occipital rhythm is 10.3 Hz at the age of 60 years versus 8.7 Hz at the age of 80 years). The speed of nerve

conduction in older adults can be 10% to 15% slower than in younger persons.⁸²⁻⁸⁴ Because of these physiological changes, if the process and structure of evaluation and care of the healthy older adult emphasize speed of execution or timed activities, they will appear less capable than they really are. The therapist may need more time when working with persons older than 70 years than is generally required with younger individuals.

The brain is the most physiologically active organ in the body. The brain represents only 2% of the total body weight, yet it consumes up to 20% of the oxygen and 65% of the glucose available in the circulation in the entire body.²⁸ The minimal cardiovascular output required to deliver this is 0.75 L/min, which is equal to 20% of the total circulation (also dependent on body size). Because of the high level of nutrient use by the brain, it is one of the organs of the body most likely to be affected by any acute change in homeostasis. The homeostasis of the older adult brain is more vulnerable to disruption because of the normal age-related changes already discussed, as well as the increased permeability of the blood-brain barrier and increased sensitivity of neurons to the effects of outside agents such as drugs,⁸⁵ food, and allergens.

Arndt-Schulz Principle

The Arndt-Schulz principle summarizes the differences between the abilities of the younger brain and the aged brain to discriminate or respond to stimuli.⁸⁶ In older adults, a higher level or a longer period of stimulation is required before the threshold for initial physiological response is reached. Their physiological response is rarely as large, as visible, or as consistent as noted in younger individuals. The implication of the Arndt-Schulz principle for clinical problem solving is that the level of a stimulus (e.g., heat, cold, sound, light, or emotional input) needs to be adjusted to compensate for the altered physiology of the older adult patient. Optimal balance of the levels of sensory stimulation and emotional stimulation that is therapeutic for a young person may not be therapeutic for the older adult. The stimulus may be too low so it does not reach the threshold for generating a physiological response, or it may go beyond the safe therapeutic range for the older adult and become harmful. Therefore when an older adult patient does not respond to treatment or presents an unusual physical response, the clinician needs to ascertain whether the strength of the stimulus is too strong or too weak and whether modification of the stimulus is necessary because of factors associated with the aging process or the patient's cognitive deficits (e.g., he or she may be unable to accurately report the response because of a cognitive deficit). The older person with mild or moderate confusion needs small, slow clinical input and precise monitoring of the general response (heart rate, blood pressure, and respiration) as well as of the local response. This adjustment in approach is especially important for people with hearing impairment. Because the patient may not hear what is being spoken, the therapist may assume that the patient does not have the capability to comprehend what is being said.

Law of Initial Values

The law of initial values is both a physiological and a psychological principle stating that with a given intensity of stimulation, the degree of change produced tends to be greater when the initial value of that variable is low at the onset of stimulation. Therefore the higher the initial level of functioning, the smaller the change that can be produced.^{87,88} The law of initial values, when defined and applied to younger individuals, presumes that homeostasis is a stable and consistent process. When the law is used to describe physiological and psychological responses in older adults, it cannot be presumed that homeostasis for any variable is predictable or consistent from one

person to the next, or even within a 24-hour period for the same individual. For example, an older person with mild dementia may eat only sweets if left without companionship at a meal. As a result, after the meal, the individual may feel unsteady and afraid to walk back to the room.

Biorhythms

The brain has a biological clock that controls all physiological functions in a precise temporal course, whether daily (e.g., secretion of some hormones), monthly (e.g., menstruation), or during a certain period of the life cycle (e.g., ability to become pregnant)⁸⁹⁻⁹¹. Before evaluating an older adult patient with dementia or a disturbance of intellectual functioning, assessment of the patient's premorbid biorhythm is helpful. What was his or her daily schedule of activities before the medical crisis? An assessment or time study can map such things as rest periods, activities and level of exertion, sleep or rest periods, mental stimulation, emotional stimulation, eating, and elimination cycles across a 24-hour period. The patient assessment must allow for and assess the current and past variability of individual biorhythms. These biorhythms should be clearly documented, and their stability should be evaluated and maintained as much as possible (critical if the patient will be going back to the family). Defining the peak times of day for awareness and intellectual capacity for each individual is necessary. For example, some patients are best able to participate in learning a new skill in the early morning, and some only in the late afternoon. If a woman has worked for 40 years as a night nurse, being primarily active from 11 p.m. to 7 a.m., she will most likely be alert and best able to participate in a rehabilitation program during those hours. In most cases the patient should be allowed to choose the best time for treatment. For patients whose dementia is too severe for them to make this determination, the staff can monitor the patient's behavior and choose a time for treatment when the person is most alert. For older adults with dementia, the time of assessment and treatment must be documented to maximize the person's rehabilitation potential.^{92,93}

Cognitive Changes in Normal Aging

The idea that cognitive decline is a necessary part of aging is a myth. This belief has been debunked by research on crystallized and fluid intelligence.^{94,95} Crystallized and fluid intelligence are components of general intelligence. Crystallized intelligence involves the ability to perceive relationships, engage in formal reasoning, and understand intellectual and cultural heritage. Crystallized intelligence can be affected by the environment and the attitude of the individual.⁹⁶ Crystallized intelligence can increase with self-directed learning and education as long as a person is alive. The measurement of crystallized intelligence is usually in the form of culture-specific items such as number facility, verbal comprehension, and general information.

Fluid intelligence, what has been called "native mental ability," is the product of the brain's information processing system. It includes attention and memory capacity and the speed of information processing used in thinking and acting.⁹⁷ It is not closely associated with acculturation. It is generally considered to be independent of instruction or environment and depends more on the genetic endowment of the individual.⁴ The items used to test fluid intelligence include memory span, inductive reasoning, and figural relationships, all of which are presumed to be unresponsive to training. Because fluid intelligence involves those intellectual functions most affected by changes in neurophysiological status, it has been generally assumed to decline with age. Several studies have shown this to be untrue; one study noted that during middle age, scores on tests for fluid intelligence are similar to scores in midadolescence.^{73,98} These changes, however, are primarily

associated with processing speed, working memory, and executive function.^{7,99}

Studies on the effects of cognitive changes in activities have shown that older people perform activities at a slower rate and use different areas of the brain in the process compared with younger people. Those additional areas of the brain used have mostly to do with monitoring and processing the ongoing activity.^{8,100} Activities are therefore performed more in a feedback rather than a feedforward manner, which also requires more time. So, if older adults are given time to complete tasks, they usually do well.

Botwinick¹⁰¹ described the classic pattern of changes in intelligence with aging. In the adult portion of the life-span, verbal abilities decline little, if at all, whereas psychomotor abilities decline earlier and to a greater extent (greater decline if the individual is not engaged in regular physical activity). The period between ages 55 and 70 years is a transition time, and some decreases in performance are noted on many cognitive tests. A substantial decline on laboratory tests of cognitive function is generally limited to those older than 75 years.¹⁰² In these latter years, however, the decline in fluid intelligence is offset by the growth in crystallized intelligence for most people unless dementia is present (Fig. 27.2).¹⁰³ Although changes may be demonstrated in the laboratory, they may not be significant in the “real world,” and the older adult may be as capable as the young of participating in rehabilitation training. For older adults to benefit maximally, however, they must control the pace of training because the tasks that are the most difficult for older adults are those that are fast paced, unusual, and complex.¹⁰⁴ All physical and occupational therapy treatments with older patients need to be structured to encourage the patient to set his or her own pace. The goal is to have a pace that allows ease of breathing and a comfortable, functional upright posture so that the person can enjoy the experience. Interventions should be predictable and progress by adding one new concept at a time.

Stress and Intellectual Capacity

Selye⁷⁵ defined stress as the nonspecific response of the body to any demand made on it. All human beings require a certain amount of stress to live and function effectively. When a stressor (stimulus) is applied, the body predictably goes through the three stages of response

Fig. 27.2 Gains in crystallized intelligence throughout adulthood compensate for potential declines in fluid intelligence. (From Avers D, Williams A. “Cognition in the Aging Adult.” Geriatric Physical Therapy, Elsevier Mosby, 2012, pp. 132–134.)

called the *general adaptation syndrome* (GAS). The first response is a general alarm reaction, a “fight-or-flight” response that mobilizes all senses in an effort to make a judgment about the response needed. The older person is at a disadvantage because collecting and processing accurate sensory data are decreased with normal aging owing to short-term memory loss. The sensory memory in an older person lasts less than 1 second.³⁶ The next stage involves judgment and the selective adaptation to the stressor. A decision is made regarding which action is needed, and all other bodily activities return to homeostasis. If the stimulus continues and goes beyond the therapeutic or functional level, then the body system or part will gradually experience physiological exhaustion. A person in physiological exhaustion is likely to manifest abnormal responses to any new stimulus.

When a person is under perceived stress (whether real or imagined), a predictable set of cognitive changes can occur such as preoccupation; forgetfulness; disorientation; confusion; low tolerance to ambiguity; errors in judgment in relation to work, distance, grammar, or mathematics; misidentification of people; inability to concentrate, solve problems, or plan; inattention to details or instructions; reduced creativity, fantasy, and perceptual field size; decreased initiative; decreased interest in usual activities, the future, or people; and irritability, impatience, anger, withdrawal, suspicion, depression, and crying. Differentiating whether the patient is having a stress reaction or has dementia is critical. If the changes occur with a sudden onset, they are probably related to a medical or pharmaceutical problem, which may be indicative of delirium and amenable to intervention.

With aging, the brain undergoes physiological changes that make the older people less physiologically efficient in her or his response to stressors. The general alarm reaction is poorly mobilized and takes longer to become activated (Arndt-Schulz principle). The stage of resistance should yield a series of responses that allows the body to economize in its response to stress. In persons of all ages who receive too many different stimuli and in older adults who experience normal levels of stimuli, the body becomes less efficient at turning off the general alarm response and replacing it with more appropriate and limited responses. When a person is overwhelmed by this type or level of stress, the individual may demonstrate mild global or specific cognitive impairments, especially mild short-term memory loss.¹⁰⁵

The assessment of an older adult, with or without dementia, must include a determination of the type, number, and severity of the patient’s current stressors. Positive life events (e.g., marriage or the birth of a grandchild) are also stressful life events. Scores that rate stressful life events can identify patients who are at greatest risk of physiological and emotional exhaustion.¹⁰⁶ Developed in the 1970s, the Holmes-Rahe Social Readjustment Rating Scale is still a commonly used life stress evaluation tool (see www.stresstips.com).¹⁰⁷ Older adults, with their numerous psychosocial problems and chronic and acute illnesses, are likely candidates for physiological and emotional exhaustion and the development of psychopathology. Thus the environment and process of rehabilitation need to be modified to counteract the effect of stress on the intellectual capacity of the older adult patient. Any action that modifies stress so that a deterioration of intellectual function is stopped or reversed is an efficient and cost-effective part of the total rehabilitation effort.

STRATEGIES FOR ASSESSING, PREVENTING, AND MINIMIZING DISTORTIONS IN INFORMATION PROCESSING

At the outset of the process of patient assessment, *it is important to identify whether the patient communicates best with verbal, written, or*

a combination of both strategies. With an overview of the patient's cognitive capacity, the rehabilitation staff may be able to modify the process of evaluation to maximize the patient's performance (e.g., several 15-minute interactions spread over the 8-hour workday instead of an hour without rest; performing the assessment in the presence of a regular caregiver the patient trusts). A basic assessment of the patient's functional abilities (ADLs and IADLs) at a given moment to allow a comparison of cognitive capacity at other times in the 24-hour cycle provides the clinician a specific description of what aspects of intellectual function appear to be impaired and pinpoints those aspects of intellectual functioning that are still intact. Based on this approach, the rehabilitation evaluation can proceed in a language (perhaps the native language of childhood) and at a pace that are comfortable for the patient and at the time of day when the patient is most alert.

