13. I will walk (rolling or ambulating) with every one of my patients outdoors as often as possible or at least every 3 days to encourage good sleep and mental and physical stimulation.
14. I will sit and visit with each of my patients for 10 min (every shift).
15. I promise to listen with an open heart to the patients' perception of life at the moment.
16. I promise to close the blinds in every room at night (unless the patient requests otherwise) and open the blinds every morning to reinforce day-night orientation.
17. I will discover and use the "personal" get ready for bed routine for all patients so that they sleep well.
18. I promise to talk and walk at a pace that encourages a sense of safety for my patients.
19. I promise to be self-nurturing and come to work well rested and ready to share myself.
20. I promise to avoid confrontational actions and body language except in an emergency.
21. I promise to respect the unique ergonomics of each patient and adapt as needed.
22. I promise to offer to add support to explore ways to increase comfort.
23. I promise to notice how my patients relate so that no one agitates or bothers another.
24. I promise to be kind to myself, other staff, and my patients.
25. I promise to be of service and adapt to meet my patients' needs.
26. I promise to report problems (equipment, environment, relationships) to the person who can do something about them.
27. I promise not to gossip (talk about others in a way that leaves a negative impression and no resolution of the problem).
28. I promise to leave my workspace clean and restocked after I have taken care of the patient (or at least to leave a note to alert the next shift about what has not been done).

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the

reader to a Medline abstract for the article cited. There are 219 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Rating Guidelines for Barthel Index

1. Feeding
 - 10 = Independent. The patient can feed himself or herself a meal when someone puts the food within reach. Patient must put on an assistive device, if needed, to cut up the food alone. The patient must accomplish this in a reasonable time.
 - 5 = Some help is necessary (with cutting up food, and so on, as listed above).
 2. Moving from wheelchair to bed and return
 - 15 = Independent in all phases of this activity. Patient can safely approach the bed in the wheelchair, lock brakes, lift footrests, move safely to bed, lie down, come to a sitting position in the wheelchair if necessary to transfer back into it safely, and return to the wheelchair.
 - 10 = Either some minimal help is needed in some step of this activity or the patient needs to be reminded or supervised for safety in one or more parts of this activity.
 - 5 = Patient can come to a sitting position without the help of a second person but needs to be lifted out of bed, or he or she transfers only with a great deal of help.
 3. Doing personal toileting
 - 5 = Patient can wash hands and face, comb hair, clean teeth, and shave. He may use any kind of razor but must put in blade or plug in razor without help as well as get it from drawer or cabinet. Female patients must put on own makeup.
 4. Getting on and off toilet
 - 10 = Patient is able to get on and off toilet, fasten and unfasten clothes, prevent soiling of clothes, and use toilet paper without help. If a bedpan is necessary instead of a toilet, patient must be able to place it on a chair, empty it, and clean it.
 - 5 = Patient needs help because of imbalance or with handling clothes or using toilet paper.
 5. Bathing self
 - 5 = Patient may use a bathtub or a shower or take a complete sponge bath. Patient must be able to do all the steps involved in whichever method is used without another person being present.
 6. Walking on a level surface
 - 15 = Patient can walk at least 50 yards without help or supervision. Patient may wear braces or prostheses and use crutches, canes, or a walker (but not a rolling walker). Patient must be able to lock and unlock braces, if used; assume the standing position and sit down; get the necessary mechanical aids into position for use; and dispose of them when sitting. (Putting on and taking off braces is scored under dressing.)
 - 10 = Patient needs help or supervision in any of the above but can walk at least 50 yards with a little help.
 - 6a. Propelling a wheelchair
 - 5 = Patient cannot ambulate but can propel a wheelchair independently. Must be able to go around corners, turn around, and maneuver the chair to a table, bed, toilet, and so on. Must be able to push a chair at least 50 yards. (Do not score this item if the patient gets a score for walking.)
 7. Ascending and descending stairs
 - 10 = Patient is able to go up and down a flight of stairs safely without help or supervision. Patient may and should use handrails, canes, or crutches when needed. Must be able to carry canes or crutches when ascending or descending stairs.
 - 5 = Patient needs help with or supervision during any one of the above items.
 8. Dressing and undressing
 - 10 = Patient is able to put on, remove, and fasten all clothing as well as tie shoelaces (unless adaptations are necessary). The activity includes putting on, removing, and fastening corset or braces when these are prescribed.
 - 5 = Patient needs help putting on and removing or fastening any clothing. Patient must do at least half the work. Patient must accomplish this in a reasonable time. Women need not be scored on use of a brassiere or girdle unless these are prescribed garments.
 9. Continence of bowels
 - 10 = Patient is able to control bowels and have no accidents. Can use a suppository or take an enema when necessary.
 - 5 = Patient needs help in using a suppository or taking an enema or has occasional accidents.
 10. Controlling bladder
 - 10 = Patient is able to control his or her bladder day and night. Patients who wear an external device and leg bag must put them on independently, clean and empty bag, and stay dry day and night.
 - 5 = Patient has occasional accidents or cannot wait for the bedpan or get to the toilet in time or needs help with an external device.

Abstract: This chapter provides a comprehensive discussion of aging, dementia, and disorders of cognition as these relate to rehabilitation therapy practice. This chapter presents the neurophysiological and neuropathological bases of cognitive problems in older adults, and the principles of rehabilitation that serve as the foundation for managing cognitive disorders in this population. The theoretical foundations of and research evidence for assessment and intervention are covered. Important concepts such as key clinical features of and diagnostic

criteria for delirium, dementia, and depression are presented, as well as physical, occupational, and psychotherapeutic strategies used in rehabilitation. Finally, emerging interventions and future trends on the role of therapists in the areas of prevention and rehabilitation are discussed.

Key words: dementia, disorders of cognition, delirium, Alzheimer's disease

Disorders of Vision and Visual-Perceptual Dysfunction

Domenique Hendershot Embrey and Laurie Ruth Chaikin

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify and analyze visual anatomy and physiology as they pertain to visual function.
2. Analyze the functional visual skills and how visual dysfunction may affect functional performance.
3. Identify the symptoms of visual dysfunction.
4. Develop the skill necessary to take a visual case history by use of behaviors and clinical observations.
5. Identify the difference between phoria and strabismus.
6. Identify and evaluate the difference between visual field loss and unilateral neglect.
7. Identify and differentiate various pediatric and age-related disease conditions that may affect vision.
8. Clearly differentiate nonoptical and optical assessment and intervention adaptations for patients with low vision.
9. Differentiate basic tools for vision screening.
10. Identify when and why to refer and the tools necessary to document that decision.

KEY TERMS

anatomy of the eye

eye diseases

functional visual skills

refractive error

strabismus

treatment

visual-perceptual dysfunction

visual rehab

visual screening

Vision is an integral part of development of perception. Some aspects of vision, such as pupillary function, are innate, but many other aspects are stimulated to develop by experience and interaction with the environment. Visual acuity itself has been demonstrated to rely on the presence of a clear image focused on the retina. If this does not occur, a “lazy eye,” or amblyopia, will result. Depth perception develops as a result of precise eye alignment. This ability will be delayed, less precise, or absent if correction of eye misalignment is not done within the first 7 years of life. Research has demonstrated that, in fact, most visual skills such as acuity, binocular coordination, accommodation, ocular motilities, and depth perception are largely intact by age 6 months to 1 year.¹ Visual skill development parallels postural reflex integration and provides a foundation for perception.

Early in infancy visual input is associated with olfactory, tactile, vestibular, and proprioceptive sensations. The infant is driven to touch, taste, smell, and manipulate what he or she sees. Primitive postural reflexes such as the asymmetrical tonic neck reflex help provide visual regard and attention.

By combining the sensory input from vision, oral exploration, and tactile input, at some point the young child is able to look at an object and determine both the texture and the shape without having to touch or taste it. In adults, vision has moved to the top of the sensory hierarchy, providing full multisensory associations from sight alone. Even the visualized image of eating an apple can recreate the smell, sound of

crunching, taste, and feel of the experience; this occurs based on previous input provided to the brain by the senses.

Early visual impairment and later acquired impairment can affect the quality of the image presented to the brain and thus affect the learning process. In addition, damage to association centers involved with spatial perception, figure-ground, and directionality can interfere with learning and performance. Altered function may be the result of congenital and developmental disorders, birth trauma, physical trauma, or neurological or systemic diseases.

It is important therefore to isolate the primary visual processes of seeing from the secondary or associational processes of perceiving in the evaluation of perceptual disorders. The identification of a vision problem becomes part of the differential diagnosis of a perceptual deficit. Visual screening must be done before perceptual evaluation so that visual problems do not bias or contaminate the perceptual testing. It is just as important to eliminate vision as a contributing factor to a perceptual problem as it is to find a possible vision problem.

Our understanding of the ability to improve vision or recover visual function frequently needs to be updated as we apply new research and understanding of neuroplasticity. Principles of visual rehabilitation involve understanding how to provide visual feedback to the system in an optimal learning environment for the patient. The boundaries of improvement are slowly expanding as we refine this understanding.

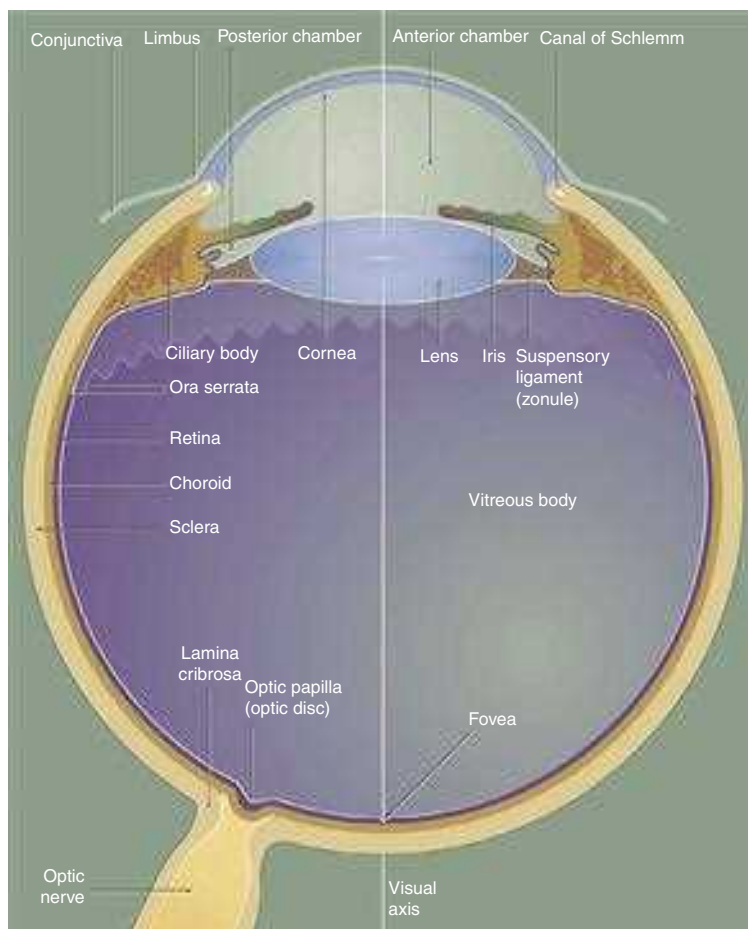

Fig. 28.1 Horizontal Section of the Eye. (From Young B. *Wheater's Functional Histology*. Elsevier: Philadelphia; 2014.)

ANATOMY OF THE EYE

An operational analogy of the eye as a camera may be useful up to a point in understanding the physical function of the structures. Once an image hits the retina and image enhancement begins, metaphors, however, must change to match our ever-changing comprehension of brain function. Using computer analogies such as microprocessing of feature detectors comes closer. Many aspects of how we see remain a mystery inside the “black box” of our brain.

Eye Chamber and Lens

Structures and function are discussed from anterior to posterior (Fig. 28.1). The first structure that light hits after it is reflected from an image is the cornea. (Technically, light first hits the tear layer, which has its own structure and rests on the corneal surface.) Corneal tissue is completely transparent. Light is refracted, or bent, to the greatest degree by the cornea because the light rays must pass through different media, which change in density, as in going from air to water.² The refraction of light can be observed by noting how a straw placed into a glass of water appears bent where it enters the water (Fig. 28.2).

Damage to the cornea from abrasions, burns, or congenital or disease-related processes can alter the spherical shape of the cornea and disturb the quality of the image that falls on the retina. In people diagnosed with keratoconus, the cornea slowly becomes steeper and more cone shaped, distorting the image and causing reduced vision.³

Radial keratotomy, a surgical procedure done in the 1980s to reduce nearsightedness by placing spoke like cuts in the cornea,

sometimes had the side effect of scarring the cornea and causing distorted vision. This surgery is no longer done, although you may see older patients who had this surgery. The newer surgeries such as laser-assisted in situ keratomileusis (LASIK) are far superior and more predictable in their reduction of refractive error (near-sightedness, farsightedness, or astigmatism) and induce virtually no scarring or distortion. In keratoconus the cornea slowly becomes steeper and more cone shaped, distorting the image and causing reduced vision.³

Iris

Behind the cornea is the iris, or colored portion, which consists of fibers that control the opening of the pupil, the dark circular opening in the center of the eye. The constriction and dilation of the pupil control the amount of light entering the eye in a similar fashion to the way the f-stop on a camera changes the size of the aperture to control the amount of light and the depth of field.⁴ Under bright light conditions the opening constricts, and under dim light conditions it dilates, allowing light in to stimulate the photoreceptor cells of the retina. This constriction and dilation are under autonomic nervous system (ANS) control, with both sympathetic and parasympathetic components.⁵ Under conditions of sympathetic stimulation (fight or flight), the pupils dilate, perhaps giving rise to the expression “eyes wide with fear.” Under parasympathetic stimulation, the pupils constrict. The effect of drugs that stimulate the ANS can be observed.⁶ For example, someone who has taken heroin will have pinpoint pupils.

Fig. 28.2 Refraction: Bending of Light at Air-Water Interface. (From Khalili K. *Diagnostic Ultrasound*. Elsevier: Philadelphia; 2018.)

Exercise 28.1: Observation of Pupillary Constriction and Dilation

Observe pupillary dilation and constriction on a willing subject (or on yourself in a mirror) by flashing a penlight at her or his pupil. Observe the decreased size of the pupil. Remove the light and watch the pupil dilate. Now go in a room with low natural light, observe the pupils, then walk into a room with bright overhead lighting. How do the pupils change? What does this tell you about the importance of lighting?

Lens

Behind the iris is the lens. The lens is involved in focusing, or accommodation. It is a biconvex, circular, semirigid, crystalline structure that fine-tunes the image on the retina. In a camera, the lens is represented by the external optical lens system. The ability to change the focus on the camera is achieved by turning the lens to change the distance of the lens from the film, which effectively increases or decreases the power of the lens, allowing near or distance objects to be seen more clearly. The same effect, a change in the power of the lens, is achieved in the eye by the action of tiny ciliary muscles, which act on suspensory ligaments, thereby changing the thickness and curvature of the lens. A thicker lens with a greater curvature produces higher power and the ability to see clearly at near distances. A thinner lens and flatter curvature produces less optical power, which is what is needed to allow distant objects to be clear (Fig. 28.3). The process of lens thickening and thinning is accommodation.^{4,5}

Fig. 28.3 Accommodation. (A) Looking far away. (B) Looking up close.

Fig. 28.4 Refractive Error. (A) Image focused on retina; no refractive error. (B) A nearsighted or myopic eye. (C) A farsighted or hyperopic eye.

Ideally, the lens will bring an image into perfect focus so that it lands right on the fovea, the area of central vision. If the focused image falls in front of the retina, however, then a blurred circle will fall on the fovea (Fig. 28.4). In this case the lens is too thick, having too high an optical power. One simple remedy is to place a negative (concave) lens externally in front of the eye in glasses (or contact lenses) to reduce the power of the internal lens and allow the image to fall directly on the fovea. In presbyopia (old eyes), the flexibility of the lens fibers decreases and the lens becomes more rigid.⁷ Accommodation gets weaker until the image can no longer be focused on the retina. Normal-sighted individuals first begin to notice these changes in their early forties. When this occurs, a plus (positive) lens (or bifocals, progressive lenses, bifocal or monovision contact lenses) may be worn to aid in reading.⁴

Other solutions to the problems of aging can be implemented during the time of cataract surgery, where a bifocal implant may be inserted, or monovision implant correction performed in each eye.

The lens can be affected by the age-related process of cataract development, in which the general clarity of vision is impaired from a loss of transparency of the crystalline lens. Incoming light tends to scatter inside the eye, causing glare problems. When vision is impaired to such a degree that it affects function, the lens may be removed surgically and replaced with a silicone implant placed just posterior to the iris.

Vitreous Chamber

The space behind the lens, which is filled with a gel-like substance, is called the *vitreous chamber*. As we age, the gel tends to liquefy, and some of the remnants of embryological development that were trapped are released to float freely. This can cause the very common perception of “floaters,” the shadows cast by these particles onto the macular region. They can be disturbing but generally float out of view over time.⁵

Retina

The retina at the back of the eye is the photosensitive layer, like the film in a camera, receiving the pattern of light reflected from objects. The topography of the retina (Fig. 28.5) includes the optic disc, which is where the optic nerve exits and arteries and veins emerge and exit. This is also the blind spot because there are no photoreceptor cells on the disc. The macula is temporal to the optic disc and contains the fovea, providing central vision. The surrounding retina provides peripheral vision and defines a 180-degree half-sphere.⁵

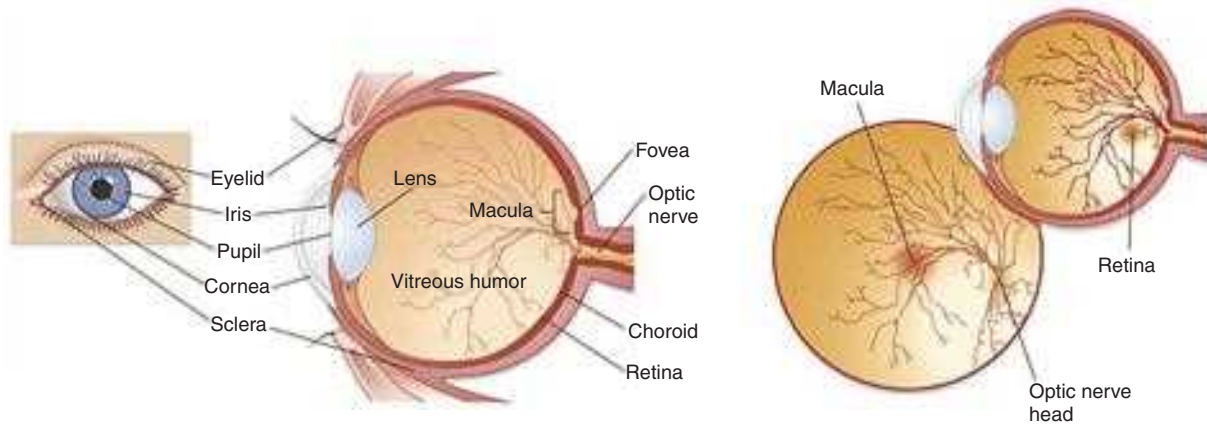

Fig. 28.5 Retinal Topography. (From Bhatia K. *Emergency Medicine*. Elsevier: Philadelphia; 2013.)

Exercise 28.2: Blind Spot

Your blind spot may be observed by doing the following: draw two dots 3 inches (7.5 cm) apart on a piece of paper. The dots can be $\frac{1}{4}$ inch (0.5 cm). Cover your left eye and look at the dot on the left. Starting at about 16 inches (40 cm), slowly bring the paper closer. Make sure you can see the two dots—one you are looking at directly and the other peripherally. At approximately 10 inches (25 cm) the dot on the right will disappear. This is your blind spot! Why can this exercise only be done monocularly (with one eye)?

Visual Pathway

The visual pathway begins with the photoreceptor cells, which begin a three-neuron chain exiting through the optic nerve. This chain consists of the rods and cones, which synapse with bipolar cells that synapse with ganglion cells (Fig. 28.6).^{5,8}

There are two types of photoreceptor cells: rods and cones. The cone or rod shape is the dendrite of the cell. Variation in shape and slight variation in pigment give each one different sensitivities. The rod cell has greater sensitivity to dim light but less sensitivity to color,

whereas the cone cell has greater sensitivity to color and high-intensity light and less to reduced light conditions. The highest concentration of cone cells is in the fovea and macula, with decreasing concentration of cone cells and increasing concentration of rod cells moving concentrically away from the macula. The high degree of low-light sensitivity can be most appreciated in survival mode conditions such as being lost in the woods on a moonless night. By swinging the eyes side to side, one can maximize the image and keep the macula from interfering.

The phenomenon responsible for the high degree of neural representation of the foveal region and that accounts for the tremendous conscious awareness of the central view is called convergence.⁵ At the periphery of the retina, the degree of convergence is great; many photoreceptor cells synapse on one ganglion cell, which accounts for poor acuity but high light sensitivity. The closer to the macula, the less the degree of convergence, until, finally, at the fovea there is no convergence. This means that one photoreceptor cell synapses with one bipolar cell and one ganglion cell.

The awareness of what is seen is directly related to the amount of convergence, which reflects the extent of neural representation. The 1:1

Fig. 28.6 The Connections Among Retinal Neurons and the Significance of Prominent Layers. The neurons shown are photoreceptors (PR), horizontal cells (H), bipolar cells (B), amacrine cells (A), and ganglion cells (G). It has been suggested that ganglion cells dominated by bipolar cell inputs represent newer circuitry. The arrow indicates the direction of light as it passes through the retina to reach the photoreceptors. (From Vanderah T. *Nolte's Essentials of the Human Brain*. Elsevier: Philadelphia; 2019.)

correspondence between photoreceptor and ganglion cell at the fovea means that there is a high degree of neural representation of the foveal image in the brain. It is even greater than the neural representation of the lips, tongue, or hands.⁹ This accounts for the primary awareness of what is in the foveal field and secondary awareness of the peripheral field. Conscious awareness of the environment is whatever is in the foveal field at the moment. But continuous information about the environment is flowing over the peripheral retina, usually subconsciously. Attention quickly shifts from foveal to nonfoveal stimulation when changes in light intensity or rapid movement are registered. This type of stimulus arouses attention immediately because it could have specific survival value. For example, a person is driving down the street and senses rapid motion off to the right. The foveae swing around immediately to identify a small red ball bouncing into the street. This information goes to the association areas, in which “small ball” is associated with “small child soon to follow.” Frontal cortical centers are aroused, and a decision is made to initiate motor areas to take the foot off the accelerator and put it onto the brake, while simultaneously moving the wheel away from the ball and scanning for the object of concern—that is, the child.

Exercise 28.3: Peripheral Central Awareness

We have a unique ability to change our awareness by consciously shifting attention from our foveal or central awareness to our peripheral awareness. For example, as you read these words, become aware of the background surrounding the paper or screen; note colors, forms, and shapes; and continue to expand your awareness to include your clothes, the floor, walls, and ceiling if possible. You are consciously stimulating your primitive, phylogenetically older visual system. The ability to do this has considerable therapeutic value because a typical pattern of visual stress is associated with foveal concentration to the exclusion of peripheral information. The ability to expand the peripheral awareness at will is a skill that can help you to relax while you drive, can improve reading skills, and can be used in visual training techniques.

The moment light hits the retina, the photographic film model must be abandoned exchanged for the image processing or computerized image enhancement model. The primary visual pathway at the retinal level is a three-neuron chain. From back to front the first neuron is the photoreceptor cell, rods, or cones. They synapse with a bipolar cell, which in turn synapses with a ganglion cell. The axon of the ganglion cell exits by means of the optic nerve. Image enhancement occurs at the two junctions of the three-nerve-cell pathway. Lateral cells at the neural junctions have an inhibitory action on the primary three-neuron pathway, and through the inhibition of an impulse the image is modulated. For example, at the first junction between photoreceptor cell and bipolar cell, there are horizontal cells. These cells enhance the contrast between light and dark by inhibiting the firing of bipolar cells at the edge of an image. This makes the edge of the image appear darker than the central area, which increases the contrast and thereby increases attention-getting value. After all, it is by perceiving edges that we are able to maneuver around objects. In a similar manner, amacrine cells act at the second neural junction between bipolar and ganglion cells to enhance movement detection.¹⁰

This image enhancement process continues throughout the visual pathway. The process has been likened to the way in which a computer enhances a distorted picture of outer space received from a satellite. The first image may be unclear and fuzzy; by adjusting the settings to improve clarity the brain ultimately is able to obtain a clear perceived image. The image goes through a series of processing stations in the inner workings of the computer—much in the same way that mapping software on your phone may initially give you an image of a grid, then

the area and finally the streets and roads that you need to take. The computer-generated, enhanced image shown on the screen is like the end product in the brain: the perceived image.

The visual pathway continues through the brain (Fig. 28.7). The ganglion cell axons exit the eyeball by means of the optic nerve, carrying the complete retinal picture in coded electrochemical patterns. From there the patterns project to different sites within the central nervous system (Fig. 28.8). Projections to the pretectum are important in pupillary reflexes; projections to the pretectal nuclei, the accessory optic nuclei, and the superior colliculus are all involved in eye movement functions.⁵ The largest bundle, called the *optic tract*, projects to the lateral geniculate body in the hypothalamus, where additional image enhancement and processing occurs. The next group of axons continues to the primary visual cortex and from there to visual association areas.

At what point does the retinal image become a perception, and with what part of the brain does one see? Current theory regarding visual perception is the result of Nobel prize-winning research by Hubel and Wiesel in the 1960s called the *receptive field theory*.¹¹ This theory states that different neurons are feature detectors, defining objects in terms of movement, direction, orientation, color, depth, and acuity. Research in 1990 by Hubel and Livingstone¹² was able to locate a segregation of function at the level of the lateral geniculate body. They identified two types of cells, one type being larger and faster magno cells, which are apparently phylogenetically older and color-blind but that have a high-contrast sensitivity and are able to detect differences in contrast of 1% to 2%. They also have low spatial resolution (low acuity). They seem to operate globally and are responsible for perception of movement, depth perception from motion, perspective, parallax, stereopsis, shading, contour, and interocular rivalry. Through linking properties (objects having common movement or depth) emerges figure-ground perception. Much of this perception occurs in the middle temporal lobe.

The other type of cell, called the *parvo cell*, is smaller, slower, and color sensitive and has a smaller receptive field. These cells are less global and are primarily responsible for high-resolution form perception. Higher-level visual association occurs in the temporal-occipital region, where learning to identify objects by their appearance occurs. It appears that these two types of cells are functionally and structurally related to the two visual systems represented in retinal topography—the foveal (central) and peripheral visual systems.

Eye Movement System

The eye movement system consists of six pairs of eye muscles: the medial recti, lateral recti, superior and inferior recti, and superior and inferior obliques (see Fig. 28.8). Together they are controlled by cranial nerves III (oculomotor), IV (trochlear), and VI (abducens). The eye movement system has both reflex and voluntary components. Reflexive movements are coordinated through vestibular interconnections at a midbrain level. The vestibulo-ocular reflex (VOR) functions primarily to keep the image stabilized on the retina. Through connections between pairs of eye muscles and the semicircular canals, movement is analyzed as being either external movement of an object or movement of the head or body. From this information the VOR is able to direct the appropriate head or eye movement.⁵

Two types of eye movements are the result. Smooth, coordinated eye movements are called *pursuits*, and rapid localizations are called *saccades*. Voluntary control of both these motions indicates cortical control. Pursuits are used for continuously following moving targets, and they are stimulated by a foveal image. Saccades are stimulated by images from the peripheral system, where a detection of motion or change in light intensity results in a rapid saccadic eye movement to

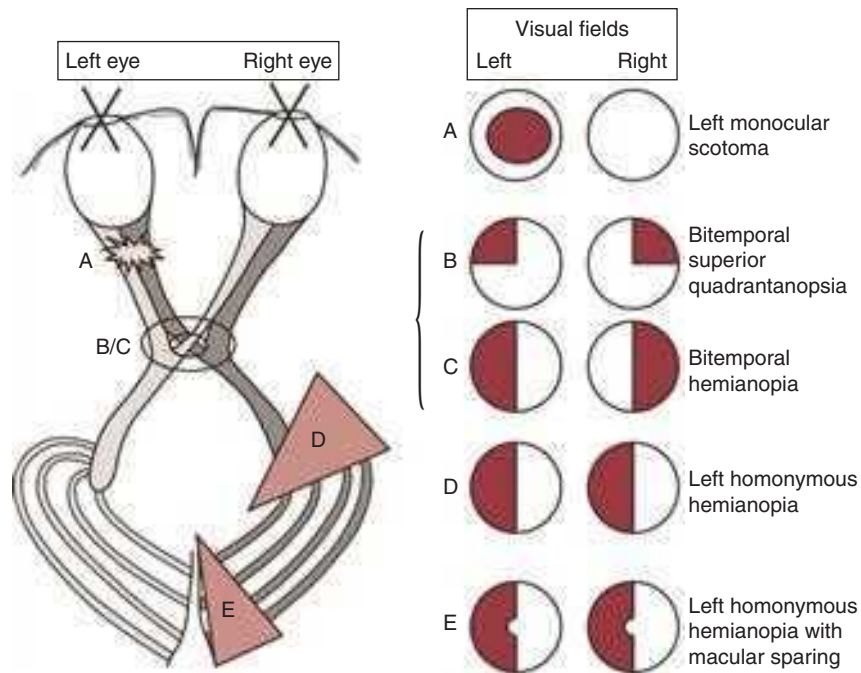

Fig. 28.7 Visual Field Disturbances at Various Points Along the Optic Pathway. **(A)** Lesions in the optic nerve could result in an ipsilateral scotoma (partial loss of vision or blind spot). **(B)** Lesions in the optic chiasm from below when small (small ring) can cause superior bitemporal quadrantanopsia (outer upper quadrant loss of vision) and **(C)** when large (larger ring) can result in bitemporal hemianopia (loss of vision in the outer half of both the right and left visual field). **(D)** Optic tract or lateral geniculate lesion can cause a contralateral homonymous hemianopia (blindness in the opposite half of both visual fields). **(E)** Lesion in the occipital lobe lesion can cause contralateral homonymous hemianopia (blindness in the corresponding half of each visual field) but with macular sparing. (From Kaufman DM. *Kaufman's Clinical Neurology for Psychiatrists*. Elsevier; 2017)

bring the object into the foveal field. Either difficulties in the eye movement system or altered functioning of the vestibular system can affect the coordinated, efficient functioning of eye movement skills.

A third type of eye movement is specifically related to eye aiming ability. This is the coordinated movement of both eyes inward toward the nose, as in crossing the eyes, or outward along the midline, as when

looking away in the distance. The inward movement is called *convergence*, and the outward movement is called *divergence*. The most important result of efficient vergence abilities is depth perception, or stereopsis. Small errors in aiming can dramatically affect stereopsis. Problems such as double vision, wandering eyes, and strabismus are discussed in greater depth in a later section.

Exercise 28.4: Pursuits, Saccades, Convergence

Pursuits. Take a pencil or pen and look at the pointed end. Follow a moving target such as a pencil point as you move it across your field of gaze, while keeping your head still. Continue to move it in different directions, vertically, horizontally, diagonally, and circularly, to stimulate all pairs of eye muscles. For a more challenging demonstration, find a fly and follow its flight path around the room. If you lose sight of it, note that the detection of the movement of the fly will signal your eye movement directly toward it.

Saccades. Hold two pencils about head width apart. Shift your eyes from pencil to pencil without moving your head. Note that your awareness is of the two pencils, not of the background between them. In general, perception occurs the moment the eyes are still, rather than while moving during saccades. For a more challenging exercise, move the pencil you are not looking at, then shift quickly to it; move the other pencil while looking at the one you just moved. In other words, you will pick up the location of the other pencil peripherally and direct your eyes to the foveal region. The size and degree of blur of the peripheral image will tell the brain where the image is and how far to move the eyes. This ability again is a result of the function of neural convergence, which is related to neural representation.

Convergence. Hold a pencil at arm's length along your midline. Slowly bring the pencil closer in toward you along your midline. Feel your eyes moving in (crossing). Try to bring the pencil to your nose, keeping the pencil visually single. (It is okay if you cannot.) Move the pencil away now, and your eyes are diverging.

FUNCTIONAL VISUAL SKILLS

Refractive Error

Before discussing binocular coordination and the individual visual skills, it is important to describe refractive errors and how they can affect binocular coordination. Three common types of refractive errors are myopia or nearsightedness, hyperopia or farsightedness, and astigmatism.^{5,10}

The myopic eye is too long, or the cornea is too steep, so the focused image falls in front of the retina. It is easily corrected with a negative or minus lens, which optically moves the image back onto the retina.

The hyperopic eye is too short, or the cornea is too flat, such that the focused image falls behind the retina. A positive or plus lens optically moves the image onto the retina. A young hyperopic person will be able to use accommodation to bring the image focus back onto the retina, but because accommodation is finite, this can cause reading difficulties earlier than normal or can affect binocular coordination at near distances.

An eye will have astigmatism if it is not perfectly spherical. An aspherical eye will cause the image to be distorted, where part of the focused image will be in front of the retina and part on or in back. A person with astigmatism may see vertical lines clearly and horizontal lines as blurry, depending on the specific aspherical shape. A cylindrical type of lens is used to correct astigmatism. This lens corrects the distortion of the image so that it is placed right on the retina.

The following are examples of ways you may see different refractive errors documented in a chart and what it means functionally:

−5.50 DS (diopter sphere): myopia

+4.00 DS: hyperopia

+1.50 c[−] − 1.50 × 180: astigmatism (Note: × stands for the axis of the cylinder correction.)

When significant refractive errors are uncorrected, they can reduce vision. Uncorrected refractive error also can interfere with binocular coordination. The symptoms are described in greater detail in the next section.

Binocular coordination is the end result of the efficient functioning of the visual skills (Box 28.1). The individual visual skills include accommodation, eye alignment or vergence, eye movements with normal vestibular coordination, stereopsis (depth perception), and peripheral and central coordination. During normal activities, all the skills are inseparable.

Accommodation

Accommodation is the ability to bring near objects into clear focus automatically and without strain. As demonstrated in Exercise 28.4, relaxation of accommodation allows distant objects to come into

focus. The primary action is that of the ciliary muscles acting on the lens, and the primary system of control is the ANS, with sympathetic and parasympathetic components.⁵

Both accommodation and pupil size changes are reflexes that work in concert: as accommodation relaxes the pupil dilates and as accommodation increases the pupil constricts.⁴ As a person focuses on a near object, the lenses thicken, allowing the near object to come into focus. At the same time the pupils constrict to increase depth of focus (just as in a camera). As a person looks into the distance, the lens gets flatter, relaxing accommodation, and the pupil dilates, decreasing the depth of field.

Accommodative ability is age dependent. A young child can focus on small objects just a few inches in front of the eyes. At about the age of 9 years, the accommodative ability slowly begins to decrease. By the mid-40s, the reserve focusing power diminishes to the point that near objects begin to blur. At this stage, reading material is pushed farther away until the arms are not long enough, and then reading glasses are needed. This is called *presbyopia* (old eyes) and, as stated earlier in this chapter, is caused by a loss of elasticity of the lens of the eye as part of aging.

Problems in accommodation may contribute to myopia, hyperopia, and presbyopia. Symptoms include blurriness at either near or far distance, depending on the age and the problem.

Accommodation is important mainly for up-close activities: reading, hygiene, dressing (specifically, closing fasteners), use of tools, typing, tabletop activities, and games.

Exercise 28.5: Accommodation

Accommodation cannot be directly observed, but it can be implied indirectly through observation of pupillary constriction while doing an accommodative task. Cover one eye. Hold a finger in front at about 10 inches (25 cm). Focus on the finger, making sure that the fingerprint is clear. Shift focus to a distant object. Continue shifting far to near and near to far while a partner observes the pupil. The partner should be able to observe pupillary constriction with near focus and dilation with far focus.

Vergence

Vergence includes convergence and divergence. It is the ability to smoothly and automatically bring the eyes together along the midline to singly observe objects that are near (convergence) or conversely to move the eyes outward for single vision of distant objects (divergence). Specific brain centers control convergence and divergence.

With regard to reflexes, vergence is associated with accommodation: convergence with accommodation, and divergence with relaxation of accommodation. The function of this reflex is to allow objects to be both single and clear, at either near or far positions. Vergence has both automatic and voluntary components. Most of the time it is not necessary to think about moving the eyes inward while looking at a close object; yet if asked to cross the eyes, most people can do this at will.

Problems can occur in vergence ability when the eye movement system is out of sync with accommodation or from damage to cranial nerves III, IV, or VI. Problems can be slight, in which there is merely a tendency for the eyes to converge in or out too far, or the eyes can be grossly out of convergence. Tendencies to underconverge or overconverge are called *phorias* and are not visible except by special testing in which they are elicited. An individual may be asymptomatic, but symptoms may occur under conditions of increased stress or fatigue, such as excessive reading or working at a computer terminal, or from drug side effects (prescription and recreational).

Some phorias may worsen to the extent that binocularity breaks down, at which point the individual becomes strabismic. There are two

BOX 28.1 Binocular Coordination

- Corrected refractive error
- Accommodation
- Eye alignment
- Stereopsis
- Central and peripheral coordination
- Efficient eye movement skills

main types of strabismus: esotropia and exotropia. An esotropia is an inward turning of the eye, and an exotropia is an outward turning. A third, less common type of strabismus is hypertropia, in which one eye aims upward relative to the other eye. Strabismus and dysfunctional phorias are discussed in greater detail in the next section.

Vergence ability is needed for singular binocular vision; thus it is basic to all activities. At near positions the patient may have difficulty finding objects; eye-hand coordination may be decreased, affecting self-care and hygiene tasks; and reading may be difficult. Distance tasks that may be affected include driving, sports, movies, communication, and, frequently, ambulation. Individuals with impaired vergence ability may also have difficulty focusing and may have decreased or no depth perception. Interpreting space can be quite difficult and confusing. If decreased vergence is a result of traumatic head injury or stroke, it may contribute to the patient's confusion, and he or she may not be able to identify or communicate the problem.

Exercise 28.6: Vergence

Hold a pencil in front of you at eye level at about 12 inches (30 cm). Look at the pencil. Look away into the distance. Looking at the pencil is convergence, and looking into the distance is divergence. As you converge and diverge slowly back and forth, note any changes you may feel: changes in how relaxed you feel, how focused or spaced out you feel, feelings of dreaminess, or nothing at all. Observe a partner's eyes as he or she shifts back and forth as well.

Pursuits and Saccades

Eye movement skills consist of pursuits and saccades. Pursuits are the smooth, coordinated movements of all eye muscles together, allowing accurate tracking of objects through space. Perception is continuous during pursuit movements. Saccades are rapid shifts of the eyes from object to object, allowing quick localization of movements observed in the periphery. The systems involved in eye movement skills are the oculomotor system with the VOR, in conjunction with coordination of the central and peripheral visual systems. The peripheral visual system is finely tuned for detecting changes in light levels and small movements.

Problems in pursuits or saccades can be the result of a dysfunction of any individual muscles, the VOR, or areas of the brain controlling pursuits or saccades.^{13–15} Because the VOR helps stabilize the image on the retina and to differentiate image movement from eye movement, simple tracking can be more difficult. In addition, visual field loss, either central or peripheral, can dramatically affect localization ability. People with blind half- or quarter-fields can be observed to do searching eye movements rather than directly jumping to the object.

Activities affected include searching for objects; visually directed movement for fine motor tasks, gross movement, and ambulation tasks; eye-hand coordination; self-care; driving; and reading.

Memory also may be affected by an eye movement dysfunction. Research by Adler-Grinberg and Stark¹⁶ and Noton and Stark¹⁷ examined patterns of eye movements as subjects looked at a picture. Distinct eye movement patterns, called scan paths, became apparent. When the subject was asked to recall the picture, the same eye movement pattern was elicited as when the subject originally saw the picture. It would appear that a type of oculomotor praxis is involved in recall. Applying this idea to the clinical setting, if a patient has inaccurate eye movement with poor pursuits or excessive saccades, then perhaps the stored memory is less efficiently stored and consequently more difficult to reconstruct from memory. In addition, if a patient has a type of brain damage with generalized dyspraxia, the eye movement system could quite likely be affected and might be involved in the patient's perceptual dysfunction. Frequently, the treating occupational

or physical therapist are the first to note a patient's dyspraxia, in which case a recommendation for a comprehensive eye exam is warranted.

Another more recent example of the relationship between eye movements and memory is the use of eye movement desensitization and reprocessing (EMDR) therapy to help individuals with posttraumatic stress disorder reintegrate traumatic experiences.¹⁸ This technique is still being evaluated, but a systematic review by Wilson and colleagues¹⁹ indicated good potential in the treatment of posttraumatic stress disorder. Although the exact mechanism is at this time unknown, the prevailing hypothesis is that the lateral eye movements elicit an orienting response, scanning the environment for further danger, and that this is an investigatory reflex associated with a relaxed physical state.²⁰

SYMPTOMS OF VISUAL DYSFUNCTION

History

The identification of a visual problem begins with case history. It is important to get some idea of the patient's prior visual status or any history of eye injury, surgery, or diseases. Information can be elicited by direct questioning of the patient or family members or by clinical observation. Sample questions include the following:

- Are you having difficulty with seeing or with your eyes?
- Do you wear glasses? Contact lenses? For distance, near, bifocals, or monovision (one eye near, other distance)?
- Does your correction (glasses, contact lenses) work as well now as before the (stroke, accident, etc.)?
- Have you noticed any blurriness? Near or far?
- Do you ever see double? See two? See overlapping or shadow images?
- Do you ever find that when you reach for an object that you knock it over or your hand misses?
- Do letters jump around on the page after reading for a while?
- Are you experiencing any eyestrain or headaches? Where and when?
- Do you ever lose your place when reading?
- Are portions of a page or any objects missing?
- Do people or things suddenly appear from one side that you did not see approaching?
- Do you have difficulty concentrating on tasks?

Clinical observations of the patient performing various activities are a valuable source of problem identification. This situation varies considerably from the physician's observations in the more contrived environment of the examination room. Therapists in general are in an ideal position to observe patients in a variety of functional tasks that require near vision, far vision, spatial estimations, depth judgments, and oculomotor tasks. This situation varies considerably from the physician's observations in the more contrived environment of the examination room. In addition, the therapist's initial observations can be used in documenting difficulties within the therapy realm that may be amenable to visual remediation in terms that can be applied to reimbursement of therapy.

Clinical observations include the following:

- Head turn or tilt during near tasks, or postural adjustments to task
- Avoidance of near tasks
- One eye appears to go in, out, up, or down
- Vision shifts from eye to eye as indicated by head tilting
- Seems to look past observer
- Closes or covers one eye
- Squints
- Eyes appear red, puffy, or irritated or have a discharge (Notify nurses or physician of these observations.)
- Rubs eyes a lot
- Has difficulty maintaining eye contact (Be aware of cultural factors.)
- Spaces out, drifts off, daydreams

- During activity, neglects one side of body or space
- During movement, bumps into walls or objects (either walking or in a wheelchair)
- Appears to misjudge distance
- Underreaches or overreaches for objects
- Has difficulty finding things

Near Point Blur

Blurred vision up close is not a symptom that by itself is indicative of a problem in any one area. It could indicate farsightedness (hyperopia), astigmatism, or reduced accommodative ability (insufficiency). The patient may move objects or the head farther or closer, may complain of eyestrain or headaches, may squint, or may even avoid near activities as much as possible. The therapist might observe excessive blinking, and the patient may complain of glasses not working well.

Distance Blur

Distance blur could also have a number of different causes, including nearsightedness (myopia), a pathological problem (such as beginning cataracts or macular degeneration), or accommodative spasm. Most people have some experience with accommodative spasm. After spending long periods of time either studying or reading a novel and then glancing up at the wall across the room, it may be blurry and then clear up slowly. For some individuals, this spasm eventually develops into nearsightedness if the reading habits continue for a long time.

Patients with distance blur may make forward head movements and frequently squint in an attempt to see. They may not respond or orient quickly to auditory or visual stimuli beyond a certain radius. The therapist may also note excessive blinking and a withdrawn attitude because the patient cannot see well enough to interact with the environment.

Visual hygiene can be recommended to assist in the development of good visual habits. This should include attention to good lighting and posture, taking frequent breaks, and monitoring the state of clarity of an environmental cue such as a clock across the room.

Phoria and Strabismus

The next area of eye alignment problems can be divided into two types of problems: phoria and strabismus. A *phoria* can be defined as a natural positioning of the eyes in which there is a tendency to aim in front of or behind the point of focus. It may or may not be associated with symptoms. Fusion is intact, and depth perception may also be intact to some degree.

Everyone has a phoria, just as everyone has a posture. It may be within normal range, or, just as someone may have scoliosis, a high phoria may cause problems. The following phorias may cause problems:

- Esophoria: The eyes are postured in front of the point of focus.
- Exophoria: The eyes are postured in back of the point of focus.

Phoria is measured in units of prism diopters, which indicate the size of the prism needed to measure the eye position in or out from the straight-ahead position.⁴

Phorias tend to produce subtle symptoms. These include having difficulty concentrating, frontal or temporal headaches, sleepiness after reading, and stinging of the eyes after reading.

A strabismus, or tropia, is a visible turn of one eye, which may be constant, intermittent, or alternating between one eye and the other. The person may have double vision, or if the strabismus is long term, the person may suppress or “turn off” the vision in the wandering eye. Suppression is a neurological function that is an adaptation to the confusing situation of double images. In the developing brain the individual must choose (unconsciously) which eye is dominant, and the image is confirmed by motor and tactile inputs as being the

BOX 28.2 Types of Strabismus

Esotropia: One eye turns in.

Exotropia: One eye turns out.

Hypertropia: One eye turns up relative to the other eye.

Intermittent: The person is strabismic at times and phoric (fusing) at times.

Fatigue or stress may bring out the strabismic state.

Alternating: The person switches from using the right eye to using the left eye. The person also switches the suppressing eye. If using the right eye, the person suppresses the left, and while using the left eye, the person suppresses the right; otherwise the person would see double.

Constant strabismus: One eye is always in or out (up or down), always the same eye.

Comitant and noncomitant strabismus: The amount of eye turn is the same regardless of whether the person is looking up, down, right, left, or straight ahead. People who have had the condition for a long time usually have comitant strabismus. People with new or acquired strabismus (i.e., from stroke or head injury) usually have noncomitant strabismus, in which the amount of eye turn changes depending on the direction in which the eyes are looking.

“real” image. The other fovea’s image is then neurologically suppressed. The peripheral vision in the suppressing eye is still normal, and the eye still contributes to other aspects of vision such as orientation and locomotion.

The essential concept in understanding the difference between phoria and strabismus is that in strabismus fusion and depth perception are not present. Definitions of different types of strabismus are presented in Box 28.2. It is not a conclusive list; many other types and permutations are beyond the scope of this discussion. The intent here is to expose the therapist to different terms that may be used by the physician in diagnosing the type of strabismus.

In strabismus, one eye appears to go in, out, up, or down, and there is frequently an obvious inability to judge distances, especially if the strabismus is of recent onset (acquired). The patient may underreach or overreach for objects, cover or close one eye, complain of double vision, or exhibit a head tilt or turn during specific activities. He or she may appear to favor one eye, have difficulty reading, appear spaced out, or avoid near activities. In addition, especially if the patient sees double but is unable or unwilling to talk about it, she or he may be confused or disoriented.

Certain postures may facilitate fusion for some patients. The eye doctor will be able to determine which head position may be best. Frequently, many patients will automatically move around to the best position. At other times, however, head position will be used to avoid using one eye. Head and body position therefore are important aspects to consider.

Many convergence problems are amenable to vision therapy,^{21–23} but some are not.²⁴ Whether a particular problem can be helped by vision therapy can be determined by an eye doctor, who can prescribe specific exercises.

Oculomotor Dysfunction

Oculomotor dysfunction is a very common sequela of neurological deficits, with an incidence as high as 90%, according to Ciufredda and colleagues.^{25,26} Commonly the smooth pursuit system will be affected, such that the smooth movement is interrupted by a series of fixation stops and the movements appear jerky. Damage anywhere along the visual motor pathway may cause a variety of eye movement disorders. This includes injury to the pontine and mesencephalic reticular formation, oculomotor nucleus in the brain stem, caudate nucleus and substantia nigra, cerebellum, and vestibular nuclei.²⁵

Patients with oculomotor disorders frequently also experience dizziness, nausea, and balance difficulties. Many times an eye movement will elicit dizziness and disorientation. It is thought that these symptoms are in part caused by a loss of integration of information coming from the two aspects of the visual system that process central vision (parvocellular pathway) and peripheral vision (magnocellular pathway).

As mentioned previously, detection of peripheral targets serves to direct an eye movement with a specific velocity and direction to bring the foveae in line for purposes of identification. Therapy for facilitating rehabilitation of eye movement disorders should be directed at using peripheral awareness with slow controlled eye movement toward the target. Once these movements are tolerated, head movement can be added, then slowly body movement.^{27,28}

While doing any sort of tracking activity, the patient is encouraged to maintain peripheral awareness. This technique will help the patient keep her or his place. The oculomotor system is guided by the peripheral location of an object.

Visual Field Defects—Hemianopsia and Quadrantanopsia

Visual field loss may indicate damage that is prechiasmatic, at the optic chiasm, postchiasmatic, in the visual radiations of the thalamus, or in the visual cortex. The resultant visual field loss is characteristic (even diagnostic) in each case. The visual field loss pattern will generally reflect the location of the lesion. It could be bitemporal (outer half of each field), half-field loss (hemianopsia) with or without macular involvement, or quarter-field loss (see Fig. 28.7). Some symptoms of field loss are an inability to read or starting to read in the middle of the page, ignoring food on one-half of the plate, and difficulty orienting to stimuli in a specific area of space.

Hemianopsia is a loss of half of the visual field in each eye, and quadrantanopsia is loss of a quarter of the visual field in each eye. *Homonymous hemianopsia* refers to the inner or nasal half and the outer or temporal half of each eye being affected. The retina itself is intact, but a neurological lesion has interrupted the ability of the visual cortex to receive recognition of the image. Vision processing may be occurring at lower centers, such as the lateral geniculate body, but if signals are not being received by the cortex, then they are not recognized as “seen.” In 1979, Zihl and von Cramon²⁹ published their findings that damaged visual fields could be trained by use of a light stimulus presented repeatedly at the border of the visual field defect. Balliet and co-workers³⁰ (when attempting to repeat the experiment, adding controls for oculomotor fixations) proposed that subjects were actually learning to make small compensatory eye movements rather than experiencing true improvements in the visual fields. In the 1980s and 1990s, a group of German researchers developed a computer-based field training system for researching the question of visual field

Fig. 28.9 Visual Field Defect (Inferior Temporal) as Measured on Humphrey Visual Field Tester.

training. They found in their research that visual fields did expand on average by 5 degrees, with functional improvements noted by more than 80% of their patients (Fig. 28.9).^{31–35} A company called NovaVision introduced the computer-based visual field restitution training program in the United States with good results (Appendix 28.A). This author has also noted documentable and functional improvements in visual fields, even when trained with less sophisticated methods.

Compensation training may also be required to allow the patient to resume activities such as reading. Compensation techniques include use of margin markers and reading with a card with a slit in it (typoscope) to isolate one line or a couple of lines at a time. Holding reading material vertically also can help. For those who do their reading using a computer, there are apps that can color code each line of a text to assist in maintaining visual attention. Changing font size or type can also help.

SUMMARY OF DISORDERS OF VISION

Table 28.1 summarizes primary visual deficits. Once a therapist or other specialist has eliminated the possibility of primary visual deficits, the clinician must assess whether the identified problem is resulting from central associative processing that is causing visual-perceptual dysfunction.

TABLE 28.1 Primary Visual Deficits Associated With Central Lesions, Functional Symptoms, Management, and Treatment

Visual Deficit	Functional Deficit	Management	Treatment
Decreased visual acuity (distance or near)	Decreased acuity for distance or near tasks (reading)	Provide best lens correction for distance and near vision	May not be correctable May be appropriate for low vision
Inconsistent accommodation	Inconsistent blurred near vision	Ensure appropriate lenses are worn for appropriate activities Determine whether bifocal is usable; if not, provide separate lenses for distance and near vision Enlarge target, control density, use contrast and task lighting	Accommodation training may be appropriate

Continued

TABLE 28.1 Primary Visual Deficits Associated With Central Lesions, Functional Symptoms, Management, and Treatment—cont'd

Visual Deficit	Functional Deficit	Management	Treatment
Cortical blindness	Marked decrease in visual acuity Severe blurring uncorrectable by lenses	Evaluated by vision specialist to determine areas and quality of residual vision Present targets of appropriate size and contrast in best area of visual field	Use headlamp to improve visual localization (i.e., functional use of residual vision) Multisensory input
Visual field deficits include homonymous hemianopsia, quadrantanopsia, scotoma, visual field constrictions	Blindness or decreased sensitivity in affected area of visual field	Be aware of normal field position in all meridians of gaze Ask patient to outline working area before beginning task Partial press-on Fresnel prism to facilitate compensation	Scanning training to facilitate compensation Training in use of prism NovaVision VF training
Pupillary reactions	Slow or absent pupillary responses	Sunglasses to control excessive brightness	
Loss of vertical gaze (external ophthalmoplegia)	Inability to move eyes up or down	Raise target or working area to foveal level Teach patient head movement to compensate	Prism glasses to allow objects below to be seen as directly in front
Conjugate gaze deviation	Inability to move or difficulty in moving eyes from fixed gaze position		
Lack of convergence	Diplopia or blurred vision for near tasks Decreased depth perception for near tasks	Convergence exercises prescribed by vision specialist	
Oculomotor nerve lesion (strabismus)	Intermittent or consistent diplopia in some or all meridians of gaze Loss of depth perception	Fresnel prism to fuse image in select cases Occlude deviant eye	Oculomotor and binocular exercises with prism use prescribed by vision specialist
Pathological (motor) nystagmus	Movement or blur of image during reading, near activities, decreased activities	Enlarge print or target to decrease blur Contact lens provides feedback, reduces movement, and increases acuity	Rigid gas-permeable contact lens prescribed by vision specialist
Poor fixations, saccades, or pursuits	Erratic scanning Unsteady fixation	Decrease density of material Isolate targets during evaluation and treatment Sensory integration activities Scanning training Use of kinesthetic and tactile systems to lead visual system (eye movements)	Oculomotor exercises prescribed by vision specialist

EYE DISEASES

Areas addressed in this section are common ocular and systemic diseases of the pediatric and geriatric populations, an introduction to low vision, and recommendations for adaptations of the treatment plan. If reduced vision (low vision) is a result of eye disease, the patient may be assisted by magnification aids. Also, the therapy treatment program may need to be altered to accommodate any special visual needs of the patient (lighting, working distance, inclusion of magnifiers, use of filters, and contrast-enhancing devices).

Pediatric Conditions

Retinopathy of Prematurity

The incidence of retinopathy of prematurity is increasing because of the improved survival of premature infants as a result of improved ventilation.³⁶ Immature retinal vessels are sensitive to high oxygen tension. The effect on the vessels is vasoconstriction, eventually leading to obliteration of the vessels. This creates a state of ischemia, which stimulates the growth of new blood vessels. These small, fragile vessels bleed easily, leading to fibrosis and traction on the retina. As a result of the traction, the macula gets stretched, interfering with the function of central vision.

The temporal vessels are most affected because they develop last. The degree of damage may be mild or severe, depending on the amount of prematurity.⁷

Retinoblastoma

Retinoblastoma is the most common malignant tumor in children.¹ The current incidence is 1 in 20,000 live births, a rate that has been increasing over the past 30 years, apparently owing to inheritance of a mutated gene.

The young child may have a strabismus resulting from impaired vision in the eye with the tumor. As the tumor grows, the pupil may appear milky white. If not detected early, the tumor will lead to loss of the eye; and if the tumor invades the brain, death will occur. Clearly, early detection is critical.

Mental Retardation

There are a higher number of visual problems in the mentally retarded populations.¹ These individuals have a higher incidence of refractive error (myopia, hyperopia, and astigmatism), strabismus, nystagmus, and optic atrophy than children with normal intelligence.

Cerebral Palsy

Therapists who work with children with cerebral palsy may have noticed a high incidence of vision problems. Many studies confirm these observations. A study by Scheinman³⁷ examining the incidence of visual problems in children with cerebral palsy and normal intelligence found the following incidences: strabismus in 69%, high phorias in 4%, accommodative dysfunction in 30%, and refractive errors in 63%.

Hydrocephalus

Various studies have found that the most common visual problem in children with hydrocephalus is strabismus, with an incidence of 30% to 55%. The strabismus may develop either from the hydrocephalus itself or from the shunting procedure.

Fetal Alcohol Syndrome

Children affected by fetal alcohol syndrome have several characteristic features and visual problems. They have a higher incidence of strabismus, myopia, astigmatism, and ptosis. These children frequently have some degree of mental retardation as well and are of small stature.

Conditions of Aging

Cataracts

The most common malady affecting vision in elderly persons is cataracts. General clarity of vision is impaired from a loss of transparency of the crystalline lens of the eye.

In the senile cataract, the lens slowly loses its ability to prevent oxidation from occurring, and liquefaction of the outer layers begins. The normally soluble proteins adhere together, causing light scatter.³ Vision slowly declines as opacification and light scatter increase, until the lens must be removed.

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is the leading cause of blindness in the Western world and is the most important retinal disease of the aged (affecting 28% of the 75- to 85-year-old age group).⁷

Loss of central vision results from fluid that leaks up from the deeper layers of the retina, pushing the retina up and detaching it from the nourishing layer. New vessel growth and hemorrhage and atrophy further destroy central vision. There is much research going on regarding treatments for AMD. The most promising at this time is the use of bevacizumab (Avastin) or ranibizumab (Lucentis), which is injected into the eye; then the eye is treated with a laser. The drug targets the neovascular network of blood vessels, and the laser treatment obliterates the vessel network, sparing the photoreceptors.³⁸

This condition has significant implications for independent functioning. Mobility tends to be less impaired because the peripheral visual system is still intact. All activities involving fine detail, such as reading, computer use, sewing, and cooking, are affected. Safety also can be affected.

Arteriosclerosis

In arteriosclerosis, vision may or may not be affected. There is a hardening of the retinal arteries, which may eventually lead to ischemia, with the areas of retina deprived of sufficient oxygen eventually dying.

Hypertension

Hypertension is usually accompanied by arteriosclerosis. There may be retinal bleeding and edema, which can affect central vision if the macula is involved.

Diabetes

Diabetes can affect the lens. In the diabetic “sugar cataract,” sorbitol collects within the lens, causing an osmotic gradient of fluid into the lens, which leads to disruption of the lens matrix and loss of transparency. As the fluid increases and decreases within the lens, the patient’s vision also can fluctuate, depending directly on the sugar level. This makes prescribing glasses during this time quite difficult. The cataract will need to be removed if vision is worse than 20/40.

The retinal effects include microvascular damage and the development of microaneurysms. Central vision may be reduced as a result of retinal ischemia. The ischemia leads to new blood vessel growth (neovascularization). These new vessels are weak, frequently leaking and causing hemorrhage. The hemorrhage leads to fibrosis, which puts traction on the retina, pulling it off and leading to retinal detachment and blindness. Laser treatment of the bleeding retinal vessels will stop the bleeding but also burns photoreceptors, creating blind spots. This result is far preferable to total retinal detachment and blindness.

Glaucoma

Glaucoma occurs in 7.2% of the 75- to 85-year-old age group.⁷ It is generally caused by an increase in the intraocular pressure. This pressure interferes with the inflow and outflow of blood and nutrients at the optic disc. As it progresses, glaucoma can cause tunnel vision and, in some, complete blindness. Because of the type of vision loss affecting the periphery, mobility and safety are significantly impaired. Try walking around holding a paper towel tube to your eye while closing the other eye, and see what happens to your ability to maneuver around obstacles or find your destination.

A less common type of glaucoma is low-tension glaucoma, in which the internal eye pressures are essentially normal. The mechanism is not understood, and the disease is treated with eye drops to lower internal pressure, just like the other types of glaucoma.

In one type of glaucoma, called *open-angle glaucoma*, the outflow of aqueous humor is reduced, leading to increased intraocular pressure. There are no overt symptoms. In another type, closed-angle glaucoma, the outflow is blocked by the iris. Symptoms are a painful, red eye, which may be confused with conjunctivitis.

Corticosteroids used to treat many conditions in the elderly for long periods of time may have side effects in some people, such as glaucoma and cataracts.

Eye Muscle Dysfunctions

Eye muscle dysfunctions causing double vision may result from several disease conditions including thyroid disease (Graves disease and others), multiple sclerosis, myasthenia gravis, and tumors. The underlying condition must be diagnosed and treated.

Visual Field Loss

Visual field loss may be either central (macular degeneration, glaucoma, or retinal disease) or peripheral field loss from glaucoma, retinal damage, or stroke at any point in the visual pathway. This is potentially the most functionally disabling form of visual impairment (see Fig. 28.7).

Environmental Implications for Functional Performance Lighting

Lighting conditions are important and vary depending on the nature of the condition. The person with presbyopia requires more light because the aging pupil gets smaller. The smaller pupil has the advantage of increasing the depth of focus, allowing the presbyope to see clearly over a wider range, but it has the disadvantage of eliminating more

light from the eye. Thus providing a good source of direct lighting, especially on fine print, is helpful. Lighting for the low-vision patient is critical. Direct sources of low-glare light such as halogen seem to work best. This is, however, quite individual, in that some patients actually see better in lower-light conditions.

Glare

People who have problems with glare, such as those developing cataracts or other disease conditions, can be helped by several approaches. Incandescent or halogen lighting is preferred over fluorescent lighting. The use of a visor or wide-brimmed hat will reduce one source of glare, improving overall comfort. For some individuals who have trouble reading because of the glare coming off the white page, a black matte piece of cardboard with a horizontal slit in it (called a *typoscope*) can be used to reduce the surrounding glare and enhance reading. Various colored filters can be quite helpful; frequently a light amber color reduces glare while enhancing contrast. Other colors such as light green, plum, or yellow can be tried. The improvement noted is quite individual to the patient. Special photochromic, tinted antiglare lenses developed by Corning are available by prescription through the ophthalmologist or optometrist. An antireflective coating may also help. This is another area where adjusting the brightness on the computer screen or using an add-on to reduce glare can be quite helpful.

Low-Vision Aids

Many types of low-vision optical and nonoptical aids are available, usually by prescription by a low-vision specialist. Patients with damage to their central vision as in AMD or diabetic maculopathy and who still have some reduced central vision may be able to use various types of magnification aids.

Hand and stand magnifiers. One type is a stand magnifier, which is placed directly on the reading material and is useful for patients who have a tremor. Hand magnifiers are held in the hand and moved away from the page to the focal point of the lens, which may range from half an inch to 5 inches, depending on the amount of magnification. Some are equipped with their own internal illumination; others are equipped with halogen lighting systems.

Telescopes. Telescopes can be used for a number of different functions. To increase independence in orientation and mobility, a “spotting” telescope is held in the hand and looked through to identify approaching bus numbers, public transportation signs, stop or walk signs, or aisle signs. There are also telescopes that are worn on the head for hands-free usage or for viewing the computer screen. A telescope system can be attached to the patient’s glasses frames. Special driving telescopes called *bioptic telescopes* are ground into the patient’s glasses, angled in such a way as to allow viewing straight ahead and, with a tip of the head, viewing through the scope to read a sign. The best corrected visual acuity needs to be at least 20/100, but regulations vary from state to state. The greatest disadvantages of scopes are the small visual field and the additional training required to learn how to effectively use them.

The implantable telescope is an exciting new option available for patients with end-stage AMD. After careful evaluation the patient may be considered to be a good candidate for implantation. The tiny telescope is surgically implanted near the lens inside the eye. It has the benefits of having magnification immediately available for use for distance targets and reading; however, the peripheral vision in the implanted eye is significantly reduced. Similar to someone adjusting to monovision contact lenses, the patient with the implanted telescope learns to look through either the *telescopic eye or the other eye* (Fig. 28.10).^{39–41}

Microscopes. Microscopes are high-powered reading glasses in which the magnification is created in the glasses rather than in the

Fig. 28.10 Eye With Implanted 3× Telescope.

hand. The disadvantage of these is the close viewing distance, depending on the power. The viewing distance could be as close as 1.5 inches, creating discomfort in reading for many.

Electronic digital magnifiers. The best systems for severely impaired patients are the electronic digital magnifiers such as closed-circuit television (CCTV). The CCTV system consists of a camera housed in a device that can be directed at the object to be viewed. The scope of magnification is significantly larger, ranging from low power to 50×. Additional benefits include no distortion, like that caused by optical magnifiers, and a field of view limited only by the size of the screen. The housing for the camera may be in a stand, with a screen above, or portable, held in the hand or strapped to the head. Examples are the Merlin, Jordy, and MaxPort by Enhanced Vision Systems, and the portable digital magnifiers such as the Compact mini by Optelec.⁴²

Nonoptical aids. Nonoptical aids include large-print materials, available at many libraries, typoscopes, mentioned earlier, and reading stands. Talking books are available for those for whom reading is an important hobby. New developments include text-to-speech synthesizers, screen reader software, computers that display large print or have large print/braille keyboards, large-print computers, and image intensifiers. Other simple aids are available such as lined paper with dark slightly raised lines, felt-tipped pens for writing, talking clocks, needle threaders, and many cooking and measuring aids. The website www.visionaware.org offers resources on this topic.

Visual field expansion. For patients with field losses, specially designed prism or mirror systems may be used. These frequently require training to get used to and are not useful for everyone. Compensation training also can be helpful, particularly in the use of eccentric viewing, or learning how to use a portion of the intact field by aiming the eye off center. The use of margin markers or reading slits and holding the book sideways so that the print is vertical are other helpful techniques.

Current research. Areas of research have included mounting a video camera onto spectacles and then transducing the visual information to electrodes implanted in visual cortical centers. In one study this system allowed a low-vision patient to see the large E (20/400) and detect large contours.^{44,45} Recently a company called Second Sight Medical Products developed the Argus II, which includes implantation of a 60-electrode grid on the retina, which is used in conjunction with a video camera mounted on eyeglasses. A wireless microprocessor with battery pack is worn on the waist. Altogether the system enables rudimentary perception of shapes and forms, allowing improved mobility in patients whose vision has been impaired by retinal diseases such as retinitis pigmentosa.⁴⁶

VISUAL SCREENING

Primary visual dysfunction must be differentiated from a visual-perceptual disorder so that appropriate treatment can be addressed for each problem. Gianutsos and colleagues⁴⁷ found that more than half the individuals in their study admitted for general head injury rehabilitation who were eligible for cognitive services had visual sensory impairments sufficient to warrant further evaluation. Visual screening can identify the need for referral for a complete eye examination. The results of the examination become part of the differential diagnosis regarding a perceptual dysfunction. **Box 28.3** presents key elements in vision screening.

This section describes vision screening tools and adaptations for various populations. The following principles should be kept in mind:

- **Acuities:** Acuities should always be tested first because decreased acuities will bias other tests except for ocular motilities and the peripheral field test.
- **Positioning:** The body and head should be in good alignment or straightened with positioning devices, with the head in midline.
- **Glasses:** If the patient normally wears glasses, for either distance or near vision, the patient should be wearing glasses for tests for which spectacle correction is required. When in doubt, try it both ways, record the best response, and note whether glasses were worn.

Observations During Testing

The patient's response during the test can provide important qualitative information about his or her visual system, including postural changes (head forward or back, body forward or back, head tilts or rotation [turning to either side]), squinting, closing one eye, excessive blinking, rubbing, signs of strain or fatigue, and holding the breath. Patients should be encouraged to relax, breathe normally, and not squint.

Distance Acuities

Equipment

Needed to measure distance acuity are a distance acuity chart, an occluder, a 20-foot measure, and the patient's corrective lenses if worn for distance.

Setup

A distance chart is taped on a well-lighted wall at the patient's eye level, and a distance of 20 feet is measured from the chart.

Procedure

One of the patient's eyes is covered, and the patient is asked to read the smallest letters that he or she can see. Exposing one letter or line at a time can help if tracking or attention is a problem. The examiner should encourage the patient to guess and instruct the patient not to squint. The number of letters that were missed on the smallest line that the patient is able to see is noted. The procedure is repeated by covering the patient's other eye, and then both eyes are tested unoccluded.

BOX 28.3 Key Elements in Vision Screening

1. Distance and near visual acuities
2. Oculomotilities (pursuits, saccades, and near point of convergence)
3. Measure of eye alignment to detect strabismus or high phoria
4. Measure of depth perception (stereopsis)
5. Measure of the visual fields

Record

The smallest line the patient was able to read is recorded. If the patient missed any letters on that line, then the number of letters missed is subtracted. For example, if the patient read four letters correctly on the 20/30 line but missed the other two, then it is recorded as 20/30-2. The scores for the patient's right eye, left eye, and both eyes together are recorded.

If the patient is unable to see the top line at 20 feet, the patient is asked to move forward until able to identify the top letters. Then the distance and letter size (top line) are recorded. For example, if the patient had to move up to 4 feet to see the top line, then 4/100 is recorded. To calculate 20-foot equivalence, an equation is used where x equals the size of the letter (e.g., $4/100 = 20/x$); thus $4x = 2000$ and $2000/4 = 500$. The patient's vision is 20/500 (**Box 28.4**).

For patients whose attention is poor, the testing distance may need to be as close as 2 feet. Other testing stimuli can be used for children, such as the Broken Wheel Test* or the Lighthouse cards. Acuity in low-functioning patients or infants can be evaluated by use of preferential looking methods. Targets are usually high-contrast grating patterns of decreasing size. One such type is the Teller cards.

Implications

A patient who fails this test may require glasses or a change in the current prescription.

Near Acuities

Equipment

A near-point test card, an occluder, and the patient's corrective lenses, if normally worn for near vision, are needed.

Procedure

The procedure is the same as for distance acuity. The standard test distance is usually 16 inches (40 cm).

Record

The smallest line read is recorded.

Interpretation and Referral

A test result of 20/20 is considered normal, 20/40 is required for reading newspaper-sized print, and 20/100 is needed for large print. Referral to an optometrist or ophthalmologist should be made if vision is 20/40 or worse or if a difference of two lines exists between the two eyes. Neurological damage can affect the accommodative system. Sometimes it corrects itself spontaneously, but not always.

Visual retraining of the focusing system may be appropriate, depending on the patient's age. This can be determined by an optometrist familiar with vision therapy.

BOX 28.4 Interpretation or Referral

20/20 is considered normal.

20/40 is required by the Department of Motor Vehicles (DMV) in most states for full-time day and night driver's license, although requirements vary in different states.

20/80 is required by the DMV for daytime driver's license.

20/40 or worse indicates referral to an eye doctor.

20/200 corrected (with spectacle prescription) is considered legally blind.

A difference of two lines or more between the two eyes indicates referral to an eye doctor (e.g., right eye is 20/20, left eye is 20/30).

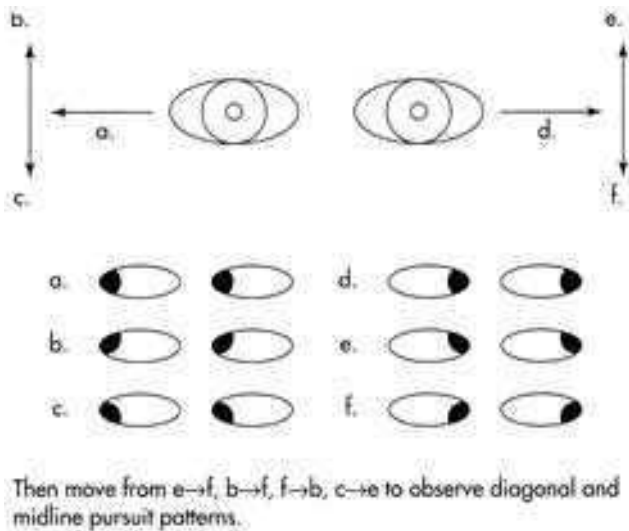

Fig. 28.11 Pursuit Patterns.

Pursuits

Equipment

Any target that holds the patient's attention can be used, such as a pencil or small toy.

Setup

The patient is seated facing the screener.

Procedure

One pencil is held 16 to 20 inches in front of the patient, and the patient is asked to look directly at one part, such as the eraser, and to keep the head still, holding it if necessary. The pencil is moved around in the pattern shown in Fig. 28.11, which is designed to incorporate all directions of gaze. The examiner should observe for smooth following, noticing and recording jerks and jumps, where they occur, or if the eyes stop at a certain point. If one or both eyes stop tracking, the patient is encouraged to look at the pencil. If the patient is unable to do this, then the movement pattern is repeated with each eye separately and where the movement stops is recorded. Patients who have had a cerebrovascular accident (CVA) or head injury should be tested first monocularly (each eye separately).

Record

Results are rated as follows:

- Poor = Difficulty following target with any accuracy, jerky or jumpy, nystagmoid movements, incomplete range of motion
- Fair = Generally able to follow target but goes off target occasionally (1 to 2 times), with slight jerkiness
- Good = Eye movements smooth with no jerkiness

If one eye stops tracking at a certain point or if the patient reports double vision (diplopia) in certain directions, the examiner should record which eye or in which direction the problem is noticed (e.g., the right eye does not pass midline when moving from left to right, or diplopia is reported on upward right gaze). This specific information can be helpful to the ophthalmologist or optometrist.

Saccades

Equipment

Tracking pencils can be used, although a few saccadic tests are available. One is the King Devick Saccadic Test; the other is the

Fig. 28.12 Developmental Eye Movement Test.

Developmental Eye Movement Test. These both require form perception (number reading) and may be difficult, depending on the patient's cognitive level.

Setup

The patient is seated facing the screener.

Procedure

A pencil is held in each hand about 17 to 20 inches from the patient, and the patient is told that he or she is going to be asked to look at one pencil while the other pencil is moved but not to look at it until told to do so. The patient is to move the eyes only, keeping the head still. While the patient looks at the first pencil, the other pencil is moved as the screener says "shift" or "look at this pencil." The screener then moves the other pencil, says "shift," then moves the pencil, says "shift," then moves the pencil, and so on, until a pattern of movement can be discerned.

This call-shift is repeated about 10 times, moving into different fields of gaze. The screener continues until the patient is seen to respond. The screener observes for overshooting or undershooting the target, for the ability to isolate the eyes from the head (hold head still), for controlled eye movement, and for ability to wait until the verbal command to look. It is important to observe for the patient's ability to shift to all fields of gaze. A lower level of testing would be to ask the patient to move the eyes from one target to the other as quickly as possible (Fig. 28.12).

Record

Results are rated as follows:

- Poor = Inability to control eyes with verbal command, consistent undershooting or overshooting, inability to isolate eyes from head
- Fair = Ability to maintain eyes on target with verbal command 50% of the time, with slight undershooting or overshooting, and ability to isolate eyes from head with verbal reminders
- Good = Ability to follow verbal commands 90% of the time, with no undershooting or overshooting, and complete eye from head isolation

Near Point of Convergence

Procedure

A pencil is introduced about 20 inches away from the patient's midline. The patient is asked whether the pencil looks single. If it is not, it is moved farther away. The patient is told that the pencil will be moved toward her or him and that it will be getting blurry but to keep

watching it as far in as possible. When the pencil appears single, it is moved toward the nose at a moderately slow rate (but not too slow). The screener should watch the patient's eyes. As long as the patient's eyes are tracking the pencil, the pencil is kept moving toward the nose. At the point where one eye moves out, both eyes move out, or the eyes simply stop tracking, the distance of the pencil to the nose is measured. If the patient is wearing bifocals, it is important to make sure the patient is looking through the reading segment.

Record

The break point is the distance at which the eyes were observed to stop tracking the pencil. If the patient was able to track the pencil all the way to the nose, then record this fact.

Interpretation and Referral

A score of poor or fair on saccades or pursuits suggests the need for training. A near point of convergence with a break point of 5 inches or more is suggestive of convergence problems, and recommendations for referral should be made.

Implications

Difficulties with smooth pursuit, accurate saccades, or convergence can all present tracking difficulties for the patient. These difficulties can cause loss of place in reading, rereading of words or lines, skipping lines, and lower comprehension and concentration. Inaccurate eye movements also may affect visual memory.

An eye movement problem may be the result of direct damage to the eye muscles themselves (Fig. 28.13) or to the nerves controlling them, as in the case of a head injury. Damage to the vestibular center also may involve visual components. Neurons from cranial nerves III, IV, and VI synapse in the vestibular nuclei. Reflex control of eye movements occurs through the VOR and the optokinetic system.

Cover Tests

Purpose

There are two cover tests. The cover-uncover test is used to determine whether strabismus is present. The alternate cover test determines what type of phoria is present. The magnitude of the phoria generally determines the extent of the patient's symptoms.

Equipment

An occluder and a tracking pencil or a small, distinct target are needed.

Setup

The patient is seated facing the screener, who is also seated.

Procedure

A pencil is held approximately 16 inches in front of the patient, and the patient is asked to look directly at the target and to keep it in focus.

Near Cover Tests

Cover-uncover test. The movement of the uncovered eye is observed. The patient's right eye is covered, and the left eye is observed for movement in, out, upward, or downward. This is repeated a few times, allowing the eyes to be uncovered for about 2 seconds between trials. Then the left eye is covered to observe for movement in the right eye.

Alternate cover test. Eye movement is observed as the eye is uncovered. An occluder is held over the right eye for a few seconds while the patient looks at a near target. The occluder is moved from the right eye to the left eye while the right eye is observed for movement in, out, up, or down. After a few seconds, the occluder is moved back to the right eye, observing the left eye for movement. This is repeated back and forth several times until the screener is sure of what is seen.

Far Cover Tests

The preceding procedure is repeated with the patient looking at a distant target.

Interpretation and referral. Any visible eye movement seen during the cover-uncover test with good maintenance of fixation on the target indicates a strabismus. If there is no previous history of strabismus, referral is indicated. A large eye movement seen with the alternate cover test, along with the presence of symptoms such as eyestrain, headaches, or apparent difficulty in making spatial judgments, also indicates referral. In the clinic the therapist may notice that the patient has difficulty finding objects in a drawer, or that the patient appears cross-eyed or seems to be looking past the target. He or she may have difficulty with spatial judgments in reaching for objects or in mobility, especially with stairs or curbs.

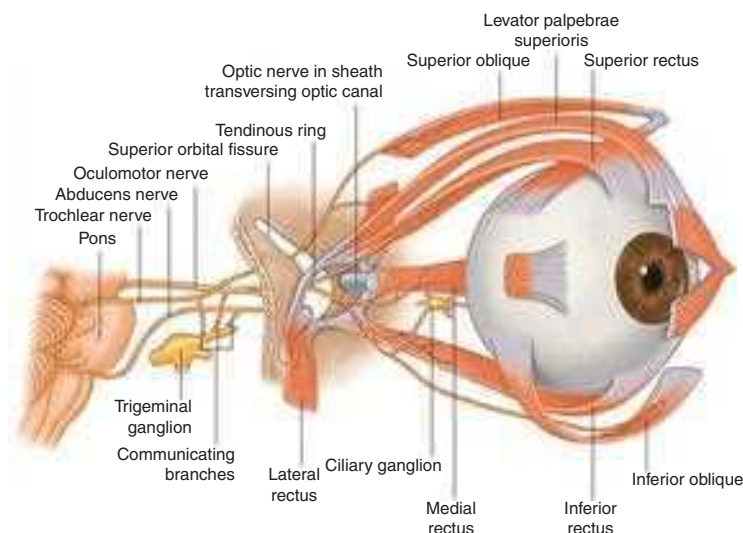

Fig. 28.13 Cranial Nerves III, IV, and VI. Oculomotor, trochlear, and abducens nerves and their innervation of the extraocular muscles. (From Tamhankar M. Liu, Volpe and Galetta's *Neuro-Ophthalmology*. Elsevier: Philadelphia; 2019.)

A visible eye movement may be part of a post-CVA patient's pre-morbid pattern. This should be determined by asking the patient or the family members before making a referral. Or the condition may be the result of neurological damage to cranial nerve III, IV, or VI from CVA, head injury, or cerebral palsy. Eye muscles are striated muscles, under voluntary control. Like other striated muscles that can be affected by neurological damage, they may recover spontaneously, they may not recover at all, or they may benefit from visual retraining. Many learning-disabled children with vestibular dysfunction have poor binocular skills. An ophthalmologist or optometrist specially trained in visual remediation can determine a patient's potential for vision therapy. Some published research has demonstrated the success of vision therapy for post-CVA patients.⁴⁸

Stereopsis (Depth Perception)

Equipment

Any test that uses either Polaroid or red-green filters can test for stereopsis ability. Examples are the Titmus stereo fly, reindeer, and butterfly.

Procedure

The patient is asked to point to or say which test object appears closer. If the patient is able to grasp for the object in space, some stereo ability is present.

Record

The patient's response should be immediate. Long delays could indicate borderline ability.

Interpretation and Referral

If the patient fails this test, a referral to an ophthalmologist or optometrist is recommended. The patient must have best-corrected acuities for this test; otherwise, the results are invalid.

Implications

A deficit in depth perception can interfere with all activities involving spatial judgments—in particular, fine motor and eye-hand type activities in which judgments of relative depth are required (e.g., threading a needle, placing toothpaste on a toothbrush, and hammering). Although ambulation itself may not be affected, ambulation involving curbs or stairs will be affected.

Vision therapy training can be helpful for patients with problems in binocular coordination. Proper diagnosis and therapy prescription are essential.

Visual Field Screening

Equipment

An occluder or eyepatch is required, and a black dowel with a white pin on the end or just a wiggling finger can be used as a peripheral target.

Setup

The patient is seated facing the examiner.

Procedure

The patient holds the occluder over the left eye. The examiner explains that he or she is going to wiggle a finger out to the side and that the patient is to say "now" when he or she first detects the movement of the wiggling finger. The patient should look at the screener's nose the entire time and ignore any arm movement. The test is begun with the examiner's hand slightly behind the patient, about 16 inches away from the patient's head. The hand is brought forward slowly while a finger is wiggled. Different sections of the visual field are randomly tested in 45-degree intervals around the visual field. The left eye is then

tested after the patient's right eye is occluded. Alternatively, if a dowel is used, it is slowly brought in from the side until the patient reports seeing the small pin at the end of the dowel.

These confrontation field tests are considered gross tests compared with a visual field perimeter test. Many patients cannot do the perimeter test because it requires a higher cognitive level. Confrontation fields will reveal a hemianopsia and a quadrantanopsia (quarter-field cut). For lower-functioning patients, the examiner can observe eye movements in the direction of the target to get a general idea of peripheral function once patients have seen it.

Record

The portion of field missing for each eye is noted.

Interpretation and Referral

If any hemianopsia or quadrantanopsia is noted, the patient is referred to an optometrist or an ophthalmologist.

Implications

A visual deficit has significant implication for the safe performance of many functional activities, including driving and mobility. Visually guided movement through space becomes impaired, as are efficient eye movements; if central field loss is present, reading and any other near activities are affected. The reader is referred to the discussion of assessment of unilateral inattention for differentiation between neglect and hemianopsia.

REFERRAL CONSIDERATIONS

The final outcome of the visual screening is referral to an optometrist or ophthalmologist, ideally to someone with an orientation toward visual rehabilitation. It is important not to make diagnostic statements but rather to indicate whether the patient passed or failed the vision screening. By law, only optometrists or ophthalmologists can diagnose visual conditions.

It is not always clear when to refer a patient or to whom. Many doctors do not test all areas of visual function. In general, behavioral or developmental optometrists have a functionally oriented philosophy quite similar to occupational therapy models of functional performance.

Recommended referral guidelines are shown in [Box 28.5](#).

BOX 28.5 Referral Guidelines

1. Failure of either the distance or near acuity test (with glasses on). This could indicate an uncorrected refractive error, a disease process, or a neurological problem.
2. Failure of the oculomotility section only does not indicate referral because treatment of oculomotor dysfunction is currently within the scope of practice for rehabilitation. *Exception:* Failure of the pursuit test as a result of a reduced ocular range of motion in any direction of gaze, which indicates cranial nerve involvement.
3. Failure of the cover-uncover test indicates strabismus and is an indication for referral unless there is a history of an eye turn.
4. A large eye movement seen on the alternate cover test, along with apparent difficulties in stereopsis, such as spatial judgments, or symptoms, such as headaches, eyestrain, or difficulty with comprehension, constitutes an indication for referral.
5. Failure of the stereopsis test alone is an indication for referral if there is no history of an eye turn and if there is movement on either cover test.
6. Patients with quarter-field loss and half-field loss (hemianopsia) should be referred.

Fig. 28.14 The Visagraph (boy with goggles) measures eye movement while the subject is reading.

Rehabilitation Optometric Evaluation

Once the patient has been referred for evaluation, the eye doctor will evaluate any changes in the refractive error and the need for new correction to achieve the best possible vision. The eye alignment will be quantified, and determination will be made regarding whether there is an eye muscle paresis, which cranial nerve is involved, whether strabismus or phoria is present, and whether the eye deviation is better or worse in particular directions of gaze.

Oculomotilities will be evaluated grossly, and more specific tests may be done. One test is the Developmental Eye Movement Test (see Fig. 28.12). Another test is the Visagraph (Fig. 28.14). This instrument records eye movements while the patient is reading text. It will measure total reading rate, number of fixations and regressions per 100 words, span of recognition, and reading comprehension. The tool is excellent for in-depth evaluation and monitoring the progress of treatment over time.

Ocular health testing will include glaucoma testing, examination for cataracts, and retinal health evaluation. For visual field testing, either a screening field or a threshold visual field will be done on some type of automated perimeter such as the Humphrey Visual Field Analyzer or the Octopus. Threshold testing is done to determine the extent and depth of a defect, and it can help determine whether there is potential for visual field retraining. In Fig. 28.9 the black portions of the visual field are areas of absolute damage. The areas of white with small dots are intact visual fields. At the border of the damage area is a gray zone, which theoretically is amenable to training.^{31–34}

The optometrist or ophthalmologist will deliver a report of the findings with recommendations for the treatment plan. Developing a professional relationship with an optometrist or ophthalmologist can be very beneficial for therapists who work in neurological rehabilitation.

Visual Intervention

Early intervention is recommended as soon as possible, when possible, to identify ways in which a vision problem may be interfering with other therapies.^{48–51} Some treatments may be applied early on, as well. For example, if the patient has an eye muscle paresis, range-of-motion exercises for the involved muscle can prevent the development of a contracture of the unopposed muscle.

In cases in which the patient has double vision, a patching regimen can be instituted. One regimen is to alternate patching the eyes daily,

allowing some time to experience diplopia, so that the eyes may attempt to make a fusion response. The stimulus to fusion is double vision. If one eye is always patched, spontaneous recovery may be slowed. Another patching regimen is binasal taping, and another is to use partially opaque materials to allow peripheral vision in the occluded eye. The patching regimen should be prescribed by an optometrist or ophthalmologist.

In some cases of double vision, a temporary plastic (Fresnel) prism can be applied to the patient's glasses to reduce or eliminate the diplopia. This may significantly enhance the patient's functioning in other therapies, particularly when spatial judgments are being made (e.g., in fine motor tasks or ambulation).

Documentation

Vision problems should be documented in functional performance terms—that is, how the vision problem affects activities of daily living. Improvement can then be monitored according to function. This will also help in reimbursement. For example, a patient with an eye muscle dysfunction will have difficulty with spatial judgments such as placing toothpaste on a toothbrush, spearing objects, reaching for a cup handle, doing pegboard tasks, and using vision for balance.

THERAPEUTIC CONSIDERATIONS

Once a referral has been made, the patient has been seen, and the examination report has been received, what else can be done? How the dysfunction affects therapy can be considered, and some visual training, prescribed by the optometrist, can be initiated.

Accommodative Dysfunction

If the patient has an accommodative dysfunction, the treatment may be the prescription of glasses for reading or tabletop tasks or possibly near-far focusing exercises,⁴ depending on the age of the patient. “Flipper bars” are special lenses that exercise the focusing system.⁵²

If the patient needs glasses for near but cannot get them for some reason, the therapist can try moving the task farther away and increasing the lighting on the task.

Eye Alignment Dysfunction

If the patient has a problem in the eye alignment system, several factors should be considered. If the patient is able to fuse some of the time but loses fusion, seeing double when stressed or tired, then the most difficult tasks should be attempted when the patient is least fatigued. Otherwise, if the patient has constant double vision or the patient is seeing double at the time the therapist is working with her or him, patching may be prescribed by the ophthalmologist or optometrist. This will reduce the patient's confusion and increase attention to the task. For patients with acquired double vision, however, it is important to provide time without a patch so that the eyes will attempt to regain fusion. Wearing the patch constantly will discourage any attempts by the brain to overcome the double vision.

Visual Dysfunction and Balance Disorders

It is important to recognize the close interplay between the visual and the balance systems, including vestibular, proprioceptive, and tactile receptors, in maintaining balance. Altered visual input can affect perception of space, even with something as simple as getting a new pair of glasses. The nonneurologically impaired individual will eventually adapt and reset the coordination of information. Neurologically impaired patients can have much greater difficulty in resetting the coordination of sensory information from multiple systems, resulting in a feeling of sensory overload or being overwhelmed. Conversely, damage

to areas of the brain that process vestibular or somatosensory information can create altered maps of space as well as affect the balance as the individual attempts to interact with the environment.

Therapy may be directed at both areas: improving balance by enhancing balance and proprioceptive mechanisms and/or by enhancing visual input through visual rehabilitation techniques. There has been recent research involving the strategic placement of small weights on the torso, which has had immediate and sometimes dramatic effects on balance.^{53,54} Interestingly, these types of inputs to the torso can also affect visual processing (observations by BalanceWear vest developer Cindy Gibson-Horn, RPT, and Laurie Chaikin, OD, OTR/L, FCOVD). It is hypothesized that the mechanism for this change may be mediated by cerebellar-visual pathways.⁵⁵

VISUAL-PERCEPTUAL DYSFUNCTION

This discussion of visual-perceptual disorders is divided into a number of categories: unilateral spatial inattention; cortical blindness, defective color perception, and visual agnosia; visual-spatial disorders; visual-constructive disorders; and visual analysis and synthesis disorders. Cortical blindness is a disorder of primary visual input; however, because its variations may influence perceptual interpretation, it is discussed here. All other disorders listed involve direct problems with the interpretation of visual stimuli. Although each of these terms represents symptoms recognized by many authors, the reader is reminded that there are no clear boundaries between one deficit and another or one system and another. Apraxia and body image disorders are not discussed under separate categories because they are not considered “visual”-perceptual disorders per se, although their presence may influence and complicate an already dysfunctional visual-perceptual system.

Problems of Unilateral Spatial Inattention

Identification of Clinical Problems

General category. In its purest form, unilateral spatial inattention is defined as a condition in which an individual with normal sensory and motor systems fails to orient toward, respond to, or report stimuli on the side contralateral to the cerebral lesion. Although this condition is not often seen in its pure form, inattention has been documented in persons who demonstrate no accompanying visual field defect (homonymous hemianopsia) or limb sensory or motor loss.⁵⁶ In most cases, however, unilateral spatial inattention is not seen alone but is associated with (although not caused by) accompanying sensory and motor defects such as homonymous hemianopsia and decreased tactile, proprioceptive, and stereognostic perception along with paresis or paralysis of the upper limb.⁵⁷

It is easy to become confused by the numerous terms used in the literature, for example, *unilateral spatial agnosia*, *unilateral visual neglect*, *fixed hemianopsia*, *hemi-inattention*, and *hemi-imperception*. All terms describe the same deficit. Unilateral spatial inattention is used in this chapter because (1) in severe cases the syndrome most likely involves tactile and auditory as well as visual unawareness (i.e., a total spatial unawareness) and (2) the syndrome results in an involuntary lack of attention to stimuli contralateral to the lesion, whereas the term *neglect* implies a voluntary choice not to respond.

Unilateral spatial inattention occurs most frequently in individuals with a diagnosis of stroke (CVA), traumatic brain injury, or tumor. Most authors agree that unilateral spatial inattention occurs more often with right hemisphere than with left hemisphere lesions.^{58–62} This frequency supports theories that the right hemisphere is dominant for visual-spatial organization. It is clear, however, that inattention may be present in individuals with left hemisphere lesions, but that the

inattention tends to resolve more quickly.⁶³ The clinician should remember that, although the chances are statistically lower, the patient with right hemiplegia may exhibit inattention to right stimuli.

Unilateral spatial inattention has been associated with lesions in both cortical and subcortical structures. It is most commonly seen in inferior parietal lobe lesions⁶¹ but has also been observed in lesions in the inferior frontal cortex, the dorsolateral frontal lobe, the superior temporal gyrus, and the cingulate gyrus⁶⁴ and with basal ganglia, thalamic,⁶⁵ and putaminal hemorrhage.^{66–68} Finally, lesions in the brain stem reticular formation have induced inattention in cats⁶⁷ and monkeys.⁶⁵

Although a number of theories have been postulated regarding the mechanism underlying unilateral spatial inattention, no mechanism has been validly documented in human subjects. The one fact that is clear from all theoretical postulates is that inattention is a hemispheric deficit. LeDoux and Smylie⁶⁹ demonstrated this point effectively in an interesting case study of a right-sided lesion. During full visual exposure (bilateral hemispheric) of visual-perceptual slides, the affected individual made visual-spatial errors in left space. However, when the same slides were directed only to the right visual field (left hemisphere), performance improved substantially. It is as if the deficient hemisphere fails to receive or orient toward incoming information while the intact receiving hemisphere remains oblivious and goes about its own business. Treatment for inattention is problematic mainly because the mechanisms underlying unilateral spatial inattention are not clearly understood.

Theories on mechanisms underlying unilateral spatial inattention have attempted to explain it as an integrative associative defect as opposed to simply a problem of decreased sensory input. Theories include a unilateral attentional hypothesis, suggesting that inattention results from a disruption in the orienting response—that is, the corticostriatal hemisphere is underaroused during bilateral input, and therefore stimuli presented to that hemisphere are neglected.^{61,64} Another theory is the oculomotor imbalance hypothesis, which suggests that individuals with inattention have a visual-spatial disorder worsened by oculomotor imbalance. The hypothesis suggests that the lesion disconnects the frontal eye fields in the damaged hemisphere from their sensory afferent nerves, resulting in an oculomotor imbalance deviating the gaze toward the lesion. This imbalance can be compensated for only momentarily by a voluntary effort to gaze toward the opposite hemispace (i.e., neglected space).⁷⁰

Unilateral spatial inattention with homonymous hemianopsia.

Inattention occurs more commonly with visual field defects and is generally better when the macular projections are not involved. Individuals with pure hemianopsia are aware of their visual loss and spontaneously learn to compensate by moving their eyes (foveae) toward the lost visual field to expand their visual space and thereby gather information right and left of midline. On visual examination, other individuals may demonstrate no visual field defect on unilateral stimulation; however, during bilateral stimulation they extinguish the target contralateral to the lesion. Other persons may perceive both targets simultaneously, yet when engaged in activity they may not respond to visual stimuli in one-half of the visual space contralateral to the lesion. These individuals are unaware of their inattention. Careful observation of their activity reveals few eye movements into the neglected space. The fovea does not appear to be directed to gather information in this space.

Unilateral visual, auditory, and tactile inattention. Inattention has been described as a multimodal sensory associative disorder involving not only visual but also tactile and auditory unawareness. Clinicians are well aware of the patient with left inattention who continues to direct the head and eyes toward the right throughout an entire

conversation, although the therapist is standing on the patient's left side. When one conceptualizes unilateral spatial inattention as a dynamic decrease or loss of sensory information within one-half of the sensory-perceptual sphere (irrespective of hypothetical mechanism), the peculiar behaviors exhibited by these patients are more easily understood as a loss of input creating a loss of response.

Unilateral spatial inattention and body image. Body image is often disturbed in individuals with inattention. The defect in these persons is unusual because it affects only that half of the body that is contralateral to the lesion—for example, the left side of the body in right-sided lesions. There appears to be a lack of spatial orientation and attention for one-half of intrapersonal space. Those with severe inattention fail to recognize that their affected extremities are their own and function as though they are absent. They may fail to dress one-half of the body or attempt to navigate through a door oblivious to the fact that the affected arm may be caught on the doorknob or door frame. In severe cases, individuals may deny their hemiparesis, or they may deny that the extremity belongs to them. This phenomenon is called *anosognosia*.

Behavioral manifestations of unilateral spatial inattention. Persons with inattention orient all their activities toward their “attended” space. The head, eyes, and trunk are rotated toward the side of the lesion for much of the time, including during gait. Careful observation of eye movements (scanning saccades) during activities indicates that all or almost all scanning occurs on only one side of the midline within the attended space; the individual never spontaneously brings the eyes or head past midline into contralateral “unattended” space. Oculomotor examination always shows full extraocular movements and no apraxia for eye movements, thereby highlighting the difference between function and exam.

Inattention, like all other perceptual disorders, may occur on a scale from mild to severe. Mild cases of inattention may go unrecognized unless behavior is carefully observed. Scanning is symmetrical, except during tasks requiring increasingly complex perceptual and cognitive demands. Leicester and colleagues⁷¹ believe that inattention occurs mainly when the individual has a general perceptual problem with the material—that is, some other problem with processing the task. This performance difficulty or stress brings on the additional inattention behavior; for example, neglect in matching auditory letter samples is more common in those with aphasia than in those with right hemisphere involvement without aphasia.

Independence in activities of daily living is often impossible because of inattention to both the intrapersonal and the extrapersonal environment. The individual may eat only half the food on their plate, dress only halfway, shave or apply makeup to only half of their face, brush their teeth only halfway, read only half a page, fill out only half a form, fail to locate items in the store if they are located in an unattended space, collide with obstacles or miss doorways on the unattended side, and, when walking or driving a wheelchair, veer toward the attended space rather than navigating in a straight line.

Assessment

Because most tests used to measure cognitive, language, perceptual, and motor skills require symmetrical visual, auditory, and tactile awareness, it is most important to rule out inattention early in the evaluation process of any patient with a central lesion. The two most common methods used to distinguish inattention from primary sensory deficits are double simultaneous stimulation testing and assessment of optokinetic nystagmus reflexes. Double simultaneous stimuli should be applied in three modalities: auditory, tactile, and visual. Initially, stimuli should be presented to the abnormal side. If primary sensation is impaired (e.g., a visual field loss), this evaluation cannot

proceed because double simultaneous stimulation testing is invalid in that modality. If responsiveness is normal, however, bilateral simultaneous stimuli should be applied. Unilateral stimuli should be interspersed with bilateral stimuli to ensure valid responses. Lack of awareness (extinction) of stimuli contralateral to the lesion during bilateral stimulation should be noted. Patients with extinction in only one sensory system often do not demonstrate inattention behaviors; however, those with extinction in more than one modality (e.g., tactile and visual) often demonstrate these behaviors. If critical diagnosis of inattention is necessary, the patient may be referred for optokinetic nystagmus testing.

One of the best evaluation tools is a keen sense of observation. The position of the patient's head, eyes, and trunk should be observed at rest and during activity. Persistent deviation toward the lesion may indicate unilateral inattention. The individual should be asked to track a visual target from space ipsilateral to the lesion into contralateral space and maintain fixation there for 5 seconds. The therapist may ask the patient to quickly fixate on visual targets both right and left of midline on command. Problems with searching for targets in contralateral space should be noted. Some erratic oculomotor searching is normal when making saccades into a hemianoptic field, because saccades are centrally preprogrammed by peripheral input. Slow saccades or failure to search should be considered indicative of inattention.

Asymmetries in performance should be noted during spatial tasks. Specific spatial tasks have been designed for detection of inattention, including the following:

- Cancellation tasks. The patient may be given a sheet of paper with horizontal lines of numbers or letters and asked to cross out all the 8s or As.
- Crossing-out tasks. In this standardized test, the patient is asked to cross out diagonal lines drawn at random on an unlined sheet of paper.
- Line-bisection tasks. The patient is asked to bisect a 4- to 8-inch line on a piece of paper placed at the midline.
- Drawing and copying tasks. The patient may be asked to draw or copy a house, clock, or flower or to fill in the numbers of a clock drawn by the examiner. For copying tasks, it is important that the copy be placed in the patient's attended space.

Patients with inattention demonstrate one or more of the following behaviors: failing to cancel figures or cross out lines in the unattended space; bisecting the line unequally, placing their mark toward the side of the midline ipsilateral to their lesion; placing their drawing toward the edge of the paper ipsilateral to their lesion rather than in the middle of the page; drawing only the right or left half of the house, flower, or clock; crowding all the numbers of the clock into the right or left half of the clock; or completing numbers on only one-half of the clock (Fig. 28.15), and demonstrating differences in reaction time.⁷² When interpreting performance, the examiner is looking specifically for asymmetries in performance. Patients with inattention often have other visual-perceptual deficits that result in faulty performance on these tasks; however, these deficits are always symmetrical—that is, evident in any space to which the individual attends.

Asymmetries in performance should be carefully observed during functional activities such as eating, filling out a form, reading, dressing, and maneuvering through the environment. The therapist may note unawareness of doorways and hallways in the unattended space; turns may be made only toward one direction. As a result, these patients lose their way in the hospital or even in the therapy clinic. This behavior should be distinguished from a topographical perceptual deficit in which the individual cannot integrate or remember spatial concepts well enough to find his or her way without getting lost. The Behavioral Inattention Test has recently been published as a standardized measure of functional inattention.⁷³

Fig. 28.15 Drawings of a clock and house by a patient with a right hemisphere parietal lobe tumor. Note the left unilateral spatial inattention in the drawings.

Finally, various studies have shown that inattention may occur during testing that requires visual processing and therefore may invalidate test results.^{58,74,75} Unresponsiveness to figures on one side of the page during visual, perceptual, cognitive, or language assessments may be subtle but must be documented to rule out the influence of inattention on raw score—that is, if the patient did not see the entire test display for an item, that test item is invalid. Responses to figures on the right half and left half of the test page should be counted. If the frequency of answers is noticeably less on one-half of the page than would normally be expected, inattention may have occurred during testing. This may be used as additional evidence of inattention; but more important, this factor should be accounted for when computing the test score. Only those test items in which the correct answer was located in the attended space should be scored—that is, only those items in which the correct answer was right of midline in a patient with left inattention should be scored.

Interventions

As previously stated, the mechanisms underlying unilateral spatial inattention are not well understood; however, recent research has uncovered a strong correlation between nonspatial aspects of attention called *tonic* and *phasic attention* and spatial aspects of neglect. Tonic attention is intrinsic arousal that fluctuates on the order of hours to minutes and contributes to sustained attention and preparation for more complex cognitive tasks. Phasic attention is a rapid change in attention in response to a sudden and brief event and is related to orienting responses and selective attention.⁷⁶ This research has postulated that nonspatial attention mechanisms affect spatial and nonspatial behavior. Some highly successful training protocols using these attentional mechanisms have been developed, and the researchers have been able to demonstrate improved responses with carryover in the environment (see Appendix 28.A). They also demonstrated that this remediation approach was more effective than just scanning strategies. A number of studies have investigated the remediation of unilateral spatial inattention. They have attempted to (1) define effective remediation techniques and (2) measure changes in trained tasks and generalization to untrained tasks—that is, determine whether inattention training in one task carries over to other unrelated tasks such as activities of daily living. Treatment techniques used in all these studies resulted in less inattention during trained tasks.^{59,77,78} An overview of these studies suggests that training may decrease inattention, although extent of change and generalization to other tasks may vary widely. Discrepancies in these results may be related to neurological variables in the

various patient samples, severity of inattention, sample size, or tasks measured. A discussion of general principles of remediation follows.

Efforts should be made to increase the patient's cognitive awareness of the inattention. The individual should be made keenly aware of what a peripheral visual field loss is and how it is affecting her or his view of the world. The person with normal visual fields but with visual extinction should be treated the same as the individual with an actual visual field loss, because the visual experience is similar. Pictures of the visual field deficit may be drawn for illustration. Actual performance examples in the environment should be pointed out to the patient to demonstrate the biased field of view.

Visual scanning should be emphasized. Initially, the patient should be made aware of how eye and eye-head movements may be used to compensate for the deficit. The individual should be trained to make progressively larger and quicker pursuits and saccades and longer fixations into the unattended space. Training may be accomplished with interesting targets held by the therapist—for example, targets secured to the tips of pencils, such as changeable letters, colored lights, or bright small objects. Pursuit or tracking movements of the target leading the eye from attended into unattended space should be stressed first, followed by saccades into the unattended space. Initially the patient may be allowed to move the head during scanning exercises; however, eye movements without head movements should be the major goal. Individuals with inattention often move the head into the unattended space while the eye remains fixed on a target in the attended space (i.e., the visual field remains the same). The patient should be taught to independently carry out a daily right-left scanning program with targets appropriately positioned by the therapist. Eventually these targets can be moved farther into the unattended space.

Increased awareness and scanning abilities should be incorporated in increasingly complex visual-perceptual and visual-motor tasks. Because inattention often increases as task complexity increases, the therapist must select and structure tasks carefully. Examples of simple yet specific scanning tasks might include surveying a room repetitively, rolling toward and touching objects right and left of midline, assembling objects from pieces strewn on a table or the floor, completing an obstacle course, or selecting letters from a page of large print.

Scanning should be stressed during functional activities, for example, dressing, shaving, or moving through the environment. The patient may be taught to constantly monitor the influence of inattention on functional performance—for example, “When something doesn't make sense, look into the unattended space and it usually will.”

Diller⁷⁹ has designed a number of specific training techniques to decrease inattention during reading and paper and pencil tasks. With a little creativity, these techniques may be applied to other activities. For example, when the patient is reading, a visual marker is placed on the extreme edge of the page in unattended space. The individual is instructed not to begin reading until he or she sees the visual marker. The marker is used to “anchor” the patient's vision. As inattention decreases, the anchor is faded. Each line may also be numbered and the numbers used to anchor scanning horizontally and vertically. To control impulsiveness, which often accompanies inattention, patients are taught to slow down or pace their performance by incorporating techniques, such as reciting the words aloud. Underlining and looping letters or words can also be used as a method to slow down impulsive scanning (Fig. 28.16). Finally, the density of stimuli is reduced; decreased density appears to decrease inattention in these tasks.

To stimulate tactile awareness in patients with tactile extinction, Anderson and Choy⁸⁰ suggest stimulating the affected arm as the individual watches. A rough cloth, vibrator, or the therapist's or patient's hand may be used. Eventually, this activity may be done before

activities that require spontaneous symmetrical scanning, such as dressing or walking through an obstacle course.

During the early phases of treatment, when inattention is still moderate to severe, the patient should be approached from the attended space during treatment for inattention or other deficits such as apraxia, balance, or speech. This ensures that the individual comprehends and views all demonstrations and treatment instructions. Subsequently, as orientation and scanning improve, activities should be moved progressively into the unattended space and the therapist should be positioned in the unattended space during treatment. In the final stages of treatment, the patient should be able to symmetrically scan, regardless of the therapist's position (i.e., the therapist should vary position).

To enhance the integration of scanning behavior during functional tasks such as gait and dressing, the patient should be reminded of scanning principles and carried through a series of scanning exercises before initiation of the activity. If inattention reappears during the activity, the therapist should stop and assist the patient in becoming reoriented before the activity is resumed. Inattention results in confusion, and confusion increases inattention. As will be pointed out repeatedly in the following pages, the therapist must control the perceptual environment continuously so that the patient is able to sequence bits of information together meaningfully to learn or relearn.

Problems of Cortical Blindness, Color Imperception, and Visual Agnosia

Identification of Clinical Problems

Cortical blindness. Cortical blindness is considered a primary sensory disorder as opposed to a secondary associative disorder. It is discussed here, however, because of the many variations of this lesion that may result in problems with interpretation of visual stimuli. Cortical blindness, also known as *central blindness*, is a total or almost total loss of vision resulting from bilateral cerebral destruction of the visual projection cortex (area 17). Similar destruction limited to one hemisphere results in hemianopsia.⁵⁶ The lesion may be ischemic, neoplastic, degenerative, or traumatic. The patient may perceive the defect as a "blurring" of vision or as a marked decrease in visual acuity or may be unaware of the complete nature of the disability and even deny it, blaming the problem on eyeglasses that are too weak or a room that is too dark.

Color imperception. Color perception may be impaired in the patient with brain damage. This symptom is usually associated with right hemisphere or bilateral lesions.⁸¹ This deficit is different from

color agnosia, in which there is a problem with naming colors correctly. Patients with defective color perception may see colors as "muddy" or "impure" in hue, or the color of a small target may fade into the background, decreasing the ability to differentiate it from the background.^{62,82} Total loss of color monochromatism is rare, but it can occur.

Visual agnosia. A lesion circumscribed to the visual associative areas (areas 18 and 19) results in a number of unique visual disorders that are categorized as some form of visual agnosia. Lesions are usually bilateral with combined parietooccipital, occipitotemporal, and callosal lesions. Visual agnosia is defined as a failure to recognize visual stimuli (e.g., objects, faces, letters), although visual-sensory processing, language, and general intellectual functions are preserved at sufficiently high levels.⁸³ It also has been described as perception without meaning; perception apparently occurs, but the percept seems "disconnected" from previously associated meaning. In this pure form, visual agnosia is a relatively rare syndrome, and there is controversy as to whether it is simply an extension of primary visual sensory deficits (variations of cortical blindness) or whether it should be considered as a separate neuropsychological entity.

Three types of agnosia have been recognized: visual, tactile, and auditory. Agnosia is most often modality specific; that is, the individual who cannot recognize the object visually will usually give an immediate and accurate response when touching or hearing the object in use. In visual agnosia, then, poor recognition is limited to the visual sphere.

Visual agnosia is divided into a number of types: visual object agnosia, simultanagnosia, facial agnosia, and color agnosia. These deficits may be seen in isolation or in various combinations, depending on the size and location of the lesion.

Visual object agnosia. During evaluation for the presence of visual object agnosia, the individual is presented with a number of common objects (e.g., key, comb, brush) and asked to name them. The evaluator may assume that the object is recognized if the patient (1) names, describes, or demonstrates the use of the object; or (2) selects it from among a group of objects as it is named by the examiner. If the person recognizes (describes or demonstrates) but is unable to name the object, failure is most likely a result of an anomia rather than an agnosic defect. Individuals with real visual agnosia have no concept of what the object is.⁸³

Simultanagnosia. Along the same vein are visual disorders that constrict or "narrow" the visual field during active perceptual analysis (i.e., when perceptions are tested separately, the visual field is within

normal limits). Simultanagnosia is a disorder in which the person actually perceives only one element of an object or picture at a time and is unable to absorb the whole. As the individual concentrates on the visual environment, there is an extreme reduction of visual span. The problem is functionally similar to tubular vision. The narrowing of the functional perceptual field decreases the ability to simultaneously deal with two or more stimuli. It appears as if the person has bilateral visual inattention with macular sparing, although perimetric testing reveals full visual fields. A typical example is the individual whose visual attention is focused on the tip of a cigarette held between the lips and fails to perceive a match flame offered several inches away.⁸⁴

Facial agnosia. Another special type of agnosia that has been documented is failure to recognize familiar faces. The disorder is also known as *prosopagnosia*. The individual is able to recognize a face as a face but is unable to connect the face and differences in faces with people he or she knows. This person is unable to recognize family members, friends, and hospital staff by face. One must be careful not to confuse this with generalized dementia. There may be categorical recognition problems with items involving special visual experience—for example, recognition of cars, types of trees, or emblems. Facial agnosia is usually seen in combination with a number of other deficits, including spatial disorientation, defective color perception, loss of topographical memory, constructional apraxia, and a left upper quadrant visual field loss. These other symptoms are most likely not causative but rather a result of the similar neurological location of these functions.⁸⁵

Color agnosia. Finally, the individual may have difficulty recognizing names of colors, that is, an inability to name colors that are shown or to point to the color named by the examiner.⁸⁶ This defect is considered agnostic (as opposed to a defect in color perception) because the patient is able to recognize all colors in the Ishihara Color Plates⁸⁷ and is also able to sort colors by hue. The determining factor here appears to be a problem with visual-verbal association. Color agnosia is most common in patients with left hemisphere lesions and is often accompanied by the syndrome of alexia without agraphia.⁸³

Assessment

Cortical blindness and variations of it should be thoroughly assessed by the vision specialist. Assessment for agnosia must be preceded by a thorough assessment for visual acuity problems, visual field deficits, and unilateral visual inattention because these primary visual sensory and scanning deficits are often mistaken for agnostic performance. Next, basic color perception should be measured by use of the Ishihara Color Plates⁸⁷ and color-sorting or color-matching tasks. Individuals with defective color perception will have difficulty with some visual-perceptual tasks because contextual cues related to color and shading are unavailable to them. Agnosia is a valid diagnosis only if (1) the aforementioned primary visual skills are intact and (2) language skills are intact (i.e., there should be no word-finding difficulty in spontaneous speech).

Although there are no standardized tests for agnosia, commonly used assessment methods have been included. The presence of simultanagnosia is determined by keen observation of performance that indicates perception limited to single elements within objects—for example, describing only the wheel of a bicycle or, within the environment, describing only one part of a room or an activity.

Object agnosia is tested for by placing common real objects (e.g., comb, key, penny, spoon) in front of the patient and asking the patient to name or point to the item chosen by the examiner. In pointing and naming tasks, the therapist must be sure that the patient is fixating on

the appropriate target. The response is considered normal if the object is named correctly or described or its functional use demonstrated. Abnormal responses will be confabulatory or perseverative, with the individual often giving the name of a previous or similar object. Responses may also be completely bizarre and unrelated. The examiner may also present objects at an unusual angle. Abnormal responses will show lack of recognition or rotation of the head or body to try to view the object in the “straight on” position. The diagnosis of visual object agnosia is further confirmed if the individual can identify the object by touch or by hearing it in use, both of which should be attempted with vision occluded.

Color agnosia is evaluated by having the patient name a color and point to colors named by the examiner. Facial agnosia is evaluated by presenting the individual with photographs of famous world figures, actors, politicians, and family members.⁶²

Interventions

There are no reliable studies regarding treatment of cortical blindness, color imperception, or visual agnosia. Treatment principles presented here are based on the experience of Bouska and Biddle⁷⁴ and Bouska and Kwatny.⁵⁸ If cortical blindness or simultanagnosia is suspected, the therapist must first attempt to increase the patient's knowledge of foveal versus peripheral vision, that is, where the patient is fixating. A small headlamp attached to the patient's forehead may be used under conditions of subdued lighting. The headlamp should not be used in a completely darkened room because the patient needs to use normal spatial cues from the environment. The movement of the projected light in the environment and kinesthetic input from the neck receptors augment knowledge of where the eye is fixed. To carry out this task, the patient must learn to position the eyes in midline of the head. The individual is asked to move the light (i.e., head and eyes) to locate and discriminate fairly large, bright stimuli placed on a plain background (e.g., yellow block on a brown table). As acuity and localization skills improve, stimuli and background should be made smaller and more complex (e.g., paper clip on a printed background or letters printed at different locations on a large page). The patient should be encouraged to accurately point to or manipulate targets once located with the light or to keep the light on a target as he or she slowly moves the target with one hand. Thus the kinesthetic input from the limb can augment visual localization abilities.⁷⁷ In patients with color imperception, treatment should initially involve materials and tasks with sharp color contrasts with minimal detail and should progress to less contrast (more hues) with more detail.

If the assessment has revealed a narrowing of the perceptual field, treatment should be aimed at progressively increasing the perception of large, bright, peripheral targets. For example, the patient may be asked to fixate on a centrally placed target while another bright target is brought in slowly from or uncovered in the periphery.^{88,89} The individual is encouraged to maintain fixation on the central target while remaining alert for the presence of another target somewhere in the periphery. As the patient improves, targets should be smaller, multiple, and exposed for briefer periods. Peripheral targets should always have bright surfaces that reflect light because the peripheral receptors in the retina are mainly rods (light as opposed to color receptors). Another powerful variation of this technique is to involve hand use in peripheral location of objects. For example, the patient senses the presence of a peripheral object then reaches with the hand to pinpoint location, then shifts the eyes to identify it. This can further help differentiate between central and peripheral vision.

The treatment of patients with object agnosia should progress according to the abilities that return first in spontaneous recovery from agnosia. Common real objects should be used before line drawings in

treatment. Presentations should be given “straight on,” rather than at an angle or rotated. The patient should be asked to point to objects named by the examiner before being asked to name them. Manipulation of the object with simultaneous visual input should be attempted. This may help recognition, or it may simply confuse the patient; each case is unique. In general, tactile input with or without simultaneous visual input should be encouraged as a compensation method, although it may not be helpful during treatment sessions.

Color and facial agnosia may be approached by simply drilling the individual with regard to two or three names of colors or names of faces of people important to her or him. The patient may be assisted with picking out or memorizing cues for associating names with faces.⁶²

Problems of Visual-Spatial Disorders

Identification of Clinical Problems

Individuals with brain lesions, particularly in the right posterior parietal and occipital areas, may have difficulties with tasks that require a normal concept of space.⁵⁶ Disorders of this nature have been termed *visual-spatial disorders*, *spatial disorientation*, *visual-spatial agnosia*, *spatial relations syndrome*, and numerous other names. Visual-spatial abilities are complexly interwoven within the performance of many perceptual and cognitive activities, such as dressing, building a design, reading, calculating, walking through an aisle, and playing tennis. An attempt is made here, however, to discuss spatial disorders in their purest form—that is, basic disorders—before dealing with visual-constructive disorders and disorders of analysis and synthesis. Constructional tasks require spatial planning, a type of planning that involves the building up and breaking down of objects in two and three dimensions. Constructional apraxia is viewed as a particular type of spatial-perceptual disorder and therefore is discussed separately under visual-constructive disorders and disorders of analysis and synthesis. Similarly, although perceptual skills such as figure-ground, form constancy, complex visual discrimination, and figure closure involve spatial concepts, tasks involving these skills often require the intellectual operations of synthesis and deduction. They, too, are discussed in the section dealing with analysis and synthesis.

All visual-spatial disabilities involve some problem with the apprehension of the spatial relationships between or within objects. Benton⁹⁰ has categorized them as the following disabilities:

1. Inability to localize objects in space, to estimate their size, and to judge their distance from the observer. The patient may be unable to accurately touch an object in space or indicate the position of the object (e.g., above, below, in front of, or behind). Relative localization may be impaired so that the individual may be unable to tell which object is closest. There may be difficulty determining which of two objects is larger or which line is longer. Holmes⁹¹ reported cases of gross disorder in spatial orientation revealed through walking; affected individuals, even after seeing objects correctly, ran into them. In another example, a man intending to go toward his bed would invariably set out in the wrong direction. Difficulty in estimating distances may also extend to judgments of distances of perceived sounds and lead to overly slow and cautious gait or fear of venturing into public areas.
2. Impaired memory for the location of objects or places. An example is not being able to recall the position of a target previously viewed or the arrangement of furniture in a room. Individuals with this difficulty often lose things because they have no spatial memory to rely on for recall.
3. Inability to trace a path or follow a route from one place to another. Persons without this ability, known as *topographical orientation*, have difficulty understanding and remembering relationships of

places to one another, so they may have difficulty finding their way in a space, as in locating the therapy clinic in a hospital or locating the housewares department in a store previously familiar to them. Normally functioning individuals often have mild signs of topographical disorientation. Everyone is familiar with the disoriented feeling of not knowing how to get out of a large department store or losing a sense of direction in a familiar city. Many of the topographical errors made by patients result from unilateral spatial inattention. For example, someone with left inattention may make only right turns. Topographical disorientation, however, may be seen in a person with no signs of unilateral inattention. This individual will demonstrate route-finding difficulties at certain points and will apparently randomly choose a direction.

4. Problems with reading and counting. These high-level tasks require directional control of eye movements and organized scanning abilities. Eye movements (saccades) during reading bring a new region of the text on the fovea, the part of the retina where visual acuity is the greatest and clear detail can be obtained from the stimulus. During reading, the line of print that falls on the retina may be divided into three regions: the foveal region, the parafoveal region, and the peripheral region. The foveal region subtends about 1 to 2 degrees of visual angle around the reader's fixation point, the parafoveal region subtends about 10 degrees of visual angle around the reader's fixation point, and the peripheral region includes everything on the page beyond the parafoveal region. Parafoveal and peripheral vision contribute spatial information that is used to guide the reader's eye.⁹² Visual-spatial disorders appear to interfere to varying degrees with the spatial schema of a page of type or numbers and the dynamic organizational scanning that must take place to gather information appropriately. Patients with unilateral spatial inattention will miss words or numbers located on one-half of the page. Other spatial problems unrelated to unilateral inattention include skipping individual words within a line or part of a line, skipping lines, repeating lines, “blocking” or having the inability to change direction of fixation, particularly at the end of a line, and generally losing the place on the total page. Performance usually deteriorates progressively as the individual continues to read. Eventually such persons cannot make sense of what they read, or if counting they complain of being lost or confused. This type of reading or counting disorder has nothing to do with recognition or interpretation of letters or numbers or their spatial configuration; rather, it represents a problem with dynamic sequential visual-spatial exploration during cognitive processing.

Other visual-spatial problems may include loss of depth perception, problems with body schema, and defective judgment of line orientation. There may also be difficulties with discrimination of right and left. Although unilateral spatial inattention is considered a visual-spatial disorder by many, it has been discussed separately in this chapter to increase clarity. Problems with judging line orientation (slant) or unilateral spatial inattention often interfere with a patient's spatial ability to tell time with a standard watch or clock. Perception of the vertical may also be considered a visual-spatial skill. Verticality perception is the interpretation of internal and external cues to maintain body balance. This maintenance is a complex neuromuscular process involving visual, proprioceptive, and vestibular systems. Patients with right lesions, particularly in the parieto-occipital region, have more difficulty perceiving verticality than those with left lesions. This may affect posture and ambulation.⁹³

Assessment

The patient should be asked to accurately touch a number of targets in all parts of the visual field while fixating on a central point. Mislocalization

should be noted as well as the part of the visual field in which it occurred. Mislocalization within the central field is infrequent; however, defective localization of stimuli on one or both extramacular fields is more frequently seen.⁵⁶ The patient should be asked to determine which of a number of small cube blocks (placed perpendicularly in front of the patient) is closest, which is farthest, and which is in the middle. Differences in binocular (stereoscopic) and monocular viewing should be measured in this and other tasks. Impairment in both of these types of depth perception and subsequent inaccuracy in judging distances have been described in individuals with brain injury.³⁰

With regard to memory for the location of objects or places, patients should be asked to describe the position of objects in their room from memory. They may also be asked to duplicate from memory the position of two or more targets (on a table or piece of paper) that have been presented for a 5-second period. As the number of targets increases, individuals with short-term memory for spatial localization will begin to make errors in spatial placement. Visual memory per se should be ruled out as a conflicting variable.

Topographical sense is assessed by asking patients to describe a floor plan of the arrangement of rooms in their house or to describe familiar geographical constellations, such as routes, arrangement of streets, or public buildings. After therapy, these persons may also be asked to find their way back to their rooms after being shown the route several times. Failure suggests a topographical orientation problem. Finally, such a patient may be asked to locate states or cities on a large map of the United States. In all of these procedures, the examiner must be sure to separate unilateral spatial inattention errors from topographical errors.

The influence of spatial dysfunction on reading and counting written material may be measured simply by asking the patient to read a page of regular newsprint. The examiner should observe performance carefully and document type and frequency of errors. If errors occur, eye movements should be observed to gather additional information. Pages of scanning material (letters or numbers) often give additional information on spatial planning during reading. These are pages of print in which the size and density of the print are controlled. Scanning behavior may be demonstrated by asking the patient to circle specific letters. Switching direction in the middle of a line, skipping letters or lines, perseveration, or any other abnormal performance behavior should be noted. Benton Judgment of Line Orientation Test⁹⁴ may be used to document problems with directional orientation of lines. If there is no indication of apraxia, the patient may simply be given a ruler and asked to match it to the directional orientation of the examiner's ruler.

Interventions

Treatment for visual-spatial deficits should follow basic developmental considerations, progressing from simple to more complex tasks. As with children, if the evaluation suggests disorders in body scheme, tactile or vestibular input, or right-left discrimination, these should be dealt with first.

Patients who do not know where they are in space need to internalize a spatial understanding before they can make judgments regarding the space around them. In gross motor spatial training, patients can be asked to roll and reach toward various targets. Supine, prone, sitting, and standing, with vision occluded, patients should try to localize tactile stimuli (various body locations touched by the therapist) and auditory stimuli (e.g., snapping fingers or ringing a bell) presented above, below, behind, in front of, and to the right and left of their bodies. The individual should state where the stimulus is and then point, roll, crawl, or walk toward it; this verbal, kinesthetic, and vestibular input augments spatial learning. In the occupational therapy kitchen,

the patient, once oriented to the room, may be asked to retrieve one type of object (e.g., cup) from “the top cupboard above your head,” from “the bottom cupboard below your waist,” from “the table behind you,” or from “the drawer on your right (or left).” These patients may also place objects in various positions within a room. They should then stand in the middle of the room, close their eyes, and from memory visualize, verbalize, and point to where the objects are in relation to themselves. Having localized them, the patients should then walk through the space and retrieve the objects in sequence. Functional carryover should always be emphasized, such as having individuals remember through visualization where they put their glasses in the living room before they begin searching. Visualization is defined as the internal “seeing” of something that is not present at that moment: a vision without a visual input or internal visual imagery.⁹⁵ Visualization (spatial and other) is part of all perceptual tasks and may be used effectively as a treatment strategy. As previously discussed, a small feedback light placed in the middle of the patient's forehead can help teach spatial localization through eye-hand movements.

More complex spatial skills may be taught by asking patients to “partition” space and then localize within it. An excellent activity is one in which patients use a yardstick to divide a blackboard into four or more equal parts and then number each section.

Objects may be presented to patients, who must select the largest, the farthest away, or the one placed at an angle; they may be asked to place various objects in certain relationships to one another. As shape, size, and angle begin to “make sense” to these individuals, form boards, simple puzzles, and parquetry blocks may be added to training.

Topographical abilities should improve as patients begin to better conceptualize space; however, they may be trained directly. The therapist may help such patients organize a basic floor plan of the hospital room and the furniture within it while looking at the room. They may then be asked to do this from memory. Activities can progress to drawing plans or larger areas with a number of rooms. These patients should first “navigate” tactually through the area with a finger. Eventually, they should walk or wheel through the route themselves, visualizing and repeating the route until spatial concepts are learned. Imaginary routes also may be taken through maps of cities, states, or countries.

Organized visual-spatial exploration (eye movements) during reading or other scanning and cancellation tasks may be taught. Number and letter scanning sheets may be used for such training. Initially the size of numbers and the spaces between numbers should be large; this places less stress on visual acuity while training scanning. Before beginning, patients should orient themselves to the page spatially by numbering the right and left edges of each line. These numbers are used as additional spatial localization cues if needed during the scanning task.⁴⁶ Patients should then be asked to circle a specific number (or numbers) whenever it occurs. To control erratic or impulsive eye movements, they should be instructed to use a pencil to underline each line and then loop the selected letter as it comes into view (see Fig. 28.16). They may also be asked to read each letter. Underlining allows the kinesthetic and tactile receptors of the arm to control eye movements; verbalization allows the language and auditory systems to influence eye movements. Visual-spatial exploration exercises should progress to large-print magazines, books, or newspapers. The *New York Times* and *Reader's Digest* are both available in large print. In all training activities, it is most important that before the activity begins the patients fully comprehend the total space in which they will work. It is equally important that they reorient themselves at any point where errors occur. Those who lose their place during reading will eventually lose it again if the therapist simply points to where they should be. Chances are better that they will not lose their place again if they reorient themselves to the page spatially when an error occurs.

Problems of Visual-Constructive Disorders

Identification of Clinical Problems

Patients with lesions in either the right or left hemisphere may have problems when trying to “construct.” Lesions in the parietal, temporal, occipital, and frontal lobes have been documented in individuals with visual-constructive disorders.^{56,96} The normal ability to construct, also known as *visual-constructive ability* and *constructional praxis*, involves any type of performance in which parts are put together to form a single entity. Examples include assembling blocks to form a design, assembling a puzzle, making a dress, setting a table, and simply drawing four lines to form a square (graphic skills). The skill implies a high level of dynamic, organized, visual-perceptual processing in which the spatial relations are perceived and sequenced well enough among and within the component parts to direct higher-level processing to sequence the perceptual-motor actions so that eventually parts are synthesized into a desired whole. Visual-constructive ability may be compromised if any part of this process is disturbed.

Typical tasks used to measure this ability include building in a vertical direction, building in a horizontal direction, three-dimensional block construction from a model or a picture of a model, and copying line drawings such as of houses, flowers, and geometric designs.⁸⁵

Patients with visual-constructive deficits, especially those with right lesions, often also have visual-spatial deficits. These individuals may rotate the position of a part erroneously, place it in the wrong position, space it too far from another part, be oblivious to perspective or a third dimension, or simply be unable to complete more than two or three steps before becoming entirely confused. This is usually evidence of breakdown because of faulty or inadequate spatial information.

Other patients, usually those with left lesions, have an “executorial” or apraxic problem; they seem to have difficulty initiating and conducting the planned sequence of movements necessary to construct the whole. The problem seems to be in planning, arranging, building, or drawing rather than in spatial concepts. This deficit in its purest form is known as *constructional apraxia*. Constructional apraxia lies clinically outside the category of most other varieties of apraxia and is considered a special kind of “perceptual” apraxia. It occurs frequently in aphasic individuals; therefore the underlying mechanisms of aphasia and constructional apraxia may be related.⁹⁷

Assessment

Constructional abilities are generally measured through tasks that require (1) copying line drawings of, for example, a house, clock face, flower, or geometric design (drawing may also be done without copying); (2) copying two-dimensional matchstick designs; (3) building block designs by copying or from a model; or (4) assembling puzzles. Table 28.2 lists common tests. The more complex the picture or design to be copied, the more complex are the constructional tasks. The following are examples of drawing and block construction deficits:

1. Patients may crowd the drawing or design on one side of the page or in one corner of the page or available space on the working surface, usually a result of the influence of unilateral spatial inattention.
2. Lines in drawings may be wavy or broken, too long or too short.
3. One line may not meet another accurately, or lines may transect one another; in block designs, parts may not be neatly placed but rather may have small gaps.
4. There may be “overdrawing” of angles or parts of the figure because of graphic perseveration (scribble), spatial indecision, or problems with executive planning.
5. Patients may superimpose their copy on the model or superimpose one of their drawings on top of another. In block design construction, they may become confused between the model and their

TABLE 28.2 Common Tests Used to Assess Visuoconstructive Skills

Test	Standardization
Drawing pictures or shapes with or without an example to copy	Not standardized
Reproducing matchstick designs	Not standardized
Assembling puzzles	Not standardized
Bender Visual Motor Gestalt Test	Standardized for children only
Kohs Blocks Test	Standardized for adults
WAIS Block Design Test	Standardized for adults
Benton's Three-Dimensional Constructional Praxis Test	Standardized for adults

reproduction and use part of the model to complete their design. This has been termed the “closing-in” phenomenon, a failure to distinguish between model and reproduction.⁵⁶

6. Parts of the drawing or design may be reversed. Horizontal reversals are more common than vertical reversals.

A note might be appropriate here regarding dressing apraxia. This problem occurs most frequently with right hemisphere damage. It is considered a “perceptual” apraxia rather than a motor apraxia because the inability to dress is believed to result from body scheme, spatial, and visual-constructive deficits rather than difficulty in motor execution. Persons with dressing apraxia cannot correctly orient their clothes to their body. They often put clothes on backward or inside out. Failure to dress one side of the body is also often noted and is directly related to unilateral spatial inattention.

Interventions

It must be remembered that both visual-constructive and visual analysis synthesis skills are often used almost simultaneously during task performance. Thus treatment should not separate the two types of skills but rather should be a precise interrelationship of activities that require finer and finer levels of each facility. For example, arranging an office filing system is both an analytical-synthesis and a visual-constructive task. The individual must first analyze overall needs and translate them into an imagined visual-spatial plan (preliminary synthesis of the whole) that will help organization. Then the organizer begins to use the hands to categorize (segment visual space). This building is a visual-constructive task. Intermittently during building, new ideas of the whole surface, and visual-constructive tasks change in response to a “better idea” (final synthesis of the whole). Task performance, except for tasks that are rote, usually follows similar perceptual processes. Treatment therefore must be integral. Visual-constructive skills, however, may be emphasized more than visual analysis and synthesis skills or vice versa.

As previously mentioned, visual-constructive disorders are thought to result from different underlying problems in different individuals (e.g., visual-spatial disorders in persons with right hemisphere lesions and executive, planning, or synthetic disorders in those with left hemisphere lesions). There are few reliable studies on treatment strategies for visual-constructive disorders. One possible treatment strategy is known as *saturational cuing*.⁹⁸ This method involves presenting controlled verbal instruction on task analysis and sequence and presenting cues on spatial boundaries (cuing is also response related).

If there are problems with planning and sequencing of steps necessary to accomplish a visual-constructive task, the therapist should begin with simple tasks that require only three or four steps, such as positioning one place setting at a table. The patient should discuss the

plan and sequence of steps before initiating the activity, while looking at the parts to be used, such as silverware, plate, and glass. These steps may even be written down for additional input. The patient should be helped to reorient the plan at any point during task breakdown. Eventually, tasks should increase in complexity (e.g., setting a table for five), and the patient should be encouraged to function more independently. Another technique often used by clinicians is known as backward chaining. This involves presenting a partially completed task and asking the patient to complete the final steps, for example, placing the knife and glass on a partially completed place setting. The perceptual cues of the task already begun appear to stimulate constructional abilities. As the patient progresses, he or she should complete more steps.

Intervention for problems with spatial planning during visual-constructive tasks should begin with the simple spatial exercises discussed previously. If problems still exist, the individual may be asked to draw around shapes (blocks) one by one. These shapes should first have been placed in a simple two-dimensional design. The patient is then asked to rebuild the design with the shapes alone. Therapy should progress from horizontal to vertical to oblique designs, from two-dimensional to three-dimensional designs, and from tasks with common objects to tasks involving abstract designs. For example, spatial problems with drawing, such as placing windows in a house or numbers on a clock face, are usually a result of an underlying spatial disorder. The patient should use a ruler or protractor to segment the space and plan placement before drawing. Dot-to-dot tasks may be designed that actually lead and sequence the drawing into a spatial whole. Simple puzzles also may be used to increase visual-spatial abilities during visual-constructive tasks. Finally, if task breakdown results from impulsive visual or motor behavior, these symptoms should be dealt with before further visual-constructive treatment continues.

Examples of visual-constructive tasks that may be designed for therapeutic use include the following:

- Setting a table for one to five people
- Wrapping a gift
- Assembling a piece of woodwork, a toy, a tool, a motor
- Changing a tire on a car
- Organizing a shelf in a library or a kitchen
- Organizing a filing system or cabinet
- Putting pieces of a sewing pattern together
- Addressing an envelope
- Rearranging furniture according to a preset plan
- Assembling a craft according to a preset plan
- Drawing from memory or copy
- Copying two-dimensional block designs
- Copying three-dimensional designs with oblique components

The key to effective visual-constructive learning, however, is not the task itself but rather how carefully the therapist organizes it and monitors performance. Patients with visual-constructive disorders are often visually or motorically impulsive; they often move or draw parts before analysis has taken place. Once a part is placed inappropriately, it begins to confuse the whole visual-perceptual process. This confusion increases anxiety and contributes to further breakdown in analysis and synthesis. Treatment should be directed at the underlying causes of task breakdown if these can be determined.

Problems of Visual Analysis and Synthesis Disorders

Identification of Clinical Problems

This separate discussion of visual analysis and synthesis is arbitrary. There is never any clear demarcation among the processes of visual-spatial orientation, visual construction, and visual analysis and synthesis. Analysis of likes and differences, relationships of parts to one another, and reasoning and deduction occur simultaneously with more basic spatial and constructive percepts. The final visual concept of a task (e.g.,

what a place setting on a table should look like) is necessary before the task is begun. Similarly, synthesis of one part of a task may be necessary before synthesis of the entire task can occur. For example, the person who is setting a table for four people must be able to conceptualize one place setting before conceptualizing the table with four place settings. Those points during perceptual processing when there is a colligation or blending of discrete impressions into a single perception are known as *synthesis*. This final stage of coordination and interpretation of sensory data is thought to be deficient in many individuals with perceptual problems. Deficits may be present with either left or right hemisphere damage but are more common and more severe with right lesions.^{62,99}

Visual-perceptual skills considered to be analytical and synthetic in nature include making fine visual discriminations, particularly in complex configurations; separating figure from background in complex configurations (figure-ground); achieving recognition on the basis of incomplete information (figure closure); and synthesizing disparate elements into a meaningful entity, as, for example, conceptualizing parts of a task into a whole.⁵

Assessment

Many tests have been designed to measure the capacity for analysis and synthesis. Test items include complex figures in which small parts of a figure differ from another figure. The patient is asked to select the one that is different. Studies have shown that basic discrimination of single attributes of a stimulus such as length, contour, or brightness is intact in many patients.^{100–102} The problem appears when these individuals are asked to discriminate between more complex configurations with subtle differences. Tests also measure figure-ground ability; the patient must select the embedded figure from the background. Functional examples of this problem are the inability of a patient to find her or his glasses if they are lying on a figured background, to find a white shirt on a white bedspread, and to find his or her wheelchair locks. Figure closure is measured by asking the patient to complete an incomplete figure, such as part of the outline of a common shape. Finally, synthesis of parts into a whole, also known as *visual organization*, is measured by asking the patient to conceptualize and organize the whole picture by, for example, looking at separate segments of the picture (e.g., cup or key) that have been divided and placed in unusual positions. This type of synthesis is necessary for high-level constructional tasks. [Table 28.3](#) outlines examples of tests used to evaluate visual analysis and synthesis.

Interventions

Intervention for deficits in visual analysis and synthesis should follow developmental considerations described in the children's section. Visual discrimination tasks should begin with simple figures and obvious differences in complex figures. Color, size, texture, lighting, and verbal direction may help the patient "cue in" on subtle differences among objects or figures. The therapist should determine the threshold at which the patient is capable of discriminating differences and vary the dimension, contrast, and functional activity at this level. For

TABLE 28.3 Common Tests Used to Assess Visual Analysis and Synthesis

Test	Use
Hooper Visual Organization Test	Standardized for adults
Motor-Free Visual Perception Test	Standardized for adults
Raven's Progressive Matrices	Standardized for adults
Embedded Figure Test	Standardized for adults
Southern California Figure-Ground Test	Standardized for children only

example, if the individual cannot select a can of vegetables from a kitchen shelf stocked with cans of similar size, the therapist may simply change the task to fit that person's level of visual discrimination by removing some of the cans (decreasing the density of the display), replacing some of the cans with boxes of food (increasing the spatial contrast), moving the can to be selected forward or to one edge of the display (decreasing figure-ground difficulty), removing the label from the can (increasing the light and color contrast), or giving cues regarding what to search for (verbal direction). This example is described not as a method of compensation but rather as an approach to be used therapeutically in slowly building the patient's visual discrimination abilities. Eventually, high-level visual discrimination skills should be incorporated within tasks requiring three or more steps, such as selecting a can of vegetables, opening the can (which involves selecting the can opener from the utensil drawer), and emptying the vegetables into a specific bowl (which involves selecting the bowl from among other bowls). Visual discrimination and figure-ground skills may appear normal until the patient is required to do multiple-step activities, is given time constraints, or becomes anxious or confused. Tabletop games that require high levels of visual discrimination along with cognitive strategies may be therapeutic and motivating. Examples include *Monopoly* and card games such as solitaire. Matching and sorting tasks also may be helpful in enhancing visual discrimination. Examples include matching picture cards and sorting laundry, tools, silverware, or files.

Drawings of figures with subtle differences also may be used for therapy. The patient should be encouraged to point to, verbalize, or outline the subtle differences in two or more pictures; this enhances visual attention to detail. If the individual cannot select the discrepant detail(s) among three or more figures, the problem most likely results from an inability to select one feature and compare it with elements in the other figures. This is a fairly high-level skill that requires selective attention and analysis with internal visualization while the individual is still viewing the complete figures. This type of patient should practice feature detection and then begin systematic comparisons of similarities and differences between two figures, eventually progressing to three or more figures. The therapist may number or outline similar areas of each figure to help the patient (1) direct attention to similar areas of all figures and (2) sequence comparisons appropriately. The patient should verbalize, draw, or write details concerning similarities and differences in individual aspects of the figures. This enhances visual analysis and also informs the therapist about how the individual is selecting and comparing features. Eventually, speed should be stressed, the highest level being presentation of tachistoscopic designs.

Visual organization may be emphasized by presenting the patient with activities that have multiple parts that must be sequenced together into a whole. Activities involving this type of synthesis are discussed in the preceding section on treatment of visual-constructive disorders. Figure closure may be emphasized by presenting parts of figures or objects (e.g., half a plate covered by a towel) and asking the patient for identification. Figure-closure task difficulty may be increased by placing many objects on a table, some of which partially occlude others. Identification of objects in such a task requires figure closure simultaneous with figure-ground abilities.

Visual analysis and synthesis deficits reflect a disruption in cognitive function with specific regard to visual-perceptual features. The affected patient may function normally when analytical tasks require another system, for example, language. In others with generalized brain damage (e.g., traumatic head injury and senile dementia), general cognitive analysis and synthesis may be at fault rather than visual analysis. Because most cognitive performance requires visual processing, however, increased ability to analyze and synthesize visual-perceptual material often generalizes to an increase in cognitive function.

PERCEPTUAL RETRAINING WITH COMPUTERS

Numerous computer programs have been developed for rehabilitation of brain damage symptoms, including those affecting cognition (e.g., attention, sequencing, or memory) and perception. Because the computer is so highly visual, it becomes an obvious tool for treatment of visual-perceptual dysfunction. Treatment with computers has been named *computer-assisted therapy*. There is a growing interest in development of and research into programs for rehabilitation, for the prevention of Alzheimer's, and in normal healthy aging adults. The largest treatment study of 487 subjects was able to demonstrate statistically significant improvements in memory and attention by using a plasticity-based adaptive training program.¹⁰³ A number of other studies are in progress. Advantages of computer-assisted therapy include control and flexibility of perceptual variables during treatment (e.g., number, size, speed), immediate feedback regarding performance, automatic control for learning (e.g., items are repeated if incorrect to facilitate learning), and being motivational. Visual-perceptual training with computers, if used, should be viewed as one part of a patient's treatment program. One should always remember that the computer, monitor, and keyboard are just that: they do not require the many perceptual, vestibular, and motor responses typical of daily performance (e.g., scanning requirements may be bilateral, but they are not global and associated with head movement). A patient's total program may include computer-assisted therapy as an additional tool; however, it should never be substituted for more significant training within the multidimensional environment. Some computer programs for visual-perceptual training are listed in [Box 28.6](#).

SUMMARY OF VISUAL-PERCEPTUAL DYSFUNCTION

Careful organized evaluation should delineate deficits well enough to result in a visual-perceptual function profile for each patient, including both primary and associative visual skills. Patients rarely come with isolated visual-perceptual deficits; more often, they exhibit a combination of visual-perceptual deficits usually interrelated with motor, language, and cognitive dysfunctions. For example, a visual-perceptual function profile may reveal strabismus, left unilateral visual inattention, visual-spatial deficits, visual-constructive deficits, and problems with visual analysis and synthesis, all affecting daily function. Treatment should be organized to progressively build skills, emphasizing one component more than another. The goal of treatment is eventual generalization of improvements in individual skills to spontaneous high-level function.

The presentation of information in this chapter is an attempt to use isolated and mechanistic terms to define a system that is

extremely subtle, integrated, and complex. The reader is reminded that much of the normal and abnormal perceptual system has not been well defined. Preliminary studies cited throughout this chapter, however, suggest that disorders may be responsive to management and treatment. Research is needed to standardize evaluation procedures well enough to further define deficits and to investigate the effectiveness of various treatment approaches with various patient populations.

Abstract: Vision and perception impact our interactions with the world from birth to death. Understanding the anatomy and functional abilities of the visual system is important for the rehabilitation professional. This chapter provides a foundation for understanding the anatomy of the eye and visual system. It explains common diseases and

their impact on function. The reader will be able to screen for basic visual deficits as well as visual perceptual dysfunction and then be given functional visual rehabilitation activities.

Keywords: anatomy and diseases of eye, functional visual skills, visual screening, visual perceptual dysfunction, visual rehabilitation

Cardiovascular and Pulmonary System Health in Populations With Neurological Disorders

Marilyn Mackay-Lyons and Emily Nguyen

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Explain the physiological principles related to cardiovascular responses to exercise testing.
2. Describe the factors that contribute to the deconditioned state in adults with neurological disorders.
3. Explain the adaptive responses to aerobic training in populations with neurological disorders and the factors underlying these responses.
4. Discuss general guidelines for designing exercise programs to improve cardiovascular health and fitness.

KEY TERMS

aerobic training
cardiovascular fitness

deconditioning
exercise tolerance

rating of perceived exertion

The cardiovascular and pulmonary health of individuals with residual movement dysfunction after a neurological insult has become a topic of great interest in neurorehabilitation. In traditional practice, the state of the neuromuscular system preoccupied the attention of clinicians in the quest to optimize neurological recovery. Most interventions were based on strategies to improve the capacity of that system—an approach that has met with limited success in terms of restoring functional independence. It is now clear that recovery cannot be explained solely on the basis of improved neuromuscular function—three decades ago Roth and colleagues¹ determined that less than one-third of the variance in functional limitations after a stroke can be explained by the extent of neurological impairment. Nevertheless, the current approach to neurorehabilitation is somewhat perplexing. Evidence has accumulated indicating that many people with neurological disabilities are woefully deconditioned. There has been widespread acknowledgement of the central role that aerobic exercise plays in improving cardiopulmonary health and fitness. Furthermore, application of the principles of exercise physiology in cardiac rehabilitation has been widely endorsed. Yet neurorehabilitation clinicians have been observed to practice without full knowledge of their patients' cardiac status or without monitoring heart rate (HR) and blood pressure (BP).^{2,3} Moreover, there is evidence to suggest that patients with neurological insults have not been challenged enough in therapy to induce the metabolic stress needed to enhance their cardiopulmonary fitness.^{4–6} A troubling explanation offered for these observations is that clinicians lack either an understanding or an appreciation of the basic physiological principles of exercise.^{7,8}

Fortunately, attention has turned to the introduction of interventions that encompass the neuromuscular, cardiovascular, and pulmonary systems and promote a more holistic approach to neurorehabilitation. The challenge of improving cardiopulmonary health and fitness in these populations is not trivial. For individuals with

chronic conditions, fitness is affected by a host of interacting influences such as the location and extent of the lesion, the presence of comorbidities (particularly cardiovascular disease), and the premorbid activity level. To complicate matters further, testing and training protocols for individuals with compromised motor and postural control need to be tailored to ensure safety and effectiveness.

This chapter begins with an overview of basic physiological principles related to cardiovascular responses to exercise testing, much of the evidence for which was derived several decades ago. A summary of the evidence of cardiopulmonary fitness levels in adults and children with neurological disabilities is followed by a description of factors that contribute to the deconditioned state. Possible mechanisms responsible for reduced exercise capacity are then reviewed. Adaptive responses to aerobic training in patients with neurological conditions are examined, as are factors underlying these responses. The chapter closes with a summary of guidelines for the design of exercise programs that can be used to improve cardiopulmonary health and fitness. [Appendix 29.A](#) at the end of this chapter clearly identifies the meanings of the abbreviations used throughout the chapter.

PHYSIOLOGICAL RESPONSES TO EXERCISE

At rest the human body consumes roughly 3.5 mL of oxygen (O₂) per kilogram per minute, or 1 metabolic equivalent (MET).⁹ In the resting state, skeletal muscle activity accounts for less than 20% of the body's total energy expenditure; the brain, making up only 2% of body weight, also consumes 20% of the available O₂.¹⁰ Activities at rest, such as breathing and contracting of the heart, can be sustained indefinitely because the power demands of these activities are met by the rate of energy turnover. In other words, these activities occur well below the *critical power* of the muscles, defined as the maximal rate of work that can be endured indefinitely.¹¹ Any physical activity beyond the resting

state requires more O_2 ; the increase is dependent on the intensity of the effort involved. The rise in metabolism relies on O_2 transport by the pulmonary and circulatory systems and O_2 usage by the active skeletal, cardiac, and respiratory muscles to convert chemical potential energy to mechanical energy.¹² The components of the O_2 transport system are outlined in Fig. 29.1.

Selective distribution of the increased blood flow to regions with heightened metabolic demands—the working muscles—is largely a result of local vasodilation mediated mainly by metabolites acting on the vascular smooth muscle (e.g., carbon dioxide [CO_2], hydrogen ions [H^+], nitric oxide, potassium ions, adenosine) and vasoconstriction in

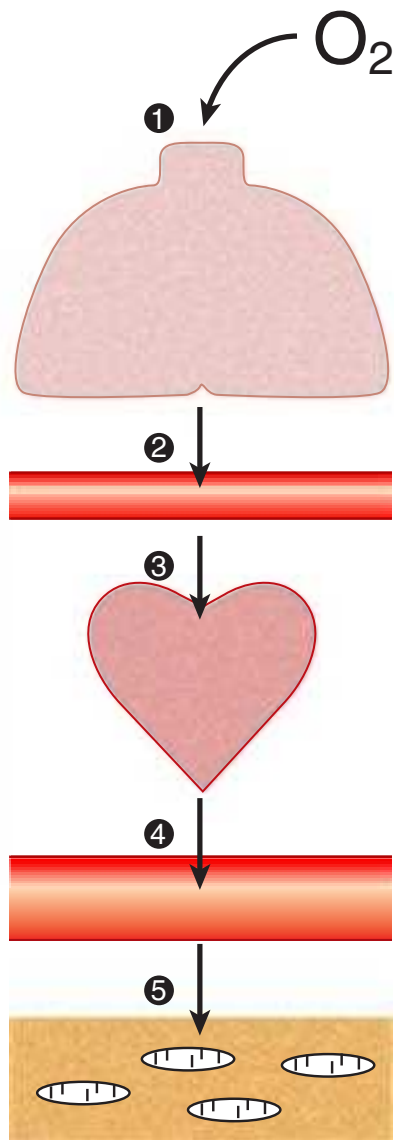

Fig. 29.1 Diagrammatic Representations of the Components of the O_2 Transport System. (1) During inspiration O_2 from the air is delivered to the alveolar gas space by the process of respiration. (2) O_2 diffuses across the blood-gas barrier into the pulmonary capillary blood, where almost all of the O_2 is bound to hemoglobin. (3) The heart acts as a pump, and (4) the vascular system acts as the plumbing to transport O_2 to the various tissues, including the exercising muscle, (5) where it diffuses from the red blood cells into the mitochondria within the myocytes. Reduced conductance of any component impairs O_2 transport, whereas improved conductance of any component augments O_2 transport.

tissues with low metabolic demands.¹³ Blood flow to other vascular beds (e.g., renal and splanchnic bed) either is unchanged or decreases through active vasoconstriction resulting primarily from increased sympathetic discharge.¹³ Cerebral autoregulation maintains regional and total cerebral blood flow and normal tissue oxygenation over a wide range of BPs¹⁴; thus cerebral blood flow and O_2 delivery during exercise either remain stable^{15,16} or increase slightly.^{17,18} As exercise intensity increases, systolic BP (SBP) increases markedly, whereas diastolic BP (DBP) either remains unchanged or lowers slightly, resulting in a moderate increase in mean arterial pressure.¹⁹

Extraction of O_2 from the muscle capillary blood to mitochondria is dependent on an adequate O_2 -diffusion gradient. During a progressive increase in workload, the arterial hemoglobin saturation and arterial O_2 content remain relatively constant, whereas the venous O_2 content decreases substantially as a result of increased O_2 extraction in the active muscles.²⁰ As the metabolic rate rises, the minute ventilation (i.e., respiratory rate multiplied by the tidal volume) increases to remove CO_2 and to regulate pH balance of the active muscles. At low-intensity exercise, ventilation (mainly tidal volume) increases in a linear manner relative to the volume of O_2 use (Vo_2) and CO_2 production (Vco_2). Above the critical power, the energy demand of the muscle exceeds the capacity of the aerobic process to supply energy for muscle contraction; the additional energy is supplied by the anaerobic glycolytic system.²⁰

During more intense exercise, ventilation is extremely variable among individuals; the respiratory rate usually increases without a substantial change in tidal volume.¹⁹ The point at which the rate of glycolysis exceeds that of oxidative phosphorylation is called the *anaerobic threshold* (which approximates the ventilatory threshold or lactate threshold).¹⁹ Pyruvic acid is converted to lactic acid, which completely dissociates to lactate and H^+ , resulting in a rise in blood lactate levels and a fall in intramuscular pH. Exercise-induced muscular fatigue is caused by the exponential accumulation of lactate and a drop in intramuscular pH, with negative effects on the actin-myosin turnover rate, enzyme activities, and excitation-contraction coupling.

Maximal oxygen consumption (Vo_{2max}) is defined as the highest O_2 intake an individual can attain during physical work.¹⁹ The Fick equation describes the relationship between cardiovascular function and Vo_{2max} :

$$Vo_{2max} = Q_{max} \times a-vO_{2diffmax}$$

where Q_{max} is the maximal cardiac output and $a-vO_{2diffmax}$ is the maximal arteriovenous O_2 difference. Given that Q_{max} equals the product of maximal HR (HR_{max}) and maximal stroke volume (SV_{max}),

$$Vo_{2max} = HR_{max} SV_{max} \times a-vO_{2diffmax}$$

Thus Vo_{2max} reflects both O_2 transport to the tissues and O_2 usage by the tissues. Increases in Vo_2 during exercise are caused by increases in both cardiac output and $a-vO_{2diff}$, with HR and stroke volume (SV) increasing progressively over the lower third of the workload range. Thereafter HR continues to increase while SV remains essentially constant,^{21,22} resulting, at maximal effort, in a cardiac output three to six times greater than baseline levels. An increase in SV (50% over resting volume) is caused by enhanced myocardial contractility and increased venous return resulting from compression of the veins by contracting muscles and reduced intrathoracic pressure.²³ At low-intensity exercise, the increase in HR is mainly a result of decreased vagal tone, but as exercise intensifies, sympathetic stimulation and circulating catecholamines play a greater role, yielding, at maximal workloads, a rise in HR 200% to 300% above the resting level.²⁴

MEASUREMENT OF CARDIOPULMONARY FITNESS

Exercise (aerobic) capacity is the principal determinant of the ability to sustain the power requirements of repetitive physical activity. Vo_2max is generally accepted as the definitive index of exercise capacity and cardiopulmonary fitness.²⁵ Vo_2max is a relatively stable measurement; variability of repeated measures of Vo_2max has been reported to be 2% to 4%²⁶ or 0.2 L/min.²⁷ Accurate determination of Vo_2max requires (1) adequate duration and work intensity by at least 50% of total muscle mass, (2) independence from motivation or skill of the subject, and (3) controlled environmental conditions. Also, because test performance is sensitive to time of day, the time of repeat testing should be consistent.

Before any fitness test, a 3- to 5-minute warm-up of slow treadmill walking on a level grade or unloaded pedaling that raises the metabolic rate twofold (i.e., 2 METs) above resting should be performed.²⁸ A proper warm-up prevents excessive local muscle fatigue from occurring before Vo_2max has been attained.²⁹ Furthermore, a 3- to 5-minute cool-down should follow test completion to aid in venous return to prevent blood pooling in the peripheral vasculature and a subsequent drop in DBP. The intensity of exercise can be increased in a continuous progressive manner (i.e., step or ramp protocol) or, less commonly, in a discontinuous progressive manner (i.e., subject rests between stages). Throughout testing, continuous monitoring of the electrocardiogram and periodic monitoring of BP are essential. The optimal duration of a graded exercise test is 8 to 12 minutes, with testing terminated when the subject can no longer generate the required power, is limited by symptoms, or is unable to continue safely.³⁰ Variables of interest during exercise testing include Vo_2max expressed in absolute terms (liters of O_2 per minute) or relative to body mass (milliliters of O_2 per kilogram of body weight per minute), MET level, percent of predicted HRmax, respiratory exchange ratio (RER; ratio of Vo_2 to CO_2), peak power, minute ventilation, tidal volume, respiratory rate, and rating of perceived exertion (RPE) according to the Borg scale.³¹ Because there is considerable variability in HRmax among healthy individuals, the percent of predicted HRmax attained is not a robust indicator of exercise capacity.³² Similarly, because both total exercise time and peak exercise intensity (or power attained; i.e., peak treadmill speed and grade or peak power on bike) are dependent on the test protocol, neither is a reliable measure of exercise capacity.^{33,34} In addition, noninvasive estimation of the anaerobic threshold by identifying the point of nonlinear increases in minute ventilation and VCO_2 can be highly subjective and thus unreliable.³⁵

The principal marker of exercise capacity is attainment of a plateau in Vo_2 , beyond which there is a change of less than 100 mL/min, with further increases in workload dependent solely on anaerobic metabolism.³⁰ In cases in which a Vo_2 plateau is not observed (typically in deconditioned or elderly individuals or in patients with heart disease), the preferred term for the value obtained is *peak Vo_2* (Vo_2peak).³⁶ Criteria for attainment of Vo_2peak include achieving the age-predicted HRmax, RER in excess of 1.15, minute ventilation greater than the predicted maximal voluntary ventilation, tidal volume greater than 90% of the inspiratory capacity, and obvious patient exhaustion.²⁹

Testing Modality

The modality of testing (e.g., treadmill walking, cycling, stepping, arm cranking) can affect Vo_2max values. The treadmill has the greatest potential to recruit sufficient muscle mass to elicit a maximal metabolic response, particularly in deconditioned individuals.³⁷ Bike ergometry yields 85% to 90%, and arm ergometry 70%, of the Vo_2max achieved with a treadmill.³⁷ Ideally the mode of exercise should be

consistent with the patient's typical activity. Thus the treadmill is often preferred because the pattern of muscle activation during treadmill walking is similar to that for most mobility tasks. In patients with neuromuscular conditions, however, impaired balance and motor control often preclude the use of standard treadmill testing protocols. To resolve this limitation, we devised and validated an exercise protocol using a body-weight support system to permit safe and valid testing of Vo_2max early after stroke.³⁸ For subjects with paraplegia, tests with wheelchair treadmills are more functionally relevant than those using arm ergometry.

PREDICTING MAXIMAL OXYGEN CONSUMPTION WITH USE OF SUBMAXIMAL EXERCISE TESTS

Although submaximal tests do not measure the systemic response, they are inexpensive to administer and have a low risk of adverse events. The essentially linear relationship between Vo_2 and HR permits the estimation of Vo_2max from HR measurements taken during submaximal exercise. For example, for people without physical disability the HR increases approximately 50 beats per uptake of 1 L of O_2 , independent of sex and body size.³⁹ For unfit individuals and patients with cardiac impairment, the increases in HR are greater per liter, except for patients taking β -blockers, who demonstrate blunting of the HR response throughout exercise. The Åstrand-Ryhming nomogram has been used to predict Vo_2max from submaximal HR.⁴⁰ The HR- Vo_2 relationship is independent of the exercise protocol. However, HR, unlike Vo_2max , is markedly affected by many stresses (e.g., dehydration, changes in body temperature, acute starvation), resulting in substantial error and inaccurate Vo_2max estimations.³⁷ In fact, discrepancies between estimated and measured Vo_2max in individuals with low exercise capacity can be as high as 25%.⁴¹

FITNESS LEVELS IN POPULATIONS WITH NEUROLOGICAL DISORDERS

Documentation of exercise capacity in populations with neurological disorders has been hindered by the lack of testing protocols that can safely and effectively accommodate the motor and balance disturbances common to these populations. Not surprisingly, the evidence to date suggests that most individuals with neurological disabilities are significantly deconditioned. Variability results from a multitude of factors, including differences in testing protocols, as discussed in the previous section, and differences in subject characteristics; these points are discussed in the following section.

Impact of Low Fitness Levels on Health of People With Neurological Disorders

People with high fitness levels use only a small fraction of the *physiological fitness reserve*⁴² of the cardiovascular, respiratory, and neuromuscular systems to respond to the metabolic challenge of activities of daily living (ADLs).^{43,44} Thus small declines in exercise capacity may not be noticeable in carrying out ADLs. In contrast, relatively minor reductions in capacity can substantially influence performance of ADLs by deconditioned individuals. Light instrumental ADLs require approximately 10.5 mL of oxygen per kilogram per minute (3 METs), whereas more strenuous activities have metabolic costs of about 17.5 mL/kg per minute (5 METs).⁴⁵ Cress and Meyer⁴⁶ reported that the Vo_2peak of 20 mL/kg per minute is needed for older adults to meet the physiological demands of independent living. It is evident that many people living with neurological disabilities (particularly stroke, tetraplegia, and post-polio myelitis syndrome) do not have the level of fitness required for the more strenuous ADLs and independent living. Moreover, relative

exercise capacities (expressed as a percentage of normative values) are of concern, given that Vo_2peak values less than 84% of normal are considered pathological.⁴⁷

For individuals with neurological disabilities, the minimum Vo_2 requirements for ADLs are actually greater than the previously mentioned levels because of the increased energy requirements resulting from gross motor inefficiencies and other related factors.^{48–50} In other words, the percentage of Vo_2peak required for activity at a fixed submaximal workload (termed *fractional utilization*) is increased. When the anaerobic threshold is exceeded prematurely and lactate accumulation is accelerated, accomplishment of low-intensity ADLs is unsustainable for extended periods and achievement of mid- to upper-intensity ADLs is virtually impossible. Moreover, the combination of poor exercise capacity and elevated energy demands results in diminished reserves to support other activities. For example, in the case of people with postpoliomyelitis syndrome, the energy costs of walking are about 40% higher than for healthy peers and are highly correlated with lower-extremity muscle strength.⁵¹ Thus in the calculation of fractional utilization for walking, the numerator (Vo_2 during walking) is increased and the denominator (Vo_2peak) is decreased, increasing fractional utilization substantially.

Of the neurological populations, people post-stroke are the largest consumer group in need of rehabilitation services. This group also has received the most attention in the literature with regard to functional capacity. Exercise capacities documented in this population are consistently low—with a reported range of 8.3 mL/kg per minute in the subacute period⁵² to 22.0 mL/kg per minute in the chronic period.⁵³ As much as 75% to 88% of Vo_2peak (almost twice that of the healthy control subjects) is required to perform household chores,⁵⁴ and one and a half to three times the Vo_2 levels of nondisabled people are needed to walk on level ground.^{48,55,56} Not surprisingly, as many as 70% of patients complain of fatigue after stroke,⁵⁷ with poor energy levels rated as the area of greatest personal concern in comparison to mobility limitations, pain, emotional reactions, sleep disturbances, and social isolation.⁵⁸

In addition to contributing to reduced ADL performance and increased fatigability, low fitness levels are associated with higher mortality. Exercise capacity has been reported to be an independent predictor of mortality in persons with coronary artery disease (CAD), a comorbidity prevalent in some populations of people with neurological conditions.^{59,60} Those with a $\text{Vo}_2\text{peak} < 21$ mL/kg per minute are classified as the high-mortality group and with greater than 35 mL/kg per minute as the excellent-survival group.⁶¹ Thus determining an individual's Vo_2peak is of clinical value. Individuals who are being encouraged, or are internally motivated, to perform beyond their capacity and beyond the capabilities of the interaction of multiple systems are in a high-risk category. Conversely, individuals who are undermotivated or depressed and are performing below their capacity can be trained to self-monitor, which empowers them to reach goals that are safe and have the potential to improve the quality of their lives.

Factors Affecting Fitness Levels in People With Neurological Disorders

To identify appropriate measures to improve fitness levels in people with neurological disorders, the myriad factors at play that contribute to the deconditioned state must be considered. A useful conceptual framework to discuss the interaction of these factors is the International Classification of Functioning, Disability and Health (ICF)⁶² (see Chapter 1). The ICF uses a biopsychosocial approach to organize factors related to the health conditions into two components: (1) personal and environmental contextual factors and (2) functioning and disability, which are further subdivided into components of body functions and structures, activity, and participation (Fig. 29.2).

International Classification of Functioning, Disability and Health

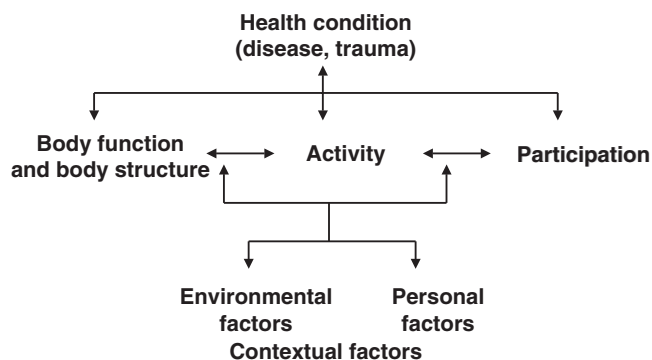

Fig. 29.2 Interaction of the Various Components of the International Classification of Functioning, Disability and Health (ICF). The ICF is a conceptual framework that uses a biopsychosocial approach to organize factors related to health condition into two components: (1) personal and environmental contextual factors and (2) functioning and disability, which are further subdivided into components of body functions and structures, activity, and participation.

Through application of the ICF framework, the complexity of interacting influences on cardiovascular and pulmonary health and fitness becomes more understandable.

Personal and Environmental Contextual Factors

For both able-bodied and disabled people, personal contextual factors contributing to individual differences in exercise capacity include age, sex, race, and lifestyle habits.

Age

A decline in Vo_2max of approximately 1% per year (0.4 to 0.5 mL/kg per minute per year) occurs from 25 to 75 years of age.⁶³ In accordance with the Fick equation, a reduction in Vo_2max is caused by reductions in both O_2 transporting (i.e., Qmax) and O_2 utilization capacity (i.e., $\text{a-vO}_2\text{diffmax}$) associated with cardiac, respiratory, and muscular changes. Decreased Qmax is the result of increasing myocardial stiffness and decreased left ventricular contractility, manifested by reductions in both ejection fraction and HRmax —hallmarks of cardiovascular aging.⁶⁴ In fact, the reduction in HRmax , which decreases 6 to 10 beats per minute (bpm) per decade, is responsible for much of the age-associated decline in Qmax .⁶⁵ Older adults also have a smaller SVmax ,⁶⁵ and BP and systemic vascular resistance are higher during maximal exercise in older versus young adults.⁶⁶

With advancing age, reduced elastic recoil of the lung and calcification and stiffening of the cartilaginous articulations of the ribs restrict compliance of the lungs, thus limiting increases in minute ventilation during exercise.⁶⁷ Age-related decline in oxidative capacity of the working muscles and hence decreased $\text{a-vO}_2\text{diff}$ during peak exercise⁶⁸ have been attributed to alterations in mitochondrial structure and distribution, oxidative enzyme activity,⁶⁹ and skeletal muscle microcirculation, as well as sarcopenia resulting from a reduced number and size of fibers, particularly type II fibers.⁷⁰ Nevertheless, despite loss of aerobic capacity with aging, people without chronic health conditions retain adequate reserves for daily activities. However, for aging individuals with a neurological impairment, the decrease in aerobic capacity with age can further reduce their reserves and thus threaten living an independent lifestyle. In fact, age is a significant independent predictor of recurrent stroke.⁷¹ Particularly disadvantaged are people with

cerebral palsy (CP) or other developmental disabilities as a result of an incomplete development of their musculoskeletal and cardiorespiratory systems at the time of the neurological event, which accelerates the aging process.⁷² In the case of people with Down syndrome, however, Baynard and colleagues⁷³ found that age-related changes in exercise capacity did not follow the typical pattern of decline after the age of 16 years. Older people with spinal cord injury (SCI) are at an increased risk for cardiac and respiratory complications.⁷⁴

Sex

The absolute and relative Vo_2max of women is typically about 77% of that of men, after adjustment for body weight and activity level.⁷⁵ However, no significant gender differences have been reported in the percentage of exercise-induced improvement in Vo_2max of older adults.⁷⁶ Although older men and women generally exhibit similar responses to maximal exercise, older women tend to have lower SBP during maximal exercise.⁶⁶

Race

Little attention has been paid to the differences in exercise capacity among racial groups; however, in one study no differences were found between 66 black and 52 white stroke survivors in the level of physical deconditioning post-stroke.⁷⁷

Lifestyle Factors

Smoking is one factor that has been shown to impair exercise capacity in the general population.⁷⁸ Smoking causes increases in HR, myocardial contractility, and myocardial oxygen demand, which can lead to atherosclerosis and acute cardiovascular events.⁷⁹ In the stroke population, smoking doubles the risk of death (equivalent of about a 7-year reduction in life-span) compared with that of nonsmokers and ex-smokers.⁸⁰

The relationship between cardiovascular disease and diet has attracted international attention.⁸¹ Indeed, obesity increases the risk of cardiovascular risk factors such as impaired glucose tolerance and type 2 diabetes, hypertension, and dyslipidemia.⁸² Abdominal obesity not only increases the risk of atherosclerotic disease but also the risk of primary ischemic stroke.^{83,84} In addition, when compared with corresponding normal-weight populations, overweight youth with SCI and spina bifida (SB) have lower cardiovascular fitness.⁸⁵

The lifestyle factor that has received the most attention in the literature is sedentary behavior. The evidence of the link between physical activity and cardiopulmonary health and fitness is irrefutable.^{78,86-88} In fact, in the stroke population, prestroke physical activity has been found to decrease stroke severity as well as to result in better long-term rehabilitation outcomes.⁸⁹ Cardiovascular alterations resulting from physical inactivity (i.e., reduced Vo_2max and Qmax) parallel, in many ways, the changes that occur with aging; in fact, sedentary lifestyles explain a significant proportion of these age-related declines. If physical activity levels and body composition remain constant over time, the expected rate of loss in aerobic power associated with senescence is reduced by almost 50%.⁷⁰ Nonetheless, people with chronic health conditions often rate poorly in terms of daily physical activity, in part because of underlying physical impairments (e.g., paralysis, pain). For example, people with SCI have been reported to spend as little as 2% of their walking time participating in leisure physical activity,⁹⁰ making them among the most sedentary members of society.⁹¹ Some people with multiple sclerosis (MS) avoid physical activity to prevent elevated body temperature and minimize symptoms of fatigue.^{92,93} Inactivity can lead to increased cardiovascular risk factors such as hypertension and dyslipidemia, as seen in youth with chronic disabilities (including CP and SCI).⁹⁴ Bernhardt and colleagues⁶ found

that after a stroke, patients spend more than 50% of their time resting in bed. Short periods of bed rest cause rapid decreases in aerobic capacity—a 15% reduction in healthy, middle-aged men after 10 days of recumbency⁹⁵ and a 28% reduction in healthy young subjects after 3 weeks.⁹⁶ Inactivity-induced reductions in Vo_2peak have been attributed to both central changes (decreased SV from impaired myocardial function and increased venous pooling) and peripheral changes characteristic of aerobically inefficient muscle fibers (decreases in oxidative enzyme concentrations, mitochondria, and capillary density).²⁴

Environmental Factors

Significant associations have been found between physical activity and physical environmental factors such as accessibility, esthetic attributes, and opportunities for activity within the general public.⁹⁷ However, the influence of such factors on cardiovascular and pulmonary fitness of people with neurological disabilities has garnered little attention in the literature.⁹⁸

Health Condition

Exercise capacity reflects both systemic capacity and the health of the component systems. Thus differences in Vo_2peak among individuals with neurological disabilities are a result of not only the contextual factors discussed previously but also pathological conditions involving the neuromuscular, cardiovascular, and pulmonary systems.