Screening Tests for Cognitive Impairment

The Mini-Mental State Examination (MMSE) provides a screening test for identifying unrecognized cognitive disorders in older adults. The MMSE assesses only cognition and can identify whether the patient is oriented; remembers (short term); and can read, write, calculate, and see and reproduce in drawing the relation of one object or figure to another. The MMSE may also be used in a serial fashion to quantify changes in a patient's cognitive status over time. All caregivers must be part of the team effort to get a real 24-hour picture of the cognitive capacities of the patient. This examination can be used as a springboard for planning how to carry out the traditional rehabilitation evaluation of a patient who has some intellectual dysfunction.^{108,109}

The MMSE has been standardized for older adults living in the community, with scores correlating significantly with the Wechsler Adult Intelligence Scale and the Wechsler Memory Test. It has been found that when a cutoff score of 24 is used for the detection of dementia, the MMSE had a sensitivity of 87.6% and a specificity of 81.6%.¹¹⁰ Several studies have noted that interviews with informants are highly consistent with older adults' scores on the MMSE.¹¹¹

The entire examination grades cognitive performance on a scale from 0 to 30. A score of 24 or less usually indicates some degree of cognitive dysfunction, but some patients with dementia may score above 24 and some with depression or delirium may score significantly below 24. A low score on this examination can mean that the patient probably has dementia, delirium, mental retardation, amnesic syndrome, or aphasia. A low score on the MMSE can indicate the areas of specific cognitive impairment and gives the rehabilitation team data about how to best communicate with the patient. MMSE scores are also correlated with educational level, with scores dropping 10% to 20% for people with an eighth-grade education or less if older than 70 years.¹¹² A shortened version of the MMSE has been developed that uses only 12 of the 20 original variables.

The MMSE was freely available when it was first released in 1975, but its developers have since enforced copyright use restrictions^{113,114} (USD 81 for 50 test forms, as of 2018).¹¹⁵ Fortunately, a growing number of screening tools have been developed and could be used as possible alternatives to the MMSE.^{114,116–118} Free educational versions of the MMSE are widely available on the Internet, including sites such as those maintained by Oxford Medical Education.^{118a} In 2013, the Alzheimer's Association formed a workgroup to develop recommendations that would operationalize cognitive assessment in the primary care setting. As mandated in the Patient Protection and Affordable Care Act of 2010, Medicare beneficiaries can avail an Annual Wellness Visit (AWV), which includes the detection of any cognitive impairment by assessing an individual's cognitive function.¹¹⁹ The assessment should be done using direct observation while taking into account

BOX 27.1 Brief Cognitive Impairment Screening Tools

Ascertain Dementia 8-item Informant Questionnaire (AD8)
 Clock Drawing Test (CDT)
 General Practitioner Assessment of Cognition (GPCOG)
 Memory Impairment Screen (MIS)
 Mini-Cog
 Montreal Cognitive Assessment (MoCA)
 Short Informant Questionnaire on Cognitive Decline in the Elderly (Short IQCODE)
 Short Portable Mental Status Questionnaire (SPMSQ)
 St. Louis University Mental Status (SLUMS)
 Verbal Fluency
 7-minute Screen (7MS)

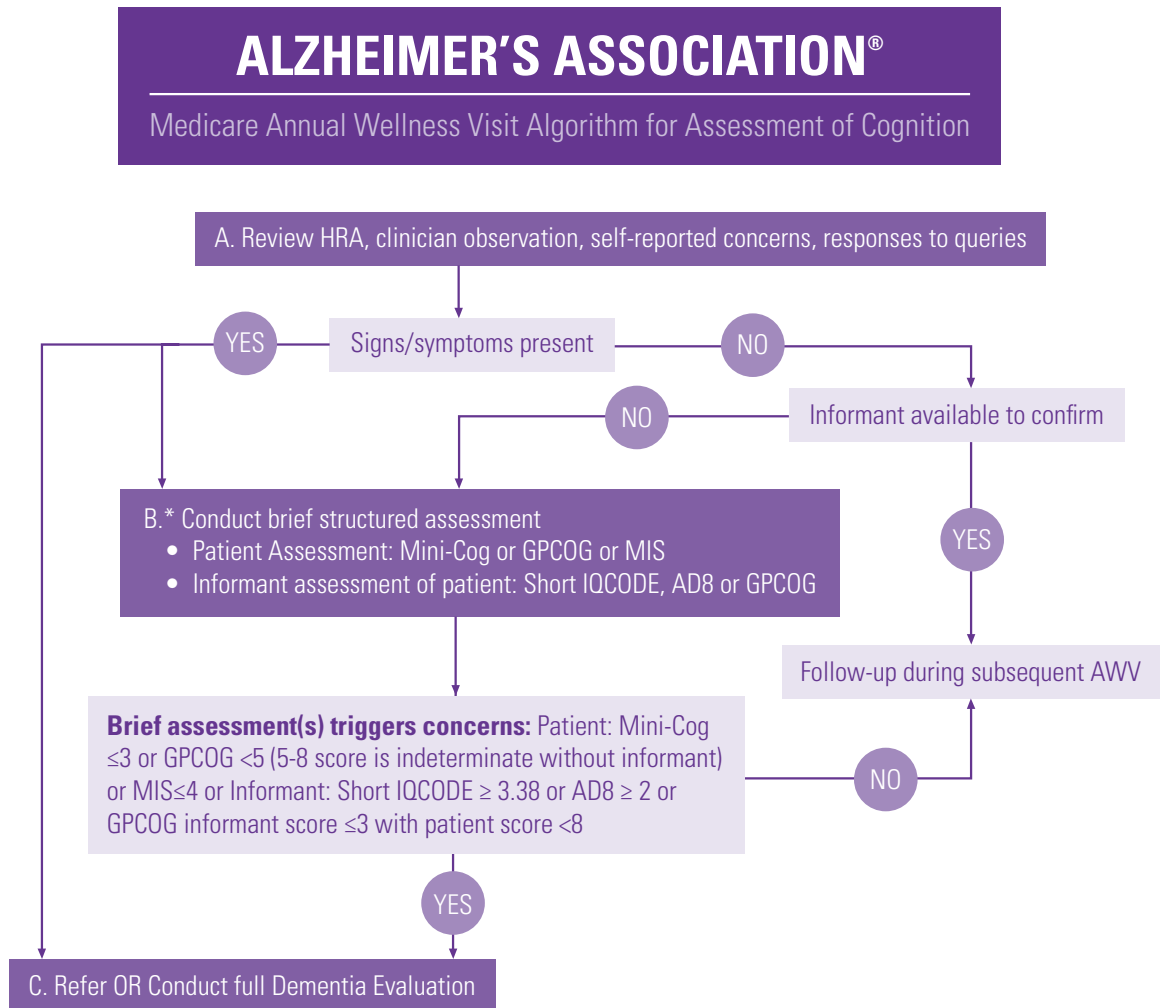

From Cordell CB, Borson S, Boustani M, et al. Alzheimer's Association recommendations for operationalizing the detection of cognitive impairment during the Medicare annual wellness visit in a primary care setting." *Alzheimers Dement.* 2013;9(2):141–150. doi:<https://doi.org/10.1016/j.jalz.2012.09.011>; Lin JS, O'Connor E, Rossom RC, et al. Screening for cognitive impairment in older adults: a systematic review for the US Preventive Services Task Force. *Ann Intern Med.* 2013;159(9):601–612.

information obtained subjectively from the patient, the patient's care providers, family, friends, and others concerned. The workgroup identified the Memory Impairment Screen (MIS), General Practitioner Assessment of Cognition (GPCOG), and Mini-Cog as suitable brief cognitive assessment tools in primary care. All three tools require less than 5 minutes to administer, have been validated in a primary care setting, have good-to-excellent psychometric properties, and do not require permission or payment for copyrights when used in the clinical setting.¹¹⁴ Clinicians may also select from a number of alternate tools in **Box 27.1** and supplement the information with those obtained from a patient informant using the Ascertain Dementia 8-item Informant Questionnaire (AD8), GPCOG informant score, and short Informant Questionnaire on Cognitive Decline in the Elderly (Short IQCODE). Patients who present with any indication/s of cognitive impairment would need to be referred for further evaluation, as shown in **Fig. 27.3**.

The recent American Academy of Neurology guideline on mild cognitive impairment (MCI) recommends the assessment for MCI in cases wherein a patient and/or a close contact voices concern about memory or impaired cognition.¹²⁰ The guideline further emphasizes that clinicians not assume such concerns as a part of normal aging. Validated assessment tools should be used in the screening process, and if positive, more formal clinical assessment should follow. The guideline cautions against a premature diagnosis of dementia in the absence of functional impairments and detailed testing. Lastly, clinicians lacking experience and training in assessing cognitive impairments should refer patients suspected of having MCI to the appropriate specialist. A summary of the practice recommendations is outlined in **Table 27.3**.

Sensory and Perceptual Changes With Dementia

Patients with dementia may have specific problems that inhibit the integration of sensory input. Aphasias and disruption of association pathways may inhibit the patient's ability to integrate accurately perceived sensory information in a meaningful way. Patients with AD, multiinfarct dementia,¹²¹ and alcoholic dementia may demonstrate disturbances in visual acuity, depth perception, color differentiation, and differentiation of figure from ground when compared with normal age-matched control adults and normal younger adults.

* No one tool is recognized as the best brief assessment to determine if a full dementia evaluation is needed. Some providers repeat patient assessment with an alternate tool (e.g., SLUMS, or MoCA) to confirm initial findings before referral or initiation of full dementia evaluation.

TABLE 27.3 Practice Recommendations in the Assessment of Mild Cognitive Impairment

Recommendation	Grade
For patients for whom the patient or a close contact voices concern about memory or impaired cognition, clinicians should assess for MCI and not assume the concerns are related to normal aging	B
When performing a Medicare Annual Wellness Visit, clinicians should not rely on historical report of subjective memory concerns alone when assessing for cognitive impairment	B
For patients for whom screening or assessing for MCI is appropriate, clinicians should use validated assessment tools to assess for cognitive impairment	B
For patients who test positive for MCI, clinicians should perform a more formal clinical assessment for diagnosis of MCI	B
For patients with MCI, clinicians should assess for the presence of functional impairment related to cognition before giving a diagnosis of dementia	B
For patients suspected to have MCI, clinicians who lack the necessary experience should refer these patients to a specialist with experience in cognition	B
For patients diagnosed with MCI, clinicians should perform a medical evaluation for MCI risk factors that are potentially modifiable	B
For patients and families asking about biomarkers in MCI, clinicians should counsel that there are no accepted biomarkers available at this time	B
For patients diagnosed with MCI, clinicians should perform serial assessments over time to monitor for changes in cognitive status	B

MCI, Mild cognitive impairment.

From Petersen RC, Lopez O, Armstrong MJ. Practice guideline update summary: mild cognitive impairment: report of the Guideline Development, Dissemination, and Implementation Subcommittee of the American Academy of Neurology. *Neurology*. 2018;90(3):126–135; DOI:10.1212/WNL.0000000000004826

An assessment of specific sensory systems is necessary when a person demonstrates cognitive losses. The challenge in rehabilitation is to design a process and environment of care so that compensation and modification maximize the ability of the older adult with sensory deficits to adapt to most life situations. The example of visual deficits is a case in point. One of every two blind persons in the United States is older than 65 years (see www.afb.org/ and click on AFB senior site).¹²² Techniques of environmental adaptation and special measures to organize care to help blind older adults have allowed many of them to live independently in the community.¹²³ However, many older adults with visual impairments are not blind. Some of the structural changes that result in mild to moderate deficits of vision include yellowing; uneven growth, striation, and thickening of the lens; increasing weakness of the muscles controlling the eye; alteration in the perception of color (especially fine distinctions in tone and brightness); and slower adaptation to light.¹²⁴ Modifications of the environment can include adequate effective lighting (including adequate intensity and controlling of reflection), dark and clear large-print, low-vision aids (e.g., magnifying glass), verbal orientation and escort by persons accompanying patients in a new environment, consistent furniture placement, explanation when changes occur, clear hallways, a systematic storage system for clothes and toilet articles, and the use of consistent contrasting colors to identify doors, windows, baseboards, and corners.^{124–127}

Older Adult Learning Styles and Communication

Learning occurs throughout life.¹⁰⁴ In physical and occupational therapy, habilitation occurs when the patient learns new skills, and rehabilitation occurs when the person relearns old adaptive skills. As with intelligence, the learning process does not change abruptly when an individual reaches old age, but differences in performance have been reported. One challenge for rehabilitation therapy is to find ways to improve the efficiency of learning by the older person (Box 27.2).

Learning and performance are not the same. Poor performance on a learning task may mean that insufficient learning has occurred, that learning has not transferred to a new environment or task, or that

the performance does not accurately reflect the extent of learning achieved.⁴ The key variables that affect a person's ability to participate in a learning task can include intelligence, learning skills acquired over the years, and flexibility of learning style. Noncognitive factors can also have a strong bearing on an individual's performance. The noncognitive factors include visual and auditory acuity, health status, motivation to learn, level of anxiety, the speed at which stimuli and learning is paced, and the meaningfulness to the individual of the items or tasks to be learned. Research has shown that learning styles change over the life-span and that people learn better when instructional approaches are matched to their learning style.³⁷ Therefore a rehabilitation assessment needs to include a review of the preferred learning style of the patient. This strategy is particularly important before discharging a patient from a rehabilitation program. The rationale is that a lack of progress may not reflect the patient's lack of capacity for rehabilitation but rather may reflect a dissonance between the patient's learning style and skills with the presentation of materials in the treatment program (e.g., verbal input has not been adapted to match the level or pace of comprehension of a person who may have a strong preference for visual learning and slower pace).

Interference

Interference can make the learning process less efficient in two major ways.¹²⁸ First, interference can result from a conflict between present knowledge and the new knowledge to be learned. Second, if the task to be learned has two or more components, secondary components may interfere with the learning of primary components. This situation is particularly true if secondary components overlap in time or use the same sensory modality.⁹⁷ Older adults have special difficulties if they must concentrate on intake, attention, and retrieval processes at the same time. Therefore the process and therapeutic environment of rehabilitation for the older adult patient must not be disturbed by background noise, other stimuli in the environment, or anxiety. When learning a new task, the older adult patient may require a quiet room with no stimuli other than that offered by the therapist. The need to rid the environment of distractions is particularly important when

working with an older adult patient with dementia because this patient will have greater difficulty filtering out irrelevant sensory input compared with other patients without dementia.

Pacing

The pacing of therapeutic intervention is a significant variable in helping an older adult learn. Older adults (with or without dementia) perform best if they are given as much time as they need and when learning is self-paced.¹⁰¹ The major drawback of a fast pace (as perceived by the patient) is that an older adult generally chooses not to participate rather than risk making a mistake. A lack of response by the patient is often interpreted as apathy, poor motivation, or “confusion.”¹²⁹ Patient participation is increased when extra time to complete a rehabilitation task is offered. After the individual assessment, group work (where concepts can be presented, reviewed, and examined at leisure) also can be used to reduce the psychological pressure of faster paced one-on-one learning. The details of therapy must be planned carefully, including how questions are asked (this involves asking clear and precise questions in nonmedical language) and, most importantly, setting aside enough treatment time so the patient can respond at a manageable pace.

Organization

If data are organized in the brain as part of the learning process, the retrieval of these data becomes easier. Older persons are less likely than members of other age groups to organize data spontaneously to facilitate learning and later retrieval (memory) of that learning.¹³⁰ Older adults who are highly verbal show fewer weaknesses in the ability to organize stimuli. Older adults with poor verbal skills show significant improvement in data retrieval when strategies for data organization are provided by others (e.g., the therapist). In addition, organizing therapy by beginning with an overview of the entire lesson may be helpful as this presents a conceptual map of the learning experience. Older learners have difficulty following content because they cannot anticipate what will be taught and do not see the “whole picture” of what is being presented.¹³¹ The use of purposeful organizing can help bridge the gap between what the older person knows and the new information or task to be learned. This is an example of how organization may influence the learning process.

Inefficient learning and, at times, an inability to learn occur in the older adult if material is presented in one way and the older person is expected to apply it in some other way. Instructions need to be provided in the format and context in which they are to be used. If possible, pieces of new data should be presented one at a time. A conscious transition needs to be made by the therapist from the patient’s current frame of reference to the understanding of the new data, and the pace needs to be set by the patient.

Several other strategies exist for maximizing the efficiency of older adult learners based on awareness of normal age-related changes. Some of the more frequently used techniques are summarized in [Box 27.2](#).

Communication

Therapists can begin by inquiring into what the reality of the patient looks like. The first goal should be to communicate with words, gestures, positioning, and so on, so that stimuli bring out functional responses in the patient.

The therapist needs to be sensitive to the entire communication—what is said and what is withheld. The patient with cognitive problems may not understand the content, but many patients still have the ability to sense and respond to the therapist’s affective state at the moment. When beginning communication, be clear of all previous concerns and

BOX 27.2 Techniques for Maximizing the Efficiency of Older Adult Learners

1. Use mediators; the association of words, story, mnemonics, or visual inputs can help the person remember.
2. Choose learning activities that are meaningful for the patient.
3. Use concrete examples to make learning easier.
4. Provide a supportive learning environment to prevent stress, which can interfere with efficient learning.
5. Use supportive or neutral feedback and avoid feedback that is presented in a challenging tone.
6. Reward all responses, but reward correct responses more than incorrect responses. This can encourage older adults persons to decrease the number of errors by omission, which are often interpreted as apathy or lack of cooperation.
7. Use combinations of auditory and visual input to facilitate the learning process. This is effective only if the data presented are similar because variation between the two kinds of messages can result in interference and a decrease in the efficiency of learning.
8. Active learning is more effective. A patient who moves the involved body part while receiving verbal and visual input is likely to better master the new skill.
9. Design the learning situation so that successful completion of the task is likely. Older people are more likely to focus on errors, which increases anxiety and lowers self-esteem. Worst of all, with all the energy focused on the error, there is a strong chance of repeating the error.

bring no extraneous emotions into the interaction. Caregivers and therapists bring into the conversation the power of intention to create a therapeutic interaction and the choice to stay on task. Patients bring their own set of concerns at any particular moment. Knowing something about the patient’s concerns helps the process.

Therapists and caregivers need to be self-aware. What is the therapist’s favorite strategy for communication? What is the therapist’s favorite sentence structure? Our habitual forms of presentation need to be assessed with regard to whether they are effective, because the patient needs to be the focus of attention. Honoring the communication habits of the patient is necessary if effective communication is to occur with a person with cognitive deficits. If the therapist chooses to speak to the patient as if there were no cognitive deficits, consistent results will not occur, and the patient may be upset or agitated. The patient could be approached as if he or she were a person from another culture that has its unique customs, norms, and ways of communication. The patient-therapist interaction becomes an inquiry in which success is measured by the achievement of functional outcomes that are needed and wanted (e.g., the patient transferring into bed and feeling safe).

Now the question becomes what is the specific process of interaction with which the patient appears to be most comfortable and feels safe? Every patient is different, and it may depend on the time of day or whether the patient is feeling tired or threatened. Persons commonly respond best to one particular style of communication and are predictably upset or agitated by another style. If a patient wants to joke around and be playful, this should be a cue to staff that this is a workable style of communication. Another patient smiles whenever the tone of the conversation is soft, nurturing, and tender, and if staff is willing, this is where ease of relating can occur. Other patients relate best to rules and need predictable structures and boundaries. They love to know what is coming next. Still another category is people who can relate and communicate when definite admiration and respect are built into the conversation or when patient and therapist can agree to disagree. Each

patient with cognitive problems needs to have caregivers develop a chart of what works to create a sense of relatedness and ease in communication. A challenge here for caregivers is that the patient's abilities can change; guidelines for communication when new caregivers are introduced to the patient can also be helpful. Someone who is familiar and enjoys interacting with the patient should introduce new staff to the patient.

For people with cognitive disturbances, familiarity and rituals are keys to the ease of adaptability. The basis for rituals is well-organized documentation to which all caregivers have access and contribute on an ongoing basis. This information needs to be filtered and organized so that each shift can see what is working for the patient today. Even a nonverbal patient can relate effectively to bathing if a ritual exists regarding dressing and undressing (e.g., the socks always come off first). Another detail that requires staff or caregiver attention, evaluation, and adaptation in daily care is *ideational apraxia*. LeClerc and Wells¹³² described this as "a condition in which an individual is unable to plan movement related to an object because he or she has lost the perception of the object's purpose." Consideration is especially important in relation to feeding, dressing, toileting, and bathing. The authors described a tool that can help caregivers assess ideational apraxia and problem-solving compensations to prevent unnecessary agitation or disability and take actions to preserve existing abilities. Savelkoul and colleagues¹³³ emphasized the importance of effective communication between staff and patients and the importance of routines for patient care to maximize functional behaviors for institutionalized older adults living in residential homes.

As a patient goes through gradual deterioration of cognitive status, as is common in AD, staff, family, and caregivers must be trained in nonverbal, positional, and manual cues and emotional communication techniques. Many patients come to a place in their lives with dementia when words are a source of confusion. Other strategies to communicate should then be used. Sign language is initially a possible tool until the associative functions begin to disappear. Accurate assessment needs to create adaptations in communication. It may be necessary to use hand-guided communication, in which the patient is led through a task or parts of a task to get his or her cooperation. At this stage of communication, ease and trust are the most important goals. It may take 5 minutes of tenderly holding a patient's hand before the patient is ready to walk to the dining room or bathroom. This strategy requires much patience on the part of caregivers. Positional communication can be used as well as simple touch. As patients begin to feel safe with their state of being, they will relax and choose to participate. At times, patients have unique needs, such as only wanting to be cared for by a female caregiver or a male caregiver. Honoring patient needs is critical because the cognitively impaired may not be able to learn or adapt to the demands of the staff member because of previous trauma (assault or incest, real or imagined).

As a way to summarize the considerations regarding communication with a person with cognitive impairment, therapists may find it useful to examine their own intentions from moment to moment. "What is my goal in this interaction?" "Who am I being at this moment?" The task may be important, and the "doing" of it may be critical. For the patient with cognitive disturbance, therapists must provide life-enhancing stimuli on the basis of the patient's perceptions. If in the zeal to "do," the patient is accidentally scared, intimidated, or bullied, the damage may not be able to be undone. The patient with cognitive impairment presents a unique challenge if a threat has been created, because reestablishing their trust is often difficult. Often, the patient may be afraid of the therapist and simply needs the therapist to leave the room for some time. The saving grace for many patients is that their short-term memory is poor so they may not remember the incident tomorrow. The problem with agitation occurs when other patients who are cognitively impaired in the area also get upset.

The solution to the crisis moment, when a breakdown in communication has occurred, is to redirect communication and the focus of the present moment effectively. For example, a staff member could purposely bump into a chair and knock it over, drop a cup of water or a book, start to sing, whistle loudly, or clap his or her hands. At that moment, a distraction is created. If the distraction works, then the patient's attention is pulled away from his or her old thought and focused to a new topic. At that moment, the staff needs to be intentional. The new focus needs to offer comfort or nurturing or a predictable sense of well-being (e.g., helping to clean up, eating some food, looking at a picture of a favorite thing, holding a favorite item, touching a favorite comfort object, hugging).

ENVIRONMENTAL CONSIDERATIONS

Hypothermia

The temperature of the living environment must be carefully controlled because older adult patients may not perceive that the environment is cold and may not experience shivering. Accidental hypothermia can develop in an older person even at temperatures of 60°F (15.5°C) to 65°F (18.3°C). Accidental hypothermia is a drop in the core body temperature to less than 95°F (35°C). Patients at risk for hypothermia are presented in [Box 27.3](#).

The symptoms of hypothermia may include a bloated face, pale and waxy or pinkish skin color, trembling on one side of the body without shivering, irregular and slowed heartbeat, slurred speech, shallow and slow breathing, low blood pressure, drowsiness, and symptoms of delirium. The two principles of treatment of hypothermia are that the person will stay chilled unless the body temperature is slowly increased and that he or she should be evaluated by a physician, regardless of the apparent severity of the hypothermia.^{4,134}

If a person continues to be at risk for hypothermia, specific measures can be taken to prevent subsequent distortions of cognitive status. First, the room temperature should be set to at least 70°F (21°C). Second, the person should wear adequate clothing; this may include long underwear and an undershirt. Adequate nutrition also may be a factor in preventing hypothermia.