Neuromuscular System

For most individuals with neurological conditions, the existence of neuromuscular impairments confounds interpretation of Vo_2peak testing. When people with an intact nervous system are tested, normal biomechanical efficiency is assumed; an impaired nervous system increases the complexity of physiological responses. Both primary effects of upper motor neuron damage (e.g., paralysis, incoordination, spasticity, sensory-perceptual disorders, balance disturbances) and secondary “peripheral” changes in skeletal muscle (e.g., gross muscular atrophy⁹⁹ and changes in muscle fiber composition¹⁰⁰) affect the response to exercise. As a result, people with neurological disabilities manifest not only metabolic but also biomechanical deficiencies, both of which contribute to reduction in functional capacity. Consequently, the decline in exercise capacity is greater than expected (e.g., in people with postpoliomyelitis syndrome, deterioration in Vo_2peak over a 3- to 5-year period was 12% greater than the predicted decline¹⁰¹).

Paresis reduces the pool of motor units available for recruitment during physical work, thereby reducing the metabolically active tissue and lowering the oxidative potential.¹⁰² In the case of stroke, on average about 50% of the normal number of motor units are functioning,¹⁰³ and a strong relationship between muscle mass and Vo_2peak has been reported.¹⁰⁴ In addition, along with altered joint kinematics and decreased postural reactions,¹⁰⁵ children with CP exhibit high levels of co-contraction (simultaneous contraction of agonist and antagonist muscle groups), which may prematurely induce skeletal muscle fatigue, further increasing the energy expenditure of walking and decreasing Vo_2peak .¹⁰⁵ Thus when compared with able-bodied individuals, children with CP experience greater levels of fatigue at slower walking speeds.¹⁰⁵ For people with postpoliomyelitis syndrome, muscle weakness of the lower extremities is strongly associated with energy expenditure of walking.⁵¹ In fact, when compared with healthy age- and sex-matched subjects, the energy cost of walking is found to be significantly higher (40%) for people with postpoliomyelitis syndrome.⁵¹

Altered fiber composition and recruitment patterns of paretic muscle may also contribute to poor fitness.¹⁰⁶ Skeletal muscles are composed of fibers that express different myosin heavy chain (MHC)

isoforms. Slow (type I) MHC isoform fibers have higher oxidative function, are more fatigue resistant, and are more sensitive to insulin-mediated glucose uptake; fast (type II) MHC fibers are recruited for more powerful movements, are more reliant on anaerobic or glycolytic means of energy production, fatigue rapidly, and are less sensitive to the action of insulin. Although relatively equal proportions of slow and fast MHC isoforms are found in the vastus lateralis of healthy individuals,¹⁰² elevated proportions of the fast, more fatigable fibers that are less glucose sensitive have been found in the paretic leg of people after a stroke.¹⁰⁷ Hence it is likely that reduced insulin sensitivity and increased use of the anaerobic processes during dynamic exercise at the level of the muscle contribute to reductions in $\dot{V}O_{2peak}$. Furthermore, alterations in the structure of mitochondria¹⁰² and reduced activity of oxidative enzymes (e.g., succinate dehydrogenase)¹⁰⁸ may contribute to the reduced oxidative capacity of paretic muscles.

Cardiovascular System

Cardiovascular comorbidities, prevalent in populations with neurological disorders, contribute to metabolic inefficiency. In fact, cardiovascular complications are leading causes of death in persons with stroke,¹⁰⁹ MS,¹¹⁰ and SCI.¹¹¹ As many as 75% of patients who have had a stroke are hypertensive,¹¹² and the same proportion of patients have underlying cardiovascular dysfunction.¹¹³ In fact, most persons who have had a stroke have atherosclerotic lesions throughout their vascular system,¹¹⁴ and a high correlation has been reported between the number and degree of stenotic lesions in the coronary and carotid arteries.¹¹⁵ The high prevalence of CAD in this population should not be surprising because stroke and cardiac disease share similar predisposing factors (e.g., older age, hypertension, diabetes mellitus, cigarette smoking, sedentary lifestyle, and hyperlipidemia) and pathogenic mechanisms (e.g., atherosclerosis).¹¹⁶

Metabolic syndrome is a usual construct in identifying patients at high risk for future vascular events (e.g., a second stroke, myocardial infarction).¹¹⁷ *Metabolic syndrome* refers to a constellation of markers of metabolic abnormalities (i.e., hypertension, abdominal obesity, abnormal lipid profile) that interact to accelerate the progression of atherosclerosis and increase the risk of development of cardiovascular or cerebrovascular disease.¹¹⁸ The prevalence of metabolic syndrome in neurological populations is high. A retrospective study reported that about 61% of 200 patients in stroke rehabilitation met the criteria for the syndrome.¹¹⁹

Factors that elevate HR for a given $\dot{V}O_2$, such as CAD, result in attainment of a peak HR (HR_{peak}) at a $\dot{V}O_{2peak}$ below that predicted for that individual. Cardiac dysfunction contributes to a lower aerobic capacity through two principal mechanisms: ischemia-induced reductions in ejection fraction and SV with exercise¹²⁰ and chronotropic incompetence—the inability to increase HR in proportion to the metabolic demands of exercise.²³ For persons who can attain HR_{max} within 15 bpm of the predicted maximum, limitations in exercise capacity probably do not have cardiovascular causes.

Impaired peripheral blood flow also contributes to reduced cardiovascular fitness. Inadequate blood flow to the periphery impairs O_2 transport and limits energy production in the working muscles, thereby compromising the ability to sustain physical activity. Both resting blood flow and postischemic reactive hyperemic blood flow have been found to be lower (approximately 36% less) in the paretic leg of people post-stroke.^{121,122} In addition, despite near-normal (above 0.90) mean ankle brachial index values, arterial diameter has been found to be reduced post-stroke.¹²¹ Potential mechanisms responsible for reduced blood flow on the hemiparetic side include altered autonomic function,¹²³ enhanced sensitivity to endogenous vasoconstrictor agents,¹²⁴ and altered histochemical and morphological features of

the vascular network itself.¹²⁵ However, the relative contribution of each of these factors is unknown. In addition, local metabolic mediators associated with changes in muscle fiber composition in the paretic limb (previously discussed) may contribute to impaired limb blood flow.¹⁰²

Trauma to the spinal cord may disrupt the autonomic reflexes and sympathetic vasomotor outflow required for normal cardiovascular responses to exercise.¹²⁶ As a result, reduced venous return and cardiac output (referred to as *circulatory hypokinesia*) impair delivery of O_2 and nutrients to and removal of metabolites from working muscles, intensifying muscle fatigue.¹²⁷ For people with paraplegia, an exaggerated HR response may occur during exercise in order to compensate for reduced SV. However, adrenergic dysfunction associated with lesions above the T1 sympathetic outflow prevent this compensatory mechanism,¹²⁸ thereby increasing the risk of cardiovascular disease.

Pulmonary System

Typically, in able-bodied individuals, the pulmonary system does not limit cardiopulmonary fitness because the lungs of people without chronic health conditions have a large reserve.¹²⁹ Nevertheless, at maximal workloads as much as 10% of $\dot{V}O_{2max}$ is needed to support the mechanical work of the diaphragm, accessory inspiratory muscles, and abdominal muscles.¹²⁰ In contrast, people with neurological impairments may have limited O_2 availability for exercise as a result of pathological conditions involving the pulmonary system, either as a direct complication of a neuromuscular condition (e.g., muscle weakness, impaired breathing mechanics) or as a result of cardiovascular dysfunction, comorbidities (e.g., chronic obstructive pulmonary disease), or lifestyle factors (e.g., physical inactivity, smoking habits).^{130,131} These impairments can reduce the *ventilatory reserve*, defined as the difference between the maximal available ventilation and the ventilation measured at the end of exercise.¹³²

As previously mentioned, minute ventilation is closely associated with $\dot{V}CO_2$ during exercise. At peak exercise, a ratio of minute ventilation to $\dot{V}CO_2$ above between 35¹³³ and 40¹³⁴ indicates an abnormal ventilatory response. Neu and colleagues¹³⁵ reported an 87% incidence of obstructive pulmonary dysfunction in patients with Parkinson disease, despite the finding that $\dot{V}O_{2peak}$ levels in this patient group tend to be in the normal range.^{136,137} For children with CP, reduced exercise capacity may be partly caused by respiratory muscle spasticity resulting in reduced breathing efficiency.¹³⁸ In the case of stroke, pulmonary function is usually affected to only a modest extent, notwithstanding acute respiratory complications (e.g., pulmonary embolism, aspiration pneumonia).^{130,139} Impaired respiration may be attributed to cardiovascular dysfunction or lifestyle factors (e.g., physical inactivity, high incidence of smoking) or a direct result of the stroke, particularly brain stem stroke. The overwhelming fatigue felt by some persons after a stroke may be partly caused by respiratory insufficiency as manifested by low pulmonary diffusing capacity, decreased lung volumes, and ventilation-perfusion mismatching.¹⁴⁰ Impaired breathing mechanics with restricted and paradoxical chest wall excursion and depressed diaphragmatic excursion have been also reported.^{130,141} Expiratory dysfunction appears to be related to the extent of motor impairment (e.g., abdominal muscle weakness), whereas inspiratory limitations appear to be related to the gradual development of rib cage contracture.¹⁴²

To summarize, a host of interacting factors are associated with abnormally low cardiopulmonary fitness in people with neurological disorders. Neuromuscular and respiratory dysfunctions are often superimposed on an already-compromised state as a result of comorbid cardiovascular disease and premonitory health- and lifestyle-related declines. Paresis and the subsequent reduction in lean muscle mass,

changes in the muscle fiber phenotype, and increased reliance on anaerobic processes for energy production result in high metabolic costs of moving paretic limbs. As a consequence, cardiac reserves available for meaningful activity-level functions are limited, which in turn has a negative impact on participation-level functions. Collectively, impairments in the neuromuscular, cardiovascular, and pulmonary systems converge to promote a sedentary lifestyle and reduced health-related quality of life, which in turn leads to further inactivity and further reductions in cardiopulmonary fitness. The contribution of skeletal system impairments to this downward spiral has received little attention. Pang and colleagues¹⁴³ studied the relationship between bone health and physical fitness in patients who had had a stroke and found a significant correlation between paretic femur bone mineral density and VO_2max . They concluded that further study is needed to determine the clinical implications of this finding.

ADAPTIVE RESPONSES TO AEROBIC TRAINING IN POPULATIONS WITH NEUROLOGICAL DISORDERS

It is well documented that healthy young and old individuals who begin participating in regular activity, even after years of inactivity, can enjoy greater health and fitness than those who remain sedentary. Training studies involving people with neurological disability, although limited in number and sample size and, in some cases, lacking a control group, provide evidence of cardiopulmonary adaptations to physical work. For example, for adolescents with chronic disabilities (including CP, SB, and SCI)⁹⁴ and younger children with CP,^{144–146} cardiovascular fitness training is found to produce positive results on aerobic capacity and fitness. There is also strong evidence supporting the benefits of aerobic training in people with stroke of mild to moderate severity.¹⁴⁷ Exercise training has been found to improve the physical capacity of people with SCI.^{148,149} In the case of people with traumatic brain injury, evidence regarding the effects of exercise training has been inconclusive.¹⁵⁰ Unlike nondisabled populations, in neurological populations, cardiovascular adaptations in response to aerobic training enhance metabolic efficiency, and neuromuscular adaptations in response to strength and gait training improve mechanical efficiency. The result is improved functional capacity with lowered energy costs of ADLs, enhanced fatigue resistance, and increased exercise tolerance (Fig. 29.3).

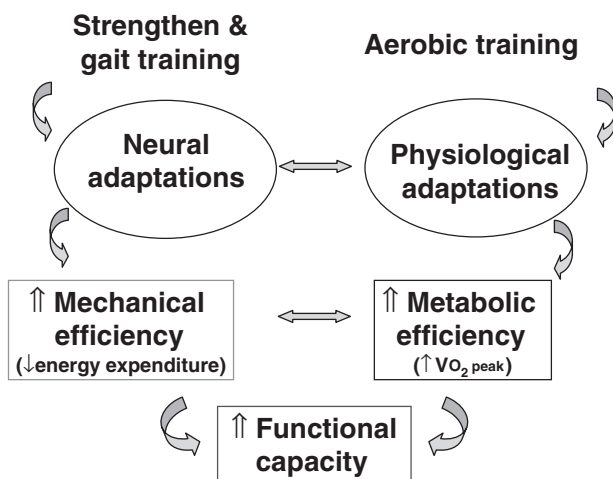

Fig. 29.3 Interaction of Influences That Enhance Functional Capacity. Neurorehabilitation interventions result in neural and physiological adaptations that in turn increase mechanical and metabolic efficiencies and ultimately improve functional capacity.

The magnitude of change in VO_2peak in training studies involving neurological populations (mean gain of approximately 20%) is comparable to the improvements^{151,152} reported for healthy, sedentary adults and participants in cardiac rehabilitation.^{153,154} Substantial intersubject variability in results is attributable to many factors, including differences in neurological condition, severity, and time after insult, as well as variations in intensity of training, mode of exercise, and level of compliance with the exercise regimen. Within studies, considerable individual differences have been noted, of which only a small portion have been attributed to recognized covariates such as initial fitness status and measurement error. The most rapid improvements in exercise capacity are seen in previously sedentary people,¹⁵⁵ and similarly, the highest overall gains occur in individuals with the lowest initial values of VO_2peak .¹⁵⁶ Age and sex have not been shown to have a substantial effect on exercise trainability.¹⁵⁷

The dramatic increases in exercise capacity reported in some of the studies (e.g., improvements of 30%¹⁵⁸ to 94%⁵²) may not be possible for most people with neurological disabilities. Yet the subtle gains realized in other studies (e.g., 8%,¹⁵⁹ 11%,¹⁶⁰ 15%¹⁶¹) may yield meaningful dividends by extending the time in which muscle contraction can be sustained through oxidative processes, thus elevating the lactate threshold. Enhanced functional capacity could spell the difference between being dependent and independent. In other words, interventions that result in even small changes in aerobic capacity may be of practical significance for people with neurological disorders.

Mechanism of Improved Exercise Capacity in Neurological Disorders

It remains unclear whether training-induced increases in VO_2peak in people with neurological disorders result from central mechanisms or peripheral mechanisms. In nondisabled individuals both peripheral and central adaptations occur; and in those with CAD and an intact nervous system, central^{162,163} and peripheral^{163,164} adaptations have been variably reported. In accordance with the Fick equation, central adaptations rely on improved SV because HRmax remains unchanged with training. Enhanced myocardial contractility, together with decreased vasoconstriction in the nonworking muscles and improved venous return, account for the higher Q_{max} without a concomitant increase in mean arterial pressure.^{165,166} There is preliminary evidence that exercise training can improve ejection fraction,¹⁶⁷ coronary blood flow,^{168,169} and possibly blood hemoglobin content.¹⁷⁰

Peripheral adaptations in the exercising muscle tissue include increases in capillary density,^{171,172} size and number of mitochondria,¹⁷³ myoglobin levels, Krebs cycle enzymes (e.g., succinate dehydrogenase), and respiratory chain enzymes (e.g., cytochrome oxidase).²⁴ As a consequence of these skeletal muscle adaptations, $a\text{-VO}_2\text{diff}$, and hence VO_2peak , increase.⁶³

The possibility of “spontaneous” increases in exercise capacity during neurological recovery should not be overlooked. There have been early reports of non-exercise-induced positive adaptations after myocardial infarction.^{174,175} In our lab we documented a significant increase (13%) in VO_2peak over the course of a stroke rehabilitation program that lacked an aerobic training component.¹⁷⁶ Haisma and colleagues¹⁷⁷ reported that patients with tetraplegia and paraplegia demonstrated improvements in VO_2peak of 17% and 23%, respectively, over the course of inpatient SCI rehabilitation; however, the extent and mode of aerobic training were not indicated. The authors speculated that the improved capacity could be, in part, a result of natural recovery and recuperation from trauma and complications.¹⁷⁷ Dressendorfer and colleagues¹⁷⁸ hypothesized that the metabolic demands of unregulated daily activities after myocardial infarction may have an insidious training effect. In support of this notion, a review of the

threshold exercise intensity to improve cardiorespiratory fitness indicated that for deconditioned participants an effective training intensity is lower than previously reported.¹⁷⁹

Additional Benefits of Aerobic Training

In addition to increased exercise capacity, other benefits of endurance training realized by healthy people appear to be attainable for individuals with neuromuscular disabilities. However, direct evidence of the impact on ICF-related domains remains limited, discussed as follows.

Cardiopulmonary Function

Decreases in HR at a fixed submaximal workload after training have been attributed to increases in total blood volume¹⁸⁰ and vagal activity and to concomitant reductions in sympathetic-adrenergic drive and resting HR (HR_{rest}).^{181,182} However, according to Wilmore and colleagues,¹⁸⁰ the decrease in HR_{rest} is of minimal physiological significance. Reductions in SBP at fixed submaximal workloads,¹⁸³ resting SBP,¹⁸⁴ and resting DBP^{28,185} have been demonstrated in individuals after stroke. Related to this finding, training can also reduce the rate-pressure product (product of HR and SBP) at submaximal loads,⁶⁵ which reflects improvement in cardiac efficiency.¹⁸⁶ After a 4-week single-limb exercise training program with the hemiparetic limb, Billinger and colleagues¹²¹ reported significant improvements in femoral artery blood flow and diameter compared with the non-hemiparetic limb post-stroke. The authors reasoned that in order to maintain homeostasis, the diameter increased to adjust for the coupling of increases in metabolic demand and improved blood flow.¹²¹

In patients with CAD, training has resulted in decreased ST segment depression (a marker of myocardial ischemia) during submaximal exercise performed at the same baseline rate pressure product,¹⁶² thus raising the anginal threshold and extending the time that submaximal tasks can be performed without triggering myocardial ischemia. Cardiovascular and muscle adaptations also lower minute ventilation at a given submaximal workload, intimating improved ventilatory efficiency.¹⁸⁷ After training, Vo_2 at a given submaximal workload is usually modestly reduced¹⁸⁸ because the increased a-vO_2 diff in trained muscles is offset by reduced blood flow to the working muscles and a less pronounced decrease in blood flow to the nonexercising muscles resulting from depressed sympathetic reflex activity.¹⁶⁵ As a result of improved pulmonary function resulting from targeted expiratory¹⁸⁹ and inspiratory¹⁹⁰ muscle training in people with MS, it may be possible for members of this population to increase exercise tolerance. In fact, cardiorespiratory training improves respiratory function, Vo_2 peak, and working capacity and reduces fatigue in people with MS.¹⁹¹ Similarly, there is strong evidence that within stroke populations exercise training increases Vo_2 peak^{159,183,192–196} and reduces fatigue.^{197,198}

Cardiovascular Risk Factor Reduction

Although limited physical activity is an independent predictor of risk of stroke,^{199,200} the capacity of exercise to confer the same protective benefits against stroke recurrence is unknown. It is clear that endurance exercise training lowers resting BP in both young and older hypertensive adults.²⁰¹ Training is also associated with lower fasting and glucose-stimulated plasma insulin levels and with improved glucose tolerance (if initially impaired), insulin sensitivity,²⁰² and glycemic control in patients with type 2 diabetes.²⁰³ Aerobic training in individuals post-stroke has been demonstrated to reduce insulin resistance^{203a} and increase glucose tolerance.²⁰⁴ Evidence also suggests that stroke populations achieve similar training-induced improvements in lipid profile,^{205–207} as previously documented for participants in cardiac

rehabilitation.²⁰⁸ Patients with MS showed reductions in triglyceride and very-low-density lipoprotein levels after a 15-week training program.²⁰⁹ Similarly, an 8-week training program for individuals early after SCI led to improved lipid profiles, with more pronounced changes in response to high-intensity training.²¹⁰ However, the previously mentioned improvements in vascular risk factors may be a result of training-induced reductions in body fat stores.²¹¹ The potential for training to reduce intraabdominal fat is particularly significant because it is the body fat depot that is associated with aging and is most closely associated with other cardiovascular disease risk factors.²¹² Because of the positive effects on glucose homeostasis, lipid lipoprotein profiles, and cardiovascular fitness, exercise training has been found to be effective in reducing the risk of cardiovascular disease and comorbidities (e.g., type 2 diabetes, hypertension, obesity) in people with SCI.¹⁴⁹ Stroke survivors participating in a 10-week cardiac rehabilitation program obtained greater improvements in cardiac risk score compared to those in usual care,²¹³ due, in part, to changes in systemic and cerebrovascular hemodynamics,¹²¹ including improved endogenous fibrinolysis profiles²¹⁴ and decreased arterial stiffness.^{215,216}

Impairments in Body Structure and Function

Benefits of training to impairments in body structure and function of people with neurological disabilities, other than improved endurance and exercise tolerance, are gradually being documented. In patients who have had a stroke, training studies have noted increases in balance,^{193,217} walking speed,^{218,219} and paretic lower-extremity muscle strength.^{220,221} A 15-week aerobic training program for patients with MS resulted not only in improvement in exercise capacity but also in upper- and lower-extremity strength.²⁰⁹ In people with Parkinson disease, aerobic exercise has immediate beneficial effects in improving motor action, balance, and gait.^{222,223} Children with CP have shown improved gross motor function after participating in an 8-month circuit-training program.²²⁴

An exercise training program designed to improve ambulatory efficiency of patients with traumatic brain injury failed to reduce energy costs of walking despite a 15% improvement in Vo_2 peak.²²⁵ In contrast, two studies reported mean reductions in energy costs of walking of 30%⁵⁴ and 23% after stroke rehabilitation (although not specifically aerobic exercise),⁵⁶ and a pilot study reported a 32% reduction in the energy cost of walking in individuals with incomplete SCI after a 12-week program of body weight supported treadmill training (BWSTT).²²⁶ The task specific nature of BWSTT is also had beneficial outcomes for individuals with improved disability scores and muscular strength and decreased fatigability.²²⁷ Macko and colleagues⁴² interpreted gains observed in ambulatory workload capacity as a reflection of both improved exercise capacity and greater gross motor efficiency. The investigative team postulated that the repetitive, stereotypic training may induce these adaptations by stimulating central neuromotor plasticity involving cerebellum-midbrain circuits.²²⁸

In the past 2 decades the possible role that dynamic exercise may play in enhancing cognitive function has become a focus of research. In fact, in older adult populations without known cognitive impairment and in cardiac populations, there is evidence supporting the benefit of exercise training on improving cognition.^{229–231} In stroke populations aerobic training has been shown to improve global cognitive ability,²¹⁹ attention and visual spatial ability,²³² and implicit memory and information processing speed.^{233,234} Similar effects on cognition have been demonstrated in populations with Parkinson disease.^{235,236}

Neepser and colleagues²³⁷ observed upregulation of brain-derived neurotrophic factor (BDNF) in the cerebral cortex of rats housed in an

environment with free access to a running wheel. Since then, other researchers have demonstrated increased BDNF production and synaptic plasticity in rodent models engaged in voluntary running.^{238–240} Gordon and co-workers²⁴¹ drew on the findings from these animal studies to postulate that the improved cognitive function of individuals with traumatic brain injury who exercised regularly may be attributable to exercise-induced increases in BDNF or other growth factors. A 2017 systematic review and meta-analysis concluded that aerobic training can increase levels of BDNF in people with a neurological disorder when compared to usual care or no therapy.²⁴²

Emotional Well-Being

Increased exercise capacity has been shown to improve mental well-being (reductions in anxiety and depression) in cardiac patients.^{243,244} There is moderate evidence regarding the effect of exercise training on improving mood in patients with MS.^{245,246} Limited evidence exists to support the relationship between aerobic exercise and emotional well-being post-stroke—a population with an increased risk for depression.²⁴⁷ High levels of physical disability, cognitive impairment, and severity of stroke have been found to be predictors of post-stroke depression.²⁴⁷ Nevertheless, a several aerobic training studies have reported outcomes of reduced depressive symptoms,^{213,248–251} improved psychosocial health, perceived health and well-being,¹⁸² and reduced mental health distress^{197,251,252} in patients post-stroke. In the Parkinson population, demonstrated benefits of aerobic training include improved mood and sleep.^{235,236} Preliminary evidence of exercise-induced reductions in general fatigue (which is associated with emotional well-being) have been reported in people postpoliomyelitis,²⁵² post-stroke,²⁵³ MS,^{227,245,254,255} and Guillain-Barré syndrome.²⁵⁶

Activity, Participation, and Quality of Life

Exercise-induced changes in activity, participation, and quality of life for people with neurological disabilities have been reported in the literature. However, whereas small improvements in Vo_2 peak can have a substantial impact on the ability to perform daily activities, particularly in individuals with limited cardiac or ventilatory reserves, there is less documentation of these benefits in people with neurological disorders. Turner and colleagues²⁵⁷ reported better physical and mental health, as well as social functioning, in veterans with MS who exercised (only 26% of the 2996 veterans engaged in physical activity). In patients with SCI, exercise and gait training were shown to have a positive impact on work, social life, family, and leisure participation.²⁵⁸ In stroke survivors, exercise-elicited gains have been observed in balance, gait speed,^{193,220} walking tolerance,^{193,194} and enhanced performance satisfaction regarding ADLs.²⁵⁹

The positive impact of exercise training on quality of life has been demonstrated in people with MS,^{209,227,244,257,260,261} CP,^{224,262} stroke, Parkinson disease,²⁶³ and postpoliomyelitis.²⁵² However, evidence on the effects of cardiovascular exercise on quality of life after stroke remains inconclusive.^{147,218,259,264,265}

Aerobic Exercise Prescription to Optimize Fitness of People With Neurological Disabilities

Safety and Screening

In general terms, the risks imposed by lack of exercise are far greater than those imposed by exercise. Nevertheless, it is of paramount importance to recognize that symptomatic and asymptomatic cardiovascular disease, and related comorbidities such as diabetes, are much more prevalent in patients with many neurological conditions than in the general population. Because there is limited evidence regarding safety of aerobic exercise for people with neurological disorders, best clinical judgment should be used in aerobic exercise prescription. Thorough

review of the health records of potential participants is critical to identify problems that may preclude safe participation in aerobic training programs. Cardiac screening is recommended, with an exercise stress test for people with a known cardiovascular condition that may be provoked by exercise at the intended training intensity. Table 29.1 provides a compilation of contraindications to testing and training.^{28,266} Before implementing an exercise program without preliminary exercise testing, the following should be considered: (1) Careful screening for possible contraindications must be conducted. (2) Motor function, mobility, balance, swallowing, and communication (ability to follow instructions and ability to express pain or distress) should be evaluated. (3) Training must be done under the close surveillance of trained personnel. (4) A period of continuous electrocardiography and telemetry at the initiation of training is recommended. (5) Monitoring of BP, HR,

TABLE 29.1 Contraindications to Exercise Testing and Aerobic Training

Signs and Symptoms	Contraindications
Myocardial infarction	Acute myocardial infarction
Angina	Unstable angina (not controlled with medication/intervention)
Cardiac arrhythmias	Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
Resting ST segment displacement	>1 mm displacement in more than one lead
Heart failure	Uncontrolled symptomatic heart failure
Aortic stenosis	Symptomatic severe aortic stenosis
Large vessel intracranial stenosis	Severe stenosis
Aortic dissection	Acute aortic dissection
Endocarditis	Active endocarditis
Myocarditis/pericarditis	Suspected or known acute myocarditis or pericarditis
Hypertension	Resting SBP >200 mm Hg or resting DBP >110 mm Hg
Pulmonary embolus or infarction	Acute pulmonary embolus or pulmonary infarction
Metabolic diseases	Uncontrolled diabetes, thyrotoxicosis, or myxedema
Acute systemic infection	Accompanied by fever, body aches, or swollen lymph glands
Impaired cognitive function	Only if unable to understand risks associated with exercise and/or express pain or distress presenting a safety concern
Dysphasia	Inability to understand risks associated with exercise and/or to express pain or distress
Emotional distress/psychosis	Significant emotional distress
Dizziness	Severe motion-induced dizziness/vertigo
Arthritis	Severe pain on weight bearing or exercise
Seizures	Uncontrolled seizure disorder

and signs of exercise intolerance is essential. For subjects with pulmonary comorbidities such as chronic obstructive pulmonary disease, O₂ saturation levels should be monitored, with saturation levels less than 85% as the criterion to terminate exercise.²⁶⁷

In the past, clinicians were apprehensive about the possibility that the overload necessary to achieve an aerobic training effect could aggravate spasticity in patients with neurological disorders; however, such concerns have not been substantiated.^{147,268,269} In fact, there is evidence from studies of cats²⁷⁰ and humans with SCI²⁷¹ that treadmill training may, in fact, reduce spasticity by improving stretch reflex modulation.

Another concern raised regarding the implementation of aerobic training in neurological disorders is the potential for eliciting excessive fatigue. For people with MS, increased fatigue levels have been reported after high-intensity exercise²⁷¹; however, exercising at an appropriate intensity actually yields benefits without aggravating fatigue.^{246,272,273} Dawes and colleagues²⁷⁴ found that early after traumatic brain injury, increasing the workload during cycling exercises did not elicit a disproportionate increase in energy cost in most of the patients with spasticity.

The issue of when it is safe to initiate exercise training with neurological populations is of ongoing interest. Most training studies on such populations have involved patients with chronic neurological impairments; however, the optimal time to introduce training is unknown. Macko and colleagues²⁷⁵ expressed caution about training in the acute post-stroke period, speculating that abnormal cardiovascular responses to exercise (e.g., hypotension, arrhythmia) may impede perfusion of ischemic brain tissue during the period when cerebral autoregulation is most often impaired. Nevertheless, no adverse events have been reported in exercise training studies of people either early post-stroke^{52,276,277} or in subacute stages post-stroke.^{278,279}

Training Environment

High-risk individuals, such as patients in the early stages of neurological recovery or with cardiac comorbidities, should be trained in a setting with quick access to emergency medical equipment and trained personnel. An adverse event protocol should be posted and rehearsed. Lower-risk individuals, after appropriate screening to ensure an appropriate response to exercise, can be trained in supervised community²⁸⁰ or home-based¹⁹³ aerobic exercise programs. A study of people with postpoliomyelitis reported reductions in fatigue and improvements in quality of life when patients were trained in either a hospital or home setting.²⁵² Similar gains in outcomes were achieved for people post-traumatic brain injury trained in an unsupervised home-based program versus a supervised facility-based exercise program.²⁸¹ Telehealth is being explored as a strategy to help deliver aerobic training remotely, particularly in rural areas.^{282,283}

Regardless of the setting, certain safeguards are required. Because thermal dysregulation is common in patients with neurological disability, particularly MS²⁸⁴ and SCI,²⁸⁵ the ambient temperature should be carefully controlled and fans, spray bottles, towels, and a water cooler are recommended. Hydration before and during exercise and rehydration after exercise should be monitored by use of a water bottle with volumetric indicators. The exercise area should be wheelchair accessible, free of obstacles and blunt objects, and sufficiently large to permit safe transfer to and from exercise equipment.

Preparation of Participants

Participants should be advised to avoid eating 2 hours before training and to empty bowel and bladder before training, when possible, especially for patients with SCI above T6 who are at risk of autonomic dysreflexia. Comfortable clothing and supportive footwear, appropriate

for dynamic exercise, prepare the participant both physically and psychologically for training.

Scheduling of Sessions

Many patients with neurological involvement report a decline in energy levels in the afternoon. If fatigability is a concern, training should be scheduled for morning hours, when circadian body temperature is at its lowest. For certain patient groups, including people with Parkinson disease, training should be coordinated with the timing of medication to optimize performance.

Duration of Program

A meaningful increase in aerobic capacity (i.e., >10% improvement) of individuals without neurological impairment is unlikely to occur in less than 4 weeks.²⁸⁶ The minimal exposure required for people with neurological disabilities has not been fully investigated. The available literature suggests a minimum of 8 weeks of aerobic training is required in patients post-stroke. In an overview of exercise studies, Ivey and colleagues²⁸⁷ noted that program durations ranging from 8 weeks to 6 months elicited improved cardiorespiratory fitness and function in stroke survivors; however, because a plateau in Vo₂peak gains was not achieved at 6 months, program durations longer than 6 months may produce even more benefits. Nonetheless, da Cunha and colleagues⁵² reported a mean improvement of 35% in Vo₂peak after 2 to 3 weeks of treadmill ergometry in people early post-stroke. Regardless of the minimum, participation in training must be sustained indefinitely to prevent return to the deconditioned state measured at the beginning of the program. Therefore a maintenance program should be followed after termination of formal training sessions.

Frequency and Duration of Sessions

To elicit a training effect, three to five sessions of aerobic exercise per week for a minimum of 20 minutes per session are required, although fitness can improve with twice-weekly sessions.²⁸ For those with low fitness levels or who are very deconditioned (which would include the majority of patients with neurological involvement) training may be initiated with 5-minute exercise “bouts” with rest periods between bouts. Two additional 5-minute periods are required for warm-up and cool-down; hence the minimal time required to complete a training session is 30 minutes. Incrementally increasing the duration to a target of 40 to 60 minutes of aerobic training is recommended. However, the greater the intensity of exercise, the shorter the duration needed to achieve improvement in cardiopulmonary fitness; conversely, low-intensity exercise can be compensated for by longer duration.²⁸⁸ In addition, the accumulation of 10- to 15-minute periods of activity throughout the day can yield similar physiological improvements, provided that the total volume of training is comparable.²⁸⁹

Mode of Training

To induce central adaptations, training must incorporate large muscle mass activities that require elevated levels of Vo₂. Treadmill or over-ground walking is a preferred mode because of its task-specific, functional relevance; however, extensive motor disability may preclude this approach. Suitable alternatives include the cycle ergometer with toe clips and heel straps, recumbent ergometer, arm-leg ergometer, wheelchair ergometer, and stepping machine and swimming. Indeed, water-based exercise post-stroke has shown positive effects on cardiovascular fitness and coping with life after stroke.^{195,290,291} Although arm ergometry activates a smaller portion of total muscle mass, its effectiveness in the aerobic training of patients with quadriplegia has been demonstrated.^{160,292}

Innovative approaches have been introduced to overcome limitations to exercise training imposed by upper motor neuron damage. For

example, body-weight-supported treadmill training provides external support while walking to facilitate lower limb advancement while reducing the risk of falls.²⁹³ Robotic-assisted gait training has been shown to improve Vo_2peak ^{294,295} and walking capacity,^{296,297} as well as reduce energy costs of walking.²⁹⁸ A combination of electric stimulation of lower-extremity muscles and voluntary upper-extremity rowing has been applied to augment the muscle activation of patients after SCI.^{160,292,299} Immersive virtual reality has been used to engage people after traumatic brain injury,^{300–302} with Grealy and colleagues²⁹⁸ postulating that interaction between the training apparatus and participant might enhance attention to the task of exercising and increase the potential of structural changes in the brain.

A continuous, interval, or circuit training regimen may be used. Typically, training studies involving patients with neurological disabilities have used short bouts of exercise with a gradual transition to continuous training. However, it has been recommended that if continuous training results in either a lack of improvement or a plateau in response, interval training should be instituted.¹⁵¹

Music, if properly selected, can be helpful in pacing the repetitive, alternating movements characteristic of aerobic exercise such as walking or cycling. With close matching of the cadence of music and alternating movements, music can potentiate muscle activation.³⁰³ For example, McIntosh and colleagues³⁰⁴ reported that music facilitated the gait pattern of people with Parkinson disease.

Muscle Strengthening

Traditionally, aerobic training programs emphasized dynamic exercise. However, the addition of resistance training improves outcome,¹⁵¹ including greater improvements in Vo_2peak , walking endurance, and lipid profile in people with type 2 diabetes.³⁰⁵ Improved fitness outcomes have also been reported in people post-stroke,²⁶⁹ despite controversy about the benefits versus risk of resistance training of the paretic upper limb, particularly in the shoulder region. To offset this concern, a meta-analysis by Harris and Eng³⁰⁶ found no reported adverse affects after upper-limb strength training post-stroke. In addition, in the SCI population, increases not only in fitness level but also decreases in shoulder pain were observed after circuit training involving resistance exercises and arm cranking.³⁰⁷

The order of performing aerobic versus resistance exercise does not appear to affect the extent of gain in exercise capacity.³⁰⁸ Strength training decreases the cardiac demands of daily tasks while simultaneously increasing the endurance capacity to sustain these submaximal activities.³⁰⁹ Muscle strengthening of key muscle groups (e.g., triceps, biceps, abdominals, hip and knee flexors and extensors, hip abductors, ankle dorsiflexors, and plantar flexors) is recommended 2 to 3 days per week, beginning with one set of 8 to 12 repetitions.¹⁵¹

Intensity of Training

Determining an appropriate intensity is the most challenging aspect of exercise prescription. The cardiovascular system responds to overload; hence, the metabolic load must be sufficient to provoke central and peripheral adaptations. However, excessive stress imposed on the heart and contracting skeletal muscles can evoke abnormal clinical signs or symptoms. The initial exercise intensity and progression must be individualized using the participant's HR or Vo_2peak data (Table 29.2). The RPE can serve as a valid proxy to more physiological measures³¹; to initiate training, ratings of 11 (“fairly light”) to 13 (“somewhat hard”) on the RPE scale of 6 to 20 are often recommended with progression to 12–16 on the Borg (6 to 20) category scale or 4–6 on the Borg (0 to 10) scale.²⁸ Despite considerable inter-individual variation in RPE, the ratings have been shown to correlate well with exercise intensity,³¹⁰ even in patients taking β -blockers.³¹¹ When exercise intensity is being

TABLE 29.2 Formulae Used to Determine Threshold Intensity for Exercise Training

Formula	Comments
Karvonen method: $\text{HRrest} + x\%$ of heart rate reserve unfit (HRR), where $\text{HRR} = \text{predicted HRmax}^a - \text{HRrest}$	Training intensities of 40%–85% HRR are recommended, ²⁸ but for patients intensities of 30% HRR can be effective. ³⁶¹
$x\%$ of predicted $\text{HRmax} = 220 - \text{Age}$, where predicted	Deconditioned individuals can benefit from intensities as low as 55%–64% of predicted HRmax . ²⁸
$\text{HRmax} = 220 - \text{Age}$ OR $206.9 - (0.67 \times \text{age})$ ³⁶² ; if on β -blockers, predicted $\text{HRmax} = 164 - 0.7 \times \text{Age}$ ³¹⁹	
$\text{HRrest} + x$ beats	The recommended intensity after myocardial infarction is $\text{HRrest} + 20$ beats and after cardiac surgery is $\text{HRrest} + 30$ beats. ²⁸
$x\%$ of Vo_2peak	Deconditioned individuals can benefit from intensities as low as 40%–50% of Vo_2peak . ²⁸

^a HRmax , Maximal heart rate.

established, other variables (e.g., anginal symptoms, arrhythmias) should also be considered. Continuous monitoring of HR and periodic monitoring of BP and RPE will ensure that an appropriate intensity is sustained during training.

In addition to the RPE, another proxy measure of intensity is the talk test, in which the participant's intensity is regulated by whether he or she can sing (in which case intensity should be increased) or whether he or she is unable to talk (in which case intensity should be decreased). In general, the appropriate training intensity is at or near the ventilatory threshold, which is the point at which a participant can speak comfortably³¹² or hear his or her breath.³¹³ The counting talk test (CTT) was introduced as another proxy measure; it measures how high the participant can count aloud without taking a second breath (e.g., “one, one thousand; two, one thousand...”).³¹⁴ The percentage of resting CTT has been reported to be strongly correlated with the percentage of HR reserve, Vo_2 reserve, and RPE, with moderate intensity coinciding with 50% of CTT.²⁶⁷ Validity of RPE has established in studies of people with MS,³¹⁵ SCI population,³¹⁶ and subacute stroke (at moderate but not high intensities).³¹⁷ However, Bae and colleagues³¹⁸ found that, for people in the chronic poststage period, HR reserve was a better guide of exercise guide than RPE (6 to 20 scale).

The American College of Sports Medicine guidelines recommend light to moderate-intensity physical activities to optimize *cardiopulmonary health*.²⁸⁹ In fact, a meta-analysis revealed that for very unfit patients (which would include many people with chronic neurological conditions), the initial intensity can be much lower than previously recommended.¹⁷⁹ However, the only consistent beneficial cardiovascular response to low levels of training is reduction in BP in older hypertensive adults. To reduce cardiovascular risk factors and increase *cardiopulmonary fitness*, moderate- or high-intensity exercise appears to be necessary.²¹² For people post-stroke, Billinger v¹⁹⁹ recommended intensities of 40% to 70% of Vo_2peak or heart rate reserve (HRR), 50% to 80% of maximal HR, or an RPE (6 to 20 scale) of 11 to 14. The exercise intensity recommendations for people with MS are similar: 40% to 70% of Vo_2peak or HRR, 40% to 60% of HRR, 60% to 80% of maximal

TABLE 29.3 Guidelines for Determining the Initial Intensity of Training of People Post-Stroke

	Low Intensity	Moderate Intensity	High Intensity
Intensity %HRR	Minimum target HR = HRrest + <40% HRR	Minimum target HR = HRrest + 40%–60% HRR	Minimum target HR = HRrest + >60% HRR
Intensity RPE	RPE _{0–10} <4 or RPE _{6–20} <10	E _{0–10} of 4–5 or RPE _{6–20} 11–13	RPE _{0–10} ≥6 or RPE _{6–20} ≥14
Cardiac signs	Mild-moderate abnormalities on ECG ± BP ± HR responses	Borderline abnormalities on ECG ± BP ± HR responses	Normal ECG ± BP ± HR responses
Fitness level	Vo _{2peak} <40% predicted	Vo _{2peak} 40%–60% predicted	Vo _{2peak} >60% predicted
Motor control	Chedoke-McMaster stage of leg: 1 or 2	Chedoke-McMaster stage of leg: 3 or 4	Chedoke-McMaster stage of leg: >4

BP, Blood pressure; ECG, electrocardiogram; HR, heart rate; HRR, heart rate reserve; RPE, rating of perceived exertion.

HR, or an RPE (6 to 20 scale) of 11 to 13.²⁴⁶ For people with CP, Verschuren and colleagues¹⁴⁴ recommended intensities of 50% to 65% of Vo_{2peak}, 40% to 80% of HRR, or 60% to 95% of maximal HR. Nevertheless, light to moderate-intensity physical activity programs may prove adequate to reduce the rate of age-associated deterioration in a variety of physiological functions, and in the long run may improve both quantity and quality of life.^{212,235,263}

For many people with neurological involvement, determination of an appropriate intensity of exercise for the individual person is confounded not only by cardiac status but also by the extent of neurological impairment. We have derived guidelines for determining the initial intensity of treadmill training for people after stroke, based on baseline cardiac signs, prescription of β -adrenergic blockade therapy,³¹⁹ fitness level, and motor control of the involved lower extremity (i.e., Chedoke-McMaster stage of recovery of the leg)³²⁰ (Table 29.3).

There is growing evidence to suggest that high-intensity training may be more effective than moderate or low intensities in increasing aerobic capacity, walking speed, and endurance in individuals post-stroke.^{279,321–326} High-intensity interval training (HIIT, >80% to 85% HRR) has been shown to induce neuroplastic, cardiovascular, and functional improvements in people who are in subacute or chronic stages of stroke.^{322,327} HIIT has the advantage of reducing overall training time, but requires careful screening for orthopedic and cardiovascular conditions, including exercise stress testing.^{322,328} While the optimal parameters of HIIT remain unknown, Boyne and colleagues³¹⁷ outlined three types of HIIT protocols: (1) short-interval, with short high-intensity bursts (15 to 30 seconds at 100% to 120% Vo_{2peak}) and a 1:1 recovery time; (2) low-volume, with small bursts of the highest neuromuscular intensity possible (10 to 30 seconds, up to 60 seconds) followed by a small burst of active recovery (1:4 or 1:12); and (3) long-interval, with high-intensity bursts (3 to 4 minutes at submaximal workload of 80% to 90% Vo_{2peak}) at 1:1 or 4:3 of active recovery.

Progression of Training Program

Exercise progression must be individualized because people with neurological disabilities have a wide range of functional capacities. Progression usually occurs over a 3- to 6-month period from an initial conditioning phase to a training phase and then to a maintenance phase. In general, the first goal of training is to reach a target frequency (i.e., a minimum of 3 days/week), then duration (minimum of 20 minutes), and finally an appropriate intensity (40% to 60% of HR reserve, or 11 to 13 on the Borg scale). Gradual progression of frequency, duration, and intensity is needed in order to minimize muscle soreness, fatigue, and injury. Careful monitoring of BP, HR, and rating of perceived exertion is necessary to assess the participant's response to

increased exercise demands. Subsequently, exercise duration should be increased at tolerated, often in increments of 5 to 10 minutes every 1 to 2 weeks for the first 4 to 6 weeks, with a goal of achieving 20 to 30 minutes of continuous exercise before increasing the intensity.²⁸ Training intensity should be increased by 5% to 10% HRR every 1 to 4 weeks, depending on individual health status, fitness, training responses, and exercise goals. Gradual increases in the percentage of HRR can be achieved by systematically manipulating training parameters such as speed, revolutions per minute, incline, and extent of balance support. Patients with higher baseline fitness levels can be progressed more rapidly than those with lower initial capacities.

Laboratory Outcome Measures

Laboratory tests are useful not only to identify limitations in exercise capacity and establish exercise training protocols but also to evaluate the effectiveness of a training program. The principal indicator of a training effect is attainment of a higher Vo_{2peak} than was achieved in the pretrained state. The greatest increments tend to occur in individuals with the lowest initial Vo_{2peak}.¹⁵⁶ Ideally, Vo_{2peak} should be measured directly because indirect methods of predicting exercise capacity are more variable and prone to error. However, because Vo_{2peak} testing requires special equipment and trained personnel, clinicians often resort to clinical measures of functional capacity.

Clinical Outcome Measures

Six-minute walk test. The distance walked in 6 minutes is sometimes used as a clinical surrogate for Vo_{2peak} testing. However, the systemic response to the 6-Minute Walk Test (6MWT) is less than that of an incremental test using a treadmill cycle³²⁹ or cycle ergometer.^{330,331} Subjects tend to walk at a constant speed, achieve a Vo₂ steady-state condition after the first few minutes of exercise, and, with practice, walk at a pace approaching critical power.^{328,332} Pang and colleagues³³³ found a low correlation ($r = 0.40$) between 6MWT distance and Vo₂ in patients after stroke, concluding that the 6MWT alone should not be used as an indication of cardiopulmonary fitness after stroke. The same laboratory recommended that, to enhance the usefulness of the 6MWT, BP and HR should be recorded at initiation and termination of the test.³³⁴ Various reference equations are available to compute the percent of predicted total distance walked in the 6MWT. For example, for men, Distance (m) = (7.57 × Height [cm]) – (5.02 × Age [years]) – (1.76 × Weight [kg]) – 309; for women, Distance (m) = (2.11 × Height [cm]) – (5.78 × Age [years]) – (2.29 × Weight [kg]) + 667.³³⁵

Shuttle walk test. The shuttle walk test is a standardized incremental test during which walking is initiated at an audio-guided set

pace for a prescribed length of time.³³⁶ Walking speed is increased at each stage until the subject can no longer maintain the required pace. Peak systemic responses have been reported to be consistent with those achieved during a progressive cycle test.³³¹ A variation of this test, the endurance shuttle walk test, involves walking as far as possible at a constant speed determined in a previously performed progressive walk test.³³⁷

Adherence to Program

The benefits of training are lost unless exposure to some form of training stimulus is maintained; therefore sustained behavioral change must be an important goal in any exercise program. A decrease in mobility or inactivity can lead to rapid loss of cardiovascular and pulmonary fitness. For example, a 25% reduction in maximum oxygen uptake has been observed in nondisabled young adults after 3 weeks of bed rest.⁹⁶ In secondary prevention of stroke, behavioral modifications may be as beneficial as antihypertensive and cholesterol-lowering agents.⁸⁰ Yet establishing and maintaining a regular fitness regimen in patients with neurological impairments pose challenges. In one study, 39% of 691 patients did not engage in the exercise program created by their physical therapist.³³⁸ In addition, a majority of people post-stroke surveyed reported that they were not ready to incorporate exercise into their lifestyle.^{213,339}

Some individuals are reluctant to engage in exercise owing to the fear of increasing their symptoms. Indeed, people with Parkinson disease avoid exercise out of fear they will increase their already high levels of fatigue.³⁴⁰ Similarly, people with MS avoid exercising to avert increases in their level of fatigue and body temperature.⁹² Furthermore, the frequency of MS-related symptoms has been found to be significantly and inversely related to physical activity.³⁴¹ It has been shown that less than 30% of 2995 people with MS reported engaging in any form of exercise,²⁵⁷ with one study revealing an overall adherence rate of 65%.³⁴² Morris and Williams³⁴³ reported that many individual factors (e.g., sex, level of disability), social factors, and environmental factors (e.g., access to facilities, travel) influence the level of engagement in exercise and physical activity in people with mixed disabilities. In addition, numerous psychological, cognitive, and emotional factors have been identified as potential mediators of engagement in physical activity (e.g., self-efficacy, attitude, competence, intention, knowledge of health and exercise benefits, motivation, readiness to change, and the value of exercise benefits).³⁴⁴

The role that self-efficacy (i.e., confidence in ability to execute a task) plays as a psychological predictor of level of engagement in physical activity and exercise has become a topic of growing interest, particularly in the stroke literature.^{345–347} French and colleagues³⁴⁸ demonstrated that self-efficacy after stroke mediates the relationships between performance-based measures of walking and real-world walking and participation. Interventions to enhance self-efficacy and participation include counseling and information,^{349–351} behavioral change techniques (e.g., goal setting, barrier identification, self-monitoring),³⁴⁷ self-management programs,^{352,353} social support and education,³⁵⁴ and motivational counseling through videotapes.³⁵⁵ Snook and colleagues³⁴¹ reported that self-efficacy was significantly and moderately correlated with physical activity in people with MS.

A better understanding of theoretical frameworks of behavior change (see overviews^{28,356}) would be helpful for neurorehabilitation clinicians to increase participant engagement. Garner and Page³³⁹ exposed community-based, chronic stroke survivors to a theoretically based intervention using the transtheoretical model with five stages of change (i.e., precontemplation, contemplation, preparation, action, and maintenance). In another stroke study a score of readiness to

change behavior based on the transtheoretical model was used to assess in patients undergoing secondary stroke prevention.³⁵⁷ The authors found that the prevention program, which consisted of conventional rehabilitation plus additional advice, motivational interviewing, and telephone support, improved exercise frequency, and increased consumption of fruits and vegetables when compared with the control group receiving conventional rehabilitation.³⁵⁷ Several other behavioral theories (i.e., social cognitive theory, theory of reasoned action, theory of planned behavior, health belief model, protection motivation theory, and self-determination theory) may also be useful in facilitating long-term engagement.³⁵⁸ The American College of Sports Medicine²⁸ acknowledged that assessing the participants' self-motivation and readiness for change can provide important information toward adapting the exercise program to meet the specific needs of the participants.

In the cardiac rehabilitation literature, Piepoli and colleagues³⁵⁹ recommended that in order for an individual to pursue and engage in an exercise program, both physiological and psychosocial changes are needed. Progression from promotion of physical activity within the patient's current domestic, occupational, and leisure settings to participating in vigorous and structured exercise programs is recommended.³⁵⁹ In a literature review of cardiac rehabilitation, evidence supported the use of educational sessions, spousal and family involvement, flexible and convenient scheduling of sessions, ongoing positive reinforcement and enjoyment (e.g., motivational letters, pamphlets, conversations), and self-management aids (e.g., self-report diaries, activity logs, individualized goal setting).³⁶⁰ Other strategies to enhance long-term exercise adherence include gradually progressing the exercise intensity, establishing regularity of training sessions, minimizing the risk of muscular soreness, and exercising in groups. Training sessions should be scheduled at a convenient time and in an accessible location, and if feasible, assistance with transportation and childcare should be offered. With the established emphasis on patient-centered care, it is consistent to have the patient identify individual goals and time frames to achieve these goals. Incorporating physical activity within everyday life will help promote cardiovascular and pulmonary fitness as a life activity and not solely an exercise program conducted within a medical environment or rehabilitation setting.

Aerobic training alone is not sufficient to optimize the health and fitness of people with neurological disabilities. Education and counseling regarding daily physical activity, nutrition, energy conservation techniques, smoking cessation, and coping strategies are essential.

CONCLUSION

Several conclusions can be made based on available evidence. Neuro-muscular, cardiovascular, and pulmonary impairments associated with most neurological conditions interact with contextual factors and the health condition itself to adversely affect exercise capacity and cardiovascular fitness. Aerobic training is now unequivocally regarded as an effective intervention to reduce the functional decline associated with the deconditioned state. Research, albeit limited, suggests that although patients with neurological impairments generally manifest poor cardiopulmonary fitness, they have the capacity to respond to exercise training in essentially the same manner as individuals without impairments. Trainability is evidenced by their ability to increase exercise capacity or VO_{2peak} in response to the metabolic stress imposed by aerobic exercise. Although not abundant, research findings also suggest that involvement in aerobic exercise can also improve walking capacity and reduce risk factors for secondary complications. On the basis of the positive results of training studies, more aggressive training

programs are now being introduced into neurorehabilitation, with the goals of interrupting the cycle of debilitation and enhancing neurological recovery. There is an obvious need for further, properly controlled research to examine the impact of aerobic training on all domains of function and quality of life, of neurological populations. Also, a more personalized approach to both screening and prescription protocols for aerobic training needs to be developed to optimize safety, effectiveness, and resource allocation. Patients with neurological insults clearly have compounding system variables that interact when they try to perform any movement. A clinician who is assisting individuals to regain functional control over movement to improve

their quality of life cannot afford to ignore the cardiovascular and pulmonary system regardless of the medical diagnosis.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 362 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abbreviations Commonly Used When Discussing Cardiovascular and Pulmonary Problems and Their Effect on Function

6MWT: 6-Minute Walk Test

ADL: activities of daily living

a-vO₂diff: arteriovenous oxygen difference

a-vO₂diffmax: maximal arteriovenous oxygen difference

BP: blood pressure

CAD: coronary artery disease

CO₂: carbon dioxide

CP: cerebral palsy

DBP: diastolic blood pressure

ECG: electrocardiogram

H⁺: hydrogen ion

HR: heart rate

HRmax: maximal heart rate

HRpeak: peak heart rate

HRR: heart rate reserve

HRrest: resting heart rate

ICF: International Classification of Functioning, Disability and Health

MET: metabolic equivalent

O₂: oxygen

Q: cardiac output

Qmax: maximal cardiac output

RER: respiratory exchange ratio

RERpeak: peak respiratory exchange ratio

RPE: rate of perceived exertion

SPB: systolic blood pressure

SV: stroke volume

SVmax: maximal stroke volume

VCO₂: carbon dioxide production per minute

Vo₂: oxygen consumption per minute

Vo₂max: maximal oxygen consumption per minute

Vo₂peak: peak oxygen consumption per minute

Abstract: This chapter provides an overview of basic physiological principles related to cardiovascular responses to exercise testing, much of the evidence for which was derived several decades ago. A summary of the evidence of cardiopulmonary fitness levels in adults and children with neurological disabilities is followed by a description of factors that contribute to the deconditioned state. Possible mechanisms responsible for reduced exercise capacity are then reviewed. Adaptive

responses to aerobic training in patients with neurological conditions are examined, as are factors underlying these responses. The chapter closes with a summary of guidelines for the design of exercise programs that can be used to improve cardiopulmonary health and fitness.

Keywords: aerobic training, cardiovascular fitness, deconditioning, exercise tolerance, rating of perceived exertion

Pain Management

Annie Burke-Doe

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Understand the definition of pain
2. Describe the pain pathways.
3. Describe how pain is modulated within the nervous system.
4. Identify the causes of acute and chronic pain.
5. List the signs and symptoms of central nervous system, autonomic nervous system, and peripheral pain and give an example of each.
6. Perform a comprehensive pain evaluation, including taking a pain history, measuring pain intensity, measuring pain character, and examining the patient.
7. Design a comprehensive pain management program that addresses the objective and subjective aspects of the pain experience.

KEY TERMS

ANS pain: complex regional pain syndrome
acute pain

behavioral manipulations: exercise,
operant conditioning, hypnosis,
biofeedback

chronic pain

CNS pain: thalamic pain

cognitive strategies: relaxation exercises,
body scanning, humor

nociceptor

pain intensity measurements: visual analog
scale (VAS), simple descriptive pain scale
(SDPS), pain estimate, faces pain scale

pain localization tools: pain drawing

pain modulation: gate control theory,
neurotransmitters, neuromodulators
pain pathway

pain quality measurements: McGill Pain
Questionnaire (MPQ), pediatric verbal
descriptor scale, caregiver checklists
point stimulation

More than 25 million adults suffer daily from pain; over 10 million report high levels of pain most days, and 8 million have pain severe enough to interfere with their lives.¹ Acute and chronic pain have a profound impact on all aspects of an individual's life. Pain influences relationships with family members, friends, co-workers, and health care providers. It affects the ability to fulfill responsibilities, to work, and to participate in social activities. Perhaps more than any other factor, the presence of chronic pain and the response to it determine the overall quality of an individual's life.

Acute pain is one of the most common reasons for patients to seek treatment at an emergency department.^{2,3} Acute pain is defined as "pain of recent onset and probable limited duration." It usually has an "identifiable temporal and causal relationship to injury or disease."⁴ Mounting evidence that tissue injury often results in changes to nervous system function has provided a new understanding of mechanisms that explain how acute pain can often lead to chronic pain.^{5,6} The Centers for Disease Control and Prevention (CDC) estimate that chronic pain affects approximately 50 million US adults, and high-impact chronic pain (i.e., interfering with work or life most days or every day) affects approximately 20 million US adults.⁷ Higher prevalence of both chronic pain and high-impact chronic pain are reported among women, older adults, previously not currently employed adults, adults living in poverty, adults with public health insurance, and rural residents.⁷

Studies of pain medicine education in medical and health care curriculums show that many medical schools have gaps between recommended pain curricula and documented educational content.^{2,8} Additionally, pain education in medical schools internationally did not adequately respond to societal needs in terms of the prevalence and

public impact of inadequately managed pain.⁹ The result is inadequate or inappropriate care of individuals who report having pain.

The use of the biopsychosocial model of pain treatment as a framework for understanding the relationship among biological (e.g., disease-specific, neurological, immunological, genetic), psychological (e.g., mood/affect, cognition, resilience), and social (e.g., discrimination, cultural influences, social support) mechanisms has been identified as the model of choice to determine the variability in the experience of pain for both populations and individuals.¹⁰ In terms of application of the biopsychosocial model of pain treatment, the clinician must understand that chronic pain is a biopsychosocial condition that often requires integrated, multimodal, and interdisciplinary treatment, all components of which should be evidence-based.¹¹

The World Health Organization's International Classification of Functioning, Disability and Health (ICF) considers determinants of health and disability from the perspective of the biopsychosocial model.¹² The ICF model is utilized in the management of pain and includes^{13–17} impairments (problems with body structure or function), activities (the execution of a task or action by an individual), activity limitations (difficulties an individual may have in executing activities), participation (involvement in a life situation), and participation restrictions (problems experienced in life situation or social role involvement). The ability to identify appropriate rehabilitation approaches to improve activity and participation depends on the clinician's ability to identify different impairments that cause pain, or the resulting impairments and activity and participation problems caused by pain through validated performance-based measures.

This chapter deals with the complex issue of acute and chronic pain management. In the first section, an overview of the anatomy and physiology of pain is presented. In the second section, examination and evaluation of pain are explained. In the third section, a number of treatment interventions are suggested. Finally, case studies are presented to guide clinicians through the problem-solving process for designing pain management programs.

DEFINING PAIN

The International Association for the Study of Pain (IASP) defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in such terms as damage.”¹⁸ The primary purpose of pain is to protect the body. It occurs whenever there is tissue damage, and it causes the individual to react to remove the painful stimulus. Pain is also a sensation with more than one dimension. To the individual, pain is both an objective and a subjective experience. The objective dimension is the physiological tissue damage causing the pain. The subjective dimensions include the following¹⁹:

- A perceptual component: the patient’s awareness of the location, quality, intensity, and duration of the pain stimulus
- An affective component: the psychological factors surrounding the patient’s pain experience, including the patient’s personality and emotional state
- A cognitive component: what the patient knows and believes about the pain resulting from his or her cultural background and past pain experiences (both personal pain experiences and those of others)
- A behavioral component: how the patient expresses the pain to others through communication and behavior

All these components taken together constitute the patient’s pain experience. Thus all must be addressed for a successful pain management program. When the subjective components of the pain experience are ignored, it is entirely possible that the patient’s underlying tissue damage may be corrected without her or his pain perception being cured.

In addition, recognizing that pain is more than simply a physical injury or disease process helps clinicians explain some of the inconsistencies observed in patients with chronic pain. Why is a patient’s pain report out of proportion to the magnitude and duration of the injury? Why is pain intolerable to one person and merely uncomfortable to another? And why is pain tolerable in one instance but overwhelming to the same individual when experienced at a different time?

The answers lie in the interconnectedness of the nervous system and the fact that pain transmission involves several higher centers. To select the most appropriate intervention, it is important for clinicians to have at least a general idea of the pain pathways. An overview of pain anatomy and physiology is discussed next.

PAIN ANATOMY

Pain arises from the stimulation of specialized peripheral free nerve endings called *nociceptors*. Injurious stimulation to the skin, muscle,

joint, viscera, or tissue can trigger these peripheral terminals, whose cell bodies are in the dorsal root ganglia and trigeminal ganglia. The density of nociceptors varies between as well as within these tissues. Nociceptors are extremely heterogeneous, differing in the neurotransmitters they contain, the receptors and ion channels they express, their speed of conduction, their response properties to noxious stimuli, and their capacity to be sensitized during inflammation, injury, and disease.²⁰

Nociceptors found in interstitial tissues become excited with extreme mechanical, thermal, and chemical stimulation,²¹ whereas nociceptors found in vessel walls become excited with these stimuli plus marked constriction and dilation of the vessels.²² These receptors respond directly to some noxious stimuli and indirectly to others by means of one or more chemicals (histamine, potassium, bradykinin) released from cells in the traumatized tissues.²³

Thermal nociceptors are triggered by intense hot or cold temperatures ($>45^{\circ}\text{C}$ or $<5^{\circ}\text{C}$). They have fibers that are of small diameter and thinly myelinated with moderately fast conduction signals of 5 to 30 m/s. Mechanical nociceptors are triggered by intense pressures applied to the skin, such as a pinch. They also have thinly myelinated, moderately conducting fibers with speeds of 5 to 30 m/s.

Polymodal nociceptors are triggered by more than one sensory modality (mechanical, chemical, or thermal). These nociceptors have small-diameter, nonmyelinated fibers that conduct more slowly, generally at velocities less than 1.0 m/s (see Table 30.1). Stimulation of these receptors causes sensations of diffuse burning or aching pain. The difference in the fibers’ size and myelination determines the speed at which impulses will travel to the brain.

These three types of nociceptors are broadly distributed in the skin and tissues and may work together. One example would be hitting one’s shin against a table: a sharp “first pain” is felt immediately, followed later by a more prolonged aching, sometimes burning, “second pain.”²³ The fast, sharp pain is transmitted by A delta fibers that carry information from thermal and mechanical nociceptors. The slow, dull pain is transmitted by C fibers that are activated by polymodal nociceptors.

Nociceptive input travels on A delta and C fibers into the dorsal horn of the spinal cord, where the gray matter is laminated and organized by cytological features. The first-order A delta and C fibers synapse with second-order neurons in lamina I (marginal layer), II (the substantia gelatinosa [SG]), and V. The second-order neurons do one of three things. A small number synapse with motor neurons, causing reflex movements (e.g., withdrawing the hand from a hot object). Others synapse with autonomic fibers, causing responses such as changes in heart rate and blood pressure and localized vasodilation, piloerection, and sweating. Most, however, travel a multisynaptic route to the higher centers by means of the ascending tracts.^{21,24}

There are four major classes of neurons²⁵ responding to pain in the dorsal horn: low-threshold nociceptive-specific neurons designated class I; wide dynamic range (WDR) neurons designated class II; high-threshold nociceptive neurons designated class III; and a fourth, non-responder group of neurons that develop spontaneous activity with exposure to

TABLE 30.1 Nociceptors

Receptor Type	Stimulus to Fire	Diameter/Myelination	Speed
Thermal nociceptors	Intense hot or cold temperatures ($>45^{\circ}\text{C}$ or $<5^{\circ}\text{C}$)	Small diameter and thinly myelinated	Moderately fast conduction signals of 5 to 30 m/s
Mechanical nociceptors	Intense pressures applied to the skin, such as a pinch	Small diameter and thinly myelinated	Moderately conducting fibers with speeds of 5 to 30 m/s
Polymodal nociceptors	More than one sensory modality (mechanical, chemical, or thermal)	Small-diameter, nonmyelinated fibers	Conduct more slowly, generally at velocities less than 1.0 m/s
			Diffuse burning or aching pain

endogenous inflammatory cytokines, designated class IV. Nociceptive-specific neurons are most abundant in superficial lamina; their receptor fields are discrete and vary from one to several square centimeters.²⁶ WDR neurons, in contrast, respond to a wide range of stimuli from A delta, A beta, and C fibers in a graded manner (i.e., the rate of firing escalates with increasing intensity of stimulation), can be found in all lamina, and are the most prevalent cells in the dorsal horn.²⁶ Because of their unique response to innocuous or nociceptive input, as well as their larger receptor field, WDR neurons play an important role in the central sensitization and the plasticity of the spinal cord.²⁶

Nociceptive input crosses at the cord level to the anterolateral quadrant of the ascending contralateral spinothalamic tract (Fig. 30.1). The axons of the anterolateral quadrant are arranged so that the sacral segments are most lateral, with the lumbar segments more medial and the cervical segments most central. This arrangement may be important clinically in that symptoms may be provoked according to dermatomal maps to some degree.²⁷ Pain dermatomes overlap to several adjacent dorsal roots, so boundaries can be less distinct, requiring the clinician to distinguish the pain and dysfunction.

The anterolateral tract is divided into three ascending pathways: the spinothalamic, spinoreticular, and spinomesencephalic. The spinothalamic tract conveys information about painful and thermal stimulation (location and intensity) directly to the ventral posterior lateral nucleus of the thalamus, as well as sending collaterals off at the brain stem to join the spinoreticular tract. Axons within the spinoreticular tract synapse on neurons of the reticular formation of the medulla and pons, which relay information to the intralaminar and posterior nuclei of the thalamus and to other structures in the diencephalon, such as the hypothalamus (emotional response to pain).

Axons in the spinomesencephalic tract relay information to the mesencephalic reticular formation and periaqueductal gray matter by way of the spinoparabrachial tract. It then projects to the limbic system, which is involved with the affective component of pain (central modulation of pain).

The thalamus processes and relays information to several higher centers.²² Each projection serves a specific purpose. Axons of the spinothalamic tract project information to both the lateral and medial nuclear groups of the thalamus. The lateral nuclear group of the thalamus is where information about the location of an injury is thought to be mediated.²³ Injury to the spinothalamic tract and the lateral nuclear group of the thalamus causes central neuropathic pain, which is discussed in further detail later.

Projections from the spinoreticular tract to the medial nuclear group of the thalamus are concerned with processing information about nociception, and they also activate nonspecific arousal systems. These pathways project from the thalamus to the basal ganglia and many cortical areas.

Projections to the postcentral gyrus (sensory cortex) are responsible for pain perception. It is from this projection that pain can be localized and characterized. Projections from the thalamus to the frontal lobes and limbic system are concerned with pain interpretation. It is from all these projections that an individual perceives pain as hurting. Projections from the thalamus, as well as from the limbic system and sensory cortical areas, to the temporal lobes are responsible for pain memory; and projections from the thalamus to the hypothalamus are responsible for the autonomic response to pain.

PAIN TRANSMISSION

Ascending transmission of pain impulses is mediated by the action of the chemical excitatory neurotransmitter glutamate (A delta and C fibers) and tachykinins such as substance P (C fibers). Glutamate and neuropeptides have distinct actions on postsynaptic neurons, but they act together to regulate the firing properties postsynaptically.²³

Tachykinins' activity is thought to prolong the action of glutamate, as levels are increased in persistent pain conditions.²⁶ The substrates of nociception that exist at the spinal level are complex in that more than 30 different neurotransmitters acting on more than 50 different receptors have been identified in the spinal cord and associated with some pain-related phenomenon.²⁸ Modulation of these substrates will assist in the effectiveness of therapeutic interventions and will be discussed next.

PAIN MODULATION

Nociceptive transmission is modulated at several points along the neural pathway by both ascending and descending systems.

The Gate Control Theory

The SG contains an ascending gating mechanism to block nociceptive impulses from leaving the dorsal horn of the spinal cord. The first-order neurons for both nociceptive and non-nociceptive information synapse with second-order neurons in the SG. The second-order neurons for both types of information project to specialized neurons named *T-cells* (transmission cells) in lamina V. For pain transmission to occur, T-cells must be stimulated while the SG is inhibited. The input from A delta and C fibers stimulates the T-cells and inhibits the SG (Fig. 30.2). Therefore A delta and C fiber input opens the gate, allowing pain transmission to the higher centers. On the other hand, when the SG and T-cells are both stimulated, the T-cells are inhibited, and the gate is closed to pain transmission. The input from non-nociceptive A beta fibers carrying information from pressure receptors and mechanoreceptors stimulates both the T-cells and the SG. Therefore A beta fiber input closes the gate, blocking pain transmission.²⁷

One example that illustrates the gate control theory is the use of transcutaneous electrical nerve stimulation (TENS) in an area that overlaps the injury. It works to reduce pain by activation of large-diameter A beta fibers that “close the gate,” thereby preventing pain transmission to the higher centers of the brain. This is also why shaking (vibrating) your hand after hitting your thumb with a hammer temporarily relieves pain.

Descending Pain Modulation System

There are at least two descending pain modulation systems. One involves the action of neurotransmitters, including serotonin, dopamine, norepinephrine, and substance P. High concentrations of brain serotonin and L-dopa (a precursor of dopamine)²⁹ have been found to inhibit nociception, whereas norepinephrine appears to enhance nociception.^{30–33} The spinal mediators of descending nociceptive inhibitory influences include serotonin, norepinephrine, and acetylcholine (ACh). This may be relevant to the action of antidepressants in relieving pain in the absence of depression. Substance P is thought to be the neurotransmitter for neurons transmitting chronic pain.³⁴

The second descending modulating system is mediated by neuromodulators—chemicals capable of directly affecting pain transmission. The neuromodulators include enkephalin and β -endorphin, which are referred to as *endogenous opiates* because they have morphine-like actions and are found in areas of the central nervous system (CNS) that correspond to opiate-binding sites. Endogenous opiates are believed to modulate pain by inhibiting the release of substance P. They have been shown to have a profound effect on nociception and mood.^{35–37} Their levels in the brain and spinal cord rise in response to emotional stress, causing an increase in the pain threshold and providing a possible reason that acute stress decreases acute pain.^{38,39}

Although serotonin is not classified as an endogenous opiate, it exerts a profound effect on analgesia and enhances analgesic drug potency. High concentrations of serotonin lead to decreased pain by inhibiting transmission of nociceptive information within the dorsal

Fig. 30.1 Pain Pathway. (From Gould BE. *Pathophysiology for the Health Professions*. 2nd ed. Philadelphia: WB Saunders; 2002.)

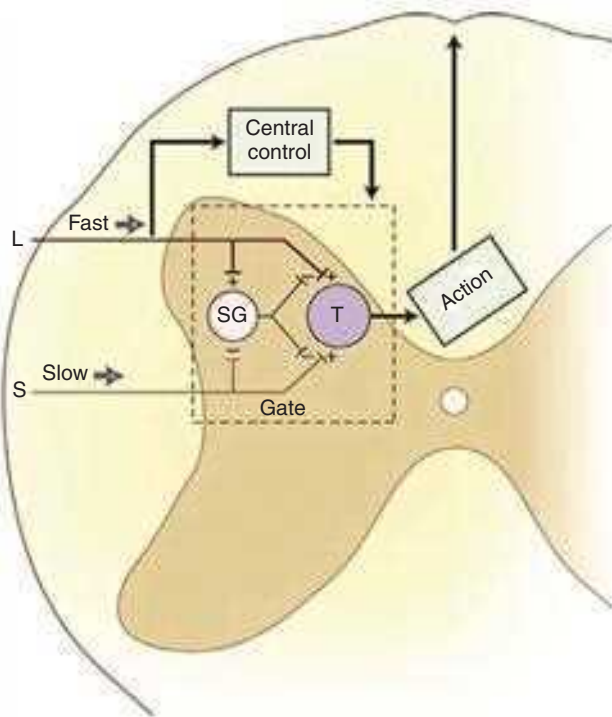

Fig. 30.2 Schematic Representation of Spinal Structures Involved in the Gate Control Theory of Pain Transmission. Afferent input by means of both large- and small-diameter fibers is theorized to influence the transmission cell (*T*) directly and through small internuncial neurons located within the substantia gelatinosa (*SG*). (From Nolan MF. Anatomic and physiologic organization of neural structures involved in pain transmission, modulation, and perception. In: Echternach JL, ed. *Pain*. New York: Churchill Livingstone.)

horn,^{40,41} whereas low concentrations result in depression, sleep disturbances, and increased pain.

The success of several therapeutic modalities, including noxious counterirritation (e.g., brief intense TENS or acupressure) and diversion (including hypnosis), is attributed to raising the level of endogenous opiates in the body.³⁹

CATEGORIZING PAIN

Pain is grouped into several categories: acute, chronic, referred, central neuropathic, autonomic, and peripheral.

Acute pain is the normal predicted physiological response and serves as a warning. It alerts the individual that tissues are exposed to damaging or potentially damaging noxious stimuli. Acute pain is localized, occurs in proportion to the intensity of the stimuli, and lasts only as long as the stimuli or the tissue damage exists (1 to 6 months).⁴² Although acute pain is associated with anxiety and increased autonomic activity (increased muscle tone, heart rate, and blood pressure),⁴³ it is usually relieved by interventions directed at correcting the injury. The pain experience is usually limited to the individual.⁴⁴

Chronic pain is usually referred to as *intractable pain* if it persists for 6 or more months. It is defined as pain that continues after the stimulus has been removed or the tissue damage heals. Physiologically, chronic pain is believed to result from hypersensitization of the pain receptors and enlargement of the receptor field in response to the localized inflammation that follows tissue damage.⁴⁵ Chronic pain is poorly localized, has an ill-defined time of onset, and is strongly associated with the subjective components outlined previously. It does not respond well to

interventions directed solely at correcting the injury. Chronic pain patients frequently report other symptoms, such as depression, difficulty sleeping, poor mental and physical function, and fatigue. The effects of the pain experience extend beyond the individual and affect the family, the workplace, and the social sphere of the individual.⁴⁴

Referred pain is felt at a point other than its origin. Pain can be referred from an internal organ, a joint, a trigger point, or a peripheral nerve to a remote musculoskeletal structure. Referred pain usually follows a specific pattern. For example, cardiac pain is frequently referred to the left arm or jaw; the referral pattern for trigger points is exact enough to be used as a diagnostic tool and is often used by physicians to diagnose pathology. Referred pain is the result of a convergence of the primary afferent neurons from deep structures and muscles to secondary neurons that also have a cutaneous receptive field.^{46,47}

Although it is now recognized that all neuropathic pain results in abnormal activity within the CNS,⁴⁸ pain initiated or caused by a primary lesion or dysfunction of the CNS⁴⁹ is referred to as *central neuropathic pain*. The involvement of the nervous system can be at many levels: nerves, nerve roots, and central pain pathways in the spinal cord and brain. In this circumstance, there is permanent damage to the nervous system (usually a peripheral nerve) and likely anatomical reorganization of spinal terminations of surviving axons or ectopic activity from a neuroma that contributes paroxysmal, persistent input to the spinal cord.⁵⁰ In addition to anatomical reorganization in the spinal cord, there could be some reorganization in the rostroventral medulla (RVM) as well, but more likely there is prolonged input to the RVM that sustains facilitatory influences that descend to the spinal cord. Less appreciated, descending facilitatory influences on spinal sensory processing could also be important to maintenance of chronic pain conditions, particularly those that persist in the absence of obvious tissue pathology.⁵⁰

Central neuropathic pain is medically diagnosed by its defining neurological signs and symptoms; it is verified with neuroimaging tests that identify a CNS lesion and rule out other causes. It is important that the therapist be able to localize the level and differentiate between central and peripheral pain. Central neuropathic pain can be caused by vascular insult; traumatic, neoplastic, and demyelinating diseases; and surgery (including vascular compromise during surgery). Central neuropathic pain is distinct from nociceptive pain (nonneuronal tissue damage).

The onset of central neuropathic pain is usually delayed after the occurrence of the initial episode that results in damage to the CNS; onset of pain may occur during the phase of recovery from neurological deficits.⁵¹ Pain originating from a cerebrovascular incident and spinal cord injury usually begins weeks or months after the insult, whereas pain originating from tumors may take years to begin.⁴⁸

Individuals with central neuropathic pain may have difficulty describing their pain and report burning, aching, pricking, squeezing, or cutting pain after cutaneous stimulation, movement, heat, cold, or vibration. A normally non-noxious stimulus, such as moving clothing across skin, becomes agonizing. In some cases, pain begins spontaneously.⁵² Pain intensity varies, but it does seem to be associated to some degree with the location of the lesion.⁴⁸ Allodynia (pain from normally non-noxious stimuli) and dysesthesia are common, and one of the characteristic features of central neuropathic pain is that the clinical symptoms persist long after the stimulus has been removed.

Central neuropathic pain is topographical. The site of the lesion determines the location of the symptoms. The pain may involve half the body, an entire extremity, or a small portion of one extremity.⁴⁸ It is frequently migratory. Thalamic pain is the classic example of central neuropathic pain.

Central neuropathic pain is difficult to treat. Surgery is not helpful for most individuals with central neuropathic pain, and medications have not been effective in permanently relieving the symptoms.²¹

Therefore the treatment of patients with central neuropathic pain stresses coping strategies and prevention of loss of activity and participation. The ideal management of a chronic pain patient is by a multidisciplinary approach, including disciplines such as internal medicine, neurology, anesthesia, nursing, psychology, pharmacy, rehabilitation medicine, physical therapy, occupational therapy, and others. The limitation of this approach is that access to such a wide range of specialists is often available only at large medical centers and special pain clinics, which restricts access to a limited number of patients.

Under normal conditions there is a fine balance between the parasympathetic and sympathetic branches of the autonomic nervous system (ANS). Parasympathetic activity maintains homeostasis, whereas sympathetic activity functions to make “fight-or-flight” changes in response to stress. Stimulation of the autonomic efferent fibers is not normally painful. However, the balance between afferent input and the descending sympathetic nervous system (SNS) is disrupted when there is injury, resulting in exaggerated and prolonged sympathetic activity, allodynia, and hyperalgesia (increased response to normally painful stimuli)—hence, autonomic pain.

Allodynia is a product of the phenomenon of central sensitization.⁵³ After injury, new axons sprout from the sympathetic efferent neurons. These fire spontaneously and, because they synapse on the cell bodies of the primary afferent neurons, cause them to fire as well. In addition, the dorsal horn neurons themselves become more excitable. They show an enlargement in their receptive field and become more sensitive to mechanical, thermal, and chemical stimulation. The result is an increase in the neuronal barrage into the CNS and the perception of pain with usually nonpainful stimuli.²³

Complex regional pain syndrome (CRPS) is an example of pain that arises from abnormal activity within the ANS.⁵⁴ CRPS has been classified into two distinct types⁴⁹: CRPS type I (formerly *reflex sympathetic dystrophy*) follows mild trauma without nerve injury, and CRPS type II (formerly *causalgia*) follows trauma with nerve injury. CRPS type I generally begins within the month after the injury, whereas CRPS type II can occur any time after the injury.⁵⁵

The main features of CRPS type I are constant burning pain that fluctuates in intensity and increases with movement, constant stimulation, or stress. There are also allodynia and hyperalgesia, edema, abnormal sweating, abnormal blood flow and trophic changes in the area of pain, and impaired motor function. CRPS type I is relieved by blocking the SNS, indicating that the pain is sympathetically maintained.⁵⁵

CRPS type II occurs in the region of a limb innervated by an injured nerve. The nerves most commonly involved in CRPS type II are the median, sciatic, tibial, and ulnar; involvement of the radial nerve is rare. Pain is described as spontaneous, constant, and burning and is exacerbated by light touch, stress, temperature change, movement, visual and auditory stimuli, and emotional disturbances. Allodynia and hyperalgesia are common and may involve the distribution of more than one peripheral nerve. As with CRPS type I, edema, abnormal sweating, abnormal blood flow, trophic changes, and impaired motor function occur. The symptoms spread proximally and can involve other areas of the body. Evidence also points to sympathetic involvement in CRPS type II.⁵⁵

The treatment of CRPS is complex and must be carefully coordinated among members of an interdisciplinary team including the neurologist (medications), psychologist (behavior), anesthesiologist (injections), and therapist (functional recovery). The therapist provides the core treatment to improve function. Therapists need to pay close attention to the following aspects of the disorder: (1) the degree of motor abnormalities, including restricted active range of motion (ROM), abnormal posturing, spasm, tremor, and dystonia; (2) true passive range restriction; (3) hyperesthesia and allodynia; (4) swelling and vasomotor changes; and (5) evidence of osteoporosis by radiograph.⁵⁶ Please refer to Case Study 30.1 for interventions for patients with CRPS.

Peripheral pain results from noxious irritation of the nociceptors. The character of peripheral pain depends on the location and intensity of the noxious stimulation, as well as which fibers carry the information into the dorsal gray matter. As noted previously, information carried on A delta fibers is sharp and well localized, begins rapidly, and lasts only if the stimulus is present, whereas information carried on C fibers is dull and diffuse, has a delayed onset, and lasts longer than the duration of the stimulus. The treatment of peripheral pain is covered in detail in Chapter 16.

The management of central versus peripheral pain is determined by the type of pain—acute or chronic—and the clinical features present, including clinical localization; time of onset; laboratory study localization; response to analgesics, including narcotics; response to antidepressants; and response to nerve block or neurectomy.⁵¹ Differentiation among features will drive the treatment plan, but because some peripheral and central forms can coexist, diagnosis may be difficult.

The multidimensional aspects of chronic pain make it important to evaluate the causes as well as the emotional and cognitive sequelae.⁵⁷ Persistent pain is now considered to have a psychogenic component.⁵⁸ The longer an individual has pain, the more a psychological component may become dominant. Many emotional factors can strongly influence pain, such as pain thresholds, past experiences with pain, coping styles, and social roles. The emotional experience that we perceive with pain reflects the interaction of higher brain centers and subcortical regions, such as the amygdala and cingulate gyrus (limbic system).⁵⁹ Positron emission tomography of patients with chronic neuropathic pain demonstrates a shift of acute pain activity in the sensory cortex to regions such as the anterior cingulate gyrus.⁶⁰ Understanding the physical limitations imposed by chronic pain is an area that therapists commonly assess; it is the mind-body connection that is often less articulated by the patient and more difficult for the practitioner.

Treatment of chronic pain should include a patient-centered approach, given the unique manifestations that occur in an individual's response to pain. Patient-centered models, such as the biopsychosocial and ICF model, provide a framework that embraces a multidisciplinary team approach practiced in pain clinics. In such models, chronic pain has been noted to include psychological factors such as feelings of fear, anxiety, and depression,⁶¹ which are known to have the ability to modulate and exacerbate the physical pain experience.⁶² For example, a patient with chronic pain who has the fear that movement will increase pain may alter his activity, causing muscular shortening, spasms, and a spiraling course of more pain and disability. The focus in treating patients with chronic pain should be on improving functional physical activity, decreasing peripheral nociception and central facilitation, and providing cognitive and behavioral strategies to help in resuming normal activities.

EXAMINATION OF THE PATIENT WITH PAIN

The examination of a patient with pain can be challenging because the therapist must frequently weed through the individual's emotions, behaviors, and secondary gains to identify the source of the symptoms. Many patients are not referred to therapy until they have participated in weeks, months, or even years of failed interventions, and their expectations and patience are at low levels. They often approach therapy anticipating more instructions, more frustration, and more pain. Despite these obstacles, therapists must strive to complete pain evaluations that include evidence-based measurable, reproducible information that identifies the source of pain and provides direction toward treatment that is both beneficial and cost-effective and that assists in establishing attainable goals. The time allotted for the examination may be dependent on the type of practice setting; many therapists send a comprehensive questionnaire to the patient or ask the patient to arrive early to complete important paperwork. It is essential to develop a trusting relationship, ensuring that the

patient feels that the therapist has listened to his or her concerns and has acknowledged his or her fears, and will participate in a plan for improving his or her physical, mental, and functional abilities.

Pain History

Every evaluation of a patient with pain should begin with a comprehensive pain history. It is important to have a standardized format to decrease chances of missing important information and to minimize having the patient “lead the interview.” The following alphabetical mnemonic device may prove helpful (OPQRST):

- **Observation:** Observation of the patient from the moment of entry until (and sometimes beyond) the moment of exit from the clinic. By observing the patient outside of the evaluation, the therapist can assess the patient’s movement. The patient’s nervous system will accurately express itself to the therapist, especially when the patient is asked to focus attention on a topic other than pain and the patient is not aware that movement is being observed.
- **Origin and onset:** Date and circumstances of the onset of pain. How did the pain start? Gradually or suddenly? Was there a precipitating injury? If so, what was the mechanism of injury? If not, can the patient correlate the onset to a activity or posture?
- **Position:** Location of the pain. Have the patient demonstrate where the pain is located rather than relying on description alone. In addition to being more accurate, demonstration allows another observation of the patient’s ability and willingness to move. Patients can also be asked to draw their symptoms on a schematic, such as the pain drawing, which is described later.
- **Pattern:** Pattern of the pain. Is the pain constant or periodic? Does it travel or radiate? Which activities and postures increase or decrease the pain? Does medication or time of day have any effect on the pain? Have there been any recent changes in the pattern? Does the patient believe that the pain is improving, worsening, or remaining the same?
- **Quality:** Characteristics of the pain. Does the patient use adjectives indicating mechanical (pressing, bursting, stabbing), chemical (burning), neural (numb, “pins and needles”), or vascular (throbbing) origin? Two tools for describing pain character are described later.
- **Quantity:** Intensity of the pain. How has the pain intensity changed since the onset? Several methods that allow for monitoring change in pain intensity are presented later.
- **Radiation:** Characteristics of pain radiation. Does the pain radiate? What causes the pain to radiate? Can the radiation be reversed? How?
- **Signs and symptoms:** Functional and psychological components of the pain. Has the pain resulted in any functional limitations? Has it caused any changes in the patient’s ability to participate in life, including employment and recreational activities? Does the patient’s personality contribute to the pain, or has the pain caused changes in the patient’s emotional stability? Does the patient benefit from the pain? How? It may be necessary to interview the patient’s significant others or family members for an accurate picture.
- **Treatment:** Previous and current medical and therapeutic treatment and its effectiveness, including medications, home remedies, and recommendations for movement activities. It is also important to determine the patient’s attitude and expectations concerning therapy in addition to obtaining a treatment history.
- **Visceral symptoms:** Physical symptoms of visceral origin that can accompany and be responsible for the pain (Box 30.1). Visceral causes of pain require referral to the patient’s physician for further investigation before the initiation of treatment by a therapist.

Pain Outcome Measurement

Outcome measures have become well established in pain research. Because of the variability in outcome measures across clinical trials

BOX 30.1 Viscerogenic Back Pain

General Signs and Symptoms

- Pain does not increase with spinal stresses or strains.
- Pain is not relieved with rest.
- Visceral symptoms accompany back pain.

Gastrointestinal Tract Signs and Symptoms

- Pain is accompanied by altered bowel habits.
- Pain is related to eating.
- Peptic pain is relieved with vomiting.

Kidney Signs and Symptoms

- Increased pain with diuresis indicates hydronephrosis.

Pelvic Signs and Symptoms

- Low back pain associated with vaginal bleeding or discharge.

Prostate Signs and Symptoms

- Low back discomfort associated with micturition.

Lung Signs And Symptoms

- Posterior thoracic pain associated with respiration in chronic obstructive pulmonary disease.

Vascular Signs and Symptoms

- Deep, boring, pulsating low back pain associated with a palpable abdominal aortic aneurysm.
- Back pain with or without calf pain after walking and relieved with standing still; possibly impaired lower extremity pulses and trophic skin changes associated with occlusive disease of the internal iliac artery or its branches.

Modified from Klineberg E, Mazanec D, Orr D, et al. Masquerade: medical causes of back pain. *Cleve Clin J Med*, 2007 Dec;74(12):905-13.

hinders evaluation of efficacy and effectiveness of treatments, the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) has recommended that six core outcome domains should be considered when designing chronic pain clinical trials. These six core outcome domains were (1) pain; (2) physical functioning; (3) emotional functioning; (4) participant ratings of improvement and satisfaction with treatment; (5) symptoms and adverse events; and (6) participant disposition (e.g., adherence to the treatment regimen and reasons for premature withdrawal from the trial).⁶³ These domains can assist in determination of outcome measures appropriate in clinical practice. Pain measurement tools are designed to provide information about the intensity, location, physical function, and character of a patient’s symptoms at the time of the evaluation. This information can then be merged with the pain history, the disease or pathology history, and the physical findings to identify the cause of the pain. The disease or pathology management and its pain measurement will be the responsibility of the physician, whereas the movement limitations caused by the pain are the responsibility of the therapist. A number of pain measurement tools are available. These tools are used by professionals whose focus is pathology, as well as professionals whose responsibility is helping the patient to regain functional activities and life participation. The applications and limitations of several are discussed.

Patient reported outcomes have been utilized in the treatment of pain. The National Institute of Health funds the Patient-Reported Outcomes Measurement Information System (PROMIS),⁶⁴ which provides psychometrically sound and validated patient-reported outcome measures free of charge that can be used in a wide range of chronic conditions. PROMIS is comprised of calibrated item banks to measure diverse health concepts such as pain, physical function, and depression; these are

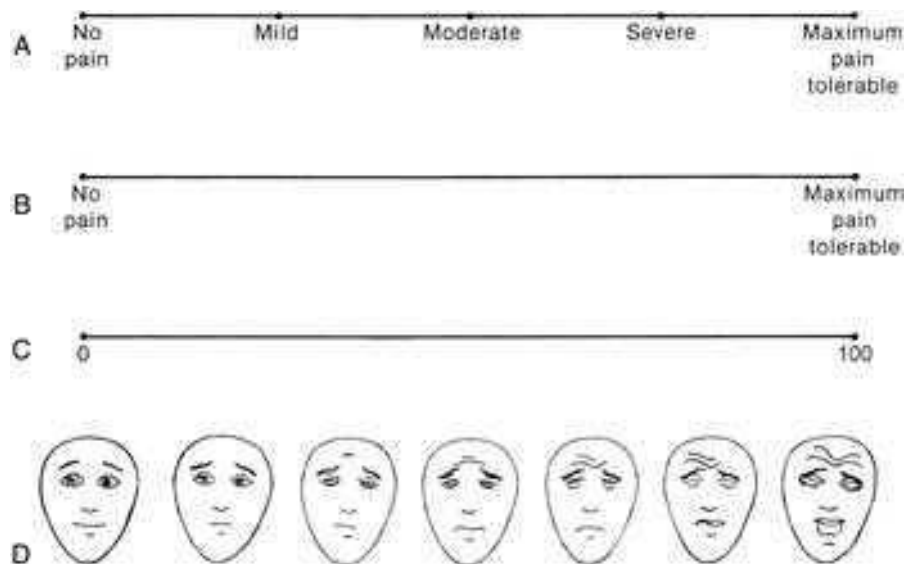

Fig. 30.3 Rating Scales for Measuring Pain Intensity. **(A)** Simple descriptive pain scale (SDPS). **(B)** Visual analog scale (VAS). **(C)** Pain estimate. **(D)** Faces pain scale. (D Reprinted from Bieri D, Reeve DA, Champion GD, et al. The faces pain scale for the self-assessment of the severity of pain experienced by children: development, initial validation, and preliminary investigation for the ratio scale properties. *Pain*. 1990;41:139–150, with permission from Elsevier Science.)

presented for each domain as individual items and/or instruments of various lengths. In addition, PROMIS includes several collections of items, termed profiles, which measure multiple domains. For example, the PROMIS-29 profile assesses seven domains, each with four questions; depression, anxiety, physical function, pain interference, fatigue, sleep disturbance, and ability to participate in social roles and activities. There is also an additional numeric pain intensity 0 to 10 rating scale (NPRS).

Measuring Pain Intensity

Research has shown that pain memory does not provide an accurate measure of pain intensity.⁶⁵

Pain intensity rating tools are scales that have the patient rate the current level of pain by marking a continuum or assigning a numerical value to the pain intensity (Fig. 30.3).

Each of the first three tools described here has been found to be reliable over time when used to measure pain that is present at the time of the rating. In general, however, patients who are depressed or anxious tend to report higher levels of pain and patients who are not depressed or anxious tend to report lower levels of pain on all three of these scales.⁶⁶

Visual analog scale. With the visual analog scale (VAS), the patient rates the pain on a continuum that begins with “no pain” and ends with “maximum pain tolerable.” This tool provides an infinite number of points between the extremes, making it sensitive to small changes in pain intensity. However, it has not been found reliable for individuals who have impaired abstract thinking skills⁶⁷ and may be unable to translate their pain intensity into a corresponding point on a line.

Simple descriptive pain scale. With a simple descriptive pain scale (SDPS), the patient rates the pain on a continuum that is subdivided using descriptors that gradually increase in intensity. Sample descriptors are “no pain,” “mild pain,” “moderate pain,” “severe pain,” and “maximum pain tolerable.” This tool is more useful than the VAS for patients with impaired abstract thinking because it is easier for them to identify with the pain descriptors than with the line found in the VAS. However, patients have been found to favor the points corresponding to each descriptor rather than points between, resulting in a less sensitive tool than the VAS.⁶⁸

Pain estimate. With a pain estimate, the patient assigns a numerical rating to the pain, staying within defined limits (most commonly between 0 and 100, where 0 represents no pain and 100 represents maximum pain tolerable). Because it provides a numerical range of scores, this tool is valuable for statistical analysis purposes. However, whereas some patients find assigning a numerical rating to their pain intensity easy, patients with impaired abstract thinking may have difficulty similar to that encountered with the VAS.

Faces pain scale. With the Faces Pain Scale, the patient selects one of seven schematic faces representing gradually increasing pain intensities. The scale begins with a face representing no pain and ends with a face representing the most pain possible. This tool is designed for use with young children who do not have the ability to use any of the three previous tools. The Faces Pain Scale has been found to be valid across cultural lines⁶⁹ and to have a strong correlation with other pain measures.⁶⁸ It is simple to use, does not require verbal skills, and requires little instruction. It has been used successfully with children as young as age 3 and with individuals who are limited in verbal expression.

Localizing Pain Symptoms

Pain drawings. The patient is asked to draw his or her symptoms on a schematic of the human body using a provided list of symbols (Fig. 30.4). The result is a diagram describing the nature and location of the patient’s pain, which can be compared with the patient’s verbal report. In addition to providing a database, the pain drawing has been found to be useful in identifying individuals who have a heavy psychological or emotional component to their pain, making it helpful also in identifying patients who would benefit from further psychological evaluation.⁷⁰

Describing Pain Quality

McGill pain questionnaire. One of the most popular scales to rate pain quality is the McGill Pain Questionnaire (MPQ), which includes 20 categories of descriptive words covering the sensory (numbers 1 to 10), affective (numbers 11 to 15), and evaluative (number 16) properties of pain (Fig. 30.5). Sensory properties are measured using temporal,

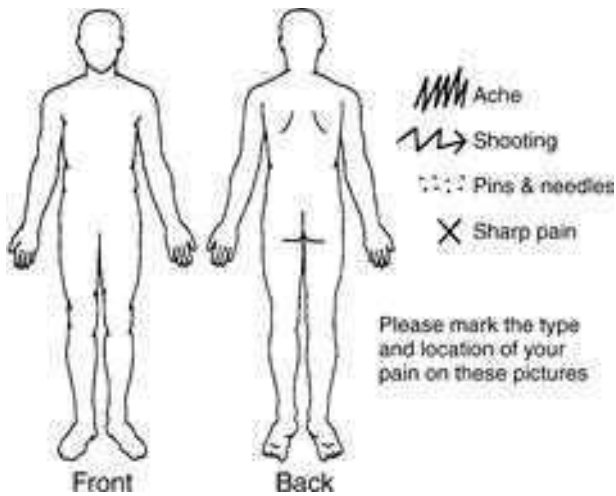

Fig. 30.4 Pain Drawing for Describing the Nature and Location of a Patient's Pain Symptoms. (From Cameron MH, ed. *Physical Agents in Rehabilitation*. Philadelphia: WB Saunders; 1999.)

thermal, spatial, and pressure descriptors. Affective properties are measured using fear, tension, and autonomic descriptors. Evaluative properties are measured using pain experience descriptors.⁷¹ Each word has a numerical value based on its position within its category.

The patient is instructed to “select the word in each category that best describes the pain you have now. If there is no word in the category that describes the pain, skip the category. If there is more than one word that describes the pain, select the word that best describes the pain.”⁷¹

The MPQ can provide the following types of information⁷¹:

- A pain-rating index based on the sum of the values of all the words selected
- A pain-rating index based on the sum of the values of all the words in a given category
- The total number of words chosen

The MPQ has been studied extensively and found valid for adults with acute and chronic pain as well as for those with a variety of specific pathological states.⁷²⁻⁷⁴ It provides clues into the specific cause of pain because it describes the patient's symptoms.

However, the MPQ does pose some disadvantages. It is time-consuming, requiring more time to complete than any of the previously

What Does Your Pain Feel Like?

Some of the words below describe your present pain. Circle **ONLY** those words that best describe it. Leave out any category that is not suitable. Use only a single word in each appropriate category—the one that applies best.

<p>1</p> <p>Flickering Quivering Pulsing Throbbing Beating Pounding</p>	<p>2</p> <p>Jumping Flashing Shooting</p>	<p>3</p> <p>Pricking Boring Drilling Stabbing Lancinating</p>	<p>4</p> <p>Sharp Cutting Lacerating</p>

described rating scales. Thus it is not appropriate for quick estimates of pain after treatment. Patients, especially children, are frequently unfamiliar with some of the descriptors and ask the evaluator to assist by defining words. However, reliability and validity of this test are based on examiner objectivity, and care must be taken to avoid the introduction of evaluator bias by helping the patient to select appropriate descriptors.⁷¹ This issue can be dealt with by telling the patient, “If you do not recognize a word, it probably does not apply to you.”

Pediatric verbal descriptor scale. Because a child's description of pain is limited by a smaller vocabulary, Wilkie and associates⁷⁵ have developed a verbal descriptor scale specifically for use with children (Table 30.2). Their list includes 56 words commonly used by children aged 8 to 17 to describe their pain experience. The word list is divided into the four categories found in the MPQ. The evaluators' research has shown the list to be useful for children with a variety of diagnoses because it is relatively free of gender, ethnic, and developmental bias.

Caregiver checklist. Patients who are unable to communicate verbally because of neurological disabilities may be unable to use any of the just-described pain measurement scales. However, because of pain associated with their medical conditions, extensive and repeated surgery, and behavioral oddities that might limit pain expression, these individuals are at high risk for having their pain go unrecognized. McGrath and colleagues⁷⁶ have attempted to develop and categorize a checklist of demonstrated pain behaviors identified by caregivers of severely handicapped individuals. Although their list did not pass validity criteria, the researchers propose that clinicians develop a patient-specific checklist that could be used to gauge changes in the patient's pain from the information gained during the caregiver interview portion of the evaluation of nonverbal handicapped patients.

In addition to qualifying and quantifying the patient's pain, pain measurement tools have an additional value. They can be used to identify inconsistencies between a patient's pain report and the clinician's

objective findings. For example, a patient with normal objective findings would not be expected to give a high pain report or draw symptoms over the entire pain drawing. Conversely, a patient with a multitude of objective findings within the severe range would be expected to provide a high pain rating. In addition, as objective symptoms subside, it is expected that the patient will report a similar decline on the rating scales. Inconsistencies between the patient's pain descriptions and the therapist's findings should serve to alert the clinician that the patient might require cognitive or affective intervention in addition to physical treatment.

PSYCHOSOCIAL ASSESSMENT

Psychosocial factors are key variables in the comprehensive assessment of chronic pain. Davidson and colleagues⁷⁷ determined seven factors using a “prototypical” pain assessment battery that included pain and disability, pain description, affective distress, support, positive coping strategies, negative coping strategies, and activity. Depression is commonly experienced in patients with chronic pain.⁷⁸ Screening for depression should be part of the clinical exam, and available evidence suggests that two specific questions from the Primary Care Evaluation of Mental Disorders patient questionnaire can be used in physical therapy settings.⁷⁹ The questions suggested for use are (1) “During the past month, have you often been bothered by feeling down, depressed, or hopeless?” and (2) “During the past month, have you often been bothered by little interest or pleasure in doing things?” The patient responds to the questions with “yes” or “no,” and the number of “yes” items are totaled, giving a potential range of 0 to 2. If a patient responds “no” to both questions, depression is highly unlikely, with a –LR of 0.07. Answering “yes” to 1 or both questions should raise suspicion of depressive symptoms.⁷⁹ Irving and Squire⁸⁰ described two key individual personality features that affect pain: catastrophizing and health-related

anxiety. Persons who catastrophically misinterpret innocuous bodily sensations, including pain, are likely to become fearful of pain, which results in pain-related fear. Pain-related fear is associated with avoidance of movement and physical activity, which directly affects recovery of function. Pain-related fear is also associated with increased pain levels and an exacerbated painful experience. Three validated tools to screen for these features include the Fear-Avoidance Beliefs Questionnaire (FABQ)⁸¹, Pain Catastrophizing Scale (PCS), and the Tampa Scale of Kinesiophobia (TKS).⁸²

EXAMINATION OF THE PATIENT

The clinical examination should begin the moment the patient enters the door. Patients frequently change posture and affect when they are being formally evaluated, and it is important to gain an accurate view of pain behavior during spontaneous activities to assess the validity of complaints. The following should be included in the examination:

- Observation of gait and movement patterns, including the use of assistive devices.
- Notation of body type and anomalies.
- Examination of sitting and standing posture, including both the normal posture and that assumed because of the pain. (Observe the patient during activities, if possible, to differentiate movement patterns altered by intent vs. automatic adjustments.)
- Inspection of the skin for pliability, trophic changes, scar tissue, and other abnormalities.
- Palpation of the soft tissue structures to identify changes in temperature, swelling, tenderness, and areas of discomfort.
- Palpation of the anatomical structures to determine end feel—the sensation felt at the end of the available movement.⁸³
 - Bone to bone: hard normal, for example, at the end range of elbow extension.
 - Spasm: muscular resistance abnormal.
 - Capsular feel: rubbery normal at the extreme of full ROM; abnormal when encountered before the end of ROM.
 - Springy block: rebound abnormal.
 - Tissue approximation: soft tissue normal at the extremes of full passive flexion.
 - Empty feel: no physiological resistance, but patient resists movement because of pain.
- Examination of ROM: active ROM testing is performed to assess the patient's willingness to move and to identify any limitations or painful areas; passive ROM testing is used to further refine the observations.⁸³
 - When active and passive movements are painful and restricted in the same direction and the pain appears at the limit of motion, the problem is most likely arthrogenic.
 - When active and passive movements are painful or restricted in opposite directions, the problem is most likely muscular.
 - When there is relative restriction of passive movement in the capsular pattern, the problem may be arthritic in nature.
 - When there is no restriction of passive movement, but the patient cannot perform the movement actively, the muscle may not be functioning, either from intrinsic problems within the muscle or interruption in the neural pathway (central or peripheral).
- Examination of muscle strength⁸³:
 - When the movement is strong and painful, there is a minor lesion in the muscle or tendon.
 - When the movement is weak and increases the pain, there is a major lesion that needs to be identified with further testing.
 - When the movement is weak but does not increase the pain, there is the possibility of either complete rupture of the muscle or tendon or a neurological disorder.

- When all resisted movements are painful, the pain may be organic, or the patient may be emotionally hypersensitive.
- When movement is strong and painless, the test results are normal.
- Assessment of bilateral neurological function:
 - Reflexes: peripheral lesions tend to diminish deep tendon reflexes (DTRs). CNS lesions tend to intensify DTRs and testing frequently elicits a clonic reaction.⁸⁴ Note any asymmetries in response.
 - Sensation: test light touch, sharp (noxious) touch, and vibration. Pressure on a nerve usually affects conduction on the large, myelinated fibers first. Therefore vibration is the first sensation to be diminished. Where there is decreased perception of touch and noxious stimuli, the lesion is more severe.⁸⁵ Note any asymmetries in response.
 - Allodynia and hyperalgesia: delineate areas of allodynia and hyperalgesia to touch, hot, and cold. Exact descriptions of these areas, along with areas of decreased perception of vibration, will provide information concerning A beta versus C fiber involvement in the production of pain.⁸⁵
 - Stretch and pressure tests to nerve trunks.

It is not always possible to complete a pain evaluation in one session. Patients may not be able to tolerate all the required activities at one time, or there may be enough inconsistencies for the therapist to want a second appointment to refocus on specific tests. However, with the limitations on number of visits common with managed care, the therapist may feel pressured to identify a cause for the patient's pain in the initial visit. This is not necessary. It is far better to take more than one visit and be accurate than to take only one visit and develop a treatment plan that is not appropriate for the patient's needs.

REHABILITATION MANAGEMENT OF THE PATIENT WITH PAIN

There are three broad avenues of intervention for pain management: physical interventions, cognitive strategies, and behavioral manipulations.⁸⁶ Each avenue addresses a different aspect of the pain experience, and each requires a different level of participation from the patient.

Physical interventions are directed at the patient's body with the goal of healing the tissue injury. Examples include medication, surgery, and the therapy modalities. Physical interventions are of use most frequently with acute pain or recurrent pain resulting from reinjury. Physical interventions are often passive and, for the most part, soothing. When used long term, they promote dependence on the clinician. Therefore it is best to use them as a short-term adjunct in the overall treatment program.

Cognitive strategies are directed at the patient's thoughts with the goal of changing the patient's pain paradigms. Cognitive strategies include body scanning and reinterpretation of self-statements. Cognitive strategies are self-initiated and performed independently; therefore they encourage personal responsibility and independence.

Behavioral manipulations involve a behavioral change on the part of the patient to bring about the desired response. They include exercise, biofeedback, hypnosis, relaxation exercises, and operant conditioning. There is usually a brief learning period until the patient becomes proficient with these techniques; however, once learned, behavioral manipulations can be initiated and performed independently. Behavioral manipulations also encourage personal responsibility and independence.

A brief review of the benefits, indications, contraindications, and precautions for many of the interventions provided by therapists should provide an overview of the complexity of pain management.

The purpose of this section is to provide guidance in the selection of one treatment option over another so that intervention will be based on sound physiological principles. Readers who wish to explore an intervention in greater depth are directed to the references listed at the end of this chapter.

Physical Interventions

Thermotherapy

The physiological effects of heat depend on the method of application, the depth of penetration, and the rate and magnitude of temperature change. In the use of thermotherapy to control pain, several mechanisms have been established. Muscle spasm decreases as a result of decreased activity in gamma motor efferents, decreased excitability of muscle spindles, and increased activity of Golgi tendon organs.^{87,88} This modality will often decrease peripheral pain. Ischemic pain is relieved by the influx of oxygen-rich blood into the dilated vessels, and muscle tension pain is decreased by interruption of the pain-spasm cycle. In addition, the pain threshold itself rises through gating at the spinal cord level.^{89,90}

Several textbooks^{91–95} on physical agents and rehabilitation discuss the physiological effects, precautions, contraindications, and method of application for these modalities. The reader is advised to refer to the textbooks for details.

Superficial heat can be applied by conduction, convection, or radiation. Conductive heating involves the exchange of heat down a temperature gradient by two objects that are in contact. The depth of penetration with conductive heating is usually 1 cm or less.⁹⁶ Moist heat packs and paraffin are examples of therapeutic conductive heating. Convective heating involves heat transfer through the flow of hot fluid. Therapeutic convective heating takes place during hydrotherapy and Fluidotherapy (Encore Medical Corporation, Austin, Texas). Molecules with a temperature greater than absolute zero are in an excited state and emit energy, thus creating radiant heat. Objects that are warmed by the energy are heated by radiation. Therapeutic radiant heat is applied with infrared or ultraviolet light. Because of the contraindications of ultraviolet light, this type of radiant heat is seldom used by therapists today in rehabilitation settings.

Patients can be taught how and when to apply superficial heat independently. Once they have demonstrated independence, responsibility for the application of superficial heat should be transferred to the patient or her or his caregiver.

The deeper tissues can be heated using conversion, the alteration of one form of energy into another. Examples of heating by conversion include use of shortwave diathermy or ultrasound.

During shortwave diathermy, the patient is placed into an oscillating magnetic field. The systemic ions create friction as they attempt to line up with the continuously reversing current, resulting in an increase in tissue temperature deep within the body. Shortwave diathermy is contraindicated for patients with metal implants because of the potential for the implant to become hot and burn the surrounding tissues. It is also contraindicated for patients with cardiac pacemakers because of the pacemaker's metal components and because the electromagnetic radiation may interfere with the pacemaker's operation. Shortwave diathermy should not be used for patients with cancer or multiple sclerosis or who are pregnant, and it should not be used over the eyes, the reproductive organs, or growing epiphyses. Female therapists should avoid prolonged exposure to shortwave diathermy because some research has demonstrated a possible negative effect on pregnancy outcome and fetal development.⁹⁷

Ultrasound is another modality that heats deep tissues by conversion. As its name implies, ultrasound consists of sound waves delivered at a frequency too high to be perceived by human hearing. Sound

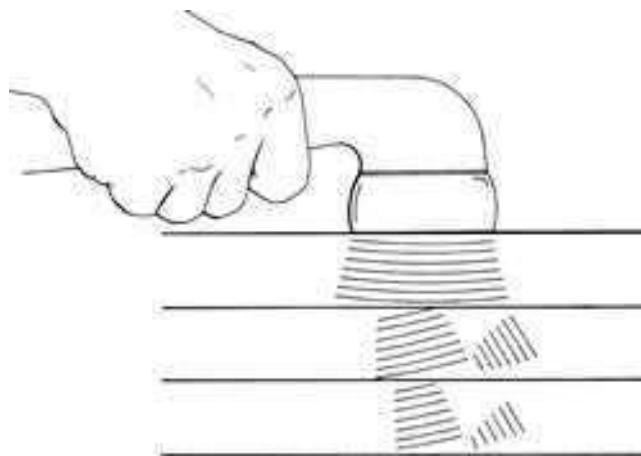

Fig. 30.6 The longitudinal wave of ultrasound is refracted at tissue interfaces where it encounters tissues of differing acoustical resistance. When the wave changes direction, energy is transferred to the tissues, resulting in the production of heat.

waves are repeatedly refracted as they encounter tissues of differing acoustical resistance while traveling through the skin toward the bone (Fig. 30.6). Tissues with high collagen content (tendon, ligament, fascia, and joint capsule) are heated more efficiently than tissues with low collagen content (fat, muscle). The extent of the temperature increase is related to the dose of ultrasound energy delivered. As the dose of ultrasound energy is increased by increasing the treatment duration or intensity, more energy is available to the tissues and the heating effect increases.³¹ Moreover, the higher the frequency of ultrasound delivered, the more superficial the effect. Ultrasound delivered at 1 MHz heats tissues at depths to 5 cm, whereas ultrasound delivered at 3 MHz heats tissues in the upper 2 cm.⁹⁸

The thermal effects of ultrasound can be used to increase tissue extensibility, cellular metabolic processes, and circulation; to decrease pain and muscle spasm; and to change nerve conduction velocity. The number of impulses traveling along the nerve decreases at low doses but begins to rise slowly beginning at 1.9 W/cm². Sounding of C fibers yields pain relief distal to the point of application, whereas sounding of large-diameter A fibers brings relief of spasm by changing gamma fiber activity, making the muscle fibers less sensitive to stretch.⁹⁹ Because it is impossible to treat C or A fibers selectively, ultrasound provides both pain relief and relief from muscle spasm, making it effective in the treatment of peripheral neuropathies, neuroma, and muscle spasm associated with musculoskeletal pathology, including sprains, strains, and contusions.¹⁰⁰

In addition to thermal effects, ultrasound has nonthermal effects that come from the mechanical effects of the ultrasound wave on the tissues. Ultrasound causes cavitation, the development and growth of gas-filled bubbles, in the tissues. Ultrasound also causes tissue fluid to move or stream. The movement of fluid around the gas bubbles formed by cavitation is called microstreaming, and the movement of fluid within the ultrasound delivery area is called acoustic streaming. The nonthermal effects of ultrasound include accelerating metabolic processes, enzyme activity, and the rate of ion exchange, as well as increasing cell membrane permeability and the rate and volume of diffusion across cell membranes. These effects are thought to explain the role of ultrasound in enhancing the healing of soft tissue and bone.^{101–103} The nonthermal effects of ultrasound can be achieved without raising tissue temperature by applying ultrasound in the pulsed mode.

Fig. 30.7 Phonophoresis. Molecules of a substance are driven into the tissues by the ultrasound wavefront. They are not free for use by the body until they are broken down into chemical ions.

Phonophoresis is the use of ultrasound to deliver pain-relieving chemicals to the tissues. Chemicals are delivered to the cells by the ultrasound wave, where they are broken down into ions and taken up into the cells (Fig. 30.7). Common pain-relieving chemicals that can be administered with phonophoresis include 5% lidocaine ointment (Xylocaine) for acute conditions in which immediate pain relief is the primary goal, and 10% hydrocortisone cream or ointment for conditions in which pain is the result of inflammation.¹⁰⁴

After phonophoresis, measurable quantities of these molecules have been found at tissue depths of up to 2 inches.¹⁰⁵ The contraindication to use of any chemical during phonophoresis is having an allergy to that chemical. Patients should be questioned about any adverse reactions to dental local anesthesia (lidocaine) or aspirin.

Cryotherapy

The physiological effects of cold make it superior to heat for acute pain from inflammatory conditions, for the period immediately after tissue trauma, and for treating muscle spasm and abnormal tone. Peripheral nerve conduction velocity in both large myelinated and small unmyelinated fibers decreases 2.4 m per degree centigrade of cooling. As a result, pain perception and muscle contractility diminish.¹⁰⁶ Peripheral receptors become less excitable.¹⁰⁶ Muscle spindle responsiveness to stretch decreases; as a result, muscle spasm diminishes.⁹⁹

Local blood flow initially decreases, local edema decreases, the inflammatory response decreases, and hemorrhage is minimized. However, cold application for longer than 15 minutes results in increased local blood flow. Known as the “hunting response,” this protective mechanism brings core temperature blood to the surface and prevents tissue injury resulting from prolonged cooling.⁹⁶ Cellular metabolic activities slow. The oxygen requirements of the cell decrease.¹⁰⁶

As with heat, several precautions must be taken when using cold as a therapeutic modality. Cryotherapy is contraindicated in individuals with Raynaud phenomenon or cold allergy. Cryotherapy should not be used in individuals with rheumatic disease who, with the application of cold, have increased joint pain and stiffness. Cryotherapy should be used with caution in young, frail, or elderly individuals and those with peripheral vascular disease, circulatory pathological processes, or sensory loss.¹⁰⁷

Cryotherapy is applied in three ways. Convective cooling involves movement of air over the skin (fanning) and is rarely used therapeutically. Evaporative cooling results when a substance applied to the skin uses thermal energy to evaporate, thereby lowering surface temperature. Most commonly, this substance is a vapocoolant spray. Conductive cooling uses local application of cold via ice packs, ice massage, or

immersion. Cooling is accomplished as heat from the higher-temperature object is transferred to the colder object down a temperature gradient. Conductive cooling is the most commonly used form of therapeutic cold application.

Because muscles, tendons, and joints respond differently, the best method of cold application depends on which tissues are causing the pain.¹⁰⁸ Acute injuries are best treated with cryotherapy along with rest, compression, and elevation (RICE). Muscle spasm is decreased with cold packs and stretching. Trigger points, irritable foci within muscles, are best treated with vapocoolant spray, deep friction massage, and stretching. Tendinitis responds well to ice massage and exercise. Cold packs are often the only source of pain relief in acute disc pathology. The inflamed joints of rheumatoid arthritis frequently respond to cold packs or ice massage with decreased inflammation, increased function, and long-lasting pain relief.^{107,109}

Patients and caregivers can be taught how and when to perform cryotherapy independently. Once they have demonstrated their proficiency, responsibility for the use of cryotherapy should be transferred to the patient or the patient’s caregiver.

Transcutaneous Electrical Nerve Stimulation

TENS is the use of electricity to control the perception of pain. It appears that at a high rate TENS selectively stimulates the low-threshold, large-diameter A beta fibers, resulting in presynaptic inhibition within the dorsal horns,¹¹⁰ either directly through the gating mechanism or indirectly through stimulation of the tonic descending pain-inhibiting pathways.¹¹¹ Research has shown that the neurons in the brain stem fire in synchrony with the TENS stimulation frequency,¹¹² and although the significance of this is not known at this time, it does indicate that the action of high-rate TENS is not limited to the dorsal columns. TENS delivered at a low rate is thought to facilitate elevation of the level of endogenous opiates in the CNS.¹¹³

Stimulation frequencies of 1 to 250 pulses per second (pps) decrease pain. Frequencies of 50 to 100 pps have proven most effective for sensory-level (high-rate) TENS, and frequencies of 2 to 3 pps are most effective for motor-level (low-rate) TENS.⁴¹ Stimulation at exactly 2 pps causes an increase in the pain threshold.⁶⁴ As the frequency is decreased, more time is needed before the onset of relief, but the effects are more long-lasting.¹¹⁴ Pulse width duration determines which nerves are stimulated. Sensory nerves are stimulated at widths of 20 to 100 ms, and motor nerves at 100 to 600 ms.¹¹⁵

There is a variety of modes of TENS delivery. Each mode relieves pain through a specific physiological mechanism and is therefore most beneficial for a specific type of pain.

When TENS impulses are generated at a high rate (greater than or equal to 50 pps) with a relatively short duration, the stimulation is referred to as *sensory-level* or *conventional* or *high-rate TENS*. Sensory-level TENS produces mild to moderate paresthesia without muscle contraction throughout the treatment area. Sensory-level TENS is thought to control pain through the gating mechanism in the spinal cord. The onset of relief is fast (seconds to 15 minutes)⁴¹ because the gate is closed at the onset of stimulation. The duration of relief after stimulation stops is short-lived (at best up to a few hours). Sensory-level TENS has been found to be beneficial for acute pain syndromes and for some deep, aching chronic pain syndromes. (Refer to Chapter 31.)

Stimulation using high-rate and long-duration impulses is called *brief-intense TENS*. Brief-intense TENS decreases the conduction velocity of A delta and C fibers, producing a peripheral blockade to transmission.⁴¹ Brief-intense TENS is useful in the clinical setting for short-term anesthesia during wound debridement, suture removal, friction massage, joint mobilization, or other painful procedures.

When the impulses are generated at a low rate (less than or equal to 20 pps) and have a relatively long duration (100 to 300 μ s), the stimulation is referred to as *motor-level* or *acupuncture-like* or *low-rate TENS*. Motor-level TENS produces strong muscle contractions in the treatment area with or without the perception of paresthesia. Motor-level TENS is associated with deployment of endogenous opiates within the CNS. The onset of relief is delayed 20 to 30 minutes, presumably the time it takes to deploy the opiates. Relief frequently lasts hours or days after treatment. Because motor nerves are not stimulated in isolation, sensory fibers are also excited, causing the gating mechanism to come into play.¹¹⁵ Motor-level TENS has been found to be beneficial for chronic pain syndromes and when sensory-level TENS has not been successful.

Modulating TENS parameters is one way to avoid the negative aspects of each of the treatment modes. Rate modulation is most commonly used to avoid neural accommodation during TENS. By setting the initial pulse rate so that, even with the programmed decrement, it will remain within the treatment range, there will be continuous variation in the stimulus, and neural accommodation will be avoided.

Width modulation is most commonly used with motor-level TENS. By setting the initial pulse duration so that, even with the programmed decrement, the impulses are able to recruit the desired motor units, there will be a continuous variation in perceived strength of the muscle contraction, rendering motor-level TENS more tolerable.

Stimulation in which the impulses are generated in pulse trains is called *burst TENS*. Burst TENS is another form of TENS modulation. The stimulator generates low-rate carrier impulses, each of which contains a series of high-rate pulses. Because burst TENS is a combination of high-rate and low-rate TENS, it provides the benefits of each. The low-rate carrier impulse stimulates endorphin release, and the high-rate pulse trains provide an overlay of paresthesia. The advantage to burst TENS is that muscle contractions occur at a lower, more comfortable amplitude, and accommodation does not occur. Burst TENS is beneficial whenever motor-level TENS cannot be tolerated and sensory-level TENS is ineffective because of neural accommodation.¹¹⁶

TENS, like all electrical stimulation, is contraindicated for patients with pacemakers, in the low back and pelvic regions of pregnant women, and over areas with thrombus. TENS should be used with caution for patients who have decreased sensation in the area being stimulated and for patients who have difficulty with understanding or expression. TENS electrodes should not be placed over areas of skin irritation, the eyes, or the carotid sinuses. It also should not be used in the immediate area of an operating diathermy unit.

TENS appears to be of greatest benefit for acute conditions with focal pain, chronic pain syndromes, postoperative incision pain, and during delivery. It has been found least effective with psychogenic pain¹¹⁷ and pain of central origin.¹¹⁸ For additional information on TENS, see Chapter 33.

Patients and caregivers can be taught how and when to apply TENS independently. Once they have demonstrated independence, responsibility for the use of TENS can be transferred to the patient or to the caregiver.

Iontophoresis

Iontophoresis is a process in which chemical ions are driven through the skin by a small electrical current. Ionizable compounds are placed on the skin under an electrode that, when polarized by a direct (galvanic) current, repels the ion of like charge into the tissues. Once subcutaneous, the ions are free to combine with the physiological ions, resulting in a physiological effect dependent on the characteristics of the ion (Fig. 30.8). Ionizable substances that are known to be effective analgesics include the following¹¹⁹:

- Five-percent lidocaine ointment (Xylocaine) administered under the positive electrode for an immediate, although short-lived,

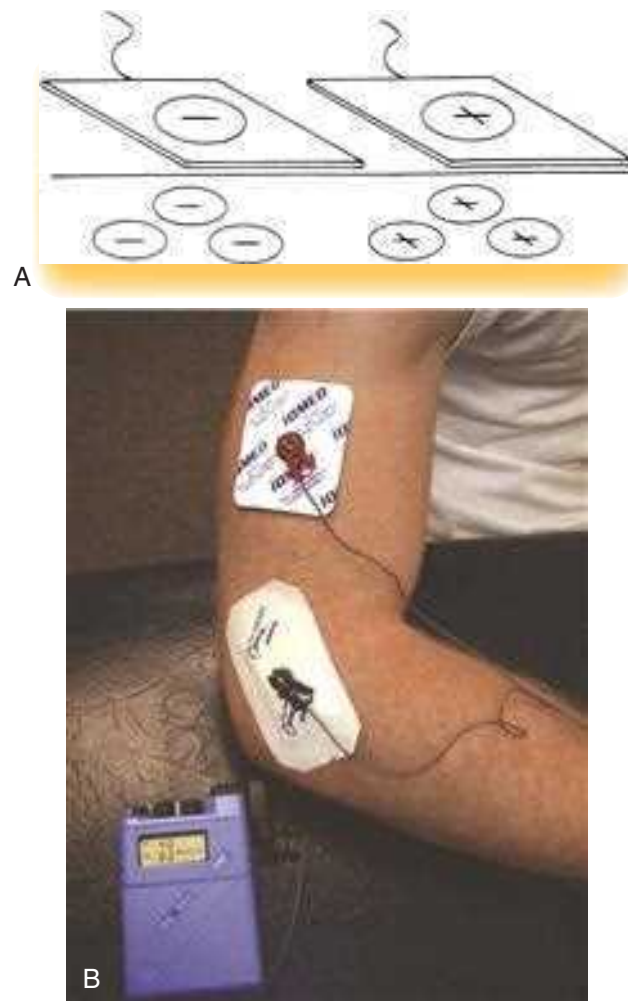

Fig. 30.8 Iontophoresis. (A) Chemical ions are driven into the tissues by a small electrical current. Once subcutaneous, they are immediately free to take part in chemical reactions within the body. (B) Iontophoresis treatment.

decrease in pain. Iontophoresis with lidocaine is recommended before ROM exercises, stretching, and joint mobilization and when immediate relief of acute pain (as in bursitis) is the object of treatment.

- One-percent to 10% hydrocortisone and dexamethasone administered under the positive electrode for relief of inflammatory pain in conditions such as arthritis, bursitis, or entrapment syndromes. Iontophoresis with hydrocortisone has a delayed onset but a prolonged effect, and it frequently eliminates the underlying cause of pain.
- Two-percent magnesium (from Epsom salts) administered under the positive electrode for relief of pain from muscle spasm or localized ischemia. High levels of extracellular magnesium inhibit muscle contraction, including the smooth muscle found in the walls of the vessels, leading to localized vasodilation.
- Iodine (from Iodex ointment [Lee Pharmaceuticals, South El Monte, California]) administered under the negative pole for relief of pain caused by adhesions or scar tissue. Iodine “softens” fibrotic, sclerotic tissue, thereby increasing tissue pliability.
- Salicylate (from Iodex with Methyl Salicylate [Lee Pharmaceuticals] or Gordogesic Creme [Gordon Laboratories, Upper Darby, Pennsylvania]) administered under the negative pole for relief of pain from inflammation. Salicylate is effective for arthritic joint inflammation, myalgia, and entrapment syndromes.

- Two-percent acetic acid administered under the negative pole to dissolve calcium deposits.
- Two-percent lithium chloride or lithium carbonate administered under the positive pole to dissolve gouty tophi. In both acetic acid and lithium iontophoresis, the insoluble radicals in the deposits are replaced by soluble chemical radicals so the deposits can be broken down through natural processes.

The contraindication to the use of any ion is an allergy to that ion. Because most patients will not have had iontophoresis previously, it is important to inquire about experiences that might indicate an allergy. For example, intolerance to shellfish may be the result of an allergy to iodine, and a poor reaction to dental local anesthesia may indicate a problem with lidocaine. Moreover, because iontophoresis involves the application of direct current, the likelihood of polar reactions under each electrode is greater than with electrical stimulations using alternating current (for example, TENS), and therefore the risk for skin burns is greater.

Massage

Massage has been recognized as a remedy for pain for at least 3000 years. Evidence of its beneficial effects first appeared in ancient Chinese literature, and then in the writings of the Hindus, Persians, Egyptians, and Greeks. Hippocrates advocated massage for sprains and dislocations as well as for constipation.¹²⁰

Massage decreases pain through both direct and indirect means. Massage movements increase circulation through mechanical compression of the tissues, resulting in reflex relaxation of muscle tissue and direct relief from ischemic pain. Massage also indirectly stimulates A delta and A beta fibers, causing activation of the gating mechanism and the descending pain-modulating system.⁴⁴

Massage movements are classified by pressure and the part of the hand that is used.¹²¹ The two massage movements that may cause a decrease in pain include stroking (effleurage) and compression (kneading or pétrissage). Stroking involves running the entire hand over large portions of the body. Stroking causes muscle relaxation and elimination of muscle spasm or improved circulation depending on the depth and force of the strokes. Compression is applied with intermittent pressure using lifting, rolling, or pressing movements meant to stretch shortened tissues, loosen adhesions, and assist with circulation.

Massage is useful in any condition in which pain relief will follow the reduction of swelling or the mobilization of the tissues. These include arthritis, bursitis, neuritis, fibrositis, low back pain, hemiplegia, paraplegia, quadriplegia, and joint sprains, strains, and contusions. Massage is contraindicated over infected areas, diseased skin, and thrombophlebotic regions.

Patients or caregivers can be taught how and when to perform massage. Once they have demonstrated independence in the appropriate technique, responsibility for the performance of massage should be given to the patient or caregiver.

A specialized massage technique is lymphatic massage, which consists of light-pressure rhythmic strokes to encourage organizational flow of the lymphatic system. This type of massage can be beneficial with patients who have peripheral swelling with or without pain. A popular form of lymph massage called *manual lymphatic drainage* (MLD) is used after surgical procedures to reduce swelling (for example, mastectomy for breast cancer). Evidence-based studies show conflicting results regarding the efficacy of this technique, and more research needs to be done to validate it.¹²²⁻¹²⁴

Myofascial Release

Myofascial release (MFR) techniques are used to release the built-in imbalances and restrictions within the fascia and to reintegrate the fascial mechanism. The therapist palpates the various tissue layers,

beginning with the most superficial and working systematically toward the deepest, looking for movement restrictions and asymmetry. Areas of altered structure and function are then “normalized” through the systematic application of pressure and stretching applied in specific directions to bring about decreased myofascial tension, myofascial lengthening, and myofascial softening,¹²⁵ thereby restoring pain-free motion in normal patterns of movement. MFR is useful in treating musculoskeletal injuries, chronic pain, headaches, and adhesions or adherent scars.¹²⁶ MFR has been shown to be effective in the treatment of chronic prostatitis (CP) and chronic pelvic pain syndrome (CPPS) in conjunction with paradoxical relaxation therapy (PRT).¹²⁷ More research is needed to provide evidence regarding the efficacy of MFR in pain control.

MFR is contraindicated over areas with infection, diseased skin, thromboembolus, cellulitis, osteomyelitis, and open wounds. In addition, it should not be used with patients who have osteoporosis, advanced degenerative changes, acute circulatory conditions, acute joint pathology, advanced diabetes, obstructive edema, or hypersensitive skin.¹²⁶ (See Chapter 39 for more in-depth information regarding MFR.)

Joint Mobilization

Joint mobilization consists of passive oscillations that restore normal accessory movements.¹²⁸ In addition, the rhythmical repetition of the motions provides pain relief through the spinal gating mechanism.¹²⁹ Grades I and II oscillations are performed to maintain joint mobility and for pain relief, making them the choice for subacute conditions in which pain and potential loss of motion are the primary considerations. Grades III and IV oscillations are performed to increase joint mobility and are indicated for chronic conditions in which regaining lost motion is the goal. Grade V thrusts are performed to regain full joint mobility and have been recommended based on strong evidence for acute and chronic patients with low back pain.^{13,128}

Joint mobilization is contraindicated with rheumatoid arthritis, bone disease, advanced osteoporosis, and pregnancy (pelvic mobilization), as well as in the presence of malignancy, vascular disease, or infection in the area to be mobilized.⁶⁴

Light Therapy

Light therapy is described by Bot and Bouter¹³⁰ as a light source that generates extremely pure infrared light of a single wavelength. When applied to the skin, infrared laser light produces no sensation, and it does not burn the skin. Because of the low absorption, it is hypothesized that the energy can penetrate deeply into the tissues, where it is assumed to have a biostimulative effect.^{92,130,131} It has been suggested that laser therapy may act by stimulating ligament repair,^{132,133} producing antiinflammatory effects,¹³⁴ increasing production of endogenous opioids,¹³⁵ reducing swelling,¹³⁶ and influencing nerve conduction velocity.¹³⁷ To promote wound healing and manage pain, rehabilitation centers use lasers with power outputs less than 500 mW at a power density of 50 mW/cm² and wavelengths ranging from 600 to 1500 nm.⁹² Contraindications to light therapy include exposing photosensitive areas, hemorrhagic areas, any area that has undergone 4 to 6 months of radiation treatment,¹³¹ neoplastic lesions, and unclosed fontanelles in children; the abdomen of pregnant women; areas over the heart, the vagus nerve, or sympathetic innervations routes to the heart of cardiac patients; or, locally, endocrine glands.^{92,131,138,139} In addition, exposure to the cornea of the eye is contraindicated, so protective eye equipment should be worn by the patient and the therapist. Caution should be used for areas with compromised somatosensation, the epiphyseal plates in children, the gonads, and infected areas and with patients displaying fever, epilepsy, or mental confusion.^{92,131,138}

Therapeutic Touch

A description of therapeutic touch can be found in Chapter 39. Therapeutic touch has been effective in treating painful conditions resulting from anxiety and tension. In a report by Keller and Bzdek, 90% of individuals treated with therapeutic touch experienced tension headache relief, and 70% had continued relief for more than 4 hours; only 37% of the placebo group expressed sustained relief.¹⁴⁰ A meta-analysis and systematic review on therapeutic touch revealed that the available studies have varying approaches and protocols on therapeutic touch, subject selection, and description. Although most of these studies confirm the efficacy of the technique, several studies also have demonstrated negative or mixed results.¹⁴¹ Therapeutic touch and other approaches are being more widely accepted; however, the therapist must continue to be diligent in using outcome studies to substantiate the use of any complementary therapy. (See Chapter 39 for additional information.)

Point Stimulation

Refer to Chapter 39 for an in-depth discussion of point stimulation. It is interesting to note that acupuncture points frequently correspond in location to trigger points, which are tight, elevated bands of tissue that are extremely sensitive when palpated and have a characteristic pattern of radiation to remote regions of the body. Trigger points appear to be areas of “focal irritability” that are myofascial in origin and are usually the site of small aggregations of nerve fibers that produce continuous afferent input when stimulated.

Needling therapies include trigger point injections (anesthetics, corticosteroids, Botox) and trigger point dry needling. Needling therapies are used in myofascial pain conditions. Trigger point injections are usually restricted to medical doctors and their professional support staff.¹⁴² Trigger point dry needling consists of superficial and deep dry needling, and the exact mechanism of pain relief is not known. It is thought that needling and injections may trigger changes in the end plate cholinesterase and ACh receptors,¹⁴² may involve central pain mechanisms, and may activate enkephalinergic, serotonergic, and noradrenergic inhibitory systems in association with A delta fibers through segmental inhibition.¹⁴² Acupressure (i.e., finger pressure applied to acupuncture or trigger points) is thought to decrease their sensitivity through the same mechanism. The therapist applies deep pressure in a circular motion to each point for 1 to 5 minutes, until the sensitivity subsides. Pressure must be applied directly to each point for the treatment to be effective. Acupressure can be accompanied by a vapocoolant spray to provide additional sensory stimulation.

Sensitive points also can be stimulated using electricity. A point locator is used to identify points along the appropriate meridians that are sensitive to stimulation or more conductive to electricity. Each is then stimulated at the patient’s level of pain tolerance for 30 to 45 seconds. The points farthest from the site of pain are treated first.

Points that are most sensitive to stimulation are beneficial sites for TENS electrode placement. When point stimulation alone does not provide enough pain relief, TENS can be used between sessions for continuous stimulation for more prolonged relief. (See Chapter 39 for additional information on electrical acupuncture.)

Cognitive Strategies, Including Cognitive Behavioral Therapy

The extent to which an individual perceives and expresses pain is a result of his or her emotional state, expectations, personality, and cognitive view. Each individual feels and responds to pain differently. Melzack and Wall¹²⁹ identified the following three nonphysical components of pain that interact and determine how an individual will respond to pain:

- The individual’s sensory and discriminative interpretation of the pain

- The individual’s motivation and attitudes relating to the pain
- The individual’s cognitive and evaluative thoughts and beliefs concerning the pain experience

Cognitive strategies are part of a holistic approach to health that looks at the total person and the interaction among the three components of body, mind, and spirit. Cognitive strategies recognize that the mind is not separate from the body, accept that there is a mental component to pain, and use the inner resources of the mind to influence the pain experience.

Cognitive strategies work in two ways. First, they activate the descending cortical modulating systems, and second, they teach the individual to control, rather than be controlled by, the pain. Used in conjunction with other modalities necessary for physical relief, these approaches can play a significant role in long-term pain management and should not be overlooked in seeking a viable pain management alternative.

As mentioned previously, current research has given the medical community a much deeper understanding of chronic pain. Many new intervention approaches have been developed based on these new theories, and physical rehabilitation clinicians play a significant role in these new interventions. Of particular importance is the increasing role of clinicians in using cognitive behavioral therapy (CBT) in the management of individuals with chronic pain.¹⁴³ CBT for pain management involves the integration of cognitive, affective, and behavioral factors into the case conceptualization and treatment.¹⁴³ It is thought that a person’s beliefs about pain are associated with various functional outcomes^{144,145} and that changes in patients’ beliefs about pain are related to changes in functioning.^{146,147} Techniques potentially used may include coping skills, education and rationale about the course of an illness, relaxation, imagery, goal setting, pacing, distraction, and cognitive restructuring as well as homework assignments. A thorough discussion of this approach as it applies to physical rehabilitation is beyond the scope of this text. The work of Butler and Moseley provides clinicians a great resource on how to better explain pain to patients and patients, as well as how to use the most current evidence on pain science and chronic pain management in treating individuals with chronic pain.^{148,149}

Relaxation Exercises

People who are in pain experience stress. Chronic stress can trigger increased pain. Both pain and stress cause an increase in SNS activity, including increased muscle tension. Relaxation exercises can bring about muscle relaxation and a generalized parasympathetic response.¹⁵⁰ Benson¹⁵¹ has named this effect the *relaxation response* and reports that it is accompanied by an increase in alpha brain waves.

Relaxation reduces ischemic pain by normalizing blood flow to the muscles by making way for more oxygen to be delivered to the tissues. In addition, relaxation reduces muscle tension, resulting in an interruption in the pain-spasm cycle.¹⁵²

Relaxation exercises all have two elements in common: a single focus and a passive attitude toward intruding thoughts and distractions. The end product of relaxation is a lowered arousal of the SNS and a lessening of the symptoms caused by or worsened by stress.¹⁵³

Deep relaxation can be achieved through progressive relaxation and attention-diversion exercises. Progressive relaxation involves alternately tensing and relaxing the muscles until, eventually, the entire body is relaxed. This activity teaches the individual how to recognize and relieve muscle tension within the body.

Attention diversion is an active process in which the individual directs her or his attention to non-noxious events or stimuli in the immediate environment to achieve distraction from the pain. Attention diversion is categorized as passive or active. Passive attention

diversion includes meditation and involves concentrating on a visual or auditory stimulus rather than the painful sensation, whereas active attention diversion involves active participation in a task (e.g., serial subtraction).

Meditation involves quieting the mind and focusing the attention on a thought, word, phrase, object, or movement. The individual becomes more alert to the constant stream of conversation taking place within the mind. Meditation calms the body through the relaxation response and keeps the attention focused in the present moment. Individuals in Eastern cultures have traditionally focused on a mantra, a word with spiritual meaning; however, there are no rules for where to focus the attention. The word or object should bring the individual a sense of peace and should allow the attention to be pleasantly directed toward the immediate moment.

Imagery is another form of attention diversion. During imagery the individual uses his or her imagination to produce images with pain-weakening potential. This can take two forms. In one, the individual imagines experiences that are inconsistent with the pain (e.g., imagining rolling in snow to alleviate burning pain). In the other, the individual imagines experiences that modify specific features of the pain experience (e.g., imagining that the pain is the result of a sports injury or that the sensation is “numbness” rather than pain).

Attention diversion works by activating the relaxation response and by diverting the individual’s attention from the pain. However, attention diversion also has been found to activate the higher brain centers and may have an inhibitory effect on pain through the spinal gating mechanisms.^{54,86} Lautenbacher and colleagues¹⁵⁴ found that individuals who used attention diversion for pain management reported decreased intensity and unpleasantness of their pain.

Patients can be taught to perform relaxation exercises independently and should be encouraged to perform them regularly because the benefits of these exercises are gained through regular practice.

Body Scanning

Patients with chronic pain frequently become one with their suffering; they do not view themselves as individuals with pain, but rather as painful individuals. Body scanning is a technique that endeavors to separate the individual from the pain.¹⁵⁵

During body scanning, the patient is taught to achieve a meditative state, and then to focus attention on each body area, one area at a time. The patient is instructed to breathe into and out from each area, relaxing more deeply with each exhalation. When the area is completely relaxed, the patient “lets go” of the region and dwells in the stillness for a few breaths before continuing. Painful areas are scanned in an identical manner as nonpainful areas. The patient notes, but does not judge, changes in sensation, thoughts, and emotions during scanning of each area.

Individuals who practice this technique report new levels of insight and understanding concerning their pain experience. They separate the pain experience into the following three parts¹⁵⁵:

- An awareness of the pain sensation and their thoughts and feelings about it
- An awareness of a separation between the pain sensation and their thoughts and feelings about it
- An awareness of a separation between themselves and their pain, because they are able to examine objectively the sensation and their thoughts and feelings about it

Once patients have accepted that they are not their pain or their reaction to the pain, they can determine how much influence and control pain will have in their lives.

Studies of chronic pain patients at the Stress Reduction Clinic at the University of Massachusetts Medical Center revealed that 72% of

patients who used body scanning along with traditional medical interventions experienced at least a 33% reduction on their McGill-Melzack Pain Rating Index score.¹⁵⁵ In addition, at the end of an 8-week training period, the individuals perceived their bodies in a more positive light, experienced an increase in positive mood states, and reported major improvements in anxiety, depression, hostility, and the tendency to be overly occupied with their bodily sensations.

Humor

Ever since Cousins¹⁵⁶ reported in his book *Anatomy of an Illness* that he used humor to manage pain and enhance sleep during his illness, the role of humor in healing has been well studied. Humor has been found beneficial for both acute and chronic pain management.^{111,157}

Laughter increases blood oxygen content by increasing ventilation. It helps to exercise the heart muscle by speeding up the heart rate and enhancing arterial and venous circulation, resulting in more oxygen and nutrients being delivered to the tissues.¹⁵⁸ Laughter decreases serum cortisol levels (cortisol levels increase with stress and are thought to have a negative effect on the immune response)^{159,160} and increases the concentration of circulating antibodies.¹⁵⁸ As little as 10 minutes of belly laughter a day has been found to decrease the erythrocyte sedimentation rate and provide 2 hours of pain-free sleep.¹⁵⁹ Finally, laughter releases energy and emotional tension and is followed by generalized muscle relaxation.^{158,161}

Therapeutic humor can be used to provide distraction from pain and as a coping mechanism to decrease the anxiety and tension associated with chronic pain. The muscle-relaxing effect can be used to interrupt the pain-spasm cycle.

Therapeutic humor should not be used with individuals who do poorly with humor. This includes individuals who despise or misunderstand humor, individuals who find joy threatening or guilt-inducing, and narcoleptic individuals who become cataleptic with laughter.¹⁶²

Very few patients will benefit from all these cognitive strategies, and it may take some trial and error to find the appropriate cognitive strategy for an individual patient. Some patients will have no difficulty learning and practicing cognitive strategies, whereas others will not be able to perform any of these techniques independently. It may be beneficial to provide the patient with an individualized relaxation tape or to have the patient repeat coping affirmations over and over throughout the day. The success of cognitive strategies is dependent on applying the appropriate strategy to the appropriate patient and fine-tuning the strategy so that it matches the patient’s needs.

In conclusion, it is important to reemphasize that all individuals with chronic pain have some degree of emotional or cognitive involvement, or both, in their pain experience. Many patients will live with pain regardless of the treatment they receive. Therefore it is imperative for health care practitioners to address the emotional and cognitive components of each patient’s pain to allow her or him to function at the highest level and as comfortably as possible and to find joy in each day.

General Conditioning Through Exercise

Deconditioning is a major source of disability with chronic pain. Pain causes an intolerance for activity, which in turn leads to physiological and pathological changes in the organ systems. Exercise improves overall functional performance by improving ROM, muscle strength, neuromuscular control, coordination, and aerobic capacity, as well as offering higher self-esteem.

All three types of exercise are beneficial for pain management. ROM and stretching exercises restore normal joint mobility and correct muscle tightness. The joints are held in normal alignment and are subjected to normal stresses during movement. ROM and stretching exercises are indicated where there is decreased mobility.

Strengthening exercises increase muscle strength and cardiovascular endurance. When performed with high intensity for a short duration, strengthening exercises result in increased muscle mass, improved neuromuscular control, and improved coordination. When performed at low intensity for a long duration, they increase the aerobic capacity of the muscles.

Aerobic exercises improve cardiovascular fitness. More oxygen is supplied to the tissues because there is an increase in the number and size of capillaries and a decrease in the diffusion distance between the capillaries and the muscles. The tissues use oxygen more efficiently, and the individual has a higher energy level.

All exercise has an analgesic effect through the gating mechanism by stimulation of the A delta neurons and a pain-modulating effect through activation of the descending systems. Exercise of enough intensity has been known to increase circulating β -endorphin levels, but exercise-induced β -endorphin alterations are related to the type of exercise and special populations tested and may differ in individuals with health problems.^{163,164}

It is important to include exercise in all pain management programs. Patients should be taught the appropriate exercises beginning with the first treatment session and encouraged to perform the exercises consistently when not at therapy. The ultimate end product of movement intervention is to empower the patient to modulate and control all functional activities, enabling that individual to participate in life.

Operant Conditioning

Coping strategies are learned. Individuals with chronic pain express their pain with behaviors that provide them with consistent positive rewards. For example, wincing might result in attention from a family member, or limping might allow the individual to avoid performing a particular task. Over time, the individual with pain becomes conditioned to perform certain behaviors for the behavior's rewards rather than as a reaction to the pain. Similarly, individuals with chronic pain also can condition their nervous systems through learning. If an individual expects to experience pain as the result of a particular level of activity, the individual will always experience pain at that level of activity.

Operant conditioning addresses the learned (or conditioned) aspects of pain.¹⁶⁵ Operant conditioning involves unlearning or separating the behavior and the response from the pain experience. If the goal of treatment is to lessen social reinforcement of the patient's pain behaviors (and thus extinguish those behaviors), the patient and the family or other involved individuals are shown how their behaviors and responses provide social reinforcement for the patient's reaction to pain. The involved individuals are provided with specific new responses to the patient's behavior. Family members might be instructed to ignore wincing, groaning, or the verbal report of pain. They might be told not to perform activities that are the patient's responsibility just because the patient reports pain. In time, the patient will become conditioned to the new response, and pain in those situations will diminish.

If the goal of treatment is to increase the patient's pain-free activity level, operant conditioning can be used to condition the nervous system to a higher level of activity before responding with pain. If the patient's usual pattern is to remain active until the onset of pain (negative reinforcement for activity) and then rest (positive reinforcement for pain), the patient is instructed to remain active to just below the pain threshold and then rest (positive reinforcement for activity). In this way the nervous system unlearns the connection between activity and pain, and the patient's activity level increases.

Hypnosis

Hypnosis is a state in which the body and conscious mind are deeply relaxed while the subconscious mind remains alert, focused, and

open to suggestion.¹⁵³ This has been demonstrated physiologically by electroencephalography (EEG), which shows an increase in the number of theta waves, which are associated with enhanced attention.¹⁶⁶ When a hypnotized individual is given a suggestion that is in alignment with his or her existing belief system, it is accepted by the subconscious mind as reality. The suggestion is not filtered through the conscious mind, which is critical and judgmental. Hypnosis allows the individual to bypass her or his critical beliefs.¹⁶⁷ For example, if the individual believes that a certain activity will cause pain (critical belief), that activity is sure to cause pain. If, however, during hypnosis, the individual accepts the suggestion that the activity does not cause pain, the pain may decrease and even disappear.

When hypnosis is used for pain management, a patient is first assisted to achieve complete relaxation, then given suggestions that reinterpret the pain experience. For example, a patient might be guided to reframe the pain into a messenger and then be encouraged to listen to its message to gain understanding of the meaning behind the pain. Or a patient might be guided to view the pain as an indication to stop a particular activity to avoid being injured. Or a patient might be instructed to feel less pain. Finally, where harmless activities have become painful through learning, the patient can be guided to disconnect the activity from his or her pain.

Biofeedback

Biofeedback is a training process in which the patient becomes aware of and learns to selectively change physiological processes with the aid of an external monitor. A monitoring instrument is placed on the appropriate area of the body. The machine provides an initial readout. The patient is instructed how to change the monitored process, and as change occurs, the machine "feeds back" that information. By mentally changing a biological function, the patient learns to gain control over it. In time, the patient learns to control the process without needing an assist from the instrument.

Muscle tension, pulse rate, blood pressure, skin temperature, and electromyography (EMG) and EEG readings are some of the physiological processes that can be consciously modified with biofeedback.¹⁵⁰

Biofeedback is proving to be an effective pain management tool for headaches, muscle spasms, and other physical dysfunction that leads to or increases chronic pain (see Chapters 33 and 39).

GENERAL TREATMENT GUIDELINES

As noted earlier, chronic pain management using the medical model has not been found effective. Treatment limited to correcting pathology promotes dependence on the therapist, as well as making full resolution of symptoms the measure of success.

The ICF model addresses the functional losses associated with impairments. Therapeutic interventions are not focused on pathology, but they are directed at improving the individual's function and preventing or improving disability. This does not mean that the impairment is ignored, however. Most times, addressing the individual's functional losses involves treating the impairments that caused them.

For example, patients with chronic pain frequently become sedentary, leading to the impairments of limited ROM, muscle weakness, and deconditioning. These factors can then, of themselves, cause pain, creating a cycle that spirals upward until the individual becomes disabled. During therapy, interventions are directed at the impairments with the goal of restoring function. Therapeutic interventions are selected based on their ability to improve functional outcome.

Impairments that do not affect function do not become the focus of therapy; therapeutic interventions that do not address functional deficits are not used.

The development of an appropriate treatment plan may seem overwhelming when the therapist is confronted with a patient who has chronic pain that has not responded to previous interventions or who has a chronic condition that has pain as one of its characteristics. The key is to identify the patient's functional deficits and then develop a treatment plan that addresses the causes of those deficits. In some cases, this may mean not treating the pain itself but rather its causative factors.

For example, if the patient has chronic pain because of joint hypomobility, the treatment plan includes interventions to increase joint mobility. Conversely, if the patient's pain is caused by joint hypermobility, the treatment plan includes interventions to increase support around the hypermobile joints. Merely addressing the joint pain by

applying modalities will do little to resolve the pain because it does nothing to correct the precipitating cause.

When a patient has pain because of a chronic disease and the treatment plan will include instruction in pain-relieving interventions, it is important for the therapist to understand the specific causes of the pain to select the appropriate intervention. For example, pain from rheumatoid arthritis most commonly is the result of either joint inflammation or biomechanical stress on unstable joints. A patient would be instructed in pain-relieving modalities for the former and instructed to wear splints to support the joints for the latter. One intervention would not be appropriate for both causes.

CASE STUDIES

Case Studies 30.1 to 30.3 demonstrate a problem-solving approach to the treatment of patients with chronic pain.

CASE STUDY 30.1 Fibromyalgia

K. E. is a 35-year-old computer programmer with a diagnosis of fibromyalgia. She reports a 6-month history of generalized muscular pain and fatigue that increase when she performs repetitive motions or holds a position for a prolonged period. K. E. is currently unable to work because she is no longer able to perform data entry without increased neck and shoulder pain. She states she awakens each morning with a headache and low back pain; she does not get much relief from pain medication. K. E. states she has not been out with friends in several months. She states she is "nervous, unable to concentrate, and depressed." She has been evaluated by several physicians. All medical test results are negative.

K. E.'s objective examination reveals pain on digital palpation of distinct points in the muscles of her neck and shoulder girdles, over both lateral epicondyles and greater trochanters, in her gluteal muscles, and just above the medial joint lines of the knees. Pain is referred from the tender points distally. K. E. sits and stands with a forward head and elevated protracted shoulders, and her cervical ROM is restricted slightly at end range because of her posture and muscle guarding. Muscle strength is 4/5 throughout. All other musculoskeletal and neurological test findings are normal.

K. E. demonstrates the impairments of pain, poor posture, decreased cervical and shoulder ROM, and decreased endurance, resulting in the activity limitations of interrupted sleep and decreased tolerance for activity and participation restrictions of inability to work at her profession.

The long-term goals of treatment for K. E. are independence with self-management of pain, normalization of posture, restoration of normal sleep, independence with a home exercise program, and return to work and appropriate social activities. The short-term goals include decreasing K. E.'s pain, helping her to achieve proper sleep positioning, correcting her postural abnormalities, improving her limited endurance, and assessing and correcting the ergonomics of her workstation. K. E. also needs intervention to address the emotional and cognitive aspects of her condition.

The lowered pain threshold and magnified pain perception seen with fibromyalgia result from a complex combination of muscle tissue microtrauma, neuroendocrine abnormalities, and changes in the levels of CNS neurotransmitters. The muscles of individuals with fibromyalgia show abnormal energy metabolism, poor tissue oxygenation, and localized hypoxia. Their blood shows decreased levels of the inhibitory neurotransmitter serotonin and increased levels of the facilitatory neurotransmitter substance P. This combination, which is unique to fibromyalgia, is thought to cause changes in the dorsal horn neurons and eventually in the areas of the brain responsible for the sensory-discriminative and affective-motivational aspects of pain.⁵²

Fibromyalgia pain has been shown to respond favorably to interventions that work through the gating mechanism. These include sensory-level TENS, light massage, muscle warming, and gentle stretching. K. E. can be taught to apply localized heat or to take a warm bath before gentle stretching of her tight muscles. She should be cautioned to stretch slowly to the point of resistance and to hold the stretch for 60 seconds to allow the Golgi tendon organs time to signal the muscle fibers to relax. Quick stretching to the point of pain will cause increased tightness and pain through the pain-spasm cycle. It is important for K. E. to understand that these measures address the pain of fibromyalgia but do not have any long-term effect on the course of her condition.

Individuals with fibromyalgia, and most individuals with chronic pain, experience a variety of emotions, including depression, anger, fear, withdrawal, and anxiety.¹⁶⁸ These individuals have been helped with hypnosis, biofeedback, and cognitive restructuring.^{52,168} In addition to giving them a sense of control over their pain, these interventions are known to bring about an increase in the individual's level of endogenous opiates, thereby activating one of the descending pain modulation systems. K. E. can be taught to perform these techniques independently.

K. E. should be asked to demonstrate her sleeping posture. Because the muscles of individuals with fibromyalgia do not relax easily, K. E. should be shown how to use pillows to support her neck and back so that they are encouraged to relax while she sleeps. This will help to decrease the frequency of morning headaches and back pain and help her to sleep through the night. She might also benefit from a warm bath before going to bed.

K. E.'s therapist can use gentle MFR to help correct the biomechanical imbalances causing her poor posture. K. E. can then be taught to selectively stretch the shortened muscles of her neck and shoulder girdles using the technique already described and to selectively strengthen their weakened antagonists using light resistance. To counter deconditioning, K. E. should be placed on a nonimpact aerobic program (walking, pool exercises, or stationary bicycle) with a goal of 30 minutes three to four times a week at 70% maximum heart rate (220 minus her age). If she is unable to tolerate 30 minutes of exercise at one time, she can be started at 3 to 5 minutes twice or three times daily and gradually progressed to three sessions of 10 minutes, then two sessions of 15 minutes, and finally one session of 30 minutes. K. E. may require a significant amount of coaxing and education to motivate her to participate in exercise; many individuals with fibromyalgia do not wish to move because movement initially increases their pain.

Before she returns to work, K. E. should be assisted with the ergonomics of her workstation. Research¹⁶⁹ has shown that individuals who work at computers need to vary their positions throughout the day even if their sitting posture is appropriate. Further research^{87,170,171} has shown that correct mouse placement is important to minimize stress to the arms and shoulders.

CASE STUDY 30.2 Phantom Limb Pain

A. R. is a 60-year-old carpenter who underwent below-knee amputation of his right leg 4 weeks ago after a motor vehicle accident. He now reports a constant burning, piercing, throbbing sensation in the distal portion of his missing limb. He states that immediately after the amputation, he was aware of an itching or tickling in the missing portion of the leg, but the sensation gradually changed to pain. He notes that the leg feels as if it is shortening, as if the missing foot is moving closer and closer to his hip. A. R. has been fitted with a shrinker but does not wear it because of fear of increasing the pain. He does not believe he will be able to wear a prosthesis and is concerned because his employer will be unable to find work for him if he is wheelchair-bound.

A. R.'s objective examination reveals a healing surgical incision and a poorly shaped stump. Right lower-extremity hip and knee strength are 3/5 and 2+/5, respectively. Sensation to light touch is diminished in the area of the incision. All other musculoskeletal and neurological test findings are normal. A. R. ambulates short distances using a walker but relies on a wheelchair for locomotion outside his home.

A. R. has the diagnosis of a below-knee amputation and demonstrates the impairments of phantom limb pain and decreased strength in the right lower extremity, resulting in the functional limitations of inability to prepare his leg for a prosthesis, inability to ambulate, and inability to work in his profession.

The long-term goals of treatment for A. R. are independent use of a prosthesis and return to work with modified job tasks. The short-term goals include resolution of his phantom limb pain, preparation of his stump for a prosthesis, at least 4/5 right hip and knee strength, and, when appropriate, gait and balance training with the prosthesis.

There are two theories of the cause for phantom limb pain. At one time it was thought that it occurred as the result of the formation of a terminal neuroma at the site of the amputation²¹; however, this theory did not explain phantom phenomena in individuals with congenital amputations or individuals with complete spinal cord injuries who also experience painful and nonpainful sensations in their missing or anesthetic limbs. This led researchers to look at the role of the CNS in phantom phenomena, and the latest theories suggest the previously described changes in the dorsal horn neurons and changes in the spinal cord caused by the sudden loss of afferent impulses after amputation.¹⁷²

These theories are supported by the effectiveness of interventions that stimulate the large nerve fibers and provide inhibitory input through the gating mechanism. Phantom limb pain is relieved by stroking, vibration, TENS, ultrasound, heat applications, and the use of a prosthesis. A. R. can be taught a progressive desensitization program. He should be encouraged to wear the shrinker both to prepare his stump for a prosthesis and to decrease pain. Because phantom limb pain is adversely affected by emotional stress, exposure to cold, and local irritants, he should be taught to avoid these factors as much as possible.

A. R.'s adjustment to a changed body image, a changed lifestyle, and the use of a prosthesis can be aided with any of the cognitive strategies described previously. He might also benefit from referral to an amputee support group.

It is important for A. R. to be aware of his abilities and limitations so that he remains safe when he returns to work. If appropriate, the therapist should accompany A. R. to his job and perform a job task analysis, making suggestions for necessary modifications. If this is not possible, the therapist could discuss needed modifications with A. R. based on his descriptions of his job tasks.

CASE STUDY 30.3 Complex Regional Pain Syndrome

P. S. is a 45-year-old right-handed secretary who sustained a Colles fracture of the right wrist 6 months ago. The wrist was placed in a cast for 6 weeks, during which time P. S. avoided using the extremity. Two weeks after the cast was removed, P. S. developed pain, swelling, and stiffness in the wrist and hand. She returned to her physician who diagnosed CRPS type I. She has received four sympathetic nerve blockades. The first provided 4 weeks of pain relief. The second and third provided 2 weeks of relief each. She has just received her fourth injection along with a referral for therapy.

P. S. is wearing a sling. She has 30-degree flexion contractures of her right fingers, along with swelling and stiffness of the wrist and hand. Her right wrist, elbow, and shoulder show limited motion as well. P. S. describes constant burning pain that becomes worse with any stimulation, even air blowing over the skin. She rates her pain as 4/10 since the block, but she states that the pain had slowly been escalating toward 10/10 before the injection. Her hand and wrist are cool, and the skin appears mottled and shiny. P. S. states that she is not using her arm and needs assistance at home for activities of daily living and household chores.

P. S. demonstrates the impairments of pain, swelling, stiffness, and decreased ROM of the right wrist and hand. These impairments cause activity limitations, decreasing her ability to use the right upper extremity for any functional activities, including activities of daily living, job tasks, and homemaking activities. In addition, because she is not using the extremity and carries the arm in a sling, P. S. is at risk for developing shoulder-hand syndrome.

The long-term goal of treatment for P. S. is restoration of pain-free use of her right upper extremity. The short-term goals include quieting the SNS, decreasing P. S.'s pain and edema, and restoring normal ROM of the shoulder, elbow, wrist, and hand.

Successful treatment of CRPS involves a coordinated effort by the physician and the therapist. The treatment of choice is interruption of sympathetic activity with nerve blocks and movement therapy.¹⁷³

Interventions included in a pain management program for CRPS should be chosen for their ability to quiet the SNS as well as accomplish the desired outcome. For example, thermotherapy is more beneficial than cryotherapy because of its ability to decrease pain without stimulating a sympathetic response.¹⁷³

A successful rehabilitation program for CRPS cannot be limited to therapy visits. Patients need to be instructed in interventions that they then perform three, four, or even five times daily. Therefore the therapist needs to become a guide, with the responsibility for performing the pain management program given over to the patient or caregiver.

Pain reduction is the first priority. This can be accomplished through the gating mechanism or through the deployment of endogenous opiates. Thermotherapy and TENS have both been found effective for pain management with CRPS. If P. S. cannot tolerate electrode placement on the right arm, the electrodes can be placed on the opposite arm or along the spinal roots of the involved segments.^{41,119} P. S. can be instructed in any of the superficial heating modalities. Stroking massage along the paravertebral muscles beginning in the cervical region and continuing to the coccyx has also been found effective in quieting the SNS.

Before P. S. can regain mobility of her wrist and fingers, the edema must be resolved. This can be accomplished with elevation, massage, lymphatic drainage, and compression. P. S. can wear a compression glove or, if she is able to tolerate it, receive intermittent compression to the arm. She should be instructed to keep the arm above heart level as much as possible.

P. S. should be advised to discontinue use of the sling and begin frequent weight bearing through her arm. Immobility increases the symptoms of CRPS. Movement of the extremity is important to increase proprioception and circulation, both of which have an inhibitory effect on the SNS.¹⁷³ Therefore P. S. should

CASE STUDY 30.3 Complex Regional Pain Syndrome—cont'd

be encouraged to begin using her hand as much as possible throughout the day. If she is reluctant to use the arm, the therapist can design a functional activity program that allows her to use the arm during simple activities, which can be progressed as her symptoms improve.

There are two forms of exercise that are beneficial in CRPS. The first is active ROM exercises, which should be performed frequently throughout the day within the pain-free range to regain motion, increase circulation, and provide non-nociceptive input. Exercise of the specific ROM should be within functional activities. The activity itself will encourage ROM while the patient is concentrating on successfully completing the activity itself. The second form of exercise is stress loading,¹⁷⁴ which involves active compression and traction activities without joint motion. For example, P. S. can use a coarse-bristled brush to scrub

a piece of plywood and apply as much pressure as possible without causing pain (compression activity). Or she can carry a briefcase or purse in her affected hand (traction activity). Compression and traction both provide increased proprioceptive input.

P. S. should also begin performing desensitization activities, which can be modified as she is able to tolerate more stimulation to her extremity. P. S. may benefit from biofeedback to gain control over the circulation in her arm and from relaxation activities to stimulate the relaxation response and enhance parasympathetic function.

Once P. S. becomes independent in the performance of her program, therapy can be decreased to once or twice weekly to monitor and modify her pain management regimen.

ACKNOWLEDGMENTS

We would like to acknowledge the contribution of Linda Mirabelli-Susens to the writing of this chapter in the fourth edition of the textbook.

Abstract: This chapter deals with the complex issue of acute and chronic pain management. In the first section, an overview of the anatomy and physiology of pain is presented. In the second section, examination and evaluation of pain are explained. In the third section, a number of treatment interventions are suggested. Finally, case studies are presented to guide clinicians through the problem-solving process for designing pain management programs.

Keywords: ANS pain: complex regional pain syndrome, acute pain; behavioral manipulations: exercise, operant conditioning, hypnosis,

biofeedback chronic pain; CNS pain: thalamic pain, cognitive strategies: relaxation exercises, body scanning, humor nociceptor; pain intensity measurements: visual analog scale (VAS), simple descriptive pain scale (SDPS), pain estimate, faces pain scale; pain localization tools: pain drawing; pain modulation: gate control theory, neurotransmitters, neuromodulators, pain pathway; pain quality measurements: McGill Pain Questionnaire (MPQ), pediatric verbal descriptor scale, caregiver checklists, point stimulation

Electrophysiological Testing and Electrical Stimulation in Neurological Rehabilitation

Alain Claudel, Arvie Vitente, Miguel Garcia, Rosniel Marinas, and Rolando T. Lazaro

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify electrophysiological tests performed on patients with neurological or muscle disorders.
2. Describe the instrumentation and general procedures for electrophysiological testing.
3. Recognize normal and abnormal findings of various electrophysiological tests.
4. Recognize the differences in instrumentation, signal processing, and interpretation when performing electrophysiological testing versus kinesiological electromyographic testing.
5. Differentiate the basic mechanism underlying functional neuromuscular stimulation, electrical stimulation, and electromyographic biofeedback.
6. Describe the appropriate instrumentation, signal processing, and interpretation for kinesiological electromyographic testing.
7. Describe the indications and contraindication for the use of neuromuscular stimulation, electrical stimulation, and electromyographic biofeedback.

KEY TERMS

electromyographic feedback
electroneuromyography

functional electrical stimulation
kinesiological electromyography

nerve conduction velocity
neuromuscular electrical stimulation

The goal of this chapter is to enhance the clinician's ability to recognize indications for the most commonly used electrophysiological tests and to integrate knowledge of these test indications and findings into the management of patients with neuropathological or myopathic dysfunction. The first section presents a basic description of the electrophysiological tests, including nerve conduction studies (NCSs), electromyography (EMG), kinesiological electromyography (KEMG), and the underlying neuroanatomical structures being tested. Normal and abnormal findings are discussed, with emphasis on how knowledge of these tests can assist the therapist in patient evaluation. The second section provides an introduction to the physiology, indications, contraindications, equipment, and applications of electrical muscle stimulation (EMS), neuromuscular electrical stimulation (NMES), and electromyographic biofeedback (EMGBF). The information integrates electrotherapeutic interventions into program planning for common neurological body system problems, their subsequent functional limitations, and perceived decrease in quality of life. Published evidence examining efficacy is included to assist the therapist in making choices about the use of these tools in the clinic. The third section provides a series of four case studies that illustrate the usefulness of electromyographic testing in patients with a variety of medical diagnoses.