Patients and their caregivers may attempt to save money by lowering room temperatures and thus inadvertently cause hypothermia. To prevent accidental hypothermia in institutions with central air conditioning, special accommodations for older adults, such as a special wing of the building or individual temperature controls in the rooms, are required.¹³⁴

Transplantation Shock

Some older adults seem to function well in a familiar environment but become severely disoriented and unable to perform ADLs if taken out of their own homes. As a general rule, these persons have mild

BOX 27.3 Patients at High Risk for Hypothermia

- Persons older than 65 years
- Persons showing no signs of shivering or pale skin in response to cold
- Persons taking medications containing a phenothiazine (to treat psychosis or nausea)
- Persons with disorders of the hormone system, especially hypothyroidism
- Persons with head injuries, strokes, Alzheimer's disease or other dementia, Parkinson disease, or other neurological conditions
- Persons with severe arthritis
- Persons with arteriosclerotic peripheral vascular disease, chronic ulceration, or amputation

symptoms of dementia that are not readily apparent when they remain in a structured, familiar, stable environment and maintain a consistent daily routine. When faced with the need to adapt to a new environment bombarded with multiple unfamiliar sensory stimuli, however, their limited brain capacity is unable to make sense of the large volume of new stimuli. If a patient was oriented before admission to an institution and then becomes disoriented, the patient's cognitive functioning will likely return to its baseline level of functioning on return to the familiar environment. Therefore all moves by a patient from one hospital room to another or from one institution to another, and all changes in a treatment regimen, need to be carefully planned. If a change is anticipated, the patient should be involved in the decision making. If the change is a permanent move, the patient needs to have a chance for one or two trial visits before the actual move. The patient needs to be informed of all changes well in advance, and this information needs to be given repeatedly to the patient with dementia. The precautions mentioned can help the patient relocate without creating transplantation shock and any related negative cognitive and emotional changes.

DELIRIUM AND REVERSIBLE DEMENTIA: EVALUATION AND TREATMENT

This section focuses on the patient's internal environment (physiological, psychological, spiritual, and pathological) and presumes that all unnecessary external environmental stressors have been removed.

Delirium and dementia have been previously defined (see Table 27.1) and differentiated (see Table 27.2). Delirium can manifest suddenly or over a period of hours or days. Delirium may occasionally be chronic, but this is relatively infrequent. Dementia usually has a much longer time of onset, although an acute onset can occur.

Diagnosis of the underlying cause of dementia or delirium is key to effective care. Although the diagnostic process is primarily at the level of pathology, the therapist can obtain information, as part of a team evaluation, which will help establish the underlying diagnosis. Historical information needs to be obtained regarding the following:

- The amount of time that has elapsed since the onset of symptoms
- The progression or lack of progression of symptoms
- Associated functional impairments and associated medical signs and symptoms
- Use of prescription drugs, over-the-counter medications, home remedies, illegal drugs, alcohol, caffeine, and nicotine
- Exposure to toxins at work or during recreation

Even in a patient with cognitive disturbances, this information can frequently be obtained and corroborated by obtaining a history from significant others.

The causes of delirium and reversible dementia are many. In older adults however, certain causes are more common than others (Box 27.4). Alcohol and drugs (prescribed, over-the-counter, or illegal medications and home remedies) are prime offenders (see Chapter 36). The delirium may be the result of intoxication, side effects, or withdrawal syndromes.¹³⁵ Benzodiazepines are among the most

BOX 27.4 Common Causes of Delirium and Reversible Dementia

Alcohol or Drug Abuse or Dependence

Intoxication
Toxicity
Side effects
Withdrawal

Cardiovascular or Pulmonary Conditions

Congestive heart failure
Cardiac arrhythmia
Hypertensive crisis
Hypoxia
Chronic obstructive pulmonary disease

Metabolic or Endocrine Conditions

Electrolyte disturbance (especially hyponatremia)
Hypercalcemia
Dehydration
Overhydration
Renal failure
Hypoglycemia
Diabetic ketoacidosis
Hypothyroidism
Hyperthyroidism
Malnutrition
Vitamin B₁₂ or folate deficiency
Hepatic failure
Wernicke-Korsakoff syndrome
Cushing syndrome

Infection

Urinary tract infection
Pneumonia or acute bronchitis

Tuberculosis
Other acute infections

Neurological Conditions

Stroke
Head trauma
Mass lesion (e.g., tumor, hematoma)
Seizure

Pharmacological Causes

Benzodiazepines
Barbiturates and other sedative-hypnotics
Antidepressants
Neuroleptics
Antihistamines
Anticholinergics
Cardiac glycosides
Steroids
Antineoplastic drugs
Narcotics
Antiarrhythmics
Antihypertensives

Miscellaneous Causes

Sensory deprivation
Sensory overstimulation
Acute or chronic pain
Constipation or fecal impaction
Urinary retention

commonly prescribed offenders; even a low dose (2 mg) may cause demonstrable cognitive changes.⁷⁴ Other common drugs that cause delirium or reversible dementia are alcohol, oral narcotics, psychotropic medications, steroids, antineoplastic drugs, digoxin, anesthetic agents, antiparkinsonian drugs, and antihistamines. However, all drugs have the potential to cause significant cognitive problems in older adults.¹³⁶ These symptoms often resolve with discontinuation of the offending agent or treatment of the withdrawal syndrome. For some patients, a medication holiday of longer than 24 hours may be needed before a positive change in cognition can be noted.⁹³

At times, the symptoms may be clearly correlated with the pharmacokinetic profiles of the medications taken by the patient. The dose or frequency of administration of medications can be a contributing factor to a delirious state.¹³⁷ Every member of the rehabilitation team needs to document the patient's ability to participate in learning tasks and the time of the assessment because timing of medication administration can affect functional performance. The rehabilitation team needs the input of a clinical pharmacologist who can help the team focus on concepts such as biological half-life, clearance, bioavailability of drugs, and the time course of drug concentration in plasma as a function of dose and frequency.

Several medical diseases are likely to cause symptoms of delirium. Urinary tract infections, more common in women, are the cause of delirium in 28%¹³⁸ of older adults patients. Fecal impaction is another common cause of acute cognitive change in older adults persons. Others are distended bladder caused by prostate enlargement or drug-induced urinary retention, dehydration, malnutrition, cardiovascular disorders,¹³⁴ metabolic disturbances (particularly undiagnosed diabetes mellitus),²⁸ endocrine diseases, renal diseases, hematological diseases, pneumonia or bronchitis,¹³⁴ and vitamin B₁₂ deficiency.

Transient (and usually mild) cognitive deficits may be the result of a cerebrovascular accident (CVA). The cognitive deficits after a CVA are often reversible, although they may last for several months after the stroke. The rehabilitation team needs to evaluate and regularly reevaluate the patient's cognitive capacity and build a program of care around current abilities. A program of therapeutic intervention that allows the older person to work in a self-paced program for 1 to 3 months can yield good therapeutic results and prevent unnecessary secondary deconditioning until part or all of the patient's cognitive capacity returns.¹³⁹

In older adults, depression shares some common characteristics with dementia, making diagnosis and management more complicated^{134,140,141}. Depression can result in mild and subtle cognitive changes affecting immediate recall, attention, and the ability to perform basic ADLs. A history of depression has been implicated in increasing the risk for both all-cause dementia and AD. Together with memory and cognitive decline, depression has also been reported to precede dementia by 12 years.¹⁴⁰ Depression is a treatable disorder, and many patients with cognitive impairments show some improvement in their cognitive functioning if the depression is treated; however, the underlying cognitive problem does not resolve with treatment of the depression.¹⁴² Because the presence of depression can interfere with the progress of rehabilitation through cognitive deficits or its effects on motivation, this disorder needs to be diagnosed early and accurately. The Geriatric Depression Scale (GDS), a 30-item yes-no questionnaire, screens for this disorder.¹⁴³ A shorter 15-item version is also available and has shown strong correlation (0.96) with the 30-item version.^{144,145} Both long and short versions have been translated in multiple languages, and can be freely accessed in the authors' website (<https://web.stanford.edu/~yesavage/GDS.html>). The 15-item GDS is also available as a free mobile app in both Android and iPhone platforms. Scores >11 in the 30-item GDS, and >5 in the 15-item version indicate possible depression in older adults.¹⁴⁵⁻¹⁴⁷

The treatment of major depression generally involves pharmacotherapy, psychotherapy, and environmental manipulation, which can require support from the entire rehabilitation team.¹⁴⁸ In the treatment of a patient with depression, therapeutic techniques can promote a relaxation response, enhance upright posture, decrease anxiety level (e.g., through massage or heat), and help bring the patient to the point at which aerobic training is possible and can provide a beneficial effect. All aerobic training for older adults needs to begin with a stress test, modified as necessary to determine the patient's exercise target heart rate. The modification most commonly required is use of the upper extremities to achieve the training effect, because lower-extremity function may be limited, or use of major ADLs involving the upper extremities as the stress test or training program.

The causes of delirium are usually treatable, and if diagnosis and care are provided in a timely fashion, the patient can likely regain full command of his or her cognitive processes. When this does not happen, the patient probably had mild, irreversible dementia that remained hidden until the onset of an acute problem that uncovered the poor cognitive functioning. The length of time in an institution (hospital or nursing home) needs to be kept as short as possible to avoid learned dependency and learned helplessness,¹⁴⁸ which make a return to full cognitive functioning and independent living difficult.¹⁴¹

Therapy for older adults with delirium consists of treating the underlying causes of the cognitive changes. A close working relationship among all members of the rehabilitation team, including a geriatric psychiatric consultant, is necessary. Even before the cause of the disorder is elucidated, the patient should receive the same emotional and physical support as any patient with dementia. The therapist must adapt all activities to the extent and types of cognitive losses that are present. The patient needs to feel secure, live in an environment that has as few changes as possible, and have a consistent and stable schedule for activities.

IRREVERSIBLE DEMENTIA

The course of dementia is unique for each patient. The variation in clinical course occurs based on the cause of the underlying disease and superimposed biological and psychosocial factors, including medications, concurrent illness (including delirium), the nature of the social support system, and the patient's premorbid personality structure. The causes of irreversible dementia are summarized in [Box 27.5](#).

Regardless of the cause of the dementia, the clinical course of these disorders has several commonalities.⁹⁸ Most of these diseases are progressive. Symptoms may be subtle early in the course of the illness, and the onset of disease is usually noted by the person with the disorder, family members, friends, or colleagues at work rather than by a physician. The signs of impairment of mental ability are typically memory loss, poor judgment, or incompetence at work. The patient can often succeed at hiding his or her symptoms for a while. The social consequences of the cognitive impairment usually bring the patient to the attention of health care professionals. In addition, the patient with dementia can manifest a variety of psychiatric symptoms, including mood disturbance, agitation, violent behavior, socially inappropriate behavior, delusions, hallucinations, catastrophic reactions, and perseveration.^{109,149} The pattern of onset and the types of psychiatric symptoms are often directly related to the underlying pathological condition.

When a physician is finally consulted, the diagnostic process can begin. When a complete diagnostic evaluation—including history, physical examination, neurological examination, neuropsychological testing, and laboratory testing ([Box 27.6](#))—is performed, an accurate

BOX 27.5 Common Causes of Irreversible Dementia

Degenerative Causes

Alzheimer's disease
Parkinson disease
Huntington disease
Pick disease
Fahr disease

Infectious Causes

Neurosyphilis (general paresis)
Tuberculosis
Acquired immunodeficiency syndrome (AIDS)
Creutzfeldt-Jakob disease

Vascular Causes

Multiinfarct dementia
Stroke
Binswanger dementia
Anoxia
Arteriovenous malformation

Other Causes

Normal-pressure hydrocephalus
Mixed dementia
Alcoholic dementia
Toxins
Head trauma
Mass lesions

BOX 27.6 Laboratory Evaluation for Delirium and Dementia

Complete blood count
Thyroid function tests
Vitamin B₁₂ or folate levels
Urinalysis
Blood levels of drugs patient is taking
Urine drug screen
Electrocardiogram
Magnetic resonance imaging scan of head (computed tomographic scan if magnetic resonance imaging is contraindicated)
Automated chemistries (including electrolytes, glucose, renal function, hepatic function, protein and albumin, cholesterol, and triglycerides)
Blood alcohol level
Human immunodeficiency virus (HIV) titer
Chest radiograph

diagnosis can be made in approximately 90% of patients, although experienced geriatric psychiatrists can make an accurate diagnosis in more than 95% of patients.¹⁵⁰

Once the diagnostic process is completed, treatment can be started. Medications can assist in reversing underlying causes in only a small percentage of cases. Currently, medications approved by the Food and Drug Administration only treat cognitive symptoms related to AD and are unable to stop AD progression (e.g., Donepezil, Rivastigmine, Galantamine, and Memantine).¹⁵¹ Psychotropic drugs may reverse depression or the behavioral symptoms associated with dementia.^{148,152,153} Medical

management also involves the prevention and treatment of other medical conditions and side effects of the new interventions as they are added.

Medical management of dementia focuses on maximizing the patient's remaining functions and roles, rehabilitating some lost functions, and providing family education and support.¹⁰⁹ Training caregivers to adapt to the patient (e.g., modifications for getting the patient out of bed, bathing), simplifying the individual's living space, and referring relatives to family support services are some of the issues to be addressed.¹⁵⁴

Alzheimer's Disease

The treatment of major neurocognitive disorder/dementia is a long-term process. Studies have found that the average duration of illness from first onset of symptoms to death is 8.1 years for AD, 6.7 years for multiinfarct dementia,¹⁵⁵ and 5.6 years for Pick disease.¹⁵² Medical and nursing care can extend the life expectancy of patients with dementia for up to 20 years or more.

In 1907, Alois Alzheimer¹⁵⁶ described the case and neuropathology of a 54-year-old woman who developed morbid jealousy, which was followed by loss of memory, inability to read and understand, and death 4.5 years after onset of the illness. AD is now the sixth leading cause of death in the United States and the fifth leading cause of death in older adults.¹⁵⁷ In 2017, the total health care cost related to the management of patients with AD and other dementias was USD 259 billion.^{158,159} In making the diagnosis of AD, all other causes of cognitive dysfunction must be ruled out. The disease can occur at any age, but the onset of the disease is almost always after the age of 65 years. The prevalence of the disease gradually increases to a rate of 20% in persons older than 85 years.⁵⁴

AD can be clinically staged. The use of staging enables the family and health care team to plan ahead for the individual's needs. Staging helps the family prepare longitudinally for the process of interacting with the patient. It allows the treatment team to plan for appropriate levels of services as the individual's abilities decline. Finally, it allows the health care team to quantify change in functional and cognitive abilities over time, which helps assess the effectiveness of the patient's treatment plan and establish evidence-based practice. The use of staging requires an accurate description of the patient's behavior (without the use of jargon) as well as an assessment of the patient's mental state.

Traditionally, the symptoms of AD have been thought to progress in three overlapping stages.

Stage 1 lasts from 2 to 4 years and involves loss of functional skills or orientation, memory loss, and lack of spontaneity. The patient is often aware of the losses and is, in many cases, able to cover up the cognitive losses by talking around the issues. During this stage, the patient and family may need to deal with the issue of giving up a job, hobbies, or other types of meaningful activity because of the patient's inability to carry them out safely and independently. The patient begins to lose the ability to handle money and a personal budget, drive a car safely, and tell time. The family or significant others may have to come to terms with the question of whether the patient can live alone. Depression is common during this stage of the disorder.

Stage 2 is characterized by progressive memory loss and the presence of a variety of neurological symptoms such as aphasias, apraxia, wandering, repetitive movements and stereotypical behavior, increased or decreased appetite, constant movement, and a peculiar wide-based gait can manifest. Psychotic symptoms (especially paranoid delusions and hallucinations), agitation, violent behaviors, and uncontrollable screaming are common symptoms during this stage of the disorder.

In stage 3, the patient develops vegetative symptoms. The patient may become mute, stop eating, and become incontinent of bowel and bladder. Muscle twitches or jerks, spasms of the diaphragm, and an inability to walk generally occur. The patient may develop seizures, and

TABLE 27.4 Barthel Index

	With Help	Independent
1. Feeding (score as “with help” if food needs to be cut)	5	10
2. Moving from wheelchair to bed and return (including sitting up in bed)	5–10 ^a	15
3. Personal toilet (wash face, comb hair, shave, clean teeth)	0 ^a	5
4. Getting on and off toilet (handling clothes, wipe, flush)	5	10
5. Bathing self	0 ^a	5
6. Walking on level surface (or if unable to walk, propel wheelchair)	10	15
7. Ascending and descending stairs	5	10
8. Dressing (includes tying shoes, fastening fasteners)	5	10
9. Controlling bowels	5	10
10. Controlling bladder	5	10

A patient scoring 100 is continent, feeds himself or herself, dresses, gets up and out of bed and chairs, bathes himself or herself, walks at least a block, and can ascend and descend stairs. This does not mean that he or she is able to live alone. The patient may not be able to cook, keep house, and meet the public but is able to get along without attendant care.

^aA score of 0 is given in the activity when the patient cannot meet the criteria as defined (see Appendix 27.A).

Modified from Mahoney FI, Barthel DW. Functional evaluation: the Barthel index. *Md State Med J.* 1965;14:61.

emotional responsiveness, if present, is at a primitive level. Eventually, the patient dies from the disease.

The MMSE also may be used as a staging tool. Scores of 26 or more are generally associated with minimal, if any, dementia; scores of 21 to 25 are associated with mild dementia, scores of 15 to 20 with moderate dementia, scores of 10 to 14 with severe dementia, and scores of 9 or less with profound dementia. The severity of most other symptoms correlates well with the MMSE score.

Selected Outcome Measures for Older Adults With Dementia

The Barthel Index (Table 27.4) is a profile scale that rates 10 self-care, continence, and mobility criteria.¹⁶⁰ The specific rating guidelines used in scoring are presented in Appendix 27.A. The advantage of the Barthel Index is its simplicity and usefulness in evaluating patients before, during, and after treatment. It is functionally oriented and may be best used when accompanied by a clinical evaluation.¹⁶¹ The scale allows documentation of functional changes over time. It is useful when discussing with families the need for help for the patient who cannot manage self-care (ADLs and/or IADLs).

Aside from the Barthel Index, clinicians could also use physical performance outcome measures to capture changes in physical function related to the disease process and assess the effectiveness of exercise interventions in older adults with AD and other related dementias.¹⁶² A 2019 scoping review categorized these outcome measures into five domains of physical performance as follows:

1. Fitness—Cardiorespiratory and muscle endurance to sustain effort that requires combined work capacities for cardiopulmonary, biomechanical, and neuromuscular function.

TABLE 27.5 Physical Performance Outcome Measures for Older Adults With Alzheimer’s Disease and Related Dementias

Performance Domain	Outcome Measures
Fitness	6-minute walk test (6MWT) 2-minute walk test (2MWT) 2-minute step test
Functional Mobility	30-sec chair stand test 5-time sit-to-stand test (FTSST) Timed up and go test (TUG) Performance Oriented Mobility Assessment (POMA) Functional Independence Measure (FIM) Short Physical Performance Battery (SPPB)
Gait	Short-distance fast-paced gait speed (m/s) Short-distance usual-paced gait speed (m/s) Quantitative gait analysis using instrumentation
Balance	Berg Balance Scale (BBS) Functional Reach Test Single-leg stance test Frailty and Injuries Cooperative Studies of Intervention Techniques-Subtest 4 (FICSIT-4) Instrumented postural sway Figure-of-8 walk test (F8W)
Strength	Isometric measures using handheld dynamometers for handgrip and lower extremity Dynamic measures using 1-RM test for lower extremity

From McGough EL, Lin SY, Belza B, et al. A scoping review of physical performance outcome measures used in exercise interventions for older adults with Alzheimer’s disease and related dementias. *J Geriatr Phys Ther.* 2019;42(1):28–47. doi:10.1519/JPT.000000000000159.

2. Functional Mobility—Ability to perform physical tasks needed for everyday mobility, including chair stands, stair climbing, transfers, and multicomponent movement patterns.
3. Gait—Spatial and temporal aspects of gait described with camera systems, electronic walkways, or inertial sensors for motion analysis.
4. Balance—Ability to maintain upright positioning during static and dynamic standing or postural sway measured with instrumentation during static standing.
5. Strength—Muscle capacity for maximum force generation.¹⁶²

Table 27.5 outlines 20 physical performance outcome measures that were identified in the study. The outcome measures were found to be reliable and responsive for older adults with mild to moderate dementia, though none was found to be optimal for severe dementia.

STRATEGIES FOR TREATMENT AND CARE

Most older adults with decreased cognitive abilities live with family or friends and not in institutions. Because of this, the rehabilitation team needs to include the caregivers and the patient as much as possible in treatment planning. The goal of rehabilitation is to ensure that the patient remains safe, independent, and able to perform ADLs and

IADLs for as long as is reasonable. The planning to reach these goals is best done within the context of the patient's social support system.

The rehabilitation process begins while the diagnostic workup is still in progress. At this stage of treatment, the rehabilitation plan includes basic training for the patient in performing and adapting the ADLs. It also includes caregiver training and support for significant others so they can make needed environmental modifications to ensure the safety of the patient with dementia.

Once the diagnosis is established, treatment planning for long-term care at home or in an institution must be carefully made. No matter where the patient will be living, involvement of the caregivers and significant others is essential to maximizing functional outcomes. The emotional, physical, and financial resources of the patient and family or significant others who will be the caretakers must be ascertained. A review of the caregivers' willingness to perform basic tasks or make visits, their willingness to learn and teach the necessary skills, and the realistic need for respites must be determined.¹⁶³ Family training and orientation manuals¹⁰⁹ that deal with all the details of caring for a person with dementia are available (see www.alz.org). The same detailed orientation is needed for institutional staff who care for patients with dementia. The structure and process of care can help patients be maximally active in their self-care and prevent unnecessary anxiety and catastrophic reactions.

Supporting Families and Caregivers With Their Own Sense of Loss, Frustration, and Helplessness

Family, significant others, and caregivers go through their own coping and adaptive process as the patient experiences gradual or sudden cognitive disturbances.¹⁶⁴ These people have a history with the patient and have expectations about what the relationship and communication should be. As cognitive disturbance occurs, they experience a series of losses because the patient is no longer able to respond and interact as he or she has in the past. With progressive cognitive decline, family and friends experience ongoing losses because the patient is continually changing and is less able to relate. For many patients with cognitive disturbances, at the final stage all communication disappears, and the family is left with only nonverbal communication or no communication at all. Staff who work with a patient over a period of time also face their own personal reactions of loss, unfulfilled expectations, and a continual need to reassess how to relate effectively to the patient. The responsibility for creating a positive relationship falls on the people who are interacting with the patient. The family and caregivers themselves need training and ongoing support in learning how to nurture and maintain an ongoing relationship with the patient. This process of training and support requires that caregivers and family members be aware that they are in a healing process as they relate to the loss of the relationship that previously existed.¹⁶⁵

Epstein: Stages of Healing for Caregivers

Epstein¹⁶⁶ provides a workable description of the stages of healing that occur when major trauma or loss occurs. Epstein defines *healing* as "putting right our wrong relation to our body, to other people and . . . to our own complicated minds, with their emotions and instincts at war with one another and not properly understood and accepted by what we call 'I' or 'me.'" The process is one of reorganization, reintegration of things that have come apart.¹⁶⁶ When a patient experiences cognitive changes, the first stage of response by those who care for or love this person is suffering. Chaos exists during this traumatic time. For example, the patient suddenly cannot understand simple directions on how to operate the new electric cart and insists on getting the old one back. The family is upset, and arguments ensue. The family and patient together eventually get a medical workup and are told that

"Mom has some type of degenerative cognitive problem." They all experience a profound sense that "something is wrong." The response to helplessness for most human beings is to resist. The lesson of this stage is acceptance. When acceptance is present, then detachment from emotions is possible. With acceptance present, adaptation and compensation for losses are possible. In the example noted, this would mean that the family would return the new electric cart and have the old (familiar) model refurbished. The family would get training from the therapist in exactly what skills of interaction Mom does not have so that they can work to avoid creating situations in which she feels "stupid and helpless." When a cognitive loss is truly present, training in skills only creates frustration in the patient that may lead to anger and rage. The staff and family need to be trained to understand the exact nature of the losses and provide appropriate compensations in their oral communication and how they relate to the patient.