ELECTROPHYSIOLOGICAL TESTING

Physical therapists (PTs) are uniquely positioned to understand and perform electrophysiological testing. This is because PTs examine patients with pain, numbness, and/or weakness and also because they

have a superior knowledge of neural and muscular anatomy and physiology. Electrophysiological testing is a sensitive and specific tool designed to assist in the diagnosis and the development of treatment plans for patients with diseases of the peripheral nervous system (PNS) and of the muscle itself.¹

An informed perspective on the application of these tests will benefit the physical therapist's interaction and communication with other members of the medical team. At the completion of the electrophysiological consultation, the clinician who performed the test generates a report. Understanding this report can guide decisions in planning and modification of intervention programs or will assist in referring to other health care practitioners. A review of components of such report follows.

Electrophysiological tests are usually performed by neurologists, physiatrists, and PTs who have education, training, and experience in these procedures. Most PTs practicing in the area of clinical electrophysiology are board certified by the American Board of Physical Therapy Specialties.² Some states (such as California) require additional licensing.

The general goal of electrophysiological testing is to answer the following questions:

- Is there a lesion in the PNS and/or muscles?
- Where precisely is that lesion (nerve, neuromuscular junction, muscle)?
- What is the extent of the lesion (myelin, axons or both)?

Most of the electrophysiological tests described involve the application of an external electrical stimulus to a nerve or muscle and observation and assessment of the muscle or nerve response. Other tests

such as needle EMG and single-fiber electromyography (SFEMG) involve the monitoring and recording of the electrical activity produced by the muscle tissue at rest or during contraction.

The electrophysiological tests most commonly used are motor and sensory NCSs, including F-wave and H-reflex latency measurements; repetitive stimulation; somatosensory evoked potential (SSEP) tests; and needle EMG. Most often, a patient referred for electrophysiological testing will undergo at least two motor nerve conduction tests, at least two sensory conduction tests, and at least one limb needle EMG. The American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM) has published evidence-based guidelines, which may be found on the AANEM website at <http://www.aanem.org/Practice/Practice-Guidelines>.³ A review of the patient's history, a relevant systems review, and a physical examination guide the examiner in the selection and sequencing of appropriate tests. In other words, muscle strength and tone, sensation, range of motion (ROM), cranial nerve assessment, reflex testing, neurological signs, and cognition are crucial in selecting and administering electrophysiological tests. Most subject matter experts consider electrophysiological testing as an extension of the clinical examination.^{4,5} It does not replace a careful history and physical examination of the patient. It does, however, establish the precise state of the nerves and muscles and can thus determine the location of a lesion more precisely than the clinical examination alone, particularly in cases of mild weakness or ill-defined sensory changes. In very clearly defined pathologies, electrophysiological tests are not necessary (except perhaps for medico-legal reasons). For example, in the case of a unilateral ankle dorsiflexion weakness coupled with a clearly defined L5 nerve root compression on magnetic resonance imaging (MRI) of the lumbar spine, the electrophysiological test may be of little added value. However, for a similar clinical presentation (foot drop) and no clear-cut imaging, the electrophysiological tests will differentiate between a fibular palsy, a sciatic nerve neuropathy, a lumbosacral plexopathy, or an L5 radiculopathy.

Finally, evidence-based practice recommends that the practitioner have a good understanding of the implication of the sensitivity and specificity of each test to rule it in or out for a specific condition.⁶

Anatomical Review

In order to best understand the systematic interpretation of data from the electrophysiological examination of nerves, the reader is invited to review the following foundational principles. These are explored in much greater detail elsewhere in this text.

At the Cellular Level

A nerve is composed of axons covered with a sheath of myelin. Depolarization inside the axon is an “all-or-nothing” phenomenon in which an action potential moves along the surface of the cell membrane. This action potential is an electrical wave caused by a flow of ions across the cell membrane. A local current opens a sodium channel, allowing Na^+ ions to rush inside the cell. The electrical resistance to this wave is inversely proportional to the diameter of the axon. Larger nerves conduct faster than smaller nerves. In order for efficiency as an organism to be achieved, nerve conduction must be fast. In complex organisms with billions of axons, increasing the nerve diameter is not a viable option; hence, the role of the myelin sheath. The myelin is produced by Schwann cells. These are special satellite cells that separate axons from the endoneurial fluid. The myelin acts as a capacitor: the conduction “jumps” between gaps in the myelin called *nodes of Ranvier*. This saltatory conduction allows human nerves to be 50 times smaller but conduct four times faster than unmyelinated nerves.⁷ Consequently, recording and analyzing the *conduction velocity* of nerves primarily reflect on the state of the myelin. The amplitude of the response (if a

supramaximal stimulation is delivered) is a reflection of the number of axons available to the stimulation.

The physiology of the nerve is such that when there is an injury to the axon, the portion of the axon distal to the injury will degenerate (Wallerian degeneration). This is important because all muscles innervated by branches of the nerve distal to the lesion will show signs of denervation approximately 11 days after the lesion. Consequently, assessing a patient too early after a lesion may lead to false-negative results.^{7,8}

At the Anatomical Level

The accurate performance and interpretation of the electrophysiological test—particularly the needle EMG—is significantly contingent on knowledge of the precise innervation of each muscle. As an example, an ulnar neuropathy at the elbow (UNE) clinically may be indistinguishable from a C8 radiculopathy. However, the astute clinician will remember that the cell body of the sensory nerve lies in the dorsal root ganglion, which is typically not involved in a radiculopathy. The therapist will also know that the abductor pollicis brevis is a C8- and median nerve-innervated muscle. Consequently, an ulnar nerve neuropathy is distinguishable from a C8 radiculopathy in that the ulnar sensory test will have decreased amplitude in the UNE and the abductor pollicis brevis will be denervated in the C8 radiculopathy. As a matter of fact, the clinician will keep in mind the innervation of each muscle while conducting the test. Electrophysiological testing is hence a dynamic process during which the choice of the next nerve to test or muscle to sample is predicated on the result of the previous test.^{7,8}

As a result, the electrophysiological examination is not a single, stereotyped investigation but an evolutionary one during which several tests (nerve conduction, both sensory and motor, and EMG of several muscles) can be applied to a clinical presentation.^{4,9}

Nerve Conduction Tests

A general overview of NCSs is presented to provide an understanding of their application and indications. Many excellent texts are available for details of the techniques.^{10–14}

Motor and sensory NCSs can provide data that are helpful in establishing the presence and location of pathological conditions in the PNS. The tests may indicate the anatomical level, such as a plexopathy, versus a localized peripheral mononeuropathy. Individual and multiple nerves may be assessed, and the findings compared with responses of the same nerves contralaterally. The site of pathology may be localized, such as median nerve compression at the wrist versus a lesion of the lateral cord of the brachial plexus.

Nerve conduction velocity is faster in myelinated fibers because of saltatory conduction. Disorders involving peripheral demyelination can thus be differentiated from impairments primarily involving axonal degeneration. A mild localized compressive disorder (neurapraxia) may be distinguished from a more severe lesion in which the axons and surrounding connective tissue have been completely disrupted (neurotmesis).^{12,15} In the event that the findings of nerve conduction studies (NCS) and EMG are normal, the clinician may be able to rule out most conditions involving the PNS and look for central nervous system (CNS) or other pathology. Knowledge of the rationale for NCSs and EMG should help the therapist decide when the tests may be indicated and understand the reasoning behind reports of tests that have already been performed on patients.

Motor Nerve Conduction

In motor NCSs the peripheral nerve is stimulated at various sites and the evoked electrical response is recorded from a distal muscle supplied by the nerve (a measure of orthodromic conduction). Surface

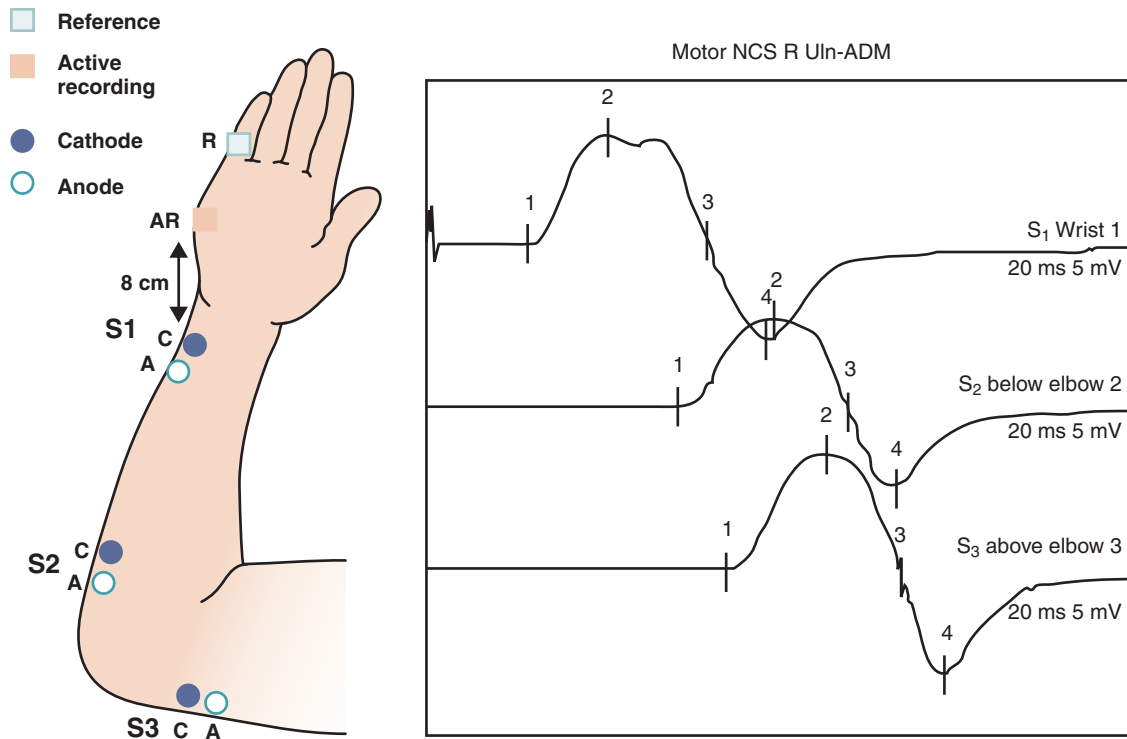

Fig. 31.1 Electrode Location for Ulnar Motor Nerve Conduction. AR, Active recording.

electrodes are usually used for both stimulating and recording. An example of electrode configuration for a motor NCS is shown in Fig. 31.1 (ulnar nerve study). The response represents the electrical activity of muscle fibers under the recording electrodes and is called the *compound muscle action potential* (CMAP). It is also called the *M wave* or *M response*. Measurements are taken of the latency (the time in milliseconds required for the impulse to travel from each stimulus site to the recording site) and the amplitude of the response in millivolts (mV). The shape and duration of the response are assessed, and motor nerve conduction velocity is calculated for each segment of interest by dividing the distance between stimulus sites (in millimeters) by the difference in latency measured at each respective site.

Velocities, latencies, and the shape and amplitude of the responses (Fig. 31.2) are studied and compared with established normal values and often with values taken from tests of the uninvolved extremity (when possible). In infants and children, nerve conduction is slower than in adults and reaches adult values by age 4 years.¹⁴ Nerve conduction velocities gradually slow after 60 years of age but generally remain within the outer limits of normal.^{12,14}

Sensory Nerve Conduction

Sensory nerve conduction can be measured from many superficial sensory nerves, such as the superficial radial and sural nerves. It can also be measured from mixed motor and sensory nerves. The stimulus is applied over the nerve in question, and the recordings taken from electrodes placed over a distal sensory branch of the nerve. The recordings are called *sensory nerve action potentials* (SNAPs). An example of recording and stimulation sites is shown in Fig. 31.3. Both orthodromic and antidromic conduction can be assessed. Response latencies and amplitudes are measured, and sensory nerve conduction velocities are calculated for each segment by dividing the distance between two adjacent stimulus and recording sites, or two stimulus sites, by the

Fig. 31.2 Velocities, Latencies, and the Shape and Amplitude of the Responses.

latency (conduction time) between these same sites. Sensory nerve responses are considerably smaller than motor responses. Their amplitudes are generally measured in microvolts (μV). Sensory conduction velocities may be calculated with just one stimulation as, contrary to motor studies, there is no neuromuscular junction to account for in sensory nerves. Sensory recordings are more sensitive than motor recordings in cases of mixed sensory-motor neuropathies.

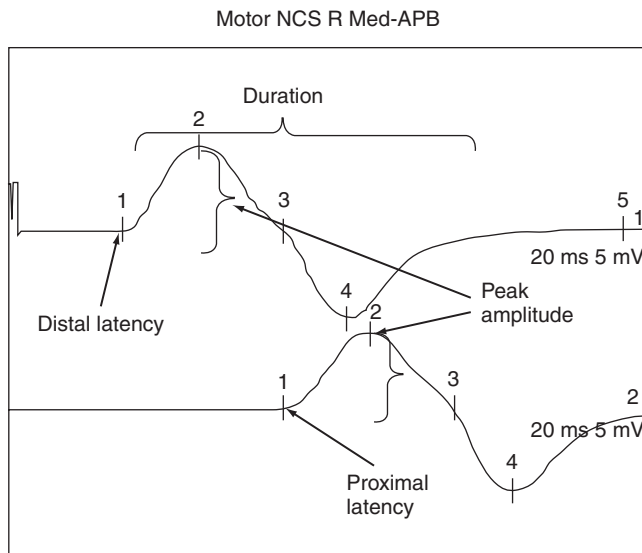

Fig. 31.3 Example of Recording and Stimulation Sites.

F-Wave Latency

When a motor nerve is stimulated in the periphery, both orthodromic (peripherally to the muscle) and antidromic (centrally toward the spinal cord) impulses are generated. A proportion of the antidromic impulses will, as it were, “bounce off” the axon hillock and return as a recurrent discharge along the same neurons to activate the muscle from which the recording is taken. This activity is termed the *F wave* (Fig. 31.4), and it is observed as a small wave occurring after the M wave.^{12,14,15} No synapse is involved. Thus the F wave is not a reflex response, but rather only a measure of conduction along the motor neuron. Specific conditions of electropotential must exist at the somadendritic cell membrane to reactivate the efferent axon; therefore the occurrence of the F-wave response is inconsistent and variable in latency and waveform.¹⁶

The F-wave latency can be useful in evaluating conduction in conditions usually involving the proximal portions of the peripheral neurons (e.g., radiculopathy, Guillain-Barré syndrome, or thoracic outlet syndrome [refer to Chapter 18]). Its value, however, has been questioned by some authors because of its variability. Normal values of F-wave latency are 22 to 34 msec in the upper extremity (stimulating at the wrist) and 40 to 58 msec in the lower extremity (stimulating at

Fig. 31.4 Example of F-Wave Study.

Fig. 31.5 Example of H-Reflex Study.

the ankle), depending on the height of the subject, with a bilateral difference in latency of no greater than 1 msec.¹⁷

H-Reflex Response

The H-reflex response latency (Fig. 31.5) is a measure of the time for action potentials elicited by stimulating a nerve in the periphery to be propagated centrally over the Ia afferent (sensory) neurons to the posterior horn of the spinal cord, to be transmitted across the synapse to α in the anterior horn of the spinal cord, and then to travel distally over these neurons to activate the muscle. The response therefore measures conduction in both the afferent and efferent neurons.^{12,14} It is also referred to as a “late” response (the other being the F wave).

The H reflex is constant in latency and waveform, and it occurs with a stimulus usually below the threshold level required to elicit the M-wave response (Ia afferent fibers are larger in diameter than α and thus more sensitive to electrical stimulation [ES]). This monosynaptic reflex response is most easily found by stimulating the tibial nerve at the popliteal area and recording from the soleus muscle. Braddom and Johnson¹⁸ reported a mean latency of 29.8 msec (± 2.74 msec) for the tibial nerve in normal adults, and a bilateral difference of no more than 1.2 msec. The H-reflex latency is a valuable measure of conduction over the S1 nerve root in differentiating suspected proximal plexopathy and radiculopathy from a herniated disc or foraminal impingement. Sabbahi and Khalil¹⁹ have reported a technique for recording the H reflex from the flexor carpi radialis muscle when stimulating the median nerve. In normal human beings older than 1 year, the H reflex is usually seen only in the tibial, femoral, and median nerves. It can be elicited from several nerves in infants and in conditions of CNS dysfunction in adults.

Repetitive Stimulation Tests

The repetitive nerve stimulation (RNS) test is used to evaluate transmission at the neuromuscular junction (motor synapse) in patients with diffuse weakness. RNS tests are helpful in the differential diagnosis of disorders such as myasthenia gravis and Lambert-Eaton myasthenic syndrome (LEMS). One protocol uses a series of supramaximal electrical stimuli applied to a peripheral nerve at a distal site (e.g., median or ulnar nerve at the wrist) at a rate of three to five per second for five to seven responses. Changes in amplitude of the muscle response are assessed. Precise technical requirements are specified to prevent movement artifacts and other testing errors. Detailed descriptions of the RNS test can be found in other texts.^{12,20} Under normal conditions the amplitude does not change more than 10% from that of the initial response in a series of 10 stimuli recorded before and after resistive exercise. An amplitude decrease in the fifth or sixth response of more than 10% is considered abnormal and is compatible with a

physiological defect at the postsynaptic receptor site of the neuromuscular junction, as in myasthenia gravis. Because myasthenia gravis most often involves facial muscles, a muscle of choice of the RNS is the nasals muscle.

In another RNS protocol, stimuli are applied to a nerve, first at a slow rate, then at a faster rate, usually 10 to 20 per second for up to 10 seconds. Normally, the amplitude can decrease up to 40% from the initial amplitude. In some defects at the presynaptic site, the response may be lower than normal during a slow stimulation rate but show a significant amplitude increase at the higher rate. Increases in amplitude greater than 100% over the initial response are consistent with presynaptic neuromuscular junction defects such as seen in LEMS, which has a strong association with small-cell bronchogenic carcinoma, and in botulism. In 1957 Eaton and Lambert²¹ reported this phenomenon as a myasthenic syndrome.

Gilchrist and Sanders²² reported another protocol referred to as a *double-step RNS test*. This test measures amplitude before and after a temporarily induced ischemia of the extremity. They found the double-step RNS test to be slightly more sensitive than the routine RNS test, but only 60% as sensitive as the SFEMG technique. The RNS test is a good alternative test for neuromuscular transmission when the SFEMG is not available, but the examiner must meticulously adhere to technical details when conducting the test.

Blink Reflex

In some conditions (e.g., facial palsy) or to establish the presence of a widespread neuropathy, it may be necessary to assess the conduction in the cranial nerves. The stimulation of the supraorbital nerve (branch of the trigeminal nerve, cranial nerve V) elicits two separate responses of the orbicularis oculi muscles, one early and ipsilateral (R1) and one late and bilateral (R2), via the facial nerve (cranial nerve VII). The early R1 response involves a synapse in the pons, whereas the late bilateral R2 responses involve a more complex pathway involving the pons and lateral medulla. Analysis of the respective latencies of each response will help in determination of the following:

- Trigeminal neuralgia (cranial nerve V) or Guillain-Barré: all responses delayed
- Acoustic neuroma or Bell palsy (cranial nerve VII): ipsilateral responses delayed
- Pontine lesion: absence of R1
- Medullar lesion: absence of R2

Hence, the blink reflex is a nerve conduction test that assesses a portion of the CNS and has shown some utility in assisting in the diagnosis of multiple sclerosis (see Chapter 19) and Wallenberg syndrome.⁸

Clinical Evoked Potentials

Electrical potentials elicited by stimulation of nerves or sense organs in the periphery can be recorded from various sites as the impulses are transmitted centrally along the neuronal pathway and from the representative area of the brain.^{12,23–25} SSEP procedures are particularly useful in assessing the integrity of afferent pathways in the CNS. They are helpful in differentiating among lesions in areas such as the plexus, spinal cord, brain stem, thalamus, and cerebral cortex. Evoked potential tests have the advantage of providing data about the integrity of both peripheral and central neuronal pathways, including transmission across axodendritic synapses.

The SSEP is valuable in assessing damage and continuity of spinal cord tracts in early spinal cord injury (SCI). For example, if an electrical stimulus is applied at the popliteal area over the tibial nerve, responses can be recorded with surface electrodes placed over the spine at the L3 and C7 spinal segments and from the lumbar representation of the contralateral sensory cortical area. Conduction time and other

parameters of the response waveforms can be measured from the recordings.

This simplified example of an SSEP illustrates how conduction over sensory peripheral nerves and afferent pathways to the cerebrum can be studied. The median nerve is usually tested to evaluate the integrity of peripheral and central pathways and their synaptic connections as the impulses travel from the upper extremity to the contralateral cortical area.

In visual evoked potential (VEP) procedures, visual stimuli such as variable light flashes of changing patterns are applied to one or both eyes under highly controlled conditions. The response is recorded from the scalp over the representative area of the cerebral cortex.^{12,24,25} The term *pattern reversal evoked potentials* (PREPs), a more descriptive term for these procedures, is recommended by the American Electroencephalographic Society.²³ These tests and other VEP procedures are useful in assessing pathology of retinal photoreceptors, the optic nerve, and postchiasm pathways. Abnormal conduction findings have been reported when VEP studies are used in demyelinating disorders such as multiple sclerosis and optic neuritis. The examiner may conclude that the patient is cortically blind because no response is recorded on the visual cortex. Although many causes for a stimulus not reaching the visual cortex are possible, the end result is considered blindness. If the cause for cortical inactivity is swelling or a neurochemical imbalance within a nuclear relay structure, once corrected, the individual may experience normal vision. A change in the reaction of the patient to the visual environment may reflect increased awareness and a change in coma scale rating. Similarly, just because an individual turns toward a light or visual stimulus does not mean an evoked potential reaches the visual cortex. Instead, the eyes as receptors and the visual tract to the brain stem may be intact even though a problem in the synaptic connections between or within the thalamus and visual cortex may exist.

Auditory evoked potential tests are used to evaluate neurological function of the cochlear division of the auditory nerve (eighth cranial nerve), central auditory pathways and synapses in the brain stem, and the receptor areas on the cerebral cortex.^{12,23–25} Brain stem auditory evoked potentials are frequently referred to as BAEPs. A series of high-intensity clicks is applied to auditory receptors in the ears through headphones, and several components of the response waveforms are recorded by using surface electrodes over the representative cortical areas. The BAEP is an effective test procedure for localizing and evaluating acoustic neuromas and other space-occupying lesions in the brain stem. This test is also used for assessment of brain damage in patients who are comatose as a result of traumatic brain injury (TBI). Robinson and Rudge²⁶ recommend caution in using BAEP tests for this purpose because other factors, such as defective receptor organs, can cause abnormalities in BAEPs.

The evoked potential tests described in this chapter all require application of appropriate external stimuli that are rapidly repeated many times. The response is electronically averaged to sort out the desired signal from interference signals. The conduction times (latencies), waveform shape and amplitude, and sometimes conduction velocities are measured and compared with normal values. Absence of a response, increased latencies, decreased amplitudes, and slowing of conduction velocities are all abnormal findings. Normal values and details of techniques for the evoked potential tests are described elsewhere.^{12,23–25}

Therapists with special interest and training administer the SSEP tests for neurological applications more frequently than other types of evoked potential tests. Because of the highly specialized techniques necessary to administer VEP tests for ophthalmological applications and BAEP tests for hearing dysfunction, they are usually performed by persons who specialize in these procedures.

Needle Electromyography

Needle EMG complements the motor and sensory NCSs; it is most sensitive in the detection of denervation.

Unlike NCSs, which use the ES of the motor nerves to elicit muscle contraction, the needle EMG is used to record and analyze muscle activity at rest and during voluntary activation. It is particularly useful in identifying pathology of the lower motor neurons and of the muscle itself. EMG can also be used to identify abnormalities of motor neuron recruitment that are associated with certain disorders of the CNS, especially when NCS findings are normal—as would be the case in radiculopathies. The primary recording studied is the insertional activity, along with activity at rest and the motor unit action potential (MUAP), which is produced by the depolarization of single motor units during voluntary or reflex activity. Spontaneous electrical activity of single muscle fibers at rest is termed *fibrillation* and is diagnostic of denervation. For recording of muscle activity, small-diameter needles are inserted within the muscles to be studied. Three electrodes are required: active (negative), reference (positive), and ground. The needles may be *monopolar*, requiring a second needle or surface electrode for reference, or *bipolar*, containing both the active and reference electrodes (usually concentric in cross section). The ground electrode is typically placed on the surface of the skin. Most commonly the needles used are disposable. The activity detected in the muscle is displayed on the video display terminal of a computer (and can be stored and printed later). It is simultaneously played through an audio amplifier. The electromyographer can often identify pathological conditions by the characteristic “sounds” of the electrical activity of the muscle. Many excellent resources are available for readers interested in details of the equipment and procedures for EMG.^{10–12,27,28} Details of contraindications and special precautions are described by Currier and Nelson.²⁸

In an EMG examination, four conditions are evaluated at each location: (1) activity during needle insertion (normally a brief burst

[250 msec at most] of high-frequency activity that abates when the needle stops moving), (2) activity during rest (electrical silence is normal unless an electrode is placed directly over a motor endplate), (3) activity during minimal and gradually increasing voluntary contraction (biphasic or triphasic MUAPs of small amplitude composed of slow-twitch type I fibers that increase in frequency and are joined by higher-amplitude potentials as larger, predominantly fast-twitch type II motor units are recruited), and (4) activity during maximal activation (an *interference pattern* caused by the blending of potentials in which individual MUAPs cannot be identified), characterized as full (complete), reduced, or absent. Several locations in an individual muscle may be studied. The specific muscles to be studied are determined by clinical findings, and results must always be interpreted in the context of the total complex of signs and symptoms. In determining the specific location of a lesion, muscles located both proximally and distally to the suspected lesion site must be assessed. Studies may be repeated at intervals to determine if changes consistent with recovery (such as reinnervation) or exacerbation are present. EMG is typically used to help determine the presence (and extent) of the following:

- Denervation
- Reinnervation
- Myopathic or neuropathic signs
- Distribution or specific location of peripheral nerve pathology

Needle EMG is sensitive in determining the state of the axons. When axons are interrupted, there is denervation of the muscle cell. The findings in denervation and partial denervation include increased insertional activity, fibrillation potentials or positive sharp waves at rest, and a reduced or absent interference pattern. CNS dysfunction can result in no resting potentials, but if motor control was impaired, a decreased or abnormal interference pattern might be apparent because of difficulty in recruitment (Fig. 31.6). Needle EMG also informs the clinician about muscle cell disorders such as myopathies. The primary

EMG FINDINGS

LESION EMG Steps	Normal	NEUROGENIC LESION		MYOGENIC LESION		
		Lower Motor	Upper Motor	Myopathy	Myotonia	Polymyositis
1 Insertional Activity	Normal 	Increased 	Normal 	Normal 	Myotonic Discharge 	Increased
2 Spontaneous Activity	—	Fibrillation Positive Wave 	—	—	—	Fibrillation Positive Wave
3 Motor Unit Potential	0.5–1.0 mv 5–10 msec 	Large Unit Limited Recruitment 	Normal 	Small Unit Early Recruitment 	Myotonic Discharge 	Small Unit Early Recruitment
4 Interference Pattern	Full 	Reduced Fast Firing Rate 	Reduced Slow Firing Rate 	Full Low Amplitude 	Full Low Amplitude 	Full Low Amplitude

Fig. 31.6 Typical findings in lower and upper motor neuron disorders and myogenic lesions. Myotonia shares many features common to myopathy in general in addition to myotonic discharges triggered by insertion of the needle or with voluntary effort to contract the muscle. Polymyositis shows combined features of myopathy and neuropathy, including (1) prolonged insertional activity, (2) abundant spontaneous discharges, (3) low-amplitude, short-duration, polyphasic motor unit potentials, and (4) early recruitment leading to a low-amplitude, full-interference pattern. EMG, Electromyography. (From Kimura J. *Electrodiagnosis in Diseases of Nerve and Muscle: Principles and Practice*. 3rd ed. New York; Oxford University Press; 2001.)

finding in the case of a myopathy is fibrillation potentials and small-amplitude polyphasic MUAPs.

Although patient cooperation during EMG testing is important, some aspects of muscle electrical activity can be studied in the patient who is very young (infant), who is unable to move, or who has only involuntary or reflex activity. Insertional and resting potentials can always be evaluated. MUAPs appear during the contraction of muscle fibers activated both voluntarily and involuntarily in both isotonic or isometric conditions. In normal conditions MUAPs are seen with voluntary movement; however, reflex activation of muscle also produces MUAPs with certain normal characteristics. In CNS disorders, hyper-tonic or spastic muscles will produce recognizable MUAPs when they are actively contracting. The electromyographer can elicit a contraction by tapping on the muscle or tendon. For example, consider a patient who is recovering from a traumatic head injury with residual spastic hemiplegia. She is unable to cooperate with the EMG exam. The patient has abnormal extensor responses in the lower extremity with the exception of the ankle and foot, which appear flaccid. An EMG of the leg and foot muscles detects abnormal resting potentials, including fibrillation and positive sharp waves in muscles innervated by the fibular nerve. Tapping on the muscles fails to elicit MUAPs. Muscles in the tibial nerve distribution have no resting potentials and respond with bursts of identifiable MUAPs when the tendon is tapped. These findings would guide the physician and therapist in looking for a possible peripheral nerve lesion in addition to the CNS dysfunction. The treatment program in this situation would differ from that for a patient without peripheral nerve pathology.

In summary, results of the needle EMG are best presented in the form of a table that indicates the following:

- Insertional activity: may be increased in acute denervation and myopathic processes
- Spontaneous activity at rest: present (positive sharp waves and fibrillation potentials) in denervation
- Fasciculations: may be present in motor neuron disorders
- Analysis of MUAPs:
 - Amplitude: Low amplitude is seen in myopathy or nascent potential; large amplitude is a sign of chronicity.
 - Phases: Normal MUAPs are biphasic or triphasic. Polyphasia is indicative of denervation-reinnervation.
 - Recruitment pattern: A less-than-full recruitment is indicative of fewer motor units discharging, as can be seen in axon loss.
 - Firing rate: If elevated, fewer motor units are contracting more often to provide the same tension in a denervated muscle.

Justification and analysis of the basic principles and results after EMG studies should assist therapists managing patients with neurological dysfunction in planning and modifying therapeutic management programs. As electrical tests are being conducted, the findings are continuously studied and used by the physician and examiner as a guide in continuing with or modifying the plan for future tests based on whether they fit the characteristics usually identified with specific pathological conditions. As previously stated, the results of the electrodiagnostic tests must be correlated with other clinical findings and data.

Summary of Clinical Electroneuromyographic and Nerve Conduction Studies

Instruments with computer-assisted analysis are now commonplace for studying electromyographic signals in great detail.^{12,29–31} Parameters of the waveform, including amplitude, duration, frequency spectrum, number of turns, or phase polarity reversals and area (the integral or total voltage of the waveform), can be automatically analyzed. The data are then compared electronically with predetermined

patterns of electrical changes, which correlate with categories of neuromuscular disorders such as myelopathies and neuropathies.

The following is a summary of the more characteristic EMG and nerve conduction changes associated with selected groupings of neurological disorders. The intent is to assist in the understanding of reports of these studies and recognize changes that may be seen in sequential tests during the course of the disorders. The following is a simplified grouping of electrical changes; actual electrodiagnostic studies show considerably more detail and frequent variations of these findings.^{10–12,27,28}

Electrical testing in CNS disorders typically shows normal motor and sensory nerve conduction. In the EMG, spontaneous activity is typically not seen, and individual motor units seen on muscle contraction usually have normal parameters. The recruitment pattern may show a slower-than-normal MUAP discharge frequency with an incomplete and irregular interference pattern. In the presence of tremor and other involuntary movements, bursts of MUAPs occur, consistent with the muscle contraction pattern. In cases involving the brain stem, the blink reflex may show abnormalities.⁸ The tests are important in differential diagnosis between a CNS and a PNS problem, but often they are not used when clinical examinations demonstrate the problem to be definitively in the CNS.

In myelopathies, which include upper and lower motor neuron disorders (e.g., amyotrophic lateral sclerosis [ALS], poliomyelitis, cervical spondylitis, and syringomyelia), motor and sensory nerve conduction is usually normal, although mild slowing may be present.¹² Motor amplitudes may be decreased. The characteristic EMG changes, which usually appear in the more chronic stages of the disorders, are increased amplitude and duration of MUAPs because of the variable impulse conduction time in sprouting axon terminals. An increased number of polyphasic potentials with increased duration is usually found. Spontaneous activity is often seen, and on strong contraction fewer rapidly firing large MUAPs are recruited, resulting in a single-unit or partial interference pattern. Fasciculations and denervation potentials are typically found in ALS. The distribution of the EMG abnormalities determines the extent of the condition.

Peripheral neuropathies show a variety of electrical changes depending on the type and location of the pathology. In a proximal pathology (e.g., radiculopathy), motor and sensory nerve conduction generally remain normal, except F waves and H-reflex responses in specific spinal segments. If motor nerve roots are compromised, spontaneous activity and increased polyphasic potentials appear, and reduced recruitment of MUAPs results in an incomplete interference pattern. In more chronic stages MUAP amplitude and duration can be increased. As the lesion improves, spontaneous activity decreases and the recruitment patterns become more normal. If only sensory roots are injured, no EMG changes occur. Again, the distribution of the EMG abnormalities (all in one myotome) is pathognomonic, especially in the presence of denervation potentials in the corresponding paraspinal muscles.³²

Lesions of peripheral nerves, which range from a focal mononeuropathy to plexopathy, frequently show abnormalities in motor and sensory nerve conduction, depending on which components of the nerve are involved. In the EMG, spontaneous activity, particularly fibrillation and positive sharp waves, is common. If the lesion is complete, no MUAPs are found. The presence of even a few MUAPs suggests a more optimistic prognosis. Often the location of the lesion can be identified by the distribution of the electrical changes. With regenerating axons, low-amplitude polyphasic MUAPs gradually appear. In the chronic stage, the amplitude and duration of MUAPs are often increased. Spontaneous activity decreases with reinnervation, but it may persist for several years.

Generalized, systemic peripheral polyradiculoneuropathies can be divided into primarily demyelinating, primarily axon loss, or mixed axonal-demyelinating polyneuropathies. Some involve mostly sensory nerves (e.g., hereditary sensory neuropathy types I to IV, Sjögren syndrome, Friedreich ataxia), and others mostly motor nerves (e.g., chronic inflammatory demyelinating polyneuropathy [CIDP], lead neuropathy), but most involve both sensory and motor nerves. In the primarily demyelinating type, such as Guillain-Barré syndrome, motor and sensory nerve conduction become markedly slow and F-wave latencies are delayed. EMG changes usually do not occur, except for a reduced recruitment pattern consistent with weak muscle contraction or conduction block (when the demyelination is such that the impulse does not propagate). With primarily axonal polyneuropathies, such as uremic neuropathy, isoniazid or cisplatin toxicity, and lead poisoning, motor and sensory nerve conduction is mildly slowed or may remain normal. The duration and amplitude of the response, however, decrease. During advanced stages, many polyneuropathies develop both demyelinating and axonal pathology (e.g., diabetic neuropathy, which is by far the most commonly encountered polyneuropathy). On EMG, spontaneous activity is commonly seen. These electrical changes generally become more severe with worsening of the pathology, but they also improve if the pathology is reversed. From a patient management standpoint, remyelination occurs at a much more expedient pace than reinnervation.^{33–35}

Again, the scope of the NCS electromyographic test is to determine the presence and extent of a neurological dysfunction. Attributing a cause to the dysfunction (e.g., diabetes versus alcoholism) requires other tests.

With myopathic disorders, motor and sensory nerve conduction are generally normal unless neural tissue is also affected. In advanced stages, however, severely atrophied muscles can produce decreased amplitude and distorted nerve conduction responses. The characteristic findings on EMG are short-duration, low-amplitude potentials. Some spontaneous potentials, particularly fibrillations and positive sharp waves, may be found but are much more frequent in the inflammatory myopathies such as polymyositis. Specific myotonic potentials appear in certain myopathic disorders (e.g., myotonia congenita). The recruitment pattern shows many low-amplitude MUAPs, appearing in a full pattern, with little voluntary effort. This type of recruitment pattern is referred to as *early recruitment*.

Neuromuscular junction disorders involve the synapse between axons and myocytes. In LEMS, the pathology is in the presynaptic

membrane (decreased release of acetylcholine [ACh]), whereas, in myasthenia gravis, the pathology involves the postsynaptic membrane. The two are differentiated by the response to RNS or jitter with single-fiber EMG (see later). In LEMS, the amplitude of the responses increases with repetitive stimulation (more quanta of ACh released), whereas, in myasthenia gravis, the responses decrease (all ACh receptors saturated). Sensory NCS findings are typically normal. Table 31.1 provides a summary of typical findings.

Single-Fiber Electromyography

Electrical activity can be recorded from two or more muscle fibers innervated by the same motor unit by using a specially designed single-fiber needle electrode. SFEMG is, at this time, the most sensitive test for evaluation of neuromuscular transmission defects such as myasthenia gravis and myasthenic syndrome. It is also used to evaluate peripheral neuropathies, motor neuron diseases, and myopathies. It is typically provided only in tertiary centers and requires a high level of patient participation.

During a carefully controlled minimal voluntary contraction, a 25 μm -diameter needle is inserted into the muscle, and several potentials from muscle fibers within the recording area are stored. Equipment with a trigger and delay line is necessary to “time lock” the tracings of the potentials. The slightly different conduction time or interpulse interval (IPI) required for impulses to be transmitted from a single motor neuron to each of its terminal endplates, cross the neuromuscular junction, and activate the muscle fiber is called *jitter*. This time difference is collected from several tracings and is converted into a mean consecutive time difference (MCD), which normally ranges from 5 to 55 msec. Values shorter or longer than this range are considered abnormal. The impulses from some axons to their muscle fibers may fail to be transmitted. This is referred to as *blocking*. Another capability of SFEMG is the measure of fiber density, that is, the average number of muscle fibers within the needle recording area. Fiber density is increased in reinnervation and also with certain myopathies because of axonal collateralization or splitting.²⁹

Macroelectromyography

A variation of SFEMG uses a macroelectrode to record the majority of muscle fibers of a single motor unit as they are triggered by an initial potential, which is then time locked with all the other muscle fiber potentials recorded from a different part of the same or a nearby

TABLE 31.1 Summary of Typical Findings

Disorder	Motor Conduction	Sensory Conduction	Electromyography
Motor neuron disease (e.g., amyotrophic lateral sclerosis [ALS])	Reduced amplitudes	Normal	Acute plus chronic neurogenic changes, fasciculations
Radiculopathies	Normal	Normal	Acute neurogenic changes in myotome
Plexopathies	Reduced amplitudes	Reduced amplitudes	Acute neurogenic changes in specific pattern
Axonal neuropathy	Reduced amplitude in affected nerve(s)	Reduced amplitude in affected nerve(s)	Acute neurogenic changes in affected nerve
Demyelinating neuropathy	Reduced conduction in affected nerve	Reduced conduction in affected nerve	Normal
Neuromuscular junction disorder	Decrement (myasthenia gravis [MG]) or increment (Lambert-Eaton myasthenic syndrome [LEMS]) with repetitive stimulation	Normal	Occasional myopathic motor unit action potentials (MUAPs)
Myopathies	Normal	Normal	Small-amplitude polyphasic MUAPs

needle.^{12,30,31,36,37} Two recording channels are used. Maximal amplitude of the potentials from several muscles has been reported by Stalberg.³⁶ The findings are analyzed, along with findings of jitter, fiber density, and conventional EMG, to evaluate the status and prognosis of various neurological and neuromuscular disorders, such as motor neuron disease, peripheral nerve lesions, and myopathies.

In summary, the astute PT in the presence of a patient reporting weakness and/or numbness will refer that patient appropriately for electrophysiological testing based on the findings of a judicious clinical examination. In reading the report of an electrophysiological consultation, the PT will first correlate the results with the findings of the physical examination of the patient, determine whether the studies performed are complete (i.e., there are sufficient data to rule in the condition but also sufficient data to rule out other conditions), and correlate the findings with the conclusion. There is evidence that PTs performing NCSs and EMG tend to follow guidelines consistently.³⁸

Kinesiological Electromyography

KEMG measures muscle activation during movement, whether it is purposeful, involuntary, dynamic, or relatively static. It is the method by which the therapist-examiner determines a muscle's (or muscle group's) onset, cessation, relative intensity, and activation sequencing during functional activities such as walking. Because normal movement depends on the CNS's ability to execute motor programs through muscle action, KEMG provides the therapist with insight, in real time, into motor function, motor control, and motor learning.

Persons with neuromuscular disorders typically exhibit control errors, including the inability to initiate, execute, or terminate movement. Selective control may be absent or abnormal with errors in muscle timing, intensity, and sequencing. Spasticity or synergistic muscle action may impede smooth execution of tasks and prevent purposeful movement. With increased emphasis on evidence-based practice, KEMG can provide objective documentation of abnormal control and intervention outcomes and provide insight into optimizing strategies for improved functional performance. Many orthopedic surgeons rely on KEMG testing to supplement clinical evaluation in planning surgical interventions (muscle transfers and releases) in children with cerebral palsy (CP),³⁹ in patients with TBI,⁴⁰ and in those who have had a stroke.⁴¹

KEMG interpretation depends on the examiner's understanding of the instrumentation chosen for testing, including electrode selection, recording techniques, signal processing, and time and intensity normalization.⁴² Coupled with three-dimensional motion (infrared camera and motion capture) and force plate analysis, external moments are calculated that define internal force demands on muscles during functional activities such as walking. KEMG delineates the muscles that participate in meeting the internal force demand.

Recording Instrumentation

KEMG can be performed by using surface or fine wire electrodes (intramuscular). Controversy exists about the choice of electrodes, with the selection dependent on the clinical or research question. If the examiner is interested in "muscle groups" (e.g., dorsiflexors, quadriceps), then surface electrodes are appropriate. Fine wire electrodes are optimal if activation of individual or deep muscles is desired (e.g., posterior tibialis, iliacus). Fine wire allows for specificity of muscle action required for surgical decisions related to muscle transfers, releases, or muscle lengthening.^{39,40,43}

Needle or fine wire electrodes (indwelling or intramuscular).

A pair of 50- μ g fine wire electrodes, also referred to as *indwelling* or *intramuscular electrodes*, are introduced through the skin and into the

muscle with a 25-gauge hypodermic needle. The 50- μ g, Teflon-coated wires are threaded through the needle's core; 2 to 3 mm of the wire's distal end are stripped of insulation and, once inserted, record adjacent motor unit activity. Before insertion the electrodes are sterilized. Inserted through the skin and into the muscle of interest, the barbed end "hooks" the muscle fibers when the needle is withdrawn. Accurate placement requires that the examiner have extensive knowledge of three-dimensional anatomy and excellent palpation skills. A maximal concentric voluntary contraction is elicited to anchor the wires into the muscle fibers, preventing displacement during subsequent contraction. This ensures sampling the same motor unit pool during subsequent tasks, trials, or conditions. ES is an essential testing element to verify electrode location. Wire electrodes allow a more precise definition of muscle timing (onset and cessation) by reducing the incidence of intramuscular crosstalk.⁴⁴ Disadvantages include decreased reliability and insertional pain caused by skin penetration.⁴⁵⁻⁴⁷ In several states, the examiner must possess specialized KEMG licensure to penetrate the skin with a needle.

Surface electrodes. When the clinical question can be answered by using surface electrodes, ES of motor points often defines optimal electrode placement over the muscle or group of muscles of interest. A maximal voluntary contraction (MVC) is elicited to confirm that optimal placement has been achieved. Standardizing electrode placement, size, interelectrode distance, and skin preparation enhances test-retest repeatability,⁴⁸ with submaximal contractions being more reliable than maximal contractions.⁴⁹ Skin displacement under the recording site may introduce movement artifact, which can be minimized by securing the electrodes to the skin with tape. To improve interday reliability, electrode placement should be marked (with ink) and standardized electrodes used. When both recording electrodes are contained in the same housing, interelectrode distance is standardized and movement artifact attenuated. Advantages of using surface electrodes include improved reliability and the ease with which they can be applied without causing patient discomfort.⁴⁵⁻⁴⁷ Specialized licensure is not required.

Instrumentation for Kinesiological Electromyography Acquisition

KEMG signal acquisition requires either a telemetry unit (FM modulation) or a hard-wired system that relies on a "cable" tethered to the subject to transmit signals from the electrode site to the receiver. The subject's performance and nature of movement strategies performed may be altered by the cabling. Telemetry allows the subject unrestricted movement; KEMG signals are transmitted through the air from a small unit worn around the subject's waist. The optimal characteristics of the receiver include a bandwidth frequency of 40 to 1000 Hz and an overall gain of 1000 Hz.⁴²

Signal processing. KEMG processing has become highly automated with the advent of high-speed computers and customized software. Once the signal has been acquired, it is stored digitally and processed by various computer programs. The "raw" signal is full wave rectified (all the negative values become positive), and a linear envelope is generated within a designated time interval. The area under the curve is mathematically integrated, and an average EMG profile is generated. Muscle-specific onset, cessation, and relative intensity are defined with a variety of software. According to a recent study, KEMG timing (onset and cessation) is optimally identified by using the intensity-filtered average (IFA) and packet analysis (PAC) when compared with ensemble average (EAV).⁵⁰ Despite a smaller recording volume with wires, Bogey and colleagues⁵⁰ demonstrated no significant difference in signal amplitude when multiple insertion sites within the same muscle were compared.

Normalization. Any acquired “raw” EMG signal needs to be referenced to a standard value. This is accomplished by dividing the raw EMG during a functional task such as walking by a reference value. The MVC serves this purpose. Subjects exert a maximal voluntary effort for each muscle that determines the maximal EMG activity possible. All subsequent efforts are compared with this maximal effort and expressed as a percentage of maximum (%MVC). In patients with neurological dysfunction who lack selective motor control, a maximal effort can be elicited in either an extensor or flexor synergy by using the upright motor control (UMC) test developed at Rancho Los Amigos National Rehabilitation Center, grading the effort as “weak,” “moderate,” or “strong” in synergy.⁵¹ Maximal efforts are elicited for 3 to 5 seconds, and the software determines the maximal activity for a 1-second interval. The muscles’ activation during a functional activity is subsequently expressed as a percentage of MVC.

Interpretation of Kinesiological Electromyography

Kinesiological electromyography and strength. KEMG testing does not directly measure muscle strength, and the examiner should resist equating raw EMG signal amplitude directly with muscle force or torque output. Grading the strength (manual muscle testing [MMT] or UMC test) of each maximal effort must accompany the interpretation of the muscle participation during a functional task.⁵² For example, patients with postpolio syndrome (refer to Chapter 35) produce large-amplitude KEMG signals that often reflect the maximal exertion of a “weak” muscle (e.g., “MMT—Poor” or $\frac{2}{5}$). Large-amplitude EMG signals represent activation of large motor units typical of reinnervation, not force output. Despite large-amplitude signals, the muscle is functionally weak. In other words, a 100% MVC normalized KEMG record for a muscle may represent the maximal effort of a “poor” or $\frac{2}{5}$ muscle.

Muscle tone versus spasticity. Therapists should resist making inferences about *tone* from KEMG testing. As previously stated, KEMG reflects the contractile activity of motor units. Muscle tone refers to the amount of *resting* tension in a muscle because of its viscoelastic properties. Because tone is not a function of motor unit activity, it cannot be measured with KEMG.⁴² In contrast, spasticity, defined as a hyperactive quick stretch response, can be recorded by KEMG because it reflects prolonged muscle activation ($\hat{O}^{\circ}\hat{u}0.1$ second). Clonus has a distinct frequency characterized by a prolonged 5- to 8-Hz signal. Using signal duration in response to quick stretch, Cahan and colleagues⁵³ identified significant decreases in spasticity in selected lower-extremity muscles in children with CP after selective dorsal rhizotomy. In these children, spasticity interfered with agonist activation during walking.

In conclusion, KEMG is useful for delineating patterns of muscle activation in motor performance, reflecting the integrity of the neuromuscular control mechanism. The examiner’s interpretation should also consider additional factors, such as the type of contraction; speed of movement; joint acceleration; and a host of physiological, biomechanical, anatomical, and neurological elements beyond the scope of this chapter.

ELECTRICAL STIMULATION AND ELECTROMYOGRAPHIC BIOFEEDBACK

NMES and EMGBF are often used as tools in the management of neurological dysfunction. EMGBF can be used both alone and in conjunction with stimulation. The primary goal of use is improvement of function by improving voluntary motor control. To that end, strengthening and alteration of abnormal tone are also common goals of treatment. EMGBF is discussed later in this chapter. More detailed

explication of treatment protocols is included in a variety of published work.^{54–65}

Electrical stimulators used in physical rehabilitation practice may be either small, portable, battery-operated units or larger line-powered clinical instruments. The clinical units often will offer a variety of stimulus forms and options for modulation of currents. Portable units provide the ability for patients and caregivers to carry out prescribed stimulation at home. Clinical units allow the therapist to customize programs to optimize treatment outcomes.

Neuromuscular Electrical Stimulation

NMES is often used as a tool in the management of neurological dysfunction. In NMES, muscle contraction is elicited by depolarization of the motor neurons. Electrodes may be placed over the muscle to be stimulated or over the motor nerve that controls the muscle. In NMES, muscle contraction is elicited by depolarization of the motor neurons. Electrodes may be placed over the muscle to be stimulated or over the motor nerve that controls the muscle. Firing order of neurons is a result of neuronal size, proximity of the electrical stimulus, and the intensity of stimulation.⁶⁶ Muscle recruitment patterns triggered by ES differ from those observed in normal muscle activation. In a voluntary muscle contraction, motor units fire asynchronously, with a larger proportion of type I, fatigue-resistant muscle fibers of the smaller motor units being recruited first. The order of muscle fiber firing occurs as a result of motor neuron size and the anatomy of synaptic connections.⁶⁷ Conversely, an electrically stimulated muscle contraction elicits initial responses from larger motor units, which contain a greater number of fatigable, type II muscle fibers. The type II fibers are innervated by larger-diameter neurons that have a lower threshold for ES than smaller neurons.⁶⁸ A study of healthy subjects demonstrated recruitment of these higher-threshold motor units at relatively low NMES training levels. In voluntary exercise a much greater exercise intensity is required for activation of these larger motor units.⁶⁸

Synchronous recruitment of muscle fibers is obtained with ES. This does not occur with volitional activation. During a sustained volitional contraction, motor units periodically “drop out” and then “drop in” to reduce fatigue. With NMES, once recruited the motor units will continue to fire until the stimulus is ended. This, coupled with the early recruitment of fatigable motor units, accounts for fatigue being a major problem in the use of NMES. It also is one reason functional activities performed under control by stimulation are much less smooth and balanced than when they are performed volitionally. At the same time, relatively low levels of NMES can recruit motor units that volitionally would be recruited only with maximal effort. This provides support for observed increases in strength with low NMES training intensities.⁶⁹ Numerous potential benefits have been identified for NMES, such as improvement in ROM, edema reduction, treatment of disuse atrophy, and improvement of muscle recruitment for muscle reeducation.⁵⁷

Parameters of Stimulation

With any ES used for patients with neuromuscular dysfunction, three parameters must be considered within the waveform: pulse (or phase) duration, pulse frequency, and pulse amplitude. Depending on the intent of the ES, instruments are available that allow all of these to be independently adjusted.

Waveform

NMES units use alternating currents. The waveform of the stimulus produced by most NMES units is either a symmetrical or an asymmetrical biphasic pulse. The two phases of each pulse continually alternate in direction between positive and negative polarity. Although an

ideal waveform has not been identified, most studies have shown the symmetrical biphasic waveform to be more comfortable than either the asymmetrical biphasic or the monophasic waveform.^{54,70,71}

Duration

Phase or pulse duration (also called *pulse width*) refers to the amount of time of a single pulse or phase. Stimulators with a pulse duration of 1 to 300 μ s (0.3 ms) can be used to activate muscles with intact innervation. Waveforms of shorter durations require a greater current amplitude to produce a muscle contraction (because the current is on for a shorter period of time). They may be more comfortable but may not possess enough charge for good contraction levels. Longer-phase durations may be used but are less comfortable. In NMES units, pulse durations may be started at 100 μ s, then increased to 200 to 300 μ s if well tolerated by the patient.^{72,73} Denervated muscles require significantly longer phase durations (20 to 100 msec) because of the longer chronaxy of muscle cells compared with motor neurons.

Frequency

Pulse frequency (or *pulse rate*) refers to the number of electrical pulses applied per unit time. In applications seeking to provide muscle contraction, the stimulus rate should be 35 to 50 pps. This is a typical critical frequency at which a muscle will respond with a smooth contraction (also called a *tetanic frequency*). Higher frequencies than this can result in early onset of fatigue. NMES used for spasm reduction may use a higher frequency, with the intent of fatiguing the muscle and decreasing spasm, which will result in decreased pain levels.

Amplitude

The amplitude (intensity) of the stimulus should be sufficient to achieve the desired strength of contraction. Battery-operated units usually indicate the amplitude only in a relative way (nonquantitatively) because the output of the battery declines over time. Depending on the impedance of the electrodes, coupling agent, skin, and soft tissue, the amount of current required at one location could be quite different than at another to produce the same degree of muscle contraction. This is why the amplitude of the stimulus is usually described according to the strength of the sensation felt by the patient. *Mild*, *moderate*, or *maximum sensory* refers to the intensity of the stimulation as felt by the patient, without eliciting a motor contraction. Similarly, *mild*, *moderate*, and *maximum motor* describe the amplitude of the stimulus needed to produce those visible muscular contractions using ES. If the intent is to strengthen the muscle or increase endurance, the patient is usually asked to participate by

voluntarily contracting the muscle being stimulated when the stimulation is on. The amplitude of stimulation should be graded based on the response of the patient, aiming at production of the clinically desired force output.

Additional Parameters: Ramp Time and On-Off Time Ratio

On time and off time. NMES for facilitation of muscle contraction should be used to supplement exercise, and goals for stimulation should be consistent with the goals of the exercise program. To simulate isotonic or isometric muscle contractions, as in voluntary movement for exercise, the stimulator must have the capability of setting cycles of on and off times. Each period of muscle contraction is followed by a period of relaxation (Fig. 31.7).^{3,57} In most cases a shorter on time than off time is desirable to avoid fatigue. For example, a 10-second on time may be followed by a 50-second off time in a cycle, resulting in an on-off ratio of 1:5. Packman-Braun⁷⁴ investigated ratios of stimulation to rest time with NMES for wrist extension in a group of hemiplegic patients. Results supported the on-off time of 1:5 as being the most beneficial in training programs of 20 to 30 minutes because of the deleterious effects of fatigue with lower ratios (1:1, 1:2, 1:3, 1:4). If the goal is to reduce edema by providing a muscle pumping action, a ratio of 1:1 or 1:2 may be preferred,⁷⁴ as the intent is to decrease the edema by continuous muscle pumping action. Lower ratios may be used when the goal is neuromuscular reeducation or endurance training.

Ramping. Ramping is another modulation that can be set by the therapist. Ramp-up is the time taken by each train of pulses to increase amplitude or intensity sequentially from zero to maximum. Ramp-off is the period set at the end of the train of maximal intensity pulses to decrease sequentially from maximum to zero amplitude (see Fig. 31.7). Ramp time can be adjusted so that the stimulation more nearly resembles a pattern of gradually contracting and relaxing muscles. For patients with hypertonicity or spasticity and a goal of facilitation and strengthening the antagonist muscle, a longer ramp-up time may avoid or minimize activation of the stretch reflex in the hyperactive agonist muscle.

Duty cycle. The term *duty cycle* is sometimes confused with the on-off time ratio. Duty cycle is the percentage of time a series or train of pulses is on out of the total on and off time in a cycle.^{3,54} For example, if the train of pulses is on 10 seconds and off 30 seconds, the total cycle time is 40 seconds. The duty cycle would be 25% (10 seconds of the total 40-second cycle). The actual on time and off time of the pulses in a cycle is a more informative description than either the duty cycle or the on-off ratio.

Fig. 31.7 Example of the relation between ramp times and on/off times. Each division on the horizontal axis equals 2 s. Note that the ramp-up time is considered part of the on time, whereas the ramp-down time is considered part of the off time. (Reprinted from DeVahl J. NMES in rehabilitation. In: Gersh MR, ed. *Electrotherapy in Rehabilitation*. Philadelphia: FA Davis; 1992.)

Muscle Reeducation

After an insult or injury affecting the CNS, problems with motor control frequently manifest. One of the common goals of therapy is to facilitate movement in the areas where control is lacking. If active movement is not present, NMES allows movement to occur by stimulation, which may be followed by resumption of active movement, possibly triggered by the sensory (visual and proprioceptive, among others) experience that accompanies the stimulation. When active movement is present but is weak or not well controlled, the therapist may choose to use NMES to supplement and strengthen the muscular contraction already present. Some evidence exists that NMES can increase activity in the somatosensory cortex and that the cortical activity is correlated with improvement in functional tasks.⁷⁵ In the presence of hypertonicity, the muscles serving as antagonists to the spastic muscle may be targeted for NMES, not only to strengthen the antagonist but to inhibit the spastic muscle by reciprocal inhibition.

Functional Electrical Stimulation

The term *functional electrical stimulation* (FES) has been used casually to describe various applications of NMES. However, FES is defined by the Electrotherapy Standards Committee of the Section on Clinical Electrophysiology of the American Physical Therapy Association as the use of NMES (on innervated muscles) for orthotic substitution.³ Baker and Parker⁷⁶ use the term to describe external control of innervated, paretic, or paralytic muscles “to achieve functional and purposeful movements.” Although NMES is generally considered to have therapeutic applications, such as increasing ROM, facilitation of muscle activation, and muscle strengthening, the key to application of FES is to enhance or facilitate functional control. It is used with patients with SCI, TBI, cerebrovascular accident (CVA), and other CNS dysfunction who have intact peripheral innervation.

An example of FES application is the ES of the fibular nerve to enhance ankle dorsiflexion during gait in patients with hemiplegia.⁷⁷ Two of the more common applications of FES on the market include the WalkAide system (Innovative Neurotronics, Austin, Texas) and Bioness (Bioness, Valencia, California). The L300 Go of Bioness (Bioness, Valencia, California) offers several features designed to optimize neurorehabilitation. This device uses a FES system with a three-dimensional motion detector of events in the gait cycle. Specifically, this device has a learning algorithm that analyzes the affected lower-extremity movement and induces ES directly to the phase of the gait cycle where it is required. Users of the earlier version (Legacy L300) have the tendency to be dependent on foot sensors or remote controls. This device has an adaptive motion detection feature and onboard controls to address this issue of dependency on foot sensors or remote controls. L300 Go also has a multichannel stimulation, which enables clinicians to adjust dorsiflexion and inversion/eversion with a novel new electrode options. To promote functional gains at home, a new mobile iOS application (myBioness) was developed to facilitate goal setting and tracking rehabilitation progress.⁷⁸ In terms of neurological dysfunctions, research has been published that indicates efficacy of these devices and FES in general in improving functional performance in people with CVA,^{79–82} multiple sclerosis, TBI, SCI,^{83,84} and CP.⁸⁵ Moreover, numerous other uses of FES have been described, ranging from isolated motor control activities, such as decreasing shoulder subluxation and reducing scoliosis, to highly technical computerized gait and bicycling capabilities, sometimes referred to as *computerized FES* (CFES).^{86–94} The trigger that activates muscle contraction in synchrony with the functional activity can be manually initiated by the patient, set within the stimulator to automatically trigger on and off cycles, or programmed into a complex computer system for bicycling or gait.

Stimulation is generally applied in short-duration pulses with a frequency sufficient to provide smooth, tetanizing muscle contractions and adjusted to cycle on and off, with adequate ramp functions, as indicated by the speed and time needed to synchronize the stimulation with the functional activity. The length of the intervention depends on the purpose and may vary from a few contractions during the functional activity, building to multiple 30-minute sessions working up to several hours, repeated daily or three to five times per week. With the more complex computerized systems used for patients with complete spinal cord lesions, electrically activated functional movements are the mechanism to achieve physiological and psychological benefits. In some situations, assisted function is also an important goal, although functional community ambulation is not yet a reality.^{90,92,95–102} Hooker and co-workers⁹⁶ evaluated the physiological effects of use of FES-assisted leg cycling in SCI. Compared with resting levels, significant increases were found in cardiac output, heart rate, stroke volume, respiratory exchange rate, pulmonary ventilation, and other physiological phenomena. CFES for cycle ergometry and ambulation has also been shown to increase muscle mass, electrically induce muscle strength and endurance,^{91,103,104} increase circulation and aerobic capacity, decrease edema, and have a beneficial impact on self-image.^{92,104,105} Jacobs and colleagues¹⁰² compared the metabolic stress of FES-assisted standing versus frame-supported standing. Cardiorespiratory stress was significantly higher with FES, and the authors concluded that FES-assisted standing alone may provide a stress sufficient to meet minimal requirements for exercise conditioning.

The demonstrated benefits of FES clearly indicate that it is a valuable tool for supplementing functional activities. The practicality and cost of applications of the more complex computerized systems need further study, especially in terms of function in community activities. (Refer to Chapter 38 for additional discussion.)

Electromyographic Biofeedback

Biofeedback is a general term used to describe the use of visual or auditory representation of physiological processes to allow an individual to modify those processes. EMGBF makes available to the patient information regarding the electrical activity of muscle. EMGBF has several well-documented applications, including alteration of physiological responses such as heart rate, temperature, and muscle tension.⁵⁵ These applications may prove beneficial for patients with neurological dysfunction. An example would be relaxation to modify pain perception. The focus of this review is the use of EMGBF for improvement of active movement, which may include reduction of hypertonicity in addition to muscle reeducation. EMGBF units range from basic single-channel portable models to clinical units with multiple channels and multiple options for provision of feedback.

EMGBF may be used to assist a patient in attaining greater levels of muscle activation in paretic muscle, decrease levels of muscle activation in spastic muscle, or attain a balance between agonist and antagonist muscle pairs.¹⁰⁶ For most practicing clinicians, EMG levels are monitored through the use of surface electrodes. Monitoring of activation of deep muscles is often not feasible. Attention to size and specific electrode placement is critical to ensure feedback that will be useful. Smaller electrodes allow specific placement, although higher impedance will be encountered. Skin must be carefully prepared to take this into account.¹⁰⁷ Because the EMG information recorded represents the sum of action potentials from motor units between the electrodes, large interelectrode distance will increase the area of muscle recorded. This may be desirable for large muscle groups or when minimal activity is present.

Smaller interelectrode distances are preferable if interference from “crosstalk” or “volume conduction” from muscles or motor units not

part of the target group is a risk. Basmajian and Blumenstein¹⁰⁷ provide an excellent review of electrode placements.

Reduction of Hypertonicity

DeBacher¹⁰⁸ described a progression of intervention with EMGBF designed to reduce spasticity. The program uses three stages of intervention: (1) relaxation of spastic muscles at rest even in the presence of distraction, mental effort, or use of muscles not targeted for EMGBF training; (2) inhibition of muscle activity during passive static and dynamic stretch of the spastic muscle, beginning with static stretch at the extremes of motion, then progressing to passive movement speed at a speed of 15 degrees per second; and (3) isometric contractions of the antagonist to the spastic muscle, with relaxation of the spastic muscle, progressing to prompt muscle contraction and relaxation of the spastic muscle, and grading of muscle contractions with movement for various force output requirements. Use of the technique in a small sample of young adults with CP demonstrated improvement in resting levels of involuntary muscle activity.¹⁰⁹ Improvements in function, however, were not demonstrated.

Inhibition of a spastic muscle alone may not be enough to improve function. Often the spastic muscle itself, once hypertonicity has diminished, is weak or has low functional tone. Weak antagonists to the affected muscle may contribute to the functional limitation. EMGBF to reinforce activity in the weak muscle may be done concurrently with its use to modify the tone in the agonist.¹¹⁰ EMGBF can be useful in helping a patient decrease abnormal muscle activation, but persistence of control problems may be related to lack of force production, deficits in speed of muscle activation, and lack of reciprocal interaction of muscle groups.¹¹¹

Muscle Reeducation

Therapists may opt to use biofeedback to provide information about the quality of the muscle contraction directly to the patient. The patient can then attempt to alter the contraction in accordance with guidelines provided by the therapist, whether the focus is to facilitate stronger contraction, decrease apparent hyperactivity, or modulate a balance of muscle activity during a functional task.

Concurrent assessment of muscle activity (CAMA) is an application of EMGBF in which the therapist uses biofeedback as an adjunct in evaluation of patient response to therapeutic exercise.¹¹² In this procedure the therapist decides which muscle group(s) are desired for activation and adjusts the position of the patient or the therapist intervention accordingly to get the correct responses. CAMA allows for the judgment of the effectiveness of a particular activity based on actual EMG responses rather than presumptions of what the intervention should cause. In a placebo-controlled study of hemiplegic patients, the addition of EMGBF to hand exercises based on the Brunnstrom approach resulted in significant improvement in active ROM in those using biofeedback compared with sham.¹¹³

Several authors suggest the use of biofeedback signals from homologous extremity muscles as a model for what the hemiplegic patient needs to alter muscle activity in a particular function.^{114,115} This has been described as a “motor copy” and was compared with a more targeted training procedure. Indications showed that the motor copy resulted in better carryover in function than the comparison therapy in follow-up evaluations. A similar training study showed indications of benefits of the procedure, but the results were not statistically significant because of the small group size.¹¹⁴ At least two studies support patterning or copying EMG from other muscles as a potentially useful tool for individuals with C4 to 7 SCI.^{116,117} A meta-analysis that compared EMGBF with conventional physical therapy for upper-extremity function in individuals after stroke reviewed

only six studies and concluded that neither approach was superior to the other.¹¹⁸

Feedback Considerations

EMGBF has the benefit of being provided simultaneously with the patient’s movement, consisting of accurate and objective information about muscle activity (given careful electrode application), and not requiring the same level of therapist skill as verbal feedback provision. EMGBF therefore may be beneficial for patients with deficient sensory feedback systems. The frequency of feedback provision, however, may require close scrutiny by the therapist.

Experiments examining feedback frequency in the learning of motor tasks support the use of less than 100% relative frequency for the subject to learn the task. Feedback provided on every trial may improve performance but degrades learning in normal subjects.¹¹⁹ In a study of stroke patients attempting a pursuit tracking task, biofeedback was used for the experimental group (electrodes over the spastic biceps), whereas the control group performed the task without feedback.¹²⁰ Posttests revealed that the use of continuous feedback had a negative transfer effect on learning of the movement task, suggesting that the experimental learners became dependent on the external feedback in performance of the task. The clinician must therefore carefully structure the use of external feedback so the patient begins to develop a sense of muscle activation or relaxation that is present without the EMGBF apparatus. This may be accomplished by turning the screen away from the patient and turning off the auditory signal as the patient progresses.

Integrating Neuromuscular Electrical Stimulation and Electromyographic Biofeedback

The use of EMG-triggered NMES, in which NMES is initiated once the patient has achieved a predetermined level of EMG activity in the targeted muscles, is an application that has been shown to have merit,^{121,122} although a more recent systematic review showed no statistically significant differences between EMG-NMES and usual care in improving upper-extremity function of the affected extremity in people who had had a stroke.¹²³ Threshold levels of EMG activity could gradually be increased as the patient gains the ability to activate muscles independently, with eventual discontinuance of the NMES as strength and active control allow. The success of this application has been shown in patients with hemiplegia in terms of increasing EMG activity and subsequent improvement in ROM and function in the involved arm and leg.¹²¹ In another study, patients who had had a stroke more than 1 year previously significantly improved wrist and finger extension strength and function after treatment with EMG-triggered stimulation compared with controls.¹²²

A variation of this application is NMES triggered by positional feedback, such that NMES is initiated once the patient actively moves through a portion of the available ROM at a joint.¹²⁴ The therapist may set the threshold angle in accordance with the patient’s goals and abilities. This method has been shown to be effective in improving wrist motion after stroke, although it was not as effective in altering control of the knee in a similar patient group.¹²⁵

Although discussions of EMGBF, NMES, and FES are often presented separately, the use of these modalities can be intertwined to achieve desired muscle control. NMES or FES may be initiated in the absence of active control (although lower levels of muscle activation may be discovered and facilitated with EMGBF). Once return of active control begins, EMGBF may be used to refine the control. An increase in muscle EMG should not be assumed to translate automatically to an improvement in functional use of that muscle in daily activities. Consequently, NMES and EMGBF need to be integrated into daily

functional activities so that appropriate muscle activity is elicited and used in its appropriate functional context.

Applications

The application of the common principles of EMGBF and NMES to different patient populations emphasizes the role of the therapist in tailoring intervention to meet specific patient needs.

Many investigators have evaluated the use of NMES and EMGBF in patients who have had a stroke.^{110,126–128} FES has been used extensively with patients with SCI. Other populations that demonstrate neuromuscular impairment or dysfunction have not been as thoroughly studied. This may be because the heterogeneity of these groups may create difficulty in research design.

Upper-Extremity Management

Electromyographic Biofeedback

EMGBF has been extensively studied, but success of the treatment is mixed, with difficulty in interpretation. A reduction in co-contraction has been observed,¹²⁹ as well as improvement in several neuromuscular variables^{126,130,131}; however, a lack of significant improvement in functional skill was noted. Given the challenge of improving upper-extremity functional ability after stroke, Wolf and Binder-Macleod¹³¹ suggested consideration of several key factors in predicting which patients may benefit from EMGBF: “Those patients who achieve the most substantial improvement in manipulative abilities initially possess voluntary finger extension; comparatively greater active ROM about the shoulder, elbow, and wrist; and comparatively less hyperactivity in muscles usually considered as major contributors to the typical flexor synergy.” Attention to the chronicity of motor dysfunction also appears critical in anticipating success with EMGBF, as patients 2 to 3 months after stroke demonstrated stronger functional gains after intervention with biofeedback compared with patients 4 to 5 months after stroke. A placebo-controlled study of EMGBF showed statistically significant improvement in active ROM of the hand in patients who received EMGBF in addition to exercise.¹¹³ A study by Doğan-Aslan¹³² and colleagues found improvements in the Ashworth scale, Brunnstrom stage, upper-extremity function test, wrist extension ROM, and surface EMG potentials in their subjects who were treated with EMGBF in conjunction with neurodevelopmental therapy (NDT) and conventional treatment in a population of subjects with hemiplegia secondary to stroke.

Neuromuscular Electrical Stimulation

Common upper-extremity applications of NMES for the patient with a stroke include reduction of shoulder subluxation (FES) and facilitation of elbow, wrist, and finger extension and motor control.

FES for shoulder subluxation reduction appears beneficial for prevention of pain and subluxation, especially if used during the early stages of recovery. In 2018, Arya and his colleagues conducted a systematic review about rehabilitation methods for reducing shoulder subluxation in post-stroke hemiparesis. The researchers have reviewed 14 RCTs or controlled trials and 8 pre- and post-single group studies. In this study, researchers have indicated that FES is effective in reducing subluxation in acute stage and that shoulder support or orthosis may reduce the subluxation temporarily while in place.¹³³ The functional benefits over the long term are not always clear, and cost-benefit ratios need to be considered. Baker and Parker,⁷⁶ Faghri and colleagues,⁸⁷ and Chantraine and colleagues¹³⁴ have reported success in management of shoulder subluxation after stroke by using gradually increasing stimulation times that ultimately reached 6 to 7 hours per day. On-off ratios were typically 1:3.

Use of NMES after stroke to facilitate motor control and function has been studied, but many studies lack controls. The extensors of the fingers and wrist are typically the targeted muscle groups. de Kroon and colleagues⁶² reported a systematic review of literature that included six randomized controlled trials. A variety of stimulation parameters were used. Three studies tested subjects with acute conditions, and three tested subjects with chronic conditions. Outcome measures for motor control included the Fugl-Meyer Motor Assessment (four studies) and strength (two studies). Functional outcomes were reported by two studies, one using the Action Research Arm test and one using the Box and Block test. The authors concluded that there was a positive effect of stimulation on motor control. Only two studies reported functional outcomes, but both were positive. Of significance is the fact that only six studies met the criteria for review in terms of rigor.^{121, 122,124,135–137}

FES has also been investigated as an upper-extremity orthosis after hemiplegia, using movement of the uninvolved shoulder to trigger stimulation of elbow extension and hand opening.¹³⁸ After an extensive training period, patients were able to demonstrate functional use of the involved hand for basic reach and grasp.

Systems with more than two channels of stimulation have proved difficult for patients to use.¹³⁹ Popovic and colleagues¹⁴⁰ reported two studies in which they used NMES to treat patients after stroke. They termed the intervention *functional electrical therapy* (FET). The stimulation was used during an exercise program composed of voluntary arm movements and opening and closing, holding and releasing objects with the stimulation serving as an electric prosthesis. Treatment was 30 minutes daily for 3 weeks in one study¹⁴⁰ and 6 months in the other.¹⁴¹ Outcomes were reported as better than controls. Initially higher-functioning subjects benefited more than those who were rated as low functioning. Unfortunately, outcome measures in these studies were not standardized.

A study of use of daily NMES in the form of neuroprosthetic FES (NESS Handmaster) stimulation of hand and finger extensors in patients with subacute strokes (6 to 12 months after onset) was reported by Ring and Rosenthal.¹⁴² All subjects were receiving physical and occupational therapy three times a week. The stimulator was used at home. Those receiving stimulation had significantly greater improvements in spasticity, active ROM, and functional hand test scores compared with control subjects. The authors concluded that supplementation of outpatient rehabilitation with NMES improves upper-limb outcomes.¹⁴²

Three-month interventions with EMG-triggered NMES, low-intensity NMES, proprioceptive neuromuscular facilitation (PNF) exercise, or no treatment were compared in a group of chronic stroke patients.¹⁴³ At 3 and 9 months after treatment, Fugl-Meyer scores improved 18% for the PNF group, 25% for the patients receiving low-intensity NMES, and 42% for the group receiving EMG-triggered NMES. The control group did not change.

These findings lend support to the use of NMES and EMGBF and NMES alone as adjuncts to physical therapy. Typically, higher-functioning patients have shown the greatest impact. Results have tended to show greater effect in patients with acute or subacute conditions, but longer-term patients sometimes benefited as well.

With the advent of the use of technology in neurological rehabilitation (see Chapter 38), an increasing number of investigations have been done to incorporate new technology with ES to improve functional performance. Sayenko and colleagues¹⁴⁴ described the use of a video game-based training system combined with NMES in a person with chronic SCI. Results indicated improvement in the strength and endurance of the paralyzed lower extremities of the individual after the intervention.

Lower-Extremity Management

Electromyographic Biofeedback

Several studies evaluating EMGBF for retraining lower-extremity control after stroke have focused on improvement of tibialis anterior control and reduction of gastrocnemius muscle activity. Results support increases in strength and ROM in ankle dorsiflexion with carryover into ambulation and maintenance of this improvement on follow-up evaluation.^{145–147}

Wolf and Binder-Macleod¹²⁶ examined a number of variables at the hip, knee, and ankle in a controlled group study of the effects of EMGBF. Subjects were assigned to one of four groups: lower-extremity EMGBF, upper-extremity EMGBF, general relaxation training, and no treatment. No significant changes were observed between experimental and control groups for EMG levels and ROM at the hip, but improvements were noted in knee and ankle active motion for the experimental group. Although subjects in the experimental group increased their gait speed, these changes were not significantly different from findings in the comparison groups.

Use of EMGBF with the intent of improving ambulation may require use of feedback during the task of ambulation instead of during static activity, as demonstrated by this study. Positional biofeedback regarding ankle position and traditional EMGBF were compared in a group of hemiplegic subjects.¹⁴⁸ A computerized system provided audiovisual feedback during ambulation for both groups. Pretreatment and posttreatment measures of ankle motion, gait, and perceived exertion were conducted for the two treatment groups and a control group. The group receiving positional feedback increased walking speeds relative to the other groups, with improvements maintained at follow-up intervals of up to 3 months. The consideration of integrating feedback into functional ambulation bears further investigation.

Neuromuscular Electrical Stimulation

Fibular nerve stimulation has been documented as an assistance for patients with hemiplegia to improve ambulation.^{77,149–151} Long-term stimulation with implanted electrodes has proved effective in improving gait patterns, but difficulties in achieving balanced dorsiflexion, infection, and equipment maintenance were drawbacks.^{151,152}

Shorter-term use of fibular nerve stimulation as an adjunct to traditional physical therapy may be considered. In a controlled study examining the use of 20 minutes of fibular nerve stimulation six times per week for 4 weeks, the stimulated group demonstrated dorsiflexion recovery three times greater than the control group, as measured by an average of 10 maximal dorsiflexion contractions. These improvements were regardless of site of lesion, age, or time since lesion.¹⁴⁹ Surface electrode stimulation is effective, and gait parameters can be improved with its use.^{153,154} If, however, a foot drop is the only major impediment to ambulation, lightweight plastic orthoses are a functional and much less expensive choice of intervention.

Multichannel ES has been used in the management of ambulation in patients who have had a stroke.^{143,155–158} Although more effective than traditional gait training in some cases in terms of gait velocity and stride length, at follow-up evaluations 8 to 9 months after therapy the difference between groups had faded. However, the expense and availability of such systems make their use unlikely at this time.

NMES used for ankle dorsiflexion triggered by heel switch during gait and biofeedback to improve active recruitment of ankle dorsiflexors or relaxation of ankle plantar flexors has been studied in hemiplegic patients.¹⁵⁹ Patients who received a combination of these interventions demonstrated significantly improved knee and ankle range parameters more rapidly than those using a single modality. This

improvement was maintained over a 1-month period. Although all groups improved in gait cycle times, results in the combined intervention group were better. This may be attributable to the synergy of biofeedback and stimulation.⁵² Granat and colleagues¹⁶⁰ also studied fibular muscle stimulation effects on gait parameters after stroke. After intervention the subjects showed significant control of eversion on all surfaces. The Barthel Index score also improved after intervention. However, no improvement occurred when the patients were not using the stimulator.

Evidence-Based Practice

Much of the literature evaluating the use of EMGBF and NMES involves patients with CVA. Although these studies have shown many significant results, interpretation of these findings in relation to what is recommended for clinical intervention is not as clear-cut. Improvements in generation of EMG activity and active movement are well documented, but the functional implications of these gains are not as well established. Clearly, in the current practice environment much of the focus is on function, so these techniques to improve muscle activation patterns must be put to functional use in the context of therapy. The therapist must consider the relevant factors that may predict success and critically evaluate outcomes during trial use of these modalities. Cost-benefit analyses must accompany any intervention using technology with the goal of regaining movement as quickly as possible and eliminating the use of equipment when practical.

Stroke

A number of studies have been published discussing the muscle recruitment problems observed after CVA.^{110,127,128} Knowledge of these problems is a prerequisite for determination of the appropriate application of NMES. Delayed recruitment of the agonist and antagonist is a relatively consistent finding. Other findings include delayed termination of muscle activity once initiated,¹⁶¹ presence of co-contraction of agonist and antagonist muscles,^{127,128} lack of co-contraction,¹¹⁰ and maintenance of agonist muscle contractions.¹²⁷

Sander and colleagues¹⁶² found that NMES application to the tibialis anterior muscle for 30 minutes three times a week for 4 weeks was effective in improving strength of the affected lower extremity.

Howlett and colleagues investigated the effect of FES in improving activity after stroke, and whether FES is more effective than training alone in a systematic review with meta-analysis. Following predetermined search and selection criteria, researchers included randomized and controlled trials up to June 22, 2014. Eighteen trials (19 comparisons) were eligible for inclusion in the review. Results of the study showed that FES had a moderate effect on activity compared with no or placebo intervention. Furthermore, researchers also noted that FES had a large effect on upper-limb activity and a small effect on walking speed compared with control groups, and appeared to have a moderate improvement in activity compared with both no intervention and training alone. In the study, researchers suggested that FES should be used in stroke rehabilitation to improve the ability to perform activities.¹⁶³

Most recently, Biasucci and colleagues demonstrated that brain-computer interfaces (BCI) coupled with FES can elicit significant lasting arm motor recovery in patients with chronic stroke. BCI translate brain signals into planned movements in patients with limb paralysis. BCI alone has an unclear efficacy and mechanisms as to motor recovery after stroke. In this study, patients who received brain-actuated functional electrical stimulation (BCI-FES) exhibit a significant arm functional recovery post intervention. The recovery lasted for 6 to 12 months after the termination of therapy. The results of the study demonstrated a promising BCI-FES combination therapy to facilitate

functional neuroplasticity leading to a significant arm functional recovery patients with chronic stroke.¹⁶⁴

Lee, Lee, and colleagues compared virtual reality (VR) combined with FES with cyclic FES for improving upper extremity function and health-related quality of life in patients with chronic stroke in a pilot, randomized, single-blind, controlled trial. In the study, participants were patients 3 months post-stroke. A VR-based wearable rehabilitation device was used in combination with FES. This device was used during the virtual activity-based training for the intervention group while the control group received cyclic FES only. Both groups received 20 sessions over a 4-week period. Results of the study have shown that FES with VR-based rehabilitation may be more effective than cyclic FES in improving distal upper extremity gross motor performance post-stroke.¹⁶⁵

In a study done by Kuznetsov and colleagues, a tilt-table with stepping features combined with FES was applied to patients with hemiparetic ischemic stroke 3 to 6 days post-stroke. Rehabilitation may be more effective if started early; however, early training is frequently limited because of orthostatic reactions. The researchers' goal is to prevent these adverse reactions through robotic tilt-table training plus FES (ROBO-FES). The researchers compared the safety and feasibility of ROBO-FES and robotic tilt-table training (ROBO) against the control, tilt-table training alone. There were no serious adverse events occurred during the study. They concluded that robotic tilt-table exercise with or without FES is safe and more effective in improving leg strength and cerebral blood flow than tilt table alone in this patient population.¹⁶⁶ Hocoma has produced a device with a tilt table with a stepping movement functionality with (ErigoPro®) or without FES (Erigo®) (see Fig. 31.8).

Page and colleagues conducted a study to assess the capacity to demonstrate cortical change in individuals with stroke utilizing an ES neuroprosthesis to facilitate repetitive task specific training (RTP). Eight chronic stroke patients (mean = 46.5 months post-stroke) received RTP five times per week for 8 weeks with each session being 30 minutes long. The sessions required the use of the neuroprosthesis (Bioness H200) during functional activities. The individuals demonstrated functional improvements in the involved upper limb as indicated by results of the Action Research Arm Test and Fugl Meyer Assessment. Functional MRI results also indicated increased cortical activation. The researchers concluded that the use of a neuroprosthesis (Bioness H200) (see Fig. 31.9) appears to increase affected arm use in a functional matter post chronic stroke.¹⁶⁷

Springer and colleagues conducted a study to assess the effects of a dual channel FES unit (NESS L300Plus) (see Fig. 31.10) on the stance phase of gait in patients with hemiparesis. Sixteen individuals (mean

Fig. 31.8 Erigo Pro. (From: Hocoma, Switzerland.)

age = 54.2) with hemiparesis resulting in a drop foot and weak hamstrings were selected for the study and properly fitted for use of the apparatus. Gait assessments with and without the unit were completed after a 6-week conditioning program with the unit. The goal of the conditional program was to have the patients using the device the entire day by the fourth week. Dual channel FES was found to potentially have a larger effect on the functionality of the ankle dorsiflexors and

hamstrings as compared to FES to solely the fibular nerve. Step length was increased in all participants.¹⁶⁸

Wolf and Binder-MacLeod¹²⁶ examined patient characteristics that are critical to success with biofeedback training for upper- and lower-extremity control after stroke. In a group of 52 patients with stroke, no significant relations between outcome and age, sex, number of EMGBF treatments, or side of hemiparesis were found. Lower-extremity treatment was associated with a greater probability of success, and this success did not seem related to chronicity of stroke sequelae. In contrast, success of upper-extremity treatment did appear to be related to length of time since onset of stroke, and poorer outcomes were noted if patients had received therapy to the involved arm for more than 1 year before EMGBF training. Improvements in elbow and shoulder function were obtained in this group of patients, but improvement in functional use of the hand was limited. Aphasia imposed a slight limitation to achieving improvement, but proprioceptive deficits were more significant in restricting functional gains. The role of patient motivation in success with EMGBF training was emphasized. On follow-up over a 12-month period, the improvements made in the initial intervention were maintained in 33 of 34 patients evaluated.

A number of studies have been published discussing the muscle recruitment problems observed after CVA.^{110,127,128} Knowledge of these problems is a prerequisite for determination of the appropriate application of EMGBF and NMES. Delayed recruitment of the agonist and antagonist is a relatively consistent finding. Other findings include delayed termination of muscle activity once initiated,¹⁶¹ presence of co-contraction of agonist and antagonist muscles,^{127,128} lack of co-contraction,¹¹⁰ and maintenance of agonist muscle contractions.¹²⁷ These reports emphasize the potential value of EMGBF in determining the best mode of intervention.

Jonsdottir and colleagues¹⁶⁹ found that the application of EMGBF in a task-oriented manner, incorporating motor learning principles, resulted in improvements in gait velocity, stride length, and peak ankle power in a population of individuals with hemiparesis. Sander and colleagues¹⁶² found that NMES application to the tibialis anterior muscle for 30 minutes three times a week for 4 weeks was effective in improving strength of the affected lower extremity.

Lourencao and colleagues¹⁷⁰ studied the effects of biofeedback with FES and occupational therapy on upper-extremity function of individuals with hemiplegia. Results indicated significant improvements in upper-extremity ROM and functional recovery with the addition of biofeedback in the treatment regimen.

Lastly, a systematic review was conducted by Woodford and Price¹⁷¹ on the use of EMGBF for recovery of motor function in individuals with stroke. The authors found evidence from a number of small studies that indicate that EMGBF resulted in improvement in gait, function, and muscle power compared with the usual physiotherapy interventions. The authors emphasized limitations in the results because of the small amount of evidence and problems with methodological designs and differing outcome measures.

Traumatic Spinal Cord Injury

NMES has a variety of applications for patients who have sustained SCI. Muscle strengthening may occur for muscles innervated by segments just above a complete SCI, or a variety of strengthening applications may be appropriate in the case of incomplete SCI. EMGBF may be used to identify muscle activity in weak musculature, as a tool to judge improvement in muscle activation, and as a method of facilitating increased strength.¹⁷² Applications of EMGBF for individuals with SCI also include facilitation of unassisted ventilation in high-level quadriplegia¹⁷³ and use of biofeedback for muscle reeducation with incomplete SCI in the acute stages when immobilization may be required.¹⁷⁴

The use of NMES, EMGBF, and other physical therapy was examined in a group of patients with incomplete cervical SCIs over a total treatment period of 16 weeks. Patients were randomly assigned to one of four groups receiving physical exercise, NMES, or EMGBF. Group 1 received EMGBF followed by physical exercise, group 2 received EMGBF followed by NMES, group 3 received NMES followed by physical exercise, and group 4 received 16 weeks of exercise only. Measurements of muscle strength, self-care ratings, mobility scores, and voluntary EMG were conducted at baseline, treatment midpoint, and conclusion of all interventions. All groups demonstrated improvement across the treatment period on all measures except voluntary EMG; however, no significant differences were seen among the four groups.¹⁷⁵ At least one other study compared conventional intervention, EMGBF, ES, and combined stimulation with biofeedback over a 6-week period in individuals with quadriplegia. An examiner who was blinded to the intervention protocol evaluated 45 subjects in the four treatment groups. All groups improved in the parameters evaluated, and no significant difference among groups was noted.¹⁷⁶ These results again emphasize the need to carefully consider cost as well as time and effort for setup and equipment operation in intervention planning.

A study by Carvalho and colleagues¹⁷⁷ studied the use of treadmill gait training with NMES to improve bone mass in people with SCI. Their research study included 21 males with chronic quadriplegia between C4 to C8, randomly assigned to a control and treatment groups. Those in the treatment group received treadmill training with NMES, unweighting the body of 30% to 50% of body weight. The training was done for 20 minutes, twice a week for 6 months. Results showed that gait training with NMES, even with 30% to 50% unweighting, resulted in the improvement of bone mass in the subjects with chronic quadriplegia. In another study also by Carvalho and colleagues,¹⁷⁸ NMES with partial body weight support resulted in hypertrophy of the quadriceps femoris muscle also in a population of subjects with quadriplegia. In both studies, NMES was helpful in producing stimulation that allowed for the subjects to advance their lower extremities while walking with body weight supported on the treadmill.

In a few studies, the application of NMES appears to be beneficial in improving impairments associated with SCI. Bittar and Cliquet¹⁷⁹ found that the use of NMES on the quadriceps and anterior tibialis of individuals with SCI was beneficial in that it allowed the feet and ankles to be placed in a better biomechanical position for ambulation. In addition, a study by de Abreu and colleagues¹⁸⁰ found improvements in the cross-sectional area of the quadriceps after NMES to these muscles.

In a study by De Biase and colleagues¹⁸¹ EMGBF training was noted to have resulted in increased EMG response of the rectus femoris muscle in 20 subjects with chronic SCI.

A study by Street and Singleton looked to assess the overall effect in walking speed using FES for motor-incomplete SCI. 35 participants (mean age = 53) with foot drop and motor-incomplete SCI (T 12 or higher, ASIA impairment scale C or D) and who could ambulate 10 m with the use of an aide were selected. The participants underwent FES to the fibular nerve, glutei, and hamstrings over 6 months while in the community. The results of the study demonstrated initial orthotic effect, total orthotic effect, and training effect and the use of daily FES may result in improved walking speeds in individuals with motor-incomplete SCI.¹⁸²

Craven and colleagues conducted a study to assess the efficacy of ES therapy assisted walking after chronic motor incomplete SCI on bone biomarkers and bone strength. Thirty-four individuals with chronic (≥ 18 months) motor-incomplete SCI (C2 to T12, ASIA impairment scale C or D) were randomized into either a treatment or conventional group. Treatment was performed three times per week,

45 minutes each for 4 months. Results of the study showed that the individuals with the FES treatment demonstrated improvements in bone turnover as compared to conventional therapy, however no significant difference in overall bone strength.¹⁸³

Galea and colleague conducted a study to assess the efficacy and safety of FES-Assisted Cycling and Passive Cycling initiated early after SCI. The researchers randomized patients into a 12-week treatment group of either assisted cycling or passive cycling with each group undergoing treatment four times per week, 1 hour maximum, over 12 weeks. The researchers used cross sectional area measurements of the thigh and calf muscles using MRI as a primary assessment tool as well as body composition measurements. Conclusions by the researchers were that both types of modalities were shown to be safe and well tolerated after SCI.¹⁸⁴

Chen and colleagues conducted a case report about the use of reciprocating gait orthosis (RGO) in combination with FES. This ambulation study of a woman with paraplegia using a RGO with FES was compared with the use of a long leg brace (LLB). The researchers concluded that RGO can help a patient with paraplegia achieve a faster and more independent ambulation. However, the combination of RGO and FES can increase the effectiveness of RGO as to locomotion. The researchers have concluded that the combination of RGO and FES is better than traditional LLB.¹⁸⁵

In 2012, a systematic review was conducted by Lam and colleagues about the evidence for the efficacy of different rehabilitation strategies on functional ambulation following SCI. They have included in their systematic review pre-test/post-test or post-test only studies about the use of FES in this condition. They have concluded that FES may augment functional ambulation in sub-acute/chronic SCI.¹⁸⁶

Ha and colleagues investigated on the utilization of cooperative control of FES with a powered exoskeleton. This research described this as a hybrid system that combines a powered lower limb exoskeleton with FES for gait restoration in persons with paraplegia. The general control structure consists of two control loops: a motor control loop and a muscle control loop. The motor control loop utilizes joint angle feedback to control the output of the joint motor to track the desired joint trajectories. On the other hand, the muscle control loop utilizes joint torque profiles from previous steps to shape the muscle stimulation profile for the subsequent step to minimize the motor torque contribution required for joint angle trajectory tracking. This system involves stimulation of the hamstrings and quadriceps muscles. The hip joints are actuated by the combination of hip motors and the hamstrings, and the knee joints are actuated by the combination of knee motors and the quadriceps. This study was implemented on three paraplegic subjects with motor complete SCI ranging from levels T6 to T10. Results suggested that the hybrid system provided consistent and repeatable gait motions. The researcher also noted a reduction in the torque and power output required from the hip and knee motors of the exoskeleton compared to walking without FES.¹⁸⁷

Upper-Extremity Management

The use of electrically stimulated hand orthotic systems for patients with C6 or higher level SCI have been refined to allow greater functional independence for a select group of patients.^{89,98,99,117,188–190} Because hand function does not occur in a cyclical pattern, the onset and termination of stimulation must be controlled by the patient in some manner, with a myoelectric or contact closing switch.⁹⁸ Multichannel stimulation is then applied with intramuscular electrodes for the flexors and extensors of the fingers and thumb, with computer-configured interplay between the different muscles to achieve a functional grasp. A chest-mounted position transducer (operated by shoulder elevation or depression and protraction or retraction) allows the user to initiate

stimulation and lock the stimulation to maintain a grasp as well as unlock it for release. A toggle switch mounted on the chest allows a choice between electronically stimulated lateral or palmar grasp patterns.^{89,99} Some investigators have used contralateral shoulder slings as well as elbow accelerometers to trigger the needed stimulation.^{191,192} Multiple authors have described successful implantation and use, with a few drawbacks, of upper-extremity FES prostheses.^{193–196} Use of this type of system may allow patients with SCI at the C5 level to operate at the same level of independence (or even a higher level) as those with C6 quadriplegia with tenodesis, gaining the ability to perform more activities of daily living (ADLs) without an attendant. Patients with SCI at the C6 level may be able to manipulate a greater variety of objects without special adaptations.

Lower-Extremity Management

Standing. In an excellent review of the use of FES for the purpose of standing patients with SCI, Gardner and Baker¹⁹⁷ described the easiest approach to stimulating the quadriceps femoris to allow paraplegic patients to stand. More complex systems may incorporate stimulation of the gluteus maximus, gluteus medius, hamstring, adductor magnus, gastrocnemius, and soleus muscles for longer-duration and better-quality standing performance. Multichannel surface and implantable systems have been and continue to be developed for assistance in sit-stand and transfer activities.^{198–200} Surgical procedures, patient selection, and technology are also factors cited in successful interventions. Despite these efforts, the duration of standing with electrically stimulated systems ranges from a few minutes to several hours. The patient with SCI may be able to use this technology to perform functional activities that require standing. The use of these systems depends on the functions unavailable to a patient without use of the technology, and the ease with which a system can be used and maintained. Peripheral to, but no less important, are the reactions of joints to these interventions. Two studies^{201,202} have reported positive benefits to the structure and functions of lower-extremity joints of adolescents with SCI after participating in FES programs. A recent study has also identified that the physiological responses to standing in SCI may provide a cardiorespiratory stress sufficient to meet minimal requirements for exercise conditioning.¹⁰²

Cycling. The use of systems to stimulate reciprocal lower limb motions electrically has increased for stationary cycling. The benefits of these interventions for the patient with SCI may relate to prevention of cardiovascular disease in the wheelchair-dependent patient. Physiological changes noted with electrically stimulated cycling include improvement of peripheral muscular and cardiovascular fitness, as demonstrated by increased power output after training with leg cycle ergometry.^{87,96,97,103,104} Combining FES and lower-extremity cycling with upper-extremity ergometry induced a higher level of cardiovascular fitness than lower-extremity ergometry alone.²⁰³ Exercise session frequency as little as two times a week induced positive changes in cardiovascular fitness.²⁰⁴ When testing of patients with paraplegia or quadriplegia is conducted with arm crank ergometry after a training program with electrically stimulated leg cycle ergometry, patients do not demonstrate differences in pretest and posttest measures of hemodynamic and pulmonary responses. These findings may relate to the specificity of the leg exercise training or the presence of a peripheral rather than a central circulatory response to the training procedure.⁹⁷ As previously noted, many cardiovascular factors can be improved and the improvements retained for at least 8 weeks after a program of FES ergometry. In the study conducted by Sadowsky and colleagues, the effect of long-term lower extremity FES cycling on the physical integrity and functional recovery in people with chronic SCI was examined. This retrospective cohort study has a mean follow-up of 29 months, and a

cross-sectional evaluation. There were 25 participants with chronic SCI that received lower-extremity FES during cycling as part of an activity-based restorative treatment regimen. Results of the study showed that FES was associated with more improvement in motor, sensory, and combined motor-sensory scores assessed using the American Spinal Injury Association Impairment scale as compared to control. Results also showed that the quadriceps muscle mass was higher and intra/inter-muscular fat was lower in the FES group. The researchers also noted that the hamstring and quadriceps muscle strength, quality of life, and daily function measures were greater in the FES group.²⁰⁵

Ambulation. As technology continues to progress, the use of electrically stimulated systems for ambulation may become more practical and useful for the patient with SCI.^{100,206,207} Acceptance and use of the systems by patients outside the clinic have been mixed, but the systems have been shown to have positive effects on characteristics of ambulation.^{152,208} Improvements in functional applications and use will also take place as the ability to select appropriate candidates improves.^{209,210} Benefits of these systems may include increased muscle bulk, a reduced risk of pressure sores and osteoporosis, and psychological benefit. Generally, improvements in functional ability are expected to produce positive psychological factors. Addressing these factors directly, Bradley,²¹¹ in a study measuring the effects of participation in an FES program on the affect of 37 individuals with SCI, demonstrated that positive affect was not significantly altered. Significant changes in negative affect occurred, however, with particular items of hostility and depression evident in those individuals in the treatment group who had unrealistic expectations. The author noted that these individuals need to be identified and monitored through the course of rehabilitation. Other drawbacks relate to the expense of the equipment and personnel and the lack of long-term efficacy studies. The speed with which a patient with a complete SCI is able to walk with electrically stimulated systems remains relatively low (2 to 54 m/min) compared with normal rates of 78 to 90 m/min.^{212,213} Many of the published reports do not provide information on the maximal distance patients are able to walk with these systems, but reported distances range from 100 to 400 m.

Some patients may perceive the technology of electrically stimulated standing and walking as moving them toward a cure for their paralysis. With a complete injury, however, the stimulation occurs passively, without expectation that voluntary control will return.²¹¹ In cases of incomplete injury, electrically stimulated ambulation may assist the patient in using and bolstering active control so that movement without the stimulation is more feasible. In considering use of electrically stimulated cycling and ambulation, discussion of the goals of treatment and the costs of the procedure must be conducted openly with the patient to allow an educated choice to be made about the use of this expensive technology.

Traumatic Brain Injury

NMES may be a useful tool with patients having sustained brain injury, with potential benefits of managing contractures by increasing ROM, facilitating active control, and reducing spasticity by strengthening the antagonist of a spastic muscle.²¹⁴ In cases in which an understanding of the purpose and principles of NMES is not feasible for a patient, the comfort of the stimulation may be critical in ensuring its continued use. Comfort may be enhanced by increasing the ramp-on time and selecting waveforms that allow stimulation at lower amplitudes yet still obtain the desired contraction.³⁷ The use of NMES with a patient at Rancho Level IV and below is not appropriate because the patient may not be able to understand the purpose and meaning of the stimulus and, hence, may perceive the stimulus as noxious.

EMGBF applications for patients with brain injury can be similar to those used with stroke, given similar motor presentations.²¹⁵

Therapists must consider residual cognitive deficits after brain injury in determining the appropriateness of EMGBF.

Guillain-Barré Syndrome

EMGBF in patients with Guillain-Barré syndrome demonstrated improvements in muscle strength in upper and lower extremities, although inconsistent improvement in functional use of the upper extremities was noted.^{216,217} Treatment regimens consisted of EMGBF for 10 trials per muscle conducted in 45-minute treatment sessions twice a week, in one case for 78 weeks and in the other case for 46 weeks.²¹⁷

Multiple Sclerosis

In a case series, Wahls and colleagues²¹⁸ found improvements in ambulation of patients with primary or secondary progressive multiple sclerosis. The authors cited the possible positive effects of NMES application on muscle spasm, muscle pain, and disuse atrophy as possible reasons behind the improvements in ambulatory function in their subjects. Street & Singleton conducted a study to assess the long-term effects of FES on individuals with MS. One hundred and forty-five individuals with foot drop (19 bilateral, 60 left lower extremity, 63 right lower extremity, and 3 not documented) and MS were assessed with a mean age of 52 (range 28 to 74). Exclusion criteria included the capacity to walk 10 m without the use of an aide. Overall, there was a significant difference noted in the individuals who walked with FES versus those who did not. The treatment group was found to have an orthotic effect when using FES, and there was also decreased complaint of pain after 5 years.²¹⁹

Pediatric Applications

Special considerations for pediatric patients need to be understood when addressing the use of electricity. Although contraindications and precautions are the same as for adults, acceptance and tolerance of these devices are not. Fear and apprehension of electricity, for both child and parent, must be addressed. The clinician must take extra care in explanation and demonstration, perhaps on themselves and possibly the parent, before placing the device on the child. Allowing the child as much control as possible in device operation may assist with acceptance. Of course, the attention span of the child must also be addressed.

Cerebral Palsy

The use of NMES with children with CP has been addressed to some degree, with several case study reports.^{220–222} Carmick^{220,221} described a variety of applications with children at 1.6, 6.7, and 10 years of age, integrating NMES into a treatment regimen that focused on a “task-oriented model of motor learning.” Improvements were noted in upper- and lower-extremity movement and functional use across a variety of tasks appropriate to the age and the movement dysfunction each child demonstrated. In a study by Nunes and colleagues,²²³ the once-a-week application of NMES on the tibialis anterior muscle of 10 children with spastic hemiplegia resulted in improvements in gross motor function, passive ROM of ankle dorsiflexion, and muscle strength.

Ozer and colleagues²²⁴ studied the effect of using NMES in combination with dynamic bracing and found the dual intervention to be more effective than either alone in reducing upper-extremity spasticity in their sample of children with spastic hemiplegic CP. A similar study by Postans and colleagues²²⁵ found that NMES combined with dynamic splinting reduced upper-limb contractures in children with CP. In another study,²²⁶ the application of NMES to the gluteus medius improved gait parameters in children with spastic diplegia.

Advancements in technology have allowed the use of EMGBF in increasing contexts, such as the computer-assisted feedback (CAF) system, which can be used to provide feedback about muscle activity

during ambulation.²²⁷ Data examining use of this system to provide feedback about the level of triceps surae activity during gait of children with CP suggest potential improvements in gait symmetry, velocity, and appropriate muscle activation patterns as a result of this intervention. The use of this modality as an adjunct to physical therapy may prove beneficial.

When reviewing the literature, one notices controversial or lack of evidence supporting electrical modalities for the treatment of children with neurological conditions. Evidence supports the implementation of electrical modalities such as NMES and FES to treat impairments secondary to CP, however.

Arya and colleagues (2012)²²⁸ assessed the effectiveness of electric muscular stimulation (EMS) in children with spastic CP. The current treatment for spasticity in the lower extremities include muscle strengthening, flexibility, and balance exercises. Other treatment approaches include orthotics, botulinum toxin injection, and surgical interventions. Electrical muscular stimulation is effective in improving ROM, strength, gait parameters and energy efficiency, and decreasing spasticity (Arya, et al., 2012).²²⁸

In their study, Arya and colleagues (2012)²²⁸ aimed to test the effectiveness of ES in the improvement of gait parameters. This study focused on the lower extremities using surface electrodes of quadriceps and tibialis anterior in conjunction with occupational therapy and physical therapy services. The control group consisted of children with CP, who received occupational and physical therapy services, but no electrical modalities. The participants were children with spastic diplegic and spastic hemiplegic type of CP. The age groups ranged from 7 to 14 years of age (Arya, et al., 2012).²²⁸

This treatment approach focused on measuring the following outcomes:

- Gait: cadence (number of steps per minute), step length, and speed
- Gross motor function classification system expanded and revised (GMFCS) classification level
- Physiological Cost Index (PCI)
- Muscle power (using modified Ashworth Scale)
- Functional improvement using Gross Motor Function Measurement (GMFM) 88 scores
- MUAP Score using EMG
- Minimum strength of current needed for contraction
- Maximum tolerated current for different pulse width (100 μ s to 300 μ s)²²⁸

The parameters of the ES on the quadriceps and Tibialis Anterior consisted of EMS mode, 200 μ s, 20 Hz for the quadriceps and 40 Hz for Tibialis Anterior, Biphasic rectangular pulses, for 20 to 30 minutes daily for four to five times a week. The tolerance of each child to the ES dictated the output current.²²⁸ In this study, ES improved gait cadence, speed, and energy consumption. ES also improved functional outcome as shown by GMFM score.

A literature review indicated that ES using surface stimulation. Surface stimulation is associated with difficulty in obtaining repeatable stimulated responses, inability to stimulate deeper muscles, stimulation of unintended muscles, decreased skin tolerance with prolonged use, and stimulation of cutaneous nociceptors in patients with CP.²²⁹ Disadvantages of surface ES are as follows:

- High levels of charge (e.g., 100+ mA for 0.2 msec), which may result in pain as cutaneous nociceptors are collaterally stimulated
- Relatively nonselective, which may stimulate untargeted muscles
- It may not stimulate deep muscles
- Donning and doffing of the equipment may be challenging for some children requiring physical assistance

- Accuracy placing electrodes over motor points to achieve repeatable motor responses²²⁹

The study author highlighted the importance of implanted neurostimulation devices to mitigate many of the disadvantages of surface stimulation listed above. These implanted devices provide substantially less charge (0.5 to 3 mA for 0.2 msec) and facilitate selective stimulation when the metal electrodes are implanted close to either motor nerves or the motor points where muscle is innervated.²²⁹ This literature review concluded that ES holds promise for therapeutic value for the treatment of impairments secondary to CP. Most studies assessed the benefits of ES using surface stimulation, which suffers from nonselectivity and the potential inability to use proper dosing because of collateral stimulation of pain receptors. Consequently, the author suggests the use of long-term implantable stimulation devices such as the Radio Frequency Microstimulator (RFM) as this device mitigates adverse effects of both percutaneous and fully implanted leaded systems.²²⁹

Cauraugh and colleagues (2010) conducted a systematic review and meta-analysis on the effects of ES on gait in children with CP. Two hundred and thirty eight participants experienced ES treatments. Two hundred and twenty four received no stimulation and served as the control group. Common outcome measures associated with impairment and activity limitations were submitted to separate random effects models meta-analyses. The primary outcome measures for impairments consisted of ROM, torque/moment, and strength/force. For the activity limitations, the outcome measures consisted of gross motor functions, gait parameters, hopping on one foot, videotaped 6-m walk, Leg Ability Index 23, and Gillette gait index 57. Moderator variable analyses validated the positive treatment effects of ES on children with CP from both functional and neuromuscular stimulation. The systematic review and meta-analyses determined medium effect sizes for ES on gait impairment and activity limitations of children with CP.²³⁰

Prosser and colleagues²³¹ conducted a study with children with CP assessing the acceptability and clinical effectiveness of the WalkAide, a novel device that delivers FES to stimulate ankle dorsiflexion. There were 21 participants with a mean age of 13 years and 2 months. The Gross Motor Function Classification System (GMFCS) levels were I and II. The experiment group was provided with FES during gait training. The control did not receive FES treatment during gait training. The experiment lasted 4 months. Ankle kinematics and spatiotemporal variables were measured. Improved dorsiflexion was observed during the swing (mean and peak) and at initial contact subphases of the gait cycle. Gait speed was unchanged. The authors concluded the WalkAide is an effective modality to address foot drop in those with mild gait impairments secondary to CP.

Galen and colleagues²³² investigated the effects of FES combined with Botulinum Toxin A (BTXA) therapy in treating dynamic equines in children with spastic CP. This study also assessed the feasibility of this combination therapy. There were eight children: six males, two females; with ages ranging from 7 to 11 years of age. The qualifying diagnosis was CP either hemiplegic or diplegic spastic type. The ankle angle at the end of the swing phase was the primary outcome measure. All subjects participated in the study for 20 weeks, which consisted of the following periods: baseline (1 week), BTXA phase (3 weeks), first FES phase (4 weeks), first control phase (4 weeks), second FES phase (4 weeks), and second control phase (4 weeks). Each participant was assessed at the end of each phase. Results indicated that there was an increase in ankle angle at the end of swing phase in most subjects and were able to sustain the positive outcome after FES was withdrawn during the control phase. The positive results lasted longer when combining BTXA and FES. The authors concluded that combining BTXA

therapy with FES is an effective treatment approach in the management of dynamic equines of children with CP.²³²

Danino and colleagues²³³ evaluated the effectiveness of FES Neuro-prosthesis in addressing gait deviations in children with CP hemiplegic-type. The device was the NESS_ L300TM, delivered ES to the common fibular nerve during the swing phase of the gait cycle. These stimuli facilitated the ankle to dorsiflex preventing foot drop. The participants consisted of four adolescents (mean age 16.5 years) with hemiplegic CP and one with diffuse pontine glioma. Results indicate an improvement in the Gait Profile Score (GPS), Gait Deviation Index (GDI), and Gillette Gait Index (GGI) with participants expressing high satisfaction and continuing to use the device at 1-year follow-up.²³³ Danino and colleagues (2013)²³³ concluded that FES targeting the dorsiflexors improves gait deviations in patients with hemiplegia (Danino et al., 2013).²³³

Spina Bifida

There is limited evidence of the effects of ES on children with myelomeningocele. Walker and colleagues²³⁴ studied the effect of ES at night on strength and function in children with myelomeningocele. There were 15 participants, but only seven completed the treatment with ES for 9 months. ES was provided on areas of muscle weakness during sleep six nights per week. This treatment resulted in small gains in muscle strength, gait, and bowel continence, but there were no changes in physical function.

In the study by Karmel-Ross and colleagues²³⁵ five subjects with spina bifida (aged 5 to 21 years) were treated with daily NMES over an 8-week period to strengthen the quadriceps femoris muscles. Increases in maximal quadriceps torque production were observed in two of the five subjects in the treated limb. Improvements in functional activity speeds were noted for all of the subjects. Lack of improvement in torque production by three subjects was speculated to be related to lack of adherence to the exercise regimen and the heterogeneity of the subject sample.²³⁵

Spinal Muscular Atrophy

Fehlings and colleagues (2002)²³⁶ evaluated the effect of low-intensity night-time therapeutic electrical stimulation (TES) to the deltoids and biceps on upper extremity strength and function in children with intermediate type spinal muscular atrophy (SMA). After 6 to 12 months of stimulation no statistically significant differences were noted between experimental and placebo-control arms in strength, muscle mass, or function.²³⁶

Scoliosis

Axelgaard and Brown⁸⁶ demonstrated in the 1970s that surface NMES could reduce idiopathic scoliosis. Criteria for this treatment required curves measuring 20 to 45 degrees by the Cobb method, at least 1 year of growth remaining, idiopathic and progressive nature of the curve, cooperative and psychologically stable and compliant patient, and tolerance of the stimulation. Electrodes were placed laterally over the midaxillary line on the convex side. A paraspinous location on the convex side was sometimes used. Settings included a pulse duration of 220 μ s, frequency of 25 pps, and an on-off ratio of 6 seconds on and 6 seconds off. The treatment time was gradually increased to 8 hours of stimulation per day (the stimulation was typically done at night if tolerated). High success and low dropout rates were reported.²³⁷ Others, however, reported much lower success rates.²³⁸ Intolerance of the treatment resulting in low compliance may be the cause of these differences. This disorder is much more common in adolescent girls. When NMES was first introduced for scoliosis, the uncomfortable and cosmetically undesirable Milwaukee brace was still the norm for treatment. With more advanced materials and orthotic management that is much more acceptable cosmetically, the use of NMES in scoliosis management has significantly declined.

Kim & Yoo²³⁹ investigated the effect of manual therapy with FES on scoliosis in children with CP and their quality of life. Two children with CP participated in the study, which consisted of 30 minutes of manual therapy and 30 minutes of FES. These modalities were provided three times a week for 3 months. The Cobb's angle and the Pediatric Quality of Life Inventory (PedsQL) were assessed before and after the intervention to determine the effect of combining these two modalities. The authors concluded that manual therapy with FES was effective for improving the scoliosis curve and quality of life of children with CP and scoliosis.

Ko and colleagues²⁴⁰ studied the effects of lateral electrical surface stimulation (LESS) on scoliosis and trunk balance in children with severe CP. The participants were children with severe CP (GMFCS level IV or V). The scoliosis was either stationary or progressive. The frequency of treatment consisted two sessions of LESS per day, 1-hour session, for 3 months at home. The intensity was set at 40 to 80 mA, pulse width at 200 μ s, the frequency at 25 Hz, on for 6 seconds and then off for 6 seconds on the convex side of the spine. The following measurements were conducted at 3 months before, just before, 1 month after, and 3 months after LESS: Radiologic (Cobb's, kyphotic, and sacral angles) and functional GMFM-88 sitting score, and trunk control measurement scale (TCMS). The results revealed a median Cobb's angle of 25 degrees. There were significant improvements after 1 and 3 months of LESS treatment. The authors concluded that LESS is effective in treating scoliosis in children with severe CP and indicated that it might improve trunk balance.

Contraindications and Precautions

Any ES application is contraindicated for patients who have epilepsy or demand-type pacemakers. In addition, contraindications exist to applications over the transthoracic area or the uterus in pregnancy as well as in a cancerous area and the carotid sinus. Other factors require precaution but are not strict contraindications, such as sensory deficits, skin problems (sensitivity to stimulation, electrodes, or gel; edema; open wounds), tolerance of stimulation intensity sufficient to elicit muscle contraction, patient's capability to participate in the training process, and financial considerations.^{57-59,241}

Matthews and colleagues²⁴² reported changes in blood pressure and heart rate suggestive of autonomic hyperreflexia when ES was applied in seven subjects with SCI above the T6 level. FES to the quadriceps produced the noted changes as stimulation intensity was increased. The mechanism for this reaction is unclear. Clinicians should monitor vital signs in patients with SCI (and possibly all patients), at least during the initial application of ES.

The use of stimulation modalities by patients outside clinical therapy sessions requires a degree of cooperation and motivation to take care of the stimulation unit, use it as instructed, and observe precautions. Long-term use of NMES (e.g., FES) may not be feasible for patients who do not have the financial resources (insurance or otherwise) to rent or purchase a unit or do not have reasonable access to support for equipment maintenance.

EMGBF does not require as many precautions because the procedure only monitors muscle activity. This form of feedback by the patient requires a basic level of attention and cognitive skill to understand the meaning of, as well as act on, the feedback to change muscle performance. Patient motivation and interest in use of this modality are also required because the patient must be able to develop sensitivity to the degree of muscle activation independently so that feedback is no longer required. EMGBF may be used in some instances that do not require the cognitive skills of the patient to use this information, such as an evaluative tool for the therapist to gather information about muscle activation to plan intervention strategies.

SUMMARY

The concepts, descriptions, and applications of electrodiagnosis presented in this chapter are intended to enrich the therapist's comprehension of these studies as applied to patients with neurological conditions. Integration of the results of these tests in differential diagnosis and in subsequent planning of intervention is invaluable.

Clearly, the use of NMES and EMGBF has numerous possibilities with patients of all ages who have sustained neurological insult or injury. Improvement of motor control has been supported in some applications, although well controlled group research in populations other than stroke and adult SCI is lacking. This underscores the need for further investigation to support the evidence for these modalities. As the therapy environment continues to change

in response to time and funding constraints, therapists must carefully evaluate the benefits of a variety of available tools to assist their patients in regaining motor control and functional ability. A benefit of FES or EMGBF is the ability of the patient to work autonomously (i.e., at home) after becoming familiar with the treatment regimen, with the therapist periodically updating a home program. This protocol allows physical and occupational therapy time to be used for direct intervention. NMES and EMGBF may efficiently assist in attaining improvement in control and may also be used in the context of functional activities, but these tools alone will not create functional changes. The case studies that follow further integrate these concepts in actual cases.

CASE STUDIES

Part 1: Electrodiagnosis

The following are cases studies from patients seen in the electrophysiology lab. The reader will receive the full benefit of studying the cases by first reading the evaluation and establishing a set of differential

possible diagnoses and dysfunctions of the nervous system. The reader can then progress through the report, test by test, and challenge the differential diagnoses. The conclusion of the study is provided. NOTE: Please refer to [Appendix 31.A](#) for a key to all the abbreviations found in the figures and tables used in the Case Studies.

CASE STUDY 31.1

The patient is a right-handed 55-year-old general contractor. He reports that 3 months prior, he purchased an exercise cycle that he started using quite vehemently. Following this bout of exercise, he started noticing muscle soreness in his hamstrings and right calf. He now reports fatigue and twitching of the muscles in both shoulders and right leg. He also has an achy back in the middle of his thoracic spine. There is no numbness. He does not have any particular stressors except for the decrease in business brought about by the change in the economy. He never lost control of his sphincters. His thinking is clear.

Prior medical history is significant only for skin cancers, which were excised from his back last year and a meniscal tear. He has no known allergies and is lactose intolerant. On questioning, the patient does report hunting and eating the game he kills but has no other exposure to heavy metals.

Physical examination shows that walks unassisted but has a slight foot drop on the right side. From an orthopedic standpoint there is some crepitus with mobilization of the left shoulder; otherwise, range of motion is full, including in the cervical spine. There is no Lhermitte sign. Inspection shows significant fasciculations in the right quadriceps and both upper arms; a mild facial asymmetry from a previously fractured upper maxilla on the left side; easily palpated dorsalis pedis pulse on both sides; and mild atrophy of the right calf, which is 1.5 cm smaller than that of the left side. Grip strength is 80 lb on the right side and 60 lb on the left side. Manual muscle testing reveals a decrease in the strength of the extensor and flexor hallucis longus on the right side, 3+/5 (½ on the left side); right tibialis anterior, ¾ (½ on the left side); right to gastrocnemius, 3–/5; right quadriceps, 4–/5; and intrinsic muscles, ½ on both sides. The patient fully detects the 3.61 Semmes-Weinstein monofilament in the lower extremities and the 2.83 monofilament in the upper extremities, which is normal. Muscle stretch reflexes are 2+ in the upper extremities and 1+ in the lower extremities; there is no Hoffmann sign in either hand; plantar cutaneous reflex is equivocal; cranial nerve scan is normal including extraocular movements. Speech is normal.

Summary of Nerve Conduction Findings

Motor distal latencies are normal in all nerves tested. Conduction velocities in all segments are normal. Amplitudes of the responses are slightly decreased or at the lower limit of normal. Sensory distal latencies, amplitudes, and conduction velocities are all within normal limits.

F-wave latencies are slightly delayed in the right fibular and tibial nerves and normal in the left fibular and right median nerves.

H-reflex latencies are delayed on both sides.

Summary of Electromyographic Findings

Insertional activity was increased in the right vastus medialis, tibialis anterior, gastrocnemius, extensor digitorum brevis, and left tibialis anterior. Fasciculations were found in the right deltoid, triceps, first dorsal interosseous, vastus medialis, and extensor digitorum brevis, as well as in the left gastrocnemius and thoracic paraspinals. Denervation potentials were found in every muscle sampled (including the tongue) except the right biceps. Analysis of the motor unit action potentials showed them to be polyphasic in the first dorsal interosseous of the right hand, right tibialis anterior, right gastrocnemius, left extensor digitorum brevis, and left tibialis anterior. Recruitment pattern was reduced in the right biceps and in the tibialis anterior, gastrocnemius, and extensor digitorum brevis on both sides. Firing rate of the MUAPs was fast in the extensor digitorum brevis on both sides as well as in the right gastrocnemius and tibialis anterior. Refer to [Tables 31.2 to 31.6](#), and [Fig. 31.11](#) for a summary of various nerve conduction studies performed on this patient.

Conclusions

The results of this study are abnormal. Findings include normal sensory distal latencies, nerve conduction, and amplitudes; normal motor distal latencies and nerve conduction, slightly reduced amplitudes; widespread denervation potentials in three limbs, paraspinals, and the tongue; fasciculations. This is consistent with an acquired motor neuron disorder.

Based on this study, laboratory tests, and the physical examination, the referring neurologist diagnosed patient 1 with amyotrophic lateral sclerosis.

Prognosis

Poor.

Interventions

The patient was issued ankle-foot orthoses, first on the right side, then the left. He later required a walker, then a powered wheelchair and continuous positive airway pressure (CPAP) machine. He died 12 months after this study.

CASE STUDY 31.2

The patient is a right-handed, 49-year-old administrative assistant. She reports a 1-year history of numbness in the right hand. Initially, this numbness was present only intermittently. The numbness involves mostly the thumb and index and long fingers. Recently the numbness has been present every morning. This impairs her ability to sleep. The patient also reports difficulty with writing. She has a positive flick sign. Finally, she reports that ibuprofen has been of some help in the sense that she no longer wakes up in the middle of the night. She has no numbness in her toes. There are no complaints regarding her cervical spine.

Prior medical history is essentially unremarkable and includes only uterine fibroids. The patient has had a hysterectomy. There are no known allergies.

Physical examination shows that the patient walks unassisted with a normal gait pattern. Inspection shows slight arthritic changes at the base of the right thumb but no noticeable muscle atrophy in the intrinsic muscles or thenar eminence. Grip strength is 45 lb on the left side and 55 lb on the right side. Sensation is slightly decreased: the patient detects the 3.61 Semmes-Weinstein monofilament at the tip of the fingers of the right hand. Result of the Phalen test is positive, and the reverse Phalen test causes wrist pain; the Finkelstein test also causes wrist pain. "Okay" sign is normal. Cervical range of motion is full in all directions; result of the Spurling test is negative. Muscle stretch reflexes are 2+ and symmetrical. Cranial nerve scan is normal.

Based on this physical examination, what is your clinical impression?

Summary of Nerve Conduction Findings

The median motor distal latency is prolonged compared with the ipsilateral ulnar motor distal latency (2.05 ms difference). Amplitudes of the median motor responses are decreased. The ulnar motor distal latency, amplitudes, and conduction velocities are within normal limits.

The median sensory distal latencies are significantly delayed. Radial and ulnar sensory distal latencies are normal. The combined sensory index (CSI) is 7.1 (cutoff value for normal conduction for the CSI is 1.3).

Median F-wave latencies are at the upper limit of normal for a patient this height. Ulnar F-wave latencies are normal.

Summary of Electromyographic Findings

Insertional activity was normal in all muscles sampled. A few denervation potentials were found at rest in the abductor pollicis brevis (fibrillation potentials). Analysis of the motor unit action potentials showed them to be of normal configuration, phases, and recruitment in all muscles tested except in the abductor pollicis brevis. In this muscle, motor units were slightly polyphasic. Refer to Fig. 31.12, and to Tables 31.7 to 31.10 for a summary of various nerve conduction studies performed on this patient.

Conclusions

This study is abnormal. Findings are consistent with a moderate to severe mono-neuropathic process involving the right median nerve at or distal to the wrist. This is shown by delayed median motor and sensory distal latencies, decreased amplitudes of the median motor responses, and abnormal electromyographic findings in the abductor pollicis brevis only.

Because the ipsilateral ulnar motor and ulnar and radial sensory nerve conduction study findings are normal and because the needle electromyography findings are limited to the abductor pollicis brevis, a polyneuropathic, plexopathic, or a radiculopathic process is unlikely in the right upper extremity.

Prognosis

Excellent. The patient and her surgeon elected to go ahead with a carpal tunnel release.

Interventions

The patient started rehabilitation after surgery and went on to a full recovery in 2 months.

CASE STUDY 31.3

The patient is a right-handed, 86-year-old retired internist. He consults today for assessment of the strength in his lower extremities and numbness in his right hand. He reports having difficulty going up the 13 steps he has at home and states that his right thumb and index and middle fingers feel like “Band-Aids are on too tight at the tip of the fingers.”

Prior medical history includes Waldenström macroglobulinemia, gastrectomy for recurrent bleeding, 7+ years of taking amiodarone, hypothyroid.

Physical examination shows that the patient walks with a bilateral foot drop and increased base of support. MMT shows decrease in the strength of ankle dorsiflexors on both sides, noted 3+/5; right quadriceps, 4/5; foot intrinsic muscles, 3/5; hand intrinsic muscles, 3+/5; right triceps muscle, 3+/5. All other muscles groups have normal strength. Grip strength is 30 lb on the right side and 35 lb on the left side. Sensation is decreased to the 3.61 Semmes-Weinstein monofilament at the sole of the right foot; the patient detects the 4.31 filament. It is also decreased to the 2.83 monofilament at the palm of the right hand; the patient detects the 3.61 filament. Range of motion (ROM) of the left shoulder is impaired in abduction. Cervical ROM is within normal limits. Spurling’s test is negative. Toes are down-going with the plantar cutaneous reflex; there is no Hoffmann sign in the hands. Muscle stretch

reflexes are 2+ in the quadriceps and upper extremities, 1+ at the ankle. Cranial nerve scan is normal. Romberg sign is positive. Refer to [Fig. 31.13](#), and [Tables 31.11 to 31.15](#) for a summary of various nerve conduction studies performed on this patient.

Conclusions

The study findings are abnormal. Findings are consistent with an axonal loss, mixed sensorimotor polyneuropathic process. This is evidenced by normal motor and sensory distal latencies, absent or significantly reduced amplitudes in both motor and sensory responses, delayed F-wave and H-reflex latencies, denervation in the distal more than the proximal muscles, and no findings in the lumbar paraspinals.

Prognosis

Fair to good. Improvement expected over the next 4 to 6 months with medical management of the polyneuropathy.

Interventions

The patient started balance rehabilitation and muscle strengthening and ultimately met his goal of safely climbing up and down his stairs.

Part 2: Neuromuscular Electrical Stimulation and Electromyographic Biofeedback

CASE STUDY 31.4

A 68-year-old woman is referred 3 weeks after left middle cerebral artery cerebrovascular accident with residual right hemiparesis affecting the upper extremity to a greater degree than the lower extremity. The patient's left extremities appear well controlled with at least functional strength. She exhibits a two-fingerbreadth right shoulder subluxation, with pain at shoulder flexion (150 degrees), abduction (135 degrees), and external rotation (30 degrees), and hypertonicity in a stereotypical flexor synergy pattern affecting the shoulder horizontal adductors and internal rotators and elbow, wrist, and finger flexors. She is beginning to develop upper-extremity movement with the ability to shrug her shoulder, abduct, and flex through partial range (with elbow flexed), full-range elbow flexion, partial-range elbow extension against gravity, and no wrist or finger extension. Right lower-extremity range of motion is within normal limits, although control is limited at the ankle (dorsiflexion only with hip and knee flexion, no eversion actively) and knee control is decreased (reduced eccentric quadriceps control, difficulty isolating knee flexion with hip extension). Ambulation is accomplished with the use of a quad cane and an articulating

Ankle Foot Orthosis (AFO) on the right for limited distances with standby assistance. This patient lives at home with her husband, who is very supportive of her rehabilitation. Both are retired, but they have an active calendar of participation in volunteer and leisure activities.

Prognosis

Independent or isolated motor function is promising for continued improvement in the condition of the patient. Lower-extremity impairments are expected to be minimized as the return of motor control progresses. Quad cane use should continue until isolated hip and knee action improves. A need for AFO is expected for an indefinite time period.

Intervention

Interventions using neuromuscular electrical stimulation (NMES) would assist in accelerating improvement in functional control. Table 31.16 provides the various intervention options using NMES for this patient.

TABLE 31.16 Neuromuscular Electrical Stimulation/Electromyographic Biofeedback Options

Patient Problem	Goals	Modality Parameters	Measures to Determine Efficacy	Considerations
Shoulder subluxation	Decrease subluxation to 1 fingerwidth, with pain manageable within patient's daily routine.	Portable FES for home use, begin with 10:30 second on-off ratio for 15-min periods tid, amplitude to generate muscle contraction without shoulder elevation. Increase on time and treatment time as tolerated so that reduction is maintained majority of day.	Trial use for 1 month. Measure amount of palpable subluxation, pain-free ROM; if improvement is not observed, discontinue FES, with instruction to maintain shoulder flexibility, consider lapboard or arm tray when sitting, support when standing.	<ol style="list-style-type: none"> 1. Requires rental of portable FES unit; patient/family compliance is needed for success in home program. 2. Cost of rental of FES and supplies. 3. Frequent use for reduction of subluxation requires close monitoring of skin for possible reactions to stimulation, gel, or electrodes. 4. Integrate scapular movement and stabilization exercises into program
Lack of active ankle dorsiflexion	Increase active control of ankle dorsiflexion with knee extended, allowing heel-strike without AFO for short-distance ambulation.	FES twice daily for 15-min duration; 10:20 second on-off ratio with slow ramping on-off; as active movement improves, consider EMGBF to further focus attention on balanced dorsiflexion (with eversion). Use of heelswitch requires decreased ramp time to minimum patient can tolerate. Switch should activate at heel-off to control dorsiflexion through the swing phase.	Monitor each session for increased active dorsiflexion in sitting, standing, and ambulation. Integrate use of heelswitch during ambulation without AFO. Trial use over 2–3 weeks. Discontinue if not seeing increase in voluntary control; compensate with AFO.	<ol style="list-style-type: none"> 1. If patient rents unit for shoulder subluxation, may also use stimulator at home instead of requiring time during therapy session. 2. Similar cost, convenience issues as above. 3. Additional education necessary if stimulator settings are to be switched for dorsiflexion and shoulder subluxation interventions.
Lack of full active wrist and finger extension	Control of active wrist and finger extension to allow release in gross grasp.	NMES and/or EMGBF twice a day for 10-min sessions initially, with gradual increase in duration up to 20 min if fatigue does not alter the quality of the contractions. Other parameters as described for ankle dorsiflexion.	Trial period of 2–3 weeks; discontinue if voluntary motion is not changing significantly. Active movement in finger extensors with wrist in neutral position. Functional ability to release grasp of objects of varying shapes and sizes.	May use portable stimulator as described for ankle or shoulder interventions, with similar considerations.
Muscle imbalance, lack of right upper-extremity functional movement	Decrease hypertonicity in flexor muscle groups; increase extensor control for gross arm movements (e.g., positioning).	EMGBF to decrease flexor muscle activity (resting and with passive movement) and increase extensor activity.	Speed and control with reciprocal elbow motions, especially with extension. Use of this motion for functional activity (e.g., positioning the arm, reaching activity).	Focus on increased extensor control may prove more effective than simply decreasing flexor hyperactivity.

EMGBF, Electromyographic biofeedback; FES, functional electrical stimulation; NMES, neuromuscular electrical stimulation; ROM, range of motion.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this

textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 242 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Key to Abbreviations

The following is a key to the abbreviations used in the Case Studies in this chapter.

μV = microvolts

ABD POLL BREVIS = abductor pollicis brevis

ADM = abductor digiti minimi

Amp PK-PK = peak to peak amplitude

AMP = amplitude

APB = abductor pollicis brevis

AR = active recording

bel. = below

ab. = above

CM = centimeters

COMM FIBULAR = common fibular nerve

D INTEROSS = dorsal interosseus

EDB = extensor digitorum brevis

EMG = electromyography

EXT DIG BREV = extensor digitorum brevis

EXT DIG COMM = extensor digitorum communis

FASC = fasciculation potentials

FLEX CARPI RAD = flexor carpi radialis

FHB = flexor hallucis brevis

FIB = fibrillation potentials

Fib head = head of the fibula

FIRST D INTEROSS = first dorsal interosseus

GASTROCN = gastrocnemius

H AMP = H reflex amplitude

H LAT = H reflex latency

H/M APML = ratio between the amplitudes of the H-reflex and the M wave or motor response

IA = insertional activity

L = left

LAT MALLEOLUS = lateral malleolus

LAT = latency

LL = lower leg

LUMB PSP = lumbar paraspinals

M/S = meters per second

MAX F AMP = maximum F-wave amplitude

MAX F LAT = maximum F-wave latency

MAX F-M = Maximum difference in F-wave and M latencies

Med = median

MIN F LAT = minimum F-wave latency

MIN F-M = Minimum difference in F-wave and M latencies

msec = milliseconds

MUAP = motor unit action potentials

MV = millivolts

PERON LONGUS = peroneus longus

POLYPH = polyphasic

CERV PSP = cervical

PSW = positive sharp waves

R = right REC SITE = recording site

SNAP = sensory nerve action potential

TEMP = temperature

THOR PSP = thoracic paraspinals

TIB ANTERIOR = tibialis anterior

VAST MED = vastus medialis

VEL PK = peak velocity

VEL = velocity

vs = versus

Uln = ulnar

Abstract: The goal of this chapter is to enhance the clinician's ability to recognize indications for the most commonly used electrophysiological tests and to integrate knowledge of these test indications and findings into the management of patients with neuropathological or myopathic dysfunction. The first section presents a basic description of the electrophysiological tests, including nerve conduction studies (NCSs), electromyography (EMG), kinesiological electromyography (KEMG), and the underlying neuroanatomical structures being tested. Normal and abnormal findings are discussed, with emphasis on how knowledge of these tests can assist the therapist in patient evaluation. The second section provides an introduction to the physiology, indications, contraindications, equipment, and applications of electrical muscle stimulation

(EMS), neuromuscular electrical stimulation (NMES), and electromyographic biofeedback (EMGBF). The information integrates electrotherapeutic interventions into program planning for common neurological body system problems, their subsequent functional limitations, and perceived decrease in quality of life. Published evidence examining efficacy is included to assist the therapist in making choices about the use of these tools in the clinic. The third section provides a series of four case studies that illustrate the usefulness of electromyographic testing in patients with a variety of medical diagnoses.

Keywords: econtilectromyographic feedback, electroneuromyography, functional electrical stimulation, kinesiological electromyography, nerve conduction velocity, neuromuscular electrical stimulation

Orthotics: Evaluation, Intervention, and Prescription*

Heidi Truman and Preeti Nair

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify and analyze the force systems produced by the use of an orthosis.
2. Comprehend the prescription rationale gained from an orthotic evaluation for individuals with neuromuscular dysfunctions.
3. Identify and differentiate the variables considered by the rehabilitation team to optimize outcomes during orthotic intervention.

KEY TERMS

ankle-foot orthosis (AFO)
knee-ankle-foot orthosis (KAFO)

lever arms, three-point pressure systems
thoracolumbosacral orthosis (TLSO)

OVERVIEW

An orthosis is an external device that produces a force that biomechanically affects the body to correct, support, or stabilize the trunk, the head, and/or an extremity. Orthoses are named by the sections of the body to which they are applied.¹ For example, an orthosis that controls and covers the ankle and foot is called an *ankle-foot orthosis* (AFO). The abbreviations for the device are used by professionals in clinical documentation. Orthotic use varies from temporary application to permanent use based on patient care goals. Careful evaluation is used to determine whether a prefabricated, custom-fit, or custom-made orthosis is most appropriate for the patient. A prefabricated orthosis is one that is available in “off-the-shelf” sizing and is intended for temporary use. Commonly used prefabricated items are often kept in stock by the orthotic provider. Custom-fit orthoses are customizable devices that can be modified to optimize the fit to an individual patient. These devices are intended for use on a more definitive basis and are often appropriate when the patient has adequate sensation and normal anatomy. Custom-made orthoses require very specific measurements or models of the patient to be obtained for the most specific fit and to accommodate any deformity. These devices are time and labor intensive and are worn definitively when the patient’s condition is permanent or when his or her condition or anatomy does not facilitate fitting of a more basic device.²

Orthoses are primarily designed on three simple biomechanical concepts: pressure, force, and the lever arm principle.^{3–5} The pressure principle simply means that pressure applied by the orthotic device is equal to the total force per unit area covered by the device. Because an orthosis is an external device that comes in contact with a part of the body, it has the ability to apply pressure based on the surface area it

covers. If pressure is to be minimized, the surface area in contact with the device has to be maximized and vice versa. For example, a total contact orthosis will distribute pressure more evenly than a device that contacts the patient only at several points. The force principle is often used in designing orthoses that work on the three-point force system or the four-point force system. In a three-point force system, the orthosis is designed such that central components of the orthosis are able to apply force in one direction while the two terminal end parts provide a counterforce in the opposite direction, and the sum of all the three forces equals zero. For example, a knee orthosis designed to correct genu varum would consist of a central force directed medially at the lateral border of the knee joint and the terminal points of the orthosis applying laterally directed forces on the femur and tibia.⁶ This way an orthosis is effectively used to permit angular change or provide control over a joint. Similarly, a four-point force system can be used to provide translational control of adjacent segments and prevent displacement of one segment over another. For example, a knee brace to prevent knee hyperextension and anterior tibial translation would consist of two parallel forces equal in magnitude and opposite in direction applied at different points on the femur to facilitate femoral flexion and two other parallel forces of equal magnitude and opposite in direction applied at different points on the tibia to facilitate tibial extension.^{3,4} Finally, the lever arm principle is important in designing orthoses to determine the force at the segment of interest based on the height/length of the orthosis. As per the lever principles, the longer the orthosis, the greater the moment arm and therefore lesser will be the magnitude of force required to produce the desired effect at the joint of interest.^{7,8} For example, an elbow orthosis that is just proximal and distal to the joint area will apply a greater force to immobilize the elbow, compared with an orthosis that extends to closer to the wrist and axilla. The longer orthosis will require less force to provide the same outcome of elbow immobilization.

*Videos for this chapter are available at studentconsult.com.

In addition to the basic biomechanical principles involved in designing an orthosis, many factors enter into the decision regarding use and type of orthosis. It is essential that the most functional, least complicated, and most cost-effective orthosis be applied to the patient. The rehabilitation team must build a priority list of desired outcomes and accept that sometimes all of the items on the list may not be achieved by either the orthosis or the patient-team combination. It is important to be aware that care may need to be attempted in stages because the patient's condition changes or if other medical concerns may arise. Effective coordination and communication between health professionals in development of patient goals are essential during the evaluation process. For instance, placing a loop closure on the side of their body that a patient cannot reach will prohibit the use of the orthotic device. A sound understanding of biomechanical and orthotic principles, as well as skilled patient management techniques, must be used to be successful with patients who require orthoses.

There are similarities in orthotic management of orthopedic and neurologically impaired patients; however, the neurological population presents additional factors that challenge prescription criteria and outcomes for the rehabilitation team. Lack of proprioception, impairments in sensation, and spasticity are some of these special considerations. Concurrent medical issues, problems with communication, and caregivers may complicate patient management.

The advancements in and access to medical technology have had a profound impact in the field of orthotics. The evolution of plastic, composite, and metals fabrication technology has dramatically improved the ability to control, support, and protect all areas of the human body. Currently, patients are fit for custom and prefabricated orthotic devices that provide a variety of functions in both a timely and cost-effective manner. These factors have led physicians to routinely prescribe orthoses for a wide range of medical conditions, whereas historically lack of availability and shortage of experienced orthotists restricted patient access and narrowed the use of orthoses.⁹ Orthoses are important considerations for postoperative management, acute fracture management, and adjunct treatment in addition to more traditional uses. For many, the proliferation of the prefabricated orthosis signaled a dilution of quality orthotic care, but in reality it has had the opposite effect. These readily available, cost-effective orthoses have not taken orthoses out of the hands of the orthotist but rather have moved them into the minds of treating professionals. There has been continued growth of new and improved orthoses and expansion into other areas of treatment previously lacking in orthotic management. For example, positional and corrective orthoses can be used for premature and newborn infants, and a wide range of sizes of orthoses that previously were made only in adult sizes have become available for pediatric patients. As with any new technological advancement, there has been incorrect application and use. It is not that many of these prefabricated orthoses are difficult to apply; rather, there has been lack of a clear understanding of the indications, contraindications, and limitations these devices present to the rehabilitation team and patient caregivers.

Identifying patient functional goals and familiarity with the current state of evidence-based care for specific patient populations and diagnoses are critical in providing optimal patient care and achieving the desired clinical outcomes. In that spirit, a broad overview of the evaluation, prognosis, and intervention of orthotic devices in neurological rehabilitation is presented.

BASIC ORTHOTIC FUNCTIONS

Alignment

Anatomical and functional alignment of the extremities and spine is a common reason for an orthotic prescription. The orthosis can provide

either temporary or permanent function. A thoracolumbosacral orthosis (TLSO) may be prescribed for stabilizing alignment after spinal fusion or for non-operative management of an unstable spinal cord injury (SCI; refer to Chapter 14). A supramalleolar orthosis (SMO) is commonly prescribed to hold the foot in proper alignment in multiple planes. When the goal of orthotic intervention is to correct alignment to a position well tolerated by the overlying soft tissue and/or the malalignment is a result of a muscle weakness, the new position should stabilize the joint. Clinicians need to remember that aligning one joint may result in the proximal or distal joint being placed in malalignment. An example of this is a patient with correctable genu valgum of the knee. Although this coronal plane deformity can be orthotically corrected, changes in knee alignment result in adjustments by the other joints up and down the kinetic chain. If the patient lacks inversion/eversion range of motion (ROM) at the ankle, placing the knee in a more vertical alignment will cause the patient to weight bear on the lateral border of the foot and possibly create instability at the ankle joint. Considerations such as the subtalar joint's mobility into pronation and supination must be accounted for when designing an orthosis that will provide coronal control at the knee.

Stability

Stability is often required for the patient with neurological deficits. These patients frequently lack the muscle control and strength necessary to maintain trunk balance or to ambulate. Patients with muscular dystrophy benefit from TLSOs to help maintain trunk stability, achieve sitting balance, and perform safer transfers. However, the orthotic prescription must be guided by the knowledge that maximum stability cannot compromise or restrain thoracic expansion for breathing capacity. An AFO that limits both dorsiflexion and plantarflexion can stabilize the ankle and the knee for the patient who has had a cerebrovascular accident (CVA).¹⁰ Although this patient may require both coronal and sagittal plane ankle stabilization, controlling the lever arms at the ankle can also provide knee stability and prevent future knee impairments created by excess coronal (varus/valgus) or sagittal (hyperextension/hyperflexion) motion at the knee. The orthosis functions in the sagittal plane by maintaining ground reaction force anterior to the knee during the stance phase of gait. Most patients requiring this type of stabilization have a foot-flat gait instead of a normal initial heel-strike pattern.

Contracture Reduction

Contracture reduction is the goal for many orthotic applications in patients with neurological involvement. The increase in the use of these types of orthoses has been dramatic because even slight increases in contractures can make the difference between nonambulatory status and ambulatory community participation. Increased awareness and proactive use of prefabricated orthoses have become routine during periods of inactivity, associated surgical procedures, and "sound side" prevention. These types of orthoses can be either dynamic or static and are used in conjunction with various therapeutic modalities to reduce the contracture. Dynamic contracture-reducing orthoses use a spring-type mechanism that applies a low force to a joint over an extended period of time to gain range of motion (ROM). Static-type orthoses range from serial casts in which a manual stretch is placed over the joint for extended periods of time, to custom-made cylindrical devices designed to spread force over larger areas, to custom-fit devices with some type of quick adjustability. Dynamic-type orthoses are usually contraindicated for patients with neurological disorders that create tone and spasticity. Low-tension stretch can trigger spasticity and create skin breakdown because of the high pressure on localized skin areas. The exception for this would be individuals with lower motor

neuron impairments and residual hypotonicity. Any type of tension orthosis needs to be monitored when there is sensory loss, regardless of the cause. To achieve results in contracture reduction, one must be cautiously aggressive because the amount of force required to improve ROM often threatens the soft tissue's ability to tolerate the pressure of the orthosis.¹¹ Experience, frequent sessions, and close communication with other members of the rehabilitation team and the family and patient are critical factors in the success of the use of orthotic devices.

EVALUATION

The examination and evaluation of the neurologically impaired patient must be comprehensive. One must not read a diagnosis and assume a total clinical picture. The diagnosis should alert the evaluator to movement patterns associated with the impairment, and these should be used to confirm potential findings. Complete patient evaluations do not end with determination of ROM, muscle test findings, assessment of proprioception, skin sensitivity evaluation, or assessment of the integrity of the affected limb or spine. The rehabilitation team must assess the total picture to determine what limitations orthotic care may impose on other important functions and activities, and patient participation in life. The evaluation must include a patient management assessment. What is the patient's or caregiver's motivation? How much equipment can the patient tolerate, and with how much can he or she function? What functional potential does the patient have once they have left the clinical or acute setting? How significant are the risks associated with orthotic intervention? As stated, the total evaluation of the patient and the patient's environment is important in developing the treatment plan, as is the communication among the physical therapist, occupational therapist, and orthotist. Whether done together or (more realistically) at separate sites, the details of the treatment plan must be discussed. The patient with neurological impairment often presents a series of complex issues: biomechanical, communication, visualization, and so on. Incomplete information or a lack of effort at communication among these professionals will not lead to a comprehensive treatment plan and ultimately optimal outcomes.

During evaluation, review of the diagnosis and gathering of patient history are extremely valuable. A complete medical diagnosis will indicate important information to the team. For example, for a patient with poliomyelitis, the orthotist is aware that it is a lower motor neuron lesion and that proprioception is intact (see Chapter 15). These patients have the benefit of skeletal balance in standing and ambulation and therefore require durable orthotic construction.¹² Compare this to a patient with T12 paraplegia with similar muscle strength. T12 level paraplegia. Assuming this is a complete lesion, patients affected at this level lack proprioception. They require other means to get feedback about standing balance and require a lightweight orthosis because they rarely use orthoses as a major means of locomotion. Although gathering patient history is a vital part of the evaluation, it is, more importantly, an opportunity to establish a productive patient management environment. Patients and family members have important information regarding the initial injury, previous medical care, reasons they sought additional care, and desired outcomes of new treatment. Most of this information can be gathered efficiently as either the therapist or the orthotist begins other professional evaluations. These are important patient and family management skills. One must hear from the patient or caregivers why they came to see the health care professional and their expectations of care. The therapist should not assume the family's goals without asking, because often patient and family goals are higher than the clinicians' expectations. Communicating at a level that is understandable is vital and

demonstrates to the patient and family that the therapist is a concerned professional, thereby engendering trust and confidence. Complete and timely documentation of these findings is vital to the evaluation and treatment plan. Whether communicating with others on the rehabilitation team, insurance carriers, or legal professionals, documentation and building medical justification are essential in treating all patients.

Evaluation of the Spine

Each area of the spinal column presents various combinations of motion and function. Beginning at the lumbar level as the base for upright position, the spinal column (1) protects vital organs, (2) serves as a supporting structure for the lungs to expand, (3) provides a base for the upper extremities to reach from, (4) acts as a scaffold for objects to be carried, (5) protects the central nervous system pathways, and (6) controls the upright position and motions of the head. The individual segments of the spine have relatively few complicated orthotic challenges. However, it is rare that only one segment is involved in the patient with neuropathic impairments. It is more common for two or more segments of the spine to be involved when there is a need for orthotic control. For example, supporting the head in a functional position is a major goal of orthotic intervention, but to accomplish this the orthosis must encompass the thoracic as well as the cervical spine to distribute the forces to minimize skin pressures.

When evaluating the cervical spine and head, one must (in addition to muscle testing) determine past what angulations the upright position of the head cannot be recovered. Limiting the head from assuming nonfunctional positions such as extreme extension is an easier orthotic function than holding the head upright. Many patients with neurological problems may have the strength to move in a 15- to 20-degree range of flexion and extension, lateral bend, and rotation but do not have the strength to recover the head from greater angles. Even the most pressure-tolerant soft tissue around the head does not tolerate long-term pressure from an orthosis; intermittent control and relief are a critical part of the design. Pressure directly on the ear is not tolerated at any time.

When the orthosis is desired to limit cervical motion due to unstable fractures or postoperative management, selecting the most appropriate design depends on how much motion is acceptable. Upper cervical motion is controlled with a Halo orthosis (Fig. 32.1) when complete immobilization is desired. If more motion is acceptable, or for lower cervical control, a collar is more acceptable to both the treating team and the patient.¹³ Many types of cervical collars exist to optimize patient fit and control (Fig. 32.2).

The thoracic and lumbar spine are almost always treated concurrently with an orthosis in the patient with a neurological deficit. The major reasons for orthotic intervention in this area are to stabilize the trunk for balance, to protect surgical correction or stabilization, and to maintain respiration.¹⁴ The pelvis is generally used as a base to prevent distal migration of the orthosis when the patient is sitting or standing. One must closely evaluate the degree of deformity, prominence of bony structure, skin sensation, and condition of soft tissue coverage. Many neurologically impaired patients also have other medical issues that need to be considered in orthotic design, such as a colostomy, gastrointestinal (GI) tubes, pressure sores, and other factors. Scoliosis and kyphosis are common biomechanical impairments within this patient group. Balance between correcting the spinal deformity to maintain respiratory function by use of a tightly fitting TLSO and the skin pressure it creates must be reached by the rehabilitation team. The evaluation of the spine and potential need for orthotic intervention would not be complete without recognizing the effect the desired orthosis may have on the extremities, whether the patient is ambulatory

Fig. 32.1 Halo Orthosis. Courtesy PMT Corporation.

or non-weight bearing. What movements of the spine are present during ambulation, and would immobilizing the spine significantly affect the patient? Will the orthosis restrict needed shoulder elevation and arm movements? Variation in materials used for fabrication of a spinal orthosis can often significantly improve the desired outcome, increase the wear time, ease the donning process, and improve skin care. From a patient and family management standpoint, one must consider many variables in potential design of the orthosis. Can the patient or family properly don the orthosis and remove it when appropriate? Do they understand potential areas of pressure? Do they know what to do if any issues arise with fitting or skin integrity?

Evaluation of the Upper Extremities

Evaluation of the upper extremities requires multiple inputs from health care professionals, patients, family, and teachers because of the wide range of specific functions an individual performs daily. Unique to the upper extremity, multiple functions generally require multiple orthotic devices for activities of daily living (ADLs). Typical functions

of orthoses of the upper extremity include maintenance of functional wrist and hand position, reduction of contracture or tone, transfer of force available in one area to another, and support of subluxations resulting from denervation. It is common for the neurologically impaired patient to require several orthoses with different functions for use throughout the day. Strength, ROM, condition of soft tissues, and sensation are all important evaluation factors. In addition, ambulatory status, bilateral or unilateral condition, status of vision, and condition of the spine and head must be factored into the indications and contraindications in assessment of the orthotic needs of the patient. Much more critical muscle tests must be performed in the upper extremity as opposed to the lower extremity, because minor increases or decreases in strength will dramatically alter orthotic need. For example, the C5 quadriplegic has the ability to function with a wrist-hand orthosis by providing enough wrist extension to use the tenodesis effect, which can produce a three-jaw-chuck type of grip.¹⁵ The difference between a functioning and nonfunctioning orthosis is minor, not only because there is limited muscle strength, but also because minor inefficiencies in the tenodesis splint (from friction or malalignment) could reduce function to unacceptable levels. Patients with unilateral involvement have far different needs than the bilaterally involved. The patient post-CVA with unilateral involvement may use a positional wrist-hand orthosis to prevent contracture and injury and a supportive shoulder orthosis to prevent shoulder subluxation (Fig. 32.3A–C).¹⁶ In these cases the other extremity becomes dominant, and there is little need to fabricate complex orthoses for use by the affected extremity.

The patient with bilateral involvement presents a much different picture. Consideration for grooming, feeding, mobility, and so on must be factored into the desired expectation during evaluation. The case of the patient with neurological impairments who requires orthotic intervention is complex because this patient typically has involvement of the trunk, head, and lower extremity. These patients require specialized wheelchairs and seating systems.¹⁷ Evaluation is most effective with all rehabilitation team members present to establish a treatment plan. Orthotic treatments maximize what limited muscle strength and ROM the patient may have. Orthoses that are used during the day to maximize function are often replaced with positional orthoses at night to preserve gains and prevent decline in ROM. The occupational therapist provides most of the functional and positional orthoses for the upper extremity. In the current rehabilitation environment, many occupational therapists work directly with orthopedic hand specialists and trauma physicians. They use low-temperature materials to mold custom devices specifically designed

for protecting surgical reconstruction or promoting or maintaining ROM or for use as assistive devices.

Evaluation of the Lower Extremities

Evaluation of the lower extremity offers additional challenges owing to the role of ambulation and its value to independence for the patient and caregivers. ROM, strength, existing deformity, proprioception, muscle tone, soft tissue condition, and sensation must all be evaluated. Where appropriate, weight-bearing evaluation and gait analysis are completed. Patient and family assessment as it relates to the ability to comprehend and follow instructions is extremely important

because the potential for injury may outweigh the benefit of orthotic intervention to transform a patient from being non-weight bearing to having limited ambulation. Lack of ROM at the hip and knee will significantly decrease the duration of potential ambulation or may totally inhibit ambulation. Lack of ROM at the hip and knee is more critical than lack of strength. In the foot and ankle, the need for normal ROM is even more critical for efficient standing balance and ambulation. Orthoses of the lower extremity provide a combination of force lever arms acting about a joint axis at the knee, hip, or ankle. These joints are significantly compromised by the lack of ROM. Using the lever arm principles within the lower extremities substitutes for the

lack of strength. For example, by blocking dorsiflexion of the ankle, the ground reaction force provides a posteriorly directed force in the sagittal plane during stance that stabilizes the knee. If the patient lacks the ability to get the ankle to a neutral alignment due to a plantarflexion contracture, this dorsiflexion limitation provides its own lever arm, which will result in a variety of undesirable forces and actions. Genu recurvatum, foot or ankle varus, a shortened stride length on the unaffected side, and the heel rising out of the shoe are common signs of this problem. These issues are further complicated when poor proprioception, spasticity, and lack of sensation are present. Lack of ROM at the ankle creates many symptoms in the lower extremity but is often overlooked during evaluation as the cause of these problems.

Genu varus and genu recurvatum are common deformities of the patient with neurological impairments. A number of factors create these problems.¹⁸ In addition to the ankle ROM limitations, leg length differences, lack of quadriceps strength, and lack of proprioception can create deformities about the knee. The patient with a history of poliomyelitis may have both a short extremity and weak knee extensors, which lead to genu recurvatum along with coronal plane deformity. However, reducing the genu recurvatum without protecting against instability created by undesirable knee flexion would be a mistake. Patients with lower motor neuron disease have excellent proprioception, which is the reason they protect the unstable knee by hyperextending it. They may even use force from their upper extremity by pushing posteriorly on the femur with the hand to increase knee stability. Allowing some knee hyperextension in the orthotic design may be necessary to stabilize the knee during gait. Polio survivors are closely attuned to the amount of knee extension that is necessary to maintain stability, and the orthosis can be designed around this angulation.¹⁹ A patient with upper neuron impairments, such as a patient who has had a CVA, has a similar knee alignment in gait. However, the typical cause of this patient's deformity is different. The upper motor neuron impairment often causes reduced proprioception even when there is adequate strength to stabilize the knee. Hemiplegic patients may present with knee hyperextension due to poor proprioception and reduced ankle ROM. An orthotic design for this population may need to have a heel lift to accommodate the plantarflexion contracture, and this will also help to limit knee extension in gait.²⁰

Reduced strength and ROM limitations about the hip limit effective ambulation and leave a patient much more reliant on trunk stability and upper-extremity ambulatory aids. Hip flexors are more critical than hip extensors because they serve to advance the limb in reciprocal gait, whereas lack of hip extensors is compensated for by the strong hip ligaments, which tighten for stability in extension. Limited ROM to at least neutral extension about the hip creates major challenges for the patient, even if the patient has excellent upper-extremity strength. This lack of ROM will not allow stability in standing once force is removed from the upper-extremity ambulatory aids (cane or walker). The patient with a hip flexion contracture will have difficulty standing from a seated position and will stand with excess hip flexion, knee flexion, and lumbar lordosis. Once standing, they will have difficulty advancing the involved side to initiate a step as the hip flexors are already shortened and are at a mechanical disadvantage. It is difficult for the patient with a hip flexion contracture to stand without support because this alignment creates a hip and knee flexion moment that will pull them into a sitting position. Maintaining hip ROM is an important goal for the rehab team, and encouraging the patient to perform stretching exercises while supine and limiting time seated with excess hip flexion is helpful. Creating hands-free standing balance is a highly desirable outcome of orthotic intervention. The patient is then able to use both upper extremities for ADLs.

Orthotic Evaluation

In addition to the comprehensive assessment of the patient which involves assessment of the patient's ROM, muscle strength, skin condition, and spasticity, it is essential to determine appropriateness of the orthotic device being prescribed for the patient. This involves both a static and dynamic evaluation.²¹ Static evaluation consists of observing fit of the orthosis on and off the patient and dynamic evaluation consists of observation of weight-bearing alignment, gait, and functional activities both with and without the orthosis and determining whether the design meets the expectations and goals for which it was prescribed. [Table 32.1](#) summarizes some of the key aspects of this evaluation.²¹ It is imperative to work closely with an orthotist for critical adjustments or modifications to optimize the fit and function of the device to best meet the goals of the patient and the rehabilitation team.

ORTHOTIC INTERVENTION

Several factors play key roles in the success of orthotic intervention. To improve function without complication or patient risk, the clinician must be sure to address the patient's major complaint. The reason the patient and family came to see the therapist or orthotist must be clearly established to ensure compliance with orthotic intervention. It is important to establish a baseline of function so that results of intervention are measurable. Validated outcome measures for certain populations are excellent tools to determine preorthosis and postorthosis function and effectiveness of orthotic management. In some situations the patient benefit is clear and immediate, whereas in others, concentrated instruction, orthotic modification, and time spent using the device are required before improved function can be observed or measured. The process of donning and doffing the orthosis as independently as possible must be well thought out by the clinician. The clinician must be conservative in setting these expectations. It is important to remember that what happens in the clinical setting may not be easily reproducible in the home situation. The orthotic interventions must be kept as simple as possible: what is the simplest orthotic intervention that will provide the expected goal? Although an obvious statement, the balance between too much and not enough can challenge the clinician's skill and experience. Patients with more impairments are more likely to use an orthotic device willingly.²²

The use of trial orthoses can provide valuable information during the evaluation and help to guide the treatment plan. It can be helpful to maintain a small stock of presized off the shelf (OTS) devices in the orthotic clinic or therapy gym setting to give both the patient and rehab specialist an opportunity to evaluate the functional effects of an orthosis. If this fits well, it may be the patient's final device, or it can serve as justification for a more custom orthosis to be fabricated.

Various types of heat-moldable plastics have been beneficial for many individuals. Custom-made and custom-fit plastic AFOs are frequently fit because they are "more cosmetic and lighter" than AFOs made of metal and leather material. With a plastic orthosis, the user must use a shoe big enough to easily fit the orthosis. Technological advancements have led to a number of additions to the arsenal of orthotists. Prefabricated orthoses with better sizing and materials have given the clinician additional tools for evaluation and for devising permanent orthoses. Preimpregnated graphite AFOs are currently available in multiple sizes and provide toe clearance during swing phase and some knee-stabilizing forces during stance phase. Although very lightweight, these orthoses provide dynamic stance phase control. They are strong and flexible, and patients often prefer the more dynamic motion and minimal bulk of the carbon material.

TABLE 32.1 Key Aspects of Static and Dynamic Evaluation

Static Evaluation

Patient's opinion of the orthosis	Evaluate whether the patient finds the orthosis comfortable, functional, and cosmetically acceptable to promote adoption and consistent use of the device.
Donning and doffing procedures	An orthosis that is difficult to don or doff is unlikely to be used by the patient. It is essential to examine: <ul style="list-style-type: none"> • comfort and safety while donning and doffing the orthosis • manual dexterity while using closures and straps • effort and time required to don and doff the orthosis • consider modifications to facilitate ease of donning such as loops, tabs, Velcro, straps, etc.
Non-weight-bearing alignment	<ul style="list-style-type: none"> • Patient must be able to sit comfortably in a chair with the orthosis such that the hip, knees, and ankles are at approximately 90 degrees to each other. • The axis of the orthosis must lie in close proximity to the anatomical joint axis. An orthotic joint axis that is too high or too low can interfere with joint motion. • The interior surfaces and edges of the orthosis must be smooth and comfortable for the patient. A sharp edge may impinge the enclosed tissues causing skin irritation and discomfort. In the case of an insensate patient, a sharp edge can cause skin breakdown before the patient is aware of a problem • Component parts of the orthosis are comfortable and correct in size, alignment, and fit including elements such as uprights, straps, mechanical joints, inserts, and shoes. • Uprights should be aligned at midline of the leg and thigh segments and should not be too high or too low. Uprights that slide anteriorly or posteriorly can reduce the effectiveness of the forces applied by the leg and thigh bands. • Weight-bearing buildups of the orthosis should align correctly with the structures that are meant to bear weight, such as the patellar-tendon-bearing brim of an ankle-foot orthosis with the tibial tuberosity or ischial-weight-bearing brim of a knee-ankle-foot orthosis (KAFO) or a Hip Knee Ankle Foot Orthosis (HKAFO) with the ischial tuberosity. • Pressure reliefs contoured inside the orthosis for sensitive structures must be correctly aligned with those structures. For example, pressure-sensitive areas such as the fibular head and malleoli must align correctly with the pressure reliefs incorporated inside the ankle-foot orthosis.
Skin integrity	The patient's skin condition should be assessed both prior to donning the orthosis and after doffing it (and both times should be carefully documented). Prior to donning the orthosis an assessment of skin color and integrity including recording any preexisting scars or cuts should be performed. After doffing the orthosis, any color changes, skin induration, blanching, chafing, or distal edema should be noted. If these changes are present for more than 15 min, it might indicate that the orthosis is causing excess pressure, and this can lead to skin breakdown and ulceration. It is especially important to perform regular skin checks with a patient who lacks normal sensation, as they will not notice discomfort or excess pressure.

Dynamic Evaluation

Patient's opinion	During weight bearing with the orthosis, it is essential to confirm patient comfort and fit during standing and walking with the orthosis.
Weight-bearing alignment	Does the orthosis align correctly to the structures meant to bear weight? Examine if pressure reliefs contoured inside the orthosis for sensitive structures are correctly aligned to those structures.
Pregait (standing) evaluation	Assess patient's posture while standing with the device. This assessment is particularly important for patients who wear an orthosis only on one limb. The height difference when using a unilateral orthosis may need to be compensated with a heel lift on the contralateral limb to achieve balance and symmetry.
Gait evaluation	<ul style="list-style-type: none"> • Gait should be compared with and without the orthosis to understand if the orthosis meets the needs for which it was prescribed. If the orthosis was meant to correct excessive foot drag during walking, it can do so by either assisting dorsiflexion or controlling excessive plantarflexion. If the problem persists, the orthosis needs further modifications or adjustments. • An orthosis can correct one problem but create another one. For example, locking the knee joint during gait will stabilize the knee in stance but can prevent the knee from flexing during the swing phase and can lead to the patient using an alternate strategy to clear the limb during swing. • Assess patient effort in walking with the device. Observing how frequently the patient has to stop and start while walking with the orthosis, whether they find walking with the device tiring, and if they are able to maintain a certain speed of walking over a specific distance are important considerations of the evaluation. • Note any noise or sounds the orthosis might make while walking. Unusual sounds from the orthosis may indicate malalignment of a joint or segment. An orthosis that is misaligned might be out of phase with the limb segment and might create forces or torques that might damage the orthosis or injure the limb.

Data from Edelstein JE, Bruckner J. *Orthotics: A Comprehensive Clinical Approach*. Thorofare, NJ: Slack; 2002.

However, at times, use of a plastic or graphite AFO adds risk and complication without improvement compared with traditional AFOs fabricated with metal and leather attached to the patient's shoe. For example, if the patient requires ankle and knee stability yet lacks sensation and/or has fluctuating edema in the foot and ankle, a double-upright metal orthosis attached to the patient's shoe creates much less risk for potential skin breakdown than a rigid total contact plastic orthosis. In the case of a neuropathic foot, significant risk would be incurred by providing a total contact AFO made of plastic. A double-upright metal AFO with a well-fitting extra-depth shoe with a custom accommodative insert would fit the patient's needs and take into consideration the sensory and motor changes within the lower extremity (Table 32.2).

Introduction of biomechanical forces to the extremities may cause unwanted movements or restrictions, and careful selection of components is essential to keep the focus on the orthotic plan. For example, a patient with a CVA may need a stronger anterior lever force to provide knee stability, so one could plantar flex the orthotic ankle joint. However, this knee-stabilizing effect in stance phase may cause a toe drag during swing phase since the foot is plantarflexed. A simple fix is to provide the opposite side with a heel and sole lift for additional clearance during swing phase of the affected extremity (see Table 32.2).

Clinicians need to set realistic, manageable, patient-centered treatment goals. All too often, treatment plans are only in the minds of the clinicians and are poorly communicated with the patient and family. Often the patient and family members will expect benefits of the intervention that will far exceed what the therapist knows are possible. The time to address those gaps is prior to orthotic treatment, not when the patient and family realize that expectations regarding functional gains while using the orthosis may not be realistic. Clear and achievable goals that are clearly communicated will engender the patient's trust and guide the potential for successful future intervention. Discussing realistic achievable goals of treatment after assessing all factors, the home situation, and individual motivation with the patient and caregivers in language they understand is critical if optimal orthotic intervention is to be achieved. In the case of a patient with hemiplegia due to a CVA, orthotic goals may be to

provide safe standing balance for transfers and minimal ambulation in the home. Patients and their caregivers will realize the major benefit this will have on the home situation. However, without this identified as the goal before initiating orthotic care, they may leave the therapeutic environment wondering why the patient cannot walk normally and participate in life activities that require longer distance ambulation skills.²³ This clinical error is an all too frequent patient management mistake. Integrating orthoses with physical and occupational therapy motor relearning and neuroplasticity should help to optimize functional recovery.

To provide a cost-effective orthosis in a timely manner with the current vast number of orthotic devices, the orthotist must stay abreast of the wide array of choices at his or her disposal to meet the needs of the patient. The reality of cost containment is not a recent event in the orthotic profession, because funding for these devices has always been challenged. This has necessitated the development of more cost-effective alternatives, such as prefabricated orthoses. The introduction of heat-moldable plastics into orthotics in the late 1960s and early 1970s on a custom basis replaced, to a large extent, the need to mold leather and/or metal to fabricate an orthosis (see Table 32.2). This provides total contact fit and dramatically reduced the time and skill level required for manufacturing. All orthoses produce a force field, some desirable and some undesirable. It requires an experienced clinician to make the most appropriate choices, because too often the failure of treatment is blamed on an orthosis. Usually such failure is the result of an inappropriate initial selection of orthotic components, lack of discernment between custom-made and custom-fit devices, or misidentification of the patient as candidate for a specific orthotic design. Prefabricated custom-fit orthoses are cost-effective only if they produce the desired goal over time. As a general rule, one should consider prefabricated custom-fit orthosis for patients who have an anatomically "normal" presentation and alignment at the areas the orthosis will contact and who will use the orthosis for only a short time. Custom-made orthoses for extremities or the spine are appropriately prescribed for patients who have deformity or unusual size, or who must use the device longer periods of time or indefinitely.

TABLE 32.2 Comparison of Orthotic Material Properties and Usage

Factor	Metal and Leather	Polypropylene	Lamination or Graphite	Polyethylene
Adjustability	Yes	Yes, with heat	No	Yes, with heat
Ability to change shoes	No	Yes	Yes	Yes
Weight-bearing strength	Yes	Yes	Yes	No
Skin at risk	Yes	Yes, close observation	Yes, where in contact	Yes
Best spinal use	No	Yes	No	Yes
Long-term wear	Yes	Yes, if custom	Yes	Least durable
Weight (lightest at 1)	4	3	2	1
Adjustability for functional changes (improvement or decline of patient's condition)	Yes	Limited unless initial articulation fabricated	No	No
Short-term need	Yes	Yes	Yes	Yes
Requires corrective force with good patient sensation	Fair	Good	Fair	Good
Ability of clinician to change angulation, ankle or knee	Best	Limited ^a	No	Not indicated for weight bearing
Upper-extremity orthoses	Limited	Yes	Limited	Yes

^aUse in combination with metal joints produces best results.

Fig. 32.4 Carbon fiber ankle-foot orthosis (AFO), preventing foot drop in swing phase of gait.

Advancements in technology have allowed the use of lighter, stronger materials in the fabrication of lower-extremity orthotics. A carbon graphite fabric with an exact amount of resin and catalyst already incorporated into the material is an example. With the fibers properly directed over a model, it can be formed with heat. Carbon graphite in other forms is used in both prosthetics and orthotics. Carbon initially had limited acceptance in orthotics because it did not significantly reduce the weight of the orthosis compared with other materials. It is difficult to modify the orthosis after the lamination process is completed. The preimpregnated graphite has a dramatically reduced weight, still maintains its strength, and gives the orthotist the opportunity to use the dynamics of loading and response during the gait cycle.²⁴ This allows for assistance in both the swing and stance phases of gait (Fig. 32.4). A clinical example at the end of this chapter demonstrates this material patient management.

Another significant advancement in component technology has been the introduction of stance control orthotic knee joints. The development of a lightweight, compact knee joint that allow locks to provide a patient with knee stability during stance²⁵ and unlocks to allow knee flexion and toe clearance during swing phase has been elusive until recently. Before this, the available knee joints for knee-ankle-foot orthoses (KAFOs) involved some type of locking mechanism that remained locked throughout the gait cycle. The joint provided stabilization of the weak quadriceps musculature during stance but kept the knee in a fully extended position, making advancement of the limb in swing more difficult for the patient. There are specific indications and contraindications for stance control KAFOs, but results are promising. This feature can potentially reduce energy output²⁶ and increase gait velocity²⁷ because it is not necessary to raise the center of gravity to clear the locked knee during swing phase. This improves patient safety when walking on uneven surfaces. Microprocessor swing and stance control knee orthosis joints also apply technology initially developed for prosthetic knee joints.²⁸

New technology for externally powered orthoses has recently entered the market. These “bionic legs” are robotic aids worn during therapy sessions for gait training. They assist and augment the strength of the patient’s muscle and are most typically used in rehabilitation for patients with SCI.²⁹ Once the patient has achieved functional improvements, the use of the orthosis can be discontinued or modified to provide only the level of assistance required.

Other advancements in orthotic technology include the development of neuroprosthetic devices. These devices act through circuitry and programming to substitute for a deficit in the neural system. External devices that provide these functions exist, and research is ongoing

regarding implantable orthotic control mechanisms and devices. Functional electrical stimulation (FES) is a method of applying low-level electrical currents to motor nerves to restore function. In the 1960s the application of FES for foot drop was demonstrated by using a simple single channel to stimulate the common peroneal nerve to activate the ankle dorsiflexors. FES has widespread applications in many other neuroprosthetic devices such as cardiac pacemakers, cochlear stimulators, bladder stimulators, and phrenic nerve stimulators. Until recently, FES devices to provide ambulation assistance were large, unreliable, complex, and restricted to use in a therapy setting. The FES used in neurological rehabilitation attempts to unmask existing voluntary control (if any) and/or initiate dormant activity of the nerves and muscles. For FES to be used, the patient must have an upper motor neuron lesion. The nerve-to-muscle pathway must be intact and the reflex arc undamaged. Goals of FES address many rehabilitative outcomes. FES can reduce spasticity, break synergy patterns, reduce swelling, and limit blood clot formation, and assist in maintaining ROM. FES used in gait can improve overall walking abilities by dorsiflexing the foot during swing to provide foot clearance, control initial contact, increase safety, decrease energy expenditure, and retrain muscles. FES has some applications in the upper extremity as well, although at this time it is purely in a therapeutic setting. Currently, there are several FES units for foot drop on the market. These devices are used by patients in their daily lives and are not limited to the rehabilitation setting. The WalkAide from Innovative Neurotronics (Fig. 32.5) and NESS L300 from Bioness (Fig. 32.6) both function to provide dorsiflexion during the swing phase by stimulating the peroneal nerve. An ideal candidate for these devices must have an upper motor neuron

Fig. 32.5 Walk-Aide Functional Electrical Stimulation (FES) Device.

Fig. 32.6 The NESS L300 Foot Drop System.

lesion, good control of the knee joint, and drop foot. Common neurological conditions in which these devices are used are CVA, SCI, and multiple sclerosis (MS).^{30–32} Both devices involve a sensor to determine when the patient is initiating swing phase and send an electrical stimulus to the nerve to dorsiflex the foot. Advantages of FES over traditional orthotic management for foot drop are that it provides activation of the muscle instead of functioning as a passive splint.³³

Future developments in the field of orthotics will provide external power and support for patients to use in community and home settings. There are already systems that can be applied to a patient with paraplegia to allow him or her to stand and walk. “Bionic” orthoses will incorporate microchips and artificial intelligence to provide “smart,” patient-specific devices. This will allow the orthosis to change its settings and parameters according to the patient’s input or position during a specific task or part of the gait cycle. In more traditional types of orthoses, the materials used will continue to become lighter, stronger, and more versatile.

A common concern of both patients and the rehabilitation team is that use of an assistive device will cause muscle atrophy and increased weakness (particularly for users of AFOs). There are several ways to address this concern. Patients indicated for an orthosis

already have weakness and are at risk of falls and instability.³⁴ If the weakness is significant enough to require orthotic management, safety outside of the therapy gym is critical. They can be provided with exercises and a program to activate the weakened musculature when in a safe environment and use the AFO when ambulating in their home and community. In addition, it has been shown that although initial muscle activation with an AFO is reduced, over time (in both healthy and paretic subjects) there is no reduction in muscle activation or electromyographic signaling.³⁵

Currently orthotist and therapy teams have a multitude of devices from which to choose to meet the needs of the patient. Options range from custom-made devices using a patient mold to prefabricated custom-fit devices. A thorough understanding of the indications and contraindications for each of these devices is essential to meet patient needs. A lack of understanding of biomechanical principles, the limitations of prefabricated orthoses, and custom orthotic devices can lead to failure and increase impairment within the patient’s environment.

CLINICAL EXAMPLES

Paraplegia

Lower-extremity orthotic intervention for a patient with paraplegia is generally considered for the lower extremities at the T12 level in the complete lesion.³⁶ Complete lesions higher in the cord leave the patient without enough trunk stability to use bilateral lower-extremity orthoses effectively. Although a thoracic extension can be added to bilateral KAFOs, this addition greatly increases the difficulty of donning the orthosis independently, and most patients will have great difficulty getting from sitting to standing.

The most appropriate orthoses for a T12 complete paraplegic are bilateral KAFOs. The patient generally uses a swing-to or swing-through gait, and successful use of orthoses requires excellent standing balance. There are three significant design requirements for these KAFOs: shallow thigh and calf bands, locking knee joints, and adjustable ankle joints. A double-adjustable ankle joint has channels on the anterior and posterior sides of the joint. This allows the orthotist to easily adjust dorsiflexion and plantarflexion position and ROM or even provide dynamic assistance via a spring added to the channel of the joint (Fig. 32.7). The shallow bands force the center of gravity forward, inducing lordosis so the patient can rest on the iliofemoral (Y ligaments) of the hip. The knee joint should lock automatically because the patient requires the upper extremities for standing. The joint will lock as the patient stands and bends over the rigid ankle joint, forcing the knee joints into extension. The lock then can catch on the back of a wheelchair seat or other chair to release and bend when the patient sits. The foot-ankle complex forms the basis for balance. A few degrees of adjustment at the double-adjustable ankle joint can make the difference between safe standing balance and limited standing balance (Fig. 32.8).

CASE STUDY 32.1 A. M.

A. M. is a 21-year-old man with incomplete T12-level paraplegia secondary to a gunshot wound. A. M. has normal upper-extremity strength and ROM. He has had surgery for spinal fusion. Trunk strength is 4/5, left hip is 3/5, knee is 2/5, right hip is 1/5, and right knee is 0/5. ROM is full at hips, knees, and ankles. A. M. can transfer independently and has the goal of household ambulation, although he is aware that it “takes a lot of work.” A. M. was fit with a right conventional (metal and leather) KAFO with shallow thigh bands,

drop lock knee joints, and double-adjustable ankle joints locked in 5 degrees of dorsiflexion (Fig. 32.9A and B). The left lower extremity was fitted with a conventional AFO with double-adjustable ankle joints adjusted to match the right orthosis. The distal attachment to the shoes was through a long metal stirrup with a reinforcement for stability and resistance to dorsiflexion as the pt’s weight shifts forward. The patient was able to ambulate with forearm crutches.

Fig. 32.7 Double-Adjustable Ankle Joint. The channels on the anterior and posterior sides allow for easy adjustment of dorsiflexion and plantarflexion range of motion. Springs can also be added to provide dynamic assistance to the movements.

Fig. 32.8 Modifications necessary to control the ankle setting in a patient with spinal cord injury (Scott-Craig shoe or stirrup modifications).

Fig. 32.9 Patient Standing Wearing a Right Knee-Ankle-Foot Orthosis. (A) Lateral view; (B) posterior view.

Hemiplegia

Patients who have had a CVA can vary widely in their need for orthotic intervention, from a simple AFO to assist toe clearance, to an AFO to stabilize both ankle and knee, to an orthosis used temporarily for training purposes. The use of a KAFO in the patient with hemiplegia is rarely indicated. Even though the more affected patient does not have knee stability, he or she rarely ambulates with a heel strike that would destabilize the knee and therefore can use an AFO with restricted ankle motion to help stabilize the knee. In addition, patients cannot don the KAFO with the use of only one upper extremity. With hip flexor weakness and knee instability on the affected side, the orthotic intervention may be to assist in transfers rather than to facilitate gait. Orthotic intervention for the patient with a CVA typically limits ankle ROM. The use of dynamic components is not effective, because they will initiate spasticity. The lack of ROM into dorsiflexion or even to neutral causes the most significant problems for these patients. An ankle that lacks dorsiflexion ROM prevents advancement of the center of gravity and produces a lever arm that induces genu

recurvatum, and often the heel comes out of the shoe or the ankle rolls into varus. Because these patients lack proprioception, this constant force directed posteriorly will be significant over time. The patient may develop pain in the knee and not ambulate, the heel cord will shorten more, and the cycle will continue. Heel cords rarely gain length after the patient has been discharged from the rehabilitation setting, and one must consider the family and home situation. Heel buildups on the affected side are used to bring the tibia into 90 degrees. Buildups of 1 to 1½ inches are not uncommon. Remember to balance the opposite shoe. When selecting between different orthotic components, it is best to choose the more stable orthosis. The use of trial orthoses during evaluation is very helpful. As the patient improves, the amount of orthotic control needed will likely decrease. A three-point pressure orthosis for the knee, such as a Swedish knee cage (Fig. 32.10), is also a valuable training orthosis and, in the case of some post-CVA patients, is used daily when the degree of recurvatum exceeds the patient's ability to control the posteriorly directed force.

Fig. 32.10 Prefabricated three-point pressure knee orthosis (Swedish knee cage) to control genu recurvatum.

Fig. 32.11 Shoe Modification With Double-Adjustable Ankle joint.

Fig. 32.12 Left conventional (metal and leather) AFO with double adjustable ankle joints and shoe build-up.

CASE STUDY 32.2 D. M.

D. M. is a 58-year-old woman who had a left CVA, resulting in a right hemiplegia, 2 years ago. She was evaluated at the request of her physician because of increased knee pain and poor standing balance. D. M. was fitted with a plastic AFO fixed at 90 degrees 14 months ago. She was wearing the orthosis, but the heel would not stay in her shoe. Evaluation showed that the patient was 15 degrees from a neutral ankle alignment (the ankle was in 15 degrees of plantarflexion), had 0/5 dorsiflexion or plantarflexion, and had fair knee extension and flexion. She also walked with the aid of a quad cane and had 10 degrees of genu recurvatum and slight genu varum at midstance. Her goal

was to walk with less pain and to be more stable. D. M. was fitted with conventional AFO with double-adjustable locked ankle joints with long tongue stirrups added to the shoe and a 1 1/2-inch heel buildup (Fig. 32.11). The left shoe was built up 1 1/2 inches in the heel and sole to balance the right shoe (Fig. 32.12). A Swedish knee orthosis also was used initially to help train the patient and to provide hyperextension control. A double-adjustable ankle joint gives total adjustability to change the ankle angle, or a 90-degree posterior stop also can be used in a thermoplastic type AFO. Patients who lack this much ROM provide an "anatomical" dorsiflexion stop.

CASE STUDY 32.3 M. H.

M. H. is a 59-year-old woman with a history of a CVA 1 year ago. She has left hemiplegia. She works as a facilities manager and walks through her office building several times per day. She underwent extensive therapy after the CVA and has good strength; ROM is within normal limits at her hip and knee. At her left ankle, M. H. has 3+/5 plantarflexion strength but 0/5 dorsiflexion or eversion strength, and she has extensor tone into plantarflexion and inversion. She ambulates very cautiously due to her inability to dorsiflex and evert the foot during the swing phase of gait. She has a high risk of falling because of her ankle instability and has sustained multiple inversion sprains at the ankle.

M. H. was tested using an FES device and had an appropriate response to the stimulus. The FES device consists of a cuff and control unit around her proximal calf, attached to electrodes on her skin near the fibular head. It allows her to ambulate barefoot and/or with various types of footwear because it is programmed using the angle of her leg to determine the transition from stance to swing phase in gait. The unit is inconspicuous and lightweight. Her walking velocity, safety, and stability are significantly improved with the FES unit.

Paralytic Spine

Many neuropathic diagnoses affect the spinal column. Spinal muscle atrophy, tetraplegia, myelomeningocele, and Duchenne muscular dystrophy can all require orthotic intervention. Although materials, padding versus no padding, trim lines, length of time used, and optional area openings can vary with different conditions, most spinal stabilizing orthoses are TLSOs. Orthoses used for postsurgical stabilization tend to be of more rigid material to support the healing spine. The paralytic spine that is not surgically stabilized can have either a flexible or a rigid curvature. An orthosis for a patient with a rigid curvature is used to avoid further deformity and differs from that used by the patient with a flexible curvature. If the curve is flexible, the orthosis will be used to provide of the correction. Patients with paralytic spine deformity usually undergo casting for custom orthoses, and although non-weight-bearing supine casts can greatly reduce the curve, many patients will not tolerate the pressure once in the upright sitting position. Orthotic intervention usually has one or more of the following goals: (1) improved sitting balance, (2) support of surgical stabilization, (3) prevention of further spinal deformity, (4) use as an assistive positional device for better use of head and upper extremities, and (5) improved respiratory function. Most TLSOs for these patients are total circumferential designs that use rigid materials (polypropylene) to less-rigid materials (polyethylene, foams) or a combination of padding with a rigid or semirigid frame with a heat-formable foam. The orthosis may require relief for bony prominences, g-tubes, etc. Fabrication and fitting of these orthoses require an experienced orthotist and adherence to detail. Establishing the distal and proximal trim lines of the orthosis will require a fine tuning between providing

enough length to support the spine and maintaining a comfortable sitting position. Several clinic visits may be necessary to achieve the desired outcome.

Spastic Diplegic Cerebral Palsy

The goals of orthotic intervention in the patient with cerebral palsy are to control tone, prevent contractures, improve function and ambulation, and provide a secondary support after a surgical procedure.³⁷ As a general rule, the orthosis used to prevent contracture should be different from the orthosis used for ambulation. Some designs may incorporate modules that can key into one another or be used separately. This feature allows flexibility, assists in donning (especially in a patient with spasticity), and meets several treatment objectives. Modular articulating joints with various settings and functions used with thermoplastic orthoses greatly increase the functional and positional options to optimize orthotic management. To meet the goals of orthotic intervention stated earlier, total contact-type orthoses are generally desirable. As with any total contact orthosis and hypersensitive or hyposensitive skin, a cautious balance between correction of deformity or alignment and skin tolerance must be reached. The fitting and follow-up for these types of orthoses require experience, knowledge, and patience. Combinations of padding, wedging, straps, and heat relief methods are often necessary to enable the patient to wear the orthosis on a daily basis. A patient with spastic diplegic cerebral palsy relies heavily on her or his orthosis and wears it out faster than most other orthotic patients. In the case of a child, she or he may grow out of the orthosis before it wears out. This should be considered in the design and fabrication.

CASE STUDY 32.4 S. G.

S. G. is a 13-year-old girl with spastic quadriplegic cerebral palsy with involvement of all four extremities. She is Gross Motor Function Classification System (GMFCS) Level 5 with significant scoliosis. Her hip ROM is from –25 to 135 degrees of flexion. S. G. is fully dependent and lacks upper-extremity use.

The goal of orthotic intervention was to prevent further deformity, maintain the thoracic and lumbar column height for internal organ function, and provide trunk stability for seated balance in her wheelchair. She was fit with a custom

TLSO fabricated from a cast impression (Fig. 32.13). It has ¼ inch of padding with a polypropylene outer layer, which has been modified over bony prominences for skin tolerance.

S. G. wears her TLSO while seated in her chair and also in bed. Frequent checks of the skin were made during the first few weeks of use to establish trim lines and window type modifications. She continues to be checked periodically for comfort and control as she grows, to ensure that the TLSO's fit and function are appropriate.

CASE STUDY 32.5 R. B.

R. B. is a 41-year-old woman with spastic diplegic cerebral palsy. She has tight heel cords bilaterally, with –5 degrees from neutral ROM at the ankle. Plantarflexion strength is 3+/5, and dorsiflexion strength is 3/5 bilaterally. The patient has 5–7 degrees of valgus calcaneus. The right side has pain in the midfemur and at the knee. She has a bilateral genu valgum deformity of 5–7 degrees (Fig. 32.14A). ROM at the knees is full, and strength of the quadriceps and hamstrings is good. Her hips are normal except for some internal rotation; leg lengths are equal and sensation is good.

Because the right lower extremity was painful at the knee and ankle (see Fig. 32.14B), the patient was fitted with an AFO that extended medially and

proximally to the medial tibial condyle; ankle joints that had a posterior adjustment to limit plantarflexion; and a medial heel wedge and heel buildup of 5/8 inch. The ankle was fitted with a submalleolar orthosis that fit inside the AFO (see Fig. 32.14C and D). The submalleolar orthosis controls valgus of the ankle and along with the medial heel wedging exerts a varus force at the knee (see Fig. 32.14E). The heel buildup reduced the posteriorly directed force from midstance to toe off. The patient's symptoms were reduced, allowing her to be more active.

Fig. 32.13 Thoracolumbosacral Orthosis (TLSO) With Anterior Opening. **(A)** Lateral view. **(B)** Posterior view. Cutouts in rigid plastic to inner soft foam are to provide relief of deformity and expansion for breathing.

Fig. 32.14 **(A)** Painful right genu valgus and pronation. **(B)** Posterior view of right ankle. **(C and D)** Patient wearing submalleolar orthosis with pronation corrected. **(E)** Patient in AFO extended to knee to control genu valgus.

Multiple Sclerosis

As MS progresses and further demyelination occurs, increased interruption of normal nerve impulses creates deficiencies in muscle control, vision, balance, sensation, and mental functions. Orthotic considerations for a patient with MS can vary as the patient's symptoms fade, recur, and change over time with the disease. Clinical presentation may vary widely over a short period of time. Fatigue plays a major role in the symptoms, and the patient's expectations and willingness to use orthotic devices changes accordingly. Typical patient reaction is reluctance to use any form of ambulatory aid or orthosis until safety is a major issue. Patients and family usually seek help when falls become more frequent. Lack of toe clearance during swing phase and poor knee stability in stance phase can benefit from orthotic intervention. The weight and simplicity of orthotic intervention must be major considerations. In many instances the evaluation will indicate the need

for a KAFO, but this will be rejected by the patient because of its weight and complexity. The benefit of the KAFO for knee stability and foot and ankle control is counteracted by the patient's inability to advance the limb during swing phase. As their strength varies from day to day, they will judge their need when they are at their strongest rather than their weakest. Traditionally, plastic AFOs are used to control foot drop and provide some medial and lateral ankle control. These orthoses also can provide knee stability if the plastic is robust and if the medial and lateral trim lines are advanced anterior to the malleoli. The anterior lever arm of the AFO stops the center of gravity's forward progression at midstance. The recent development of prefabricated AFOs made of graphite has met the needs of many of these patients (Fig. 34.15). This ultralight orthosis fits inside the patient's shoe. It will provide toe clearance during swing phase and some dynamic knee stability and push off during stance phase.

CASE STUDY 32.6 D. K.

D. K. is a 38-year-old mother of three young boys and works outside the home. She was diagnosed with MS at the age of 30. Until 4 years ago she was managing the symptoms with medication and having minimal mobility problems. With the birth of her son, she had to cease use of medication, and the symptoms recurred and weakness increased. At age 36 she was limiting her activity outside the home because of safety issues—she was falling and unstable in standing

and walking. She was prescribed with a right AFO because she had foot drop and knee instability and lacked the ability to recover her balance if she caught her toe. A prefabricated graphite AFO was fit to the patient (see Fig. 34.15). D. K. now has toe clearance during swing phase and dynamic knee extension during stance phase. Shortly after beginning to use the orthosis, she was able to walk safely on uneven ground and walk down stairs step over step for the first time in 3 years.

SUMMARY

All orthoses create a force system. It is important to understand and integrate the appropriate force to achieve the desired outcome of intervention. A thorough initial evaluation and knowledge of the multiple orthotic options available are vital to reaching treatment goals. There has been a dramatic improvement in material technology, along with far greater access to orthotics and a much wider range of indications

for orthotic intervention. This should challenge the rehabilitation team to establish measurable goals and then to develop new goals leading from the treatment interventions with the most effective outcomes. This evidence-based practice will help to provide better care and outcomes for your patients.

ACKNOWLEDGMENT

The authors would like to thank Walter Racette for his significant contributions in this chapter in the previous editions of this text.

Abstract: After reading this chapter the student or therapist will be able to: (1) Identify and analyze the force systems produced by the use of an orthosis. (2) Comprehend the prescription rationale gained from an orthotic evaluation for individuals with neuromuscular dysfunctions. (3) Identify and differentiate the variables considered

by the rehabilitation team to optimize outcomes during orthotic intervention.

Keywords: ankle-foot orthosis (AFO), knee-ankle-foot orthosis (KAFO), thoracolumbosacral orthosis (TLSO), lever arms, three-point pressure systems

Integrating Health Promotion and Wellness Into Neurorehabilitation*

Janet R. Bezner and Elissa C. Held Bradford

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Define and differentiate the terms *health* and *wellness*.
2. Describe the characteristics of wellness.
3. Compare illness, prevention, and wellness paradigms.
4. Discuss theories of behavior change and their application to wellness and neurorehabilitation.
5. Determine the appropriateness of screening and standardized measures of health and wellness within the role of physical and occupational therapy.
6. Apply an evidence-based, person-centered holistic wellness approach to an individual or a population living with a chronic neurological condition.
7. Identify barriers and potential strategies to overcoming barriers to wellness for individuals living with neurological injury or disease.
8. Synthesize a wellness approach to neurorehabilitation through case examples.

KEY TERMS

health promotion
perceptions
salutogenic

self-efficacy
well-being

wellness
whole person

In learning to cope with the often chronic nature of their conditions, individuals with neurological disease, not unlike individuals with health conditions of other systems, learn to rely on their abilities to adapt and compensate for their activity limitations and participation restrictions to regain the ability to participate in life. Although not an uncommon approach to life for any human being, the achievement of health or wellness takes on an increased focus for individuals with chronic health conditions, and it is strongly correlated with the quality of life they achieve. A casual consideration of the terms *health* and *wellness* indicates that they are similar, if not the same, in meaning, a commonly held belief among those without health conditions. This interpretation of the terms becomes problematic, however, in the presence of health conditions. Can an individual with a health condition be well? Can a person without a health condition be ill? The concepts of health and wellness and their associated meanings and measures will be explored in this chapter to provide a perspective for movement specialists that will enhance their ability to promote health and well-being in patients with neurological conditions. The evidence examining wellness approaches in patients with neurological conditions will be presented, along with common barriers and enablers to implementation. A synthesis of concepts will be promoted through case study.

DEFINITIONS AND RELATIONSHIPS AMONG TERMS

The classic understanding of the term *health* from a biomedical perspective is “absence of disease.” The antonym of *health*, therefore, is

disease. The World Health Organization (WHO) contributed to the confusion between the terms *health* and *wellness* when in 1948 it defined *health* as “a state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity.”¹ Indeed, there are numerous illustrations of the influence of the mind and spirit on the body and thus the importance, from a public health perspective, of considering more than the physical state of the body when formulating solutions to health problems. However, there is also value in differentiating health from more global concepts such as wellness and quality of life, if for no other reason than to explain the phenomenon that an individual can be diseased and well or can experience a high quality of life while simultaneously living with a chronic disease. Considering the catastrophic nature of many neurological diseases that compromise physical health, it is even more important to distinguish between health and wellness to recognize and pursue avenues to enhance overall quality of life and well-being.

H.L. Dunn first conceptualized the term *wellness* in 1961 and offered the first definition of the term: “an integrated method of functioning which is oriented toward maximizing the potential of which the individual is capable.”² Since Dunn’s introduction of the term, numerous researchers and educators have attempted to explain wellness by proposing various models and approaches.^{3–7} Although the literature is full of references to and information about wellness, including numerous definitions of the term, a universally accepted definition has failed to emerge. However, a leading wellness organization, Wellness Council of America (WELCOA), defined wellness in 2018: “Wellness is the active pursuit to understand and fulfill your individual human needs—which allows you to reach a state where you are flourishing and able to realize your full potential in all aspects of life. Every

*Videos for this chapter are available at studentconsult.com.

person has wellness aspirations.”⁸ Several conclusions can be drawn from the abundance of literature regarding wellness.

For many people, including the public, health and wellness are synonymous with physical health or physical well-being, which commonly consists of health-promoting behaviors such as physical activity, efforts to eat nutritiously, and adequate sleep. Health behaviors have been defined as “those personal attributes such as beliefs, expectations, motives, values, and other cognitive elements; personality characteristics, including affective and emotional states and traits; and overt behavior patterns, actions, and habits that relate to health maintenance and wellness, to health restoration, and to health improvement.”⁹ Research in the 1990s indicated that when the public was asked to rate their general health, they narrowly focused on their physical health status, choosing not to consider their emotional, social, or spiritual health.¹⁰ This recognition has influenced researchers to ask specific questions about dimensions of health and wellness, such as physical and mental dimensions.¹¹ Referring to the definitions of wellness from Dunn and WELCOA, and consistent with numerous other theorists, it is clear that wellness, as it is defined, includes more than just physical behaviors or beliefs about the physical self.

The common themes that emerge from the various models and definitions of wellness suggest that wellness is multidimensional,^{2,3-7,11} salutogenic or health causing,^{1,12} and consistent with a systems view of persons and their environments.^{2,10,12-15} Each of these characteristics will be explored.

First, as a multidimensional construct, wellness is more than simply physical health, as the more common understanding of the term might suggest. Among the dimensions included in various wellness models are physical, spiritual, intellectual, psychological, social, emotional, occupational or vocational, financial, and community or environmental.¹⁶⁻¹⁸ Adams and colleagues¹⁶ in 1997, toward the aim of devising a wellness measurement tool, proposed six dimensions of wellness on the basis of the strength and quality of the theoretical support in the literature. The six dimensions and their corresponding definitions are shown in Table 33.1.

The second characteristic of wellness is that it has a salutogenic or health-causing focus, in contrast to a pathogenic focus in an illness model. Emphasizing the factors that promote health (e.g., salutogenic) supports Dunn’s² original definition, which implied that wellness involves “maximizing the potential of which the individual is capable.” In other words, wellness is not just preventing illness or injury or maintaining the status quo; rather, it involves choices and behaviors

that emphasize optimal health and well-being beyond the status quo. Thus an individual who may or may not be *well* even though there is no physical pathology, may similarly be *well* during an acute episode, or chronic pathology or health condition whether that chronic problem results in static activity limitations or even progressive participation restrictions.

Third, wellness is consistent with a systems perspective. In systems theory, each element of a system is independent and contains its own subelements, in addition to being a subelement of a larger system.^{10,13-15} Furthermore, the elements in a system are reciprocally interrelated, indicating that a disruption of homeostasis at any level of the system affects the entire system and all its subelements.^{13,15} Therefore overall wellness is a reflection of the state of being within each dimension and a result of the interaction among and between the dimensions of wellness. Fig. 33.1 illustrates a model of wellness reflecting this concept. Vertical movement in the model occurs between the wellness and illness poles as the magnitude of wellness in each dimension changes. The top of the model represents wellness because it is expanded maximally, whereas the bottom of the model represents illness. Bidirectional horizontal movement occurs within each dimension along the lines extending from the inner circle. As per systems theory, movement in every dimension influences and is influenced by movement in the other dimensions.¹⁶ As an example, an individual who has a complete T6 spinal cord injury will experience at least a short-term decrease and likely long-term challenges in physical wellness. Applying systems theory and according to the model, this individual may also have a decrease in other dimensions such as emotional or social wellness. The overall effect of these changes in these dimensions will be a decrease in overall wellness initially following the injury, and increased risk of reduced wellness through the individual’s life-span.

Systems theory has been used recently to define the identity of the physical therapist. The American Physical Therapy Association (APTA) has identified the movement system, the collection of systems (cardiovascular, pulmonary, endocrine, integumentary, nervous, and

TABLE 33.1 Definitions of the Dimensions of Wellness

Emotional	The possession of a secure sense of self-identity and a positive sense of self-regard
Intellectual	The perception that one is internally energized by the appropriate amount of intellectually stimulating activity
Physical	Positive perceptions and expectancies of physical health
Psychological	A general perception that one will experience positive outcomes to the events and circumstances of life
Social	The perception that family or friends are available in times of need, and the perception that one is a valued support provider
Spiritual	A positive sense of meaning and purpose in life

From Adams T, Bezner J, Steinhardt M. The conceptualization and measurement of perceived wellness: integrating balance across and within dimensions. *Am J Health Promot.* 1997;11(3):208-218.

Fig. 33.1 The Wellness Model.

musculoskeletal) that interact to move the body or its component parts, to describe succinctly what physical therapists do and address with patients/patients.¹⁹ Physical therapists address movement system issues with patients/patients along the spectrum of wellness to illness. Indeed, the majority of interventions for those with neurological disease focus on restoring or enhancing movement. The movement system typifies a systems approach as described previously, and physical therapists “maximize an individual’s ability to engage with and respond to his or her environment using movement-related interventions to optimize functional capacity and performance.”¹⁹ When rehabilitation is conducted with a biopsychosocial approach, movement, health, and well-being are optimized.

A term related to wellness, *quality of life*, is also used to indicate the subjective experience of an individual in a larger context beyond just physical health. Quality of life has been defined as “an individual’s perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns. It is a broad ranging concept affected in a complex way by the person’s physical health, psychological state, level of independence, social relationships, and their relationship to salient features of their environment.”²⁰ Parallel to the issues related to the concept of wellness, there is lack of agreement on the definition of quality of life and its theoretical components,²¹ as well as variation in the use of subjective or objective quality-of-life indicators. Implied by the WHO definition, and supported by several other authors, quality of life is best conceptualized as a subjective construct that is measured through an examination of a patient’s perceptions. In other words, quality of life, like wellness, is the subjective experience of health, illness, activity and participation, the environment, social support, and so forth, and it is best measured through an assessment of patient perceptions.

A final concept important to define is the social determinants of health (SDoH)—conditions in the environments in which people are born, live, learn, work, play, worship, and age.²² A number of social determinants have been found to relate to health and health outcomes, including access to health services, features of the built environment,

economic stability, education, and the social environment. Within the International Classification of Functioning, Disability and Health (ICF) framework, disability and functioning are the result of interactions between health conditions and contextual factors, including factors relative to the environment and those relative to the person. SDoH can be found within both the environmental (built environment, social environment) and personal (education, income) contextual factors of the ICF model.

Numerous efforts are ongoing to address SDoH across the country, for example, addressing food deserts through the establishment of farmer’s markets and community gardens, public mandates to ensure all children have access to early intervention programs and preschool, and consideration for human transportation in the design and build of cities and towns.^{23,24} To the extent that physical and occupational therapists recognize the contributions of SDoH to the health and wellness of the patients they treat, and they consider SDoH in the development of plans of care, more targeted and effective plans of care will be developed and there will be a higher likelihood of adherence and better outcomes.

A PARADIGM SHIFT TO WELLNESS

The importance of gaining an understanding of health and wellness is to be able to apply it and use this lens when interacting with patients/patients. The ultimate goal is thus to improve the health and well-being of the patient, as the therapist helps the patient improve movement and participation. This is critical to further the paradigm shift from a reactive illness-focused sick care system to a proactive wellness-focused health care system.^{25,26} Numerous facilitators and markers of this paradigm shift exist, ranging from the Healthy People 10-year national health objectives²⁷ to health care reform with Triple Aim,²⁸ focus on value-based care²⁹ and the US Department of Health and Human Services’ National Prevention Strategy released in 2011.³⁰ To learn more about these initiatives see Table 33.2 for a listing of health and wellness resources. In 2017, the National Study of Excellence and

Patient status	Patient	Person at risk	Whole person
Intervention focus	Symptoms	Risk factors	Dispositions
Intervention method	Prescription	Lifestyle modification	Values clarification

Innovation in Physical Therapist Education stated “Individual therapists and the profession must fully commit to eliminate health disparities, address the SDoH, and improve the health care, health, and well-being of our communities and promote the health of populations.”³¹ To help conceptualize the implications of this paradigm shift, a comparison of the traditional “illness” paradigm with both “prevention” and “wellness” paradigms will identify ways in which a physical or occupational therapist can incorporate a wellness paradigm into the treatment of a patient with a neurological condition in the context of rehabilitation. The three approaches, or paradigms, are contrasted in Table 33.3 on six parameters, including the view of human systems, program orientation, dependent variables, patient status, intervention focus, and intervention method.

As stated previously, in a wellness paradigm each dimension or part of the system affects and is affected by every other part, resulting in an integrative view of the human body and the human movement system. In contrast, in a traditional illness or medical model, the systems are independent. There are specialties in medicine by body system (e.g., neurology, orthopedics, gynecology), and in many physical and occupational therapy education programs courses are arranged by body system (e.g., neurology, orthopedics, cardiopulmonary, physical dysfunction, psychosocial) as indicators of the independence of the systems. In a prevention approach, there is recognition that the systems interact, or influence one another, but not in the reciprocal fashion characteristic of wellness.

The program orientation of an illness paradigm is the pathology or disease-causing issue, whereas the orientation of a prevention paradigm is normogenic, meaning efforts are aimed at maintaining a normal state or condition (e.g., normal muscle length, tone). Shifting to a wellness paradigm requires a salutogenic or health-causing approach, with a focus on how to achieve greater well-being, health, or quality of life. This shift emphasizes the capabilities and abilities of the individual rather than the limitations and deficits.

The variables of interest in an illness paradigm are clinical variables, such as blood tests, VO_{2max} (maximum volume of oxygen use), and tests of muscle strength. Changes in these variables result in labeling the patient more or less ill. In a prevention paradigm, the variables measured are behavioral, for example whether the individual smokes, exercises, or wears a helmet. Positive improvement in a prevention approach typically results in a change in an individual’s behavior. In contrast, the variables measured in a wellness paradigm are perceptual, indicating what the patient/client thinks and feels about herself or himself. Although clinical, physiological, and behavioral variables are useful and important indicators of bodily wellness and are commonly used to plan individual and community interventions, their utility as wellness measures falls short.³² Clinical and physiological measures assess the status of a single system, most commonly the systems within the physical domain of wellness. It can be argued that behavioral measures are a better reflection of multiple systems because

of the importance and influence of motivation and self-efficacy on the adoption of behaviors, but they do not describe the wellness of the mind. On the other hand, perceptual measures, capable of assessing all systems and having been shown to predict effectively a variety of health outcomes,^{16,33,34} can complement the information provided by body-centered measures insofar as they are valid, congruent with wellness conceptualizations, and empirically supportable.³²

The influence of perceptions on health and wellness has been demonstrated repeatedly in the literature with a multiplicity of patient/client populations and in a variety of settings. Mossey and Shapiro³³ demonstrated more than 35 years ago that self-rated health was the second strongest predictor of mortality in the elderly, after age. Numerous other researchers have replicated these findings in other populations, lending support to the value of perceptions in understanding health and wellness and indicating that how well you *think* you are may be more important than how well you are as measured by clinical tests and measures or the judgment of a health professional.

Shifting to patient status in each of the three paradigms, the subject receiving treatment in an illness paradigm is called the *patient*, whereas in a prevention paradigm the subject is a *person-at-risk* because of the focus on risk factors and the maintenance of a state of normalcy. In a wellness paradigm, the patient is considered a whole person, to emphasize the multiple systems interacting to produce a state of well-being, and, more importantly, that a high-functioning or intact physical dimension, although important, is not necessary to achieve a state of well-being or a high quality of life. This concept of whole person is reflected in the ICF framework built on a biopsychosocial approach.

Consistent with the patient status elements, the focus of intervention in an illness paradigm is on symptoms, and in a prevention approach on risk factors. Consistent with a whole-person focus in a wellness approach, the intervention focuses on dispositions. Defined as a prevailing tendency, mood, or inclination or the tendency to act in a certain manner under given circumstances, dispositions produce perceptions, which can be measured to indicate a global or psychosocial assessment of the whole person, given input from all of the systems. Combined with symptom and risk factor assessment, perceptions of the individual provide valuable additional information about a patient that can enhance the therapists’ ability to intervene and the success of the interventions selected. Table 33.4 lists a few measurement tools that assess patient perceptions.

The intervention method used in an illness paradigm is prescriptive. The prescriptive meaning is based on the system affected and symptoms reported. An intervention in an illness paradigm is prescribed to correct or improve the illness. Given that risk factors are the focus in a prevention paradigm and the aim is to maintain or return the person-at-risk to a normal state, the intervention method that is most appropriate is lifestyle modification in an attempt to change the behavior that is producing the identified risk. The intervention method in a wellness approach is called *values clarification*, and it is consistent with the focus on dispositions and measurement of perceptions. The

TABLE 33.4 Sample Items From Perceptual Measurement Tools

Instrument	Perceptual Construct	Sample Items (Responses)
Short Form 36 ⁶⁰	General health perceptions	<p>"In general, would you say your health is _____?" (excellent, very good, good, fair, or poor)</p> <p>"Compared with 1 year ago, how would you rate your health in general now?" (much better than 1 year ago, somewhat better, about the same, somewhat worse, much worse)</p>
Satisfaction With Life Scale ⁷⁰	Life satisfaction	<p>"In most ways my life is close to my ideal"</p> <p>"I am satisfied with my life" (7-point Likert scale from strongly disagree [1] to strongly agree [7])</p>
Perceived Wellness Survey ¹⁶	Perceived wellness	<p>"I am always optimistic about my future"</p> <p>"I avoid activities that require me to concentrate" (6-point Likert scale from very strongly disagree [1] to very strongly agree [6])</p>
NCHS General Well-Being Schedule ⁶²	General well-being	<p>"How have you been feeling in general?" (in excellent spirits; in very good spirits; in good spirits mostly; up and down in spirits a lot; in low spirits mostly; in very low spirits)</p> <p>"Has your daily life been full of things that were interesting to you?" (all the time, most of the time, a good bit of the time, some of the time, a little of the time, none of the time)</p>
Philadelphia Geriatric Center Morale Scale ^{66,67}	Morale	<p>"Things keep getting worse as I get older"</p> <p>"I am as happy now as when I was younger" (yes, no)</p>
Memorial University of Newfoundland Scale of Happiness ⁶⁹	Happiness	<p>"In the past months have you been feeling on top of the world?"</p> <p>"As I look back on my life, I am fairly well satisfied" (yes, no, don't know)</p>

aim of values clarification is to enhance self-understanding by surfacing the person's perceptions of the situation and its impact on his or her life. When values clarification can precede intervention prescription and lifestyle modification, wellness will be enhanced because the intervention will be more targeted and truly person-first or whole-person-based, rather than focused on the health condition.

THEORIES OF BEHAVIOR CHANGE

A shift to a wellness paradigm from an illness paradigm will not yield positive outcomes without consideration given to factors beyond the individual (behaviors, cognitive and physical state, experience, etc.), including the physical and social environments.^{35,36} A social-ecological approach describes the multiple levels of influence on health and wellness, including individual factors, family and friends, communities and employers, policies, and social norms. Factors beyond the individual

include the SDoH and other features of the environment that impact access to and use of health and wellness enhancing resources. This approach recognizes that behavior is affected by and affects multiple levels of influence,³⁷ and it is necessary to do more than educate and motivate people to engage in health-promoting behaviors. Social and physical environments must support the healthy choice as the easy choice for positive health behaviors to become consistent and sustainable. There are numerous examples of the impact of health-promoting programs designed to address multiple levels of influence, but perhaps the success that has been achieved in reducing rates of cigarette smoking provides the best example, in which environmental changes occurred at multiple levels simultaneously to curb the incidence of smoking (e.g., social norms [while it was once cool to smoke, nonsmoking became cooler]), policy (cigarette taxes were increased), organizations (nonsmoking sections of restaurants, airplanes, and places of employment were created). Fig. 33.2 illustrates the social-ecological model.

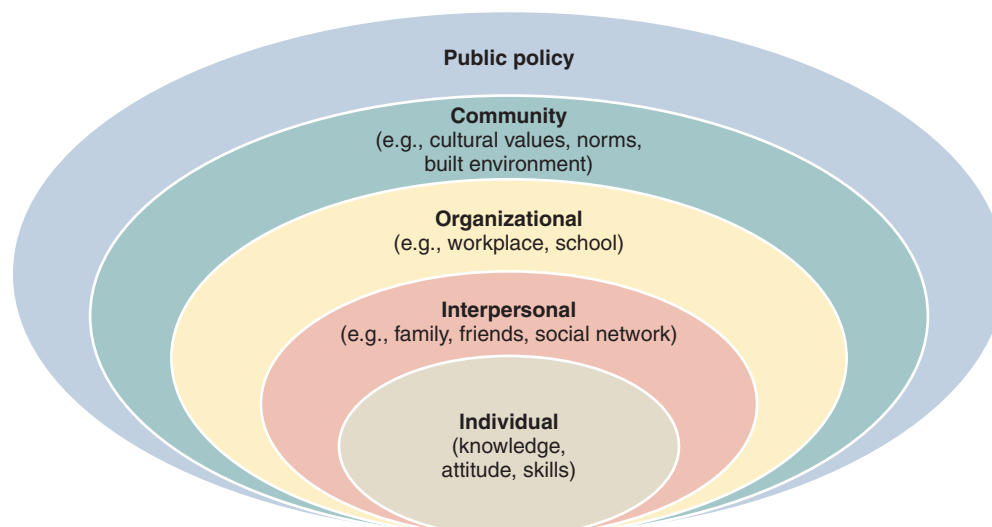

Fig. 33.2 Social-Ecological Model.

As illustrated by the social-ecological model, frameworks are useful to guide intervention programs. Theories of behavior change are frameworks that have been used for decades to explain, interpret, guide, and predict behavior in a specified context. Theories, or systematic explanations for naturally occurring phenomena, explain behavior and provide insight into ways to modify it.³⁸ Consistent with a wellness paradigm, the use of theories creates a more holistic approach in the provision of physical or occupational therapy because they address the cognitive and emotional factors related to readiness and motivation to behave that so frequently derail intervention programs (attitude, motivation, negative emotions, etc.). Understanding and applying theories of behavior change will enable the therapist to create more targeted intervention programs, enhance patient participation in and adherence to intervention programs, and improve outcomes. Several key health behavior change theories will be discussed in the following section, starting with interpersonal theories (social cognitive theory [SCT], resilience theory) that include environmental influences on individual behavior, and moving to individual theories (the transtheoretical model [TTM], self-determination theory [SDT]) in which variables within the person are the focus.

Social Cognitive Theory

One of the most widely used and robust health behavior change theories, SCT emerged from social learning theory, which identified that people learn from their own experiences and by observing the experiences of others.³⁷ There are three major constructs in SCT that interact to influence behavior: personal factors (age, cognitions, previous experience with the behavior, etc.), environmental factors (access to resources, safety, support from family/friends, etc.), and aspects of the behavior itself (vigor of the behavior, outcomes achieved as a result of practicing the behavior, competence with the behavior, etc.). Successful efforts to change behavior depend on identification of the positive supports and the detractors in each of the three constructs. For example, if a therapist is managing the physical or occupational therapy services of a patient who has multiple sclerosis and this patient is motivated to be physically active yet does not have a safe place to walk or be physically active near home, the patient will likely not be able to consistently perform physical activity. If the same patient works for an employer who provides an onsite gym, the patient could negotiate with her supervisor to utilize the gym to be physically active a few days a week.

Of the multiple additional constructs in SCT, several are worth mentioning. Albert Bandura, the author of SCT, identified self-efficacy, the confidence a person has in his or her ability to perform a behavior, as having a significant influence on behavior change.^{39–41} Self-efficacy has been shown to predict the amount of effort an individual will expend to learn and practice a behavior, the persistence demonstrated in the process, and the effort expended to overcome barriers.^{42,43} Self-efficacy is behavior specific. Therapists are familiar with the importance of self-efficacy in neurological rehabilitation as patients learn and relearn movement strategies after neurological insults and the way in which repetition, small steps, verbal persuasion, and observational learning build confidence and thus competence in the movement. These same strategies enhance self-efficacy for behavior change related to enhancing wellness, and self-efficacy is key to the development of sustainable health habits.

Goal setting and social support are two additional useful constructs in SCT that fall into the broad category of self-regulation, an important skill to develop when adopting new health behaviors.⁴¹ The setting and achievement of goals can have a profound positive impact on learning new health behaviors, like the positive role goals play in physical and occupational therapy plans of care, with the additive effect of enhancing self-efficacy when goals are both challenging and

achievable. When goals are not adequately challenging, they can decrease self-efficacy. Social support involves identifying others who will provide encouragement in the form of moral support, participation in the behavior, and accountability. For certain populations, social support has been shown to be significantly related to physical and mental health, pain, coping, adjustment, and life satisfaction.⁴⁴

In summary, the application of the SCT can identify both barriers and facilitators to behavior change that can become the target of interventions that support the development of health and wellness enhancing behaviors. Attending to the self-efficacy of the patient as he or she develops a new behavior and intentionally implementing an approach that enhances self-efficacy will lead to more positive results. The use of goal setting and social support within the plan of care have been shown to support positive behavior change.

Resilience Theory

The concept of resilience arose from the science related to both the physiological aspects of stress and neuroplasticity and psychological aspects of coping.⁴⁵ Resilience, as defined by the American Psychological Association, is “the process of adapting well in the face of adversity, trauma, tragedy, threats or even significant sources of stress.”⁴⁶ Resilience is thus a complex construct representing a process of adaptation to a life disturbance based on the interaction of the individual and the environment. Resilience has also been viewed as a trait or outcome.⁴⁵ As a trait, resilience is considered a protective factor. On an intrapersonal and cognitive level, resilience traits include optimism, intelligence, humor, locus of control, and a belief in purpose in life.^{45,47} On an environmental level, perceived social support has been associated with higher levels of resilience. Resilience is demonstrated behaviorally through successful coping strategies, social skills, and educational abilities.⁴⁵

Resiliency as a model or theory may be first credited to Richardson and colleagues in 1990, although the concept of resilience can be found in prior work. In the Resiliency Model, Richardson and colleagues⁴⁸ describe the characteristics of a resilient individual as protective against distress and disease. The authors describe resilience as a process of psychological reintegration with four possible levels where adversity can promote growth. In the highest level of true psychological reintegration, the individual learns new skills and strengthens characteristics of resilience from a disruptive experience ultimately reframing his or her perspective in a way that is enabling and not disabling. In 1998, Carver and colleagues⁴⁹ depicted an individual’s level of functioning after an adverse event as having four possible courses similar to Richardson’s levels of psychological integration: (1) succumbing, (2) survival with impairment, (3) resilience (or recovery), and (4) thriving, seen as bouncing back and *above* the stressful life event, true psychological reintegration.

Resilience has been studied across a wide range of conditions including environmental stressors such as war, developmental life stressors such as adolescence, and also health stressors such as chronic and neurological illness. Based on this work, resilience may be best conceptualized within individual domains as resiliency in one area does not necessarily equate to resilience in another, similar to the concept of self-efficacy. Given the disruption of a life-changing event such as a traumatic brain injury or a spinal cord injury, or the uncertainty and stressors associated with neurodegenerative diseases such as multiple sclerosis or Huntington disease, the study of resilience and of resilience promotion programs has grown in recent years.^{50,51} In a small randomized control pilot study of the program “Everyday Matters” developed by the National Multiple Sclerosis Society, Alschuler and colleagues⁵¹ found persons with multiple sclerosis improved their resilience and satisfaction with social roles. Trends were seen towards

improvement in positive affect and well-being, and reduction in depressive symptoms. The 6-week program was delivered by teleconference and included readings, videos, and online group participation focused on improving resilience through development of optimism and happiness, and building upon opportunities for forward movement and positive outcomes.

Physical and occupational therapists can use the concept of resilience to empower choice and opportunity for patients to grow (thrive or psychological reintegration), versus simply recover or perhaps succumb⁴⁷ when faced with living with a neurological condition. By incorporating components of optimism and humor, as well as positive appraisals and reframing into therapeutic encounters, therapists can build resilience as a powerful tool to promote health and wellness. Therapists can also connect patients with existing community-based programs that build resilience for the life-long pursuit of wellness.

Transtheoretical Model

An individual theory, the TTM has four main constructs—stages of change, decisional balance, self-efficacy, and processes of change. James Prochaska, who with colleagues first described the TTM, hypothesized that individuals cycle through the stages as they adopt a specific behavior, from precontemplation (not thinking about changing the behavior), to maintenance (having performed the behavior consistently for at least 6 months).^{52,53} Together with the other three stages (contemplation—feeling ambivalent about the behavior; preparation—committed to changing the behavior but hasn't started yet; action—engaged in performing the behavior), the five stages describe varying degrees of readiness to engage in a specific behavior. The processes of change can be used as interventions to move an individual from one stage to another and include cognitive (thinking about the influence of the behavior on self and others) and behavioral (cues and rewards) activities. Decisional balance, weighing the pros and cons of the behavior, influences movement from one stage to another, as does self-efficacy. The higher the list of pros for performing the behavior, the closer to the action stage the individual will move, and the higher an individual's self-efficacy, the more likely the person is to be performing the behavior. It is important to note that the stages are not meant to be linear, but cyclical, in that individuals don't progress from one stage to the next necessarily. For example, individuals who stop smoking "cold turkey" can move from contemplation to action without spending time in the preparation stage.

Identifying the stage of change an individual is in allows targeted interventions to be developed that both respect the individual's readiness to change and resonate with the person's thoughts and feelings about the change. For example, if a patient is in the contemplation stage for performing his home exercise program daily, it would be appropriate to discuss the pros and cons of the behavior and identify strategies to overcome the cons or barriers and ways to increase the pros or benefits. This approach will ideally move the individual to the preparation or action stage where performing the home program can be achieved. Geertz and colleagues⁵⁴ used TTM constructs in a study with 40 subjects with multiple sclerosis aged 35 to 65 with moderate disability. Subjects in the experimental group participated in 16 to 24 standardized exercise sessions in 8 to 12 weeks individually tailored to each participant based on baseline stage of change, self-efficacy, barriers to exercising, and social support. Following the intervention, subjects in the experimental group reported a higher stage of change compared to the control group; self-efficacy stayed the same compared to the control group in which it decreased over time, and perception of barriers changed to a less restricting view in experimental group subjects.⁵⁴

The TTM can be useful to identify a patient's readiness to change a behavior, to identify cognitive and behavioral interventions that will

create greater readiness, and, like the SCT, to note when self-efficacy is low and to intentionally apply strategies to improve it.

Self-Determination Theory

Recognizing that human behavior is the largest single source of variance in health outcomes, that the effectiveness of most interventions is highly dependent on the patient's ability to adhere to recommendations, and that adherence is generally poor, Edward Deci and Richard Ryan created the SDT to explain how humans can successfully change their behavior.^{55,56} Constructs in the SDT include three innate psychological needs of humans: autonomy, competence, and relatedness to others. Autonomy refers to the process by which behaviors become regulated over time. The authors describe motivation or regulation on a continuum, including amotivated/nonregulated, extrinsically motivated/regulated, and intrinsically motivated/regulated. When people behave to gain a reward (fit into a size 8 dress for a wedding) or avoid a negative consequence (spouse nagging, feeling guilty), they are motivated by extrinsic factors, which generally do not sustain behavior long term. Intrinsic motivation includes behaving a certain way because it is consistent with a person's deeply held values or goals, for example, to be a better parent or student or employee. Intrinsic motivation is consistent with being self-determined and can sustain behavior and health habits as lifestyle choices.⁵⁷ Competence is the degree to which individuals feel able to change and achieve goals and outcomes and is supported by the provision of skills and tools for change and effective feedback from health care providers.⁵⁸ The theory authors state that autonomy facilitates competence because when individuals choose to engage in a behavior they are more likely to take risks, learn, and apply new strategies.⁵⁸ The third construct, relatedness, refers to the degree to which individuals feel connected to others in a warm, supportive way.⁵⁶ When individuals feel respected and supported, especially by health care providers in a patient-provider relationship, they are more likely to achieve intrinsic motivation and experience success sustaining health behaviors over time.

Physical and occupational therapists can apply the SDT by providing meaningful rationale for why a behavior is recommended, acknowledging feelings and perspectives so patients feel understood, and integrating choice wherever possible in plans of care to minimize external control and pressure from the provider.⁵⁶ Numerous studies have been published illustrating the value of guiding patients toward autonomous motivation so that they can adhere to health behaviors and improve their quality of life and health outcomes.⁵⁹

MEASUREMENT OF WELLNESS

As a result of the varied ways that wellness has been defined and understood, a variety of wellness measures exist. Consistent with the characteristics of wellness described, a wellness measure should reflect the multidimensionality and systems orientation of the concept and have a salutogenic focus. In the literature, as well as in daily practice, clinical, physiological, behavioral, and perceptual indicators are all touted as wellness measures. Clinical measures include serum cholesterol level and blood pressure, physiological indicators include skinfold measurements and maximum oxygen uptake, behavioral measures include smoking status and physical activity frequency, and perceptual measures include patient/client self-assessment tools such as global indicators of health status ("Compared with other people your age, would you say your health is excellent, good, fair, or poor?")¹¹ and the Short Form 36 (SF-36) Health Status Questionnaire (see Table 33.4).⁶⁰

Although some perceptual measures assess only single system status (e.g., psychological well-being, mental well-being), numerous multidimensional perceptual measures exist that can serve as wellness measures. Perceptual constructs that have been used as wellness

measures include general health status,⁶⁰ subjective well-being,^{60,61} general well-being,⁶² morale,^{63–67} happiness,^{68,69} life satisfaction,^{70–72} hardiness,^{73,74} resilience,^{75–77} and perceived wellness^{16,78} (see Table 33.4). Refer to Fig. 33.3 for the “Perceived Wellness Survey” used by professionals to help conceptualize the patient’s perception of her or his wellness. This survey was first published in the *American Journal of Health Promotion* in 1997.¹⁶ Physical therapists assess perceptions as a part of the patient/client history, as recommended in the “Guide to Physical Therapist Practice.”⁷⁹ Occupational therapists assess perceptions as part of their focus on human performance and occupation. Some of the kinds of perceptions that can be assessed include perceptions of general health status, social support systems, role and social functioning, self-efficacy, and functional status in self-care and home management activities and work, community, and leisure activities. Although a few of these categories are included in overall wellness,

such as general health status and social and role functioning, measuring wellness perceptions specifically can provide additional and more complete information about the patient that both the physical and occupational therapist can use to formulate a plan that can be insightful to the patient/client. Therefore perceptual tools should be used when measuring wellness.

MERGING WELLNESS INTO REHABILITATION— THE ROLE OF PHYSICAL AND OCCUPATIONAL THERAPISTS IN HEALTH PROMOTION AND WELLNESS

Incorporating wellness into rehabilitation requires that the therapist modify the traditional approach used in rehabilitation. This change

Perceived Wellness Survey

The following statements are designed to provide information about your wellness perceptions. Please carefully and thoughtfully consider each statement, then select the one response option with which you most agree.

	Very Strongly Disagree	Very Strongly Agree
1. I am always optimistic about my future.	1 2 3 4 5 6	
2. There have been times when I felt inferior to most of the people I knew.	1 2 3 4 5 6	
3. Members of my family come to me for support.	1 2 3 4 5 6	
4. My physical health has restricted me in the past.	1 2 3 4 5 6	
5. I believe there is a real purpose for my life.	1 2 3 4 5 6	
6. I will always seek out activities that challenge me to think and reason.	1 2 3 4 5 6	
7. I rarely count on good things happening to me.	1 2 3 4 5 6	
8. In general, I feel confident about my abilities.	1 2 3 4 5 6	
9. Sometimes I wonder if my family will really be there for me when I am in need.	1 2 3 4 5 6	
10. My body seems to resist physical illness very well.	1 2 3 4 5 6	
11. Life does not hold much future promise for me.	1 2 3 4 5 6	
12. I avoid activities which require me to concentrate.	1 2 3 4 5 6	
13. I always look on the bright side of things.	1 2 3 4 5 6	
14. I sometimes think I am a worthless individual.	1 2 3 4 5 6	
15. My friends know they can always confide in me and ask me for advice.	1 2 3 4 5 6	
16. My physical health is excellent.	1 2 3 4 5 6	
17. Sometimes I don't understand what life is all about.	1 2 3 4 5 6	
18. Generally, I feel pleased with the amount of intellectual stimulation I receive in my daily life.	1 2 3 4 5 6	
19. In the past, I have expected the best.	1 2 3 4 5 6	
20. I am uncertain about my ability to do things well in the future.	1 2 3 4 5 6	
21. My family has been available to support me in the past.	1 2 3 4 5 6	
22. Compared to people I know, my past physical health has been excellent.	1 2 3 4 5 6	
23. I feel a sense of mission about my future.	1 2 3 4 5 6	
24. The amount of information that I process in a typical day is just about right for me (i.e., not too much and not too little).	1 2 3 4 5 6	
25. In the past, I hardly ever expected things to go my way.	1 2 3 4 5 6	
26. I will always be secure with who I am.	1 2 3 4 5 6	
27. In the past, I have not always had friends with whom I could share my joys and sorrows.	1 2 3 4 5 6	
28. I expect to always be physically healthy.	1 2 3 4 5 6	
29. I have felt in the past that my life was meaningless.	1 2 3 4 5 6	
30. In the past, I have generally found intellectual challenges to be vital to my overall well-being.	1 2 3 4 5 6	
31. Things will not work out the way I want them to in the future.	1 2 3 4 5 6	
32. In the past, I have felt sure of myself among strangers.	1 2 3 4 5 6	
33. My friends will be there for me when I need help.	1 2 3 4 5 6	
34. I expect my physical health to get worse.	1 2 3 4 5 6	
35. It seems that my life has always had purpose.	1 2 3 4 5 6	
36. My life has often seemed void of positive mental stimulation.	1 2 3 4 5 6	

Fig. 33.3 The Perceived Wellness Survey. (From Adams T, Bezner J, Steinhart M. The conceptualization and measurement of perceived wellness: integrating balance across and within dimensions. *Am J Health Promot.* 1997;11(3):208–218.)

involves multiple steps, including shifting the focus from illness to wellness, being a role model of wellness, promoting active living,^{80,81} incorporating behavioral^{82,83} and perceptual wellness measures into the examination, and ensuring that the therapist is addressing the whole person within his or her system including values, preferences, and social context. Within the scope of rehabilitation this approach may include screenings, consultation, referral, education, resource identification, individual health behavior management, and advocacy for individual and population health.^{80,83} Establishing a wellness approach also requires that the therapist assume the role of a facilitator or partner rather than that of an authority figure.⁸⁴ This shift involves utilization of practices consistent with evidence-based communication and counseling methods based on principles of shared decision making^{85,86} such as the 5 A's/5 R's^{87,88} motivational interviewing⁸⁹⁻⁹¹ and health coaching.^{92,93} In this section, current recommendations for incorporating health promotion and wellness practices into rehabilitation will be shared.

There are numerous resources available to assist the therapist in facilitating health promotion and wellness into his or her practice (see Table 33.2). At minimum, the APTA recommends⁹⁴: (1) identify patient/client health risks during the history and physical via the systems review, (2) take vital signs of every patient during each visit, (3) collaborate with the patient to develop and implement a plan to address health risks, (4) determine readiness for behavioral change, (5) identify available resources in the community to assist in achievement of the plan, (6) identify the secondary and tertiary effects of the disability, (7) demonstrate healthy behaviors, and (8) promote health and wellness in the community. This minimum skill set for the promotion of health, wellness, and prevention in physical therapist practice was developed in 2004 and updated in 2009. Since that time, work has been done at the national and global levels to clarify the role of the therapist in screening and promotion of healthy behaviors and behavior change.^{25,82,83,95-97} This work has focused largely on the importance of addressing and preventing the rising prevalence of lifestyle-related noncommunicable diseases (NCDs)

(e.g., heart disease, stroke, type 2 diabetes mellitus, obesity) in developing countries across the world.⁸² Based on this work, the following health behavioral domains and health behaviors have been proposed for minimum assessment in rehabilitation practice in physical therapy^{25,97} (Table 33.5): physical activity (including sedentarism, lifestyle physical activity, structured exercise), nutrition, sleep, stress (representative of mental health, including depression, anxiety and stress), and smoking. Table 33.5 includes a synthesis of published work highlighting the behavioral domain, the behavioral competency or goal, and assessment and intervention recommendations.

Recently, Lein and colleagues²⁶ proposed a health-focused physical therapy model for incorporating health promotion and wellness into standard of care practice. The key components of this model include a needs assessment of the population served; a needs assessment of the individual for lifestyle behavior change; collaboration with the patient to classify lifestyle behavior change needs into one of three categories: does not need change, needs change but not ready to change, needs change and ready to change; and finally providing lifestyle behavior change interventions. While this model demonstrated good content validity for application to the lifestyle behaviors of physical activity and smoking cessation,³⁹ further research is needed to determine its validity for sleep, nutrition, and stress management, as well as its effectiveness in guiding clinical practice across diverse populations and settings, including persons living with chronic neurological conditions.

It may be most instructive to consider first how a wellness approach could be adopted with patients who are seemingly healthy or without pathology. As experts in movement problems associated with the causes and consequences of pathological conditions, physical and occupational therapists should play a significant role in primary and secondary prevention. Indeed, intervention programs designed by therapists for patients/clients with pathology generally include instruction in preventive behaviors and activities (secondary prevention). Although appropriate and worthwhile, these efforts do not produce the significant outcomes that primary prevention programs

TABLE 33.5 Lifestyle Behaviors for Assessment and Intervention

Domain	Core Competency/Goal	Assessment ^a	Intervention ^b
Physical activity	Reduction of sitting/sedentary behavior Promotion of lifestyle physical activity Promotion of structured exercise	Sedentarism (hours/day) Physical activity (e.g., GLT, PADS-R, pedometer) Structured exercise (FITT; guidelines:150 min/week moderate intensity, resistance training 2 days/week)	Advice and intervention (e.g., sedentarism and physical activity guidelines; individualized structured exercise prescription; counseling for behavior change and self-management)
Nutrition	Healthy nutrition/diet (may include weight loss)	Brief nutritional assessment BMI Waist-to-hip ratio	Potential recommendation (basic nutritional information, e.g., ChooseMyPlate.gov) or referral to other health professional
Sleep	Healthy sleep	Sleep habits (hours/night, quality; guidelines: 7–9 h)	Potential recommendation or referral to other health professional
Stress	Stress, anxiety, and depression management	Mental health (e.g., psychological stress measure, depression screen)	Potential recommendation or referral to other health professional
Smoking	Smoking cessation	Smoking history Quit attempts	Potential recommendation or referral to other health professional

^aPatient values, priorities, and readiness to change should be assessed within each competency.

^bMinimum intervention approach includes 5 R's if patient is in precontemplative stage of behavior change and 5 A's if in contemplative or higher stage of behavior change for each competency; additionally, follow-up, reevaluation, and progression as needed is recommended.

BMI, Body mass index; *FITT*, frequency, intensity, timing, type; *GLT*, Godin leisure-time exercise questionnaire; *PADS-R*, physical activity and disability survey—revised for persons with chronic neurological conditions.

See references 25, 26, 82, 83, 95–97.

might because they are applied after the onset of risk, illness, or injury. Contemporary practice includes a role for the physical and occupational therapist in primary prevention, that is, interacting with patients to promote health and improve wellness *before* they become patients.

Because individuals without overt disease are typically unmotivated to seek professional assistance, consideration must be given to how a provider recruits those without disease. Competence in communication is imperative to ensure that providers do not offend individuals or generate defensiveness when exploring opportunities for health enhancement. Strategies related to effective communication are presented later in this section. A focus on wellness and health-causing activities is a powerful solution to this dilemma. In a sports or athletic context, this approach would be considered “performance enhancing” and would be marketed to individuals who have goals and ambitions related to improving athletic performance in a specific context (e.g., improving 10K time, increasing cycling distance or speed). In a general wellness context, an appropriate marketing message might be to improve quality of life or productivity, or any subjective measure that a patient deems important. The same knowledge and skills therapists use when intervening to prevent injury, delay or prevent the progression of disease, or enhance quality of movement are useful in a primary prevention context in which the goal is to improve quality of life, well-being, and productivity. The difference is the context in which the knowledge and skills are applied. Adopting a wellness paradigm and a patient-centered perspective or focus creates an environment surrounding the patient-provider relationship that both empowers the patient to make meaningful changes and establishes a partnership that is most conducive to change and improvement. The improvement of quality of life or wellness requires a consideration of the patient as a whole person, by definition, as discussed previously in this chapter. Using a patient-centered, whole-person approach to the design of an intervention program requires a considerably different approach than the traditional, biomedical approach of measuring clinical and behavioral variables to identify impairments and functional loss and creating an intervention aimed at ameliorating the impairment.^{98,99} Suddenly patients are more than their diseases, which sends a much different message and creates a much different relationship between the provider and the patient. This approach also broadens the intervention focus beyond the physical domain, opening the door to issues related to the nonphysical domains of wellness, such as emotional, spiritual, social, and psychological wellness, which at any given time could be the most important challenge to high quality of life or wellness. In this case, the therapist may refer to other providers who may be better suited to guide the patient in these domains.

COMMUNICATION STRATEGIES TO IMPLEMENT BEHAVIOR CHANGE THEORY

The way in which a physical or occupational therapist begins a conversation with a patient about a health behavior or about something more sensitive, like meaningful participation, emotional well-being, or spiritual pursuits, should be consistent with the partnership relationship discussed previously in this chapter, rather than consistent with an expert role. Patients may have limited previous experience with these types of conversations with a health care provider, so they may be surprised or caught off guard when the therapist raises these issues. Previous conversations may have been based on a paternalistic approach versus an autonomy supporting approach and weren't effective at promoting change and may have even resulted in feelings of shame or guilt in the patient. A low pressure, casual approach to beginning conversations about wellness is suggested, wherein the therapist gauges the patient's interest in discussing a topic in more depth and asks

TABLE 33.6 The 5 A's Model for Behavior Change

A	Definition
Ask	Ask permission to discuss behavior
Advise	Provide information about the behavior and the associated risks and provide treatment options
Assess	Assess readiness to change; assess biometric and psychosocial variables
Assist	Explore barriers and benefits; refer to another provider
Arrange/agree	Make arrangements to follow up; agree on SMART goals and intervention approach

Agency for Healthcare Research and Quality. *Five Major Steps to Intervention (The “5 A’s”).* Rockville, MD: Agency for Healthcare Research and Quality; 2012. www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/tobacco/5steps.html. Accessed August 19, 2018.

permission to discuss a topic further. The following examples serve to illustrate the type of statements that may result in patient agreement to discuss an issue in greater depth.

- I noticed that you weren't regularly physically active prior to your injury/disease; is physical activity something we could discuss? I think I can help you become more physically active if you are interested.
- Are you familiar with the relationship between smoking and risk for neurological diseases such as multiple sclerosis and stroke? If yes, “Would you be interested in discussing your smoking habit? I would like to understand more about your choice to smoke and explore ways you can successfully quit.” If no, “Would it be okay if I shared some information with you about the relationship?”
- I'm concerned because you've seemed down lately. Is there something you would like to talk about with me or with another provider?
- You don't seem as committed to your home program as you were when we first started working together. Can we talk about your home program? I would like to support you to find a way to make it a consistent priority.

Another approach to entering a conversation with a patient is to use the 5 A's schemata, developed from work in tobacco cessation (Table 33.6).^{87,100} The first A is to ask the patient about the behavior, similar to the approach discussed above in this section. The second A, advise, involves the provision of advice about the behavior, which should be done cautiously so as not to elicit defensiveness in the patient, and not at all if the patient is not open to discussion about the behavior. The third A, assess, means determining readiness to change, discussed next in this section. The fourth A, assist, refers to the role the provider can serve to help the patient set goals and take the next steps toward change. The final A, arrange, refers to follow-up at some point in the future to discover how the patient is progressing with the behavior change.

Once patient interest has been assessed, the therapist should determine readiness to change or stage of change from the TTM. A 5-response question assessing readiness to change the behavior of interest can be utilized, as illustrated in Table 33.7. Or a verbal 1 to 10 scale can be used to assess readiness. The therapist can ask, “On a scale from 1 to 10, with 1 being not ready to change at all and 10 being this is the most important thing I can do for myself right now, how ready are you to change?” Patient responses above 6/7 indicate readiness to change, whereas responses in the range of 3 to 5 may indicate contemplation and 1 to 2 precontemplation. For patients who appear ready to change,

TABLE 33.7 Stages of Change Question for Physical Activity

Instructions: Physical activity is defined as 150 min/week of moderate or 75 min/week of vigorous physical activity or a combination of both. Please read the statements below and select the statement that most closely describes your physical activity level.

Stage	Question
Precontemplation	I have no intention of taking action to become more physically active.
Contemplation	I intend to become more physically active within the next 6 months.
Preparation	I have taken a few steps to become more physically active and intend to start in the next 30 days, or I am active but am not meeting the current guidelines.
Action	I am currently engaged in physical activity and have been for less than 6 months.
Maintenance	I am physically active and have been for more than 6 months.

From Prochaska J, Redding C, Evers K. The transtheoretical model and stages of change. In: Glanz K, Rimer BK, Viswanath K, eds. *Health Behavior: Theory, Research, and Practice*. 5th ed. San Francisco, CA: Jossey-Bass; 2015:125–148.

the therapist can proceed to inquire about the patient's past success with the behavior, if any, and goal setting to begin to develop the behavior. Small, measurable, challenging yet achievable goals can be set to build self-efficacy and determine how the patient can successfully adopt a regular habit of the behavior of interest.⁹² If goals are set too hard or too easy, the result will be decreased self-efficacy, thus the importance of determining challenging yet achievable steps toward the behavior. Patients who are in the preparation stage of change may do best to start with “thinking goals” or cognitive steps (planning) to build confidence, like finding healthy recipes, or discovering different types of physical activity of interest, or talking to family members about supporting the patient's efforts, prior to creating goals involving participation in the actual behavior. Success with cognitive goals will move the patient toward the action stage and build readiness and confidence to engage in the actual behavior of interest.⁵⁰ Behavior change goals can be set and achieved similar to therapy goals, making sure the goals are S.M.A.R.T. (specific, measurable, achievable, realistic, and time-referenced), are constructed by the patient (with assistance from the therapist), and the therapist ensures the patient has the resources and self-efficacy to achieve them. The therapist should routinely inquire about confidence in achieving a goal after setting a goal. If confidence on a 1 to 10 scale (1 = no confidence at all, 10 = I will definitely achieve the goal) is not at least a 6 or 7 for a specific goal, the therapist should consider revising the goal because it may be too difficult, or it may be unrealistic and therefore not achievable. It is suggested that therapists assess self-efficacy in this manner for each goal written, each time a goal is set to enhance the ability of patients to achieve goals and to increase self-efficacy, ensuring goals are set appropriately challenging and realistic.^{84,90} Patients who are in the contemplation stage of the TTM, indicating that they are likely ambivalent about adopting a healthy behavior, or patients who are not intending to change in the near future (precontemplation), may benefit from motivational interviewing, a conversational tool used to facilitate discussion about behavior change. The goal of a motivational interview is to

identify intrinsic motivation to adopt a healthy behavior and facilitate movement to an action stage and thus readiness to change.⁸⁹ Adopting a collaborative versus a coercive approach, therapists using motivational interviewing recognize that the motivation to change comes from within the patient, rather than from the therapist (Table 33.8). The process of motivational interviewing is designed to elicit the intrinsic motivation necessary to create sustainable behavior change.⁸⁴

Recognizing that a patient may benefit from motivational interviewing, the therapist expresses empathy for the current behavior, inquires about the patient's history with the behavior (previous successful performance of the behavior), solicits benefits of the healthy behavior from the patient, and asks the patient to identify barriers to performing the healthy behavior. Throughout the conversation, the therapist looks for opportunities to identify discrepancy between the patient's current values and goals, and the behavior of interest and supports autonomy and self-efficacy using the four primary skills.^{84,89} While motivational interviewing requires practice and feedback to learn and apply, its use by health care providers for a variety of medical conditions has demonstrated that it is a useful adjunct to traditional approaches to behavior change.¹⁰¹

An approach parallel to the 5 A's, called the 5 R's, has been developed to discover and enhance motivation to change and is shown in Table 33.9.⁸⁸ A helpful acronym for the clinician, the 5 R's are a mnemonic that guides the therapist through the steps of decisional balance and developing discrepancy that can support the patient to develop greater readiness to change.

TABLE 33.8 Four Primary Stages Required to Conduct a Motivational Interview

- Ask open-ended questions (vs. closed-ended yes/no questions) to provide the opportunity for the patient to guide the conversation and to respect patient autonomy.
- Affirm and support the patient to prevent judgment and reflect back what the patient is saying to more easily identify discrepancy between the patient's deeply held values and current behaviors.
- Reflective listening, or mirroring what the patient says, allows the therapist to maintain a focus on the patient, avoids interjecting one's own experience, enables a deep dive into the patient's experience, and ensures the patient feels understood.
- Summarize what the patient tells the therapist periodically throughout the conversation to transition between topics, support and highlight the patient's motivations to change and progress made, and to ensure understanding.⁸⁹

TABLE 33.9 The 5 R's of Motivation

R	Definition
Relevance	Ask the patient why the behavior is personally relevant
Risks	Ask the patient about the risks of continuing with the unhealthy behavior
Rewards	Ask the patient to discuss the benefits of adopting the healthy behavior
Roadblocks	Ask the patient about the barriers to performing the healthy behavior
Repetition	Repeat the conversation at each visit until the patient adopts the behavior

From Agency for Healthcare Research and Quality. *Patients Not Ready to Make a Quit Attempt Now (The “5 R's”)*. Rockville, MD: Agency for Healthcare Research and Quality; 2012. www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/tobacco/5rs.html. Accessed August 19, 2018.

The development of intrinsic motivation is an imperative step in the process of building autonomy for sustainable behavior change and is a component of a more comprehensive communication approach to addressing health behaviors called health coaching or health counseling.⁹² Health coaching “is a partnership with patients in a thought-provoking and creative process that inspires and supports them to maximize their personal and professional potential.”⁹² Health coaching is consistent with a wellness approach, requiring the following practitioner competencies:

- The application of a patient-centered approach,
- The ability to assist patients in identifying their goals and motives for change,
- The use of patient self-discovery to explore intervention strategies that are realistic and achievable and engage the patient in active learning,
- The ability to help the patient hold himself or herself accountable and create self-monitoring practices, and
- The attainment of health knowledge to support health behavior change.^{84,102}

Therapists will likely discover that adopting more of a health coaching communication approach versus an expert approach will result in a patient-therapist partnership that will support the development of autonomy, self-efficacy, and growth and enhance both the patient’s success and the therapist’s satisfaction. Applying the recommendations and approach in this section is a good first step toward this shift to a health coaching communication approach and will be illustrated in the case studies that appear later in this chapter.

APPLICATION TO INDIVIDUALS WITH NEUROLOGICAL CONDITIONS

A health and wellness approach has many specific indications and benefits for those living with, and for those at risk for, neurological disease or injury. While examples have been given throughout this chapter, this section will focus exclusively on application to neurological conditions. A case study example highlighting these concepts in multiple sclerosis is available at the end of this chapter.

Benefits begin with primary prevention for those at risk but have not yet developed signs and symptoms of a neurological condition. The clearest example is stroke prevention. Strong evidence exists for the modifiable cardiovascular risk factors of physical inactivity, poor nutrition, and smoking, such that the American Heart Association in 2018 published a scientific statement calling for routine assessment and promotion of physical activity in health care settings for all adults.¹⁰³ Additionally, evidence exists for the power of healthy lifestyle behaviors and subjective well-being to potentially delay onset or prevent development of many neurodegenerative diseases.^{104,105} For example, smoking has been identified as a risk factor for the onset of multiple sclerosis in individuals with a genetic predisposition.¹⁰⁶ Therefore screening and advocacy for not smoking and engagement in other healthy lifestyle behaviors across the dimensions of wellness may delay the onset of multiple sclerosis. Inadequate physical activity has been linked to dementia in Alzheimer disease and Parkinson disease.^{104,105} Thus screening and advocacy for meeting minimum health guidelines for physical activity (150 minutes of moderate intensity physical activity or 75 minutes of intense physical activity a week)¹⁰⁷ may reduce overall disease incidence. While greater research is needed, the time is now for routine screening and advocacy for healthy lifestyle behaviors^{82,83,97} by physical and occupational therapists within individual scope of practice.

In addition to primary prevention, healthy lifestyle behaviors including adequate physical activity, sleep, nutrition, stress management,

and not smoking may modulate and slow disease progression in neurodegenerative disorders and prevent secondary and tertiary complications of neurological injury such as stroke or spinal cord injury. Growing literature supports the benefits of exercise to enhance cardiorespiratory fitness, muscle strength, and cognition, and reduce depression in the general population¹⁰⁸ and in those poststroke, with spinal cord injury, and those living with multiple sclerosis, Parkinson disease, and Huntington disease.¹⁰⁹ Physical activity and exercise at the right dose has the potential to be neuroprotective and neuromodulatory, inducing synaptogenesis, neurogenesis, and neurotransmitter synthesis.^{109–111} Determining and achieving the proper dose of lifestyle physical activity and structured exercise for individuals living with neurological conditions can be difficult. Broad guidelines include the general population physical activity health recommendations inclusive of persons with disabilities,¹⁰⁷ although individual disease-specific populations may differ and more research is needed. For example, for those individuals living with mild to moderate multiple sclerosis, the minimum physical activity guidelines set to demonstrate improvement in aerobic capacity and muscular strength are moderate intensity aerobic physical activity two times per week for a total of 60 minutes and moderate strength training of major muscle groups two times per week.¹¹² Physical activity at this level may additionally induce improvements in mobility, fatigue, and health-related quality of life, although research is insufficient to support a full claim of these benefits at this time.¹¹²

The physical or occupational therapist who strives for a health-focused wellness approach in neurorehabilitation must remember to look fully within and also to look beyond the physical domain to address the whole person. Within the physical domain, this includes ensuring sedentary behavior and lifestyle physical activity are addressed in addition to structured exercise during therapy encounters. Evidence demonstrates sedentarism independent of meeting the minimum guidelines of 150 minutes of aerobic activity is associated with poorer health outcomes.¹¹³ Beyond the physical domain, a health-focused wellness approach includes addressing at minimum the emotional and psychological domains through screening assessment of stress and mental health. Additional considerations in line with the social-ecological and ICF frameworks could include the role of social support in the patient’s path to recovery, identifying intellectually stimulating activities in the absence of adequate intellectual pursuits in the patient’s life, supporting the patient to reframe a pessimistic attitude to a more optimistic attitude, and encouraging the patient to find meaning and purpose in life when appropriate. Incorporating perceptual and behavioral standardized measures of wellness into the systems review and examination will provide the therapist with strong evidence for decision making and tracking of outcomes and impact. As the evidence continues to grow for the system-wide benefits, including the potential neuromodulator benefits, of healthy lifestyle behaviors^{114,115} and subjective well-being in various neurological conditions, routine screening and intervention will hopefully become the standard of practice. The reader is referred to [Table 33.5](#) discussed previously for details on assessment and intervention recommendations.

For successful implementation of a health-focused wellness approach, anticipating and addressing barriers is needed. Many barriers to habitual engagement in healthy behaviors exist. In the neurological population these barriers to physical activity commonly fall across the ICF domains from impairments in body structure and function (fatigue, presence of secondary conditions) to participation restrictions (embarrassment) and to barriers in environmental and personal contextual features (lack of access to accessible equipment and facilities and decreased self-efficacy).¹¹⁶ Based on a recent review of qualitative

studies,¹¹⁷ the most commonly reported impairments and activity and participation restriction barriers include fluctuating fatigue, lack of walking balance, muscle weakness, pain, stiffness, bladder and bowel problems, depression, thermoregulation, and fear of injury. The most common environmental barriers are accessibility, costs, transport, and insufficient information and knowledge from health professionals. The most frequent personal barriers reported are lack of motivation, feelings of self-consciousness and embarrassment in public, anxiety, frustration, and anger. Barriers may also include impaired cognition and communication skills, which can make patient-therapist interactions difficult. On the opposing end, facilitators, or motivators, commonly reported in this diverse population include maintaining independence, function, and weight; the prevention of secondary conditions; having sufficient social support; goal setting; achieving enjoyment, feeling good, and feeling “normal;” motivation and optimism, redefining self, and escapism from everyday boundaries.¹¹⁷ While it is important for the therapist to understand common barriers and facilitators to guide overall clinical reasoning and the promotion of health and wellness at a population health level, it is also crucial for the therapist to uncover and support the individual in reducing barriers and enhancing facilitators at the individual level. This approach requires strong communication and time management skills by the therapist and is where training in motivational interviewing and health coaching can be very valuable tools in the neurorehabilitation therapist’s toolbox.

CONCLUSION

Individuals living with a neurological injury or disease are at increased risk for having lower levels of perceived wellness, health-related quality of life,⁷ and physical activity, as well as a greater number and severity of barriers to wellness. Thus there is strong need for a wellness approach in neurorehabilitation. A wellness approach in neurorehabilitation should include the minimum skills set recommended by the APTA, the assessment of the seven lifestyle behavioral competencies recommended by Dean, education on the interrelationship between lifestyle behaviors and rehabilitation and wellness goals, direct evidence-based theory-driven interventions within scope of practice, and referral to qualified and accessible providers as appropriate to ensure a comprehensive whole person approach. Utilizing Lein’s health-focused physical therapy model may assist the neurorehabilitation therapist in structuring his or her wellness approach to incorporate these components into practice. A wellness approach in neurorehabilitation may ultimately resemble the dental model with annual or biannual evaluations and intermittent episodes of care to best help the individual meet his or her health and wellness needs. This approach may include assisting the patient in the transition to community-based programs and providing skilled maintenance therapy services as appropriate. Individuals living with a chronic neurological condition can be well. Rehabilitation therapists, for both the benefit of the individual and for society, need to make a wellness approach standard practice.

CASE STUDY 33.1 Exploring Exercise and Physical Activity Motivation After Stroke: Case Script and Video Example

The patient is a 70-year-old post-stroke (cerebrovascular accident [CVA]) woman who lives with her husband, and both are retired from working, she as a librarian. The patient is very sedentary, preferring to sit and read during the day, and the physical therapist has been encouraging her to be more physically active and to do her home exercise program regularly. Recognizing that the patient lacks motivation to perform her home exercise program or to be physically active, the physical therapist decides to use health coaching communication strategies to explore the patient’s motivation. The initial conversation may follow the outline below.

PT: Mrs. X, would it be okay if we talked about your physical activity?

Mrs. X: Yes, I think so.

PT: I would like to learn about another time in your life when you were physically active.

Mrs. X: I’ve never been physically active, always very sedentary.

PT: So, you don’t really have any previous positive experiences with physical activity. How important is it right now for you to be more physically active on a scale from 1 (not important at all) to 10 (the most important thing in the world right now)?

Mrs. X: I would say a 6.

PT: Why didn’t you answer a 2 or 3?

Mrs. X: Because I know it’s important and I think it would make me feel better and sleep better if I did it.

PT: So, you understand the value of being physically active and you think it could enhance your sleep and make you feel better. What would it take for physical activity to be an 8 or 9 in importance?

Mrs. X: I would have to have a reminder to do it regularly, and I would have to put my reading away.

PT: So, you think you would be more physically active if you had something to remind you, how so?

Mrs. X: Yes, I just get carried away reading a book, and I don’t think about it.

PT: Okay, we can talk about setting a reminder. How confident are you that you could be physically active at home on the same scale, 1 to 10?

Mrs. X: I think about a 4.

PT: Why didn’t you answer a 1 or 2?

Mrs. X: Because I do the exercise when I’m in physical therapy and I know how to do it. Also, I can walk with my husband who would help me.

PT: You have exercises you can do at home, and you can go walking with your husband. What would it take to be a 7 in confidence?

Mrs. X: I think my health would have to depend on it or require me to be physically active. I can do the things I need to do right now, and there is nothing I can’t really do with a little help.

PT: Let me see if I can summarize what I’ve learned so far from our conversation. You have never really been physically active, so it’s not an automatic behavior you have like brushing your teeth. You understand and can articulate why it’s important for you to be physically active, but you don’t think about being active during the day. You see benefits from being physically active, and you think it would be helpful to have a reminder to be physically active, and you know how to do your exercises, and you can walk with your husband. Is all of this information accurate?

Mrs. X: Yes.

PT: What would you think about setting a goal to set a reminder to do your exercises to find out if this approach will work for you?

Mrs. X: I think that would be okay.

PT: What kind of reminder do you have in mind?

Mrs. X: I could ask my husband to remind me.

PT: That’s one option, but what if he forgets or isn’t around on that day? Can you think of another reminder that would not depend on your husband or another person?

Mrs. X: I could set an alarm on my iPad, which is usually with me because I read on it.

PT: Great idea. What time of day would you like to do some exercise?

CASE STUDY 33.1 Exploring Exercise and Physical Activity Motivation After Stroke: Case Script and Video Example—cont'd

Mrs. X: How about 2:30? That's a time when we are usually sitting around reading, and it would be good to get up and move around in the middle of the afternoon.

PT: Sounds reasonable. Let's say the goal will be to set an alarm on your iPad for 2:30 on Tuesday and Thursday this week to get up and exercise. How long do you want to exercise on those days?

Mrs. X: We can start with 15 minutes I guess.

PT: Okay, the goal will read, "I will set an alarm on my iPad to go off at 2:30 on Tuesday and Thursday, and I will get up and exercise for 15 minutes each time." Can you repeat the goal back to me to make sure you've got it?

Mrs. X: Yes, I will set an alarm on my iPad to go off at 2:30 on Tuesday and Thursday, and I will do 15 minutes of exercise each day.

PT: You've got it. How confident are you on a scale of 1 to 10 that you will accomplish this goal?

Mrs. X: I would say a 5.

PT: What's in the way of feeling like a 7 or 8 in confidence?

Mrs. X: Well, I might just ignore the alarm when it goes off, especially if the book I'm reading is really interesting.

PT: How can we change the goal to make you more confident that you can achieve it?

Mrs. X: I could find out if I can download a program that would turn off my iPad so I would have to stop reading and get up so I wouldn't have the option of ignoring it and continuing to read.

PT: How does that plan sound to you?

Mrs. X: I think that would be a good idea.

PT: Okay, let's write two goals. The second goal can be "I will download an app that disables my iPad at the time I set it." When can you work on finding the app?

Mrs. X: I can do that tonight.

PT: Let's revise the goal to read, "I will download an app tonight that I can set to alarm and disable my iPad for 15 minutes." How confident are you that you'll accomplish this goal?

Mrs. X: I'm an 8/10.

PT: Now, how confident are you that you'll get up and exercise for 15 minutes when the alarm goes off?

Mrs. X: I'm a 7.

PT: Sounds like you have realistic but challenging goals to work on this week. I'm confident that you will learn something from this approach.

Questions to Assess Learning

1. What was the therapist attempting to elicit by asking the question, "Why isn't your importance level a lower number?"
2. What was the therapist attempting to elicit by asking the question, "What would it take for your level of importance to be a higher number?"
3. Identify examples of motivational interviewing skills the therapist used in this role play.
4. What stage of change was the patient in for physical activity at the beginning of the conversation?
5. What stage of change was the patient in for physical activity at the end of the conversation? Answer: Action, based on the fact that she set an action-oriented goal.
6. How could the therapist debrief the patient's experience with her goals when the patient returns to therapy for the next visit?

Answers to Case Study 33.1

1. This question elicits the patient to describe the benefits she sees from physical activity. When the patient describes the benefits (rather than the therapist), it builds motivation, autonomy, and self-efficacy.
2. This question elicits the barriers that may be in the way of performing the behavior. If the patient describes barriers, a discussion about how to overcome the barriers can ensue, which will move the patient to a higher stage of change and build self-efficacy and autonomy.
3. Open-ended questions: What kind of reminder do you have in mind? How can we change the goal to make you more confident that you can achieve it? Affirm and support the patient: Sounds like you have realistic but challenging goals to work on this week. I'm confident that you will learn something from this approach. Reflective listening: So, you understand the value of being physically active, and you think it could enhance your sleep and make you feel better. Summarize: Let me see if I can summarize what I've learned so far from our conversation. You have never really been physically active, so it's not an automatic behavior you have like brushing your teeth. You understand and can articulate why it's important for you to be physically active, but you don't think about being active during the day. You see benefits from being

physically active, and you think it would be helpful to have a reminder to be physically active, and you know how to do your exercises, and you can walk with your husband. Is all of this information accurate?

4. Probably contemplation based on the fact that she was a 6/10 in importance to change and that her barriers and benefits were competing.
5. Action, based on the fact that she set an action-oriented goal.
6. The therapist should start by asking the patient if it would be okay to debrief about her experience with the goals. If the patient replies affirmatively, the therapist can ask about one of the goals by stating "Which goal would you like to discuss first?" Once the patient selects the goal to discuss, the therapist can start by asking, "Tell me about your overall positive experience with this goal." Soliciting the positive experience helps build self-efficacy, autonomy, and learning. The therapist can also ask the patient to describe what she learned from the goal and what was her best experience with the goal. Finally, the therapist can ask the patient to assess her level of success with the goal on a 1–100 scale (e.g., 75%). This method of debriefing can be applied to assess all of the patient's goals and is an important aspect of health coaching to build autonomy and self-efficacy.

CASE STUDY 33.2 Health Promotion and Wellness Strategies Applied to Neurorehabilitation in Multiple Sclerosis

The patient is a 32-year-old woman living with multiple sclerosis who is in an outpatient neurorehabilitation setting recovering from an exacerbation of her multiple sclerosis 3 weeks ago.

History and Interview

During the initial examination, the patient expresses despair and worry over her ability to care for her two small children at home, now that she needs a cane to walk and her left hand is weak. She reports prior to the exacerbation she was

barely managing and now this is just too much. The therapist notes the patient has checked difficulty sleeping and changes in her diet on the initial intake form. She reports she does not smoke, nor does she have a history of smoking.

Review of Systems

During her review of symptoms, the therapist explores her mental health asking several open-ended questions about her prior and current levels of stress. The therapist screens for depression using the 2-item depression screen for multiple

CASE STUDY 33.2 Health Promotion and Wellness Strategies Applied to Neurorehabilitation in Multiple Sclerosis—cont'd

sclerosis¹¹⁸; it is positive. The therapist also follows up on the intake form to explore current and past sleep habits regarding sleep quantity and quality as well as dietary habits and any changes in weight. The therapist explores the patient's values and how they fit or do not fit with her current behaviors and goals.

Systems Review and Tests and Measures

During the systems review as part of the therapist's standard examination, the therapist records heart rate, blood pressure, respiration, and weight. The therapist utilizes several standardized outcome measures to assess movement and abilities within reported limited activities and participation. This information guides targeted collection of tests and measures of hypothesized underlying impairments in body structure and function.

Evaluation, Diagnosis, Prognosis, Intervention

At the end of the examination, the therapist engages in shared decision making with the patient on mutual realistic goals using the goal attainment scale.¹¹⁹ The therapist provides brief counsel to the patient on the role of mental health, sleep, and nutrition in her rehabilitation recovery and her long-term well-being. The therapist inquires into the patient's social support network and asks if the patient's referring physician is aware of her mood, perceived stress levels, and changes in weight. The patient reports her physician is aware. Her physician has recommended counseling, but the patient is reluctant to go because she doesn't want to appear weak. The therapist expresses empathy and encourages the patient to consider her values and goals, what it will take to accomplish them, and how her psychological and emotional health will either facilitate or be a barrier to her goals. The therapist expresses that the role of rehabilitation is to maximize her abilities as a whole person in order to achieve her movement-based wellness goals for engagement in

meaningful activities and life roles. The session ends with a preliminary action plan that includes establishing a sleep schedule to help with energy management and stress reduction, increasing lifestyle physical activity by 10 min each day over the next week while self-monitoring and adjusting for her daily fatigue levels, and following up with her physician regarding the counseling recommendation. They agree to discuss adding structured exercises at her next therapy session.

Note: The therapist-patient discussion on goals, values clarification, and action planning occurs while the patient is engaging in a submaximal exercise test on a recumbent elliptical. The therapist is providing skilled intervention through assessment and monitoring of physical activity and cardiopulmonary response and providing education.

Questions to Assess Learning:

1. To incorporate a health-focused wellness approach to practice, how did the therapist incorporate screening and assessment of the five behavioral domains of healthy lifestyle behaviors identified in Table 33.5?
2. How might the therapist's health-focused wellness approach maximize the patient's rehabilitation prognosis to achieve personal goals? Hint: There are many right answers.
3. Provide two examples of how the therapist attempted to develop a strong therapist-patient alliance.
4. Did the therapist utilize a standardized perceptual measure of wellness? If so, what was it and when was it utilized? If not, what tool could have been used and when would be the best time to do so?
5. Is this patient appropriate for application of the "dental model" of rehabilitation? Why or why not?

Answers to Case Study 33.2

1. An intake form was used for an initial screening on sleep, nutrition, and smoking. Stress was noted in the interview and the therapist followed up with open-ended questions related to stress and mental health and utilized the 2-item depression screening tool. Physical activity was assessed through standardized outcomes of movement and abilities, and a submaximal exercise test.
2. Option one: By addressing the whole person the therapist enhances the therapist-patient alliance, which has been shown to enhance rehabilitation outcomes. Option two: Through screening and identification of several at-risk lifestyle behaviors including a positive screen for depression, the therapist is able to develop a comprehensive plan that will enhance the patient's physical and mental potential and reduce barriers to goal achievement and wellness. For example, depression is a significant barrier to rehabilitation participation and is strongly linked to fatigue in multiple sclerosis. Helping the patient connect and utilize appropriate resources to help her manage her symptoms of depression will enhance the patient's potential to engage in rehabilitation for her exacerbation and her sense of well-being during and after discharge.
3. Examples may include: One, the therapist expressed *empathy* with the patient's worry of appearing weak if she sees a counselor. Two, the therapist took time to explore the *patient's values*. Three, the therapist engaged in *shared decision making* to develop mutually agreeable goals.
4. No, the therapist did not utilize a standardized perceptual measure of wellness. The therapist could have utilized the Short Form-36 or the Perceived Wellness Survey (see Table 33.4). Either of these tools could have been utilized as part of the initial pre-screening process along with the intake form, or given to the patient at the end of the session to complete prior to her next visit. These options maximize time management for both the patient and therapist and ensure a comprehensive wellness approach.
5. This patient is appropriate for several reasons. One, she presents with a chronic progressive neurological condition that will likely result in changes in functionally and across the dimensions of wellness throughout her lifespan. Two, she presents with multiple barriers and challenges across the dimensions of wellness that may require ongoing intermittent services, time, and multiple resources to best meet her needs.

REFERENCES

Abstract: In learning to cope with the often chronic nature of their conditions, individuals with neurological disease, not unlike individuals with health conditions of other systems, learn to rely on their abilities to adapt and compensate for their activity limitations and participation restrictions to regain the ability to participate in life. Although not an uncommon approach to life for any human being, the achievement of health or wellness takes on an increased focus for individuals with chronic health conditions, and it is strongly correlated with the quality of life they achieve. A casual consideration of the terms health and wellness indicates that they are similar, if not the same, in meaning, a commonly held belief among those without health conditions. This interpretation of the terms becomes problematic,

however, in the presence of health conditions. Can an individual with a health condition be well? Can a person without a health condition be ill? The concepts of health and wellness and their associated meanings and measures will be explored in this chapter to provide a perspective for movement specialists that will enhance their ability to promote health and well-being in patients with neurological conditions. The evidence examining wellness approaches in patients with neurological conditions will be presented along with common barriers and enablers to implementation. A synthesis of concepts will be promoted through case study.

Human Immunodeficiency Virus Infection: Living With a Chronic Illness*

Kerri Sowers, Mary Lou Galantino, and David M. Kietrys

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Understand how the involvement of various systems (immune, integumentary, musculoskeletal, cardiopulmonary, and neurological) may lead to episodic disability and affect function in individuals living with HIV disease.
2. Discuss the neuropathological features of HIV infection and understand potential neurocognitive and neuropsychological alterations that may occur.
3. Incorporate psychoneuroimmunology, pain management, and movement strategies for HIV rehabilitation management.
4. Establish safe exercise parameters in the HIV-positive population.

KEY TERMS

acquired immunodeficiency syndrome (AIDS)
episodic disability
HIV disease

human immunodeficiency virus (HIV)
interprofessional rehabilitation

IDENTIFICATION OF THE CLINICAL PROBLEM

Initially recognized in 1983, human immunodeficiency virus (HIV) infection was one of the leading causes of death among young adults, peaking in 2005.¹ Since then, HIV-related deaths have declined by 48%,¹ emphasizing the metamorphosis of the diagnosis from a death sentence to a chronic medical condition. Even with significant advancements in the medical management of the disease, there continues to be a devastating impact in the developing world, where access to appropriate pharmaceutical intervention and public health initiatives remains limited.^{2,3} The course of HIV disease in industrialized nations, including the United States, has changed dramatically as a result of advancements in medications used to treat the disease, as well as increased public awareness and the expansion of public health programs in poverty-stricken areas.

The long-term prognosis for those diagnosed with HIV or with acquired immunodeficiency syndrome (AIDS) has drastically changed in most industrialized countries. In the United States, HIV is no longer found in the 10 leading causes of death for the entire adult population. In fact, there has been a dramatic decline, from 10.2 (1990) to 1.9 (2015), for the age-adjusted death rate per 100,000 population⁴; consider this value in comparison to the number of deaths due to malignant neoplasms (99.0 per 100,000) or heart disease (86.5 per 100,000) in 2015.⁴ HIV remains on the list of leading causes of death for those aged 25 to 44 in the United States, although it has dropped to the ninth position.⁵ It is no longer found in the top 10 causes of death for other age groups. Globally, there continues to be a slow increase in

the number of people living with HIV (PLHIV); for 2016, this number totaled 36.7 million (30.8 to 42.9 million).¹ The number of new global infections continues to decline, from 3.0 million in 2000 to 1.8 million in 2016.¹ HIV-related deaths have also continued to decline globally, from 1.5 million in 2000 to 1.0 million in 2016.¹ Much of this decline can be contributed to improved global access to antiretroviral therapy (ART); an estimated 685,000 PLHIV received treatment in 2000, as compared with 20.9 million who received treatment in June 2017.¹ With only 53% (39% to 65%) of PLHIV having access to treatment in 2016, it is clear there is still room for improvement.¹

Most epidemiologists and clinicians attribute improved life expectancy to the impact of highly effective ART and community health education and prevention practices. Implementation of these medications has resulted in a decline in HIV deaths nationally.^{6,7} ART regimens have fostered longevity for many, resulting in the evolution of HIV infection into a chronic disease. Individuals previously disabled by the disease currently have the potential to return to work and functional activities and often can expect to live a normal life expectancy. However, PLHIV may experience disability that is episodic in nature, characterized by periods of wellness and illness.^{8,9} Qualitative research found four phenotypes of episodic disability over time: decreasing, increasing, stable, or significant fluctuations.^{8,9} Understanding a person's episodic trajectory may help to tailor interventions to promote stability, mitigate an upward trajectory of increasing disability, and increase the time between episodes of illness.¹⁰ Therefore HIV disease, related comorbidities, and the side effects of medications used to treat the disease have a great impact on rehabilitative medicine because of the multisystem involvement. The advancements in medications that have led to increased life

*Videos for this chapter are available at studentconsult.com.

expectancies and improved functional capabilities have also led to a greater demand for rehabilitative services.

ART has slowed and prevented the progression from HIV infection to AIDS and from AIDS to death.¹¹ In communities with access to antiretroviral medications, the incidence of perinatally acquired AIDS has declined significantly because of administration of ART during pregnancy.¹² Perinatal transmission of the virus in developing nations continues to be a concern, despite a 47% decline since 2010.¹

The clinical and pathological information about this disease is constantly increasing. Certainly, our understanding of the disease process and advances in drug regimens will change between the writing and the publication of this book. Changes in terminology reflect this evolution of clinical knowledge. The definitions used throughout this chapter reflect current usage.

The virus thought to be responsible for the transmission of HIV was first identified in 1983; it was named *human immunodeficiency virus* in 1986 at the International Conference on AIDS in Paris. A second virus, HIV-2, was identified soon after in western Africa, and the original strain was renamed HIV-1. Infection caused by HIV-2, less widely distributed, has since been established in Europe and in South, Central, and North America. Both HIV-1 and HIV-2 have resulted in AIDS, but evidence suggests that HIV-2 may be less virulent than HIV-1. In addition to these subtypes, several strains or mutated forms of HIV-1 have been identified. Different strains reflect variations in cellular affinities and resistance to medications. The context of discussion, for this chapter, will be regarding the HIV-1 strain, herein discussed as *HIV*. HIV infection is identified via a positive HIV antibody screening test (rapid diagnostic test [RDT] or enzyme immunoassay [EIA]) and confirmation with a supplemental HIV antibody test (Western blot), and/or a positive result from an HIV virological test (nucleic acid detection test, p24 antigen test, or viral culture).

The Centers for Disease Control and Prevention (CDC) recognizes three stages of HIV infection.¹³ Stage 1 represents acute HIV infection. This stage is characterized by a high viral load, where acutely infected

individuals are highly contagious. Some individuals may notice flulike symptoms 2 to 4 weeks following the initial infection, part of the body's natural response to an infection. Stage 2 represents a period of clinical latency and is referred to as the asymptomatic stage. HIV remains active, but there is a reduced viral load as compared with the spike after initial infection. The goal of ART during this period is to reduce the viral load to nondetectable levels. Those who do not have access to ART may eventually begin to experience symptoms and will eventually progress to stage 3, representing advanced HIV disease (AIDS). This stage is when viral replication leads to increasingly high viral loads. It is recognized when the CD4 count is less than 200 cells/ μ L, and/or when opportunistic illnesses are present, and/or when there is evidence of HIV-related wasting or dementia. The entire spectrum of illness from initial diagnosis to AIDS can be covered by the term *HIV disease*. In addition, the terms *acute HIV infection*, *asymptomatic HIV disease*, *symptomatic HIV disease*, and *advanced HIV disease (AIDS)* are used throughout this chapter. In general, acute HIV infection corresponds with stage 1, asymptomatic HIV disease (or symptomatic HIV disease but not yet classified as AIDS) with stage 2, and advanced HIV disease (AIDS) with stage 3. [Table 34.1](#) presents the various modifiers of quality of life (QOL) throughout the various stages of HIV disease.

Epidemiology

It is estimated that more than 36.7 million people¹ are infected with HIV globally. In the United States the CDC estimated that 1,122,900 adults and adolescents were living with HIV at the end of 2015.¹⁴ Because of complex social and economic factors, African Americans and Hispanics/Latinos are disproportionately affected, with approximately 44% of HIV diagnoses in 2016 being African American and 25% being Hispanic/Latino.¹⁴ There is a higher geographical distribution of HIV diagnosis in US southern states, with 16.8 per 100,000 people in 2016.¹⁴ Alarming, it is estimated that approximately 51% of young individuals (aged 13 to 24) in the United States infected with HIV are unaware of the infection.¹⁴

TABLE 34.1 Quality-of-Life Issues for Human Immunodeficiency Virus Disease Stages

Stage	Moderators of Quality of Life		General Quality-of-Life Issues
Stage 1 Acute HIV Infection	Appraisals Anticipatory grieving, catastrophizing, and other cognitive distortions Changed expectations of future Identity and self-esteem issues	Coping Dealing with present and future uncertainties At risk for denial, disengagement, substance abuse, risky sex, suicide Issues of eliciting social support	Emotional Functioning Anxiety, anger, often increasing at diagnosis and diminishing and recycling as individual confronts realities of living with HIV disease Role Functioning Often able to work Possible decrements in job mobility and career opportunities Job loss Social Functioning Fear, isolation, issues of trust in relationships Stigmatization Changes in social support networks because of deaths Relationship and sexual changes Isolation, withdrawal Physical Functioning Normal but may be altered because of depression or anxiety May have hypervigilance regarding all physical symptoms Spiritual Functioning Opportunity to direct attention inward, thus yielding to contemplation of life's meaning, reassessment of spiritual and existential issues

TABLE 34.1 Quality-of-Life Issues for Human Immunodeficiency Virus Disease Stages—cont'd

Stage	Moderators of Quality of Life		General Quality-of-Life Issues
Stage 2 Clinical Latency	Appraisals Anticipatory grieving, catastrophizing, and other cognitive distortions Changed expectations of future Identity and self-esteem issues related to threats to occupational and functional abilities	Coping Dealing with present and future uncertainties At risk for denial, disengagement, substance abuse, and risky sex	Emotional Functioning Anxiety, anger, often increasing on emergence of symptoms and then fluctuating with challenges and threats to present and future functioning Role Functioning Often able to work May take on new roles as part of HIV support network Social Functioning Changes in social support networks resulting from deaths, isolation, withdrawal, relationship and sexual changes, and stigmatization Physical Functioning May have reduced energy levels Moderate symptomatology Possible cognitive deficits Pain Spiritual Functioning Anticipatory grieving, sense of relatedness to something greater than the self, unavoidable confrontation with one's own mortality
Stage 3 Advanced HIV	Appraisals Facing chronic illness and death Grieving about current and anticipated losses; catastrophizing and other cognitive distortions Reassessment of spiritual and existential issues	Coping Coping strategies may be overwhelmed in dealing with current difficulties such as financial losses, medical costs, treatment and side effects, housing May lose some traditional coping strategies such as recreational outlets	Emotional Functioning Anxiety and anger may cycle according to fluctuations in disease status and appraisals Relief from uncertainty Role Functioning Diminished capacity for work Role changes—often need care instead of being a caretaker Social Functioning May have diminished social networks because of lack of mobility, illness, and deaths among friends Physical Functioning Self-care difficulties Fatigue Wasting Much time spent in medical care Debilitation from infection and treatments Possible cognitive deficits Spiritual Functioning Essential worth is to provide a framework from which to pose and seek responses to metaphysical questions generated by presence of life-threatening disease Integration and transcending of biological and psychosocial nature, which gives access to nonphysical realms as prophecy, love, artistic inspiration, completion, and healing actions

HIV, Human immunodeficiency virus.

In 2017 the World Health Organization (WHO) estimated that 940,000 people died from HIV-related causes globally.¹⁵ Worldwide, in 2017, of the 36.9 million people (all ages) living with HIV, 35.1 million are adults, 18.2 million are women, and 1.8 million are children (<15 years).¹⁶ New HIV infections in 2017 totaled 1.8 million, with 1.6 million in adults and 180,000 in children (<15 years).¹⁶ Global AIDS deaths have continued to decline, totaling 940,000 in 2017; adult deaths were 830,000, whereas children (<15 years) totaled 110,000.¹⁶ For the United States, in 2015, 6465 people died from HIV disease, with 53% living in the southern United States.¹⁷ For 2016, in the United States, there were 39,782 new infections (with approximately

50% in the southern states); 26,570 were gay and bisexual men, 9578 were heterosexuals, and 3425 were individuals who inject drugs.¹⁴ Of those new infections, 14,740 were for ages 20 to 29, 9943 for ages 30 to 39, 6490 for ages 40 to 49, 4882 for ages 50 to 59, 1930 for ages 60 and older, and 1675 for ages 13 to 19.¹⁴

Normal Immunity

The immune system is complex and dynamic, comprising a multitude of components and subsystems, all of which interact continuously. The normal immune system has two main components, or lines of defense, against illness (Fig. 34.1). The first is the innate, or inborn, immune

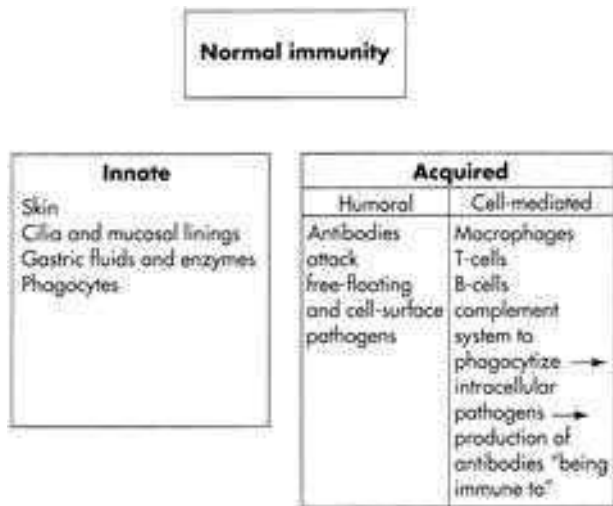

Fig. 34.1 Main components of immunity.

system, which includes aspects such as the skin, the cilia and mucosal linings of the respiratory and digestive systems, the gastric fluids and enzymes of the stomach, natural killer cells, phagocyte cells, and the complement system. This innate component of the immune system keeps pathogens out of the body by creating barriers against them, by ejecting them, or by enveloping them and eliminating them. The second, the acquired component of the immune system, develops defenses against specific pathogens; it begins in utero and continues throughout life. It is the acquired (or antibody-based) immunity that is most pertinent to understanding HIV infection and its progression.

Acquired Immunity

Acquired immunity is divided into humoral and cell-mediated responses. Humoral immunity depends on the production of antibodies. This response is effective for disposing of free-floating or cell-surface pathogens. The cell-mediated response is required to destroy infected cells, those with intracellular pathogens. Cell-mediated immunity is essential for destroying pathogens responsible for the opportunistic infections and neoplasms that are associated with HIV infection.^{18,19}

For the study of HIV pathology, it is important to consider three types of immune system cells: macrophages, T-lymphocytes (T-cells), and B-lymphocytes (B-cells). Macrophages originate in the bone marrow and then migrate to the organs in the lymphatic system. Macrophages recognize and then phagocytize antigens (substances deemed foreign to the body). All but a fragment of the antigen is digested by the macrophage. This remaining fragment protrudes from the cellular surface, where it is then recognized by T- and B-cells, allowing those cells to develop an appropriate immune response.²⁰

Both types of lymphocytes (T- and B-cells) originate in the bone marrow. Their differentiation into T- and B-cells depends on where they develop immunocompetence. Immunocompetence is the ability of the immune system to mobilize in response to an antigen; it can be weakened secondary to age-related changes, radiation therapy, chemotherapy, or viral infections. T-cells migrate to the thymus to develop this ability, whereas B-cells develop it before leaving the bone marrow. T-cells travel to lymph nodes, the spleen, and connective tissues, where they wait to phagocytize the antigens in the manner previously described. B-cells function in the same way against free-floating blood-borne pathogens.²⁰

There are at least eight types of T-cells with various functions. Two relevant types when considering HIV infection are helper T-cells

(CD4) and suppressor T-cells (CD8). The CD4 cells enhance the immune response, whereas CD8 cells regulate the immune response. HIV primarily attacks these two types of T-cells, impairing the body's immune response. On recognition of an antigen, CD4 cells chemically stimulate production and activation of other lymphocytes to destroy the foreign material. When the action of the T- and B-cells elicits a sufficient immune response, the CD8 cells will halt the action, thus preventing the destruction of normal (uninfected) cells. HIV causes the destruction of the CD4 cells. Declining CD4 cell counts occur in untreated disease; in healthy (uninfected) individuals, CD4 counts should be 500 to 1600 cells/ μ L. However, because T-cell counts fluctuate somewhat under normal circumstances, the ratio of CD4 to CD8 cells is considered a valuable laboratory value in tracking the progression of the disease (a normal ratio is approximately 2.0, whereas a ratio close to 1.0 is associated with advanced HIV infection).

In the process of identifying and destroying antigens, the normal acquired immune system retains a memory of the antigen. This allows the immune system to respond more rapidly and effectively to the pathogen if it is reintroduced into the body. Herein lies the pertinence of vaccination and the phenomenon of being immune to an illness.²⁰

PATHOGENESIS OF HUMAN IMMUNODEFICIENCY VIRUS DISEASE

HIV belongs to a class of viruses known as *retroviruses*, which carry their genetic material in the form of ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA). HIV primarily infects the mononuclear cells, especially CD4 and macrophages, but B-cells are also infected.²¹ HIV binds to the receptor sites on the surface of the CD4 lymphocytes, eventually fusing with and then entering the cells. Reverse transcriptase released from the HIV allows a DNA copy of the virus to be made within the host cell, which then becomes integrated into the host cell genome. Other enzymes, such as integrase and protease, turn the lymphocyte into a "virus factory," and replicated virions bud out of the cell to infect others.

Within days of acute HIV infection, lymph nodes become sites of rampant viral replication, and viral loads in the blood are high. During the stage of acute HIV infection, the individual may remain asymptomatic or may experience nonspecific and self-limited flulike symptoms including fever, diarrhea, myalgias, and fatigue; these symptoms may last for a period of 2 to 12 weeks. In the weeks after an acute infection, the body gradually produces an antibody response. The point at which antibodies can be detected with a blood test is known as *seroconversion*. Typically, seroconversion occurs within 3 to 4 weeks after the time of infection, but it can take as long as 12 months. Thus there is a period, after HIV infection, when the outcome of an HIV antibody test will present as negative, due to the delay in seroconversion. Tests for viral load can detect HIV in the bloodstream at time points earlier than antibody tests. It is important to remember that antibody testing can be unreliable in individuals with primary or secondary immunodeficiency disease.

In stage 2 of HIV disease, individuals will typically have a positive antibody test result. This stage of clinical latency may last from 1 to 20 years and is often dependent on the compliance with ART treatment. Although generally asymptomatic, individuals in this stage may express periods of generalized lymphadenopathy. Laboratory tests may reveal slowly declining immune dysfunction, as evidenced by an abnormally low CD4 cell count and an abnormal CD4/CD8 ratio. The viral load is typically at a "set point" during most of the asymptomatic stage of HIV disease. This set point is typically much lower than the viral load occurring during the period of acute infection.

In an untreated individual, the viral load will escalate as the disease progresses. In an individual successfully treated with ART, the goal is to achieve an undetectable viral load.

In an individual who is not treated with ART, the disease will progress over time. If the CD4 cell count drops to less than 200 cells/ μ L, and/or an opportunistic infection occurs, and/or an individual presents with HIV-related wasting or dementia, the individual has entered stage 3, advanced HIV disease (AIDS). It is possible for patients in this stage to demonstrate remarkable recovery in terms of both laboratory values and function with an appropriate ART regimen. Individuals who do not have access to ART or individuals in whom ART has failed will eventually die because of the effects of opportunistic infections that inevitably occur.

In patients with advanced HIV disease (stage 3), there may be an array of symptoms such as weight loss, weight gain, fatigue, night sweats, fever, thrush, yeast infections, prolonged recovery from other illnesses, or neurological complications. Increased rates of osteoporosis, chronic liver disease, and, in particular, cardiovascular disease (CVD) have been reported among PLHIV. With the aging HIV-infected population, the burden of these comorbid illnesses may continue to accrue over time.²² Due to the changing nature of HIV infection to a chronic medical condition, individuals are developing a plethora of comorbid conditions and symptoms, even with the progression to advanced HIV disease (stage 3), that present new challenges in treatment and rehabilitation.

MEDICAL MANAGEMENT

CD4 Cell Counts

Medical management of HIV infection is most often guided by the CD4 cell count and viral load. For the healthy HIV-negative adult, the average CD4 cell count may fluctuate between 500 and 1600 cells/ μ L.²³ Typically, ART is initiated soon after an individual learns that they are HIV-positive; ideally, this is before there is a detrimental decline in CD4 cells.

Exercise, stress, seasons of the year, serum cortisol level, and the presence of acute or chronic illness and infection have all been reported to affect CD4 cell counts.^{24,25} The initial CD4 count should be confirmed by repeat testing, and caution should be exercised to avoid overinterpretation of small changes in CD4 test results. The overall trend of CD4 counts is more significant than any single value. In addition to CD4 cell counts, CD4/CD8 ratios are used to evaluate the status of the immune system. In 2012 the Department of Health and Human Services and the WHO began recommending that ART be initiated for HIV-positive individuals, regardless of the CD4 count.²⁶ In an individual who has not been successfully treated with ART, a CD4 cell count of 200 cells/ μ L marks a critical point during HIV infection, often indicating that the stage of advanced HIV disease, or AIDS, has been reached. Serious opportunistic infections are likely to occur once this level of immune depletion has been attained in an individual who has not been successfully treated with ART.^{27–29} Table 34.2 is a summary of common ARTs. A complete listing of pharmacological interventions to combat the opportunistic infections associated with HIV infection are beyond the scope of this chapter.

Viral Load Measurement

Testing for HIV in plasma by measuring viral RNA (copies of HIV per milliliter) has become a standard component of the management of HIV infected patients. In 2013 the WHO began recommending viral load testing as the preferred method for diagnosing and confirming ART treatment failure.²⁶ There are important prognostic implications for viral load in persons with HIV disease.³⁰ In patients with higher

viral loads, disease progression is more rapid, both immunologically, in terms of the rate of CD4 cell count decline, and clinically, in terms of development of AIDS-defining illness. In addition, the plasma levels in HIV-positive pregnant women directly correlate with the risk of perinatal transmission.³¹ Viral load is an important useful marker for judging the effectiveness of various antiretroviral drug interventions.^{32,33} The guidelines established by the WHO recommend routine viral load monitoring at 6 and 12 months, then every 12 months after if the HIV-positive individual is stable on ART.²⁶ The goal of ART is to have an undetectable viral load in the bloodstream.

The WHO has concerns about the increase in HIV drug resistance, both pretreatment drug resistance and developed resistance to first-line ART.³⁴ There are several assays available for testing HIV for resistance to antiretroviral agents. Genotype or phenotype testing is used to determine whether the virus has mutated. The results of genotype or phenotype testing provide important information about resistance to specific antiretroviral drugs. If a mutant form is resistant to an antiretroviral drug, the ART regimen may be altered so that the potential for viral suppression is maximized. Changes in the drug combinations used for ART to respond to viral resistance are referred to as *salvage therapy*. Like genotypic testing, phenotypic testing may not detect small subpopulations of resistant HIV.³⁵

Until a functional cure and/or vaccine is discovered, advances will continue to be made in ART. The primary goal of ART is to achieve prolonged suppression of HIV replication.^{36,37} At this time, there are five classes of ART drugs. Entry inhibitors, such as CCR5 antagonists and fusion inhibitors, work to prevent HIV from successfully entering the cell. The CCR5 antagonist currently in use is maraviro (Selzentry); this drug works by blocking the CCR5 coreceptors on an immune cell surface, thereby preventing HIV from entering the cell.

Other classes of drugs work within the cell by interfering with one of three enzymes that are involved with the replication process: reverse transcriptase, integrase, and protease. These classes include nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), integrase inhibitors (INIs), and protease inhibitors (PIs). In 1987, zidovudine (AZT, brand name: Retrovir), an NRTI, was first approved by the US Food and Drug Administration (FDA). Since that time, several more NRTI drugs have been approved.³⁸ NNRTIs, such as nevirapine (NVP, brand name: Viramune) and efavirenz (EFV, brand name: Sustiva), also inhibit the reverse transcriptase enzyme, but they are not nucleoside analogs.³⁹ The NNRTIs bind to the enzymatic binding pocket of the reverse transcriptase gene and block binding by the nucleosides.^{39,40} Like reverse transcriptase, integrase is an enzyme that is active in the early stages of the replication process, and INIs can be used to interrupt its function by preventing the integration of the virus in the host cell's DNA.³⁹ INIs include drugs such as dolutegravir (DTG, brand name: Tivicay) or raltegravir (RAL, brand name: Isentress).³⁹ Another drug target for anti-HIV agents is the protease enzyme, an enzyme necessary for HIV to replicate.³⁹ The PI drugs are structurally different from other drugs and include agents such as atazanavir (ATV, brand name: Reyataz), darunavir (DRV, brand name: Prezista), and fosamprenavir (FPV, brand name: Lexiva).³⁹ Pharmacokinetic enhancers, such as cobicistat (Tybost), are used to increase the effectiveness of another drug included in ART.³⁹

Triple combination therapy (three different drugs from at least two different classes) has been the mainstay of ART since 1995. ART may be NNRTI or PI based (e.g., NNRTI and PI drugs are used in combination with an NRTI). The current recommendation from the Department of Health and Human Services, for a treatment-naïve patient, is two NRTIs in combination with a third drug (either an INI, an NNRTI, or a PI with a pharmacokinetic enhancer).⁴¹ Because of the

TABLE 34.2 Human Immunodeficiency Virus Drugs, by Class, Used in Antiretroviral Therapy

Brand Name	Generic Name	Brand Name	Generic Name
Entry Inhibitors		Protease Inhibitors	
Fuzeon	enfuvirtide	Aptivus	tipranavir
Selzentry	maraviroc	Crixivan	indinavir
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)		Evotaz	atazanavir + cobicistat
Cimduo	lamivudine + tenofovir + disoproxil	Invirase	saquinavir
Combivir	zidovudine + lamivudine	Kaletra	lopinavir + ritonavir
Descovy	tenofovir alafenamide + emtricitabine	Lexiva	fosamprenavir
Emtriva	emtricitabine	Norvir	ritonavir
Epivir	lamivudine	Prezcobix	darunavir + cobicistat
Epzicom	abacavir + lamivudine	Prezista	darunavir
Retrovir	zidovudine	Reyataz	atazanavir
Trizivir	abacavir + zidovudine + lamivudine	Viracept	nelfinavir
Truvada	tenofovir disoproxil + emtricitabine	Single Tablet Regimens (Combination ART)	
Videx EC	didanosine	Atripla	efavirenz + tenofovir disoproxil + emtricitabine
Viread	tenofovir disoproxil	Biktarvy	bictegravir + emtricitabine + tenofovir alafenamide
Zerit	stavudine	Complera	rilpivirine + tenofovir disoproxil + emtricitabine
Ziagen	abacavir	Genvoya	elvitegravir + cobicistat + tenofovir alafenamide + emtricitabine
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)		Juluca	dolutegravir + rilpivirine
Edurant	rilpivirine	Odefsey	rilpivirine + tenofovir + alafenamide + emtricitabine
Intelence	etravirine	Stribild	elvitegravir + cobicistat + tenofovir disoproxil + emtricitabine
Rescriptor	delavirdine	Symfi / Symfi Lo	efavirenz + lamivudine + tenofovir disoproxil
Sustiva	efavirenz	Triumeq	dolutegravir + abacavir + lamivudine
Viramune	nevirapine		
Integrase Inhibitors			
Isentress	raltegravir		
Tivicay	dolutegravir		

Note: Triple combination therapy, the mainstay of antiretroviral therapy (ART), involves three different drugs from at least two different classes. Single tablet regimens (combination ART) incorporate drugs from two or more different classes.

Tyboost (cobicistat) may be used to boost certain drugs used in ART.

Drugs used in ART may cause side effects that range from mild to serious or life threatening.

Side effects range from transient and manageable symptoms such as headache or nausea to severe problems that may affect neurological, musculoskeletal, cardiovascular, gastrointestinal, and/or multiorgan systems.

The US Department of Health and Human Services provides listings of side effects at <http://aidsinfo.nih.gov/drugs/>.

rapidly evolving nature of ART drugs, the reader is advised to consult with the CDC and WHO for the most current clinical practice guidelines. There has been a gradual evolution of pharmacology that has allowed for multiple drugs to be combined into one pill. This results in a more manageable ART dosing, which is more convenient and encourages improved patient compliance.

Side effects and toxicities are common with drugs used to treat HIV disease. Purported side effects of NRTIs include peripheral neuropathy, myopathy, anemia, gastrointestinal (GI) disturbances, hepatomegaly, and pancreatitis. NNRTIs may cause rash, liver dysfunction, cognitive problems, and lactic acidosis. PIs may cause lipodystrophy, peripheral neuropathy, GI intolerance, hyperlipidemia, hyperglycemia, and liver toxicity. This list of side effects is cursory, and the full impact of these and other HIV drugs on the various systems of the body is a

continually emerging area. Occasionally an individual's ART regimen is modified to mitigate the side effects that may occur with specific drugs.

Although ART can reduce serum viral loads to undetectable levels, it is not a cure because HIV continues to exist within the lymphoid tissue and the central nervous system (CNS).⁴² Another challenge with ART is resistance to one drug in a class of agents, which may induce partial or complete resistance with other agents, depending on the specific mutations involved.^{35,43} In a field that is rapidly changing, specific recommendations for ART are best made by an infectious disease specialist with experience in the management of patients with HIV disease. The major therapeutic decisions include (1) when to initiate therapy, (2) what drugs to prescribe, (3) when to modify therapy, and (4) which drugs to change to. The mortality rate of

PLHIV and the incidence of opportunistic infections decreased markedly since 1995 due to triple combination ART becoming available at that time.⁷ The role of drugs with immunomodulating activity in combination with ART is also undergoing extensive research.^{44,45} Drug regimens for HIV disease are dynamic, and clinical practice guidelines are consistently updated; many changes in the approach to drug interventions can be expected as HIV infection continues to be a chronic disease.⁴⁶ There remains concern regarding the occurrence of noncommunicable diseases among individuals aging with HIV, but few studies have described whether disparities between demographic subgroups are present among individuals on ART with access to care. Racial disparities in the occurrence of diabetes, chronic kidney disease, and hypertension emphasize the need for prevention and treatment options for these HIV populations receiving care in North America.⁴⁷

Vaccines for Other Antigens

HIV-positive individuals with impaired immune systems respond less well than do uninfected persons to most vaccines for other (non-HIV) antigens. The degree of immunodeficiency present at the time of vaccination has an impact on the response to hepatitis A or B, pneumococcal, and influenza A and B vaccines.⁴⁸ Patients with a CD4 count of more than 200 cells/ μ L have a more successful response to the vaccine. Patients should be informed that the extent and duration of the protective efficacy of these vaccines are still uncertain.

Vaccines and Functional Cures for Human Immunodeficiency Virus

Vaccination for HIV has the potential to prevent or control disease progression, but a successful vaccine has not yet been found. The development of an effective preventative vaccine for HIV is an area of continuing research. A true cure for HIV would require complete eradication of the virus from body, which might not be feasible. Thus several routes to “functional cures” are currently being studied. This includes exploration of use of therapeutic vaccines, antibody therapy, and gene therapy.

Prevention

Transmission routes of HIV have been well known since the late 1980s. Because the two most common routes of HIV infection are unsafe sex and sharing of needles and/or syringes among IV drug users, the keys to prevention are linked to safer sex practices and, for IV drug users, use of sterile syringes. For decades, use of latex condoms was the mainstay of HIV prevention during sexual activity. More recently, using preexposure prophylaxis (PrEP), in the form of Truvada, has been shown markedly reduce the risk of HIV transmission during sex.^{49,50}

Nutrition

Involuntary loss of more than 10% of baseline body weight in a 12-month period or a 5% loss in baseline body weight in a 6-month period with chronic diarrhea or unexplained weakness and fever constitute HIV wasting syndrome.⁵¹ Early retrospective demographic research in the United States found that 17.8% of individuals with AIDS had wasting syndrome.^{52,53} The ensuing malnutrition contributes to further immunosuppression.⁵⁴ With the widespread use of ART, HIV wasting syndrome has declined significantly.⁵⁵ Those PLHIV with delayed initiation of ART or poor compliance may still experience weight loss or wasting through the loss of fat mass and lean body mass; this may contribute to muscle fatigue and weakness.⁵⁵ Nutritional consultation is critical for those patients experiencing wasting syndrome and as a preventative measure for those who newly diagnosed. Studies have been done investigating the effects of nutritional counseling and other measures such as medications, hormone

supplementation, and exercise on lean body mass in patients with HIV wasting syndrome. It has been shown that nutritional counseling, medications to inhibit tumor necrosis factor, androgen supplementation, growth hormone administration, and resistance strength training have all been effective in improving lean body mass. Increased caloric intake alone increases lean body mass but primarily through fat stores. Resistance strength training may prove to be the most beneficial in increasing lean body mass with minimal side effects and minimal cost.⁵⁶

There are new nutritional concerns that have developed since the prolonged use of ART in PLHIV. The development of changes in body fat distribution, dyslipidemia, insulin resistance, lipodystrophy syndrome, sarcopenia, and frailty are currently primary concerns when considering nutritional interventions.⁵⁷ Weight loss or reduction in lean body mass may also be a problem for some patients using ART. Comprehensive nutritional intervention is advocated during the early stages of HIV infection to maintain nutritional status. ART compromises nutrition in HIV patients because of complicated drug and nutrient interactions, adverse side effects including diarrhea and nausea, and, in some cases, excessive pill loads that must be consumed. Furthermore, ART has been directly linked to HIV-associated lipodystrophy. This syndrome is marked by various combinations of insulin resistance, hyperlipidemia, visceral adiposity, loss of peripheral fat stores, and dorsocervical fat accrual.⁵⁸ Lipodystrophy is a syndrome that makes the nutritional management of HIV more difficult and may necessitate exercise, pharmacological intervention, and diet modifications.⁵⁹ Insulin resistance has been observed in approximately 50% of ART users taking a PI, compared with approximately 25% of ART users who are taking an NRTI; this can result in eventual symptomatic atherosclerosis.⁵⁷ Dietary modification has only a modest effect on serum lipid concentrations; the use of statins and ART modification may be a more effective treatment.

Diet modification and resistance exercise training have been shown to help reduce total-body and regional fat mass. In addition, the FDA approved a growth hormone-releasing factor to treat visceral fat accumulation in PLHIV diagnosed with HIV lipodystrophy.⁵⁷

Many patients who take antiretroviral drugs also take alternative therapies, including dietary supplements. Some drug-herb-supplement combinations may result in clinically meaningful interactions. Twenty-eight pharmacokinetic studies and case-series/case reports were selected for inclusion in a recent systematic review. Calcium carbonate, ferrous fumarate, some forms of ginkgo, some forms of garlic, some forms of milk thistle, St. John's wort, vitamin C, zinc sulfate, and multivitamins were all found to significantly decrease the levels of selected antiretrovirals and should be avoided in patients taking these antiretrovirals. Cat's claw and evening primrose oil were found to significantly increase the levels of antiretrovirals. PLHIV should be monitored for adverse effects while taking these dietary supplements with antiretrovirals. This evidence shows the importance of screening all PLHIV for dietary supplement use to prevent treatment failure or adverse effects related to an interaction.⁶⁰

SYSTEMIC MANIFESTATIONS

Integumentary System and Neoplasms

Cutaneous disorders develop as many as 90% of all PLHIV.⁶¹ Most HIV-induced skin findings develop only when the CD4 count falls to less than 500 cells/ μ L. As the CD4 cell count decreases further, multiple cutaneous disorders may develop.⁶² Skin conditions may be defined as infectious, neoplastic, or inflammatory; a large percentage of PLHIV will also develop primary pruritus.⁶¹ Chronic itch may be cutaneous, systemic, or psychiatric in nature and can directly impact

QOL for PLHIV. Treatment for inflammatory skin conditions may include ART modification, oral antihistamines, topical corticosteroids, topical antipruritic agents, skin moisturizers, psychiatric interventions, or phototherapy.⁶¹

There are three malignancies common in advanced HIV or AIDS: Kaposi sarcoma (KS), non-Hodgkin lymphoma (NHL), and cervical cancer. KS was the first neoplastic condition to be related to HIV infection, and it remains the most common in PLHIV who have limited access or poor compliance with ART. The incidence of KS has continued to diminish because of the use of more powerful ART and maintenance of immune status.^{62,63} KS can involve almost every part of the body, but the most common site of initial KS presentations is the skin or mucous membranes.⁶⁴ The disorder manifests as cutaneous purple nodular lesions or as rife visceral lesions. AIDS-KS has been intimately associated with the lymphatic system, specifically deficient lymphatic transport, nodal dysfunction, and tumors, which contribute to lymphedema.⁶⁵

In KS there is a broad therapeutic spectrum from cryotherapy to systemic chemotherapy.⁶⁶ ART plus chemotherapy is more effective than ART alone in patients diagnosed with severe or progression KS.⁶³ In NHL, early therapeutic intervention is necessary because of the fast progression of the tumor.⁶⁷ A systematic review,⁶⁸ conducted in 2015, found that the prevalence of nondiffuse large B-cell lymphoma has declined significantly since the introduction of combination ART, yet the prevalence of Burkitt or Burkitt-like lymphoma has not shown the same reduction; there remains a poor prognosis for those with Burkitt or Burkitt-like lymphoma.⁶⁸ The cervical cancer in HIV-positive women seems to be more aggressive than in HIV-negative women and requires early therapeutic intervention.⁶⁹ The cancer incidence in patients with HIV is reported to be higher among nonblack patients.⁷⁰ The incidence is seven times higher in HIV-positive women, as is the prevalence of a positive HPV viral DNA test, when compared with HIV-negative women.⁷¹

Several other tumors occur in people with HIV infection: anorectal cancer, lung cancer, malignant testicular tumor, Hodgkin lymphoma, basal cell carcinoma, and malignant melanoma.^{67,72} It is beyond the scope of this chapter to detail all aspects of integumentary and neoplastic concerns; however, the therapist needs to be aware of the importance of differential diagnosis because the skin is the first line of defense of the immune system and further work-up may be warranted. See [Table 34.3](#) for integumentary conditions associated with HIV.

Musculoskeletal System

Musculoskeletal symptoms are common in PLHIV. Knowledge of abnormalities that may occur in the musculoskeletal system is crucial as it influences morbidity and mortality. PLHIV develop inflammatory rheumatic diseases, which require screening, assessment, and management.⁷³ Arthritis in HIV disease has a wide spectrum of presentations ranging from mild arthralgia to severe joint disability.⁷⁴ Arthritides seen in this population has been classified into five groups on the basis of clinical presentation: (1) painful articular syndrome, (2) acute symmetrical polyarthritis, (3) spondyloarthropathic arthritis (Reiter syndrome, psoriatic arthritis), (4) HIV-associated arthritis, and (5) septic arthritis.⁷⁵ Standardized diagnostic tests and treatments are the same for PLHIV with musculoskeletal impairments.

Primary abnormalities include osseous and soft tissue infections, polymyositis, myopathy, and arthritis. Spinal infections such as pyogenic discitis, osteomyelitis, spinal tuberculosis, and epidural abscesses can occur with avascular necrosis (AVN) and osteoporosis as common comorbidities of HIV.^{73,76} Secondary musculoskeletal complications are often a result of the various compensatory patterns of gait secondary to HIV-related peripheral neuropathy syndrome or the change in biomechanics of the foot and ankle.⁷⁷ These lead to potential spinal changes and back pain. PLHIV should be evaluated from a

TABLE 34.3 Human Immunodeficiency Virus and Integumentary Conditions

Viral Infections	Acute morbilliform rash Herpes simplex Varicella zoster Molluscum contagiosum Human papillomavirus Oral hairy leukoplakia
Fungal Infections	Tinea Blastomycosis Candidiasis Cryptococcosis Histoplasmosis Pityrosorum folliculitis Pityriasis versicolor Systemic mycoses Pneumocystosis
Bacterial Infections	Cellulitis Ecthyma Impetigo Folliculitis Bacillary angiomatosis
Arthropod Infections	Insect bites Scabies Demodicosis
Inflammatory Conditions	Seborrheic dermatitis Eosinophilic folliculitis Psoriasis Eczema Pruritic papular eruption
Malignancies	Kaposi sarcoma Cutaneous B-cell lymphoma Cutaneous T-cell lymphoma Skin cancer (melanoma, squamous cell carcinoma, basal cell carcinoma, and anal carcinoma)
Other	Medication side effects Xerosis Lipoatrophy Postinflammatory hyperpigmentation

Many skin conditions listed in this table are seen in the general population but may be more severe or more difficult to treat in human immunodeficiency virus-infected patients.

systems perspective to underscore the primary driver of movement dysfunction.

In PLHIV, acute myopathy manifests as proximal muscle weakness and elevated creatine phosphokinase levels.⁷⁸ Patients may have initial symptoms of difficulty with basic activities of daily living (ADLs), such as rising from a chair or climbing stairs. If myopathy is in an acute inflammatory stage, resisted exercise is contraindicated.

AVN, a pathological process that is associated with a variety of medical conditions or pharmacological interventions, has been linked to prolonged use of ART. A systematic review and meta-analysis, published in 2014, found there was a statistically significant increased odds of AVN in PLHIV who were exposed to PI therapy (odds ratio 2.09, 95% confidence interval [CI] 1.01 to 4.31; $P = .05$).⁷⁹ In addition to the higher prevalence of AVN since the widespread use of ART, there is also a notable increase in the incidence of osteoporosis, especially in

young men diagnosed with HIV; the higher prevalence of osteoporosis associated with ART becomes further complicated by the increased life-spans and development of frailty as PLHIV progress through the natural course of aging.⁸⁰

Chronic pain is highly prevalent in PLHIV; it has been associated with mental health disorders and is frequently reported with other symptoms.^{81–83} This is discussed in more detail in a later section of the chapter.

Patient reports of musculoskeletal symptoms may indicate possible underlying inflammation, which has been implicated as a key predictor in HIV disease progression, early aging, and non-HIV-related morbidity and mortality.^{84,85} A key difference to consider is the effect of ART medications when side effects of ART may evoke symptoms that may complicate the differential diagnosis. ART drugs may limit pharmaceutical treatment options for musculoskeletal conditions, namely immunosuppressant medications. See [Table 34.4](#) for musculoskeletal conditions associated with HIV. PLHIV continue to have high musculoskeletal symptom burden despite viral suppression and decreased side effect profiles.⁸⁶ These symptoms experienced may have underlying pathophysiology due to inflammation, even in the context of viral suppression. Clinicians should proactively ask patients about

symptoms that contribute to pain and distress, assist PLHIV with coping mechanisms, and improved QOL.

Cardiopulmonary System

Pulmonary diseases continue to be important causes of illness and death in PLHIV, but changes in therapy and demographics alter their manifestations. The risk for development of specific disorders is related to the degree of immunosuppression, HIV risk group, area of residence, and use of prophylactic therapies.⁸⁷ Sinusitis and bronchitis occur frequently in the HIV-positive population, more so than in the general public. The increasing population of HIV-positive drug users is reflected in the increasing incidence of tuberculosis (TB) and bacterial pneumonia.

Anti-*Pneumocystis* prophylaxis has reduced the incidence of and mortality from *Pneumocystis carinii* pneumonia (PCP). The PCP-causing organism is usually acquired in childhood, and 65% to 85% of healthy adults possess PCP antibodies. Reactivation of latent infection is responsible for the recurrent fever, dyspnea, and hypoxia that characterize PCP.^{88,89} Adjunctive corticosteroid therapy has improved the outlook for respiratory failure.⁸⁷ Multiple studies have shown that the use of corticosteroids in PLHIV in acute respiratory failure did not increase the risk for the development of opportunistic infections.⁹⁰

TABLE 34.4 Human Immunodeficiency Virus and Musculoskeletal Conditions

Condition	Symptoms and Presentation	Interventions
Acute Symmetrical Polyarthriti	Exclusive to HIV-infected patients Resembles rheumatoid arthritis Develops in the small joints of the hand Characterized by ulnar deviation of the digits and swan neck deformities Acute onset Negative rheumatoid factor test result (helps differentiate from rheumatoid arthritis) Radiographical results mimic rheumatoid arthritis (periarticular osteopenia, joint-space narrowing, and marginal erosions)	Gold therapy ROM activities
Avascular Necrosis or Osteonecrosis	Results from direct or indirect damage to the vascular supply of the affected bone (leading to in situ death of subchondral bone) Most common sites are the femoral head followed by the humeral head May occur in other locations including the wrist (scaphoid [Preiser disease] or lunate [Kienböck disease]), knee, and ankle Deep, throbbing, intermittent pain that may be insidious or sudden onset In later stages, a loss of range of motion	Early treatment by minimizing the forces across the joint (avoiding lower-extremity weight-bearing activity or by greatly limiting upper-extremity lifting and carrying activities) Advanced stages require surgical intervention to improve/restore vascularity, provide stabilization, or replace the joint ROM activities
Diffuse Infiltrative Lymphocytosis Syndrome (DLS)	Massive parotid enlargement, xerostomia, and lymphocytic hepatitis caused by CD8 lymphocytic infiltration of the liver Xerophthalmia (dry eyes), xerostomia (dry mouth), salivary gland enlargement, and arthralgias Extraglandular features may be pulmonary, neurological, gastrointestinal, renal, or musculoskeletal	Symptomatic treatment with artificial saliva and tears Antibiotics to address recurrent sinus, middle ear, and oral cavity infections Immunosuppressive therapy should be used only in life-threatening situations (pulmonary insufficiency or renal disease) Corticosteroids can be used for extraglandular features Radiotherapy to reduce the enlarged parotid gland
HIV-associated Arthralgia	Asymmetrical, oligoarticular arthritis exclusive to HIV-infected persons Occurs predominantly in the late stages Acute onset of severe pain and disability (predominantly large joints such as the knees or ankles) Self-limiting, lasts a few weeks to 6 months Mild to moderate severity Synovial fluid commonly contains only 50–2600 white blood cells/ μ L Radiography may show diffuse osteopenia but without erosive changes Serum is negative for human leukocyte antigen-B27 and rheumatoid factor Synovial biopsy reveals a chronic mononuclear cell infiltrate	Symptomatic relief with NSAIDs Intraarticular corticosteroid injections ROM activities

Continued

TABLE 34.4 Human Immunodeficiency Virus and Musculoskeletal Conditions—cont'd

Condition	Symptoms and Presentation	Interventions
Hypertrophic Osteoarthropathy	Systemic disorder affecting bones, joints, and soft tissues Often develops in patients with PCP Severe pain in the lower extremity, digital clubbing, arthralgias, nonpitting edema, periarticular soft tissue involvement of the ankle, knees, and elbows Skin over the affected areas is glistening, edematous, and warm Chronic erythema, paresthesias, and hyperhidrosis may be noted in the hands and feet Radiography reveals extensive periosteal reaction and subperiosteal proliferative changes in the long bones of the lower extremity Bone scan demonstrates increased uptake along the cortical surfaces	Treatment of PCP usually alleviates this condition Surgical or chemical vagotomy or radiation therapy may be necessary in refractory cases
Idiopathic Polymyositis	Bilateral proximal muscle weakness Elevated serum CK levels Often occurs early in infection Exact mechanism is still undetermined	Discontinue medication that causes inflammation or irritation of the muscle Antiinflammatory medications Corticosteroid medications
Psoriatic Arthritis	Cutaneous manifestations (macropapules on the knees, elbows, scalp and trunk), nail changes, arthritic changes or deformities, soft tissue swelling, juxtaarticular erosions, osteopenia, osteolysis Five types: asymmetrical oligoarthritis, symmetrical polyarthritis, dominant desquamative interstitial pneumonia, arthritis mutilans, and sacroiliitis or spondylitis without peripheral involvement Synovial fluid usually contains 7000–15,000 white blood cells/ μ L	NSAIDs Second-line agents (gold, methotrexate, and azathioprine) Intraarticular steroid injection (every 4–6 months) ROM activities
Pyomyositis	Solitary or multiple muscle abscesses that are not formed by local extension from superficial subcutaneous tissue Acute, severe muscle pain with or without erythema, fever, edema Elevated ESR and CK levels Pathogen is most often <i>Staphylococcus aureus</i> Differential diagnosis includes muscle strain, contusion, hematoma, cellulitis, deep venous thrombosis, osteomyelitis, septic arthritis, and neoplasm	Without treatment, septic shock and death can result in 3 weeks Open drainage or débridement of the site Antibiotic therapy
Reactive Arthritis Septic Arthritis Bursitis	Asymmetrical oligoarthritis or monoarticular arthritis, dactylitis, enthesopathy, joint effusion Most common in the foot and ankle May range from mild to severe Inflammation of synovial fluid, often gram negative	Surgical débridement Aspiration of fluid from the joint Antibiotics ROM activities
Reiter Syndrome	Urethritis, conjunctivitis, and arthritis Nail involvement with subungual hyperkeratosis, circinate balanitis, keratoderma hemorrhagica, oral ulcers, uveitis, AIDS foot, weight loss, malaise, lymphadenopathy, and diarrhea Severe course of persistent and erosive polyarthritis, fevers, and enthesopathies (responds poorly to treatment or has a mild and self-limited course) Common enthesopathies include Achilles tendinitis, lateral or medial epicondylitis, rotator cuff tendinitis, and de Quervain tenosynovitis Axial skeleton involvement is rare Broad-based gait and stiff ankles with weight bearing through the lateral margins of the feet because of the painful heel May become severely disabled and require use of a wheelchair	NSAIDs Second-line agents (gold, methotrexate, and azathioprine) Relief after 5–7 days of therapy Intraarticular steroid injection (every 4–6 months) Methotrexate, other immunosuppressive agents, and phototherapy should be used with extreme caution Early physical therapy and splinting of affected joints as needed to prevent atrophy and contractures
Zidovudine-associated Myopathy	Causes mitochondrial toxicity Gradual myalgias, muscle tenderness, proximal muscle weakness Elevated CK levels	Discontinue AZT therapy CK levels return to normal within 4 weeks (after discontinuing AZT) Weakness resolves in 8 weeks

AZT, Zidovudine; CK, creatine kinase; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; NSAIDs, nonsteroidal antiinflammatory drugs; PCP, *Pneumocystis carinii* pneumonia; ROM, range of motion.

Mycobacterial infections in PLHIV usually manifest as either *Mycobacterium avium* complex (MAC) infection or TB.⁷ Steadily increasing incidence of infection by *Mycobacterium tuberculosis* is likely the result of two factors: better medical management of HIV and the development of multidrug-resistant strains of mycobacteria. MAC infection tends to appear late during HIV infection, with the initial infection affecting the GI and pulmonary tracts; this eventually disseminates throughout the body. This disorder is probably not caused by latent reactivation of the organism but rather by primary infection by ingestion or inhalation.⁹¹ Signs and symptoms of MAC infection include pneumonia, fever, weight loss, malaise, sweats, anorexia, abdominal pain, and diarrhea.

As in many other infections, initial signs and symptoms of TB include fever, weight loss, malaise, cough, lymph node tenderness, and night sweats. Pulmonary involvement accounts for 75% to 100% of cases of TB infection in PLHIV, but extrapulmonary infection, especially in lymph nodes and bone marrow, occurs in up to 60% of these individuals as well.^{88,91–93} Less common areas of infection include the CNS, cardiac, and mucosal tissues. TB is communicable, preventable, and treatable. Tuberculin skin testing with follow-up chest radiographs when appropriate should be available and routinely offered to individuals at HIV testing sites. Individuals at highest risk for concomitant HIV and TB infections include the homeless, intravenous drug users, and prison inmates.^{88,93} The risk of infection in health care personnel and in the public is a concern. Isolation rooms that provide negative-pressure, nonrecirculated ventilation, specific air filters, and higher air exchange rates offer the best protection to health care providers exposed to TB-infected individuals. Properly fitted face masks that filter droplet nuclei should be worn. Monitoring of personnel who work with these populations will identify the need for necessary preventive therapy.⁸⁸ The majority of health care facilities require personnel to have yearly screenings and have established guidelines to prevent the spread of TB in their patient population and within their workforce.

Cytomegalovirus (CMV) can affect the GI and respiratory tracts but primarily targets optic structures and the CNS; 40% to 100% of healthy adults possess CMV antibodies.⁹⁴ However, an individual who is immunosuppressed becomes more vulnerable to symptoms of infection with CMV. Predominant consequences of HIV-CMV coinfection are unilateral or bilateral deficits in visual acuity, visual field cuts, and blindness. PLHIV are more likely than the general population to have subclinical bursts of CMV replication at mucosal sites. Production of antigens can activate the immune system and stimulate HIV replication, and it could contribute to the pathogenesis of adverse outcomes of aging, such as CVD or neurocognitive impairment.⁹⁵

Since the introduction of ART, the QOL and longevity for PLHIV have significantly improved. However, given the impact and negative effects of the virus and prolonged intervention with ART, the effects of aging from CVDs have emerged as one of the most common causes of death.⁹⁶ This accounts for up to 15% of total deaths in high-income countries.⁹⁷ As ART availability expands to low-income countries, the burden of CVD mortality will rise. Over the next decade, HIV-CVD disease burden is expected to increase globally.⁹⁷ Factors that contribute to the atherosclerotic process and its role in the development of acute coronary syndrome in the setting of infection requires close monitoring in rehabilitation settings.

Clinical CVD tends to appear approximately 10 years before in infected individuals, when compared with the general population. The pathogenesis behind the cardiovascular, HIV-associated complications is complex, involving traditional CVD risk factors, as well as factors associated with the virus itself including chronic inflammation and resultant immune activation, along with metabolic disorders related to ART regimens.⁹⁸ Determining the cardiovascular risk among HIV-infected patients, as well as targeting and treating conditions that

predispose to CVD, are currently emerging concerns among health care professionals. CVD, especially coronary artery disease, are among the leading causes of death in this population.⁹⁹

Pericardial effusion and myocarditis are among the most commonly reported cardiac abnormalities. Cardiomyopathy, endocarditis, and coronary vasculopathy have also been reported. HIV infection, the medical management of HIV disease, and secondary opportunistic infections can all affect the myocardium, pericardium, endocardium, and blood vessels.^{94,100} Cardiovascular risk in PLHIV depends on several factors: direct and indirect vascular effects of chronic exposure to the virus, metabolic effects from prolonged ART, the normal aging process (important to consider given the increased life expectancy of PLHIV), and other cardiovascular risk factors (such as diet and genetics).¹⁰¹

Body fat changes and lipid abnormalities,¹⁰² known as *lipodystrophy* or *fat redistribution syndrome*, have been connected to PI use.¹⁰³ These body fat changes may have strong implications for patients undergoing rehabilitation interventions. Signs and symptoms of the syndrome vary, and not all need to be present in any patient. However, in both men and women, three main components of the syndrome have emerged. These include changes in body shape, hyperlipidemia, and insulin resistance. Clinically, distinct body shape changes are apparent. The most prevalent include increased abdominal growth, dorsocervical fat pad, benign symmetrical lipomatosis, lipodystrophy, and breast hypertrophy in women.^{104,105} The increased abdominal growth is characterized by a redistribution and accumulation of fat in the central visceral areas of the body.^{105,106} Corresponding symptoms include GI discomfort, bloating, distention, and fullness.¹⁰⁶ In addition to visible signs and symptoms, adverse changes in lipid, glucose, and insulin levels have been reported.¹⁰⁷ Several studies have revealed hyperlipidemia to be present in PLHIV, many of whom, but not all, were undergoing PI therapy.¹⁰⁸

Prevention of CVD risk remains the first and essential step in a medical intervention. Lifestyle modification, including weight reduction, exercise, smoking cessation, and education on healthy dietary practices, are key target areas. Statins are the primary medication used to treat hypercholesterolemia. They have been shown to slow the progression or promote reduction of coronary plaque and could also exert an antiinflammatory and immunomodulatory effect.¹⁰⁹ Current ARTs are less toxic and more effective than regimens used in the early years. Lipodystrophy and dyslipidemia are the main causes of long-term toxicities. PIs may cause dyslipidemia and lipodystrophy, whereas INIs have a minimal impact on lipids profile and no evidence of lipodystrophy.¹⁰⁹

Metabolic syndrome, which is a cluster of risk factors for type 2 diabetes and CVD, has become an important public health problem.¹¹⁰ In HIV, new evidence suggests that the use of optimal waist cut-off points specific for the various ethnic populations is recommended.¹¹¹ Although metabolic disorders have been associated indirectly with ART, in the aging HIV population and newer, less metabolically toxic antiretroviral drugs are available. Lipotoxicity and adipokines have been key issues to explain this metabolic syndrome. Prevention strategies and therapeutic options for all metabolic syndrome and CVD need to be addressed in the light of the recent Adult Treatment Panel IV recommendations and the new antiretroviral drugs.¹¹¹

Therapists need to be apprised of various changes in laboratory results and signs and symptoms of metabolic syndrome and cardiac disease when designing an exercise program and facilitating the return to functional activities. Screening guidelines^{112,113} (from the Infectious Diseases Society of America HIV Medicine Association [IDSA HIVMA]) include the following:

- Monitor fasting lipid levels before beginning highly active antiretroviral therapy (HAART) and during the first 4 to 6 weeks of treatment

TABLE 34.5 Effects of Human Immunodeficiency Virus Treatment on Cardiovascular Factors

Cardiovascular Factor	Incidence	Effects
Lipid Metabolism HDL-C	Decreases in early infection Will increase modestly with viral suppression (not to preinfectious levels)	Greater increases seen with NNRTI medications Increased visceral adipose tissue and upper trunk fat associated with low HDL-C
Lipid Metabolism LDL-C	Decreases later in infection Will increase modestly with viral suppression	No evidence of direct medication effects on LDL-C
Lipid Metabolism Triglycerides	Increases in late infection with viral suppression Decreased in early studies of AZT use	No change (primarily with PIs) with ART medications Increased visceral adipose tissue and upper trunk fat associated with elevated triglyceride levels
Glucose Metabolism Insulin Sensitivity	Decrease if untreated Trend toward decreased insulin sensitivity with viral suppression (regardless of medications)	Some PIs and NRTIs may decrease insulin sensitivity Increased visceral adipose tissue and upper trunk fat associated with insulin resistance
Glucose Metabolism Insulin Secretion	No evidence of effect if untreated No evidence of effect with viral suppression	Some PIs may decrease insulin secretion
Glucose Metabolism Fasting Glucose	No evidence of any effect if untreated No evidence of effect with viral suppression	Some PIs may increase glucose production
Glucose Metabolism Glucose Tolerance	No evidence of any effect if untreated No evidence of effect with viral suppression	May be higher rates of impaired glucose tolerance with ART
Glucose Metabolism Diabetes	No evidence of differences in prevalence or incidence rates if untreated May be a higher prevalence of diabetes with viral suppression	Higher prevalence of type 2 diabetes associated with certain PIs and NRTIs
Body Composition Lean Body Mass	Decreases disproportionately with severe wasting, if untreated Increases modestly with the initiation of effective ART	No consistent evidence of direct medication effects
Body Composition Peripheral Fat	Decreases proportionately with wasting, if untreated Will initially increase with the start of effective ART	Subsequent depletion of subcutaneous fat in the face, arms, legs, and buttocks is associated with some NRTIs
Body Composition Visceral fat	Decreased minimally when untreated Increases with effective ART	Preserved or increased visceral fat in some patients on ART
Renal Function Renal Disease	HIV-associated nephropathy, proteinuria, microalbuminuria and elevated cystatin C if untreated Decreased HIV-associated nephropathy (may still have microalbuminuria and elevated cystatin C with viral suppression)	Some ART may cause impaired renal function

ART, Antiretroviral therapies; AZT, Zidovudine; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor.

- Monitor fasting glucose levels before and during HAART
- Monitor body weight and body shape changes on a routine basis
See Table 34.5 for effects of HIV treatment on cardiovascular factors and Table 34.6 for cardiovascular risk factors associated with HIV.

Neurological System

The neurological manifestations of HIV disease are numerous and involve the autonomic nervous system (ANS), CNS, and peripheral nervous system (PNS).^{114,115} Over the course of the disease, up to 70% of patients have some form of neurological symptom.¹¹⁶ Significant progress in understanding and treating the neurologically involved HIV-positive patient has been made over the past decade. However, HIV continues to affect every division of the human nervous system. HIV-positive infants show early, catastrophic encephalopathy, loss of brain growth, motor deficits, and cognitive dysfunction.¹¹⁷ This static or progressive HIV-encephalopathy is characterized by acquired microcephaly, delay or loss of developmental milestones (motor, mental, and language), and pyramidal tract motor deficits.¹¹⁸ Unfortunately, neurobehavioral dysfunction in early pediatric AIDS remains unchanged after therapy. Dementia develops in some adult patients despite the use of combination ART drugs, whereas other patients have subtle

neurobehavioral changes that diminish the quality of their prolonged lives. HIV infection of the CNS remains an important clinical concern.

A variety of host and viral factors are associated with an increased risk of developing HIV-associated neurocognitive disorders (HANDs). HAND is associated with a decreased survival time and is characterized by an insidious onset and slow progression of cognitive decline. In the early stages, individuals may report reduced concentration, poor memory, and impaired executive functioning.¹¹⁹ As the condition progresses, the individual's affect may change, with psychomotor slowing and reduction in motor skills.¹¹⁹ Approximately 18% to 50% of PLHIV who are on ART have some degree of HAND.^{120,121} As PLHIV are living much longer life-spans, it is critical to differentiate HAND from the more commonly diagnosed dementias. Studies are demonstrating similarities between factors that predispose PLHIV to HANDs and the risk factors of Alzheimer dementia, suggesting the potential for a common pathological mechanism.¹²² Evidence has shown that HIV-infected monocytes are carried across the blood-brain barrier and infect the macrophages and microglia in the CNS.^{123,124} HIV enters the CNS early, yet HANDs may not occur until advanced stages of HIV infection. Hypotheses for the development of HANDs in the advanced stages include the loss of immune control with disease progression,

TABLE 34.6 Cardiovascular Risk Factors and Human Immunodeficiency Virus

Risk Factor	Intervention	Result
Cigarette smoking	Interpersonal counseling Medical or pharmaceutical treatment Behavioral modification	Increased rates for quitting
HTN	Dietary and physical activity counseling Calcium channel blockers Other antihypertensive agents	Reduced blood pressure Drug interactions between calcium channel blockers and PIs
Dyslipidemia	Dietary and physical activity counseling Statins, fibrates, fish oil, niacin	Modest improvements in lipids Statins improve endothelial function Multiple drug interactions with ART
Disordered Glucose Metabolism	Dietary and physical activity counseling Metformin and thiazolidinediones	Improvement in glycemia Metformin reduces insulin resistance and visceral adipose tissue Thiazolidinediones may improve subcutaneous adipose tissue
Use of ART	Modification of initial ART based on metabolic profile and CVD risk Switching ART to reduce metabolic side effects	Modest effects on lipids and insulin resistance Statins and fibrates may be more effective

ART, Antiretroviral therapies; CVD, cardiovascular disease; HTN, hypertension; PI, protease inhibitor.

heightened immune activation, increased transfer of infected monocytes into the CNS, and variations or mutations in the virus. Because many ART medications have reduced CNS penetration, HANDs continue to pose significant challenges for advanced HIV/AIDS patients.¹²⁵ See [Table 34.7](#) for neurological conditions associated with HIV.

Autonomic Nervous System

Dysfunction of the ANS has been associated with HIV infection. This has implications for overall function and the design of a rehabilitation program for PLHIV disease. In one study, individuals with the greatest ANS involvement had dementia, myelopathy, and sensory peripheral neuropathy. Additional symptoms of autonomic neuropathy include orthostatic dizziness, postprandial nausea, urinary incontinence, and dysfunction in thermoregulation.¹²⁶ Variations in heart rate, including resting tachycardia, were common. Abnormal blood pressure readings were identified in response to isometric exercise and positional changes (sit-to-stand and tilting).¹²⁷ Opportunistic infections, such as CMV and varicella zoster virus, have been shown to contribute to autonomic dysfunction.¹²⁶ Individuals with suspected autonomic neuropathy should be carefully evaluated to rule out other sources, such as polypharmacy, end-organ disease, or comorbid conditions.

Central Nervous System

HIV enters the CNS during the early stages of the disease and is hypothesized to traverse the blood-brain barrier during the initial acute primary infection stage. Although the initial CNS invasion by HIV is asymptomatic in most individuals, affective and cognitive deficits may develop.¹²⁸ It is not possible in this context to discuss the neuropathological features of each of the many secondary infections and neoplasms of HIV illness. However, it is important to realize that the clinical manifestations of these pathological processes overlap with one another and with the signs and symptoms of primary HIV infection of the CNS; lesions of the CNS can be the site of more than one opportunistic disease process simultaneously. A wide variety of organisms or conditions are responsible for the neurological manifestations associated with HIV infection. These include primary and secondary viral, protozoan, fungal, and *Mycobacterium* infections, as well as neoplasms and iatrogenic conditions. Infectious processes may cause large lesions in the brain and lead to meningitis, encephalitis, or both. Such infections cause neurocognitive impairments that develop as

dementia, amnesia, or delirium.¹²⁸ Thirty percent to 40% of healthy adults have contracted toxoplasmosis, caused by *Toxoplasma gondii*.^{42,129} Unchecked by the immune system, toxoplasmosis results in CNS dysfunction: altered cognition, headache, focal neurological deficits, encephalitis, and seizures. Cerebellar disorders associated with HIV infection are typically the result of discrete cerebellar lesions¹³⁰ resulting from opportunistic infections such as toxoplasmosis and progressive multifocal leukoencephalopathy or primary CNS lymphoma.¹³¹ CNS lymphoma results in cognitive dysfunction and presentation of fever, focal neurological impairments, headache, seizures, and motor deficits.¹²⁸

Evidence supports that the neurotoxic effect of HIV is more likely to affect the basal ganglia, the frontal neocortex, the white matter tracts connecting the regions (such as the fronto-striato-thalamocortical loops), the temporal cortices (including the hippocampus), and the parietal cortices.¹³² A relationship between cerebrovascular disease and AIDS has been reported.^{133,134} There are estimates of a 20% to 80% increase in ischemic or hemorrhagic stroke risk (after adjustment for established stroke risk factors) in PLHIV.¹³⁵ The most common cause of cerebral infarction in both clinical and autopsy series was nonbacterial thrombotic endocarditis. Intracerebral hemorrhages were usually associated with thrombocytopenia, primary CNS lymphoma, and metastatic KS.

HIV-related conditions in the spinal cord include not only HIV myelitis, opportunistic infections, and lymphomas, but also vacuolar myelopathy, which affects predominantly the dorsolateral white matter tracts. The cause of vacuolar myelopathy is not understood, and it has not been unequivocally linked with HIV infection.¹³⁶ Vacuolar myelopathy may affect up to 30% of untreated adults with advanced HIV/AIDS, and the incidence may be even higher in children infected with HIV.¹³⁷ Unless it is treated with effective ART, vacuolar myelopathy of the spinal cord associated with moderate clinical disability develops in many patients with AIDS.¹³⁸

Treatment for CNS impairments includes an eclectic blend of rehabilitation strategies. Neuromuscular disturbances may first appear as movement disorders. Subtleties of altered movement can be detected early and during subsequent treatment phases. A neurological examination can be performed to determine a diagnosis and prognosis. This may include the level of the lesion, neuromuscular deficits, need for assistive devices, ability to perform ADLs, and functional abilities. Various QOL assessments used with this population can be found in [Table 34.8](#).