Stage 2 has been alluded to as a part of stage 1. Therapists, the family, and caregivers search for second opinions, see other types of physicians, and try alternative treatments to gain power over the sense of helplessness. The polarities and rhythms of this process define this stage. All persons involved, even the patient, eventually begin to note that the emotions of the interactions may actually be making things worse. Acceptance that no magic solution is available begins. Everyone involved looks with interest at the proposition, "What can I do to make *this* life—*this* person—cope more effectively and have a reasonable quality of life (regardless of my opinion about what cognitive loss means to me personally)?" The lesson at this stage is another level of acceptance.

The third stage invites an examination of the ways in which people are "stuck in a perspective." When overwhelming stimuli occur, people commonly resort to their favorite strategy from childhood. For some people, the favorite strategy is to withdraw, whereas for others it may be to eat to create a distraction, and for others it may be anger. The emotional and mental options created to adapt to a difficult situation are as varied as the human race itself. Human beings dwell in the desire to know why or how to fix something. The lesson of this stage is, again, another level of acceptance and insight about how involved individuals contribute to the problem by reactions at the moment.

Stage 4 begins the process of "reclaiming power." This is the stage at which people realize that the "script" (their internal dialogue) from the last three stages is not workable or even desirable. The anger is recognized, and it brings an awareness that this reaction is not helping. Recognition begins that resisting is also not working because the condition of the patient is not affected in a positive way by the emotional reaction on the part of the caregiver(s). The truth of the matter is that the first four stages of healing often cause family and caregivers to become part of the problem and not part of the solution. The problem is how to support the patient to heal and adapt to the cognitive changes, whether temporary or permanent. Family and caregivers need to bring their healing process to their own support system, which needs to be separate from the patient. When caregivers attempt to share their frustration, suffering, sadness, or anger with the patient, the patient is usually upset because he or she cannot comprehend what the details of the issue really are. The patient knows only that people are upset. This will cause the patient to be increasingly upset and agitated. The stages of healing in staff and family must be recognized and services created or referral to support groups made so the patient can interact with people who are able to adapt to his or her needs and not cause further upset.

Stage 5 is called "merging with the illusion" and represents the first step in being able to "relate to the facts in a powerful way" rather than resisting or trying to manipulate them. It is the step at which family and caregivers begin to integrate the facts into their view of the world. The adult son may say, "I hate the fact that my mom cannot live alone;

it makes me feel so helpless [or frustrated or angry or upset or inadequate].” Many health care providers get upset when cognitive losses occur in their loved ones. The cognitive loss seems to be a failure that they take personally.

Stage 6 begins with active steps to prepare for the resolution of the emotions connected with the process. Many people describe this stage as the time when they really admit that their parents are never going to be able to give them advice again, babysit, or travel alone. The healing comes in allowing people to notice the emotions that come with accepting these big changes in reality.

Stage 7 brings the actual physical or emotional discharge. The process can be expressed as laughter, crying, fever, the urge to be physically active, sneezing, coughing, and so on. Resolution is marked by a deep sense of peace and inner strength. The person will have gone through the six stages, and the release of emotions or movement results in a deep shift away from resistance. *Family and caregivers need to create their own healing experiences separate from or away from the patient with cognitive losses.* When therapists work with the patient with cognitive losses, they must create for the patient a world that works and is safe and respectful of his or her unique abilities. In most cases, the profound emotional and physical release that comes with resolution tends only to upset the patient.

At stage 8, affected individuals are emptied and the board has been wiped clean. In the space of nothingness is an opportunity for new possibilities for relating to the patient. *The relationship should not be based on the past but on moment-to-moment information that comes from the patient.* Therapists can now enjoy being with the patient and begin to feel gratitude. Family and caregivers begin to look for ways to make things work more easily.

Stage 9 is a time when the caregivers and family relate to the energy of the universe and begin to see the connections to all life around them. At this stage, involved individuals begin to see that they are also a part of the great flow of time and energy and that an opportunity for joy exists. The process of illness and dying becomes the focus of awe and a reason to connect with other people and appreciate other people because they are a part of the whole process of life.

Stage 10 is the time to connect with the creative force of the universe. The spiritual process is brought to the issue at hand. A sense of great wisdom and oneness with all creation is felt. *When working from this state of being, the caregiver has the unique capacity to speak or act to bring out the best in others.* In health care, some caregivers have the special gift of allowing themselves to step into the mental world of the other person and thereby create communication that will be heard and that can be acted on even by those with limited mental capacities. The most interesting thing is that the patients can often tell if a caregiver is in this unique state because they will come and sit next to the caregiver or want to hold hands. This state of ease and connection can be learned. A possible resource for exploring these skills is an organization called Landmark Education ([415] 981-8850; www.landmarkeducation.com), which provides programs and courses that examine how people listen, what bias they bring to the communication process, and specific speech strategies to bring out the best in others.

Epstein stage 11 is when people live day to day without being attached to the situation. Epstein notes that in this stage, “we communicate with ourselves and others through our wounds instead of from them.” As healing progresses, caregivers become part of the solution in the care of the patient with cognitive losses. They know they can make a positive difference and take action to create what needs to be done. *They are able to sort out the facts of a situation from the first impression, which is often loaded with judgments and wishful thinking. As caregivers relate to the verifiable facts, they speak to the issues at hand with power and create positive outcomes in which “win-win” becomes the norm.*

In the last stage, caregivers bring their unique individuality to the service of the community. They become aware that the limits to what they can bring to the community are connected to the limits to their sense of wholeness. This insight sends them back to their earlier stages of healing to create further self-awareness and healing on other issues.

In-service training can offer a basic introduction to strategies for lifelong learning, healing, and self-awareness. “What works for me?” “What is the easiest way to learn new skills?” “What strategies enhance adaptability?” This type of learning is nonlinear and is the model a scientist uses to conduct an inquiry. Recently, more attention has been paid to managing stress and the role of spirituality in processing grief and loss among caregivers and family.¹⁶⁷⁻¹⁶⁹

Nonlinear Learning

Nonlinear learning begins with the posing of a question. Then data and information are collected, and additional questions are generated that are related to the first question. At some point an “Aha!” moment or insight occurs. A new relationship is suddenly made possible that was not possible before. Nonlinear learning is not about small gradual steps of progress but occurs similarly to how learning balance occurs when riding a bicycle—one minute balance is impossible, and the next is the breakthrough moment. Nonlinear training offers precise strategies that can enhance communication with someone who has cognitive deficits. Nonlinear learning is built on scientific communication that operates on the basis of verifiable facts at the present moment. Nonlinear learning invites each person to examine all strategies for communication to be sure that problems are not occurring as a result of misinterpretation of the facts. Communication can occur without verbal language, and fear does not need to be present. When a patient has cognitive deficits, the art and science of human interaction need to be precise so that caregivers do not speak in words that are not understandable to the patient. Which caregiver prejudgments are brought to the interaction with the patient needs to be understood: experiencing the stage of awe, sharing joy in the moment, or suffering because the person is “difficult”? The care and therapy provided to a person with cognitive disturbances need to be created based on the facts of the moment and carried out in a state of gratitude, vulnerability, and nurturing for the staff and the patient.

Role of the Clinician: Development of Interventions and Caregiver Training^{170,171}

All people with cognitive losses should have access to caregivers who are trained to manage emotional responses in order to provide precise strategies for communication with those with dementia. A gracious and secure existence is possible even when cognition is diminished if the caregivers are committed to adapting the environment and its demands to match the capacity of the patient. The challenge for health care is designing training programs that truly prepare families and caregivers to be effective, empowering communicators. All caregivers need training to create this experience for a person with cognitive deficits.

As a part of the rehabilitation program, caregiver training for this group of patients needs to emphasize reassurance, hands-on interventions, and communication to allow treatment to proceed at a pace perceived as reasonable by the patient.⁹³ In the early and middle stages of all dementias, physical therapy intervention usually can prolong the ability to move with ease in ADLs and IADLs, and maintain the ability to participate in some social activities. This therapeutic outcome is extremely important for caregivers because deficits in the patient’s ability to perform ADLs and IADLs often relate to the inability to physically perform these activities under supervision.⁶⁷ The ability to walk is lost late in most dementias, but gait and coordination disturbances

Fig. 27.4 Achieving and maintaining high cognitive fitness through exercise and physical activity in early to mid-adulthood may influence the onset and severity of cognitive impairment in later life.

are common and can benefit from physical therapy.^{172–174} Therapeutic intervention to assist the patient and train the caregivers involves facilitation of ease of movement and motor planning and developing or refining environmental and cognitive cues to assist in carrying out complex tasks. Ultimately, caregivers require training in how to move, lift, and otherwise assist the patient.

Although not able to reverse the progressive cognitive decline, the exercise intervention that the physical therapist can develop may improve the level of function, confidence, vitality, and safety of the patient and ease the burden of care for the caregivers. Research has demonstrated an important role for exercise in maintaining physical activity^{175–177}—contributing to general health, improving cognitive¹⁷⁸ reserve,⁵⁷ and slowing of cognitive decline,^{179–182} as well as maintaining strength and aerobic conditioning^{55,183} (Fig. 27.4). Guidelines for exercise prescription include aerobic, strength, balance, coordination, and flexibility activities determined by direct assessment, and suggestions for motivational and problem-solving strategies. The Seattle Protocols are an important contribution in this area.^{184,185} Research shows that exercise not only increases strength, coordination, and aerobic capacity but also creates beneficial changes in brain plasticity.^{81,186,187} Further studies need to be done to work out more clearly what types of exercise are beneficial in what ways and for which populations.¹⁸⁸

Cognitive impairment is a key limiting factor in the performance of ADLs and IADLs as well as a limiting factor for participating in rehabilitation. Accurate assessment and training by the therapist help the caregiver provide only the help that is absolutely needed, with patients continuing to perform for themselves as many ADLs as possible. For example, when brushing the teeth, the patient needs to be able to remember the command to brush, must recognize the toothbrush, and must perform a complex but repetitive motor action. The patient may only need the help of someone placing the toothbrush in his or her hand and slowly guiding it to the mouth to be able to safely brush the teeth.

The accurate assessment of IADLs and ADLs is more reliable than medical diagnosis for predicting the amount of assistance and interaction a person will need in a nursing home (see Table 27.4, Table 27.5, and Appendix 27.A).¹⁶⁰ The first goal of rehabilitation for

patients with dementia is to create a supportive emotional and physical environment. The environment must actively work to compensate for the patient's cognitive and functional losses as they occur. The ultimate goal is to help patients feel they are capable so that they will continue to try to do those things for themselves that they can do safely, whether they remain in their home or live in an institution. Orientation and training of significant others are also important so that they feel comfortable allowing the patient to participate safely in activities and basic self-care tasks modified to their cognitive level.

The Alzheimer's Association ([800] 272-3900; www.alz.org) is a resource for professionals and caregivers of people with dementia. The goals of the association are the following:

- To support research related to the diagnosis, therapy, cause, and cure of AD and related disorders
- To aid in organizing family support groups; to educate and assist affected families
- To sponsor educational programs for professionals and laypersons on the topic of AD
- To advise government agencies of the needs of the affected families and to promote federal, state, and private support of research
- To offer help in any manner to patients and their caregivers to promote the well-being of all involved

The Alzheimer's Association promotes the provision of humane care to the patient with dementia or related disorders throughout the course of the illness. Other support groups have been tried in communities in which spouses have worked to develop ongoing respite care.¹⁸⁹

As a member of the rehabilitation team, the physical or occupational therapist can conduct an inventory of services as a part of the annual review of the quality of care that is provided for a patient with dementia. Surveys of persons caring for patients with dementia listed the following services in their perceived order of importance^{98,190}:

1. Availability of respite care services (i.e., short-term care provided by a third party to relieve the primary caregiver; a paid companion can come and stay at home for a few hours to several days giving caregivers a chance to go away and rest)^{190a}
2. Assistance in locating people or organizations to provide patient care
3. Assistance in applying for government programs, such as Medicaid, disability insurance, and income support programs
4. Personal home care for the person with dementia to help with activities such as bathing, dressing, or feeding in the home
5. Support groups composed of others who are caring for people with dementia and other cognitive deficits
6. Special nursing home care programs only for people with dementia and other cognitive deficits while the caregiver is away
7. Adult day care providing supervision and activities away from the home
8. Visiting nurse services for care at home

In the home care category, information about the availability of services and government programs and various forms of respite care were also highly ranked in the survey. Overall, caregivers (family and friends) of the patient are often able and willing to provide care for the patient throughout the illness if appropriate professional consultation can help them cope with problematic situations and if adequate respite time is provided to the caregiver(s).