TABLE 34.7 Human Immunodeficiency Virus and Neurological Conditions

Condition	Symptoms and Presentation	Prognosis and Treatment
CNS Lymphomas	<p>Cancerous tumors (begin in the brain or result from a cancer that has spread from another site in the body)</p> <p>Almost always associated with the Epstein-Barr virus (EBV)</p> <p>Symptoms: headache, seizures, vision problems, dizziness, speech disturbance, paralysis, and mental deterioration</p> <p>May develop one or more CNS lymphomas</p>	<p>Prognosis is poor owing to advanced and increasing immunodeficiency</p>
Cerebrovascular Accident (CVA): Ischemia or Hemorrhage	<p>Causes include hypertension, blood vessel abnormalities (aneurysms, vein or artery malformations), hypotension, coagulopathies, thrombotic thrombocytopenic purpura, elevated lipids, viral infections of the heart muscle, herpes zoster, hepatitis C, and cocaine or heroin use</p> <p>Characterized by the abrupt onset of weakness, language problems, or sensory loss</p> <p>Symptoms often occur on only one side of the body</p> <p>Imaging studies help to differentiate stroke, hemorrhage, infection, and tumors</p>	<p>Treatment parallels the HIV-negative population</p> <p>CVA diagnosed <3 h after onset may be a candidate for tissue plasminogen activator (tPA); tPA is contraindicated in cases of brain hemorrhage</p> <p>Lipid-lowering drugs (statins), blood thinners such as warfarin (Coumadin), or antiplatelet agents such as aspirin or clopidogrel (Plavix) are indicated</p> <p>Specific causes of stroke may require other forms of treatment</p> <p>Brain hemorrhages may require surgery</p> <p>Prognosis depends on size and location; recovery is greatest during the initial few weeks, but improvement often continues for months</p> <p>Inpatient and outpatient rehabilitation is often helpful</p> <p>Preventive treatment parallels the HIV-negative population; includes antiplatelet agents or blood-thinning drugs, removal of plaque from the walls of carotid arteries, and newer techniques of endovascular stenting</p>
Cryptococcal Meningitis	<p>Manifests as meningitis, a space-occupying lesion, or meningoencephalitis</p> <p>The fungus first invades the lungs and spreads to the covering of the brain and spinal cord, causing the inflammation</p> <p>Symptoms: fatigue, fever, headache, nausea, memory loss, confusion, photophobia, stiff neck, altered vision, drowsiness, and vomiting</p> <p>Develops when CD4 cell counts fall to less than 100 cells/μL</p>	<p>If untreated, may lapse into a coma and die</p> <p>Treatment relies on amphotericin B (Fungizone), which may be combined with flucytosine (Ancobon)</p> <p>Alternative for less severe cases is fluconazole (Diflucan), which is also the drug of choice for long-term prophylaxis (preventive therapy)</p> <p>Amphotericin B is an alternative maintenance therapy for those who relapse on fluconazole or do not tolerate it</p> <p>Hydrocephalus can occur; requires a ventriculoperitoneal shunt</p> <p>Visual loss can be addressed by optic nerve surgery</p>
Cytomegalovirus (CMV) Infections	<p>Herpesvirus that causes infection of the brain, spinal cord, meninges, or nerve roots</p> <p>Lead to neurological problems such as encephalitis, myelitis, retinitis, polyradiculitis, peripheral neuropathy, or mononeuritis multiplex</p> <p>Infection of the spinal cord and nerves can result in weakness in the lower limbs and paralysis, severe lower back pain, and loss of bladder function</p> <p>Findings include low-to-normal glucose, normal-to-high protein, and increased numbers of white blood cells</p>	<p>Untreated CMV encephalitis is almost always fatal and causes death within days to weeks</p> <p>Anti-CMV drugs must be started immediately, often based on a suspected rather than proven diagnosis</p> <p>Treatment relies on ganciclovir (Cytovene) and foscarnet (Foscavir), used alone or in combination when monotherapy fails</p> <p>Lifelong maintenance treatment is often necessary</p>
Distal Sensory Polyneuropathy	<p>Damage to sensory nerves in the extremities</p> <p>Most common type of HIV-associated neuropathy</p> <p>Nerves may be injured directly by HIV or by HIV-induced macrophages that secrete neurotoxic substances</p> <p>May also be caused by nutritional and vitamin imbalances or drug toxicity (especially use of d4T [stavudine, Zerit], ddI [didanosine, Videx], or ddC [zalcitabine, Hivid])</p> <p>Occurs at any stage of HIV disease</p>	<p>Treatment of symptoms may include local ointments (capsaicin, Aspercreme), antidepressant medications (amitriptyline [Elavil]), or antiepileptic medications (gabapentin [Neurontin], lamotrigine [Lamictal], carbamazepine [Tegreto])</p> <p>Duloxetine (Cymbalta; an SSRI antidepressant) is FDA approved for painful diabetic polyneuropathy</p> <p>Pregabalin (Lyrica; antiepileptic drug)</p> <p>Drugs should be chosen that are unlikely to interact with or influence the effectiveness of ART</p> <p>Lidoderm patches may provide partial pain relief without any systemic side effects and can be combined with oral drugs.</p>

TABLE 34.7 Human Immunodeficiency Virus and Neurological Conditions—cont'd

Condition	Symptoms and Presentation	Prognosis and Treatment
Herpesvirus Infections	<p>Herpes zoster virus can infect the brain and produce encephalitis or myelitis</p> <p>Signs of shingles include painful blisters, itching, tingling, and nerve pain</p>	<p>Anti-herpes drugs: standard treatment for shingles is acyclovir; other medications include famciclovir and valacyclovir</p> <p>Nerve blocks: anesthetic drugs and/or steroids injected into peripheral nerves or into the spinal column</p> <p>Drugs normally used to treat depression, epilepsy, or severe pain are sometimes used for the pain of shingles; nortriptyline (antidepressant) is frequently used for shingles pain; pregabalin is an epilepsy medicine used for pain after shingles</p> <p>Skin treatments: creams, gels, and sprays may provide temporary relief from pain; capsaicin has shown good preliminary results; the patch form of the anesthetic lidocaine provides pain relief for some people with shingles</p>
HIV-dementia Complex (HIV-associated Encephalopathy)	<p>Occurs primarily in persons with advanced HIV infection</p> <p>Mild cognitive impairment may occur in earlier stages</p> <p>Symptoms: encephalitis, behavioral changes, and a gradual decline in cognitive function (decreased concentration, memory, and attention)</p> <p>May develop severe global dementia with memory loss and language impairment</p> <p>Progressive slowing of motor function (decreased balance, weakness, decreased coordination) and loss of dexterity and coordination</p>	<p>Can be fatal if left untreated</p> <p>If HIV-dementia develops during treatment with ART, additional or alternative agents should be tried</p> <p>Neuroprotective therapies or global memory-enhancing agents such as memantine (Namenda) or donepezil (Aricept) may be useful</p> <p>Polypharmacy can affect thinking and memory and make symptoms worse</p>
Inflammatory Demyelinating Polyneuropathy (IDP)	<p>Inflammation of the myelin sheath that surrounds the spinal and peripheral nerves</p> <p>Acute form of IDP (AIDP), also known as <i>Guillain-Barré syndrome</i> (GBS)</p> <p>Characterized by rapid onset and progression over hours to weeks</p> <p>Chronic form (CIDP) has slower onset and progression over weeks to months, sometimes with a relapsing course</p> <p>Both forms are autoimmune conditions in which the immune system attacks nerves</p> <p>Causes varying degrees of weakness and sensory loss, which can develop in the limbs</p> <p>Nerves around the head may be affected and cause symptoms of facial weakness and double vision.</p> <p>Other symptoms may include pain and diminished reflex responses</p> <p>May have difficulty with urination and bowel movements, respiratory paralysis, irregular heartbeat, and dangerously high or low blood pressure</p>	<p>Treatment and response rates are similar to the HIV-negative population</p> <p>Intravenous immunoglobulin (IVIG), a highly concentrated antibody infusion from many pooled blood donations, is the primary treatment</p> <p>Plasmapheresis (removal of antibodies from the blood) may be helpful</p> <p>CIDP may also necessitate use of corticosteroids such as prednisone</p>
Meningitis	<p>Inflammation of the meninges, the membranes surrounding the brain and spinal cord</p> <p>Signs and symptoms are malaise, fever, stiff neck, photophobia, and headache; less common are cranial neuropathies (one-sided facial weakness or double vision), confusion, drowsiness, and personality changes</p> <p>HIV invades the brain early and may cause meningitis within days to weeks after infection</p> <p>Chronic meningitis, or episodes of idiopathic acute (rapid onset) meningitis can occur anytime during the course of HIV disease</p>	<p>Treatment and prognosis vary by the specific cause of meningitis, severity at presentation, delay from symptom onset to treatment, and status of immunosuppression</p>

Continued

TABLE 34.7 Human Immunodeficiency Virus and Neurological Conditions—cont'd

Condition	Symptoms and Presentation	Prognosis and Treatment
Mononeuritis Multiplex	<p>Painful condition involving isolated nerves over the arms, legs, or trunk</p> <p>Nerves are affected asymmetrically</p> <p>Involvement of >2 nerves is generally seen in advanced HIV</p> <p>Burning or shooting pain down an arm or leg, then (even if resolving) another burning pain emerges over another nerve pathway in a different arm or leg</p> <p>Weakness in the distribution of specific nerves is common</p> <p>Nerves can be affected in the head and the body</p>	<p>Occurring early in HIV infection</p> <p>May resolve with ART</p> <p>IVIG or plasmapheresis should be considered in early or late HIV stages</p> <p>Advanced HIV disease may require anti-CMV medications (ganciclovir, foscarnet)</p>
Myopathy	<p>May be due to drug toxicity (statins, ddl, or AZT), bacterial, viral, or other infections</p> <p>Polymyositis is caused by an abnormal immune response</p> <p>HIV wasting syndrome may result from HIV infection itself.</p> <p>Progressive muscle weakness is the typical presentation; the speed of progression depends on the cause</p>	<p>If due to drug toxicity, discontinue or replaced medication</p> <p>Muscle infections treated with drugs specific to the responsible bacterium, virus, or other infectious agent</p> <p>Inflammation from an overactive immune system can be treated with corticosteroids</p>
Neurosyphilis	<p>Sexually transmitted infection caused by the spiral-shaped <i>Treponema pallidum</i> bacterium</p> <p><i>T. pallidum</i> gains access to the body through tiny abrasions of the skin or mucous membranes; this organism may invade the CNS a few months after initial infection</p> <p>May proceed rapidly from the primary stage (skin chancres, or lesions, appearing about 21 days after infection) to secondary syphilis (skin rash) and tertiary syphilis (infection of different organs, including the brain) as early as 2 months after exposure</p> <p>Tertiary syphilis may cause hearing loss, dizziness or vertigo, headache, failing vision, cognitive impairment, personality changes, peripheral polyneuropathy, gait imbalance, seizures, or CVA</p>	<p>Antibiotic use depends on the stage of syphilis and follows general guidelines</p> <p>Most common are different forms of penicillin</p> <p>Although HIV-infected patients with neurosyphilis respond to antibiotics, they are less likely to have serological improvement (compared with HIV-negative individuals)</p> <p>HIV-associated neurosyphilis may be more difficult to treat and more aggressive</p>
Polyradiculopathy	<p>Damage to the nerve roots where the nerves exit the spinal cord to form peripheral nerves</p> <p>May be caused by CMV, or lymphoma (less likely); may be idiopathic</p> <p>Rapidly progressive ascending numbness, pain, and weakness affecting the legs, and later occasionally the arms, is characteristic of the CMV form</p> <p>Early bowel and bladder control problems may suggest the syndrome</p> <p>More benign, slower clinical progression characterizes the idiopathic form</p>	<p>CMV polyradiculopathy is rapidly fatal without therapy</p> <p>Treatment with foscarnet or ganciclovir may improve or stabilize the condition</p> <p>ART may be useful</p> <p>Idiopathic form may improve spontaneously, without treatment</p>
Primary Central Nervous System Lymphoma	<p>Characterized by the growth of abnormal lymphocytes, or white blood cells (B- and T-cells)</p> <p>Occurs in the brain, rarely in the spinal cord; causes brain lesions and changes in mental functioning</p> <p>In almost all cases, EBV is found in the lymphoma-related lesions or the CSF</p> <p>Often associated with CD4 cell counts less than 100 cells/μL</p> <p>Symptoms: impaired cognition, aphasia, hemiparesis, and seizures</p> <p>Onset is often subtle and progression slower</p>	<p>Prognosis is generally poor</p> <p>Whole brain radiation therapy (radiotherapy) has been the mainstay of treatment; provides for a median survival of 2–5 months</p> <p>Steroids are required for at least 48 h before radiotherapy to minimize swelling; steroids should be continued throughout the course of treatment</p> <p>High-dose methotrexate has been used with some success, given as frequently as every week for five cycles; combining methotrexate and radiotherapy can achieve survival of 1–2 years</p> <p>Experimental chemotherapy agents include thiotepa (Thioplex) and procarbazine (Matulane)</p> <p>ART should be continued</p>

TABLE 34.7 Human Immunodeficiency Virus and Neurological Conditions—cont'd

Condition	Symptoms and Presentation	Prognosis and Treatment
Progressive Multifocal Leukoencephalopathy (PML)	<p>Characterized by widespread demyelinating lesions (around nerves in the brain and spinal cord) and caused by the JC papovavirus</p> <p>Symptoms: mental deterioration, vision loss, speech disturbances, ataxia, paralysis, brain lesions, and coma</p> <p>Some may have compromised memory and cognition</p> <p>Seizures may occur when CD4 cell counts fall below 200 cells/μL</p> <p>Onset is usually weeks to months</p>	<p>Relentlessly progressive; death usually occurs within 6 months of initial symptoms</p> <p>Typically progresses to severe dementia and death over several months</p> <p>Whether ART improves survival remains controversial</p> <p>Survival correlates with suppression of plasma HIV viral load and higher CD4⁺ cell counts</p> <p>Death may result not from PML, but from end-stage immunodeficiency</p> <p>Some positive response has been reported with use of cidofovir (Vistide)</p>
Psychological and Neuro-psychiatric Disorders	<p>Occurs in different phases of the HIV infection; may take on various and complex forms</p> <p>Some illnesses are caused directly by HIV infection of the brain, whereas other conditions may be triggered by the drugs used to combat the infection</p> <p>Symptoms include anxiety disorder, depressive disorders, increased thoughts of suicide, paranoia, dementia, delirium, cognitive impairment, confusion, hallucinations, behavioral abnormalities, malaise, and acute mania</p>	<p>Treatment options include antidepressants and anticonvulsants</p> <p>Psychostimulants may also improve depressive symptoms and combat lethargy</p> <p>Antidementia drugs may relieve confusion and slow mental decline</p> <p>Benzodiazepines may be prescribed to treat anxiety</p> <p>Psychotherapy may help</p>
Toxoplasmosis	<p>Caused by the parasite <i>Toxoplasma gondii</i></p> <p>Symptoms include encephalitis, fever, severe headache that does not respond to treatment, weakness on one side of the body, seizures, lethargy, increased confusion, vision problems, dizziness, problems with speaking and walking, vomiting, and personality changes</p> <p>Onset is over days to weeks</p>	<p>Condition is treatable, most improve by day 14 of therapy</p> <p>Generally responsive to intravenous antibiotics, and response to therapy is often rapid</p> <p>Agents of choice are sulfadiazine combined with pyrimethamine and folinic acid; for people with sulfa intolerance, clindamycin is an alternative</p> <p>Steroids may be used to reduce associated swelling in the brain</p> <p>After the initial regimen is completed, oral maintenance treatment, usually TMP-SMX (Bactrim, Septra), is continued indefinitely to suppress reactivation of the parasite</p> <p>Prognosis is linked to parallel treatment with ART to raise CD4 cell count</p>
Tuberculosis Meningitis	<p>Bacterial disease caused by <i>Mycobacterium tuberculosis</i> (can be suspended in tiny droplets in the air and transmitted person to person by inhalation)</p> <p>May cause persistent headache, fever, confusion, hemiparesis, seizures, stiff neck, double vision, or hearing loss</p> <p>Hydrocephalus associated with tuberculosis may lead to drowsiness or stupor and, later, coma</p> <p>Spinal cord damage can occur if the vertebrae are infiltrated by TB (Pott disease) or from abscesses inside or outside the spinal cord</p>	<p>Triple antibiotic therapy: isoniazid, rifampin (Rifadin), and pyrazinamide, for 12–24 months is required</p> <p>In cases of drug-resistant TB, a fourth drug, ethionamide (Trecator), should be administered</p> <p>ART should be continued</p> <p>Significant interactions can occur between rifampin and PIs, so an alternative anti-TB drug may be necessary</p>
Vacuolar Myelopathy	<p>Causes the protective myelin sheath to pull away from nerve cells of the spinal cord, forming small holes called <i>vacuoles</i> in nerve fibers</p> <p>Symptoms include weak and stiff legs and unsteadiness when walking; walking becomes more difficult as the disease progresses, may necessitate use of a wheelchair</p>	<p>Prognosis is poor, options are limited, and care is primarily supportive</p> <p>May improve after starting ART to stabilize spinal cord damage; maximally potent ART is required</p> <p>I-Methionine (also known as <i>SAMe</i>, a common dietary supplement) is an experimental treatment</p>

ART, Antiretroviral therapies; AZT, Zidovudine; CMV, Cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; FDA, US Food and Drug Administration; PI, protease inhibitor; PML, progressive multifocal leukoencephalopathy; SSRI, selective serotonin reuptake inhibitor; TB, tuberculosis; TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 34.8 Quality-of-Life Assessments in Human Immunodeficiency Virus (HIV) Disease

Outcome Measure	Dimensions	Length and Administration
AIDS Health Assessment Questionnaire (AIDS-HAQ)	Physical function, mental health, cognitive function, social health, energy, and fatigue	30 items Self-administered (5 min)
AIDS Specific Functional Assessment (ASFA)	Evaluates usefulness of functional assessment	Varies Self-administered, care provider
Functional Assessment of Chronic Illness Therapy—Spiritual Well-Being (FACIT-Sp-12)	Faith, meaning, and peace	12 items Self-administered
Functional Multidimensional Evaluation of People with HIV (VFM/HIV)	Self-sufficiency with ADL, economic resources, social resources, physical health, mental health	12 items Self-administered
HIV/AIDS-Targeted Quality of Life (HAT-QOL) Instrument	Overall function, sexual function, disclosure worries, health worries, financial worries, HIV mastery, life satisfaction, medication concerns, provider trust	42 items Self-administered (15 min)
HIV Assessment Tool (HAT)	Physical symptoms related to HIV disease, social and role functioning, psychological well-being, and personal attitudes related to well-being	34 items Self-administered
HIV Disability Questionnaire	Describes the presence, severity and episodic nature of disability experienced by adults living with HIV using six domains of disability	69 items Self-administered (14 min)
HIV Quality Audit Marker (HIV-QAM)	Captures nurse data collector's judgment of status of patient based on observations, interviews, and recorded interviews	Varies based on duration of interview Nurse
HIV-Related Quality-of-Life Questions (HIV-QOL)	Mental health, energy and fatigue, fever, limitations of basic ADL and intermediate ADL, disability days, all symptoms, sleep symptoms, neurological symptoms, memory symptoms, pain	30 items Self-administered (5 min)
HIV Overview of Problems Evaluation System (HOPES)	Global, physical, psychosocial, medical interaction, significant others, sexual components	139 items Self-administered (15 min)
HIV Patient-Assessed Report of Status and Experience (HIV-PARSE)	Physical health, mental health, general health	38 items Self-administered (5 min)
HIV Visual Analog Scale	Rates HIV-related symptom severity and general well-being	Varies Nurse or self-administered
Idiographic Functional Status Assessment (IFSA)	Patient-generated activities associated with pursuit of following goal types: achievement; problem-solving; avoidance-prevention; maintenance; disengagement	75 items Self-administered
Medical Outcomes Study HIV Health Survey (MOS-HIV)	General health perceptions, role functioning, mental health, QOL, pain, social functioning, health distress, physical functioning, energy and fatigue, cognitive function, and health transition	35 items Self-administered or interview (5–10 min)
Multidimensional Quality of Life Questionnaire for Persons with HIV (MQOL-HIV)	Mental health, physical health, physical functioning, social functioning, social support, cognitive functioning, financial status, partner intimacy, sexual functioning, medical care	40 items Self-administered (10 min)
Neuropsychiatric AIDS Rating Scale (NARS)	Assesses patient's orientation, memory, motor ability, behavioral changes, problem-solving ability, and ADL	Varies Health care provider
The Self-Efficacy for Managing Chronic Disease 6-Item Scale	Covers several domains that are common across many chronic diseases: symptom control, role function, emotional functioning, and communicating with physicians; less subject burden than other surveys	6 items Self-administered
World Health Organization-Quality of Life HIV Instrument (WHOQOL-HIV)	Physical, psychological, level of independence, social, environmental, spiritual, general QOL and health, symptoms of HIV, social inclusion, death and dying, forgiveness and fear of death	115 items Self-administered

ADLs, Activities of daily living; AIDS, acquired immunodeficiency syndrome.

Peripheral Nervous System

Possible neurological complications associated with HIV disease that may affect the PNS include meningitis, ataxia, myelopathy, and encephalitis. PNS diseases have been reported in up to 50% of HIV-infected individuals, resulting in distal polyneuropathy, Guillain-Barré syndrome, and mononeuropathy.¹³⁹

Distal symmetrical polyneuropathy (DSP) is the most common form of neuropathy in HIV infection, impacting 30% to 60% of PLHIV.¹²⁶ The most frequent complaints in DSP are numbness, burning, tightness, allodynia, and paresthesias in the feet. These symptoms are typically symmetrical and often so severe that patients have contact hypersensitivity and gait disturbances. Involvement of the upper extremities and distal weakness may occur later during DSP. Neurological examination shows sensory loss or hyperalgesia to pain and/or temperature in a stocking-glove distribution, decreased vibratory thresholds, and diminished ankle reflexes compared with knee reflexes; proprioception is often spared.^{126,140,141} The development of DSP correlates with increased age, increased height, exposure to ART, substance use, diabetes, hypertriglyceridemia, and metabolic syndrome. Predictors for elevated levels of pain are older age, female sex, current and past ART use, lack of virological suppression, lifetime history of opioid use, and depression.¹²⁶ The pain associated with DSP typically improves if the individual is started on ART.

The incidence of DSP increases with advancing immunosuppression, in parallel with decreased CD4 counts.¹⁴² Thirty-five percent of patients with advanced HIV may have electrophysiological or clinical abnormalities.¹⁴³ Furthermore, pathological evidence of DSP is present in almost all patients who die of AIDS.¹⁴⁴ Various theories regarding the mechanism of DSP have been proposed. It was formerly thought that direct HIV invasion of the nervous system caused DSP¹²⁹; however, most investigators currently believe that this is not the sole cause.¹⁴² A “dying-back” neuropathy affecting all fiber types, with prominent macrophage infiltration of the peripheral nerve, has been described.¹⁴⁴ Additional theories include ART drug toxicity, neurotoxic effects of cytokines, toxicity of HIV proteins, and mitochondrial damage.¹⁴⁵ Cytokines, tumor necrosis factor, and interleukin-1 have been identified in the peripheral nerves of patients with AIDS.¹⁴⁶

Oral gabapentin and cutaneous lidocaine patches are often prescribed to manage pain associated with peripheral neuropathy. Evidence for physical therapy interventions for DSP is very limited. One randomized controlled trial (RCT) found decreases in pain with use of night splints.¹⁴⁷ Soft tissue massage, joint mobilization, stretching exercise, yoga and low-voltage electroacupuncture,¹⁴⁸ and electrical stimulation have also been proposed, but more research is needed to determine their effectiveness.^{149,150}

Certain ART drugs may also contribute to dysfunction of the PNS. Several NRTIs are suspected to contribute directly to peripheral neuropathy through mitochondrial toxicity (especially noted when didanosine and stavudine are used concurrently).¹²⁶ The drug stavudine has been linked to HIV-associated neuromuscular weakness syndrome.¹²⁶ This syndrome presents with acute, progressive ascending weakness (similar to acute inflammatory demyelinating polyneuropathy), lactic acidosis, and hepatomegaly.¹²⁶ Mitochondrial toxicity is thought to be the cause, and treatment is removal of the ART medication (symptoms may continue for 90 days after the drug is discontinued).¹²⁶

Balance and Postural Mechanisms

Balance disturbances may be seen with HIV involvement of either the CNS or PNS. Polyneuropathy caused by AZT (AZT polyneuropathy) and CMV (a common pathogen in advanced HIV) may manifest in the form of a generalized asymmetrical demyelination and chronic denervation of muscles.¹⁵¹ Demyelination and denervation of nerves that supply postural muscles may weaken such muscles and result in

balance problems (e.g., distal pain, paresthesia, numbness, or core weakness). It is also possible that, apart from muscle demyelination and denervation, the pathological process, which also includes macrophage infiltration of neural structures, could spread to affect the vestibular neural complex of the inner ear, which is important in the maintenance of both static and dynamic balance. Clinical reports show that sensory changes are common in the lower limbs of neuropathic HIV/AIDS patients. The balance problems of these patients are likely to be connected to a lack of adequate proprioception from the legs during stance, and it is well known that diminished sensory information makes gait control more difficult. Refer to the discussion of balance dysfunction presented earlier in this text.

Peripheral neuropathy weakens the neuromuscular system and causes a limitation in functional activities. These effects on the neuromuscular system manifest in disturbances of postural control. An appropriate posture should be regarded as the starting position for a functional activity. However, compromise of the postural pattern is so characteristic of HIV peripheral neuropathy that it is diagnostic for HIV-1 infection.¹⁵² The neurological abnormality resulting from peripheral neuropathy in HIV/AIDS produces postural disturbances¹⁵³ that may take various forms that worsen with the severity of the neuropathy¹⁵⁴ and compromise functional activity at various levels. This means that as the condition of HIV/AIDS patients deteriorates, balance deficits may increase.

According to Husstedt and colleagues,¹⁵⁵ peripheral neuropathy in HIV disease progresses much more rapidly than that associated with diabetes or hereditary polyneuropathies. Again, because of demyelination as the HIV infection progresses, distal symmetrical peripheral neuropathy increases, resulting in a depression of certain motor functions such as gait and manual dexterity, and a worsening of the condition is caused by demyelination.¹⁵⁵ There is therefore a need to treat HIV neuropathy as soon as it is diagnosed, to avoid complications that lead to impairments in functional mobility. This includes changing type of ART if necessary and evaluating fall risk, promoting pain management and fostering improvement in gait parameter.

One group⁷⁷ has identified DSP and its complications as causes of functional limitations in individuals with HIV disease. A patient who, for instance, has balance impairment resulting from peripheral neuropathy may not function effectively with ADLs. Functional impairments may impede a patient's ability to return to gainful employment. For PLHIV, peripheral neuropathy and its resulting pain may be a limiting factor in the ability to complete ADLs and IADLs. Use of the lower-extremity functional scale or the lower limb functional index may assist clinicians in identifying subtle changes over time. Our research showed significant functional differences in patients with DSP versus those without diagnosed HIV-DSP.¹⁵⁶ Emphasis on restoring range of motion through reduction of pain and improvement in ambulation skill can aid in the reduction of functional limitations should be incorporated into the rehabilitation plan of care.

Pain

Pain management is a critical part of the overall care of PLHIV. Pain is the second most common reason for hospitalization of patients with AIDS.¹⁵⁷ A study of 72 AIDS patients found that 97% had pain related to the disease process.¹⁵⁸ Newshan and Wainapel,¹⁵⁸ who surveyed 100 patients who had pain associated with AIDS, showed that the two reported pain types were abdominal and neuropathic pain. In a longitudinal study of HIV-positive men, painful peripheral neuropathy was one of the most common types of pain.¹⁵⁹

Chronic pain is one of the most prominent and distressing symptoms for PLHIV, and it has a significant effect on QOL and

psychological state. Pain may affect patients at any stage of the disease process; however, it is more frequent during the advanced stages. A systematic review in 2014 found the occurrence of moderate to severe pain for PLHIV varies from 54% to 83%¹⁶⁰; this review also noted that there was less than adequate treatment of pain in the reported studies. Pain is the result of a complex process that involves psychological and neurophysiological mechanisms, and therefore it should be assessed with use of sensitive tools that examine its multidimensional nature. One model that evaluates the evaluative, affective, and sensory aspects of pain is the McGill Pain Questionnaire. This assessment tool is useful in evaluating HIV disease-related pain because different causes and nonsensorial factors related to the disease often make clinical assessment of pain difficult.¹⁶¹

Chronic pain in PLHIV may be attributable to a specific condition but is often multifactorial; it can be related to direct effects of HIV infection, chronic inflammation and immune activation, side effects of ART drugs or other drugs, neurological mechanisms, comorbidities/multimorbidity, opportunistic infections, aging, psychosocial influences, prescription opioid misuse and heroin use, and/or gender and ethnic differences in perception and expression of pain.^{162–164} The most common characteristics of chronic pain in PLHIV are spinal pain, arthralgia, and neuropathic pain.¹⁶⁵ Pain in PLHIV has been shown to greatly increase the odds of impairments in mobility, self-care, and usual activities.¹⁶⁶

Most PLHIV require various pain treatment interventions. Common options for pain management include nonopioid-based pharmacological therapy (acetaminophen, nonsteroidal antiinflammatory drugs, anticonvulsants, antidepressants, and topical agents), opioid therapy (which is no longer supported as the choice intervention for chronic pain), and nonpharmacological approaches (including cognitive-behavioral therapy, acupuncture, and physical therapy); recent findings are supporting that these nonpharmacological approaches to chronic pain are the most effective.^{164,167} A 2016 review found that of 11 studies of pharmacological and nonpharmacological treatments for chronic pain in PLHIV, only capsaicin and cannabis have positive results.¹⁶⁷ There is a paucity of published research regarding physical therapy and other nonpharmaceutical interventions to manage chronic pain in PLHIV, although there some evidence to suggest a favorable role for exercise, self-management programs, and patient education.^{168–170}

As discussed previously, distal symmetrical peripheral neuropathy has been shown to be the most common peripheral neuropathy complaint in patients with HIV-1 infection.^{171–173} Peripheral neuropathy is one of the most common types of pain in HIV-positive men,¹⁵⁹ and peripheral neuropathies occur in as many as 40% to 60% of PLHIV. Peripheral neuropathy is the most prevalent neurological complication associated with HIV. CNS or PNS involvement has been found in 30% to 63% of patients across the arena of HIV and is often related to ART.¹⁷⁴ When neuropathy results in distal painful paresthesia, imbalance in stance and gait may result from compensatory measures aimed at relieving pain in dynamic standing activities. Postural compensations may further exacerbate musculoskeletal, cervical, thoracic, or lumbosacral back pain. DSP results in painful paresthesias that are challenging to treat with pharmacological interventions. Refer to the earlier section on the Peripheral Nervous System for more about management of pain associated with DSP.

Psychopathology

Medical and neuropsychiatric sequelae of HIV infection present a spectrum of diagnostic and treatment challenges to health care practitioners. Both HIV infection and the various opportunistic infections that manifest in patients as the result of an immunocompromised state

can affect the CNS. Epidemiological studies indicate that greater than 60% of PLHIV will experience at least one major psychiatric disorder during their infection. Depression is the most common disorder, closely followed by anxiety and substance abuse disorders.¹⁷⁵ It is estimated that between 18% and 81% of PLHIV will experience depression¹⁷⁶; this may be further impacted by ART side effects. A 2017 systematic review attempted to determine the prevalence of anxiety in PLHIV. The study found a median value for anxiety disorders to be 22.85% (nearly 5% higher than the general population); this can be divided into panic disorders at 10.26% (7% higher than the general population), generalized anxiety disorder 5.6% (2% higher than the general population), and social anxiety disorder 9.1% (3% higher than the general population).¹⁷⁷ Studies have found that high levels of anxiety are related to lower QOL, poor medication compliance, and higher frequency of substance abuse.¹⁷⁷ Therefore therapists need to be familiar with the diagnosis and management of HIV infection-related medical and psychiatric disorders. These disorders have a great impact on the outcomes of rehabilitation.

Careful consideration of psychological function is warranted during clinical encounters with PLHIV. HIV-related psychopathologies mimic many previously described consequences of primary HIV infection, opportunistic infections, and drug side effects. These psychiatric complications can be affective or organic. Indicators include disturbances in sleep and appetite patterns, diminished memory and energy, psychomotor retardation, withdrawal, apathy, and emotional lability. Anxiety disorders (particularly posttraumatic stress disorder), adjustment reactions, reactive and endogenous depressions, and obsessive disorders frequently result.^{178–180}

With use of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision, one study found axis I disorders (excluding substance abuse) in 61.9% of the subjects.¹⁸¹ Indeed, the virus's affinity with subcortical structures of the CNS that regulate affect and mood supports research indicating a prevalence of manic episodes that is 10 times higher than in the general population.¹⁸² Manic episodes have been identified at all stages of the disease process and may also occur in response to AZT therapy.^{21,52,183} When associated with HIV infection, mania appears to be secondary to structural CNS changes.^{184,185} Described manic episodes generally respond well to psychiatric medications and may not recur.^{52,186–188}

Analyses of new-onset psychosis among PLHIV yielded the following information. Psychotic episodes are preceded by a period (days to months) of affective and behavioral changes.¹⁸⁹ Admitting diagnoses to psychiatric units included "undifferentiated schizophrenia, schizophreniform disorder, "reactive psychosis," atypical psychosis, depression with psychotic features and mania."¹⁸⁹ Some psychiatric diagnoses were revised during the course of hospitalization to "AIDS encephalitis, cryptococcal meningitis, or 'organic psychosis.'"¹⁹⁰ Eighty-seven percent of the subjects in one study displayed delusions that were usually persecutory, grandiose, or somatic. Affective disturbances were present in 81% of the subjects. Hallucinations and thought process disorders were each prominent in 61% of patients. Several subjects received the diagnosis of AIDS during their psychiatric hospitalization.¹⁹⁰

Remarkable progress has been made in recent years in the therapeutics of HIV-associated dementia. Viral replication in and outside the CNS has been greatly reduced by ART. This has resulted in partial repair of cellular immune function with improvement in, and prevention of, neurological deficits associated with HIV disease.¹⁹¹ Extensive use of PIs is associated with dramatic declines in overall mortality and morbidity, including HIV-associated dementia.^{44,192}

Neuropathological abnormalities seen in the brain tissue of patients with HIV-associated dementia are usually diffuse and

predominantly localized to the white and deep gray matter regions. Myelin pallor and inflammatory infiltrates composed of macrophages and multinucleated giant cells are the hallmarks of this disease process, although a spectrum of lesions has been identified from encephalitis to leukoencephalopathy.^{193,194} The characteristic clinical feature of HIV-associated dementia is disabling cognitive impairment, often accompanied by behavioral changes, motor dysfunction, or both.¹⁹⁴ Degrees of impairment have been recorded, and a five-part staging system was subsequently developed.^{195–197} Motoric manifestations of HIV dementia complex include gait disturbances, intention tremor, and abnormal release of reflexes.

Differentiation between psychiatric and physiological manifestations is complicated. Psychiatric and organic disorders are initially indistinguishable based on behavior and may exist concurrently. Furthermore, other primary disease processes and drug reactions imitate psychopathological conditions. Differentiation is nonetheless essential because many disorders respond well to established therapies, both psychological and pharmacological, once differential diagnoses have been established. Research is supporting the use of psychosocial interventions, such as cognitive-behavioral therapy, over the previously preferred pharmacological interventions.¹⁹⁸ Awareness of the intricate interplay of all factors is essential for competent rehabilitative efforts for PLHIV.

PEDIATRIC HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Pediatric HIV infection differs from that most commonly seen in adults. Symptoms develop much earlier in pediatric patients compared with adults. Children infected with HIV may be classified as “rapid progressors” or “slow progressors.” Rapid progressors are children infected with HIV who manifest symptoms within the first 12 to 24 months of life. These children progress quickly to AIDS-defining conditions and have a rapid decline in CD4 count. Children who are slow progressors have a more gradual progression of symptoms and are likely to show evidence of immune system compromise by 7 to 8 years of age. A small percentage of children remain healthy and have only nominal or no symptoms of the disease and a normal to slightly decreased CD4 count through 9 to 10 years of age.¹⁹⁹

An accurate understanding of the timing of HIV transmission from mother to fetus is important for the design of intervention strategies. The AIDS Clinical Trial Group (ACTG) study 076, which included treatment from the 14th week of gestation in women with CD4 counts of more than 200/ μL , prompts other considerations.²⁰⁰ Onset of HIV-1 infection in children has a wide spectrum of clinical manifestations.²⁰¹ Thus prevention of transmission from mother to fetus via ART is a critical component of managing this worldwide epidemic. The WHO recommends that all HIV-positive women who are pregnant or breastfeeding should receive ART regardless of clinical stage or CD4 count.²⁰² Without ART intervention, transmission rates from HIV positive mother to child range from 15% to 45%; with effective treatment, the transmission rate is less than 5%.²⁰² In 2016, clinical guidelines recommended starting ART in all pediatric HIV cases, regardless of age or immunological status.²⁰³ Support for this recommendation resulted from the findings of the South African Children with HIV Early Antiretroviral Therapy (CHER) randomized trial; this study showed a reduction in mortality by 76% among infants randomized to immediate ART, compared with those who were given deferred ART.²⁰³

Pediatric HIV is neurotrophic in nature in that the virus most often initially affects the CNS rather than the PNS. As the virus spreads, pediatric HIV patients can have CNS disorders that include encephalopathy, pyramidal tract signs, receptive and expressive language

difficulties, cognitive deficits, psychomotor impairments, and upper respiratory infections.¹⁹⁹ Neuroimaging shows HIV has an influence on neurological function in the basal ganglia, frontal cortex, and other connecting structures in the CNS. Studies also support that there is an environmental component that contributes to developmental and behavioral issues in HIV-positive children.²⁰⁴

In the first year of life, severe immunodeficiency develops in 15% to 20% of pediatric patients with serious recurrent infections or neurological dysfunction, whereas in school-age children the disease progresses more slowly and the risk for development of HIV-related encephalopathy becomes less.²⁰⁵ Some infants have features of severe immunodeficiency, whereas others have nonspecific findings, such as hepatosplenomegaly, failure to thrive, unexplained fever, parotitis, and recurrent gastroenteritis. Adenopathy is common, and salivary gland enlargement occurs more frequently than in adults. Otitis media and measles, despite immunization, are also more frequent complications in children.^{67,107} Cardiac involvement in children with HIV infection is a well-known entity and occurs clinically more often in patients with advanced disease.²⁰⁶

Studies have shown that children diagnosed with HIV demonstrate behaviors often associated with attention-deficit/hyperactivity disorder (ADHD), including impulsivity, hyperactivity, difficulty attending, and decreased ability to focus on stimuli. In one study, the most common behavioral issues were psychosomatic disorders (28%), learning disorders (25%), hyperactivity (20%), impulsive-hyperactive disorder (19%), conduct problems (16%), and anxiety (8%); standardized intelligence scores were lower compared with established population norms. Hyperactivity was more common in children with a Wechsler IQ less than 90, anxiety issues were more common in children older than 9 years, and conduct disorders were more often seen in children with CD4 counts less than 660 cells/ μL .²⁰⁴ HIV-positive children are noted to have lower cognitive and motor development scores on standardized testing, as compared with healthy, unexposed children.²⁰⁷ In one study, HIV-positive children who had exposure to ART scored worse than HIV-positive children who were untreated.²⁰⁷ This result should be interpreted cautiously; it does not indicate that children should not be treated, but it does provoke concerns about the impact of potentially neurotoxic medications in the developing brain.

Children are also susceptible to disorders seen in adults, especially opportunistic infections such as herpesvirus, pneumonia, toxoplasmosis, meningitis, and encephalitis. HIV encephalopathy is noted to have the most serious side effects because of its progressive deteriorating pattern and associated CNS abnormalities,²³ although static encephalopathy can be characterized by severely delayed cognitive functioning and neuromotor skills without deterioration.²⁰⁸ Manifestations in children include cerebral atrophy, ataxia, rigidity, hyperreflexia, and the inability to achieve or sustain developmental milestones. Although the HIV neurodevelopmental involvement causes a prognostic worsening, most studies of pediatric cases of advanced HIV with neurological involvement demonstrate that an early diagnosis followed by adequate antiretroviral therapeutic regimens can lead to significant, even if temporary, improvement.²⁰⁵

Rehabilitation of the pediatric patient requires a multidisciplinary approach to meet the medical, emotional, and psychosocial needs of these children and their families. Children are encouraged to give form to their psychological experiences through play, writing or telling stories, and creating works of art.²⁰⁹

REHABILITATION INTERVENTIONS

The examination procedures for HIV illness are broadly outlined in the following paragraphs. Of course, each case brings about its

own unique challenges, and the evaluation process is individualized according to the specific needs of the patient (Box 34.1). Due to the widespread use of ART and improved health education program, HIV is currently considered a chronic disease, characterized by episodic disability, rather than the progressive decline to AIDS. PLHIV who are on a successful ART regimen are able to live normal life-spans and be more productive in their own lives and in their communities. Rehabilitation professionals are seeing a different HIV patient as compared with when the epidemic first began. A condition once characterized by opportunistic infections and wasting syndrome is currently characterized by obesity, lipodystrophy, and CVD; this requires rehabilitation professionals to take a more holistic approach to patient care and will require interprofessional collaboration to achieve optimal patient outcomes.

What is the relationship of the PLHIV to the environment, both at present and in the future? The rehabilitation therapist should keep this question in mind throughout the examination process. In this context the term *environment* is meant to include not only the physical aspects of surroundings but also the psychological and emotional climate in which the individual functions (see Table 34.1).

The examination process has a different focus for different stages of the disease. If the patient is in the early stages of the disease, the therapist should determine whether she or he is still managing in accustomed life roles. Important issues may include new or adapted vocational and leisure skills. During the advanced stage, the focus may change to more basic daily functional concerns and ADLs. However, the therapist must remember that the patient may place more importance on participation in avocational interests than on independent self-care. This choice is valid and must be respected and supported by health care professionals. If the patient is evaluated in an inpatient setting, another crucial determination to be made is whether the person is to be discharged to home or some other supervised setting. It is critical to determine what kind of community-based support networks are available to the individual. Case managers or social workers are often adept at identifying home and community resources available and will assist in setting up these resources before the patient's discharge. Rehabilitation professionals need to collaborate with a variety of health care providers to achieve optimal outcomes for PLHIV. This includes physicians, nurses, social workers, case managers, recreational therapists, physical therapists, occupational therapists, speech-language pathologists, occupational health and safety officials, psychologists, and any other professions that may play a role in assisting the patient maximize their physical and emotional well-being.

Astute evaluative questions about the psychosocial status of the patient include the following:

- Does the patient's perception of his or her status and prognosis agree with that of the treatment team?
- What is the patient's predominant coping style?
- Who are the patient's caregivers?
- What is the social support system?
- What is the patient's home environment?
- What is the patient's prior level of function?

The support system can be a critical issue for many PLHIV, especially those who are part of the high-risk groups, such as homosexual and bisexual men and intravenous drug users.²¹⁰ Many of these people have traditional networks of family, spouse, and friends; a significant number have equally strong nontraditional support systems. Some will be lacking in the kinds of support needed to cope with the devastating physical and emotional effects of the disease and the need for chronic medical interventions.

It is possible to use models developed for oncology and progressive neurological disorders for HIV involvement of the CNS and PNS. An orthopedic approach may be taken when pain is a presenting factor or biomechanical alterations are a result of other disease processes. Functional fluctuations that characterize HIV infection and secondary infections must be understood; the therapist must appreciate the effects that HIV infection has on various body systems and the resultant secondary complications.

The examination of an individual who has HIV disease should include standard cognitive, perceptual, and sensory and motor function evaluative tools. The idiosyncratic nature of the disease may necessitate more detailed evaluation of these specific areas. It is recommended that cognitive and perceptual evaluations are both formal and observational. Safety, judgment, functional mobility, ADL management, community management skills, and independent financial management skills need to be assessed. Evaluation of the systemic

complications of HIV infection is necessary for optimal rehabilitative planning and treatment team efficacy.

The ADL evaluation is best made within the context of the immediate and projected life roles of the individual. Maximal independent functioning is the goal of rehabilitation, whatever the stage of illness. If the person is at home or is being discharged to home, a crucial component of the ADL examination is the assessment of community management skills; consider the individual's access to transportation, socialization opportunities, shopping, and banking. The ability to negotiate health care and insurance systems and participate in community activities is critical to returning to independence. Many PLHIV and their caregivers have minimal experience with disability because of their age or social status. This, combined with the stressors of a chronic illness, can create unrealistic expectations and unnecessary frustrations.

Rehabilitation Process

The neuromuscular rehabilitation intervention procedures for HIV infection and an overview of treatment techniques for opportunistic infections are presented in [Box 34.2](#).

Cognitive deficits in attention, concentration, and memory necessitate consistency, structure, and environmental cues to minimize

confusion. Safety and judgment deficits can be countered by environmental adaptations. Lethargic patients benefit from sensory enhancement. Maintenance of endurance, strength, and passive and active range of motion are important components of any motor function treatment plan. Neuromuscular facilitation and inhibition, positioning, and splinting are feasible modalities to normalize tone as needed. Gait training, the use of assistive devices, training in motor planning, balance activities, and endurance exercises may be appropriate.

In addition to techniques and modalities, active listening, empathy, and unconditional positive regard are important aspects of the therapeutic process. The clinician must set aside personal biases and beliefs to accurately hear the perspective of the individual patient. The use of expressive modalities facilitates the development of coping skills while providing appropriate exploration and release of powerful emotions. Human touch can counter the powerful and isolating effect of fear of contagion. Rehabilitation therapists can demonstrate and educate caregivers about the safety and benefit of therapeutic touch.

Motoric manifestations of HAND and HIV infection-related dementia include gait disturbances, intention tremor, and abnormal release of reflexes. Rehabilitation and progression of independent functional mobility become more complex in these patients secondary to the cognitive involvement.

Pain management is best approached through a biopsychosocial lens. Pain reduction is achieved through training in cognitive-behavioral therapy, meditation, breathing techniques, visualization, progressive muscle relaxation, autogenics, music, meditation, and engagement in meaningful activities. Various forms of electrotherapy such as electroacupuncture, thermal agents, and manual therapy are useful therapeutic tools.

The impact of HIV infection can be evident in cerebral, emotional, psychosocial, and other physical domains, affecting the PLHIV and those around her or him. The prognosis and psychological and physical consequences of HIV infection are associated with significant emotional distress and clinical syndromes, such as adjustment disorders, depression, and anxiety in some patients.²¹¹ Increasing focus is being placed on the potential impact of HIV infection-related stress on the course of infection because of the observed and postulated relationship between psychosocial stress, neuropsychological functioning, and immune status.²¹² Minimizing stressful events throughout the management of chronic HIV infection can be approached in various ways, such as meditation, cognitive-behavioral therapy, relaxation, and various forms of exercise.

Exercise

Exercise is an intervention commonly used by movement specialists to address a multitude of impairment and functional limitations. Thus understanding of the implications of the HIV disease process on exercise prescription is important. A review of published studies²¹³ on the effects of exercise on individuals with HIV disease revealed the following: (1) although intense bouts of exercise may result in transient immunosuppression, there is no evidence that regular exercise by individuals with HIV disease results in a detrimental effect on the immune system over time, (2) some studies have shown actual improvement in immune system function in response to regular exercise, (3) improved cardiovascular function has been observed in response to aerobic exercise, and (4) resisted exercise may be effective in counteracting the effects of wasting syndrome and improving strength and lean body mass. A systematic review of progressive resistive exercise (PRE) showed that PRE or a combination of PRE and aerobic exercises lead to statistically significant increases in weight, arm girth, and thigh girth. Trends were also found supporting an improvement in submaximal heart rate and exercise time. In addition, PRE was found to

contribute to improved strength and psychological status and to be safe and beneficial for medically stable HIV-positive adults.²¹⁴

From a psychoneuroimmunological perspective, psychological stress has been implicated among the cofactors that contribute to the immunological decline in HIV disease. Good evidence supports the stress management role of exercise training to explain a buffering of these suppressive stressor effects, thereby facilitating a return of the CD4 cells. Early intervention with exercise, in compliance with guidelines, is most prudent to stave off opportunistic infections throughout the spectrum of HIV disease.

Precautions and Concerns During Exercise

It is important to address any orthopedic or neurological concerns before embarking on an exercise or movement therapy program. If musculoskeletal problems exist or other pain symptoms are present, a concerted effort to modulate pain is necessary for the successful completion of an exercise regimen.²¹⁵ If HIV-related peripheral neuropathy exists, it is important to implement proper foot care and supportive shoes when weight-bearing activities are performed.^{77,216} In addition, appropriate safety measures, such as guarding during balance activities, should take place when working on exercise programs with patients who have decreased balance and postural stability.

There is some concern about aerobic exercise increasing the body's metabolic rate and thus increasing additional muscle loss. However, with a balanced diet and incorporation of a sound nutritional program, this should not pose a problem for the asymptomatic PLHIV. If wasting is present, the cause needs to be addressed and treatment rendered.⁵³ One study determined the contribution of total energy expenditure to weight changes in individuals with HIV infection-related wasting. The researchers observed a significant positive relation between total energy expenditure and the rate of weight change. During rapid weight loss, total energy expenditure fell from an average 2750 kcal/day to 2189 kcal/day. The key determinant of weight loss in HIV infection-related wasting, they concluded, was reduced energy intake, not increased energy expenditure.²¹⁷

If fatigue is present as a symptom, a differential diagnosis for anemia, low albumin, low testosterone levels, and/or specific vitamin deficiencies must be made before any exercise regimen is begun. Proper caloric intake must be adequate to meet the energy expenditure required for the activity. Seeking the advice of a nutritionist is recommended for proper guidance. Education about sleep hygiene may also be beneficial if restorative sleep is not being achieved.

Evidence of autonomic neuropathy (a peripheral neuropathy that affects involuntary body functions including heart rate, blood pressure, perspiration, and digestive functions) on provocative testing is common in HIV infection, with estimates of incidence ranging from 30% to 60%.^{218,219} Underlying cardiac parasympathetic dysfunction may need to be assessed throughout the course of HIV disease. One method described by Mallet and coworkers²²⁰ is the use of the 4-second exercise test, which consists of pedaling an uploaded ergometer at maximal individual speed from the fourth to the eighth second of a 12-second maximal inspiratory apnea. From an electrocardiogram, vagal activity is estimated through a ratio. In that study, subjects were subjected to respiratory sinus arrhythmia, which is a valid method to detect vagal dysfunction. The researchers found that there was a tendency for lower values of the vagal function test in HIV-positive subjects. Vital sign monitoring is prudent throughout any exercise regimen. Exercise can help control long-term side effects, including altered body composition; elevated cholesterol, triglyceride, and blood glucose levels; and elevated blood pressure.²²¹ Certain comorbidities associated with HIV disease, such as inflammatory myopathy, acute infectious arthritis, or compromised cardiac status, may result in restrictions on exercise prescription.²¹³

A supervised training program should be consistent with recommendations of the American College of Sports Medicine. Guidelines have been established for the spectrum of the stages of HIV disease.²²¹ During the stage of asymptomatic HIV disease, there are no limitations on maximum graded exercise testing. Exercise should consist of resistance training, cardiovascular training, flexibility training, balance training, and mind-body training.²²¹ In this stage, all metabolic parameters are within normal limits for most individuals. Thus unrestricted activity is generally encouraged. Most sports do not pose a significant risk of HIV transmission. However, sports such as boxing, in which there is a risk of open wounds and contamination with infected blood, should be viewed with great caution.²¹³

Exercise is safe and beneficial for most individuals with HIV disease; however, caution is warranted with symptomatic HIV disease and advanced HIV disease. In individuals with symptomatic HIV disease, there may be reduced exercise capacity, Vo_{2max} , and oxygen (O_2) pulse max. There may also be other cardiovascular and pulmonary problems, anemia, and peripheral muscle abnormalities. Pain, side effects of medications, psychosocial issues, and unplanned events may also create obstacles to exercise for individuals in the symptomatic or advanced stage of HIV disease. For individuals with cardiac myopathy or hyperlipidemia, submaximal aerobic capacity testing should be followed with a staged cardiac rehabilitation program⁹¹ because of the risk of cardiac failure in patients with compromised cardiac status.²²²

Patients with AIDS have dramatically reduced exercise capacity, vital capacity, Vo_{2max} , and O_2 pulse max. Elevated heart rate and breathing reserve persist in this stage. Neurological dysfunction, opportunistic infections, and progressive disability indicate a need for careful monitoring of the exercise program during this stage of the disease. In general, individuals with advanced HIV disease should remain physically active and exercise on a symptom-limited basis. Precautions related to comorbidities should be implemented. Individuals in this stage of the disease are at greater risk for exercise-induced injuries as a result of chronic tissue changes in both muscle and peripheral nerve. For individuals with severe morbidity and extensive disability, treatment should emphasize enhancement of basic functional tasks, ADLs, and energy conservation.²¹³

As the number of older adults with HIV increases, it is important to analyze increased risk for frailty. Frailty indices have been used to establish diagnostic criteria. However, it is generally recognized as an accumulation of deficits in functional capacity and ability to perform ADLs. Using the Fried phenotype, PLHIV can be evaluated for (1) unintentional weight loss; (2) reduced walking speed; (3) weakness as measured by a grip dynamometer; (4) exhaustion by responses to a depression scale; and (5) low physical activity determined by assessing caloric expenditure.²²³ Frailty may be present in up to half of older adults living with HIV and is associated with significant morbidity and mortality risk in this group.²²⁴ Frailty in HIV can either be transient, and linked to the status of HIV-infection, or resemble a more typical gradual decline in functional capacity. Several tools have been developed and adapted to assess different domains of frailty, yet medical treatment of this condition can be complex and should include interprofessional management with appropriate medication, nutrition services, and exercise interventions. However, few concrete strategies have been developed to prevent, or treat, frailty in the context of HIV infection.²²⁴

Psychoneuroimmunology: Prevention and Wellness in Human Immunodeficiency Virus Infection

Psychoneuroimmunology-based interventions are used to attenuate disease progression and/or side effects of pharmacological treatment. It is the field that investigates the interrelationships among

psychological constructs (e.g., stressors and mood states) of the neuroendocrine and immune systems. Psychoneuroimmunology offers a useful framework for our understanding of how stressors play a role in immunomodulation. The progression of HIV disease can be modulated by psychosocial factors and by factors such as the viral strain, genetic characteristics of the host immune system, coinfections with other pathogenic organisms, and health maintenance habits (diet, exercise, medical treatments).²²⁵ These factors may have a profound influence on the occurrence and progression of ill health in chronic diseases such as HIV infection.

Findings of studies related to psychoneuroimmunology suggest that it is useful to evaluate the influence of behavioral factors on immune functioning and disease progression in PLHIV.^{226–228} The stress response is physiologically mediated by certain immune parameters (catecholamines and glucocorticoid hormones). A study by Leserman and colleagues²²⁹ in 2002 concluded that “stressful life events, dysphoric mood, and limited social support” are correlated to the increased rate of progression from initial HIV infection to AIDS.²²⁹ Behavioral interventions with immunomodulatory capabilities may help to restore competence and thereby slow the progression of HIV disease, especially at the earliest stages of the infectious continuum.

A growing body of literature indicates that many different stressors have deleterious effects on the immune system.²³⁰ It has been well documented in healthy individuals that changes in immune function and disease susceptibility are correlated with times of “psychic distress.”²²⁵ These stressors in the case of PLHIV infection may be attenuated by an exercise training program. Research indicates that continued aerobic exercise training may result in increased CD4 cell counts, heightened immune surveillance, and a potential for a slowing of disease progression.²²⁸ Other researchers have demonstrated similar benefits of exercise for PLHIV who are at more advanced stages of disease. However, these are studies conducted on traditional modes of exercise and do not investigate alternative activities such as yoga or tai chi.

A recent systematic review evaluated the different therapeutic and/or clinical psychoneuroimmunology-based interventions associated to both psychological, neuroendocrine, and immunological variables. Decreased levels of epinephrine, norepinephrine, and cortisol were associated to interventions including tai chi, yoga, meditation, acupuncture, mindfulness, religious/spiritual practices, cognitive behavior therapy, coping, and physical exercises. From a biophysical perspective, those interventions were also associated with reduced inflammatory processes and proinflammatory cytokines in cancer, HIV, depression, anxiety, wound healing, sleep disorder, CVD, and fibromyalgia.²³¹ A holistic rehabilitation approach to PLHIV is key to successful outcomes.

Complementary and Integrative Therapies in Human Immunodeficiency Virus Infection

There is substantial evidence to suggest that traditional, aerobic, and progressive resistance exercises can provide notable physiological and psychological benefits for most individuals, especially those with chronic diseases. However, the mode, duration, and intensity of many traditional standardized exercise programs may not always be entirely appropriate during episodic illness. The stage of disease and the type of illness itself may preclude more strenuous exercise activities at various times. During such times, less strenuous movement therapies may prove to be more appropriate and efficacious. In fact, movement therapy includes several similar constructs used in physical therapy and can be quite complementary to an individual’s program of more traditional exercise.^{232,233} Refer to Chapter 39 for additional information.

The US National Center for Complementary and Integrative Health (NCCIH), formerly National Center for Complementary and Integrative Medicine (NCCIM), established five medical system categories: whole medical systems, mind-body medicine, biologically based practices, manipulative and body-based practices, and energy therapies. Whole medical systems include homeopathy, naturopathy, traditional Chinese medicine and Ayurveda. Mind-body medicine includes meditation, prayer, mental healing, tai chi, yoga, art therapy, music therapy, and dance therapy. Biologically based practices include dietary and herbal supplements. Manipulative and body-based practices include massage and spinal manipulation. Energy-based therapies include qi gong, reiki, therapeutic touch, healing touch, and electromagnetic therapy. The NCCIM, the Alternative Medicine’s Strategic Plan, and the Healthy People 2020 envision a society in which all people live long, healthy lives.^{234,235}

Research findings indicate that the use of complementary and integrative medicine (CIM) is often greater among people living with a chronic or life-threatening illness compared with the general population. For example, chronic pain occurs in as many as 85% of individuals with HIV and is associated with substantial functional impairment, and many PLHIV seek integrative therapies for relief.¹⁶⁷ Little guidance is available for HIV providers seeking to address their patients’ chronic pain, especially in the current opioid epidemic in the United States. A recent systematic review found seven studies examined pharmacological interventions (gabapentin, pregabalin, capsaicin, analgesics including opioids) and four examined nonpharmacological interventions (cognitive behavioral therapy, self-hypnosis, smoked cannabis). The only controlled studies with positive results were of capsaicin and cannabis and had short-term follow-up (≤ 12 weeks).¹⁶⁷

Recent investigators evaluated the experiences and perceptions of people using integrative therapies considering the prevalence of CIM use within this population. In the United States and Canada, the rate of CIM use among HIV-positive persons is approximately 50% to 70%, whereas in Africa, rates of CIM use range from 36% to 68%. Popular forms of CIM among PLHIV include herbal or nutritional supplements, mind and body practices, and spiritual or religious healing. Worldwide, only a small percentage of persons who have access to ART refuse to take them and use CIM exclusively to treat their HIV infection.²³⁶

PLHIV with HIV often report using CIM because of side effects of medication, and they believe these therapies will improve their overall health and well-being. Furthermore, it provides an opportunity to take some responsibility in managing their personal health. Understanding CIM use is essential so that health professionals will have the most accurate information about which integrative therapies may or may not be helpful for PLHIV.²³⁶ The Institute of Medicine report entitled *Integrative Medicine and Patient Centered Care* encourages health professionals to find innovative ways of obtaining evidence and expanding knowledge about diverse interpretations of health and healing.²³⁷

The HIV epidemic has resulted in an increase use of integrative therapies, some more traditional than others.²²² Estimates show that 53% of PLHIV in the United States report the use of at least one CIM therapy.²³⁸ Approximately one-third of HIV patients in a recent cross-sectional study used CIM, but virtually none informed their health care provider. Medicinal herbs were the most common type of CIM, followed by spiritual therapy and vitamins, and a patient’s decision to use CIM was influenced for the most part by the mass media and non-hospital health care personnel.²³⁹ This is concerning because drug-herb interactions may render ineffective ART for viral suppression. Given people’s diverse health-seeking practices, biomedical providers need to recognize the cultural importance of traditional health

practices and routinely initiate respectful discussion of traditional medicine use with individuals from various cultural contexts.²⁴⁰

The impact of yoga has shown promise for PLHIV. A significant improvement in QOL scores was observed for three health-related QOL domains through Sudarshan Kriya yoga, with improvements in physical and psychological states of PLHIV.²⁴¹ A pilot study incorporating yoga and meditation showed a high level of feasibility and acceptability and modest effects on measures of QOL among PLHIV who use crack cocaine.²⁴² Yoga is a safe and inexpensive format to improve QOL in a population that has many medical difficulties and extenuating stressors.²⁴² Research has shown yoga has impact on HIV-related neuropathy with improvements in flexibility, balance, and gait speed.¹⁵⁰ Further yoga-based research is needed to explore the many complex dimensions of chronic HIV disease. Overall, use of integrative therapies can have preventative and additive impact on holistic treatment of PLHIV.

Social Interactions and the Association With Disease Management

The process of grieving is often mistakenly associated solely with the death of another. It is a natural reaction to loss, including the loss of one's own health and diminished independence. Loss of abstract human qualities, such as perceived attractiveness and productivity, results in grief. Such emotions are often difficult for a patient to articulate. It is the therapist's responsibility to be sensitive to the patient's individualized grief pattern (see Chapter 5).

Placement issues accompany discharge planning from acute health care facilities. The rehabilitation professional is often called on to make recommendations regarding the level of assistance the patient will need. All the previously discussed areas of cognitive-perceptual, sensorimotor, and ADL management, combined with available psychosocial and practical support, influence these recommendations. Options include a return to independent living and work, assisted independent living with help from a loved one, home with supportive services (often supplied by community-based AIDS organizations), home with

hospital-based home care, hospice, assisted living facility, level I (inpatient acute) rehabilitation, level II (subacute) rehabilitation, or an extended care facility.

Literature on long-term survivors with advanced HIV is replete with anecdotal evidence linking survival to one or more of the following: (1) holding a positive attitude toward the illness, (2) participating in health-promoting behaviors, (3) engaging in spiritual activities, and (4) taking part in advocacy activities related to the HIV community.^{195,243,244} Positive relationships have been demonstrated between hardiness and perception of physical, emotional, and spiritual health, participation in exercise, and the use of special diets.^{245–247}

Research provides support for the hypothesis that interpersonal relationships influence patterns of physiological functions. Data from experimental studies have shown that social contact can serve to reduce physiological stress responses.^{248,249} Community-based studies have also shown negative associations between reported levels of support and physiological parameters such as serum cholesterol, uric acid, and urinary epinephrine levels.²⁴⁹ Studies of immune function have demonstrated that social relationships have both positive and negative impacts on immune function. Loss of a partner to cancer or HIV, family caregiving for patients with Alzheimer disease, and divorce or poor marital quality all show negative associations with immune function, whereas more supportive relationships are associated with better immune function.²³⁰

Exercise and movement therapy in a group context may provide the socialization necessary to foster these physiological changes and adherence to an exercise regimen. Another area of potential socialization is the workplace. The QOL issues for PLHIV are becoming more complicated as more people with the disease achieve higher CD4 counts and lower viral load levels. Improvement in health status is directly related to the improved effectiveness of newer treatment regimens, and many individuals are improving enough to either continue working or reenter the work force. Exercise and movement therapy may augment the stress and fatigue that may be associated with the adjustment to the workplace.

SUMMARY

Research and resultant treatments are extending lives so that more people require rehabilitative services that maximize function and QOL. Medical management has focused on the treatment of reducing viral load, preventing secondary illnesses, and improving the immunological status of those with chronic HIV disease. Examination of the neuromusculoskeletal system and interventions for PLHIV disease are similar to those for other progressive neuromusculoskeletal disorders. HIV disease should be addressed like other life-altering diseases such as cancer, but with an emphasis on cognitive and perceptual function. Rehabilitation interventions should focus on specific impairments, disabilities, and psychosocial ramifications of the disease. Adaptive compensations, mobility, ADL retraining, pain control, and community management skills constitute a well-developed treatment plan.

The HIV epidemic is a major challenge on both a personal and professional level because of the continued natural fear of contagion. The illness originally appeared in subcultures that are often disenfranchised. Social, racial, economic status, and controversial behaviors contribute to prejudice, fear, and limited access to health care. Rehabilitation professionals have responded significantly to this challenge. Continued advocacy and compassion combined with professional enlightenment will, in a small way, alter the course of the disease.

Future Directions for Research

Although the primary focus of most research into HIV is focused on the eradication of the disease through potential vaccine development and expanding the development of effective pharmaceutical interventions that eliminate disease progression, transmission, and HIV drug resistance, novel treatments based on immunotherapy, which has been showing great promise in cancer research and clinical treatments, may prove to be an approach to treating and preventing HIV disease.

Research also needs to focus on optimal management of the comorbid conditions now associated with chronic HIV disease. The issue of HIV disability warrants a careful investigation into our current health care system. Many long-term survivors with chronic HIV, who formerly received a disability ranking, are potentially able to return to work. However, their grave concern about the long absence from work, reflected in the resume, and fears about potential opportunistic infections while on the job require specific strategies. Vocational rehabilitation and on-the-job counseling are necessary for optimal return to work. The systemic issues of acquisition of disability and the loss of all benefits when one relinquishes disability are quite complicated and overwhelming. The diagnosis of advanced HIV disease is a determining factor for disability, and many PLHIV with CD4 counts less than 200/ μ L have experienced considerable improvement in their

immunological status with a concomitant drop in viral load. Prognosis for these individuals has great variability. Promoting QOL may be greatly enhanced using complementary therapies. An integral aspect of self-perception is often the role played in society. The workplace affords individuals a sense of identity and a self-sustaining purposefulness.

Therefore our health and governmental systems need to conduct further research on return-to-work outcomes, with ease of transition and on-the-job accommodations when necessary. Future directions in the HIV epidemic as we see people living longer will be the full return to function in all domains of ADLs and return to productive work.

CASE STUDIES

Three case studies are presented to help the reader understand and identify various stages of this clinical problem and how each stage may require a different therapeutic focus.

CASE STUDY 34.1 Asymptomatic HIV Disease Versus Symptomatic HIV Disease: Mario

Examination

History

Mario is a 58-year-old male chemistry teacher who tested positive for HIV 5 years ago. He was not experiencing any symptoms related to HIV at the time, and his CD4+ nadir was 325 cells/ μ L. He began antiretroviral therapy (ART; Stribild) shortly thereafter and has continued with it since, rarely missing a dose. Currently, his CD4+ count is 550 cells/ μ L, and his HIV viral load is nondetectable (<20 copies/mL). Mario runs 5 miles three times per week for exercise. Recently he began to experience pain and tingling in the soles of his feet that is most noticeable after running. His weight has been stable. He has noticed that he has become somewhat forgetful over the past 2 years, which he attributes to being middle aged. He is otherwise healthy and denies other symptoms. His wife and 28-year-old son serve as his primary emotional support system. The rest of his family lives in Italy. He attends church regularly. Current medications include aspirin as needed after running.

Tests and Measurements

Lower-extremity sensation testing with Semmes-Weinstein monofilaments²⁵⁰ reveals normal light touch sensation in the feet bilaterally. Lower-limb neural tension test (straight leg raise with dorsiflexion) and Tinel test over the tarsal tunnel reproduce symptoms results when performed on either side. Screening of the lumbar spine, hips, and knees is negative. Foot and ankle range of motion and strength are normal. Pain is not provoked with passive stretching of the plantar fascia. Lower-extremity reflexes are normal, and no abnormal reflexes are present. Excessive pronation is noted during the gait cycle; gait is otherwise normal. In standing, an excessive calcaneal valgus angle is noted; normal medial arches are observed in non-weight bearing. Foot pain on a visual analog scale is 0/10 at rest and 5/10 after running.

Evaluation and Diagnosis

A differential diagnosis that should be considered is distal sensory polyneuropathy (DSP). DSP is the most common neurological complication in people living with HIV. DSP is a potential side effect of certain ART drugs and may also be related to chronic HIV infection itself. Sensory dysfunction with DSP involves multiple peripheral nerves and occurs first in the most distal distribution. Decreased Achilles deep tendon reflexes (DTRs) are another clinical sign of DSP.

However, Mario's toes have no sensory impairment, and his DTRs are normal. Furthermore, his symptoms are provoked by repetitive stress (running). Myelopathy should be considered in patients with chronic HIV disease who appear to have peripheral neurological symptoms, but Mario does not demonstrate any signs that would suggest myelopathy as the cause of his foot symptoms. Mario does present with signs and symptoms of flexible pes planus and tarsal tunnel syndrome bilaterally. His gait pattern of excessive pronation is likely contributing to compression and/or adverse tension on the tibial nerve within the tarsal tunnel when he runs.

Prognosis, Goals, and Outcomes

Mario is expected to have full recovery with interventions directed at reducing biomechanical stress on the tarsal tunnel during running. Mario's goal is to run for 5 miles without any symptoms within the next 3 weeks. Outcomes will be measured with the Global Rating of Change (GROC) scale and the visual analog scale for pain associated with running. Reexamination will determine changes in clinical signs (lower-extremity neural tension test and Tinel test).

Intervention Plan and Recommendations

Mario will receive low-dye taping²⁵¹ to decrease his pronation and provide temporary relief of symptoms. Orthotics will be fabricated to reduce pronation and adverse stress on the tarsal tunnel. Mario will replace running with aerobic training on a stationary bike until his orthotics are adequately broken in, after which he can slowly resume running. He will receive instruction in general lower-extremity and plantar fascia flexibility exercises. If his foot symptoms are related to running and biomechanics and his memory loss is deemed to be normal (age-related), then he will remain classified in the asymptomatic HIV disease stage. If foot symptoms are recalcitrant to biomechanically based interventions, further consultation with Mario's HIV specialist will be warranted to rule out possible tibial nerve mononeuropathy related to his HIV disease. If Mario's foot symptoms are determined to be related to his HIV disease, he will be restaged to symptomatic HIV disease. The therapist will encourage Mario to discuss his complaints of memory loss with his physician or a mental health professional. The HIV Dementia Scale²⁵² or other instruments may be used to assess the patient's cognitive function and rule out the possibility of HIV dementia.

CASE STUDY 34.2 Advanced HIV Disease (AIDS) and a Plan for the Future: Ruby

Examination

History

Ruby is a left hand-dominant 23-year-old woman of African-American and Hispanic descent. She has history of intravenous drug abuse and has bipolar disorder. Five years ago, she learned she was HIV positive during a hospitalization due to *Pneumocystis carinii* pneumonia and oral thrush. At that time, her CD4+ count was 15 cells/ μ L and her HIV viral load was 750,000 copies/mL. Her low CD4+ count and opportunistic infections classified her as having advanced HIV disease (AIDS). Her opportunistic infections were successfully treated with

antibiotics, and antiretroviral therapy (ART) was initiated prior to leaving the hospital. Within a few months, her viral load was undetectable and her absolute CD4+ level climbed to 400 cells/ μ L. Since then, she has had intermittent periods of homelessness. She is currently residing with a friend. She stopped adhering to her ART regimen approximately 9 months ago, during a period of depression. Recently Ruby has been working as a prostitute to earn money for crack cocaine, which she uses daily. Ruby was admitted to the hospital 12 days ago with complaints of abdominal bloating and severe left shoulder pain. Her behavior was clearly agitated. Her psychiatric consultation confirmed she was

Continued

CASE STUDY 34.2 Advanced HIV Disease (AIDS) and a Plan for the Future: Ruby—cont'd

experiencing a manic episode. Her CD4+ count was 175 cells/ μ L and HIV viral load was 200,000 copies/mL. A large abscess was present over the left deltoid. Medical work-up revealed that Ruby had a staphylococcal infection in the left anterior deltoid and infectious arthritis of the left glenohumeral joint. Magnetic resonance imaging (MRI) of the shoulder region was negative for osteomyelitis. It was determined that she was 4 months pregnant. Ruby's abscess was incised and drained. The shoulder infection was treated with intravenous methicillin. She was placed on psychotropic medication for mood stabilization. Because during the prior months she had not been adherent to ART, her blood was genotype tested to determine if she had developed any HIV mutations that might be resistant to certain medications used in ART. Fortunately, there were no HIV mutations, and thus she was prescribed Truvada and Isentress. (HIV-positive pregnant women are placed on ART with the goal of achieving undetectable viral loads by the time of birth to minimize the risk of perinatal transmission). Consultation with nutrition services was ordered to ensure adequate nutrition during the remainder of her pregnancy. Medical clearance for examination and interventions for the shoulder was obtained from her infectious disease physician. Ruby has disclosed that her arm infection was probably caused by injecting drugs. She has agreed to see an addiction counselor and the social worker.

Tests and Measurements

Ruby has a wound over the left anterior deltoid region that was 1.5 cm \times 1.1 cm with a depth of 0.5 cm. The wound appears to be clean with 100% granulation tissue, and the most recent laboratory report is negative for *Staphylococcus*. Ruby reports that the swelling and redness in her left shoulder have resolved, and no swelling or redness is observed during the examination. Left shoulder strength is 3/5 (fair) for abduction, internal rotation, and external rotation and 4/5 (good) for other motions. Passive range of motion (PROM) of the left side is limited as follows: external rotation 70 degrees, abduction 160 degrees, and internal rotation 45 degrees. Her score on the Disabilities of the Arm, Shoulder and Hand questionnaire (DASH)²⁵³ is 85/100 for the left upper extremity. Screening examination of the cervical spine is clear; however, hypertonicity is noted in the elbow and wrist and the finger flexors on the left side. PROM of the elbow, wrist, and hand is within normal limits; however, slight resistance is noted with quick passive stretching of flexor muscles. Ruby has weakness in grasp and demonstrates a mild flexor synergy pattern with attempts to elevate the left arm. She reports her arm and hand have been "feeling this way" for a few months.

Evaluation and Diagnosis

As a result of abnormal neurological signs found during the examination, neurology is immediately consulted and brain MRI is performed. The MRI reveals a

mild right cerebrovascular accident (CVA) involving the middle cerebral artery. Physical and occupational therapy will be initiated to address the following findings: impaired integumentary integrity associated with partial-thickness skin involvement over the left anterior deltoid region; impaired glenohumeral joint mobility, muscle performance, and range of motion limitations associated with capsular tightness (as sequela of infectious arthritis); and impaired motor function (spasticity and weakness in the left upper extremity) associated with the right CVA.

Prognosis, Goals, and Outcomes

Ruby's outcomes will be strongly influenced by her complex psychosocial status. She states that she is highly motivated to have a healthy baby and learn how to become a stable provider, which may help her adherence to ART and drug rehabilitation. Continuing communication among all team members (infectious disease, obstetrics-gynecology, social work, addictions counseling, nutrition, physical therapy, and occupational therapy) will be critical to optimize her care. Because of multisystem involvement and multiple impairments, it is expected that Ruby will require 6–8 weeks of outpatient therapy upon discharge from the hospital. Goals specific to physical therapy include the following: facilitate wound healing and prevent reoccurrence of infection, restore full PROM to the left shoulder, improve strength and function throughout the left upper extremity, achieve independence in performance of ADLs with the left upper extremity, improve the DASH score,²⁵³ and minimal functional limitation as per the Barthel Index score.²⁵⁴ Outcomes will be measured with continuing assessment of wound characteristics, the DASH score,²⁵³ the Barthel Index score,²⁵⁴ shoulder PROM measurements, and strength assessment of upper-extremity musculature.

Intervention Plan

Wound healing will be facilitated with dressing changes and use of topical agents as prescribed by her physician. Glenohumeral impairments will be addressed with joint mobilization, therapeutic exercises, and functional retraining. Upper-extremity impairments involving tone and weakness will be addressed with motor learning techniques, functional activities, and strengthening exercises. Ruby will receive daily physical and occupational therapy until she is discharged from the hospital. Social work will facilitate discharge to a structured group home for women because Ruby's current roommate is using drugs and working as a prostitute. On discharge from the hospital, Ruby will return for outpatient therapy at a frequency of three times per week. She will continue to follow up with the social worker regarding vocational counseling.

CASE STUDY 34.3 Advanced HIV Disease (AIDS) at the End Stage of Life: Walter Examination

History

Walter is a 78-year-old man who was diagnosed with AIDS in 1986. He lost his life partner to the same disease in 1988. He has no living relatives. At the time of his diagnosis, Walter had cerebral toxoplasmosis, Kaposi sarcoma, AIDS wasting syndrome, and anemia. He was one of the first patients to receive zidovudine (AZT), which, along with other medications used to treat the opportunistic infections, proved to be lifesaving. In 1995, when new classes of drugs became available, his antiretroviral therapy (ART) regimen was updated to include triple combination therapy. In subsequent years, Walter's lab values were good (nondetectable viral loads and CD4 cell counts in the 300–400 cells/ μ L range).

Walter lives alone in a modest studio apartment. He employs a daily home health aide to assist with food preparation and personal hygiene. Walter had been ambulating short distances in his apartment using a walker because of fatigue and unsteadiness. Walter's gait became increasingly ataxic over the past

month. Currently, Walter is experiencing multiple side effects and complications of long-term HIV survival, including peripheral neuropathy in the hands and feet, fibromyalgia, myelopathy, chronic pain in his back and legs, liver toxicity, hypertension, hyperlipidemia, and severe lipodystrophy. Over the past decade, Walter's Medical Outcomes Study HIV Health Survey²⁵⁵ scores have indicated worsening QOL. Walter has been hopeless and depressed about his physical appearance and level of function. Approximately 1 year ago, Walter stopped taking ART and most other medications for multimorbid conditions. His current CD4 count is 65 cells/ μ L, and his HIV viral load of 200,000 copies/mL. Last week, he had a seizure that resulted in the current admission to the hospital. Testing revealed progressive multifocal leukoencephalopathy (PML). Walter's physician expects that this brain infection, combined with his immunosuppression, will lead to death within a few months. Walter has refused antibiotics to treat his PML and does not wish to resume ART or other medications that

CASE STUDY 34.3 Advanced HIV Disease (AIDS) at the End Stage of Life: Walter Examination—cont'd

had been previously used for his comorbidities. Walter wishes to explore hospice placement. Current medication: OxyContin.

Tests and Measurements

Inspection of the integumentary system reveals redness over the sacrum; otherwise the skin is intact. Diminished light touch sensation is noted in a stocking-glove distribution over the hands and feet. A Hoffman reflex, consistent with his myelopathy, is present in the upper extremities. Walter rates his pain at rest as ranging from 4/10 to 7/10. His pain drawing indicates low back, bilateral leg, and foot pain. Pulse oximetry reveals 96% oxygen saturation. Vital signs sitting: heart rate 70 beats/min, blood pressure 130/70 mm Hg, and respiratory rate 16 breaths/min with no apparent distress. Pitting edema (+1) is noted in the ankles and feet.

Walter is independent with all bed mobility but moves slowly due to pain. Sitting balance is good. Standing balance is fair. Contact guard is required for sit-stand transfer and for ambulation a distance of 10 feet with a rolling walker. Vital signs after ambulating 10 feet: heart rate 110 beats/min, blood pressure 150/70 mm Hg, respiratory rate 24 breaths/min, and oxygen saturation 96%. His Borg scale rating of perceived exertion (RPE) was 15/20 ("hard") during the 10-foot walk. He demonstrates erratic foot placement and a wide base of support during gait. His Functional Independence Measure (FIM)²⁵⁶ score is 4. Because of fatigue and pain, strength and range-of-motion assessments are abbreviated. The following strength data are obtained (all measured bilaterally): shoulder abduction 3/5 (fair), elbow extension 4/5 (good), knee extension 3/5 (fair), and dorsiflexion and plantarflexion 4/5 (good). Passive range of motion data (bilateral): dorsiflexion 5 degrees; knee flexion 125 degrees (full knee extension not available, 10-degree flexion contracture noted); hip flexion 120 degrees; hip extension 10 degrees; shoulder flexion and abduction 140 degrees; and elbow, wrist, hand within normal limits.

Evaluation and Diagnosis

Walter exhibits multiple impairments related to his advanced HIV disease, multimorbidity, and a current opportunistic infection (PML), including pain, impaired integumentary integrity associated with superficial skin involvement, impaired sensory integrity, impaired joint mobility and range of motion (knees, shoulders), impaired muscle performance, impaired gait, impaired balance, and impaired endurance.

Prognosis, Goals, and Outcomes

Walter's prognosis for survival is poor. It is likely that he will deteriorate slowly over the upcoming months. Goals and outcomes will thus focus on optimizing QOL during Walter's remaining days. Specifically, goals are to reduce pain, prevent adverse sequelae of immobility that would further reduce his QOL (such as pressure wounds, pneumonia, deep venous thrombosis, or joint contracture), and promote safety. Depending on Walter's energy and participation, another goal is independent ambulation with a wheeled walker up to 15 feet.

Intervention Plan

During the current hospital admission, physical therapy will first be provided at bedside. If the patient wishes, treatment may be provided in the physical therapy department. Interventions will include relaxation techniques, passive range of motion and grade I joint mobilization (knees and shoulders), gait training with a wheeled walker, balance activities, and gentle strengthening and endurance exercises as tolerated. Occupational therapy will be consulted to address bed mobility and self-care tasks. Walter's vital signs will be closely monitored during therapy because it is possible that his autonomic nervous system dysfunction may become evolved as a result of the central nervous system infection. Walter's physician will be contacted regarding Walter's pain ratings. It is likely that increased dosage of pain medication is warranted as a result of reports of moderate pain at the current dosage. Walter will be seen by a dietician. The social worker will plan for transfer to a hospice setting. In hospice care, physical therapy will focus on basic functional activities, such as transfers, gait, and endurance. Palliative interventions (moist heat, gentle massage) will be provided as needed for pain control. Caregiver education will be provided regarding prevention of the effects of immobility and safe functional mobility. The same universal precautions used in providing care to any patient apply to Walter. Staff should be cognizant of protecting all hospice patients from seasonal cold or flu contagion. In the hospice setting, Walter will have the opportunity to work with a spiritual counselor. Walter has expressed an interest in exploring Eastern medicine for pain control. Therefore a consultation with an acupuncturist will be arranged.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the

reader to a Medline abstract for the article cited. There are 256 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: This chapter discusses human immunodeficiency virus (HIV) infection: living with a chronic illness. In this chapter, readers will understand how the involvement of various systems (immune, integumentary, musculoskeletal, cardiopulmonary, and neurological) may lead to episodic disability and affect function in individuals living with HIV disease. The chapter also covers the neuropathological features of HIV infection and the potential neurocognitive and

neuropsychological alterations that may occur. Finally, this chapter covers rehabilitation management for HIV, incorporating psychoneuroimmunology, pain management, and movement strategies, as well as safe exercise parameters in the HIV-positive population.

Keywords: Human Immunodeficiency Virus (HIV), Acquired Immunodeficiency Syndrome (AIDS), HIV disease, Episodic disability, Inter-professional rehabilitation

Aging With Chronic Nervous System Conditions and Impairments

Myla U. Quiben

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Analyze how the aging process may affect people with lifelong functional limitations and challenges in life participation.
2. Analyze the unique challenges faced by people with chronic motor impairments such as those associated with cerebral palsy, developmental disabilities, postpolio syndrome, spinal cord injury, and traumatic or acquired head injury during the aging process.
3. Evaluate this population of patients/clients with sensitivity and skill, incorporating precautions and effectiveness of interventions.
4. Provide a framework for the examination process for individuals with chronic conditions.
5. Present holistic intervention considerations for individuals with chronic motor impairments.
6. Identify gaps in knowledge and research in the management of aging individuals with chronic neuromuscular conditions.
7. Appreciate the complexity of examination, evaluation, and management of the aging patient with chronic motor impairments.

KEY TERMS

adaptation
aging
chronic disease

developmental disability
fatigue
health disparities

health promotion
postpolio syndrome

Improvements in health care delivery, research, medicine, nutrition, and knowledge of health and physical activity have resulted in a new challenge for health care professionals—a growing population of individuals who have sustained an initial injury to the central nervous system (CNS) with resulting secondary impairments and functional limitations and who are now experiencing the added effects of aging.

The aging process typically leads to gradual physiological changes in muscle strength, flexibility, and joint mobility, and changes in balance and endurance. Physical activity and a healthy lifestyle have been shown to address age-related changes by delaying the decline and deterioration; however, age-related changes such as osteoarthritis and vascular changes are still likely to occur to varying degrees despite a healthy lifestyle. Healthy but sedentary older individuals report more problems in activities of daily living (ADLs) than do those who continue to be physically active and who previously had an active lifestyle.¹⁻³

To compound the aging process, chronic diseases (multimorbidity or comorbidity), disability, and frailty are common issues that are on forefront of health prevention and rehabilitation. While multimorbidity, disability, and frailty have considerable similarities and have been used interchangeably at times, these terms are conceptually distinct.⁴

Broadly, the presence of a number of health conditions is common among many of the definitions of multimorbidity, but the cut-off point, or the minimal number of conditions, is inconsistent. No consensus on the definition of multimorbidity currently exists.

Broadly, multimorbidity has been defined with the coexistence of two or more chronic diseases,⁵⁻⁷ while others have specified a number of chronic diseases that constitute multimorbidity. Frailty, a clinically recognizable geriatric syndrome of increased vulnerability from age-associated declines in function and reserve across multiple systems, results an increased risk of physical decline with aging and or further health stressors.^{8,9} The overlap among frailty, multimorbidity, and disability is conceivably seen in the initial description of the frailty phenotype by Fried and colleagues.^{4,8,10} Since then, evidence has shown that these entities are interrelated but are distinct from each other.^{4,11,12}

In an otherwise relatively healthy aging adult, the development of multimorbidities or frailty, coupled with decreased physical activity, may lead to limitations on activity and community participation. Consider that in an individual with a preexisting chronic nervous system condition and functional limitations, the aging process may present new or *additional* losses of components of functional activities and participation in an already taxed body—a new challenge to the individual who may have had the opportunity to successfully participate in life activities after the CNS injury. Individuals with existing disabilities undergo a similar aging process; however, the typical changes associated with aging are superimposed on the body system problems and functional limitations caused by the initial CNS injury.

In the realm of chronic problems in life participation, individuals who had polio in their younger years give clinicians an enlightening example of the chronic interaction among neurological impairments,

recovery, activity limitations and participation restrictions, effects of aging, and health care. As a chronic condition, individuals who dealt with polio can teach therapists to reconsider and reevaluate their approach to individuals who are now aging and likely experiencing new activity limitations, impairments, and ineffective postures and movement. The challenges of aging with chronic body system impairments are encountered by individuals who acquired CNS insult at birth (developmental conditions such as cerebral palsy [CP; see Chapter 10]) and those who acquired injury through disease or trauma sometime in the life-span development process (those who have post-polio syndrome [PPS], traumatic brain injury [TBI], multiple sclerosis [MS], and spinal cord injury). This chapter focuses on aging with chronic CNS conditions in the latter classification.

The discussion of aging with chronic disease brings several questions to the forefront:

- What is the course of age-related medical conditions common in individuals with chronic impairments?
- Do age-related conditions vary among the developmental/genetic diseases or among conditions occurring at one point during the life-span?
- What is the prevalence and/or incidence of secondary medical conditions in individuals with chronic impairments?
- Have specific treatment protocols for health provision for this population been identified?
- What is the state of dissemination of information related to aging and health to people affected by these conditions?
- How has the effect of aging with chronic body system problems changed the ability of these individuals to participate in life, as well as their perceived quality of life?

As an emerging population, individuals with chronic impairments have not been on the receiving end of much research. Much of what is known about nervous system disorders is in the pediatric realm and in the initial stages of care immediately after the initial injury or diagnosis. Only recently have studies begun to look at the health care implications of aging with chronic conditions. Therefore definitive answers to the questions posed previously are still nonexistent or in the early stages of conception. Based on a review of existing literature, the consensus appears to be that there is a dearth of definitive information on the health status and effect of age-related processes among individuals with chronic conditions from developmental or genetic disorders, or from disease or injury sustained at one point in the life-span, such as TBI or MS. Moreover, there is agreement that further evidence-based research is needed in this emerging population.

This chapter aims to provide a holistic view of the management of the chronic problems of individuals with nervous system impairments, with consideration given to the effects of aging and compensation over time. Movement emerges from the interaction among the individual, task, and environment,¹³ with several variables and degrees of freedom. Therefore physical therapists (PTs) and occupational therapists (OTs) need to examine and address multisystem impairments and contributions to movement, while appreciating the changing dynamics of a highly complex movement system influenced by aging superimposed on the body system impairments and functional limitations from an existing CNS dysfunction.

DIAGNOSES WITH UNDERLYING CHRONIC CONSEQUENCES

Developmental Conditions

With increasing life expectancy, mainly as a result of innovations in health care, a unique group of individuals with chronic conditions are

subject to age-related changes. Individuals with developmental disabilities constitute a growing segment of the aging society. This is a broad topic, in part because of the many conditions that are categorized as developmental disability. According to the Developmental Disabilities and Bill of Rights Act of 2000¹⁴ developmental disabilities are severe, chronic functional limitations attributable to mental or physical impairments or a combination of both, that manifest before age 22 years and that are likely to continue indefinitely. These result in substantial limitations in three or more of the following areas: self-care, receptive and expressive language, learning, mobility, self-direction, capacity for independent living, and economic self-sufficiency. These individuals also have a continuous need for individually planned and coordinated services.¹⁵ The definition envelops a wide range of conditions leading to significant and lifelong disabilities. This group includes those with genetic and neurological conditions, which includes CP.

The question of whether unexpected changes among people with neurodevelopmental disabilities occur as they age and how these changes compromise functioning with progressive aging is of massive importance with the emergence of a population of individuals with developmental disabilities with increased life expectancy and concurrent increase in age-related diseases. According to Heller¹⁶ the number of adults with intellectual and developmental disabilities aged 60 years and older is projected to nearly double from 641,860 in 2000 to 1.2 million by 2030 owing to increasing life expectancy and the aging of the baby boomer generation. With the aging of adults with developmental and genetic disorders, a new societal issue looms, as individuals with developmental disabilities have a lifelong need for external support. Much is unknown about the long-term effects of aging and maturation in adults with these conditions.

Adults with several types of developmental disabilities have life expectancies similar to those of the general population, excluding adults with particular neurological conditions and with more severe cognitive deficits. Recent studies show the mean age at death ranges from the mid-50s for adults with severe disabilities to the early 70s for those with mild to moderate intellectual disabilities.^{17–19}

Concurrent with an increased life-span, some evidence exists that certain individuals with developmental disabilities have experienced an increase in age-related diseases. Of the limited information available, research has shown that aging affects certain genetic and neurologically based intellectual and developmental disabilities that may increase the risk of age-related pathologies and lead to an increased occurrence of coincident conditions.²⁰ Among several developmental conditions, Down syndrome (DS) has been the subject of a substantial body of research. DS is known for resulting in advanced aging, which includes a higher risk for Alzheimer's disease and select organ dysfunctions.^{20–22}

CP is considered a life-span disability, and evidence exists that adults with CP lose functional abilities earlier than individuals who are able-bodied.²³ In addition, evidence is also increasingly pointing to specific age-related outcomes such as the effects of deconditioning, limitations with performance reserve, and possibly a shorter life-span.²⁰ In adults with CP, secondary conditions commonly described in research primarily are related to the long-term effects on the musculoskeletal system, such as pain, degenerative joint disease, and osteoporosis.^{20,24,25} Secondary impairments in CP can progress subtly and may not appear until late adolescence or adulthood.²⁴ Age-related health conditions are also seen in other genetic and neurological disorders as the affected individuals age. However, the nature of these risks lacks extensive substantiation in the literature.

Overall, knowledge of adult health issues for adults with developmental disabilities is limited.¹⁶ Several reasons contribute to the lack of

knowledge. Limited health care programs exist for this population, likely because this is an emerging population. Most of the existing literature deals with pediatric domain issues rather than dealing with age-related issues. Although these individuals were likely seen by therapists for various functional limitations throughout their lives, the professional training that health care providers have received regarding the care of these individuals has focused on early childhood and school-aged children. As a result, many adolescents and adults with developmental disabilities have difficulty accessing appropriate health care information regarding secondary conditions resulting from their specific disabilities. Moreover, in general, older individuals with developmental disabilities have more difficulty in finding, accessing, and paying for high-quality health care.¹⁶ Communication difficulties also limit the understanding of the experiences of aging adults with developmental disabilities. Evidence exists, however, showing that obesity and inactivity are more common in individuals with developmental disabilities than in the general population.²⁶ Bazzano and colleagues²⁶ identified several reasons for this health discrepancy, including individual and community factors, physical challenges, segregation from the community, lack of accessible fitness facilities and developmentally appropriate community programs, and cognitive deficits.

Given trends of increasing survival and longevity observed among individuals with developmental disabilities, it is sensible to consider a more in-depth look at the aging process among a variety of neurodevelopmental conditions and the need for a holistic approach. Although some literature exists regarding life-span changes with these disorders, particularly DS and CP, there is lack of confirming evidence for most of these conditions. Horsman and colleagues²³ advocate for research on the expectations regarding aging for adults with CP, including preventive measures to lessen the effects of secondary impairments. This recommendation applies to developmental life-span conditions and other chronic conditions that are subject to age-related changes that may be magnified or made worse by existing impairments and limitations. Evidence-based research is necessary to better understand the long-term effects of aging on adults with developmental and chronic conditions. The challenge then is to provide a holistic examination that involves a multisystem approach and to provide appropriate referrals as necessary to address the multiple needs of individuals with developmental disabilities.

Acquired Neurological Conditions: Spinal Cord Injury, Traumatic Brain Injury, Postpolio Syndrome

In the realm of management of chronic movement dysfunction, PPS—the late effects of polio—becomes a model case for other chronic neuromuscular conditions. There is much to learn from the complex nature of the late effects of polio and the effects of aging on an already stressed system. The cause must be briefly discussed to further understand the possible effects of aging. PPS can affect polio survivors years after recovery from the initial polio infection and is characterized by multifaceted symptoms that lead to decline in physical functioning.²⁷ PPS manifests with progressive or new muscle weakness or decreased muscle endurance in muscles that were initially affected by the polio infection and in muscles that were seemingly unaffected; generalized fatigue; and pain.²⁷ The exact cause of PPS remains unknown on the basis of review of the literature. Although it is not clear what exactly causes the new symptoms, there appears to be a consensus that insufficient evidence implicates the reactivation of the previous poliovirus.²⁸ Underlying causes have been proposed in a variety of hypotheses from several authors, with aging playing a key role.^{29–33}

The suggestion that aging contributes to PPS is supported in the literature.^{30,34,35} By the fifth decade of life, loss of anterior horn cells

begins, and by age 60 years the loss of neurons may be as high as 50%.³⁶ Age-related changes superimposed on the already limited motor neuron pool after polio appear to be important factors in the development of PPS. With the effects of the normal aging process, the remaining anterior horn cells are further reduced to a point at which the deficits caused by the initial insult cannot be overcome. The loss of even a few neurons from a greatly exhausted neuronal pool potentially results in a disproportionate loss of muscle function.^{29,37} The loss of motor neurons from aging alone may not be a considerable factor in PPS because studies²⁹ have failed to link chronological age and the onset of new symptoms. Rather, it is the length of the interval between the onset of polio and the appearance of new symptoms that seems to be more critical.

Another plausible hypothesis alludes to overuse and fatigue of the already weakened muscles as a factor in the development of new muscle weakness.^{28,38,39} A study by Trojan and colleagues³⁹ provides support to this hypothesis. Their results suggest that length of time since acute polio, joint and muscle pain, physical activity, and weight gain are factors associated with PPS. Years of overuse after recovery from polio causes a metabolic failure leading to an inability to regenerate new axon sprouts. The exact cause of degeneration of axon sprouts is not known. Evidence to support this hypothesis can be inferred from muscle biopsies, electrodiagnostic tests, and clinical response to exercise.²⁹ McComas and colleagues⁴⁰ suggested that neurons that demonstrated histological recovery from the initial virus were possibly not physiologically normal and were potentially vulnerable to premature aging and failure.

Other proposed hypotheses include the persistence of dormant poliovirus that was reactivated by unknown mechanisms, an immune-mediated response, hormone deficiencies, and environmental contaminants.²⁹ Another hypothesis points to the loss of anterior horn cells during the initial polio as a factor.^{28,30} Findings from Trojan and colleagues³⁹ support the hypothesis that the severity of the initial motor unit involvement, seen as weakness in acute polio, is critical in predicting PPS. Individuals at greatest risk for PPS had severe attacks of paralytic polio, although individuals with milder cases also had symptoms.²⁹ These hypotheses have not been completely examined, and currently the evidence is not strong enough to support any one possible cause. Clinically it is difficult to assume that only one factor causes symptoms. The chronicity of the disease lends weight to the possibility that more than one factor contributes to the individual's symptoms.

Medical practitioners must consider the effects of existing comorbidities and aging in the examination and management of PPS. The complexity and nonspecificity of symptoms warrant consideration of all possible contributors to the symptoms of PPS. Based on the recent literature, there appears to be some confusion regarding terminology pertaining to PPS. Compounding the general symptoms are the common problems in aging: decreasing muscle strength and endurance, joint problems, and a myriad health deficits leading to functional losses. Physiological aging, overuse, and comorbidities play contributory roles in disrupting the state of stability after the initial infection.

McNaughton and McPherson⁴¹ state that the simple descriptive labels “late problems after polio” and “of late deterioration after polio” are less limiting and do not imply a direct link with the previous polio diagnosis. Post-Polio Health International⁴² uses the terminology “late effects of polio and polio sequelae” as the most inclusive category. *Late effects of polio* and *polio sequelae* pertain to health problems that are a result of chronic impairments from polio and may include degenerative arthritis from overuse, bursitis, or tendinitis. A subcategory under this heading is “PPS leading to decreased endurance and decreased function.”

Currently no definitive test exists in the literature to diagnose the late effects of polio or PPS. It remains a diagnosis of exclusion, and as such, the diagnostic process for PPS is challenging and may be long. Halstead and Gawne⁴³ identified cardinal symptoms of PPS as new or increased muscle weakness, fatigue, and muscle and joint pain with neuropathic electromyographic changes in an individual with a definite diagnosis of polio. Diagnostic electromyography (EMG) may be required or used when the muscle pattern or history is atypical.

The criteria most commonly used for establishing a medical diagnosis of PPS were developed by Halstead⁴⁴ and is recommended by the European Federation of Neurological Societies (EFNS)^{45,46}:

1. A confirmed history of paralytic polio in childhood or adolescence
 2. Partial to complete muscle strength and functional recovery after the acute paralytic poliomyelitis
 3. A period of at least 15 years of neurological and functional stability
 4. Gradual or sudden onset of two or more new health problems: muscle weakness or abnormal muscle fatigability with or without generalized fatigue, muscle atrophy, weakness in the limb(s), or muscle and joint pain.
 5. Symptoms persist for at least 1 year
 6. No other medical conditions to explain these new health problems
- Dalakas⁴⁷ identified additional inclusion criteria in the diagnosis: residual asymmetrical muscle atrophy, with weakness, areflexia, and normal sensation in at least one limb and normal sphincteric function and deterioration of function after a period of functional stability unexplained by primary or secondary condition.

Several individuals who recovered from polio during the early epidemics were encouraged to exercise for years and to use heroic compensatory methods for function. An exhaustive regimen of daily stretching and strengthening, demanding compliance from individuals and their support systems, was strongly encouraged. Orthotics and assistive devices were promoted as a means toward independent mobility. The outcomes of rigorous training were individuals who adapted and compensated with their remaining capabilities. Compensations include use of muscles at high levels of their capacity, substitution of stronger muscles with increased energy expenditure for the task, use of ligaments for stability with resulting hypermobility, and malalignment of the trunk and limbs. With the late effects of polio or a diagnosis of PPS, many of these individuals may have extreme difficulty dealing with these new problems because of the attitude of “working hard” to reeducate weakened muscles and compensate for loss of function after the initial diagnosis.⁴⁸⁻⁵¹ The new symptoms of PPS, which limits their motor function and likely impairs established personal and societal roles, require that they not work hard or overexert themselves. These two approaches are contradictory and can leave an individual frustrated and confused over therapeutic recommendations.

Spinal Cord Injury and Traumatic Brain Injury

For people with SCI and TBI, a trend is seen toward increasing awareness on the effects of aging on the functional status of this group. Owing to medical advances, patients are now living 20 to 50 years past their time of injury. Numerous studies have been done describing quality-of-life issues for people with TBI; however, those studies seldom look specifically at changes in functional levels or what can be done to ameliorate the declines.⁵²⁻⁵⁴

Signs of “premature aging” in multiple organ systems in people with SCI have been supported in literature.⁵⁵ In a review of 92 studies by Jensen and colleagues,⁵⁵ the findings indicated several salient points about the aging adult with SCI: many secondary health conditions occur with aging, many at higher rate compared to the typical population; pain, bowel and bladder impairments, muscle spasms, fatigue,

esophageal symptoms, and osteoporosis are the most common conditions reported; and several chronic health conditions, including cardiovascular disease, diabetes, bone mineral density loss, fatigue, and respiratory complications or infections, occur with higher frequency in older individuals or those with longer SCI duration compared with younger individuals or those with shorter SCI duration.

McColl and colleagues,⁵⁶ studying the impact of aging on people after SCI, echo the major categories of problems related to aging, such as musculoskeletal problems and joint, sensory, and connective tissue changes; chronic urinary tract infections; heart, respiratory, and other chronic diseases; secondary complications of the initial lesions, such as syringomyelia; and problems related to social and cultural acceptance and access or barriers. Evidence on specific age-related changes is presented in the section on examination.

Decreases in perceived health status and in functional abilities with increases in additional assistance for ADLs have been documented for aging individuals with SCI.⁵⁷⁻⁶¹ In a study of 150 people aging with an SCI, nearly 25% reported decreases in the ability to perform functional activities that they had been able to handle after the acute rehabilitation phase. The subjects who reported decreases in functional ability were generally older (45 years compared with 36 years) and had longer postinjury periods (18 vs. 11 years). The most common symptoms reported by the individuals with decreases in functional status were related to fatigue, pain, and muscle weakness. The ADLs reported to be more difficult were transfers, bathing, and dressing. To maintain their functional levels, those with declines in functional ability reported needing additional equipment.⁵⁷

The need for further assistance with ADLs was echoed in a study by Gerhart and colleagues of individuals with SCI 20 years after the initial injury.⁵⁸ The study showed that 22% of the subjects reported an increased need for support with ADLs. Compared with a general group of nondisabled men and women aged 75 to 84 years in which 78% of the men and 64% of women did not need help with ADLs, the population of people with SCI needed increasing support to remain independent, and the need for help occurred at a younger age. On average, those with quadriplegia required more help with ADLs around the age of 49 years, whereas those with paraplegia were able to maintain their functional level until age 54 years. The groups showing functional decreases reported greater fatigue, increased muscle weakness, pain, stiffness, and weight gain.⁵⁸ Other studies support the findings that 5, 10, and 15 years after the initial SCI, an association with the need for additional help with increasing age existed.⁵⁹

Liem and colleagues,⁶⁰ referencing an international data set of people with SCI, investigated a subset of 352 people at least 20 years after their injury. Increased help with transfers and housework were needed by 32% of the subjects, compared with their functional abilities at acute hospital discharge. With increasing age, women had a higher incidence of reported musculoskeletal impairments, which may have been related to biomechanical differences between men and women (e.g., 40% lower upper body strength).

In addition to the need for ADL support, neurogenic bowel and bladder symptoms also worsen with age in some people with SCIs. With changes in general health status, polypharmacy, decreased activity, and poor nutritional patterns, bowel problems (particularly constipation) become more of an issue. Although constipation seems like a minor issue relative to paralysis, those with SCIs report significant abdominal distention and pain, an increased incidence of perineal and sacral skin breakdown, and in some cases autonomic dysreflexia. In addition to the discomfort of chronic bowel dysfunctions, the required bowel care programs may take more time, which can lead to increased psychosocial issues associated with anxiety about bowel accidents in social and work situations. Additionally, these programs

may take time away from social activities for both the person with an SCI and the caregiver. For those with continuing bowel problems that interfere with life and work activities, a colostomy may be an option that increases independence from caregiver support during the bowel program.⁶² Another complicating factor related to bowel dysfunction is the typical treatment for pain complaints. Because the origin of pain is often illusive, the most common treatment involves oral medications rather than referrals for therapeutic interventions. Pain medications, especially opioids, increase gastrointestinal difficulties in nondisabled populations,⁶³ and the problem for patients with SCI is compounded.

Charlifue and colleagues,⁶⁴ drawing on the National Spinal Cord Injury Database of 7981 individuals with SCIs that occurred from 1973 to 1998, found a slight decrease in perceived health status the longer one lived after SCI. Evidence was also found that those injured later in life had a higher number of rehospitalizations after injury than those injured at a younger age. Despite palpable problems with the statistical issues within the sample, the study clearly indicated that the best predictor of a complication is a previous history of that complication. On the basis of their results, Charlifue and colleagues⁶⁴ suggest that prevention of complications is the best approach to improve quality of health and quality of life for people aging with SCI.

In addition to many multisystem impairments that occur in this population, a recent study⁶⁵ confirmed a high occurrence of cardiovascular risk factors among older adults with long-term SCI. In 123 older adults (mean age: 63 years) with SCI with a mean time of 24 years since injury, the median number of risk factors was 3. The presence of these risk factors in individuals with existing disabilities can pose additional consequences to their health and must be addressed.

Across the literature, a call for further research and a need for longitudinal studies is a consistent recommendation. Research is needed to help understand when problems are most likely to emerge in the aging process, to identify modifiable factors can be targeted in this population, what prevention strategies may be efficacious, and to develop and test the efficacy of interventions to address and potentially prevent secondary health conditions.

Individuals with TBI are often neglected by professional health care and insurance providers after the acute rehabilitation period. According to Levin,⁶⁶ before 1980, individuals with brain injuries were considered “dead on arrival.” People who would have died from the TBI several decades ago are now living into old age and are coping with the changes caused by the aging process superimposed on their physical limitations and cognitive problems. Of great concern is the possible relationship between a history of brain injury and increased cognitive changes along the dementia continuum.^{67–69} Cognitive decline in the nondisabled population is a problem, but the additive effect for a person with a previous TBI may seriously impair the person’s coping mechanisms when dealing with his or her own health and self-care needs.⁷⁰ TBI was found to be an independent significant risk factor in developing dementia even in mild TBI.⁶⁸ A meta-analysis in 2017⁶⁹ of 32 studies showed that head injury was associated with increased risks of dementia and Alzheimer’s disease. Further, recent TBI with loss of consciousness acquired in older adulthood has been associated with an increased risk for mortality.⁷¹

Extensive work has been done on rehabilitation programs and quality-of-life issues related to head injury and, to a lesser extent, cerebral vascular accidents.⁷² Unfortunately, the focus of rehabilitation after a TBI has been on the acute and rehabilitation stages of treatment and not the chronic problems that follow this group of patients into their older years. As with other chronic conditions, few patients see a therapist after they are discharged from rehabilitation unless they

have new acute events such as musculoskeletal problems or a medical condition that causes a change in functional status.

Although TBI is a lifetime disability, little attention has been paid to the needs of aging people with a TBI who may have recurring needs for physical and cognitive rehabilitation and retraining over the lifespan. Individuals who sustain a TBI later in life years will likely have different needs from those injured at a younger age. In a study on the effect of age on functional outcome in mild TBI, Mosenthal and colleagues⁷³ found that those injured later in life (after age 60) had longer inpatient rehabilitation periods and lagged behind younger patients in functional status at the point of discharge; however, similar to the younger individuals who sustained a head injury, the over-60 individuals showed measurable improvement during the 6-month study period. Therefore aggressive management of older patients with TBI is recommended, and older patients may require continuing management owing to the overlying issues of the aging process.⁷³ This is echoed in the National Institutes of Health (NIH) consensus document on the treatment of people with TBI, which suggests that specialized interdisciplinary treatment programs need to be put in place to deal with the medical, rehabilitation, family, and social needs of people with TBIs who are over the age of 65 years. The document also concludes that access to and funding for long-term rehabilitation is necessary to meet long-term needs; however, it recognizes that changes in payment methods by private insurance and public programs may jeopardize the recommendations.⁷⁴

Although the authors of the NIH document recognize the need to deal with the aging processes associated with TBI, there continues to be a lack of services and trained professionals available, especially at the community level.⁷⁵ As with the SCI population, work is now being done to investigate the relationships among TBI, aging, and health. Breed and colleagues⁷⁶ found that older individuals with TBI were more likely than their age-matched nondisabled peers to report metabolic, endocrine, sleep, pain, muscular, or neurological and psychiatric problems. Their findings support those of Hibbard and colleagues⁷⁷ and Beetar and colleagues,⁷⁸ which suggest that medical personnel need to be prepared to treat a broad range of health issues in the aging TBI population. Fewer of the studies on long-term outcomes and issues in TBI extend to the 10- and 15-year postinjury periods that have been examined for patients with SCIs. In studies 5 years after the initial TBI, improvements in physical and social functions were noted in most areas for at least the first 2 years after injury, with the exception that those with a history of alcohol or drug abuse did less well. One could assume that continued abuse of alcohol or drugs would bode ill for individuals aging with a TBI.⁷⁹ In one study of 946 children and adolescents who sustained a TBI, Strauss and colleagues⁸⁰ found that patients with severe and permanent mobility and feeding deficits had higher mortality rates, with a 66% chance of surviving to age 50 years. In contrast, survivors with fair or good mobility had a life expectancy only 3 years shorter than that of the general population. However, because both severely and mildly injured individuals with a TBI can live well into and beyond their 50s, the impact of aging on the physical and cognitive deficits must be dealt with assertively to prevent superimposed disability.

Because aging individuals with an SCI or a TBI may have health problems similar to those of any aging population, primary impairments in muscle strength and endurance may be magnified. Therefore individuals with these chronic conditions who make repeat visits regarding medical problems such as musculoskeletal, cardiac, respiratory, and renal diseases should be referred for a comprehensive therapy examination and program that focuses on education, lifestyle changes, and health and wellness promotion interventions.

EXAMINATION OF INDIVIDUALS WITH CHRONIC IMPAIRMENTS

The National Council on Aging (NCOA) approximates 80% of older adults have at least one chronic disease and 77% have at least two.⁸¹ The statistics on chronic disease continue to grow with a current estimate of approximately 45% or 133 million of all Americans having at least one chronic disease.⁸² Conditions are diverse and may be related to trauma or chronic conditions such as MS.⁸³ Trends of increasing survival and longevity are now being observed among individuals with chronic conditions as they experience aging processes. Given the huge financial, human resource, and health costs of chronic disease, it is timely to consider how to manage individuals with chronic impairments.

Examination of individuals with chronic impairments and disabilities is challenging to say the least. Not only are the impairments and activity limitations diverse, but the combinations of these impairments and limitations are many and unique to each individual owing to societal, personal health, environmental, and psychological considerations. Moreover, the effects of aging will likely affect individuals differently depending on existing impairments, functional limitations, current health status, and each individual's attitude toward health and maintaining their functional status and lifestyle. This entails a more thorough, methodical, multisystem examination with a meticulous health interview and wellness model.

EXAMINATION: SYSTEMS MODEL

Aging with existing neuromuscular disorders, be it from a late-onset pathology or from a developmental condition, is a challenge for both the individual and the health care professional. There is a small body of literature on the later-life complications of early-onset acquired disabilities. Several problems may result from complex interactions among physical, medical, environmental, behavioral, and psychosocial factors.

Aging may confound late-onset symptoms or magnify the deficits from the initial CNS insult. With the trend of increasing longevity and survival rates from improvements in health care, it is necessary to look at how the health care provider approaches the examination of individuals with chronic impairments and activity limitations. As individuals with chronic neuromusculoskeletal impairments age, there will be an increasing number of comorbidities, and sorting out the cause of each new symptom will be increasingly complicated.

Bottomley⁸⁴ identifies essential components of a comprehensive geriatric assessment as psychosocial, functional, mental, and social health elements. These components are applicable to individuals with chronic neuromuscular impairments, who with aging are experiencing new symptoms or a magnification of preexisting impairments. [Box 35.1](#) shows a sample examination template for this population.

Challenges of Examination of Individuals With Chronic Conditions

Assessment of individuals with chronic nervous system conditions is challenging because of the diversity of impairments, the nonspecific nature of symptoms, and the complex interaction of several factors, including the heterogeneous effects of aging. Depending on their underlying health conditions, individuals with chronic conditions may have higher risks than others of developing preventable health problems.⁸³ In comparing nondisabled individuals with people with disabilities, Iezzoni and O'Day⁸⁵ found that the latter group is much more likely to have higher obesity and overweight rates and higher

BOX 35.1 Examination Profile for Chronic Neuromuscular Impairments

Examination: Systems Model

- Examination guidelines, include nutritional and sleep screen
- Movement observation
- Health history
- Systems review
- Tests and measures
 - Musculoskeletal: strength, range of motion, power, and muscle length
 - Balance and coordination
 - Pain
 - Tone
 - Cardiovascular and pulmonary function
 - Integumentary
 - Cognition and mental function
 - Mobility
 - Posture
 - Sensory deficits
 - Sleep
 - Temperature intolerance
 - Psychosocial considerations
 - Functional assessment

rates of depression, anxiety, and stress. Of adults with major physical and sensory impairments, 27% are obese, compared with 19% of those without major impairments.⁸⁵ Of individuals with major difficulties in walking, 34% reported frequent depression or anxiety, compared with 3% among those without disabilities.⁸⁵ Information on predisposition to conditions such as these is important for the health care provider during the health interview and examination process.

The examination of individuals with chronic impairments presents a different challenge than examining patients or patients with acute diagnoses. For both cohorts, the task of the health care provider is to determine the effect of the active pathology on the varied systems and function. However, for the individual with chronic impairments, an added challenge exists: the impact of the active pathology can be seen with the underlying preexisting deficits in function and/or impairments that may leave the individual with a narrow margin for health.

Individuals with developmental and genetic disabilities and with conditions acquired through diseases or trauma sometime in the lifespan have activity limitations and participation restrictions that are diverse and unique to each individual. Therefore some individuals may have higher risks than others of developing certain preventable health problems or may be more susceptible to developing secondary conditions owing to the long-term effects of the primary impairments from the original health condition.

The absence of specific medical diagnostic tests adds to the dilemma, as does the continuing uncertainty of the underlying cause and the lack of curative intervention. Health care professionals' limitations in knowledge of age-related medical disorders that are common in people with these conditions, including the prevalence and incidence of medical conditions with neurodevelopment disabilities also add to the complexity. [Box 35.2](#) provides several important pointers for examining this population of patients and patients.

The individual with chronic impairments who is currently facing an active pathology likely has adapted to his or her existing system impairments and activity limitations. Depending on their underlying health conditions, some individuals with chronic conditions may have higher risks than others of developing preventable health problems.⁸³

BOX 35.2 Examination Pointers

- **Comprehensive:** A systems approach to address the number, complexity, and diversity of the deficits is a must. Essential components are physical, functional, mental, and social health.
- **Interdisciplinary:** Consideration for the functional, medical, vocational, and psychosocial issues warrants a coordinated evaluation of a team versed in addressing the unique needs of individuals with chronic neuromusculoskeletal conditions and disabilities.
- **Patient/client-centered:** Factors that influence performance, such as fatigue, must be considered during the examination. Recognition of the individual's and family's values and goals is essential.
- **Thorough:** Assessment may take several hours and extend for two to four visits^{86,87} to better integrate the evaluation process and allow the patient to fully participate, contend with the recommendations, and engage in long-term management.

Thus from an examination viewpoint, the critical task of the health care provider is determining what new changes to the individual's current abilities and disabilities have been brought on by the active pathology. These changes will likely affect the current functional abilities (e.g., mobility, ADLs), as will preexisting system impairments such as deficits in strength and endurance, pain, and so on. Regardless of the level of deficit, these individuals have some prior knowledge of deficits that affect function, which may help or may hinder their willingness to participate.

On the other hand, for the patient/client who has been otherwise healthy and functional and now has an acute diagnosis, active pathology may bring on impairments and limitations that are "new" experiences to the individual. The level of education should thus be adapted to the individual, and education performed on a case-by-case basis.

Moreover, the psychosocial aspect of a new pathology and its effect on function may be very different in an individual who has dealt with chronic impairments and limitations versus one who has been active up until the disease process. As with the level of education, the health care provider's approach to a patient/client should always be professional and respectful, with open lines of communication and active listening.

PTs may develop diagnostic focuses based on movement dysfunction, activity limitations, and impairments, different from those by OTs. These variances depend on the functional activity limitations identified by the patient and the professional.^{88,89}

It is critical for the clinician to examine all possible contributors to symptoms reported by the individual with chronic impairments. A thorough review of systems may identify symptoms that are related to the primary medical diagnoses, but equally important, it may identify symptoms that are associated with one or more existing comorbidities that have developed over time since the initial nervous system insult.

Health History

Therapists typically collect health history information as part of a comprehensive examination. The history information along with the symptom investigation and review of systems and physical examination will provide guidance in the differential diagnosis process and in the choice of examination and intervention techniques.

The information from the history will be useful in determining the possible cause of current difficulties or symptoms for which the patient/client is now seeking intervention (**Box 35.3**). Fatigue or pain may be present from unnecessary and inefficient movement strategies or from high levels of activity. Information on the habitual sleeping,

BOX 35.3 Components of Patient/Client History

- **Demographics,** include body mass index
- **Growth and developmental history** (particularly in those diagnosed with developmental disabilities and those with acquired diagnoses such as polio in childhood or spinal cord injury as an adolescent)
- **Past medical-surgical history:** Include information on interventions and outcomes from initial diagnosis
- **Family medical history:** Critical in ruling out possible contributors to symptoms such as pain from rheumatoid arthritis; critical for possible genetic contributor to original diagnoses
- **Social and vocational history:** Include work status, modifications to work or home environment, and support system
- **Living environment:** Include adaptive equipment, modifications done or necessary to home
- **General current health status:** Include nutritional and sleep information
- **Current functional status,** activity level, and perceived quality of life

sitting, standing, and walking postures along with ineffective use of devices may alert the clinician to possible factors contributing to the patient's current symptoms or difficulties.

Systems Review

A systems approach to the examination is essential because individuals with chronic conditions have a multitude of possible impairments with superimposed age-related conditions. This situation is best illustrated when examining individuals with PPS. The patient presentation in this condition is a complex interaction of all systems along with the effects of aging, previous interventions, and environmental, psychosocial, and medical aspects of care. The initial diagnosis of polio, which is critical in the diagnostic criteria, will need to be established. This may be difficult because approximately 10% to 15% of individuals who were believed to have or were diagnosed with polio did not have it, and some individuals with mild weakness were diagnosed as having nonparalytic polio.^{44,90}

Chapter 7 of this text discusses the review of systems as a vital component in the PT's role in medical screening and differential diagnosis. OTs are responsible for this same vital component. Possible multisystem involvement warrants review of all systems to determine if current problems are associated with existing comorbid conditions or occult disease or are indeed late manifestations of the initial disease process, as in the case of polio.

Providing further substantiation for the need for a methodical and multisystem approach are findings of high rates of secondary conditions related to obesity and inactivity common in individuals with developmental disabilities. These secondary conditions include type 2 diabetes, cardiovascular disease, and metabolic syndrome, diagnoses that affect multiple systems.²⁶ Individuals with developmental disabilities also have four to six times the preventable mortality of the general population.^{18,92} As therapists are entering into the decade of becoming primary care providers, anyone with a preexisting functional problem may walk into a PT or OT clinic searching for help. The importance of medical screening cannot be overemphasized.

The nonspecificity of symptoms seen in individuals with chronic movement dysfunction lends credibility to the need for review of all body systems. Fatigue, for example, a symptom frequently seen in individuals with chronic conditions such as MS and PPS, among others, is associated with several systems, such as endocrine, nervous, psychological, and cardiopulmonary.

Tests and Measures

Through system assessment by the PT and/or OT, each individual with chronic movement problems should have an opportunity to participate in development of a unique clinical profile. This profile should reflect the strengths and limitations of that individual. Simultaneously these data should aid both the patient and the therapist in identifying realistic treatment goals and selecting the most appropriate intervention strategies. The choice of outcome measures will depend on the individual's current functional skills, the medical status, and the desires and expectations of the individual. Because the severity of symptoms is variable and nonspecific, the clinician is strongly urged to perform a thorough examination and take into consideration factors that may influence performance specific to that individual's functional impairment problems, such as fatigue and pain.

Critical to the examination process is the determination of secondary conditions. Secondary conditions have been defined as injuries, body system impairments, functional limitations, or disabilities that occur as a result of a primary condition or pathology^{24,93–97} as well as physical problems that were caused by small insults to one of the body systems not related to the primary condition. Musculoskeletal problems account for many of these secondary conditions; thus the musculoskeletal examination is of critical importance in individuals with developmental disabilities. Gajdosik and Cicerello⁹⁶ outlined numerous conditions that may affect the adult with CP; some can lead to significant loss in function and pain from complications such as fractures and osteoporosis. Other musculoskeletal conditions, including scoliosis, subluxations, dislocations, patella alta, foot deformities, pelvic obliquities, and contractures, further complicate the life progression of an adult with developmental disabilities.⁹⁶ Frequently these chronic conditions may have their origins in childhood, but because of the lack of sensory awareness may go undetected until later adolescence, adulthood, or well into advancing age when the body no longer has the ability to compensate for these abnormal biomechanical forces. Furthermore, as the aging process progresses, less regeneration of damaged tissue occurs, leading to greater cumulative trauma in joints and other load-sensitive structures.⁹⁷ Again, these conditions need to be closely monitored over time to ensure appropriate intervention, optimizing an individual's function and minimizing damage to various tissues.

Fatigue

Fatigue is one of the most common symptoms reported by individuals with chronic conditions such as PPS⁹⁸ and MS.⁹⁹ Movement and performance of daily activities are more energy-consuming for individuals with disabilities and may cause greater fatigue.¹⁰⁰ Evidence also points to individuals with disabilities aging faster than those without disabilities; cardiovascular data from individuals with SCI indicate that people with SCI may age faster than those without SCI.^{101,102} Cook and colleagues¹⁰⁰ identified the lack of age-specific general population norms as an obstacle in the understanding and estimation of the influence of aging on the fatigue of individuals with neuromuscular conditions.

It is likely that an earlier increase in fatigue with age might be observed in other chronic neuromuscular conditions; however, the effects of chronological age on fatigue in individuals with disabilities are not entirely clear.¹⁰⁰ In a recent study, Cook and colleagues¹⁰⁰ assessed fatigue and age in four clinical populations of individuals with PPS, SCI, MS, and muscular dystrophy (MD), comparing self-reported fatigue experience in different age cohorts with age-matched, US population norms. A total of 1836 surveys were used in data analysis.

The authors concluded that individuals with disabilities reported higher levels of fatigue than the general US population, regardless of

age or disability type.¹⁰⁰ Interestingly, the authors noted that the causes of fatigue likely vary by disability type—that is, MS, PPS, and MD are more likely to cause fatigue through a combination of central neurological processes, the effect of sleep disorders such as periodic limb movements (PLMs),¹⁰³ or increased physical effort, whereas in SCI fatigue may be a side effect of medications or result from sleep disorders.¹⁰⁰

Results revealed not only that individuals with disabilities have a higher risk of experiencing fatigue than those without disabilities, but also that the risk for increased fatigue, compared with normative values, increases with age.¹⁰⁰ The reported mean fatigue levels were the highest observed in older PPS age cohorts among the disability samples. In the MS group, fatigue was higher than in any other clinical group except PPS. The highest fatigue reported in the MS sample was in the 35- to 44-year-old age cohort, with lower fatigue in older cohorts except for those 75 years of age and older, but the older group had a small sample size. In the SCI group, peak reported fatigue was in the 55- to 64-year-old age cohort. The results for the SCI group younger than 55 years old were very similar to those for the general population.¹⁰⁰

In the general population, very little change in fatigue levels for most adults was found moving from young (65 years) to middle (75 years) old age, whereas in the disability samples the authors saw a slight but consistent increase toward greater fatigue at this point in the life-span.¹⁰⁰ This increase in fatigue could be associated with current physical decline associated with disease progression.¹⁰⁰ The authors concluded that more research is needed to determine the specific effects of fatigue on the functioning of people aging with disabilities and to further explore interventions that may shield against or reduce any negative effects that occur.¹⁰⁰

Bruno and colleagues⁹⁸ state that fatigue has been identified as the most commonly reported, most debilitating, and least studied symptom in the postpolio sequelae. Generalized fatigue is typically described as overwhelming exhaustion or flulike aching accompanied by marked changes in level of energy, endurance, and mental alertness.²⁹ The lack of energy with minimal activity is often described as “hitting a wall,” thus the term “polio wall.” Polio survivors differentiated between the fatigue associated with weakness and a “central fatigue” that leads to attention and cognitive problems.⁹⁸ Severe fatigue affects not only physical function but mental function as well—hence the controversial suggestion that the fatigue associated with postpolio is caused by impaired brain function rather than the diffuse degeneration of motor units and motor junctions.⁹⁸

Descriptors for fatigue associated with PPS are significantly different.¹⁰⁴ The fatigue of PPS may not appear at the time of the activity, and recovery does not occur with typical rest periods. It has also been described as a sudden and total wipeout. In a few instances headaches and sweating appear, suggestive of autonomic nervous system overload.¹⁰⁵ Fatigue commonly occurs in the late afternoon or early evening. Fatigue that tends to last all day is atypical in PPS⁴⁴ and should alert the therapist to consider other possible diagnoses.

Similar to the fatigue of PPS, MS fatigue profoundly disrupts multiple aspects of general well-being.⁹⁹ Krupp¹⁰⁶ reported that 67% of individuals with MS reported fatigue as a major limiting factor in their social and occupational responsibilities compared with no reports in healthy adults. The fatigue of MS is unique in that it is exacerbated by heat, as are many MS symptoms. Fatigue may be acute, chronic, or intermittent or persistent, whether related to a specific diagnosis such as MS, CP, or polio or having no relation to the initial medical diagnosis. It is necessary to consider the role of other symptoms related to the specific medical diagnosis during the examination of fatigue.

The evaluation of fatigue includes the various factors that can induce or worsen fatigue. The history and examination also are used to assess for new medical diagnoses or the possibility of infection, an impending relapse, heat exposure (in the case of MS), and side effects from medications.

Differential diagnoses for fatigue are extensive and may include disorders of several systems, including psychological, cardiopulmonary, neurological, and endocrine disorders, and medication use. Specific conditions that may cause fatigue include depression, myasthenia gravis, hyperparathyroidism, congestive heart failure, sleep apnea, cancer, and infections. Numerous medications commonly used in symptom management can cause fatigue, including antispasticity agents, tricyclic antidepressants, and β -blockers. The challenge is to differentiate the fatigue caused by typical activities from the fatigue of chronic conditions.

Pain

Individuals with chronic diseases often have pain as a common symptom, most likely from long-term atypical biomechanical forces on joints and muscles or from long-standing disease processes. Many developmental disabilities have a component of disordered movement, from hypomobility in the case of DS to hypermobility in the case of spastic CP. These abnormal joint stresses and strains cause long-term damage to the musculoskeletal system.^{96,107,108} The natural degradation of joint structures with aging coupled with weakness and atypical ground reaction forces leads to higher incidence of musculoskeletal pain.^{109–111}

Pain that occurs with chronic conditions may be muscular, joint-related, or both. The source of pain needs to be considered because pain may limit the individual's functional abilities and lead to further decline. Muscle pain is often described as a deep, aching pain similar to the pain experienced during the initial infection. The pain is frequently aggravated by physical activity, stress, and cold temperature. Pain is unusual in that it does not occur at the time of activity but rather 1 to 2 days after a precipitating event.

Joint pain in itself usually results primarily from long-term micro-trauma from abnormal biomechanical forces. An example might be the overuse of the shoulder girdle muscles and joint from a lifetime of use of Lofstrand crutches to compensate for lower-extremity impairments after polio. Joint pain is frequently associated with physical activity but is rarely associated with inflammation. Interventions are complicated by the presence of osteoporosis, lack of compensatory substitutions to rest the injured part, and, often, poor response to exercise. Failing joint fusions, uneven limb size, progressive scoliosis, poor posture, and abnormal mechanics may also contribute to pain.¹¹²

Although pain is not a hallmark of many chronic conditions such as DS and MS, it may occur in some individuals with long-term impairments and thus should be part of a comprehensive examination. Pain frequently associated with MS is related to postural problems and inefficient use of muscles and joints to compensate for loss of function or spasticity.

More than 65% of individuals with PPS have reported neck, shoulder, and back pain radiating to the hip and leg.¹¹³ This pain is expected because the incidence of major postural abnormalities and gait deviations is also high, as shown in [Table 35.1](#) and [Box 35.4](#).

Differential diagnosis for acute muscle and joint pain includes consideration of chronic musculoskeletal conditions leading to wear and tear and disorders with significant muscle or joint manifestations. The list is extensive and may include osteoarthritis, tendinitis, bursitis, fibromyalgia, rheumatoid arthritis, and polymyalgia rheumatica. The challenge is determining whether muscle or joint pain occurs from long-term wear and tear or from an acute or exacerbating occurrence.

TABLE 35.1 Major Postural Abnormalities in Sitting, Standing, and Walking in 111 Confirmed Postpolio Clinic Clients

Posture	Abnormal Deviation	No.	%
Sitting (<i>n</i> = 111)	Absent lumbar curve	64	54
	Forward head (loss of cervical curves)	50	45
	Uneven pelvic base ^a	29	26
	Structural scoliosis	38	34
Standing (<i>n</i> = 76)	Absent lumbar curve	52	68
	Uneven pelvic base ^a	40	53
	Weight bearing on stronger leg	29	38
Walking (<i>n</i> = 76)	Abnormal gait deviations	76	100
	Major lateral trunk oscillations	33	43
	Obvious forward lean	40	53

^aPelvic asymmetry was ½ inch or more.

Strength

Examination of strength is another critical component of the examination of individuals with chronic impairments. Long-standing weakness is an expected occurrence from decreased physical activity common in individuals with disabilities and chronic diseases. Strength deficits may result from several causes other than disuse, such as upper motor neuron weakness, fatigue, compensatory movements, pain, or spasticity. It is likely, however, that aging individuals with chronic conditions have adapted to the initial weakness associated with their diagnoses, as in the case of people with SCI or PPS who have led productive and functional lives since the initial diagnosis or acute onset.

Typical aging involves the losses of muscle strength, loss of power, and sarcopenia—processes that may intensify or build on the initial losses of strength. Delineation of weakness from age-related processes versus weakness as part of the disease process or that from lack of physical activity common in people with chronic impairments is difficult if not impractical from both research and clinical perspectives. Too many variables need to be controlled and accounted for unless specific muscle groups were examined initially and the findings well documented, which may have been the case for people with PPS. Many individuals with PPS have extreme difficulty dealing with these new

problems because they were taught that hard work was the only way to correct physical problems that followed acute polio. These new problems, which also limit motor function, require that these individuals not work hard. These two concepts are contradictory and can leave an individual frustrated and confused over therapeutic recommendations.

Manual muscle testing of the entire body, although time-consuming, may be necessary to determine the muscular involvement. Muscle testing, however, may not always reveal the full extent of muscle involvement, and functional assessment may provide a better picture of individuals' potential and true difficulties. Performance and participation in daily activities will provide a better picture of a person's strengths and impairments. Therefore current functional activities are critical in determining whether current mobility difficulties are related to the aging process, represent an exacerbation of initial disease processes such as in PPS, or are signs and symptoms of new medical concerns.

Weakness and postpolio syndrome. Weakness may occur in both previously affected and clinically unaffected muscles; however, it is primarily prominent in muscles most severely affected in the initial infection.⁴⁴ It is typically asymmetrical and may be proximal, distal, or patchy.¹¹² Weakness is primarily observed in repetitive and stabilizing contractions rather than with single maximum efforts. The decreased ability of the muscles to recover rapidly after contracting may be a factor. Recovery of quadriceps muscle strength after fatiguing exercise was significantly less in symptomatic PPS subjects compared with asymptomatic and control subjects.¹¹⁵ Overuse of muscles in relation to their limited capacity has long been associated with these new problems.¹¹⁶⁻¹¹⁸ New weakness and atrophy have been attributed to metabolic overload of the motor units, with more pruning of muscle fibers than axon sprouting.^{119,120}

New muscle involvement may also cause signs and symptoms such as muscle fasciculations, cramps, atrophy, and elevation of muscle enzymes in the blood. Yet many of these physical signs and symptoms are also present in other neuromuscular problems such as amyotrophic lateral sclerosis. Fasciculations occur at rest and during contraction and tend to persist even when muscle pain and fatigue have been resolved. Muscle cramps are common in fatigued muscles and are alleviated by decreased activity. The new weakness may or may not be accompanied by atrophy. New postpolio muscular atrophy of muscles is sometimes reported. It is very noticeable when it occurs in the gastrocnemius or the anterior tibialis owing to the effect on everyday ambulation. Elevation of muscle enzymes, indicative of muscle damage, has been found in individuals with PPS and has been related to the intensity of work.^{117,121,122}

Gross muscle testing may mask the true involvement because several muscles that were initially believed to be uninvolved were truly subclinically affected by polio. The pattern of definitive manual test findings (spotty, flaccid, and asymmetrical paresis or paralysis) is also used to confirm the initial polio diagnosis.

Several polio survivors are able to function at high levels of activity with few strong muscle groups as a result of the random, diffuse nature of the motor deficits and the body's ability to compensate with uncommon muscle and joint function. This delicate balance may be maintained for years, and a disruption from late-onset weakness of a significant muscle group can lead to disproportionate functional losses.

Superimposed pathological problems have been proposed as a possible cause of the later exhibition of new signs and symptoms in postpolio survivors. Several conditions may contribute to weakness, including arthritis, fibromyalgia, deconditioning from disuse, and coronary heart disease.¹²³

Range of Motion and Muscle Length

Limitations in joint motion from muscle contractures and from shortening of ligamentous joint structures are common in individuals with chronic disabilities. Likewise, hypermobile joints may also result from compensatory techniques forcing more mobility. An evaluation of the individual's activity levels and goals is vital before intervening with muscle and joint deficits. In some instances, during the convalescent stage of the initial diagnoses, as in polio or SCI, selective tightness was allowed to give some stability to joints with paralyzed muscles. In addition, the body may develop useful contractures to maintain or regain function. The presence of spasticity, particularly in severe cases, may have also contributed to the development of contractures in older adults with CP, SCI, MS, or TBI. Before making attempts to stretch contractures, therapists should carefully evaluate the functions that may be lost if gains in range of motion (ROM) are achieved. Equally important is to evaluate what functions would be gained and what the cost would be. Consider that after 20 to 40 years these contractures resist any significant elongation, and aggressive intervention may cause more harm and loss of function.

Box 35.5 lists the secondary conditions that may develop in an individual with CP. These impairments not only cause pain but also limit mobility and interfere with performance of ADLs and leisure activities. Thus a thorough evaluation of musculoskeletal status and periodic monitoring are imperative to maintaining quality of life and social participation for these individuals.

Tone

Examination of tone is a focal component of the examination of individuals with chronic neuromuscular conditions. This group of individuals may demonstrate a wide range of tone deficits from hypotonia seen with DS, to hypertonicity seen in people with TBI, SCI, MS, or CP, to a mixed type with episodes of high and low tone.

Spasticity can interfere with mobility and may coexist with weakness. It may cause pain and atypical postures, predispose the individual to contractures (particularly those with severe spasticity), and interfere with hygiene and self-care. On the opposite end of the tone spectrum, people with DS have hypotonia that may or may not limit mobility. Tone deficits in DS are not a primary limiting factor to mobility and physical activity, as the characteristic finding of marked hypotonia tends to gradually diminish with age.

Cognitive Function

Cognitive deficits may be a major disabling feature in genetic and developmental conditions such as DS and CP. Similarly, cognitive dysfunction may be a key symptom in chronic conditions such as MS, TBI, and SCI. The degree of cognitive deficits affects not only health management, but also the long-term planning for aging processes in people with chronic disabilities and conditions. The need for lifelong external support is a considerable issue for those who are unable to independently care for themselves as they age. The degree of cognitive deficits in this population may range from memory deficits to mental retardation; the degree of cognitive and perceptual deficits determines participation in functional activities and self-care, mobility, compliance, and even health status.

Standardized outcome measures exist to measure cognitive impairments; the examiner is cautioned to consider the validity and reliability of outcome measures for specific populations before use. The reader is referred to chapters discussing specific diagnoses for detailed outcome measures. Because cognition is multidimensional, examination for deficits will need to be directed at different components of cognition. Screening may be as simple as a three-item recall or short questions determining the ability to follow commands, attention, level of

BOX 35.5 Secondary Conditions Common in Individuals With Cerebral Palsy

Pathological Conditions

Fractures
Osteoporosis
Cardiovascular disorders
Degenerative joint disease
Spinal cord compression
Dental problems
Seizures
Pulmonary dysfunction

Impairments

Constipation
Contractures
Depression
Emaciation
Obesity
Incontinence (bowel and bladder)
Pain
Ulcers
Dysphagia
Gastrointestinal problems
Low self-esteem
Nerve entrapments
Overuse syndrome
Balance problems

Functional Limitations or Activity Restrictions

Inability to indicate toileting needs
Dependence on others for activities of daily living
Limitations in mobility
Difficulties using public transportation

Disabilities or Limitations in Life Participation

Difficulties living independently
Limited recreational opportunities
Problems with social relationships and intimacy
Social isolation
Difficulty with role as patient when medical professionals fail to make accommodations for treatment
Underemployment

consciousness, orientation, judgment, construction, and higher memory function.

Mobility and Posture

In individuals with chronic impairments, addressing inefficient alignments and postures is of critical importance, particularly if this area was not addressed early in their care. The dire effects of such malalignments and compensations described in the following paragraphs eventually affect functional abilities.

Asymmetrical or abnormal gait patterns, crutch walking, and propelling manual wheelchairs for several decades are frequently the major sources of the pain, weakness, and fatigue in people with chronic movement dysfunctions after a medical problem such as TBI, SCI, CP, PPS, or cerebrovascular accident (CVA). The incidence of pain

in a group of 114 patients with confirmed PPS increased from 84% in those who were ambulatory without orthotics to 100% in those who used crutches or wheelchairs for locomotion.¹¹³ A high prevalence of osteoarthritis in patients with PPS was documented in the hand and wrist by radiography.¹²⁴ More than twice the number of subjects with PPS had osteoarthritis of the wrist or hand than would be expected in a healthy population of the same age. The risk factor was significantly increased with lower-extremity muscle paralysis and use of assistive devices.

In an electromyographic study of walking in patients with PPS, Perry¹²⁵ demonstrated overuse and substitution activity of the vastus lateralis, biceps femoris, and gluteus maximus muscles when the soleus is nonfunctional. Such substitution and overcompensation in the long term, however, lead to microtrauma of ligaments and joint structures and exhaustion of neuromuscular units.

In addition to sitting in poorly supporting chairs, sofas, auto seats, and wheelchairs, the individual with chronic impairments may have trunk muscle paresis or asymmetries of the pelvic base and may spend up to 16 h/day in the seated position. The typical posture is slumped, hanging on posterior vertebral ligaments with loss of lumbar and cervical curves. Neck, shoulder, and back pain are therefore commonly reported.

Levels and types of mobility will be diverse in individuals with chronic neuromuscular impairments. Mobility may range from independent ambulation to gait with an assistive device all the way to wheelchair dependency, depending on existing impairments and cognitive function. Thorough examination should determine the current mobility levels and possible modification needs depending on new impairments or functional limitations. It may be necessary to include a seating examination in people who are wheelchair dependent or sit for the majority of the awake hours.

Balance and Coordination

Deficits in balance and coordination in individuals with chronic conditions predispose these people to falls and limit safe mobility. As individuals with these conditions age, typical age-related changes in balance may add to the existing deficits and magnify functional limitations and impairments. Coordination and balance deficits need to be examined under functional conditions and in the context of the individual's daily activities. Standardized outcome measures are also available to objectively measure impairments; however, the reliability and validity of such measures in specific populations may be deficient. The use of outcome measures may provide a multidimensional look into deficits and provide objective baseline measures to track progress with intervention as well as progression of the movement dysfunction.

Environmental Temperature Intolerance

Consideration for the effects of heat and/or cold may be necessary when working with individuals with chronic diseases, and the examination must include a component of temperature intolerance. Two specific diagnoses embody this phenomenon: PPS for cold intolerance and MS for the negative effects of environmental heat.

Regulation of body temperature is often a problem for individuals with MS (see Chapter 17). Earlier, it was noted that a feature of fatigue unique to MS is that the fatigue is exacerbated by heat. Other MS symptoms may also be aggravated by heat. The Uthoff phenomenon¹²⁶ is an adverse response to external heat, causing fatigue or deterioration of symptoms; it often occurs with exercise. Specific recommendations for cooling during exercise intervention may be necessary to counteract the deleterious effects of heat. It is important that the examiner meticulously determine during the health interview the symptomatic

effects, if any, of increased temperature in the aging individual with MS.

Sensory deficits per se are not hallmark features of polio; however, cold intolerance is a commonly reported late-onset symptom. Involved extremities in individuals with PPS are frequently abnormally cold as a result of sympathetic nerve cell involvement leading to decreased vasoconstriction and venoconstriction with heat loss to the environment.¹²⁷ The impairment may become worse with PPS. Environmental adaptation can create an easy solution to this problem as long as the individual with PPS is aware first of the problem and second of the adaptations necessary to avoid thermoinstability within the extremities. Preventing versus responding to the inadequate vasoresponse to cold empowers the individual to develop environmental control.

Sleep Disturbances

It is common knowledge that older individuals report and manifest sleep disorders.^{128,129} Thus this impairment certainly can be associated with aging individuals with chronic movement dysfunction. Disturbances in sleep are a common symptom in people with chronic neuromuscular diseases. Sleep deprivation is a contributing factor to fatigue in individuals with MS. Similarly, more than 50% of individuals with PPS have been found to have sleep disturbances.¹³⁰ These disturbances may be caused by pain, stress, hypoventilation, or obstructive apnea.^{131–133} Bruno¹³⁴ proposed a high incidence of abnormal movements in sleep in nearly two thirds of polio survivors, with 52% reporting sleep disturbance caused by these movements. All seven of subjects with PPS in the study demonstrated abnormal movements in sleep. The author points to the importance of eliminating sleep disorders as a cause of fatigue before the diagnosis of postpolio sequelae is made, particularly because it remains a diagnosis of exclusion.¹³⁴

In addition to the typical symptoms of muscular weakness, pain, and fatigue associated with PPS, some individuals also develop sleep disorders such as PLMs.¹⁰³ PLMs in sleep are repetitive episodes of muscular contractions with durations of 0.5 to 5 seconds; frequencies of five or more per sleep hour are deemed pathological. The association of PLMs with insomnia or daily sleepiness suggests the diagnosis of PLM disorder.¹⁰³ Whereas PLM has been related to the pathophysiology of PPS,¹³⁴ the occurrence of PLM in PPS is not well known.¹⁰³ In a recent retrospective study of 99 patients with PPS, researchers assessed the frequency of PLMs during sleep, including other sleep-quality variables such as total sleep time, efficiency of sleep, apnea-hypopnea index, and awaking index.¹⁰³ Sixteen patients showed a PLM index that was considered pathological. The authors concluded that a close relationship between PLM and PPS exists; however, the prevalence of PPS with or without PLM and its combination with apnea-hypopnea is not clearly established, a finding in agreement with the conclusions of Jubelt and colleagues.^{103,135}

A thorough history and review of systems including a sleep history may reveal the potential causes and guide the therapist in the clinical decision making process for referral and consultation. Sleep apnea, which occurs frequently in polio survivors, and other sleep disorders, including abnormal movements in sleep, may be revealed with specific questioning, triggering the referral process. The therapist plays a role when the sleep disorder is associated with the area of pain management.

Life-Threatening Conditions

Limited knowledge exists of adult health issues for older individuals with developmental disabilities. Secondary medical conditions warrant further examination, particularly in aging adults with chronic conditions. Acute onset of new symptoms may suggest exacerbation of

disease or decreased functional reserves or may arise from long-standing effects of impairments from the initial disease process.

In the case of PPS, bulbar muscle dysfunction¹¹² may also result from the new weakness. Life-threatening conditions such as hypoventilation, dysphagia, sleep apnea,¹³⁶ and cardiopulmonary insufficiency require management by medical specialists.^{131,137,138} These problems occur in people with previous bulbar poliomyelitis who may or may not be using ventilatory assistance and in those with severe kyphosis or scoliosis. Respiratory failure may occur primarily in individuals with residual respiratory insufficiency and minimal reserves.¹³⁵

Functional Assessment

Performance in functional activities often provides a better picture of the losses stemming from chronic impairments. Decreases in strength are not usually revealed in a single-effort maximum contraction such as required in the manual muscle test. Resistive force during testing is a necessary element for two grades, 5 (normal, “N”) and 4 (good, “G”), whereas the other four grades are nonresistive and mostly nonfunctional, and few examiners are now tested for reliability.¹³⁹ In a 1-year follow-up using quantitative muscle force testing, no differences were found in muscle strength, work capacity, endurance capacity, or recovery from fatigue of the quadriceps in either asymptomatic or symptomatic groups with PPS.¹⁴⁰ Nevertheless, there is at best a slow decline in functional ability, which patients may describe as loss of muscle strength. Clinically, individuals seeking therapy report functional loss or limitation more easily than a specific loss of muscle strength.

Functional assessment of individuals with chronic movement limitations provides a more practical and clearer picture of the abilities and limitations related to the initial condition or stemming from new impairments. Functional activities are visible and reportable performances of relevant tasks in the context of the individual’s culture.¹⁴¹ Functional tasks imply a specific goal and can range from simple to complex activities. In functional motor performance, the specific task and environmental context is as important as the individual functional movement (refer to Chapter 8). Consideration for these factors is necessary during examination. Detailed functional assessment is outlined by Howle¹⁴² and Zabel.¹⁴³

Functional limitations are difficulties in performing specific tasks. Difficulty in performing daily tasks including mobility and transfers may stem from overuse of muscles and joints that are already performing beyond their typical use, pain, fatigue, muscle weakness, weight gain, cognitive impairments, and decreases in functional endurance, among others. It can be logically inferred that individuals living with chronic movement impairments will reach a tipping point at which the performance of current activities will be hindered, or the way activities are performed will require modification.

Decreases in functional activities over time for varied chronic conditions^{44,57–61,144} have been documented in the literature. As early as 5 years and up to 20 years after the initial SCI, individuals have reported decreases in functional activities and increased need for assistance with ADLs.^{57–60} An association with the need for increasing support with advancing age in individuals with SCI is seen in the literature.^{57–59}

According to Agre and Rodriguez,¹⁴⁵ postpolio survivors with significant weakness perform daily activities at a different level of effort than other individuals; muscles of polio survivors may have to work near maximal effort during activities that individuals without polio can execute at relatively lower levels of effort. Individuals with PPS commonly report difficulty in walking, stair climbing,⁴⁴ and dressing. Westbrook¹⁴⁴ described a 5-year follow-up study examining physical and functional abilities and health status of 176 individuals

with PPS. During the course of the study, most subjects reported increases in muscle weakness, muscle and joint pain, and changes in walking. Notably, the participants reported more difficulty in four of the eight daily living activities (stair climbing, walking on level surfaces, transfers in and out of bed, and meeting the demands of home or work). Most of the participants (87%) also reported problems in meeting the demands of their job and completing household tasks. Clearly, the ability to perform motor tasks essential to completing one's goals and desires is multifactorial. Therefore functional limitations are usually related to a combination of systems impairments.

In people with PPS, to determine whether the cause of the new weakness is overuse or possibly disuse, a detailed assessment is required of home, work, recreational, and community activities.¹⁴⁶ This paradigm of multidimensional assessment is applicable to all individuals with chronic movement problems. If the patient is merely asked what his or her activity level is, the response may lead to assumptions that weakness is from disuse. With specific questioning, one usually finds that the patient is doing an extraordinary amount of physical activity. It is vital to establish a total picture of the patient's activities in sitting, standing, walking, lifting, carrying, climbing stairs, using a telephone or a computer, and performing daily activities such as self-care and home management.

PSYCHOSOCIAL CONSIDERATIONS

The challenges of chronic diseases are ongoing as the individual ages. Despite new pharmacological interventions, several genetic, developmental, and neuromuscular conditions remain incurable with uncertain courses as the person ages. Although individuals and their families cope effectively with the initial disease process, the incidence of depression is common in the presence of chronic disease and impairments. The impact of chronic conditions on family, marital life, and socioeconomic and financial functions is persistent. The clinician's attitudes, beliefs, support, and understanding will play a major role in the management of individuals with chronic impairments.

Most individuals living with chronic impairments and functional limitations have learned to adapt not only with their movement strategies, but also with the psychological and socioeconomic impact of the initial diagnoses. Not only have these individuals learned to live with the challenges of their initial diagnosis and its movement-related, functional, financial, and psychosocial impact, but their families and caregivers have likewise done so. It may not be surprising, then, that changes to once-established routines, either from acute medical conditions or from gradual but significant changes from the aging process, are resisted and negatively viewed. These individuals will possibly need more assistance, move slower, and need to cut back from activities once engaged in; the consequent changes in philosophy and lifestyle will not likely be welcomed by most individuals and their support systems.

Over the past years, several authors have addressed the prevalence of PPS, its causes, and the effects of aging on the development of PPS.^a Some literature addresses the effects of aging on developmental and genetic disabilities, yet information on how aging affects individuals with existing impairments is still not conclusive. Because the population of people who are aging with chronic disabilities is increasing owing to improvements in health care delivery and nutrition, evidence concerning the consequences of the aging process remains uncertain. Similarly, the psychological effects are not widely addressed in the literature. Not much is known about the quality of life for older adults

with congenital or childhood-acquired disabilities. Psychological adjustment is difficult with any disease with an unpredictable course and differentiating organic psychological problems from adjustment issues may complicate the management of individuals with chronic diseases.

As a chronic disease, PPS provides an informative example of the interaction among neurological and functional impairments, recovery, effects of aging, and health care. Much has been written about the psychological and psychosocial issues with PPS that is applicable to other chronic disabilities as well. A brief synopsis of the psychosocial considerations of PPS follows.

Postpolio Syndrome

Although the physical manifestations of and interventions for PPS are recognized, psychological symptoms become evident in polio survivors. Bruno and Frick⁴⁸ described psychological symptoms such as chronic stress, depression, anxiety, compulsiveness, and type A behavior in polio survivors; these symptoms not only cause distress but limit these individuals in making lifestyle changes to manage late-onset symptoms. Currie and colleagues¹²³ generalized about adults with childhood-onset or congenital disabilities spanning a range of disability types. Understanding the background of individuals with PPS and a few of the myths that helped to shape their lives is beneficial in their care. Fear of the disease was rampant during the early epidemics. Despite safety measures, children and adolescents contracted polio. Part of the coping strategy was encouraging the child to high levels of physical achievement; approval and rewards were gained by walking farther or faster and keeping up with or exceeding the performance of other children. The best treatment available for all polio victims at that time was from the March of Dimes, which entailed hospitalization for months at a time away from the individuals' families and communities. The situation led to feelings of abandonment, anxiety, and total dependence on strangers. The "polio patient" was expected to be a "good patient" and to "work hard." Indeed, these patients did work hard to reeducate weakened muscles and compensate for lost function.⁴⁸⁻⁵¹ Courage, determination, and cheerfulness were attributes to be prized, self-pity was viewed unfavorably, and talking about the functional loss was not encouraged. Later in the recovery process, parents made decisions to have their children undergo multiple surgical procedures to allow removal of heavy braces so that they would "look normal" and "fit in." One can understand why patients react so negatively to the suggestion of orthotics.

Coping Strategies

The psychosocial issues confronting people with PPS often are more disruptive than the physical problems.^{31,32,90,152-154} An increasing population of polio survivors is experiencing, with aging, an unanticipated late onset of new symptoms. Associated with loss of physical function and independence are social and psychological problems stemming from the inability to perform personal and societal roles. Previous research suggests that well-established, often compulsive behavior patterns may impair the ability to deal effectively with the new threats to functional independence. Bruno and Frick³³ confirmed the presence of psychological stress in survivors, noting that type A behavior and stress could precipitate or exacerbate postpolio sequelae. In a later study in 1991⁴⁸ the same researchers suggested that the acute experience conditioned survivors into lifelong patterns of compulsive type A behavior, a behavior pattern that impairs the ability to cope with new late postpolio symptoms. Kuehn and Winters¹⁵⁵ also noted that symptom distress and intensity were less in individuals with greater coping resources. In this study¹⁵⁵ in Sweden of 113 patients with postpolio sequelae, results revealed that the prevalence of distress

^aReferences 28, 30, 34, 35, 40, 41, 44, 47, 90, 98, 112, 124, 147-151.

was highest in the physical dimensions of physical mobility, pain, and energy and lowest in social isolation. The high scores for the triad of dimensions were similar to the findings of previous studies.¹³⁶

Individuals with PPS developed several styles to cope with their disability. Maynard and Roller¹⁵⁶ described coping styles according to severity of muscular involvement. Survivors with little or no obvious physical involvement were able to hide atrophy with clothing and avoided activities that revealed the weakness. Many individuals invested much energy in projecting normality and were so adept at denial that they disconnected themselves from the polio experience; often spouses do not know of the history of polio. This group can develop the most severe cases of PPS. The denial renders them detached from other individuals with PPS and thus difficult to assist.

Polio survivors with obvious physical involvement such as a limp or an atrophied extremity or who use an assistive device have usually pushed themselves to function at normal or supernormal levels. These individuals will tolerate high levels of pain before acknowledging the late effects of polio. The third group, the most severely impaired of the individuals with PPS, may have respiratory involvement or more mobility deficits. Several use or have used wheelchairs for mobility and required great effort and persistence to gain independence in self-care activities. The members of this group integrated their functional problems into their self-image and have led active, productive lives.

In a 5-year study of 176 individuals with PPS, it was unexpectedly found that participants' stress levels decreased over time.¹⁴⁴ The author hypothesized that eventually, lifestyle modifications and treatment contributed to the coping process. Kuehn and Winters¹⁵⁵ in their study found that more than half of their subjects of working age had gainful employment. Moreover, no difference in employment rate as a result of distribution of polio involvement was found, implying that this was not a deciding factor. The authors hypothesize that people with severe polio involvement were either forced to choose or encouraged to take up an appropriate profession early in life, whereas those with less involvement had not needed such planning. Nevertheless, vocational issues encompassing satisfactory accessibility and equipment are an important part of management.

Response to new diagnosis. The response to the diagnosis of PPS can range from relief to despair. Relief comes to polio survivors who have been told their symptoms were psychosomatic. Despair occurs when survivors are given a program of lifestyle changes and management suggestions that are opposed to the adage they followed during the initial infection. The proposed philosophy shift from "no pain, no gain" to energy conservation and rest may be viewed unfavorably or with disdain. Polio survivors who have led active lives may have significant difficulty adjusting their lifestyle to new symptoms and decreasing abilities, and psychological support may be indicated.¹⁵⁷

The stresses of the diagnostic process also add to the challenges. Most health care professionals have limited understanding of the initial polio experience and the late effects of polio, and therefore the diagnostic process of PPS may take time and involve a series of physician consultations.^{48,49,158–160} Publicity from support groups has helped refer patients to PPS clinics or to specialists with knowledge of PPS.¹⁶⁰

Fear of the threat to independence, inadequate knowledge about the physiological changes, and the expectation of functional loss may contribute to the anxiety of polio survivors. Individuals with PPS will feel anxious about the prospects of changing roles with their families, friends, and co-workers.^{49,156,159} Defenses and coping strategies that have been successfully used for years have broken down, and the individual experiences overwhelming anxieties and conflicts.¹⁵⁹

Compliance. The patient-clinician relationship is an important determinant of compliance. Several authors^{33,48,161} have identified

compliance as a significant problem in type A polio survivors. Although a few individuals with PPS readily accept suggestions for lifestyle changes, a few immediately make changes, and a few refuse to consider any changes at all, most will eventually make changes but will require support, patience, and time to process. Compliance is an issue encountered not only in individuals with PPS but in many individuals with chronic conditions. Clinicians' sensitivity, support, and respect will play a major role in the response of the patient/client to management suggestions. Acknowledging the individual's current activities, values, and goals is an important step in establishing a relationship with the patient/client. Allowing patients to express feelings about the new challenges, their prior high levels of physical achievement, and previous treatment is equally important.

A health care provider perceived to be knowledgeable, interested, and concerned significantly increases compliance with recommendations.¹⁶² Adherence of the patient/client with PPS may be improved by the therapist's ability to suggest management strategies that are accepted as conventional and the ability to alleviate pain in the initial examination. Conservative management should be attempted first before more aggressive or life-changing interventions such as orthoses, mobility changes, or motorized carts, which they may have used in the past and eventually discarded. Therapists can also be a source of information about support groups.¹⁶⁰ Support groups offer information about multiple facets of living with chronic impairments, and these members may be positive role models to help the newly diagnosed individual in the transition process as well as the aging individual with chronic disease and impairments in dealing with issues in terms of maturation and advancing age.

HEALTH-RELATED DISPARITIES IN AGING ADULTS WITH CHRONIC DISABILITIES

Individuals aging with chronic impairments and conditions are exposed to the effects of aging and maturation differently than the general population. People with disabilities often start at the lower end of the health continuum owing to secondary conditions that overlap with the primary disability.¹⁶³ Few will argue that despite medical advances and public health initiatives, the reality is that health disparities, including decreased access to high-quality health care, health promotion, disease prevention, and health literacy, are still present and reflect areas that need to be addressed. Outlined here are some health disparities facing adults with chronic disabilities and conditions.

- Compared with the general population, higher rates of disability and obesity are seen among adults with developmental delay.^{83,164,165} Of adults with major physical and sensory impairments, 27% are obese, compared with 19% of those without major disability.⁸⁵
- Cardiovascular disease is one of the most common causes of death among aging adults with developmental delay.^{26,166,167}
- Evidence supports the earlier appearance of age-related health conditions in individuals with developmental delay. Conditions include cognitive decline, incontinence, and sensory losses.¹⁶⁸ Examples of health conditions that may be influenced by aging in people with developmental delay were discussed earlier regarding individuals with CP¹⁶⁹ (who may have increased issues with musculoskeletal deformities, progressive cervical spine degeneration, dental problems, bladder or bowel dysfunction, or osteoporosis) and individuals with DS (who have a higher prevalence of early-onset Alzheimer's disease compared with the general public).^{22,170}
- Generally, individuals with intellectual and developmental disabilities have poorer health and more difficulty in finding, accessing, and paying for higher-quality health care.¹⁶

- Adults with developmental disabilities also have limited access to medical care, which may result in lack of obesity screening, counseling, and management.¹⁷¹
- Higher rates of depression, anxiety, and strong fears and stress are seen in people with chronic disabilities. Iezzoni and O'Day⁸⁵ found that 34% of adults with major impairments in walking reported frequent depression or anxiety, compared with 3% in those without disabilities.

MANAGEMENT OF CHRONIC IMPAIRMENTS

Aging With Chronic Impairments

The management of individuals with chronic impairments is challenging, not only because of the possibility of multisystem involvement warranting a holistic approach, but also because much is unknown about effects of the aging process on chronic neuromuscular impairments.

Aging adults with chronic conditions may be more vulnerable to conditions that will make their old age potentially more difficult with an increased possibility for infirmity and dependence.¹⁶ Individuals with chronic and disabling impairments are often at an increased risk for the development of secondary conditions and further disability that can lead to further decline in independence and functional status and to mobility deficits. It has been suggested that people with chronic conditions, such as living with developmental delay, may age differently based on the nature and severity of their disability, other coexisting health problems, and secondary chronic conditions. With increased life expectancy, health care professions will likely see an increase in the care of those aging with chronic impairments. There is then a unique challenge for health care professionals to develop and implement programs for the management of aging adults with chronic impairments to effect optimal health status.

The heterogeneity of aging adults with chronic neuromuscular impairments lends to the need for individualized management programs. The aging process is unique for each individual, as is the recovery process in people with chronic conditions and the overall manifestation of late-onset or secondary symptoms. Therefore intervention will be dependent on the individual's current symptoms, functional needs, level of activity limitations, and values or goals.

Although evidence exists regarding interventions for individuals with chronic disease, overall, there is a dearth of information on specific treatment strategies if one considers the magnitude of associated diseases and the increasing population of individuals aging with chronic functional limitations and impairments. The reason for this is multifactorial; it may stem from the mismatch between the increase in number of individuals with chronic diseases that is resulting from longer life expectancies because of advancements in medicine and the gaps in our knowledge about the effects of aging in this population. The limitation on specific knowledge about interventions is echoed by Marks and colleagues, who state that there is a lack of framework for assessing health-related interventions for individuals aging with developmental delay.¹⁷²

A finite number of research and treatment centers have been established to deal with comprehensive care issues for individuals with disabilities.¹⁷³ The statement by Kailes¹⁷⁴ regarding the lack of helpful information related to exercising for those aging with a disability is troubling yet accurate. Considering the extensive evidence showing that many of the physical limitations that occur as part of aging in nondisabled people can be prevented or delayed by changing health habits, Kailes¹⁷⁴ suggests that individuals with disabilities need (1) appropriate fitness assessment measures that can be used with

various types of disabilities, (2) exercise guidelines that are appropriate for age and types of limitations, (3) exercise facilities that are accessible, integrated, and not separate from those of nondisabled populations, and (4) exercise equipment that incorporates universal design features.

Unfortunately, in today's health care environment, many individuals with PPS, SCI, TBI, or developmental disabilities do not have access to specialists, including PTs, who understand their complex movement limitation-related needs and how these limitations affect participation in life. Care is fragmented, and physicians and therapists, if involved in the care at all, seldom have a comprehensive picture of the person's needs. Although one might assume that the managed-care system would provide coordination of care within the provider system, the reality is that there may be more restrictions in care, particularly for disability-related care that may require a period of continuing rehabilitation treatment and retraining. Even providers within the group seldom communicate because the group is composed of practitioners who accept the insurance contract rather than practitioners working together to improve health. In my experience, hardly any individuals aging with neurological conditions such as TBI, CVA, or SCI seek therapy past their initial episode of care in the acute phase of the condition. This reality is confirmed in the literature; today people with SCI or TBI are followed in comprehensive specialty centers or clinics as they age.^{175,176}

Multisystem Approach

Individuals with chronic neuromuscular conditions have multidimensional impairments across multiple systems. Chronicity of impairments in one system likely and eventually affects other systems. For example, an individual with limited physical mobility because of impairments in the neuromuscular system likely has decreased levels of physical activity, which in turn are correlated with lower muscle strength, which is associated with a greater degree of disability. Although the initial impairments may be in the neuromuscular system, over time the condition will affect the cardiovascular system because of inactivity and potentially the integumentary system. An increased likelihood of multisystem effects in an individual with chronic impairments is a reality. Therefore a multisystem, holistic approach to management is warranted.

The rehabilitation clinician is in a unique position to provide holistic care to the patient with chronic impairments. In the realm of management of chronic movement dysfunction, PPS becomes a model case for other chronic neuromuscular conditions—there is much to learn from the complex nature of the late effects of polio. Designing an intervention program may be as challenging as the evaluation because of the interactions of the systems and the influences of the environment, medical treatment, and aging. Before beginning physical or occupational therapy, it is necessary for the team to first identify and treat other medical and neurological conditions that may produce the reported symptoms.¹⁷⁷

The individual's values and goals are the most significant variables to take into consideration in designing the interventions. Improvement will largely depend on the patient's commitment and thus compliance. Relatively simple interventions may result in distinctive positive changes. Conservative management should be attempted first before major life-changing interventions. Psychological considerations play a major role in designing an acceptable and appropriate management plan that will encourage compliance. Lifestyle modifications may not be favorably viewed by some individuals who have "conquered" the disease and pushed themselves to be independent, as in the case of those with PPS or SCI in their younger years. Prescription of interventions that are perceived to be "radical" should be done

with sensitivity and caution. The rationale for interventions should be carefully considered in light of the patient's current functional status and goals. Introduction of orthoses, assistive devices, and mobility modifications is often difficult for the individual with chronic impairments to accept, given the long, arduous effort expended over years to avoid such devices and the movement adaptation achieved without such devices.

The long-term goals for individuals with chronic conditions center primarily on self-management of home exercise programs and appropriate lifestyle changes to reduce physical demands. No definitive, curative intervention currently exists for chronic neuromuscular conditions ranging from developmental delay (CP) to those acquired through trauma or disease sometime in the life-span (SCI, TBI, PPS); therefore symptom management is a key element in both the short and long terms. Short-term goals focus on the symptoms present and may address the following areas:

- Modified strengthening and conditioning
- Postural correction
- Energy conservation
- Lifestyle modifications
- Mobility and locomotion
- Balance during functional activities
- Walking aids, mobility devices, orthoses
- Pain reduction
- Improved functional endurance
- Ability to transfer
- Respiratory care
- Weight control

The information is presented with an evidence-based approach and will specifically address the management of adults with PPS, SCI, and TBI. When possible, the intervention approaches first offered should focus on several problems at one time (Table 35.2). The importance of individualized programs that address the variability of symptoms cannot be overemphasized. The reader is referred to specific references for further details on management prescriptions.

Before discussion of specific intervention strategies, a shift in the philosophy of management of chronic disease and disability is presented. Within the past decade, in an effort to affect the trajectory of further decline from chronic conditions, there appears to have been a shift toward the promotion of health rather than the control of the disease itself.

HEALTH PROMOTION

Health Promotion With Chronic Conditions

Emerging in the public health arena is a call for attention to the growing population of aging adults with chronic disabilities and for reducing health disparities involving this aging population. There is consensus on a need to address issues related to the health and care of aging individuals with developmental and intellectual disabilities related to primary care, health promotion, health literacy, and health care providers.^{83,172}

Decreasing health disparities affecting aging adults with chronic impairments is an increasing area of focus, as evidenced by its inclusion in the national health goals for individuals with disabilities outlined in several documents such as the Healthy People 2020 initiative,¹⁷⁸ the New Freedom Initiative,¹⁷⁹ the US Department of Health and Human Services document *Closing the Gap: A National Blueprint to Improve the Health of Persons with Mental Retardation*,¹⁸⁰ and the US Surgeon General's Call to Action to Improve the Health and Wellness of Persons with Disabilities.¹⁸¹ Healthy People 2010 cautioned that people with disabilities would be expected to experience disadvantages

TABLE 35.2 Evidence-Based Approach to the Management of Post-Polio Syndrome

Generalized weakness	Lifestyle changes Therapeutic nonfatiguing strengthening exercises Aerobic exercise Orthoses Assistive devices Avoidance of overuse Weight loss
Pain	Therapeutic heating modalities ^a Cryotherapy ^a Activity reduction and lifestyle changes Pacing of activities Stretching Weight loss Assistive devices Orthoses Motorized mobility devices Nonsteroidal antiinflammatory drugs ^b
Dysphagia	Dietary changes or restrictions Breathing techniques Swallowing techniques Monitoring fatigue and timing eating when not fatigued
Fatigue	Lifestyle changes Energy conservation techniques Nonfatiguing exercise programs Lightweight orthoses and assistive devices Pacing of activities Frequent rest breaks Naps during the day Motorized mobility devices
Cardiopulmonary conditioning	Aquatic exercise training Endurance training Cycle or arm exercises
Psychosocial concerns	Postpolio support groups Interdisciplinary approach Counseling from psychologists, psychiatrists Vocational counseling Behavior modification
Pulmonary dysfunction	Preventive measures Noninvasive ventilatory assistance Pulmonary therapy Breathing exercises: glossopharyngeal breathing

^aEffectiveness of heat and cold modalities are patient specific and must be used with caution.

^bAntiinflammatory drugs have been shown to be effective in pain management in medical treatment of postpolio syndrome. The specific drug and dosage must be prescribed by the physician. Modified from Trojan D, Finch L. Management of post-polio syndrome. *NeuroRehabilitation*. 1997;8:93-105; and Jubelt B, Agre J. Management of post-polio syndrome. *JAMA*. 2000;284:412-414.

in health compared with the general population. Five years after the release of the US Surgeon General's Call to Action, it was reported that some individuals with disabilities still lacked equal access to health care, and health promotion has been outlined as a goal to be achieved by people with disabilities.¹⁸¹

Health promotion is defined by Pender and colleagues¹⁸² as activities motivated by the desire to increase well-being and actualize human potential. It includes self-initiated behaviors and stresses the need to enhance the responsibility and commitment of each person to achieve a healthy lifestyle. Health promotion was reflected in Healthy People 2010. Healthy People 2020 includes individuals with disabilities in all health promotion efforts as an emerging area in disability and health, reflecting a continuation of the initiative's prior goals for the well-being of people with disabilities.¹⁷⁸

Shift to Health Promotion

In 1997, Patrick¹⁸³ found that research on health promotion for individuals with health disabilities was almost nonexistent. Fast-forward to 2011: a shift from disability prevention to health promotion has emerged, and literature on health promotion efforts for people with a variety of chronic diseases is emerging.

In contrast to health protection or disease-management behaviors, which are motivated by the desire to avoid illness or its effects, health promotion is not disease- or injury-specific.¹⁸² Whereas both wellness and disease-management interventions may focus on improving similar health behaviors, a critical difference between these approaches has been proposed by Stuijbergen and colleagues.¹⁸⁴ They assert that the significant difference is in how the individual is viewed with regard to the interaction between his or her chronic disability and the purpose or intention of the change in behavior—that is, control and management of disease versus maximizing quality of life and health. Furthermore, whereas wellness interventions have wellness or health in the forefront and the disease in the background,¹⁸⁵ wellness and health promotion interventions allow the individual to choose behaviors that improve and/or sustain the quality of life within the perspective of living with chronic conditions.¹⁸⁶

Part of the national initiative to improve the health of aging adults with developmental disabilities, the US Surgeon General's Call to Action to Improve the Health and Wellness of Persons with Disabilities¹⁸¹ stated that people with disabilities can promote their own health through developing or maintaining healthy lifestyles. Embedded in this statement is the responsibility of the individual for his or her own health trajectory. This responsibility is shared with health care providers and support persons. A need to develop skills to improve health literacy related to health care issues is paramount to this responsibility¹⁷² and to encouragement of active participation. Health literacy is defined by Selden¹⁸⁷ as the degree to which individuals have the capacity to obtain, process, and understand basic health information and services necessary to make apt health decisions.

Early education combined with opportunities for lifelong learning can help individuals develop the skills and confidence needed to improve or manage healthy lifestyles with aging.¹⁷² Similarly, health care professionals need to improve, maintain, and use clear communication.

Health promotion and disease prevention activities should consist of specific health education programs and preventive or screening programs.¹⁷² In the paradigm shift to health promotion, some interventions have focused on a single behavior such as exercise or nutrition or a combination of interventions for a more inclusive lifestyle approach.^{184,186,188}

Community-Based Programs

With approximately 35% of Americans aged 65 and older with a disability¹⁸⁹ targeted by public health initiatives, assistive technology advancements, and cultural changes, many barriers still exist to access community-based programs.¹⁷⁹ Community-based interventions for health promotion are ideal for those with developmental disabilities

because they address social inclusion, self-efficacy, and sustainability.¹⁹⁰ However, few community-based lifestyle interventions targeting those with developmental disabilities exist.²⁶ Developing and implementing accessible programs in the community setting for adults with long-term disabilities remain challenging.¹⁷²

Today, adults with chronic movement dysfunction have more of an opportunity to participate in sporting events and recreational activities. Therapists need to be involved in the process to ensure optimum benefit of these activities for patients to be not only successful but also safe. As research supports fitness training for people with chronic disabilities and impairments, more effort will be needed to maximize the availability of community-based facilities to meet the demand. Again, therapists can be instrumental not only in the design of equipment but also in advocacy efforts by educating governmental officials and third-party payers regarding the needs of those aging with chronic conditions. Therapists not only possess the knowledge of the physiological effects of exercise but also understand biomechanical principles critical to ensuring safety in fitness and recreational activities. Therapists can work with these individuals on maximizing strength, flexibility, body mass indices, and cardiorespiratory reserves. This focus will not only increase functional capacity and social participation of the adult with functional limitations but will lower the risk of medical comorbidities associated with the effects of physical inactivity.

Health Promotion Interventions: Evidence and Challenges

Iezzoni⁸³ identified several barriers faced by people with disability to accessing health care and public health interventions. Physical access, communication, financial barriers, and discriminatory and stigmatizing attitudes were identified as externally imposed barriers.

Although there has been a shift in philosophy and growing interest in health promotion in individuals with chronic impairments, the supporting evidence on the effectiveness of these interventions has not been examined in depth. Although there are published studies on health promotion in people with chronic diseases, several challenges arise. Studies often involve varied chronic diseases such as cancer, heart failure, arthritis, or human immunodeficiency virus (HIV) infection, with few studies examining individuals with chronic neuromuscular conditions. The studies often involve small experimental interventional strategies, use small population samples, and have varied intervention delivery from individual, group, or community-based programs. Moreover, Stuijbergen and colleagues¹⁸⁴ found that despite the benefits of health promotion for improving or maintaining function and independence in older adults, very few studies had samples of older subjects. Iezzoni⁸³ asserts that improving access to health promotion and disease prevention should be a national public health priority.

A mounting body of evidence regarding the positive impact of health promotion and wellness interventions on individuals with chronic conditions is seen in the literature.¹⁸⁴ Although these studies report significant effects and used multiple outcome measures, they had small population samples that encompassed varied chronic conditions not specific to those with neuromuscular impairments alone. Moreover, types, lengths, and delivery of interventions varied greatly from community-based to independent settings. Therefore, generalization and comparison across studies are difficult to say the least. It is noteworthy that a review of the literature supports the benefits and positive effects of health promotion and wellness interventions; however, in agreement with the findings of Stuijbergen and colleagues,¹⁸⁴ minimal information exists about the long-term effects or efficacy of interventions.

INTERVENTION STRATEGIES

A paucity of evidence specifically addresses precise exercise or intervention plans in individuals with chronic impairments. This lack of data is evident in specific neurological populations: SCI TBI and PPS, to name a few. Although no published studies were found on exercise plans and aging in SCI, the interest in promoting exercise and lifestyle changes to prevent secondary medical problems has been identified. Similarly, most studies are conducted in the early years after TBI, and although TBI is a lifetime disability, little attention has been paid to the needs of aging people after a TBI who may have recurring needs for physical and cognitive rehabilitation and retraining over the life-span. The information presented is directed more toward PPS, for which a body of evidence supports specific intervention strategies. There is still a marked lack of longitudinal research examining the natural course of health conditions, much less targeted interventions for aging adults with PPS. In a recent review on the treatment of PPS through the Cochrane Collaboration, Koopman and colleagues²⁷ found inadequate evidence from randomized controlled studies pointing to definitive conclusions on the effectiveness of different treatment options for individuals with PPS. Their results indicate that pharmacological intervention, specifically drugs such as lamotrigine and intravenous immunoglobulin (IVIG), and nonpharmacological interventions, specifically muscle strengthening and static magnetic fields, may be beneficial but need further research.²⁷

As with other chronic neuromuscular conditions, there currently exists no curative treatment for PPS,²⁷ and therefore rehabilitation management is regarded as the key intervention. The succeeding discussion presents strategies for the rehabilitation of chronic neuromuscular dysfunction with the goals of improving and/or maintaining functional capacities and decreasing secondary impairments magnified by aging or the chronicity of the condition.

Although primarily directed at PPS, most of, if not all, the intervention strategies are applicable to people with other chronic impairments; there are commonalities to all chronic neuromuscular conditions that need to be identified and analyzed from a long-term quality-of-life perspective. Individuals who are aging with these chronic functional limitations should be allowed to age with the dignity given to any other individual. The challenge to therapists will be to step out of the model of regaining functional skill through repetitive practice and into the model of maintaining function, energy conservation, and empowerment of that function to the individual needing service. The patient/client is and should be the individual who determines what aspect of functional activities are critical to quality of life and what compensations are acceptable and unacceptable as part of an adult life expectation. From that information and the analytical understanding of what is happening to the CNS of these individuals, patients and therapists together can establish realistic goals and intervention strategies that will optimize and maintain the potential motor function of those individuals.

Therapeutic Exercise

Strengthening and Conditioning

Evidence suggests that both physical activity and strength are significant factors in severity of disability.¹⁹¹ It has been shown that muscle strength has a significant role in a spiraling model of decline. Specifically, lower muscle strength is correlated with a greater degree of disability. In terms of function, difficulties in motor activities are reported by those with poor strength. It is logical, then, that the management of chronic disabilities involves a strengthening program.

A mounting body of evidence supports strengthening exercises for individuals with PPS,^{112,192-196} contrary to the initial approach of no

exercise because of fear of overuse or symptom exacerbation. Generally, individuals with PPS who exercised and avoided overuse demonstrated positive results without detrimental effects. Several types of non-fatiguing strengthening exercises, aerobic exercise, and the evidence supporting them have been examined. Willen and colleagues¹⁹⁷ suggest that water exercise may be beneficial because it decreases the biomechanical stresses on the muscles and joints. Specific exercise prescription is dependent on several factors such as the current level of function, other presenting symptoms, and the patient's interests.

Jubelt and Agre¹¹² note that the most important advance in the treatment of weakness in PPS involves the findings of several studies that mild to moderate weakness can be improved with nonfatiguing exercises. The benefits of nonfatiguing exercises using both submaximal and maximal contraction with limited number of repetitions are documented in the literature.^{112,192}

Isokinetic and isometric dynamometers have been used to record maximum muscle forces (or torques) in PPS subjects before and after resistive exercise programs designed to increase muscle strength. Two of the studies were of single cases,^{198,199} and two had 12 and 17 subjects.^{193,194} Both of the multisubject studies tested the quadriceps femoris. Einarsson¹⁹³ investigated the effects of a standardized, 6-week, maximal effort and isometric strength training program on the quadriceps muscles of 12 individuals with post-polio muscles, nine of whom met the criteria for PPS. Einarsson¹⁹³ reports an average gain of 29% in isometric strength and 24% in isokinetic strength over a period of 6 weeks; muscle biopsy specimens revealed no muscle damage. In addition to the feeling of well-being in most of the subjects during and after the training program, 10 of 12 subjects stated a feeling of increased strength in the trained muscle. In subsequent follow-ups 6 to 12 months after intervention, gains in strength did not decrease, and several subjects reported better performance in daily activities such as climbing stairs, walking, and standing from a chair.¹⁹³

Fillyaw and colleagues¹⁹⁴ reported a strength gain of 8% over a 2-year period. An isometric contraction was used for testing, and concentric-eccentric contractions were used for the exercise. These results do not compare with the strength gains of 100% and higher made by healthy subjects undergoing training but rather compare with serial testing when no exercise was done.^{195,196} For example, Munin and colleagues¹⁹⁵ measured the affected and unaffected quadriceps muscle every 6 months over 3 years to document muscle weakness in people with PPS. They reported increases in muscle strength up to 25%. In older people without polio, test performance gains of the quadriceps increased an average of 174% in 90-year-old subjects²⁰⁰ and 107% in 60- to 72-year-old men.²⁰¹ In these two studies, thigh muscle area (as documented by computed tomography) increased by 9% and 11%, respectively, indicating an increase in muscle bulk.

The effects of nonfatiguing resistance exercises are well documented in the literature. Fillyaw and colleagues¹⁹⁴ in a study of 17 subjects with PPS concluded that muscle strength may be increased in individuals with PPS and suggested supervision of exercise programs by PTs and quantitative muscle testing every 3 months to guard against overuse weakness. Agre and Rodriguez²⁰² suggested that a supervised exercise program could safely increase strength in subjects with PPS with at least a grade 3+ strength. Their program of a supervised 12-week nonfatiguing quadriceps strengthening program with rest intervals revealed no detrimental effects. Most of the participants reported improvements in quadriceps strength, endurance, and work capacity, and half noted increased strength recovery with rest periods after activity, walking, and stair climbing. A nonfatiguing weight lifting program used for at least 24 weeks was examined in six subjects with PPS by Feldman and Soskolne.²⁰³ The results showed increased strength in 14 of the 32 muscle groups with maintained strength in 17 muscles.

Alternate-day, low-intensity, muscle-strengthening quadriceps exercises showed no adverse effects, with reported findings of increased endurance, strength, and work capacity. As a result of the low-intensity program, no increased muscle strength was found, although half of the participants sensed increased strength recovery after exercise.²⁰⁴ The same protocol, but with a more vigorous program of 4 days per week, revealed improvements in muscular work performance and endurance without unfavorable effects noted.²⁰⁴

Because there are neural adaptations specific to the type of muscle contraction used for measurement and training, it is difficult to determine the differences in true increases in strength from the ability to improve performance on a specific test. Another term for this phenomenon or improvement in performance is *motor learning* (see Chapter 4). The theory states that the subject learns to perform the measurement or the exercise better without true gains in strength. This happens even with an apparently simple weekly maximum isometric contraction.²⁰⁵ Evidence of this phenomenon can be seen when improvements are made in the opposite untrained muscle group (transfer of training), when the apparent strength gains are maintained for months after cessation of the training, and when there are no increases in the size of the muscle. The greatest improvements in test performance occur when the muscle contraction is the same for both the test and the training. Smaller increases are seen when the measurement and training muscle contractions are different and when measures to decrease the effect of motor learning have been used.

The neural adaptation specific to the type of measurement or training is illustrated in the following study on older men.²⁰¹ Multiple tests to assess strength were performed. The training program required lifting and lowering 80% of the weight of one repetition maximum (1 RM), which was assessed weekly. After 12 weeks, there were average increases in quadriceps muscle strength of 104% for the 1 RM, 7% for maximum isometric, 8% for maximum isokinetic at 60 degrees per second, and 10% for isokinetic at 240 degrees per second. In addition, there was an increase in cross-sectional area of the quadriceps of 10%, and muscle biopsy showed approximately a 30% increase in muscle fiber size.²⁰⁶ This study illustrates some of the complexities of designing or evaluating studies that attempt to measure changes in muscle strength.

In chronic movement dysfunction, high tone is a symptom that may be considered a deterrent to exercise. As therapeutic procedures became based on motor control, motor learning, and neuroplasticity theories, strengthening of spastic muscles may still be underused.^{207,208} In the past, placing resistance on a spastic muscle was thought to increase the spasticity. This tenet was interpreted to preclude anyone from advocating strength training in these individuals.^{207,209} Interestingly, the literature identified that one of the major problems of CP is weakness. Clinicians during the 1960s and 1970s believed that the answer to this weakness underlying spasticity was to increase proprioceptive and tactile stimulation.^{207,209} Current research would say that true strengthening would not occur through feedback alone and that resistance on muscle tissue is a necessary variable for strength training.^{109,210,211} Damiano and colleagues^{110,212–214} have shown that resistance training does not affect spasticity negatively and in fact improves many functional measures of gait. On the basis of these findings, clinicians should evaluate individual patients to determine whether the level of weakness is affecting functional performance or the attainment of personal goals. If indeed the individual's weakness is found to be clinically significant, then strength training is indicated. Strength training within functional patterns should lead to the greatest carryover.

Physical Activity

The literature clearly documents the benefits of physical activity, and in polio survivors with PPS, activity that falls within a safe range is

BOX 35.6 Functional Exercise: Key Points

1. Consult with a health care team before starting an exercise program. A physical and occupational therapist can provide valuable insight and recommendations on activity type and intensity.
2. Avoid overuse of muscle groups.
3. Judicious exercise programs of low to high intensity can result in positive results. Include warm-up and cool-down periods.
4. Short periods of activity are encouraged.
5. Allow for adequate rest between bouts of activity.
6. Alternate days may be necessary for full recovery (depending on activity type).
7. Individualized therapy program to address unique needs is critical.
8. Use energy conservation and joint protection techniques in regular routines.
9. Incorporate breathing, relaxation, mental imagery, and meditation exercises into daily activities.
10. Be cognizant of the body's alignment during exercise and functional activities.
11. Incorporate postural exercises and correction to address malalignments and unnecessary use of muscles and joints.
12. Compliance with clinical recommendations can significantly reduce symptoms and prevent further decline.
13. Listen to your body—pain is typically your body's way of alerting you to slow down or to stop.

beneficial to overall functional performance (Box 35.6). In a study involving women with disabilities in the Women's Health and Aging Study,¹⁹¹ the authors found an inverse relationship between disability and physical activity, with the most disabled women being more inactive. In addition to diseases and musculoskeletal pain being directly associated with motor disability, lower levels of physical activity associated with poorer muscle strength contributed to a greater degree of motor disability.

Physical inactivity and obesity have been shown to be more common in individuals with developmental disabilities than in the general population.^{26,165} Specifically, Rimmer and Wang²¹⁵ in a study of 306 individuals with physical and mental disabilities found that the rate of obesity in those with intellectual disabilities was twice as high as in the general population. More alarming was the finding that the rate of extreme obesity (body mass index [BMI] equal to or greater than 40 kg/m²) was approximately four times higher among individuals with disabilities than in the general population. Moreover, individuals experience high rates of secondary conditions associated with obesity and inactivity, such as type 2 diabetes, cardiovascular disease, and metabolic syndrome.¹⁶⁶

Although few studies have been done on the impact of exercise or the best type of exercise for people aging with a TBI, Gordon and colleagues²¹⁶ studied 240 people living in the community with a TBI. They compared exercisers and nonexercisers with a TBI and exercisers and nonexercisers without a TBI. Typical exercise activities were swimming, jogging, biking, or sports that increased heart rate for more than 30 minutes at least three times per week for a six-month period. Their findings suggest that although exercise did not decrease functional impairments related to the TBI, people who exercised reported fewer physical, emotional (less depression), or cognitive complaints (sleep problems, irritability, memory problems, and disorganization). Of interest was that the exercisers in the group with a TBI had more severe brain injuries than those who did not exercise. In their online TBI consumer report, Gordon and colleagues²¹⁶ recommend aerobic and nonaerobic exercises as beneficial. They also suggest that individuals

with TBIs check out local exercise centers, independent living centers, or adult education classes and seek out videotapes that might provide encouragement or support for engaging in exercise. There is no mention of referrals to PTs or OTs for guidance in setting up exercise or lifestyle change programs or locating resources within the community.²¹⁷

Cardiopulmonary Conditioning

Because cardiovascular disease is one of the most common causes of death among aging adults with developmental delay,^{26,166,167} and physical inactivity and obesity occur at higher rates in this population, cardiovascular conditioning is a critical part of the management of individuals with chronic impairments. The following information pertains to interventions for individuals with PPS, as the evidence is strong for this population. Although limited information exists for those with SCI or TBI, one can logically infer that some benefits are likely to occur with aerobic activities in these groups.

Aerobic testing using modified protocols to reduce fatigue has been used on the treadmill,²¹⁸ bicycle ergometer,²¹⁹ and arm ergometer²²⁰ in individuals with PPS. There were no cardiorespiratory training effects in the first study, probably owing to the low intensity of the exercise, but the duration and distance of walking increased.¹⁹⁵ The two ergometry studies showed an increase in maximum oxygen consumption of 15% and 19%, which is a training effect comparable to normal values for age. There were, however, no changes in blood pressure or heart rate, particularly the expected decrease in resting heart rate that occurs with aerobic training. Although the intensity of the exercise protocols had to be reduced for some of the subjects, none had to terminate the exercise because of overuse symptoms, nor did these symptoms occur at the end of the studies. A problem in evaluating these studies is that it is not always clear whether the study subjects with PPS were asymptomatic, symptomatic (PPS), or mixed.

An endurance training program in subjects with PPS demonstrated beneficial cardiovascular and strength effects without adverse consequences.²²¹ Aerobic exercise such as using a bicycle ergometer, walking, or swimming may be useful, but the patient must be interested in the activity to increase compliance.¹⁷⁷ Willen and colleagues¹⁹⁷ in a study of 28 individuals with late effects of polio found that a program of nonswimming dynamic exercise in warm water twice weekly resulted in decreased heart rate at submaximal work level, less pain, and positive functional impact. As with the previous studies on exercises, no adverse effects were noted. Their general fitness training, however, did not result in changes in muscle strength or endurance. Previous studies documenting improvements in muscle function and aerobic capacity were designed for three or more times per week; the authors hypothesize that a twice-a-week program was not enough to show improvements in the subjects' aerobic capacities or muscle strength.

The literature indicates that exercise within constraints can lead to several beneficial physiological and psychological adaptations in individuals with PPS.^{177,192} It appears that therapeutic exercise is beneficial when performed without causing undue pain and fatigue. As with any intervention, a comprehensive examination will assist in developing a well-rounded and individualized program tailored to the specific needs of the individual with PPS.

Pulmonary Status

Older individuals with neuromuscular diseases may have increased vulnerability to respiratory complications.¹²³ Respiratory insufficiency and sleep apnea may mandate intermittent or constant use of ventilatory devices. Nighttime noninvasive positive pressure ventilation may be beneficial.²²² Pulmonary therapy and breathing exercises may help some individuals avoid tracheostomy.¹²³ In individuals with PPS who have respiratory impairments, respiratory muscle training may be

beneficial in improving respiratory muscle endurance and general well-being.²²³

The role of the therapist is to modify activities and teach glossopharyngeal breathing, manually assisted coughing, or bronchial drainage as indicated.^{224,225} If trunk supports are considered, vital capacity should be checked with and without an abdominal binder to determine the effect on breathing. The therapist's attention should also be directed toward prevention of problems that may occur from bed rest and maintaining as much function as can be permitted.

Fatigue Management

Use of muscles at high levels for extended periods will result in muscle overload. To perform the same activity with weak muscles, the muscles need to contract at a higher percentage of their capacity than is normally required. For example, in walking, individuals with PPS contract their muscles at both higher intensities and for prolonged or even continuous periods in the gait cycle.¹¹⁸ Energy expenditure for the task is increased, and the prolonged contractions keep the capillaries compressed, limiting needed muscle nutrition. Patients with PPS are often observed using nearly maximum voluntary contractions to perform a daily activity. The muscles of individuals with PPS cannot maintain these high levels of activity indefinitely.

A general program addressing fatigue may include nonfatiguing daily activities and energy conservation techniques. Relaxation, breathing, and meditation exercises may also be useful. Lifestyle changes that incorporate methods to decrease physical demands and prevent further decline in function are the most efficacious way to target fatigue impairments. In a study by Agre and Rodriguez,¹⁴⁰ symptomatic subjects with PPS demonstrated the ability to perceive muscular exertion. This is indicative of a mechanism to monitor local muscle fatigue that may be used to avoid exhaustion. Their study of pacing, defined as interspersed activity with rest, revealed less local fatigue and significantly greater strength recovery in subjects who paced their activities than when they worked at a constant rate to exhaustion. The Borg Rating of Perceived Exertion (BRPE) is an outcome measure that may be used to judge effort. Finch and colleagues²²⁶ in a study of individuals with PPS found that after one training session subjects reliably used the RPE in an exercise test to monitor their effort and complete the test. Finch and colleagues²²⁷ have gone on to establish reliability and construct validity on an effort-limited treadmill test for individuals with PPS.

Peach and Olejnik²²⁸ found that compliance with recommendations affected fatigue. Fatigue was resolved or improved in a group of individuals who complied with recommendations and was unchanged or increased in the group of individuals who did not.²²⁸

Sleep Disturbance

Sleep disturbance is a significant age-related change, with an estimated 50% of older adults reporting difficulty initiating or maintaining sleep.^{128,129} Several factors may contribute to reports of sleep disturbance, ranging from relatively apparent reasons to more medically complex reasons such as sleep apnea. Habitual sleeping patterns may provide important information. Sleep disturbances from medical or psychiatric conditions (e.g., chronic pain, dementia), or a primary sleep disorder that may be age-related, or a combination of these, may further produce changes in sleep that may be reflective of typical normal developmental processes.¹²⁸ Loss of sleep with aging is often a result of the decreased ability to sleep in older adults.¹²⁹ According to Neikrug and Ancoli-Israel,¹²⁹ this diminished ability is less a function of age and more a function of other age-related factors such as medical and psychiatric diagnoses, increased medication use, and a higher frequency of specific sleep disorders.

A history of pain or numbness that is worse at night or on rising points to sleeping surfaces that are too firm or sleeping with joints in close-packed positions (usually the neck and shoulders). These problems are correctable with foam mattress covers or air pressure mattresses, cervical pillows, and modification of sleeping postures.

Given the frequency and significant number of older adults with sleep problems, health care professionals need to be more aware of sleep disturbances.¹²⁹ Changes in sleep quality and quantity in later life influence quality of life and level of function;¹²⁸ thus it is critical to distinguish typical age-related changes in sleep from pathology-related sleep disturbances. More complex reasons for sleep disturbance such as sleep apnea may necessitate referral to specialists. Sleep disturbances have been identified as common secondary conditions that develop in aging adults with chronic CNS dysfunction.^{114,229}

Decreasing the Workload of Muscles

Energy Conservation Techniques

Energy conservation techniques provide the easiest way to decrease the work of muscles without loss of function. Analysis of all activities by type, time, distance, and intensity is valuable in designing interventions. Such an inventory forms the basis for setting priorities and determining where and how individuals wish to use their limited neuromuscular capacity.¹⁴⁶

Questions addressed include the following:

1. Can one trip do for two or three?
2. Can the activity be performed in a less strenuous way, such as by sitting or using a rolling basket?
3. Can the activity be broken up into parts with change of activity or rest?
4. Are there easier ways to perform the activity with modern comforts and technology, including motorization and electronics?
5. Can someone else perform some of the physical aspects of the activity?

Particular attention should focus on activities that produce fatigue and pain. Specific suggestions may address breaking tasks into subtasks, making environmental adaptations such as to work height and locations, taking frequent rest breaks during activities, and using adaptive or ergonomic equipment.

Orthotics and Assistive Devices

Reduction of muscular overuse and fatigue may be accomplished with lightweight splints and braces, adaptive equipment, walkers, or crutches.^{112,123} The use of orthotics and/or assistive devices is individualized and specific to the patient, whose goals, along with the therapist's expertise, will ultimately determine the use of devices. For example, unlike most individuals with chronic mobility impairments, individuals with PPS may have strong and usually negative feelings about orthotics. The use of orthotics or assistive devices may be challenging for the individual newly diagnosed with PPS and facing a relatively "new disability." Polio survivors may have previously relied on devices or may have refused such devices earlier in life, and consenting to use them again may symbolize defeat and acceptance of losses.

As with every intervention, a thorough explanation of the specific rationale and goals for the intervention not only will be helpful in gaining the patient's/client's trust but will also improve compliance. Rationale for orthotic use includes preventing falls and potential fractures, limiting joint motion and preventing pain, restoring weight bearing on the weaker extremity to decrease the work of the less affected leg in locomotion, improving posture and decreasing back pain, and decreasing energy expenditure.

Fig. 35.1 The functional compensations of a boy with paralysis of the right lower extremity show increased energy expenditure and progressive ligamentous laxity. (Adapted from Ducroquet R, Darroquet J, Darroquet P. *Walking and Limping—A Study of Normal and Pathological Walking*. Philadelphia: JB Lippincott; 1968.)

Thoughtful consideration for the appropriateness of orthoses or assistive devices is critical; such devices should not be haphazardly prescribed or given as the only intervention of choice. They should be prescribed cautiously. Ineffective and inappropriate use of such devices will lead to malalignments, ineffective movement strategies, and postures that will cause more harm. Therapists should carefully evaluate the functions that may be lost or gained and the emotional and physical cost of the use of these devices.

Most individuals have long discarded braces and assistive devices and have relied on compensatory techniques for walking (Fig. 35.1). If an orthosis has been used and is essential for walking, it often becomes a part of the individual's body image; thus the patient/client may be resistant to changes in braces or devices. For other individuals, prior attempts to use plastic orthoses may have been painful or resulted in no functional use, and thus these patients may previously have rejected the potential of such devices. Thus it may be difficult to persuade the long-term user to consider orthoses or an orthotic change. When given the appropriate orthosis or prescription, however, polio survivors may benefit significantly enough to improve their current symptoms. A retrospective study of lower-extremity orthotic management for ambulation in 104 postpolio clinic patients by Waring and colleagues²³⁰ revealed that 78% of patients noted that the appropriate orthotic prescription improved the ability to ambulate, increased apparent walking safety, and decreased pain.

In instances in which both the talocrural and subtalar ankle joints were fused surgically, the increased stresses on the posterior structures of the knee or the transverse tarsal joint for ambulation eventually lead to hypermobility and pain in these areas. Rocker-bottom shoes may assist with restoring motion for walking. An ankle-foot orthosis (AFO) may address pain in the transverse tarsal joint, whereas a knee-ankle-foot orthosis (KAFO) may help with knee pain.

AFOs are recommended for dorsiflexor weakness resulting in drop-foot or slapfoot, for plantarflexor weakness with absent heel rise, and for mediolateral instability. Individuals with PPS have difficulty with solid AFOs because of the structural design; they are typically made with 5 to 10 degrees of dorsiflexion and are then placed in a shoe with a slight positive heel, thus increasing the angle of the posterior shell to the floor. In standing and walking, this causes a knee flexion torque, with potential buckling of the knee if the quadriceps muscle is weak. Patients/clients may attempt to straighten the knee by pushing back against the posterior shell of the AFO, potentially causing pain. In such instances, AFOs should be made in slight plantarflexion so that the

tibia is perpendicular to the floor in the usual shoes worn. This is the normal position of the ankle for toe and heel clearance.²³¹ In cases of plantarflexion contracture, more plantarflexion is required in the AFO. Most jointed AFOs are of limited value because of their bulk and weight. Moreover, they require a larger shoe and do not provide much control for the ankle. Jointed AFOs allow adjustment to find the best angle in function.

A floor reaction AFO prohibits all ankle motion and can place forces to control the knee.^{232–234} The orthosis prevents dropfoot, promotes heel rise, provides an extension torque on the proximal tibia to supplement weak quadriceps muscles, and can limit hyperextension of the knee. It requires precision in fabrication for the knee extension torque to occur only when the tibia is perpendicular to the floor during gait. When used with rocker-bottom shoes, the patient with a flail foot can walk with a more typical gait pattern. Subjects with ligamentous laxity of the knee, excessive tibial torsion, or paralysis of the quadriceps muscles are poor candidates for this type of AFO.

Shoe inserts, heel lifts, and molded foot orthoses can provide a number of inconspicuous corrections. Positive heel shoes with a broad base, such as cowboy boots, stacked or Cuban heels, or the Swedish clog,²³⁵ decrease the amount of dorsiflexion and plantarflexion motion and the work needed for ambulation. Rocker-bottom soles, which provide mechanical heel rise to assist the calf muscles, can be added to shoes and are commercially available. Work boots, dress boots, or basketball shoes may provide needed ankle stability.

Asymmetrical standing is typical in individuals with unilateral lower-extremity paralysis or pain. Standing is accomplished with more weight on the stronger limb, which must perform continuous, high-level isometric contractions (Fig. 35.2). Unloading the stronger leg requires restoration of weight bearing on the more involved leg using a KAFO or in some instances an AFO that prevents advancement of the tibia in the stance phase (Fig. 35.3).^{113,232–234}

An obvious forward-leaning posture is seen in some ambulatory individuals with PPS. This posture requires continuous contraction of the erector spinae muscles and leads to back pain, often radiating to

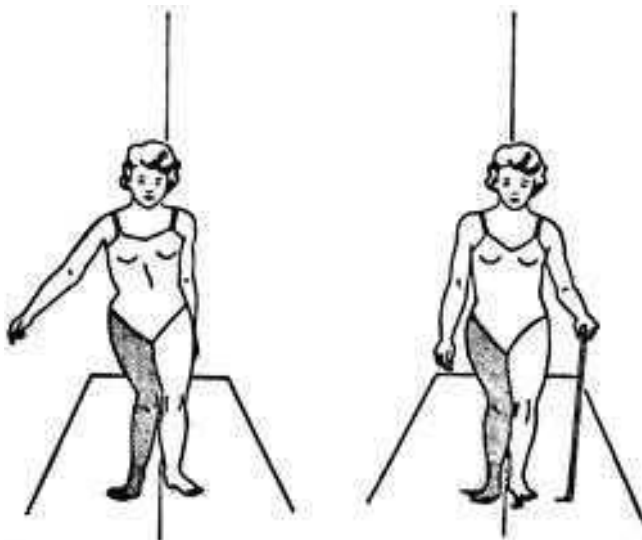

Fig. 35.2 Lateral trunk shift in a postpolio individual to illustrate abnormal forces occurring in the back, knee, and ankle with resulting joint dysfunction and pain. Prevention of these abnormal forces and some correction can be provided by use of a cane or forearm crutch. (Adapted from Ducroquet R, Darroquet J, Darroquet P. *Walking and Limping—A Study of Normal and Pathological Walking*. Philadelphia: JB Lippincott; 1968.)

Fig. 35.3 This man has paralysis of the left lower extremity with severe fatigue, low back pain, pain and weakness in the right lower extremity, and decreased function. He can be seen to bear weight and stand on the right leg. Application of a left knee-ankle-foot orthosis with a free knee joint (with a drop lock for use in prolonged standing and walking on rough terrain) and a limited-motion ankle joint unloaded his right leg and permitted him to walk in an erect posture. His pain disappeared, and he has regained function at work and in social activities.

the hip and leg. The forward-leaning posture is found in people with quadriceps muscle paresis and in those with ankle weakness. Those with quadriceps weakness must move the center of gravity of the body anterior to the knee axis to lock the knee and prevent knee flexion in stance. This posterior force also produces ligamentous instability and genu recurvatum (see Fig. 35.1). In some instances, lightweight athletic knee braces allowing 10 to 15 degrees of hyperextension provide adequate control. More often, a KAFO with an offset knee joint allowing necessary hyperextension is required.^{236–238} People with dorsiflexor muscle paralysis or ankle instabilities walk in the forward-leaning posture to watch the floor and foot placement to avoid tripping and falling. Athletic ankle supports or boots may be sufficient to control some ankle instabilities. Molded and posted plastic AFOs with or without ankle joints are needed for more control. Flexible plastic AFOs and the dynamic spring dorsiflexion assists can correct simple dropfoot.¹¹³ Once the forward-leaning posture is addressed, the individual can walk upright and back pain will lessen and may disappear within days.

Walking with lateral trunk shift in the stance phase (gluteus medius gait) produces abnormal forces and joint dysfunction from the spine to the foot. In addition to a strengthening program, these forces may be reduced with use of a forearm crutch or a cane (see Fig. 35.2).

Long-term crutch walkers with or without orthoses and those with slow, precarious, or labored gait should be evaluated for appropriateness for use of motorized vehicles as their primary form of locomotion, whereas orthotic corrections or applications may be indicated to assist with transfers and short-distance walking.

Changes in Locomotion

In individuals with chronic neuromuscular impairments, the extent of impairment is influenced by the degree of neurological deficit in motor control, tone, and strength. This scenario illustrates the challenges

associated with aging with chronic impairments and may very well be reflected in other neuromuscular diagnoses.

In a recent study that investigated the rate of decline of mobility and the potential predictors for the rate of decline in walking capacity in 48 individuals with PPS, investigators found the rate of decline could not be predicted from baseline capacities of strength, walking/mobility, or demographics.²³⁹ Individual variations existed on substantial loss of walking capacity (27% decline) and self-reported physical mobility (38% decline).²³⁹ Despite severe difficulties with locomotion from overuse, asymmetrical gait patterns and movement, or ineffective use of assistive devices, changes or modifications are hard for many people with chronic mobility problems, such as many polio survivors, to consider. Average walking capacity and self-reported physical mobility has been shown to decline by 6% and 14%, respectively, over 10 years.²³⁹ As locomotion becomes more arduous or painful, many begin to limit outside activities rather than modify individual methods of locomotion. Resistance to lifestyle changes is common in the PPS population and leads to needless suffering and functional decline.²²⁸

Prevention of this spiraling disability and restoration of lost function require a marked decrease in the amount of walking or propelling a chair and a change to methods of locomotion that do not cause pain, weakness, and fatigue. Independent ambulators or those with inadequate assistance may need to use a cane, forearm crutches, trunk support, shoe corrections, or new orthoses. Clients who have been walking for years with crutches with or without orthoses develop shoulder, elbow, and wrist injuries, as well as new muscle weakness, muscle pain, and fatigue. Use of personal mobility vehicles (motorized carts) for distance locomotion or as the primary form of locomotion may need to be explored, with walking reserved for transfers and short distances only. Lightweight manual wheelchairs only perpetuate the problems and eventually create new ones; use may lead to development of repetitive stress injuries of the shoulder, elbow, wrist, and hand. The use of motorized mobility devices will need to be explored to prevent fatigue, muscle overuse, and further damage to joints.

The use of motorized vehicles for locomotion should be considered and explored with sensitivity and caution. Specific rationales should be thoroughly understood by a seemingly resistant patient, and perceptions regarding the use of such vehicles should be addressed. Changes in methods of locomotion may be justified to increase safety and prevent costly falls, reduce energy expenditure and decrease fatigue, prevent further repetitive injury and pain, and, most important, increase function and quality of life. Those who do make these difficult changes in their methods of locomotion seem to undergo a metamorphosis from pain and dysfunction to renewed activity and increased function.

Management of Postural Deviations

Altered biomechanics from atypical postures or faulty physiological neuromuscular processes over time may lead to deviations that may cause pain and further functional limitations. In polio survivors, common biomechanical deficits abound, including genu recurvatum, genu valgum, inadequate dorsiflexion in swing, mediolateral ankle instability, and dorsiflexion collapse during stance, as described by Clark and colleagues.²³⁶ These deviations are very likely to be seen in people with other neuromuscular diagnoses. Strengthening exercises may be used to correct these impairments initially, with orthoses as an alternative management.

Postural exercises incorporated with breathing and stretching exercises are a way to address ineffective postures identified in all positions. Mental imagery, which may avoid impairments from fatigue, may be used early in addressing postural correction. Mechanical

Fig. 35.4 Man with athetoid cerebral palsy working at his computer. His power chair has been modified with a back support and a seat cushion for proper positioning.

restoration of the lumbar curve in all seating and all settings and activities can address the problem if contractures do not limit motion. Properly fitted clerical chairs, ergonomic chairs, anterior tilt seats, gluteal pads, and several types of lumbar rolls, back supports, and seating systems may be beneficial (Fig. 35.4).

Individuals with abdominal muscle paralysis may benefit from custom-made thoracolumbar corsets, in which the posterior rigid stays bent to produce a normal standing lumbar curve. Paretic or paralyzed neck muscles can be rested and supported by soft foam collars or supportive microcellular neck collars. People with severe trunk muscle paralysis or scoliosis with or without spinal fusion often support the trunk or relieve pain by pushing down with their hands or elbows on chairs, on tables, and on their hips. In time, such self-traction results in pain and weakness in their arms. Chair inserts and fixed supports as well as custom-made corsets, back braces, and molded body jackets should be considered. The rigid trunk supports, however, take away mobility used for function. Usually such supports can be worn for part of the day in activities in which trunk mobility is not essential.

For people with abnormal biomechanical alignment resulting from spasticity, orthopedic deformation, or severe muscle imbalance, care must be taken to maintain proper alignment throughout the exercise. Additional positioning equipment may be required to assist the person in exercising independently. For example, people with lower-extremity spasticity frequently exhibit medial rotation of their femurs and bilateral pronation. Combined with asymmetrical patterns of weakness and tightness, a squatting motion produces an excessive valgus angle at the knee. Ensuring satisfactory alignment throughout the arc of

motion improves the efficacy of the exercise. Conversely, without this attention to biomechanical alignment, these imbalances and deformities can be exacerbated.

Limitations in Range of Motion

A thorough evaluation of muscle length and ROM is critical in the overall management of life activities in individuals with chronic mobility impairments. The clinician should consider that not all tightness or limitation in motion is detrimental. Selective tightness may have provided some stability to otherwise unstable joints with paralyzed muscles, and useful contractures may have been developed by the body to achieve function. An excellent example can be seen in individuals who contracted polio as children. Muscle involvement was primarily in one lower extremity with a decrease in growth of that extremity as a result of diminished weight-bearing forces. If the individual has at least a G- (4-) manual muscle test grade in the plantarflexors, the person will walk on the toes (in some plantarflexion) to decrease large drops in the center of gravity, resulting in increased energy expenditure for walking. Over the years, a plantarflexion contracture develops that can provide up to 3 to 4 inches for weight bearing on the shortened extremity. With a custom-made shoe, gait is similar to walking in a high-heeled shoe. This can be far more energy efficient than if motion were permitted to have dorsiflexion ROM.

Gentle myofascial release can also be beneficial for recent secondary impairments of muscles to decrease pain and muscle spasms, increase nutrition to the area, and slightly lengthen muscles.

Weight Management

Adults with chronic impairments, particularly those with developmental disabilities, are at high risk for obesity and its sequelae. Weight reduction, when appropriate, addresses this health disparity and is an effective way to decrease the muscle workload, but it is one of the most difficult ways. Clinicians recommend a modest weight loss of 5% of body weight as an achievable and maintainable goal that may result in decreased hyperlipidemia, hypertension, and glucose intolerance.²⁴⁰ Weight loss is slow without exercise, but it can be accomplished. Weight control needs to be incorporated as a permanent modification of nutritional habits rather than achieved in a short-term diet. Dietetic counseling and support groups are important components of this challenging lifestyle modification.

In a study of 431 community-dwelling individuals with developmental delay who participated in a community-based health promotion intervention, two-thirds of participants maintained or lost weight (mean of 2.6 pounds, median 7 pounds, range 2 to 24 pounds) over a 7-month, twice-weekly program.²⁶ The authors stated that even without the weight loss, the decreased abdominal girth achieved by participants may be predictive of a decrease in cardiovascular risk factors.²⁴⁰

Pain Management

Pain management in the patient with chronic movement dysfunction is dependent on the cause of the muscle or joint pain. As an example of how pain management contributes to secondary health problems, patients with SCI who reported pain from musculoskeletal problems and overuse were seldom referred for therapeutic interventions but were treated primarily with prescription medications to treat painful conditions. This medical management often resulted in increased problems, such as constipation, fatigue, irritability, and frustration.²⁴¹ The cause of pain must be carefully determined to establish appropriate intervention and management strategies. Typical interventions for pain include activity reduction, therapeutic heating

modalities, cryotherapy, stretching, or energy and joint conservation techniques.

If chronic overuse is the only or major underlying cause of the symptoms present, conservative measures can often slow or prevent further deterioration and may even lead to improved function. Conservative measures include reducing mechanical stress, pacing activities, supporting weak muscles, stabilizing abnormal joint movements, and improving biomechanics of the body. Interventions that address fatigue and weakness such as nonfatiguing functional activities, energy conservation,¹⁴⁶ more frequent rest periods, or change of activity²⁴² are also useful in pain management. Antiinflammatory agents have been used to supplement conservative measures.

Joint conservation techniques may include use of ergonomic devices, elevated chairs, bathtub bench or shower stool, and weight control. Recommendations for the neck and upper extremities include seating and workstation corrections, telephone headsets, rolling carts for carrying items, newspaper support for reading, ergonomic computer screens, wrist rests, and keyboards.

Successful intervention for joint pain, however, requires identification and elimination of the cause of the pain. This is frequently difficult because the person with chronic movement dysfunction may not have the strength in other parts of the body to compensate and carry out an essential function, or the person may be unable or unwilling to make necessary lifestyle changes. Intervention techniques may include inhibiting muscle spasm, stretching fascia and muscles, decreasing edema and increasing nutrition in joint structures, and mobilizing or stabilizing joints.²⁴³ At some point, relaxation, meditation, modified tai chi (see Chapter 33), aquatic therapeutic exercise, or body awareness techniques such as Feldenkrais²⁰⁵ may be beneficial.

Local pain and dysfunction can be treated as athletic injuries from overuse, but they require major modifications and careful monitoring of performance, pain, and fatigue. Many joint pain problems can be relieved and controlled by home program interventions such as rest for the injured part, mechanical postural corrections, cold packs, nonsteroidal antiinflammatory drugs, orthotics, and pain-free ROM exercises.

With regard to McConnell taping, although no radiological evidence shows changes in actual alignment of bone, individuals without neurological diagnoses have experienced a 50% to 78% reduction in patellofemoral pain during activities.^{243,244} In the Post-polio Clinic of the Institute for Rehabilitation and Research in Houston, Texas, these taping techniques relieved anterior knee pain for several months at a time in all individuals with PPS who were selected to receive the taping. Relief occurred, although the ability to strengthen surrounding muscles was limited or impossible. The therapy program should also include assisting the patient in carrying out the home program and lifestyle changes, along with the development of a continuing program of appropriate exercises.

As with the management of fatigue, compliance of the individual with chronic impairments with suggested recommendations plays a significant role in pain management. In those with PPS, Peach and Olejnik²²⁸ found that muscle pain was resolved in 28% and improved in 72% of people who complied with recommendations. In those who were noncompliant, muscle pain was improved in 14%, unchanged in 57%, and increased in 29%.

Alternative Pain Management

Pain sensitivity must be acknowledged by clinicians when providing therapy that may be perceived as painful, such as stretching, and in the treatment of acute pain.²⁴⁵ People with chronic movement dysfunction have undergone extensive orthopedic surgery in attempts to overcome their initial deficits, as in the case of some polio survivors, and some have pain or hypersensitivities at the surgical sites. Desensitization

exercises may decrease the hypersensitivities if the patient is willing to devote the necessary time. The most frequent old surgical sites of pain are in the trunk from surgery for scoliosis, the ankle near a subtalar arthrodesis, and the foot with hypermobility of the transverse tarsal joint. In most instances of foot pain, stabilization of the ankle and foot in a custom-made AFO and use of a rocker-bottom shoe has relieved the pain and permitted weight bearing and walking.²³⁵ Custom-made corsets and trunk supports in chairs may help with the pain at previous surgical sites in the trunk. Transcutaneous electrical nerve stimulation may be helpful for pain control (see Chapter 31). Most individuals, however, stop using these devices because masking the pain permits them to physically overdo, leading to further injury to their bodies.

Static magnetic fields have become a familiar alternative approach in the treatment of athletic injuries as well as in people with PPS who have localized pain. In a double-blind randomized clinical trial, Vallbona and colleagues²⁴⁶ applied active (300 to 500 Gauss) and placebo magnets in a group of 50 subjects with PPS and chronic pain. The magnets were applied to the palpable pain pressure point for 45 minutes. There was a significant ($P > .0001$) and prompt decrease in pain in the group receiving the active magnets compared with those who received the placebo.²⁴⁶

Cold and Heat Intolerance

Strumse and colleagues²⁴⁷ investigated the effect of climate on the outcomes of individuals with PPS. In a randomized controlled trial of 88 individuals diagnosed with PPS, subjects received one of three interventions: (1) warm climate rehabilitation (dry and sunny, temperature around 25°C or 77°F) consisting of individual and group therapy with daily treatment in a swimming pool, physical therapy, and an individually adapted training program for 4 weeks, (2) cold climate rehabilitation consisting of indoor treatment as described for the first intervention in a rehabilitation center in Norway with rainy or snowy weather with temperatures around 0°C or 32°F, or (3) the usual health care program (control). This study was included in the review by the Cochrane Collaboration, and the authors concluded that there is low-quality evidence of no beneficial effect of rehabilitation in warm and cold climates 3 months after intervention.²⁷ The reviewers suggest that a more thorough description of the components of the program and outcome assessment for the usual control group would have clarified the short-term effects on both rehabilitation groups and the results of the study. The study could not demonstrate a positive effect of rehabilitation in warm or cold climate for PPS, and further studies are warranted.²⁷

Most individuals with chronic conditions who have cold intolerance have learned to control heat loss as best as they can with clothing, massage, and local heat. For interventions, however, cold intolerance can pose a potential problem with the use of cold modalities in the treatment of injuries and pain. Most people with PPS are hesitant to use local cold on any part of the body. They may typically use heating pads and hot water, which feel good at the time, but may perpetuate or increase the edema, inflammation, and pain. Local cold is often more effective and is well tolerated by most people with PPS. Successful application of cold requires more patient education about the use of cold and demonstration of the effects.

In people with MS who are sensitive to environmental heat or an increase in body temperature, specific recommendations for cooling during exercises may be necessary to counteract the deleterious effects of heat. Aquatic exercises and swimming in a cool pool with temperatures at or below 82 degrees may be beneficial for cooling. The use of cooling vests, ice packs, air conditioning, and hydration during activities is also recommended.^{248–250} An example of a specific exercise recommendation is the use of a Schwinn Airdyne bicycle to help with cooling while cycling.²⁴⁸

Other Interventions

The reader is referred to specific pharmacological texts and specific chapters within this text for detailed pharmacological interventions for specific neuromuscular diagnoses. As emphasized earlier, the management of chronic conditions is individualized and dependent on the unique needs of the individual based on the interaction of multisystem involvement. Thus the pharmacological management of people with chronic conditions is also individualized and wide-ranging. Although there are classes of medications that are commonly used across varied neurological conditions (e.g., spasticity medications), the use of medication is still symptom- and patient-dependent. A literature review of pharmacological approaches for PPS revealed that controlled trials of pyridostigmine and prednisone have not been beneficial.^{34,251,252} Currently, there is no specific pharmacological agent widely recommended to address the multiple symptoms of PPS.

As part of the evaluation, oral motor function is an important component in terms of sensation, speech, and swallowing. Because of their prevalence in people with developmental delay, dysphagia and aspiration potential need to be carefully explored in the history. Owing to disturbances in muscle tone, these individuals often have difficulty with feeding, which may lead to serious medical complications and potential death. In general, intervention may consist of performing breathing exercises, using swallowing techniques, monitoring fatigue levels, avoiding eating when fatigued, and initiating dietary restrictions or changes. For those with dysphagia, specific management will warrant a thorough evaluation by a speech therapist. Recent advances in treatment including deep pharyngeal neuromuscular stimulation and neuromuscular electrical stimulation, which offer people with poor motor control and weakness in pharyngeal musculature opportunities to improve safe oral feeding (Fig. 35.5).²⁵³

KEY POINTS

- Much individual variation exists in the aging process of individuals with chronic CNS conditions and chronic impairments. The individual variability of the development of secondary conditions and the current lack of predictive factors underscore the need for

individually tailored care based on actual functional decline and restrictions in participation in society.

- Further research and longitudinal studies are consistently recommended to understand the effects of aging with a disability from a chronic CNS condition, to determine when problems are most likely to occur, and to develop and examine the efficacy of targeted interventions to prevent and/or address secondary health conditions and their negative impact on health, function, and quality of life.

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 253 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY 35.1 Aging With Traumatic Brain Injury

Mark was 19 years old when he was involved in a motor vehicle accident in which a drunk driver hit Mark's car while he was stopped at an intersection. He had severe injuries that included fractures of the left femur, both forearms and wrists, and right ankle; multiple internal injuries; "swelling" of the spinal cord; and increased intracranial pressure necessitating removal of part of his skull. He had sustained frontotemporal brain injury with no injuries to the spinal cord despite severe injuries from the accident. He had complicated postsurgical sequelae and was in a coma for 3 weeks. He stayed in the acute hospital for another 3 weeks and was sent to inpatient rehabilitation, where he stayed for 4 months. At discharge he was able to stand and walk short distances at home with minimal assistance, although primarily he used a power wheelchair as his main mode of mobility. Although his upper extremities were functional, he had to learn how to write and use his dominant extremity all over again. He had dysphagia and dysarthria yet was able to communicate functionally. Mark reports he had difficulty with memory and other cognitive deficits, and those were as hard to deal with as the physical impairments from his injury. He continued outpatient physical, speech, and occupational therapy services for another 3 months and worked on the physical, cognitive, and psychological effects of his injury. He stayed with his parents who at that time became his primary caregivers as he transitioned to a new lifestyle.

In the 20 years after his injury, Mark learned to live with the chronicity of his injury and its secondary effects. He learned to walk with a walker, then a cane, and eventually walked without an assistive device with a slow, ataxic gait. He learned to use public transportation and navigate his way in the community by using landmarks for spatial orientation. He was involved with support and volunteer groups for several years that provided him the socialization and support he needed, particularly in the early stages of his injury. He married in his mid-20s, and his wife assists him with daily activities as needed, although Mark says he is independent with "everything" except with instrumental ADLs, specifically balancing the checkbook, grocery shopping, and cooking. They live in a one-level home with steps at the front and side entries and have done "some modifications" with bars and a shower chair installation in the bathrooms and wider doors in the bedrooms. Mark says he has seen a PT "maybe once or twice" in the subsequent years for back pain or walking, but has not received continued care since his long episodes of therapy after the initial injury. He candidly states that he gets by with all physical abilities, although it is "hard at times" and he does not currently engage in a specific health or exercise program. He says he

has "learned to live with it" and shares some sadness at being unable to finish his education and care for his parents, who are now in their early 80s.

Now at 48 years old, Mark reports he is starting to feel more fatigued with walking and has noticed the need for more frequent rests. He continues to walk without an assistive device indoors and short distances but uses a single-tip cane for long distances in the community and outdoors. He and his wife are saving to renovate the front and side entries of the home, which currently have five steps and handrails. Although Mark is able to navigate the steps on his own, he has noticed more difficulty over the years. In the previous year, he fell once on the steps and once in the community as he stepped off a curb. He now uses a "memory" notebook more frequently. He volunteers at the local library three times a week and continues to use public transportation as his primary mode of transportation. "I'm slower, but I get there," he states. He "feels" the secondary impairments from his initial injuries—for example, contractures of the hamstrings, decreased ROM of the ankles and shoulders, postural impairments, gait deficits, and memory deficits—"more now that I'm getting old." He has more frequent bouts of back and hip pain from a combination of biomechanical changes from chronic impairments and possible contributions from aging. He has not sought physical therapy services despite the symptoms, difficulties, and changes in the past couple of years. Although he is interested in seeking physical therapy services, he has not done so, thinking that he will not qualify for services because of the chronicity of his condition. He volunteers at a local physical therapy program where he is provided pro bono services at least twice a year.

Points for discussion (suggested answers can be found online) include the following:

- What further secondary impairments and functional limitations do you anticipate?
- What recommendations regarding lifestyle changes would you give Mark?
- If he decides to seek physical therapy services, what recommendations would you give for a holistic program?
- What specific systems need to be examined and addressed in the intervention?
- What services are available for individuals with chronic conditions? Community and hospital or outpatient-based services?
- What health care and community services *should* be available to individuals with chronic conditions?

CASE STUDY 35.2 Personal Report: Post-Polio Syndrome*

Today my life is filled with optimism and hope. This was not the case long ago. I am 58 years old and have been diagnosed with PPS. I contracted polio at the age of 2 years, but for the first time in my life I feel disabled.

It is difficult for me to determine when the symptoms began. My life has been filled with caregiving, of first my mother-in-law, who was ill for the last year of her life, and then my parents, who had special needs. I had a vague

awareness that I was slowing down, not able to do some of the things that I had always done. But at that point in my life, the focus was not on me. It seems like when I was able to take a deep breath again, I was in a lot of pain.

I was able to see a doctor who specializes in PPS. She recommended a new leg brace, and she also recommended physical therapy. The new brace, while better for my body, is asking it to do different things. I basically am trying to

CASE STUDY 35.2 Personal Report: Post-Polio Syndrome—cont'd

learn how to walk all over again. My pain stems from weakness and tight muscles in my unaffected limb. My unaffected leg has been stressed by many years of overuse. The pain I experience is mainly in my hip and occasionally in my knee. Because of the stress of this pain, my stamina is less than it once was; my balance is not good, and just the task of moving from point A to B is a challenge. I found that I needed to use crutches to help take weight off of my leg. The pain that I felt a little over a year ago became the focus of my life. It affected everything I did. My day was reduced to struggle to even shower and dress, let alone do anything else. I had to depend on my husband to do more and more.

During this period, I would allow myself, if I was having a really bad day, to just do nothing. Some days I wouldn't even get out of bed until 11:00 AM. This didn't happen too often, but if it did, I allowed myself to not feel guilty. I think that this helped with my mental state. Yes, some days I would get frustrated and impatient and other days depressed, but it never lasted for too long. I have seen, on a personal level, what positive thinking can do. My parents were told that I would never walk again. I walked.

Having had polio, I learned at an early age how to "figure things out." If I couldn't do things one way, I perhaps could another. I think that this mindset has helped with my newest challenge. After meeting with my PT, she helped to map out a plan to achieve my goals. My goals are simple; I want to walk without pain and without crutches. I want to cross my left leg over my right knee to tie

my shoe. I want to build up my stamina so that I can go shopping. I want to be in the best health that I can be in. I want to remain independent.

I am learning that achieving my goals may be a long process. It has been a little over a year, and I still have a long way to go. I have gained some strength, my stamina has increased, and I am a bit more flexible, but more important, the pain level some days is just an afterthought. I am starting to regain my life.

I have learned in the past year how important it is to listen to your body. I have learned how to manage my work, rest, and exercise time. I understand that to achieve my goals it has and will take a lot of hard, sometimes painful, work. I also understand the importance of working toward my goal and achieving it. I consider myself to still be a relatively young woman who has a lot left to do in my life. Life is a gift, and that is what I want to do—live mine fully.

Points for discussion (suggested answers can be found online):

- If this individual were to seek physical therapy consultation, what history information should the therapist ask?
- What screening questions should the therapist ask?
- What specific systems should the therapist screen?
- What specific tests and measures are appropriate for this case?
- What possible interventions are possible for this individual?
- What considerations should be considered when planning for intervention?

*Orva Klopfer, as relayed to Holly Klopfer Holton, PT, DPT.

Abstract: This chapter aims to provide a holistic view of the management of the chronic problems of individuals with nervous system impairments, with consideration given to the effects of aging and compensation over time. Movement emerges from the interaction among the individual, task, and environment,¹³ with several variables and degrees of freedom. Therefore physical therapists (PTs) and occupational therapists (OTs) need to examine and address multisystem

impairments and contributions to movement while appreciating the changing dynamics of a highly complex movement system influenced by aging superimposed on the body system impairments and functional limitations from an existing central nervous system dysfunction.

Keywords: adaptation, aging, chronic impairments, fatigue, health promotion, postpolio syndrome

Impact of Drug Therapy on Patients Receiving Neurological Rehabilitation

Annie Burke-Doe and Timothy J. Smith

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify how drugs may positively or negatively affect the behavior of individuals within a neurological rehabilitation setting.
2. For a given disease state, comprehend how drugs may affect that disease state and the implications on an individual's potential for neurological rehabilitation.
3. When one or more impairments are being considered, recognize the influence of drug therapy on these impairments and on an individual's potential for neurological rehabilitation.
4. Recognize the importance of a collaborative approach in resolving drug-related issues and how those issues affect an individual's potential for neurological rehabilitation.

pharmacogenomics

Drug therapy is one of the most rapidly expanding therapeutic interventions in the health care system. Whereas monotherapy (the use of one drug for treatment of a single disease state) is preferred, complex pathologies and comorbid conditions usually render this goal impossible. In addition, most of the problems associated with multidrug therapy were at one time generally isolated to geriatric patients. Today, however, such problems have expanded because of more aggressive drug treatment in all age groups. Only rarely will an occupational or physical therapist manage a patient who is not receiving drug therapy for conditions either related or unrelated to the therapist's scope of practice. Drugs used for the management of a wide variety of disease states may have unintended or undesirable effects on a therapeutic plan for a patient undergoing neurological rehabilitation. Although the occupational or physical therapist may not be responsible for monitoring all aspects of a patient's therapeutic plan, the scope of drug-related complications must be recognized. A patient's pharmacist, who is acutely aware of the prescribing practices of the patient's physician or physicians, may be instrumental in resolving the drug-related impact of any medication on a therapeutic plan. The patient will benefit greatly from an effective collaboration that includes the therapist and a pharmacist. Focusing on drug effects, diseases, and impairments, this chapter addresses these interactions from three perspectives. First, the chapter discusses what the body does to a drug (pharmacokinetics), followed by what a drug does to the body (pharmacodynamics), and then pharmacogenetics (the involvement of genes in an individual's response to drugs).¹ Second, the chapter covers a disease- or pathology-driven model that focuses on the pharmacological approaches used in drug therapy of major diseases that are often concurrent with rehabilitation. Finally, the chapter presents an impairment, activity, or functional limitation-driven model that focuses on the effects of drugs on the impairment and resulting functional deficit and the impact on

the therapeutic plan. Although defining every problem associated with a class of drugs or among patients with an impairment is not possible within the scope of this chapter, it is important to highlight common difficulties.

CLINICAL PHARMACOLOGY

Medications do not affect all patients in the same way, and rehabilitation specialists should be concerned whether a drug achieves or falls short of its therapeutic response. Many situations may alter a drug's response; drug dose, drug interactions, the patient's comorbidities, and the effect on functional recovery can be positive or negative. To understand the impact of prescriptions, this chapter discusses the pharmacology of medications used by patients. Pharmacology—or the science of drug origin, nature, chemistry, effects, and uses—is commonly divided into two important areas: pharmacokinetics and pharmacodynamics.² *Pharmacokinetics* refers to how drugs are absorbed, distributed, biotransformed (metabolized), and eliminated from the body, whereas *pharmacodynamics* can be defined as the study of the biochemical and physiological effects of drugs and their mechanisms of action.² Many patients in the rehabilitation population undergo pharmacotherapy, and clinicians must understand how drugs work in the body and how they work differently in different populations to achieve their effects.

In looking at pharmacokinetics, how the drug is absorbed into the body from its site of administration must be considered. Drugs may cross many membranes before reaching their targets, and they can be affected by factors such as the size of a tablet or capsule, its physical state, and the temperature when it is dispensed.³ The absence or presence of food in the digestive tract, characteristics of the membrane, and the drug's ability to bind to plasma proteins can also play a role in

the rate of absorption and distribution. Some medications, such as Sinemet for Parkinson disease, can be absorbed more slowly with a high-protein meal, thus decreasing their availability and potentially affecting function. When a drug binds to a plasma protein such as albumin, the drug is held in the bloodstream and thus is unable to reach its target cells.² The term *bioavailability* is often used to describe how much of a drug will be available to produce a biological effect after its administration.

Metabolism is the next step in pharmacokinetics, involving the biochemical pathways and reactions that affect drugs, nutrients, vitamins, and minerals. The first-pass effect is an important phenomenon because many drugs absorbed across the gastrointestinal (GI) membrane are routed directly to the liver.² The liver is then the primary site of metabolism before the drug is distributed to target organs. Variations in drug response and metabolism may be caused by genetic factors, the presence of disease, drug interactions, age, diet, and gender.³ Drug doses in the elderly and young are often reduced to compensate for these patients' physiological differences. Specific prescribing guidelines for the elderly, known as the Beers criteria,⁴ have been developed, and guidelines for the pediatric population are currently being developed titled Pediatrics: Omission of Prescriptions and Inappropriate Prescriptions (POPI)⁵ to assist healthcare professionals. Any drug or disease that affects metabolism has the potential to affect drug activity. Excretion, which removes drugs from the body, is the last step in pharmacokinetics. Most substances that enter the body are removed by urination, exhalation, defecation, and/or sweating.² The main organ of excretion is the kidney. *Elimination* is another term for excretion and is often measured so that dosages of drugs can be determined more accurately. The rate of elimination is helpful in determining how long a drug will remain in the bloodstream and thus indicates for how long the drug will produce its effect.

Pharmacodynamics focuses on how the body responds to drugs; it deals with the mechanism of a drug's action or how drugs exert their effects. Successful pharmacotherapy is based on the principle that to treat a disorder, a drug must interact with specific receptors in its target tissue. Drugs activate specific receptors to produce a therapeutic response. Optimal treatment with medications will result only when the prescriber is aware of the sources of variation in responses to drugs and when the dosage regimen is designed on the basis of the best available data about the diagnosis, severity, and stage of the disease; presence of concurrent diseases or drug treatment; and predefined goals of acceptable efficacy and limits of acceptable toxicity.² Rehabilitation professionals are poised to assist the other members of the medical team with the data needed to assist in determining the effectiveness of a pharmacotherapeutic plan.

Pharmacogenomics is the study of how individuals differ in their responses to drug therapy and the mechanisms underlying variable drug responses by utilizing genomics, proteomics, transcriptomics, and metabolomics-based knowledge.⁶ The rationale behind pharmacogenetics is to find polymorphisms in the genes encoding the proteins and enzymes involved in drug transport, metabolism, and action that can predict the usefulness of a drug, thus increasing the number of responders and decreasing the number of subjects who experience adverse drug reactions.⁷ Pharmacogenetics is a growing field in neurogenetics; it can facilitate the prescription of specific therapeutics best suited for a given individual, taking into consideration both the genetic and environmental factors that influence the individual's response to therapy. This personalized approach is being applied to the management of several neurological disorders, and there are still other such disorders undergoing investigation. Examples include Alzheimer disease, Parkinson disease, multiple sclerosis (MS), traumatic brain injury, epilepsy, stroke, major depressive disorders, and attention-deficit

disorders.⁸ Although genetics contributes to only a fraction of the explanations behind interindividual difference in drug metabolism, a better understanding of how genetics influences drug responses is an emerging field and will be key to the future of individualized medicine.

DISEASE PERSPECTIVE

Many diseases and their treatment regimens may be concurrently managed while a patient is in a neurological rehabilitation environment. The pharmacological interventions for these conditions and their implications from both a physiological and a disease or pathology model are addressed in this chapter. Although not a comprehensive list, these include Parkinson disease, cancer, seizure disorders (epilepsy), cardiovascular disorders, disorders of mood, autoimmune disorders, diabetes, infectious diseases, pulmonary diseases, and GI disorders.

Parkinson Disease

Parkinson disease is a degenerative disorder involving a progressive loss of dopaminergic neurons in the substantia nigra, with the appearance of intracellular inclusions known as Lewy bodies.² A loss of 70% to 80% of dopaminergic function accompanies symptomatic Parkinson disease, causing a resting tremor and difficulty in the control of voluntary movement. Olfaction, sleep, cardiovascular function, bowel motility, and cognitive function are all often compromised.⁹ Although not directly associated with motor system pathology, the functional deficits are emotionally devastating to the patient, resulting in depression and other mood disorders. The predominant pharmacological approach in the management of Parkinson disease is the enhancement of dopaminergic function in the affected brain regions. Among the earliest successful approaches was the use of levodopa (L-dopa), a precursor of the neurotransmitter dopamine in the central nervous system (CNS). The use of this agent (and most agents to date) only enhances dopaminergic function in the remaining neurons but has no effect on the progressive loss of neurons. In addition to central conversion of L-dopa to dopamine in the substantia nigra pars compacta, a similar conversion occurs in the limbic system, a brain center associated with the regulation of behavior. Excessive dopaminergic influence in the limbic system has been associated with aberrant disease manifestations including paranoia, delusions, hallucinations, and related psychiatric disturbances, all of which may influence sleep and mood. These behavioral changes are obviously antagonistic to any therapeutic plan. In addition to L-dopa, a dopamine precursor, agents that inhibit the breakdown of dopamine, enhance the release of dopamine, or have dopaminergic agonist activity will have similar behavioral effects (Box 36.1). Dopaminergic agents may produce postural hypotension and syncope because of their ability to produce vasodilation based on CNS and peripheral actions.^{10,11} If patients are unable to take their medication, an increasing danger exists (with extended therapy) that movement may become impossible and normal chest wall expansion and contraction may be compromised.

Because Parkinson disease is progressive in nature, patients may have different presentations depending on the stage of the disease and the presence of pharmacological interventions. In the early months of the disease, the motor signs may be particularly subtle, and patients may report only slowness, stiffness, and trouble with handwriting. Attention to the history of tremor, slowness of fine motor control, a hunched and slightly flexed posture, and micrographia may lead the physician to diagnose Parkinson disease in its early phases.¹² As the disease advances, patients have increasing difficulty in activities of daily living and gait as well as bradykinesia and distal tremor.

Once a definitive diagnosis has been made, the control of symptoms and the side effects of medications is balanced with the level of

BOX 36.1 Agents Facilitating Dopaminergic Activity in the Management of Parkinson Disease

Agents That Are Converted to Dopamine

L-dopa (in Sinemet, Rytary, and DUOPA)

Agents That Stimulate the Release of Dopamine

amantadine (Symmetrel)

Agents That Reduce the Breakdown of Dopamine

carbidopa (in Sinemet, Rytary, and DUOPA)

entacapone (Comtan)

rasagiline (Azilect)

selegiline (Eldepryl)

tolcapone (Tasmar)

Agents That Are Dopaminergic Agonists

apomorphine (Apokyn)

bromocriptine (Parlodel)

pergolide (Permax)

pramipexole (Mirapex)

ropinirole (Requip)

Anticholinergic Agents

benztropine (Cogentin)

diphenhydramine (Benadryl)

trihexyphenidyl (Artane)

The effects of these agents on muscle tone are complex and dose-dependent.

functional involvement. The physician and patient may discuss the option of several medications (see Box 36.1) but must determine the best approach based on the clinical presentation. One limitation is the side effect of involuntary movements (dyskinesias). These dyskinesias can be difficult to control and are different from the involuntary movements caused by the disease itself. As mentioned earlier, dopamine agonist regimens that do not cause dyskinesias can also be prescribed, but their effect on symptoms is not as potent.¹³ Often physicians may begin treatment with a dopamine agonist (Ropinirole) and continue with the agonist as long as symptoms are satisfactorily controlled. Later the physician can initiate treatment with L-dopa when the disease is in the advanced stages. With the elderly patient who has cognitive deficits, combination therapy may be the initial choice. Once a medication regimen has been initiated, the patient and therapist may notice improvements in symptoms and therefore also in functional abilities. After taking a medication over time, patients may find that the effect of the medication begins to wear off before the next dose is scheduled. At this point consultation with the rehabilitation team is recommended to potentially change the timing of the medication release ability (extended release), or they may combine the treatment with other antiparkinsonian medications.

Great emphasis is placed on treating the motor features of Parkinson disease, but patients may have nonmotor manifestations, including depression, anxiety, cognitive impairment, and dementia. Often the patient does not mention these difficulties because he or she does not link them with Parkinson disease. Patients may demonstrate some of these difficulties, and the therapist should recognize the symptoms and refer the patient for further follow-up.

The major problems that patients have after 5 years of treatment for Parkinson disease are fluctuations (both motor and nonmotor), dyskinesias, and behavioral or cognitive changes.^{14,15} The mechanisms

behind these complications relate both to the underlying disease and the effects of medications. Motor fluctuations take several forms. Most commonly, a predictable decline in motor performance occurs near the end of each medication dose (“wearing off”). Patients change gradually from “on,” with a good medication response, into an “off” period 30 minutes to 1 hour before the next medication dose is due. Often patients have involuntary movements (dyskinesias) as a peak-dose complication, and sometimes similar movements occur at the end of the dose. Sudden and severe cataclysms of motor fluctuation occur rarely, with ambulatory patients becoming immobilized over a period of seconds (“sudden on-off”).¹⁶ Because these fluctuations occur throughout the day, accurate detection requires the cooperation of the patient, who must be trained to keep and complete a diary recording function.¹⁷ These journals generally divide the 24-hour day into 30-minute segments to detect good medication response (“on”), poor medication response (“off”), disabling dyskinesias, and sleep. Recently two new formulations of L-dopa intended to address wearing off have been approved.² Rytary carbidopa-levodopa extended-release capsules contain both immediate- and extended-release beads that provide reduced off time in patients with motor fluctuations.¹⁸ DUOPA carbidopa-levodopa intestinal gel is administered through a gastrostomy tube into the jejunum using a pump and can have a dramatic effect in reducing “off” time.¹⁹

In general, to meet functional goals and outcomes effectively, therapists working with patients taking antiparkinsonian medication must be aware of both the positive and negative side effects of medications. Learning the difference between tremor and dyskinesia is crucial. The therapist must coordinate therapy sessions during good medication response times to facilitate optimal outcomes. In addition, patients should be monitored for postural hypotension, dizziness, and cognitive changes. Therapists have the unique opportunity to determine the best timing, frequency, and duration of the treatment; understanding the impact of a patient’s drug regimen will only enhance the outcome. Therapists must also be aware that exercise increases metabolism. Increased metabolism may use up the medication faster; thus an individual who generally remains symptom-free (no off times between doses) and whose metabolism is increased will again exhibit signs of the disease (distal tremors and axial or proximal rigidity). These increases in symptoms may stem from a problem of drug dosage, not being signs of further degeneration of the basal ganglia. All changes in symptoms should be discussed with both the pharmacist and the physician.

Cancer

Cancer is a general term for disorders associated with abnormal and uncontrolled cell proliferation. Virtually any organ system can be affected, either as the primary site of disease or as a secondary site associated with metastasis. Cancer pharmacology has improved significantly during the recent past with an expanded understanding of cancer biology and newly developed drugs that target cancer vulnerabilities. Effective early treatments, adjuvant chemotherapy, and hormonal therapy can extend overall survival and prevent disease recurrence. In the past 5 years the ability to harness the power of the immune system in the treatment of cancer has brought about a paradigm shift whereby some of the most feared diseases—such as melanoma, lung cancer, and even late-stage metastatic disease—can be eradicated.²⁰ Cancer may interfere with neurological rehabilitation in various ways. Tumors within the brain may interfere with cognitive, motor and sensory function as well as autonomic and metabolic control (see Chapter 25). Peripherally tumors may interfere with nerve function and associated motor control or may produce pain. In addition, drugs that reduce cancer pain may interfere with cognitive and

BOX 36.2 Examples of Narcotic Analgesics, Morphine, and Related Agents

alfentanil (Alfenta)	morphine (MS-Contin)
buprenorphine (Buprenex)	nalbuphine (Nubain)
butorphanol (Stadol)	oxycodone (Roxicodone)
codeine	oxymorphone (Numorphan)
fentanyl (Duragesic)	pentazocine (Talwin)
hydrocodone (Vicodin)	propoxyphene (Darvon)
hydromorphone (Dilaudid)	remifentanil (Ultiva)
levorphanol (Levo-Dromoran)	sufentanil (Sufenta)
meperidine (Demerol)	tapentadol (Nucynta)
methadone (Dolophine)	tramadol (Ultram)

Effects on motor systems are systemic or indirect.

motor function.²¹ Among such drugs, morphine and related opiate derivatives (Box 36.2) are notable. A significant degree of tolerance to the CNS depressant effects will develop with long-term administration. Currently cannabinoids are being studied not only for the treatment of cancer symptoms but also for their anticancer effects. Cannabinoids are considered useful in combating anorexia, chemotherapy-induced nausea and vomiting, pain, insomnia, and depression.^{22,23} Nabiximols (Sativex), a cannabinoid drug, is still under study. An oral mucosal spray made up of a whole-plant extract with tetrahydrocannabinol (THC)/cannabidiol (CBD) is available in Canada and parts of Europe to treat pain linked to cancer as well as muscle spasms and pain from MS.²⁴ In cancer chemotherapeutic regimens, many antiemetic agents are used. These include dopaminergic antagonists (which may produce motor deficits similar to those of Parkinson disease), dronabinol (a chemical component of marijuana, which can affect cognitive function), and nabilone (a synthetic cannabinoid) as well as high-dose corticosteroids (which affect mood). Some antitumor agents may be neurotoxic; reduced deep tendon reflexes, paresthesias, and demyelination are associated with vincristine (Oncovin) and oxaliplatin (Eloxatin).^{20,25} Naturally any change in drugs involving cancer treatment (directly or indirectly) requires the approval of the patient's oncologist.

The main role of rehabilitation specialists is to help patients with cancer recover from the physical changes that accompany their illness, promote function in activities of daily living, and help provide adaptations to activities within the limits of each patient's function and the illness. Clinicians should be aware of chemotherapy side effects and the side effects of medications given to treat the toxic effects of chemotherapy. The importance of recognizing toxic effects early in the treatment regimen cannot be overstated and will help the oncologist to alter the dose or discontinue the offending medication.

A number of chemotherapeutic and nonchemotherapeutic medications are used to fight cancer. Most anticancer therapies operate on the simple principle that because cells in tumors are actively dividing, agents that kill dividing cells will kill tumor cells.²⁶ Tissue cells that divide rapidly are therefore at risk, including hair, mucosal linings, bone marrow, immune cells, and skin epithelial cells. Nonchemotherapy medications called *biological response modifiers* (BRMs) are naturally made by the body but in anticancer treatment are delivered in large quantities and at higher doses than those produced by the body.²⁷ Interferon and interleukin are two of the most commonly used medications. Monoclonal antibodies that target oncogenic pathways are also used as chemotherapy to suppress the immune system.

Chemotherapy often has side effects that affect the integumentary, GI, hematological, and neurological systems. Each type of therapy has potential side effects along with the more general side effects of the

treatment regimen. Because of their chemotherapeutic treatment of cancer, patients often have muscular weakness, neuropathy, fatigue, pain, immobility, and reduced flexibility. Often the therapist will have to be supportive and flexible with treatment plans to accommodate for changing physiological, psychological, and social factors during treatment.

GI symptoms such as nausea and vomiting may occur; medications such as Compazine and Reglan may be given to help control these episodes. Symptoms of diarrhea may be addressed through prescriptions or the use of over-the-counter (OTC) medications including milk of magnesia and magnesium citrate. The development of mucositis or esophagitis is also possible. A prescription solution of three medications (diphenhydramine [Benadryl], nystatin, and viscous lidocaine) can help to relieve pain, inflammation, and potential associated fungal infections. Bone marrow suppression from chemotherapeutic regimens may lead to an increased risk of infection, risk of bleeding, and fatigue as well as a lack of exercise capacity and musculoskeletal weakness. Patients undergoing chemotherapy may receive one or more medications to signal the bone marrow to increase its output of white blood cells (filgrastim [Neupogen]), stimulate the production of red blood cells (epoetin alfa [Epogen]), and stimulate increased production of platelets (oprelvekin [Neumega]). These therapies may be instituted to help the patient more quickly reverse suppression of bone marrow and allow the chemotherapy to continue without interruption.²⁸ Generalized symptoms include fever, body aches and pains, and feelings of ill health and fatigue. No specific medications are used to improve these symptoms. In general taking medications such as acetaminophen, ibuprofen, or narcotics for fever and pain may help. The use of exercise as an adjunctive therapy for cancer treatment-related symptoms has gained favor in oncology rehabilitation as a promising intervention.^{29–32} Exercise is thought to help improve endurance, functional ability, and quality of life.^{29,31,32} The major side effects associated with BRMs and monoclonal antibodies are generalized as well and include fever and flulike symptoms with associated arthralgia and myalgia. Other side effects include lymphedema, which is characterized by fluid retention caused by disruption of lymphatic drainage or the removal of lymph nodes. As mentioned earlier, neurological changes may occur, with the development of neurological signs as well as forgetfulness, suicidal ideation, and depression.

In treating cancers, selection of the most appropriate treatment or treatments, dose, and dose intervals as well as the management of adverse effects requires specialized knowledge and a team effort.²⁰ In addition, cancer treatment regimens undergo frequent updates due to findings of ongoing clinical trials. The availability of drugs with new mechanisms of action (e.g., immune checkpoint inhibitors), good target selectivity (e.g., kinase inhibitors), efficacy in specific cancers, and different adverse-effect profiles permits the use of new drug combinations and regimens.²⁰ The rehabilitation professional is an important team member in oncology because his or her actions potentially affect quality of life.

Seizure Disorders (Epilepsy)

Epilepsy is associated with a diverse group of neurological disorders resulting in motor, psychic, and autonomic manifestations. Many antiseizure medications may produce drowsiness, ataxia, and vertigo (Box 36.3). Some may produce cognitive disorders in children and adults.^{33,34} Although these adverse effects may be exhibited throughout therapy, they are most troublesome during its initiation, the addition of a drug, and the escalation of dosage. Sudden discontinuation of antiseizure medications may result in status epilepticus, which can be fatal. Many antiseizure medications are finding successful applications outside epilepsy, especially in the area of pain management. As with cancer, clinical evidence has shown that cannabinoids such as CBD can

BOX 36.3 Anticonvulsants

acetazolamide (various brand names)	oxcarbazepine (Trileptal)
carbamazepine (Tegretol)	phenobarbital (various brand names)
clonazepam (Klonopin)	phenytoin (Dilantin)
diazepam (Valium)	pregabalin (Lyrica)
ethosuximide (Zarontin)	primidone (Mysoline)
felbamate (Felbatol)	rufinamide (Banzel)
fosphenytoin (Cerebyx)	tiagabine (Gabitril)

lacosamide (Vimpat)	valproic acid (Depakene)
lamotrigine (Lamictal)	vigabatrin (Sabril)
levetiracetam (Keppra)	zonisamide (Zonagran)
lorazepam (Ativan)	

Effects on motor systems are direct and may decrease tone at higher doses. Direct effects on muscle are minimal. This list includes benzodiazepines that have antiseizure applications.

be used to reduce seizures effectively, particularly in patients with treatment-resistant epilepsy. However, many questions remain regarding the mechanism, safety, and efficacy of cannabinoids in short- and long-term use.³⁵

The practicing clinician working with patients who have a history of seizure disorders must be prepared for the onset of a seizure and be aware of any adverse side effects of medications. Adverse side effects are typically determined on a clinical basis, signifying the importance of recognition by the health care provider. Many of the common side effects can also have negative implications for motor learning, especially while the patient is getting used to the medication or the dosage is being elevated or tapered.

The treatment of seizure disorders with pharmacotherapy is typically intended to control the seizure activity completely without producing unwanted side effects. Pharmacological intervention usually begins with one medication (monotherapy); if this drug is unsuccessful, a second is added while dosage of the first is tapered. Or a combination may be needed. The effects of the medications vary and may include enhancing the inhibitory effects of γ -aminobutyric acid (GABA) (benzodiazepines); reducing posttetanic potentiation, thereby reducing seizure spread (imino-stilbenes); or modulating neuronal voltage-dependent sodium and calcium channels (hydantoin).³⁶ The overall result is a reduction in abnormal electrical impulses in the brain. The choice of antiseizure drugs primarily depends on the seizure type and, if possible, the diagnosis of a specific syndrome. If seizures are recurrent and occur during critical periods of childhood, adolescence, and early adulthood, they may result in significant impairments in function and increased disability.

Some side effects may be slow to develop and difficult to diagnose because seizures can often be mistaken for sedation or cognitive dysfunction, especially in children, who may not report drug side effects. Practitioners can also mistakenly accept reversible drug toxicity as a necessary consequence of a seizure disorder. The number of seizures occurring during physical or occupational therapy should be tracked to assist in determining appropriate pharmacotherapy.

One common antiseizure medication, valproic acid (Depakene), may cause nausea, vomiting, hair loss, tremor, tiredness, dizziness, and headache. Valproic acid has also been reported to aggravate absence seizure in patients with absence epilepsy.³⁷ Metabolic side effects may include an increase in glucose-stimulated pancreatic insulin secretion, which may be followed by an increase in body weight.³⁸ Long-term use of valproic acid is known to increase bone resorption in adult epileptic patients and can decrease the mineral density of bone.³⁹

Another seizure medication, carbamazepine (Tegretol), is considered a safe drug, but it has a long list of adverse effects, most commonly ataxia and nystagmus.⁴⁰ Other systems frequently involved are the skin, the hematopoietic system, and the cardiovascular system. Gabapentin (Neurontin) is another well-tolerated antiseizure medication with proven clinical efficacy and a low incidence of adverse events in clinical trials. Common side effects include dizziness, fatigue, and headache. Phenytoin (Dilantin) has adverse effects including ataxia, nystagmus, slurred speech, confusion, dizziness, and, at high doses, peripheral neuropathy.

Benzodiazepines (e.g., diazepam) are useful in managing status epilepticus, but their effects are not long-lasting, so they are often used along with a primary anticonvulsant. The most frequent side effects are dose-related sedation, difficulty with concentration, dizziness, and difficulty walking.

Pharmacological adverse events that occur under the influence of seizure medications must be recognized by the rehabilitation specialist to participate in a team approach to patient care. Therapists can assist in determining the effectiveness of a specific treatment regimen, appropriate timing of rehabilitation interventions, and the overall progress of the patient during rehabilitation.

Stroke, Hypertension, and Related Disorders

Stroke, by virtue of its interference with blood flow and oxygenation, produces both reversible and irreversible neurological deficits. The loss of function associated with stroke has at least two major causes. The first involves loss of oxygenation to a critical brain region, followed by glutaminergic rebound and excessive calcium influx with apoptosis (programmed cell death). Current drugs and those under development are aimed at restoring blood flow and inhibiting glutaminergic hyperexcitability and intracellular apoptotic mechanisms.⁴¹ The second pathogenic issue is related to reperfusion injury associated with oxygen free radicals and associated cellular damage. In this case, free radical scavengers have shown some promise in animal models of stroke.⁴² To reduce the damage associated with thromboembolism in such cases, tissue plasminogen activator (tPA) has been recommended.⁴³ However, this agent is most effective when given within an hour and up to 4.5 hours after the vascular insult.⁴⁴ Currently some studies have provided strong evidence to support the efficacy of endovascular therapy with intravenous thrombolytic treatment in patients with acute ischemic strokes due to large vessel occlusions. Speed of delivery, multidisciplinary care, and access to specialized teams with endovascular capability is required to achieve results similar to those seen in these trials.^{44–48}

Drugs with other mechanisms used to improve the prognosis of stroke are under development,^{49,50} showing variable promise. However, drugs used for concurrent conditions (atherosclerosis and hypertension) before and after a stroke are complicating factors for optimal outcomes from rehabilitation. These drugs include β -adrenergic antagonists, which reduce heart rate and correspondingly alter exercise tolerance. Occasionally calcium channel blockers, α -adrenergic blockers, and related agents may cause similar effects, including weakness, dizziness, syncope, and cognitive disorders. Changes in serum electrolytes induced by diuretics and the angiotensin-converting enzyme inhibitors may affect the heart, the vasculature, and skeletal muscle and ultimately cause impairments in areas such as strength of contraction.⁵¹ Box 36.4 lists many of these drugs. Many of the cholesterol synthesis inhibitors (agents used to reduce serum cholesterol) may induce muscle weakness, which may impact rehabilitation (Box 36.5), but this adverse effect is considered rare despite the increase in prescribing.^{52–55} Abrupt discontinuation of antihypertensive medications may result in a hypertensive crisis, dramatically increasing the risk of stroke and related disorders.

BOX 36.4 Commonly Used Antihypertensive and Cardiovascular Drugs **β -Adrenergic Blocking Drugs**

acebutolol (Sectral)
 atenolol (Tenormin)
 betaxolol (Kerlone)
 bisoprolol (Zebeta)
 carteolol (Cartrol)
 esmolol (Brevibloc)
 metoprolol (Lopressor)
 nadolol (Corgard)
 nebivolol (Bystolic)
 penbutolol (Levatol)
 pindolol (Visken)
 propranolol (Inderal)
 sotalol (Betapace)
 timolol (Blocadren)

Agents That Affect α - and/or β -Adrenergic Systems

carvedilol (Coreg)
 clonidine (Catapres)
 doxazosin (Cardura)
 guanabenz (Wytensin)
 guanadrel (Hylorol)
 guanfacine (Tenex)
 labetalol (Trandate)
 methyl dopa (Aldomet)
 prazosin (Minipress)
 silodosin (Rapaflo)
 tamsulosin (Flomax)
 terazosin (Hytrin)

Calcium Channel Blocking Drugs

amlodipine (Norvasc)
 bepridil (Vascor)

clevidipine (Cleviprex)
 diltiazem (Cardizem)
 felodipine (Plendil)
 isradipine (DynaCirc)
 nicardipine (Cardene)
 nifedipine (Procardia)
 nimodipine (Nimotop)
 nisoldipine (Sular)
 verapamil (Calan)

**Agents That Affect the Renin-Angiotensin System
Angiotensin-Converting Enzyme Inhibitors**

benazepril (Lotensin)
 captopril (Capoten)
 enalapril (Vasotec)
 fosinopril (Monopril)
 lisinopril (Zestril)

BOX 36.5 Hypolipidemic Drugs (HMG-CoA Reductase Inhibitors)

atorvastatin (Lipitor)	pravastatin (Pravachol)
fluvastatin (Lescol)	rosuvastatin (Crestor)
lovastatin (Mevacor)	simvastatin (Zocor)
pitavastatin (Livalo)	

These drugs may rarely produce muscle damage through a direct effect on the muscle.

Clinicians caring for patients with stroke, hypertension, and cardiac disorders will benefit from understanding the impact of any medication on the therapeutic plan. These patients may be taking any number of medications to manage the acute and subacute complications of cardiovascular impairments and their resulting sequelae. Other complications after stroke that may require pharmacological intervention include urinary tract infections, musculoskeletal pain, deep vein thrombosis, pressure sores, shoulder subluxation, and depression. All these medications have their own issues, and health care providers must be aware of adverse events and any alteration in function of the heart that may occur in relation to exercise.

Anticoagulants such as heparin, warfarin, and aspirin (so-called *blood thinners*) are used to prevent another stroke after the first one has

occurred. Side effects may include bleeding, allergic reactions, thrombocytopenia, and, in the case of aspirin, stomach irritation.⁵⁶ New oral anticoagulants have been developed for stroke prevention in atrial fibrillation. These newer agents such as dabigatran (Pradaxa), rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa) have a predictable pharmacological profile so that international normalized ratio (INR) monitoring and dose modifications are not required.^{57–60} Their main advantages, apart from their treatment efficacy, include the reduced rate of intracranial hemorrhage, the lack of need for routine coagulation monitoring, the predictable anticoagulation response, and the limited interaction with food and drugs.⁶¹ Blood thinners make the patient more susceptible to bruising; therefore care must be taken in patient handling and choice of activity. Antiarrhythmics are used to restore the heart's normal conduction patterns. Antiarrhythmic drugs may make some patients experience lightheadedness, dizziness, or faintness when they get up after sitting or lying down (orthostatic hypotension).⁶² Antiarrhythmic drugs may also cause low blood sugar or changes in thermoregulation.⁶³ The most common side effects are dry mouth and throat, diarrhea, and loss of appetite.⁶⁴ These problems usually go away as the body adjusts to the drug and do not require medical treatment. Therapists must be prepared for hypotensive events and the need to educate patients on positions that will reduce the effects of orthostatic hypotension.

Hypertension is a common disorder that is frequently encountered when treating patients in the rehabilitation environment. Antihypertensive medications are used to lower blood pressure (see [Box 36.4](#)) by limiting plasma volume expansion, decreasing peripheral resistance, and decreasing plasma volume. Often patients under medical management will undergo changes in dose and additions or deletions of medication, which may lead to problems during rehabilitation. Side effects of these medications may include increased frequency of urination, increased urinary excretion of potassium, orthostatic hypotension, hypotension, dehydration, tiredness, fatigue, cold hands and feet, and dizziness.⁶⁵ Health care providers working with a patient who is taking antihypertensive medications should monitor for side effects, clinical signs, and the patient's perceived exertion. Generally people on antihypertensive medications require careful cardiovascular monitoring during any physical activity.

Many patients tend to become depressed after experiencing a stroke, a cardiac event, or another neurological disorder.⁶⁶ Such changes in mood may be attributable to a natural loss of physical function or a neurochemical response to changes in brain chemistry. Patients with signs and symptoms of depression (sadness, anxiety, hopelessness, suicidal ideation) should be referred for further follow-up by the physician. Many antidepressant medications take at least 2 weeks to achieve a therapeutic level. Antidepressants may cause temporary side effects (sometimes referred to as *adverse effects*) in some people. These effects are generally mild. Any unusual reactions, side effects, or behaviors that interfere with functioning should be reported to the physician immediately. The most common side effects of tricyclic antidepressants (TCAs) are dry mouth, constipation, bladder problems, sexual problems, blurred vision, dizziness, and drowsiness.⁶⁷ The newer antidepressants have different types of side effects, including headache, nausea, nervousness, insomnia, agitation, and sexual problems.⁶⁸ Therapists working with patients who are depressed may have to delay rehabilitation until the depression is well managed.

Hyperlipidemia is considered a modifiable risk factor for heart disease and stroke. Many patients may be receiving pharmacological treatment to reduce their cardiovascular risk. Several types of drugs are available for cholesterol lowering, including statins, bile acid sequestrants, nicotinic acid, and fibric acids.⁶⁹ The statins are considered first-line drugs and are generally well tolerated, but they can produce myopathy under some circumstances.⁶⁹ An elevation of creatine kinase level is the best indicator of statin-induced myopathy and should be checked for when patients report leg pain. Bile acid sequestrants also produce moderate reductions in cholesterol. Sequestrant therapy can produce a variety of GI symptoms, including constipation, abdominal pain, bloating, fullness, nausea, and flatulence. Nicotinic acid (niacin) therapy can be accompanied by a number of side effects. Flushing of the skin is common with the crystalline form and is intolerable for some persons. However, most persons have tolerance to the flushing after more prolonged use of the drug. The fibrates have the ability to lower serum triglycerides and are generally well tolerated in most persons. GI symptoms are the most commonly reported, and fibrates appear to increase the likelihood of cholesterol gallstones.⁶⁹

Overall, patients taking cardiovascular medications need careful monitoring for any drug impact on cardiorespiratory or metabolic responses in relation to rehabilitation activities. Thus the effects of drugs must be considered in developing the rehabilitation plan.

Anxiety and Depression

Agents used in the management of anxiety, whether from acute or chronic disease, must be carefully titrated. Among these agents are the benzodiazepines, whose anxiolytic (anxiety-reducing) dosage range immediately precedes a dose that may affect motor skills and

BOX 36.6 Anxiolytic Benzodiazepines

alprazolam (Xanax)	halazepam (Paxipam)
chlordiazepoxide (Librium)	lorazepam (Ativan)
clorazepate (Tranxene)	oxazepam (Serax)
diazepam (Valium)	

Note that benzodiazepines indicated for sleep induction are not included in this list. The agents listed here reduce muscle tone through a direct effect on motor systems at higher doses.

cognitive function ([Box 36.6](#)). In subjects of all ages but especially the geriatric population, the administration of benzodiazepines may produce paradoxical excitement, confusion, and behavioral changes.⁷⁰ Geriatric subjects also have an increased incidence of injury from falls concurrent with use of benzodiazepines and other sedative-hypnotic drugs. Although benzodiazepines may have variable effects on learning and declarative memory, these effects may differ among the benzodiazepines; there may also be considerable variation in individual responses. If producing sleep alone is desired, zolpidem (Ambien) and zaleplon (Sonata) are attractive alternatives because these agents do not have anxiolytic effects. Although the anxiolytic agent buspirone (Buspar) is relatively free of benzodiazepine-like effects, the onset time for the desired anxiolytic effect is characteristically delayed.⁷¹ Lack of compliance with anxiolytic agents may increase panic attacks and reduce effective interactions with a therapist.

The emergence of the selective serotonin reuptake inhibitors (SSRIs) has revolutionized the treatment of depression. The older agents, such as the TCAs, are just as effective in the management of several forms of depression; however, their adverse effect profile is somewhat different. TCAs often produce drowsiness and orthostatic hypotension, effects that complicate any rehabilitation regimen.⁷² Although these effects may also be produced by SSRIs, their incidence is much reduced. Certain TCAs, by virtue of their ability to inhibit the reuptake of norepinephrine in adrenergic nerve terminals, may be used at lower doses for neuralgia. Although these low-dose regimens are usually not associated with the side effects previously mentioned, some patients may be more sensitive to these effects than others. This requires increased vigilance for the care team in determining iatrogenic versus pathological sources of somnolence and syncope. A partial list of antidepressants is presented in [Box 36.7](#). Noncompliance with antidepressant therapy may result in lack of interest in any therapeutic regimen.

Patients with stroke and other neurological diagnoses often have depression, which reduces motivation and decreases compliance with

BOX 36.7 Antidepressants: Examples of Tricyclic Antidepressants and Selective Serotonin Reuptake Inhibitors

Tricyclic Antidepressants	Selective Serotonin Reuptake Inhibitors
amitriptyline (Elavil)	citalopram (Celexa)
amoxapine (various trade names)	escitalopram (Lexapro)
clomipramine (Anafranil)	fluoxetine (Prozac)
desipramine (Norpramin)	fluvoxamine (Luvox)
doxepin (Adapin)	paroxetine (Paxil)
imipramine (Tofranil)	sertraline (Zoloft)
nortriptyline (Pamelor)	
protriptyline (Vivactil)	

These agents may produce complex direct and indirect effects on motor systems with minimal effects directly on muscle.

a therapeutic regimen. Although obviously linked, the degree of functional restoration after a stroke does not always correlate with resolution of depression.

Many patients with neurological disorders are diagnosed with or experience anxiety and depression. Affective symptomatology can be the result of cognitive and emotional deficits or impairment of brain function from the existing pathology.⁶⁶ In the rehabilitation environment, many patients may show signs and symptoms of anxiety or depression that can make the process of recovery more difficult. The rehabilitation professional must recognize the manifestations of both anxiety and depression, such as fear of dying or “going crazy,” heart palpitations, shortness of breath, difficulty concentrating, depressed mood, diminished interest or pleasure in activities, sleep disturbance, changes in appetite, psychomotor retardation and agitation, and suicidal ideation.⁷³ Anxiety and depression may limit the patient’s full participation in recovery of function and are associated with poorer outcomes.^{68,74}

Anxiety and depression can be managed well when treated with the medications discussed previously, but some drugs—including centrally acting hypotensives (methyldopa), lipid-soluble β -blockers (propranolol), benzodiazepines, and other CNS depressants—may cause a depressed mood.² Therefore in the case of a patient with depression, review of the medication regimen can be useful as it can help to determine whether one of the medications is implicated.

Pharmacological treatments for anxiety and depression should be administered at a dosage and time that ensure the best patient response during treatment. Antianxiety medications (see Box 36.6) act within a short time after ingestion, producing their effects of sedation and relaxation and thereby reducing anxiety. Higher levels may cause drowsiness, sleep, and anesthesia and are associated with falls, which may not be ideal when the aim of treatment is to promote recovery of function. Antidepressant medications (see Box 36.7) typically take weeks for therapeutic levels to be achieved in the brain and an improvement in mood to be demonstrated. Rehabilitation may be appropriate for a patient taking these medications when they have improved the patient’s mood and outlook. Side effects of antidepressants can also cause some difficulties, including lightheadedness, drowsiness, short-term memory loss, disturbed sleep, clumsiness, sedation, and low blood pressure.

Some evidence has shown that recovery from brain injury may be positively influenced by antidepressants^{75,76} and that antidepressants can play a role in brain plasticity.⁷⁷ These studies suggest that recovery of function after brain injury can be influenced by experience and pharmacological intervention. Rehabilitation specialists must be prepared to assess responses to pharmacotherapy, recognize adverse effects, manage minor side effects, and seek appropriate assistance for adverse events.

Arthritis and Autoimmune Disorders

Autoimmune mechanisms play an important role in the inflammatory process and progressive joint destruction of rheumatoid arthritis (RA). Because of the constant pain associated with movement, patients tend to seek nonprescription drugs (including dietary supplements) that often escape prescription drug monitoring programs in pharmacies. It is important for all health professionals to recognize this issue, particularly with RA. In the management of RA, the therapeutic approach may influence the progress of rehabilitation. Pharmacological agents that reduce RA symptoms and impede joint damage can be categorized as either nonbiological disease-modifying antirheumatic agents (DMARDs) or biological DMARDs, which include inhibitors of tumor necrosis factor (TNF)-alpha biologics or non-TNF biologics.⁷⁸ DMARDs are the key mediators that should be initiated as soon as

possible after disease onset.^{79–81} Nonsteroidal antiinflammatory drugs (NSAIDs) and/or corticosteroids can be used for symptomatic improvement as they provide rapid relief of symptoms compared with DMARDs, which may take weeks to months to have an effect.

Treatment with glucocorticoids may reduce joint pain and facilitate movement, but it may also produce changes in mood and muscle wasting.⁸² Although this is reversible and limited to systemic administration of high-dose corticosteroids, its impact cannot be overlooked and certainly affects the prognosis of physical or occupational therapy. Corticosteroids should not be used as monotherapy; they are valuable in controlling symptoms before DMARDs can take effect and are used in acute RA flares as burst therapy.⁷⁸ Continuous low doses of corticosteroids may be used as adjunctive therapy when DMARDs do not provide adequate disease control. Some data suggest that they have disease-modifying activity^{83–85}; however, it is preferable to avoid chronic use when possible so as to avoid long-term complications. NSAIDs and DMARDs have steroid-sparing properties that permit reductions in corticosteroid dose. Prednisone and related glucocorticoids may often produce a false sense of well-being that may exceed the ability of the patients to engage safely in certain exercise regimens. From the patient’s perspective, this pharmacological effect is perceived as a “cure” and does not provide the motivation to continue with exercise therapy. The same problems may exist with the use of corticosteroids in other autoimmune disorders.⁸⁶

NSAIDs (Box 36.8) have long been used for the relief of pain due to arthritis; however, depletion of prostaglandins in the gastric mucosa produces bleeding, which has limited their usefulness.⁸⁷ NSAIDs should seldom be used as monotherapy for RA because they do not alter the course of the disease; instead, they should be viewed as adjuncts to DMARDs. The development of newer agents that are more selective for isoforms of cyclooxygenase (COX-2 inhibitors), which are involved in joint inflammation, is a major advance. An example is celecoxib. Although bleeding disorders are dramatically reduced, the incidence of ataxia with these agents may be increased.⁸⁸ Unfortunately cardiovascular toxicity risk has led to the withdrawal of most of the COX-2 inhibitors from the market. Patients with neurological diseases or pathological processes with problems requiring anti-inflammatory medications may develop side effects that interact with and complicate existing motor deficits. Failure to comply with the arthritis medication regimen will likewise reduce effective movement.

Clinically, patients with the onset of RA may have a number of systemic manifestations, including fatigue, anorexia, generalized weakness, and musculoskeletal symptoms followed by synovitis. These forewarning symptoms may continue over weeks or months before

BOX 36.8 Commonly Used Nonsteroidal Antiinflammatory Agents and Salicylates

aspirin or acetylsalicylic acid	ketorolac (Toradol)
celecoxib (Celebrex)	meclofenamate (various trade names)
diclofenac (Voltaren)	mefenamic acid (Ponstel)
diffenisal (Dolobid)	meloxicam (Mobic)
etodolac (Lodine)	nabumetone (Relafen)
fenopropfen (Nalfon)	naproxen (Aleve, Naprosyn)
flurbiprofen (Ansaid)	oxaprozin (Daypro)
ibuprofen (Advil, Motrin, Nuprin)	piroxicam (Feldene)
indomethacin (Indocin)	sulindac (Clinoril)
ketoprofen (Orudis KT, Oruvail)	tolmetin (Tolectin)

Only at higher doses will these agents affect motor systems directly. Most problems arise through systemic or indirect effects.

more specific symptoms occur. The initial evaluation of the patient with RA should document symptoms of active disease (e.g., degree of joint pain, duration of morning stiffness, degree of fatigue), functional status, objective evidence of disease activity (e.g., synovitis, as assessed by the number of tender and swollen joints and the erythrocyte sedimentation rate), mechanical joint problems (e.g., loss of motion, crepitus, instability, malalignment, or deformity), the presence of extraarticular disease, and damage detected radiographically.⁸⁹ Neurological complications of RA may occur in the CNS (cerebral vasculitis), the peripheral nervous system (nerve compression), the neuromuscular junction (myasthenic syndrome), and muscle (myopathy).⁹⁰ Depending on the stage of involvement, the patient may be undergoing nonpharmacological modalities (education, weight loss, range-of-motion exercises) and pharmacological therapy including analgesics, NSAIDs, steroids, DMARDs, and BRMs.

The goals of pharmacological treatment of RA are to prevent or control joint damage, prevent loss of function, decrease pain, and improve joint function.⁸⁹ NSAIDs assist in analgesia and decrease inflammation and reducing stiffness, thus allowing the therapist to work on range of motion and strengthening. Because NSAIDs regulate the production of chemicals (prostaglandins) in the body that help trigger inflammation by inhibition of an enzyme (COX), they sometimes lead to the unwanted side effects discussed previously. Data suggest that although selective COX-2 inhibitors pose a significantly lower risk of serious adverse GI effects than do nonselective NSAIDs, they are no more effective than nonselective NSAIDs, are related to cardiovascular events, and may cost as much as 15 to 20 times more per month of treatment than generic NSAIDs.^{91,92}

Steroids are synthetic forms of naturally occurring hormones produced by the adrenal glands and are typically administered orally or by injection. They provide a rapid and powerful reduction of pain and inflammation resulting in improved function. Recent evidence suggests that low-dose glucocorticoids slow the rate of joint damage and therefore appear to have disease-modifying potential.⁹³ Side effects, depending on the dosage and length of treatment, include blood sugar elevations, cataracts, hypertension, increased susceptibility to infection and bruising, osteoporosis, and weight gain. These drugs are often used at disease onset or with disease flares as a temporary aid in obtaining control. Disabling synovitis frequently recurs when glucocorticoids are discontinued, even in patients who are receiving combination therapy with one or more DMARDs. Therefore many patients with RA are functionally dependent while taking glucocorticoids and continue using them on a long-term basis.⁸⁹

An important foundation in the treatment of RA is the use of DMARDs, which reduce signs and symptoms, reduce or prevent joint damage, and preserve the structure and function of the joints. Their use alone or in combination has been reported to allow patients to remain active and productive.⁹⁴ The most common DMARDs in current use include methotrexate, sulfasalazine, hydroxychloroquine, leflunomide, and cyclosporine. The biological agents with disease-modifying activity include the anti-TNF drugs (etanercept, infliximab, adalimumab, certolizumab, golimumab), the costimulation modulator abatacept, the IL-6 receptor antagonist tocilizumab, and rituximab, which depletes peripheral B cells. Others include gold salts, azathioprine, and D-penicillamine. Side effects may include diarrhea, eye damage, liver damage, and nausea/vomiting; these reactions depend on the DMARD taken.

Finally, BRMs are a newly developed class of medicines that restore or stimulate the immune system to fight disease. BRMs target specific parts of the immune system that destroy joints. Some do so by blocking the effects of TNF, a protein involved in RA through the inflammatory cascade, and are credited with improving signs, symptoms, and

function in patients with RA.⁹⁵ The anti-TNF and non-TNF biological agents have proven to be effective for patients who fail treatment with other DMARDs and were previously reserved for this subset particularly due to cost. However, the American College of Rheumatology⁹⁶ now endorses the use of anti-TNF biologics in patients with early disease of high activity and a poor prognosis.

Rehabilitation therapy is important in maintaining physical function in patients with RA. With combinations of medications, health care providers can reach goals of increasing or maintaining joint mobility; decreasing pain; improving functional abilities; improving cardiovascular fitness; and educating patients on the use of assistive devices, joint protection, and energy conservation.

Infectious Diseases

Both bacterial and viral diseases may produce neurological disorders (see Chapter 26). The neurological impact of treatments and prophylactic measures must be understood. Although this may be clear for drugs, vaccines have also been implicated in causing similar problems. The association of a hypotonic-hyporesponsive episode with the pertussis vaccine is such an example.⁹⁷

In the course of treating bacterial diseases, many antibiotics and antiinfective agents may compromise sensory, motor, and cognitive function. These functions may be compromised temporarily or permanently and may be patient specific. First, in the critically ill patient, aminoglycosides (gentamicin, tobramycin, and amikacin) and vancomycin may produce ototoxicity, such as hearing loss (reversible and irreversible) and vestibular damage (dizziness, vertigo, and ataxia). Minocycline is also associated with vestibular toxicity.⁹⁸ Extra precautions may be necessary to prevent falls during and after therapeutic exercise sessions. Fall-prevention programs must be developed in these cases as well as with the use of sedative-hypnotics, as previously noted.

A wide variety of viral diseases interfere with neurological function. Polio is historically the most widely recognized. Acquired immunodeficiency syndrome (AIDS) may manifest as a wide variety of neurological disorders. Protease inhibitors, which reduce the assembly of viral particles, may dramatically reduce and possibly reverse the neurological manifestations of AIDS.⁹⁹ Although adverse effects associated with antiviral and antibiotic agents may be intolerable, noncompliance may result in increased resistance of the virus or microorganism to retreatment.

The guiding principle of chemotherapy for infection is selective toxicity, in which the agent must cause more harm to the pathogen than to the host. Problems associated with antimicrobial therapy include resistance to drugs, side effects, allergies, and suppression of normal flora. Clinicians ask patients to exercise under conditions in which they may potentially have a compromised immune response because of trauma, a pathological condition, or surgery. These conditions may make patients more susceptible to infection, slow healing, and slow recovery.¹⁰⁰

An increasing number of strains of antibiotic-resistant bacteria are now emerging (*Clostridium difficile*, carbapenem-resistant Enterobacteriaceae), in large part because of the overuse and misuse of antimicrobial drugs by health care providers.¹⁰¹ Overuse of antimicrobial drugs exerts a selective pressure on bacteria, encouraging the emergence of antibiotic-resistant strains by eliminating antibiotic-sensitive strains, promoting the establishment of bacteria with rare mutations of resistance, and permitting the spread of resistant strains from infected individuals.¹⁰² One example is the use of antibiotics for upper respiratory tract infections caused by viruses. This has been shown to have no beneficial impact on the course of the disease.¹⁰³ Infection control in the rehabilitation environment is essential to stop the spread

of disease. Therapists must be diligent with infection-control procedures such as handwashing, updating vaccinations, and cleaning all equipment. Educating patients to use antibiotics only when needed and complete the entire course of medication can potentially slow the proliferation.

Common adverse effects from the use of antimicrobials and antiviral drugs include nephrotoxicity and ototoxicity (aminoglycosides), GI complications (cephalosporins, clindamycin), thrombophlebitis and vertigo (tetracyclines), jaundice (erythromycin), photophobia (vidarabine), neurotoxicity (metronidazole), and allergic reactions (β -lactam antibiotics). The therapist must be aware of adverse side effects to assist with early recognition and referral to the physician.

Antibiotics kill various normal commensal bacteria in the gut, altering the balance and allowing overgrowth of pathogens.¹⁰⁴ This change of bacterial flora is believed to result in increased toxins from pathogens and can cause infection with resistant microbes.¹⁰⁴ When patients are taking drugs to fight infection or undergoing procedures or surgeries that place them at risk for infection (indwelling catheters), they can be more susceptible to infectious agents. Abscesses or contamination because of the normal flora into a normally sterile body site is often the reason for perioperative antimicrobial prophylaxis.¹⁰⁵ Rehabilitation specialists will most likely see many patients who are undergoing chemotherapy with anti-infective medications and play a crucial role in preventing and controlling infectious disease in the health care setting. Therapists need to update their knowledge foundation with evidence-based protocols for specific diagnoses and treatments as well as understand when infections may or may not call for antimicrobial medications. In addition, education of patients about why antimicrobial agents are not indicated in specific situations, how to alleviate symptoms, and what signs indicate further follow-up may help them to understand the growing problem of antibiotic resistance.

Diabetes

Diabetes, as a disorder of insulin production and sensitivity, has two major forms. Type 1 has an autoimmune component based on the destruction of pancreatic islet cells, but success in modulating this pathogenic feature has been limited. As a result, patients with type 1 diabetes are necessarily insulin-dependent. The pathogenic features of insulin insensitivity characteristic of type 2 are not well understood, but a wide array of therapeutic agents have been developed for managing this condition. Although the metabolic states of type 1 and 2 pathologies may differ somewhat, the chronic pathologies associated with poorly controlled hyperglycemia are remarkably similar. The development of peripheral neuropathy, which compromises sensory and motor control, is a progressive problem in patients with diabetes. In addition to long-term management of diabetes from a glucostatic perspective, other agents show promise. Treatment of diabetic neuropathy with trazodone or mexiletine is an example.^{106,107}

A more acute problem is swings in blood glucose level from inappropriate diet, exercise, insulin, and oral hypoglycemic drug administration. The balance of these factors is important, and monitoring of blood glucose level is essential. Swings in blood glucose level are often associated with changes in behavior and sensorium. This may pose a safety concern because cognitive and motor function may be impaired as a result. An increase in exercise will decrease the blood glucose concentration, thereby reducing insulin requirements. These factors should be carefully considered in any exercise regimen for the patient with diabetes.¹⁰⁸ A list of oral hypoglycemic agents is presented in [Box 36.9](#). Lack of glucose control because of noncompliance with medications that are useful in controlling diabetes will only return the patient to an accelerated course to peripheral neuropathies and related sequelae.

In the clinical setting the health care practitioner must remember that the main goal of diabetes management is to prevent both the

BOX 36.9 Oral Hypoglycemic Agents

Sulfonylureas	glipizide (Glucotrol)
acetohexamide (Dymelor)	glyburide (Micronase)
chlorpropamide (Diabinese)	
tolazamide (Tolinase)	Related Agents
tolbutamide (Orinase)	repaglinide (Prandin)
glimepiride (Amaryl)	nateglinide (Starlix)

These drugs may have direct and indirect effects on motor systems by producing hypoglycemia.

small-vessel complications (e.g., retinopathy and neuropathy) and large-vessel complications (e.g., heart disease and amputation) of the disease linked with elevated blood glucose levels. Diabetes is therefore often controlled through intensive, tailored treatment regimens of diet and physical activity, oral agents, and insulin.¹⁰⁹ Each of these regimens is designed to potentially reduce hyperglycemia and can result in hypoglycemia if the patient is not monitored.

Initially the physician and patient with diabetes can work together on a treatment plan to manage the disease. An important first step includes diet, physical activity, and a program to reduce body weight by 5% to 10%.¹¹⁰ The effects of exercise as a cause of hypoglycemia deserve particular consideration because physical activity represents the most variable factor in the routine of many patients, especially those in rehabilitation.¹¹¹ With vigorous exercise, glucose use can increase severalfold, and this increase can persist long after the completion of the exercise, resulting in a fall in blood glucose long afterward. Although diet and activity are important cornerstones for diabetes care, oral agents and/or insulin may eventually be required to achieve glycemic control.

Several classes of oral agents are available to help or make the body use its own insulin or lower blood sugar, including sulfonylureas (chlorpropamide), meglitinides (repaglinide), biguanides (metformin), α -glucosidase inhibitors (acarbose), thiazolidinediones (rosiglitazone), dipeptidyl peptidase-4 (DPP-4) inhibitors (vildagliptin), and sodium-glucose cotransporter-2 inhibitors (canagliflozin). These classes of medications have specific regimens and may be prescribed as monotherapy or taken in combinations that may include insulin. Side effects vary from weight gain to GI symptoms to hypoglycemia. Hypoglycemia as a side effect of pharmacotherapy is of concern in the rehabilitation setting because abnormally low glucose levels can cause alterations in cognition, cardiovascular hemodynamic changes, and an increased risk of physical injury.¹¹² The signs and symptoms of hypoglycemia can vary from person to person and may depend on how fast the blood sugar drops. Early signs include shaking, sweating, fatigue, and weakness. Later signs may include confusion, combativeness, and exhaustion; these may inhibit eating, which may lead to loss of consciousness.

Insulin is a primary therapy in type 1 diabetes, in which the body has no ability to produce its own insulin. When oral antidiabetic agents no longer assist in maintaining glycemic targets, insulin is usually instituted in the diabetic with low production or resistance to insulin (type 2 diabetes).¹¹³ Many forms of insulin are available, and administration is typically through subcutaneous injection or insulin pumps. Insulin can be long-acting or short-acting and is often used in combination to maintain the optimal level of glycemic control. Hypoglycemia is the primary problem associated with insulin use because of its ability to lower blood sugar.¹¹³

Health professionals working with patients who have diabetes should consider a number of strategies for prevention of hypoglycemia and be able to analyze the risk and benefits of exercise. Because glycemic control is individualized, each patient must be addressed uniquely, and as a member of the health care team the rehabilitation specialist can

potentially assist in education of all those involved in the care of the patient. The following are lifestyle management guidelines published by the American Diabetes Association (ADA) and should be implemented in patients with known type 2 diabetes.^{114–116} Preexercise evaluation of the asymptomatic patient is currently not recommended, but a careful history, assessment of cardiovascular risk factors, and caution to be aware of the atypical presentation of coronary artery disease in diabetic patients. Before exercise begins, it is important to determine the extent of involvement and complications present. Providers should assess patients for conditions that might contraindicate certain types of exercise or predispose injury, such as uncontrolled hypertension, untreated proliferative retinopathy, autonomic neuropathy, peripheral neuropathy, and a history of foot ulcers or Charcot foot. Prepare the patient for exercise by monitoring glycemic control before, during, and after exercise. Exercise is contraindicated if fasting glucose levels are above 250 mg/dL and ketosis is present; use caution if glucose levels are greater than 300 mg/dL and no ketosis is present. The patient should ingest added carbohydrate if glucose levels are less than 100 mg/dL.

Document when changes in insulin or food intake are necessary and learn the glycemic response to different exercise conditions (e.g., light, moderate, heavy). Food intake should include consumption of carbohydrates as needed to avoid hypoglycemia. Carbohydrate-based foods should be readily available during and after exercise.

Clinicians must understand what causes diabetes, the effects of medications and exercise on the regulation of blood sugar levels, signs and symptoms of hypoglycemia, and what should be done in a diabetic emergency.

Pulmonary Diseases

Many patients with neurological problems have pulmonary disease as well. The treatment of pulmonary diseases presents an unusual challenge. Many drugs used for treatment of asthma, emphysema, and chronic obstructive pulmonary disease (COPD) are intended to have direct effects on the lung, yet systemic effects are often unavoidable. Adrenergic bronchodilators, such as albuterol (Proventil), epinephrine (EpiPen), and metaproterenol (Alupent), may increase heart rate and tremor.¹¹⁷ If tremor first manifests because of a neurological insult, then these drugs may exaggerate the motor impairment. Although ipratropium (Atrovent) is an anticholinergic with bronchodilating properties, the associated systemic anticholinergic effects (such as urinary retention with prostatic hypertrophy) are not well tolerated in geriatric men.¹¹⁸ Prednisone (Deltasone) and related corticosteroids may dramatically reduce the degree of pulmonary hyperresponsiveness but often produce systemic effects, as previously noted. These are often reduced (but not necessarily eliminated) with the use of inhaled corticosteroids such as beclomethasone (Qvar), budesonide (Pulmicort), flunisolide (Nasalide), and triamcinolone (Aristocort). Although the use of xanthines in asthma is declining, theophylline (Uniphyll) in asthma and obstructive pulmonary diseases can, in higher doses, produce changes in cognitive function, including delusions and hallucinations. General CNS stimulation—including nervousness, insomnia, and seizures—is well recognized.¹¹⁹ Tremor and nausea are often produced with theophylline, even with the commonly accepted clinical dosage regimens. Finally, the increase in diuresis caused by theophylline in patients with prostatic hypertrophy is certainly troublesome. The metabolism of this drug is often changed by other medications, which complicates therapy. These changes in drug metabolism may increase toxicity or decrease efficacy.¹²⁰ Newer classes of disease-modifying agents known as *leukotriene modifiers* (montelukast [Singulair] and zafirlukast [Accolate]) are being favored in some regimens for the management of asthma. Although cardiovascular and neurological side effects of these drugs appear to be dramatically reduced when compared with other agents, they have been implicated in several

important drug interactions.¹²⁰ For severe asthma *anti-IgE antibodies* (Omalizumab [Xolair], benralizumab [Fasenra]) bind to the IgE on mast cells or target interleukins to prevent activation and release of inflammatory mediators.¹²¹ Lack of compliance with these medications decreases pulmonary gas exchange, ultimately decreasing motor performance.

Patients may have signs and symptoms of lung dysfunction during exercise, including nonproductive cough, dyspnea, alterations in breathing rate and chest expansion, changes in skin color, as well as changes in auscultation and percussion findings. Symptomatic pharmacotherapy may be required to reduce disease-related symptoms such as shortness of breath and improve exercise tolerance.¹²² The patient should begin exercise after medications to improve exercise tolerance. With chronic lung disease, exacerbations may often be caused by an infection; therefore antibiotics may be prescribed.¹²³ In addition, thinning and mobilization of secretions in airways with mucolytics and chest therapy may be necessary.¹²⁴ Oxygen therapy is a secondary therapy that may be necessary for hypoxemic patients.¹²³ This therapy reduces the hematocrit level to more normal levels, moderately improves neuropsychological factors, and ameliorates pulmonary hemodynamic abnormalities.¹²⁵ Oxygen therapy may be indicated during exercise for patients whose levels become desaturated during low-level activity.¹²⁶ An understanding of the use of pharmacological treatments for pulmonary dysfunction can help the rehabilitation professional to promote improved strength, exercise tolerance, and functional abilities in patients with pulmonary dysfunction.

Gastrointestinal Disorders^{127,128}

Among the wide variety of agents used in the treatment of GI disorders, problems with agents affecting GI motility are among the most frequently encountered. Antiemetics that are dopaminergic antagonists, such as prochlorperazine (Compazine), chlorpromazine (Thorazine), and promethazine (Phenergan), are on Beers criteria⁴ and may produce extrapyramidal side effects resembling Parkinson disease through the drug's actions on the basal ganglia.¹²⁹ Dronabinol (Marinol), a cannabinoid derivative from marijuana, is an effective antiemetic but may produce cognitive and sensory disturbances, including drowsiness, dizziness, ataxia, disorientation, orthostatic hypotension, and euphoria.¹³⁰ The selective serotonin antagonists dolasetron (Anzemet), granisetron (Kytril), and ondansetron (Zofran) are effective and valuable antiemetics, especially in cancer chemotherapy. The most common adverse effect is severe headache.¹³¹ The benzodiazepine lorazepam (Ativan) is an effective adjunct for the control of emesis. Problems associated with benzodiazepines have been discussed previously. Corticosteroids such as dexamethasone (Decadron) should be included among the antiemetic agents; their adverse effects have also been discussed.

In producing normal motility, metoclopramide (Reglan), domperidone (Motilium), and cisapride (Propulsid) are often used. The adverse effects of metoclopramide are primarily through dopaminergic antagonism. Domperidone was developed to reduce these CNS effects and has been used to treat diabetic gastroparesis with some success.¹³² Cisapride, a restricted-use prokinetic agent, may have a wide variety of CNS effects, including dizziness, mood disorders, vision changes, hallucinations, and amnesia, although with low incidence compared with concerns of arrhythmias induced by this drug.¹³³ Compliance with medications that reduce GI problems may have little direct effect on motor performance but may prove troublesome to the patient's quality of life.

In the rehabilitation setting, GI signs and symptoms are common problems for many patients. The side effects of drugs reported in formularies show that almost all oral preparations are the potential cause of some form of GI disturbance.¹³⁴ Signs and symptoms include upper GI effects such as nausea, vomiting, indigestion, gastric reflux, and

stomach pain or lower GI effects such as diarrhea, constipation, colonic pain, and blood in stools. These symptoms may be caused by an underlying GI condition (gallstones and acid reflux) or side effects from medications (nausea and vomiting). Because GI problems can be prevalent and challenging, cause poor compliance, and may be a sign of a more serious condition, the causes and potential approaches used to ameliorate the symptoms must be understood.

Medications can modify GI absorption, cause dysmotility, damage the mucosal lining, or change the bioavailability and resulting effectiveness of drugs. Some drugs modify the absorption or activity of nutrients, ions, and drugs. Drugs such as metformin (Glucophage) (used in the treatment of diabetes) may reduce the absorption of vitamin B₁₂, with the potential development of megaloblastic anemia, necessitating exercise precautions.¹³⁵ Other drugs that damage the mucosal lining (methotrexate [Otrexup], allopurinol [Zyloprim], neomycin [Mycifradin], colchicine [Colcrys], methyldopa [Aldomet]) may reduce nutrient absorption, leading to deficiencies.¹⁰⁴ One class of agents, NSAIDs, is estimated to be regularly used by 5% to 10% of the US population, with more than 70 million prescriptions filled annually and more than 30 billion OTC tablets sold.^{136,137} These drugs are implicated in patients reporting gastric dyspepsia (pain or discomfort in the upper abdomen), and concomitant administration of proton pump inhibitors (Prilosec) (which block production of stomach acid) and prostaglandin analogs (Cytotec) (which protect the stomach lining) may often reduce mucosal erosion.¹⁰⁴

Drugs that cause dysmotility of the small intestine—such as TCAs (for depression), anticholinergics (for asthma), calcium channel blockers (for heart failure), and opiates (for pain)—may be commonly administered to patients within the rehabilitation population.¹⁰⁴ The large intestine is more likely to have reduced motility, with abdominal pain, constipation, nausea, vomiting, and abdominal distention present. Many patients require increased activity, change of dietary habits, or laxatives to improve motility.¹³⁸ Precautions must be taken because of the potential for chronic use of laxatives, fluid and electrolyte imbalance, steatorrhea, protein-losing gastroenteropathy, osteomalacia, and vitamin and mineral deficiencies.¹⁰⁴

It is important to note that some supplements and fluids (e.g., grapefruit juice) taken with medications can potentially cause changes in the bioavailability of drugs. Concurrent ingestion of iron causes a marked decrease in the bioavailability of a number of drugs such as tetracycline (an antibiotic), methyldopa (an antihypertensive agent), levodopa (for Parkinson disease), and ciprofloxacin (an antimicrobial).¹³⁹ Grapefruit juice is also known to change the bioavailability of some medications, leading to an elevation of their serum concentrations; these drugs include cyclosporine (an immunosuppressive agent), calcium antagonists (for hypertension), and coenzyme A reductase inhibitors (statins).¹⁴⁰

Most medications have the potential to cause some form of GI difficulties, whether taken systemically, topically applied, or given by the parenteral route.¹⁰⁴ Most adverse effects can be reduced with identification of the causal relation, proper administration of the drug, and administration according to all the guidelines on the label. Therapists may suggest specific timing of medication administration to relieve symptoms and increase participation in therapy. The role of physical and occupational therapists should be recognized in observing adverse drug events to warn patients of early signs of potential problems, provide education, and refer for further follow-up by the pharmacist or physician.

AN IMPAIRMENT PERSPECTIVE

Different forms of neurological impairments are discussed in this section, and appropriate drugs are identified that either reduce or increase the degree of impairment. Although not a comprehensive list, these

impairments include sensory impairments, motor problems, cognitive deficits, problems with balance and coordination, cardiovascular impairments, and problems with muscle tone; a brief overview of neuroplasticity is included. Pharmacists have been educated and work closely with physicians who have been educated in a disease or pathology model. A large portion of a physician's practice is related to drug therapy for the treatment of disease and pathology. Looking at drugs from an impairment/functional activity/life participation model is not the role of either the physician or the pharmacist. Thus movement specialists, whose model for care is based on function and quality of life, must bridge the gap between these concepts because the outcome of the interactions dramatically affects the potential of the individual after any CNS dysfunction. Currently interprofessional education has been a focus in medical professional education to assist in improved communication between the professions in order to reduce improve patient satisfaction as well as the health of the global population and reduce cost and errors.

Sensory Impairment

Drugs that affect hearing, vision, and touch may influence any type of sensory, cognitive, and motor impairment. In any impairment, the processing of accurate sensory information is crucial to modify and adjust procedural programming during movement. A subject must be able—through visual, manual, or auditory cues (even through olfactory means)—to relate to or recognize the relevance of the external environment, engage the specific motor programming centers that reach consensus regarding the specific motor response, and produce the series of signals that may progress uninterrupted through spinal mechanisms and the motor endplate to a regional muscle group for an appropriate response. Any impairment or drug that affects any component within these systems, whether early or late in this sequence, will affect the motor performance. Patients with sensory integrative problems are often given medications such as those for attention-deficit disorder, anxiety, seizure, and depression.¹⁴¹ As previously discussed, certain drugs may influence hearing (as previously indicated regarding infectious diseases) or produce tinnitus (e.g., aspirin), which may be distracting and thus ultimately affect motor performance.⁹⁸ Changes in the visual field (e.g., with ethambutol and anticonvulsants) are likewise important. Analgesics and topical anesthetics may dangerously affect surface heat or cold discomfort and undermine avoidance cues. However, elimination of excessive pain (peripheral and central) may enhance cognitive focus and learning as well as allow an individual to move as part of daily living, which will help maintain power, range, balance, and thus quality of life. The CNS functions with the consensus of multiple interactions. Because the branched as well as sequential nature of systems links sensory and motor functions, the peripheral effects of drugs commonly modify the function of central systems. This is a relatively unappreciated reason why drug therapy can modify rehabilitation techniques both positively and negatively. Therapists must be aware of medications when they are working with patients who have sensory impairments. Medications can increase or alleviate signs and symptoms, as well as produce unwanted side effects. Patients may benefit from alterations in the environment to limit sensory sensitivities, timing of treatment to coincide with the most effective dose of medications, and monitoring for unwanted side effects.

Cognitive and Central Motor Control Impairment

Disorders of mood (anxiety and depression) reduce initiative in the rehabilitation process. In this context, anxiolytics and antidepressants may have a positive impact. However, if the dose is not carefully titrated, drowsiness and anterograde amnesia will cloud effective response and learning. Both antidepressants and many of the benzodiazepines may cause these effects, as previously discussed. Behavioral

BOX 36.10 Examples of Antipsychotic Agents

Standard Antipsychotics	Atypical Antipsychotics
chlorpromazine (Thorazine)	aripiprazole (Abilify)
fluphenazine (Prolixin)	asenapine (Saphris)
haloperidol (Haldol)	clozapine (Clozaril)
loxapine (Loxitane)	olanzapine (Zyprexa)
molindone (Moban)	quetiapine (Seroquel)
perphenazine (Trilafon)	iloperidone (Fanapt)
pimozide (Orap)	paliperidone (Invega)
thioridazine (Mellaril)	risperidone (Risperdal)
thiothixene (Navane)	ziprasidone (Geodon)

These drugs may produce a parkinsonian-like effect through dopaminergic antagonism.

disorders, especially those associated with untreated psychoses or dementia, impede cognitive function. Although antipsychotics may correct these disorders, the dopaminergic antagonism associated with these may interfere with the function of the basal ganglia and facilitation of movement. Many newer antipsychotic agents (also known as the *atypical antipsychotics*) have, in addition to dopaminergic antagonism, serotonin antagonist activity, which may reduce the extrapyramidal side effects of the earlier agents when analyzed as movement dysfunction (Box 36.10). The therapist should be monitoring for signs of depression, which is common in patients who have had loss of function. Effective management of depression is dependent on finding an appropriate formulation and therapeutic dose, which may take weeks, and patients will need education and support. Extrapyramidal motor signs should be monitored and reported to the health care team.

Vertigo, Dizziness, Balance, and Coordination

Many agents with histamine antagonist and anticholinergic activity have been used for treatment of vertigo and dizziness. Meclizine (Dramamine) and related antihistamines are primary examples. Occasionally sinus congestion can result in impaired vestibular function and dizziness. In the absence of hypertension or related autonomic dysfunction, an indirect-acting adrenergic agonist such as ephedrine (Primatene) or pseudoephedrine (Sudafed) can reduce this congestion and improve this condition.¹⁴² Dizziness is a common clinical problem, affecting at least a third of the population in one form or another at some point during their lives.¹⁴³ Medications should be reviewed in all patients with dizziness, as numerous medications can be associated with this effect, including alcohol and other CNS depressants, aminoglycoside antibiotics, anticonvulsants, antidepressants, antihypertensives, chemotherapeutics, loop diuretics, and salicylates.¹⁴⁴ Patients should be monitored for orthostatic hypotension and hyperventilation. Depending on the cause of dizziness, patients with dizziness may benefit from canalith repositioning procedures,¹⁴⁵ vestibular exercises,¹⁴⁶ instrumental rehabilitation training on a moving platform,¹⁴⁷ positional education (sitting at bedside before standing), use of compression garments, dietary changes (salt and fluid intake), and use of simple physical counter-maneuvers such as squatting to temporarily but rapidly raise blood pressure.¹⁴⁸ Symptoms of dizziness and balance dysfunction should be reported to the health care team for determination of the underlying cause and best management strategies.

Cardiovascular Impairment

In the management of hypercholesterolemia, the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (Statins) (see Box 36.5) may produce myopathies to various degrees. Overall, statin use among US adults 40 years of age and older in the general

population increased 79.8% from 21.8 million individuals in 2002–2003 to 39.2 million individuals in 2012–2013¹⁴⁹ indicating the increased need to be aware of potential myopathy. Changes in hemodynamics caused by antihypertensive regimens must be monitored because these agents can produce syncope and lower exercise tolerance. Weakness from intermittent claudication is a challenge that can be managed in part with cilostazol (Pletal).¹⁵⁰ Any drug that is used to decrease spasticity as a consequence of stroke and related cerebrovascular disorders may impair motor control and thus affect motor learning. A discussion of these drugs is outlined in the next section. Cardiovascular impairments are common in the rehabilitation setting. Knowing the pharmacological management for and side effects of medications related to the cardiovascular system will assist the therapist in providing high-quality care. Patients will benefit from education on modifiable and nonmodifiable risk factors, monitoring blood pressure and heart rate, signs of heart failure, vascular effects of modalities, and responses to exercise and positional changes.

Spasticity and Muscle Tone

Muscle spasms may be controlled with centrally acting and peripherally acting agents, all of which produce drowsiness, dizziness, and muscle weakness to various degrees.¹⁵¹ Commonly used agents are listed in Box 36.11. Pharmacological management of muscle tone, spasticity, and coordination of movement is of primary importance in neurological rehabilitation.

With regard to spasticity, several additional options are available. Tizanidine (Zanaflex) is an α -adrenergic agonist available to reduce spasticity, primarily through activation of descending noradrenergic inhibitory pathways.¹⁵² Clonidine (Catapres) has similar actions. Intrathecal administration of baclofen (Lioresal) produces an antispasmodic effect through enhancement of GABAergic function, both central and spinal.¹⁵³ Likewise, enhancement of GABAergic function and reduced spasticity can be realized through the antiseizure drug gabapentin (Neurontin).¹⁵⁴ Selective motor neurons can be inactivated through the local injection of botulinum toxin (Botox).¹⁵⁵ These agents inhibit the release of acetylcholine at the neuromuscular junction. The agent 4-aminopyridine (Ampyra) has been shown to reduce spasticity in patients with Lambert-Eaton myasthenic syndrome, MS, and spinal cord injury.¹⁵⁶ It acts by blocking voltage-gated potassium channels, prolonging action potentials and thereby increasing neurotransmitter release at the neuromuscular junction.¹⁵⁷

The involvement of serotonin in the maintenance of muscle tone and spasticity is complex and controversial. Cyproheptadine, a relatively nonselective serotonergic antagonist, can reduce spasticity and maintain muscle tone.^{158,159} However, SSRIs used as antidepressants may occasionally increase spasticity,¹⁶⁰ and clozapine (Clozaril), a selective serotonin antagonist, may produce muscle weakness.¹⁶¹

In addition to spinal cord injuries, MS may cause spasticity as a complication. Although several interferons have been used in the management of MS, interferon β -1b has been shown to increase spasticity.¹⁶² Therapists often work closely with patients who are undergoing

BOX 36.11 Muscle Relaxants and Antispasmodics

baclofen (Lioresal)	metaxalone (Skelaxin)
carisoprodol (Soma)	methocarbamol (Robaxin)

Direct effects on motor systems to reduce tone.

treatment with antispasticity medications. Knowing the underlying cause of the spasticity in the patient with neurological impairments (disruptions of inhibitory control) and using concomitant rehabilitation therapy may help to decrease pain and improve range of motion and functional ability. Therapists should have an understanding of the desired effects of agents and also their adverse effects, including sedation and addictive properties.

Neuroplasticity

The effects of drugs on plasticity are highly controversial. In Alzheimer disease a loss of plasticity may occur through deficits in hippocampal and cortical function, leading to memory loss. Many anticholinesterase agents (e.g., Aricept) improve memory, which may provide evidence that they enhance neuroplasticity.¹⁶³ Agents affecting the glutaminergic system, specifically the N-methyl D-aspartate (NMDA) antagonist memantine (Namenda), are prescribed to treat symptoms of moderate to severe Alzheimer disease.¹⁶⁴ These agents work by blocking the toxic effects associated with excess glutamate and regulate glutamate activation.¹⁶⁵ Based on the putative molecular mechanisms of the pathology, inhibitors of β -amyloid formation and related modulators may hold additional promise.¹⁶⁶ This rapidly evolving area of research may provide interesting avenues for the treatment of Alzheimer disease. Neuroprotective agents that aim to prevent neuronal death by inhibiting one or more pathophysiological steps in the process that follows brain injury or ischemia are currently under development for neurological disorders including stroke, spinal cord injury, traumatic brain injury, and Parkinson disease. In addition, studies on enriched environments including robotics, virtual and augmented reality, and neurogaming are¹⁶⁷ providing knowledge related to neuronal capacity for regeneration and repair in the adult and aging brain and spinal cord.¹⁶⁸ The future of neuroplasticity in rehabilitation may be enriched when medications that protect or promote neurological recovery can be paired with techniques to improve function.

RESEARCH AND DEVELOPMENT PROSPECTS

It is difficult to predict which areas of pharmacological research will have the most valuable impact on the management of neurological disorders and the resulting residual impairments. Drug development is a continuous process, although this text must have a definitive end point. Many drugs with outstanding promise for treating neurological

diseases will have adverse effects that may be less acceptable than the neurological problem (or in fact may be lethal in rare cases) and may require its removal from the market. In spite of these disappointments, many reasons for optimism exist.

Among the burgeoning areas of biotechnology that will have an influence on neurology will be the discovery, characterization, and application of neuronal growth factors, related growth modifiers, and cellular implants, which may have the long-term promise of either partially or completely restoring nerve function. Among these are stem cell implants, whose function and development have been tested in a limited number of patients.¹⁶⁹ It is also likely that drugs will continue to play an important role as adjuncts in disorders partially treated with stem cell therapies. Although these developments are unlikely to have extensive application within the next few years, these and related developments will take root over a period of decades and revolutionize our understanding and treatment of a wide variety of neurological disorders.

The pharmacist stands as a valuable resource for physical and occupational therapists today and will continue to do so in the future. Pharmacists must participate in the management of drug therapies that may be related to each area discussed in this chapter. Therapists should consult the pharmacist about new drug developments and discuss the potential effects that these new drugs may have on neurological rehabilitation. This is especially true when new drugs not mentioned in this text are being administered. These discussions can illuminate intended and adverse effects that may influence interventions and change patient outcomes. These drugs may cause improvements as well as exacerbations in movement function. Some of those changes are disease- or pathology-related. Other changes are attributable to spontaneous return, new learning, and neuroplasticity within the CNS. Changes can also occur because of drug therapy. Those changes, as stated, can be both positive and negative. The scope of practice for occupational and physical therapists does not involve differentiating which change is caused by which process, but these professionals certainly can recognize functional changes. When changes are positive, the team must be made aware of them, and most likely everyone will take credit for the changes. When the changes take away function, families and therapists are often the first to identify those changes. The pharmacist and physician will have to determine why the system is deteriorating. The therapist is responsible for sharing reports of those negative behavioral changes with the team and monitoring for future changes when drug regimens have been altered.

SUMMARY

The vast array of drugs, along with their intended and unintended consequences, can pose significant challenges to all clinicians. An awareness of the patient's perspective in dealing with diseases and impairments can yield valuable information that may help to prevent and/or manage the potentially adverse impact of drugs on rehabilitation. One component of this perspective is the patient's desire to self-medicate in addition to undergoing clinician-prescribed therapy. The pharmacist can often provide guidance that can be effectively relayed to a patient's therapists. This

degree of vigilance can yield greater rewards for the patient in terms of effective management of multiple diseases and reduced interference with rehabilitation. A team approach is required to resolve problems posed by drug treatment. When drugs play a role in a patient's treatment, the patient's physician, pharmacist, therapist, nurse, and caregiver must be aware that drugs pose a certain degree of risk with every positive step. The team must work closely to investigate possible drug problems as well as opportunities for therapeutic success.

Abstract: This chapter focuses on the effect of drug therapy on patients receiving neurological rehabilitation. First, the chapter discusses what the body does to a drug (pharmacokinetics), followed by what a drug does to the body (pharmacodynamics), and also the involvement of genes in an individual's response to drugs (pharmacogenetics). Second, the chapter covers a disease- or pathology-driven model that focuses on the pharmacological approaches used in treating major diseases that are

often concurrent with rehabilitation. Finally, the chapter presents an impairment, activity, or functional limitation–driven model that focuses on the effects of drugs on impairments, resulting functional deficits, and the impacts of drugs on the therapeutic plan.

Key words: adverse drug reactions, disease, drug interactions, drug therapy, impairment, pharmacist, pharmacogenomics, pharmacogenetics

Use of Neuroimaging in Rehabilitation

Rolando T. Lazaro, Darcy A. Umphred, and Preeti Deshpande Oza

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify conventional and advanced neuroimaging techniques.
2. Classify the different neuroimaging techniques into structural and/or functional imaging techniques.
3. Describe strengths and weaknesses of different neuroimaging techniques.
4. Recognize various slices of the central nervous system; what nuclear masses are visible in that slice; how the ventricles change from one slice to another; and how sagittal, horizontal, and coronal slices present those nuclear masses and/or ventricles differently.
5. Recognize the difference in diagnostic capabilities of radiography, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine scans.
6. Describe images using the correct neuroradiological descriptive terminology.
7. Recognize normal and abnormal neuroanatomy on CT scans and MRI images.
8. Analyze information obtained from imaging of the central nervous system and integrate this information into the neurological clinical presentation and the patient's intervention.
9. Recognize and analyze how neuroimaging may and may not be reflected in the movement diagnosis made by a physical or occupational therapist.
10. Summarize relevance of neuroimaging to rehabilitation and patient care.

KEY TERMS

computed tomography (CT) diagnostic imaging

diffusion tensor imaging (DTI) functional imaging

magnetic resonance image (MRI) radiograph

Direct access practice for physical therapists in several states of the United States has increased the role of these professionals as primary care providers engaged in value-based and patient-centered care for improving mobility outcomes. Physical therapists are now part of the emergency department, sometimes serving to triage, and manage patients with nonsurgical musculoskeletal disorders. Physical therapists serving in the military, Public Health Service, Indian Health Service, Veterans Health Administration, Bureau of Prisons, and health care organizations, such as Georgetown University Hospital, Kaiser-Permanente, Northern California, now have imaging privileges.¹⁻⁴ Expanding roles have made it particularly important for therapists to recognize the need of diagnostic imaging and analyze diagnostic imaging for improving patient care and decisions related to patient care.

As relates to patients with neurological injuries (e.g., brain injury or stroke) and dysfunction (e.g., Parkinson disease or hereditary disorders), therapists should be able to interpret images of the nervous system to better understand how the neural insult and medical procedures affect movement and function in daily life. Expert analysis of neuroimaging, using differential diagnosis skills and knowledge of neuroanatomy, is critical in order for these professionals to know when to refer a patient to another health care

practitioner, when to refer and treat, when to merely treat, and when to neither refer nor treat.

Entry-level knowledge of content such as pharmacology, radiology, and medical screening has become an accreditation requirement for doctoral education programs in physical and occupational therapy. Orthopedic radiology is now a common part of curricula; however, content on neuroradiology, more specifically the application of neuroradiology in practice, is lacking. In a study by Little and Lazaro,⁵ it was found that many of the physical therapy practitioners in California use medical imaging in their practice. When inquired about the types of imaging, the majority of respondents felt comfortable using results (and radiology reports) from radiographs obtained because of a musculoskeletal problem. This study showed the lack of access to and confidence in using medical images of the central nervous system (CNS).

In certain instances, it may be easier for therapists to recognize musculoskeletal problems when viewing radiographic images because the abnormality in the structure directly correlates with the orthopedic movement problem. When images of the CNS are viewed, correlations with movement system disorders may be much more complex, requiring knowledge of neuroanatomy, such as relationship of nuclei, tract systems, and basic neurochemistry. For example,

Fig. 37.1 (A) Radiograph showing a fractured olecranon. (B) Computed tomography scan showing an infarct of the middle cerebral artery. (B, From Wikipedia. <http://en.wikipedia.org/wiki/File:INFARCT.jpg>.)

when looking at a bone fracture (Fig. 37.1A) versus a vascular insult (see Fig. 37.1B), it is clear that the fracture and its effects on the bone, muscle, or skin can easily be visualized and interpreted. The second image of the CNS has many surrounding structures that must be identified in relation to the vascular insult. Good knowledge of neuroanatomy and neuroimaging is therefore essential for adopting imaging in PT practice.

In 2007, the journal *Physical Therapy* produced a special issue on neuroradiology in physical therapy practice. It is encouraging to note that this issue offered physical therapy clinicians an opportunity to understand the modalities used in the imaging of the brain and the spinal cord (for details, see the article by Kimberley and Lewis⁶). However, the rest of the article presented the application of neuroradiology in physical therapy research,^{7,8} and although these articles provided valuable information for the practicing clinician, the articles did not specifically give insights as to how clinicians can use the knowledge of neuroradiology in their actual patient/client management.

It has been known for a long time that physical therapy interventions improve function by making new neural connections or by unmasking the neural networks that were previously dormant.⁹ Though not a common practice in patient care, the advent of functional neuroimaging techniques has made it possible to study the benefits of the therapy and has opened more ways to guide clinical practice. Some of the benefits that therapists may have with current neuroimaging methods include being able to (1) assess the changes with therapy, (2) make treatment plans appropriate for patient by correlating clinical symptoms with neuroimaging results, (3) assess prognostic implications, (4) provide family and patient education, and (5) develop appropriate goals and accordingly develop treatment plans.

VISUALIZING THE CENTRAL NERVOUS SYSTEM

Before jumping into viewing images of the nervous system, the reader needs to be very familiar with the position and type of slices presented in those images. Fig. 37.2 illustrates the three types of slices common to the nervous system. The horizontal slices shown in Fig. 37.3 are cuts made horizontally through the brain beginning with a superior slice at the level of the beginning of the lateral ventricles. This individual would be lying supine if the brain was cut as shown. If a person were standing, the horizontal slice would be horizontal to the ground with the frontal lobes facing forward (toward the nose) and the occipital lobe in the back. The slices cut horizontally are always perpendicular to the brain stem and spinal cord or perpendicular to the upright position of the brain regardless of the position of the head in space. All right and left slices will look exactly the same as long as the nervous system has not sustained any insult. Fig. 37.4 shows the position of an upright human and what the skeleton would look like in the same position. Can you visualize what the horizontal slices would look like? The horizontal section would be perpendicular to this upright position. When viewing radiological slices in horizontal, the slices will often be on a slight angle with the lower portion slightly forward. Most of these films are taken when individuals are supine, which places the brain off vertical so a correction is made. The film usually slices horizontally through the brain as if the head were slightly tucked, similar to the image of the adult in Fig. 37.4A. Also, some radiologists want a slightly different angle to the slice because they are looking for specific orientations. When viewing these films, try to look at the radiological slice pattern (scanogram), if shown. Fig. 37.3 shows a progression of horizontal slices as if the individual were supine and the slices began anteriorly with emphasis on ventricular changes as

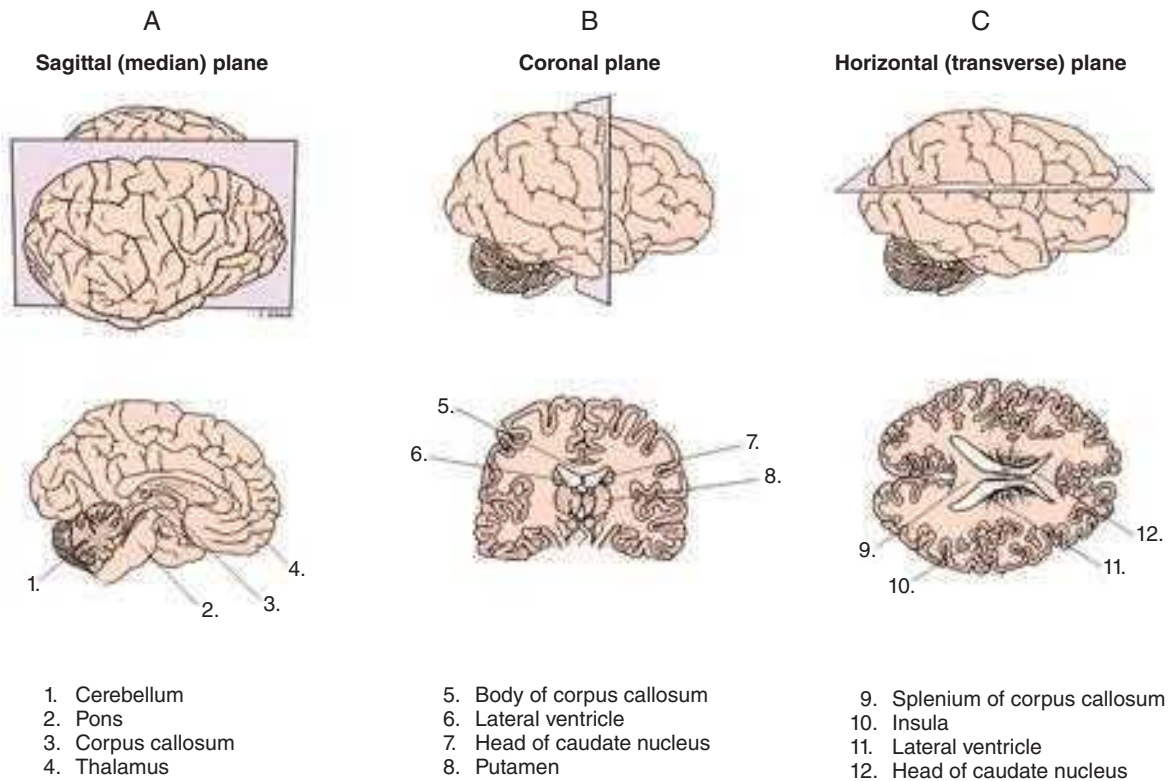

Fig. 37.2 Orientation of Brain Slices. (A) Sagittal. (B) Coronal. (C) Horizontal. (Courtesy Stephen Schmidt, PT, OCS, FAAOMPT.)

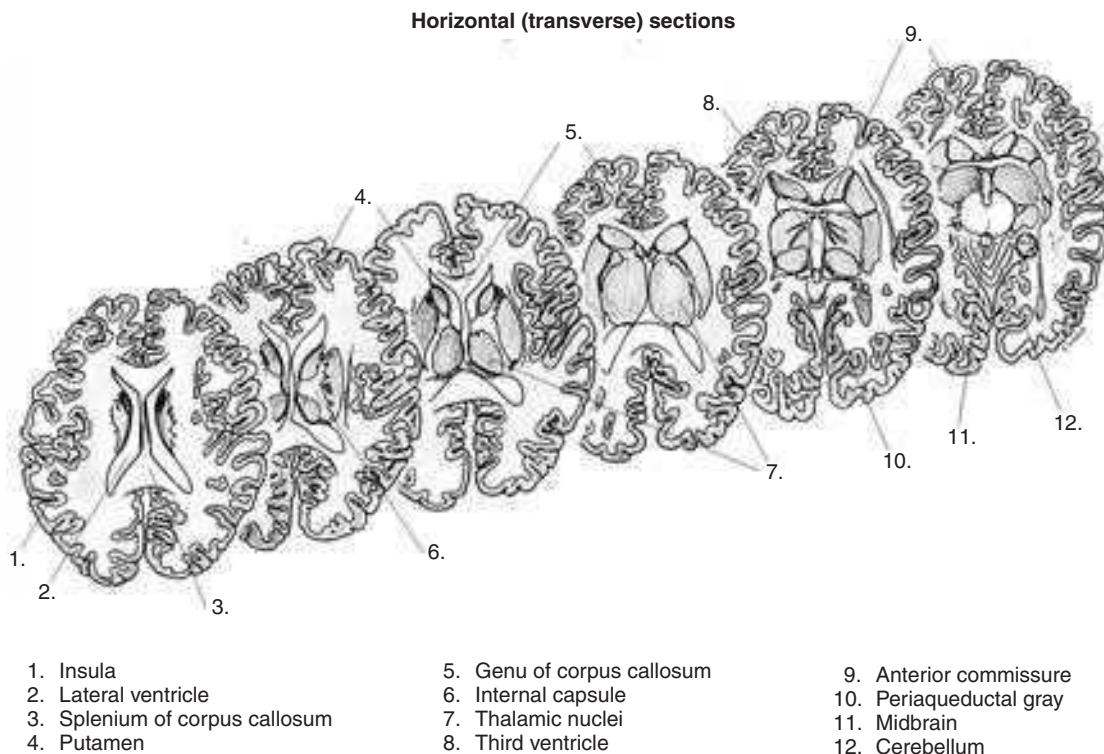

Fig. 37.3 Illustration of Horizontal Slices. (Courtesy Stephen Schmidt, PT, OCS, FAAOMPT.)

Fig. 37.4 (A) Photograph of a human standing. (B) A skeleton standing.

part of the progression. Many of the medical images of the brain are viewed as horizontal (or axial) slices or views. The person is lying supine when undergoing computed tomography (CT), magnetic resonance imaging (MRI), or positron emission tomography (PET). Therefore the imaging process cuts 90 degrees off the horizontal plane of earth in order to achieve horizontal slices of the brain. Remember to look at the scanogram, if available, to identify the position of the head in relation to the cuts.

Coronal slices in the right hemisphere look similar to those in the left hemisphere except that the top of the slice will not look like the bottom on either side (see Fig. 37.2). The two sides will reflect each other, with the tops being alike as well as the bottoms. Depending on where the cut is made, the result will be cortex on the outside, tracts (white matter) projecting downward, and gray matter again inferior and medial within the slices as the thalamus, basal ganglia, caudate, hippocampus, and so on are viewed. These slices begin at the top and cut down through both sides of the brain, with the slice ending on the inferior section. The progression of the slides can go from front (frontal lobe) to back (occipital lobe) or back to front. If visualized in a standing subject, the slice would begin in the superior frontal area and slice downward through the brain toward the feet, thus cutting equally on both sides. These slices can proceed in the posterior (backward) direction of the brain but always cutting from the top toward the bottom with equal distribution on each side. Fig. 37.5 progresses from the front of the brain toward the back using the ventricles as a point of reference.

For sagittal cuts (see Fig. 37.2), most cuts start by slicing down through the central fissure separating both sides of the brain. This cut is called a *midsagittal section*. Each sagittal slice proceeds outward toward the lateral aspect of the brain on each side respectively, depending on which side is being sliced. Anatomically, you begin as if you were slicing down through the middle of the face and the back of the head when a person is standing. Each sagittal slice moves from the inside outward toward the ear or laterally away from the midsagittal

Fig. 37.5 Illustration of Coronal Slices. (Courtesy Stephen Schmidt, PT, OCS, FAAOMPT.)

slice. Each slice cuts through the front and back of the brain from top to bottom and proceeds from medial to lateral. Sagittal images usually begin on either the right or the left side and continue slicing toward the middle to the midsagittal section separating the two sides of the brain, and then proceed toward the outside on the opposite side of the brain from the beginning slice.

Another way to conceptualize the nervous system is by visually sequencing from a view of a human in a specific position to the skeleton of a human in that position to an intact plastinated nervous system in that same position. The reader is encouraged to try to visualize what the horizontal, coronal, and sagittal slices might look like given the spatial position of the individual. Once you can easily recognize the various types of slices and where the slice was made when viewing the nervous system, you are ready to begin viewing radiological images.

IMAGING OF THE CENTRAL NERVOUS SYSTEM

It is beyond the scope of this chapter to discuss the physics behind the more common imaging modalities (see article by Kimberley and Lewis⁶ for background). The purpose of this chapter is to provide the clinician a method of systematically evaluating images of the CNS and, more important, to provide examples of how clinicians can use these images to guide practice.

Neuroimaging include different techniques to directly or indirectly “image” the brain and the spinal cord to understand function or physiology of the nervous system. CT and MRI remain the two most common modalities for imaging the CNS. CT scans of the brain are widely used in acute neurological injuries in which the speed of the examination is of primary importance. A common application of this is in acute traumatic brain injuries, when rapid assessment of information about hematoma formation and brain swelling is imperative to make appropriate decisions regarding medical management. Although there is less anatomical detail in CT than in MRI, the level of detail being generated by a CT is generally sufficient for the appropriate management of the patient with an acute injury. Because CT also administers the highest dose of radiation (as it is a series of x-ray exposures), it causes a higher risk of development of conditions associated with increased levels of radiation exposure.

Owing to its increasing availability, MRI can also be an ideal choice for imaging the brain and the spinal cord. MRI provides excellent resolution and can also be performed with contrast agents to enhance the detail even more. MRI, however, generally takes longer than CT to perform, and it requires the subject to avoid excessive movement while the machine is actively scanning. Also, because MRI uses powerful magnets, the use of this modality in patients with metal implants is contraindicated. With regard to cost, MRI is still more costly than CT, but this expense is rapidly coming down as more hospitals and clinics are investing in this technology.

As mentioned previously, contrast media can also be used in both CT and MRI to enhance the image, although that will increase the scanning time. There are also additional risks associated with contrast, such as possible allergic reactions to the medium being used to enhance the image.

Besides the conventional CT and MRI, advanced neuroimaging techniques such as Positron Emission Tomography (PET) scan, Functional Magnetic Resonance Imaging (fMRI), and Diffusion Tensor Imaging (DTI) may also be encountered by therapists. Whatever the technique, studying the neuro images should be made a regular practice for improved clinical decision making and prognostication.

Clinical Decisions Regarding the Need for Imaging Studies

Patients with acute neurological symptoms should be seen by a medical practitioner who will determine the type of imaging most appropriate.

For individuals with chronic neurological problems, a therapist may be in a situation to recommend the timing and type of new images. For example, when a mismatch exists between the movement diagnosis and the anatomical lesion(s) present on past images, it is the responsibility of the physical or occupational therapist to report the inconsistencies between the imaging report or medical diagnosis and the specific movement dysfunction seen and reported in the therapy situation. The objective of new images would be to render an anatomical explanation for a change in impairments and movement function. While it is outside the scope of a therapist’s practice and responsibility to correct a physician’s medical diagnosis, therapists should advocate for further diagnostic exploration when a patient presents with evolving clinical characteristics.

GENERAL GUIDELINES FOR REVIEWING MEDICAL IMAGES

Radiodensity

Because CT scans, like conventional radiographs, are images formed by the absorption of x-rays by the body at different densities, evaluation of CT images is the same as evaluation of conventional radiographs. Structures in the body that absorb a lot of x-ray energy are *radiopaque* and will be white on the image. Structures that absorb less x-ray energy will be different shades of gray. Air does not absorb any x-rays and will be black on the film, and is said to be *radiolucent*. Bone is an example of a radiopaque structure and will be white on the image. Because the skull is composed of bones of varying thickness, portions of this structure that have more bone will be whiter than those with less bone. Contrast media can be positive (white; heavy metals such as gadolinium) or negative (black; air, however, is not used as a contrast medium in the CNS). Brain matter and spinal cord will be varying shades of gray. The sinuses are normally filled with air and will therefore show as black, whereas the ventricles are filled with cerebrospinal fluid and will be a shade of gray on a CT image.

There are a few steps to follow when evaluating neuroradiological images. These steps are presented in the following sections.

Step 1

Gather All Pertinent Information Regarding the Patient’s Neuroimaging Studies

As mentioned earlier, because of the complexity of the structure and function of the CNS, it is appropriate to have a radiologist and a neurologist or neurosurgeon to read the images first and make a report before the physical or occupational therapist reviews the images. Previous neuroimaging scans and reports will also provide additional information regarding the progression or improvement of the conditions, or the involvement of other structures that may have implications for the patient’s care. Review the report thoroughly, making note of the structures that were reported to be normal as well as the ones that were reported to be pathological. This will provide insight as to the patient’s potential movement disorders, as well as functions that may be normal for the patient. This review can also reveal a mismatch between the report and the presented movement diagnosis.

Step 2

Familiarize With Patient Background Information and Identify Image Type and Orientation

After reviewing the imaging report, the clinician then examines the actual images. The clinician must be familiar with the basic background information presented on the image. Normally the film will

contain information such as the patient's name, age, and medical record number; the date of the scan; and the name of the hospital or facility that performed the procedure (Fig. 37.6). The date of the scan is particularly important when attempting to establish relationships between what can be seen on the image and the patient's presentation. There might be a mismatch between what is shown on the image and what the patient is doing because of either resolution of the condition or worsening of the pathology. Comparing scans taken at different intervals will also assist the clinician in arriving at some general impressions on the rate or recovery (or lack thereof) or prognoses following physical rehabilitation.

Markers may also be available. The use of markers significantly simplifies analysis by allowing the examiner to easily orient the film correctly. Common markers include *R* and *L* for right and left, respectively, and *A* and *P* for anterior and posterior.

Often a scale is provided for the clinician to relate the size of the structures on the image to actual size.

Fig. 37.6 Computed tomography scan of the brain with identifying information. (Courtesy Dr. John Wells. How to Read a CT Scan of the Brain. www.neurosurgical.ca/ComputerAssistedLearning/readingCTs/scanogram.htm.)

Next, the clinician should be familiar with some of the basic technical detail. CT and MRI can provide multiple “slices” of the brain, much like slices in a loaf of bread. Often a single large film containing all the images arranged in order can be found. Usually, the first image on the left top most corner is the “scout view” or scanogram and serves to illustrate the orientation and thickness of each slide. Depending on the suspected pathology, the slice orientation could be frontal, coronal, or sagittal, based on the specific structure in question.

Certain views of the CT image can also be produced by the radiology team by manipulating certain image parameters. These “windows” are presented in Fig. 37.7. A bone window shows bone the best and is helpful when a skull fracture is suspected. A brain window shows brain matter the best and is used when the suspected pathology is caused by or affects the brain matter (tumors, atrophy of the nuclear masses, or general atrophy of the brain itself). A subdural window is beneficial when suspecting the presence of subdural hematoma or swelling of the brain. With MRI, the images can also be “weighted” (for example, T1 vs. T2). T1-weighted images show better gray matter–white matter contrast, whereas T2-weighted images might show edema better. As mentioned previously, contrast agents may be used with either CT or MRI to improve visualization of the structures in question.

Step 3

Quick Scan Followed by Thorough Image Examination

After becoming familiar with the basic information, the clinician should then make a “quick scan” of the image, noting the pathology that quickly stands out. After doing so, a more thorough analysis of each film in the series must be done. Multiple windows and/or successive slices are often helpful in visualizing the extent of the pathology. The clinician mentally constructs a three-dimensional image of the brain from the two-dimensional scan. In a CT scan, knowledge of radiodensity is helpful in making this accurate representation, as is knowledge of normal structure and function of the CNS.

Several resources recommend slightly different methods of analyzing an image. The following are suggestions to make the process more organized and efficient.

1. Examine the symmetry.¹⁰ Compare both sides of the brain as represented on the image. In orienting the images, the right side of the brain is usually shown on the left. Look for a midline shift by drawing an imaginary line from the anterior falx cerebri to the posterior falx cerebri. Identify the side of the greatest shift and measure it (in centimeters or millimeters). It would also be

Fig. 37.7 Computed Tomography Scan of the Brain showing Three Different Windows. **(A)** Bone window. **(B)** Subdural window. **(C)** Brain window. (Images courtesy Dr. John Wells. How to Read a CT Scan of the Brain. www.neurosurgical.ca/ComputerAssistedLearning/readingCTs/windows.htm.)

helpful to look for signs of mass effect (when structures on one side are “pushed” to the other side, or a possible atrophy on the structures on one side that pushes the structures on the other side across the midline). Additional structures to inspect for symmetry include the basal ganglia, thalamus, and corpus callosum.

2. Examine the size and shape of the structures.¹⁰ This is particularly helpful when looking at the integrity of the ventricles and cisterns. When filled with excessive fluid as in hydrocephalus, the ventricles enlarge disproportionately. This enlargement is seen in babies as a result of a variety of pathologies (see Chapter 9) and in children and adults after brain trauma (see Chapters 22 and 23). Likewise, in atrophy of the brain tissue, the ventricles may also become enlarged; this is often seen in elderly adults as the brain loses gray matter and the ventricles enlarge to fill in the extra space (see Chapter 27). Examining the size and shape of the sulci may also be beneficial when looking at atrophy of the specific structure, thereby accounting for the abnormalities of movement being observed.
3. Look for lesions in the brain. Space-occupying lesions such as brain tumors or hematoma can be visualized (Fig. 37.8). Because the brain has such a finite size to fit snugly within the cranial vault, any lesion in the brain has the potential to push brain structures to the midline or to displace the structure and create more serious pathology. Plaque formations secondary to multiple sclerosis can also be visualized as bright white spots in the gray matter (Fig. 37.9).
4. Examine densities.¹⁰ As mentioned previously, different tissues will have different densities, and these differences are what forms the generated images. Hyperdensities may include blood, tumors, or enhancing lesions, whereas common hypodensities include air, nonenhancing tumors, and chronic hematoma.

Step 4

Establish Relationships Between the Structures Involved and the Presenting Impairments, Movement Dysfunctions, and Activity Limitations

There are two possible clinical scenarios in which the medical imaging information is reviewed. First, the therapist may be reviewing the medical imaging information before seeing the patient for the initial examination or evaluation. If this is the case, the therapist is expected to use this information in relation to other medical information in the chart (from physician’s history and physical examination,

Fig. 37.8 (A) Fluid-attenuated inversion recovery magnetic resonance image showing a tumor in the left inferior frontal gyrus. (B) Follow-up imaging at 9 months shows growth of tumor. (From Brandao LA, Shiroishi MS, Law M. Brain tumors. *Magn Reson Imag Clin N Am.* 2013;21[2]:199–239.)

(From Sicotte NL. Magnetic resonance imaging in multiple sclerosis: the role of conventional imaging. *Neurologic Clin.* 2011;29[2]:343–356.)

nursing notes, etc.) to get an initial sense of what the patient may be able or unable to do. This will allow the therapist to plan for the appropriate tests and measures to perform during the examination (Case Study 37.1).

CASE STUDY 37.1 A Patient With a Brain Tumor

The patient was a 71-year-old woman with history of glioblastoma multiforme, the most aggressive form of brain tumor (refer to Chapter 25). It has been reported that a second recurrence of this condition is associated with a less favorable prognosis.¹¹ The patient had previously undergone tumor resection, chemotherapy, and radiation. She had then been found to have another recurrence of the left frontal glioblastoma multiforme of 4 cm (Fig. 37.10), for which she had undergone a stereotactic resection (Fig. 37.11) of the tumor. After this surgery, she underwent intensive inpatient rehabilitation.

Her past medical history included history of radiation therapy, seizure disorder, diabetes mellitus, hypertension, anemia, and leukopenia. Medications include Dilantin, Lipitor, dexamethasone, fosinopril, and metformin.

The patient’s primary caregiver was her husband. They were both retired, living in a single-story home with two steps to enter. She had two supportive daughters who lived nearby and were available for support as needed. Before the most recent hospitalization, the patient had been at a supervised level of assistance with ambulation outdoors and independence for household ambulation, with no assistive device required.

The medical images revealed a resected parietal lobe tumor in the left side of her brain. In the imaging report, it was noted that there was significant edema in the surrounding area and that mainly white matter tracts were affected. However, no midline shift or mass effect was noted. In addition, the tumor was reported to be located near the Broca and Wernicke areas but superficial to the ventricles.

Continued

CASE STUDY 37.1 A Patient With a Brain Tumor—cont'd

Based on the information provided by the imaging reports and the associated medical images, the clinician developed several initial impressions about the patient's presentation and care. First, the note about significant edema indicated more diffuse, global effects on movement and function; associated structural impairments rather than only dysfunctions specific to parietal lobe damage would be expected. The lack of midline shift or mass effect indicated a more favorable prognosis for survival for the patient. The information about the tumor being located near the speech areas indicated the possibility of deficits in expressive and receptive communication. Finally, damage to the parietal lobe indicated the potential for agraphia, aphasia, and agnosia. Because the parietal lobe is also largely important for perception and interpretation of somatosensory information, the formation of the idea of a complex purposeful motor act may also have been impaired.

The initial examination confirmed and supported all the expected movement deficits and clinical presentation of the patient. She underwent intensive occupational, physical, and speech therapy to improve her functional mobility and ambulation, self-care and activities of daily living, as well as speech, swallowing, and communication. There was a concerted effort among the rehabilitation team and the patient's family to optimize communication strategies while minimizing patient frustration. For example, more complex tasks such as transfers

were broken down into smaller components and then practiced extensively as components and as whole functions. The transfer task was broken down into three steps: (1) locking the brakes, (2) removing the leg-rests, and (3) standing and turning to sit on the destination surface. These step-by-step instructions were written on the patient's whiteboard; practiced during speech, physical, and occupational therapy; and communicated to the family and rehab team. Hand-over-hand guidance and facilitation were also included during instruction, as was use of mental rehearsal to remediate executive and visuomotor deficits to improve motor sequencing and problem solving while decreasing perseveration and frustration.¹² The rehabilitation team worked closely together to standardize treatment techniques, increase opportunity for task carryover, and decrease the patient's frustration with learning. Speech therapy started to integrate pictures and words representing tasks learned in physical and occupational therapies. In addition, therapy became more focused on repeated task training of three or four essential skills versus multiple activities, games, and skills.

This case example demonstrated how medical imaging information not only confirmed the expected presenting deficits in movement, function, communication, and learning of the patient but also included information that guided the rehabilitation team in selecting interventions that optimized function for this patient.

Case adapted from Parikh M. *The Use of Medical Imaging in Neuromuscular Physical Therapy Practice: A Case Report*. Samuel Merritt College Physical Therapy Case Report Presentations. May 2007.

Fig. 37.10 (A) Axial view showing tumor. (B) Coronal view showing tumor.

The second clinical scenario involves the use of medical imaging information to guide clinical decisions during the actual occupational or physical therapy session. One of the major goals of this step is to make sure that the movement dysfunctions presented by the patient match the information obtained from the medical images. The therapist is expected to act accordingly and to demonstrate sound judgment, especially when the mismatch indicates a possible life-threatening situation. For example, if the imaging results indicate a small focal area involvement but the patient demonstrates

significant impairment in movement and function, the mismatch may be indicative of a worsening and potentially life-threatening condition that must be communicated to the physician and other members of the medical team.

As mentioned earlier, the complexity of the structure and function of the nervous system makes interpretation of imaging information very challenging. There may be situations in which images may not fully explain what the patient or client is able to do in terms of function and movement (as illustrated in [Case Study 37.2](#)).

Fig. 37.11 Images After Surgery for Tumor Resection. **(A)** Lateral view. **(B)** Axial view.

CASE STUDY 37.2 A Pediatric Patient With Developmental Problems at 18 Months

An infant identified as high neurological risk based on prenatal ultrasound was eventually born full term. Prenatal findings of unusually large head were further explored after birth with computed tomography scans while the infant was in the neonatal intensive care unit (NICU). Imaging confirmed that the infant did not have closure of his lateral and third ventricles. The physicians' prognosis had been that the child would die within days after birth, and the family was encouraged to take him home and spend as much time with him as they had before his death.

Once home, the infant was evaluated by a physical therapist and asked by the child's medical team to help establish realistic expectations and treatment protocols for this child.

The child was 18 months of age at the time of this therapist's first visit. The child's motor development was very delayed owing to the large size of his head (hydrocephaly). He was also nonverbal, and the doctors had concluded that he had an extremely low level of intelligence. His loving parents played with him, fed him, bathed him, and interacted with him all day. They felt he had more ability than the pediatrician had stated.

This video case study illustrates a situation in which there is a mismatch between the medical diagnosis/medical imaging results and what the patient presents in terms of function and movement. This case will engage and guide the therapist in a clinical decision making process of analyzing the patient's movement and functional capabilities and relating those to the integrity of the specific areas of the nervous system that are responsible for the movement or behavior. It is recommended that the reader first look at and analyze the motor function of this child at 18 months and then 6 months later, looking specifically for increased motor function and potential. During the interim, the child did receive weekly therapy, but most of the practice was done at home with the parents interacting with the child. Analyze the movement from a motor learning and neuroplasticity perspective as you determine the potential for motor control. Then look at the magnetic resonance image images that lead the doctors to diagnosis the medical problem and the prognosis of death. Then ask yourself, what could be happening to cause such a mismatch between a movement and a medical diagnosis?

Note: The continuation of the case, including the video clips and imaging results, can be found on the companion website.

FUTURE OF NEUROIMAGING IN REHABILITATION

Potential use of neuroimaging to predict long-term outcomes of neuro rehabilitation and to investigate priming methods for neuroplasticity are being studied in several labs. Real time neuroimaging and neural recording for brain-computer interfaces in neuroprotheses and neuroimaging guided sensorimotor rehabilitation are some of the future possibilities.

Abstract: This chapter provides an overview of the use of neuroimaging in rehabilitation. As relates to patients with neurological injuries (e.g., brain injury or stroke) and dysfunction (e.g., Parkinson disease or hereditary disorders), therapists should be able to interpret images of the nervous system to better understand how the neural insult and medical procedures affect movement and function in daily life. Expert analysis of neuroimaging using differential diagnosis

skills and knowledge of neuroanatomy is critical in order for these professionals to know when to refer a patient to another health care practitioner, when to refer and treat, when to merely treat, and when to neither refer nor treat.

Integrating Technology in Neurological Rehabilitation*

Jeric Uy, Sophie Lefmann, Laurie A. King, Martina Mancini, and Bradley W. Stockert

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Summarize the need, demand, and principles for integrating advanced robotic technology in neurological rehabilitation.
2. Define common terminology used in the field of rehabilitation robotics and technology.
3. Classify the different types of advanced technology used in neurorehabilitation.
4. Apply the guidelines for integrating robotics and assistive technology into a patient's rehabilitation program.
5. Discuss the benefits of performing a cost-effectiveness analysis when considering the application of robotic technology in rehabilitation.
6. Describe the challenges of commercializing robotic devices.
7. Discuss the future of advanced technology and rehabilitation.

KEY TERMS

brain-machine interfaces
exoskeleton

human robotic interfaces
rehabilitation robotics

virtual reality training

Rehabilitation professionals face an ongoing challenge to provide clinically effective interventions that are also engaging and meaningful to the patient. The objective of rehabilitation technology is to empower clinicians and patients to take responsibility and control of the environment and facilitate physical and cognitive recovery. Technology assists patients during learning-based practice that drives neural adaptation and neural reorganization.¹ For these reasons, robotic-assisted rehabilitation technology has been embraced by allied health and rehabilitation medicine over the previous two decades. It seeks to take interventions and dosages of therapy to the “next level”: a novel approach to offering high-volumes of computer/external force-guided body retraining.²

Timely rehabilitation maximizes people's performance of motor, speech, function, and cognition.³ The timing and purpose of introducing rehabilitation robotics and technology into the rehabilitation process will vary greatly. The “how” and “why” of robotic rehabilitation interventions need to be just as thoughtfully targeted as any other land-based approach for function, engagement, time-efficiency, and performance optimality.

Rehabilitation approaches across disciplines consider the influence of neuroplasticity on outcomes, and also consider the relationship of intervention to the World Health Organization's International Classification of Functioning, Health and Disability (WHO-ICF). Whether the patient is an adult following a stroke or a child with cerebral palsy, the treating therapist should have a sound understanding of the principles of motor learning and neuroplasticity.

Furthermore, when reading this chapter, the clinician should reflect on the principles of experience-dependent plasticity (Table 38.1) and align how robotic rehabilitation can augment each of these components for their patient.³

Robotic devices come in many shapes, sizes, and price points, which must be considered in selecting the best option.^{4,5} For example, is it in the patient's interest to have a wearable robotic device for everyday functional support? Is it more appropriate to access therapeutic bursts of complex, laboratory-based technology? There is no one answer, and the fine details of a patient's therapy will be individualized. However, the path pursued by therapists alongside patients should be motivated predominantly by the patient's own functional goals.