Not mentioned in this chapter is the need for psychological support for caregivers. The stress on caregivers is extreme, and symptoms of anxiety and depression are common. Because of the relative lack of counseling services for caregivers, however, the use of (and probable abuse of and dependence on) psychotropic medications by caregivers is high.^{85,191} Because these medications may impair the cognitive

functioning of caregivers, the risk of harm to the patient with dementia is also high.

EMERGING INTERVENTIONS AND FUTURE TRENDS ON THE ROLE OF REHABILITATION THERAPISTS IN DEMENTIA CARE

Most current research in delirium and dementia is focused on AD. Research is underway to explore possible causes of dementia, including work that examines the roles of neurotransmitters, structural brain changes, nutrition, viruses, drugs, immunological deficits, and heredity in the etiology of AD. Studies to increase the diagnostic accuracy of different forms of dementia, including making a distinction between cortical and subcortical dementia¹⁹⁰ or using *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V) criteria⁴¹ or neuropsychological criteria, are also underway. Newer diagnostic models of dementia, including that caused by stage II or III human immunodeficiency virus infection, are also being studied.^{192,193} The recent discovery of lymphatic vessels in the dural venous sinuses offers a potential direct link between the human brain and the body's immune system, a connection which was previously believed to be nonexistent.^{194,195} This development raises the possibility of the role the immune system plays in brain function and in the development of AD. In a separate study, increased levels of two human herpesviruses (HHV-6A and HHV-7) were observed in the brains of people with AD compared with normal controls.^{196,197} The herpes virus genes were then found to interact with genes known to increase AD risk and those that modulate amyloid precursor protein processing. People with dementia who also have parkinsonian symptoms, delusions, and hallucinations have been reported to experience faster decline than those

who do not.¹⁹⁸ This research team found a relation between the presence of Lewy bodies (abnormal structures in the brain that contain a protein called *synuclein*) and parkinsonian symptoms; affected individuals had lower survival rates than those with either symptom present by itself.

Finding a cure for AD has been largely unsuccessful, with a failure rate of 99.6%.¹⁹⁹ The last time a drug was approved for AD was in 2003. In a review of the drug development pipeline, 63% of agents targeted disease modification, 23% have cognitive-enhancing effects, and 12% controlled neuropsychiatric symptoms.²⁰⁰ Almost all were directed at patients with mild AD, severely limiting treatment options for patients already in the moderate to advanced stages. In the absence of a drug to halt or reverse the progression of AD, nonpharmacological strategies such as exercise, increasing physical activity, having a healthy/nutritious²⁰¹ diet, and improving sleep quality could play a role in preventing and/or delaying the onset of AD^{202,203} (see **Box 27.7**). Results from a 44-year longitudinal population study in women suggest the importance of maintaining high cardiovascular fitness in midlife in reducing dementia risk and delaying its onset. In the said study, women who had high fitness (assessed by step-wise ergometer cycling) decreased their dementia risk by 88% compared to those with medium fitness, and those that developed dementia manifested it 11 years later than those with medium fitness.²⁴

The most exciting area of research is dementia prevention by targeting known modifiable risk factors. Findings from the Singapore Longitudinal Ageing Study showed a 1.5- to 2-fold increased risk of developing MCI in those who had metabolic syndrome, diabetes mellitus, central obesity, and dyslipidemia; a fourfold increased risk of progressing from MCI to dementia in those with metabolic syndrome, and a twofold risk in those with diabetes mellitus.²⁰⁴ Thus it is imperative to address these risk factors as early as possible to mitigate

BOX 27.7 Highlights From the 2017 National Academies of Sciences, Engineering, and Medicine Report on the State of Knowledge Regarding Prevention of Cognitive Decline and Dementia

The National Institute on Aging, in partnership with the National Academies of Sciences, Engineering, and Medicine, convened a committee to examine the current state of knowledge on the prevention of cognitive decline and dementia. Specifically, the Committee on Preventing Dementia and Cognitive Impairment was tasked to *evaluate the existing evidence on interventions for preventing cognitive decline and dementia, and based on this evidence, to recommend the appropriate content for inclusion in public health messages, as well as priorities for future prevention research.*

The Committee was not able to identify a specific intervention supported by conclusive evidence that would justify a widespread, assertive public health campaign for its adoption. However, **"encouraging but inconclusive evidence"** have been found for three classes of intervention:

1. Cognitive Training, interventions aimed at enhancing reasoning, memory, and speed of processing to delay or slow age-related cognitive decline
2. Blood Pressure Management in People with Hypertension, to prevent, delay or slow clinical Alzheimer's-type dementia
3. Increased Physical Activity, to delay or slow age-related cognitive decline

The report also highlights that these areas of study were the "highest priorities for research" for the National Institutes of Health and other interested organizations. Research is needed to elucidate the effectiveness of cognitive training, blood pressure management, and increased physical activity. In particular, it is important to *evaluate the comparative effectiveness of different forms of*

cognitive training interventions and determine which specific intervention elements are responsible for the observed positive and long-term impacts on cognitive performance; determine whether there are optimal blood pressure targets and approaches across different age ranges; and comparing the effects of different forms of physical activity such as aerobic and resistance training.

Aside from the above-mentioned interventions, the Committee also identified several that were currently supported by **insufficient evidence** from RCTs, but had promising findings derived from observational studies, knowledge of dementia risk factors, and/or strong argument for biological plausibility.

- New antidementia treatments that can delay onset of slow disease progression
- Diabetes Treatment
- Depression Treatment
- Dietary Interventions
- Lipid-lowering Treatment
- Sleep Quality Interventions
- Social Engagement Interventions
- Vitamin B12 plus Folic Acid Supplementation

Full report can be accessed online for free via <http://nationalacademies.org/hmd/reports/2017/preventing-cognitive-decline-and-dementia-a-way-forward.aspx>

cognitive impairment in later life. A landmark multiple-center randomized controlled trial, the Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER),^{20,205–209} has shown that a 2-year multiple-domain intervention consisting of nutritional guidance; exercise; cognitive training and social activity; and management of metabolic and vascular risk factors can prevent cognitive decline in older people from the general population who are at risk of dementia.^{20,208} The success of the FINGER Trial helped establish the World Wide FINGERS (WW-FINGERS) initiative, an international collaborative effort to identify cost-effective preventative approaches for various at-risk groups that are accessible, feasible, and sustainable for different geographical, economic, and cultural settings.²⁰⁹ As of the writing of this chapter in 2018, the US study to PrOtect through a lifestyle INTERvention to Reduce risk (US POINTER), a clinical trial modeled after the FINGER, has begun identifying its targeted 2500 participants aged 60 to 79 years. Aside from the US POINTER study, similar projects are being planned in China (Multimodal Intervention to delay dementia and disability in rural China/MIND-CHINA), Singapore (Singapore intervention study to prevent cognitive impairment and disability/SINGER), Australia (Maximising technology and methodology for internet prevention of cognitive decline: the Maintain Your Brain Trial/MYB trial), and Europe (Multimodal preventative trials for Alzheimer's Disease: towards multinational strategies/MIND-AD trial). These studies highlight the critical contribution of physical exercise in dementia prevention and rehabilitation therapists are

strategically placed with the expertise to design and implement appropriate physical activity and exercise interventions. Findings from a 2×2 factorial randomized clinical trial in adults with cognitive impairment but no dementia showed that those who engaged in aerobic exercise had significant gains in executive function compared to those who were assigned in the Dietary Approaches to Stop Hypertension (DASH) diet group.²¹⁰ Adults who exercised and adhered to the DASH diet had the largest increase in executive function compared to controls. To further underscore the positive impact of exercise on cognitive function, the American Academy of Neurology now recommends exercise as part of the overall management plan for patients with diagnosed with MCI.²¹¹ The guideline specifically states that, “*For patients diagnosed with MCI, clinicians should recommend regular exercise (twice/week) as part of an over-all approach to management*”.

Various interventions have shown promise in improving cognitive and physical functions in people who already have dementia.²⁰³ These interventions include the use of virtual reality or gaming technology like the Nintendo Wii for physical activity and exercise,^{212,213} dance,^{214,215} and the use of assistive technology to promote home safety²¹⁶—all of which have been demonstrated to be feasible at various stages in the progression of dementia and are being further examined in research.

Research is also being funded to investigate the best ways to provide care and support in the home and in long-term residential settings.⁵⁴

SUMMARY

Why some people stay lively and creative in their older years is not known; Michelangelo designed St. Peter's when he was nearly 90; Picasso painted at 90; and Arthur Rubenstein, Pablo Casals, and Martha Graham all worked creatively in their older years. What is clear is that lonely, isolated older people are much more likely to be confused and disoriented than their peers who remain actively involved with family and friends. Perhaps what is needed is to invite the world to explore rules of conduct in which older persons are honored and included.

In working with an older person with dementia or delirium, the therapist can do much to improve the quality of life for the patient, family, and caregivers.¹⁰⁹ A thorough listing of the details needed to develop an environment and process of care for older adults and people with cognitive deficits can be found in other texts (see www.alz.org/living_with_alzheimers.asp).^{109,149}

Specific examples of modifications of physical and occupational therapy examination and treatment may include working in collaboration with the family, close friends, and other members of the rehabilitation team and developing a consultative relationship with key caregivers (professional and nonprofessional and all shifts of institutional staff) to encourage problem solving and patient participation in self-care. Another important modification includes the evaluation of each patient's communication abilities before the therapy assessment to adapt the assessment in such a way as to promote patient participation. Case study examples in the next section (refer to [Case Studies 27.1](#) and [27.2](#)) to provide clinical scenarios and corresponding physical and occupational therapy examination and treatment strategies.

CASE STUDY 27.1 The Complexity of Aging

The patient was a 78-year-old woman who had the following deficits on the MMSE: She was not aware of where she lived, the date, or the year; had poor short-term memory; could not spell the word “world” backward; and could not copy two overlapping pentagons. The patient was generally happy and enjoyed having someone sit with her. The patient had fractured her femur and, because of the location of the fracture site, a surgical procedure was performed to allow total weight bearing. The surgeon and the psychiatrist decided that partial weight bearing would not be a concept that the patient could understand. The physical therapist and assistant worked together with the family and caregivers in the nursing home to develop a plan of care. At the initial care conference, the main question was whether the patient should receive physical therapy. The family was fearful that the patient would fall again if she were taught how to walk. The focus of the conference was to educate the family and other staff regarding the importance of physical therapy so the patient could learn how to

participate in and eventually perform transfers from wheelchair to toilet as well as to bed. The decision was made to begin physical therapy, with the initial goal being to achieve all functional ADL transfers with standby physical assistance.

The patient was not interested in walking and was fearful of falling. The key change in physical therapy intervention was in the style of communication used to teach basic bed mobility and the components of transfer skills. Through the use of trial-and-error, it was determined that the patient responded best to a smile, verbal encouragement, hand signals, and gentle manual pressure to indicate the desired task to be performed. If the task was broken down and components were identified, the patient became frustrated and refused to participate. If the patient was invited by manual cues and verbal reassurance to stand up and sit on the bed, the patient would hesitate for up to 1 minute and then would attempt to perform the task. It became obvious that the patient needed at least 30 to 60 s of waiting time between when a verbal request was made and when

Continued

CASE STUDY 27.1 The Complexity of Aging—cont'd

she was ready to act on the request. If additional time was not given, the patient appeared to become frustrated and would refuse to cooperate. A sign was placed over her bed with instructions for communication: smile, reassure, use your hands to guide her to perform the desired action, and wait 60 s; let her feel there is plenty of time.