The first part of this chapter will provide an overview of the clinical utility of robotic technology in neurorehabilitation. As the field of robotic rehabilitation is dynamic, this section will not provide an exhaustive list of device options, nor will it provide explicit instructions on how to use devices. Interest in specific devices or approaches is best explored with the latest research outputs as they emerge and with the devices' manufacturers directly. Instead, the aim of this chapter is to equip the rehabilitation professional with an awareness of how robotic and rehabilitation technology can be broadly applied to patients with neurological impairments and relate it back to the overarching principles of the WHO-ICF.⁶ Included in this part is the use of robotics for simulation for student education. The second part of this chapter will address other technology that is used in clinical and teaching environments, including inertia sensors, virtual reality (VR), and noninvasive brain stimulation.

TYPES OF ROBOTIC REHABILITATION AND THEIR APPLICATIONS

Robotic technology can provide service, body support, unweighting, and movement assistance that is passive, active, variable, and on-demand assistance.^{7,8} Computerized and robotic technology provides the foundation for patients to practice and attend to purposeful,

*Videos for this chapter are available at studentconsult.com.

TABLE 38.1 Principles of Experience-Dependent Plasticity³

Principle	Description
1. Use it or lose it	Failure to drive specific brain functions can lead to functional degradation
2. Use it and improve it	Training that drives a specific brain function can lead to an enhancement of that function
3. Specificity	The nature of the training experience dictates the nature of the plasticity
4. Repetition matters	Induction of plasticity requires sufficient repetition
5. Intensity matters	Induction of plasticity requires sufficient training intensity
6. Time matters	Different forms of plasticity occur at different times during training
7. Salience matters	The training experience must be sufficiently salient to induce plasticity
8. Age matters	Training-induced plasticity occurs more readily in younger brains
9. Transference	Plasticity in response to one training experience can enhance the acquisition of similar behaviors
10. Interference	Plasticity in response to one experience can interfere with the acquisition of other behaviors

goal-oriented, progressive tasks spaced over time. This technology can also minimize the risk of injury during retraining. Robotic rehabilitation devices may include service robots, nonwearable assistive robotic devices, wearable assistive robotic devices, or neuromuscular stimulators. There are also vocational rehabilitation robotics, communication devices, and emotional interactive entertainment/friendly robots, which will not be investigated in depth in this chapter. Fig. 38.1 and Box 38.1 provide an overview of the classifications of robotics technology.

Service robots usually focus on task performance, movement assistance, and stability. These devices can be fixed, movable, or attached to a wheelchair.¹ Assistive robotic devices help patients perform a task with direct or indirect assistance. Some of the assistive robotics are nonwearable but assist through unweighting or movement assistance. Wearable robotic devices are specifically designed to be worn by patients to assist movements. These are designed for the upper or lower limb.¹ Vocational robotics can enhance performance at work either in terms of repetitive motions or high-force task production that would otherwise be dangerous to humans. Communication robotic devices are designed to improve communication potential for patients who cannot adequately speak or hear. Emotional support robotic devices are designed to provide emotional support for isolated individuals at home.¹

Prosthetics for amputees, vocational robotics, communication robotics, emotional support robotics, or socially assistive devices⁹⁻¹¹ are not outlined in detail here as these areas are considered specialty oriented and may or may not be included in traditional neurorehabilitation programs coordinated by physical or occupational therapists.

For simplicity, we will focus on our examination on service robots, nonwearable assistive robotic devices, and wearable assistive robotic devices. It is also important to acknowledge there are a number of motorized chairs, lifts, and walkers available that can be used to transition a patient from sitting to standing, or provide unweighting

while walking, or working on balance. These devices are not usually programmable and are not classified as “rehabilitation robotics” or “advanced technology.” However, these types of devices are very beneficial for helping patients maintain walking and training to improve safety and quality of gait at home and with supervision. It is important for therapists to be sure these types of assistive devices have been considered and/or integrated into a patient’s rehabilitation program and at home before recommending more sophisticated technology.

SERVICE ROBOTICS

Service robots primarily assist individuals with severe disabilities. Most commonly, the robot performs everyday activities (e.g., assisting with eating, drinking, object replacing, ambulating).¹² There are three main types of schemes: desktop-mounted robots, wheelchair-mounted robots, and mobile autonomous robots. In general, these robots are used in the home, are interconnected to a variety of control systems, are programmed to the environment and consequently are not very portable.¹²⁻¹⁴

These types of robotic devices are often preprogrammed to perform certain tasks. There are also some autonomous robots in which the cognitive interface between the user and the robot is used to tell the robot to perform a new task or to help the patient perform the task.¹⁵ These robotic systems are successful if the robot, the user, and the manipulated objects remain in the same initial set position every time a concrete task is performed. With the wheelchair-mounted manipulator, the relative position of the user with respect to the manipulator needs to remain the same. Although there are a variety of simple service-based robotic devices, most are complex, and setting them up at home generally requires a computer or engineering specialist.

Service robots may include smart wheelchairs¹⁶ and smart devices in the home (e.g., The Robotic Room¹⁰) or wheelchair-mounted upper extremity manipulators.¹⁷ A major consideration for patients using service robotic devices are the control options. For example, through the use of headpieces on robotic devices, information can be detected from flexion and extension, rotation, and side bending of the head to operate wheelchairs, TV sets, telephones, doors, and security systems. There are also interfaces that are sensitive to facial movements and optoelectronic detection of light-reflective head movements.¹⁸ Other interfaces are sensitive to eye movements or use voice recognition, brain control,^{19,20} and gesture recognition.²¹ These interfaces not only may allow control of the robot but also may be applied to move a limb or perform a task. A more detailed discussion of robotic interfaces is included later in this section.

Service robotics is recommended when patients have achieved their maximum potential and still need assistance to live independently. A therapist may continue to work with a patient at home to maintain range of motion, minimize skin problems, and review whether the robotic technology is still providing the necessary assistance. However, an engineer will usually assume the primary responsibility for maintaining and adjusting the robotic equipment.

NONWEARABLE ASSISTIVE ROBOTIC DEVICES

This group of robotic devices primarily includes powered wheelchairs with autonomous intelligence, robots for body support, and hands-off service robotic devices. Body weight supported treadmill systems (BWSTSs) with and without robotics²² and body weight-support mobile walking aids (BWSMWA) are also aligned to this category.^{23,24} The value of BWSTSs and similar nonwearable assistive robotic devices is that patients can be supported to develop their body structures and functions (e.g., step length, weight shift abilities, balance)

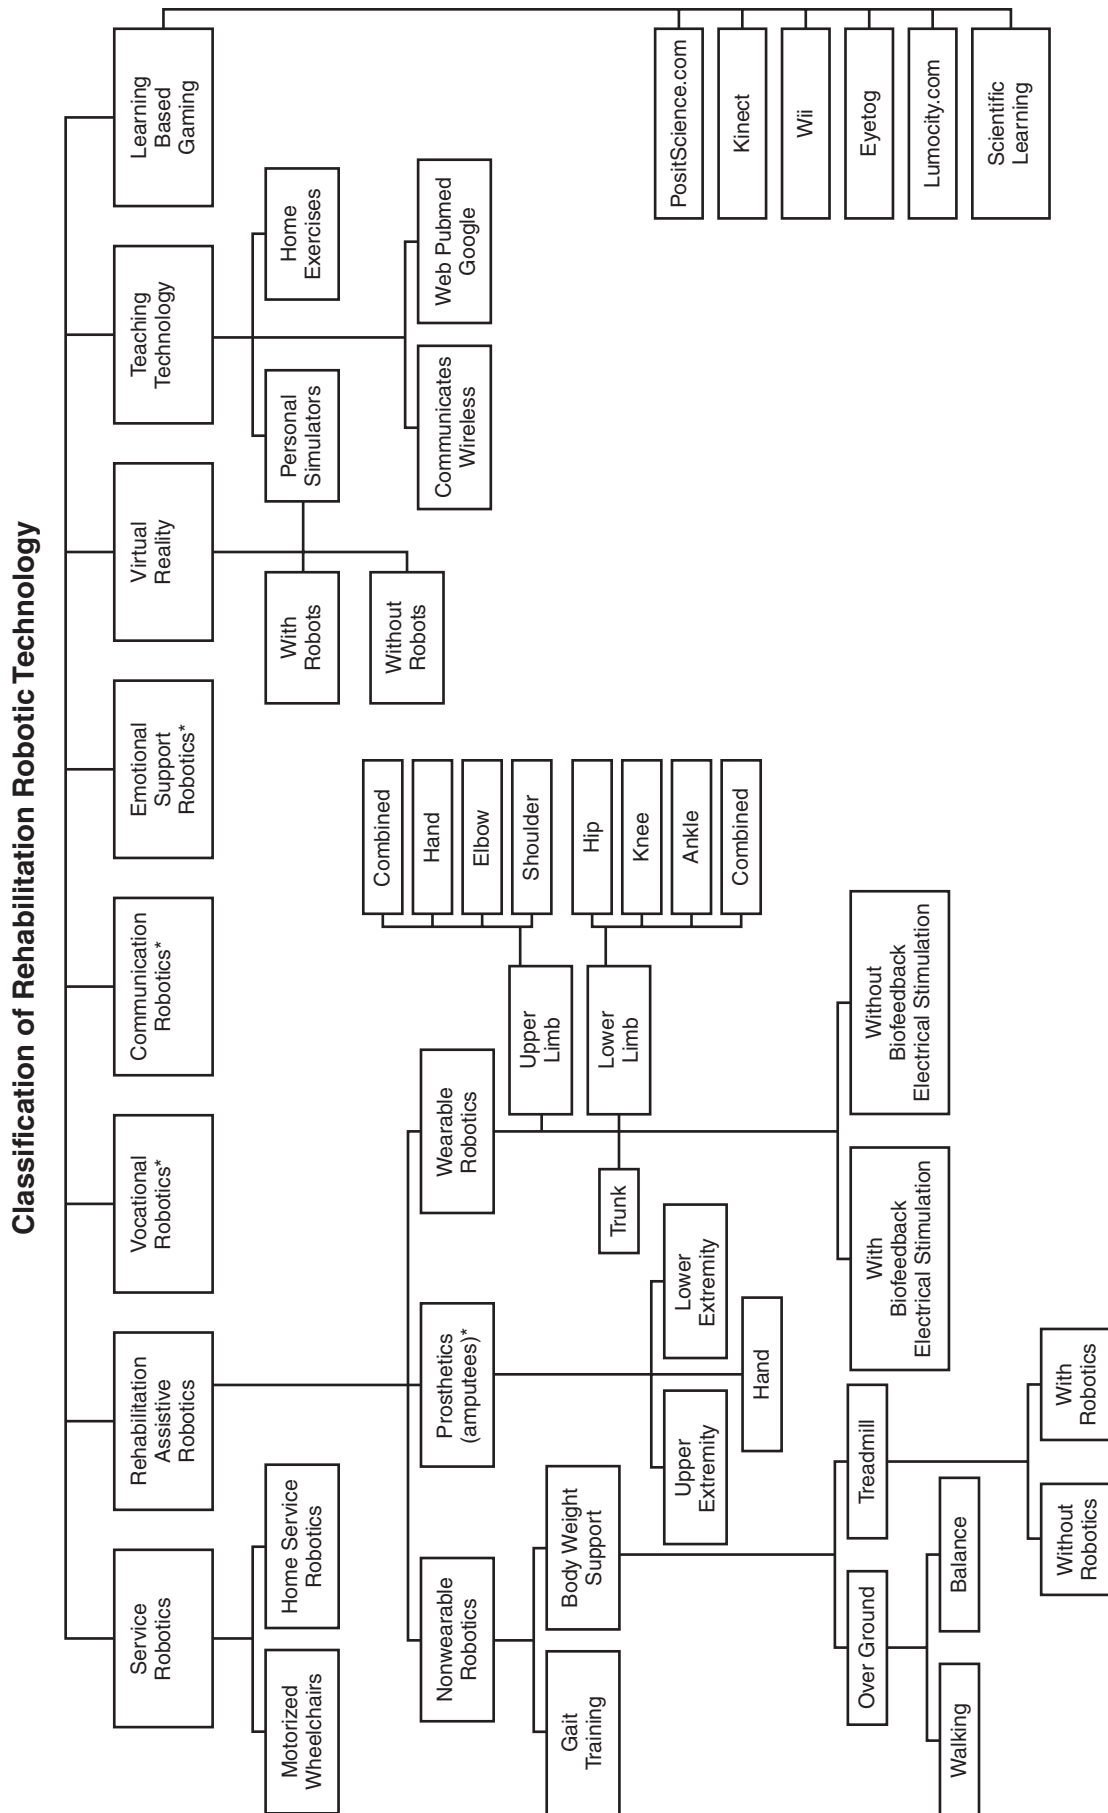

Fig. 38.1 Classification of Rehabilitation Technology.

BOX 38.1 Classification According to How the Robotics are Used

- Service robotics
- Assistive robotics
- Vocational robotics
- Prosthetic robotics
- Emotional robotics
- Communication robotics
- Virtual reality technology and robotics (including personal simulators)
- Learning-based gaming technology
- Technology for teaching

as a precursor to practicing tasks at the activity/participation level in more authentic, natural settings.²⁵ Body weight–supported gait training systems were initially designed to unweight the body, decrease ground reaction forces (GRFs), and protect against falling (Fig. 38.2). Under these assisted conditions, it is easier for patients to achieve intense levels of exercise such as walking, skipping, and running with less pain and less trauma to the joints.

Assistive robotic devices hold a prominent place in the rehabilitation of adults and children with neurological dysfunction.^{22,26} Robotic-assisted BWSTT has been investigated for individuals with chronic spinal cord injury²⁷ and stroke.²⁸ Evidence of greatest efficacy of these robotic or electromechanical-assisted devices has been reported in the first 3 months following stroke, and of most benefit to those with very limited walking ability.²⁸ Furthermore, it is important to support patients to walk at community-level velocities of at least 0.8 m/s (faster than 2.0 mph).^{29–33} Devices such as the Lokomat, which robotically augment joint placement and walking execution on a treadmill, have been examined in children with neurological impairments.²⁵ Children with cerebral palsy may experience greatest benefit when they have moderate-to-severe degrees of gait impairment (e.g., GMFCS levels II, III, and IV). The opportunity for clinically noticeable training change is greatest and more likely to achieve physiological and possibly neuroprotective benefits.^{34,35}

Nonwearable assistive robotic devices can offer patients the potential for high degrees of repetitive practice by adjusting, placing, and guiding the limb through repeated movements.^{2,5,36} It can help reduce the taxing

physical effect and awkward positioning of rehabilitation on clinicians while offering even higher volumes of practice in a single session.⁴ However, at some point, clinicians and patients must face the possibility of a ceiling effect of high-dose practice in a predictable environment. The therapeutic course should take the patient to eventually progress to task-specific training outside of assistive robotic devices, which is where conventional approaches to therapy take precedence.

WEARABLE ASSISTIVE ROBOTIC DEVICES

Assistive robotic devices are also popular in upper limb rehabilitation. The upper limb is highly complex, with a requirement for devices to be appropriately light and responsive to degrees of movement. The shoulder and hand/wrist will demand multidimensional options compared to the elbow. This becomes challenging for designers to balance aligning the device with joints, as well as incorporating motors, actuators, and cabling.³⁷ The clinician will therefore decide whether the patient requires an exoskeleton device (e.g., Armeo) with torque actuators that control single/multiple joints, or an end-effector-type device (e.g., In-Motion 2.0), which focuses on the distal portion of the upper limb. A recent study on post-stroke intervention notes a higher degree of exploration of end-effector devices as newer exoskeleton technologies have been less commonly investigated.³⁸ It also notes that meaningful change, especially with earlier intervention, will be assisted with some degree of voluntary muscle initiation of wrist and fingers; timing of intervention remains an important consideration.³⁸

Wearable assistive robotic devices can support patients to participate in everyday tasks with greater autonomy.³⁹ Structures may be exoskeleton but with rigid or soft wearable features. They may be fixed in place in a clinical training station or they may allow great portability with movement and use.⁴⁰ Examples of these include the ironHand system⁴¹ or those that are triggered with neuromuscular stimulation, such as the Bioness upper limb or lower limb systems (see Fig. 38.3). The primary impairment that can be addressed with neuromuscular stimulation is muscle weakness, but the patient may also have neuromotor control problems or abnormal synergies of movement. These devices work only when peripheral nervous system function is preserved. The electrodes, located within the device's control unit, stimulate a peripheral nerve causing a movement effect.⁴² However, in the case of patients with spinal cord injuries, multiple electrodes may need to be used to sequentially activate a series of muscle contractions to enable walking. Similar robotic devices and principles of operation are available for patients post-stroke.

Wearable assistive robotic technology extends, complements, empowers, replaces, or enhances the function or capability of the individual. For some patients, using these is an ongoing component of their rehabilitation. For others, the wearable assistive robotic device is used as it can complete the action of a task that is no longer an effective or efficient option for the patient. These robotic devices may facilitate muscle contractions in one or more directions around one joint such as the elbow, wrist, or ankle. The objectives of reducing muscular fatigue and energy conservation during task practice are met when devices are lightweight, flexible, sensitive to movement change, and easily portable.^{5,41,43–45}

Upper limb and lower limb wearable robots are obviously worn by the individual, but the internal or external interface must be mapped to the anatomy, a cognitive control mechanism, or the brain. The extremities can be used to perform multiple tasks, and the redundancy of the joints and degrees of freedom (e.g., at the ankle, or the wrist) allow people to perform tasks in a variety of ways. Redundancy of the joints and degrees of freedom allow a variety of ways patients can perform a task; however, these

Fig. 38.3 Wearable Upper-Limb Devices and Assistive Robotic Exoskeleton Devices. **(A)** Myomo upper-limb robotic assistive device. **(B)** Bioness L200 arm and wrist trainer. **(C)** Shoulder, elbow, and wrist upper-limb assistive robotic bilateral device. **(D)** Armeo robotic arm. **(A,** Courtesy Myomo, Cambridge, MA. **B,** Courtesy Bioness, Valencia, CA. **C,** Courtesy Jacob Rosen/Jim Mackenzie, UCSC. **D,** Courtesy Hocoma, Volketswil, Switzerland.)

redundancies may be hard to control. Wearable robotic devices will vary by type of human interface system incorporated (e.g., brain neurons, cognitive, sensory [tactile, pressure], physical [movement], or breath). At a minimum, the physical interface of a wearable robot requires an actuator and a rigid structure to transmit forces to the neuromusculoskeletal system.⁴³

Ideally, wearable systems use both muscle stimulation and active voluntary muscle contractions to increase functional use. Devices such as the ReWalk and the Hybrid Assistive Limb (HAL) are well known commercially, and among clinicians working in neurological rehabilitation, for their wearable design and capacity to support patients with spinal cord injuries particularly, to ambulate with relative independence.

With actuation componentry at the hip and knee, these devices facilitate gait with electromyographic triggered stimuli (HAL) or battery powered, remote-control operation mechanisms (ReWalk).⁴⁶ As with the upper limb orthoses though, wearable exoskeleton technologies guiding lower limbs have key limitations around their size, bulk, weight, and responsiveness to the external environment. There can be some limitations in transferring the device usage into more complicated, unpredictable terrains.⁴⁶ However, as a concept, wearable lower limb exoskeletons such as the ReWalk and HAL can have significant influence at the activity and participation level. If accessible to rehabilitation staff, they may be worthy of consideration for goals that align to these dimensions of the WHO-ICF. Other device examples recently cited in the literature include Ekso exoskeleton, REX Personal, and the Indego exoskeleton.⁴⁶

ROBOTIC SYSTEM MECHANISMS FOR OPERATION

Robotic interfaces, actuators, and controllers can convert sensory, physical, and cognitive signals to:

- control robots
- permit perception of spatial relationships

- mobilize individuals in space
 - assist in object manipulation
 - provide emotional support
 - allow individuals to call for help and communicate with others
- In addition, through creative virtual training environments and gaming technology, patients can improve memory, motor skills, and movement quality.

Different robotic designs enable different performance outcomes. Understanding robotic mechanisms of operation is an important first step for a clinician as it may guide the selection of devices for patients.⁴⁷ Robotic devices in general may be active, passive, haptic, or predominantly performance feedback-oriented.^{5,8} The degree of assistance offered will determine the suitability of robotic mechanical design, and vice-versa. Maciejasz and colleagues⁵ best summarized different robotic systems by feature, outlined in Table 38.2.

The robotic device's mechanical design (e.g., exoskeleton) also has specific properties, which may require some understanding. These properties can help determine the degree of augmented movement available in the device,^{5,49} as outlined in Table 38.3.

TABLE 38.2 Mechanical Design of Robots⁵

Term	Description
Exoskeleton devices	These use an externally-fitted framework to replicate the targeted limb/limbs' skeletal structure. The limb's joints are aligned with the framework's joints to support movement. An exoskeleton device may replicate multiple joint movements, but also can be set up to both assist and inhibit body segment use
End-effector-based devices	Usually simpler than a full exoskeleton device, end-effector designs have a single, distal point where mechanical forces are applied to the distal limb segment. ⁴⁸ Note that the simplicity of the design may offer challenges when the limb position demands multiple degrees of freedom
Back-drivable devices	A feature of robotic design where the patient can move the device without robotic augmentation. Importantly, limb movement is not constrained while fitted to the device
Planar robotic devices	These devices operate in a specific plane of movement and are often associated with end effector designs
Modularity	A property of a device indicating that optional parts may adapt it to a specific condition or simply to perform additional exercises
Reconfigurability	A property of a device indicating that its mechanical structure may be modified without adding additional parts in order to adapt it to the condition of the subject or to perform other forms of training

TABLE 38.3 Glossary of Actuation Terms⁵

Term	Description
Electric actuators	Actuators powered by electric current. They are the most common because they easily provide a relatively high power and are able to store energy. There is a wide selection of commercially available electric actuators; however, some of them are heavy and/or their impedance is too high for rehabilitation settings
Hydraulic actuators	Actuators powered by hydraulic pressure (usually oil). They are able to generate high forces. Their system is relatively complex considering the maintenance of pressurized oil under pressure to prevent leakage. Commercial hydraulic actuators are also heavy; therefore only specially designed hydraulic actuators are used in rehabilitation robotics
Pneumatic actuators	Actuators powered by compressed air. They have lower impedance and weigh less than electric actuators. Special compressors or containers with compressed air are required for power
Pneumatic Artificial Muscle (PAM, McKibben type actuator)	A special type of pneumatic actuator with an internal bladder surrounded by a braided mesh shell with flexible, but nonextensible threads. Because of their specific design, an actuator under pressure shortens, similarly to the contracting muscle. It is relatively light and exerts force in a single direction. It is difficult to control because of its slow and nonlinear dynamic functions
Series Elastic Actuator (SEA)	A generic name used for a mechanism with an elastic element placed in series with an actuator. This solution is relatively often met in the design of rehabilitation robots. It decreases the inertia and intrinsic impedance of the actuator to allow a more accurate and stable force control and increase patient safety
Functional Electrical Stimulation (FES)	It is a technique that uses electrical current to activate nerves and contract their innervated muscles. It produces the movement of the limb using natural actuators of the body. However, it is difficult to achieve precise and repeatable movement using this technique, and it may be painful for the patient

Fig. 38.4 Re-Walk Personal 6.0.

Clinical rationale for the use of robotic devices is specific to the patient and the particular device. Robotic devices can be used to improve body structure and function, activities, and participation. For example, the Lokomat (see Fig. 38.2) uses a body weight–supporting exoskeleton and provides augmented limb movement to improve the functions of weight-bearing tolerance and sagittal plane joint mobility.^{8,25} Other devices, such as the ReWalk (Fig. 38.4), support the spinal cord-compromised patient to ambulate with crutches, allowing community mobility and potentially greater autonomy⁵⁰; performance

factors that align with “participation” expectations. Patients in early rehabilitation phases may respond better to a particular type of robotic device, superseded by an alternative option as the patient’s capabilities evolve or diminish. There also may be changes between genuine neurological structure recovery (e.g., CNS reactivation) and the emergence of effective compensatory strategies for movement.⁴⁷ Iosa and colleagues⁸ have recently proposed the “ideal” interactional loop between the patient, the rehabilitation professional, and the robotic rehabilitation device selected (Fig. 38.5).

Aligning the device category, actuation componentry, design, and function to the patient’s needs can confidently provide the clinician with a plan for robotic application. Many therapists will be limited by what their workplace has access to.

General Screening Considerations

There is a potential pitfall for patients and therapists to pursue technology for “technology’s sake.” A robotic device does not replace an individualized, task-specific, land-based regime and should not be a substitute for goal-oriented therapy.⁴⁷ Importantly, the patient and therapist should not become tempted to force the robotic options on offer to become a part of the patient’s therapy if it does not align with functional goals. Box 38.2 summarizes the principles to support the use of technology and robotics in therapy.

The criteria used to determine which patients might benefit from rehabilitative technology will change over time. Devices will come with specific instructions and suggestions for use/contraindications to use. However, the treating therapist must also make an informed decision to use the robotic technology because it holds promise to “value-add” to the patient’s performance. Before screening a patient for robotic technology, clinicians need to be certain that all standard assistive devices have already been integrated into the individual’s rehabilitation program. Ultimately, guidelines should be developed to match the potential of the individual with the prognosis for independence, with and without dependable, user-friendly technology.

An objective evaluation is needed to match a patient with a commercially available robotic device. This evaluation must include a thorough assessment of anatomical, physiological, cognitive, and sensory impairments. Whenever possible, standardized tests should be used to document strength, flexibility, endurance, balance, coordination,

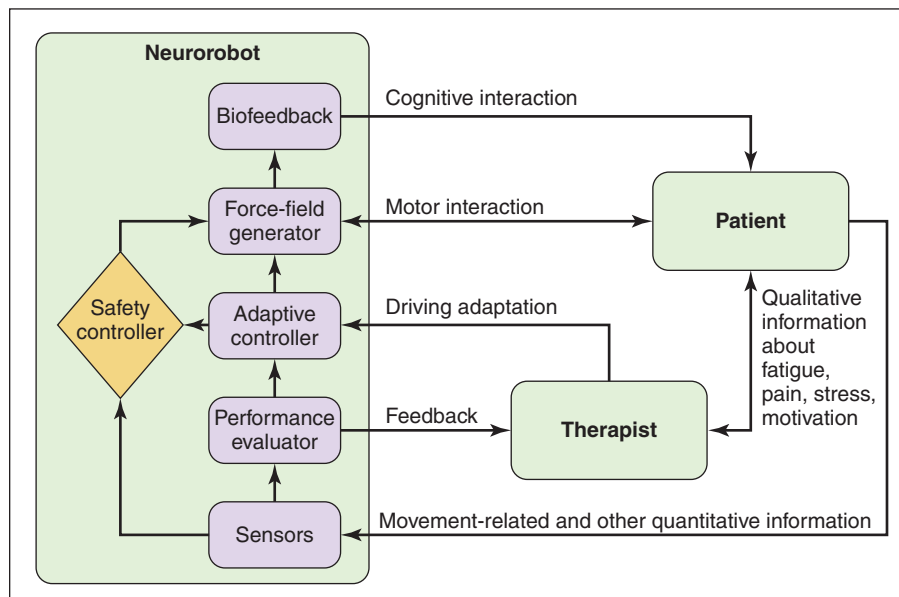

Fig. 38.5 Interactional Loop Between Robotic Device, Patient, and Therapist.^{8,51(p. 8)}

BOX 38.2 Principles Supporting Advanced Technology and Rehabilitation Robotics in Neurorehabilitation

Principle I

Goals for advanced technology and rehabilitation robotics include the following:

- A. *Indirectly augmenting* functional independence of individuals with impairments by:
 1. performing mobility tasks for individuals at the home (e.g., using automatic motorized wheelchairs to move individuals from room to room; transitioning individuals from bed to chair and from chair to standing; moving patients who are standing; smart houses; calling for help)
 2. minimizing the need for assistance from another individual
 3. performing functional activities of daily living (activities of daily living; e.g., getting objects, cooking food, doing dishes, bathing, transferring)
 4. helping perform difficult or repetitive tasks at work (e.g., assembly line tasks; lifting and moving heavy objects)
- B. *Directly improving* human motor skill capabilities of individuals with impairments to enable them to:
 1. perform functional tasks independently
 2. improve voluntary control
 3. perfect quality of movement
 4. learn new skills

Principle II

Advanced technology and rehabilitation robotics should maximize neural adaptation and reorganization through the creation of practice opportunities that:

- A. are attended, repetitive, purposeful, goal oriented, progressive, and spaced over time
- B. are fun, interesting, and practical
- C. are task oriented
- D. provide feedback on accuracy of task completion
- E. can be matched to patient abilities

Principle III

The objectives of assistive rehabilitation robotic devices need to be clearly defined in terms of:

- A. unweighting a limb to reduce patient effort required for movement
- B. actively canceling mechanical limitations on movement of the patient and robot arm dynamics (e.g., friction, inertia, and weight under gravity)
- C. gently and progressively moving a limb to assist patient effort to perform a task
- D. stabilizing a joint to enable a patient to produce a controlled movement
- E. assisting the patient to improve the accuracy and quality of a movement
- F. assisting the sequencing of movements
- G. providing resistance to strengthen movements

Principle IV

Robotic technology must be:

- A. safe for training
- B. reliable in performance

- C. able to reduce risks of injury (e.g., falls)
- D. able to minimize injury during use

Principle V

Robotic technology should be:

- A. adaptable (across patient needs, side, type of actuation)
- B. able to integrate interfaces, actuators, and controllers sensitive to the ability of the individual

Principle VI

Robotic devices need to be:

- A. reasonably priced and cost-effective
- B. versatile
- C. durable
- D. repairable
- E. easy to use

Principle VII

Wearable robotic devices must be:

- A. lightweight
- B. easy to get on and off
- C. portable
- D. cosmetically acceptable
- E. interfaced to patient ability (sensory, motor, cognitive, brain)
- F. minimally harmful to the skin
- G. dynamically adaptable to performance capabilities

Principle VIII

Robotic technology for rehabilitation needs to be defined by:

- A. location of the control system relative to the patient (controlled at a distance from the user [e.g., Web, Skype]), controlled in proximity to the user [e.g., by a therapist or engineer], or controlled by the user [e.g., wearable device or interface])
- B. environmental connection of the device and the patient (fixed to a nonmobile surface [e.g., wall], attached to a mobile platform [e.g., wheelchair], freely mobile with the patient [wearable])
- C. type of control system (e.g., joystick, sensor, breath)
- D. type of interface (physical, sensory, cognitive, brain)
- E. type of anatomical connection (e.g., by end effector only, end effector and multiple points of attachments with serial links or temporal links)

Principle IX

Brain controlled interface rehabilitation robotics must be:

- A. considered after all other alternatives have been unsuccessful
- B. minimally intrusive despite surgery
- C. physically accessible via remote control outside the brain
- D. controlled with minimal patient risk and with safety
- E. potentially controlled by cognition or the patient's mental effort
- F. able to extend patient's independent task performance

synergistic responses, hypertonicity, gait, balance, posture, and postural righting skills. These impairments need to be integrated into functional and task-specific assessments of motor learning, motor control, activities of daily living (ADLs), work requirements, and recreational needs. Then each patient should be screened by defined objectives relative to outcomes in terms of quality of life and independence. Subjective and emotional issues such as attention, motivation, history of positive health behaviors, durability, depression,

desire for independence, and commitment to learning must also be considered. As an additional consideration for children, the parents and caregivers must confidently understand the value and purpose of including the device in a therapy regime and the therapist must feel comfortable that the child can express discomfort or displeasure with the device, to minimize adverse effects. There is evidence to suggest that with devices such as the Armeo and LokomatPro, for example, the more motivated to avatar-based games the child is, the greater the

clinical effects.^{2,25} Speculation is that active involvement in gaming will increase the responsiveness of body structures and functions (e.g., postural control, weight shift) to gait rather than the passivity that comes with walking on a treadmill engaging in less-interactive watching of movies on screens.²⁵ Indeed, recovery for patients may even be compromised if tasks are monotonous, demand less effort or focus.⁵

The patient needs to go through general and specific screenings to determine the appropriateness of integrating a nonwearable assistive robotic device into the rehabilitation program (Table 38.4). The patient who is most likely to benefit from body weight–supported gait training is the patient who has the prognosis for functional independence but needs to train to improve quality, endurance, speed, and stability of gait. Thus many patients with problems described within this text might benefit from this type of training. Those who do not have the potential for independent ambulation could still benefit from training on a BWSTS. In these cases, the training would be directed toward enhancing metabolic health, providing a sense of well-being, increasing circulation, and minimizing secondary impairments associated with excessive sitting such as decubitus ulcers and bone demineralization. These patients may need robotic, human, or harness assistance to achieve standing or stepping as well as bracing of the neck and trunk when upright. Patients with joint pain in the back or knee may also benefit from wearing supports when standing or exercising.

If a patient does not demonstrate the ability to bear weight on a single limb, then robotic control of the lower limbs may be the preferred mechanism to facilitate secondary benefits. However, when all the movements are passive, there will be minimal gains in terms of neural adaptation and reorganization. On the other hand, it may counter the secondary problems of bone demineralization and decubitus ulcers and be of value as a maintenance strategy.

In spite of advancements in rehabilitation robotic technology, some patients may still have difficulty taking advantage of this type of therapeutic assistance. In patients with challenging impairments, for safety the use of an overhead harness to access the treadmill may be required, in addition to close supervision by one or more therapists.

Specific Screening of Patients for Wearable Assistive Devices

Screening must be sensitive to the characteristics of the individual and consistent with factors in Table 38.4. After identifying the parameters of performance and the potential benefits of assistive wearable technology, the patient, the family, the therapist, and sometimes the orthotist should determine what assistive robotic devices or advanced technological equipment are available to meet the patient's needs. The team also has to assess where the devices are located, whether they are accessible, whether the device should be rented or purchased, and

TABLE 38.4 Screening Patients for Integrating Advanced Technology or Rehabilitation Robotics Into Neurorehabilitation

Screening Criteria	ASSISTIVE ROBOTIC DEVICES		
	Service Robotic Devices	Nonwearable—Mobility and Unweighting	Wearable—Mobility and Object Manipulation
Criteria for determining potential benefit for patient to integrate advanced or robotic technology	<p>Patient with severe physical impairments challenged to be independent without personal assistance:</p> <ol style="list-style-type: none"> 1. Has significant weakness of trunk and limbs (0, trace, poor) 2. Has minimal voluntary control of trunk and limbs 3. Cannot use a manual chair independently 4. Requires personal assistance to transfer to and from chair 5. Cannot step without maximum assistance 6. Unable to walk or stand independently 7. Unable to meet ADL needs without personal assistant 8. Is cognitively alert and aware 	<p>Patient with mobility impairments compromising safety, full independence, and quality of life:</p> <ol style="list-style-type: none"> 1. Has impaired ability to walk 2. Has poor or slow balance responses 3. Demonstrates unstable single-limb support (unilateral or bilateral) 4. Is at risk of falling 5. Could benefit from fall protection when standing 6. Is weak (has poor strength) 7. Has difficulty initiating stepping 8. Lacks high-quality voluntary control for walking 9. Has involuntary synergistic movements 10. Has reduced flexibility 11. Uses an assistive mobility device 12. Needs to reduce ground reaction forces when walking or during intense exercise owing to pain, inflammation, osteoporosis, joint replacement, incoordination, and so on 13. Walks very slowly (household ambulatory but limited community ambulation) 14. Must maintain cardiopulmonary and metabolic health 15. Could benefit from stimulation of neurotransmitters and endorphins 	<p>Patient with impairments compromising mobility and/or independent task performance at home, at work, or during recreation:</p> <ol style="list-style-type: none"> 1. Is unable to perform common daily tasks for independence without an assistive device or personal assistance 2. Needs assistance at one or more joints 3. Needs assistance to complete a task 4. Takes excessive time to complete task 5. Needs assistive device to ensure stability to walk 6. Has experienced a fall or an injury when performing a daily task (e.g., toileting) 7. Cannot live safely alone without personal assistance 8. Cannot cross the street in time 9. Needs more controlled forced task practice 10. Needs assistance to improve quality 11. Is not afraid of computerized or electromechanical devices 12. Is learning “abnormal” movements 13. Lives alone, but safety is in question 14. Drives but needs some assistance with transfers and/or arm or leg movements

TABLE 38.4 Screening Patients for Integrating Advanced Technology or Rehabilitation Robotics Into Neurorehabilitation—cont'd

Screening Criteria	ASSISTIVE ROBOTIC DEVICES		
	Service Robotic Devices	Nonwearable—Mobility and Unweighting	Wearable—Mobility and Object Manipulation
Screening criteria to determine if patient has the ability to use advanced or robotic technology	<p>Patient has potential to achieve independent wheelchair mobility and ADLs at home with reduced human assistance:</p> <ol style="list-style-type: none"> Has cognitive ability to control motorized and robotic devices Has the sensory, physical, and cognitive abilities to control a motorized chair (e.g., via joystick, head movement, button press, breath, piezoelectricity, voice) without human assistance Can activate an automated harness system to transfer into a wheelchair Can sit in a chair with or without positional assistance Has sufficient understanding and ability to activate robotic service and emergency devices to be independent without human assistance (smart house designs) 	<p>Patient has the potential to improve walking quality and speed, endurance, and independence with progressive practice or training:</p> <ol style="list-style-type: none"> Has cognitive ability to participate in training Has sufficient attention and understanding to cooperate in gait training Has adequate head and trunk control to maintain postural uprightiness when legs moving Has sufficient strength in legs to stand up when unloaded or protected from falling Has some sensation in lower limbs or can see legs Has partial movement in major muscle groups in lower limb (hip, knee, ankle) Has sufficient range of motion to get into standing or walking position Can transfer onto the treadmill or transfer from chair to standing Tone does not prevent the feet from staying on the ground or stepping when unloaded Has ability to step when standing over ground or over treadmill Steps after perturbation of the treadmill Can swing leg through clearing floor or treadmill (with or without AFO) Stepping speed can be changed with treadmill speed Can tolerate training several hours a week 	<p>Patient has the sensory, physical, and cognitive ability to control a wearable device to achieve independence in mobility and/or object manipulation:</p> <ol style="list-style-type: none"> Has intellectual ability to understand how to use the wearable assistive orthotic device Has the ability to don the wearable assistive device (or has someone at home to help) Is motivated to use a wearable assistive robotic device to improve independence Has basic stability of the head and trunk to move the limb(s) (even if positioning device is required) Involuntary movements do not interfere with robotic assistance Has adequate standing balance (with or without cane or walker) to work with a wearable assistive orthotic gait training exoskeleton Has the range of motion to allow full or partial task function Has adequate sensation to sense rubbing and chaffing of orthotic device If inadequate sensation, has sufficient vision, audition, touch, or cognition to monitor wear and control of interface Has adequate strength to lift the weight of the exoskeleton Has sufficient voluntary control to assist the exoskeleton Able to use the robotic assistive device several hours per day Has the physical, sensory, sensorimotor, and/or cognitive skills to control the interface of the assistive robotic device If unable to meet 13, may be eligible for advanced technology using a brain interface
Screening criteria to determine temporary versus permanent need for technology	<p>Patient has:</p> <ol style="list-style-type: none"> Goals and objectives to be functionally independent without personal assistance Predictable disease- or impairment-specific issues that are not going to change or may get worse A support system (family or community) to check on status at home Home that can be modified to accommodate robotic equipment 	<p>Patient has:</p> <ol style="list-style-type: none"> Goals and objectives to be functionally independent without personal assistance Predictable disease- or impairment-specific issues that necessitate regular exercise to maintain independence A progressive neurodegenerative condition that could be slowed with regular exercise A support system (family or community) to check on status at home Access to public transportation to access resources The ability to drive (e.g., take driver's training or simulation; car modification) to maintain independent access to needed resources 	<p>Patient has:</p> <ol style="list-style-type: none"> Goals and objectives to be functionally independent without personal assistance Predictable disease- or impairment-specific issues that require regular exercise to maintain and maximize independence despite injury or disease Ability to maintain if not maximize independence despite injury Ability to use robotic technology to improve functional recovery Ability to put on and remove the assistive devices Ability to slow down progression or maintain or improve function despite neurodegenerative condition that could be slowed with protected, guarded, stress-reduced intense exercise A support system (family or community) to check on status at home Access to public transportation to achieve community independence Ability to maintain independent community driving with regular training, simulation, car modification

TABLE 38.4 Screening Patients for Integrating Advanced Technology or Rehabilitation Robotics Into Neurorehabilitation—cont'd

Screening Criteria	ASSISTIVE ROBOTIC DEVICES		
	Service Robotic Devices	Nonwearable—Mobility and Unweighting	Wearable—Mobility and Object Manipulation
Screening criteria to determine safety	Patient has: <ol style="list-style-type: none"> 1. Ability to call for emergency help if devices do not work 2. Secondary harness systems to prevent falling with robot-assisted transfers 3. Ability to manipulate control devices to stop or encourage function of the robot 4. Ability to turn off the robot when inappropriate movements develop 	Patient can: <ol style="list-style-type: none"> 1. Safely step on and off the treadmill 2. Tolerate the tension of the harness or unweighting system 3. Spontaneously step as triggered by the moving treadmill 4. Express concern if exercising beyond his or her limits 5. Manipulate the parameters of the treadmill 6. Tolerate the end range parameters for performance (e.g., high speed) 	Patient has: <ol style="list-style-type: none"> 1. Adequate sensation to notice increased pressure or chaffing or skin sensitivity to electrodes 2. Ability to decrease the hypertonicity that interferes with function or causes pain 3. Sufficient cognitive awareness to recognize abnormal robotic behaviors (e.g., forced movement in abnormal directions) 4. Ability to stop excessive, abnormal movements 5. Ability to initiate self-directed movements with robotic assistance
Screening criteria to determine accessibility of advanced or robotic technology	Patient has: <ol style="list-style-type: none"> 1. Access to financial resources to afford advanced technology 2. Access to technology that is currently commercially available 3. Access to technology that is currently accessible in his or her geographical area 4. Opportunity to arrange for technical help to maintain equipment 5. Evidence available in terms of cost-effectiveness 6. Insurance that will help cover costs 	Patient has: <ol style="list-style-type: none"> 1. Resources to purchase needed equipment for home use 2. Resources to pay to use equipment in the community 3. Equipment that is commercially available in his or her community 4. Equipment available in the community 5. Evidence on cost-effectiveness of the technology 6. Insurance that will help pay for lease or purchase 	Patient has: <ol style="list-style-type: none"> 1. Resources to obtain assistive robotic devices 2. Access to commercially assistive robotic devices in his or her area 3. Ability to have equipment brought to his or her residence 4. Access to someone to fit, maintain, and repair the device 5. Evidence on cost-effectiveness 6. Insurance to assist with payment
Screening criteria to determine cost-effectiveness of advanced technology or rehabilitation robotics	There are clinical research trials reporting: <ol style="list-style-type: none"> 1. Objective outcomes as measured by decreased personal assistance, which can be documented in terms of hourly costs saved 2. That resource investment costs can be amortized across 5 years 3. That patients could gain 5–10 years of independent function at home 4. That the patient would be able to sustain independence at home (versus in skilled living environment) in the last few months of life 	<ol style="list-style-type: none"> 1. Objective outcomes focused on maintaining independence at home in lieu of an extended care facility 2. Patient can minimize falls and decrease risks for inpatient stay resulting from fall injuries 3. Patient able to sustain safe, independent indoor navigation without personal assistance 4. Patient able to get out of house and move in community independently or with public transportation 	<ol style="list-style-type: none"> 1. Objective outcomes focused on maintaining independence at home 2. Patient can perform ADLs and community activities safely 3. Patient uses assistive devices to minimize risk of falls 4. Patient remains committed to brain and physical fitness 5. Patient maintains safe, independent indoor and outdoor navigation without personal assistance 6. Patient able to get out of house and move in community independently or with public transportation

ADL, Activities of daily living; AFO, ankle-foot orthosis.

whether the insurance company will help pay for the rental or purchase of the device.

Ideally patients will use a wearable robotic assistive device to try to drive neural adaptation to recover function. Thus some patients may “train out” of the robotic device as they recover more function. Obviously, it would be better for these patients to rent rather than purchase the orthotic. Other patients would benefit from purchasing the assistive device because the robotic device improves function and independence despite ongoing impairments. Long-term use is also common when a patient has a degenerative condition, when the impairments are likely to get worse rather than better, and when with assistance independence can be prolonged.

In addition to the general and specific screening criteria, it is important to note that some assistive robotic devices may target control of one specific joint. However, given the biomechanical links, the flexibility, sensory, and motor characteristics must be assessed at each major joint above and below the primary assisted joint. The less affected side also needs to be evaluated. To maximize the benefit of a wearable assistive device, patients should ideally have some ability to voluntarily initiate movement and a grade of poor or greater strength to be able to assist in the movement.

Wearable robotics must be programmed not only to assist patient function but also to stop to avoid harm. This requires a balance between the dynamic nature of the wearable assistive device and a patient’s weakness, lack of voluntary motor control, and the presence of involuntary muscle activity including hypertonicity (e.g., spasticity, dystonia, rigidity, tremor). For example, how much force would the assistive device need to provide to overcome involuntary tone? Other relevant questions must then be asked: If a robotic device is programmed to assist with flexion and the patient initiates movement into extension or abduction, will the robot have to stop assisting the limb to prevent harm? If the robot stops assisting, is there a negative effect caused by the mismatch of force between the patient and the robot? Does the patient need consistent assistance or variable assistance? How will the therapist, the robot, or the patient determine how much assistance is needed? In one case a patient may need unweighting of only a limb, and in another case, both unweighting and assistance may be needed. In theory, the amount of assistance needed should decrease with recovery of function. It is helpful if the wearable assistive device can easily be adjusted by the therapist or the patient.

Despite the advancements in rehabilitation robotics, some patients will still have difficulty wearing an assistive orthotic. For example, wearable assistive orthotic devices may not work well for patients with severe sensory impairments, severe balance problems, a fear of falling, inadequate assets to control the device or for elderly patients who are afraid of computerized technology. Sophisticated rehabilitation robotic devices (Boxes 38.3 and 38.4) also may not be recommended for patients who are disoriented, who have severe pain or neural hypersensitivity, or who cannot don the apparatus independently.

It may be appropriate and helpful for patients with severe sensory and motor impairments to train using VR technology with or without assistive technology. Patients may begin with mental imagery and practice before engaging in physical practice, without and then with the

BOX 38.4 Types of Nonwearable Assistive Robotic Devices

- Robotic devices for unweighting and robotic stepping on a treadmill

integration of wearable robotic devices. It is also possible to begin the training with the assistive technology while in a harness system to protect the patient from falling. In addition, depending on the severity of balance and voluntary abilities, it may be necessary for patients to train with technology under careful direct supervision. In cases in which balance and motor control are good but can be improved, it may be possible for patients to train at home with wireless telemetry-type supervision.

Please refer to the Evolve site for a video case illustrating the use of technology in the rehabilitation of a child with cerebral palsy.

Patient Simulator Robotics

Purpose

One area of robotics contributing to improved rehabilitative care and education of rehabilitation professionals is the development of programmable human patient simulators. This section of the chapter describes programmable human patient simulators that are currently available. Programmable human patient simulators can be used to replicate many common medical conditions. Simulation is used to train clinicians so that when those rehabilitation professionals encounter a similar clinical situation they can respond more efficiently and effectively.

Introduction

Simulation using task trainers, actors, and standardized patients is not new to the education of rehabilitation professionals. While task trainers are useful for development of specific skills (e.g., cardiopulmonary resuscitation [CPR]), immersive simulation using high-fidelity robotics can be used to simulate and practice working with a variety of medical conditions, situations, and health care personnel. In addition, these scenarios can be repeated so every student has an opportunity to deal with a variety of specific medical conditions including rare but critical events (e.g., acute myocardial infarction [MI]).

In 2011 Stockert and Brady reported that approximately 44% of entry-level physical therapist professional education programs in the United States were using some form of programmable human patient simulator.⁵² In 2017 Stockert and Ohtake reported that the percentage of entry-level physical therapist professional education programs using programmable human patient simulators for immersive simulation had increased to 70% and about 40% of those programs were using the technology for interprofessional education (IPE).^{53,54} Education programs reported using the technology to train health care providers from multiple disciplines for interprofessional team responses to the challenges of providing care for a patient suffering an acute MI or a patient in need of early mobility in the intensive care unit. About 90% of the programs using simulation for IPE reported including the IPE Collaborative learning objectives for interprofessional, collaborative practice.^{53,55} The vast majority of these programs included interprofessional teams of de-briefers consistent with best practice patterns described in the literature.⁵⁶ The authors noted that they anticipate a

- Automatically guided wheelchairs
- “Smart houses”—designed for independence

further increase in the utilization of immersive simulation as an educational strategy for IPE in order to promote interprofessional collaborative practice and to comply with recently revised accreditation standards related to IPE in multiple health care professions.⁵⁴

Currently available robotic patient simulators can be programmed to demonstrate clinical signs and symptoms consistent with a diverse group of clinical conditions seen by Physical Therapists and other rehabilitation professionals. The patient simulator can be programmed to present signs and symptoms that require a participant to analyze and determine the urgency of the situation, assess the “patient” status, determine an appropriate intervention, and see the consequences of their action or inaction without compromising patient safety. A wide variety of clinical conditions and situations can be presented in an effort to ensure that each participant has an opportunity to practice and receive feedback regarding their clinical performance with multiple medical conditions. Simulation experience is critical for practicing how to respond to common as well as rare but critical events (e.g., acute MI). The learner’s ability to respond appropriately during a simulated event can increase the likelihood that those rehabilitation professionals are adequately prepared to respond efficiently and effectively when encountering a similar situation in the clinic.

Technology

At the beginning of 2018 there were two primary manufacturers of programmable human patient simulators. METI Learning (Medical Education Technologies, Inc.) started making patient simulators in 1996 and was acquired by CAE Healthcare in 2011 (<https://caehealthcare.com/>). Asmund Laerdal, with Drs. Lind and Safar, developed “Resusci Anne” for learning CPR in 1960. The Laerdal Corporation has been making a variety of patient simulators since that time (<https://www.laerdal.com/us/>). In this chapter on rehabilitation robotics, the properties and capacities of programmable human patient simulators are discussed based on currently available models by those two manufacturers. This analysis will hopefully help rehabilitation professionals evaluate the benefits of new robotic simulators for professional education.

Features

The number of features available on programmable human patient simulators continues to increase and raise the degree of realism (fidelity) attainable during immersive simulation. Many features, including eyes that blink and the simulated patient conversing in real-time, make the clinical scenario realistic for the participant. Several clinically relevant characteristics of human patient simulators are described on the following pages.

Size. The size of the adult human programmable patient simulator mannequins is similar to an average-sized full-grown adult, but the weight is significantly less than average (approximately 85 pounds). In addition to adult models, there are baby simulators, child simulators, and birthing simulators. Some models are wireless. This discussion focuses on the features and properties of the adult high-fidelity simulators available in 2018.

Limb and chest mobility. The upper and lower extremities of most programmable patient simulator models have very limited passive mobility with the exception of the shoulders, hips, knees, and ankles, which approach “normal” for an adult. The limited mobility of the limbs allows for some range of motion and bed exercises to be simulated. However, clinicians will note the completely passive, and somewhat awkward, nature of the movement and that the limb weight is significantly less than normal.

The chest wall moves realistically during ventilation. The excursion of the chest can be programmed to be symmetrical or asymmetrical in order to mimic specific clinical conditions. In addition, the rate and depth of ventilation can be manipulated during the course of a simulation.

Physiological features. High-fidelity programmable human patient simulators have realistic physiological features. A library of normal and abnormal breath sounds, heart tones, bowel sounds, and other sounds is available to aid in simulating a variety of clinical conditions. All of the breath sounds, heart tones, etc., can be changed during the course of a simulation to reflect a change in “patient” status during a scenario.

The simulation mannequins can be connected to multiple lines and tubes to simulate an acute care and/or critical care environment; for example, arterial line, intravenous line, nasogastric tube, electrocardiograph wires, and nasal cannula. Lines and tubes, appropriate for the simulated condition, add to the realism of the scenario. The presence of multiple lines and tubes allow the participant to practice identifying the lines and tubes, verify the patient status, and practice “clearing” the lines.

A patient monitor, similar to those found in critical care settings, is part of the setup to enhance realism. The monitor can be customized to display a number of different physiological variables including arterial blood pressure, pulmonary blood pressure, respiratory rate, cardiac rhythm, hemoglobin saturation, intracranial pressure, pH, temperature, and others. The value and number of variables shown on the monitor provide real-time patient data and can be programmed to change during the course of the simulation to simulate clinical conditions and/or a change in patient status.

Pulses are palpable in a variety of locations including the carotid, brachial, radial, femoral, popliteal, and dorsalis pedis pulses. The pulse is synchronized with the electrocardiogram (ECG), and the pulse strength can be varied during a simulation. When a simulation participant palpates the pulse, a notation is made in the computer log that specifies which pulse was palpated and at what point in time during the simulation the pulse was taken. In addition, when blood pressure is low, some pulses (e.g., the dorsalis pedis) are no longer palpable, simulating the clinical condition of systemic hypotension.

High-fidelity human patient simulators are capable of vocalizations using a variety of sounds stored in the simulation computer. However, the simulation operator is able to speak into a microphone and/or use audio files to produce sounds that appear to come from the mouth of the mannequin where a speaker is located. The capacity to converse in real-time greatly elevates the fidelity of the scenario.

Cyanosis is simulated through the use of a light contained within the mouth that makes the lips and gums appear blue. The eyes can form tears, the eyelids blink, and the pupils are reactive to light. The skin in the forehead is capable of diaphoresis. In some areas, the skin has “wound modules” that can be inserted and connected to ports that contain “blood” used to simulate bleeding from the wound site.

Cerebrovascular system features. High-fidelity human patient simulators can be programmed to display signs and symptoms consistent with an acute cerebrovascular accident (CVA) or traumatic brain injury (TBI). The simulator has the potential to display a slurred speech pattern, a drooping eyelid, asymmetrical pupils, and emotional lability. The simulator can state that their arm or leg feels heavy and that they cannot feel the limb. The patient monitor can be programmed to show a variety of changes consistent with an evolving CVA or TBI, such as changes in blood pressure, heart rate, intracranial pressure, and respiratory rate.

Cardiovascular and pulmonary system features. The onset of an acute MI is a scenario commonly used in simulation to train clinicians. The patient simulator can be programmed to complain of chest pain while simultaneously developing diaphoresis. The patient monitor can show the changes in the blood pressure, heart rate, respiratory rate, and cardiac arrhythmias consistent with an acute MI. Scenarios can be used to practice recognizing the signs and symptoms related to multiple acute medical conditions as well as to practice

interdisciplinary health care team responses to acute crises. The advanced features of the cardiovascular system include the capacity to bleed from a variety of portals. The system permits health care personnel to practice advanced cardiac life support (ACLS) protocols and to practice team responses to medical emergencies. The ACLS features built into the patient simulators measure and record the rate and depth of chest compressions, as well as hand placement, during CPR. This allows “coaching” of the participants’ CPR skills/technique in real-time.

The physiological response to a variety of drugs and clinical conditions is programmed into high-fidelity models. This feature allows participants to witness the response to the administration of medications as well as adverse drug reactions. The advanced clinical features for the pulmonary system include the ability to intubate (esophageal and endotracheal) and insert chest tubes into the mannequin, providing students and clinicians an opportunity to practice their clinical skills with “patients” who are intubated and/or have a chest tube. Some simulators allow the participant to practice pulmonary suctioning techniques.

A variety of cardiac arrhythmias are programmed into the patient simulators, and these can be displayed on the patient monitor, for example, atrial fibrillation and ST segment depression. This feature allows the operator to alter the ECG tracing on the patient monitor during the course of a simulation indicating a change in patient status. All of this physiological information is stored in the computer log and can be used during the debriefing session to enhance the learning experience for participants.

Programmability of Patient Simulators

In addition to the features discussed previously, high-fidelity simulators have the capacity to be defibrillated and undergo cardioversion. The physiological response to many drugs and clinical conditions is programmed into some models so that participants can witness the acute response to the administration of medications as well as adverse drug reactions and/or the physiological response to the acute onset of a clinical condition (e.g., acute MI). In addition, instructors can design custom simulations to meet specific instructional needs and learning objectives.

Costs of Establishing a Simulation Laboratory

The costs associated with establishing a simulation laboratory will vary with the type of programmable human patient simulator selected, additional equipment required and/or desired, and the amount of training needed. High-fidelity programmable human patient simulators can cost \$100,000 to \$200,000 for top-of-the-line models with state-of-the-art features. However, the price of the simulator(s) is only a portion of the setup costs. Establishing a simulation laboratory will also require (1) space designed for the simulation laboratory; (2) audiovisual equipment; (3) networking infrastructure; and (4) training in how to operate the system. The cost for each of these individual components can vary markedly depending on the type of equipment and infrastructure present as well as the level of sophistication desired in terms of audiovisual and networking capacity.

SUMMARY

Each new generation of programmable human patient simulators has improved our ability to teach excellence in examination, assessment, and problem solving in acute, critical care situations. Programmable patient simulators have advanced in (1) the degree of realism provided by the technology and (2) the ability of the operator to manipulate and alter the “patient” status at any point in time. Human patient simulators are now found in multidisciplinary clinical teaching centers

in academic health care institutions. They have been incorporated into community-based training courses for practicing health care professionals. A high degree of realism can be provided during simulation using currently available robotics when high-fidelity simulators are placed in a realistic mock intensive care unit. The combination of a high-fidelity patient simulator and a realistic environmental setting provides an opportunity to train rehabilitation professionals to recognize and respond to changes in patient status and to practice working as members of an interprofessional health care team without compromising patient safety.

Wearable Inertial Sensors

Introduction

Assessment of mobility is complex because it includes many different neural control systems associated with balance and gait, as well as adaptive mechanisms for maintaining mobility under altered conditions.⁵⁷ Neurorehabilitation is particularly challenging since there is not one specific joint angle or measure to focus on for assessment and treatment. However, it is well accepted that balance and gait should be evaluated and monitored in patients with neurological deficits. Clinical characterization of balance and gait abnormalities can be highly dependent on examiners’ expertise since subjective rating scales are typically used in the clinic.^{58,59} Furthermore, there is a need for sensitive and objective documentation of deficits, either for recovery or decline, to help incrementally measure performance at all levels of disability. Although there are many performance-based, clinical tests of balance and gait, many tests suffer from ceiling effects in highly functioning or compensated individuals.^{58,60} Sophisticated laboratories have been characterizing balance and gait disorders for many decades, but it has not been practical for physical therapy practitioners to routinely use information obtained in the gait laboratory for clinical decision making. In the majority of circumstance, gait laboratories and clinical spaces are entirely separate. However, these laboratory measures of balance and gait are now becoming available to physical therapists via new technologies involving small, body-worn, wearable inertial sensors. Over the past 15 years, advances in wireless technology, such as small wearable inertial sensors, have emerged as a viable tool for objective movement assessment.⁶¹ This chapter will provide an overview of the potential uses, benefits, and obstacles of utilizing wearable sensors in the field of neuro-rehabilitation.

What Are Wearable Inertial Sensors?

Wearable inertial sensors, also called movement monitors, are small and lightweight sensors embedding usually a tri-axial accelerometer, tri-axial gyroscope, and magnetometer (for heading measures with respect to the earth magnetic field). One or more sensors placed on different parts of the body are used for mobility assessment, and synchronized data can be collected from multiple sensors, with high frequency data-sampling. Clinical user-interfaces that provide useful information and sophisticated automatic data analysis are transforming this technology for clinical use. In fact, body segment orientation and displacement in space can now be measured, replacing more expensive, time-consuming, and nonportable, motion analysis systems in laboratories.^{62–64} This means that joint range of motion can be measured accurately during dynamic movements, such as gait, lunges, and stair climbing, not only in static conditions, as with goniometers. Thus gait measures, such as stride length, pitch ankle of the foot at heel strike, and foot clearance from the floor, can now be calculated from these inertial sensors.^{65–67}

Some commercial systems have only one sensor, placed on the lumbar region, which allows a physical therapist to measure postural

sway and, sometimes, temporal characteristics of gait, such as cadence, trunk stability, and number of steps (e.g., *McRoberts*, *SwayStar*, *BTS*). Other systems include a sensor on each foot to more fully characterize the spatial and temporal characteristics of foot motion during gait and turning (*GaitUp*, *APDM*, and *BioSensics*). Currently two systems (by *APDM* and *BioSensics*) allow additional synchronized sensors on the legs, trunk, and arms that allow full body characterization of balance, gait, and postural transitions, such as sit-to-stand and turning. Multiple inertial sensors can also be used to measure kinematic joint angle movements (*Xsens*), but clinically friendly systems with simple user-interfaces are needed. It is important for physical therapists to consider the quality and quantity of the validation and reliability studies of movement monitor systems as well as their ease of use, quality of reports, and supported clinical protocols, such as the Timed Up and Go (TUG) and Clinical Test of Sensory Integration for Balance (CTSIB).

Wearable inertial sensors are different from activity monitors. Activity monitors have been around for 50 years and are designed to measure the *quantity* of movement, such as how long a person is walking or running or when they are sedentary versus active. Activity monitors, such as the *StepWatch*, *activPAL*, and *Actigraph*, use only accelerometers (either uni-axial or tri-axial) to detect the number and size of acceleration spikes associated with body motion, usually to count steps or calculate time spent in different postures.^{68–70} Activity monitors are popular devices for lay consumers because they can count steps per day (such as pedometers), hours of sleep (from periods of nonmoving, and horizontal posture), time spent in different postures (walking, lying down, and sitting), sedentary time, and estimates of calories burned and cadence (steps per minute). Usually, a single activity monitor is worn on the wrist or belt. They also have the advantage of a long battery life, with up to 30 days of continuous recording, and they are increasingly inexpensive. However, physical therapists should be cautioned about using widely available consumer devices, such as smart phone applications and exercise devices (e.g., *Jawbone*, *Basis*, and *NikeFuel*), in their clinical practice because they have not undergone validity testing for accuracy or reliability, especially with patient populations. Activity monitors of any type provide limited information on gross activity patterns and cannot provide physical therapists information on quality of movement, joint kinematics, or motor impairments.

Can Wearable Sensors Improve our Assessment of Balance and Gait in the Neurological Population?

Wearable inertial sensors have the potential to improve physical therapy assessments by (1) providing objective measures at the impairment

level, (2) providing a greater sensitivity to detect subtle changes in balance and gait, and (3) providing data on gait and balance during regular daily function (home monitoring).

Measure Impairment

A key recommendation from the International Classification of Functioning, Disability and Health framework (ICF) is to assess a person across several levels of function and disability to include items measuring participation, activity, and impairments.⁷¹ Many validated scales used in physical therapy measure participation (i.e., quality of life or balance confidence) and activity (i.e., Berg Balance Scale or TUG). Impairments are problems in body function and structure, such as significant deviation of symmetry, muscle weakness, or increased postural sway. An accurate impairment-level assessment of balance and gait is often difficult to obtain, but wearable inertial sensors during activity-based assessment may help. Wearable inertial sensors have recently been used to quantify aspects of mobility during the TUG test, CTSIB, and 2-minute walk.^{72–83} Although each of these assessment tools fall under activity level assessment, adding inertial sensor information may provide impairment level details. These objective impairments can then be used by physical therapists to precisely target and monitor progress in their therapy (Fig. 38.6).^{84–86}

Detect Subtle Deficits

Assessment tools that objectively capture deficits in the mildly impaired population are an important goal for neurorehabilitation therapists.^{87–90} To make measurable treatment goals, the physical therapist must first identify objective measures of gait and balance to target. Reimbursement of physical therapy services requires evidence of the problem⁹¹ and of gradual improvement with therapy. Many clinical balance scales and stopwatch measures are insensitive to mild impairments in high-level performers,^{58,92,93} such as athletes and military populations. Even in those people with early stage disease, there is evidence to support early rehabilitation intervention for promoting neuroplasticity, emphasizing the value in early detection of balance and gait problems.

Recent research has shown added value, over traditional clinical measures, of objective measures in several neurological populations, such as multiple sclerosis (MS), Parkinson disease (PD), and mild traumatic brain injury populations (mTBI).^{77–80} For example, although patients with very mild, untreated PD have normal 3m TUG performance time compared to age-matched controls, (10.8 ± 0.5 seconds

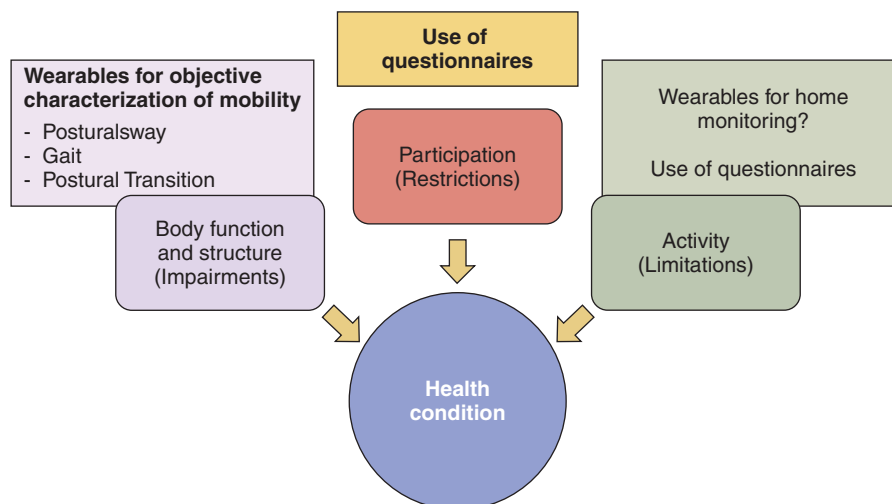

Fig. 38.6 Integrative Model of Functioning and Disability.

vs. 9.9 ± 0.3 seconds, respectively), they show other impairments in quality of walking and turning.⁹⁴ Interestingly, sometimes the same parameter can be impaired in a different neurological population but in the opposite direction (see example in new Fig. 38.7 for the trunk rotation during gait). This measure is a lower than normal value in untreated PD but is higher than normal in mild MS. These results are important since a physical therapist would address each one very differently to improve this aspect of gait.

Several studies have shown that patients with mTBI, both chronic and acutely concussed, may have normal Balance Error Scoring Systems (BESS) scores but simultaneously have abnormal postural sway profiles during the same test.^{92,95} The BESS relies on the examiner to count how many errors the person makes during progressively harder stance positions, while the sensor objective details several aspects of postural sway such as amplitude, velocity, frequency, and jerkiness. Particularly, we found in a population of 76 healthy controls and 52 mTBI that the objective measures of the instrumented BESS outperformed the clinical BESS, even in the simple double stance condition (Fig. 38.8).⁹⁵

Fig. 38.7 Group mean and standard errors of trunk rotation during gait (instrumented 7 m Timed Up and Go) in healthy control, people with mild multiple sclerosis ($n = 31$), and people with mild Parkinson disease ($n = 12$).

Fig. 38.8 ROC curves to discriminate among healthy controls and people with mild traumatic brain injury populations for the clinical mBESS errors count, and instrumented mBESS models of one or a combination of two postural sway objective measures. mBESS, Modified Balance Error Scoring System; RMS ML, root mean square medial-lateral; ROC, receiver operating characteristics. (Modified from King LA, Mancini M, Fino PC, et al. Sensor-based balance measures outperform modified balance error scoring system in identifying acute concussion. *Ann Biomed Eng.* 2017;45[9]:2135–2145.)

Fig. 38.9 Stride time for each gait cycle over 2 minutes of walking in a representative healthy control and mild traumatic brain injury (mTBI) subject. Larger spread indicates larger variability of gait. (Modified from Horak F, King L, Mancini M. Role of body-worn movement monitor technology for balance and gait rehabilitation. *Phys Ther.* 2015;95[3]:461–470.)

This distinction may occur in gait in this population as well. For example, Fig. 38.9 compares step-by-step stride duration during a 2-minute walk in a person with mTBI and a representative control subject. Such increase in variability of stride time while walking is indicative of dynamic balance deficits during gait.⁹⁶ These relatively “high-level” mobility impairments could easily be missed by physical therapists limited to traditional balance and gait testing.

Home Monitoring

Assessment of mobility in the clinic does not always reflect mobility in daily life. It is often reported that patients walk better when they are examined in an outpatient clinic or in a research laboratory than at home. This phenomenon is known as the “white coat effect”; physical therapists who work in both the clinic and in-home health care settings may be familiar with this concept. Motor performance can be changed depending on attention, alertness, and effort to impress the examiner during testing. Therefore mobility measured during functional activities of daily life can provide further insights on function, disability, and the effect of therapies. Recent advances in better battery life and ease of use point to the possibility of continuous and/or home monitoring of specific aspects of movement. Several research groups have demonstrated feasibility including new studies that take place in the home and community settings using wearable, lightweight inertial sensors to measure mobility for multiple days.^{97,98} Novel measures of turning and gait characteristics, calculated from wearable inertial sensors, enable a detailed analysis of mobility over weeks of continuous monitoring. Previously, continuous monitoring was limited to use of activity monitors to measure the quantity of activity, but now inertial sensors allow continuous monitoring of quality of activity.^{97–99} Although this approach to measurement holds promise, it is primarily limited to research studies at this point. In particular, research has been focusing on gait bouts characteristics and turning, from either a single sensor on the belt, or three sensors (two on the feet and one on the belt).^{97–105} Novel measures determined from both accelerometers and gyroscopes enable a detailed analysis of variability, consistency of gait bouts and turning in both healthy and neurological populations. However, standardization or a consensus on a specific set of measures and on a definition of gait bout at home are still missing.¹⁰⁰

Can Wearable Sensors Improve Treatment for Balance and Gait in the Neurological Population?

Impairment-Focused Rehabilitation

Rehabilitation focused on improving mobility may benefit from having sensitive, quantitative measures of specific impairments underlying balance and gait disorders. Performance tests of mobility, such as the Berg Balance Scale or the TUG, measure whether an individual can accomplish tasks, such as turn in a circle or walk a particular distance. However, inertial sensors provide objective measures of impairments documenting *how* and *why* the individual's balance and/or gait is impaired. Physical therapists can then use objective measures to guide their exercise programs to specific impairments.

Specific balance and gait impairments identified by inertial sensors are potentially modifiable when therapy is targeted to the impairments. Consider the two groups of patients with mild disability in Fig. 38.7, one with MS and the other with untreated PD. Both groups had normal gait speed, measured with a stop-watch during the Time-to-Walk 25 feet (T25FW) or the TUG. However, both groups showed abnormal balance and gait characteristics with instrumented tests. Specifically, both groups showed significant impairments in the rotation of their upper trunks while walking.^{83,106} However, the patients with PD showed significantly *decreased* trunk rotation, whereas the MS patients showed significantly *increased* trunk rotation during gait, compared to healthy subjects. Therefore therapy focused for the PD group may be focused on increasing trunk rotation, such as by increasing arm swing and reducing axial rigidity, whereas therapy for the MS group may be focused on decreasing trunk instability during gait, as by increasing core strength and use of a cane. In contrast, when physical therapists are limited to measuring only the duration of the TUG, which was normal in both groups of patients, it may be more difficult to justify, focus, and measure effects of therapeutic intervention.

Therefore different impairments may reflect problems with different, independent, neural control systems.^{107–109} Identification of specific types of balance problems allows for more specific rehabilitation to remediate the constraints on safe mobility.¹¹⁰

Biofeedback Rehabilitation

An important role of the physical therapist is to provide patients with accurate feedback about their performance and movement errors. Wearable inertial sensors have great potential to augment feedback (biofeedback) using more immediate and more sensitive feedback than therapists can apply without technology. Biofeedback is an approach that can use technology to provide biological information to patients in real-time that would otherwise be unknown.¹¹¹ Thus biofeedback complements normal internal feedback and acts as an additional “sixth sense” or as “sensory substitution” for patients who have lost sensory function. For example, we are currently using an audio-biofeedback approach in patients with mTBI who have excessive postural sway during quiet stance, when vision is limited.¹¹² In this project we will compare standard vestibular rehabilitation with the same rehabilitation program using real-time audio-biofeedback to reduce postural sway and provide feedback on body position. Audio-biofeedback is applied as a tone that increases in volume as postural sway increases, with more sound in the right ear during right direction sway and in the left ear during left direction sway. Forward and backward sway are indicated by a high-pitch tone and low-pitch tone, respectively. Since it is not possible for physical therapists to manually provide quick, accurate feedback about postural sway, biofeedback can supplement balance training (see example in Fig. 38.10).

Wearable sensors based-biofeedback is currently being developed to train dynamic tasks such as walking and turning. Preliminary data

Fig. 38.10 Reduction of postural sway with audio-biofeedback from a wearable inertial sensor on the belt during stance on a firm surface with eyes closed in a patient with a mild traumatic brain injury. (Modified from Horak F, King L, Mancini M. Role of body-worn movement monitor technology for balance and gait rehabilitation. *Phys Ther.* 2015;95[3]:461–470.)

in the laboratory have demonstrated the validity and efficacy of a tactile biofeedback system to improve turning in a cohort of 43 people with PD.¹¹³ The data collected with a *tactile biofeedback* prototype showed a significant improvement in turning mobility in the laboratory in 23 people with PD and freezing of gait (FoG) and 18 people with PD without FoG of similar age (70 ± 7 years old vs. 69 ± 7 years old), disease duration (8.2 ± 4.7 years vs. 9.3 ± 6.5 years), and MDS-UPDRS III (43.6 ± 11.6 vs. 47.1 ± 10.1). Subjects turned in place for 1 minute (changing turning direction after each 360 degree turn) in a single- and dual-task (counting backward by threes) for three randomized conditions: (1) baseline (no cues); (2) turning to the beat of a metronome (open-loop); and (3) turning with phase-dependent tactile biofeedback (close-loop). All subjects who reported FoG showed mild-to-moderate freezing during the assessment. Objective measures of freezing, such as the percentage of time spent freezing and FoG ratio, were decreased when turning with both open-loop and close-loop cueing compared to baseline (Fig. 38.11A). The dual-task did not worsen FoG in freezers, but significantly slowed down turns in both groups. Both cueing conditions significantly improved turning smoothness in both groups (see Fig. 38.11B), and reduced turning velocity and number of turns compared to baseline. Interestingly, it was found that the benefit obtained with the biofeedback persisted during a turning task with a concurrent cognitive task, suggesting that these benefits could translate during everyday life. In addition, the slowing of turning with cueing has been previously reported^{114–117} and could be seen as improvement considering that we previously found that larger postural instability is associated with fast turns by people with PD.^{118–119}

This technology is not yet available for clinical practice, but we foresee integration of this and other systems in rehabilitation to compliment and reinforce the therapist feedback in the clinic, and ultimately, may be used to help the patient at home (Fig. 38.12).

Important Considerations in Wearable Inertial Sensors for Balance and Gait Rehabilitation

There are some important obstacles to consider when implementing wearable inertial sensors for neurorehabilitation. A major barrier to use in the clinic is the added training and time it will take for the physical therapist to add wearable inertial sensors to the evaluation (clinical utility, Fig. 38.12). Furthermore, it is unclear how billing will be handled for insurance claims.

Moreover, an ideal system based on wearable inertial sensors should be cost-effective, user friendly, and easy to use and administer (feasibility and practicality). It is of paramount importance that the

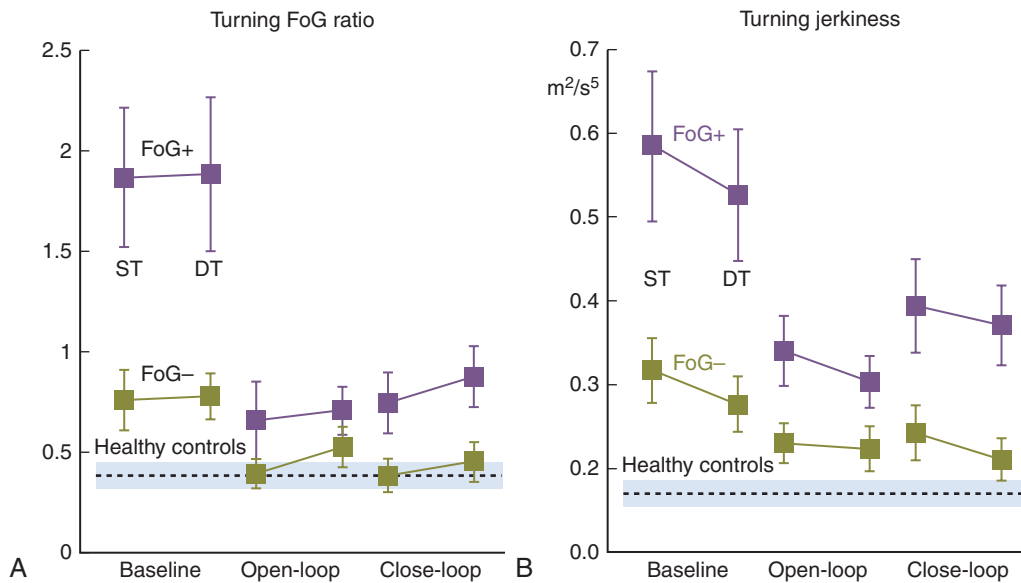

Fig. 38.11 (A) Freezing severity, measured by the FoG ratio for baseline, open-loop and closed-loop conditions in freezers (FoG+) and non freezers (FoG-) for both single-task, ST and dual-task, DT. **(B)** Turning jerkiness in the same conditions.

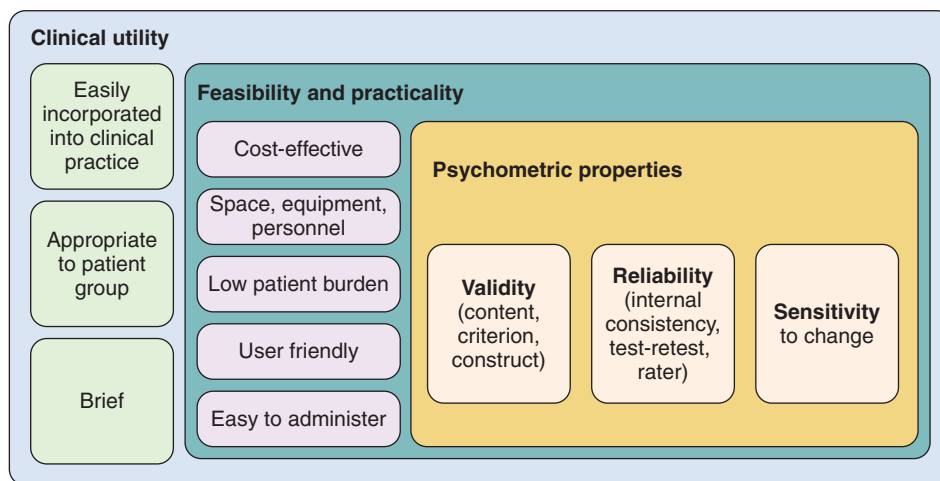

Fig. 38.12 Summary of General Requirements for Outcome Measures.

end-user of wearable inertial sensors systems understands the provided measures of mobility, and with the rapidly changing products in the market it is important to research the specific clinimetrics (validity, reliability, and sensitivity to change). As many measures extracted from wearable inertial sensors are novel, minimal detectable change and minimal important clinical difference have yet to be established.

Future Direction/Conclusions

It is an exciting time to follow the interface of technology with clinical neurorehabilitation for assessment and treatment of our patients. Ideally, the best products for use would have input during development from the end-user, the physical therapist. It is predicted that physical therapists will soon use inertial sensors to evaluate balance and gait continuously, during daily activities for more ecological and realistic understanding of patients’ mobility in the real world. Physical therapists will soon be able to incorporate real-time biofeedback to improve motor learning and motor performance both during a regular training session as well as remotely. With technology becoming more and more

accessible and pervasive, physical therapists need to critically evaluate the advantages and limitations of implementing emerging technologies, such as body-worn sensors, into their clinical practice.

Virtual Reality Technology

Introduction

VR is defined as an approach to user-computer interface that involves real-time simulation of an environment, scenario, or activity that allows for user interaction via multiple sensory channels.¹²⁰ The use of VR allows for interaction between the patient and a computer-generated, three-dimensional environment.¹²¹ In VR, the user networks with an artificial world through visual, aural, and haptic interfaces. Other ways of interaction with a VR environment include a computer mouse, a joystick, or using VR goggles.¹²² In some instances, the VR technology allows for customization of avatars, which provide the person another way of immersing the physical body into the VR environment.¹²³

Following a neurological injury, the ability to interact with the environment can be limited by physical impairments. The availability of VR technology allows a person to interact with a realistic replica of physical space or certain situations. This has contributed to the rapidly emerging use of VR in neurological rehabilitation. This section will discuss the use and potential clinical application of VR in patients with neurological dysfunction.

The Rationale for Virtual Reality in Rehabilitation

The facilitation of neuroplasticity is what underpins neurological rehabilitation. However, not one therapy intervention is able to address the core principles of neuroplasticity.³ As such there is an impetus for the therapist to find multiple, novel ways to facilitate neuroplastic change and to enhance functional recovery following a neurological injury.

Following a neurological injury, the resulting impairments often lead to activity restriction and eventually to limited participation with one's role in life and society. The use of VR has shown potential in being able to address impairment, disability, and handicap.¹²⁴ Following damage to the central nervous system, there is often an inability for a person to actively engage and interact with the environment and surroundings. This can often lead to a lack of sensorimotor stimulation and creates an impoverished environment in which one recovers.

Numerous studies in animal models have demonstrated the positive effect of environmental enrichment on the brain. Increases in brain weight¹²⁵ and cortical thickness¹²⁶ after environmental enrichment have been reported. Synaptic plasticity has also been reported after exposure to an enriched environment with studies demonstrating increased synaptogenesis,¹²⁷ synaptic strengthening,¹²⁸ neurogenesis,¹²⁹ and increased dendritic branching, length, and density.¹³⁰ The influence of an enriched environment has also been positive in the injured brain. Rats given experimental brain lesions and housed postoperatively in enriched environments were shown to perform significantly better than rats housed in impoverished environments.¹³¹ The enriched environments comprised of opportunities to perform different activities and social interaction with other rats. The social interaction component when combined with an enriched environment was further shown to result in the best outcome.¹³² The mechanism behind the beneficial effects of an enriched environment in postinjury outcome has been attributed to the increased synthesis of neurotrophic factors.¹³³ Neurotrophic factors are thought to be capable of promoting the neuronal survival and are likely to be involved in synaptic reorganization and alteration in receptor expression.^{133,134} As neuronal changes in response to an enriched environment have been documented in the cortex, hippocampus, cerebellum, and striatum, future studies should look into its therapeutic benefits. Stimulation from an enriched environment may prove to be an important causative factor in enhancing functional plasticity following neuronal injury and damage.

Emerging experiences that bring about motor learning can also drive plastic changes in the motor cortex. The use of VR has inherent attributes that can lead to experience-dependent plastic changes and motor learning.¹³⁵ One key principle of neuroplasticity centers around the concept of practice.³ The need for constant, intense, contextual practice is thought to be a major driver of plastic changes in the brain. With VR, clinicians are given a variety of conditions in which practice can be manipulated¹³⁵ and enable frequent and task-specific training.

Feedback is another major component in motor control and learning.¹³⁶ With VR, there are multiple sources of feedback comprising visual, auditory, and tactile.¹³⁵ This augmented feedback has been shown to have merit in terms of recovery of function in a stroke population.¹³⁷ The ability of controlling the type of feedback has added benefits in tailoring VR experiences to a particular patient's needs or goals.¹³⁸ Motivation is another key driver of motor learning.¹³⁹ Often

because of the resulting physical impairments from a neurological injury, patients are not motivated to move because of the associated difficulty and increased effort needed for movement. The visual, auditory, and tactile feedback a person receives from VR can be used easily by clinicians as an effective motivation tool.

The motor imagery that is triggered by VR can induce the activation of mirror neurons.^{140,141} Mirror neurons are activated by observation and fire the same way as when one actively moves.¹⁴² This ability to respond through perception and execution makes the activation of mirror neurons attractive in the rehabilitation and recovery of function. Practicing within a VR environment allows for observational experience and, theoretically, may enhance physical practice of a task.¹⁴³

Clinical Application of Virtual Reality

With the potential for enhancing neuroplasticity at hand, there has been an increase in studies reporting the benefits of using VR (Fig. 38.13; a video example can be found at: www.youtube.com/watch?v=IT3Klg7_KVo) in neurological rehabilitation. Using 3D-simulated tasks practiced through a desktop computer, improvements were noted in the performance upper limb functional tasks in one of the two subjects presented in a case report.¹⁴⁴ In a bigger sample, enhanced feedback from VR was evaluated in terms of improving arm function in patients with stroke.¹⁴⁵ Following 1 hour of daily VR training in a month, improvements over baseline values in the mean scores on the Fugl-Meyer (FM) and Functional Independence Measure scales were reported. In comparing conventional therapy with one that is supported by VR, both groups were able to demonstrate improvements in FM scores with greater improvements observed in patients who had additional VR training.¹⁴⁶

The effects of VR on gait parameters have also been explored. Using a treadmill mounted on a 6-degrees-of-freedom motion platform with a motion-coupled VR environment, patients with stroke were able to demonstrate increased gait speed and improved their ability to adapt to physical terrain.¹⁴⁷ The subjects received auditory and visual cues as a form of positive/negative feedback. In a comparison of a robot-assisted rehabilitation protocol with or without VR support, improvements in moments and powers generated in the ankle and hip of subjects in the robot-VR group were significantly greater than those in the robot-alone group.¹⁴⁸ A meta-analysis of 21 studies looking into the effects of VR training on balance and gait suggested that balance and gait training using a VR environment was more effective than balance and gait training without VR.¹⁴⁹

The immersive nature of VR has been used in cognitive rehabilitation. A computer-simulated virtual kitchen was used to assess the ability to process and sequence information in a group of patients with

Fig. 38.13 Scene From a Virtual Reality Simulator. (Courtesy of Add-Life Technologies.)

brain injury and volunteers without brain injury.¹⁵⁰ Although this was not used as a therapeutic tool, the study reported the merit of using a computer-generated VR environment assessing cognitive function in persons with acquired brain injury. In a reported case study, VR was used to assess and train people with memory issues.¹⁵¹ The subject was trained using a detailed computer-generated nonimmersive 3D virtual environment based on a route of an actual rehabilitation unit. Following 2 weeks' training, the subject was able to learn the route practiced in the virtual environment, but not the route practiced in the real unit, and retained her knowledge of the route in the virtual environment.

The ability of VR to provide training in a controlled and standardized setting has given it merit as a therapeutic tool in facilitating recovery following a neurological injury. Clinicians are also able to tap into the novel concept of VR to enhance neuroplasticity. The challenge there is for developers of VR technology to update the settings and scenarios to prevent adaptation and boredom with the system. The clinical effectiveness of VR in neurological rehabilitation, although increasingly being reported, lacks the statistical power to warrant recommendation as part of standard rehabilitation practice. As with most emerging technologies, further investigation into the principles, parameters, and variations of VR is needed to allow clinicians and patients to make an informed choice regarding its use in rehabilitation.

Noninvasive Brain Stimulation in Neurological Rehabilitation

Introduction

The development of noninvasive brain stimulation (NBS) techniques have enabled a quick, easy, and well-tolerated method of studying brain function in normal and pathological conditions. NBS also has been used to modulate the excitability of the cortex and enhance the functional plasticity of the brain. The clinical use of NBS has been studied in patients with stroke, PD, dementia, and other neurological conditions. Numerous studies have reported the use of NBS as a diagnostic and prognostic tool after a neurological issue as well as using NBS as a neuromodulation adjunct in rehabilitation and therapy.

The use of NBS in a therapeutic environment has primarily been aimed at modulating cortical excitability. NBS is used either to increase the excitability of the damaged motor cortex or to inhibit the activity of the intact cortical hemisphere. This neuromodulation has also been reported to balance neural activity between the two cortical hemispheres following injury. Furthermore, NBS has been reported to induce changes in synaptic efficiency, which can be used to drive motor relearning and the recovery of function.

This section will discuss two NBS techniques involving the use of transcranial magnetic stimulation (TMS) and transcranial direct current stimulation (tDCS).

Transcranial Magnetic Stimulation

TMS (Fig. 38.14) is a common technique used to activate and test propagation of impulses from the central to the peripheral nervous system. First introduced by Baker in the 1980s, TMS allows for an easy, painless and noninvasive method in obtaining information regarding the excitability of the nervous system and the functional integrity of neural structures and connections.¹⁵² TMS also provides valuable, quantifiable measurements such as motor evoked potentials (MEP), conduction time, and cortical maps, which offer variables such as map area, map volume, and center of gravity (CoG). These variables are often used to describe and detect the subtle changes associated with neural plasticity.^{153,154}

TMS works on the principle of electromagnetic induction. A high-current pulse is passed through an insulated coil, which induces a magnetic field that then passes painlessly through tissues. This magnetic field

Fig. 38.14 Transcranial Magnetic Stimulator.

Fig. 38.15 Motor Evoked Potential (MEP).

runs perpendicular to the plane of the coil.¹⁵³ When the coil is held over the scalp, the skull offers very little impedance to the magnetic field produced. As the magnetic field passes through, it induces electric currents or eddy currents that flow at right angles to the magnetic field.^{153,155} With the appropriate current direction, duration, and amplitude, depolarization of the motoneuron pool will occur and generate an MEP on the target muscle.¹⁵⁶

The MEP (Fig. 38.15) is a common reference used to assessing corticospinal excitability in both normal individuals and those of neurological dysfunction.^{157,158} The amplitude of the MEP indicates the integrity of the corticospinal tract and that there is intact propagation of impulses from the cortex to the nerve roots, down to the target muscle. In addition, the amplitude gives an indicator of the size of corticospinal projection to a given muscle as well as the excitability of the projection.^{159,160}

Apart from MEP, other TMS variables reported include central conduction time¹⁶¹ and motor threshold.¹⁶² TMS is also used to produce cortical representational maps of areas of the motor cortex in normal and pathological populations.^{163–166} These TMS variables provide objective and quantifiable measures to describe and detect the subtle changes associated with neural plasticity.¹⁵³

As TMS provides focal stimulation of the motor cortex, the excitability of the cortex can theoretically be easily influenced. TMS offers differing stimulation parameters that can either induce cortical inhibition or cortical excitation.^{167,168} Repetitive transcranial magnetic stimulation (rTMS) (Fig. 38.16) is a form of NBS used to drive cortical excitability and facilitate functional plasticity of the brain.

Fig. 38.16 Repetitive Transcranial Magnetic Stimulation.

Using a series of repetitive transcranial magnetic stimuli, rTMS at a low frequency (<1 Hz) has been shown to induce inhibition in the corticospinal network, while stimulation at a high frequency (>5 Hz) increases cortical excitability.^{169,170}

Using high-frequency TMS bursts at 30 to 50 Hz at theta frequency has also been used to modulate cortical excitability.¹⁷¹ Theta Burst Stimulation (TBS) is a form of rTMS that also leads to facilitatory and inhibitory effects on the motor cortex.¹⁶⁷ The desired effect of TBS works on the timing on when you apply the burst. Huang and colleagues showed that using a continuous TBS (3 stimuli at 50 Hz repeated every 200 ms) resulted in a suppression of MEPs.¹⁶⁷ Subsequently, using an intermittent TBS pattern (a 2-second train repeated every 10 seconds for a total duration of 190 seconds) resulted in the facilitation of MEPs.

It has been proposed that combining peripheral afferent stimulation with low-frequency transcranial brain stimulation facilitates changes in cortical excitability. Using a paired associative stimulation (PAS) paradigm, synchronously combining median nerve stimulation with low-frequency TMS over the optimal cortical activation site for hand muscles showed significantly increased resting MEP amplitude for abductor pollicis brevis.¹⁷² The improved MEP was conditionally dependent on the timing of the arrival of the afferent stimulation and the TMS on the motor cortex. In addition, the plastic changes induced by synchronously pairing stimulation evolved rapidly, persisted, reversible, and remained topographically specific. Using a similar dual stimulation protocol, significant changes in excitability were seen together with cortical expansion of the scalp representation area for First Dorsal Interosseus (FDI).¹⁷² The expansion was accompanied by a significant movement of the CoG of the cortical map taken from FDI and the changes observed persisted for at least 2 days. The changes observed in the stimulated muscles persisted for up to 5 days without the need for further stimulation. It has been suggested that the immediate neuroplastic changes associated with a dual stimulation intervention may be analogous to mechanisms that involve fast-learning of a motor task. With repeated sessions of dual stimulation, these changes were found to be persisting and long-lasting and indicate that a process of consolidation maybe taking place.¹⁷³ The persistent and prolonged changes reported may have therapeutic value and provide another method of improving motor control and function in people with neurological injury.

Using Transcranial Magnetic Stimulation in Rehabilitation

The ability of using TMS to modulate cortical excitability has made it an attractive tool in neurological rehabilitation. Its application has been reported in patients with stroke, PD, and dementia, to name a

few. Using the ability to facilitate or inhibit cortical excitability, TMS has been shown to influence improvements of function in people with neurological issues.

The clinical application of TMS has been widely reported in stroke rehabilitation. It has been proposed that following a stroke, the inhibitory interactions between the two hemispheres are affected and can contribute to impaired function. There is a mutual transcallosal inhibition that occurs between the two hemispheres, but this is usually asymmetrical with the dominant hemisphere (usually the left) providing more inhibition to the nondominant hemisphere.¹⁷⁴ Following a right hemisphere stroke, the interhemispheric inhibition would be lost with the left hemisphere becoming even more dominant and providing more inhibition to the usually less dominant and now injured right hemisphere. This hyperexcitability of one hemisphere usually contributes to patients showing neglect or issues with spatial awareness on their affected side. In such situations, it is feasible to consider using TMS to decrease the excitability of the unaffected hemisphere and to modulate the balance of excitation and inhibition between hemispheres. Improved motor function of the paretic hand was demonstrated using rTMS with improved scores on with the pegboard test, and improved reaction times and force production.^{175,176} Using an inhibitory rTMS protocol over the stroke-lesioned parietal cortex have demonstrated improvements in the clock drawing and line bisection tests.¹⁷⁷⁻¹⁷⁹ Significant improvements were also reported following use a continuous TBS (cTBS) protocol in outcome measure scores of the affected hand.¹⁸⁰⁻¹⁸² Although current literature is showing great potential for using rTMS to downregulate the intact hemisphere to address motor function in stroke, most of the studies have not reported any long-term follow-up and thus puts into question the possible long-term benefits of its therapeutic use. As with most approaches in physical therapy, longer, larger, and more robust trials are needed to inform rehabilitation practice.

Following a stroke, MEPs elicited by TMS have been shown to be delayed or absent^{183,184} and the intensity of stimulation needed to evoke an MEP higher.¹⁸⁵ There is also great variability of MEP amplitude in people with chronic stroke when compared to healthy adults or the contralesional hemisphere.¹⁸⁶⁻¹⁸⁸ The MEP response latencies were also reported to be longer in the stroke-affected side when compared to the unaffected side and was associated with impairments of the upper and lower limbs.^{189,190} These parameters have been used to assist in the prognosis of motor and functional recovery following stroke.¹⁹¹⁻¹⁹³

The ability of TMS to increase the excitability of the cortical network has been extensively reported. The use of high-frequency rTMS has been shown to assist in improving hand function across the different stages of stroke. In a group of patients in the acute stage of stroke, rTMS was shown to significantly improve disability scores following 10 days of stimulation combined with usual rehabilitation treatment.¹⁹⁴ Significantly larger MEP amplitudes were reported following rTMS of the affected hemisphere.¹⁹⁵ The increased MEP amplitude was also accompanied by improved accuracy in a sequential finger motor task. Improvements that lasted up to 1 week were also seen following rTMS in grip strength, range of movement, and pegboard scores.¹⁹⁶ In two groups of patients in the subacute stage of stroke who received either rTMS or sham TMS, improvements were noted for the Motoricity Index and the Box and Block test. The rTMS group showed additional improvements in motor function in the FM assessment.¹⁹⁷

Changes in motor cortex excitability following rTMS targeting the lower limb areas in patients with stroke has also been reported. Applying rTMS for 20 sessions combined with physical therapy showed a significant improvement in gait velocity and TUG scores, as well as a significant reduction in physiological cost index measures.¹⁹⁸ This preliminary study also reported that using high-frequency rTMS at 10-second bursts at 10 Hz with 50-second intervals for 20 minutes was safe and well

tolerated. Improvements in the 10 m walk test was also reported following 3 weeks of high frequency rTMS.¹⁹⁹ The effects persisted for 4 weeks but did not reach statistical significance owing to the small sample size. A randomized controlled trial using rTMS plus task-oriented training on people with chronic stroke showed improvements in motor control and walking ability.²⁰⁰ The study used a 1-Hz stimulation frequency over the leg area of the motor cortex of the unaffected hemisphere for 10 minutes. This resulted in a reduction of interhemispheric asymmetry of MEP amplitude and increased cortical excitability as well as improved lower limb impairments. However, the subjects showed measurable MEPs from their rectus femoris, which may indicate that they may already have a higher level of function.

The use of rTMS also has been reported in the treatment of post-stroke dysphagia where the stimulus is usually applied to the pharyngeal/oropharyngeal motor cortex. This application of rTMS resulted in increased corticobulbar excitability, improved swallowing, and deglutition in both acute and chronic stroke patients.^{194,201–203} Alongside conventional rehabilitation, the use of rTMS seem to provide a novel therapy in the management of swallowing issues after a stroke.

Improvements in motor function also has been reported from the application of PAS in people with stroke. In a pilot study combining TMS with a 10-Hz stimulation of the peroneal nerve, a dual stimulation paradigm was able to show an increase in neurophysiological (Fig. 38.17) and functional gait parameters in a group of patients with chronic stroke.¹⁶⁶ Following 4 weeks of dual stimulation, subjects showed improvements in maximal MEP amplitude and cadence, stride length, and time to heel strike. However, as it was only a small pilot study, the improvements reported were not statistically significant.

Using an inhibitory PAS paradigm applied to the contralesional motor cortex resulted in a 91% decrease in MEP amplitude of tibialis anterior (TA) in the nonaffected side and a 130% increase in the MEP amplitude of TA on the stroke-affected side.²⁰⁴ The same group compared the effects of contralesional rTMS and PAS with ipsilesional anodal tDCS on walking ability post-stroke. Although the results revealed changes in cortical excitability, there was considerable variability in the responses to the protocol, and they were unable to demonstrate any significant change in lower limb muscle responses. In a single intervention of combined rTMS, peripheral nerve stimulation,

Fig. 38.17 An example of raw data traces from a subject from Uy et al.,¹⁶⁶ who responded positively to the dual stimulation intervention. *Left panel:* Average rectified motor evoked potentials (MEPs) in the weak peroneus longus muscle. The top trace shows that on day 1 before any dual stimulation the MEP was very small. The MEPs evoked at the same stimulus intensity increased dramatically in amplitude over successive days during the course of this intervention. *Right panel:* Mean rectified Electromyography (EMG) recorded during maximal voluntary contractions of the peroneus longus on the same days. The dotted lines are at 0 V. *EMG*, Electromyography.

and wrist and finger extension exercises, combining motor training with rTMS and neuromuscular stimulation facilitated user-dependent plasticity and improved motor function that persisted for 2 weeks.²⁰⁵ A single session of rTMS applied on the ipsilesional cortex revealed improvements in index finger tapping as well as a reduced activity of the contralesional cortex as revealed by functional magnetic resonance imaging (fMRI).²⁰⁶ These studies highlight the possible merit of using NBS as a method of priming and modulating the cortical excitability in stroke rehabilitation.

The effect of using TMS as a therapeutic modality of PD has also been reported. In PD, measuring the cortical silent period following TMS has been correlated to dopamine deficiency as this has been linked to cortical inhibitory circuits.²⁰⁷ The cortical silent period (cSP) has also been reported to shorten when “off medication,” normalizes while on medication, and is lengthened during the dyskinetic state.^{208,209} The improvements reported from using TMS in PD are varied having a positive effect on gait parameters¹⁹⁴ or no effect at all.^{210,211} The use of TMS in PD is not as widely reported as with the stroke population and with inconsistent reports on its benefits. The clinical usefulness of using TMS as an adjunct for rehabilitation in people with PD is still being questioned.

In patients with MS, the use of rTMS has been reported to have a beneficial effect on spasticity,²¹² gait performance,²¹³ hand dexterity,^{182,214} and working memory.²¹⁵ Similar to PD, the evidence to its benefits are limited and warrants further investigation to its clinical application.

Also there has been limited reports on the possible application of TMS in people with Alzheimer disease (AD). Improvements in cognitive function has been reported following rTMS, including improvements in reaction to a working memory task,²¹⁶ sentence comprehension,²¹⁷ naming performance,²¹⁸ and action naming²¹⁹ across various stages of AD. These findings again provide initial promising evidence in using rTMS as an adjunct in managing cognitive decline in AD.

Another variation of using TMS in modulating cortical excitability is TBS. This involves using high-frequency bursts of stimulation, usually around 30 to 50 Hz, delivered at theta frequency. Similarly, TBS can either have an excitatory or inhibitory effect on the cortical network. Delivering a cTBS results in a reduction of cortical excitability while intermittent bursts of TBS (iTBS) can increase the excitability of the cortical network.¹⁶⁷ These two protocols have been applied to patients with stroke and have resulted in increased MEP amplitude on the affected side following iTBS, and a suppression of cortical excitability in the nonaffected cortex following cTBS.²²⁰ However, during the acute stage of stroke, both cTBS to the nonlesioned cortex and iTBS to the lesioned cortex resulted in increased excitability of the affected cortex with accompanying functional benefits.²²¹ Combining iTBS to the ipsilesional motor cortex with task training resulting in improvements in grip lift of the affected upper limb.²²² An interesting finding of this study was the reduction of upper limb function following cTBS of the nonlesioned hemisphere, highlighting the role of the nonlesioned hemisphere in the recovery of upper limb function following stroke. In a group of chronic stroke patients, no significant difference was found between the TBS treated and the sham group, with both groups showing clinically important improvements.²²³ These conflicting reports of results from TBS puts into focus the high variability of patient response to the treatment and the need for further refinement of the parameters of TBS when applied to a lesioned brain.

Mechanism of Cortical Plasticity Following Transcranial Magnetic Stimulation

The attractiveness of using NBS in neurological rehabilitation lies in its ability to modulate cortical excitability. Various mechanisms have been proposed to explain the changes in the excitability of the cortical network. Studies using animal models, healthy human brains, and the

injured cortex have provided vast evidence that the cortical changes observed following TMS are brought about by stimulation-induced neuronal activation and from changes in synaptic efficiency.²²⁴

The mechanism underlying the changes seen following various forms of TMS correlate to mechanisms involved in activity dependent long-term potentiation (LTP) and long-term depression (LTD).²²⁵ LTP is defined as a sustained increase in synaptic strength brought about by high-frequency stimulation of excitatory afferents.^{226,227} The process of LTP follows Hebb's postulate wherein simultaneous pre- and post-synaptic activity provide multiple inputs to a cell and results in the strengthening of synapses in the activated pathway. Another form of activity-dependent plasticity is LTD, which induces rapid, activity-dependent reduction of responses in relation to irrelevant sensory stimuli.^{228,229} Heterosynaptic LTD, wherein a second pathway is activated to produce a depression in the inactive pathway, has been suggested as the possible mechanism involved in the reorganization of cortical representational maps.²³⁰ The capacity of LTP and LTD to induce a bi-directional change in synaptic efficiency is influenced by the arrangement and organization of the stimulation arriving in the cortex, with adjustment of the strength of the synaptic connections dependent on parameters such as frequency, timing, and intensity of inputs.^{231,232} The mechanisms involved in the induction of LTP and LTD in the cortex also can be influenced by the administration of drugs that interfere with glutamatergic activity. The application of *N*-methyl-D-aspartate (NMDA) receptor antagonists has been shown to block the inhibitory and excitatory effects of rTMS. Glutamatergic NMDA receptor activity has been linked to facilitation LTP and LTD in cortical circuits.^{233,234}

The nature of the changes induced by TMS when combined with PAS also suggest a role for LTP- and LTD-like processes.¹⁷² The process may involve the unmasking of previously silent cortico-cortical or cortico-subcortical connections. The mechanisms by which this unmasking is brought about may include both a reduction of local inhibition or changes in synaptic efficacy.¹⁷⁰ The significance of LTP or LTD changes is its connection to neuroplasticity. Specifically, LTP has been linked to learning and memory.²³⁵ These attributes have given value to the use of NBS such as TMS as a substrate for functional recovery following neurological injury.

Transcranial Direct Current Stimulation

Another method of induction of cortical excitability is tDCS. This technique uses weak direct currents (DCs) to modify the excitability of cortical cells. The application of tDCS uses two surface electrodes placed over the scalp wherein a continuous electrical current of 1 to 2 mA is applied for around 10 to 20 minutes. The resulting cortical stimulation does not induce the necessary action potential and hence does not produce any visible muscle contraction. The application of tDCS in humans has been shown to be safe and without any side effects, and to date there has been no report or evidence to show that tDCS has harmful or adverse effects on humans (Fig. 38.18).^{236,237}

The stimulation brought about by tDCS results in a depolarizing or hyperpolarizing effect on cortical neurons. The polarization effects result to changes in MEP amplitude and have been attributed to changes in cortical excitability.²³⁷ Increases in cortical excitability are generally expected when using anodal tDCS, and a reduction in excitability is seen with cathodal tDCS. A reduction in TMS evoked MEP amplitude was seen following cathodal stimulation; however, TES evoked MEPs did not show any change. Similarly, no effect was found on H-reflex measurements, suggesting that tDCS influences cortical neurons and has no significant effect on spinal excitability. These induced changes were dependent on the polarity, intensity, and duration of the stimulation as well as the orientation of the electrodes.^{168,238,239}

Fig. 38.18 Typical Transcranial Direct Current Stimulator.

Applying Transcranial Direct Current Stimulation in Neurorehabilitation

The use of tDCS in facilitating the recovery of function has become an emerging area of interest in rehabilitation (Fig. 38.19). The inhibitory and excitatory capacity of tDCS has been explored in people with stroke. Improvements in function was reported following anodal tDCS over the stroke affected cortex and a cathodal, tDCS on the nonaffected hemisphere.^{240,241} highlighting the possible asymmetry of interhemispheric activity in stroke. The effect of using anodal and cathodal tDCS on the affected and nonaffected hemisphere also has been applied in stroke patients showing neglect. With one to two sessions of tDCS application, there were significant effects on the results of the line bisection test and the shape-unstructured cancellation test.^{242,243} Using anodal tDCS over the lower limb primary cortex of the stroke affected hemisphere during motor practice of the affected ankle resulted in improvements in ankle control.²⁴⁴ There was no mention of any measurement of gait parameters, and the subjects tested were either moderate to well recovered from their stroke. A meta-analysis on the use of anodal tDCS to facilitate upper limb recovery following stroke reported an overall increase in the level of upper limb motor function. There was small to moderate change in function when comparing baseline outcome scores with scores at the end of the studies analyzed.²⁴⁵ Although there were encouraging results from the therapeutic use of anodal tDCS, there was still great variability in patient responses and minimal follow-up to ascertain its clinical effectiveness.

Mechanism of Change

The mechanisms underlying the effects of tDCS has been proposed to involve changes in the behavior of neuronal membranes.²⁴⁶ It was suggested that tDCS manipulates ion channels or shifts electrical gradients to affect neuronal signaling and have an effect on the electrical balance of ions, involving primarily nongated and voltage-gated channels.²⁴⁶

Fig. 38.19 Application of Transcranial Direct Current Stimulation on the Scalp Surface.

The application of tDCS stimulation has been shown to affect membrane depolarization. The depolarizing effect of a DC can result in the activation of voltage-sensitive events that involve presynaptic sodium channels increasing the release of excitatory neurotransmitters and postsynaptic elevation of Ca influx.²³⁹

The application of a Na⁺ channel blocking agent carbamazepine and NMDA receptor antagonist dextromethorphan (DMO) resulted in changes in DC-stimulation-induced neuroplasticity. DMO suppressed the induced plastic change by anodal and cathodal DC stimulation in a group of healthy human subjects. Anodal stimulation has been shown to increase excitability and cathodal stimulation to reduce excitability.²³⁹ The suppression of these effects by DMO would suggest the involvement of NMDA receptors in DC-stimulation-induced synaptic plasticity.²⁴⁷ NMDA receptors in the postsynaptic neuron act as Ca channels, thus their activation will lead to an increased influx of Ca. The entry of Ca in the postsynaptic neuron activates Ca dependent

TABLE 38.5 Summary of the Different Types of Noninvasive Brain Stimulation and Its Effects

NBS	Type	Effect
TMS	<u>rTMS</u>	
	Low frequency	Inhibitory
	High frequency	Excitatory
	<u>TBS</u>	
	Continuous	Inhibitory
	Intermittent	Excitatory
	+ PAS	Excitatory
tDCS	Anodal	Excitatory
	Cathodal	Inhibitory

NBS, Noninvasive brain stimulation; PAS, paired associative stimulation; rTMS, repetitive transcranial magnetic stimulation; TBS, theta burst stimulation; tDCS, transcranial direct current stimulation; TMS, transcranial magnetic stimulation.

second messengers, which results in the increased availability of the glutamate receptor AMPA. This will enable the postsynaptic neuron to be more sensitive to presynaptic release of glutamate, which is necessary for maintaining LTP.

Clinical Application of Noninvasive Brain Stimulation

There is a growing interest in using NBS as a therapeutic adjunct in the rehabilitation of people with neurological issues. This is mostly from the ability of NBS to influence motor learning by priming or modulating the excitability of the cortical network (Table 38.5). The notion of being able to provide rehabilitation and training during a period of increased cortical excitability will be an attractive option for therapists.

In spite of the plausible benefits from using NBS in rehabilitation, its therapeutic effectiveness is often variable. Most of the studies available lack statistical power to warrant clinical recommendation, and with such varied protocols available, it is difficult to ascertain which one is suited for a particular type of patient. The future clinical application of NBS will be highly dependent on the development of more advanced tools of monitoring and evaluating cortical activity and the collaboration of neuroscientists and clinicians with the goal of improving the quality of life of people affected by neurological disorders.

CASE STUDY 38.1 Vestibular Rehabilitation Training Using a Virtual Reality Environment

Mrs. S. was a 52-year-old woman who came to the clinic with a diagnosis of unilateral vestibular hypofunction and the chief complaint of being unable to go into large crowds or stores or to shop without feelings of dizziness and disorientation. Clinical and laboratory findings revealed bilaterally reduced vestibular evoked myogenic potentials and a unilateral caloric weakness on the right. The patient reported onset of her symptoms 1 month ago with tinnitus and difficulty walking in crowds and in grocery stores. She was referred to physical therapy by a neuro-otologist. Mrs. S. signed informed consent to participate in a VR treatment trial. This treatment trial consisted of testing her function and symptoms pretreatment during six intervention sessions, immediately posttreatment, and at a 6-month follow-up.

PROCEDURES

The Virtual Reality Protocol

Each VR session consisted of six 4-minute exposures walking and “shopping” on the treadmill. The Balance Near Automatic Virtual Environment (BNAVE) was used as the Virtual Intervention.²⁴⁸ (Fig. 38.20.)

The BNAVE consists of three walls that surround the person with a treadmill in the center. The patient was instructed to push the instrumented grocery cart (which had a force sensor on the push bar of the grocery cart) at the speed at which she wanted to ambulate through the store. The upper speed limit of the treadmill was fixed at 1.2 m/s. The specially designed treadmill was built to be wider than a normal treadmill to accommodate the turning required at the end of the grocery store aisle.

Continued

CASE STUDY 38.1 Vestibular Rehabilitation Training Using a Virtual Reality Environment—cont'd

The three rear-projected scenes were merged to form one image on the BNAVE screens with the hope that persons would be immersed and “feel” as though they were shopping in a grocery store.²⁴⁸ During the 4-minute exposures to the scene, Mrs. S. was introduced first to the easiest aisle (the white paper products). There were 16 different aisles, and they were designed to be increasingly more complex either via a greater number of products on the shelves, more vibrant colors, or a greater population density of products per square inch.

Mrs. S. was asked throughout the VR experience to “find” certain products in each aisle. She reported verbally when she found the product on the shelves and then continued walking. Some patients are able to continue to “walk” and “shop” at the same time. Mrs. S. was able to fairly smoothly ambulate through the store without stopping. She would occasionally slow down significantly if she was having difficulty finding a particular product and then would continue walking in the “store.”

Safety

The patient was secured to an overhead harness to prevent a fall. In addition, the therapist held a switch and could stop the treadmill if there was any indication that Mrs. S. was having a problem. The patient could also stop pushing on the grocery cart in order to stop the treadmill, plus the technician who ran the computer also had the ability to immediately stop the treadmill with a stroke of a key.

One last safety measure was incorporated into the design of the study. If the patient’s leg went too far back toward the edge of the treadmill, the motor turned off the treadmill immediately in order to prevent a fall. A physical therapist stood behind and toward the side of the patient and monitored the patient’s condition.

OUTCOMES

Mrs. S. tolerated the treatment well, and the sessions were never terminated because of patient intolerance of the visual surround. Mrs. S. provided subjective ratings on a visual analog scale at the beginning and end of each VR treatment

session (Table 38.6²⁴⁹). The following symptoms were rated: nausea, headache, dizziness, and visual blurring. No nausea was experienced, but she did rate symptoms of headache, dizziness, and visual blurring over the six sessions. Headache was experienced during only the first VR exposure. Dizziness decreased from 1.8 (10 is the maximum score) to 0.1 at the end of the last session. Visual blurring had the highest rating at the start, at 1.9; at the end of the last session her visual blurring was self-reported to be 0.1. She appeared to be better able to tolerate the virtual experience over the six treatment sessions, and she was able to progress from the first aisle to aisle 16, the most difficult aisle, where the products were much smaller and more closely packed on the shelves.

At the beginning of physical therapy, Mrs. S. was asked to complete the Dizziness Handicap Inventory (DHI),²⁴⁹ the Situational Characteristics Questionnaire parts A and B (SCQ-A and SCQ-B),²⁵⁰ the Dynamic Gait Index (DGI),²⁵¹ the Functional Gait Assessment (FGA),²⁵² the Timed Up-and-Go Test (TUG),²⁵³ a gait speed assessment, and the Sensory Organization Test (SOT) of computerized dynamic posturography.^{254,255} Data for all of the these tests before therapy, after therapy, and at the 6-month follow-up for Mrs. S. are included in Table 38.7. Scores on all measures were better after the 6-week VR intervention program except for the TUG, and the scores remained relatively stable at 6 months. Lower scores on the DHI, SCQ-A, SCQ-B, and TUG indicate improvement, and higher scores on the DGI, the FGA, gait speed, and the SOT are “better” scores.

Mrs. S. was very satisfied, as she was able to shop again without symptoms. A clinically meaningful change on the DHI has been reported to be 18,²⁴⁹ and Mrs. S. improved 34 points. The Activities-specific Balance Scale (ABC) change from 29% to 69% over the course of the VR intervention was probably meaningful, as Lajoie and colleagues²⁵⁶ have reported, where scores of less than 67% are related to increased risk of falling. The patient’s DGI score improved by 4, which has also been reported to be clinically meaningful.²⁴⁹ Gait speed over the course of the intervention improved only by 0.07 m/s, and 0.1 m/s has been reported as a clinically meaningful change.²⁵² Overall, Mrs. S. made positive changes after the VR physical therapy intervention.

CASE STUDY 38.2 Noninvasive Brain Stimulation

A 68-year-old male who sustained a unilateral left pontine infarct 9 years prior to the study. He had right-sided hemiparesis with moderate spasticity of the affected side. At the time of evaluation, he had voluntary gross movement of the shoulder and minimal grasp movements of the hand. Baseline wrist extension measurement was at 31.5 cm passive and 35.5 cm active; Action Research Arm Test (ARAT) score at baseline was 16. Sensory evaluation and cranial nerve functions were both intact. Subject was ambulating independently with the use of an ankle-foot orthosis.

Hand function will be tested on three levels: impairment, activity, and participation. To test for impairment, the passive and active range of the wrist was measured. Hand disability was assessed using the ARAT. To test the level of participation limitation, a motor activity log and a general functioning questionnaire was used. Mapping of the motor cortex of both hemispheres was also performed using a Magstim 200 stimulator (Magstim Co., Dyfed, United Kingdom). Motor-evoked potential and EMG were measured from the affected wrist and finger extensors.

The patient consented to having a dual stimulation protocol for 5 days a week for 4 weeks. It involved combining TMS and peripheral electrical stimulation (ES) delivered at an inter-stimulus interval of 25 ms to allow for the afferent volley from the ES arriving at the motor cortex at approximately the same instance as the magnetic stimulus. TMS intensity was set at 15% above resting threshold. The ES consisted of a 10-Hz 500-ms train with a 1-ms pulse duration repeated

every 10 seconds (McKay et al., 2002);^{252a} intensity was set at the level that evoked visible twitches in the wrist and finger extensors.

Functional Test

At the end of the fourth week of treatment, the patient showed an increase in active wrist extension measures and an increase in the overall ARAT scores (Fig. 38.21). These scores were maintained on follow-up 2 weeks post-stimulation. Subjective scores also improved with the patient reporting using the affected arm twice as much prior to stimulation and found that the quality of movement improved by as much as 50%. The patient also noted that his affected upper extremity felt less stiff during the period of treatment.

Neurophysiological Measures

TMS of the affected hemisphere produced weak responses on baseline measurement. After the stimulation period, TMS responses were distinct and clear showing a 50% increase from baseline when measured during the passive state for extensor carpi ulnaris (ECU) and extensor digitorum (ED) (Fig. 38.22). EMG activity improved by 38% when compared to baseline measures. The TMS CoG measure was shown to be stable over the first two baseline measures, shifting an average of 0.5 mm. Comparison of baseline map parameters with those taken at the end of the 4-week stimulation reveals a shift in latitude. The CoG for the ECU for the subject shifted 5 mm (Fig. 38.23) and for ED shifted 2 mm.

ACKNOWLEDGMENTS

The editors would like to thank the following for their work in this chapter in the 6th edition: Katie Byl, PhD; Nancy N. Byl, PT, MPH, PhD, FAPTA; Marten Byl, PhD; Sebastian Sovero, MS; Clayton D. Gable, PT, PhD; and Darcy A. Umphred, PT, PhD, FAPTA. The editors would also like to thank Dr. Susan L. Whitney, PT, PhD, DPT, NCS, ATC, FAPTA, for her contribution of the case study on virtual reality training for a patient with unilateral vestibular hypofunction.

Dr. Jeric Uy would like to thank Dr. Brenton Hordacre, Research Fellow, University of South Australia, for the use of the TMS and tDCS pictures. He also would like to thank Dr. Tony Aitchison of Add-Life Technologies for the picture and video used. Dr. Sophie Lefmann would like to thank her research colleagues, Associate Professor Ray Russo and Mr. Christopher Innes-Wong, from the Little Heroes

Foundation's Centre for Robotics and Innovation at the Women's and Children's Hospital in Adelaide for their ongoing support in this field. She would also like to thank the patient and his family who permitted the use of video illustrating robotic rehabilitation in action.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 257 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: This chapter presents and discusses the integration of computer-assisted technology as one approach to maximize independence and quality of life in older adults and people with physical impairments. Rehabilitation robotics and computer-assisted technology use brain interfaces, sensorimotor interfaces, virtual reality environments, and learning-based gaming programs to remediate sensory, motor, and cognitive impairments and improve memory skills and physical abilities required for independent mobility and self-care at home, in the community, at work, and during the performance of recreational activities.

Keywords: brain-machine interfaces, exoskeleton, human robotic interfaces, rehabilitation robotics, virtual reality training

Complementary and Integrative Therapies: Beyond Traditional Approaches to Intervention in Neurological Diseases and Movement Disorders*

Darcy A. Umphred and Mary Lou Galantino

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Differentiate the four historical to modern worldviews of health care delivery.
2. Analyze how complementary and integrative-based health care practices overlap with allopathic traditional medical models and movement diagnoses.
3. Analyze how mind, body, and spiritual interactions have the potential to lead to health, healing, and quality of life.
4. Compare and contrast the various therapeutic models discussed and identify similarities and differences between these and the traditions of Western medicine, occupational therapy and physical therapy practice, and the International Classification of Functioning, Disability and Health (ICF) World Health Organization (WHO) model.
5. Appreciate the role of complementary and alternative approaches in the examination and intervention of individuals with movement-based problems from neurological disorders.
6. Use evidence-based practice to measure outcomes in body system functions, functional activities, and life participation even when the science is not available to explain how and why the intervention was successful.

KEY TERMS

alternative therapies
belief-based theories
complementary models
complementary therapy interventions
energy-based theories
evidence-based practice

integrative therapies
movement diagnosis
movement-based therapies
interprofessional models
traditional concepts with new focus

The use of complementary and integrative methods or therapies (CIM/T) in the treatment of patients with neurological disorders and resultant movement problems is evolving into common practice. Clinicians and patients/clients are seeking less traditional approaches to relieve signs and symptoms of neurological diseases, syndromes, and movement disorders to attempt to alter the progression of diseases of the central nervous system (CNS) through integrative therapies and movement or manual therapeutic approaches.¹ The National Center for Complementary and Integrative Health (NCCIH), formerly known as the National Center for Complementary and Alternative Medicine (NC-CAM), is the US federal government's lead agency for scientific research on the diverse medical and health care systems, practices, and products that are not generally considered part of conventional medicine. The NCCIH conducts research to help answer important scientific and public health questions about complementary health approaches and works to determine what is promising, what helps and why, what doesn't work,

and what is safe.² Thus the researcher, clinician, or patient can seek evidence-based information to make informed choices.

It is important that professionals working with patients with neurological problems through a traditional rehabilitation environment understand the principles and practices of complementary, alternative, and interdisciplinary approaches to the treatment of movement problems. Therapeutic approaches are proposed as options in the management of body system problems with the goal of reduction of restrictions in daily life activities and independence. The clinician needs to be cautious in the application of any treatment modalities or techniques that has paucity of research to identify the level of evidence. We do not want to accept alternative therapies as intervention solutions without significant evidenced-based research substantiating the use of these approaches, but even without evidence, some integrative approaches may be efficacious. Patients, as case studies, help us begin the path of outcome evidence, and thus it is very important to accurately measure how a patient responds to intervention. The reader must also be reminded that evidence comes from *effectiveness*, and many complementary approaches have established that result.³

*Videos for this chapter are available at studentconsult.com.

This chapter presents a sampling of integrative therapeutic models and philosophies that could potentially assist patients/clients who have movement dysfunction because of CNS pathology. Many of the techniques discussed in this chapter have been firmly established by sound research; some less-evidenced-based models are also included to widen the scope of therapeutic models with emerging evidence. Clinicians are continually being exposed to the therapeutic potential of less scientifically established theories and therefore need to be aware of their existence and impact. Creating evidence-based practice is not an all-or-none principle, nor do we suggest that models that do not have a strong research base are ineffective. We do suggest that to adopt a model because of belief or the charisma of the founder will be and should be challenged by colleagues today and in the future. Many of today's integrative health models whose theoretical constructs are based on sound rationale or that link effective-based practice across multiple areas still need to be scrutinized and approached cautiously but should not be nullified because they are considered potential complementary approaches. In time, if those models maintain their sound scientific base, more research will emerge, and efficacy may be established and become standard of care. New models may be created, and available research will develop to prove or disprove their benefit. Everything starts with a clinician using the evidence in tandem to identifying a key element that works for a specific patient, and from that strong foundation, treatment ideas develop into theories and models of practice. NOTE: A detailed historical perspective of the development of complementary and integrative therapies can be found in the online resources for this text.

ALTERNATIVE INTEGRATIVE MODELS

Darcy A. Umphred

As physical and occupational therapists, we primarily evaluate and treat movement dysfunctions that have consistencies when observed from a functional perspective and limitations in life activities. Although many of these emerging complementary approaches have not been able to show effectiveness or efficacy using a linear research model, when analyzed using social models, these approaches have been shown to create patient satisfaction and improve quality of life.^{4,5} Today, models that consider patient-centered, individual's strengths can be used in conjunction with traditional therapies and will empower patients to become an active participant in his or her own health care. Many of these techniques are considered complementary or integrative therapies and are the base of most of the individual approaches presented within this chapter.⁶ Personally, I have been a patient for the last three decades with interactive health issues that medical practitioners cannot explain because these medical problems fall outside of their respective evidence and always seem to overlap with other medical specialties. I have been told by more than 12 highly respected medical specialists that, when looking at their specific area of specialization, they have never seen the specific system problem that my body system presented. Thus not knowing what the causation of the specific system problem is or how it interacts with the other systems, the doctors do not know exactly how to treat the problem and each doctor reacts differently. This medical case was submitted to the National Institutes of Health (NIH) as a potential syndrome for which they might find a diagnosis. NIH returned the case, saying they do not have the finances or the ability to determine the diagnosis because it is much too complex. Obviously, there are many people with health issues that are outside current medical evidence-based practice, yet those same individuals often look to Western medicine for help. If they don't get any answers or help, they often go to practitioners outside Western medicine. Although doctors dealing with my case have had to stretch beyond their comfort zone to help and work with me in order for

my body to remain on this plane we call life, this success has led to cooperation between all individuals involved in a plan of care, with the patient playing a primary role in the key to success. Before the advent of research tools of the 21st century, doctors were constantly confronted with unknowns, and their skills in analyzing the problem and potential ways to treat it made them highly respected physician at that time. Society still refers to medicine as the "practice" of medicine, which infers that there is more to study and learn in relation to disease and pathology. This is also true for clinicians working in the area of movement science, functional recovery following any body system insult, and how an individual might regain quality of life. In contemporary medical school, the introduction and use of integrative medicine has become an intricate part of medical education and is often used by doctors if there is research to support its validity.^{4,7-10}

Interprofessional practice is evolving, as are the practices of physical and occupational therapy. Future research will help validate the combination of Western and Eastern medicine along with all the theories of energy and quantum physics. OTs and PTs are movement specialists and not practitioners that evaluate and treat pathologies. Pain, a common problem among patients in our society, may be alleviated by traditional medical treatment in acute stages, but when necessary, integrative treatments may be very effective.^{11,12} Movement dysfunction can be the result of pain or due to a number of system problems. As clinicians and movement specialists, we need to be able to classify movement problems and how those problems interact with function and not necessarily with the specific disease or pathology, unless that medical aspect will continue to progressively affect movement function. These problems may be specific movement functions, such as walking or reaching, or how they interact with activities, such as walking to school or reaching for a toothbrush. The patient must determine whether that activity itself has value, because if it doesn't, the patient will not practice that movement outside of therapy. Without practice, learning will not occur, as has been discussed in Chapter 3. If the patient is motivated to gain or regain specific movement function, then the probability that the motor system will regain those skills is much greater (refer to Chapter 3). Similarly, research has demonstrated the effectiveness of components of complementary approaches (refer to the list of research articles throughout this chapter for specific approaches). Additional research is needed to establish the clear reliability and validity of any methodology. In the future, some components will need to be eliminated and new creative ideas and therapeutic techniques developed. But, the true effectiveness of any integrative therapy is based on each patient's response and their ability to identify that they now can participate in activities of their choice with improved quality of life.

The models for patient management presented in this chapter have a common thread. All approaches focus on helping the patient/client maintain or regain a quality of life that cultivates their individual potential. The specific philosophy or conceptual framework embraced by any one approach may vary. As these integrative approaches are introduced in the following sections, subheadings will help the reader categorize similarities of philosophies. When we no longer need to view problems with a specific model influencing our approach, but are able to base our decisions on reliable and valid information, we will finally be able to access what is truly available to us as practitioners and give the best possible guidance and suggestions to our patients to help them regain or maintain functional control over movement as they experience life on a daily basis. In the future, there may never be a best approach but rather only options that best match the learning style of the individual and the environment and culture specific to that person. There are many ways to approach these opportunities for learning, but the clinician must remember that the patient need to learn this process, choose their path, and not be expected to just follow because he or she is being told by some practitioner that it is the best.

MOVEMENT THERAPY APPROACHES

Equine-Assisted Therapy

Kerri Sowers

Introduction to Hippotherapy and Therapeutic Riding

At the 1952 Helsinki Olympic Games, a Danish dressage rider named Liz Hartel won the silver medal and inspired a renewed interest in the field of hippotherapy and therapeutic horseback riding (THR). This master equestrian used horseback riding as a form of rehabilitation to aid her recovery from poliomyelitis, which left her lower extremities paralyzed.^{13,14} The use of horses in therapy to improve physical and mental health has its founding roots in Greek culture. The term *hippotherapy* originated from the Greek word *hippos*, meaning “horse.”^{15,16} A renewed interest in hippotherapy and THR grew first in Europe and was especially popular throughout England.¹⁵ In 1969, the North American Riding for the Handicapped Association (NARHA) was founded; this organization established standards for the developing THR centers in the United States.¹⁷ The American Hippotherapy Association (AHA) was founded in 1992 and worked to establish an international protocol for hippotherapy practice.^{13–16} Studies conducted in North America show that approximately 90% of children with disabilities participate in THR programs, while the remaining 10% participate in hippotherapy sessions.¹⁸

It is crucial to understand the differences between hippotherapy and THR, as both programs are commonly offered at the same facility and are often mistakenly thought to accomplish the same goals. According to the AHA, “term hippotherapy refers to how occupational therapy, physical therapy, and speech-language pathology professionals use evidence-based practice and clinical reasoning in the purposeful manipulation of equine movement to engage sensory, neuromotor, and cognitive systems to achieve functional outcomes. In conjunction with the affordances of the equine environment and other treatment strategies, hippotherapy is part of a patient’s integrated plan of care.”¹⁹ During hippotherapy, the horse is used as a modality or treatment tool; the therapist and his or her assistants control the horse to effect a change in the patient/client. In contrast, THR teaches the patient specific riding skills that allow the rider to gain control of the horse’s movement; the focus is on teaching horseback riding skills to riders with disabilities.¹⁷ AHA attempts to clarify the difference by stating that hippotherapy “treatment takes place in a controlled environment where graded sensory input can elicit appropriate adaptive responses from the patient. Specific riding skills are not taught as in therapeutic riding, but rather a foundation is established to improve neurological function and sensory processing.”¹⁷

Benefits, indications, and precautions. Hippotherapy and THR are perceived to be beneficial because the equine walk provides a multi-directional input, resulting in movement responses that closely mimic the movement of the pelvis during the normal human gait.^{20–22} The movement is both rhythmic and repetitive, allows for variations in speed and cadence, and triggers neuromuscular responses through the stimulation of postural reflex mechanisms.^{20–23} Research has demonstrated that the pelvic motion trajectories and displacement amplitudes are similar in walking and riding;²¹ while there can be significant variation due to the different horses used, this variation does not cause significant alterations in the movement patterns generated. In hippotherapy, the horse is used as a dynamic base of support (BOS) to assist in improving trunk control, postural stability, core strength, and righting reactions to improve balance.^{22,23} Vestibular, proprioceptive, tactile, and visual sensory inputs are incorporated during a hippotherapy session.

Hippotherapy is indicated for neuromuscular conditions. These conditions are characterized by reduced gross motor skills, decreased

mobility, abnormal muscle tone, impaired balance responses, poor motor planning, decreased body awareness, impaired coordination, postural instability or asymmetry, sensory integration deficits, impaired communication, and limbic system dysfunction (impaired arousal or attention skills).^{23,24}

Common conditions that may benefit from hippotherapy and THR include autism spectrum disorder, cerebral palsy (CP), developmental delay, genetic syndromes, learning disabilities, sensory integrational disorders, speech-language disorders, traumatic brain injury (TBI), and cerebral vascular accidents. There have been a multitude of suggested therapeutic benefits from hippotherapy and THR, which affect many body systems. Suggested physical benefits include improvements in endurance, symmetry, and body awareness; development of trunk and postural control; improvements in head righting and equilibrium responses; normalization of muscle tone; mobilization of the pelvis, lumbar spine, and hip joints; and improved sensory awareness.²³ Suggested cognitive, social, and emotional benefits include improvement in self-esteem, confidence, interaction with others, concentration, attention span, and communication skills.^{14,25}

Contraindications for the use of hippotherapy or THR include excessive hip adductor or internal rotator tone accompanied by potential hip subluxation or dislocation. Similarly, lack of head control (in large children or adults), pressure sores, spinal instability, extreme aggressive behavior, or anxiety around animals are also contraindicated.^{14,25}

Regulations. AHA offers a Clinical Specialty Certification for therapists demonstrating advanced knowledge and experience in the practice of hippotherapy. Physical therapists, occupational therapists, and speech-language pathologists must have been practicing in their profession for 3 years (6000 hours) and have had 100 hours of hippotherapy practice within the 3 years prior to application. Certification is valid for 5 years; once applicants pass a multiple-choice test, they are entitled to use the designation Hippotherapy Clinical Specialist (HPCS).²⁶ An entry-level certification has also been available since 2014, with the designation of American Hippotherapy Certified Therapist (AHCB) Hippotherapy Certified Therapist; this requires 1 year of professional practice (2000 hours), completion of AHA Level I and II skills courses, and 25 hours of hippotherapy practice.²⁶

American Physical Therapy Association recognizes hippotherapy as a treatment tool to address impairments and functional limitations in patients with neuromusculoskeletal dysfunction. APTA recommends that PT sessions that incorporate hippotherapy be billed as neuromuscular education, therapeutic exercise, gait training, or therapeutic activities based on the treatments completed.²⁷ The American Occupational Therapy Association (AOTA) also recognizes hippotherapy as an interventional tool, which can be billed as neuromuscular education, therapeutic exercise, therapeutic activities, or self-care management training.²⁷ The American Speech and Hearing Association (ASHA) recognizes hippotherapy as a treatment tool, which can be billed as speech-language therapy (individual or group), treatment of swallowing dysfunction and/or oral function for feeding, and therapeutic intervention for cognitive function.²⁷

Evidence and clinical implications. Research and studies concerning the use of hippotherapy and THR have expanded in recent years. Research has primarily focused on children diagnosed with CP but has expanded to include conditions such as multiple sclerosis (MS), autism spectrum disorder, attention-deficit/hyperactivity disorder, psychological disorders, TBI, and stroke. In addition to the large number of articles focusing on the pediatric population, the literature has expanded to include research into the benefits of hippotherapy and THR for the adult and geriatric populations.

One systematic review investigating the use of hippotherapy and THR for children with CP found improved gross motor function;

normalization of pelvic motion; improvements in weight shifting, postural and equilibrium responses, muscle control, and joint stability; improved recovery from perturbations; and improved dynamic postural stabilization.¹⁸ A systematic review and meta-analysis reported that short-duration hippotherapy (8 to 10 minutes of riding time) significantly reduced asymmetrical activity of the hip adductor muscles and improved postural control in children with spastic CP.²⁸ Another meta-analysis found that postural control and balance were improved in children with CP after hippotherapy and THR interventions.²⁹ A systematic review by Whalen and colleagues³⁰ suggests that large randomized controlled trials that utilize specific and well-defined protocols are needed to provide stronger evidence for the use of hippotherapy and THR; however, the current evidence appears to support the positive effects of these interventions on gross motor function in children with CP. Support for hippotherapy has been shown by improvements in the areas of muscle symmetry, gross motor function (as measured by valid and reliable tools), energy expenditure, and postural control.²³ Researchers suggest that hippotherapy will lead to improved head righting and equilibrium reactions and dynamic postural control, normalization of abnormal muscle tone or symmetry, improved muscle control, and better endurance.²³

Studies have supported that hippotherapy can improve postural stability in individuals with MS and can assist in treatment of balance disorders.^{31,32} A systematic review by Bronson and colleagues³³ found that hippotherapy has a positive effect on balance and enhances quality of life for individuals²⁰ with MS; individuals with primary progressive MS demonstrated the greatest improvement in balance, as compared with other subtypes, assessed with the Berg Balance Scale (BBS).

Hippotherapy has been shown to reduce lower-extremity spasticity in patients with spinal cord injury (SCI).³⁴ For individuals with hemiparetic stroke, hippotherapy, combined with conventional treatment, helped improve lower extremity motor control, independent ambulation, and gait speed and cadence; individuals treated with hippotherapy had improved normalization of gait as compared with a control group.³⁵

A randomized controlled trial, conducted by de Araújo and colleagues²⁰, used a sample of convenience to investigate the effect of hippotherapy on functional mobility, muscle strength, and balance in a group of elderly participants. The Timed Up and Go (TUG) was used to assess functional mobility, the 30-second Chair Stand Test (30CST) was used to assess lower extremity muscle strength, and the BBS was used to assess balance.²⁰ After the 8-week intervention, improvements were found in muscle strength and balance in the group that participated in the hippotherapy intervention.²⁰ A systematic review by Hilliere and colleagues (2018)²² investigated eight studies about hippotherapy and simulated horse riding for older adults. The results suggested that hippotherapy may lead to improvements in balance, mobility, gait ability, and muscle strength; there was also potential for hormonal and cerebral activity changes with the use of hippotherapy (Hilliere, 2018). The use of horse simulators for riding contributed only to physical fitness and muscular activity changes (Hilliere, 2018).

In addition, hippotherapy has the potential to contribute to psychosocial well-being and improved motivation by allowing interaction and acceptance with another living being and the opportunity to be mobile while astride the horse; being positioned high up on a horse gives the child the chance to be at eye level with his or her peers, and the fun of riding encourages participation and enjoyment of the therapy sessions.³⁶ A systematic review evaluated 33 studies involving children and adolescents with autism; hippotherapy and THR demonstrated improvements in behavior, social interaction, positive emotions, motor skills, and communication for children and adolescents diagnosed with autism.³⁷ A systematic review by O’Haire³⁸

suggests that the research supporting the use of animal-assisted interventions, including hippotherapy and THR, for individuals with autism is promising, but further research with substantial methodological rigor is required; preliminary research suggests the potential benefits of increased social interaction and communication and reduced problem behaviors, autistic severity, and stress.

While the methodological rigor in many studies involving hippotherapy and THR is lacking, the results remain promising for a wide variety of conditions. Hippotherapy and THR are effective in the areas of gross motor function, balance, symmetry, postural control, muscle strength, gait normalization, communication, behavior, and social interaction. Continued research in hippotherapy and THR using larger, randomized controlled studies with well-defined protocols to investigate specific outcomes and account for the variations within a variety of neuromusculoskeletal conditions will be necessary to conclusively determine all potential benefits that exist.

Feldenkrais Method of Somatic Education

James Stephens

The Feldenkrais method is about learning the following:

We do not treat patients. We give lessons to help people learn about themselves. Learning comes from the experience. We tell them stories [and give them experiences of movement] because we believe learning is the most important thing for a human being. (p. 117)³⁹

Development of the Feldenkrais method. Moshe Feldenkrais, a boy in Palestine, developed a method of hand-to-hand combat that was used by settlers for self-defense. Later, as a student in Paris where he trained in physics at the Sorbonne, he studied judo and became the first person in Europe to receive a black belt. When he injured his knee playing soccer, he relearned pain-free walking on his own. Later, he studied with F. M. Alexander, Elsa Gindler, and George Gurdjieff. He also studied psychology, progressive relaxation, bioenergetics, and the hypnosis methods of Milton Erickson. Also, he was familiar with the physiological concepts of his day: Sherrington, Magnus, Fulton, and Schilder. With this background, Feldenkrais developed two approaches to facilitating learning that are now known as Awareness Through Movement (ATM) and Functional Integration (FI).⁴⁰

Feldenkrais was ultimately interested in the development of human potential. He saw that, although all people encounter trauma and difficulty in their lives, those who are most successful were able to develop new, adaptive behaviors to overcome those difficulties. He proposed that a type of learning that reconnected the brain to the control of the musculoskeletal system would be the most effective way to approach this problem of adaptation. His initial thinking in this area is set out in his first book, *Body and Mature Behavior: A Study of Anxiety, Sex, Gravitation, and Learning*.⁴¹

Background theory—dynamical systems theory. For Feldenkrais, learning was an organic process in which cognitive and somatic aspects were completely integrated. Presented first in 1949, this idea prefigured our current sense of dynamic systems functioning of the brain and body.⁴² The learning experience should proceed at its own pace in an individualized way following the learner’s intention and guided by the learner’s perception that the performance of the task, movements of the body, and interaction with the environment become easier.⁴¹ This interactive cycle of action and perception has been described well by the motor learning model proposed by Newell.⁴³

Learning is a complex process with overlays from the intention of the learner, interference from environmental distraction, misperception of the task and the body, desire related to self-image, fear of injury,

or incorrect performance. Thus it is possible to learn poorly, incorrectly, or in such a way as to interfere with performance and not improve it. This kind of process has been suggested by Byl and colleagues⁴⁴ as the underlying cause of focal dystonia. One of the definitions Feldenkrais gave for learning took this process into account: “Learning is the acquisition of the skill to inhibit parasitic action (components of the action unrelated to the intention behind an action but resulting from a secondary intention) and the ability to direct clear motivations as a result of self-knowledge.”⁴³ An adult engaged in learning to walk again after a stroke with a fear-related reluctance to bear weight on the involved limb would be an example of such a secondary intention.

The process of learning proposed by Feldenkrais is one of discovery. The outcome desired is one of increased awareness. Vereijken and Whiting⁴⁵ have proposed that discovery learning, in which learners are free to explore any range of solutions in learning to perform a task in any way that they want, is as effective as or more effective than any formal approach to motor learning involving controlled schedules of practice or feedback. This process of discovery has the added dimension of allowing learners to focus on the perceptual understanding of the body/task/environment as a component of the learning process both within the human organism as well as participation within the external world. This suggests that a home exercise program should not be strictly proscribed, but patients should be encouraged to experiment with movement and be guided in that process by the therapist. In the Feldenkrais method, this discovery and perceptual learning process are explicit.

Our understanding of how experience and learning restructure almost all areas of the CNS is expanding rapidly.⁴⁶ A large focus of current thinking in rehabilitation is how to translate neuroplasticity concepts into more effective techniques for rehabilitation.^{47–49} The method developed by Feldenkrais and practiced by people around the world who are trained in this method is clearly explained by these new principles, creating new approaches to rehabilitation.

Approaches to the Feldenkrais method. The two approaches to facilitating learning created by Feldenkrais, ATM and FI, are similar in terms of principle and process, although they differ in practice. They are essentially two methods for communicating a sensory experience that the patient can consider and act on. The first requirement of the process is to create an environment that is comfortable, safe, and conducive to learning, whether the learner is being moved passively or creating the movement experience voluntarily. The second requirement is that the amount of effort associated with making the movements be reduced greatly so that it is possible to make fine discriminations about the effects of forces acting on the system from inside or outside the body. The goal is to develop a rich understanding of changes throughout the system produced by small perturbations. This understanding becomes the basis for creating new solutions to movement problems as the patient progressively approaches functional movements that she or he desires to perform.⁵⁰

In FI the practitioner will manually introduce small perturbations into the learner’s system after placing the learner into a safe position closely approximating some desired activity to be learned. Here the practitioner is providing the force inputs, and the patient is asked to attend to the changes created in response to the perturbation. For example, the practitioner might press gently into the bottom of the patient’s foot and ask the patient to notice where in the body movement and pressure are felt as a result. This will be repeated a number of times, and then some other forces or movements will be introduced. The guiding idea for the practitioner might be to build sensory experiences in the body that are associated with a particular movement, such as rolling. This goal is rarely explicitly expressed to the patient and is

left to emerge in the patient’s understanding of the experience: “Oh, now I am rolling,” or “This feels like rolling to me.” Also, there is no strict expectation by the practitioner about what specific movement might emerge. Thus it is possible to create novel and unexpected outcomes of how a particular task might be best performed by this particular person at this time. This allows for a process of assessment that is continually evolving as the intervention is unfolding.⁵⁰

In ATM the practitioner verbally provides suggestions for movements for a patient to explore and asks the patient to focus on the sensory outcomes throughout the body. Thus the patient introduces the experimental forces into his or her own system with the intention of understanding how the body as a whole responds. The underlying idea, however, is the same. In my practice, FI is used to assess body image and capacity for movement and as a form of communication when patients do not understand how a force might act on the body or when the patient is unable to produce a range of movements that we might desire to explore. An example might be in a case where spasticity prevents fine discrimination in both sensory and motor realms.

In practice with an individual patient, it is common to move back and forth between ATM and FI during the same session. The session is usually focused on the development of understanding and performing a specific function: turning, rolling, standing, stepping, a functional activity important to the patient, and so on. ATM is a verbal process in which patients perform their own movements; thus a practitioner can work with many individuals simultaneously. At the same time, individuals within the learning group are free to respond differently from one another in ways that may be appropriate only for each of them as individuals.⁵¹ Because ATM is under the active control of the patient, this method is often a more effective tool in reestablishing voluntary control.

Note: A case study on the Feldenkrais method can be found in the online resources associated with this text.

Research

Evidence of effectiveness. In a review of studies of evidence-based studies of effectiveness up to 2004, Stephens and Miller divided⁵⁰ the literature into four different areas: pain management, postural and motor control, functional mobility, and psychological and quality-of-life impact. These categories still hold with more studies being done since in the areas of pain and posture, mobility, and balance, especially in the geriatric population. A growing amount of the literature is in the randomized, control trial format. That literature (through 2015) has been reviewed by Hillier and Worley,⁵² including meta-analysis for outcomes, effect sizes, and biases.

The theory underlying the Feldenkrais method predicts that there should be changes in perception of the body or body image. Elgelid⁵³ reported positive changes in body perception, as evaluated by the semantic differentiation scale in a group of four subjects after a series of ATM lessons. Dunn and colleagues⁵⁴ reported that subjects who had had a unilateral sensory imagery ATM lesson perceived their experimental sides to be longer and lighter and demonstrated increased forward flexion on that side, linking the changes in perception to changes in motor control. Bitter and colleagues⁵⁵ found significant improvements in dexterity compared with a control group following a single ATM lesson. Stephens and colleagues⁵⁶ have shown that ability to image movement is improved in people post stroke after a series of ATM lessons, and furthermore that there is a high positive correlation between the Movement Imagery Questionnaire (MIQ) score and improvements in balance assessed by the BBS. In a qualitative study, Connors and colleagues⁵⁷ made a compelling argument that ATM lessons are based on principles of motor learning and therefore the general literature in an important point of reference.

Pain. The work on pain management suggests that the Feldenkrais method may be especially effective in treating pain that is biomechanical in origin. Mohan and colleagues⁵⁸ in a systematic review, conclude that there is now sufficient evidence to support the use of the Feldenkrais method for the treatment of neck and low back pain. Other examples of research on intervention that addresses pain management reach different conclusions.^{59–64} A number of these papers conclude that the Feldenkrais approach to pain management is better than the traditional approaches used in comparison. Although no research has been reported that looks specifically at the Feldenkrais approach to pain management in patients with movement dysfunction from neurological insults, these treatments may help these patients, especially when the pain is caused by biomechanical malalignment. Current ongoing, not yet published, work with individuals with SCI begins to address the question of pain in this population.

Balance mobility and function. Hall and colleagues⁶⁵ found improvements in balance, mobility, functional activity, and vitality (SF-36) in a large group of elderly women compared with control subjects as a result of a 16-week ATM intervention. These results have been confirmed with other elderly subjects by a variety of researchers.^{66–72}

In the areas of psychological and quality-of-life impact, Kerr and colleagues⁷³ have shown a decrease in state anxiety in subjects who participated in ATM lessons, and Laumer and colleagues,⁷⁴ working with young women with eating disorders, have demonstrated positive changes in self-concept, self-confidence, and behavior resulting from participation in ATM lessons.

The use of ATM with specific medical diagnoses can be found online and can be integrated with the various chapters written on the specific movement problems associated with those diseases of specific areas of the brain.

Multiple sclerosis. The initial study, done in Germany in 1994, looked qualitatively at the effects of a 30-day ATM experience on a group of people with MS. The investigators concluded that ATM improved overall well-being, resulted in greater self-reliance of the participants, and led to better self-acceptance and a more positive self-image.⁷⁵ Johnson and colleagues⁷⁶ studied the effects of FI in people with MS and reported a decrease in perceived stress in the FI compared with the massage controls. Stephens and colleagues⁵¹ reported the cases of four individuals who participated in the same ATM classes over a period of 10 weeks. Three of four reported large improvements in their Index of Well-Being score. All individuals reported improvements in gait and balance; however, there were no measures of gait that consistently improved across the group. Instead, it was found that changes were appropriate to the participant's individual needs and resulted in a greater sense of control. In a follow-up to this study, using a randomized controlled group design, Stephens and colleagues⁷⁷ found improvements in postural control and balance confidence measures, along with a strong tendency toward an increase in self-efficacy and decreased falling. It was also found⁷⁸ that the ATM group had significant improvements in memory of recent events and perception of positive social support. It is interesting to note that they also had a decrease in pain effects.

Cerebrovascular accident. The original publication in this area is the classic work, *The Case of Nora*, in which Feldenkrais explained his work in great detail and described improvements in sensation, perception, and mobility of a woman several years after a right-sided cerebrovascular accident (CVA).⁷⁹ More recently, results from pilot studies have been reported in patients with diagnoses of CVA. Connors and Grenough⁸⁰ reported a decrease in spatial neglect as measured by line and star cancellation tests in a patient after a series of ATM lessons. Nair and colleagues⁸¹ reported the recovery of upper-extremity function

and the return to playing golf in a 68-year-old man after an 8-week program of ATM and FI. This Feldenkrais program was begun only after a 9-month program of traditional rehabilitation had left him with a nonfunctional hand. The Feldenkrais program included mental imagery and bimanual activities. This subject was also studied before, during, and after the Feldenkrais program with functional magnetic resonance imaging. This imaging analysis showed that there was a return to higher activity in the involved contralateral primary motor cortex, with activity of the right hand compared with higher activity in the ipsilateral M1 and SMA that has been shown in other reports of CVA recovery⁸² before the Feldenkrais sessions began. This finding suggests a return to more normal brain function, even after a period of 1 year after the stroke. In a small pilot study (three subjects),⁸³ Batson found an average 33% decrease in movement times on the Wolf Motor Function Test. In another pilot with four subjects, Batson and Deutsch⁸⁴ found significant improvements in Dynamic Gait Index ($P = .033$, 55% average) and the BBS score ($P = .034$, 11% average) and a 35% improvement on the Stroke Impact Scale (SIS). A larger study is in progress to further assess these findings. In a larger follow-up study, Stephens and colleagues⁵⁶ confirmed improvements in balance and gait and documented a strong positive correlation between improvements in balance and increased movement imagery ability.

Other Neurological Diagnoses

Cerebral Palsy

There are some preliminary findings with other neurological diagnoses. Shelhav-Silberbush⁸⁵ reported improvements in motor, sensory, kinesthetic, perceptual, and learning functions in two case studies of children with CP.

Spinal Cord Injury

The first report of a Feldenkrais method intervention with SCI was by Ginsburg in 1986.⁸⁶ He reported improvements in mobility and reductions in pain following FI and ATM classes. For several years, Allison has been writing about work with people with SCI. Her first reports documented improvements in sensory and motor function.⁸⁷ More recently, she has noted improvements in pain management.⁸⁸

Parkinson Disease

Shenkman and colleagues⁸⁹ first reported improvements in balance, gait, and functional movement in two people with Parkinson disease (PD) as a result of interventions that were based partly on a Feldenkrais approach. This work has been supported more recently by Teixeira-Machado,⁹⁰ reporting that working with Feldenkrais method-based exercises has led to improvements in quality of life and decrease in depression scores in people with PD.

Dementia

Ann published the first case study work on people with dementia in 2006.⁹¹ In these cases, she documented her work using FI to transform the lives of several people with dementia, not to reduce the dementia but to change the nature of their interaction with the world so that they were able to communicate better with staff and family, were less fearful, and were safer and more independent in their mobility. This study was followed by two other studies by a group in San Francisco under a guiding idea of preventing loss of independence through exercise (PLIE). This program used an integrative exercise program, combining conventional aerobic and strength exercise and complementary approaches, of which Feldenkrais played a significant part. These studies looked at function and behavior over 36 weeks in a crossover study. The first was a qualitative study by Wu and colleagues⁹² which had

three main findings: improved body awareness and memory for movement, more emotional comfort and positive feeling about sharing personal stories, and development of social skills leading to more positive social interactions. This study was followed up by Barnes and colleagues⁹³ who found clinically meaningful improvements in measures of quality of life, physical performance, and cognitive function.

Other Areas of Research

Gilman and Yaruss⁹⁴ have reported significant improvements in several young children who had problems with stuttering. Ofir⁹⁵ reported improvements in flexibility, mobility, and level of dependence in two young women who had sustained traumatic brain injuries.

Conclusion

The Feldenkrais method, in its two forms, embodies a process of somatic learning that aims to develop the perceptual capabilities of patients as it underlies the control of movement and affects function. Research literature suggests that predicted results of improved body perception and motor control are supported in work with people with neurological diagnoses, including dementia. These findings are encouraging and suggest that the Feldenkrais method makes positive contributions to our understanding and methods of rehabilitation. However, we must approach these findings with caution because many are from case studies or small pilot investigations. Research continues to substantiate these initial findings at a higher evidence-based level.

The Pilates Method

Brent Anderson

German-born Joseph H. Pilates developed his unique method of movement therapy and lifestyle in the early 1900s. As a young man, Pilates was affected by a multitude of illnesses that left him physically weak. To strengthen his frail body, Pilates studied boxing, yoga, martial arts, Zen meditation, and ancient Greek and Roman exercises. Joseph was interned in England at the Isles of Man during World War I, where he continued to develop his philosophy of health and happiness. His experiences led him to develop his own unique method of physical and mental conditioning. In 1926 Pilates brought his movement exercise program with him to New York City. Joseph Pilates's studio was soon embraced by many artists and choreographers from the dance companies of Martha Graham, George Balanchine, and Jerome Robbins. At the time, traditional allopathic medicine lacked the knowledge of how to restore injured dancers to their prior level of activity. Pilates encouraged nondestructive movement early in the rehabilitation process and worked to correct underlying biomechanical problems. This early movement intervention without pain was believed to hasten the healing process and allowed dancers and athletes to quickly return to their life activities that had meaning to them. Thus they realized that Pilates had improved their quality of life.

Almost a century later, the Pilates method has gained popularity within the rehabilitation setting because of its assistive nature in restoring functional movement. Rehabilitation practitioners are currently using the method in a variety of fields, including orthopedics,^{96–104} pain management, women's health,¹⁰⁵ neurological rehabilitation, geriatrics, pediatrics,^{102,106,107} and even acute care. Most Pilates exercises in the rehabilitation setting are performed on specifically designed apparatus: the Reformer (Fig. 39.1), the Trapeze table (Fig. 39.2), the Wunda Chair (Fig. 39.3), and the Ladder Barrel (Fig. 39.4). The apparatus regimen evolved from Joseph Pilates's original mat work, which was too difficult for many injured individuals. On the apparatus, the use of springs and manipulation of the orientation to gravity can be modified to assist an individual with movement restrictions to successfully complete movements that would otherwise be

Fig. 39.1 The Reformer Apparatus Used in Pilates.

Fig. 39.2 The Cadillac Table Apparatus Used in Pilates.

Fig. 39.4 The Ladder Barrel Apparatus Used in Pilates.

difficult. Ultimately, by altering the spring tension or increasing the challenge of gravity, an individual may progress toward functional movement safely, efficiently, and without pain.

Pilates Principles

Joseph Pilates espoused only three guiding principles according to the Pilates Method Alliance: (1) Whole Body Healthy, (2) Whole Body Commitment, and (3) Breath. A number of the first-generation Pilates practitioners known as *the Elders* expanded Pilates principles to include concentration, control, precision/coordination, isolation/integration, centering, flowing movement, breathing, and routine.^{100,108} Polestar Pilates has modified the eight first-generation principles into six principles that have a greater practicality in the rehabilitation environment and stronger scientific support than the classic principles. The six Polestar Pilates principles include breathing, trunk control and axial elongation, mobility, alignment, efficiency of movement, and movement integration.*

Breathing. Faulty breath patterns can be associated with complaints of pain and movement dysfunction.¹⁰⁹ Pilates movements create an environment where breath facilitates improved air exchange, breath capacity, and posture. During Pilates exercise, breathing is used to facilitate stability and mobility of the spine and extremities. Because of the movement of the rib cage on the thoracic spine, inhalation can promote spinal extension while exhalation can promote spinal flexion. Breath may or may not facilitate movement based on where the breath is occurring. If accessory breath occurs while attempting spine extension, it would not have a positive movement on the spine articulating into extension. It is then important to realize that the direction of movement in the ribs facilitated by breath determines whether breath facilitates movement or not. Similarly, breath may assist with stability of the spine through the coordinated contraction of the diaphragm and the lower abdominal muscles, both of which attach to the lumbar spine and pelvis.^{110,111}

Trunk control and axial elongation. Core control is the optimal recruitment of the trunk musculature required to perform a given task

in relation to the anticipated load. The transversus abdominis, internal abdominal obliques, external abdominal obliques, multifidi, erector spinae, diaphragm, and pelvic floor muscles are key organizational muscles that work together during the movement in healthy individuals.^{112–114} Motor control studies indicate that the coordinated, subthreshold contraction of these local and global stabilization muscles modulate the level of spinal stability required to safely perform activities of daily living (ADLs).¹¹⁵

Axial elongation is the proper alignment of the head, spine, and pelvis that provides optimal joint spacing during movement. Correct joint spacing avoids working or resting at the end of range, which can place undue stress on the inert and contractile structures of the trunk and extremities.^{116,117} Through emphasis on axial elongation of the spine and maintaining appropriate joint spacing, soft tissue surrounding the joint can move more freely, and the risk of injury can be minimized. Recent discussion has challenged the Pilates approach to trunk control and has passed through the fitness and rehabilitation fixation on core control, where the assumption is that the stronger the core muscles, the healthier the spine. Research has been leaning away from this paradigm to one of motor control and efficiency. Though Pilates uses the trunk musculature and coactivation to successfully perform the vast repertoire of exercises, the focus is on efficiency and spontaneous contractions of the trunk musculature based on the anticipated load and the amount of intraabdominal pressure required in that moment.¹¹⁸

Mobility. Spine mobility allows for the distribution of movement throughout the cervical, thoracic, and lumbar spine. This principle can also be thought of where distribution of movement equals distribution of force. It has been suggested that repetitive movement at a hypermobile spinal segment may result in microtrauma or macrotrauma.^{119–121} Hypermobility is often a result of a lack of movement in a neighboring segment or joint.¹²² Pilates exercise attempts to facilitate a change in movement strategy during functional tasks and distribute the forces through other motion segments. Patients are trained to distribute movement in the spine over a greater number of spinal segments, thereby decreasing potentially harmful forces at the hypermobile segment. The ability to segmentally move the spine decreases unwanted stress and shear of the spinal segments and increases the efficiency and fluidity of movement. The clinical findings of decreased low back pain because of Pilates exercise may be due to changed strategy that reduces the stress afforded to the pathological segment(s).

Efficiency of movement. Efficiency of movement is the minimization of unnecessary muscle contractions that tend to interfere with healthy movement. The excessive recruitment of antagonist muscles is obstructive and significantly increases the amount of energy required to perform a task.^{123,124} This principle can be applied to functional movement skills as well as performance skills. Inefficient motor recruitment can often be recognized by the amount of tension or faulty posture in the head, face, neck, and shoulder girdle, in relation to the thoracic spine and trunk.

Alignment and weight bearing of extremities. Alignment and posture are concepts often incorporated in the field of rehabilitation. The Pilates principle of *alignment* refers to the most energy-efficient posture (static or dynamic) of the body for a given task. Proper postural organization can significantly decrease energy expenditure during daily activities by improving mechanical advantage.^{125,126} Faulty alignment in the extremities and the spine can be a source of decreased range of motion, loss of joint congruency, early fatigue of muscle groups, or abnormal stresses on inert structures and may potentially cause degeneration and injury.^{127,128}

Pilates provides a closed chain environment that facilitates compression and decompression forces on the axial skeleton and

*The six modified Pilates principles were developed by the Polestar Pilates method.

extremities through a full range of motion. Adjusting the spring resistance or patient's orientation to gravity can alter the amount of load. The ability to regulate load based on an individual's physiological limits, set by age or pathological condition, allows practitioners to more safely and effectively stress the skeletal and soft tissue systems. Theoretically, these forces can help stimulate osteoblastic activity and provide nutrition to a larger surface area of the joint and its surrounding connective tissue.^{129–131}

Movement integration. Many forms of rehabilitation focus on treating limitations of anatomical structures and neglect the neuromuscular reeducation required to learn to regain the motor control necessary to perform a complex task. Pilates provides a more holistic approach by emphasizing the synthesis of mind (motor control) and body (physical strength and flexibility) to achieve fluid movement. Mobility, control, and coordination of the extremities with the trunk and the trunk with the extremities are examined and trained through motor learning and repetition of practice. In addition to the physical and mental capacity to complete a task, the environment in which a task is performed can greatly affect the success of movement organization.^{132,133} Pilates provides an environment that can be modified on the basis of a patient's impairments and limitations, providing a safe, successful, and pain-free movement experience.

Clinical Application

Within the Pilates environment, faulty movement strategies are broken down into components and addressed through task-oriented interventions. By adaptation of the environmental constraints, such as gravity, assistance, and BOS, the degrees of freedom that must be controlled by the nervous system are reduced.¹³⁴ The successful manipulation of the environment can hasten the functional reeducation process and allow exercises to be safely progressed until the desired outcome is achieved. Pilates practitioners are also trained to be able to modify any exercise, so it is pain-free for the patient. It has been suggested that successful, pain-free movement, in addition to enhancing physical attributes, helps alleviate anxiety.^{135,136} By decreasing anxiety levels and improving self-efficacy, the development of chronic pain and dysfunction related to the injury may be prevented.^{137–139}

The potential causes of faulty movement patterns include congenital defects and abnormalities, habitual adaptations, and compensation because of injury. Motor control problems associated with the pathological condition need to be addressed before the application of therapeutic interventions that are temporary coverups for problems that have deeper roots. For example, a pathological condition at the L4/L5 segment could be a result of faulty movement patterns in the hips and other lumbar vertebrae. The lack of movement in surrounding joints might be the mechanism of the lesion; however, treatments are often focused on the site of the lesion rather than the mechanism of the lesion.

One problem often encountered in the rehabilitation setting is flawed movement progression. On a spectrum of movement progression, practitioners often jump from passive movement to resistive movement too quickly. Through facilitation of assistive movement, a pattern can be practiced without irritating the lesion. Assisted movement with the use of springs can allow for a decrease in unwanted muscle activity or guarding that is often associated with pain, weakness, or abnormal tone. As the pattern progresses and symptoms decrease, assistance decreases, and dynamic stabilization can be emphasized to challenge the newly acquired mobility or stability in a more functional and gravity-dependent position. Resistive movements are introduced only after adequate dynamic stability of the trunk is demonstrated through controlled movements that prevent excessive loading of the injured tissue. The five environmental conditions in

Pilates that are altered to allow a therapist to facilitate motor changes are the following:^{132,140}

1. Narrow or widen the BOS
2. Raise or lower the center of gravity
3. Lengthen or shorten the length of the levers
4. Decrease or increase the degree of assistance (spring tension)
5. Progress from a foreign environment to a familiar environment

Traditional modes of muscle conditioning focus on isolating specific muscles and producing a maximal voluntary contraction. Although this has been found to positively alter the targeted muscle, the gains achieved have not always been shown to correlate with functional return. Pilates progresses patients through stages of motor learning via neuromuscular reeducation of functional movement patterns and emphasizes efficient recruitment of motor units. The patient is first trained to become aware of or gain a perception of current movement strategies. Then the patient must cognitively learn a new strategy. Finally, the patient must practice or act until efficient with the new strategy of movement. Task-specific interventions are progressed from a foreign to familiar environment by altering the level of assistance and the patient's orientation to gravity.

Summary

Pilates is an effective exercise system that works well in conjunction with traditional PT and OT practice.^{141–143} The Pilates-evolved apparatuses allow patients to safely perform exercises that improve strength, flexibility, balance, coordination, and motor control in an environment that can be easily progressed as they advance in their rehabilitation process. In addition, Pilates is thought to address the psychosocial components of an injury that leads to chronic pain or disability by decreasing anxiety and improving self-efficacy.^{137,139} Early return of functional movement after an injury helps physically and mentally empower individuals with regard to the demands of life and is crucial in the long-term success of patient outcomes. The Pilates environment is a clinical tool that can be used by practitioners to provide patients with a safe, successful, and pain-free way of restoring function and quality of life.

Tae Kwon Do

Clinton Robinson, Jr., 9th Degree, Grand Master

Darcy A. Umphred, 4th Degree

Philosophy. The overall philosophy of Tae Kwon Do (TKD) can be summed up in the student oath recited by all practitioners at the beginning of each class: *"I shall observe the tenets of Tae Kwon Do: courtesy, integrity, perseverance, self-control, and indomitable spirit."* The tenets are to be practiced outside as well as inside the training hall in all aspects of life. All aspects of these tenets reflect CNS control and neuroplasticity as well as incorporate cognitive, emotional, and motor aspects into an integrated whole. The oath continues with, *"I shall respect the instructors and seniors,"* which refers to having respect for all people—our teachers, our parents, our peers, our students, our patients—all individuals with whom the student may interact throughout a lifetime. *"I shall never misuse Tae Kwon Do."* No matter what motor skill a student develops, it is not to be used to build one's ego or to injure another unnecessarily. *"I will be a champion of freedom and justice."* Individuals are expected to develop a sense of responsibility for those less fortunate than themselves and to be active participants in the development of humanity as a whole. These tenets are basic philosophies of both occupational and physical therapy as well as in many martial arts. Empowering our students or patients to overcome their movement limitations and once again actively participate in life should be the goal of all therapeutic treatment outcomes. *"I will build a more peaceful world."* Understanding that change begins with self and

developing and integrating the mind, body, and spirit while helping others do the same will set an example not only in the classroom but in our society both nationally and worldwide, so that others may improve themselves. The profession of occupational therapy has identified similar educational outcome criteria for students who graduate from an accredited educational program. Physical therapy has begun to integrate the mind, body, and spirit into outcomes, including the interactions of those three human characteristics as part of the accreditation criteria set forth by the Commission on Accreditation in Physical Therapy Education (CAPTE). There are commonalities between the practice of TKD and some of the expectations of students in educational programs in both physical and occupational therapies.

The overall goal of TKD training is the development of self-sufficiency through rigorous physical and mental practice. With this training, an inner balance or peace can be attained, thus balancing all aspects of a person's life. Students are expected to strive for their own personal excellence versus comparing that skill with another's. Thus individuals with physical challenges are always encouraged to participate.^{144–146} Their challenges and expectations are different, but achieving personal excellence gives them the same respect and confidence that any other student would receive. Thus TKD as a movement science empowers participants to gain or regain a feeling of empowerment over the mind, the spirit, and the physical body. It engages all students to participation in a community of people who all begin as novices and advance only as each respective mind, body, and spirit grows as a whole unit.^{147–149} At times, an individual may have physical restrictions that limit the ability to do specific techniques, but that never limits one's ability to grow and advance as a human being and continue to learn as a student of TKD.¹⁵⁰

Philosophy of training. Training in TKD consists of three primary components: forms, breaking of solid objects, and sparring. Other martial arts focus on some of the same components. The practice of tai chi focuses on the first component: forms. But with practice, a TKD student not only will have the skill to perform a sequential pattern or combinations of simple and complex movements (forms), but also will overcome a perceived obstacle (board) and interact with another person using quick movement techniques with control (sparring).

Poomsee. Poomsee is a prearranged dance of defensive and offensive techniques against an imaginary opponent. The practice of poomsee increases the practitioner's memory, coordination, balance, and body awareness. All poomsee components have predetermined patterns of movements with a proper beginning and ending point that include various stances, along with hand and kicking techniques. The complexity and difficulty of these forms increase as the student progresses. Simple movements and combinations of patterns challenge beginners, and appropriate levels of complex patterns challenge the highest-ranking black belts. Thus all individuals studying TKD are challenged to be in a state of growth and learning.¹⁵¹

Kyukpa. Kyukpa is breaking of solid objects such as boards, concrete, and bricks using a body part as a weapon. Kyukpa represents overcoming limitations and obstacles and facing fear. It requires tremendous concentration and belief in one's abilities. In addition, it allows participants to demonstrate the power they have attained, thereby increasing self-confidence. Self-confidence is the primary attribute in conflict resolution skills and leads to the understanding that there are few situations in life in which physical confrontation is necessary. Board breaking helps teach the student that an object, such as a board, is only an obstacle if you, the student, empower that object to have that role. Once the board is broken and the limb has passed through the obstacle, it no longer is an obstacle. This philosophy reflects life and plays a role in the establishment of values and motivation

by teaching practitioners to go beyond the known and through the obstacles that life poses. Facing the unknown is always a part of life. Some of us run from that challenge and some just keep hitting the obstacle over and over without any resolution, which causes pain and frustration. Others going beyond the obstacle allow the mind to realize that it is now in the past and no longer needs to expend energy worrying about the challenge. Kyukpa allows any student of TKD whether a child, adolescent, adult, or senior citizen to face and go beyond those perceived obstacles.