A sliding board was introduced in therapy, and the patient enjoyed the idea. The board allowed transfers for all ADLs to involve no lifting for the staff. The patient would lean her head on the shoulder of the staff member while sitting and then she would assist in sliding across on the board. All transfers for ADLs using the sliding board were possible within five visits of physical therapy. A bed was located that was 17 inches high to facilitate bed-to-wheelchair transfers. The bed could be raised to assist the nursing aide in cleaning activities. The decision was made to leave the bed at 17 inches unless the nursing staff needed to perform special in-bed procedures with the patient. The wheelchair footrests were modified so that they formed a solid flat surface to allow the patient to rest in a natural position. The patient was only 5 feet 2 inches tall, and the standard wheelchair allowed her only to comfortably put both feet on one foot pedal and sit with her weight mostly on one buttock. A smaller wheelchair and the adapted footrest provided the patient with equal pressure on both sitting bones, and the patient began to sit at rest in a natural upright posture. The other goal of physical therapy was to teach the patient wheelchair mobility by using her hands to push the chair. Once the patient was given gloves for her hands (she did not like germs), she was willing to try to push the wheelchair. The patient was instructed in the physical therapy department during two visits. The patient was next seen by the therapist on the unit to allow the nurse's aide to become a part of the physical therapy instruction. The rationale was that the nurse's aide would need to help reinforce the skills and encourage the practice of wheelchair mobility skills as a part of daily activities. During the last visits, the physical therapist watched daytime, afternoon, and evening staff practice with the patient and addressed new situations that arose. All caregivers on three shifts were trained to ensure consistency of verbal and manual cueing for the patient.

Before discharge to restorative nursing, the patient's current level of functional abilities was documented by using an ADL chart that specified the task(s) and times of day when they were easiest, equipment needs, special positioning, clothing and other assistive devices, verbal cueing, and other communication requirements for each critical task that had been mastered in physical therapy. The cataloging of functional skills reminded the nurse's aide of the ingredients involved for the patient to successfully perform ADLs. The other advantage of the detailed discharge summary to the nursing staff was that new staff could use the document and, as needed, contact physical therapy for clarifications if the patient was suddenly unable to perform the tasks (a signal of possible medical or psychosocial problems).

Key Points

1. Common goals were identified and agreed upon among all team members and the patient's significant others.
2. Education was provided as needed to allow for consistency of verbal and manual cueing to the patient.
3. Physical therapy treatment began in a quiet, undisturbed area where the patient could concentrate. As mastery of a skill was achieved, the skill was practiced with supervision, and instruction of other staff was provided as needed.
4. Equipment and furniture were adjusted to help the patient perform tasks with minimal assistance.
5. Discharge from therapy involved providing nursing staff with a detailed description of functional abilities and the conditions required to help maximize patient participation, sense of safety, and control (as had already been reviewed with all aides working with the patient).
6. The physical therapist was designated as a resource person for nursing staff for simplifying functional tasks in patient care, problem solving, communication, and movement-related issues.

CASE STUDY 27.2 A Patient in the Early Stage of Alzheimer's Disease

The patient was a 64-year-old man who, until 1 month ago, was working. He was forced to retire because he kept forgetting the natural sequences of his work tasks. For example, his partner would see him direct someone to wait for him in the waiting room and subsequently forget about that person. On the MMSE, he had difficulty with date and year and would try to redirect the question in an apparent attempt to cover up for the loss of short-term memory. He could not or would not spell the word "world" backward, and he poorly copied the overlapping hexagons (looked more like squares). He was a runner but now could not remember how to get home and, as a result, would pretend to be hurt and get someone to drive him there. The man reported feeling restless.

The patient, along with his wife and two sons, were seen by the team at a psychiatric clinic. The wife was very upset, and the family was asking for help. The role of therapy at this early stage of AD involved the following:

1. Functional assessment of basic ADLs and IADLs and home assessment.
2. Orientation of spouse and significant caregivers regarding the functional changes that could occur in the near future and how to compensate for current functional losses (e.g., patient had difficulty dressing in the morning and would become frustrated).
3. Orientation to the role of therapy in hands-on treatment related to techniques to help the patient relax. After initial evaluation, the team decided to teach caregivers massage techniques identified by the therapist as soothing and relaxing for the patient. (Note: The emphasis in hands-on intervention is to create slow, predictable, and nurturing contact that is perceived by the patient as soothing and relaxing.)
4. Orientation of caregivers to the use of manual contact and hand signals to communicate and reinforce the intention. Kinesthetic contact and the ability to follow kinesthetic cues can help the patient with ADL tasks at home. At this time, the kinesthetic cueing may not be critical for the patient, but the caregivers need to get in the habit of cueing the patient as a compensatory tool for future cognitive losses.
5. Orientation of caregivers to the benefits of a ritualized schedule of daily events for the patient and assistance in developing the daily schedule. The predictability of the ritual would help the patient feel safe and in control. The ritualizing would be especially helpful to address the frustrations with dressing in the morning.
6. Written information about local support groups, day treatment centers, and the availability of the rehabilitation team, including therapy for problem solving.
7. Participation in the evaluation of patient and family need for placement in a day treatment center or use of a home health aide. Supervision was needed for cooking (he would leave burners on), working in the woodshop (he would leave power tools running), and in self-care to ensure his safety. Supervision in the home was decided, with family members sharing the load. The idea of going to a new place was not positively received by the patient. (Note: The patient may function better in the environment where he or she has lived for a long time because of the familiarity with the details of the surroundings.)
8. The therapist participated in development of the home care plan and provided patient and family education during a home-health visit. The next contact

CASE STUDY 27.2 A Patient in the Early Stage of Alzheimer's Disease—cont'd

that the family made with therapy was 1 month later to address the patient's inability to settle down and go to sleep at night. A home visit was made to evaluate the bedtime ritual, the relaxation strategies being used, and communication with the physician about current medications taken. The patient disliked bathing and undressing for bed. After discussion with caregivers, the patient was allowed to go to bed in his clothes without bathing and undressing (bathing and undressing would be carried out in the morning when he was less tired). Relaxation massage was modified to involve the face, neck, hands, and feet, and the caregivers were instructed and practiced during two visits under the supervision of the therapist. A satisfactory bedtime ritual was developed, and home health care was workable for the patient and the caregivers.

The next request for therapy consultation came 4 months later when the wife and the daughter-in-law (who had been taking turns being the primary caregiver) both felt the need to hire and train an attendant-companion for the patient for 8 h a day. At this time, the patient preferred to be in the home, walk in the yard, or take long walks in the local park. The therapist, in cooperation with other team members, trained the patient regarding how to sequence for ease in ADL tasks; the use of kinesthetic cuing; how to facilitate ADLs, bathing, and dressing with a slow pace and ritualized format; and how to sequence the tasks and relaxation techniques to help the patient settle down and go to sleep. Foot massage was the only technique that the patient now allowed and appeared to enjoy. After three physical therapy visits over a 2-week period, the attendant was able to carry out home health care effectively for the patient.

The last request for help occurred when the family was concerned because the patient was trying to run away. The therapist made a home visit and found that the patient sat most of the day. The MMSE showed that he could not give his own first or last name and had no short-term memory. Based on the evaluation, the therapist proposed that the family or attendant go with the patient for a walk when the patient showed an interest in leaving the house. This strategy worked for a few months, but then the patient began to sit down on the sidewalk when he was tired. Another visit was made after a wheelchair was ordered to train the caregivers in use of the wheelchair and to orient the patient to the desired procedures and to reassure the patient. After this visit, the patient showed gradually less interest in leaving the home over the next few months until he eventually stayed in the house constantly. At this time, the patient also became incontinent of bowel and bladder. The patient refused to use the toilet, and the decision was made to seek nursing home placement.

Key Points

1. Physical (or occupational) therapy is a part of the team providing guidance and care for the patient and the family of the patient with AD and other dementias.
2. Evaluation of functional skills, communication related to functional skills, and home modifications to enhance patient participation in self-care can be continued as long as the caregivers request support and help problem solving.
3. Problem solving with caregivers and educating caregivers are the primary roles once the therapist has identified the intervention of choice to solve the key functional problems.
4. All therapy intervention needs to be coordinated with actions of others providing care for the patient (family, neighbors, and friends as well as other health care providers).

Modifications of treatment include the use of gentle, nonverbal neurological rehabilitation techniques (e.g., the Feldenkrais Method). The key is to acknowledge the now well-established research finding that nondeclarative learning and memory (procedural) are available long after declarative learning and memory (ability to consciously learn and remember facts and events) are lost for a person with AD. Motor ability is one of the last areas to be affected by AD.²¹⁷ Assisting a person with AD to edit procedural memory and increase walking safety is

therefore possible. The functional outcomes of this learning can include a decrease in abnormal muscle tone, enhanced sensory awareness and organization for the position of the eyes and head in space, an increase in the ease of movement, an increase in the ease of breathing, enhanced endurance, minimized anxiety, minimized resting muscle rigidity in the chest, and increased patient coordination. The therapist needs to modify the process of neurological facilitation by decreasing patient effort and adding extra cuing and more frequent breaks for integration of learning. Tasks may need to be simplified so that the patient can perform them, and the caregiver is trained to perform only those tasks that the patient cannot perform.

Each month, the therapist, treatment team, patient, and caregiver(s) need to identify safe physical activities that the patient can be encouraged to perform for recreation, relaxation, and overall fitness. The goal is to enhance the performance of simple ADL and IADL tasks (e.g., washing socks, setting the table), which can enhance patient self-esteem. In addition, the physical therapist, along with other members of the rehabilitation team and caregivers, needs to monitor the patient for new signs and symptoms of concurrent delirium or reversible dementia so that treatment can be initiated early and further deterioration can be prevented.

A hospital and nursing home patients' "Bill of Rights" defines the minimal quality of care required for any patient. The concepts presented apply to the care of patients with cognitive deficits no matter what the setting. The provision of considerate and respectful care for the patient with dementia or other cognitive deficits is possible and necessary. Well-planned and gentle care prevents unnecessary distortions in cognitive function brought on by feelings of fear or being rushed and thereby maximizes all remaining cognitive function. To use his or her remaining emotional and cognitive resources, the patient with cognitive deficits needs to live in an environment and experience a process of care that is modified to meet the special needs created by delirium or dementia.

AD is progressive and irreversible, but pharmacological therapies for cognitive impairment and nonpharmacological and pharmacological treatments for behavioral problems associated with dementia can enhance quality of life. Psychotherapeutic intervention with family members is often indicated, as nearly half of all caregivers become depressed. Health care delivery to these patients is fragmented and inadequate.²¹⁸

Physical and occupational therapy are key resources for the creation of a therapeutic environment and for the effective and timely assessment and treatment of the patient with cognitive deficits. The goal of therapy is to create a process of care in which the patient feels safe and the caregivers are given training and support in problem solving to guide the patient to participate in self-care, ambulation, and recreation as long as it is safe and functionally possible.

Caregiver agreements can enhance the capacity of older people with dementia to participate in daily life—exploring the possibility of living a life with safety, dignity, and love. The following is a brief list of basic environmental supports for encouraging the activation of procedural memory:

1. I will ask my patient if he or she would like to pray or worship today, and I will make arrangements to meet those needs.
2. I will speak or communicate in a way that is functional and workable for the patient.
3. I will repeat what I hear and perceive back to the patient to ensure that I capture her or his perspective.
4. I will encourage natural participation by creating a pace that is pleasant for the patient.
5. I will close doors quietly.
6. I will not raise my voice or shout except in a real emergency.
7. I will talk to someone on staff when I get upset or take something personally so I can have peace with co-workers, creating a positive atmosphere in which the patients can live.

Continued

CASE STUDY 27.2 A Patient in the Early Stage of Alzheimer's Disease—cont'd

8. I will offer to warm up the patient's tea or coffee and make sure it is not so hot that it could cause a burn.
9. I will create only one choice at a time so the patient can understand and then choose yes or no.
10. I will know what "my" patient has eaten on my shift.
11. I will know my patients' timing for toileting so I can support their continence and dignity.
12. I will tell the patient I am going to touch him or her before I do so to avoid surprises.