Kyorugi. Kyorugi is actual sparring between two people using both defensive and offensive techniques learned through fundamental TKD practice. Kyorugi can be further broken down into two types. (1) In *one-step sparring*, practitioners take turns initiating a prearranged attack—one person attacks while the other defends. This allows the practitioners to engage each other without risk of injury to either party. It also allows them to practice proper distancing, execution of the techniques, and timing of that execution. This develops confidence in the ability to use the techniques properly if the need arises. (2) In *free sparring*, neither opponent knows what the other is going to do. Although free sparring may appear dangerous to one untrained in TKD, it is a relatively safe activity. Free sparring requires respect for your partner and absolutely controlled motions at all times. It is an exercise in which the aim is for all involved to increase their skill level.¹⁵² It develops the practitioner's quick motor responses, confidence in his or her abilities, and overall awareness, as well as a cooperative learning environment.

Although both offensive and defensive techniques are viewed as equally important, all training is begun with blocking techniques to indicate that TKD never allows any initial offensive attack in its technique. Blocking techniques are practiced diligently so that they may function equally as offensive techniques. This way one can defeat an opponent, whether in the classroom or in real life, without either suffering or inflicting serious injuries. This builds self-confidence and replaces a perception of the "role of a victim."¹⁵³ Defensive techniques are not only power against power but truly reflect power of the attacker and deflection by the opposition. This deflection can stop the attacker, redirect the power back onto the attacker, or incapacitate the attacker in order for the opposition to get away. The skill in redirecting the force and intent of an attacker is not too different from redirecting a patient's motor pattern into a direction that would be functional as a motor program. The TKD practitioner and the therapist are working with the pattern of movement presented to them. The intent of the TKD student would be to disempower the attacker by redirecting energy, and the intent of the therapist would be to empower the patient with the same energy.^{154–156} In Tai Chi, this would be considered the Ying and Yang of life and movement.

In TKD training, all students begin in the same place. There is no concern for one's status in life. The white belt is used to denote the beginning student. With all students beginning at that level, it allows another aspect of training that is critical to all students and individualized. Training encompasses setting and achieving goals or empowering oneself toward excellence and to one's own quality of life. In TKD, there is a belt ranking system, and the object is to progress through the various levels of proficiency, culminating in attainment of the black belt. Everyone, regardless of social status or physical skill, has the same opportunity to advance in TKD. Students who persevere and obtain a first-degree black belt soon learn that they have only begun their circle of growth and learning. With additional years of training, students may advance in black belt ranks that should reflect a greater understanding and acceptance of those initial tenets. The circle of growth will always lead to further integration of mind, body, and spirit and an inner peace and balance.¹⁵⁷ The balance of mind, body, and spirit is the

core of other complementary therapy paradigms and ultimately seems to be an element linked to health and healing.¹⁵⁸

Tae Kwon Do and complementary therapy^{157–163} Although TKD is a martial arts style whose original intent was not to heal a body system condition or to allow one to regain a functional movement activity lost after some acute health care crisis, the concepts and procedures learned, repetitively practiced, and transformed into life behavior have established the foundation for health and healing in individuals. Most students in TKD fall within a health and wellness model of life.^{164,165} *Their choice to participate is not based on a bodily system problem, as often seen in a physical or occupational therapy clinic. These individuals are looking to participate from a wellness perspective and expect that Tae Kwon Do will enhance their balance and their cardiopulmonary and musculoskeletal systems through exercise.* Yet many individuals have experienced some aspect of musculoskeletal system problems during their lives. These individuals, as a result of life activities, have forced the CNS to adapt and accommodate to prior bodily system problems such as ligament tears or *physical or emotional* trauma from bullying in school. These experiences create change whether the deficits are motor, cognitive, or affective.^{166,167} Similarly, with identified chronic motor limitations that have caused functional activity restriction after a birth trauma, an external head trauma, or an internal insult, TKD can help maintain existing motor function, cognitive integrity, emotional balance, and a feeling of self-worth in the face of a long-term and possibly progressive neurological problem. All these components encourage an individual to participate in life and base advancement not only on the standards of TKD but also the individual goals set by each student.

As in all martial arts, TKD requires active participation by the student. When any TKD movement pattern is examined, certain motor control components are seen to be interacting. There are a variety of activities that generally occur during a class. First, there are warm-up exercises, after which the student will work on (1) her or his respective form or *poomsee* or *hyung* (dancelike patterns that may have 18 to 100 different movement sequences), depending on the level of advancement; (2) sparring, which is done either with one partner moving with an identified pattern while the other stays in one position or with both moving and learning to respond to the movements or feints of the other; or (3) learning to focus and perform specific strikes or blows that will lead to skills in board or brick breaking or defending oneself against a life-threatening attack.

When demonstrating the forms, the student will need to work on balance, postural tone, the state of the motor generator, synergistic patterns of movement, trajectory, speed, force, directionality, sequencing, reciprocal patterns, and the context within which the movement is being done. Similarly, memory of the specific pattern, movement sequences, and direction of the movements requires concentration. As the student progresses in rank, the specific patterns become more and more complex, increase in number of specific movements, and frequently change from quick movements to slow, controlled patterns. This repetition of practice and increase in difficulty leads to higher skill and cortical representation.^{168,169} If other students are also practicing in class, then each individual needs to be aware of the total environment to respect the space of all other students. This unique individual experience during a group activity allows for variance during each class and thus should lead to greater motor learning and cortical representation.^{169,170}

When students learn and practice either one-step sparring or free sparring, they not only work on learning combinations of movement patterns and how they interact or conflict with their partners, but they also learn how to control their emotional responses to threatening situations. Little in life is worth hurting another—a basic principle of

TKD. During sparring, the potential for injury is directly correlated with the control over the force and direction of movement of each individual. That control can be dramatically affected by emotion. Once students learn to control the emotional aspect, their skill and techniques become procedural, which allows their cognitive analytical ability to drive responses. The student is then ready to begin the study of the mind, body, emotional, and spiritual connections that need to intertwine and become harmonious if the student is to learn the true meaning of TKD. Sparring *should be* a controlled situation in which injury or damage to another person is never acceptable. Research over the last 15 years has pointed out the danger a student faces during TKD competition. Mistakes both in techniques themselves and in emotional force placed behind the techniques do create a potential danger to students.^{171–177} Therefore safety gear is required at all TKD competitive events for color belt students, and mouth guards are always required no matter the student's age. During class the instructor is never to spar above the skill level of the student nor is the student to enter into a sparring match with the intent to prove power whether emotional or physical. In reality, when a student does take that emotional stance, the motor skills reflect only just how much more that student needs to learn. It is the teacher's responsibility to help redirect students' emotional stances and teach that TKD represents control, not lack thereof. Board and brick breaking are the activities in which a student can demonstrate force production as it interlocks with trajectory, speed, and position in space. If any perceptual or motor variables are incorrect, the student will not succeed. These skills are taught and practiced not to damage or destroy, but rather to learn to go beyond or through the obstacle. In reality, to be successful at these tasks, the hand, elbow, or foot that is used to go through the obstacle is only an extension of the body. Success is based on the learner's ability to tie the entire body's motor response, its rotation, its balance, its trajectory, its force, and its speed into a motor program that will project through one or more obstacles as a knife cuts butter. If the student, emotionally, believes that the obstacle will not break, it will not! The student will stop the movement before completing the task and often empower the wood or brick as a successful obstacle versus empowering herself or himself to overcome that obstacle as if it were not there. This concept is a critical element of TKD. It is also a critical component of any patient's learning of any motor program, turning the program into a functional activity, and improving one's quality of life and ability to participate in that life's adventure. If a patient's CNS is convinced that the movement is not possible, then that individual will fail. Without internal motivation by an individual to accept the possibility of success, acceptance of failure is embraced. This internal environment plays a key role in any individual's overcoming what he or she perceives as an obstacle in life.¹⁷⁸ It is the role of the TKD teacher and the therapist teacher to empower the student to the possibility of success while creating an external environment that will enhance the probability of that success.^{151,168} Patients and TKD students need an environment that creates safety, promotes success, and empowers the individual to overcome life obstacles.

Those who respond best to TKD training to maintain motor function are individuals who are motivated to move, enjoy interactions with others, have cognitive integrity, and have some control over their motor system. When instructing a TKD club of individuals who had all had traumatic head injuries, the teacher, a TKD instructor, and physical therapist, whose focus had always been in neurological rehabilitation, found that using therapeutic skills through TKD movement patterns augmented the students' learning and helped them regain motor function through guided activities without the students ever realizing there had been any kind of therapeutic intervention. To those students, they were learning and advancing in a martial arts style, were

tested and judged according to their development of skills, and felt accomplished as adults participating in an adult activity. Carryover and improvement in balance, postural integrity, reciprocal patterns of movement, and control of trajectory, force, and speed, as well as development of emotional stability and confidence, could be easily identified and evaluated by the use of standard objective measurement tools. As long as the student continued training, improvement would be expected and carry over into other life activities anticipated. These are the principles of neuroplasticity and have meaning both within the pre-disease or wellness model as seen in TKD^{47,179} and after acute injury, disease, or insult to the CNS.^{180–184}

Note: A case study on Tae Kwon Do can be found in the online resources associated with this text

As therapists, we desire all patients to continue with movement activities that encourage participation in life. TKD provides an excellent movement-based activity that leads to physical fitness,^{185–191} and has been studied in relation to changes in vitamin and hormonal levels in elite athletes.^{192–195} One systematic review studied martial arts training, looking at a variety of martial arts styles, including TKD and Tai Chi (TC). Both styles lead to an increase in health status of participating individuals.¹⁹⁶

When considering the elderly population, a group frequently referred to both PT and OT for movement and balance disorders, TKD training has been shown to improve balance, walking abilities, and somatosensory organization in standing.^{165,197} Looking at a martial art that encourages participants to stretch to their respective limits of stability both with fast and slow movement patterns, a valid question must be asked: “Would TKD be harmful to this population, especially if the participants had osteoporosis?” Two research studies investigated that question and determined that training in martial arts such as TKD can teach fall training, prevent hip fractures, and be safe for individuals with osteoporosis.^{198,199} Accelerated patterns of the head and pelvis during upright walking can lead to falling in community-dwelling elderly people.²⁰⁰ Individuals with Parkinson disease show evidence of body system problems causing impaired head and trunk control, thus increasing their risk of falling.²⁰¹ During TKD practice as a beginner or advanced student, individuals learn to use the head and hips in rotational patterns, which increases neural efficiency or reaction time while maintaining an upright posture and moving their upper extremities.^{202–204} All these components should help maintain the physical capabilities of an elderly individual.²⁰⁵

Over the last decade, many research articles have been written that look at one aspect of TKD training, whether it be strength, balance, coordination, motivation, cardiac fitness, emotional self-control, or the effect on the many other bodily systems that interact during a TKD workout. The reader must understand that it is all those elements that make up a TKD student, teacher, or master. In the future, more research will identify this martial art as a potential form of physical exercise for all populations of individuals who have comorbidities after CNS injury (see the case study on *Tae Kwon Do* online). Physicians and therapists should consider recommending this martial art as an exercise activity for individuals who wish to maintain or regain their abilities to participate in life activities.¹⁹⁷ Until then, students of all ages will be welcomed into TKD studios and encouraged to reach beyond their perceived potential. The age ranges of TKD students now include the elderly population, with classes focusing on strength, balance, and core work, without the need for strenuous sparring or board breaking.²⁰⁵ A TKD instructor will modify each senior’s class experience to allow each individual to reach his or her potential without injury or trauma.

Tai Chi.

Howe Lui

As one of the more popular Chinese martial arts, TC was designed and developed 400 years ago. Its slow, gentle, and graceful movements in coordination with breathing in a calm, relaxed, and meditative way has made TC not only a defensive martial art, but a health-promotion exercise program as well.²⁰⁶ Currently, TC has been recognized as an effective intervention for improving health, increasing social interaction, preventing falls, and enhancing posture not only for the general population, but for patients with neurological disorders.²⁰⁷

The term “Tai Chi” is the common English spelling of the martial art/exercise, but it is also spelled in the literature as “taiji,” “tai ji quan,” “tai chi chuan,” and “t’ai chi”; the Chinese pinyin romanization is the form most often found in scholarly social science literature.^{206,208} The Library of Congress and most university libraries also catalog Romanized Chinese with pinyin. The romanization Tai Chi is most popularly used because it is the spelling most familiar to both clinicians and patients and is the standard rendition of the term in PubMed.²⁰⁸

During TC practice, a practitioner holds a semisquatted posture and shifts his and her body weight from one leg to the other in slow, repetitive, and alternating movements that emphasize smooth trunk rotation and coordination among the body, extremities, and breathing.^{206,209,210} The TC intensity is moderate and approximately equivalent to walking at a speed of 6 kilometers or 3.7 miles per hour.^{211,212} Because of its beneficial effects on health promotion and improvement of human dysfunctions, including neurological disorders, TC has been considered one of the most promising exercise programs that people with neurological diagnoses can practice to improve their medical conditions.^{207,213}

Tai Chi Styles and Forms

The term “style” refers to sequences of TC movements generally differentiated by lineage names (Chen, Yang, Wu, etc.). What is now known as Chen-style TC was the earliest TC, originating around the middle of the 16th century in China. The term TC or TC Chuan (supreme ultimate boxing) does not appear in historical documents until the late 19th century, but the “internal” or “soft” martial art styles that adopted the name can be documented as early as the late 18th century.²¹⁴ Besides Chen style, there are four other styles of TC that are popular today (Yang, Wu, Sun, and Wu/Hao) and claim their origins in Chen style, though this is a matter of some debate among Chen-style practitioners.²⁰⁶ It should be noted that “Wu/Hao” TC bears no relation to “Wu”-style TC. Wu and Hao are family names, but the two Wus are represented by different Chinese characters.

Today, Yang style is the most popular style practiced by TC practitioners.^{209,213} Its characteristics are slow, large, graceful, and sequential movements from one pose to the next with a semisquatted but upright posture (knees bent slightly, less than 30 degree).^{208,209} Chen style^{208,215} is ostensibly more “martial” in appearance. It requires a lower stance (knees bent more, around 30 to 60 degree) that may need more energy expenditure during practice.²¹⁶ Chen also intersperses quick, explosive movements and stamping with slow movements,^{210,216} which may explain why Chen style was not as common as Yang style in patient populations. The Sun style features relatively fast hand and slow leg movements.²¹⁰ The Wu style set is slow, requiring internal power to maintain the trunk in a constant upright posture,²⁰⁶ whereas the Wu/Hao style requires a high stance position (like Yang style) with relatively rapid execution of small movements.²¹⁰

The term “form” refers to individual movements within those styles. The number of forms practiced by TC practitioners can range from 6 forms²⁰⁹ to 108 forms.²¹⁷ In 1956, the Chinese Sports

Commission²⁰⁶ adopted Yang style to develop a simplified 24-form TC for ordinary Chinese to learn and practice. The 24-form Yang style was the most frequently reported and commonly used among TC practitioners in the world. Currently, many short TC forms were adopted or modified from the 24-form Yang style.²⁰⁸ The number of forms was selected on the basis of the subject's functional level. Healthy, functionally independent subjects could learn and practice 24 or more forms, whereas those with lower functional levels might learn much shorter forms.^{207,208,213} For patients with neurological disorders, usually only TC movement components or short forms are taught.^{207,213,218–220}

Characteristics of Tai Chi Movement

Several characteristics of TC performance may need to be highlighted, as they are often emphasized by a TC master to new learners.^{207–209,213} *First*, to seek the quietness in moving, each TC movement should be full, gentle, calm, and graceful. The slow and alternative opening-out and closing-in of body parts (e.g., the upper extremities) may make the movements look like a moving light silk fabric or like a quiet, smoothly running creek. *Second*, to coordinate the body movements with deep-breathing patterns, when the arms move away from the body, it is time to breath in; while the arms move back toward the body, it is time to breath out. *Third*, to coordinate the body movements with the eyes focused, the trunk, neck, and head rotations should direct the eyes to focus on the palm. During this time, the practitioner should always target the hand with the palm facing up. *Fourth*, to maintain a meditative technique, the mind should be constantly clear, relaxed, and calm, with awareness of body parts in the external three-dimensional environment during TC movements.

Effects of Tai Chi Practice on Movement Science

It has been extensively studied and reported that through the practice of TC, an individual is able to improve bone density, cardiopulmonary function, physical abilities, risk of falls, quality of life, self-efficacy, psychological response, and even the immune system.^{213,221} In addition, effects of TC on posture, balance, strength, flexibility, and gait have also been largely studied and reported.^{207,208} As a mind-body exercise, the main part of a TC movement is correct posture. Regardless of what styles or forms of TC is performed, the performer always tries to maintain an upright trunk with the lower extremities semisquatted—this is the starting point and foundation of each TC movement.^{207,208,213,222}

Research has shown that TC practice improves the dynamic balance through assessments of posturography, stepping reaction time, maximal step length, Timed Up & Go, BBS, Tinetti Balance Scale, and functional reach. But such improvements seemed to be inconsistent to static balance, as tested with single leg stance and tandem stance.²⁰⁸

Effects of TC on strength are primarily on the lower extremity hip,²²³ knee and ankle,^{223–225} and erector spinae in the trunk.²²⁵ Additional evidence includes improvement of upper extremity function and range of motion,²²⁶ but its effect on strength in the upper extremities is not clear. Its effect on grip strength was reportedly not improved.²²⁷ From the authors' experience, while incorporating TC in patients with neurological disorders, the initial focus was aimed at correcting or regaining adequate range of motion. After the patient was able to demonstrate and practice TC movement patterns progressively, a cuff weight was added (starting from ½ pound) to the wrist with continued TC practice, thus improving upper extremity strength.

Studies showed improvement in function and gait with greater control of movement and breathing slowly.²²⁸ These practitioners of Tai Chi and considered patients in a traditional medical environment demonstrated more timely posture correction, postural recovery from potential loss of balance, and dynamic postural control when body

weight shifted between the left and right lower extremities or at gait initiation.^{225,229,230} During double-support time, the mechanical loading on the TC practitioners' knee joint is reduced.²³¹

Yin-Yang Philosophy in Tai Chi Theory and Practice

Tai Chi is developed based on the Chinese philosophy that everything, regardless of the macro- or the micro-world, is formed by Yin (the negative) and Yang (the positive). Yin and Yang are relative: Yin can be Yang and Yang can be Yin. For example, Earth is the Yin in relation to the Sun, but can be the Yang in relation to the Moon. Also, Yin and Yang are constantly and interactively coordinating to reach a dynamic harmony. Other environmental examples include the mountain is Yang and the river is Yin; the hot is Yang and the cold is Yin; the day is Yang and the night is Yin; the external is the Yang when the internal is Yin; and the rigid is Yang and the soft is Yin. As human beings, we live in a world where Yin and Yang are always working together to maintain the internal and external harmony.

According to *I Ching* (an ancient Chinese book of wisdom) and traditional Chinese medicine, Yin and Yang also coexist in the human body. For example, the Yang indicates the upper body and the back of the body, while the Yin indicates the opposite. Body extroversion (with extremities opened up) is the Yang, and body introversion (with extremities closed in) is the Yin. More specifically in the respiratory system, the nose is the Yang while the mouth is the Yin, as the nose is above the mouth. In terms of breathing action, words from *I Ching*, "Inspiration is the Yang, (Qi) flowing on the back of the body; Expiration is the Yin, (Qi) flowing on the front of the body. The alternating change of Yang (inspiration) and Yin (expiration) is the fundamental component of human life."

With these precepts, it is understandable that during TC practice, we emphasize the arm movements to coordinate with the respiration pattern. Namely, for Yang, one must take deep breaths in with the nose while the arms are opened up or away from the body in an upright relatively rigid posture. While for Yin, one must perform in an opposite pattern by deeply breathing out with the mouth while the arms are closed in or moving back toward the body in a relatively relaxed soft trunk posture. Through the Yin-Yang theory and activities, TC leads the learner to reach harmony within the body as well as between the body and the outside natural world. In other words, through TC practice, one may be able to develop more and more awareness of his and her body parts during movements in a conscious way and gradually and progressively toward a subconscious automatic process. Basically, TC practice is a mechanism that allows one to internally harmonize the connection between mind and body, or activities among the nervous, cardiorespiratory, and musculoskeletal systems, and externally harmonize the relationship between the physical body and the surrounding world. The final goal of performing TC is to achieve the status of ultimate harmony of external and internal body ("Tian-Ren-He-Yi" in Chinese).²³²

Mechanism of Tai Chi Effect

TC practice can promote general health and improve cardiopulmonary function, neuromuscular activities, mood, memory, cognition, and ultimately neural plasticity. In the last 20 years, the mechanism of TC benefits has been increasingly studied. TC may have immune enhancement benefits with impact on inflammatory factors to promote general health.^{233,234} At the cellular and genetic level, Interleukin-6 (IL-6) and tumor necrosis factor (TNF) are proinflammatory biomarkers, and the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) is for proinflammatory gene expression. After 12-weeks of weekly TC practice in a group of 40 subjects with breast cancer,²³⁴ it was found that subjects had marginal reduction of IL-6,

significant reduction of TNF (RR5), and action of NF- κ B, as well as downregulated genes for the generation of white blood cells—all indicating that the cellular inflammatory response may decrease after TC practice.

The effect of TC on the nervous system was investigated by studying BDNF (brain-derived neurotrophic factor), which is one of the growth factors for the central and peripheral nervous systems.²³⁵ The investigators found significant increases in BDNF after a 6-month TC practice, indicating potential neural plasticity for improvement of memory and executive functions.²³⁵ The mechanism was also noted through neural activity and neuroimaging levels.^{236,237} Researchers reported that after TC practice, there was significant increase in parasympathetic activity in the heart and oxygen load in the prefrontal cortex.²³⁶ Similarly, there was an increased volume of gray matter in the insula, medial temporal lobe, and putamen.²³⁷ These changes significantly enhanced resting-state functional connectivity between hippocampus and the medial prefrontal cortex (mPFC),²³⁷ known to be essential for the memory process.^{237,238} These morphological changes in the brain may explain why TC is able to improve memory performance in TC practitioners.

The nervous and the muscular systems respond to TC practice.^{239,240} After 12 weeks of TC practice, N-Acetylaspartate (NAA), an important biomarker used to assess neuronal health, was significantly increased in the posterior cingulate gyrus, a key area for emotion, meditation, and memory; recovery time of phosphocreatine (PCr), a substance often used to quantify mitochondrial function, was significantly improved in leg muscles. Toh and colleagues²⁴⁰ analyzed the mechanism of TC's effect on Parkinson disease. TC practice may be able to (1) normalize neurotransmitter (e.g., dopamine) levels in the motor cortex-basal ganglia-motor cortex loops; (2) promote development of new neural pathways, particularly the somatosensory and neuromuscular control pathways; and (3) improve anticipatory postural adjustment and allow or elicit quick responses to postural changes. Together, these may indicate that neuroplasticity, neurotransmitter normalization, and extremity muscle oxidative capacity can all be improved effectively and significantly after TC practice.

Two recent reviews identified significant changes or improvement in cortical thickness, neural plasticity and functional connectivity, brain homogeneity, antiinflammatory action, motor function, pain perception, and metabolic profile, which may attribute to the mechanism of benefits with TC practice.^{241,242}

Tai Chi for Neurological Disorders

TC appears to be a safe and cost-effective exercise program for patients with neurological disorders and has been shown to improve the condition of patients with a variety of neurological disorders. The use of TC with movement problems arising from brain areas associated with specific medical diagnoses can be found online and can be integrated with those chapters written on those specific medical diagnoses.

Stroke

TC improves ADLs, social interaction, general function, motor function, balance, gait, mood, and mental health.^{213,242} TC has positive impact on social and general functioning for community-dwelling patients with stroke (2 times per week for 12 weeks), with improved reaction time and limits of stability in the affected and nonaffected side.²⁴³ TC improves general health, sleep quality, anxiety, and depression²⁴⁴ and demonstrates excellent adherence rates (92%) with TC exercise 150 minute/week for 12 weeks.²⁴⁵

In a meta-analysis, Ge and colleagues²²⁰ and Lyu and colleagues²⁴⁶ found that regardless of the various TC forms or components of TC

movement, significant improvement of upper and lower extremity and overall motor function were identified. However, the effect of TC on mood and mental health in stroke patients is inconsistent. Lyu and colleagues²⁴⁶ reported that TC might be able to promote sleep quality and improve depression, anxiety, and cognition.

In terms of TC dosage parameters for patients with stroke, the most common recommendation is 30 to 60 minute/day, 5 to 7 times/week, for an average duration of 12 weeks (can be ranged from 2 to 52 weeks). Most TC studies were conducted with community-dwelling patients versus acute settings.^{213,220,247} (Refer to Chapter 24 for additional information.)

Parkinson Disease

TC has been prescribed as a sensorimotor agility exercise program for patients with PD²⁴⁸ to improve general function, balance, gait, quality of life, and mental health.²¹³ Patients with mild to moderate idiopathic PD, TC (60 to 90 minute/day, 2 to 3 days/week for 12~24 weeks) improves 50-foot speed walk,²⁴⁹ Timed Up & Go,²⁴⁹⁻²⁵¹ functional reach,²⁴⁹ BBS,²⁵⁰ Unified Parkinson Disease Rating Scale (UPDRS),²⁵⁰ tandem stance,²⁵⁰ 6-minute walk,²⁵⁰ backward walking,²⁵⁰ maximum excursion, and directional control.²⁴⁹ Patients in the TC group had better results as compared to the resistance training or stretching exercise programs in terms of functional capacity and fall reduction.²⁴⁹

From published literature, including a meta-analysis study,^{219,240,252} patients with PD can benefit from TC practice in motor performance, in balance and functional mobility, in quality of life (assessed by Health-Related Quality of Life), and in stride length in gait and fall prevention. TC may have beneficial effects on mood and stress for PD patients.^{253,254}

However, no significant difference was reported in gait speed and strength after practice for 12 weeks.²⁵⁰ Later, in large and well-designed TC studies among patients with PD, after a longer 24-week TC practice, subjects could retain their improvements after 3 months.²⁵¹

In terms of TC dosage parameters for PD, 30 to 60 minutes in session length, 1 to 5 times per week, and 4 to 24 weeks in duration were recommended,²¹⁹ but the most commonly used were 60-minute sessions, 2 to 3 times/week with 12 weeks in duration. Patients in mild to moderate severity or in Hoehn and Yahr stage 1 to 3 could benefit more from TC practice.²¹⁹

Traumatic Brain Injury

Many patients with TBI demonstrate ADL, motor, and nonmotor functional deficits.^{206,213} Manko and colleagues²⁵⁵ added TC exercise to a self-care-skill goal-oriented program for 6 weeks for patients who aroused from a long-term coma. Patients had significant improvement in the skills assessed by the Standard Self-Care Skills.²¹³ Blake and Batson²⁵⁶ did not find significant differences in physical functioning when compared with the control group, who received social and leisure activities. This might be due to insufficient short-term TC performance (only 60 minutes/week for 8 weeks). However, in a three-case report²⁵⁷ with patients who suffered from TBI, but practiced TC for 2 to 4 years, patients had significant improvements in walking without assistance, and one individual even performed ADLs independently and returned to driving a car.^{207,257} For the nonmotor functions, two studies^{256,258} reported that TC practice could improve mood, happiness, stamina/energy, and self-esteem in patients with TBI.^{256,258} TC may help patients with TBI improve their nonmotor symptoms and general mind-body health.²⁵⁹

TC parameters in the literature varied from 1 to 3 times a week for a duration of 6 weeks to 4 years.²¹³ Patients can benefit once aroused from a coma and able to perform.²⁵⁵ This is achieved through

long-term practice, which is consistent with concepts of motor learning and development of neuroplasticity.²⁵⁷ (Refer to Chapters 3 and 22 for additional information.)

Multiple Sclerosis

Positive effects on patients with MS include balance, gait, flexibility, strength, quality of life, depression, and fatigue.²¹⁸ Balance was assessed by Modified Clinical Test of Sensory Organization and Balance (mCTISB),²⁶⁰ single leg stance,²⁶¹ functional reach,²⁶⁰ 14-task balance test,²¹⁸ and BBS,²⁶² but results on significant differences in quiet static stance were inconsistent.²¹⁸ Incremental improvement of lower extremity strength was reported by assessment of the chair-rise test.²¹⁸ Range of motion and gait velocity were improved.²⁶³ Quality of life was enhanced in two studies.^{263,264} Depression was also diminished.^{261,264} TC effect on fatigue is mixed, and future research will have to answer this question more thoroughly. Postinterventional assessment using the Fatigue Scale of Motor and Cognitive Functions (FSMC) and Modified Fatigue Impact Scale (MFIS-5) showed significant decrease in fatigue, but no significant change was identified as measured with the Fatigue Severity Scale.²¹⁸

The range of TC dosage parameters for MS varies from 30 to 60 minutes in session length, 6 to 50 sessions, and 3 to 25 weeks in duration.^{218,262} The most commonly used parameters are short 6 TC forms, 30 to 60 minutes with multiple rest intervals per session, and 1 to 2 sessions each week for 12 weeks.^{218,262} Patients in various stages of MS can learn to perform TC, but those living in the community seemed to benefit more from the practice,²¹⁸ which is consistent with current literature on motor function and the need to practice to maintain movement function. (Refer to Chapters 3 and 17 for additional information.)

Spinal Cord Injury

Wheelchaired TC exercises are modified for patients with SCIs.²⁶⁵ Published studies indicate that seated TC is able to improve sitting balance, trunk and hand grip strength, quality of life, sense of pain, emotion, mental distraction, and physical sense of well-being.^{266,267} However, no significant effect was identified on fatigue and depression among SCI patients.²⁶⁶

TC dosage parameters for this population may include 90 minutes per session, 1 time a week for 12 weeks,²⁶⁶ while others choose 30 minutes, 2 times per day, 5 times a week for 6 weeks.²⁶⁷ These indicate that short session length and high frequency with short duration might lead to more improvement in physical function, while the long session length, low frequency, and long duration would lead to more positive changes in emotion and mood. (Refer to Chapter 14 for additional information.)

Vestibular Dysfunction

There was a lack of literature in patients with vestibular dysfunction. McGibbon and colleagues²⁶⁸ studied the neuromuscular mechanism of TC practice in patients with vestibulopathy. They found that after 10 weeks of TC practice, patients with vestibulopathy demonstrated a significant positive relationship between change of leg mechanic energy expenditure and change of trunk velocity and range during gait. This suggests that patients with vestibulopathy will have enhanced body control to avoid loss of balance after TC practice.

Summary

Although TC is one of many integrative approaches to enhancing both movement function, it has also been shown to motivate an individual's quality of life through participation. Group TC is often found within many communities throughout the world, which helps enhance life

participation. Furthermore, social interactions through TC can improve quality of life among all ages, regardless of age or movement dysfunction.

Yoga Galantino

Mary Lou Galantino

Yoga is an ancient Indian mind-body practice that has been in existence for more than 2000 years.²⁶⁹ It focuses on a combination of meditation, mindfulness, self-exploration, breathing control, and body movement to improve flexibility, focus, balance, and strength. The two types of yoga popular in the United States are Hatha and Iyengar. Hatha involves optimal breathing while holding the body in particular postures known as *asanas* for periods of time and controlling breathing rate and focus.²⁷⁰ Iyengar yoga uses the aid of supports, props, blocks, and belts to allow better control to perform the *asanas*.^{271,272} Although yoga has been accepted in other countries for centuries, the evolution in the United States has been a recent phenomenon. Research on the effect of yoga in the musculoskeletal areas is promising,^{272–274} yet research in the neurological population is emerging and in need of larger randomized clinical trials. This section will present a general analysis of the benefits and efficacy of yoga for individuals with a variety of common neurological issues.

Carpal tunnel syndrome. Physical and occupational therapists treat carpal tunnel syndrome (CTS), an upper-limb neuropathy caused by compression of the median nerve. Symptoms involve numbness, tingling, and pain from repetitive movements that respond to a variety of treatments.^{275,276} Two studies specifically explored the use of yoga to treat subjects with CTS. A yoga trial with 42 individuals tested the effectiveness of a yoga regimen on CTS symptoms. Those in the experimental yoga group were given 11 postures designed to stretch and strengthen the upper limbs, along with relaxation techniques, twice a week for 8 weeks at a local geriatric center. A control group was given wrist splints or no treatment at all.²⁷⁷ Significant improvements in grip strength, pain reduction, and Phalen sign were noted. However, no statistically significant change was recorded in sleep improvement, Tinel sign, or median nerve conduction; however, improvements were noted in pain and function 4 weeks later.²⁷⁷ A second study investigated the impact of yoga in patients with osteoarthritis. Twenty-six participants performed a 1-hour yoga session each week for 8 weeks with reported significant improvement in joint and hand pain during activity.²⁷⁸ Larger randomized clinical trials could provide definitive evidence for patients with CTS.

The specific use of YOGA when dealing with movement problems caused by brain problems arising from specific medical diagnosis can be found on line and should be integrated with specific chapters dealing with those movement problems.

Stroke and hemiparesis. Strokes are the primary cause of adult disability in the United States and Europe, with 4.7 million individuals in the United States living with the sequelae of stroke. Extreme difficulties encountered while performing simple movements result in a sedentary lifestyle in this population, and resultant muscle atrophy further potentiates fall risk.²⁷⁹

A pilot study with four subjects observed the impact of yoga as a treatment for impairments post-stroke. Baseline measurements included the BBS, Timed Movement Battery (TMB), and SIS version 2.0. Three of the four participants had statistically improved BBS scores indicating improved balance, improved self-selected speed on the TMB indicating enhanced ability to perform everyday tasks, and positive changes in quality of life based on the SIS.²⁷⁹

Other factors may have affected the outcome of this pilot study, including differing adherence to the home exercise program with varying participation levels, degree of impairment, and fear of pain, which

reduce participation with certain *asanas*. Those who adhered to the program witnessed more improvement than those who did not follow it as closely. Yoga appears to have some level of positive impact on function in post-stroke patients,²⁷⁹ and a recent systematic review of eight clinical trials was done on the effects of yoga after a stroke for improvement of balance. Many stroke survivors have a least some degree of difficulty with balance, which can then affect all areas of daily living activities. The current research is not consistent with the duration or the type of yoga practice that should be performed, as studies varied based on the regions they were done. The exact reasons that yoga is beneficial in this population are unknown. It is hypothesized that it helps improve proprioception through posture, movement, and breathing techniques, but the protocol for treatment needs to be better defined.²⁸⁰

Multiple sclerosis. Individuals with MS can suffer from virtually any neuropathy, fatigue, ataxia, and chronic or acute pain. In addition, cognitive, digestive, visual, and speech problems may also occur. Although there is no cure for MS, patients have life expectancies similar to those unaffected by the disease, and yoga may be an option to manage the various impairments encountered through the years.^{281,282} It is interesting to note that 65% of those diagnosed with MS use some CAM, with yoga being the most popular.²⁸³ Perhaps the best study to date was a 6-month study that compared Iyengar yoga and exercise interventions. Participants underwent multiple cognitive assessment tests such as the Stroop Color and Word Test and the Cambridge Neuropsychological Test Automated Battery to test reaction times in performance of certain tasks that are difficult for individuals with MS. These tests measure attention and visual and auditory abilities to determine the impact of cognitive abilities. Alertness, mood, fatigue, and quality of life were also measured using the Profile of Mood States (POMS), the SF-36, electroencephalography, and physical activities such as a timed walk.²⁸¹ Of those who completed the study, both the exercise and yoga intervention groups had greater quality of life based on data from self-assessment forms (SF-36), a reported increase in vitality and energy, and a decrease in fatigue.²⁸¹

Research exploring the use of yoga for MS is promising, and while the evidence for mind-body medicine in MS is limited, they are safe and may provide a nonpharmacological benefit for MS symptoms.^{284,285}

Epilepsy. Yoga, as well as other mind-body practices, has shown promise in helping control seizures. One yoga meditation trial reported a 62% decrease in seizure occurrence at 3 months, 86% at 6 months, and 40% of the subjects becoming seizure free.^{286,287} The patients in this study had hyperventilation-related epilepsy caused by anxiety, so the meditation and controlled breathing exercises along with the *asanas* may have led to a better understanding of how the subjects could control their diaphragm and experience relaxation, resulting in the high success rates. In this study, electroencephalographic data recorded a large shift in frequency from 0 to 8 Hz to 8 to 20 Hz, with an increase in A-band power and a decrease in D-band power. These results showed improvement in control and power of breathing. Yogic meditation regulates the limbic system, providing better control over endocrine secretions and lowering the chance of over-firing neurons.²⁸⁷ Another investigation tested the use of yogic meditation for 1 year versus a control of no meditation in patients with drug-resistant epilepsy.²⁸⁸ Data showed significant differences between the experimental and control groups, with the experimental group having significantly lower seizure activity over the observation period.²⁸⁷

Efficacy of a yoga meditation protocol (YMP) as an adjunctive treatment in patients with drug-resistant chronic epilepsy²⁸⁹ was a trial based on the frequency of complex partial seizures, which was assessed after 3, 6, and 12 months. Participants sat in a relaxed position

with legs crossed (*sukhasana*) and focused on deep, slow, controlled breathing (*pranayama*) for 5 to 7 minutes, followed by silent meditation.²⁸⁹ Patients were instructed to perform YMP daily for 20 minutes in the morning and evening at home and at supervised sessions.²⁸⁹ Individuals with greater than or equal to a 50% reduction in the rate of monthly seizures were classified as responders, whereas patients with less than this percentage in seizure reduction were classified as nonresponders.²⁸⁹ After the first 3 months, there was a reduction in the frequency of seizures in all but one patient. Fourteen patients continued the YMP for 6 months or more and were tested again. Of these, six were seizure free for a 3-month period, and three were seizure free for 6 months.²⁸⁹ The authors of this study concluded that yoga was cost-effective with less adverse events with drug-resistant forms of epilepsy.

Human immunodeficiency virus. A pilot study examined the use of a yoga intervention for individuals with human immunodeficiency virus (HIV) infection who experienced pain and anxiety.²⁹⁰ Results indicated a decrease in pain and anxiety symptoms and a reduction in amount of pain medication after an 8-week yoga program.

Another study examined the effect of yoga practice that included breathing, movement, and meditation techniques for 47 participants with HIV disease. Positive changes were noted in the Mental Health Index (MHI) and general physical health on the Medical Outcomes Study HIV Health Survey (MOS-HIV).²⁹¹ The Daily Stress Inventory showed a decrease in stress after the yoga program and improvements in activities of daily living were reported. Finally, the impact of Iyengar yoga for 1 month may reduce depression and improve immunity in individuals living with HIV disease.²⁹²

Fear of falling and insufficient balance. A 12-week yoga practice for adults aged above 65 years with fear of falling and balance problems included sessions of yoga *asanas* and breathing exercises in sitting and standing.²²⁷ Fear of falling was measured using the Illinois Fear of Falling Measure, and balance was captured with the BBS before and after the yoga intervention. Results showed a 6% decrease in fear of falling, 4% increase in static balance, and 34% increase in lower-body flexibility.²⁹³ Our chair yoga study showed a reduction of fear of falling and improvements in the Short Physical Performance Battery in seniors above the age of 65 years who received previous physical therapy interventions for a fall.²⁹⁴ Another observational study explored the effect of yoga on balance, fear of falling, and quality of life in 26 postmenopausal and osteoporotic women aged 55 years and above. Results of the Quality of Life Questionnaire of the European Foundation for Osteoporosis (QUALEFFO) and a neuromuscular test battery revealed improvements in all aspects of the QUALEFFO for the yoga participants as well as improved ability to stand on one leg and improved perception of general health.²⁹⁵

There is also research that states yoga can help improve balance in patients with Parkinson disease, while also improving anxiety, depression, and overall quality of life. There were only two studies that were examined, so more research is needed in this area.²⁹⁶

Conclusion. Available data on the use of yoga as a therapeutic intervention for people with various neurological disorders are promising. Most studies have small sample sizes but do show trends toward improved function and reduced impairments. In general, yoga can assist in the establishment of the mind-body connection and awareness of self for individuals with neurological challenges. Greater self-awareness may explain why patients report improvements in quality of life, improved ability to better manage their disease, and a deeper understanding of their own bodies. Relaxation that results from yogic meditation fosters stress management and may improve the outlook on long-term management of neurological conditions. Yoga may serve

as an adjunct to traditional exercise and can be adapted for elderly patients who are unable to perform strenuous exercise. Yoga may be modified to accommodate patients with almost any physical or cognitive disability, and potentially provide mental enhancement, which can create a significant relaxation effect. Further research is needed to further explore specific effects of yoga practice in neurological populations.

Energy Therapy Approaches

Reiki: Feng Shui, Chakras

Lexie Hashimoto

When reviewing holistic practices, it should be remembered that these practices came from ancient times when people were in tune with nature, their surroundings, each other, and ultimately the universal energy. Today we have made many strides in science and technology, but that also brings more distraction, more stress, the ability to “get more done,” more comparison, and ultimately less connection with that universal life-force energy fueling our bodies, minds, and nature around us. The quote below from Lao Tzu, one of the greatest Chinese sages, touches the very importance of working on subtle energies when healing others.

“In ancient times, various holistic sciences were developed by highly evolved beings to enable their own evolution and that of others.

These subtle arts were created through the linking of the individual minds with the universal mind.

They are still taught today by traditional teachers to those who display virtue and desire to assist others.

The student who seeks out and studies these teachings furthers the evolution of mankind as well as her own spiritual unfolding.

The student who ignores them hinders the development of all beings.”

—*The Unknown Teachings of Lao Tzu*

Hua Hu Ching

Translated by Brian Walker²⁹⁷

What Is Reiki?^{298–307}

Reiki is a Japanese word for “universal life force energy.” The system of healing was introduced to the United States from a lineage of Reiki called Usui Shiki Ryoho. Dr. Mikao Usui was a Buddhist monk in Japan with a desire to understand the nature of spontaneous healing like that of the Buddha and Jesus. Looking for that answer, he was guided to secluded meditation for 21 days. It has been said that he took the Yoga Sutras of Patanjali with him to Mt. Kurama and placed 21 stones in front of him to count the days.³⁰⁸ On the last day, he experienced his awakening and claimed to have a Reiki as a form of healing that incorporates clear consciousness and uses strong intention not only as a healer but also from the patient.

The Seen and Unseen Influences of Energy Around and Within Us

When we begin to discuss ancient healing techniques, we need to recognize that the components of the bodily system go further than what the eye can see. Reiki works with the part of the person that doesn’t need any language or belief system to be understood. The souls’ connection through emotions, instinct, and intuition may be the universal language among not only humans, but all living things. Energy can be measured as over active, deficient, or stagnant. The chakra system is a way of measuring the unseen energy flow in the body. People tend to

suppress and/or store emotional or painful experiences instead of accepting and resolving the situation. These unseen energies will eventually manifest in the physical body in forms of disease or pathology. That becomes what is often seen by the person and where Western medicine often begins treatment. Looking for external healing sources for an internal soul disease may heal the manifest illness but won’t resolve the disease. Aligning the body, mind, and spirit will access new levels of healing. Being able to connect that a headache may be from stress is the first part of identifying the disease, but being able to get the root source and cause of the stress someone feels may rid the person of recurring headaches over time. Reiki helps assist someone to access their soul so that the individual can tap into one’s own suffering—by quieting the mind and reaching into those deep inner samskaras (emotional impressions and/or conditioning) and finding ways of healing the past to not impact the future.

Feng Shui: The Art of Arranging Your Outer World to Enhance Your Inner World

Another way of looking at the idea of energy is the ancient art of Feng Shui. This is where the placement of buildings and interior décor is used to enhance the flow of energy. Feng Shui means “wind and water,” the unseen energy of wind along with the seen energy of water. When both wind and water are balanced, there is a harmonious and pleasant effect on the surroundings. If out of balance, just as a hurricane, it can be destructive. Again, this is a system of recognizing energy that may be stagnant, overactive, or deficient. When a person has a lot of clutter in a home, they may suffer from stagnant energy, finding it hard to gather the motivation to create change in their life. Or if they have a layout where their energy disperses quickly, they may always be on the run or always working from a never-ending to-do list. As an example, imagine painter’s plastic hanging on a doorway in the back of first level of your house. When the front door opens and closes, unseen energy is moved. Eventually, the unseen energy will reach the plastic hanging in the back doorway, and you will see and hear the plastic move. If the plastic doesn’t move eventually, that would be a signal to look at the energy flow. This is a visual way for recognizing unseen energy. Therefore the space someone lives in can drastically impact her and his quality of life. The practice of working with this invisible *ki/chi/prana*, life-force energy, can either enhance one’s life or hinder it. Once again looking at the connection one has with their own *ki* is part of the cultivation that Reiki brings to light for people.³⁰⁹ Taking accountability in how one lives in all areas is essential to self-cultivation. Feng Shui is not about simply placing or arranging items around a home in a certain way with set expectations of certain outcomes. It is the connection to one’s intention and investing in overall subtle energies to enhance the quality of life. The more we begin to sense energy in the external sense, the more we can recognize the connection of our internal world’s chaos or harmony, which eventually manifests our external reality.

Chakra: Internal Energy Wheels

The chakra system is a way of measuring energy fields within the body. Looking at the Hindu chakra system, there are seven main energy vortices stacking along the spine from the coccyx region or the root to the crown of the head considered the link to spiritual energy.³¹⁰ These energy wheels may correspond to locations in the physical body; however, they are inductive of the subtle energetic field we all have.³¹¹ “*The chakras are connected to the functions of the way, all organs, tissues, and cells receive the energy for their various uses.*”³¹¹ Energy then is the vibration and frequency that either stabilizes, overstimulates, or slows

down the chakra wheels, which then leads to other physical forms in the body that can be seen in the quality of health of a person. If you have a glass of water sitting on a table and if something hits the table, you will be able to see the water go from stillness to motion. The vibration travels and impacts the water without the water being touched by any physical outside force. When we begin to observe the body beyond the physical form and tap into the energetic field of someone, these subtle frequencies that may need work could be the starting point of treatment, saving more invasive or altering methods for cases that need immediate life-saving assistance.³⁰⁹

Five Reiki Principles and Self-Cultivation

With the right intention and working with the basic principles of Reiki (even if one is not attuned to Reiki energy), the healing effects on oneself can be powerful. Across any alternative or holistic practice, a consistent theme is *self-cultivation*. A practitioner can only help with assisting someone who comes to her and his clinic. The patient or patient also needs to have the intention of healing, and the practitioner can work with their intention. Should the patient or patient not have the will to either heal or assist in healing, the practitioner can certainly connect with the patient and plant a seed of insight that may sprout an interest in healing.

The cultivation of ones' internal peace is essential to understand the magnitude of healing. We study our whole lives to accomplish many things; however, one area that we don't spend much time mastering is our thoughts and minds. Our mind is the gateway to how we perceive everything. Creating healthy, accurate, and clear perceptions is integral in being able to handle the full array of emotions we all experience without getting stuck on any particular one. Reiki offers a daily practice of shaping how we exercise our thoughts and mind.

The five precepts of Reiki are as follows:

1. *Just for today, I will not worry.*
2. *Just for today, I will not have anger.*
3. *Just for today, I will work with integrity.*
4. *Just for today, I will be grateful.*
5. *Just for today, I will be kind to all living things.*

Reiki understands the demands on humans and how challenging it can be to keep up with virtuous habits. Therefore the precepts all start with "*just for today...*" Each day we can start fresh. It cannot be stressed enough that simply *knowing* these precepts is not a means to connection; it must be a cultivated practice. This means that someone who wishes to work with Reiki, or simply having a higher level of connection with others, must practice self-reflection, self-study, meditation, living with intention, and gaining clear perspective. Current research supports the use of Reiki as a potential method of reducing pain and improving one's well-being.^{10,312,313}

Methods and Tools

There are different levels of Reiki, the first is self-healing and learning to feel energy in one's own body and, when comfortable, gifting healing to recipients who are open to receiving it. When attuned to Reiki First Degree, the individual learns the hand positions and commits to a 21-day period of self-practice. This is a wonderful way to learn what subtle energy is personal and experience what it is like to heal personal samskaras. Level II is where one receives sacred symbols to aid in healing and begin hands on healing for others along with distance healing. The third and final attunement is becoming a Reiki Master, where the practitioner becomes the teacher.

When initiating a Reiki healing session, the practitioner should be intent on calling in the highest form of healing energy for their patient and making a strong and clear connection with the patient. This means no "*to-do*" lists running through his and her head, not thinking of the

next person, and not allowing personal stressors to interfere. Single-point focus is a tool that takes practice, especially in our modern world of distractions and multitasking. When the patient arrives, having an open discussion to allow the chance to relax and become present in the healing space and release distracting thoughts is important to allow the patient to truly open herself and himself to healing.

Hands-on healing is used either directly on a patient or working a few inches above their physical body in their energy field. Other tools may be singing bowls, tuning forks, crystals, essential oils, etc. As mentioned previously, vibrations and frequencies are able to reset chakras and energy fields. These methods of sensory stimulation create a vibration within the body that will resonate throughout.³¹⁴ People may experience several forms of energy during a healing session, such as heat, vibration, pulsation, tingling, seeing colors, sensing smells, laughter, crying, muscle twitches, etc. After a healing session, patients may feel much lighter, so much that you need to allow them to have the chance to become grounded again.

Future of Healing and Interaction With Patients

People are searching for alternative forms of healing or help. There is a *tanha* (a Pali word meaning thirst or desire) among people for healing on a level much deeper than the physical body. The more each of us can become heart-minded (*kokoro* in Japanese) with our thoughts, actions, and connection, the more we will all be emanating a healing nature. When the practitioner is able to connect to a patient or patient on her and his level, that clinician may open a new form of communication that uses active listening (to their history or ongoing issues that create hindrances for that individual), thus engaging the patient from her and his perspective and offering ongoing expertise or input in forms that the patient will hear and receive and may stimulate healing in a way that individual has not been exposed to before. Effective communication goes much deeper than simply offering information. It connects to someone on an energetic level and uses empathy and compassion to relay information that may impact their life.

The energy that each therapist brings to the environment when meeting an individual can impact that person. If a clinician rushes into an appointment carrying the mental and emotional load of the day or the stress and anxiety he and she may feel, the patient will be exposed to that energy. Conversely, if the clinician is mindful, able to isolate and compartmentalize, and has intention and connection with her and his spirit for the highest good or healing possible, then that patient will also be exposed to the clinician's higher self.³¹⁵ Recognizing the importance of taking moments to do less, become comfortable with silence, and connect to the inner self is important in the current world we live in. Realizing that giving ourselves moments to calm our system down will bring clarity and allow us to ultimately heal more deeply. Sometimes just stopping long enough to take two or three deep cleansing breaths before greeting the next patient can center your emotions and allow you to regain equilibrium and inner harmony.

After a Reiki healing session is over, a practitioner releases her and his connection of healing that individual and gives back the responsibility of healing to the patient. Teaching patients about self-cultivation is also necessary to empower patients or patients to take part in her and his own healing journey. Life is an adventure from the moment we take our first breath to the moment we take our last. In between are those opportunities to grow, learn, and connect to the pure universal life-force energy within each of us.

For additional information on Reiki, chakras, and Feng Shui as a tool to help others regain balance and function in their daily lives, a suggested reading list has been provided online.

Therapeutic Touch

Ellen Zambo Anderson

Therapeutic Touch (TT) is a complementary health approach based on the concept of energy fields, sometimes referred to as *biofields*. TT is practiced by nurses, rehabilitation specialists, and others for the purposes of reducing pain and anxiety, accelerating the healing process, and promoting a sense of well-being.³¹⁶ Although not specifically named or described by the US NCCIH, TT is considered a mind and body practice.³¹⁷

Assumptions. There are four assumptions that form the foundation for TT as an intervention that can facilitate healing and health. The first assumption, described by Delores Krieger, RN, PhD, the developer of TT, is that the body is an open energy system. The open system allows energy, often referred to as *subtle energy*, to flow within and through the body. This flow allows for a dynamic interface with the environment.³¹⁸ The second assumption suggests that individuals are bilaterally symmetrical, so that the right and left and front and back mirror each other. This symmetry allows for a balanced energy flow. The third assumption is that an imbalance or an irregular flow of subtle energy is associated with physiological impairments, illness, and disease. The fourth assumption is that the body can initiate and achieve a process of self-healing through manipulation of biofields and restoration of subtle energy balance and flow.³¹⁸

The concept of internal and external subtle energies and their relationship to health and illness can be found in many whole medical systems, such as Ayurveda,³¹⁹ traditional Chinese medicine,³²⁰ and Navajo medicine.³²¹ More specifically, the assumptions of TT described by Krieger have their roots in the ancient concepts of prana and chakras.^{322,323} Prana, which is coined *chi* or *qi* in other systems of medicine, is the universal life force or energy that circulates through the universe and all living things. Chakras are the centrally aligned energy centers that are able to receive, transform, and send prana throughout the body. A blockage, interruption, void, or imbalance of prana is thought to exist when there is pathology or disease. Restoration of an individual's energy flow and balance is important for self-healing and health.³²⁴

Krieger, along with her colleague Dora Kunz, investigated the phenomenon and characteristics of people known as “healers” and concluded that healers possess a heightened sensitivity to their patients' states of health and being and are able to effect change through intention and energy. Through her description of sensing and effecting change in an individual's energy or biofield, Krieger has elucidated a four-step process that defines TT as a distinct therapeutic intervention different from other energy-based therapies such as Reiki and Healing Touch.

Procedure. TT is often performed with the patient or patient fully dressed and sitting. Despite the name, TT can be administered without actually touching the patient because TT practitioners are able to sense and manipulate the patient's subtle energies from a distance of 2 or more inches away from the patient's body. The first step in the TT process is called *centering*. During centering, practitioners center their consciousness so that a state of integration and quiet can be achieved. From the state of centeredness, practitioners initiate the assessment step by placing their hands 2 to 3 inches from the patient's head and slowly moving their hands down the patient's body, noting the patient's biofield. Practitioners may perceive the patient's energy as hot or cold, or sense that a patient's energy is blocked in a particular area. Perceived disturbances in a biofield suggest that the practitioner should return to that area later in the process.

Krieger has described the next step in the TT process as “unruffling the field.”³¹⁸ To unruffle the field, TT practitioners sweep away bound

up or congested energy, which allows the patient's energy field to become open and unrestricted. Opening the energy field sets the stage for the final step of the TT process. During the final step, TT practitioners direct and modulate the transfer and flow of energy so that the patient's energy fields can achieve balance and symmetry and healing can occur. Krieger points out that TT does not “cure” people of their diseases. Rather, she suggests that TT can have positive effects on energy fields and the flow of energy, and that these effects create an environment in which the patient's own self-healing processes can be optimized.^{317,318} Sessions usually take 20 to 30 minutes, but TT practitioners have reported that frail patients and children can benefit from as little as 5 to 8 minutes of TT; other patients may require 60 minutes of TT to achieve a state of relative energy balance.

Scientific literature. The application of TT for people with neurological diseases and disorders has not been widely investigated in the scientific literature. Researchers have, however, investigated the efficacy of TT for the reduction of anxiety and pain in a variety of patient populations and disruptive behaviors in people with dementia and Alzheimer disease (AD).

Anxiety. *Anxiety* is a general term associated with nervousness, fear, apprehension, and worrying. An anxiety disorder differs from feelings of anxiety associated with a specific event and is characterized by an irrational dread of everyday situations or excessive and long-standing anxiousness regarding nonspecific events and objects.

Robinson and colleagues³²⁵ performed a systematic review of the effect of TT on symptoms related to anxiety disorders but were unable to identify any studies in which subjects met the definition of anxiety disorder as defined by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) or the International Classification of Diseases (ICD-10). In all of the studies of TT and anxiety included in the review, Robinson and colleagues³²⁵ noted that pretest anxiety was measured in all subjects, but these subjects did not have “anxiety disorder” as their primary diagnosis. This systematic review helps show that individuals with neurological disorders and other medical diagnoses may not be diagnosed with an anxiety disorder but may experience some anxiety as they face the challenges of their condition.

Several researchers have investigated the effect of TT in different patient populations, such as those with severe burns,³²⁶ cardiovascular diagnoses,^{327,328} and breast cancer.^{329,330} Turner and colleagues³²⁶ found that for hospitalized patients with severe burns, TT was associated with a reduction in anxiety with no adverse effects. Quinn³²⁷ and Heidt³²⁸ investigated the application of TT in people with cardiovascular conditions and determined that compared with sham TT, subjects who received TT reported significant reductions in anxiety on the State-Trait Anxiety Inventory (STAI). Women with breast cancer were studied by Samarel and colleagues³²⁹ and Frank and colleagues.³³⁰ Samarel and colleagues³²⁹ found that women who received 10 minutes of TT and 20 minutes of dialogue before surgery reported significantly lower preoperative anxiety than women who received quiet sitting and dialogue, but no differences in anxiety were observed postoperatively. Frank and colleagues³³⁰ found that TT was helpful for reducing restlessness, fear, and nervousness in women who were scheduled to undergo a stereotactic core biopsy (SCB) but that the results were similar between the TT group and the sham TT group.

The application of TT with older adults has been reported by Simington and Laing³³¹ and Lin and Taylor.³³² Both research studies found that older subjects who received TT had significant postintervention reductions of anxiety as measured by the STAI. In the study by Simington and Laing, TT was paired with a backrub in the experimental group. The control group received just a backrub.³³¹ In the study by Lin, TT was compared with sham TT.³³² For inpatients with psychiatric diagnoses, TT was compared with sham TT and relaxation therapy.³³³

The researchers found that TT was more effective than sham TT but not more effective than relaxation therapy for reducing anxiety in this population.

A review of the TT literature and anxiety suggests that TT's efficacy for reducing anxiety is inconclusive. Several researchers have reported benefits of TT, yet others have found no effects when comparing use of TT with a control group or with use in patients with another condition. Reasons for the inconclusive results may be differences in the criteria for anxiety and variability in the measurement instruments. Other reasons may include research design issues such as assignment methods, blinding, and the frequency and duration of the TT intervention and comparison conditions.

Pain. Pain is strongly linked to anxiety and is associated with depression, anger, and fear. Pain also has physiological effects, including increased heart and respiration rates, and, when chronic, can result in structural changes in the brain. Pain can interfere with the ability to participate in physical rehabilitation and impair ability to function efficiently and effectively. Nonpharmacological methods for managing pain have the potential for assisting patients in their rehabilitation and achievement of functional independence without adverse effects. Investigations of TT for pain associated with neurological conditions are extremely limited. In a case report of a subject with long-standing phantom limb pain, Leskowitz³³⁴ found that TT was effective in reducing the subject's pain from an 8 to 10 out of 10 on a visual analog scale (VAS) to a 0 in one session. Self-administered TT was then able to maintain pain at a 0 to 1 on a VAS, in which 10 is the maximum intensity. Before TT, medication, stress management, hypnosis, transcutaneous electrical nerve stimulation (TENS), and ultrasound had been successful in temporarily reducing the subject's pain to 6 to 8, but long-term pain management with these approaches was inadequate.

TT was investigated in subjects with chronic pain associated with fibromyalgia syndrome³³⁵ and CTS.³³⁶ Denison³³⁵ found no significant improvement on the Short-Form McGill Pain Questionnaire (SF-MPQ), VAS, or Fibromyalgia Health Assessment Questionnaire (FHAQ) after subjects received 6 weekly sessions of TT. TT and sham TT groups both demonstrated immediate significant improvement in median motor nerve distal latencies, pain scores, and relaxation scores; however, there were no significant differences between the two groups on any of the outcome measures.

Other researchers have investigated the use of TT for pain management with older adults^{332,337} and people with cancer,^{329,330,338,339} osteoarthritis,^{340,341} headache,³⁴² postoperative pain,^{343,344} burns,³²⁶ and various chronic pain complaints.³³²

In older adults, pain from a range of sources was reduced by 38% with TT,³³⁷ and chronic musculoskeletal pain was significantly reduced following three 20 minute sessions of TT compared with sham TT and usual control groups, although no long-term measurement of pain reduction was conducted.³³² Musculoskeletal pain due to osteoarthritis was also significantly reduced with 6 weekly sessions of TT.^{340,341}

Giasson and Bouchard³³⁹ found that after each session of TT, people with terminal cancer reported improved well-being, which included a reduction in pain, compared with individuals in the control group. In a randomly controlled trial (RCT), including 90 patients with cancer undergoing chemotherapy, Aghabati and colleagues³³⁸ found that five 30 minutes of TT significantly helped reduce pain and fatigue immediately following the session compared with those who received either standard care or sham TT. However, in a study of women with breast cancer, a session of TT had no effect on reducing their pain or anxiety when undergoing a stereotactic core breast biopsy.³³⁰

When utilized postsurgically, TT has been demonstrated to be effective in reducing pain when compared with a usual care group in

two studies.^{344,345} However, in a study that compared TT with sham TT and the standard intervention of narcotic analgesic, there were no significant differences in reports of pain. Nevertheless, TT may have decreased the patients' need for analgesic medication.³⁴³

The results of studies that have included TT and measures of pain suggest that TT may be helpful in managing pain that arises from many different conditions. There are, however, inconsistencies across the studies that raise questions about both significant and insignificant findings. Inclusion of a control group, use of sham TT, sample size, measurement instruments, and the duration and frequency of TT are factors related to the studies' validity that limit the ability to draw firm conclusions about the efficacy of TT for reducing pain. There is also a scarcity of information about the long-term effects of TT.

Disruptive behaviors. TT has been investigated for its effect on disruptive behaviors in people with AD and dementia. Although most patients with neurological conditions do not typically manifest AD, alterations in cognitive functioning and behavior are often observed. Studies using a within-subject design and the Brief Agitation Rating Scale (BARS) have found that TT provided twice a day for 5 to 7 minutes was beneficial for reducing overall agitation and behaviors of vocalization, pacing, and restlessness in people with dementia.^{346,347} When applied in the same way in a RCT, TT was found to be helpful for significantly decreasing overall behavioral symptoms of dementia, including restlessness and vocalizations, when compared with usual care and sham TT groups.³⁴⁶ In people with AD, results of an RCT that compared TT to sham TT and usual care suggest that 30 to 40 minutes TT over 5 days can be helpful in reducing physical nonaggressive behaviors but had no effect on physically aggressive and verbally agitated behaviors.³⁴⁸

Studies^{332,333,349} have provided some preliminary evidence for TT's potential use for modifying at least some forms of disruptive behaviors. Additional studies need to be conducted to determine the effect of frequency and dose of TT on the duration of quelling undesirable behaviors. Application of TT to people with post-TBI or other conditions who exhibit agitated behaviors needs to be investigated.

Conclusion. As a noninvasive, nonpharmacological intervention, TT may be helpful to patients with AD or dementia who demonstrate disruptive behaviors and people with pain or anxiety. Research that investigates the mechanism by which TT may alleviate pain and the physiological changes that may occur with TT will advance the acceptance of TT as a useful modality and suggest patient diagnoses that might benefit from the incorporation of TT into a rehabilitation plan of care.

Physical Body Systems Approaches

Craniosacral Therapy

John Upledger and Mary Lou Galantino

Craniosacral therapy (CST) is a gentle, noninvasive yet powerful and effective treatment approach that relies primarily on hands-on evaluation and treatment. It focuses on the normalization of bodily functions that are either part of or related to a semiclosed hydraulic physiological system, which has been named the *craniosacral system*.

Structure of the craniosacral system. The anatomy of the craniosacral system includes a water-tight compartment formed by the dura mater, the cerebrospinal fluid (CSF) within this compartment, the inflow and outflow systems that regulate the quantity and pressure of the bones to which the dura mater attaches, the joints or sutures that interconnect these bones, and other bones not anatomically connected to the dura mater. The bones of the cranium and the second and third cervical vertebrae, the sacrum, and the coccyx are also included in the structures of the craniosacral system.^{350,351} In combination with the

message sent to the patient through the intentional touch of the therapist is the corrective work that is done on a basic physiological level by gentle hands-on manipulations applied both directly and indirectly to the craniosacral system. The semiclosed hydraulic system includes the dural sleeves, which invest the spinal nerve roots outside the vertebral canal as far as the intervertebral foramina, and the caudal end of the dural tube, which ultimately becomes the cauda equina and blends with the coccygeal periosteum. The fluid within the semiclosed hydraulic system is CSF. The inflow and outflow of CSF are regulated by the choroid plexuses within the brain's ventricular system and arachnoid granulation bodies, respectively. CSF outflow is not rhythmically interrupted, but its rate may be adjusted by intracranial membrane tension patterns, which are broadcast primarily by the falx cerebri and tentorium cerebelli to the anterior end of the straight venous sinus, where an aggregation of arachnoid granulation bodies is located. This concentration of arachnoid granulation bodies is known to affect venous backpressure, which has an effect on the rate of reabsorption of CSF into the blood-vascular system.^{352–354}

Technique. The therapist, after mobilization of bony restrictions, focuses on the correction of abnormal dural membrane restrictions, perceived CSF activities, and energy patterns and fluctuations as they relate to the craniosacral system. It is during this time that the patient often moves from a phase of being corrected and having obstacles removed to a phase of self-healing, with the therapist serving as a facilitator of the process. The tenets of CST include the concept that the dura mater within the vertebral canal (dural tube) has the freedom to glide up and down within that canal for a range of 0.5 to 2.0 cm. This movement is allowed by the slackness and directionality of the dural sleeves as they depart the dural tube and attach to the intertransverse foramina of the spinal column.³⁵⁰

A basic assumption in CST, as it has evolved, is that the patient's body contains the necessary information for the discovery of the cause of any health problem. The treatment relies primarily on hands-on evaluation and treatment. The hands-on contact is tender and supportive. It is accompanied by a sincere intention to assist the patient in any way that is possible. In short, the therapist serves primarily as a facilitator of the patient's own healing processes. The rapport that develops during the patient-therapist interaction lends itself powerfully to the positive therapeutic effect that many patients experience.

Western medicine imparts a therapeutic modality for curative measures, whereas CST fosters facilitation, wherein the patient directs the treatment session. The inherent participation of the patient through CST promotes a holistic approach to healing. Conventional medical diagnosis will usually be more closely related to what the therapist views as the result rather than the cause. For example, the therapist would search for a cause of strabismus within the intracranial membrane system and the motor control system of the eyes, rather than considering the strabismus as a diagnosed condition to be corrected by surgery. The cause of strabismus can be found as an abnormal tension pattern in the tentorium cerebelli. The therapist then searches for the cause of the abnormal tentorial tension pattern. Quite often, these tension patterns are referred from the occiput or from the low back or the pelvis. If this is the case, the CST "diagnosis" would be intracranial membranous strain of the tentorium cerebelli as a result of occipital or low back or pelvic dysfunction, individually or severally, resulting in secondary motor dysfunction of the eyes (strabismus). The therapist would focus on the sacrum, the pelvis, the occiput, and then the tentorium cerebelli. Correct evaluation and treatment would be signified by a "spontaneous correction" of the strabismus.

Somatoemotional release is a technique that involves the bodily, and usually conscious, reexperiencing of episodes, the energies for which have been stored in the totality of body tissues. A powerful

emotional content is typically connected with this technique, and it has proved to be extremely effective in cases of severe posttraumatic stress disorder. It was tested through qualitative research with a group of six Vietnam veterans in 1993. It proved to be successful in all six of these patients.^{350,351,355,356}

Outcomes. Objective responses to CST are based on the removal of obstructions to smooth and easy physiological motions of the patient's body, the absence of energy cysts, the free movement of the dural tube in the spinal or vertebral canal and the rate and quality of the craniosacral rhythm, the absence of pressing responses during the somatoemotional release process, and statements from the deeper levels of consciousness through dialogue with various images encountered in the session that "all is well."^{350,351,355}

Subjectively, patients report an increased sense of well-being, improved sleep patterns, reduced manifestation of stress, reduction in or disappearance of pain, increased energy levels, and fewer episodes of transitory illness. How long it takes to achieve these results is extremely variable and dependent on the complexity of the layers of adaptation, the defense mechanism, and the level of spiritual evolution of the patient.

Use in treatment intervention. CST is useful as a primary treatment modality and as an adjunct to a wide variety of visceral dysfunctions. It works well to balance autonomic function, specifically reducing sympathetic nervous tonus. It has proved beneficial in chronic headache problems, temporomandibular joint problems,³⁵⁷ whiplash sequelae, and chronic pain syndromes. We have used it as an intensive treatment for people rehabilitating from head injuries, craniotomies, spinal cord injuries, post-stroke syndromes, transient ischemic attacks, seizure disorders, and a wide variety of rare brain and spinal cord dysfunctions.^{358–361} Little positive effect has been reported in people with amyotrophic lateral sclerosis. However, some remarkable success has been seen in patients with MS.³⁶⁰

CST has been used extensively and effectively in a great number of children with spastic CP, seizure disorders, Down syndrome, and a wide variety of motor system disorders, including problems with the oculomotor system, learning disabilities, attention deficit disorder, speech problems, childhood allergies, and autonomic dysfunction.^{362–364} CST seems to be safe in preterm infants³⁶⁵ and has cost-effective outcomes.³⁶⁶ We have used CST for people living with HIV disease who have peripheral neuropathy and other chronic musculoskeletal and neurological problems. Pain management techniques can be used by the therapist and also taught to the family members to implement for a home program.³⁶⁷ Future studies addressing the interaction of the immune system with the craniosacral system would be helpful in elucidating the neuroendocrine response to this technique.

Clinical experiences also suggest that CST is a powerful evaluative and treatment modality for patients with vertigo who have not responded well to or have not found relief from traditional medical treatments. CST has been found to be an effective means for treating lower urinary tract symptoms and improving quality of life in patients with MS.³⁶⁸ Osseous, dural membrane, and fascial restrictions leading to asymmetrical temporal bone movement and, hence, vertigo are some of the dysfunctions of the craniosacral system. More clinical trials are necessary to verify that CST is an effective treatment as well as to determine the full range of symptoms for which CST is beneficial.

Recent studies have found an impact of CST on chronic pain pain,³⁶⁹ including fibromyalgia.³⁷⁰ CST improved quality of life in this population, reducing the perception of pain and fatigue and improving night rest and mood with an increase in physical function.³⁷¹

CST along with other osteopathic techniques to treat chronic lateral epicondylitis as opposed to treating it with traditional orthopedic techniques revealed increased strength and decreased pain for both

osteopathic and orthopedic groups. The assumption is that osteopathic techniques such as CST can be successful in treating chronic lateral epicondylitis;³⁷² however, future studies will need to isolate CST to ultimately reveal its efficacy in treatment for this problem.

To date, there have been several studies refuting the value of CST. One example is in *The Scientific Review of Alternative Medicine*. According to this group of researchers, interexaminer reliability among CST practitioners is zero.³⁷³ Other studies suggest that the sutures that CST practitioners are attempting to mobilize are fused in the adult population; therefore the techniques are ineffective.^{374–378} Future studies are necessary for CST to achieve recognition as a valid and reliable treatment option.

Training. The prerequisites for training in CST by the Upledger Institute are quite simple. It is believed that any kind of therapist who has a license to see and treat patients/clients might find CST, in its more basic form, a useful adjunct to practice.

There are six levels of training within the series that are required before one can enroll in the advanced-level workshops. The workshops are all 4 or 5 days in length and are about evenly divided between academic work and hands-on supervised practice. The training program is designed to develop the sense of touch, motion, and energy perception slightly before the academic material is presented.

A certification process was established in 1995, along with an International Association of Healthcare Practitioners, of which the American CST Association is a subdivision. The American CST Association, a nonprofit organization, was founded by a group of therapists and concerned laypersons in 1994, and the stated objectives are to bring CST into public awareness, to enhance networking among practitioners who use CST, and develop a certification program that will result in the recognition of CST as a specialty for people who are licensed as health care practitioners in other fields.

Myofascial Release (Barnes Method)

Richard Harty and Carol M. Davis

Myofascial release has become a significant method of treatment for many therapeutic professionals, with some specializing in its application. This approach can stand by itself as treatment or can be used in conjunction with other therapeutic approaches. Due to the nature of the fascial system, changes to the fascial system can have a significant influence on every system in the body. Understanding what the fascial system is anatomically, energetically, and structurally is essential to understanding myofascial release and the profound effects it can have on physical movement, pain relief, the transmission of information, the flow of nutrients, and restoration of function.³⁷⁹

The technique of myofascial release (Barnes method) discussed here encompasses both art and science, which requires the practitioner to learn how to feel the quality and direction of restriction within the fascial system with the tactile and proprioceptive senses within their hands and body, as well as understand the physical reactions to different types of force and energy being directed toward the body. Fully understanding the art of myofascial release requires one to be treated by a skilled therapist as well as apply the techniques to others.

The rationale behind this is based on the observation of the anatomical nature of the fascial system and how it responds to injury and strain. No two people are going to present the same pattern of restriction. Restrictions don't follow anatomical structures exactly, because fascia surrounds everything in the body down to the cellular level and restrictions are governed more by the patterns of damaging force placed on the fascia (or body) and how those forces move through the body. They present complex three-dimensional distortions that go in many directions. A skilled therapist should be able to map these through skilled sensory awareness.

These facts prevent myofascial release from being quantified in the same manner as when measuring range of motion, muscle strength, balance, or a functional activity. Trying to quantify the application of specific directional holds on living individuals and then looking at specific outcome measurements ignore the unique nature of every patient and assume the skill of the therapist as an artist is not a factor. This approach to measurement would assume the specific hold has the same effect on every person, which is not true. Myofascial release is a dynamic process that treats living beings whom are continually changing. Quantitative measurements only see one aspect of a single moment in time. The variables and feedback mechanisms are too complex for a simplistic double-blind study to give us any understanding of how myofascial release works or accurately predict specific outcomes. That does not mean myofascial clinicians don't have any curiosity around why it works. Myofascial practitioners can do specific studies on the tissue itself.

Dr. Paul Standley has been able to quantify the effects of sustained strain on small sections of engineered fascia and has determined that fascia produces interleukins, a crystalline protein or cytokine.³⁸⁰ Interleukins (IL) play a large part in the immune system of the body. Standley demonstrated the increase in IL1b, IL3, and IL8 with the application of myofascial release. IL1b is a mediator of inflammatory response and is involved with long-term memory dependent on the function of the hippocampus. IL3 regulates hematopoiesis by controlling the production, differentiation, and function of granulocytes and macrophages. IL8 induces chemotaxis in target cells, primarily neutrophils, but also other granulocytes, causing them to migrate toward the site of infection. IL-8 also stimulates phagocytosis once they have arrived. It also stimulates the reformation of blood vessels. The increase in interleukins was more pronounced after 5 minutes of myofascial release with decreased production with holds less than 3 minutes. He also noted that tension greater than 9% of the original length caused the effect to start to fall off from the peak at 9%.

This study focuses upon only one aspect of the fascial system that interacts with a large number of components, such as the cytoskeletal microtubular network, the immune system, the lymphatic system, the circulatory system, the nervous system, the muscular system, and others, all with complex feedback mechanisms. These aspects of the fascial system present, within the living person, something far greater than the sum of its parts. So, as we explore the details of individual aspects of the fascial system, which surrounds and infuses every other system in the body, remember, the order of complexity is multiplied when these aspects are combined, not only with themselves, but when combined with each bodily system, the fascia infuses.

Fascial tissue is intimately involved in the moment-to-moment function of all of our cells and is intricately involved with central, peripheral, and autonomic nervous system tissue. It is no longer useful to view the body or the fascial system as a mechanical system alone. Nonlinear system dynamics are at work as we now understand the involvement of fascia with the neuroendocrine system, the brain, and the neurological plexus in the lining of organs, such as the stomach and gut. Fascia must not be viewed by practitioners and/or patients as static, but as innervated, alive, functional, fluid, and self-regulatory. Involving the patient or patient in the process of manipulation of fascia and its embedded tissue enhances the response of the tissue and the patient.³⁸¹

Central to the complete understanding of the effectiveness of energy-based myofascial release for the relief of pain and the facilitation of healing are the following points:

- There are 12 different fasciae or connective tissues in the body, each with varying concentrations of collagen, elastin, and ground substance.³⁸²

- “Our richest and largest sensory organ is not the eyes, ears, skin, or vestibular system, but is in fact our muscles with their related fascia. Our CNS receives its greatest amount of sensory nerves from our myofascial tissue.”³⁸¹
- “The presence of smooth muscle cells within fascia, along with the widespread presence of myelinated and unmyelinated sensory and motor nerve fibers and capillaries, has led to a hypothesis that fascia is an actively adapting organ with functional importance, rather than a passive structural organ alone. This may be the root of myofascial pain syndromes.”³⁸¹
- There are 9 or 10 sensory nerve endings in the fascia for every one sensory nerve ending in the muscle. Thus fascia plays a major role in helping us to sense where we are in space and sense our inner tissue in ways not fully appreciated previously.¹⁶⁶
- Fascia contains myofibroblasts that can tense or release in fascial sheets.³⁸³
- Fascia has been hypothesized to play a role as the seat of consciousness in the body-mind system.³⁸⁴ As one example, there are 10 times as many connective tissue cells as nerve cells in the brain. Previously thought only to provide support and nutritional pathways to nerve, the latest brain scan research indicates glial cells “light up” during certain brain states, particularly emotional states. Also, they have been shown to play a role in regulating neuropeptides and neurotransmitters, thereby regulating mood.³⁸⁵
- Fascia plays a role in the maturation of stem cells. The fascia that surrounds all cells as the cell wall, and the fascia of the extracellular matrix, which is the environment of all cells in the body, determine the pressures sustained on developing stem cells into their mature forms.³⁸⁶
- Three specialized stretch receptor nerve endings in fascial structures help us sense what is happening in our tissue moment to moment as well as when receiving manual therapy. Golgi tendon organs in both tendons and in aponeuroses give feedback about the straightening of the fibers in the tendon. Paciniform endings in the myotendinous junction, joint capsules, and ligaments report vibration and rapidly changing pressures in the fascial net. Ruffini endings respond to deep and sustained pressure.³⁸¹
- Fascia is piezoelectric tissue. Myofascial release that emphasizes sustained pressure and tension over fascial restrictions generates a flow of electrical activity, or information, throughout the fascial system. Electrical impulses are generated in the collagen by compressive and distraction forces within the musculoskeletal system. These impulses trigger a cascade of cellular, biomechanical, neural, and extracellular events as the body adapts to external stress. In response to internal stress, components of the extracellular fluid change in polarity and charge, affecting fascial motion.³⁸⁷ This response is thought to be involved with the phenomenon of unwinding, an involuntary movement, and repositioning of the body to facilitate the release of emotions, holding patterns, and other reactions based on past experiences still held in the body.
- With myofascial release, the extracellular matrix softens from “gel” to “sol,” allowing the fascial restriction to melt and release pressure on pain-sensitive tissue and to rehydrate to allow for conduction of flow of photons and vibration.³⁸⁸ It is hypothesized that this action facilitates the cell-to-cell communication required in homeostasis and self-regulation and thus facilitates the body-mind’s ability to heal itself.³⁸⁹ This rehydration, combined with the gel-like water formed within the microtubular network of the fascial system as described by Dr. Gerald Pollack, provides the possibility of super conduction, because in crystal form the molecules of water line up, clearing an unobstructed path for photons and electrons to travel through the body.³⁹⁰

There are a couple of areas of research that hold great promise in helping practitioners understand why there are such powerful movements in the tissue along with shifts in consciousness reported by many patients. Patients will often express a general feeling of lightness and observe they no longer are triggered by emotions and life experiences that caused them to react in the past. They will describe being able to feel where their body is in space and being able to stand with good posture without trying to force their body into position(s). There is often a sense of peace and contentment after treatment, as if something “heavy” has been removed. While these are subjective experiences, they are desirable outcomes in regard to the quality of life experience. And these are only a few common descriptions heard from patients after treatment.

It is very possible the fascia is a major communication and computation network. It may also be involved in photosynthesis and the conversion of light energy into the flow of water down to the cellular level. This has to do with the microtubular structure of fascia, the water content in fascia, and holoenzymes on the surface of these microtubules.

The first area of research is the work by Dr. Gerald Pollack at of the University of Washington.³⁹⁰ He has done extensive research on the fourth phase of water.³⁹⁰ We commonly understand water to have three phases: solid, gas, and liquid. Water forms a fourth gel-like phase when it resides against a hydrophilic (water-loving) surface such as fascia. Water can build millions of molecular layers of a crystalline gel from the exposure to light energy when it is next to a hydrophilic surface such as fascia. The infrared spectrum of light is significantly more powerful than other frequencies of light in driving the formation of these crystalline layers. Infrared light is electromagnetic radiation released during the production of heat. It has longer wavelengths than the human eye can see, and it behaves both like a wave and like its quantum particle, the photon. During myofascial release, there are a number of sources of infrared spectrum light that naturally comes from living beings who naturally produce heat. The release of infrared light is also increased by the application of pressure, which is a significant aspect of myofascial release, because pressure or force creates heat through the mechanisms of compression and the piezoelectric effect.

When water forms these crystallized gel layers, the molecules of water remove impurities and form, which is called an exclusion zone or EZ water. When hydrophilic material such as fascia is in the form of a tube, the water in the center of the tube will begin to flow as an EZ layer forms on the inside of the tube. In addition to the mechanical flow of water being stimulated, there is a conversion of light energy into electrical charge as the EZ water forms an electrical differential between the non-EZ water and the EZ water forming on the hydrophilic surface. Pollack noted that this effect continued to rapidly increase up to 5 minutes and then continued to increase at a slower rate.³⁹⁰

Fascia forms microtubules in its many forms, including the cytoskeleton of the cell. Researchers have recently been able to observe fluid-filled spaces between cells with the work of Petros C. Benias and Rebecca G. Wells at Mount Sinai Beth Israel Medical Center, Icahn School of Medicine at Mount Sinai in New York, NY.³⁹¹ They describe how they discovered this new organ that they call *interstitium*: “Confocal laser endomicroscopy (pCLE) provides real-time histologic imaging of human tissues at a depth of 60 to 70, Åµm during endoscopy. pCLE of the extrahepatic bile duct after fluorescein injection demonstrated a reticular pattern within fluorescein-filled sinuses that had no known anatomical correlate.”³⁹¹

These researchers “propose here a revision of the anatomical concepts of the submucosa, dermis, fascia, and vascular adventitia, suggesting that, rather than being densely-packed barrier-like walls of

collagen, they are fluid-filled interstitial spaces.³⁹¹ While there are many areas of this research that have to be studied in more detail, what they have shown provides a clearer view of the interstitial pathways formed by fascia that have powerful influences on the flow of nutrients and energy throughout every system in the body.

The final area of research related to fascia is the possibility that it may be involved with communication and intelligence at a much more significant level than scientists have suspected in the past. Hammeroff and Penrose have collaborated together to show how the microtubules within the connective tissue of the brain may in fact be the primary source of consciousness and the awareness of self.³⁹² Hammeroff, an anesthesiologist, noted that neuronal activity did not cease in patients under anesthesia. He began to question if consciousness was driven by neuronal activity as neural activity did not cease while patients were unconscious. He did studies to see what areas of the brain ceased to function while under anesthesia. He determined that anesthetics altered the quantum channels in brain microtubules to prevent consciousness.³⁹³ It was at this point Hammeroff brought in Penrose, a quantum physicist, to determine if these microtubules within the cytoskeleton of the neuron were capable of quantum states from a physics perspective. They have since developed a theory of consciousness based on a very sophisticated mathematics based on the structures that compose the cytoskeleton of the cell called the Orch OR theory.³⁹⁴

Neuroscientist Charles Sherrington in 1940 broadly observed that the cytoskeleton was the nervous system of the cell.³⁹⁵ There is precedent for this because we can observe the single celled animal called the paramecium hunt, run from predators, demonstrate awareness of its surroundings, and navigate. It can do all of this without any neurons. It does have a microtubular cytoskeleton. This suggests that the microtubules within cells might act as information carriers.³⁹⁶

Hammeroff and Penrose noted that neurons had highly organized microtubular networks within their cytoskeleton. They also noted holoenzymes on the surfaces of these microtubules and noted they had characteristics of sophisticated computational systems. The holoenzymes could alter the spiral path of energy waves traveling up the microtubules by structurally changing the molecules that formed the microtubule. Cytoskeletons exist in all cells and appear to be connected by an equally sophisticated intercellular microtubular network.³⁹⁷ This suggests a much finer scale of intelligence processing. They determined that there were microscopic anatomical features present, which could produce quantum states needed to produce consciousness.³⁹² This might suggest that the restoration of this fascial communication and computational network might provide a global effect on many levels of well-being or peacefulness or a feeling of safety reported by patients. The simple use of touch through sustained, gentle, myofascial release, accurately directed at areas of restriction by a skilled therapist, has been reported by patients to provide significant improvement to the quality of life.

There is a saying that states, “We don’t even know what we don’t know.” As we look at the complexity of the human body and more specifically the microscopic features of the fascial system, any claim to know how it works in total is ridiculously premature. There is a sense of wonder as we contemplate the deep complexity of what it means to be human. As myofascial therapists, we do have the art of this work and the ability to respond to feedback from our patients as we navigate these complex systems through our equally complex ability to feel and respond to our environment. Also, we see empirical results from the application of myofascial release, even though we may not understand how it works.

Researchers in science are often working at a microscopic level, while as clinicians, we are working with the entire human being. It will

take many years before the two are totally connected, but that does not mean the patients are not improving in function and back engaging in activities that they value. Thus until we can make those links, therapists need to remain keen observers through their hands, their eyes, and the emotional bond made in therapy. There is an art to myofascial release that requires specific abilities from a therapist to be applied effectively. Some therapists automatically feel and begin to change those restrictions in patients, but most need to get additional training and education before they accurately apply these techniques. For that reason, there are sequences and levels of training that can be taken to become a qualified myofascial practitioner. Training can help sharpen the focus, but to master this technique, one needs to put in the hours to hone the skills required by any art.

As an illustration of the relationship between knowledge and skill, one can be completely wrong about how the internal combustion engine of a car works and yet still be able to drive. The skill of driving depends on the ability to react to the surroundings and sense the connection between moving the controls of the car and the change in movement of the vehicle and not on the specific knowledge of how the engine processes fuel into forward motion. In fact, if you are focused on the specifics of the car’s theory of locomotion and operation while driving, you won’t be able to focus your attention effectively on driving itself.

A typical myofascial release technique (Barnes Method) will be applied by gently allowing one hand to sink into the skin and then, without sliding and using the skin as a handle, direct force in the direction of greatest resistance. A therapist may place the other hand in another area of the body and direct a counter force related to what they feel with the first hand. This is modified dynamically as the tissue changes and is held at least 5 minutes—many times longer. In this way, a skilled therapist, with cooperation and feedback from the patient, will map and treat restrictions in the fascial system using their proprioceptive, tactile, thermal, and energetic senses.

In regard to the fascial system, we have barely scratched the surface of understanding how it works, but experiencing myofascial release as a human being is really the best way to appreciate, feel, and comprehend what this approach can do to relieve pain, reduce tension, and restore functional movement.

Models of Health Care Belief Systems

American Indian Healing Traditions of North and South America

Richard W. Voss

Bob Prue, Member of the Rosebud Sioux Tribe

American Indians are understandably wary of the written word. Some may criticize the inclusion of this section in this chapter. This criticism is understandable, because the written word objectifies understandings out of the cultural context and can be manipulated outside the relationship in which the understanding was shared. However, not to include a discussion of American Indian views about medicine and health care is also a concern because it perpetuates the invisibility of American Indian people. The purpose here is to honor the continuing journey of understanding between medical science practitioners and traditional American Indian medicine practitioners to see how these two medicine paths can help restore health to the people and bring about increased understanding—*wo’wableza*—among people.

Contemporary American Indian Health Care and Traditional Healing: North and South American Indian or indigenous perspectives.

In a report to NIH, *Alternative Medicine: Expanding Medical Horizons*,³⁹⁸ the Lakota (a Sioux people) were cited for the use of healing ceremonies by specialists who are essentially shamanic in their

approach to treatment. To understand American Indian medicine ways, one cannot rely solely on written accounts. Although written ethnographical studies may provide a wealth of descriptive data, it is best to talk to authoritative sources personally. Professionals interested in learning more about traditional approaches to help and heal should contact any one of the federally recognized tribal headquarters and the tribally sponsored American Indian colleges and universities for more specific information. Many colleges conduct summer courses on Lakota culture and philosophy that are open to non-American Indians as well as American Indians interested in learning the culture. Readers wanting to know more about the cultural and linguistic revitalization with the Lakota and Dakota people are urged to visit the website for the Lakota Language Consortium.³⁹⁹

Today, many of the old American Indian healing traditions are experiencing a renaissance and are beginning to be viewed with a renewed sense of respect and credibility as an alternative and complement to more invasive or secular Western medical models of treatment.^{399–405} For example, on the Cheyenne River Sioux Reservation at Eagle Butte, South Dakota, the tribe has incorporated traditional methods and approaches to a variety of social service programs, including services for at-risk youth and care for people with alcoholism, which is viewed as a problem with social, emotional, physical, and spiritual dimensions.^{401,402,404,405} A survey of Urban Indian Health Organizations revealed that 100% of the responding program utilized some kind of traditional healing in their behavioral health services.⁴⁰⁶ American Indian veterans utilize traditional healing methods to relieve the symptoms of posttraumatic stress disorder.⁴⁰⁷ These traditional methods include the *inipi*, or purification ceremony (popularly called the “sweat lodge”), the *hanblecaya*, or pipe fast (often called the “vision quest”), and the *wiwang wacipi*, or the Sundance. The inclusion of these ceremonies within the treatment process has collectively been called the “Red Road approach.”^{401,402,405}

A number of medical facilities on various reservations include medicine men as consultants on a formal and informal basis,^{405,408–410} and the use of traditional ceremonies in health care settings is encouraged and respected.⁴¹¹ Where the ceremonial burning of sage (a common medicinal herb burned for purification) had been discouraged in the past, hospital staff report increased acceptance of this practice and now arrange appropriate space for traditional ceremonial practices both within the health care facility and outside on hospital grounds.^{410,411} One Lakota friend commented on his recent hospitalization at an allopathic hospital. He was visited by a medicine man that placed a bundle of sage under his pillow. This made him feel better and showed how simple cooperation among allopathic medicine, health care practices, and alternative, complementary health care practices can be.

A Lakota centric perspective on health. A traditional American Indian perspective on health care and medicine begins with the spiritual reality of the human being who is part of all creation and dependent on creation. Traditional understanding views human beings as intimately related to plants and all other creations in the natural world that sustain life. Reality is not linear; it is circular. Everything is connected to everything else. Good and bad, sickness and health, and physician and patient are not separate processes, they are all related aspects and part of the whole. For the Lakotas and other traditional American Indian people, there is no split or dualism in reality or creation. This traditional view challenges the intervention model and offers a prevention model as the starting place for social health and assistance. The emphasis from a Lakota-centric view is on building up the immune system and seeing the important role of the community in promoting good health care and well-being, a cultural emphasis often overlooked in conventional health care practices.

Traditional Lakota values of health and well-being emphasize the participation of the family in the healing process, including the extended family and the larger kinship community, to bring about good health to the individual. The health of the individual is connected to the health of the community, so there is an important tribal dimension to this understanding. For traditional Lakota people, the health and healing process are not impersonal but highly personalized and individualized around specific needs. The roles of medicine practitioners are multidimensional and include those of healer, counselor, politician, and priest.

Another important contribution of the Native American perspective on health is that it provides a rich topology of spirit. The human creation, like all creations, is a spirit being composed of multilayered aspects of spirit. “Spirit” here is not some supernatural reality outside the human being but an intrinsic dimension of everything that is, including the human creation (person). To speak of human beings is to speak of spiritual reality. For traditional American Indians, medical treatment or any kind of social, human, or mental health service is first and foremost a spiritual endeavor.

Ayahuasca: a spiritual pathway to consciousness and healing.

Traditional Indian people of South America have similar and yet distinctive traditions of health and healing where the rain forest provides the pharmacopoeia of medicinal plants, bark, herbs, and vines. Of course, the forest itself is viewed as a powerful source of spiritual healing. In 2004, a study in the Tambopata River area of the southeastern Peruvian Amazon (through the Amazon Center for Environmental Education and Research), Voss had an opportunity to meet with various shamans, their patients, and public health care representatives at a local community center where the regional public school and health care station are located. It is interesting to note that all members of the health care staff rotate, making visits to the area community members, including both indigenous traditional people, who mainly live dispersed through the forest (Amazon), and mestizo or mixed-blood settlers, many of whose families have lived in the river settlements since the mid-1970s.⁴¹⁰ Both indigenous natives and mestizo settlers seek assistance from the shaman, the curanderos, and the health station outpost, staffed by nurses and a visiting physician. The South American indigenous community Prue who visited the Tambopata River region of the southeast Peruvian Amazon used both herbal remedies and spirit-calling ceremonies, often incorporating the use of forest tobacco and other vegetation gathered from the forest as a means of purification. The use of ayahuasca, a concoction or tea made from various plants, tree bark, and vines gathered from the forest, is administered to both patient and shaman and is a common shamanic practice throughout Amazonia, according to the shamans I interviewed.⁴¹⁰ A detailed description of an ayahuasca ceremony is reported by Salak,⁴¹² providing a fascinating participant observer’s experience of an ayahuasca ceremony. A brief audio-video capture of the beginning of an ayahuasca ceremony may be viewed at www.nationalgeographic.com/adventure.⁴¹³ Clinical applications of ayahuasca are being studied by Jacques Mabit, Director del Centro de Rehabilitacion de Toxicomanos (Rehabilitation and Detoxification Center) at the Takiwasi Center, Peru. Mabit combines the traditional use of ayahuasca and psychotherapy techniques and holistic methods (consciousness expansion methods such as fasting, hyperventilation, and nonaddictive plants) mainly for the treatment of coca paste addictions. The center is funded by the French government. Conventional allopathic medicines are not used, except in unusual circumstances.

Riba and colleagues⁴¹⁴ published their neuropsychobiology study on the effects of ayahuasca. Hence traditional medicine has captured both the imagination and the attention of medical science.

Physical detoxification is accomplished through the use of medicinal plants. Conventional Peruvian approaches to addiction treatment are based on prison or military models, which have raised human rights concerns among health care workers. All studies on the clinical use of ayahuasca have European or South American sponsorship, and most have been published in Spanish.⁴¹⁵

Health risks associated with ayahuasca. Religious groups in the United States have obtained a First Amendment exemption to use ayahuasca in their ceremonies. Despite the US government's opposition to the use of dimethyltryptamine (DMT), which is the main chemical substance found in ayahuasca, the government could not meet the burden of showing that ayahuasca posed a serious health risk to church members who use it in their ceremonies.⁴¹⁶ Gable reports that there have been no deaths caused by hoasca or any other traditional DMT/ β -carboline ayahuasca brews.⁴¹⁶ Furthermore, he writes, "The probability of a toxic overdose of ayahuasca is seemingly minimized by serotonin's stimulation of the vagus nerve, which, in turn, induces emesis near the level of an effective ayahuasca dose. The risk of overdose appears to be related primarily to the concurrent or prior use of an additional serotonergic substance. People who have an abnormal metabolism or a compromised health status are obviously at greater risk than the normal population and might prudently avoid the use of ayahuasca preparations" (p. 29).⁴¹⁶ A systematic review of the scientific literature "suggests that acute ayahuasca administration to healthy volunteers is relatively safe. The literature also gives support to the idea that long-term ritual ayahuasca consumption by adults and adolescents does not appear to be seriously toxic or harmful" (p. 73).⁴¹⁷

Although there is generally no known harm to ingesting ayahuasca in a ceremonial context, common sense about nonceremonial use is imperative. Using watchers to sit with the person while using ayahuasca and of course not allowing driving or use of heavy machinery is common sense. Therefore a harm reduction approach is necessary. That said, the pharmacology of ayahuasca is such that "selective serotonin reuptake inhibitors can have potentially harmful interactions with MAO inhibitors, so people taking these kinds of medications are advised to avoid ayahuasca" (p. 301).⁴¹⁸ This is consistent with Gable's findings. There are no significant associations between the typical dosage of ayahuasca in ceremonial usage and long-term psychosis. Gable reports that "Many or most of UDV [União do Vegetal] psychiatric episodes were transient in nature and resolved spontaneously" (p. 30).⁴¹⁶

Gable notes, "The ritual context in which ayahuasca is ingested provides some control of dosage and subsequent psychological effects. Because the natural sources used in preparation of the tea do not allow UDV members to standardize their hoasca brew with respect to DMT or β -carbolines, the person conducting the ceremony drinks the brew before administering it to UDV members as a means of testing for potency. Different amounts of the brew are initially offered to individual participants, and, depending on reactions, a participant may be offered a second cup at his or her request" (p. 26).⁴¹⁶

Another area of concern is risk of dependency on ayahuasca. There is no convincing evidence that ayahuasca leads to physiological dependence. Of course, this is an area worth careful attention in continuing research, although Gable notes that the general psychopharmacological profile of hoasca "suggests that it lacks the abuse potential of amphetamines, cocaine, opiates, or other widely abused substances." Elsewhere, Gable notes that "tryptamine derivatives such as DMT (found in ayahuasca) result in erratic patterns of self-administration indicating that 'these compounds have weak reinforcing effects, or alternatively, mixed reinforcing and aversive effects.'" (p. 31).⁴¹⁶ Gable notes, "The unpredictable occurrence of frightening images and thoughts, along with predictable nausea and diarrhea, makes it a very

unlikely candidate for a 'club drug'" (p. 32).⁴¹⁶ On the other hand, Grob reported that "all of the 15 UDV subjects claimed that their experience with ritual use of hoasca as a psychoactive ritual sacrament had had a profound [positive] impact on the course of their lives." Most of the UDV members had a "history of moderate to severe alcohol use prior to joining the UDV" (p. 30).⁴¹⁶ Most therapies for alcohol or drug abuse involve a thorough and sometimes unpleasant examination of the self. Providing a psychological support system around the patient in shamanic healing is a profound aspect of the healing process in the peyote using Native American Church.^{419,420} The safety in clinical settings of similar psychedelic substances (psilocybin and LSD) to treat addictions is well established.⁴²¹

Shamanic Mythology in Palliative Care: New Frontiers

There is expanding international interest in the use of indigenous methods, and mythology and psychological processes in palliative care.⁴²² Using structured interviews and shamanic interventions studied the effect of shamanic narrative and mythology on a patient receiving palliative care. These authors noted, "[that] facing the end of life, death, evoked by serious diseases. . . is not only a question of techno-scientific medicine, of medical treatment, but also a therapeutic work on our narrative identity."⁴²³ Here, both the therapist and patient enter into the shared shamanic experience and each tells their story discovered in the encounter. Santarpiá and colleagues⁴²² state, "The shamanic tradition insists on the idea that disease is a message for the patient's soul; it marks the need for a change and a new existential meaning."⁴²⁴ Elsewhere, Santarpiá and colleagues note that "the patient's experience of healing does not necessarily connote a 'cure,' but it denotes instead the renewal of the person's ability to reconnect with his or her self. This relationship . . . extends beyond the parameters of the individual's ego and also embraces a connection with the entire universe or 'spiritual world.'"⁴²²

Shamanic mythology, narrative, and methods have a place in medical knowledge, care, and practice, with a long tradition dating back 30,000 and 40,000 years, with archeological evidence in discoveries of ancient cave paintings depicting shamanic activities such as dance, drumming, and use of animal skins and totems.^{425–428} Shamanic practice, mythology, and methods represent both the ancient and future trajectories of medical and health sciences particularly relevant in palliative and end-of-life care.

Traditional Acupuncture

Jeffrey Kauffman and Darcy Umphred

This section has been edited by Umphred to include new references on evidence-based practice to support Dr. Kauffman's previous materials, which was based on the Laws of Five Elements. His wisdom, understanding, and appreciation of the human body and how to integrate various philosophies of health care practices were amazing. When one met him, he presented himself as another human being just trying to find ways to help others with their health care issues.

History. Acupuncture as it is practiced in the United States is a huge conglomerate of different styles of acupuncture coming from China, Japan, Korea, Thailand, Vietnam, and Western Europe. The styles differ radically depending on who is doing the acupuncture, where he or she learned it, and how much individuality has been instilled into the practice. Within this discussion, the similarities among practices are described, followed by an in-depth analysis of the style that Kauffman used.

Acupuncture is one of the five categories that make up Chinese medicine. The other four are herbal medicine, diet and nutrition, exercise, and massage. Acupuncture is a healing method that tunes a human being. Just as a piano tuner tunes a piano or one tunes a guitar or an auto mechanic does a tune-up on a car, it is possible to tune a

human being. After this process, or intervention, is done, the body-mind functions more efficiently in a balanced, harmonious fashion. As a result, the aches and pains often are eliminated and illnesses and diseases reversed. Acupuncture can be used by itself and, even better, in combination with other holistic and traditional Western medical methods.

Methods. Acupuncture involves the use of tiny needles made of stainless steel, their diameter two or three times the width of a human hair, sharpened by a diamond. These needles are put into particular points on the surface of the body. There are at least a thousand of these points all over the human body.^{429,430} They have a lower electrical potential compared with the surrounding skin, as is evidenced by a galvanometer. These points are also known as *acupuncture points*, *acupressure points*, *trigger points*, and perhaps by other names as well. These points are about 1 mm in diameter and are located pretty much in the same place for everyone, according to bony landmarks, skin landmarks, and anatomical structures such as nipples, umbilicus, fingernails and toenails, eyes, ears, nose and mouth, and so on. The points can be found with practice by the trained finger of the practitioner. There are electrical instruments that can help locate these points, but their reliability has not been established. Needles are put into these acupuncture points, and after being inserted, the needles are turned either clockwise or counterclockwise one revolution. They are either taken out immediately or left in for a period of time, depending on the individual patient's imbalance and illness.

Examination and evaluation. Deciding where to insert the needles is really the key and the most difficult and important part of acupuncture diagnosis. This is where styles of acupuncture come into play. There is a spectrum of acupuncture styles or methods that ranges from completely symptomatic to perfectly holistic, just as there is in traditional Western medicine. The symptomatic methods involve simply putting needles into acupuncture points at anatomical sites that are

specifically related to symptoms. For example, for shoulder pain, or arthritis or bursitis, an acupuncturist using a symptomatic method would select acupuncture points that are in or around the shoulder area. Headache would be treated with needles in the head area.^{431,432} Constipation would be treated with needles in the belly area. Hemorrhoids would be treated with needles around the anus and coccygeal area. This method pays little attention to where the constitutional imbalance exists within each person. An opposite philosophy, which is called *holistic acupuncture*, treats the underlying constitutional imbalance within the person. Described earlier, such imbalances are considered the vulnerable, or weak, links in the chain in each human being—the part that always gives out first because it is not as strong or disease resistant as the rest of the body-mind. The type of acupuncture Kauffman used is a holistic form. Specifically, it is called *five-element acupuncture*. It is based on the Law of Five Elements, which is a law of nature that comes from Chinese philosophy and is one of the basic foundations of Chinese medicine. It is sometimes known as the *Five Phases* and is considered the most holistic form of acupuncture available.

The law of five elements. The Law of Five Elements states that there are five elements in nature (fire, earth, metal, water, and wood) and that these elements all relate to one another in a particular fashion (Fig. 39.5). The diagram in Fig. 39.5 shows an outer creative cycle (known as *Shen*) that goes in a clockwise fashion and demonstrates that fire creates earth, earth creates metal, metal creates water, water creates wood, and wood creates fire again. Also, a star-shaped control, or destructive, cycle (known as *K'o*) shows that fire destroys or controls metal, metal does the same to wood, wood to earth, earth to water, and water to fire. These two cycles, the creative and destructive cycles, are necessary to keep balance in nature. These five elements are also found in human beings because the body is composed of elements that come from nature and return to nature when the body dies. The emotions and feelings in our personality align themselves with these same elements (Fig. 39.6).

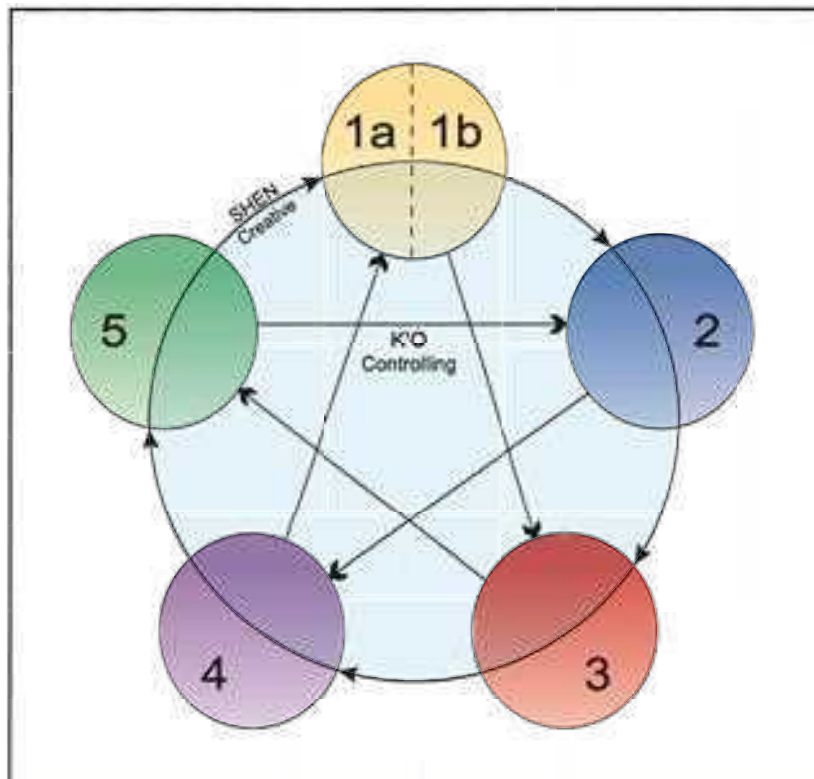

Fig. 39.5 Law of Five Elements: Demonstrating the Shen (Creative) and K'O (Controlling) Cycles.

	1a	1b	2	3	4	5
Element	Fire		Earth	Metal	Water	Wood
Meridian	Small Intestine	Three Heater	Stomach	Colon	Bladder	Gall Bladder
	Heart	Heart Protector	Spleen	Lung	Kidney	Liver
Color	Red		Yellow	White	Blue	Green
Emotion	Joy		Sympathy	Grief	Fear	Anger
Odor	Scorched		Fragrant	Rotten	Putrid	Rancid
Sound	Laughing		Singing	Weeping	Groaning	Shouting

Fig. 39.6 Law of Five Elements Linking Fire, Earth, Metal, Water, and Wood With Interlocking Variables.

People in Western society have not been taught to think of their bodies in elemental forms, but nevertheless these elements are there. The concept of fire is present in each and every cell. The cells burn glucose to survive, and this is referred to as “burning calories.” It is this burning that causes our body temperature to remain at 98.6°F throughout most of our lives. It is not difficult to picture each cell of the body having a little bonfire in the center with mitochondria sitting around roasting pieces of glucose on a stick. Obviously, water is present in our bodies. Students in grammar school are taught that our bodies are 98% water with all the tears and urine and lymph and blood. Similarly, metal can be found in the body in the form of calcium in the bones and iron in the blood, in our teeth, and so on. The concept of wood is most easily seen in the fingernails and toenails, which are similar to the bark of a tree. Also, the ligaments and tendons are much like a strong fiber. The concept of earth is best seen in the gastrointestinal tract. Picture taking a microscopic journey down the gastrointestinal tract starts from the mouth, going down the esophagus into the stomach and the intestines; the further down you get, the more the material seems earthlike, until it is excreted into the outside world.

Each of the elements has a particular color that emanates from the face, a particular emotion that comes from the personality, a particular odor that comes from the body, and a particular sound that comes from the voice, as well as a particular taste, season, climate, secretion, and body part or system that it fortifies.

Every human being has a constitutional imbalance in one of these elements. The explanation for how this happens lies in spiritual law. Suffice it to say that this imbalance is well engrained sometime during the first 5 years of life. Diagnosing this constitutional imbalance is both an art and a science and is done primarily by determining the color, emotion, odor, and sound belonging to each human being. The reader probably has noticed these colors, emotions, odors, and sounds previously with friends or even with strangers. Yet the realization that these are diagnostic clues that reveal a person’s constitutional imbalance may not be as self-evident. The person who is always angry, no matter what, is displaying the emotion that goes with the wood element. The person who is always happy, joyful, bubbling over (or the opposite, more commonly seen—very sad and depressed) goes with the element of fire. The person who is always sympathetic and loves to take care of you or is always caring for children is displaying the emotion of sympathy, and that goes with earth. The person who is always grieving, who has tremendous loss and cannot seem to get over it, goes with the element of metal. The person who is always fearful, paranoid, and afraid of life fits into the water element. People have different sounds to their voice.

People who laugh excessively and are always humorous go with the fire element. People who shout a lot, their voices very powerful and strong, and knocking you over go with the wood element. People who have a singsong quality to their voice go with the earth element; groaning goes with the water element; and a weeping sound of the voice, although the person is not crying, goes with the metal element. You have probably smelled people who have a strong body odor and wondered why they did not bathe or use deodorant. There are five different odors, and each one belongs to one of these elements. And perhaps you have seen a person who is green with envy or ash white, white as a sheet, or has pallor in the face. Each one of these colors goes with an element as described in the diagram (see Fig. 39.6).

Each element also has organs relevant to it, with energetic pathways, called *meridians*, which are housed by that element.⁴³³ These pathways, or meridians, are just under the surface of the skin, throughout the body, and serve as channels for an electrical form of energy that flows in all human beings. This energy is the life force. In Chinese it is called *chi*. In the East Indian culture it is known as *prana*. This life force is always circulating round and round the body-mind along these pathways. And the acupuncturist can get in touch with this energy at certain points on these meridians, which are the acupuncture points.

Intervention. Once the examination is complete and the diagnosis is made, paying close attention to the color, emotion, odor, and sound, and the elemental constitutional imbalance determined, it is simply a matter of treating the points along the meridians that are housed by that element on a week-to-week basis. Generally, this tunes the human being and everything starts to function more efficiently and more harmoniously, enhancing the person’s quality of life.

There are 12 major meridians, two in each element, except for fire, which has four. Each of these meridians is named after the organ to which it is connected, which is also described in the diagram. Each meridian has 9 to 67 points on it. Each point has a name described by the Chinese that has been translated into English. It is the names and the functions of the different points that allow the acupuncturist to decide which points are to be used on which day and time and treatment. For example, the point Kidney-24 is actually named *spirit burial ground* and can be used to help a person suffering from grief, having lost a loved one. Taking the history at each visit and determining blockage of the chi energy flowing in the meridians are used to select the points used in treatment.

As patients get better, not only do their symptoms decrease in intensity and dissolve and often totally disappear with time, their emotional and feeling states also change for the better. People tend to

become happier and peaceful and calm and more capable of handling stress. They often will say, “I feel better in myself.” The reason for this is that the patient is not just having her or his symptoms treated. This form of acupuncture, the five-element style, treats the body, the mind, and the spirit and integrates these three spheres of the human being. The point names are particularly revealing. There are names connected to nature and physical objects such as *small sea*, *greater mountain stream*, *blazing valley*, *sea of chi*, and *skull breathing*. There are also point names that have to do with emotions and feelings, such as *palace of weariness*, *gate of hope*, *rushing the frontier gate*, *intermediary*, *little merchant*, and *abdominal sorrow*. And then there are the points that relate to the spiritual qualities of life, such as *spirit burial ground*, *heavenly ancestor*, *heavenly pond*, *heavenly window*, *gate of destiny*, *inner frontier gate*, *soul door*, and *spirit deficiency*. When these spirit points are used, the person’s spirit is buoyed up—it turns back on.

Each treatment lasts 15 to 60 minutes, depending on the individual practitioner. The practitioner can also include any of the following in the treatment sessions: conversation, history taking, massage, joint adjustments, instructions on diet and nutrition, psychosocial counseling,⁴³⁴ exercise recommendations, and so on. The initial visit takes longer because a history and physical examination are done and sometimes the initial treatment as well. This depends on the technique and abilities of the practitioner. In general, the treatments are done twice a week for the first two to four visits and then once a week as the patient starts to get better. The interval continues to lengthen to every 2 to 4 weeks, and as the patient improves, the optimal interval is once every 3 months—once every season, the patient comes in for a tune-up for maintenance and prevention. In general, a series of 10 treatments is a good way to start this type of therapy. Improvement in the patient’s condition may be noticed as soon as the first treatment is done. It may take 5 or 10 treatments before it is noticed by the patient. Depending on the ability of the practitioner, improvement in the patient’s condition generally occurs in 80% to 90% of patients. This, of course, also depends on the severity of the patient’s imbalance and illness.

When acupuncture treatment is combined with psychosocial counseling, nutritional advice, exercise instruction, massage, or other forms of body work, in which the person is touched with warmth, peace, and love by another human being, great healing can take place. Acupuncture has been shown to be beneficial as part of the treatment of various medical conditions such as stroke rehabilitation,^{435–438} treatment of Parkinson syndrome,^{439,440} acupuncture for cardiovascular disease,⁴⁴¹ treatment for various clinical problems following cancer diagnosis such as anorexia,⁴⁴² pain management due to cancer,^{443–448} pain due to back problem,^{449,450} or patients with restless leg syndrome.⁴⁵¹ There are many places in the literature where the reader can find additional information on the use of acupuncture with various medical conditions.

Benefits of intervention. Five-element acupuncture can be used for all sorts of clinical problems: physical, mental, emotional, and spiritual. Any and every type of person can and does respond. There are always exceptions to this, but the general rule is one of success. This includes acute problems and chronic problems in outpatients and hospitalized patients. In China, all patients with stroke are automatically treated with acupuncture as well as the more traditional Western methods. It works on babies, toddlers, adolescents, and the elderly. It can be used as a primary form of therapy to which other therapies are added, or it can be an adjunct to surgery,^{452,453} radiation, and medication or to other holistic therapies. How much all these positive outcomes stem from the individual’s belief that acupuncture will be beneficial is not known. But, as Kauffman stresses, acupuncture interlinks with the mind, body, and the spirit, so possibly the one thing a clinician needs to recognize is that the patient has gotten better in daily function; pain, whether physical or emotional, had been reduced, and

the individual’s quality of life is reported to have been enhanced.^{454,455} Today’s research continues to help all practitioners evaluate the effects of acupuncture on the human organism in relation to our understanding of the physical body.⁴⁵⁶ Many colleagues are embracing the use of dry needling for relief of pain.^{457,458} Much research is still needed regarding the efficacy of this type of intervention,^{459,460} but similar to acupuncture with wet needles, dry needling seems to affect the body, mind, and spirit, and thus confuses Western researchers trying to use a linear, one variable model for research efficacy.

Future treatments. The amount of time it takes for a person to heal depends on how long the person has been ill. A rule of thumb is that for every year a person has had a particular physical or mental problem, it is going to take about a month’s worth of treatment, with each session done weekly. So, if a person has had arthritis for 20 years, 20 months of treatment should be expected.

On the other hand, if symptoms have been present for only a month or two, it is possible that they could go away with one or two treatments unless they are the result of some kind of serious illness, such as the sudden onset of cancer or heart disease or something that has been present for 1 or 2 years but has been subclinical. The general average is 10 treatments over a 4- to 8-week period, with a good possibility of illness being relieved partially or almost completely during that period, depending on the severity.

Summary. In summary, acupuncture is a healing therapy that is both an art and a science that comes from the Orient, specifically starting in China approximately 4,500 years ago. Recently, they have found signs that acupuncture may have been used in the Copper Age, with the discovery of the Tyrolean Iceman as the world’s oldest glacier mummy.⁴⁶¹ There are many styles of acupuncture, and the most holistic style is known as *five-element acupuncture*. It truly helps integrate the body, mind, and spirit. When acupuncture is combined with teaching the patient how to live a healthier lifestyle, including eating a healthy diet, reducing stress, making healthy choices, thinking healthy thoughts, and including fun and relaxation, true healing can occur. Because of the chronic and degenerative nature of many illnesses in the United States, it is possible that total healing cannot occur. Nevertheless, this type of therapy, along with the adjuncts mentioned earlier, should definitely help create a healthier human being.

Allopathic Links to Models of Health Care Belief Systems

Aquatic Therapy: A Link Between Traditional Therapy and the Community

Darcy Umphred, Matthew Baudendistel, and Arthur Baudendistel

The use of water and body immersion has been a part of physical therapy practice and intervention since the very beginning of the profession, but the clinical focus has generally been on musculoskeletal impairments and functional limitations.^{462,463} In the past, these interventions have not been as frequently cited as a common therapeutic approach to assist patients with movement impairment that developed from neurological disorders. Today, research has shown the beneficial effect of aquatic therapy for both pediatric and adult patients with certain neurological disorders. Individuals with medical diagnoses of CP,^{464,465} CVA,^{466–470} MS,^{471–474} PD,^{475–477} and SCI⁴⁷⁸ have been able to improve aspects of movement function when aquatic therapy was part of their intervention protocol. Specific benefits of aquatic therapy in patients with these disorders include evidence for improving mobility factors such as dynamic balance and gait speed, with the goal being to achieve an optimal level of quality of life.⁴⁷⁹

With the use of water as a medium or base for movement therapy, there are additional attributes that therapists need to consider. First, the viscosity or resistance of the water can add resistance to movement, giving the patient additional feedback, as well as slowing down movement if control is needed. Second, the water adds buoyancy or support of the body, which allows freedom of movement without the same demand for gravity when on dry land, as well as reduces the fear of falling. Lastly, the thermodynamic of water allows heat to be transferred into the water at a much higher rate than when moving against air.⁴⁷³ All of these components can contribute to the patient feeling less anxious, more capable, and having greater willingness to participate in the activity.

With the development of underwater equipment such as bikes and treadmills, therapists can begin to teach movement activities that lead to strength, endurance,^{480,481} cardiovascular fitness, and balance. Individuals with various movement disorders following neurological insult have benefited from aquatic therapy and improved their functional abilities.^{467,478,482,483} Although different types of exercises have been introduced within the water environment without one standing out as superior, the consistent outcomes for intervention are that aquatic therapy helps patients regain functional skills and improves their quality of life.^{474,482,484,485} Aquatic therapy has a beneficial effect on the cardiovascular system by reducing its demands and cardiac workload.⁴⁷⁰ This is due to the redistribution of blood from the dependent limbs to the thoracic cavity that occurs with head-out water immersion. This is an important benefit particularly for anyone who is at risk for stroke or recurrent CVA, as it enables the patient to reap the benefits of exercise and movement while reducing cardiac workload and blood pressure, thereby minimizing the risk for stroke. This is evident by the reduction in systolic, diastolic, and mean blood pressures. In addition, the rate pressure was significantly reduced with underwater treadmill training compared with land treadmill training.⁴⁷⁰ This is an important finding, as it allows the chronic stroke population to become more physically active through aquatic exercise while keeping their risk for recurrent insult at a minimum and preventing the deleterious effects of physical inactivity.⁴⁷⁰ Although future research needs to be done to correlate this study with other populations of individuals with movement problems associated with neurological insult, the potential bridge is certainly present.

Individuals with neurological movement disorders may have their core postural muscle system compromised, which leads to less stability within the trunk and axial musculature and limits movement, with potential for fall risk. This risk by gravity can be reduced or eliminated within the aquatic environment. These same movement limitations and fears often lead to inactivity, which has been shown to cause additional health problems.^{486,487} Thus it is critical to motivate individuals to move in a safe environment, which encourages freedom of movement in aquatic therapy.

One additional attribute of aquatic therapy is within the area of pain management. Research linking aquatic therapy with patients who have both motor impairments and back pain has demonstrated positive outcomes.^{488–490} Back pain may develop prior to the neurological insult due to lifestyle choices, poor posture, and inactivity; as a result of a neurological insult and trauma; or as a secondary problem due to the postural instability of the trunk and abnormal movement patterns. The original causation of the pain is a medical problem, but the movement impairments pain causes limits function. Regardless of the etiology, back pain often causes impairments in functional mobility, strength, and self-reported disability and can increase fall risk. Patients arrive to therapy to relieve pain, regain function, and improve quality of life.^{491–493} If exercise in the water reduces pain and the fear of additional pain during movement, an environment that optimizes learning

can be created and participation in activities within the aquatic environment more motivating. Aquatic therapy offers the opportunity to take away the force of gravity due to buoyancy and support the trunk through water pressure, and flotation tools can support any body part, thus reducing pain. Water can help reduce anxiety and fear of additional pain, in addition to creating a social environment where patients can interact and participate in water activities. Although no study has been done that links back pain specifically with neurological movement disorders, the obvious association can be drawn by watching individuals within this population move during any functional activity and by listening to their complaints.

Although all of these concepts when linked with pain management and musculoskeletal impairments are familiar to therapists, oftentimes the carryover to aquatic therapy's overall benefit to function in patients with neurological challenges is limited. Similarly, patients with movement limitations often never regain the total function that may have been lost following their specific insult or disease progression. For both reasons, these individuals need to maintain and/or continue to practice the movements that will lead to functional recovery or participation in life as defined by the individual. Once individuals leave a traditional therapeutic environment, such as acute, rehabilitation, or outpatient therapy, what was learned needs to become a life activity, where movements are practiced and environments challenged to facilitate nervous system learning and potential neuroplasticity. Aquatic therapy is an important link between clinic-based intervention and community-based activities. Aquatic movement exercises can become a life activity once the individual completes clinical therapeutic interventions. There is evidence that aquatic therapy can help maintain functional skills and life participation and continue to engage individuals in group activities that create a social and motivating environment.^{494–500}

Note: A case study on Aquatic Therapy can be found in the online resources associated with this text.

Electroacupuncture and Dry Needling

Mary Lou Galantino

Acupuncture, a part of traditional Chinese medicine, has been used for more than 4,500 years. Mapping of 12 meridian points, which are named primarily after the visceral organs they transverse, incorporates 361 regular points. There are also “Ashi points,” which are typically tender points used for treatment of pain syndromes.⁵⁰¹ The acupuncturist must decide which acupuncture points to stimulate on the basis of a specific diagnosis. The goal is to balance chi, which is considered vital energy. If there is an imbalance caused by disease, the altered flow of chi can be detected and subsequently treated through needles or electrical stimulation over specific acupuncture points.

Training for acupuncture varies throughout the United States (refer to the section on traditional acupuncture). Because needling is considered an invasive technique, physical therapists are prohibited from incorporating acupuncture in clinical practice. Therefore an alternative to needle acupuncture is noninvasive electroacupuncture (EA) or electrical neurostimulation. Concerning the effects of electrical neurostimulation, there are various interpretations of the methods and underlying physiological mechanisms. One mechanism is neural.⁵⁰² Another study has indicated that electrical stimulation applied to acupuncture points may activate both neurological and endocrine functions that control pain.⁵⁰² Anderson and Lundberg's study supported the release of β -endorphin and oxytocin, which are important for the control of pain and the regulation of blood pressure and body temperature.⁵⁰²

Therapeutic effects of electroacupuncture. The use of acupuncture is gaining popularity in most Western countries,⁵⁰³ and the

effectiveness of EA as a modality for the treatment of pain has significantly decreased VAS scores.⁵⁰⁴ With the increasing acceptance of acupuncture as an effective modality for pain relief, the scope of research on this modality has widened considerably to include other health care conditions. The intensive research efforts on other therapeutic effects of acupuncture have produced encouraging results.^{505–507} These results point to a reduction in pain, improvement in motor function, better balance, and improved gait; the results therefore have a neurophysiological interpretation.

The conditions most commonly treated with EA include musculoskeletal, neurological, obstetric, and gastrointestinal, along with intraoperative and postoperative analgesia. EA studies, particularly with low frequency stimulation, are more likely to support the role of endogenous opioid mechanisms than manual acupuncture studies, and opioid release is more likely in the CNS than the circulation. EA is used in clinical and especially experimental research, particularly for nonpain conditions. Acupuncture does release endogenous opioids, but this probably depends on “dosage,” with the evidence more consistent and convincing for EA than for manual acupuncture. Different frequencies of EA appear to activate different endogenous opioid mechanisms.⁵⁰⁸

The effect of spasticity has been explored by researchers for multiple diagnoses such as SCI and stroke. EA has been found to have more of an effect on spasticity the earlier the treatment is implemented, ideally within 3 weeks of injury. Findings reveal positive short- and long-term effects;^{509–511} however, future research needs to include frequency of treatment and specific points of stimulation for a more comprehensive understanding.⁵¹² Some of the possible mechanisms by which acupuncture may affect motor function include the following:

1. Stimulation of the release of endogenous opioids.⁵¹³
2. Changing of the amplitude of end plate potential, thus facilitating the events at the neuromuscular junctions. It has been suggested that peripheral factors contributing to the potentiation of a reflex (e.g., the H reflex) may affect the afferents and the neuromuscular junction.⁵¹⁴
3. Stimulation of the sensory system, which will result in integrative actions at the spinal cord level, where acupuncture may facilitate the stretch reflex arc through both the γ and α motor neurons. Facilitation may depend on the intensity and timing of the stimuli used to activate muscle afferents.⁵¹⁵
4. Revealed on neuroimaging of acupuncture in patients with chronic pain, changes in cerebral blood flow associated with pain and acupuncture analgesia that correspond to areas of the brain involved in such phenomena.⁵¹⁵

EA combined with conventional rehabilitation care has the potential of reducing spasticity in the upper and lower limbs and improving overall and lower extremity motor function and activities of daily living for patients with spasticity, within 180 days post-stroke.⁵¹⁶

Further studies of high methodological and reporting quality are needed to confirm the effects and safety of EA and to explore the adequate and optimal protocol of EA for post-stroke spasticity, which incorporates comprehensive outcome measures with different populations. Eighteen systematic reviews were evaluated for evidence in a range of nonpharmacological interventions currently used in managing spasticity in various neurological conditions. There is “moderate” evidence for electroneuromuscular stimulation and acupuncture as an adjunct therapy to conventional routine care (pharmacological and rehabilitation) in people following stroke.⁵¹⁷ Electrical sensory input can contribute to routine rehabilitation to improve early post-stroke lower-extremity impairment and late motor function, with no change in spasticity. Prolonged periods of sensory stimulation, such as TENS,

combined with activity can have beneficial effects on impairment and function after stroke.

Research

Acupuncture is beneficial in some peripheral neuropathies, but more rigorously designed studies using sham-acupuncture control groups are needed to characterize its effect and optimal use.⁵¹⁸ Research on the effects of EA on HIV-related neuropathy found significant reduction in pain, which suggests an excitatory effect on the neuromuscular system. Such an effect may be on membrane potential (possibly through influencing ionic transport) and improvement in body fluid circulation.⁵¹⁹ The effect on the sympathetic system is often reduced, and the same explanation is proposed for the action of electrical stimulation on pain,^{520,521} with some effects on pain-mediating neurotransmitters at the level of the spinal cord and an endogenous modulation from the brain stem.⁵²² All reviewed trials of acupuncture for neuropathy and neuropathic pain use acupuncture points that are closely associated with the peripheral nerves treated. Local needling is crucial for successful treatment of peripheral neuropathy.⁵²³

In patients after cardiac surgery, relief of pain through EA was shown to reduce the use of opioids such as fentanyl.⁵²⁴ One case report showed excellent results in chronic pain reduction over a 2-year period in a patient with a pacemaker. In answer to the initial question regarding safety, EA was shown to be an excellent alternative for individuals with pacemakers.⁵²⁵

Studies have shown that EA may enhance the effect of strength training on motor function. One study compared upper-limb motor functional improvement in chronic stroke survivors who received a combination of EA and strength training with that of subjects who received strength training alone. After the combined treatment, the quantitative spastic level, active wrist extension range of motion, and Fugl-Meyer upper-limb motor score changed significantly. No significant changes were noted in isometric wrist strength. The strength training alone resulted in no significant changes to any measured variable. These results indicate that the combined acupuncture and strength training treatment reduced muscle spasticity and may have improved motor function for chronic stroke survivors with moderate or severe muscle spasticity.⁵²⁶

Although two mechanisms underlying the physiological mechanisms of EA were presented previously, it would be prudent for physical therapists to consider maximizing the benefits of electrical modalities in various musculoskeletal and neurological disorders.⁵²⁷ One prospective study⁵²⁸ investigated the physiological effects of stimulation of acupuncture points ST36 and ST39 of the stomach meridian with Dynatron 200 microcurrent. Hemodynamic functions and skin temperature were monitored, with no significant differences found. However, further research is necessary to elucidate the nature of physiological effects of specific surface electrodes and various types of stimulation to determine the efficacy of EA treatment.

Research applying EA on the PC6 acupoint found reduction in postsurgical nausea and vomiting. A review of 5 trials that included 426 patients studied nausea rates from 0 to 24 hours after surgery in which PC6 electroacupuncture was used to reduce nausea rates from 54.50% to 26.51%. The same studies were used to assess the use of PC6 electroacupuncture to reduce vomiting postoperatively from 0 to 24 hours; rates were reduced from 35.07% to 17.67%. When compared with PC6 acupressure and PC6 acupuncture, PC6 electroacupuncture was found to be the most effective in reducing postoperative vomiting between 0 and 24 hours after surgery and had the lowest RR rates. In addition to lowering the rate of nausea and vomiting postoperatively, electroacupuncture also has a pain-relieving effect. More research is

needed to see if combining electroacupuncture of the PC6 acupoint with others would have a great effect.^{528,529}

A review of different types of acupuncture used for the treatment of fibromyalgia found that electroacupuncture was the best for improving pain, overall well-being, sleep, stiffness, and fatigue. The most effective treatment sessions were found to have occurred for 25 minutes twice a week for 4 weeks with the use of 2 to 5 Hz of electrical stimulation on the acupuncture points of ST36 and L14. More research is needed in the areas of needle depth, other acupoints, and choice of needles in the treatment of fibromyalgia.^{530,531}

As mentioned in the acupuncture section, dry needle therapy (DN) is used by physical therapists to reduce pain and musculoskeletal movement problems. Dry needle therapy is a method of needling the trigger points using a syringe needle without the use of a drug and is commonly used for pain at the shoulder, neck, waist, and back. The available literature shows mixed results from DN, but it is becoming an accepted treatment for pain.^{457–459,460,532–537} In an RCT for patients post-stroke,⁵³⁸ the inclusion of deep DN into a treatment session following rehabilitation strategies was effective at decreasing spasticity and improving balance, range of motion, and the accuracy of maintaining stability.^{539,540} Specific to upper extremity fine motor skills, DN reduced wrist flexors spasticity and α motor neuron excitability in patients with stroke, and improvements persisted for 1 hour after DN.⁵⁴¹ This research is growing significantly as DN becomes common practice in rehabilitation settings. Thus noninvasive EA and DN may have positive impact on spasticity and result in improvements in quality of life.

Lymphedema Management for Patients With Neurological Movement Disorders

Jennifer Brooks and Arlette Godges

Edema management is a skill that belongs in every clinician's toolbox and may begin with basic elements, including elevation, rest, and other strategies taught in entry-level clinical education. Manual lymphatic drainage (MLD) and complete decongestive therapy (CDT) is an approach considered traditional physical therapy in many European countries (but not in the United States) and is often primarily associated with postsurgical cancer patients. Yet most patients with swelling problems could benefit from approaches used in this therapeutic intervention. This is often referred to as *lymphedema management* or complete or complex decongestive therapy.⁵⁴²

In the United States, there are various training and certifications available, with differing schools of thoughts regarding the approach. All forms of decongestive therapy include the same basic components: MLD, skin care, exercises to improve lymphovenous drainage, compression in some form, and patient education. The use of pneumatic compression pumps, kinesiology tape, garments, and multilayered compression bandages or alternatives are used to enhance the experience and effectiveness of treatments⁵⁴³ based on an individual's need and preference.

As a bundled intervention,⁵⁴⁴ MLD/CDT has been found to be effective in lymphedema management; however, continued compliance with self-care is of utmost importance. The intent of this section is to remind therapists that a consultation with a trained lymphedema specialist may be particularly helpful for optimal and comprehensive patient care for a patient with chronic swelling issues, with the end goal of training patients, family members, and friends to use this modality to improve function, decrease pain, and decrease the burden of comorbidities limiting functional activities. Edema may collect for many reasons, such as after trauma or injury, with infection, when a limb is left in a dependent position, or other more concerning "red flag"

causes, such as congestive heart failure, kidney dysfunction, cancer-based lymphatic obstruction, or deep vein thrombosis (DVT).⁵⁴⁵ In the current environment of direct access practice and autonomous practice, any new swelling or edema should be viewed from a differential diagnostic perspective, and may require referral to physician for further testing, particularly in our most vulnerable populations. Swelling can be found in both healthy and unhealthy tissues, or as a result of another disease or injury process, but lymphedema is a specific condition involving abnormal accumulation of high protein lymphatic fluids as a result of lymphatic dysfunction or compromise⁵⁴⁶ that requires physician diagnosis. It is important to embrace opportunities for a collaborative care model, including referral to physiatry or other medical specialty for proper diagnosis, followed by referral to a lymphedema specialist, for optimal and comprehensive patient care.

Integrating Lymphedema Therapy in Neurorehabilitation

Although the most common medical condition where CDT is used is in cancer survivors with lymphedema, comprehensive edema management interventions can be a bridge to a more effective and successful course in neurorehabilitation.⁵⁴⁷ It is a concept often missed in busy practices and settings outside of oncology. Any patient will logically have better outcomes, with less swelling and collection of fluids in their tissues. Although the literature supports the use of lymphatic drainage in orthopedic injuries,⁵⁴⁸ MLD/CDT has a place in the treatment of all individuals with diagnosed lymphatic dysfunction, no matter the underlying medical or referral diagnosis.⁵⁴³ Properly implemented treatments to decrease swelling after injury or trauma will lead to a faster rehabilitation toward optimal function.

Our neurology patients can greatly benefit from this different perspective. Patients with neurological impairments, such as CVA or SCI, can develop swelling of upper and lower extremities due to low motor function and general immobility, possibly triggering a secondary lymphedema. While there is little research on these populations, one retrospective study found CDT approach to be safe and well-tolerated by patients with SCI. The intervention was associated with decreased edema, was feasible for use in a clinical setting, and recommended CDT approach for management of edema in individuals with SCI, while remaining vigilant about skin inspection.⁵⁴⁹

With lymphatic therapy, a body's natural pathways are utilized to return the lymph into the circulatory system and eliminate it effectively from the body without excessive strain. Many clinicians need to be reminded that MLD techniques and lymphedema management services are becoming more widely available as trained lymphedema specialists are more prevalent. Decreased swelling in extremities may lead to decreased pain and earlier ability to weight bear on extremities for functional tasks. The ability to incorporate the breath and perform active movement may enhance further healing as it increases a muscle pump, efficiently increasing lymph flow and restoring tissue homeostasis.⁵⁵⁰ Working with diaphragmatic breathing and treatment in the abdominal region⁵⁵¹ may improve the patient's overall wellbeing and create opportunity for improved mobility via core awareness. A secondary benefit is increased oxygenation throughout, including imperative brain areas responsible for mood and motivation.

It is important to consider precautions and relative contraindication to consider when using MLD/CDT principles: For the diagnoses listed as follows, treatment of diagnosed lymphedema may still be indicated in individual cases and may require additional monitoring or oversight:

General: acute infections, uncontrolled asthma or COPD, cardiac edema, history of or suspicion of malignancy, acute bronchitis, renal insufficiency and/or bladder dysfunction, and hypertension.

Head and neck: cardiac arrhythmia, age >60 (possible sclerosis of vessels), thyroid disorders, and sensitivity of carotid sinus.

Abdominal treatment: pregnancy, menstrual cycle (relative), recent abdominal surgery, radiation therapy related complications, chronic inflammatory conditions (e.g., ulcerative colitis, Crohn disease, diverticulitis, etc.), undiagnosed abdominal pain of any kind, aortic aneurysm or suspicious symptoms, and diabetes (relative).

Lower extremity: acute DVT, phlebitis, thrombophlebitis, arterial disease, and acute infections.

Special considerations should be given and close multidisciplinary coordination will be required for modified or full MLD/CDT for the following populations: those with hypertension, paralysis, or paresis, sensory loss or changes, diabetes, asthma, malignant lymphedema, or pulmonale/congestive heart failure.⁵⁵²

In conclusion, the most powerful component of MLD/CDT is patient and family education. Family members and patients can be trained in edema management to the best of their ability, whether temporary or more chronic and long-lasting. There is evidence to support the adoption of remedial exercises in the management of lymphedema and for a greater emphasis on self-treatment practice. Empowerment care for themselves with access to supportive professional assistance has the capacity to optimize self-management practices and improve outcomes from limited health resources. Family members⁵⁵³ and patients can be assisted with simple diagrams of the system and arrows pointing the direction of optimal flow. It is important to create a safe and encouraging environment. This can be established with informing patients and caregiver that even if their techniques are not textbook perfect, any mobility and any movement of the fluid helps. It may be less effective, or less permanent, but it still is of no harm and may provide some relief from the discomfort of the swelling via comforting touch. Explanation of why this is an effective way to help the family member and why a sedentary life is harmful and increases the risk of more fluid accumulation is also important.

The use of decongestive modalities in the care of our patients with neurological movement limitations is underutilized. Untreated swelling, lymphedema or not, becomes a cycle of pain and disuse, leading to immobility and breakdown of normal tissue. Joining lymphedema and edema management to other rehabilitative offerings and complementary care, such as yoga, Pilates, aquatic therapy, and meditative breathing, will enhance outcomes and quality of life for our patients.⁵⁵⁴ For this reason, decongestive therapy can be considered an integrative therapy approach. It can easily be combined with other interventions along with traditional therapy services. The end result is empowering the individual back to optimal function and enhancing quality of life.

Music Therapy

Concetta M. Tomaino and Therese Marie West

Music therapy is the clinical and evidence-based use of music interventions to accomplish individualized goals within a therapeutic relationship by a credentialed professional who has completed an approved music therapy program.⁵⁵⁵

Although music is not a “universal language” in the sense that a particular piece of music would have the same meaning and effect for any person anywhere, music *is* a universal human phenomenon. Most people today could describe ways in which music might be used to enhance health or well-being, and we find evidence of the use of music as part of healing practices throughout history.^{556,557} Within a first worldview perspective, magical or mystical powers were attributed to music, and healing occurred within a context of social structures and shared beliefs. Music was often a part of rituals conducted by a shaman or healer who served as a spiritual intercessor or guide in a process

designed to reestablish balance and harmony for the individual. Music, sometimes with dance, served as a gateway to altered states of consciousness and entry to deep altered states of consciousness, where creative experiences manifested multiple sources of information not available through observation alone. This process supported insights about the causes of and remedies for physical, emotional, social, and spiritual imbalance. Where patient, healer, family, and community members participated together in healing rituals involving the use of music, treatment occurred within the natural environment and social fabric of everyday life. Examples of music healing within a first worldview perspective can still be found within indigenous cultural groups to this day.

The rise of the second worldview brought new values that emphasized logical and rational approaches to the use of music to address health issues. During this phase in history, we see the first examples of published work asserting the theory that music could influence emotions and mood states, thereby improving physical or mental health.⁵⁵⁶ Anecdotal evidence and case reports were used to support emerging theories and practices into the early 20th century. In the latter part of the 20th century, we began to see the scientific method applied systematically to the study of music in relation to single variable changes in (1) disease and pathological states or (2) functional activities and willingness to participate in rehabilitation treatment settings. Researchers continue to explore possible mechanisms through which music may contribute to improved physical or mental health via its influence on various factors such as emotional responses, mood states, relaxation, activation, or motivation.

History of music therapy. In the United States, music therapy began to develop as a profession after World War II, when it was found that music could facilitate both physical rehabilitation and recovery from emotional trauma in veterans returned from the war. Although early music therapists were often musician volunteers, music educators, or musician-physicians, it had become clear that specific education and training were needed, and music therapy curricula and academic programs were developed beginning in the mid-1940s. The first professional music therapy organization (the National Association for Music Therapy [NAMT]) was formed in 1950. A second professional organization, the American Association for Music Therapy (AAMT), formed in 1971. The NAMT and AAMT merged in 1998 to form the American Music Therapy Association (AMTA). The AMTA sets standards for education and clinical training in music therapy programs accredited at more than 70 colleges and universities in the United States and Canada. The Certification Board for Music Therapists (CBMT) was accredited in 1986 by the National Commission for Certifying Agencies and certifies music therapists to practice throughout the United States. Certification is via competency-based certification process that includes specialized coursework, 1,200 hours of supervised clinical training, and a certification board examination. There are currently more than 7,900 music therapists maintaining the MT-BC (Music Therapist, Board Certified) credential and participating in at least 100 hours of continuing education for recertification every 5 years to maintain and increase competencies for practice in this rapidly evolving field.⁵⁵⁸ Music therapists may also need to obtain a state license. The development of music therapy in the United States parallels the stages of health care development as discussed earlier (see the discussion of historical perspective in this chapter). The profession has advanced in clinical research providing evidence-based models to advance the practice of music therapy. Therapists observe that patients who are unable to speak as a result of stroke or AD are often able to sing coherently when presented with familiar music. How is it that the gait of a patient with PD improves markedly in the presence of a rhythmic auditory stimulus?⁵⁵⁹ How does music-evoked imagery (such

as experienced with the Bonny Method of Guided Imagery and Music) alter physiological and psychological indicators of stress?^{560,561} In recent years, advances in neuroscience have provided new understanding of how and why music and the components of music are effective in clinical interventions. In the United States, music therapy is recognized as “an established health profession in which music is used within a therapeutic relationship to address physical, emotional, cognitive, and social needs of individuals. After assessing the strengths and needs of each patient, the qualified music therapist provides the indicated treatment including creating, singing, moving to, and/or listening to music. Through musical involvement in the therapeutic context, patients’ abilities are strengthened and transferred to other areas of their lives.”⁵⁶²

Specialization. Music therapists develop specialized areas of practice, treating across the life-span from perinatal to palliative care, in schools, hospitals, skilled nursing, rehabilitation, outpatient, or community settings. Goals addressed support progress in developmental tasks, rehabilitation of physical and cognitive functioning, adaptation and coping, pain management, recovery from trauma, and quality of life. Music therapists work in private practice, as members of interdisciplinary teams, and as consultants and collaborators. There are many music therapists, including the authors, who work in rehabilitation settings in cotreatment, consultation, or collaboration with speech-language pathologists, physical therapists, and occupational therapists, as well as with a wide range of practitioners from other professions in medicine and mental health arenas. During early clinical collaborations in rehabilitation settings from the mid-1980s to the early 1990s, the authors found little research to support an understanding of observed phenomena in the rehabilitation clinic setting and had to depend largely on basic skills of music therapy assessment, careful documentation, and evaluation of treatment outcomes and effectiveness. In recent years, the music therapy profession has focused on increasing the quality and scope of research to support empirically validated best practice with reliable outcomes for a number of specific populations of interest to professionals in rehabilitation settings. Rehabilitation music therapists now have the benefit of empirically supported treatment protocols and continuing research regarding effectiveness and safety of music therapy methods. NIH is supporting music therapy research through the National Center on Complementary and Integrative Health (NCCIH),⁵⁶³ with funding sources now available.

Music therapy in neurological rehabilitation. Music therapists have been working in neurological rehabilitation settings in the United States for more than 25 years. Tomaino⁵⁶⁴ describes her long professional collaboration (from 1980 to 2015) with the neurologist Dr. Oliver Sacks and shares insights developed through extensive clinical application of music in the individualized assessment and treatment of various neurological diseases and injuries. Music can access intact neurological functions and is used to facilitate relaxation, increase attention and motivation, improve the readiness for (priming) and timing of motor activities, and enhance communication and emotional expression while providing supports for coping and adaptation. Tomaino^{565–569} describes the music therapy process from assessment and treatment planning through treatment and evaluation of outcomes, focusing not only on physical and behavioral changes but also on the engagement of the whole person through a trust-based therapeutic relationship. Familiar music can provide the patient a sense of safety, with predictable elements of rhythm, melody (prosody), words and lyrics, and structure across time within socially and culturally relevant contexts. Musical elements are systematically applied to support functioning in cognition and memory, speech and communication, gait, and upper-extremity activities.

Music therapy has been used in many rehabilitation settings to support cognitive functioning in areas such as attention, sensory filtering and focusing, memory, sequencing, and executive functioning. Ongoing development of theoretical foundations for clinical uses of music in the cognitive treatment of those with brain insult or injury is supported by brain imaging and in vivo functional studies providing evidence of shared mechanisms among musical and nonmusical perceptual and cognitive brain functions⁵⁷⁰ and effects of music on electroencephalographic activities in cortical networks.⁵⁷¹

West has observed the phenomenon commonly reported in rehabilitation music therapy, where people with various aphasias are able to sing, but not able to speak fluently. The patient is often able to sing clearly in time with the singing of the music therapist, who adapts the tempo and other elements as needed. There appears to be an entrainment process, not only rhythmically, but also in elements of prosody and articulation. The mechanisms are not yet fully understood, but at least one study suggests that singing in synchrony with an auditory model (choral singing) may be more effective than choral speech in improving word intelligibility because choral singing may entrain more than one auditory-vocal interface.⁵⁷² Kim and Tomaino⁵⁷³ have developed and pilot tested a music therapy treatment protocol for people with nonfluent aphasia, integrating extensive clinical experience with recent findings from experimental studies using cognitive-behavioral, electrophysiological, and brain imaging techniques. Whereas specific brain structures have been well established for speech and language and were thought to be distinct from music processing areas, it now appears that music and language may share some aspects of neurological processing in bilateral hemispheric activities.⁵⁷³ The evolving brain research may help us better understand our clinical observations and will most certainly support increasingly effective treatment protocols for expressive aphasia.

One particularly valuable discovery in music therapy for neurological rehabilitation is the fact that rhythmic elements of music can influence the timing and execution of motor sequences in both gross motor and fine motor activities. A neuroscience approach to understanding potential effects of rhythmic auditory stimulation (RAS) and motor-rhythm synchronization phenomena in neurological rehabilitation is supported by a well-developed body of basic research and clinical studies with a number of rehabilitation populations.^{574–576}

The use of music therapy with movement problems arising from brain areas associated with specific medical diagnoses can be found online and can be integrated with chapters that address specific medical diagnoses.

Music therapy as a complementary modality. Music therapy continues to play an important role in holistic care, even while some phenomena yet elude our scientific methods. West was asked to assess two different teenage boys, hospitalized and in comatose states after head injuries. The treating neurologist was preparing to recommend longer-term follow-up disposition for these young patients, and while considering all the medical evidence at his disposal, this physician also wanted to see what music therapy might discover in terms of responsiveness to stimuli. Although one patient showed no response of any kind to any auditory or tactile stimuli, the second patient proved to be a most interesting example of the mysterious recovery. His neurological tests indicated that his prognosis would be very poor; “persistent vegetative state” was the expectation. In the absence of any evidence that he could benefit from more intensive rehabilitation services, he would be sent to a facility where he would receive long-term custodial care but no therapies. During the music therapy assessment, this young man began to show signs of responsiveness to musical stimuli. A professional skeptic, West was reluctant to consider his eye gaze changes, head movement, and smiling to be meaningful responses to

the music without additional testing. These could be random events coincident with the stimuli. West presented music in a popular style familiar to the patient (according to family sources) and gently applied tactile rhythmic stimulation to his hands, arms, legs, and feet in time with the music. The patient began to move his own extremities in rhythmic time to the music and continued to do so when the therapist removed her hands. The therapist carefully documented the procedures and patient responses and returned a report to the referring physician. Over the next few days, the patient's responsiveness increased dramatically. The neurologist had this young man placed in a rehabilitation treatment setting. A month later, he had begun to walk and showed promise of significant recovery of functions in a number of areas, including speech. This patient was initially medically evaluated as having little potential for recovery, yet after music therapy, he was interactive and a participant in life. This case is a good example of how music can access and bring forward what is yet intact (whole) within a person whose body has been damaged by illness or injury. More recent research by Magee illustrates the evidence for music therapy assessment and treatment for those with acquired brain injuries.⁵⁷⁷

Although basic and clinical research activities are increasing an understanding of “how” and “for what, when, and for whom,” music therapy can be of specific benefit in neurological rehabilitation and medicine, music therapists are also facing the new challenges and opportunities of new worldviews. Music therapy is among the complementary modalities provided as part of a response to increasing demand for holistic and patient- and family-centered health care. With the increase in evidence-based practice and well as increased opportunities for collaborations between clinical and basic science researchers, the NIH has identified a new initiative to explore music and the mind.⁵⁷⁸ Because music interacts with every domain of human experience (physical, cognitive, emotional, social, and spiritual), it has the potential to influence multiple needs simultaneously, in a unified way that respects both the uniqueness of the individual and the deep common ground of the person within the whole.

A case study presented in [Box 39.1](#) and another case located in the online resources of this text illustrate how integrative therapy approaches can improve individuals' quality of life.

BOX 39.1 Integration of Philosophies—An Author's Experience

Darcy A. Umphred

This case study is being shared so colleagues can realize that there are many more unknowns in life than knowns. There may be clinical experiences that just do not match the available research or evidence within our profession or even in other professions or areas of science that might explain a treatment outcome.

This case began the day before I (Umphred) arrived at a Board of Directors' (BOD) spring meeting for a National Association. Each Board member was a health care provider and certainly based their practice on evidence at that time. One elected Board member had fallen on the way back to the hotel from dinner the night before. The streets were dark, the pavement uneven, and she stumbled and fell forward onto her chest and face. She went to the ED, and it was determined that she broke her nose and rib and was in a lot of discomfort/pain.⁵⁷⁹ The next morning, I and other professional members representing various special interest groups had been invited and were present to join the meeting. During the morning, it was obvious that the BOD member that had fallen had hit her face very hard due to the swelling and distortion of her nose and the two black eyes she presented.

At the end of the day, I had planned to have dinner with that individual, who was a very cherished friend. We went to her suite to just talk and decide where to go for dinner. We began to talk, time went quickly, and we did not realize it was then 10 PM. We both decided it was too late to go for dinner. I turned to my friend and said, “Let me treat you and help reduce your pain and discomfort.” I recommended that she get ready for bed, take whatever meds she needed, and then lay down on the bed, because I knew she would fall asleep during treatment if the treatment was effective in pain reduction and relaxation.

I asked her lay crosswise on the bed so I had access to her head and neck from the side of the bed. I pulled up a chair to sit and reduce the postural demand of my body. With me being relaxed, she could also relax during the treatment. I began by holding the sides of her head in my hands with my two index fingers across the occiput and C1. Her cranium rested in the palms of my hands totally supporting her head. Her ears were not covered to avoid any changes in sound. I then started doing slow gentle oscillation up and down the spine from the head region. As she began to relax, one could see that the oscillations or slight movement were beginning to flow from the head, first down into her cervical region and then down her entire spine and finally all the way to the feet.⁵⁸⁰ Once relaxation was established, I did an occiput release to allow for full extension of the neck and increase range of motion and circulation to the head. Once released, I began to move her head slowly in a pure plane with slight flexion of the chin

(a small tucking moving) toward upper cervical flexion and then back toward extension. Then I slowly rocked the head into diagonal motions with flexion and extension. All movements were slow, and initially the range was small. I would feel the movement in the upper cervical region and then slowly increase the range as she relaxed and gave into the movement. As I moved her head, she showed no sign of resistance to the movement. As I began to increase the range of motion in all these diagonal movement, her CNS took over control and she began to move her head/neck from one position to another automatically. I did not resist any of her movement, just letting her continue in the direction and force as her nervous system directed and redirected. I just stayed connected to make sure she did not hurt herself. I am not a certified myofascial release therapist, but if one reads that literature, the term “Unwinding” can be found.^{581,582} This response is often explained as a release of the memories of prior trauma to the muscles, fascia, the entire body, or the brain. Whether these memories are held in deep gray matter nuclei within the CNS or in the muscles or the fascia or the energy pattern around the person is truly theoretical, and the science not totally understood. A few years earlier, my friend had a brain tumor, which was successfully removed. I have no idea the emotional and spiritual memories or trauma that this experience may have caused my friend, and again it is not relevant. She continued to unwind and at times violently for at least 40 minutes. Finally, the movements slowed down and finally stopped. At that time, she was sound asleep and deep in relaxation.

I had just finished a level one Reiki course, which is explained earlier in a section of this chapter and as an approach is based in the philosophy of the use of energy. I knew I could not hurt my friend by trying Reiki, so I stood up in order that I could place my hands about 3 inches above the top of her head and body to feel my friend's energy field. Then I began to scan beginning above her forehead with my hands open and palms flat. As I approached the area over her eyes, the sensation I felt was a dipping toward the eyes or a valley as I approached and came over the eye sockets. So, I just held my hands over her eyes and visualized filling in the energy field under my hands until the dip was gone, and the energy felt as if it came back into balance. How exactly that thought process interacts with the energy around the person is dependent upon what you believe or have been taught. But once the process seemed complete, it gave me, a practitioner, the feeling or sensation of balance similar to having your hands on a solid surface, which is a smooth structure around the person. I continued to move off her eyes toward her nose. Again, there was a deep dip in what I felt as

BOX 39.1 Integration of Philosophies—An Author’s Experience—cont’d**Darcy A. Umphred**

the total energy field around my friend’s nose. I used the same thought process used for the eyes until the nose area felt back in homeostasis or symmetrical. Then I continued down the body, and when I reached her ribs, especially on the right side again, it dipped. My intent was once again to pull the energy back up or to fill in the gap with energy that I perceived was coming through me and my palms into her energy field. At the time, I truly had no neuroscience research to substantiate either rationale but could not deny the sensations I felt in my hands and palms, which suggested that the energy gaps were gone. Once the gaps were no longer present, it felt as if I was pushing on a very calm, smooth surface. After I finished scanning the entire body, I turned off the light in the hallway and went down to my own room to sleep. I had been treating my friend in very little light, so I could not physically observe if any change had occurred, but my friend was very relaxed and in a deep sleep, which was my initial intent. Today, there is research to³¹³ substantiate the Reiki intervention I provided, but at the time I simply responded to her body and what it was telling me. (Please refer to the section on Reiki within this chapter for additional research.)

The next morning, I arrived before my friend and was sitting in my seat. When my friend walked into the room, her eyes were no longer black, her nose straight, and the swelling was reduced tremendously. I was surprised to say the least, but was pleased to see my friend out of all that discomfort. The president of the Board looked shocked and asked her: “What happened between when you left the meeting yesterday and this morning?!” She said in a relaxed voice that I had treated her and that her rib pain was also gone. So, the entire Board turned to me at one time and the President asked: “What have

you done!???” I told him “physical therapy” because I did not know what else to say. Although today, the research may give us a better indication as to potential variables that affected the outcome of the previous evening,^{313,579–583} I was as shocked as the BODs. In reality, I had not even known she had broken a rib. I just felt that dip the previous evening around her ribs and visualized bringing the energy back into balance. All I can now say is: “I did my usual approach to relaxing the body and getting rid of pain, letting her body unwind previous memories, and then treated her using Reiki.” Some colleagues would say I also did craniosacral from the head, as well as Feldenkrais using gentle oscillation. It could be any if not all of these integrated techniques that helped my friend regain function and reduce the pain. The one fact that was obvious was something significantly happened that evening to change her quality of life. Whether what happened was her self-healing, the energy around her fostering recovery, some of the various techniques employed playing a role in what happened, or all of them together as an integrative whole, again does not matter. What is important to realize is that all these techniques can fall under integrative approaches to treatment. None of those present that day at the meeting would deny significant healing or change had occurred in those 12 hours. Similarly, we would have all agreed that those changes were far beyond our evidence-based research, even today when considering the evidence and environment as a whole. This case study illustrates there is much more going on in the learning environment between individuals than research can substantiate, especially when people are empowered to regain function and take hold of the quality of life they desire.

CONCLUSION**Darcy A. Umphred and Mary Lou Galantino**

Before the clinician embraces any complementary or integrative approach, the individual needs to identify which philosophy or paradigm matches her or his own belief system and aligns with her or his own emotional safety issues. Tethering an understanding of any integrative approach or concepts to an established evidence-base professional model will allow clinicians to stretch beyond their comfortable paradigms. When treating patients, clinicians are not recommended to jump from one theory to another or from one intervention strategy to another without clinically reasoning why those choices have been made or without using outcome measures to illustrate clinically meaningful changes. Therapists, during their professional education, are taught to use an evidence-based model developed from current research and the most current scientific understanding of what leads to functional movement and participation in life. This quality of life is based on choices of the patients and not what functional activities professionals believe the patient should accept as important. Similarly, the student and clinician are taught to develop the ability to evaluate and analyze both normal and abnormal movement and synthesize what components within and outside the human body will influence those movements. Emphasis is placed on movements that lead to the functional skill that allow individuals to interact in daily living and work environments and those movements that the patient considers critical for quality of life. The last category encompasses valued functional movements such as golf, gold panning, fly fishing, birdwatching, hiking in the mountains, scuba diving, playing cards, social sports, leisure interactions, or any other functional activities of importance identified by the patient. Therapeutic variables that might influence the quality of movement may or may not be a result of the disease or pathology commonly considered the reason for medical management

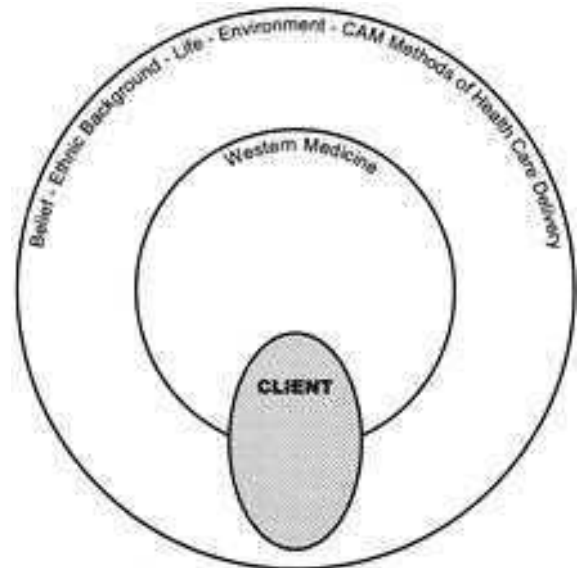

Fig. 39.7 Patient enters Western medicine owing to disease or pathological condition or with functional limitations that prevent participation in life. CAM, Complementary and alternative methods.

(Fig. 39.7). No one who studies and works with individuals who have had a CNS injury would imply that the medical management of that injury or disease is not critical to the outcome of the patient’s motor recovery and/or quality of life. Simultaneously, clinicians in the past 20 years and today’s clinicians have an in-depth scientific knowledge of motor control, motor learning, and neuroplasticity. These therapists observe, analyze, and influence motor, emotional, and

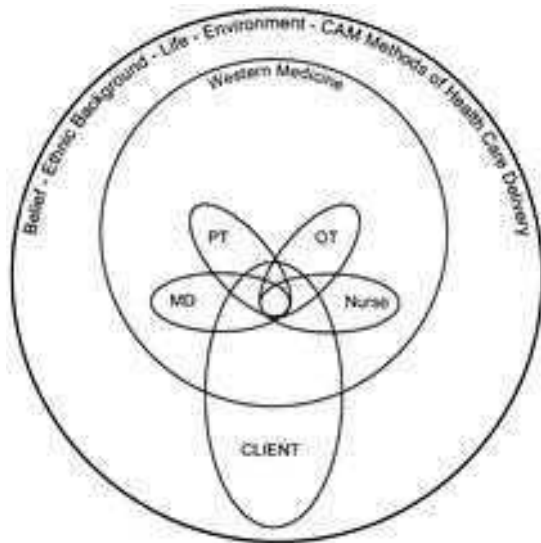

Fig. 39.8 Transdisciplinary Interactions Within Western Medical Model. CAM, Complementary and alternative methods; OT, occupational therapist; PT, physical therapist.

cognitive recovery in patients through movement interactions that physicians might have prognosed impossible. Physicians never want to imply false hope, but what therapists have learned about movement is that taking away hope for functional recovery can simultaneously take away motivation to drive the CNS to regain that function, which is critical for any potential recovery. (Refer to Chapters 3 and 4 regarding motor learning, neuroplasticity, and the limbic systems drive over motor function.) How an individual regains that functional control is often initially based on how the motor system easily learns to control those movements. (Refer to Chapter 2 on movement analysis across the life-span.)

When treating patients with neurological insults of any kind, students are taught to accept that there is an interdisciplinary interaction among professional disciplines, and each profession not only uniquely affects the patient but also has an interactive effect that is dependent on other professions and their respective impact on the patient's health, wellness, and potential to attain a maximal quality of life (Fig. 39.8). If complementary and integrative approaches to health care are introduced into today's health care models, then our colleagues need to determine which approaches link with the current Western medical model and which do not (Fig. 39.9). Why one approach interacts with the patient and another does not is based on the *patient's beliefs, needs, and responses* to intervention as well as the clinician's beliefs and knowledge. Because the professions of occupational and physical therapy have always been rooted and tethered to Western medicine, therapists need to critically analyze the interactions of those approaches that clearly overlap with our existing paradigm (Fig. 39.10). Disease and pathology link to medical practice and the use of surgery and medications, while PT and OT are linked to functional movement and movement analysis, which may or may not be tied closely to disease and pathology. As therapists we must realize that the CNS often learns in spite of disease and pathology, and functional outcomes are based on CNS learning and an individual's desire to learn and regain that function. Those components of integrative approaches that obviously overlap with acceptable practice and result in functional recovery following CNS trauma or change need to be identified and their effectiveness established and measured (Fig. 39.11). Evidence-based practice is considered the norm today and not just a gold standard. Yet clinicians must appreciate that evidence is often

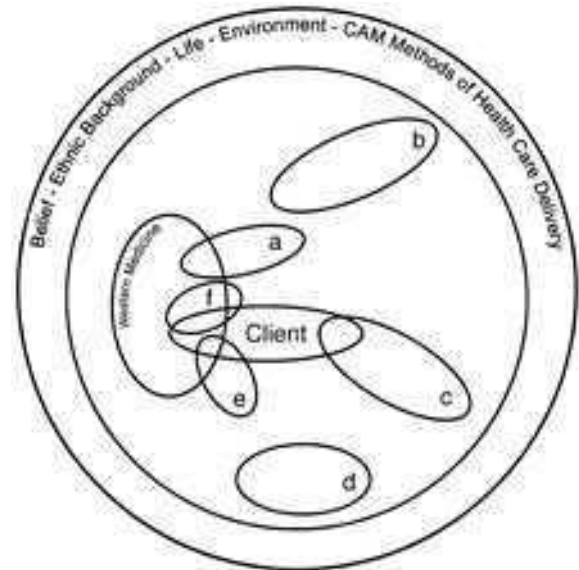

Fig. 39.9 Complementary and alternative methods (CAMs) of health care delivery. Some CAMs interact with Western medicine: *a, f, e*; Some alternative models do not interact with Western medicine: *b, c, d*; Some alternative models meet needs of the patient: *c, e, f*; Some alternative models do not meet the needs of the patient: *a, b, d*.

Fig. 39.10 Complementary and alternative methods (CAMs) interacting with Western medicine. Some models interact to a large extent with Western medicine and some to a small extent. Some models interact with both Western medicine and other complementary models. The extent of complementary interactions with either physical or occupational therapy or both reflect which models fall within respective scopes of practice and thus become part of the professional's treatment tools. OT, Occupational therapist; PT, physical therapist.

based on comparison of one variable against another and that our research tools cannot look at all variables simultaneously as seen when observing and interacting with a patient. Thus clinicians need to be constantly vigilant in analyzing the variables that affect recovery of functional movement. Accepting that a treatment will create change because the evidence suggests so does not guarantee that the specific patient will benefit optimally from the intervention. Thus when considering

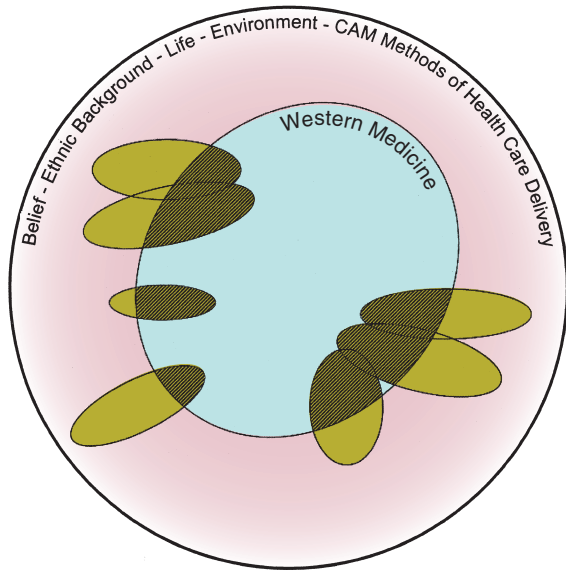

Fig. 39.11 The portion of each alternative or complementary model that overlaps with allopathic medicine and traditional occupational and physical therapy has been the focus of this chapter. As efficacy is established for those components that interlock, therapists will more readily accept these approaches as part of their practice. CAM, Complementary and alternative methods.

using a “complementary or integrative treatment approach,” therapists need to remain critical in their analytical skill to determine if the patient experiences clinically meaningful change and is *actually improving*. With the establishment of those clear clinical correlations (those that match Western science models and those that show improvement in the patient), the remaining components of identified complementary paradigms seem naturally to become part of the established delivery system. As a result, a new model for Western health care practice as identified by PT and OT is formed. This new more integrative model allows the therapist to be grounded in current evidence-based interventions while enlarging a professional comfort zone to encapsulate integrative models by objectively measuring individual patient outcomes to intervention. A clinician with a neuroscience background and these individual case study measurements can conceptually establish a new model (Fig. 39.12). A clinician must always be cognizant of the fact that despite the method, philosophy, or intervention he or she selects to help a patient reach a desired functional outcome, there is no way to eliminate the fact that other aspects of human system processing will be interacting and impacting the outcome. For a century, master clinicians have been observed treating patients. Often colleagues comment that, although therapists seem to use the same methods or treatment tools, they get different outcomes. The question is are those more successful therapists using other interventions without those techniques ever being brought to consciousness? That is, if as a therapist I am aware that I use myofascial techniques along with traditional intervention, could I also be affecting craniosacral rhythm or affecting chakras and energy fields even though I don’t recognize that fact? Could I be setting the stage for the nervous system to learn by optimal augmentation without knowing the literature? Could that allow the patient’s nervous system to select better options for motor responses and the learning of movement function? If so, what truly is leading to somatosensory retraining, motor learning, neuroplasticity, and eventual improved motor control

Fig. 39.12 New Model of Western Health Care Delivery Beyond Complementary Therapies. As the overlapping components of each alternative model are accepted as part of existing Western health care delivery practice, the barriers to the remaining aspects of these models become transparent. With barriers disappearing, a new model with a different shape and different alternative becomes what will be known as traditional medicine in the future. CAM, Complementary and alternative methods.

and function? It may be that master clinicians use *all* these integrative approaches along with traditional treatments but only verbalize the paradigm with which they are most comfortable and that they are most capable of verbally explaining. The adventure is a process of learning, enlarging one’s skill to provide the best service to patients, and differentiating what *is* effective within the clinical setting from what *is believed* to be effective. Not all evidence-based treatment approaches will be as effective for all clinicians, nor will all patients respond exactly the same way, even though their medical diagnosis may be similar. Learning to differentiate true behavioral responses on a patient-by-patient basis from what one is taught should happen may attribute to the effectiveness of master clinicians. *Best practice is constantly evolving and changing*. As movement specialists, we have the responsibility to evolve as well. That change needs to come flexibly tethered to current knowledge and models of the human CNS and analysis of how humans learn or relearn functional control over movement. This leads to many options being available for enhancement of learning, emotional openness, and freedom to venture beyond a comfort zone while objectively measuring positive change in the functional abilities of our patients and improving quality of life as defined by the patient.

Additional material regarding this chapter, including an in-depth discussion on the history of complementary and integrative therapies and sample cases, can be found on the accompanying Evolve site.

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 583 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: This chapter presents a sampling of integrative therapeutic models and philosophies that could potentially assist patients/patients who have movement dysfunction because of CNS pathology. Many of the techniques discussed in this chapter have been firmly established by sound research; some less-evidenced-based models are also included to widen the scope of therapeutic models with emerging evidence.

Keywords: alternative therapies, belief-based theories, complementary models, complementary therapy interventions, energy-based theories, evidence-based practice, integrative therapies, movement diagnosis, movement-based therapies, interprofessional models, traditional concepts with new focus
